The rAdEasy-A20 and the empty control rAdEasy containing green fluorescent protein were generated in our laboratory^[33]. The *Nco*I → *Sal*I fragment (2332 bp) of the A20 gene, which was obtained from the plasmid pCAGGS-FLAGmA20 (a kind gift from Dr. Rudi Beyaert from Department of Molecular Biology, Flanders Interuniversity Institute of Biotechnology, University of Ghent, Belgium) and carries the entire mouse A20 cDNA sequence, was cloned into the shuttle plasmid pAdTrack-CMV. Homologous recombination took place between the resultant plasmid and the backbone plasmid pAdEasy-1 in *Escherichia coli* BJ5183, and the recombinant adenoviral plasmid was generated. The adenovirus was packaged in 293 cells, and the recombinant adenovirus rAdEasy-A20 was generated. The empty Ad vector (rAdEasy) was generated following the same principle.

Animal model

Inbred male DA (RT1^a) and Lewis (RT1^b) rats weighing 260–320 g were used as liver donors and recipients, respectively. The animals were maintained under standard conditions and treated according to the Guidelines for the Care and Use of Laboratory Animals of Sichuan University. Orthotopic liver transplantations (OLT) were performed with the two-cuff technique. All operations were performed under ether anesthesia under sterile conditions. Cefazolin (40 mg/kg, injected intramuscularly) was given after the implantation operation for 5 d to prevent infection. More than 90% of the rats survived this operative procedure. To induce chronic liver allograft dysfunction, a low dose of tacrolimus (0.1 mg/kg per day) was administered intramuscularly for 5 d after the implantation operation^[5]. To examine chronic liver allograft dysfunction, recipient rats were given physiological saline (PS), rAdEasy-A20 (1×10^9 pfu/30 g weight) or rAdEasy (1×10^9 pfu/30 g weight) through the tail vein once every 10 d from postoperative day (POD) 10 for 3 mo. Five recipient rats per group were allowed to survive until they died. Ten recipient rats per group were killed on POD 30 and POD 60 before rAdEasy-A20 or rAdEasy injection. Blood samples were harvested from the inferior vena cava. The left lateral lobes and caudate lobes from 5 liver allografts per group were harvested for Western blotting, Masson staining and immunohistochemistry, and the other liver lobes were harvested for KC and LSEC isolation. Another 5 liver grafts per group were harvested for HSC isolation.

Histological analysis

Liver fibrosis was analyzed on POD 30 and POD 60. The liver tissue lobes were fixed in 10% neutral-buffered formalin embedded in paraffin. For histological analysis, the sections were stained with hematoxylin-eosin. For fibrosis analysis, the sections were stained with Masson stain.

Hepatic A20 expression

Liver graft specimens were harvested on POD 30 and POD 60. Immunohistochemistry was performed for hepatic A20 protein expression in five sections from per graft after the samples were fixed in 10% neutral-buffered formalin embedded in paraffin. The liver sections were incubated with a 1:100 dilution of anti-rabbit polyclonal A20 antibody (Abcam, ab45366) for 45 min and EnvisionTM for 45 min. The sections were counterstained with hematoxylin. Positive cells were counted at 400 × magnification. Ten random fields were observed in each of the liver portal tract areas.

Liver function assay

Serum samples from POD 30 and POD 60 were also analysed for alanine aminotransferase (ALT) and total bilirubin (TBIL) levels as indices of hepatocellular injury. The levels of ALT and TBIL were measured with an automatic biochemical analyser using diagnostic kits from Sigma Chemical Co.

Hepatic protein production study

TGF- β_1 , IL-1 β , caspase-1, caspase-8, CD40, CD40L, Intercellular adhesion molecule (ICAM)-1, vascular cell adhesion molecule (VCAM)-1 and E-selectin protein levels in the liver allografts were analysed by Western blotting. Liver tissue lysates were electrophoresed on sodium dodecylsulfate polyacrylamide gel electrophoresis gels and transferred to polyvinylidene chloride (PVDC) membranes for Western blotting analysis. Briefly, the PVDC membranes were incubated in a blocking buffer for 1 h at room temperature followed by incubation for 2 h with Abs raised against TGF- β_1 , IL-1 β , caspase-1, caspase-8, CD40, CD40L, ICAM-1, VCAM-1 and E-selectin. The membranes were washed and incubated for 1 h with horseradish peroxidase-labelled immunoglobulin G. Immunoreactive bands were visualised using enhanced chemiluminescence detection reagent. The bands were quantified using a scanning densitometer from Bio-Image Analysis System. The results were expressed as the relative optical density.

Hepatic cells apoptosis

The paraffin sections of liver grafts on POD 30 and 60 were analysed for apoptotic cells using the terminal transferase dUTP nick end-labelling (TUNEL) method (*in situ* Cell Death Detection Kit, Roche Biochemicals, Mannheim, Germany). For all staining procedures, positive and negative cells were counted in 3 randomly selected fields under a light microscope. Quantitative analysis was performed

using the Coulter EPICS Elite ESP cell sorting system, United States.

Isolation of KC and LSECs

KCs and LSECs were isolated using a modified method of Braet and colleagues^[34]. In brief, the liver graft was perfused with Ca²⁺-Mg²⁺-free Hanks' balanced salt solution followed by 0.6% collagenase A (Sigma type 1) *via* a polyethylene catheter inserted into the portal vein trunk. After incubation of the fragmented tissue in the same solution, the resulting cell suspension was centrifuged at 100 r/min for 10 min to remove the parenchymal cells. The supernatant containing a mixture of the hepatic nonparenchymal cell fraction was subsequently layered on top of a two-step Percoll gradient (25% to 50%) and centrifuged for 10 min at 900 r/min. The intermediate zone located between the two density layers, which was enriched with LSECs and KCs, was cultured for 20 min in plastic flasks, and the LSECs and KCs subsequently were further isolated based on the selective adherence of KCs to plastic flasks and the spreading of the LSECs on collagen.

Isolation of HSCs

Hepatic stellate cells were isolated from the liver allografts by a modified method that has been described previously^[35]. Briefly, HSCs were isolated from the liver grafts by sequential *in situ* perfusion with collagenase and digestion with pronase. Suspensions of liberated HSCs were prepared by centrifugation on a double-layered (17%/11.5%) metrizamide solution (Sigma). After centrifugation at 1700 *g* for 15 min, the HSCs were harvested from the top of the upper layer. More than 90% pure and viable HSCs were routinely obtained using this procedure, as determined by ultraviolet-excited fluorescence microscopy and Trypan blue dye exclusion, respectively. Isolated HSCs were used for nuclear protein or RNA extraction.

NF- κ B activation of LSECs, KCs and HSCs

The NF- κ B activity of the LSECs, KCs and HSCs was analysed with the electrophoretic mobility shift assay (EMSA) as previously described^[33]. Nuclear proteins were extracted from LSECs, KCs and HSCs. The protein concentration of the nuclear extracts was determined by Bradford assay^[36]. Nuclear extracts were frozen on dry ice and stored at -80 °C until they were assessed in the EMSA. The double-stranded NF- κ B consensus oligonucleotides (5'-AGTTGAGGGGACITTTCCAGGC-3', and 3'-TCAACTCCCCTGAAAGGGTCCG-5')^[37] used in EMSA were end-labelled with γ -³²P adenosine triphosphate (3.7 × 10⁵ Bq/L at 5 μ L) using T4 polynucleotide kinase. The reaction products were separated in 6% non-denaturing polyacrylamide gels subjected to gamma autoradiography at -70 °C for 48 h and were analysed with a gel imaging system.

mRNA expression of cytokines in LSECs and KCs

Analysis of mRNA expression of ICAM-1, VCAM-1,

E-selectin, IL-1 β and CD40 in LSECs and mRNA expression of TGF- β 1, IL-1 and CD40 L in KCs was performed by semiquantitative reverse transcription polymerase chain reaction (RT-PCR) amplification and compared with the expression of the house-keeping gene β -actin using the one-step PCR Kit. Total RNA from LSECs and KCs was extracted using the TripureTM reagent. PCR was performed in a 25 μ L reaction system. The PCR reaction produced a 513-bp product for ICAM-1, a 257-bp product for VCAM-1, a 239-bp product for E-selectin, a 388-bp product for CD40, a 395-bp product for CD40L, a 378-bp product for IL-1 β , a 383 bp product for TGF- β 1, and a 813-bp product for β -actin. The PCR products from each sample were subjected to electrophoresis in a 15 g/L agarose gel containing 0.5 mg/L ethidium bromide. Densitometrical analysis using NIH imaging software was performed for semiquantification of the PCR products. The mRNA expression of each target was evaluated by determining the ratio of the band intensity to β -actin and was presented as the percent of β -actin (%).

TGF- β 1 protein level in HSCs

Supernatant samples from the HSCs were analysed for TGF- β 1 using enzyme-linked immunosorbent assays (ELISA) according to the manufacturer's instructions.

Statistical analysis

SPSS 13.0 statistical software (SPSS Inc., Chicago, IL) was used to analyse the relevant data. The results are expressed as the means \pm SD. Significant differences between two groups or more were identified by the paired Student *t* test. *P* values less than 0.05 were considered statistically significant.

RESULTS

A20 protein over-expression in liver grafts by successful venous adenoviral gene transfer

Immunohistochemical staining confirmed significant hepatic A20 protein expression on POD 30 (data not shown) and POD 60 in the group of rats that received venous A20 adenovirus, whereas only some hepatic A20 protein expression was shown in the rats treated with rAdEasy and PS POD 30 (data not shown) and POD 60 (Figure 1A-C).

Survival study

The survival days of the liver-grafted rats are shown in Table 1. The results suggested that the rats in the A20 treatment group survived longer than the rats in the PS and rAdEasy groups.

Liver fibrosis

Fibrosis of the liver allografts was detected on POD 30 and POD 60 with Masson staining. The histological findings showed that postoperative administration of low-dose tacrolimus without A20 treatment resulted in marked liver fibrosis on POD 60. However, tacrolimus

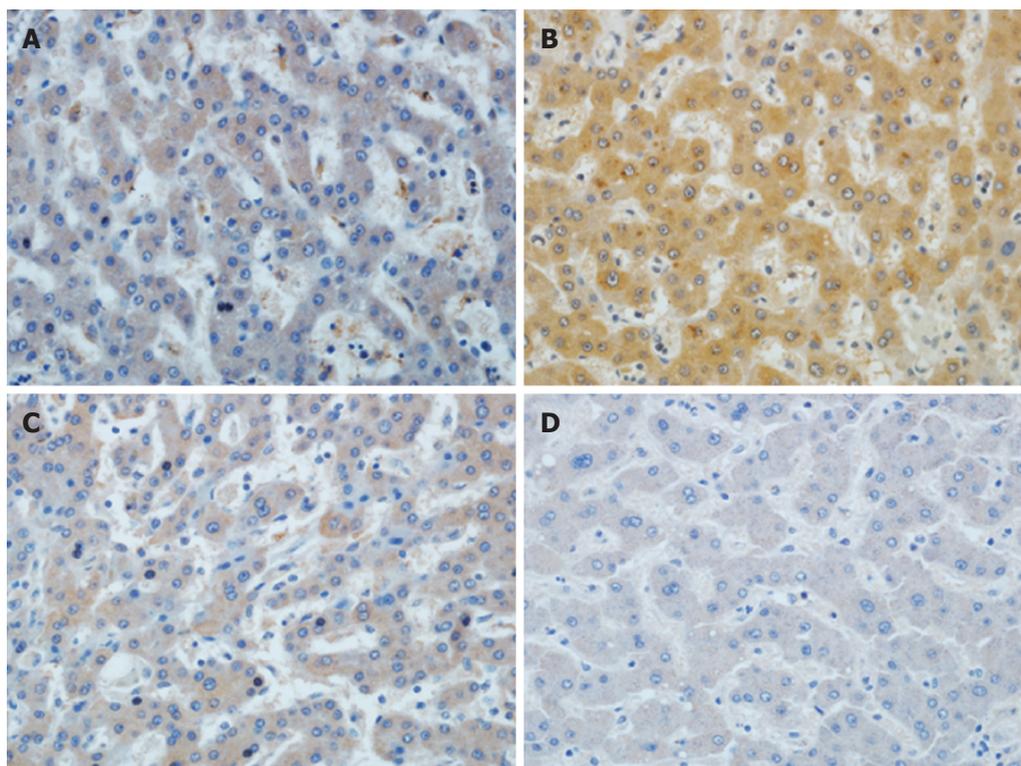

Figure 1 Immunohistochemical analysis of A20 expression in liver grafts on postoperative day 30. Representative immunohistochemical sections from FK506 + physiological saline (A) treated livers demonstrate lower A20 expression compared to the substantial number of A20-positive liver cells in the FK506 + A20 treated liver grafts (B). Furthermore, the expression of FK506 + rAdEasy (C) is also low. D: The results of the normal control group (brown staining) (original magnification, 400 ×).

Table 1 Effect of A20 on the survival of Lewis rats transplanted with Dark Agouti livers

Treatment ¹	Survival (d)	mean ± SD
FK506 + PS	52, 57, 60, 72, 78	63.80 ± 10.83
FK506 + rAdEasy A20	117, 121, 123, 128, 136	125.00 ± 7.31 ^a
FK506 + rAdEasy	44, 50, 57, 58, 67	55.20 ± 8.70

¹Lewis rats transplanted with Dark Agouti livers were given 0.1 mg/kg FK506 for 5 d after transplantation. Lewis rats receiving transplants were given rAdEasy-A20 (1×10^9 pfu/30 g weight) or rAdEasy or physiological saline (PS) once every 10 d from postoperative day (POD) 30 to POD 90. ^a $P < 0.01$ vs FK506 + PS and FK506 + rAdEasy treatment.

combined with A20 treatment resulted in reduced hepatic fibrosis (Figure 2).

Serum ALT and TBIL levels

As shown in Table 2, the results showed that postoperative administration of low-dose tacrolimus led to a significant increase of TBIL and ALT levels on POD 30 and POD 60. A20 treatment markedly decreased serum TBIL and ALT levels on POD 30 and POD 60.

A20 decreases hepatic protein production of TGF-β1, IL-1β, caspase-8, CD40, CD40L, ICAM-1, VCAM-1 and E-selectin

High levels of TGF-β1, IL-1β, caspase-1, caspase-8, CD40, CD40L, ICAM-1, VCAM-1 and E-selectin protein were detected in liver grafts from rats that did not receive

Table 2 Serum total bilirubin and alanine aminotransferase levels after liver transplantation (*n* = 5)

Group	ALT (IU/L)		TBIL(μmol/L)	
	POD 30	POD 60	POD 30	POD 60
FK506 + PS	163.41 ± 35.28	257.35 ± 42.78	85.72 ± 16.47	165.43 ± 24.63
FK506 + A20	66.79 ± 17.56 ^b	90.28 ± 22.37 ^{b,d}	37.61 ± 8.06 ^b	63.71 ± 11.38 ^{b,d}
FK506 + rAdEasy	187.66 ± 43.54	282.75 ± 53.64 ^d	106.37 ± 21.35	182.93 ± 28.75 ^d

^b $P < 0.01$ vs FK506 + physiological saline (PS) or FK506 + rAdEasy; ^d $P < 0.01$ vs postoperative day (POD) 30. ALT: Alanine aminotransferase; TBIL: Total bilirubin.

A20 treatment liver graft on POD 30 (data not shown) and POD 60. However, A20 treatment markedly down-regulated the protein levels of TGF-β1, IL-1β, caspase-8, CD40, CD40L, ICAM-1, VCAM-1 and E-selectin in liver allografts (Figure 3).

A20 treatment suppresses liver cell apoptosis

Liver cells apoptosis on POD 30 and POD60 were measured with the TUNEL assay. TUNEL staining revealed a decreased apoptosis index among the liver cells in the A20 group (11.83% ± 3.52% on POD 30, 14.66% ± 3.84% on POD 60) compared with that of the PS group (20.62% ± 5.36% on POD30, 32.78% ± 6.74% on POD 60) and rAdEasy group (21.58% ± 6.17% on POD 30, 35.27% ± 7.38% on POD 60) ($P < 0.01$) (Figure 4).

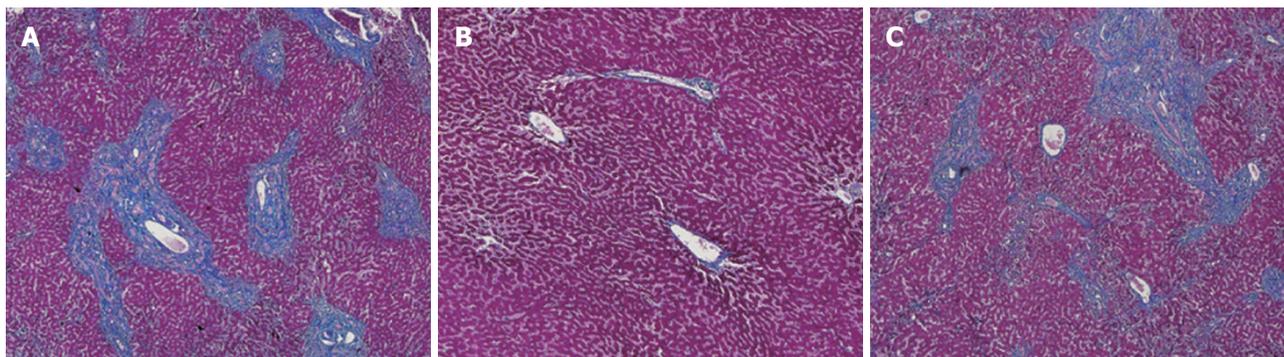

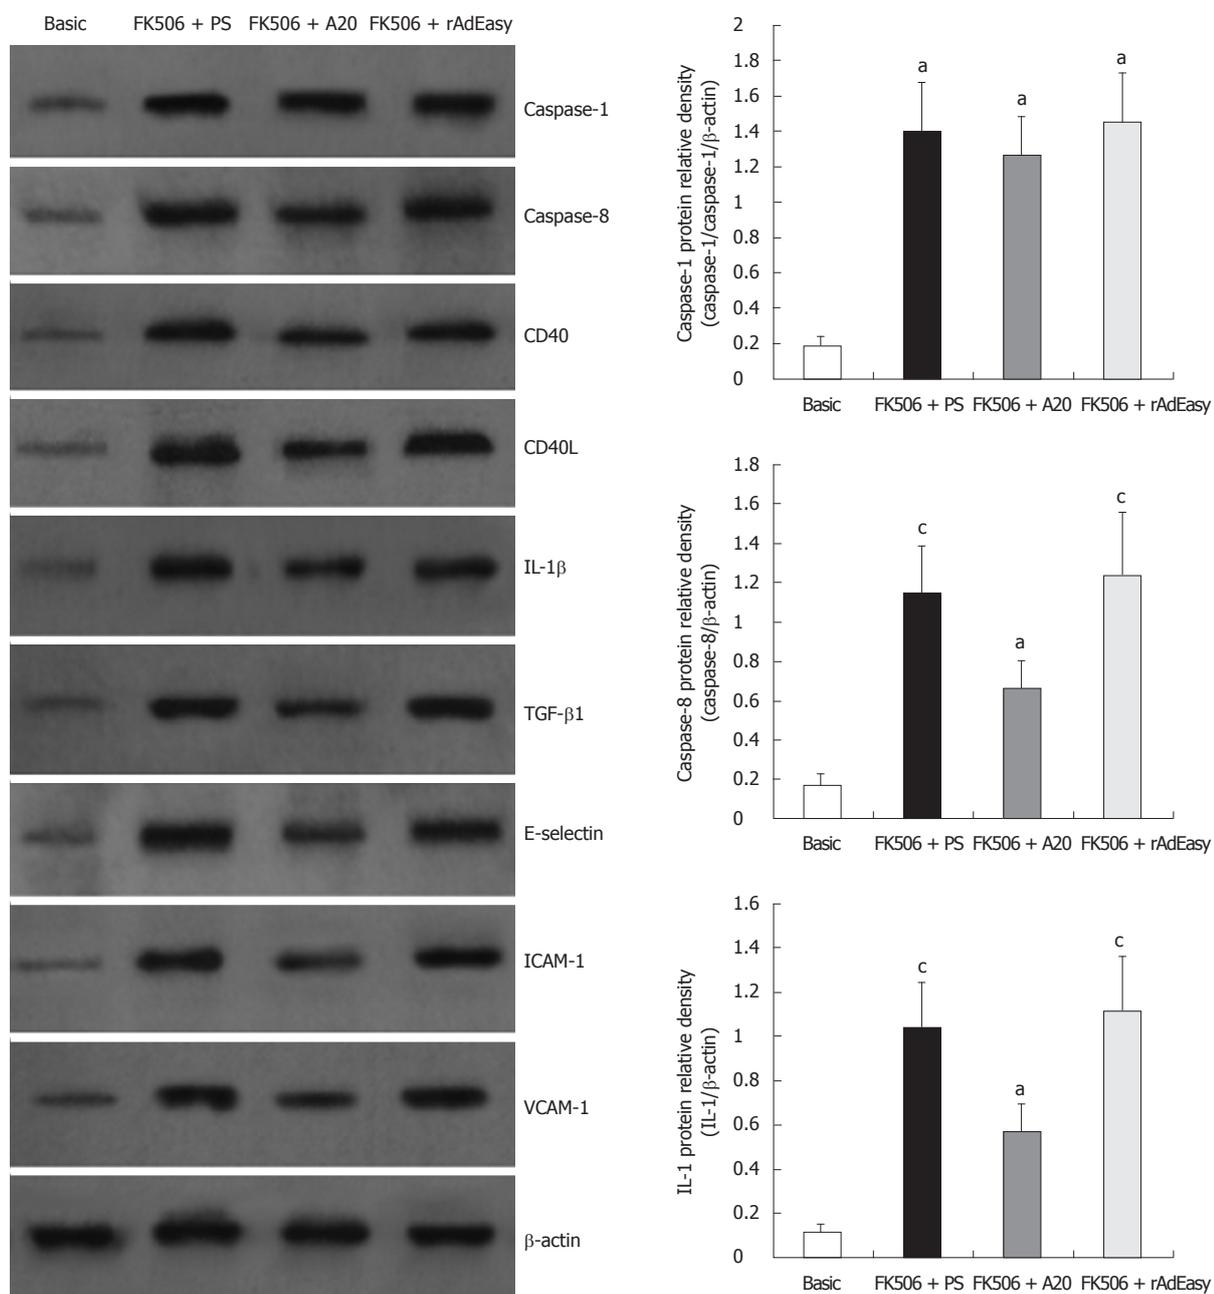

Figure 2 Representative liver fibrosis samples from FK506 + physiological saline treated group (A), FK506 + A20 treated group (B) and FK506 + rAdEasy-treated group (C) on postoperative day 60 (100 ×).

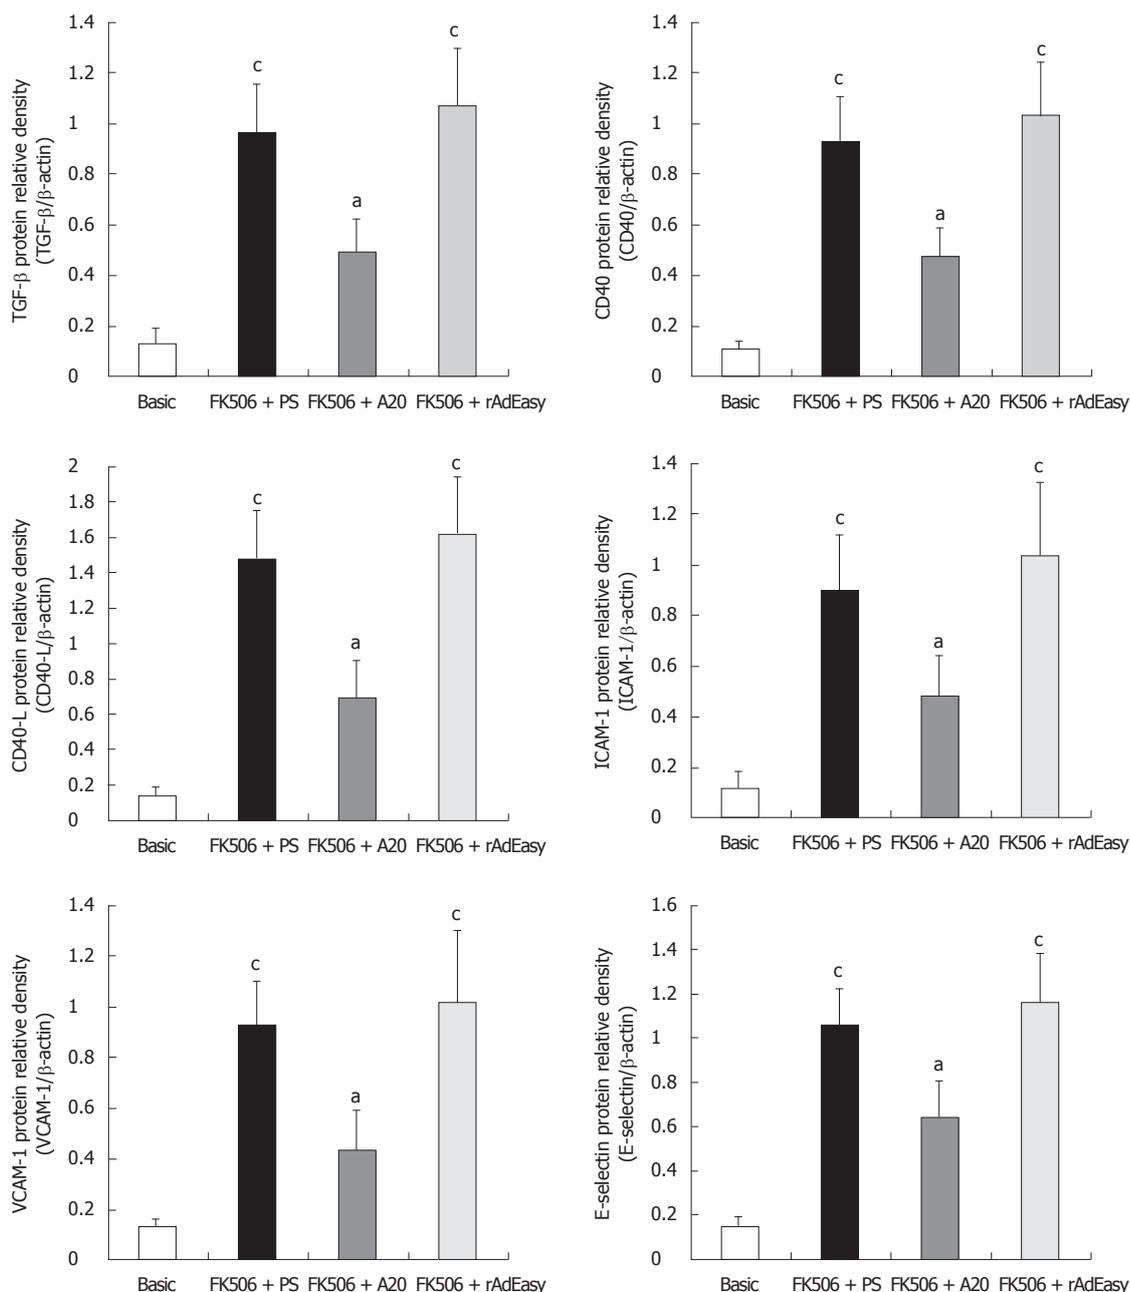

Figure 3 Western blotting analysis and densitometric analysis of associated cytokines in liver graft tissue. Data were expressed as the relative intensity vs β -actin. ^a*P* < 0.05 vs basic control; ^c*P* < 0.05 vs FK506 + A20. IL: Interleukin; TGF: Tumor growth factor; ICAM: Intercellular adhesion molecule; VCAM: Vascular cell adhesion molecule; PS: Physiological saline.

A20 suppresses NF- κ B activation of LSECs, KCs and HSCs

The EMSA showed that postoperative low-dose tacrolimus treatment led to a significant activation of NF- κ B in LSECs, KCs and HSCs on POD 30 (data not shown) and POD 60, and A20 treatment markedly inhibited NF- κ B activation in these cells (Figure 5).

A20 suppresses cytokine mRNA expression in LSECs and KCs

High levels of ICAM-1, VCAM-1, E-selectin, IL-1 β and CD 40 mRNA in LSECs, as well as high levels of TGF- β ₁, IL-1 β and CD40L, in KCs on POD 30 and POD 60 were detected by RT-PCR. The increased mRNA expression

levels of these cytokines were significantly reduced by A20 treatment (Figure 6).

A20 suppresses TGF- β ₁ protein production in HSCs

The ELISA showed that A20 overexpression significantly reduced TGF- β ₁ protein production in HSCs from liver allografts (Table 3).

DISCUSSION

To improve the survival of OLT patients, it is particularly important to protect liver grafts from chronic dysfunction. In the present study, we demonstrated that the zinc

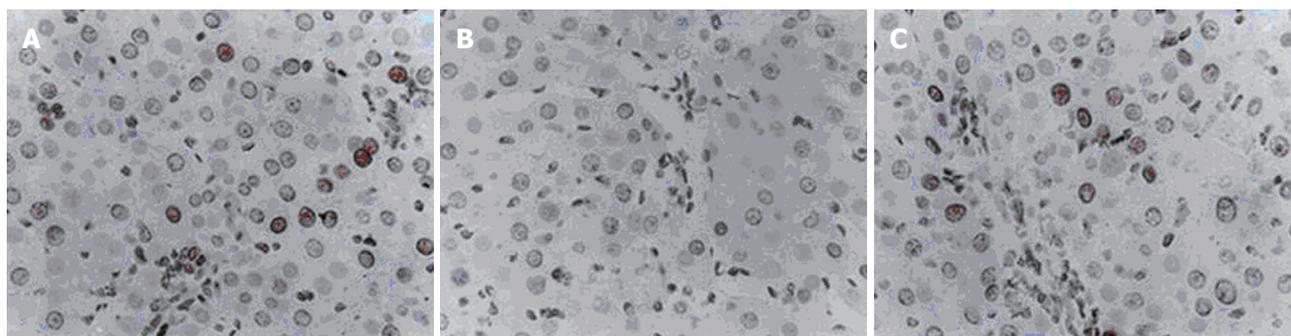

Figure 4 Terminal transferase dUTP nick end-labelling analysis of liver cells apoptosis (red stained) (original magnification, $\times 400$). Overexpressed A20 in liver graft resulted in a significantly decreased number of transferase dUTP nick end-labelling-positive liver cells (B) compared with physiological saline group rats (A) and rAdEasy group rats (C) ($P < 0.01$).

finger protein A20, a potent negative feedback inhibitor of NF- κ B activation and a hepatoprotective gene, could suppress chronic liver allograft dysfunction in rats.

The identification of NF- κ B as a key factor for the pathogenesis of allograft rejection suggests that NF- κ B-targeted therapeutics might be useful in transplant patients. Although many drugs, such as corticosteroids and cyclosporin, can inhibit NF- κ B activation^[38-40], these immunosuppressants have few effects on chronic liver allograft dysfunction. Therefore, novel effective agents for chronic liver allograft dysfunction should be investigated.

Previous studies have identified A20 as a critical component of the physiologic hepatoprotective role of hepatocytes. The effects of A20 on lipopolysaccharide-induced acute toxic lethal hepatitis^[22,23], liver regeneration^[22,23,33], hepatic I/R injury^[60] and liver allograft rejection^[33] have been investigated. Furthermore, as a role for NF- κ B is inferred in the pathological changes involved in chronic liver allograft dysfunction, such as liver cell death, arterial proliferative occlusive disease and/or bile duct disappearance, and eventually liver fibrosis, we reasoned that A20 would probably attenuate chronic liver allograft dysfunction. In the present study, we found that A20 is also an effective agent for chronic liver allograft dysfunction by showing that fibrosis was markedly attenuated in A20-overexpressing liver allografts compared with the controls. The suppressed NF- κ B activation in LSECs, KCs and HSCs, the decreased production of TGF- β 1, IL-1 β , caspase-8, ICAM-1, VCAM-1, E-selectin, CD40 and CD40L, as well as the suppressed level of liver cell apoptosis, are possible mechanisms for these effects.

Overproduction of TGF- β 1 is a chief cause of liver fibrosis. TGF- β 1 is mainly produced by HSCs and KCs. HSC has been affirmed to be the main effector cell of liver fibrosis. As the main macrophage and proinflammatory cell, KCs not only perform phagocytosis, but they also release many proinflammatory cytokines, including TNF- α , IL-1, IL-6 and TGF- β 1, meaning that the role of KCs in liver grafts may change during different phases, including the early phase of induction of hepatic I/R injury^[41], the acute rejection phase in human liver allografts^[42] and during the establishment of tolerance in the OLT model of transplantation from one Sprague-Dawley (SD) rat to another SD rat^[43]. However, the role of KCs in chronic liver graft dysfunction has not been investigated. IL-1 has been shown to contribute to chronic

rejection^[6]. IL-1 produced by activated macrophages and many other cell types, including injured ECs, increases smooth muscle proliferation *in vitro* and the adhesive properties of the vascular endothelium. LSECs provide a barrier against the infiltration of the liver graft infiltrating mononuclear cells (LIMCs), and blocking of adhesion molecules, such as ICAM-1, on ECs interferes with recruitment of sinusoidal NK-like cells into the rat liver^[44]. NF- κ B activation is the key regulatory factor of nuclear transcription of TGF- β and IL-1 in these cells; therefore, inhibition of NF- κ B activation could inhibit transcription of TGF- β and IL-1. In our previous study, we showed that A20 could inhibit NF- κ B activation and apoptosis in LSECs, which subsequently suppresses ICAM-1 mRNA expression and recruitment of LIMCs, including T cells and NK/NKT cells^[33]. Thus, we reasoned that LSECs and KCs could play important effect on the development of chronic liver allograft dysfunction. Therefore, functional changes of KCs and LSECs in liver allografts, including NF- κ B activation and transcription of TGF- β and IL-1, were investigated in the present study.

Low-dose tacrolimus was administrated post-OLT for 5 d to induce liver allograft dysfunction in the present study. Short-term postoperative administration of low-dose tacrolimus resulted in significant liver fibrosis on POD 60 and reduced liver function on POD 30 and POD 60. Excessive NF- κ B activation and a high level of mRNA expression of ICAM-1, VCAM-1, E-selectin, IL-1 β and CD40 in LSECs were found on POD 30 and POD 60. Similar changes were detected in KCs and HSCs, including marked NF- κ B activation and high levels of TGF- β 1, IL-1 β and CD40L mRNA expression in KCs, as well as elevated TGF- β 1 protein levels in HSCs. Increased hepatic protein production of TGF- β 1, IL-1 β , ICAM-1, VCAM-1, E-selectin, CD40 and CD40L were also detected on POD30 and POD 60. These results suggested that excessive NF- κ B activation and the associated production and secretion of cytokines by LSECs, KCs and HSCs may be the important steps inducing chronic liver allograft dysfunction. This hypothesis was confirmed by the results obtained with the combined A20 treatment. Liver fibrosis and liver function were significantly improved by the combined A20 treatment. Furthermore, the NF- κ B activity in LSECs, KCs and HSCs was significantly down-regulated by A20 treatment, and consequently the elevated cytokines mRNA expression and protein production were more suppressed. Suppression of ICAM-1, VCAM-1 and E-selectin production in LSECs could inhibit the recruitment of LIMCs into the liver graft^[33], reducing the hepatic injury caused by LIMCs. The down-regulated IL-1 β secretion in LSECs and KCs might theoretically suppress chronic rejection^[6]. The CD40/CD40 L signalling pathway is a potent activator of ECs and a promoter of atherosclerosis. A20 works at multiple levels to protect ECs from CD40/CD40L-mediated activation and apoptosis. A20-based therapy could be beneficial for the treatment of vascular diseases, such as atherosclerosis and transplant-associated vascu-

lopathy^[15]. A20 can also inhibit NF- κ B activation induced by LPS, IL-1 and CD40 cross-linking through a negative feedback loop^[24-26]. Previous data suggested that FasL expression on APCs and phagocytosis of apoptotic T cells by FasL⁺ KCs were indicators of acute and chronic rejection activity in human liver allografts^[41]. In the present study, the A20-induced decrease in the expression of IL-1 and CD40 in LSECs, as well as IL-1 and CD40L in KCs, might inhibit NF- κ B activation in LSECs through a negative feedback loop and protect LSECs from apoptosis, subsequently inhibiting recruitment of LIMCs into the liver graft. Suppression of NF- κ B activation in KCs could inhibit hepatic ischemia/reperfusion injury, which represents an important cause of chronic liver allograft dysfunction. The decreased expression of TGF- β 1 in KCs and the suppressed NF- κ B activation in HSCs by A20 might inhibit the transition from HSCs to myofibroblast-like cells and consequently suppress TGF- β 1 protein production in HSCs. The present study also revealed suppressed TGF- β 1 production and reduced fibrosis in combined A20-treated liver grafts.

A20 has a dual cytoprotective function in ECs and hepatocytes. In addition to its anti-inflammatory function, A20 is also antiapoptotic through inhibition of the caspase cascade at the level of initiator caspase 8^[21-23]. A20 can also protect hepatocytes from TNF-mediated apoptosis^[21,22]. Furthermore, it has been well-established that hepatocytes undergo apoptotic cell death in the course of rejection of a liver graft, and apoptosis is a mechanism of cell death in liver allograft rejection^[45,46]. FasL expression on activated NK cells was augmented^[47,48], and FasL ligation to Fas expressed on hepatocytes could mediate hepatocyte apoptosis^[49,50]. In the present study, high levels of caspase-8 and caspase-1 protein were demonstrated in the liver grafts with chronic dysfunction, and caspase-8 but not caspase-1 production was markedly decreased by A20 treatment. This result was the opposite of the findings presented in the previous study^[5] in which hepatocyte growth factor significantly suppressed the production of caspase-1 but not caspase-8 in liver allografts with chronic dysfunction. However, the A20-induced decrease in hepatic caspase-8 production observed in the present study was consistent with the report by Daniel *et al.*^[23], who demonstrated that A20 could protect ECs from TNF-, Fas-, and NK-mediated cell death by inhibiting caspase-8 activation. Our previous study^[33] also showed a marked down-regulation of the number of LIMCs by A20, including a more prominent decrease in the subproportion of NK and NKT cells in the liver allograft. Thus, we could hypothesise that A20 could inhibit infiltration of LIMC (including NK cell) by suppression of LSEC caspase-8 activation in the liver allograft and consequently attenuate hepatic injury, including acute rejection and chronic dysfunction. In the present study, liver cell (including hepatocyte) apoptosis increased chronic dysfunction progressed, and the apoptosis indices in the PS group and the rAdEasy group on POD 60 were markedly higher than on POD 30 in the same groups. However,

A20 treatment significantly inhibited liver cell apoptosis, and the results showed that the apoptosis index on POD 30 and POD 60 in A20 group were similar.

In summary, A20 could protect the liver allograft from chronic dysfunction, which might be caused by the re-established functional homeostasis of KCs, LSECs and HSCs, as well as the suppressed liver cell apoptosis.

COMMENTS

Background

In spite of the introduction of the use of tacrolimus in liver transplantation recipients, the incidence of chronic liver allograft dysfunction is still high in long-surviving recipients. Chronic liver allograft dysfunction, which results in the loss of approximately 2000 liver grafts every year, has a great impact on liver graft function and long-term survival. The mechanisms of chronic liver allograft dysfunction are still unclear, and there is no effective treatment. The possible factors that induce chronic liver allograft dysfunction include immune and non-immune events.

Research frontiers

Many important events, such as activation of liver graft sinusoidal endothelial cells (LSECs), activation of Kupffer cells and hepatic satellite cells, atherosclerosis, hepatic fibrosis and liver cells' apoptosis through nuclear factor- κ B (NF- κ B) activation, were reproduced in the rat model of chronic liver allograft dysfunction, and the effects of the zinc finger protein A20 on chronic liver allograft dysfunction were investigated, including the effects of A20 on recipient survival, hepatic fibrosis and liver function, NF- κ B activation in LSECs, Kupffer cells and hepatic stellate cells, liver cell apoptosis, and the expression of the related cytokines.

Innovations and breakthroughs

This study sought to elucidate the cellular mechanisms of chronic liver allograft dysfunction. This study also intended to provide a theoretical basis for the use of A20 as a treatment of liver allograft chronic dysfunction.

Applications

The study results suggest that the zinc finger protein A20 may be an effective tool for the prevention and treatment for chronic liver dysfunction after liver transplantation.

Terminology

A20 is a zinc finger protein originally identified as a tumor necrosis factor-responsive gene in endothelial cells (ECs). A20 is expressed in multiple cell types, including fibroblasts, B cells, T cells, and β cells, in response to a variety of stimuli that activate NF- κ B, including interleukin-1, lipopolysaccharides, phorbol 12-myristate 13-acetate, H₂O₂ and CD40 ligand. In ECs and hepatocytes, A20 has a dual cytoprotective function. It has been shown that A20 is a protective gene for the liver.

Peer review

This is an original study in which the authors provide strong evidence demonstrating the important finding that the zinc finger protein A20 might protect liver allografts from chronic dysfunction. These results are easily comprehensible and convincing. Additionally, the study explores the cellular and molecular mechanisms of chronic liver allograft dysfunction.

Abstract

AIM: To complete a quality audit using recently published criteria from the Quality Assurance Task Group of the National Colorectal Cancer Roundtable.

METHODS: Consecutive colonoscopy reports of patients at average/high risk screening, or with a prior colorectal neoplasia (CRN) by endoscopists who perform 11 000 procedures yearly, using a commercial computerized endoscopic report generator. A separate institutional database providing pathological results. Required documentation included patient demographics, history, procedure indications, technical descriptions, colonoscopy findings, interventions, unplanned events, follow-up plans, and pathology results. Reports abstraction employed a standardized glossary with 10% independent data validation. Sample size calculations determined the number of reports needed.

RESULTS: Two hundreds and fifty patients (63.2 ± 10.5 years, female: 42.8%, average risk: 38.5%, personal/family history of CRN: 43.3%/20.2%) were scoped in June 2009 by 8 gastroenterologists and 3 surgeons (mean practice: 17.1 ± 8.5 years). Procedural indication and informed consent were always documented. 14% provided a previous colonoscopy date (past polyp removal information in 25%, but insufficient in most to determine surveillance intervals appropriateness). Most procedural indicators were recorded (exam date: 98.4%, medications: 99.2%, difficulty level: 98.8%, prep quality: 99.6%). All reports noted extent of visualization (cecum: 94.4%, with landmarks noted in 78.8% - photodocumentation: 67.2%). No procedural times were recorded. One hundred and eleven had polyps (44.4%) with anatomic location noted in 99.1%, size in 65.8%, morphology in 62.2%; removal was by cold biopsy in 25.2% (cold snare: 18%, snare cautery: 31.5%, unrecorded: 20.7%), 84.7% were retrieved. Adenomas were noted in 24.8% (advanced adenomas: 7.6%, cancer: 0.4%) in this population with varying previous colonic investigations.

CONCLUSION: This audit reveals lacking reported items, justifying additional research to optimize quality of reporting.

INTRODUCTION

Colorectal cancer (CRC) is the second leading cause of death from cancer in Canada^[1]. Screening of asymptomatic average-risk persons for this type of cancer is strongly recommended^[2-6]. Colonoscopy is one of the most accurate screening tests for CRC. It is used for primary CRC screening but also for surveillance of patients with prior colorectal neoplasia (CRN), including cancer, and diagnosing patients with lower gastrointestinal (GI)-tract symptoms. The effectiveness and safety of colonoscopy depends, However, on the quality of examination in what is a high-volume procedural setting. A growing body of evidence suggests that the quality of clinical practice varies^[7-12].

In 2007, the Quality Assurance Task Group of the National CRC Roundtable developed a reporting and data system for colonoscopy (CO-RADS) to assist endoscopists in establishing standards that permit the monitoring of quality indicators in their practice. The Quality Assurance Task Group created a standardized reporting system that represents a consensus among experts in gastroenterology, diagnostic radiology, primary care and health care delivery^[2]. A national US study was recently conducted, using the standardized reporting system, and uncovering lacks in the colonoscopy reports. Yet in Canada, to our knowledge, no such initiative has been published to date^[13].

The objective of this study was therefore to assess the level of adherence of a sample of colonoscopy reports from an academic university-based endoscopy unit using the criteria set out by the Quality Assurance Task Group CO-RADS, and to determine reporting of quality indicators with the poorest adherence.

MATERIALS AND METHODS

Patient population

We selected consecutive colonoscopy reports completed from procedures performed in June 2009. We only considered procedures carried out for the screening or surveillance of patients with prior CRN, excluding colonoscopy reports completed for other reported indications.

Electronic reporting system and institutional database

The Montreal General Hospital site of the McGill University Health Centre (MUHC-MGH) is a tertiary care institution with a 4-room endoscopy unit staffed by 12 medical and surgical endoscopists. Patients can access the services of the unit both through a same-day consultation and procedural critical path of care at the request of a referring physician providing screened information, or on a subsequent date, after the specialist endoscopist has initially assessed the patient in the office. On average, 11 000 procedures are performed at the MUHC-MGH per year, of which 75% were colonoscopies in 2008. Average waiting time between the indication of the colonoscopy and the colonoscopy is currently around 2-3 mo. All patients receive an information sheet on the procedure

prior to colonoscopy and consent is obtained by the endoscopist. Patients also receive written instructions after the colonoscopy is performed.

The unit is equipped with a structured, computerized endoscopic report generator allowing for image and video capture (Endoworks, Olympus Corporation, Center Valley, PA, United States). It is used for all cases performed during and outside regular hours by all endoscopists. The data file from the report is electronically transmitted to a central data repository housed at the MUHC-MGH. The information is then securely locked in an MUHC Endoworks database.

The routine colonoscopy report at the MUHC-MGH endoscopy unit includes some compulsory fields, default population of certain fields included in the final report for which the endoscopist needs to approve or choose alternatives, drop down menus for selecting other components of the report, and data acquisition fields for free text entries. Endoscopists were not aware we would be carrying out the audit at the time the reports were entered in Endoworks. Any *post-hoc* amendment of a report can be identified through a review of the electronic log entries.

We also accessed pathology results from an institutional electronic medical file software (OACIS, Telus, Vancouver, Canada) which is not part of Endoworks as the current practice is not to link directly the pathology results as part of the actual colonoscopy report. These latter data provided us with the prevalences of adenomas, advanced adenomas, and cancer detection rate.

Quality indicators

Based upon continuous quality improvement indicators established by the Quality Assurance Task Group of the National CRC Roundtable^[2], we developed a specific list of quality indicators (Table 1) that should be explicitly addressed in the colonoscopy reports, and made available to the referring physician. Unplanned interventions for adverse events included only those interventions that were reported at the time of colonoscopy since no specific mechanism or manpower support currently exists at the MUHC-MGH digestive endoscopy unit to allow for the reliable capture of downstream adverse events once the patient has returned home.

Data collection

The current study is a retrospective review of all consecutive eligible reports using a standardized checklist developed using the Quality Assurance Task Group of the National CRC Roundtable publication^[2]. We dichotomized screened patients into those for whom the indication for colonoscopy was average or increased-risk (patients with a family or personal history of CRC or polyps). Data were compiled and individually analyzed by a trained research assistant using a specially developed electronic data abstraction form. Using a standardized glossary of study variables, 10% of all entered data was reviewed by an independent observer and validated.

MRN: Medical record number; ASA: American Society of Anesthesiology; GI: Gastrointestinal.

Statistical analysis

The sample size was based on a preliminary analysis of the first 111 consecutive reports. The widest point estimate for presence (or absence) of documentation of a quality indicator was for that of polyp removal (51.1%; 95% CI: 35.9%-63.3%). We estimated the number of reviewed reports, needed to narrow the range of uncertainty around this point estimate to 10%. Assuming an identical projected point estimate of 51%, we calculated that we would need to audit 250 scope reports to narrow a 95% CI down to 45.5%-55.8%. We therefore completed the audit up to this consecutive number of patients.

Descriptive variables are presented as means and standard deviations for continuous variables and proportions with 95% confidence intervals for categorical variables. All analyses were performed by using SAS software version 9.1 (SAS Institute Inc, Cary, NC, United States).

Table 2 Patient population and endoscopists description *n* (%)

Specialty of endoscopists	
Surgical	3 (27.3)
GI	8 (72.7)
Average years of endoscopists practice (yr)	17.1 ± 8.5

HNPCC: Hereditary nonpolyposis colorectal cancer syndrome; FAP: Familial adenomatous polyposis; GI: Gastrointestinal.

RESULTS

From June 1st to June 30th 2009, 250 reports on 250 consecutive patients were audited for the frequency of reporting of patient demographics and history, procedure indications, technical descriptions, colonoscopy findings, interventions, unplanned events, follow-up plan, and we reviewed the corresponding histological information. These 250 colonoscopy reports were reported by 11 different physicians including 2 colorectal surgeons, 1 general surgeon, and 8 gastroenterologists. Not all endoscopists were included since they do not all perform screening colonoscopies. The average number of years of practice of the 11 endoscopists was 17.1 ± 8.5 years.

Patient demographics and endoscopists' description

The overall patient population and endoscopists' description of the reports are presented in Table 2. The mean age of the patient population was 63.2 ± 10.5 years with 42.8% of the patients being women. The procedure indication pertaining to the risk of the patient was indicated in every report. Overall, 38.5% of examinations were performed on average risk individuals, 43.3% of patients had a past personal history of prior CRN, while 20.2% of patients had first-degree relatives with CRC or a CR adenoma. Only one patient had a hereditary nonpolyposis CRC syndrome, while another had familial adenomatous polyposis.

Pre-procedure indicators

The American Society of Anesthesiology (ASA) classification field was not completed in any of the reports. The documentation of informed consent was noted in all reports. Overall, 9.6% of patients had had previous colonoscopies, but the date of the prior examination was only noted in 14% of reports with details about previous polyp resection in 25%. In most cases, the colonoscopy report lacked sufficient information to determine wheth-

¹Usually documented elsewhere, but not in the endoscopy report. ASA: American Society of Anesthesiology; GI: Gastrointestinal.

er the surveillance interval respected published guidelines (Table 3).

Procedural indicators

The date of the examination was recorded in 98.4% of reports. Administered medications and dosage were indicated in 99.2%, while the level of difficulty of the procedure was reported in 98.8%. The quality of the bowel preparation was not recorded in 0.1% of the reports. When reported, the quality was described as good in 85.1%, fair in 10.8% and poor in 4%. All reports included information about cecal intubation. The cecum was reached in 94.4% of examinations, while cecal landmarks (appendiceal orifice and/or ileocecal valve) were noted in 78.8% when the cecum had been reached. Photo-documentation was present in 67.2% of reports. Retroflexion in the rectum was performed in 70.8% of procedures. Total procedural and withdrawal times were never recorded. Intra-procedural complications were reported in 0.4% (Table 4).

Colonoscopic findings

Polyps were found in 111 procedures (44.4%). Amongst all patients with polyps, polyp size was recorded in 65.8%, and morphology in 62.2%. The mean polyp size was 17.6 ± 33.1 mm. The anatomic location of the polyp(s) was documented in 99.1%. The method of polyp removal was not mentioned in 20.7% of the reports. When specified, 25.2% of the polyps were removed by cold biopsy, 18% by cold snare, and 31.5% using hot snare cautery. Eighty-four point seven percent of all polyps were retrieved and 76.5% were sent to pathology (Table 4).

Of all retrieved polyps (44.4% of all patients), 70% were adenomas (24.8% of all patients), 21% (7.6% of all patients) were advanced adenomas, and 1% (0.4% of all patients) were cancerous.

Post-procedural indication

Ninety-nine point six percent of all endoscopy reports included documentation of discharge plans. Although documented elsewhere, none of the reports included post-discharge precautions to patients nor the documentation of pathology.

Sent to pathology	85 (76.5, 95% CI: 67.3-85.7)

DISCUSSION

The effectiveness of colonoscopy in reducing cancer prevalence cannot be improved if procedural reports do not include critical quality indicators to track performance in colonoscopy. In other words, the potential benefits of colonoscopy depend on the quality of the examination^[14], and thereby its reporting. The final version of the Standardized Colonoscopy Report includes important elements that can be measured in diverse clinical practice settings. Patient demographics and history, assessment of patient risk and comorbidities, procedure indications, procedure technical description, colonoscopy findings, assessment, interventions and unplanned events, follow-up plan, and pathology are the main variables proposed by the Standardized Colonoscopy Report established by the Quality Assurance Task Group of the National CRC Roundtable, requiring recording^[2].

The current study revealed that even with a computerized endoscopic report generator, some key quality fields were lacking, some often. Several of these fields are

Table 5 Comparison between national United States study and the current audit

ASA: American Society of Anesthesiology; GI: Gastrointestinal.

important in determining the quality of the examination including photo documentation of cecal landmarks present in only (67.2%; 95% CI: 61.3%-73.1%). Of course, the absence of these data does not allow us, to infer about a poor examination quality, but makes its tracking difficult, and even impossible for certain aspects. Assuming all past procedures were indicated, the current reports should include documentation of the prior colonoscopy examinations and their findings. In most cases, we found this documentation lacking (86%; 95% CI: 81.5%-90.5%), and, therefore, it was often not possible to determine the appropriateness of the screening interval. Additional important missing information in the report included historical data which, according to current local practice, may be present in a separate consultation report. Nonetheless, the Quality Assurance Task Group of the National CRC Roundtable has mandated that, to facilitate adequate benchmarking, this information should be found in the endoscopic report.

The omission of key polyp descriptors like polyp size absent in (34.2%; 95% CI: 25.3%-43.2%), the number of polyps found, and the morphology lacking in (37.8%; 95% CI: 28.7%-47.0%) of reports can impact subsequent decisions on surveillance colonoscopy intervals^[15], although a more accurate determination of polyp size is available from the histological reports, when available. This information should eventually find its way back to the endoscopy report for benchmarking purposes of endoscopists and for good clinical practice to ensure a copy is sent to the referring physician^[16]. Here too, these data may have been documented in a separate follow-up form. However once again, Lieberman *et al.*^[2] have suggested that these data be present in the actual (follow-up) endoscopy report. Indeed, any subsequent quality initiative would otherwise be limited with various pieces of information being present in different places-i.e., not all documented in the electronic report. Furthermore,

if the documentation of whether the polyp was sent to pathology or not was omitted in many (23.5%; 95% CI: 14.3%-32.7%) of examinations, and affects the immediate patient care, that could lead to risks of undiagnosed cancers if this information is not efficiently retrieved and integrated in overall management. We also had no way of validating whether post-procedural complications were noted without reviewing a patient's file (and even then, such information may be lacking) These data should also find their way back to the endoscopy report. Perhaps data cross links or integrated data management will help future enhancement of reporting quality across pre, intra- and post-procedural domains of quality reporting.

Procedure durations (withdrawal and total times) were never recorded. Although, somewhat of a controversial subject, there is evidence that there exists a significant correlation between withdrawal time and adenoma detection rates^[15,17]. It is thus recommended as a quality indicator and has been found useful in previous audits^[7].

We noted other lacks in reporting of selected variables which are recommended but do not directly impact examination quality including the ASA classification which was absent in all reports in this audit. Although, this indicator does not reflect examination quality, it can be an important surrogate of co-morbidity^[18], and better defines the screened population, aiding the explanation of possible subsequent morbidity and the interpretation of medications dosing and the interpretation of reported patient satisfaction.

Another controversial variable was retroflexion in the rectum (performed in 70.8% of examinations); it provides additional data that can be added to complete an accurate colonoscopy report, and its recording may be useful either in demonstrating its need in identifying pathology; it remains a controversial quality indicator^[12,13].

A number of the variables were recorded in the great majority of the reports such as the date of the exam (98.4%; 95% CI: 96.8%-100.0%), used medications with dosage (99.2%; 95% CI: 98.1%-100.0%), the level of difficulty of the procedure (98.8%; 95% CI: 97.4%-100.0%) and the bowel preparation quality. The compulsory nature of some fields, pre-formatted text, and drop-down menus in the electronic reporting system no doubt participated in this high level of reporting, and should serve to guide improvement in areas of in which the recording of variables was lacking. Indeed, these fields likely need to be developed for other variables which are less frequently reported yet needed.

We compared the findings of the current study with the one conducted by Lieberman *et al.*^[13]. The study using a national CORI database^[13] included 73 US gastroenterology practice sites, and 43 8521 reports. Some differences in patient characteristics existed (Table 5). Quality outcomes from the procedure were similar or superior in the Canadian study polyp detection rate (44.4% vs 36.3%; 95% CI: 38.2%-50.6%), while the documentation of patient or procedural variables was poorer in many instances [such as for ASA classification, withdrawal times, previous colonoscopy date, photo-documentation of

cecal landmarks, and polyp description, (Table 5)]. They also used the proportion of patients with polyp(s) > 9 mm or with suspected malignant tumour as a surrogate end point for advanced neoplasia.

Although not our primary aim, this quality initiative also allowed us to benchmark the quality of the colonoscopies performed in this successive sample, and compare them to established consensus thresholds. In total, 111 polyps were found (44.4%). The adenoma detection rate was of (24.8%; 95% CI: 19.4%-30.2%) which suggests that even in this population with a varying colonoscopy screening history, adenoma pick-up rates were excellent, since respective recommended thresholds are > 25% in men older than 50% and > 15% in women according to current recommendations by the United States Multi-Society Task Force on CRC^[7,15] and a recent meta-analysis^[19]. Furthermore, the recommended benchmark for cecal intubation rate is 95% which is comparable to the cecal intubation rate achieved in this study (94.4%; 95% CI: 91.5%-97.3%)^[7,15,20,21]. These recommendations are part of a series of recent studies published in the world literature aimed at improving the quality of colonoscopy^[22-24] in an attempt to optimize patient outcomes in CRC screening^[25].

In summary, the overall quality of the reports was good (considering the location of reported information pre- and post-procedures), although not optimal. Indeed, the MUHC-MGH group appears to perform within the threshold set by the Quality Assurance Task Group of the National CRC Roundtable^[2] for most indicators, although improvement is required for some documentation (for e.g., ASA score, and withdrawal time). It is now imperative to continue to improve the appropriate use of the reporting system and revise the user-interface of the software accordingly to optimize the quality of colonoscopies and CRC screening care. Moreover, further improvements are needed in linking databases for optimal consolidation of information on past procedures, post-procedural complications, and pathology results such that they all appear in a single report that can be provided to referring physicians and patients.

COMMENTS

Background

Colonoscopic quality is critical in colorectal cancer screening. Formal quality assessments of colonoscopy reporting are few. The authors completed a quality review according to criteria of the Quality Assurance Task Group of the National Colorectal Cancer (CRC) Roundtable.

Research frontiers

Prospective studies assessing the completeness of colonoscopic reporting for CRC screening are few in the literature.

Innovations and breakthroughs

The authors audited reports of 250 patients (63.2 ± 10.5 years, 42.8% female) scoped in June 2009 by 8 gastrointestinal and 3 surgeons (mean practice years = 15.3). While some quality indicators were routinely reported, others were systematically lacking.

Applications

Modification of the electronic reporting software for colonoscopy reporting is required to optimize quality indicator reporting.

Peer review

This is a good descriptive study in which authors complete a quality audit using

recently published criteria from the Quality Assurance Task Group of the National CRC Roundtable. The results are interesting and suggest two hundreds and fifty patients were scoped in June 2009 by 8 gastroenterologists and 3 surgeons.

Abstract

AIM: To compare natural orifice transluminal endoscopic surgery (NOTES) vs standard laparoscopic ovariectomy in mini pigs with respect to technical aspects, complications and parameters of systemic inflammatory response.

METHODS: This was a randomized, experimental,

survival study. Ten female mini pigs underwent NOTES transgastric ovariectomy (NOTES group) and ten female mini pigs underwent laparoscopic ovariectomy (LAP group). A "percutaneous endoscopic gastrotomy" approach with guidewire and sphincterotome was used for gastrotomy creation. The ovary was resected using standard biopsy forceps and a snare. The access site was closed using a "KING" closure with a single endoloop and several clips. In the laparoscopic group, a three-port laparoscopy and an ovariectomy were performed with the use of standard laparoscopic devices. C-reactive protein (CRP), white blood count and interleukin (IL)-6 plasma levels were used as indicators of systemic inflammatory response. All animals were euthanized 28 d after surgery.

RESULTS: All animals survived without complications. The mean procedure time was 41.3 min \pm 17.6 min (NOTES group) and 25.7 min \pm 5.25 min (LAP group, $P < 0.02$). Postmortem examinations demonstrated that 50% and 70% of animals were free of any complications in the NOTES and LAP groups, respectively. The remaining animals developed minor complications (adhesions) in a comparable frequency between the two groups. In the NOTES group, one animal developed a small intramural gastric abscess close to the gastrotomy site. A minor serous exudate that was present in 50% and 40% of the animals in the NOTES and laparoscopy groups, respectively, was not considered a complication. In both groups CRP levels increased significantly on the 2nd and 7th postoperative days (POD) and returned to normal after 28 d. On POD 2, an increase of CRP level was significantly higher in the NOTES group compared to the LAP group. Values of IL-6 did not differ from baseline values in either of the groups postoperatively. Interestingly, the platelet count decreased significantly on POD 2, but returned close to baseline values on POD 7 and PODs 28-30.

CONCLUSION: Both NOTES and laparoscopic ovariec-

tomies had a similar frequency of minor complications. However, the NOTES technique produced an increased systemic inflammatory response on POD 2.

INTRODUCTION

Natural orifice transluminal endoscopic surgery (NOTES) is a surgical procedure that enables intraperitoneal surgical interventions with the elimination of abdominal wall incisions. The potential benefits of NOTES include no remnant scars and obviating the possibility of abdominal wall infection and hernia formation. Although several NOTES procedures have already been performed in humans^[1], NOTES still remains an experimental surgical technique. Since laparoscopy serves as a golden standard for mini-invasive surgery, NOTES should be compared to laparoscopy in all imaginable aspects. If NOTES is to be used in the future, it must at least reach standards comparable to the existing procedures.

Several small experimental studies have compared NOTES with laparoscopic procedures. These included peritoneoscopy, transvaginal cholecystectomy, colon injury repair and distal pancreatectomy^[2-6]. NOTES procedures were feasible but they usually lasted longer. Most studies found a comparable frequency of abdominal complications. Only a few studies tested the differences in systemic inflammatory response, however, no finding has ever suggested a clear difference between NOTES and laparoscopy^[3,4,7]. Only one study found a potentially significant relative thrombocytopenia in NOTES as compared to laparoscopy during a simple peritoneoscopy^[8].

The aim of our randomized experimental survival study was to compare both the outcome criteria (mortality, morbidity and complications such as peritonitis or adhesion formations) and indicators of postoperative systemic inflammatory response and platelet count in NOTES and laparoscopic ovariectomy in mini pigs. There is currently no data available comparing laparoscopic and NOTES

experimental ovariectomy. In addition, ovariectomy can serve as a model for appendectomy from a technical point of view since pigs do not have an appendix. The main working hypothesis was the non-inferiority of NOTES to standard laparoscopic procedures.

MATERIALS AND METHODS

Twenty female domestic mini pigs weighing between 10-31 kg were used for this study. Ten animals underwent a NOTES procedure and 10 animals underwent a laparoscopic procedure. The animals were randomly assigned to one of the two groups using a block randomization allowing an equal number of animals in each group.

Before the procedure, the animals were fed with a liquid diet for 2 d and consequently left fasting overnight. Premedication with Ketamine 10 mg/kg (Narkamon 1%, SPOFA, Czech Republic) and Atropine 0.2 mg (Atropine Biotica 0.5 mg, BB Pharma, Czech Republic) was given IM 30 min before the procedure. Oral intubation of the mini pigs was performed, a marginal ear vein cannula was placed and anesthesia was maintained using 1.5% isoflurane and fentanyl (3-5 mL/h). Antibiotics were administered neither before nor after the procedure.

The protocol was approved by The Committee for the Protection of Animals of The Czech Academy of Sciences and the experiment was performed in accordance with Act No. 246/1992.

Natural orifice transluminal endoscopic surgery procedure

All procedures were performed with a double-channel endoscope (GIF 2T160; Olympus Medical Co., Tokyo, Japan). The percutaneous endoscopic gastrostomy was used to gain access into the peritoneal cavity^[9]. After transillumination, the stomach was punctured with a needle and the guidewire (Jagwire; Boston Scientific, Natick, Mass) was introduced through the needle into the stomach. The guidewire was then locked-in with a snare and pulled out through the endoscope. Consequently, the sphincterotome (KD-V411M-0330 Papillotome, Olympus Medical Co.) was introduced with the guidewire to the gastric wall. A gastric wall incision measuring approximately 15-20 mm was then performed with a tightened sphincterotome, and the endoscope was advanced into the peritoneal cavity. Afterwards, a brief exploration of the peritoneal cavity was performed with the endoscope.

Air was used for moderate insufflation, but intraperitoneal pressure was not measured during the procedure.

The ovary was then exposed and resected using both standard biopsy forceps and a snare with a coagulation current.

The endoscope with a resected ovary using a tightened snare was then pulled back to the stomach and the peritoneal cavity was completely desufflated. The desufflation was possible without reintroducing the scope into the abdominal cavity since a double-channel endoscope was used. After the ovary was withdrawn from the mouth, the endoscope was reintroduced for the gastric wall closure.

The gastric wall closure was performed with one en-

doloop (HX-400U-30 Aset PolyLoop Colo5; Olympus Medical Co.) and 4-5 clips. This technique provides a reliable full-thickness closure^[10]. An open endoloop with a diameter of 30 mm (MAJ-340, Olympus Medical Co.) was fixed around the gastrotomy site with 4-5 clips (HX-610-90L, Olympus Medical Co.). A big endoscopic grasper (Olympus FG-48L, 026235, Olympus Medical Co.) was then advanced through an open endoloop. Both edges of the incision were grasped and pulled through the endoloop toward the endoscope. Subsequently, the endoloop was closed and released.

Laparoscopic procedure

The laparoscopic group consisted of ten animals undergoing a standard three-trocar laparoscopic ovariectomy. After the induction of anesthesia, a pneumoperitoneum was established with CO₂ using a standard laparoscopic insufflator. The insufflation pressure was set to 10 mmHg and gas flow was initiated. After pneumoperitoneum was established, the intra-abdominal pressure was monitored throughout the procedure. After the exposure of the fallopian tube, the ovary was resected using scissors with a monopolar coagulation current, and the ovary was grasped and withdrawn using grasping forceps. The pneumoperitoneum was evacuated and all skin incisions were closed with a single absorbable suture.

Postoperative period and blood drawing

All pigs recovered well after extubation and were placed in an animal facility unit where they were monitored twice a day for any signs of complications, whether in feeding or in general well-being. All pigs resumed pig chow on the first postoperative day. Their survival was assessed on the 28-30th postoperative day, at which point the animals were euthanized and a necropsy was performed. The adhesions were assessed using the Adhesion Scoring Group system (none; minor = avascular, flimsy; major = dense and/or vascular or cohesive)^[11].

Blood samples for the blood count, C-reactive protein (CRP)-levels, and interleukin 6 (IL-6) levels were taken before the procedure (15-60 min) and on days 2, 7 and 28-30 after the procedure. The blood count was analyzed immediately using a fully automatic hematology analyzer (Scil ABC Vet 16p, ABX Diagnostics, France). Blood samples for CRP and IL-6 analyses were centrifuged and plasma kept frozen (-80 °C) until the final analysis.

Analysis of C-reactive protein and IL-6

Both CRP and IL-6 were analyzed in duplicate with one control. A commercially available enzyme-linked immunosorbent assay kit Quantikine Porcine IL-6 Immunoassay (R and D Systems, Inc.) was used to measure IL-6 levels. The dynamic range of the assay was 39.1-2500 ng/L. An Immunoperoxidase Assay for Determination of C-Reactive Protein in Pig Samples (Gen Way Biotech, Inc.) was used for CRP level assessment. Its dynamic range was 6.25-200 µg/L. An analysis was performed according to the manufacturer's instructions by a researcher blinded to the operative procedure.

Table 1 Necropsy findings 4 wk after the procedure *n* (%)

	Laparoscopy	Notes	
Adhesions	3 (30)	4 (40)	NS
Abscess	0	1 (10) ¹	NS
Peritonitis	0	0	NS
Pigs without any complication	7 (70)	5 (50)	NS

¹Small intramural abscess (8 mm) at the healed gastrotomy site. NS: Not significant.

Statistical analysis

For descriptive statistics, the data is presented as median values with appropriate percentiles. As all variables confirmed the normality and equal variance assumption, a Student *t*-test was performed for testing the differences between and within the groups. Binary variables (e.g., presence or absence of complications) were assessed with the Fisher exact test. Statistical significance was defined as a *P*-value of less than 0.05 and all *P*-values were two-sided. For multiple comparisons, a Bonferroni correction was used.

RESULTS

Procedure

Access into the peritoneal cavity was gained within 3-7 min in all animals in the NOTES group. A peritoneoscopy did not show any injuries to adjacent organs. Seven right-sided and three left-sided ovariectomies were performed without major technical problems. All gastrotomies were successfully closed using the technique described above.

All laparoscopies were performed without major technical problems. Nine right-sided and one left-sided ovariectomies were performed.

The NOTES procedure took significantly longer than the laparoscopy procedure - medians were 42.5 min [interquartile (IQ) range: 30-45 min] vs 25 min (IQ range: 25-29 min), *P* = 0.02.

Survival and complications

All animals had lived and had been fed normally without any clinical signs suggesting complications until they were euthanized. They gained the desirable weight after the procedure. At necropsy no signs of organ damage or peritonitis were discovered in either group. The gastrotomy site healed completely in all pigs. Only minor complications were found (minor adhesions and one small abscess) in similar frequencies in both groups (Table 1). A minor serous exudate that was present in 50% and 40% of the animals in the NOTES and laparoscopy groups, respectively, was not considered a complication.

Systemic inflammatory response and other laboratory parameters

White blood count and platelets: White blood count (WBC) had a tendency to increase after the procedure (on days 2 and 7 after the procedure) and to return to base-

Diversion rate (%): (Postoperative value-preoperative value/preoperative value) \times 100. Data is median with interquartile range. ^a*P* = 0.01 vs natural orifice transluminal endoscopic surgery (NOTES), no other significant differences between NOTES and laparoscopy groups. POD: Post-operative day; CRP: C-reactive protein; WBC: White blood count; IL-6: Interleukin 6.

line values (on days 28-30) in both groups (Table 2). No significant differences were detected between the groups (Table 3).

CRP: CRP levels increased on days 2 and 7 after the procedure and returned close to the baseline values on day 28-30 (Table 2, Figure 1A). Changes in CRP levels were similar among the two groups on PODs 7 and 28. However, on POD 2, according to the diversion rate analysis, an increase of CRP level was significantly higher in the NOTES group compared to the LAP group (Table 3).

IL-6: No significant changes with respect to IL-6 within the groups or between the groups were discovered (Tables 2 and 3, Figure 1B).

Platelets: The platelet count decreased significantly on POD 2, but it returned close to baseline values on POD 7 and PODs 28-30. The values of platelet count on POD 2 were, however, not dangerously low from a clinical point of view (Tables 2 and 3, Figure 1C).

DISCUSSION

Currently NOTES still represents an experimental surgical technique. If NOTES is to be introduced into clinical practice, it must show advantages in comparison with commonly available procedures. One of the potential advantages of NOTES is a “scar-less” surgery, whilst other real advantages are more or less speculative. Since laparoscopy is a golden standard for several surgical procedures, NOTES should be compared to laparoscopy in different experimental settings.

Given the potential advantages of the NOTES method in comparison with the classical laparoscopic techniques, our survival experimental study compared a standard laparoscopic ovariectomy with a NOTES ovariectomy in a sample of mini pigs. At the moment, there are no studies comparing NOTES and laparoscopic techniques involving ovariectomy.

All procedures were performed without any significant technical problems. The NOTES procedure lasted longer than the laparoscopy. However, the duration of the fastest NOTES procedure was 18 min, which was very close to the time of the fastest laparoscopic ovariectomy (14 min). Most studies comparing NOTES with laparoscopy also showed a better technical feasibility of laparoscopy^[5,6]. This can be explained by the absence of appropriate equipment currently available for NOTES. We believe that an improvement of technical performance would reflect the implementation of new “NOTES” equipment.

Apart from the procedure duration, no significant differences between the two techniques regarding any other outcome criteria were found. All animals survived without any clinical signs of complications. At necropsy only minor adhesions were found in a small number of pigs in both groups. One pig in the NOTES group developed a small intramural abscess next to the gastrotomy site. This complication was most likely related to our otherwise safe gastric-closure technique rather than the NOTES procedure itself. Importantly, there were no signs of peritonitis in either group. Based on this finding, NOTES is not an inferior procedure to laparoscopy with respect to main outcome criteria despite lower aseptic conditions (an endoscope cannot be sterile as opposed to laparoscopic equipment), the absence of antibiotics administration and

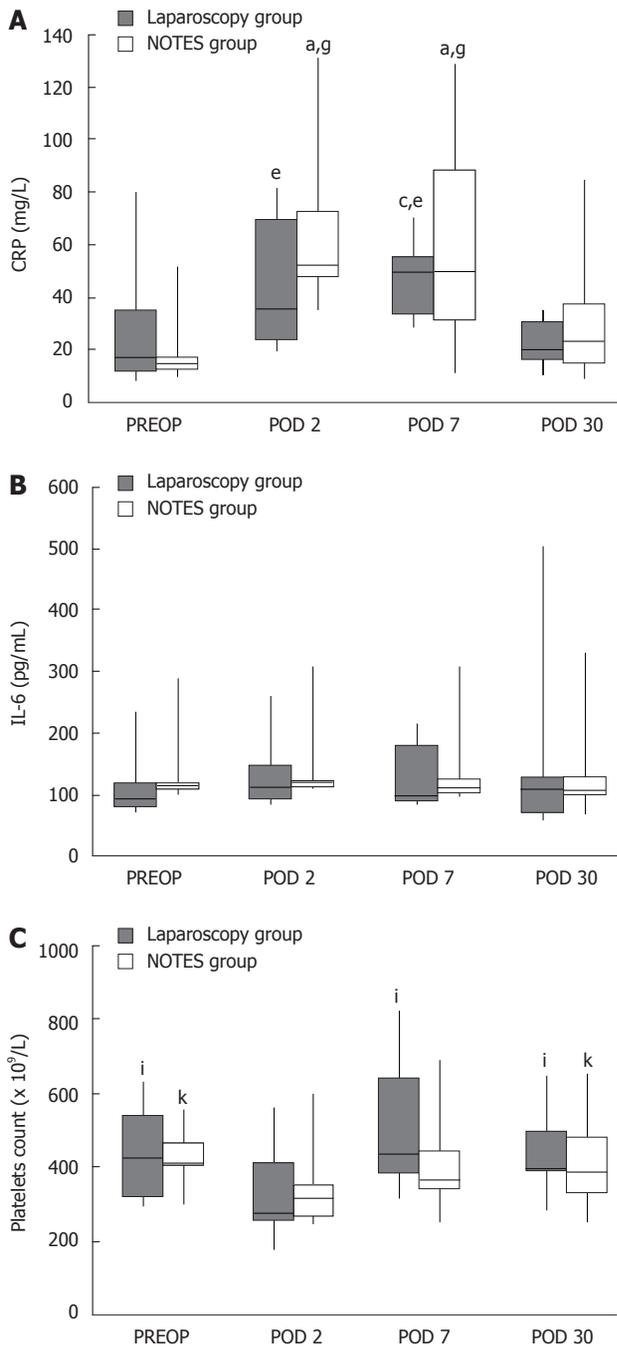

Figure 1 Box-whisker plot of C-reactive protein (A), interleukin 6 (B) and platelets (C) response in Natural Orifice Transluminal Endoscopic Surgery and the laparoscopic group before the procedure and on post-operative days 2, 7 and 28-30. Horizontal bars represent medians, ^a*P* < 0.05 vs before the procedure [natural orifice transluminal endoscopic surgery (NOTES) group]; ^c*P* < 0.05 vs before the procedure [laparoscopy (LAP) group]; ^e*P* < 0.05 vs postoperative days (POD) 30 (LAP group); ^g*P* < 0.05 vs POD 30 (NOTES group); ⁱ*P* < 0.05 vs POD 2 (LAP group); ^k*P* < 0.05 vs POD 2 (NOTES group). IL-6: Interleukin 6.

the absence of disinfection of the gastric lumen. Similar outcome criteria were used in several other studies comparing NOTES with laparoscopy^[2,4-8,12]. A majority of these studies did not show significant differences between the two techniques regarding the frequency of major complications. This involved procedures such as peritoneoscopy^[2,3,7,8], transvaginal cholecystectomy^[4], colon injury

repair^[5], salpingectomy^[12] and distal pancreatectomy^[6].

However, in some cases the occurrence of adhesions or histological peritonitis was higher in NOTES as opposed to laparoscopy^[2,13]. The slightly higher frequency of adhesions or intraperitoneal infections is possibly related to the quality of the access site closure. Safe closure is thus considered a prerequisite for any study comparing NOTES with laparoscopy. For example, von Renteln *et al*^[14] showed a higher frequency of infectious complications, including one fatal case of peritonitis with an incomplete gastrotomy closure using endoclips. In our study a single-loop and clips technique providing full-thickness closure was used.

In order to assess the physiological impact of NOTES compared to laparoscopic surgery, changes in interleukin-6 levels, white-blood cells, platelet count and CRP levels were analyzed. IL-6 has been extensively studied as an indicator demonstrating a lower invasiveness of laparoscopy in comparison to open surgery^[15-17]. IL-6 alterations have been directly correlated to the operation duration^[15]. IL-6 levels culminate 24 h after surgery and its serum level increases later than the serum level of other cytokines (tumor necrosis factor- α and IL-1 β). It also remains longer in circulation. This cytokine was hence chosen for the purpose of our study.

No significant changes with respect to IL-6 values were detected in either group. Furthermore, no increase in IL-6 levels after either procedure was observed. It can be argued that measuring IL-6 levels on POD 2 is too late to detect such an increase. Freeman *et al*^[18] showed a peak serum concentration of IL-6 levels 2 h after NOTES ovariectomy in dogs. IL-6 levels returned to baseline values within 18 h. The possible explanation for this increase is that the procedures lasted an average of 157 min, which is considerably more than in our study. Other studies investigating IL-6 levels showed elevated levels even on POD 5 in a group of patients undergoing laparoscopic colorectal resection or laparoscopic cholecystectomy^[19,20]. On the other hand, Fan *et al*^[4] did not show any significant changes with regard to IL-6 levels after transvaginal cholecystectomy on PODs 1 and 2. Their study, though, was rather small with only 2 pigs in the laparoscopic control group.

We did not assess the peritoneal inflammatory response as measured by IL-6 levels in the peritoneal fluid. It has been demonstrated that the degree of such a response correlated with the extent of adhesions^[2,13]. Since we detected similar occurrence of adhesions in both groups we did not expect to find a differing local inflammatory response.

Several studies have investigated the way in which laparoscopic surgery affects the acute-phase response by assessing CRP. CRP-levels have been found to be elevated in a majority of laparoscopic procedures as late as on POD 14^[21,22]. In agreement with these findings, we observed an increase in CRP-levels on POD 2 and 7 in our laparoscopic group. CRP-levels returned to the baseline values on PODs 28-30. In the NOTES group a quite sim-

ilar behavior in CRP response was found. We detected a significantly higher increase of CRP levels in the NOTES group compared to the LAP group on POD 2; however, on POD 7 this difference was no longer present. This suggests that an inflammatory response in the NOTES procedure is not lower than that in the LAP group.

An increase of WBC after both laparoscopic and NOTES peritoneoscopy on PODs 2 and 7 has been reported^[8], however, no significant changes in WBC were found after the same procedure in another study^[7]. In our study, only an insignificant trend in WBC increase on PODs 2 and 7 was observed in both groups.

Bingener *et al.*^[8] showed relative thrombocytopenia after NOTES peritoneoscopy but not after standard laparoscopy. In contrast, we found a decrease in platelet count in both groups on POD 2. However, the decrease was not clinically significant. The explanation for this phenomenon is unclear. Bingener thought that the possible reason for his finding was heparin-induced thrombocytopenia. In our study no heparin was used (for the flushing of invasive monitoring lines) as in the study conducted by Bingener. It cannot be excluded that thrombocytopenia in the porcine environment occurred due to a bacterial infection^[23]. A possible explanation could also be the Stage II of Systemic Inflammatory Response when small quantities of local cytokines are released into circulation to improve the local response. This leads to a stimulation of the growth factor and the recruitment of macrophages and platelets. We believe that the phenomenon of a decreasing platelet count in the NOTES procedure should be addressed in further studies.

There are several limitations to our study. Primarily, it is a study conducted on animals. The clinical implications and applicability of these findings in human medicine are unclear.

Secondly, the use of an infant animal model in a limited number is also a significant limitation when translating results into practice. The limited number of animals cannot exclude a type II error when interpreting our results. Thirdly, intraperitoneal pressure was not measured systematically and also microbiological contamination was not assessed. Also, for the NOTES procedures we used room air for insufflations, while for laparoscopic procedures we used a standard carbon dioxide insufflation. This could, theoretically, have influenced the results regarding the higher CRP levels in the NOTES group. Finally, IL-6 levels were not measured on the first day after the procedure.

In conclusion, both NOTES ovariectomy and laparoscopic ovariectomy were performed without any major technical problems and both were accompanied by a similar frequency of minor complications. However, the NOTES technique produced an increased systemic inflammatory response on POD 2 in comparison to the laparoscopic technique.

commonly used procedures. Natural orifice transluminal endoscopic surgery (NOTES) is an experimental surgical technique whereby "scar-less" abdominal operations can be performed with an endoscope passing through a natural orifice (mouth, anus, etc.) and then through an internal incision in the stomach or rectum. Although some NOTES procedures have already been performed on humans (e.g., transvaginal cholecystectomy), NOTES remains an experimental method.

Research frontiers

Several NOTES procedures have been examined and studied in experimental studies-NOTES peritoneoscopy, cholecystectomy, colon injury repair, etc. Should NOTES be implemented into clinical practice, it must be compared to the current surgical standards (laparoscopy and open surgery). The authors compared the technical feasibility, complications, and indicators of postoperative systemic inflammatory response in an experimental study.

Innovations and breakthroughs

The authors found that NOTES ovariectomy is not an inferior procedure to the standard laparoscopic ovariectomy in terms of technical feasibility and frequency of complications, although the NOTES procedure lasted significantly longer. The postoperative systemic inflammatory response was mild, almost identical to laparoscopy. However, C-reactive protein increase on postoperative day 2 was significantly higher in the NOTES group as compared to the laparoscopy group.

Applications

The study shows the feasibility of the NOTES procedures in the experimental setting. This is the first research study that compares laparoscopic and NOTES ovariectomy procedures and that provides evidence to the similarity between both of them. In other words, the study shows no inferiority of the NOTES ovariectomy as compared to laparoscopy with regard to the majority of variables.

Peer review

This is a rarity of published works in the literature concerning natural orifice transluminal endoscopic surgery versus laparoscopy. The manuscript is well structured. NOTES is a challenging topic for recent minimal invasive surgery. This experimental study claimed that NOTES had similar effects with laparoscopy for ovariectomy.

Abstract

AIM: To evaluate the inhibitory effects of carbon dioxide (CO₂) insufflation on pneumoperitoneum and bowel distension after percutaneous endoscopic gastrostomy (PEG).

METHODS: A total of 73 consecutive patients who were undergoing PEG were enrolled in our study. After eliminating 13 patients who fitted our exclusion criteria, 60 patients were randomly assigned to either CO₂ (30 patients) or air insufflation (30 patients) groups. PEG was performed by pull-through technique after three-point fixation of the gastric wall to the abdominal wall using a gastropexy device. Arterial blood gas analysis was performed immediately before and after the pro-

cedure. Abdominal X-ray was performed at 10 min and at 24 h after PEG to assess the extent of bowel distension. Abdominal computed tomography was performed at 24 h after the procedure to detect the presence of pneumoperitoneum. The outcomes of PEG for 7 d post-procedure were also investigated.

RESULTS: Among 30 patients each for the air and the CO₂ groups, PEG could not be conducted in 2 patients of the CO₂ group, thus they were excluded. Analyses of the remaining 58 patients showed that the patients' backgrounds were not significantly different between the two groups. The elevation values of arterial partial pressure of CO₂ in the air group and the CO₂ group were 2.67 mmHg and 3.32 mmHg, respectively ($P = 0.408$). The evaluation of bowel distension on abdominal X ray revealed a significant decrease of small bowel distension in the CO₂ group compared to the air group ($P < 0.001$) at 10 min and 24 h after PEG, whereas there was no significant difference in large bowel distension between the two groups. Pneumoperitoneum was observed only in the air group but not in the CO₂ group ($P = 0.003$). There were no obvious differences in the laboratory data and clinical outcomes after PEG between the two groups.

CONCLUSION: There was no adverse event associated with CO₂ insufflation. CO₂ insufflation is considered to be safer and more comfortable for PEG patients because of the lower incidence of pneumoperitoneum and less distension of the small bowel.

Inhibitory effects of carbon dioxide insufflation on pneumoperitoneum and bowel distension after percutaneous endoscopic gastrostomy. *World J Gastroenterol* 2012; 18(27): 3565-3570 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i27/3565.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i27.3565>

INTRODUCTION

Percutaneous endoscopic gastrostomy (PEG) has been widely accepted for enteral access since the introduction of the procedure in 1980^[1,2]. The procedure of PEG is rapid, but it requires maximal insufflation of the stomach with air in order to tightly attach the gastric wall to the abdominal wall. Percutaneous puncture into the stomach with a needle is conducted under the fully insufflated stomach and a gastrostomy tube is placed thereafter. Abdominal distension and pneumoperitoneum are frequent symptoms after PEG^[3]. Carbon dioxide (CO₂) insufflation was initially introduced for colonoscopic polypectomy in the field of gastrointestinal endoscopy^[4]. Applications of CO₂ insufflation for endoscopic procedures have also been reported for the performance of routine colonoscopy, small bowel endoscopy, endoscopic retrograde cholangiopancreatography (ERCP), peroral cholangioscopy, and endoscopic submucosal dissection in the upper and lower gastrointestinal tracts^[5-12]. These studies showed that CO₂ insufflation reduces the post-procedural abdominal distension and pain without CO₂ retention and adverse events. However, there has been no report on the safety and efficacy of CO₂ insufflation with PEG procedures. In the present study, we evaluated the inhibitory effects of CO₂ insufflation on bowel distension and pneumoperitoneum after PEG by randomized controlled trial. The safety of CO₂ insufflation was also investigated.

MATERIALS AND METHODS

Participants

Consecutive patients who were scheduled for PEG from November 2009 to March 2011 at our institution were recruited for this study. Exclusion criteria included any of the following: chronic obstructive pulmonary diseases (COPD), severe congestive heart failure (cardiothoracic ratio on chest radiography > 60%), previous upper gastrointestinal surgery, for the purpose of decompression *via* PEG, hypercapnea [arterial partial pressure of CO₂ (PCO₂) > 50 mmHg], and refusal to participate. Randomization was conducted individually into two treatment groups (1:1) using a computer-generated sequence. Sealed envelopes were used for the allocation of individual patients and opened by assistants at the endoscopy unit just before the procedure of PEG. The present study was approved by the Ethics Committee of our institution, and

written informed consent was obtained from the patients or the patients' family members.

Percutaneous endoscopic gastrostomy procedure and carbon dioxide monitoring

CO₂ was administered using a commercially available CO₂ regulator system (UCR, Olympus Optical Co., Ltd., Tokyo, Japan). The flow rate of the CO₂ insufflation was 1.5 L/min using the wide size of the connective tube, the volume of which was equivalent to the medium strength setting of the air insufflation system. Endoscopy assistants set up the insufflation system according to the allocation of the individual patients.

Conscious sedation was conducted by the intravenous administration of midazolam, the amount of which was previously determined by their primary doctor depending on the condition of the patient. An endoscope (GIF-H180, Olympus Optical Co., Ltd., Tokyo, Japan) was inserted up to the second portion of the duodenum to screen the upper gastrointestinal tract and pulled back to the stomach. Then, the stomach was fully inflated with air or CO₂ and the site for placement was determined by transillumination of the abdominal wall and finger pressure against the stomach. The abdominal skin surface of the placement area was cleansed with povidone-iodine and local anesthesia was performed by administering 1% lidocaine. After test-puncturing with a 21-gauge needle, 3-point sutures were made using a gastropexy device (Easy Tie, Boston Scientific Japan K.K., Tokyo, Japan) to fix the stomach against the abdominal wall in order to form tight fistula formation. A Seldinger needle was then punctured at the center of the 3-point sutures and a loop wire was inserted through the outer sheath of the needle. The loop wire was grasped by a snare from the endoscope, and a 20F gastrostomy tube was placed by the pull-through technique. The materials used for PEG tube placement were a Ponsky PEG (Bard Access Systems, Inc., Salt Lake City, UT, United States) or a Safety PEG kit (Boston Scientific Co., Natick, MA, United States). The endoscope was reinserted into the stomach to secure the proper placement of the gastrostomy tube. Arterial blood gas analysis was conducted just before and immediately after the PEG procedure to measure PCO₂, arterial partial pressure of O₂ (PO₂), pH and base excess.

Evaluation of post-procedural outcomes

The clinical pathway after PEG was determined as follows. Prophylactic intravenous administration of cefmetazole was conducted for 3 d following PEG. The gastrostomy tube was drained for 24 h and feeding was then started in those patients without serious events. Initial feeding was 100 mL of 5% glucose solution followed by 500 mL of glucose solution on the next day. Commercially available isotonic nutrients were administered from the third day and gradually increased up to 800 kcal/d for 7 d. Target calorie intake was achieved within 2 wk.

Abdominal computed tomography (CT) was conducted 24 h after PEG to detect pneumoperitoneum. In patients with pneumoperitoneum, the volume of the

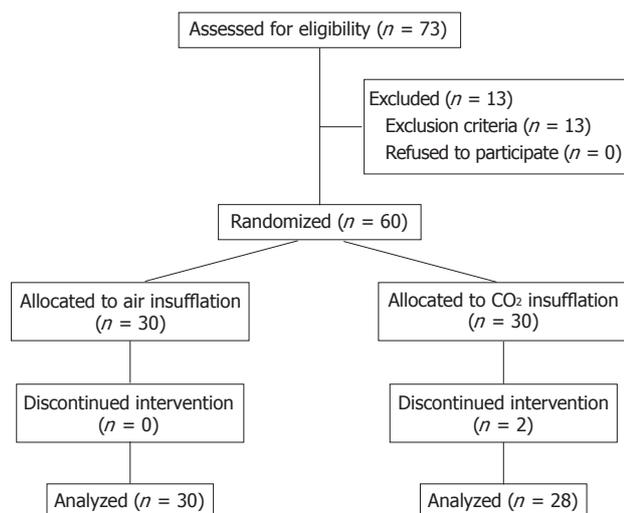

Figure 1 Flow diagram showing selection of study subjects. CO₂: Carbon dioxide.

intraabdominal free air was estimated by CT scan. Abdominal plain radiography was conducted at 10 min and 24 h after PEG to evaluate the bowel distension. The degree of bowel distension was determined by scoring the radiographic images according to the method of Bretthauer *et al*^[8]. In brief, grade I: No distension; grade II: Light distension; grade III: Moderate distension; and grade IV: Severe distension. The radiological estimation was conducted by a physician (Iwashita M) who had not been informed of the insufflation condition.

Evaluation of clinical symptoms after PEG was assessed by the frequency of body temperature elevation (> 38 °C), complications, and whether the scheduled clinical pathway had been pursued for 7 d after PEG. Blood examination [C-reactive protein (CRP) and leucocyte count] was conducted before, one day and 7 d after PEG. The treatments of the patients who had undergone PEG were conducted by individual primary doctors who were not informed of the patient's allocation. Each patient was followed-up along the clinical pathway if their condition was stable. When complications or troubles occurred for the patients, treatments other than the scheduled clinical pathway were conducted by the primary attending doctor.

Statistical analysis

The continuous values were expressed as mean ± SD and analyzed using the Student's *t*-test. The analysis of dichotomous categorical variables was performed using the χ^2 test. The analysis of the grades of bowel distension was conducted by Fisher's exact test. Statistical significance was defined as a *P* value of less than 0.05. All data were analyzed using JMP software for Windows (Version 5.1; SAS Institute Inc., Cary, NC, United States).

RESULTS

Patients

A flow diagram of this study is presented in Figure 1. A

total of 73 patients were enrolled for this study. Thirteen patients were excluded by the exclusion criteria; 6 patients for COPD, 3 patients for hypercapnea, 2 patients for severe congestive heart failure, and one each for post distal gastrectomy and for the purpose of decompression. The remaining 60 patients were equally randomized and underwent PEG with air or CO₂ insufflation. All of the PEG procedures in the air group were successfully performed, whereas those in the CO₂ group were not completed in two patients using the above-described PEG procedure. One of the reasons for failure was inability to insert an endoscope into the stomach because of benign esophageal stenosis. The other reason was failure of gastropexy, although the PEG was performed without gastropexy. These two patients were excluded from the analyses.

The demographic data of the patients are shown in Table 1. The mean age and male/female ratio were not significantly different in the two groups. The serum albumin concentration, an indicator of nutritional status, did not differ significantly.

Percutaneous endoscopic gastrostomy procedures

There were no significant differences in the amount of midazolam administered and the duration of the procedure between the two groups. The mean elevations of PCO₂ in the air and CO₂ groups were 2.67 mmHg and 3.32 mmHg, respectively (*P* = 0.408). The mean depressions of PO₂ in the air and CO₂ groups were 3.72 mmHg and 1.34 mmHg, respectively (*P* = 0.302). The mean pH after PEG of the CO₂ group was significantly lower than that of the air group (*P* = 0.018), whereas the depression of pH during the procedure was not significantly different between the two groups (*P* = 0.125). There were no significant differences in base excess between the two groups (data not shown) (Table 2).

Bowel distension

The most frequent distension grades of the small bowel at 10 min in the air and CO₂ groups were grade IV and grade II, respectively, and those at 24 h were grade II and grade I, respectively (Figure 2) (*P* < 0.001). The most frequent distension grades of the large bowel in the air and CO₂ groups were grade II at both 10 min and 24 h in the two groups (Figure 2).

Pneumoperitoneum

Pneumoperitoneum was observed in 8 patients of the air group, whereas there was no patient with pneumoperitoneum in the CO₂ group by abdominal CT (*P* = 0.003). The mean volume of the free air of the 8 patients in the air group was 36.3 mL. In addition to the 8 patients, faint extragastric air leakage around the stoma was observed in 5 patients of the air group. No such transluminal air leak was observed in any patient of the CO₂ group.

Postprocedural outcomes

The values of CRP levels and leukocyte counts were not different between the two groups at any time. The rates

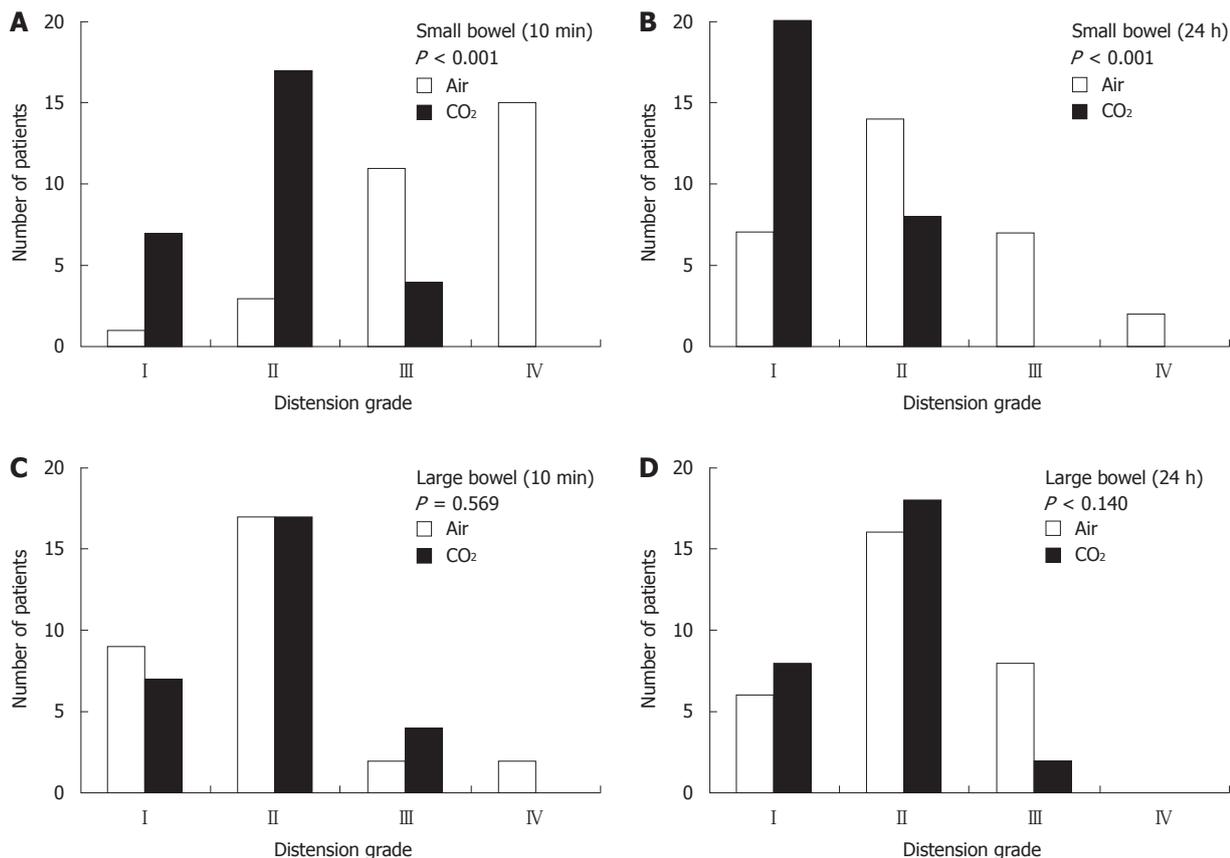

Figure 2 Radiographic evaluation of abdominal distension after percutaneous endoscopic gastrostomy. The degree of small bowel distension [A: 10 min after percutaneous endoscopic gastrostomy (PEG), B: 24 h after PEG] and large bowel distension (C: 10 min after PEG, D: 24 h after PEG) was evaluated by radiography as follows: grade I : No distension; grade II : Slight distension; grade III : Moderate distension; grade IV : Severe distension; CO₂: Carbon dioxide.

of the patients with fever of more than 38 °C in the air and CO₂ groups were 33.3% and 17.9%, respectively ($P = 0.179$). The numbers of patients who did not follow the clinical pathway during the first 7 d post-procedure were 4 each for the air and CO₂ groups (13.3% and 14.2%, respectively). The reasons for the discontinuation of the pathway were aspiration after feeding (3 and 2 patients for the air and CO₂ groups, respectively), stomal infection (1 patient each for the two groups), and hemorrhage in 1 patient in the CO₂ group. Among these complications, 1 patient in the air group and 3 patients in the CO₂ group

were interrupted for feeding until the complications recovered. There was no mortality within 30 d in this study (Table 3).

DISCUSSION

The present study is the first investigation of the effects of CO₂ insufflation during PEG. Our results clearly indicate that the use of CO₂ insufflation reduces the post-procedural abdominal distension and pneumoperitoneum compared to air insufflation. The usefulness and safety of CO₂ insufflation for colonoscopy, ERCP and double balloon enteroscopy have been reported, including effects on the respective therapeutic procedures^[5-12]. PEG is also an endoscopic operation, but the procedure is simple and of relatively short duration compared to the above-mentioned endoscopic procedures. However, the PEG procedure requires maximal insufflation of the stomach and penetration of the gastric wall by a needle and a gastrostomy tube, leading to postprocedural abdominal distension and pneumoperitoneum.

Pneumoperitoneum associated with PEG procedure is thought to be due to air leakage around the needle puncture site of the stomach during the period from the puncture to the placement of a gastrostomy tube^[13]. The reported frequencies of pneumoperitoneum range from 8.6% to 56%^[14-16]. The variation of the frequency may depend on multiple factors. Abdominal CT scan is a more

sensitive modality to detect intraabdominal free air compared to plain radiography. The methods or devices used for the PEG procedure may also affect the frequency of pneumoperitoneum. The performance of gastropexy may have a preventive effect on pneumoperitoneum. We introduced the gastropexy technique in the present study using a T-fastener type fixation device just before the percutaneous needle puncture^[17]. Our intention with gastropexy is to prevent peritonitis if the gastrostomy tube dislodges in the early phase after PEG. In the present study, the frequency of pneumoperitoneum in the air group was 27%, the value of which was comparable to the previous reports. However, the amount of the free air was fairly small (36.3 mL on average), which would be difficult to detect by plain abdominal radiography. Although there are no reports of the preventive effects on pneumoperitoneum by the gastropexy, the procedure is supposed to reduce the amount of the free air.

Most cases of pneumoperitoneum are considered to have no clinical significance and to require no further interventions^[13,14,16]. Pneumoperitoneum after PEG usually causes no symptoms and spontaneously recovers. However, a few patients with pneumoperitoneum showed severe symptoms and underwent laparotomy in larger scale analyses. Dulabon *et al.*^[15] reported that 20% of patients with pneumoperitoneum developed peritonitis which required exploratory celiotomy. Blum *et al.*^[18] retrospectively analyzed 722 patients who had undergone PEG, and reported that pneumoperitoneum was observed in 5 out of 6 patients who had complications requiring laparotomy. They postulated that the presence of intraabdominal free fluid in addition to the free air is an indication of peritonitis requiring surgical intervention.

The inhibitory effect of CO₂ insufflation on pneumoperitoneum or pneumomediastinum at the perforation of endoscopic submucosal dissection was reported by Nonaka *et al.*^[11]. They showed 3 cases of perforation with endoscopic submucosal dissection (2 cases with es-

ophageal cancer and 1 case with gastric cancer) using CO₂ insufflation but no subcutaneous or mediastinal emphysema or pneumoperitoneum developed after perforation.

CO₂ insufflation has also been reported to reduce post-procedural abdominal pain as well as abdominal distension during colonoscopy and double balloon enteroscopy^[5-7]. The reduction of abdominal symptoms by CO₂ insufflation was also reported for ERCP^[8,9], although the effects remain controversial^[19]. Although the mean duration of the PEG procedure was only about 14 min in the present study, a significant reduction in small bowel distension was observed in the CO₂ group compared to the air group. The evaluation of the bowel distension was analyzed by radiography at 10 min and 24 h after PEG. The result of remarkable reduction of small bowel distension at only 10 min after the procedure was consistent with the report of Nakajima *et al.*^[20]. Almost all of the patients in our study were unable to express their symptoms due to their underlying diseases and we could not use a visual analog scale for their abdominal pain and distension, but CO₂ insufflation may reduce the abdominal symptoms after PEG.

There were no significant differences in clinical outcomes after PEG between the two groups. These results indicate that the reduction of pneumoperitoneum and bowel distension did not affect the outcomes after PEG. We experienced 8 out of 58 patients with complications, including 5 cases of aspiration, 2 cases of peristomal infection and 1 case of hemorrhage in this study. These complications were not derived from the CO₂ or air insufflation itself.

The elevation of PCO₂ using CO₂ insufflation in this study was very low and the degree of elevation was comparable to that of air insufflation. These results indicate that the elevation of PCO₂ is not derived from CO₂ insufflation itself but derived from conscious sedation by midazolam. This assumption is consistent with previous reports^[8,11,21,22]. Because the PEG procedure is of short duration, strict continuous monitoring of CO₂ status by the measurement of transcutaneous PCO₂ or partial pressure of end-tidal CO₂ would not be necessary. Suzuki *et al.*^[23] reported that the PCO₂ level increased with the duration of CO₂ insufflation for endoscopic submucosal

dissection under general anesthesia. They also found that patients with lower respiratory function showed a tendency toward CO₂ retention compared to patients with normal respiratory function. Our study excluded patients with COPD and severe chronic heart failure, but the target patients for PEG are usually elderly and often have impaired cardiorespiratory function. Further investigation of the safety of CO₂ insufflation for elderly patients will be required. In conclusion, CO₂ insufflation during the PEG procedure is considered to be safe and provides comfort by reducing pneumoperitoneum and bowel distension.

COMMENTS

Background

Carbon dioxide (CO₂) insufflation has been reported to reduce the post-procedural abdominal distension and pain in gastrointestinal endoscopy for diagnostic and therapeutic purposes. However, there has been no report on the safety and efficacy of CO₂ insufflation for percutaneous endoscopic gastrostomy (PEG) procedures.

Research frontiers

Utilizing the nature that CO₂ is rapidly absorbed from the bowel, the authors investigated the effect of CO₂ insufflation on patients undergoing PEG.

Innovations and breakthroughs

CO₂ insufflation remarkably reduced pneumoperitoneum and small bowel distension without any adverse events.

Applications

Safety of CO₂ insufflation during PEG procedure for elderly patients was demonstrated in this report. Further investigation in patients with cardiopulmonary disorders is necessary.

Peer review

This is the first randomized control study of CO₂ insufflation in PEG procedure and describes the effects of CO₂ insufflation on pneumoperitoneum and bowel distension after PEG. The presented article is a major contribution in the research field.

Abstract

AIM: To investigate endoscopic and clinicopathologic characteristics of early gastric cancer (EGC) according to microsatellite instability phenotype.

METHODS: Data were retrospectively collected from a single tertiary referral center. Of 981 EGC patients surgically treated between December 2003 and October 2007, 73 consecutive EGC patients with two or more microsatellite instability (MSI) mutation [high MSI (MSI-H)] and 146 consecutive EGC patients with one or no MSI mutation (non-MSI-H) were selected. The endoscopic and clinicopathologic features were compared between the MSI-H and non-MSI-H EGC groups.

RESULTS: In terms of endoscopic characteristics, MSI-H EGCs more frequently presented with elevated pattern (OR 4.38, 95% CI: 2.40-8.01, $P < 0.001$), moderate-to-severe atrophy in the surrounding mucosa (OR 1.91, 95% CI: 1.05-3.47, $P = 0.033$), antral location (OR 3.99, 95% CI: 2.12-7.52, $P < 0.001$) and synchronous lesions, compared to non-MSI-H EGCs (OR 2.65, 95% CI: 1.16-6.07, $P = 0.021$). Other significant clinicopathologic characteristics of MSI-H EGC included predominance of female sex (OR 2.77, 95% CI: 1.53-4.99, $P < 0.001$), older age (> 70 years) (OR 3.30, 95% CI: 1.57-6.92, $P = 0.002$), better histologic differentiation (OR 2.35, 95% CI: 1.27-4.34, $P = 0.007$), intestinal type by Lauren classification (OR 2.34, 95% CI: 1.15-4.76, $P = 0.019$), absence of a signet ring cell component (OR 2.44, 95% CI: 1.02-5.86, $P = 0.046$), presence of mucinous component (OR 5.06, 95% CI: 1.27-20.17, $P = 0.022$), moderate-to-severe lymphoid stromal reaction (OR 3.95, 95% CI: 1.59-9.80, $P = 0.003$), and co-existing underlying adenoma (OR 2.66, 95% CI: 1.43-4.95, $P = 0.002$).

CONCLUSION: MSI-H EGC is associated with unique endoscopic and clinicopathologic characteristics including frequent presentation in protruded type, co-existing underlying adenoma, and synchronous lesions.

logic characteristics of early gastric cancer with high microsatellite instability. *World J Gastroenterol* 2012; 18(27): 3571-3577 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i27/3571.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i27.3571>

INTRODUCTION

Microsatellites are simple repetitive DNA sequences that are scattered throughout the genome. Instability within these sequences is a marker of DNA mismatch repair deficiency^[1]. The molecular mechanism of high microsatellite instability is the accumulation of frameshift mutations in the genes containing microsatellites within coding regions^[2]. The resulting inactivation of these target genes is believed to contribute to tumor development and progression.

Previous research has focused on the analysis of microsatellite instability (MSI) in various cancers^[3-5]. In colorectal cancer, high MSI (MSI-H) phenotypes are found in most cases of hereditary nonpolyposis colorectal cancers and in 15% to 20% of sporadic colon cancers^[6]. The clinicopathologic characteristics of MSI-H colorectal cancers are younger age, lower incidence of lymph node metastasis, proximal location, and better survival rate^[7,8].

In gastric cancer, the frequency of MSI-H phenotype varies from 8.2% to 37%, depending on the number of cases investigated and the definitions used^[9,10]. The distinct features frequently reported for MSI-H gastric cancers include older age, antral location, intestinal type by Lauren classification, expanding type by Ming classification, and better survival^[10-13]. However, studies with limited numbers of patients have reported conflicting results regarding the association of the MSI-H phenotype with better survival^[14,15].

Since a limited number of previous studies have dealt with endoscopic and pathologic findings of early gastric cancer (EGC) according to MSI phenotype and most were focused on advanced gastric cancer (AGC)^[10-13,16], we set out to analyze and clarify endoscopic and pathologic characteristics of EGC according to MSI phenotype in this study.

MATERIALS AND METHODS

Patients and tissue samples

From December 2003 to October 2007, 981 patients underwent radical total or subtotal gastrectomy and lymph node dissection for EGC, and the specimens of all patients in this period were examined for MSI status. EGC was defined as gastric cancer limited to mucosa or submucosa, irrespective of lymph node status^[17]. Of 981 patients who were pathologically confirmed as having EGC, 73 (7.4%) cases were categorized as MSI high EGC. For comparison, 146 non-MSI high EGC cases from the remaining 908 patients were consecutively selected as controls. Authorization for the use of these tissues for

research purposes was obtained from the Institutional Review Board of Yonsei University College of Medicine.

Microsatellite analysis

Areas of tumor and non-tumorous tissues on the slides were examined and marked under light microscopy. DNA was extracted from the uncovered hematoxylin and eosin-stained 6 μm -thick sections from formalin-fixed, paraffin-embedded tissues, using the QIAamp DNA Mini Kit (Qiagen, Hilden, Germany) according to the manufacturer's instruction.

A panel of five National Cancer Institute workshop-recommended microsatellite markers (BAT25, BAT26, D2S123, D17S250 and D5S346) was used for analysis^[18]. Polymerase chain reaction (PCR) was performed using a fluorescently labeled multiprimer, HotStar Taq polymerase (Qiagen) and the GeneAmp PCR system 2700 (Applied Biosystems, Foster City, CA). The PCR conditions comprised of an initial cycle of 15 min at 95 °C, followed by 30 cycles of 1 min at 94 °C, 1 min at 57 °C, and 1 min at 72 °C. Amplification was completed with a final 5 min at 72 °C. Automated ABI PRISM sequencer model 3100 Genetic Analyzer (Applied Biosystems) was used to analyze amplified PCR products according to the manufacturer's instructions.

MSI-H was classified as shift of two or more microsatellite markers. Microsatellite instability at only one marker was classified as MSI-low (MSI-L). A case with no microsatellite instability was classified as microsatellite stable (MSS). The PCR results of typical MSS and MSI-H cases are illustrated in Figure 1.

Analysis of endoscopic features

Two experienced endoscopists retrospectively reviewed the digital PACS images and the endoscopy database for all 219 cases. Most of the upper endoscopies were performed using GIF-Q260 or GIF-H260 (Olympus Optical, Tokyo, Japan), and a few cases were performed using GIF-Q240 in the early period of 2003. The endoscopic variables included in the analysis were the macroscopic classification of EGC by the Japanese Gastric Cancer Association, which has been internationally accepted^[19,20], location, color pattern and demarcation of the tumor. Additionally, the endoscopic degree of mucosal atrophy and intestinal metaplasia in the surrounding mucosa, and the presence of synchronous neoplasm were also included in the analysis. A synchronous lesion was defined as a distinctly separated lesion from the main EGC based on endoscopic findings. The endoscopic variables were compared between the MSI-H and non-MSI-H EGC groups.

Analysis of clinicopathologic features

Clinical information, including age and sex, was obtained from medical records. The pathologic specimens of all 219 cases were reviewed again by an experienced gastrointestinal pathologist, and categorized as intestinal, diffuse, or mixed according to the classification of Lauren. The mixed type by Lauren classification was regarded

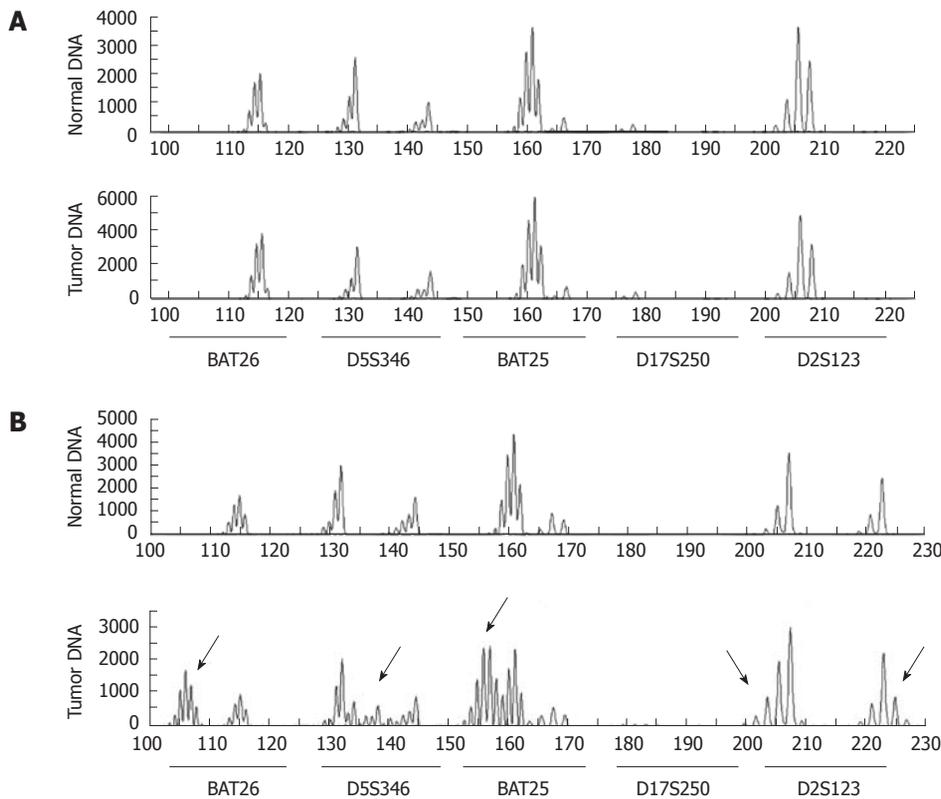

Figure 1 Polymerase chain reaction results of microsatellite analysis markers. as intestinal type on analysis. The presence of a mucinous component or a signet ring cell component were defined when these components exceeded 10% of the tumor area. Lymphoid stromal reaction was categorized subjectively as absent, mild, moderate, or severe. Other pathologic variables for analysis included differentiation by World Health Organization (WHO) classification, invasion depth, lymphovascular invasion and co-existing underlying adenoma.

Statistical analysis

The statistical analysis was performed using PASW version 18.0. (SPSS Inc., Chicago, IL, United States). The χ^2 test was performed for comparison between the MSI-H and MSS/MSI-L groups in terms of various clinicopathologic parameters. The data for age and tumor size were analyzed by Student’s *t*-test. Each parameter was also assessed by logistic regression. Differences were considered significant at $P < 0.05$. Estimated relative risks of MSI-H with endoscopic and clinicopathologic factors of EGC were expressed as odds ratios (OR) with corresponding 95% confidence intervals (95% CI).

RESULTS

Clinical and endoscopic features of MSI-H EGCs

Of 981 EGC cases, 73 cases (7.4%) showed the MSI-H phenotype. The endoscopic features of MSI-H EGCs are summarized in Table 1. MSI-H EGCs presented more frequently with elevated gross type (60.3% of type I or

II a; $P < 0.001$), antral location ($P < 0.001$), moderate-to-severe atrophy in the surrounding mucosa ($P = 0.032$), and presence of a synchronous lesion ($P = 0.018$) than non-MSI-H EGCs. The typical endoscopic findings of MSI-H EGC are illustrated in Figure 2.

The color pattern and demarcation of the tumor, and the degree of intestinal metaplasia in the surrounding mucosa, were not significantly different between the MSI-H EGC and non-MSI-H EGC groups.

Clinicopathologic features of MSI-H EGCs

The clinicopathologic features of MSI-H EGCs are summarized in Table 2. In comparison to non-MSI-H EGCs, MSI-H EGCs were characterized by more frequent female sex ($P = 0.001$), older age ($P < 0.001$), better differentiation by WHO classification ($P = 0.003$), intestinal type by Lauren classification ($P = 0.017$), presence of a mucinous component ($P = 0.017$), absence of a signet ring cell component ($P = 0.041$), moderate-to-severe lymphoid stromal reaction ($P = 0.002$) and co-existing underlying adenoma ($P = 0.001$). There was no significant difference between the MSI-H EGC and non-MSI-H EGC groups in terms of tumor size, depth of invasion, lymphovascular invasion, and lymph node metastasis. The endoscopically identified synchronous lesions of the MSI-H EGCs were diagnosed pathologically as EGC in 9.6% and adenoma in 9.6%. Synchronous lesions ($P = 0.018$) were significantly more frequent in the MSI-H EGC group when cases of EGC and adenoma were combined. However, this difference lost its significance when syn-

chronous EGC ($P = 0.110$) or adenoma ($P = 0.163$) were compared separately.

Correlation between MSI-H and endoscopic and clinicopathologic features of EGCs

We analyzed the interrelationship between MSI-H phenotype and other endoscopic and clinicopathologic factors of EGC by logistic regression analysis (Table 3). Upon logistic regression analysis, MSI-H EGC was significantly associated with elevated gross type (OR 4.38, 95% CI: 2.40-8.01, $P < 0.001$), antral location (OR 3.99, 95% CI: 2.12-7.52, $P < 0.001$), moderate-to-severe atrophy of the surrounding mucosa (OR 1.91, 95% CI: 1.05-3.47, $P = 0.033$), female sex (OR 2.77, 95% CI: 1.53-4.99, $P <$

DISCUSSION

Although the worldwide incidence of gastric cancer has been declining steadily, it remains the fourth most common cancer and the second most common cause of cancer death worldwide^[21]. Despite identification of numerous genetic alterations in gastric cancers, their roles in tumorigenesis remain unclear. Across the gastrointestinal tract, the role of MSI-H tumor has been studied more often in colorectal cancer than in gastric cancer, and MSI is one of the clinically significant prognostic factors that is recommended for collection in the 2010 tumor, node, metastasis staging criteria for colorectal cancer^[22,23]. On the other hand, there is no definite consensus about the role of MSI-H in gastric cancer, and up to now, the majority of MSI-H gastric cancer studies have focused on AGC and its prognosis. However, the clinicopathologic features and therapeutic approaches, such as endoscopic submucosal dissection, for EGCs are different from those for AGCs. In the present study, we focused on endoscopic and clinicopathologic features of MSI-H phenotype in EGCs.

Our results revealed that EGC with MSI-H exhibits distinct clinicopathologic features, including distribution of older age and female sex, antral tumor location,

elevated gross morphology, better histologic differentiation, intestinal type by Lauren classification, absence of a signet cell component, presence of a mucinous component, moderate-to-severe lymphoid stromal reaction, co-existing underlying adenoma, and more synchronous lesions including EGC and adenoma. Among the endoscopic features, the correlation between MSI-H and elevated gross morphology was a significant novel finding.

It is reasonable to suspect that elevated gross type of MSI-H EGCs could be explained by cancer progression from co-existing underlying adenoma. And if we take into account the adenoma-carcinoma sequence in carcinogenesis of gastrointestinal tract cancers, our data indicate that MSI-H EGC could more frequently originate from the co-existing underlying adenoma than non-MSI-H EGC. As a consequence, EGC characterized by elevated mass might be preceded by transformation of co-existing underlying adenoma.

A high MSI level has been shown to play an important role in the development of multiple carcinomas in colorectal cancer^[24,25]. Several previous studies, which did not distinguish between AGC and EGC, have also shown that multiple synchronous gastric cancer is frequently associated with MSI-H^[26,27]. In the present study, MSI-H EGCs were more often associated with synchronous epithelial neoplasm including EGC and adenoma than non-MSI-H, although the difference was not significant when the definition of synchronous lesion was limited to carcinoma, but this may be due to small sample size in each group. Nevertheless, our data indicate that clinicians must consider the potential for synchronous lesions including adenomas and carcinomas in cases of EGC with a confirmed MSI-H phenotype.

In our analysis, MSI-H EGCs were more frequently associated with co-existing underlying adenoma than non-MSI-H EGCs, and had a tendency to have synchronous adenoma. Given this association between MSI-H phenotype and adenoma, we cautiously propose that MSI impacts tumorigenesis at an earlier phase than dysplasia. This hypothesis is supported by results from previous studies revealing that MSI might play an important role in the early events of progression from metaplasia or dysplasia to precancerous lesions, and then to gastric cancer^[28,29]. Although there are a limited number of studies on the significance of the main 5 MSI mutations in EGC, a retrospective study from a high risk area of gastric cancer in Italy showed that MSI is part of the spectrum of genetic alterations in gastric non-invasive neoplasia^[30].

Our study was limited by the fact that we only included cases of EGC treated with surgery, which may serve as a bias. We excluded patients with EGCs who underwent endoscopic resection due to uncertainty of lymph node metastasis. Therefore, careful interpretation of our results is needed to avoid bias and additional data from other studies that include all EGCs are required to validate our findings. Also, since this is a retrospective study and there are no actual data to support the temporal relationship between adenoma and progression into EGC, speculation that EGC originated from underlying adenoma may

be overstretching. We used the term “co-existing underlying adenoma” instead of “origin in underlying adenoma” to cope with this limitation.

In conclusion, this study found that MSI-H EGCs more frequently present as protruded (type I or IIa) type in comparison to non-MSI-H EGCs, which is a novel finding; this is likely related to frequent co-existing underlying gastric adenoma. MSI-H EGC was found to have specific clinicopathologic characteristics, including older age, female dominance, antral location, moderate-to-severe atrophy of the surrounding mucosa, better histologic differentiation, intestinal type by Lauren classification, presence of mucinous component, absence of a signet ring cell component, moderate-to-severe lymphoid stromal reaction, underlying adenoma, and synchronous lesions. The finding of more frequent synchronous lesions in MSI-H EGC warrants us to inspect the stomach more thoroughly for other synchronous adenoma or EGC. Altogether, these findings could be used to better serve our understanding of tumorigenesis and progression in MSI-H EGC, and could be used to set up diagnostic and treatment strategies in EGC patients.

COMMENTS

Background

Gastric carcinoma is the fourth most common cancer and the second most common cause of cancer death worldwide. Various genetic alterations have been found in gastric cancers, although their roles in tumorigenesis remain unclear. Detection in the early stage and prevention of progress to advanced cancer are crucial in lowering gastric carcinoma related morbidity and mortality.

Research frontiers

Microsatellite instability (MSI) is a hallmark of a deficiency in the DNA mismatch repair system and is one of the pathways leading to gastric carcinogenesis. However, there are limited data on endoscopic and clinicopathologic characteristics of early gastric cancer (EGC) according to MSI phenotypes.

Innovations and breakthroughs

EGCs with high MSI frequently presented with elevated or protruded pattern, which is a novel finding. In addition, EGCs with high MSI showed more frequent synchronous lesions. Other significant endoscopic and clinicopathologic findings of high MSI (MSI-H) EGCs included moderate-to-severe atrophy in the surrounding mucosa, antral location, predominance of female sex, older age, better histologic differentiation, intestinal type by Lauren classification, absence of a signet ring cell component, presence of mucinous component, moderate-to-severe lymphoid stromal reaction, and co-existing underlying adenoma.

Applications

EGCs with MSI-H seem to originate from underlying adenoma, following an adenoma-carcinoma sequence. Furthermore, more synchronous lesions in MSI-H EGCs indicate that thorough inspection and shorter follow up period is needed for endoscopic surveillance after diagnosis of early gastric carcinoma with MSI-H.

Peer review

This study evaluates relationship of phenotypic characteristics (endoscopic and clinicopathologic) of EGC with MSI-H. Multivariate logistic regression analysis revealed that MSI-H EGCs more frequently presented with elevated pattern (type I or IIa), moderate-to-severe atrophy in the surrounding mucosa, antral location and synchronous lesions than non-MSI-H EGCs.

Abstract

AIM: To evaluate whether weekend or nighttime admission affects prognosis of peptic ulcer bleeding despite early endoscopy.

METHODS: Retrospective data collection from four referral centers, all of which had a formal out-of-hours emergency endoscopy service, even at weekends. A total of 388 patients with bleeding peptic ulcers who were admitted via the emergency room between January 2007 and December 2009 were enrolled. Analyzed parameters included time from patients' arrival until endoscopy, mortality, rebleeding, need for surgery and length of hospital stay.

RESULTS: The weekday and weekend admission groups comprised 326 and 62 patients, respectively. There were no significant differences in baseline characteristics between the two groups, except for younger age in the weekend group. Most patients (97%) had undergone early endoscopy, which resulted in a low mortality rate regardless of point of presentation (1.8% overall vs 1.6% on the weekend). The only outcome that was worse in the weekend group was a higher rate of rebleeding (12% vs 21%, $P = 0.030$). However, multivariate analysis revealed nighttime admission and a high Rockall score (≥ 6) as significant independent risk factors for rebleeding, rather than weekend admission.

CONCLUSION: Early endoscopy for peptic ulcer bleeding can prevent the weekend effect, and nighttime admission was identified as a novel risk factor for rebleeding, namely the nighttime effect.

INTRODUCTION

Upper gastrointestinal bleeding (UGIB) is a common medical emergency and timely endoscopy plays an im-

portant role in hemostasis. UGIB is also a significant healthcare problem in the United States, with an annual hospitalization rate of approximately 150 per 100000 individuals and an overall mortality rate of 6% to 7%^[1-4]. In South Korea, the incidence of UGIB has been reported to be 1 per 1000 individuals with a mortality rate of 5% to 10%, however, the mortality rate has decreased recently due to advances in endoscopy^[5,6].

It has been suggested that patients with UGIB who are admitted on weekends have lower rates of early endoscopy, higher mortality, and more frequently undergo surgery^[7]. Previous studies reported that outcomes are worse on weekends due to lack of availability of staff and services, which is collectively referred to as the “weekend effect”^[8]. Nahon *et al*^[9] suggested that early endoscopy could prevent the weekend effect and reduce mortality. However, Shaheen *et al*^[10] claimed that the weekend effect did not diminish even after adjusting data for the timing of endoscopy. Studies on the prognosis of UGIB on weekends have shown different results from numerous research centers, leaving the weekend effect on UGIB controversial^[7-10].

This issue might have regional and socio-organizational differences, and it is possible that the weekend effect depends on the specific situation and medical environment, such as the availability of emergency endoscopy services on the weekends. The majority of tertiary referral hospitals in South Korea have formal out-of-hours emergency endoscopy for UGIB. We sought to determine whether the weekend effect still influences the outcomes of peptic ulcer bleeding patients in hospitals that offer out-of-hours emergency endoscopy for UGIB, even on weekends. The primary aim of this study was to investigate the difference in prognosis between weekend and weekday admissions for peptic ulcer bleeding at referral hospitals in South Korea. In addition to the weekend effect, we also evaluated whether nighttime admission affected the prognosis of peptic ulcer bleeding.

MATERIALS AND METHODS

Patients

Data was retrospectively collected from an endoscopic database of four referral training hospitals in South Korea. A total of 388 consecutive patients, who were admitted for peptic ulcer bleeding *via* the emergency room (ER) between January 2007 and December 2009, were enrolled. All subjects had endoscopically confirmed peptic ulcer bleeding.

Patient data were collected from medical records, which were reviewed by endoscopists who were blinded to the aim of this study. The Institutional Review Board of Gangnam Severance Hospital approved this study.

We excluded patients with variceal bleeding, Mallory-Weiss tear, lower gastrointestinal bleeding, or bleeding from malignant ulcers. Peptic ulcers without stigma of recent bleeding (Forrest III^[11]) were also excluded due to the obscure source of bleeding.

Endoscopy procedure

All four hospitals that participated in this study were referral training centers in urban areas and have formal out-of-hours emergency endoscopy services. In these centers, at least one endoscopist is scheduled to be on duty for emergency calls for endoscopy, regardless of time and day, even on weekends or at night. Endoscopy is generally conducted as soon as possible in patients with suspected UGIB. However, we do not have a night shift; therefore, one of the day shift endoscopists has to be on duty at night when on emergency call. All on-duty endoscopists can handle the available endoscopic hemostatic procedures. All endoscopic hemostatic procedures were performed using the same protocol set by the guidelines of the Korean Society of Gastroenterology^[12]. Hemostatic procedures were carried out on Forrest Ia to Ib peptic ulcers^[11].

The levels of experience of endoscopists who performed endoscopic hemostasis in UGIB varied slightly among the four centers according to their policies. In one institution, senior instructors were responsible for both daytime and nighttime endoscopic hemostasis, while hospital staff took charge of hemostatic interventions in both daytime and nighttime in the other three institutions. Thus, for a given institution, available expertise remained generally constant day and night.

Definitions

The weekend group was defined as patients who presented to the ER from Friday midnight to Sunday midnight, and the remaining patients were categorized as the weekday group. The nighttime group was defined as patients who presented to the ER between 18:00 and 8:00 the next day. Endoscopy was classified as “early” if the procedure was performed within 24 h^[13]. Active bleeding indicated spurting or oozing, which was based on classification from Ia to Ib according to endoscopic findings^[11]. Rebleeding was defined as bleeding within 2 wk that required secondary hemostasis or was associated with hematemesis; melena with overt decrease in hemoglobin over 2 mg/dL; status requiring blood transfusion; shock (systolic blood pressure < 90 mmHg); or endoscopic findings of recent bleeding, such as spurting, oozing, or adherent clot^[14,15].

Parameters and endpoints

Parameters were chosen only for characteristics representative of bleeding, and were classified into baseline characteristics and treatment outcomes; the following intergroup comparisons were made: weekday *vs* weekend and daytime *vs* nighttime. The baseline parameters were age; disease type; endoscopic findings, including Forrest class; Rockall score^[16,17]; and Charlson score. The Charlson score is a system for the classification of severity that uses recorded data on a patient’s diagnosis to assign a weight to morbidity, thereby predicting a patient’s risk of death. To calculate the Charlson score, we included age factor in the comorbidity score, which is called the Charl-

son age comorbidity index (CACI)^[18]. As treatment outcome parameters, the primary endpoints were mortality rate, rebleeding, length of stay, and the need for surgery or embolization.

Statistical analysis

Data was analyzed using the Statistical Package for the Social Sciences (SPSS, 18.0 Inc, Chicago, United States) software with the assistance of the Yonsei University Statistical Consulting Center. Sensitivity and specificity were calculated with 95% confidence intervals and *P* values less than 0.05 were regarded as significant. According to the 95% confidence interval, we present data as the mean \pm SE. The comparison of categorical variables between the two groups was carried out using the χ^2 test. A logistic regression model was used to analyze the effect of categorical variables and adjust for potential confounders. The comparison of continuous variables between the two groups was carried out by *t*-test. A linear regression model was used to analyze the effect of continuous variables and adjust for potential confounders.

RESULTS

Baseline patient characteristics

The weekday group included 326 patients and the weekend group comprised 62 patients. There were no significant intergroup differences in demographics, except for age (Table 1). The mean age of the weekend group was younger than the weekday group by 5 years (60.7 ± 0.85 years in the weekday group *vs* 55.7 ± 2.10 years in the weekend group, *P* = 0.023). The ages in both groups had normal distributions; the weekday showed skewness and kurtosis values of -0.191 and -0.627, respectively, and the skewness and kurtosis values of the weekend group were -0.83 and -0.760, respectively. All outcome analysis was age-adjusted because age is an important confounding factor for treatment outcomes, including mortality. In order to adjust for age, linear regression was used for continuous variables and logistic regression was used for categorical variables. However, there were no significant differences between the two groups in the patterns and sites of bleeding, Rockall scores, Charlson scores, or comorbidities (Table 1).

Endoscopic procedure

Endoscopic therapy was performed in patients with Forrest I a to II b ulcers, and the following hemostatic tools were frequently used: argon plasma coagulation, hemoclipping, and epinephrine injection as a combination therapy (43%) or monotherapy (57%). However, there was no significant discrepancy between the weekday and weekend groups in hemostatic tool usage, and rebleeding rate did not differ with regard to the applied hemostatic method (from 11% to 19%).

The endoscopists who performed the endoscopic hemostasis could be divided into two groups (instructors and hospital staff) according to the level of experience.

Table 1 Baseline characteristics and treatment outcomes of the weekday and weekend groups *n* (%)

Factors	Weekday	Weekend	<i>P</i> value
Number of patients	326 (84.0)	62 (16.0)	
Age (yr)	60.7 \pm 0.8	55.7 \pm 2.1	0.023
Male	250 (76.7)	47 (75.8)	NS
Gastric ulcer	221 (68.1)	43 (69.4)	NS
Duodenal ulcer	104 (31.9)	19 (30.6)	NS
Active bleeding (Forrest I a, I b)	119 (36.5)	18 (29.0)	NS
Rockall score	5.0 \pm 0.0	4.7 \pm 0.2	NS
Charlson score	3.4 \pm 0.1	3.1 \pm 0.3	NS
Comorbidity	123 (37.7)	26 (41.9)	NS
Endoscopic hemostasis	309 (94.8)	57 (91.9)	NS
Time to endoscopy (min)	338.9 \pm 24.9	306.8 \pm 45.6	NS
Rebleeding	39 (12)	13 (21)	0.030
Angiographic embolization	4 (1.2)	1 (1.6)	NS
Surgery	3 (0.9)	1 (1.6)	NS

Mortality	6 (1.8)	1 (1.6)	NS

NS: Not significant.

Among a total 388 subjects, 67% (260 patients) of endoscopic hemostases were performed by hospital staff and the other 33% (128 patients) were performed by instructors. However, there was no significant difference in the level of experience between the weekday and weekend group, and between the daytime and nighttime group (proportion of procedures by hospital staff was 68% in the weekday group *vs* 59% in the weekend group, *P* = 0.14; 69% in the daytime group *vs* 58% in the nighttime group, *P* = 0.11). Also the rate of rebleeding was not different between the two groups (instructors and hospital staff).

Most patients (97%) underwent early endoscopy regardless of weekend or nighttime admission. Overall, the mean time interval between presentation to the ER and endoscopy was 333.8 ± 22.2 min. The time to endoscopy was slightly shorter in the weekend group, although the difference was not significant (338.9 ± 24.9 min in the weekday group *vs* 306.8 ± 45.6 min in the weekend group, *P* = 0.56) (Table 1). However, when time to endoscopy was compared between the daytime group and the nighttime group, it was significantly shorter in the nighttime group (352.9 ± 26.3 min in the daytime group *vs* 255.0 ± 30.0 min in the nighttime group, *P* = 0.016) (Table 2).

Treatment outcomes

Mortality: The overall mortality rate was only 1.8% (7/388). The subgroup that had high Rockall scores (≥ 6) included 146 patients, and their mortality rate was 4.1% (6/146). There was no significant difference in mortality between the weekday and weekend groups (1.8% in the weekday group *vs* 1.6% in the weekend group, *P* = 0.902) (Table 1). In addition, the mortality rate did not differ between the daytime and nighttime groups (1.9% in the daytime group *vs* 1.3% in the nighttime group, *P* = 0.757) (Table 2). All deaths occurred in patients with comorbidities, who had significantly higher CACI (7.0 ± 0.7) and Rockall scores (7.6 ± 0.6) than surviving patients (*P* <

NS: Not significant.

Table 3 Significant risk factors for mortality

Risk factor	Alive (<i>n</i> = 381)	Dead (<i>n</i> = 7)	<i>P</i> value
Comorbidity rate (%)	37.3	100.0	0.001
Age (yr)	59.7 ± 0.8	72.1 ± 5.3	0.037
Charlson score	3.3 ± 0.1	7.0 ± 0.7	< 0.001
Rockall score	4.9 ± 0.1	7.6 ± 0.6	< 0.001

0.001). The significant risk factors for mortality were age, comorbidity, Rockall score, and Charlson score (Table 3).

Rebleeding: The level of experience did not affect the rate of rebleeding (16% in procedures by instructors *vs* 14% by hospital staff, *P* = 0.39) in our study. Age-adjusted analysis revealed a significantly higher rebleeding rate in the weekend group (12% in the weekday group *vs* 21% in the weekend group, *P* = 0.030) (Table 1). In addition, despite earlier endoscopy, the rate of rebleeding was also higher in the nighttime group, which we called the nighttime effect, than in the daytime group (11.5% in the daytime group *vs* 21.1% in the nighttime group, *P* = 0.018) (Table 2). When the rebleeding rate was compared between the four subgroups that were divided by weekday/weekend and daytime/nighttime, the highest rebleeding rate, which reached up to one third of the patients, was noted in the weekend-nighttime group (11.4% in the weekday daytime, 15.1% in the weekday nighttime, 12.8% in the weekend daytime, and 34.8% in the weekend nighttime, *P* = 0.040) (Table 4).

Multivariate logistic regression was used to analyze potential factors that affected the in-hospital rebleeding rate. The significant independent risk factors for rebleeding were a high Rockall score (≥ 6) and nighttime rather than weekend admission (Table 5). Therefore, statistically, the risk factor associated with rebleeding was not weekend but nighttime admission.

Length of stay: Age-adjusted analysis revealed a shorter

length of stay in the weekend group (8.5 d in weekday *vs* 6.2 d in weekend, *P* = 0.009). However, linear regression analysis revealed that the length of stay was not associated with age or weekend admission, but was strongly associated with the type of comorbidity, which correlated well with the CACI. The length of stay increased in proportion to the increase in the CACI.

DISCUSSION

In this multicenter study, our treatment outcomes were generally favorable. The overall mortality rate due to peptic ulcer bleeding was only 1.8%, which is lower than previous studies that had reported mortality of 6% to 7%^[1-3]. In addition, the need for surgery and angiographic embolization was also low, at 1% and 1.2%, respectively. These outcomes, including mortality, might have been significantly affected by the severity of disease and comorbidities. However, mortality in the subgroup whose Rockall score was above 6 was also only 4.1% in our study (6/146), and mortality was only 0.3% in patients with Rockall scores under 6 (1/388); thus, our low mortality was not due to a milder presentation of bleeding. Such favorable outcomes should result from timely endoscopic hemostasis and appropriate intensive care. We provided early endoscopy within 24 h in most patients (97%), even for weekend and nighttime admissions. The mean time to endoscopy was only 333.8 ± 22.2 min overall. Therefore, we suggest that early intervention could reduce the mortality of peptic ulcer bleeding to 1.8%.

Regarding the so-called weekend effect, our study demonstrated no weekend effect on mortality, need for surgery, angiographic embolization, or length of stay. In fact, the patients in the weekend group showed favorable outcomes comparable to those of the weekday group. We expected to nullify the weekend effect since all four participating hospitals were teaching referral hospitals with well-organized duty systems and formal out-of-hours emergency endoscopy services, which allowed early endoscopy at any time of any day. Contrary to our expectations, the time interval between presentation to the ER and endoscopy was shorter for weekend and nighttime admissions. The reasons for shorter time to endoscopy at night and on weekends might be longer waiting time during weekdays due to previously appointed outpatients, and fewer traffic jams at night and on weekends in urban settings.

However, a higher rebleeding rate was noted in the weekend group, and it is possible that the weekend effect might exist in spite of early endoscopy. In multivariate logistic regression analysis, weekend presentation was not a significant risk factor for rebleeding, but nighttime presentation and a high Rockall score were independent risk factors for rebleeding. Therefore, statistically, the risk factor associated with rebleeding was not weekend but nighttime admission. The rebleeding rate in the weekday-nighttime group was also higher than weekday-daytime group, although the difference was not statistically sig-

Table 5 Multivariate analysis for risk factors of rebleeding

Risk factor	Rebleeding rate (%)	<i>P</i> value	Odds ratio	95% confidence interval
Rockall score (≥ 6) ¹	18	0.016	2.083	1.144-3.791
Nighttime	21	0.044	2.012	1.020-3.968
Weekend	21	0.120	1.782	0.861-3.689

¹According to the receiver operating characteristic curve, a Rockall score of 6 points was used as the cutoff value.

nificant (weekday-daytime 11.4% *vs* weekday-nighttime 15.1%, *P* = 0.487). The weekend-daytime group showed a similar rebleeding rate to that of the weekday-daytime group, but the weekend-nighttime group had a significantly higher rebleeding rate (rebleeding rate 34.8% in the weekend nighttime group *vs* 12.8% in the weekend daytime group, *P* = 0.040). However, we cannot completely rule out a weekend effect because the rebleeding rate of the weekend-nighttime group was higher than that of the weekday-nighttime group. Thus, it is reasonable to infer that these findings represent a nighttime effect or a weekend-nighttime effect rather than a weekend effect. Therefore, we concluded that the nighttime effect represented a new risk factor for rebleeding and was more powerful on the weekend through a combination with the weekend effect. Rebleeding after endoscopic hemostasis could also be affected by various endoscopic and clinical factors, such as an active bleeding pattern, gastric location of the peptic ulcer, larger ulcer size^[19-21], comorbidities^[21-23] and even by the level of experience of endoscopists^[24], but our finding of increased rebleeding in the nighttime group, especially the weekend nighttime group, was not associated with these factors. However, we were unable to identify specific factors that accounted for this nighttime effect; potential reasons include fatigue and decreased concentration of endoscopists at night and reduced staffing patterns of physicians, nurses, and other support staff at night. It is necessary to be more alert and particularly careful regarding hemostasis in patients with UGIB who present at night on the weekend.

Rockall scores and Charlson scores were predictors of mortality, rebleeding, and length of stay^[16-18]. The Rockall score was designed to predict mortality and can also be used to predict rebleeding^[16,17,25,26]. To allow for clinical application of the Rockall score and to verify our data (because we observed such a low mortality rate), we used a receiver operating characteristic (ROC) curve to determine the cut-off value predictive of mortality and rebleeding. According to the ROC curve, a Rockall score of 6 points could be chosen as the cut-off value. Rockall scores greater than six were significantly associated with rebleeding [odds ratio (OR) = 2.08] and an increased mortality (OR = 1.77) of 4.1% (6/146). Bessa *et al.*^[27] also reported that the Rockall score indicated a risk of mortality up to 15% if the score was above six. Our data support a Rockall score of 6 points as a critical point.

Contrary to our expectation, length of stay was shorter in the weekend group than in the weekday group. The length of stay increased in proportion to the CACI, and linear regression analysis showed that length of stay was strongly associated with the type of comorbidity rather than weekend presentation, emphasizing the type and severity of illness.

One weak point in our data was that the mean age of the weekend group was 5 years younger than the weekday group. Through a review of the medical records, we observed that there were some weekend patients who postponed visiting the hospital due to a busy work schedule or other circumstances despite having experienced melena for several days. Younger patients are more likely to be employed, thus they are potentially more inclined to present on the weekend rather than on a weekday due to their work. Socio-environmental factors, such as employment, social status, and personal characteristics, might have an influence on visiting the hospital and could be a possible explanation for the younger age of the weekend group compared to the weekday group. However, such factors were not available in the majority of medical records due to the retrospective nature of our study, and we were unable to identify a satisfactory reason in our results. Despite this weakness, we are confident that the

age discrepancy was not a problem because all analyses of outcomes were age-adjusted.

Additional limitations of our study were that the number of deaths was too small to allow for satisfactory analysis and that our study was retrospective; however, all of the endoscopic procedures were based on the same protocol, which should overcome this weakness. In addition, our study was not a nationwide study, but we think that the results of this multicenter study are sufficient to conclude that early endoscopic intervention can lead to favorable outcomes in peptic ulcer bleeding even on weekends and at night.

In conclusion, early endoscopy for peptic ulcer bleeding could reduce mortality to 1.8% and could prevent the weekend effect on the majority of outcomes in patients with peptic ulcer bleeding. However, we identified nighttime presentation as a new risk factor for rebleeding, despite early endoscopy. The Rockall score was also a useful predictor of rebleeding, and we should take this into consideration in the prognosis of peptic ulcer bleeding. Therefore, we need to be more careful and alert at night when dealing with peptic ulcer bleeding, especially in patients who present at nighttime and those with high Rockall scores (≥ 6).

COMMENTS

Background

Upper gastrointestinal bleeding (UGIB) is a common medical emergency and timely endoscopy plays an important role in hemostasis. The "weekend effect" which means a worse outcome in UGIB patients following weekend admission, has been suggested by previous reports, but remains controversial.

Research frontiers

Some authors have suggested a weekend effect on UGIB resulting in higher mortality and more frequent surgery. One report suggests that early endoscopy can prevent the weekend effect and reduce mortality, however, contrary results have also been reported. The issue of the weekend effect on UGIB should be whether early endoscopic hemostasis even at weekends can prevent worse outcomes.

Innovations and breakthroughs

The study analyzed various endoscopic and clinical data from 4 centers which can affect the outcome of UGIB. From their results, they can suggest that early endoscopy for peptic ulcer bleeding, even at weekends, can almost prevent the weekend effect. The most important risk factor for rebleeding was a high Rockall score, however, nighttime admission was also identified as a novel risk factor for rebleeding, namely the nighttime effect.

Applications

Although early endoscopy for peptic ulcer bleeding can prevent the weekend effect in patients with peptic ulcer bleeding, nighttime presentation and high Rockall score were significant risk factors for rebleeding. The authors need to be more careful and alert when dealing with peptic ulcer bleeding, especially in patients who present at nighttime and those with high Rockall score.

Terminology

Weekend effect: The weekend effect has previously been reported as worse outcomes in UGIB patients following weekend admission, such as higher mortality and more frequent surgery; **Nighttime effect:** The nighttime effect is a novel term used in the current study, which means worse outcome due to a higher rebleeding rate in patients with peptic ulcer bleeding following nighttime admission.

Peer review

This is a well-written manuscript of a retrospective multi-center study investigating the weekend and the nighttime effect on the outcomes of patients with upper GIB requiring endoscopic hemostasis. The results were clearly presented and the contents are easily comprehensible.

Abstract

AIM: To identify the frequency of bacterial growth, the most commonly grown bacteria and their antibiotic susceptibility, and risk factors for bacterial colonization in bile collected from patients with different biliary diseases.

METHODS: This prospective study was conducted between April 2010 and August 2011. Patients with various biliary disorders were included. Bile was aspirated by placing a single-use, 5F, standard sphincterotome catheter into the bile duct before the injection of contrast agent during endoscopic retrograde cholangiopancreatography (ERCP). Bile specimens were transported to the microbiology laboratory in blood culture bottles within an anaerobic transport system. Bacteria were cultured and identified according to the standard protocol used in our clinical microbiology laboratory. The susceptibilities of the organisms recovered were identified using antimicrobial disks, chosen according to

the initial gram stain of the positive cultures.

RESULTS: Ninety-one patients (27% male, mean age 53.7 ± 17.5 years, range: 17-86 years) were included in the study. The main indication for ERCP was benign biliary disease in 79 patients and malignant disease in 12 patients. The bile culture was positive for bacterial growth in 46 out of 91 (50.5%) patients. The most frequently encountered organisms were Gram-negative bacteria including *Escherichia coli* (28.2%), *Pseudomonas* (17.3%) and *Stenotrophomonas maltophilia* (15.2%). There were no significant differences between patients with malignant and benign disease (58% vs 49%, $P = 0.474$), patients with acute cholangitis and without acute cholangitis (52.9% vs 50%, $P = 0.827$), patients who were empirically administered antibiotics before intervention and not administered (51.4% vs 60.7%, $P = 0.384$), with regard to the bacteriobilia. We observed a large covering spectrum or low resistance to meropenem, amikacin and imipenem.

CONCLUSION: We did not find a significant risk factor for bacteriobilia in patients with biliary obstruction. A bile sample for microbiological analysis may become a valuable diagnostic tool as it leads to more accurate selection of antibiotics for the treatment of cholangitis.

INTRODUCTION

Usually the bile ducts are sterile. However, the presence of gallstones within either the gallbladder or biliary tree is associated with the bacterial colonization of the bile^[1]. In patients without stone disease, previous biliary intervention is associated with high rates of bacteriobilia^[2,3]. Under conditions of normal bile flow, bacteria in the biliary system are of no clinical significance. Upon bile duct obstruction, bacteria proliferate within the stagnant bile while biliary pressure increases. Eventually, the bacteria presumably translocate into the circulation causing a systemic infection. Acute cholangitis spans a continuous clinical spectrum and can progress from a local biliary infection to advanced disease with sepsis and multiple organ dysfunction syndrome^[4]. Even recent studies have reported mortality rates of up to 10%^[5,6]. Acute cholangitis is mainly a result of microbial infection caused by bacteria and fungi^[7].

Blood cultures provide an opportunity to detect the causative organism but, even in febrile patients with cholangitis, blood cultures remain negative in more than half of the cases^[8]. Although definitive management of cholangitis involves the relief of bile stasis, effective empiric antibiotic therapy is an indispensable part of the treatment^[4,9]. Antimicrobial therapy recommendations state that antibiotics should be administered as soon as the diagnosis of acute cholangitis is suspected or established. Empirically administered antibiotics should be selected on the basis of antimicrobial activity against the causative bacteria, the severity of the cholangitis, the presence or absence of renal and hepatic failure, a recent (one year) history of antimicrobial therapy, local susceptibility pattern (antibiogram) and the biliary penetration of the antimicrobial agent^[4]. Previous studies have shown that Gram-negative bacteria, in particular *Escherichia coli*, are the most common pathogens isolated from infected bile^[9,10]. Because of the rapid development of multi-drug-resistant Gram-negative organisms, the choice of appropriate empiric antimicrobial therapy has become more complicated. Whenever any empirical antimicrobial agents are used, they should be switched for the best available narrower-spectrum agents to avoid superinfection or the emergence of antimicrobial resistance as a cause of treatment failure^[4]. Thus, knowledge of the common etiologic agents and their local susceptibility profile is essential to ensure the appropriate choice and timely administration of empiric antimicrobial therapy.

The aim of this study was to identify the most common bacteria grown in the bile and their antibiotic susceptibility. Furthermore, we investigated risk factors for microbiological colonization of the bile in patients with different biliary diseases.

MATERIALS AND METHODS

Ethics

This work has been carried out in accordance with the Declaration of Helsinki (2000) of the World Medical

Association. This study was approved ethically by Dicle University, School of Medicine. All patients provided informed written consent.

Patients

This prospective study was conducted between April 2010 and August 2011 in the Department of Gastroenterology, Dicle University Hospital. Patients with various biliary disorders were included. Written informed consent was obtained from all patients and the trial was approved by the Local Ethical Committee. Exclusion criteria were age under 16 years, incomplete clinical and laboratory data or the absence of written, informed consent before the procedure.

Methods

All duodenoscopes (Olympus-TJF-260V, 2601168) were disinfected according to the guidelines and contamination was excluded by regular smear tests. The diagnosis of cholangitis was made when a patient had a fever (higher than 38 °C), abnormalities in liver function test results, and the exacerbation of jaundice (if any), with and without right upper quadrant pain, provided that other septic complications were ruled out. Bile was aspirated by placing a single-use, 5F, standard sphincterotome catheter (after guide-wire cannulation) into the bile duct before the injection of contrast agent for endoscopic retrograde cholangiopancreatography procedure. Approximately 2 to 8 mL of bile (mean of 4 mL) was collected and transferred in a sterile tube.

Bile specimens were transported to the microbiology laboratory in blood culture bottles and in an anaerobic transport system (BacT/Alert 3D Culture Media bioMérieux SA; Marcy l'Etoile, France). Bacteria were cultured and identified according to the standard protocol used in our clinical microbiology laboratory. The susceptibilities of the organisms recovered were identified using antimicrobial disks, chosen according to the initial Gram stain of the positive cultures. Microorganisms in concentrations of > 10 000 per mL were considered as an infection; lower concentrations were accepted as contamination or colonization.

Statistical analysis

Data from each group (cholangitis *vs* no cholangitis, malignant *vs* benign biliary disease, antibiotic administered *vs* not administered before procedure) were compared using the χ^2 test or the Fisher's exact test. All *P*-values were based on two-tailed tests. Analysis was performed with SPSS for Windows (SPSS Inc., Chicago, IL). A *P* value < 0.05 was considered significant.

RESULTS

Patients and general microbiological characteristics

Initially 125 patients were included in the study. Seventeen patients were excluded because of inadequate bile aspiration and 17 patients were excluded because of missing bile culture data. Finally, a total of 91 patients (27%

male, mean age 53.7 ± 17.5 years, range: 17-86 years) were analyzed. The main indications for cholangiographic interventions (Table 1) were benign biliary disease in 79 patients and malignant disease in 12 patients. Two patients with choledocholithiasis also had plastic stents and choledochojejunostomy was performed in one patient with choledocholithiasis. Seventeen (21.5%) patients with benign biliary disease had acute cholangitis before cholangiography. Thirty-five out of 91 (38.4%) patients were administered antibiotics empirically prior to the cholangiography (at least a single dose). All patients with acute cholangitis were administered antibiotics before cholangiography.

Bile culture was positive for bacterial growth in 46 out of 91 (50.5%) patients including 39 patients with benign disease and 7 with malignant disease. There were no patients in whom the concentration of microorganisms was lower than 10 000 per mL of bile. Table 2 shows the frequency of different organisms in positive bile cultures. A total of 48 organisms were isolated, comprising 15 different species. The most frequently encountered organisms were Gram-negative bacteria including *Escherichia coli* (28.2%), *Pseudomonas* (17.3%) and *Stenotrophomonas maltophilia* (15.2%).

Of 39 patients with benign biliary disease and positive bile cultures, there were aerobic bacteria grown in bile culture of 34 patients (87%), anaerobic bacteria in 3 (8%) and both aerobic and anaerobic bacteria grown in bile culture of 2 (5%) patients. Of 7 patients with malignant disease and positive bile cultures, there were aerobic bacteria grown in 6 bile cultures (86%) and anaerobic bacteria grown in 1 bile culture (13%). Monomicrobial growth was more frequent (96%) in comparison with polymicrobial cultures (4%). There was bacterial growth in bile culture of 9 out of 17 (52.9%) patients with acute cholangitis and in bile culture of 37 out of 74 (50%) patients without acute cholangitis. There was bacterial growth in bile culture of 17 out of 35 (48.6%) patients who were administered antibiotics and in bile culture of 34 out of 56 (60.7%) patients who were not administered antibiotics.

There were no significant differences between patients with malignant and benign disease (58% *vs* 49%, $P = 0.474$), patients with acute cholangitis and without acute cholangitis (52.9% *vs* 50%, $P = 0.827$), patients who were administered antibiotics empirically before the intervention and patients who were not administered them (51.4% *vs* 60.7%, $P = 0.384$), as regards the bacterial growth in bile culture.

Antibiotic susceptibility testing and resistance profiling

Antibiotics administered were ceftriaxone in 6 patients, ceftriaxone + ciprofloxacin in 1, ceftriaxone + ornidazole in 6, ciprofloxacin + sulbactam/amoxicillin in 5, ciprofloxacin in 10, cefuroxime axetil in 1, amoxicillin/clavulanic acid in 1, cefoperazone/sulbactam in 2, meropenem in 2 and cefazolin in 1 patient. Antibiotic susceptibility was measured for at least 11 types of antimicrobial substances. Table 3 shows the antibiotic susceptibility rate

Table 3 Results of antibiotic susceptibility tests

Antibiotic	Susceptibility (%)
Meropenem	86
Amikacin	86
Imipenem	79
Piperacillin/tazobactam	61
Gentamicin	53
Ciprofloxacin	52
Levofloxacin	51
Ceftazidime	46
Ampicillin	21
Cefotaxime	14
Ampicillin/sulbactam	11

of the identified bacteria in the bile culture. We observed a broad spectrum or low resistance to meropenem, amikacin and imipenem. There was high resistance for gentamicin (47%), ciprofloxacin (48%), levofloxacin (49%), ceftazidime (54%), ampicillin (79%), cefotaxime (86%) and ampicillin/sulbactam (89%). The most common bacterial organisms growing outside the covering antibiotic spectrum or with high resistance profile were *Pseudomonas aeruginosa*, *Escherichia coli* and *Enterococcus faecium*.

DISCUSSION

The traditional presentation of cholangitis includes the

triad of jaundice, fever and right upper quadrant pain^[11], though the actual presentation can be quite diverse, ranging from mild abdominal discomfort to life-threatening septic shock. Both biliary obstruction and bacteria in the bile are required for the development of cholangitis. In a healthy person, the biliary tree is normally sterile, but biliary pathologies are often associated with secondary bacterial colonization^[1]. Other studies have detected bacteriobilia in 16% to 85% of patients, depending on different disease groups^[8,10,12-15]. Bacterial bile culture positive rates are 58% to 76% in patients with choledocholithiasis + cholangitis, 29% to 54% in patients with acute cholecystitis, 13% to 32% in patients with cholelithiasis, and 70% to 93.9% in patients with hepatolithiasis + cholangitis^[4]. There is an increased incidence of positive bile culture in patients with acute cholangitis as compared to without cholangitis (67% *vs* 33%, $P = 0.012$), which has been reported by Salvador *et al*^[9]. Risk factors for bacteriobilia are orthotopic liver transplantation (OLT), steroid treatment, biliary stenting and repeated biliary intervention^[10]. Although some studies have reported that malignant biliary strictures and biliary stents increase risk of fungal colonization^[10], others have not reported this association^[16]. In our study, bacteriobilia was found in 50.5% of all patients. There were not any patients with OLT, steroid treatment or repeated biliary intervention and only two patients had biliary stenting. We did not find significant differences between patients with malignant and benign biliary disease, with cholangitis and without cholangitis and in patients who have been administered and not administered antibiotics before the intervention, as regards bacterial growth in the bile culture. These results may suggest that bacterial colonization in bile is dependent on multiple factors. The ineffectiveness of antibiotic administration before cholangiography on the bacterial growth in the bile culture may be related to high bacterial resistance against the antibiotics used. Although we identified bacterial growth in half of all patients, there were clinical findings of acute cholangitis in only 9 out of 46 patients with positive bile culture. We also found that 8 patients had all signs of acute cholangitis, but the bile culture was negative. Therefore, we suggest that all bacteriobilia can not cause obvious clinical symptoms of acute cholangitis and some patients with acute cholangitis may have negative bile culture. However, we cannot totally exclude contamination of the endoscope when it is passed through the upper gastrointestinal tract. To avoid contamination *via* cross-transmission between different patients, the duodenoscope was vigilantly disinfected. In all our patients with positive bile cultures, the concentration of microorganisms was higher than 10 000 per mL of bile. Therefore, we conclude that all patients with positive bile culture had actual bacterial growth that originated from aspirated bile.

It has been reported that microbial organisms contained in the bile from various biliary diseases are of intestinal origin. Aerobic bacteria such as *Escherichia coli*, *Klebsiella*, *Enterococcus* and *Enterobacter* are most frequently isolated, whereas *Streptococcus spp*, *Pseudomonas* and *Proteus*

are less frequently isolated^[17-19]. Although anaerobic bacteria such as *Clostridium* and *Bacteroides* are often isolated, most of these patients have polymicrobial infections with aerobic bacteria^[20-22]. Salvador *et al*^[9] have found that Gram-negative bacilli (or *Enterobacteriaceae*) are the most commonly isolated bacteria in the bile culture of both patients with (94%) and without (95%) cholangitis. In a large study involving 243 consecutive patients in Germany, polymicrobial growth in bile culture has been found more frequently (67%) in comparison with monomicrobial growth (33%). In this study, Gram-negative bacteria were found in 43% of patients, Gram-positive bacteria in 40%, *Candida* species in 10% and strict anaerobes in 7% of patients. The most frequently encountered organisms were *Enterococcus* species (31%), *Escherichia coli* (10%) and *Klebsiella* species (9%)^[10]. In our study, Gram-negative bacteria were the most common bile culture isolates for patients with and without acute cholangitis and almost all patients (95%) had monomicrobial growth in bile culture. *Escherichia coli* and *Pseudomonas* were the most frequently isolated bacteria. The results of our study may suggest that most of the bacteria in bile originate from the intestinal tract.

The management of cholangitis depends primarily on interventional biliary drainage and supplementation with antibiotic treatment. The combination of ampicillin and an aminoglycoside was regarded as a standard regimen for cholangitis in the 1980s^[4] and most randomized, controlled trials have concluded that recently developed antimicrobial drugs are effective and useful equivalents to that of ampicillin and aminoglycosides^[23,24]. Therefore, according to the clinical trials available so far, piperacillin, ampicillin and an aminoglycoside, and several cephalosporins, are recommended for the treatment of acute cholangitis^[4]. In the Tokyo Guidelines, the selection of antimicrobial agents is based on the severity of acute cholangitis. It has been recommended that antimicrobial agents administered empirically should be changed in favor of more appropriate agents, according to the identified causative microorganisms and their sensitivity to antimicrobials^[4]. In our patients, the most common empirically administered antibiotics were ceftriaxone, ciprofloxacin and sulbactam/amoxicillin. We did not identify a bacterial susceptibility test for ceftriaxone, but there was high resistance to other routines using antibiotics for cholangitis in our clinic. This high resistance may be related to commonly inappropriate use of these antibiotics in our region. A bile sample collected during cholangiography for microbiological analysis and antibiotic susceptibility tests may be valuable in the selection of appropriate antibiotics for the treatment of cholangitis.

In conclusion, our results indicate that about half of patients with biliary obstruction had bacteriobilia in their bile culture and the most commonly isolated bacteria were Gram-negative bacteria including *Escherichia coli* and *Pseudomonas*. When antibiotics were administered before cholangiography, the presence of cholangitis and the etiology of biliary obstruction had no significant effect on the incidence of bacteriobilia. There was a high resistance

against routinely used antibiotics, such as ciprofloxacin, and ampicillin and ampicillin/sulbactam. A bile sample for microbiological analysis may become a valuable diagnostic tool as it leads to more accurate selection of antibiotics for the treatment of cholangitis.

COMMENTS

Background

Acute cholangitis spans a continuous clinical spectrum and can progress from a local biliary infection to advanced disease with sepsis and multiple organ dysfunction syndrome. Knowledge of the common etiologic agents of cholangitis and their local susceptibility profile is essential to ensuring the appropriate choice and timely administration of empiric antimicrobial therapy.

Research frontiers

Blood cultures provide an opportunity to detect the causative organism but, even in febrile patients with cholangitis, blood cultures remain negative in more than half of the cases. Gram-negative bacteria, in particular *Escherichia coli*, are the most common pathogens isolated from infected bile. Because of the rapid development of multi-drug-resistant gram-negative organisms, the choice of appropriate empiric antimicrobial therapy has become more complicated.

Innovations and breakthroughs

Other studies have detected bacteriobilia in 16% to 85% of patients, depending on different disease groups. In this study, bacteriobilia was found in 50.5% of all patients. There was a large covering spectrum or low resistance to meropenem, amikacin and imipenem. The authors did not find significant risk factors for bacterial growth in the bile culture. The findings show that all bacteriobilia can not cause obvious clinical symptoms of acute cholangitis and some patients with acute cholangitis may have negative bile culture.

Applications

A bile sample for microbiological analysis may become a valuable diagnostic tool as it leads to more accurate selection of antibiotics for the treatment of cholangitis.

Terminology

Acute cholangitis is bile duct microbial infection caused by bacteria and fungi. Its main clinical findings are right upper quadrant pain, fever and jaundice.

Peer review

The authors have investigated the frequency of bacterial growth in the bile, the most commonly grown bacteria, their antibiotic susceptibility and risk factors for the bacterial colonization of the bile. They show that a bile sample for microbiological analysis during cholangiography may become a valuable diagnostic tool as it leads to more accurate selection of antibiotics for the treatment of cholangitis.

Abstract

AIM: To assess the gender preferences, specifically the gender of the nursing staff (endoscopy assistants) and the impact on acceptance for screening colonoscopy (SC).

METHODS: Patients or relatives attending the clinics or health care workers working in a tertiary center were invited to participate in this questionnaire study. The questionnaire enquired on the general demographics (1) age, gender, ethnicity, education level, and employment status, previous history of colonoscopy, family or personal history of colonic pathologies, personal and family history of any cancers; (2) subjects were asked if they would go for an SC if they had appropriate indications (age over 50 years, family history of colorectal cancer (CRC), fecal occult blood positive, anemia especially iron deficiency anemia, bleeding per rectum with or without loss of appetite, weight loss and abdominal pain) with and without symptoms attributable to CRC; and (3) preferences for the gender of the endoscopists and assistants and whether they would still undergo SC even if their preferences were not met.

RESULTS: Eighty-four point seven percent (470/550) completed questionnaire were analysed. More female

subjects expressed gender preferences for the endoscopists [overall 70%; female (67.7%) and male (2.3%)] compared to male subjects [overall 62.8%; male (56%) and female (6.8%), $P = 0.102$]. Similarly, more female subjects expressed gender preferences for the assistants [overall 74.5%; female (73.4%) and male (1.1%)] compared to male subjects [overall 58%, male (49.3%) and female (8.7%), $P < 0.001$]. Overall, a third would decline an SC, despite having appropriate indications, if their preferences were not met. On univariate analysis, male gender, non-Malay ethnicity (Chinese and others) and previous colonoscopy experience were more likely to undergo an SC, even if their preferences were not met (all $P < 0.05$). Gender and previous experience [odds ratio (OR) 1.68, 95% confidence interval (CI) 1.00-2.82, $P < 0.05$] with colonoscopy (OR 4.70, 95% CI 1.41-15.66, $P < 0.05$) remained significant on multivariate analysis.

CONCLUSION: Genders preference for the endoscopy nurses/assistants is more common than for the endoscopist among women and has implications for the success of a screening colonoscopy program.

INTRODUCTION

Colorectal cancer (CRC) is the third most common cancer in both men and women and remains an important cause of morbidity and mortality^[1,2]. The incidence rates are reported to be increasing, especially in the developing nations, but are stable or are leveling off in the more developed nations, such as the United States and Canada^[1,2].

Currently, colonoscopy is the recommended procedure of choice for CRC screening^[3-5]. Despite the effectiveness of CRC screening programs, with reduction in subsequent development of CRC and related mortality^[6,7], the uptake rates are still low. Ethnicity, socioeconomic status, public knowledge of CRC and availability of services are some of the factors that can affect the uptake of screening programs. Gender disparities among health care providers are evident in certain specialties^[8-10]. A similar situation exists in the gastroenterology fraternity^[11-14]. Several studies have shown that women prefer women endoscopists^[15-21]. However, none of these studies have looked at the gender of the endoscopists' assistants. This study assesses preferences with regard to the genders of the endoscopists and the assistants and their implications for screening colonoscopy (SC) uptake.

MATERIALS AND METHODS

Setting

This study was conducted (March to June 2008) in a referral center (RIPAS Hospital) in a country with a predominant Malay population. The study was conducted in accordance with the standard set out in the Declaration of the Helsinki and ethics approval was obtained from the Institutional Medical Health and Research Ethic Committee of the Hospital, Ministry of Health.

Subjects

Subjects included patients attending the various clinics or accompanying relatives and health care workers working in the center. Subjects were randomly approached and invited to participate in this self-administered questionnaire study. Verbal and detailed written explanations were given prior to handing out the questionnaires. Consents were also obtained. Only subjects 18 years old or above were included in the study.

Questionnaire

Development: The questionnaire was provided in two versions, English and Malay. The initial questionnaire was developed in English and forward translations to Malay were carried out by two persons fluent in both languages. Inconsistencies were amended based on consensus. This process was repeated until the two versions were consistent. The questionnaire was tested ($n = 20$) to assess for any problem before starting the survey.

Data collection: The questionnaire consisted of three parts; (1) demographic data (gender, age, ethnic group,

education level, and employment status, previous colonoscopy, family or personal history of colonic pathologies (polyps and cancer), personal and family history of any cancers (specifically CRC, other gastrointestinal cancers, pulmonary, obstetric and gynecology and breast cancers); (2) in the second section, subjects were asked if they would go for an SC assuming they had appropriate indications (age over 50 years, family history of CRC, fecal occult blood positive, anemia especially iron deficiency anemia, bleeding per rectum with or without loss of appetite, weight loss and abdominal pain)^[3-5]. They were also asked if they would go for an SC if they had appropriate indications but without any gastrointestinal symptoms attributable to a CRC. All these questions required only a "yes" or "no" response; and (3) subjects were asked for their preferences for the gender of the endoscopists and assistants (nursing staff involved with the procedure). These two questions required one out of three responses (same gender, opposite gender or no preferences). The final question inquired if they would still go for an SC if they had definite indications, but without their preferences being met. Subjects were informed that colonoscopies are carried out following the practice of the unit using conscious sedation (titrated intravenous midazolam and fentanyl).

Statistical analysis

The data were entered into the Statistical Program for the Social Sciences (SPSS, Version 10.0, Chicago IL, United States) for analysis. Univariate analysis (χ^2 test) was used to compare the categorical variables and only those variables that were found to be significant ($P < 0.10$) were entered into multivariate analysis. The level of significance was set at $P < 0.05$.

RESULTS

There were 470 completed questionnaire out of total 550 distributed, giving a response rate of 84.5%. The mean age of the sample was 39.4 ± 12.8 years old, with a male to female ratio of 44:56. Family history of any cancer was reported at 19.8% and of these, 7.4% were CRC. The demographic data is shown in Table 1.

In the presence of appropriate indications, including symptoms attributable to CRC, 90.9% would agree to undergo an SC. However, in the absence of any symptoms, only 59.4% would agree to undergo SC ($P < 0.05$).

With regard to the genders of the endoscopists, more female subjects expressed a gender preference (overall 70%; 67.7% for a female endoscopist and 2.3% for a male endoscopist), with 30% having no gender preference, compared to male subjects, of whom 62.8% ($P = 0.102$) expressed a gender preference, (56% for male endoscopists and 6.8% for female endoscopists) and 37.2% had no preference.

With regard to the gender of the assistants, significantly more female subjects expressed a gender preference [overall 74.5%; female (73.4%), male (1.1%) and no

preference (25.5%)] compared to male subjects [overall 58%, male (49.3%), female (8.7%) and no preference (42%) ($P < 0.001$).

Overall, a third would decline an SC if their preferences were not met (for either or both endoscopists and assistants), even if there were indications for an SC. Factors that were associated with likelihood of agreeing to undergo SC even when their preferences were not met included male gender, non-Malay ethnicity and previous experience of colonoscopy. Education level, marital status, employment status and family history of cancers, including CRC, were not predictive (Table 2).

On multivariate analysis, male gender and previous experience of colonoscopy remained significant predictive factors for agreeing to undergo an SC, despite preferences not being met (Table 3).

DISCUSSION

To date, there have been several studies that had looked at gender preferences during colonoscopy^[15-21]. However,

SC: Screening colonoscopy; CRC: Colorectal cancer.

they only assessed the preference for the gender of the endoscopists and not that of the endoscopy nurses or assistants.

Of these studies, most looked at mainly Caucasian populations^[15-18,20] and one study from the States concentrated on a Hispanic population^[19]. To date, there is only one study from the East, which assessed the preferences of Korean women^[18]. Two studies specifically looked at female subjects^[17,18]. Most of the studies recruited subjects from clinics^[17-21] and two studies looked at patients who were scheduled for colonoscopy^[15,16]. All these studies showed similar findings, with women expressing more preferences for female endoscopists, even among healthcare professionals^[21]. The present study showed the highest preference rates reported for both women (70%) and men (62.8%). The findings of these studies are summarized in Table 4.

Generally, when patients express a preference, they usually prefer an endoscopist of the same gender. Several factors have been reported to be important and not just for endoscopic procedures^[22]. Factors reported to be important include ethnicity, female gender, younger age, low income, history of abuse (either physical or emotional), being cared for by a female primary care physician, being employed, and being single^[17-21]. However, not all the studies reported consistently similar findings. One of the reasons that may account for the finding in the current study is cultural differences. Asian populations are gener-

Table 4 Comparison of gender preference during colonoscopy

Authors (yr)	Subjects	Setting	Genders	Population	Gender preference
Fidler <i>et al</i> ^[14] , 2000	Patients undergoing colonoscopy	Endoscopy	Both	United Kingdom	Women (48%) and men (0%)
Varadarajulu <i>et al</i> ^[15] , 2002	Patients undergoing colonoscopy	Endoscopy	Both	United States	Overall (26%): Women (45%) and men (4.3%). No difference post procedure
Menees <i>et al</i> ^[16] , 2005	Subjects not scheduled	Clinics	Female	United States	44.4% expressed preference [endoscopist: Women (43%) and men (1.4%)]
Lee <i>et al</i> ^[17] , 2008	Subjects not scheduled for colonoscopy	Clinics	Female	South Korea	45.5% expressed preference [endoscopist: Women (32.1%) and men (13.4%)]
Schneider <i>et al</i> ^[18] , 2009	Patients undergoing colonoscopy	Endoscopy	Both	United States	Women (42%) and men (24%)
Zapatier <i>et al</i> ^[19] , 2011	Patients not scheduled for colonoscopy	Clinics	Both	United States	Overall (25.7%): Women (30.8%) and men (20.4%); women: Hispanic (35%) and Caucasian; men (20.4%): Hispanic men
Shah <i>et al</i> ^[20] , 2011	Patients not scheduled for colonoscopy	Primary clinics	Both	United States	Patients: Women (53%) and men (27.8%); Health care professionals: Women (43.1%) and men (26.1%)
Present study, 2012	Subjects not scheduled for colonoscopy	Clinics	Both	Southeast Asia	Endoscopists: Women (70%; women 67.7% and men 2.3%); men (62.8%; women 6.8% and 56% men) Assistants: Women (74.5%; women 73.4% and men 1.1%); men (58%; women 8.7% and 49.3% men)

ally more reserved, especially women, and are more likely to prefer to deal with health care providers of the same gender.

When the preference for the gender of the assistants was assessed, similar findings were seen. However, the preference rate for women subjects was higher compared to the rate expressed for the endoscopist. In contrast, it was slightly lower for men. This indicates that, the gender of the assistants is more important for female patients than for male patients. The reasons for this are probably similar to those found in studies looking at gender preferences among endoscopists^[15-21]. Colonoscopy can be considered as invasive, uncomfortable, and embarrassing and patients usually have more interactions with the endoscopists' assistants or nurses. For women, embarrassment, feeling at ease talking to, and being examined by, female health care providers are some of the important factors. Most were willing to wait or pay extra for their preferences to be met.

When subjects' preferences were not a problem, the uptake of SC was good in the presence of symptoms attributable to colonic pathology, but not in the absence of symptoms. However, when their preferences were not met, a third would decline an SC even if an SC was indicated. On univariate analysis, male gender, non-Malay ethnicity and previous experience of colonoscopy were significant predictive factors for agreeing to undergo an SC, even if preferences were not met. Only gender and previous experience of colonoscopy remained significant on multivariate analysis. None of the previous studies assessed the uptake of colonoscopy if subjects' preferences were not met^[15-21]. The finding of the present study are not unexpected. Previous studies have already shown that women expressed more preferences. Interestingly, one study showed the rates of SC did not increase when women were offered a female endoscopist in a health promotion outreach program^[23], suggesting other factors are involved^[24,25]. Surprisingly, socioeconomic status and family history of cancer, including gastrointestinal cancers, did

not influence subjects' decisions for SC.

There are several limitations with the present study. First, it was a single center study and the result may not be generalizable to other populations. However, the findings are consistent with findings of previous studies. Second, the mean age of the studied population was much younger than the other studies and the recommended screening age. However, as with all screening programs, all subjects are potential screening subjects and all will eventually become eligible with time.

In conclusion, the gender of the endoscopy nurse or assistant is more important than the gender of the endoscopist among female subjects. Importantly, a third of the subjects, particularly women, would decline an SC if their preferences were not met. Male gender and previous experience of colonoscopy were predictive factors for agreeing to undergo an SC, even when their preferences were not met. Therefore, addressing the gender disparities of health care providers, not just of the endoscopists, but also of the endoscopists' assistants is important to improve the uptake rate of any SC programs.

ACKNOWLEDGMENTS

I would like to thank all the endoscopy unit staff who helped this questionnaire study (Suriawati Bakar, Wasnati Bahrom, Saiful Ramli and Dyana Mahali).

COMMENTS

Background

Colorectal cancer (CRC) is the third most common cancer and remains an important cause of cancer related mortality. Screening colonoscopy (SC) has been shown to reduce the incidence of CRC and prevent CRC related death. However, uptake of SC remains low for various reasons, including both patient and non-patient factors. Gender preference for the healthcare service providers is common and may impact on uptake rates of service delivery.

Research frontiers

Several studies based on patients scheduled for lower gastrointestinal endoscopy and clinics have shown that gender preference for a same gender en-

doscopist is more common among women than men. This is true even among health care professionals. Most of those who expressed a gender preference were willing to wait or pay for their preferences to be met.

Innovations and breakthroughs

Previous studies have only assessed subjects' preferences for the gender of the endoscopist. This study also assessed the subjects' preferences for the gender of the assistants and their impact on uptake of SC.

Applications

This study showed that the gender of the endoscopist's assistants or staff nurse involved with the procedure is also important. It also showed that not meeting the preference of patients, especially women, would affect the uptake of SC if indicated. In this study of a Southeast Asian population, a third of subjects would decline an SC if their preferences were not met.

Terminology

CRC is a malignant neoplasm of the colon and rectum and commonly develops through the adenoma-dysplasia-carcinoma sequence, which usually takes many years. SC is now the recommended screening procedure of choice for CRC, as it allows detection and removal of early neoplasms (adenoma with or without carcinoma *in situ*).

Peer review

This study shows that gender of not just the endoscopist but also of the endoscopy nurse or assistants need to be considered in the delivery of colonoscopy and that this may impact on the uptake rate of an SC program.

Abstract

AIM: To investigate whether the incidence of hiccups in patients undergoing esophagogastroduodenoscopy (EGD) or same-day bidirectional endoscopy (EGD and colonoscopy; BDE) with sedation is different from those without sedation in terms of quantity, duration and typical onset time.

METHODS: Consecutive patients scheduled for elective EGD or same-day BDE at the gastrointestinal endoscopy unit or the health examination center were allocated to two groups: EGD without sedation (Group A) and BDE with sedation (Group B). The use of sedation was based on the patients' request. Anesthesiologists participated in this study by administering sedative drugs as usual. A single experienced gastroenterologist performed both the EGD and the colonoscopic examinations for all the patients. The incidence, duration and onset time of hiccups were measured in both groups. In addition, the association between clinical variables and hiccups were analyzed.

RESULTS: A total of 435 patients were enrolled in the study. The incidences of hiccups in the patients with and without sedation were significantly different (20.5% and 5.1%, respectively). The use of sedation for patients undergoing endoscopy was still significantly associated with an increased risk of hiccups (adjusted odds ratio: 8.79, $P < 0.001$) after adjustment. The incidence of hiccups in males under sedation was high (67.4%). The sedated patients who received 2 mg midazolam developed hiccups more frequently compared to those receiving 1 mg midazolam ($P = 0.0028$). The patients with the diagnosis of gastroesophageal reflux disease (GERD) were prone to develop hiccups ($P = 0.018$).

CONCLUSION: Male patients undergoing EGD or BDE with sedation are significantly more likely to suffer from hiccups compared to those without sedation. Midazolam was significantly associated with an increased risk of hiccups. Furthermore, patients with GERD are prone to develop hiccups.

INTRODUCTION

Esophagogastroduodenoscopy (EGD) and colonoscopy are important diagnostic tools for evaluating gastrointestinal diseases or for the early detection of malignant lesions. Although same-day bidirectional endoscopy (EGD and colonoscopy; BDE) has many advantages, including shorter hospital stays and expedited decision making for patient care^[1], BDE remains a difficult and longer endoscopic procedure. Sedation is usually used to alleviate patient discomfort. Several regimens are available for inducing moderate sedation, but the combination of propofol with an opioid^[2-4] and/or a benzodiazepine^[5,6] is most commonly used. The combined regimens could improve the safety profile of propofol by reducing its dose-dependent potential to induce deep sedation^[7], in which patients may develop inadequate spontaneous ventilation and may require assistance to maintain a patent airway. In addition to hemodynamic or respiratory depression, the other frequently encountered clinical situation during endoscopic procedures with sedation is hiccups.

Hiccups are an involuntary spasmodic contraction of the diaphragm and accessory muscles followed by the sudden closure of the glottis^[8]. Hiccups during an endoscopic procedure are commonly acute and temporary, but the intermittent involuntary contraction of the diaphragm may interfere with spontaneous breathing and hamper endoscopic investigations and interventions^[9]. In addition, this powerful reflex can result in markedly negatively intrathoracic pressures and increased abdominal pressures^[8]. Accompanied by gastric distension due to the air inflation that is required during EGD, hiccups can induce reflux of gastric contents into the esophagus and can cause regurgitation and aspiration, particularly in sedated patients^[10,11].

Although their exact mechanism remains unknown, hiccups may be induced by stimulating the postulated hiccup reflex arc, which is a complex interaction mainly composed of the phrenic and vagus nerves, the sympathetic chain and accessory nerves connecting to the glottis and the inspiratory intercostal muscles^[12-14]. Vagus and phrenic nerve irritation, central nervous system disorders, toxic-metabolic disorders, and psychogenic factors are 4 possible mechanisms leading to hiccups^[12,14,15]. As described above, gastric distention during endoscopy stimulates the phrenic nerve and causes hiccups. Drug-induced hiccups are uncommon, but anesthetics and sedative agents, such as benzodiazepines, opioids, and intravenous general anesthesia drugs, are suspected agents in cases of drug-induced hiccups^[13]. On the other hand, the sedation of patients to relieve anxiety and discomfort appears to decrease the incidence of hiccups during endoscopic procedures^[12]. Therefore, whether sedation can protect the patients undergoing endoscopic procedures against the onset of hiccups is unknown and requires further investigation.

Gastroesophageal reflux disease (GERD) is a common outpatient gastroenterology problem^[16,17]. Patients with GERD may present a variety of symptoms, ranging

from typical symptoms, such as heartburn or regurgitation, to atypical symptoms, such as chest pain, asthma, laryngitis, or chronic cough^[16]. Hiccups represent an atypical symptom of GERD, with a prevalence of 4.5% to 9.5% in GERD patients^[18,19]. The major pathophysiology of GERD includes increased episodes of transient lower esophageal sphincter (LES) relaxations, ineffective esophageal motility, and reduced LES tone^[20-22]. Interestingly, hiccups could also induce the transient decrease of LES tone^[8,20] and even the loss of LES tone^[23]. Therefore, the increased probability of hiccups in GERD patients during sedation requires further investigation.

The goals of this study were to determine the incidence of hiccups in patients undergoing EGD or BDE with or without sedation, the possible causes of hiccups in sedated patients and the association of hiccups with GERD in sedated patients.

MATERIALS AND METHODS

Patient selection

This prospective study was approved by the Institutional Review Board of the E-DA hospital (EMRP-098-125). Consecutive adult (18 years or older) patients scheduled for outpatient EGD or same-day BDE at the gastrointestinal endoscopy unit or the health examination center were included. The exclusion criteria included history of esophageal, gastric or colorectal cancer; history of esophageal or gastric surgery; esophageal or gastric varices; allergy to propofol or eggs; and American Society of Anesthesiology risk Class 3 or higher.

The participating patients were allocated into 2 groups: EGD without sedation (Group A) and BDE with sedation (Group B). Sedation used for endoscopic examination was based on the patient's explicit request. The sample size was calculated from the results of our pilot study of patients who underwent EGD without sedation. We assumed that the patients with sedation would show a different (approximately 15%) prevalence of hiccups than the nonsedated patients. Therefore, 195 patients per group were required [where $\alpha = 0.05$ (two-tailed), $\beta = 0.2$]. At least 400 patients were studied to allow for any loss of follow-up.

Study design

After consent was obtained, demographic, medical and drug history data were recorded for each patient. On arrival in the endoscopy room, each patient was routinely given supplemental oxygen (4 L/min) thorough a nasal cannula. In addition, an intravenous route was set up in patients of Group B, and no intravenous fluids were given before the initiation of sedation. Routine patient monitoring included electrocardiography, noninvasive arterial blood pressure measurement, and pulse oximetry.

In all the participating patients (Group A and Group B), 20 mg hyoscine *N*-butyl bromide (Buscopan) was administered intravenously as premedication except in those with glaucoma, obstructive uropathy, coronary heart diseases, or a history of allergies to anticholiner-

gic drugs. Anesthesiologists participated in this study by administering sedative drugs. Fifty microgram of fentanyl plus midazolam were given, followed by the administration of propofol approximately 1 to 2 min later. However, the choice of whether to use midazolam as an adjuvant and the administration dosage were determined by the anesthesiologists without further input from the researchers. To avoid any pain from injecting propofol, lidocaine was mixed with propofol before administration (1 mL of 2% lidocaine in every 20 mL of 1% propofol). An initial bolus of 1.5 mg/kg of propofol was given and then titrated in 10- to 20-mg increments to achieve an adequate level of sedation.

A single experienced gastroenterologist performed both the EGD and the colonoscopic examinations for all the patients. The EGD started when an adequate level of sedation (in which the patient was asleep, not responding verbally but ventilating spontaneously) was achieved. Once the EGD was finished, the subsequently colonoscopy was preformed immediately. During the endoscopic procedure, the need to add more propofol was estimated by the patient's pain response (i.e., moans, grimaces, gag reflex, and movements).

Predefined complications (hypotension, bradycardia, airway obstruction, hypoventilation, and hypoxia) were managed according to the hospital's routine protocol. At the end of the procedure, the patients were transferred to the recovery room. The time when the patient was ready for discharge according to hospital criteria (oxygen saturation > 95% on air, heart rate > 60 beats/min, systolic blood pressure \pm 30 mmHg from preoperative values, orientated, pain score < 4/10, and no nausea or vomiting) was recorded.

Measurements

Demographic data were recorded, including each patient's age, gender and body weight. Medical data were collected, including diabetes, hypertension, cigarette smoking/alcohol consumption, cerebrovascular diseases, gastrointestinal disorders, GERD-like syndromes, liver diseases, psychological disorders, and history of intractable hiccups. The patients' drug histories regarding agents suspected of causing hiccups [i.e., non-steroidal anti-inflammatory drugs (NSAIDs), benzodiazepines and aminophylline] was also recorded. Sedative regimens, midazolam and propofol dose titrated to an adequate level of sedation for EGD insertion and total propofol dose were recorded. Oxygen saturation, heart rate and arterial blood pressure were recorded every 5 min during sedation. All the times were recorded from a continuously running stopwatch. Endoscopy time was defined as the time from the insertion and until withdrawal of the colonoscope from the anus. If hiccups occurred during the procedure, the time hiccups occurred, the time hiccups subsided and the administered doses of propofol were recorded. After the endoscopic examinations, the patients with a diagnosis of GERD and other gastrointestinal disease revealed by the EGD were collected.

Statistical analysis

All the continuous data were tested for normality. Normally distributed continuous data were expressed as the mean \pm SD, and *t* tests were used to compare the means of continuous data. Skewed data were expressed with medians and ranges and were compared using Wilcoxon's ranked sum test. Categorical data were analyzed using the Pearson χ^2 test with Yates' correction or Fisher's exact probability test. When there were more than two groups, normally distributed data were compared using analysis of variance, and skewed data were compared using the Kruskal-Wallis test.

In all tests, a 2-tailed *P* < 0.05 was considered statistically significant. The relative magnitudes of the associations between individual (categorical and continuous) variables and the likelihood of the occurrence of hiccups was compared using crude odds ratios (ORs). The precision of the estimated ORs was assessed by examining the 95% confidence intervals (CIs). A multivariate logistic regression model containing all the candidate variables was used to examine the independent contribution made by each variable, while controlling for all the variables. This resulted in an adjusted OR and a calculated 95% CI. The statistical analyses were performed with SPSS for Mac version 19.0 (SPSS Inc., Chicago, IL).

RESULTS

A total of 435 patients were invited to participate in our study. Ten patients were excluded from the analysis because of incomplete data collection. Therefore, a total of 425 data sets were eligible for analysis: 215 data sets were from the non-sedation group, and 210 were from the sedation group. Table 1 summarizes the baseline characteristics of the patients in this study. There was no significant difference between the 2 groups regarding gender, body weight, hypertension, psychological disorders, or aminophylline intake history. However, there were more patients in Group A who took NSAIDs and benzodiazepines and had histories of diabetes, cigarette smoking/alcohol consumption, cerebrovascular diseases, gastrointestinal disorders, GERD-like syndromes and liver diseases than in Group B.

Though the indications for endoscopic examination in our patients were including epigastralgia, abdominal fullness, dysphagia, change in bowel habit, positive fecal occult blood test, and bloody stool *etc.*, the indication in most patients was for health check-up. Hence, these significant differences in baseline characteristics were because most Group B participants undergoing endoscopic examination were for health check-up.

Assessment for the association between sedation and hiccups

The incidences of hiccups in Group B (under sedation) and Group A (without sedation) were 20.5% and 5.1%, respectively. The ORs and 95% CI for the occurrence of hiccups induced by sedation were calculated. The use of sedation for patients undergoing endoscopy was

Table 1 Baseline characteristics of patients in the study *n* (%)

	Group A (<i>n</i> = 215)	Group B (<i>n</i> = 210)	<i>P</i> value
Gender (male)	118 (54.9)	111 (52.9)	0.675
Body weight (kg)	63.6 ± 12.4	64.3 ± 17.6	0.675
Age (yr)	53.1 ± 15.3	48.9 ± 11.6	0.002

Aminophylline	7 (3.3)	2 (1)	0.175

The data are presented as the mean ± SD (normally distributed data), or *n* (%) (categorical data). Group A: Esophagogastroduodenoscopy (EGD) without sedation; Group B: Bidirectional endoscopy (BDE) with sedation; NSAIDs: Non-steroid anti-inflammatory drugs; GERD: Gastroesophageal reflux disease.

significantly associated with an increased risk of hiccups (OR, 4.78; 95% CI: 2.39-9.56). This association remained significant and independent after adjustment for age, diabetes, cigarette smoking/alcohol consumption, cerebrovascular diseases, gastrointestinal disorders, GERD, liver diseases, and the use of NSAIDs or benzodiazepines (adjusted OR, 8.79; 95% CI: 3.27-23.60).

Comparison of the contributing factors to hiccups

Table 2 summarizes the characteristics of the patients who developed hiccups and those who did not during sedation. Gender was the only significant difference between these groups (*P* < 0.05). The majority of the patients who developed hiccups during sedation were male (67.4%).

Comparison of the effect of sedative drugs on hiccups

The onset time (counted from the insertion of EGD) of hiccups was 6 min (1-21 min) [median (range)], and their duration was 1 min (1-19 min) [median (range)]. All the hiccups occurred before the end of the EGD in sedated patients, except in 3 patients who suffered from hiccups after the insertion of the colonoscope (onset time was 21, 17 and 16 min). Two patients suffered from hiccups that lasted for 19 and 15 min.

In the pharmaceutical characteristics of the development of hiccups, the effect of the midazolam dose was observed (Table 3). The patients who received 2 mg midazolam (1-2 mg) (range) developed hiccups more frequently compared with patients who received 1 mg midazolam (range: 0-2.5 mg, *P* = 0.028).

Assessment for the association between diagnostic findings of endoscopy and hiccups

Diagnostic findings of endoscopy were listed in Table 3.

Table 2 Baseline characteristics of patients in the sedation group (Group B) *n* (%)

	Hiccups (<i>n</i> = 43)	No hiccups (<i>n</i> = 167)	<i>P</i> value
Gender (male)	29 (67.4)	82 (49.1)	0.032
Body weight (kg)	66.0 ± 10.1	63.9 ± 19.0	0.524
Age (yr)	47.3 ± 11.5	49.3 ± 11.5	0.306
Diabetes	4 (9.3)	8 (4.8)	0.256
Hypertension	7 (16.3)	26 (15.6)	0.909

Drugs history			
NSAIDs	3 (7.0)	3 (1.8)	0.069
Benzodiazepines	1 (2.3)	6 (3.6)	0.680
Aminophylline	0 (0)	2 (1.2)	0.471
Premedication			
Buscopan	37 (86.0)	121 (76.5)	0.066

The data are presented as the mean ± SD (normally distributed data) or *n* (%) (categorical data). NSAIDs: Non-steroid anti-inflammatory drugs; GERD: Gastroesophageal reflux disease.

The patients with diagnosed GERD were more prone to develop hiccups (*P* = 0.018).

DISCUSSION

To the best of our knowledge, this is the first study to examine the prevalence of hiccups in patients undergoing EGD or BDE. In this prospective study, sedation was associated with a significantly increased occurrence of hiccups. Midazolam, which was used in our combined sedation regimens, was associated with the onset of hiccups. In addition, the patients diagnosed with GERD revealed by EGD were more prone to develop hiccups while undergoing endoscopic procedures with sedation.

Clinically, most hiccup episodes begin with an acute onset, are benign, and are self-limited, typically ceasing within minutes^[24]. However, the sudden onset of hiccups may become a safety hazard while patients are sedated. Hiccup-associated acute negative intrathoracic pressure may occur, resulting in hypotension and bradycardia^[24]. This effect is attributed to decreased vascular resistance resulting from increased dilation and volume of the thoracic aorta^[25]. In our study, no statistically significant changes occurred in any hemodynamic measure following the onset of hiccups. Whether hiccup-associated systolic hypotension is deleterious to cardiovascular function in adults is unclear, but it remains a plausible etiology of pathological hemodynamic changes in those patients with underlying heart disease^[26].

Hiccups could influence the respiration of the patient during anesthesia. Unexpected pulmonary aspiration has been diagnosed in positron emission tomography (PET) screening following panendoscopy under conscious sedation^[27]. In our patients, we observed no respiratory

distress associated with cyanosis or desaturation on pulse oximetry in patients with hiccups during the endoscopic examinations or in the recovery room. Although aspiration during sedation may be silent and uneventful, hiccups in sedated patients do carry clinical risks^[10,28].

Acute gastric distention due to air inflation during endoscopy might result in hiccups by stimulating gastric vagal afferent activity^[24]. To avoid any influence of the gas inflation that is required during a colonoscopy, we conducted EGD before colonoscopy in the patients of Group B. Furthermore, to avoid inter-observer variation, a single physician performed all the EGD and colonoscopy procedures. In the sedation group, the hiccups all occurred during the EGD, and almost all of the hiccups ceased before the initiation of colonoscopy. Further, the incidence was significantly greater than in the nonsedated group (Group A). Therefore, causes other than this mechanical factor could have induced hiccups. Psychogenic factors (e.g., anxiety, stress, and excitement) are other possible causes of hiccups^[12]. Therefore, sedation for EGD or BDE relieves patient anxiety and seems to decrease the incidence of hiccups. However, Group B did not show a lesser incidence of hiccups than Group A. In fact, the use of sedative drugs during endoscopic procedures favored the onset of hiccups.

Although there was insufficient evidence in Thompson's^[15] review to conclude that any specific drug induces drug-related hiccups, corticosteroids and benzodiazepines are the most frequently suspected agents in cases of drug-induced hiccups^[15,29]. Midazolam is a benzodiazepine with rapid onset, brief duration of action and an amnestic effect^[30], and it is commonly administered in combination with an opiate and/or propofol to achieve adequate sedation for an EGD or colonoscopy. In addi-

tion, midazolam has gained popularity for use in procedural sedation and anxiolysis in pediatric patients. Midazolam is water-soluble and can be safely administered in a variety of ways. Marhofer *et al*^[31] had investigated that the incidence of hiccups in pediatric patients who were pre-medicated with two different doses of rectally administered midazolam for minor surgery. Their patients in group A received 0.5 mg/kg of midazolam, while their patients in group B were treated with 1 mg/kg. Twenty-four percent of the children developed hiccups, but no statistically significant difference was noted between the two doses (22% in group A *vs* 26% in group B). Hiccups were more common among younger children (i.e., those aged 5-6 mo *vs* 20 mo). In our sedated patients, the total incidence of hiccups was similar, but age was not a statistically significant variable. In addition, the development of hiccups was associated with higher doses of midazolam.

Interestingly, drug-induced hiccups are reported more commonly in men than women^[29]. In our study, the majority of patients who developed hiccups during sedation were male. This finding is consistent with recent studies revealing a significant male predominance of hiccups in patients receiving cytotoxic chemotherapy^[32,33]. However, the mechanisms for the male predominance of hiccups and the midazolam-induced hiccups are still unknown. Hiccups might be induced by the influence of midazolam on a supraspinal hiccup center localized in the brain stem^[34]. Another factor causing midazolam-induced hiccups could be a direct stimulation of the inspiratory muscles, specifically on diaphragm contractility^[35]. By contrast, Fujii *et al*^[36] indicated that midazolam decreases the contractility of the diaphragm in a dose-dependent manner in an animal study. Furthermore, intravenously administered midazolam has been successfully used in patients with terminal hiccups^[37]. The discrepancies among these results perhaps reflect the complicated etiology of hiccups; further studies are required to improve our understanding of their etiology. Nevertheless, our study provides further evidence for the association of midazolam administration with the onset of hiccups.

Graham^[23] showed that there is no detectable LES tone during a hiccup attack. Hiccups add tension to the phrenoesophageal ligament and thus have the same sphincter-dilating effect. Therefore, hiccups could induce episodes of transient decrease of LES tone^[8,20] that result in reflux both in normal subjects and in esophagitis patients^[38]. Furthermore, LES function can be overcome by the transient peritoneal-pleural gradient created during hiccups^[39]. In the study of Werlin *et al*^[40], 27% transient increases in intra-abdominal pressure, such as would be caused by a hiccup, were associated with reflux. According to Vanner^[11], approximately 40% of patients who hiccup after induction of anesthesia develop detectable gastroesophageal reflux.

The most important aspect of the pathophysiology of GERD is the competency of the anti-reflux barriers^[22]. Factors contributing to their integrity include the

LES pressure, the presence or absence of a hiatal hernia, and the occurrence of transient LES relaxation^[22,41]. Transient LES relaxation is considered the most common pathophysiologic event at the time of a reflux episode^[22,41]. Hence, the fact that patients with GERD are prone to develop hiccups during sedation might be due to previous abnormalities of LES.

This study had several weaknesses. Because of the use of sedation is a self-pay service and based on the patients' request, it is difficult to perform a randomized controlled trial to detect the incidence of hiccups in patients undergoing EGD or BDE with or without sedation. Though there is potential for bias in our prospective and cross sectional study, the study design could examine the association among the variables (e.g., sedation *vs* hiccups in our study)^[42]. In addition, the fact that the choice of midazolam as an adjuvant was not random limits the ability to draw conclusions about its hiccup-inducing effect, but it raises interesting hypotheses and provides pilot data for testing in the future.

In conclusion, sedation was associated with the occurrence of hiccups in patients undergoing gastrointestinal endoscopic procedures, and hiccups occurred primarily in males. Midazolam, a sedative drug, was significantly associated with an increased risk of hiccups. Furthermore, patients with GERD were prone to develop hiccups.

COMMENTS

Background

During esophagogastroduodenoscopy (EGD) and colonoscopy procedure, sedation is usually used to alleviate patient discomfort. In addition to hemodynamic and respiratory depression, hiccups are the other frequently encountered clinical situation during endoscopic procedures with sedation. Hiccups, though commonly acute and temporary, may interfere with spontaneous breathing and hamper endoscopic investigations and interventions. However, the exact mechanism of hiccups remains unknown.

Research frontiers

There are 4 possible mechanisms leading to hiccups, including vagus and phrenic nerve irritation, central nervous system disorders, toxic-metabolic disorders, and psychogenic factors. Anesthetics and sedative agents are suspected agents in cases of drug-induced hiccups. On the other hand, the sedation of patients to relieve anxiety and discomfort appears to decrease the incidence of hiccups during endoscopic procedures. Therefore, whether sedation can protect the patients undergoing endoscopic procedures against the onset of hiccups is unknown and requires further investigation. In addition, hiccups represent an atypical symptom of gastroesophageal reflux disease (GERD), the increased probability of hiccups in GERD patients during sedation also requires further investigation.

Innovations and breakthroughs

To the best of our knowledge, this is the first study to examine the prevalence of hiccups in patients undergoing EGD or colonoscopy. Sedation for endoscopic procedures relieves patient anxiety and seems to decrease the incidence of hiccups. However, in this prospective study, the use of sedative drugs during endoscopic procedures favored the onset of hiccups. Although there was insufficient evidence to conclude that any specific drug induces drug-related hiccups, benzodiazepines are the most frequently suspected agents in cases of drug-induced hiccups. Midazolam, a benzodiazepine with rapid onset and brief

duration of action, was associated with the development of hiccups, especially in higher doses. In addition, the study also shows that patients with GERD are prone to develop hiccups during sedation.

Applications

The study results suggest that the development of hiccups was associated with higher doses of midazolam. Therefore, avoid using midazolam or decreasing the midazolam dosage in combined sedation regimen for endoscopic procedure can decrease the incidence of onset of hiccups.

Terminology

Hiccups: Hiccups are an involuntary spasmodic contraction of the diaphragm and accessory muscles followed by the sudden closure of the glottis; GERD: Patients with GERD may present a variety of symptoms, ranging from typical symptoms, such as heartburn or regurgitation, to atypical symptoms, such as chest pain, asthma, laryngitis, chronic cough, or hiccups. The major pathophysiology of GERD includes increased episodes of transient lower esophageal sphincter (LES) relaxations, ineffective esophageal motility, and reduced LES tone.

Peer review

The results of the study are interesting and it was well written. Nevertheless, there are some major points of concern.

Abstract

AIM: To investigate the clinicopathologic features which

predict surgical overall survival in patients with proximal gastric carcinoma involving the esophagus (PGCE).

METHODS: Electronic pathology database established in the Department of Pathology of the Nanjing Drum Tower Hospital was searched for consecutive resection cases of proximal gastric carcinoma over the period from May 2004 through July 2009. Each retrieved pathology report was reviewed and the cases with tumors crossing the gastroesophageal junction line were selected as PGCE. Each tumor was re-staged, following the guidelines on esophageal adenocarcinoma, according to the 7th edition of the American Joint Commission on Cancer Staging Manual. All histology slides were studied along with the pathology report for a retrospective analysis of 13 clinicopathologic features, i.e., age, gender, *Helicobacter pylori* (*H. pylori*) infection, surgical modality, Siewert type, tumor Bormann's type, size, differentiation, histology type, surgical margin, lymphovascular and perineural invasion, and pathologic stage in relation to survival after surgical resection. Prognostic factors for overall survival were assessed with uni- and multi-variate analyses.

RESULTS: Patients' mean age was 65 years (range: 47-90 years). The male: female ratio was 3.3. The 1-, 3- and 5-year overall survival rates were 87%, 61% and 32%, respectively. By univariate analysis, age, male gender, *H. pylori*, tumor Bormann's type, size, histology type, surgical modality, positive surgical margin, lymphovascular invasion, and pT stage were not predictive for overall survival; in contrast, perineural invasion ($P = 0.003$), poor differentiation ($P = 0.0003$), > 15 total lymph nodes retrieved ($P = 0.008$), positive lymph nodes ($P = 0.001$), and distant metastasis ($P = 0.005$) predicted poor post-operative overall survival. Celiac axis nodal metastasis was associated with significantly worse overall survival ($P = 0.007$). By multivariate analysis, ≥ 16 positive nodes ($P = 0.018$), lymph node ratio > 0.2 ($P = 0.003$), and overall pathologic stage (P

= 0.002) were independent predictors for poor overall survival after resection.

CONCLUSION: Patients with PGCE showed worse overall survival in elderly, high nodal burden and advanced pathologic stage. This cancer may be more accurately staged as gastric, than esophageal, cancer.

INTRODUCTION

Carcinoma in the gastroesophageal junction (GEJ) region can be sub-grouped by the Siewert classification system into 3 types on the basis of the distance between tumor epicenter and the GEJ line^[1,2]. Type I carcinomas are centered in the distal esophagus, 1-5 cm above the GEJ. They arise largely from Barrett's esophagus (BE), may or may not invade the GEJ, and are commonly reported as Barrett's adenocarcinoma. Type II tumors straddle the GEJ line and are believed to be true GEJ cancers with epicenter within 1 cm above and 2 cm below the GEJ. Type III tumors are sub-cardial gastric cancers with epicenter 2-5 cm below the GEJ that is crossed as they grow proximally.

Although the Siewert classification system has been widely used internationally, its prognostic value has been challenged^[3-5]. In Asian countries, type I GEJ cancer is rare and types II and III carcinomas behave similarly^[5,6]. In China, almost all GEJ carcinomas arise in the proximal stomach with a stable or slightly increased incidence in recent years^[7-10]. In our most recent study comparing clinicopathologic features of GEJ cancer between Chinese patients treated in Nanjing, China, and American patients treated in Boston, the United States, we showed that almost all GEJ cancers in Chinese patients were Siewert types II and III tumors^[11], unlike those seen in American patients in which the distribution of these three types of tumors was almost evenly^[12]. Their tumors were not BE-related, but associated with proximal gastritis with *Helicobacter pylori* (*H. pylori*) infection and a better overall survival rate, despite a larger tumor size and more advanced pathologic stages at diagnosis^[11]. Surprisingly, the

studies on factors predicting post-operative overall survival in Chinese patients with proximal gastric carcinoma involving the esophagus (PGCE) are scarce. The purpose of the present study was to investigate clinicopathologic features that may predict overall survival after surgical resection in Chinese patients with PGCE who were treated at a single high-volume tertiary medical center in Nanjing, China.

MATERIALS AND METHODS

Selection of patients

A total of 177 consecutive resection cases of histopathologically confirmed proximal gastric carcinoma were identified through a search of the computerized pathology database established in the Department of Pathology of the Nanjing Drum Tower Hospital in Nanjing, China, over the period from May 2004 through July 2009. Each pathology report was reviewed (by Huang Q) for cases with tumors crossing the GEJ line. Inclusion criteria were: (1) a tumor with epicenter in the proximal stomach within 5 cm below the GEJ and invading into the distal esophagus, which corresponded to Siewert types II and III tumors; (2) no chemotherapy or radiation therapy before the surgical resection; and (3) the availability of follow-up information through telephone interviews (by Feng AN) to the patient or family members. Exclusion criteria consisted of: (1) the tumor not crossing the GEJ; and (2) the patient lost to follow-up. Following a standard comprehensive surgical pathology processing protocol, all resection specimens were evaluated for the Bormann's gross type and surgical margins. The GEJ line, defined by the proximal end of gastric longitudinal mucosal folds, was evaluated in each case. The tumor epicenter location and its distance from the GEJ were recorded. The number of overall survival months after surgery was calculated until May 2010, based on whether the patient was alive or had died of any cause. For all selected patients, medical records and pathology reports were re-evaluated for demographic and clinicopathologic information, tumor stage, surgical approach (total or partial gastrectomy or Ivor-Lewis procedure), completeness of resection, and histopathology of the tumor. The study protocol was approved by the Medical Ethics Committee of the Nanjing Drum Tower Hospital in Nanjing, China.

Tumor staging

All tumors were staged with the esophageal cancer staging criteria, according to the 7th edition of the American Joint Commission on Cancer Staging Manual (AJCC 7)^[13]. The status of regional involved lymph nodes in the para-distal esophageal, para-cardial and peri-gastric regions was determined microscopically. The lymph nodes in the celiac axis region, including the left gastric artery, celiac artery, hepatic and splenic hila, *etc.*, were identified by the surgeon during the operation, submitted as separate specimens and examined microscopically. Lymph node metastasis was determined by the routine histological examination. In this study, since PGCE was classified as GEJ cancer

and staged as esophageal cancer, metastases to celiac axis regional nodes were considered as distant metastasis^[13,14].

The proximal, distal and radial margins of resection were routinely inked for microscopic examination and classified as negative or positive if there was histological evidence of carcinoma present at, or within 1 mm of the inked resection edge. Lymphovascular and peri-neural invasion was assessed microscopically on routine histology sections. Suspected distant tumor metastasis in the liver or other organs detected and biopsied intraoperatively was confirmed microscopically.

Statistical analysis

All patients' demographic and tumor gross characteristics were considered categorical variables except for age, overall survival month, number of lymph nodes retrieved and number of lymph nodes involved, which were classified as continuous variables. All statistical analysis was carried out (by Shi J) using the SPSS software (SPSS Inc., version 15.0, Chicago, IL, United States). Specific comparison between groups was performed using χ^2 and Student *t* tests. Patient overall survival rates after surgical resection were estimated with the Kaplan-Meier method and the log rank test. The patients who were alive at the last follow-up were censored for calculation of the overall survival rates. Cox multivariate proportional hazards regression models were used to assess the overall survival power of these parameters. The *P* value of < 0.05 was considered statistically significant.

RESULTS

Clinicopathologic characteristics

A total of 142 cases were eligible for this study. The patients' demographics, clinicopathologic characteristics, and the results of univariate overall survival analysis were shown in Table 1. Most (82%) tumors were type II of the Siewert classification, while there was no type I tumor in this cohort. The mean patient age was 65 years (range: 47-90). The male-female ratio was 3.3. The number of months of patient follow-up after surgical resection was 29 ± 17 mo (mean \pm SD, range: 1-70 mo). By the time of the last follow-up, 58 (41%) patients had died and the remaining survivors were censored. Overall, the 1-, 3- and 5-year overall survival rates were 87%, 61% and 36%, respectively. Among the demographic and pathologic variables, perineural invasion and poor tumor differentiation were associated with worse overall survival (Table 1). None of the surgical modalities were found significant for overall survival prediction. The status of *H. pylori* infection, tumor gross type, gender, age, tumor size, lymphovascular invasion, and even positive surgical margins were not significant for overall survival prediction by univariate analysis.

Pathologic staging

Following the AJCC 7 staging guidelines, the vast majorities (88%) of tumors were skewed to pT3 and only a few staged at pT1 (*n* = 4), pT2 (*n* = 12) and pT4 (*n* = 1). The

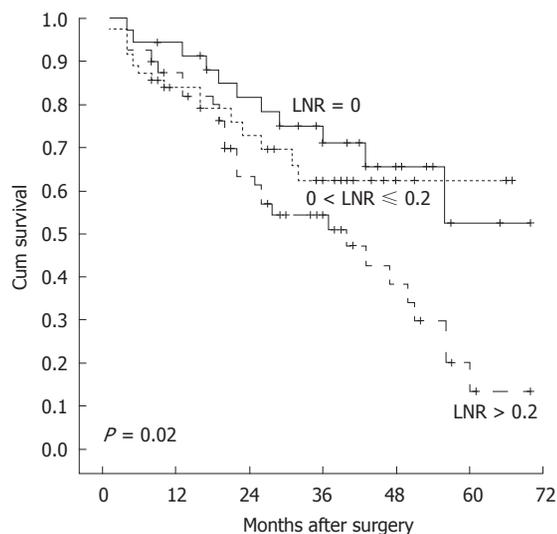

Figure 1 Kaplan-Meier overall survival curves of patients stratified by various lymph node ratios. The difference in overall survival among lymph node ratio (LNR) groups was statistically significant.

pT stage was found not to be a relevant factor for overall survival prediction. In contrast, positive lymph node metastasis were detected in 106 (75%) cases and significantly associated with worse overall survival (Table 2). Twelve of 142 patients (8%) had distant metastasis at the time of operation and showed significantly worse overall survival.

Lymph node status with overall survival

The mean number of lymph nodes retrieved per case was 21 (range: 4-66). The presence of lymph node metastasis was found in 106 (75%) cases. There were 12 patients (8%) with cancer metastasis in celiac axis lymph nodes, which significantly predicted worse overall survival by univariate analysis (Table 2). There was a statistically significant overall survival difference between patients with a total number of retrieved lymph nodes ≤ 15 and ≥ 16 (Table 2). The numbers of positive lymph nodes more than 7 and 16 were worse overall survival predictors. The ratio of the number of positive nodes to the total number of nodes retrieved, i.e., the lymph node ratio, was significantly associated with worse overall survival (Tables 2 and 3, Figure 1).

Significance of the lymph node ratio on overall survival

Among 3 different lymph node ratio groups, the lymph node ratios were significantly associated with the worse overall survival (Tables 2 and 3). The overall survival status was better illustrated on a Kaplan-Meier plot among groups with lymph node ratios > 0.2 , compared to that with the ratio ≤ 0.2 (Figure 1). We found that the relative risk for poor overall survival was 37-fold when the lymph node ratio was over 0.4 and 75-fold when over 0.5, compared with the ratio at 0.

Independent factors predicting overall survival retained at multivariate analysis

By multivariate analysis, over 16 positive lymph nodes per

¹Hazards ratios (HR), 95% confidence interval (CI) and *P* values for post-operative time to recurrence and overall survival were adjusted according to important clinical characteristics. Survival time was defined as the period from the surgical treatment to endpoint of follow-up.

case, lymph node ratio > 0.2, and the overall pathologic stage were found to be independent factors for predicting worse surgical overall survival (Table 3).

DISCUSSION

In this study, the factors predicting overall surgical survival in Chinese patients with PGCE are similar to those of gastric cancers but different from those of GEJ cancers reported in patients from Western countries^[15-18]. We show that in Chinese patients, type I GEJ carcinomas remain vanishingly rare and PGCE tumors are mostly as type II and some as type III GEJ cancers. The factors predicting surgical overall survival are comparable to those reported in Japan^[6] and China Taiwan^[5]. Importantly, nodal burden in PGCE correlates highly with post-operative overall survival, as seen in gastric cancer. Nodal metastasis in the celiac axis region is a significant predictor of worse overall survival. Finally, the independent risk factors for worse overall survival in our patients include tumor metastasis in more than 16 nodes, the lymph node ratio > 0.2, distant metastasis, and overall pathologic stage; in contrast, the prognostic factors, such as > 70 years, BE, the male gender, tumor histology type, the surgical resection method, and even positive resection margin, *etc.*, are not significant for predicting overall survival in Chinese patients with PGCE, which are predictive in type I GEJ carcinomas in Western patients^[15,19], probably

because of the rarity of the type I GEJ carcinomas in Chinese patients. Our results would impact upon surgical management of Chinese patients with PGCE, if confirmed in a larger prospective trial(s).

Accurate GEJ cancer staging is difficult. The AJCC 7 staging system requires the use of the esophageal scheme for pathologic staging of this group of cancers, regardless of the location of tumor epicenters. This new mandate is controversial. In a recent study, we showed that PGCE staged with the gastric cancer staging rules was better stratified, especially for the pN and pIII stages, compared to the use of the esophageal scheme that showed an erroneously better overall survival in the patients staged at pIII A than those at p I A and p II B^[20]. The results shown in this study further substantiate the above conclusion and lent support to the contention that the current AJCC 7 cancer staging system for GEJ cancer needs to be modified when applied to Chinese patients with PGCE.

Lymph node metastasis in gastric cancer has been shown to be more significant in predicting overall survival than tumor invasion depth. This concept was confirmed in this study. For instance, we found no significant differences in overall survival among patients with different pT stages by either univariate or multivariate analysis. In contrast, the number of positive lymph nodes dictated patient overall survival^[16]. Furthermore, the total number of nodes retrieved (> 15) had a significant overall survival predictive value, as suggested by others^[17]. This may have resulted in a more precise evaluation of positive nodes and thus more accurate pN staging. In the current series, the overall survival was significantly worse in the patients with considerable nodal burden such as more than 7 positive nodes and higher lymph node ratios. Apparently, a rich lymphatic network in the GEJ region, and/or protein lytic enzymes secreted by neoplastic cells, may facilitate the lymphatic dissemination of neoplastic cells to intra-abdominal nodes^[16,21]. It was reported that even for pT1b GEJ cancers, 30% of cases with positive

nodes had a 5-year overall survival rate of only 33%^[18]. Moreover, patients with primary tumors in the middle to lower esophagus and the proximal stomach were found to have nodal diseases within the abdomen at rates of as high as 45% to 93%^[22,23]. Taken together, our data emphasize the important overall survival predictive value for a thorough abdominal nodal dissection in Chinese patients with PGCE^[21].

The significance of the ratio between involved and retrieved lymph nodes for overall survival prediction has not been described in patients with PGCE. Our results add into a growing body of evidence for the value of a lymph node ratio in predicting overall survival of patients with PGCE. In the late 1990s, Siewert *et al.*^[24] published their findings of prognostic significance of the lymph node ratio in gastric cancer in a large German cohort of 1654 cases. Their conclusion was repeatedly confirmed by the studies in gastric cancer patients in Japan^[25,26], China Taiwan^[5], mainland China^[27,28], South Korea^[29], Spain^[30] and Italy^[31]. The advantage of the use of this parameter in patients with PGCE lies upon its ease to use, irrespective of the surgical methods used by different surgeons and various types of resection specimens from different patients^[24]. In reality, the number of retrieved lymph nodes is largely influenced by the extent of lymph node dissection by different surgeons, whose nodal dissection skills vary^[32,33]. It was reported that patients with a lymph node ratio smaller than 0.2 had a better overall survival rate^[33,34], which is also our experience. As the lymph node ratio increases, so is the increased relative risk of poor overall survival. Our data show that in patients with PGCE, the lymph node ratio could be used clinically as a powerful overall survival predictor.

The significance of metastatic nodal disease in the celiac axis region in patients with GEJ cancers for overall survival prediction remains obscure due to limited studies in the literature^[18,21]. When nodal metastasis is discovered in this region, some studies classify it as a pM1a disease of distal esophageal or GEJ cancers^[14], according to the 6th AJCC cancer staging system. The overall survival predictive value of positive celiac lymph nodes in proximal gastric cancer stays controversial^[18,35-37]. It was reported that the patients with undetected celiac nodal disease at the time of surgical resection were subsequently found to have celiac nodal involvement with overall survival similar to that of patients with stage III disease^[21]. In our previous^[28] and current studies on PGCE, nodal disease in the celiac axis region was also an important overall survival predictor by univariate analysis, which, however, did not reach a statistically significant level by multivariate analysis, probably due to the small sample size. Nevertheless, it appears that the site of nodal disease may be as important as the number of nodal metastasis in predicting overall survival for patients with PGCE.

The major limitations of this study are several. First, the sample size of the current cohort was relatively small and most cancer cases were advanced and staged at pIII. There were only a few cases staged at pI or pIV, which might have contributed to the lack of significance for the

tumor pT stage in overall survival prediction. Second, the patient follow-up was carried out by telephone interview only. This might have invited inaccurate and biased results. At present, an accurate electronic patient medical record system has not been established in China and the government death record of citizens is not available to the public. Therefore, telephone interview has been the primary tool to collect the overall survival information. Finally, because of the retrospective nature of the study, the methods for surgical resection, lymph node retrieval, and specimen dissection were not standardized, which might have caused inconsistent nodal retrieval results. However, in over 75% of cases in this study, the number of lymph nodes retrieved per case was over 21. Therefore, the overall data quality should be reasonably solid and reliable.

In conclusions, PGCE, like gastric cancer, has similar overall survival after resection in patients with no or minimal nodal burden in this cohort of consecutively treated Chinese patients. However, the elderly patients over 70 years and those with considerable nodal diseases including celiac nodal metastasis, distant metastasis, and advanced summary pathologic stage fare worse in overall survival after resection. Application of the AJCC 7 esophageal staging scheme to PGCE may be less accurate in predicting overall survival than applying the gastric staging scheme^[20]. Because of the small sample size and a single institution experience, further larger, prospective studies are required to validate our findings in the Chinese patient population.

COMMENTS

Background

In China, almost all gastroesophageal junction (GEJ) carcinomas arise in the proximal stomach with a stable or slightly increased incidence in recent years. In our most recent study comparing clinicopathologic features of GEJ cancer between Chinese patients treated in Nanjing, China, and American patients treated in Boston, the United States, the authors showed that GEJ cancers in Chinese patients were unlike those seen in American patients. However, the studies on factors predicting post-operative overall survival in Chinese patients with proximal gastric carcinoma involving the esophagus (PGCE) are scarce.

Research frontiers

The purpose of the present study was to investigate clinicopathologic features that may predict overall survival after surgical resection in Chinese patients with PGCE who were treated at a single high-volume tertiary medical center in Nanjing, China.

Innovations and breakthroughs

In this study, the factors predicting overall surgical survival in Chinese patients with PGCE are similar to those of gastric cancers but different from those of GEJ cancers reported in patients from Western countries. The authors show that in Chinese patients, type I GEJ carcinomas remain vanishingly rare and PGCE tumors are mostly as Siewert type II and some as type III GEJ cancers. The factors predicting surgical overall survival are comparable to those reported in Japan and Taiwan. Importantly, nodal burden in PGCE correlates highly with post-operative overall survival, as seen in gastric cancer. Nodal metastasis in the celiac axis region is a significant predictor of worse overall survival. Finally, the independent risk factors for worse overall survival in our patients include tumor metastasis in more than 16 nodes, the lymph node ratio > 0.2, distant metastasis and overall pathologic stage; in contrast, the prognostic factors, such as > 70 years, Barrett's esophagus, the male gender, tumor histology type, the surgical resection method, and even positive resection margin, *etc.*, are not significant for predicting overall survival in Chinese patients

with PGCE, which are predictive in Siewert type I GEJ carcinomas in Western patients, probably because of the rarity of the Siewert type I GEJ carcinomas in Chinese patients.

Applications

Their results would impact upon surgical management of Chinese patients with PGCE, if confirmed in a larger prospective trial(s). The authors suggest that the GEJ cancer in Chinese patients be treated as gastric cancer.

Peer review

This study was designed as the next step to examine the clinicopathologic features that may predict survival after surgical resection of proximal gastric carcinoma, keeping in mind that this tumor type is rare in Chinese patients. The manuscript is well written and methodology is accurately described. By multivariate analysis, > 16 positive nodes, lymph node ratio > 0.2, distant metastasis and summary pathologic stage were found to be independent predictors for poor survival. The authors stress that the lymph node ratio could be used as a reliable survival predictor, as this parameter is not influenced by the surgical methods and the number of retrieved lymph nodes.

Abstract

AIM: To determine the prognostic value of lymphatic and/or blood vessel invasion (LBVI) in patients with stage II gastric cancer.

METHODS: From January 2001 to December 2006, 487 patients with histologically confirmed primary gastric adenocarcinoma were diagnosed with stage II gastric cancer according to the new 7th edition American Joint Committee on Cancer stage classification at the Department of Gastric Cancer and Soft Tissue Surgery, Fudan University Shanghai Cancer Center. All patients underwent curative gastrectomy with standard lymph node (LN) dissection. Fifty-one patients who died in the postoperative period, due to various complications or other conditions, were excluded. Clinicopathological

findings and clinical outcomes were analyzed. Patients were subdivided into four groups according to the status of LBVI and LN metastases. These four patient groups were characterized with regard to age, sex, tumor site, pT category, tumor grading and surgical procedure (subtotal resection *vs* total resection), and compared for 5-year overall survival by univariate and multivariate analysis.

RESULTS: The study was composed of 320 men and 116 women aged 58.9 ± 11.5 years (range: 23-88 years). The 5-year overall survival rates were 50.7% and the median survival time was 62 mo. Stage II a cancer was observed in 334 patients, including 268 T3N0, 63 T2N1, and three T1N2, and stage II b was observed in 102 patients, including 49 patients T3N1, 51 T2N2, one T1N3, and one T4aN0. The incidence of LBVI was 28.0% in stage II gastric cancer with 19.0% (51/269) and 42.5% (71/167) in LN-negative and LN-positive patients, respectively. In 218 patients (50.0%), there was neither a histopathologically detectable LBVI nor LN metastases (LBVI⁻/LN⁻, group I); in 51 patients (11.7%), LBVI with no evidence of LN metastases was detected (LBVI⁺/LN⁻, group II). In 167 patients (38.3%), LN metastases were found. Among those patients, LBVI was not determined in 96 patients (22.0%) (LBVI⁻/LN⁺, group III), and was determined in 71 patients (16.3%) (LBVI⁺/LN⁺, group IV). Correlation analysis showed that N category and the number of positive LNs were significantly associated with the presence of LBVI ($P < 0.001$). The overall 5-year survival was significantly longer in LN-negative patients compared with LN-positive patients (56.1% *vs* 42.3%, $P = 0.015$). There was a significant difference in the overall 5-year survival between LBVI-positive and LBVI-negative tumors (39.6% *vs* 54.8%, $P = 0.006$). Overall 5-year survival rates in each group were 58.8% (I), 45.8% (II), 45.7% (III) and 36.9% (IV), and there was a significant difference in overall survival between the four groups ($P = 0.009$). Multivariate analysis in stage II gastric cancer patients revealed that LBVI independently affected patient prognosis in LN-negative

patients ($P = 0.018$) but not in LN-positive patients ($P = 0.508$).

CONCLUSION: In LN-negative stage II gastric cancer patients, LBVI is an additional independent prognostic marker, and may provide useful information to identify patients with poorer prognosis.

Impact of lymphatic and/or blood vessel invasion in stage II gastric cancer. *World J Gastroenterol* 2012; 18(27): 3610-3616 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i27/3610.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i27.3610>

INTRODUCTION

Gastric cancer remains a major public health issue as the fourth most common cancer and second leading cause of cancer-related death worldwide despite a decrease in its incidence level^[1-3]. Surgery, including gastrectomy in combination with systemic lymph node (LN) dissection, is the current treatment of choice for gastric cancer^[4-6]. A correct definition of poor prognostic factors may help to guide more aggressive adjuvant treatment protocols. Therefore, it is urgently needed to identify new biological or pathological markers related to survival in addition to well-known prognostic factors such as the tumor-node-metastasis (TNM) staging classification and clinical stage.

According to the new American Joint Committee on Cancer (AJCC) TNM staging classification (7th edition), staging of gastric cancer by TNM classification is composed of nine groups^[7]. Stage II gastric cancer is an intermediate stage between stage I and stage III. Stage II gastric cancer is defined as tumor that invades into or through the muscular wall of the stomach, but not into nearby local structures, or has regional LN involvement with any extent of primary cancer, but no invasion of local structures. Surgical resection with regional lymphadenectomy is the treatment of choice for patients with stage II gastric cancer. However, preoperative and intraoperative staging to confirm stage II disease is difficult. Failure to distinguish stage II from stage I disease may lead to under- or over-treatment. Therefore, the identification of additional prognostic factors, which is timely and cost-efficient as well as available, would help in detecting those patients with poorer prognosis among the

different groups of patients with stage II gastric cancer. It might be of clinical significance to select candidates for treatment considerations, such as the extent of LN dissection and further adjuvant and neoadjuvant chemotherapy. Comparisons of survival in subgroups of stage II have been reported^[8]. However, to date there is no study on the subgroups of stage II gastric cancer classified by the 7th edition of the AJCC TNM, and the prognostic factors for each subgroup.

As the cancer stage advances, tumor cells invade blood vessels and lymphatic vessels near the tumor; lymphatic and/or blood vessel tumor invasion (LBVI) is the critical step of tumor cell dissemination and metastasis in various types of cancer^[4-6]. The prognostic significance of LBVI in gastric cancer has been previously investigated in a few studies, without reaching a consensus^[7-11]. To date, LBVI has not been studied in patients with stage II disease alone.

In this study, we investigated the value of LBVI as a prognostic factor in patients with stage II gastric cancer who underwent curative resection. The association of LBVI with the clinicopathological factors and the effect of LBVI on survival were analyzed.

MATERIALS AND METHODS

Patients

From January 2001 to December 2006, a total of 487 patients with histologically confirmed primary gastric adenocarcinoma were diagnosed with stage II gastric cancer according to new 7th edition TNM stage classification. All 487 patients underwent curative gastrectomy with standard LN dissection at the Department of Gastric Cancer and Soft Tissue Surgery, Fudan University Shanghai Cancer Center. Fifty-one patients who died in the postoperative period, due to various complications, or other conditions, were excluded from the study. Data were retrieved from operative and pathology reports, with follow-up data being obtained from the outpatient clinical database. All subjects were preoperatively diagnosed with gastric adenocarcinoma by analysis of endoscopic biopsy specimens. Standardized operative procedures were performed, such as total or subtotal gastrectomy, depending on the location of the gastric cancer, and D2 LN dissection according to the rules of the Japanese Research Society for Gastric Cancer. All chemotherapy for the enrolled patients was postoperative, and no patient with stage II gastric cancer underwent neoadjuvant chemotherapy. Patient survival was evaluated from information collected by using mail, telephone, or outpatient records.

All of the resected primary tumors and regional LNs were examined. The final diagnosis for each patient was decided by 2 pathologists to avoid misdiagnosis. Hematoxylin and eosin (HE) staining is commonly used for pathological examination. When it was difficult to identify the lymphatics or the venous structures by HE staining, either Elastica staining or Victoria-blue HE staining was performed. LBVI was defined according to

the Japanese Classification of Gastric Carcinoma (absence *vs* presence). LBVI presence is defined as lymphovascular invasion and is detected in lymphatics or small veins in a mounted specimen containing the deepest portion of the tumor on a glass slide. The histology was grossly divided into the differentiated type (papillary and tubular adenocarcinoma) and the undifferentiated type (poorly differentiated adenocarcinoma, signet-ring cell carcinoma, mucinous carcinoma, and miscellaneous).

Gastric carcinoma was classified according to the new AJCC TNM staging criteria (7th edition). The clinical and pathological parameters evaluated included sex, age, depth of the tumor (T category), involvement of the LNs, and lymphatic and vascular invasion.

For the prognostic evaluation of isolated LBVI, the patients enrolled according to the criteria mentioned above were further subdivided into four prognostic groups: Group I: no detection of LBVI or any LN metastases (LBVI⁻/LN⁻); Group II: detection of LBVI but no LN metastases (LBVI⁺/LN⁻); Group III: detection of LN metastases but no detection of LBVI (LBVI⁻/LN⁺); Group IV: detection of LN metastases and LBVI (LBVI⁺/LN⁺). These four patient groups were characterized with regard to age, sex, tumor site, pT category, tumor grading, and surgical procedure (subtotal resection *vs* total resection) and compared with regard to the 5-year overall survival by univariate and multivariate analysis.

Statistical analysis

Statistical analysis was performed using SPSS 11.0 software. Survival analysis and curves were established according to the Kaplan-Meier method and compared by the log-rank test. Survival time was calculated from the month of surgery until the time of death or confirmation of survival, and survival rate was represented by the percentage of survivals at the end of the observed interval (in years and months). Multivariate analysis with Cox proportional hazard model was used to assess the role of LBVI and the other clinicopathological features as prognostic factors. $P < 0.05$ was considered significant.

RESULTS

Patients' clinicopathological characteristics

The study was composed of 320 men and 116 women aged 58.9 ± 11.5 years (mean \pm SD, range: 23-88 years). According to the new AJCC 7th edition TNM stage classification among those with stage II gastric cancers, stage II a was observed in 334 patients, including 268 T3N0, 63 T2N1, and three T1N2, and stage II b was observed in 102 patients, including 49 T3N1, 51 T2N2, one T1N3, and one T4aN0. Histological grade was reported as differentiated in 177 (40.6%) and undifferentiated in 259 (59.4%) cases. Total gastrectomy was performed in 113 (25.9%) cases, and subtotal gastrectomy in 323 (71.4%) cases. Overall follow-up ranged from 11 to 99 mo (median: 39 mo). The 5-year overall survival rates were 50.7% and the median survival time was 62 mo.

Comparison of clinicopathological features

LBVI was identified in 122 (28.0%) and absent in 314 (72.0%) cases. When the patients were classified into two groups according to LBVI, the LBVI group had a higher incidence of LN metastasis (30.6% *vs* 58.2%, $P = 0.032$) and higher tumor stage (39.6% *vs* 54.8%, $P < 0.001$). However, other clinicopathological variables, such as age, sex, tumor stage, tumor size, operative methods, and histological type showed no significant differences between the two groups (Table 1).

The incidence of LBVI was 19.0% (51/269) and 42.5% (71/167) in LN-negative patients and LN-positive patients, respectively. In 218 patients (50.0%), there was neither a histopathologically detectable LBVI nor LN metastases (LBVI⁻/LN⁻, Group I); in 51 patients (11.7%), LBVI with no evidence of LN metastases was detected (LBVI⁺/LN⁻, Group II). In 167 patients (38.3%), LN metastases were found. Among these patients, LBVI was not determined in 96 patients (22.0%) (LBVI⁻/LN⁺, Group III), and was determined in 71 patients (16.3%) (LBVI⁺/LN⁺, Group IV). An overview on the patient groups is shown in Table 2. There were no significant differences between the four patient groups with regard to age ($P = 0.367$), sex ratio ($P = 0.160$), distribution of tumor sites ($P = 0.959$), surgical procedures ($P = 0.328$), total number of retrieved LNs ($P = 0.413$) and tumor size ($P = 0.929$) (Table 2).

LBVI: Lymphatic and/or blood vessel invasion; LN: Lymph node.

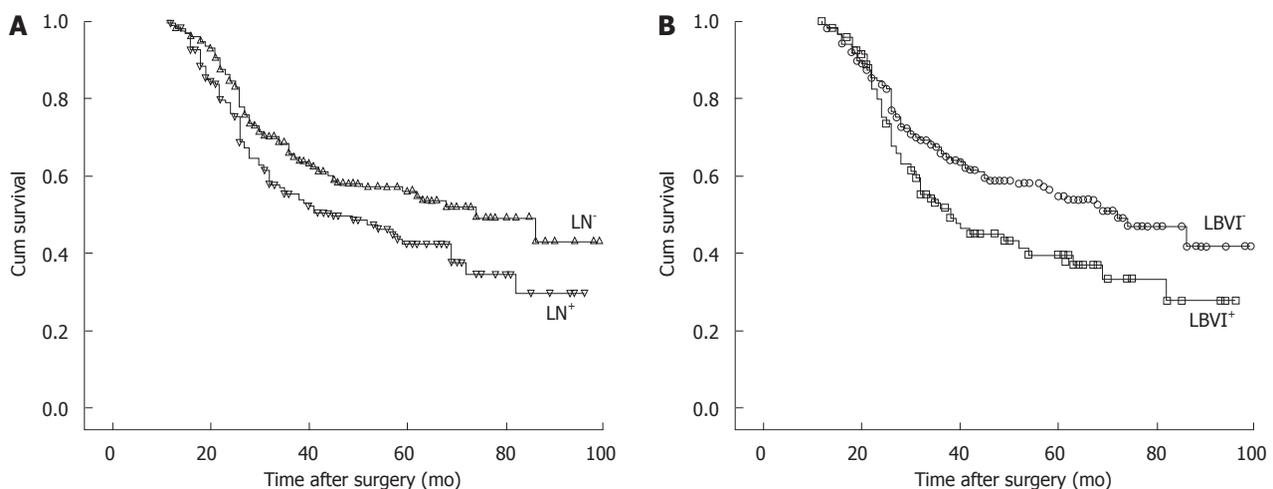

Figure 1 Survival curves of patients with stage II gastric cancer according to lymph node metastasis and lymphatic and/or blood vessel invasion. A: Overall survival curve of the lymph node (LN)-positive patients (LN⁺) was significantly worse than that of the LN-negative patients (LN⁻) ($P = 0.015$); B: Overall survival curve of the lymphatic and/or blood vessel invasion (LBVI)-positive (LBVI⁺) patients was significantly worse than that of the LBVI-negative (LBVI⁻) patients ($P = 0.006$).

Correlation analysis

Correlation analysis with the Spearman correlation coefficient showed that LBVI and LN category or the number of positive LNs were significantly correlated (correlation coefficient 0.255, 0.317; $P < 0.001$). There was a significantly greater incidence and number of positive LNs when LBVI was present than when LBVI was absent. Of the 122 patients with LBVI⁺ tumors, 71 (58.2%) had positive nodes compared with 96 (30.6%) of the 314 patients with LBVI⁻ tumors ($P < 0.001$). The average number of positive nodes in patients with LBVI⁺ tumors was 1.59 compared with 0.62 in patients with LBVI⁻ tumors ($P < 0.001$).

Survival

The 5-year overall survival was significantly longer in LN-

negative patients compared with LN-positive patients (56.1% *vs* 42.3%, $P = 0.015$; Figure 1A). There was a significant difference in the 5-year overall survival between LBVI-positive and LBVI-negative tumors (39.6% *vs* 54.8%, $P = 0.006$; Figure 1B). Five-year overall survival rates in each group were 58.8% (I), 45.8% (II), 45.7% (III) and 36.9% (IV), and there was a significant difference in overall survival between the four groups ($P = 0.009$; Figure 2).

Comparison of survival time in LN-negative gastric cancer patients according to LBVI: The 5-year overall survival rate was 58.8% in LN-negative gastric cancer patients with no LBVI, and 45.8% in LN-negative patients with LBVI. There was a significant difference in

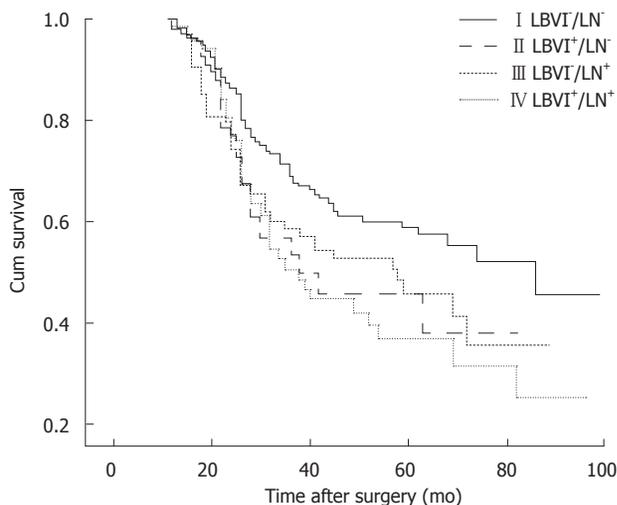

Figure 2 Cumulative survival of Groups I-IV according to the status of lymph node metastasis and lymphatic and/or blood vessel invasion. There was a significant difference in overall survival between the four groups ($P = 0.009$). Moreover, there was a significant difference in overall survival between Groups I and II ($P = 0.022$). However, the comparison of Group III with IV revealed no significant difference ($P = 0.482$). LBVI: Lymphatic and/or blood vessel invasion; LN: Lymph node.

overall survival between Groups I and II ($P = 0.022$). The 5-year overall survival rate was 42.3% in LN-positive gastric cancer patients and 45.7% and 36.9% in Groups III and IV, respectively. By the paired log rank test, the comparison of Groups III and IV revealed no significant difference (log rank test, $P = 0.482$).

Comparison of survival time between LN-negative stage II gastric cancer patients with LBVI and LN-positive stage II gastric cancer patients: No difference was observed in survival between group II and LN-positive patients ($P = 0.924$) or between each group ($P = 0.753$).

Cox regression analysis

To assess the independent prognostic relevance of several parameters such as LBVI, in particular, with regard to 5-year overall survival rate, the Cox proportional hazard analysis, including lymphatic vessel invasion (LBVI *vs* LBVI⁺), T category (T1-T4a), metastatic tumor growth within the LNs (LN⁻ *vs* LN⁺), tumor histological type, tumor location, type of surgical procedure (subtotal *vs* total), sex (male *vs* female), age, and tumor stage (IIa *vs* IIb) were determined. Multivariate analysis in all stage II gastric cancer patients revealed that no factor influenced patient prognosis independently. Multivariate analysis in LN-negative patients showed that LBVI and age independently affected patient prognosis ($P = 0.018$, $P = 0.036$). However, the multivariate analysis did not detect any independent impact of LBVI on 5-year overall survival in LN-positive patients ($P = 0.512$).

DISCUSSION

In the present retrospective study, the effect of LBVI on

survival in patients with stage II gastric carcinoma who underwent D2 curative gastrectomy was investigated. According to the study of del Casar *et al.*^[12], LBVI was defined as either the presence of neoplastic cells with fibrin clots, erythrocytes, or both within an endothelium-lined space without erythrocyte extravasation into the surrounding tissue, or by the presence of neoplastic cells within a smooth-muscle-cell-lined space. We found that 122 of the 436 patients (28%) were LBVI-positive. Multivariate analysis LN-negative patients showed that LBVI independently affected patient prognosis. However, multivariate analysis did not detect any independent impact of LBVI on 5-year overall survival in LN-positive patients. We also found that survival outcomes between LN-negative stage II gastric cancer patients with LBVI and LN-positive stage II gastric cancer patients were similar, suggesting that it may be necessary to treat these two groups as having the same malignant potential.

The incidence of LBVI in gastric cancer varies from 5.4% to 86%, with the lowest incidence of 20%-26.8% reported in patients with node-negative tumors, using routine pathological examinations with HE staining or different staining methods with endothelial markers^[12-17]. This could be caused, in part, by the different patient populations included in the different studies. In our analysis, 28% of stage II gastric patients who underwent curative resection were found to have evidence of LBVI. The incidence of LBVI was 19.0% (51/269) and 42.5% (71/167) in LN-negative and LN-positive patients, respectively.

In our study, the impact of LBVI on survival in patients with stage II gastric carcinoma who underwent D2 curative gastrectomy was investigated, and we found that there was a significant difference with respect to survival between LBVI-positive and LBVI-negative patients. By proportional hazards analysis, LBVI was an independent prognostic factor for survival. The mean and median overall survival interval for patients with LBVI-positive tumors was 52.9 and 38 mo, respectively, which was significantly worse than that of the patients with LBVI-negative tumors at 64.7 and 72 mo. The presence and prognostic importance of LBVI have been investigated previously in patients with gastric cancer by only a few studies and a consensus was not reached^[12-19]. Several studies have shown that LBVI can be a useful marker to predict cancer recurrence and prognosis in gastric cancer patients^[12,15,17]. In contrast, the presence of LBVI showed no prognostic value as an independent factor in the overall group of patients with curatively resected gastric cancer^[18,19]. A possible explanation for the different results in assessing the prognostic impact of LBVI could be the methodological discrepancies in the various analyses.

In the current study, LBVI was not also an independent prognostic factor in LN-positive stage II gastric cancer. Liu *et al.*^[20] found that, in patients with T1N1M0 gastric cancer, the survival rate was not significantly different between those with and those without lymphatic vessel invasion. Therefore, LBVI may not be a prognos-

tic factor in LN-positive gastric cancer. In contrast, our results showed that LBVI independently influenced prognosis in LN-negative stage II cancer patients, and were in agreement with previous studies examining node-negative gastric cancer, further supporting LBVI as a potential marker of biological behavior. This observation was subsequently supported in a study by Lee *et al.*^[21], which showed that LBVI was an adverse prognostic indicator, independent of clinicopathological factors in node-negative gastric cancer. The above-mentioned study concluded that LBVI may provide useful information for prognosis and clinical management in the subset of patients with node-negative gastric cancer. More recently, Kooby *et al.*^[22] showed that vascular invasion in node-negative patients was an independent predictor of poor outcome, and identified more aggressive lesions independent of tumor size and depth of invasion. This finding was consistent with our results, in which a subgroup analysis demonstrated that LBVI was independently associated with poor outcome in patients with node-negative gastric cancer. We also found that survival outcomes between stage T3N0 gastric cancer patients with LBVI and stage II gastric cancer patients with positive LN metastasis were similar, suggesting that it may be necessary to treat these two populations as having the same malignant potential.

According to our results, a possible indication to investigate LBVI after radical gastric cancer resection might be the case if there were no LN metastases detectable in conventional pathohistological investigation. However, analysis of various studies have shown that in 10.0%-30.1% of tumor-cell-negative LNs, revealed by conventional histopathological investigation, micrometastases were detectable with immunohistochemistry, which have been described as a negative prognostic factor^[23-27]. Therefore, it is recommended to investigate LNs in a more subtle manner in patients with positive LBVI, so that detection of micrometastases is made more cost-efficient and time-saving, with selective immunohistochemical and gene-amplifying investigations of the prepared LNs in patients who have been previously classified as pN0.

However, there were some limitations in the present study due to its retrospective nature, despite our efforts to make a clinically and scientifically sound experiment design. First, due to the inherent limitations of a retrospective study and the small sample size of this study, the results require further investigation to reach a firm conclusion. Second, the presence of LVBI was identified by routine histological HE staining. The accuracy of the identification of LBVI is affected by various parameters. A crucial factor is the number of reference slices obtained from the primary tumor lesion and the level of serious attention for LBVI in the histopathological routine examination. Currently, the presence of LBVI is detected by a routine HE staining method. How novel immunohistochemical lymphangio-markers may improve the sensitivity and specificity of detection needs to be proved in further studies. The third limitation was the heterogene-

ity in clinical decision-making, surgical intervention and pathological evaluation. Radical gastric cancer resection was performed by several surgeons, and the specimens were evaluated by several pathologists. These doctors were trained in academic centers with experience in gastrectomy and the data are probably valid. Another limitation of our study was the choice of overall survival as the end point. In some ways this can be regarded as a powerful end point, given that overall survival is a concrete end point that we were able to ascertain reliably. Although time to recurrence would be an interesting end point to analyze, patients were not on a predefined follow-up schedule and were observed at the discretion of the treating physician. Therefore, although we tried to collect recurrence data for these patients, there were limitations to the validity of investigating this end point due to the lack of a predefined surveillance plan and schedule.

In conclusion, patients with LBVI⁺ tumors had a significantly increased incidence and number of positive nodes and a shorter 5-year overall survival. On multivariate analysis, LBVI was an independent prognostic factor in stage II gastric cancer patients with negative LNs. This suggests that the presence of lymphovascular invasion in stage II gastric cancer patients may provide valuable information to determine which patients would benefit from radical surgery, adjuvant chemotherapy or radiotherapy after surgery.

COMMENTS

Background

Surgical resection with regional lymphadenectomy is the treatment of choice for patients with stage II gastric cancer. However, preoperative and intraoperative staging to confirm stage II disease is difficult. Failure to distinguish stage II from stage I disease may lead to under- or over-treatment. Therefore, the identification of additional prognostic factors, which is timely and cost-efficient as well as available, would help in detecting those patients with poorer prognosis among the different groups of patients with stage II gastric cancer.

Research frontiers

A retrospective study was conducted, attempting to clarify the risk factors and to investigate the effect of lymphatic and/or blood vessel invasion (LBVI) on survival in patients with stage II gastric cancer who underwent D2 curative gastrectomy.

Innovations and breakthroughs

The study revealed that LBVI independently affected patient prognosis in lymph node (LN)-negative patients but not in LN-positive patients with stage II gastric cancer.

Applications

In LN-negative stage II gastric cancer patients, LBVI is an additional independent prognostic marker, and may provide useful information to identify patients with poorer prognosis. This suggests that the presence of LBVI in stage II gastric cancer patients may provide valuable information to determine which patients would benefit from radical surgery, adjuvant chemotherapy or radiotherapy after surgery.

Terminology

LBVI is the critical step of tumor cell dissemination and metastasis in various types of cancer. As the cancer stage advances, tumor cells invade blood vessels and lymphatic vessels near the tumor.

Peer review

This is a retrospective clinicopathological study on the implication of LBVI in the patients who received surgical therapy for gastric cancer. The results are important and applicable to clinical practice and studies.

Abstract

AIM: To evaluate anti-hepatitis B virus (HBV) activity and cytotoxicity of interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α) following lamivudine treatment of HepG2.2.15 cells.

METHODS: HepG2.2.15 cells were treated with 2 μ mol/L lamivudine for 16 d (lamivudine group), cultured for 10 d, followed by 5 ng/mL TNF- α and 1000 U/mL IFN- γ for 6 d (cytokine group), or treated with 2 μ mol/L lamivudine for 10 d followed by 5 ng/mL TNF- α and 1000 U/mL IFN- γ for 6 d (sequential group), or cultured without additions for 16 d (control group). Intracellular DNA was extracted from 3×10^5 HepG2.2.15 cells from each group. The extracted DNA was further purified with mung bean nuclease to remove HBV relaxed circular DNA that may have remained. Both HBV covalently closed circular DNA (cccDNA) and HBV DNA were examined with real-time polymerase chain reaction. The titers of hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) were quantified with enzyme-linked

immunosorbent assay. Cell viability was measured with the cell counting kit-8 assay.

RESULTS: Compared to lamivudine alone ($22.63\% \pm 0.12\%$), both sequential ($51.50\% \pm 0.17\%$, $P = 0.034$) and cytokine treatment ($49.66\% \pm 0.06\%$, $P = 0.041$) showed a stronger inhibition of HBV cccDNA; the difference between the sequential and cytokine groups was not statistically significant ($51.50\% \pm 0.17\%$ vs $49.66\% \pm 0.06\%$, $P = 0.88$). The sequential group showed less inhibition of HBV DNA replication than the lamivudine group ($67.47\% \pm 0.02\%$ vs $82.48\% \pm 0.05\%$, $P = 0.014$); the difference between the sequential and cytokine groups was not statistically significant ($67.47\% \pm 0.02\%$ vs $57.45\% \pm 0.07\%$, $P = 0.071$). The levels of HBsAg and HBeAg were significantly decreased in the sequential treatment group compared to the other groups [HBsAg: 3.48 ± 0.04 (control), 3.09 ± 0.08 (lamivudine), 2.55 ± 0.13 (cytokine), 2.32 ± 0.08 (sequential), $P = 0.042$ for each between-group comparison; HBeAg: 3.48 ± 0.01 (control), 3.08 ± 0.08 (lamivudine), 2.57 ± 0.15 (cytokine), 2.34 ± 0.12 (sequential), $P = 0.048$ for each between-group comparison]. Cell viability in the cytokine group was reduced to $58.03\% \pm 8.03\%$ compared with control cells ($58.03\% \pm 8.03\%$ vs 100% , $P = 0.000$). Lamivudine pretreatment significantly reduced IFN- γ + TNF- α -mediated toxicity of HepG2.2.15 cells [$85.82\% \pm 5.43\%$ (sequential) vs $58.03\% \pm 8.03\%$ (cytokine), $P = 0.002$].

CONCLUSION: Sequential treatment overcame the lower ability of lamivudine alone to inhibit cccDNA and precluded the aggressive cytotoxicity involving IFN- γ and TNF- α by decreasing the viral load.

INTRODUCTION

Hepatitis B virus (HBV) infection is a global health problem, and more than 350 million people are chronically infected with this virus worldwide^[1]. Chronic hepatitis B infection is associated with an increased risk of cirrhosis, hepatic decompensation, and hepatocellular carcinoma^[2]. Seven drugs are currently approved for the treatment for chronic hepatitis B, including conventional interferon (IFN)- α , pegylated IFN- α , and the nucleos(t)ide analogs lamivudine, adefovir, entecavir, telbivudine and tenofovir. However, none of the currently available drugs can eliminate viral covalently closed circular DNA (cccDNA) from the nucleus of infected hepatocytes^[3,4].

During HBV infection, HBV cccDNA accumulates in cell nuclei where it persists as a stable episome and acts as a template for transcription of viral genes^[5]. The elimination of cccDNA is a prerequisite for curing HBV infection^[6]. Current knowledge suggests that clearance of HBV cccDNA occurs mainly through two pathways. The first is long-term and potent antiviral therapy, which effectively depletes the mature cytoplasmic nucleocapsid pool available for conversion into cccDNA. Based on mathematical models, the period needed to achieve complete clearance of intrahepatic cccDNA is 14.5 years^[7]. Short-term antiviral therapy cannot completely exhaust the viral pool, which is stable and constitutes the source of renewal of viral production after cessation of therapy^[8,9]. Nevertheless, long-term antiviral therapy can result in the development of antiviral resistance, and it is very expensive^[10,11]. The second mechanism of cccDNA clearance involves two immune mechanisms: A cytotoxic T lymphocyte (CTL)-dependent cytolytic mechanism by which infected cells are eliminated and replaced with non-infected cells^[12] and a non-cytolytic cytokine-dependent mechanism^[13]. In addition to killing HBV-positive hepatocytes, HBV-specific CTLs can downregulate hepatocellular HBV gene expression and replication via a non-cytopathic, cytokine-induced process. These processes are mediated by inflammatory cytokines such as IFN- γ and tumor necrosis factor- α (TNF- α), which are secreted by CTLs following antigen recognition in the liver^[14,15].

We previously reported that IFN- γ and TNF- α play a role in cell death of HBV-expressing HepG2.2.15 cells, a human hepatoblastoma cell line. Lamivudine treatment significantly reduces killing of HepG2.2.15 cells that is mediated by IFN- γ and TNF- α ^[16]. Lamivudine is the first

oral nucleoside analog to be approved for the treatment of chronic hepatitis B patients, and it has been shown to suppress HBV replication by interfering with HBV DNA polymerase and disease activity, reducing the incidence of hepatocellular carcinoma and prolonging survival^[17,18]. Lamivudine is potent and well tolerated, but its use is limited by the development of resistance. Viral breakthrough, which is defined as an abrupt increase in serum HBV DNA levels after a period of persistent suppression, may occur during lamivudine therapy^[19]. Persistence of HBV cccDNA in hepatocytes plays a key role in viral persistence, reactivation of viral replication after cessation of antiviral therapy, and resistance to therapy^[20]. To achieve effective suppression of HBV replication and elimination of HBV cccDNA and to avoid aggressive immune-mediated hepatitis and liver damage, we combined the above two established strategies of HBV cccDNA clearance. HBV-expressing HepG2.2.15 cells were initially given lamivudine to inhibit viral replication and reduce the level of HBV, and then the cells were given IFN- γ and TNF- α , two important immune mediators. We evaluated the antiviral potential of sequential treatment with lamivudine followed by IFN- γ and TNF- α in HepG2.2.15 cells, especially the potential to inhibit cccDNA amplification and eliminate its persistence.

MATERIALS AND METHODS

Cell culture and treatment

HepG2.2.15 cells, which were derived from the stable transfection of HepG2 cells with a plasmid containing two head-to-tail dimers of the HBV genome, were used in this study. The HepG2.2.15 line supports persistent replication of HBV and produces intact HBV particles^[21]. HBV cccDNA is detectable in the culture medium and intracellularly in HepG2.2.15 cells^[22,23]. Cells were cultured in Dulbecco's modified Eagle's medium supplemented with 2 mmol/L L-glutamine, 50 IU/mL penicillin, 50 mg/L streptomycin, 500 mg/L G418, 5% (vol/vol) fetal bovine serum in 5 mL/L CO₂ at 37 °C.

HepG2.2.15 cells were treated as follows: (1) with medium alone (control group); (2) 2 μ mol/L lamivudine (GSK, London, United Kingdom) for 16 d (lamivudine group); (3) culture medium for 10 d, followed by 5 ng/mL recombinant human TNF- α (Invitrogen, CA, United State) and 1000 U/mL recombinant human IFN- γ (R and D Systems China, Shanghai, China) for 6 d (cytokine group); or (4) 2 μ mol/L lamivudine for 10 d followed by 5 μ g/L TNF- α and 1000 U/mL IFN- γ for 6 d (sequential group). The supernatant was replaced with fresh medium (with or without lamivudine and cytokines as per treatment protocols) every 2 d.

Detection of HBV cccDNA

Intracellular DNA was extracted from 3×10^5 HepG2.2.15 cells from each group with the QIAamp Mini DNA kit (QIAGEN, Hilden, Germany) according to the manufacturer's instructions. The extracted product was further purified with mung bean nuclease (Gibco, Camarillo, CA,

United State) to remove HBV relaxed circular DNA that may have remained. The purification reaction was carried out in a 50- μ L volume containing 44 μ L extracted DNA solution, 1 μ L mung bean nuclease (10 000 U/mL), and 5 μ L 10 \times mung bean nuclease buffer at 37 $^{\circ}$ C for 30 min. EGTA (2 μ L; 100 mmol/L, pH 7.4) was then added to stop the reaction. HBV cccDNA was quantified with real-time polymerase chain reaction (PCR) using the ABI 7500 Real-Time PCR System (ABI, Foster City, CA, United States). Amplification was performed in a 20- μ L reaction containing 2 μ L isolated DNA and the Premix Ex Taq (Perfect Real-Time) kit (Takara, Dalian, China). The PCR primers were: forward 5'-TGAATCCYGC-GGACGACC-3' (nucleotides 1444-1461) and reverse 5'-CAGCTTGGAGGCTTGAACAG-3' (nucleotides 1862-1881) (Y = C/T). The TaqMan probe was: 5'-FAM-CCTAATCATCTCWTGTTTCATGTC-MGB-3' (nucleotides 1836-1858) (W = A/T). For HBV cccDNA amplification, the cycling conditions were an initial incubation of 30 s at 95 $^{\circ}$ C followed by 40 cycles of 5 s at 95 $^{\circ}$ C and 34 s at 60 $^{\circ}$ C. The inhibition ratio of cccDNA was calculated as: (control-treatment)/control \times 100%.

Quantification of HBV DNA using real-time PCR

Intracellular DNA was extracted from 3×10^5 HepG2.2.15 cells from each group with the QIAamp Mini DNA kit. HBV DNA was quantified with real-time PCR using SYBR Premix Ex Taq (Perfect Real Time) (Takara) with the ABI 7500 Real-Time PCR System. The PCR primers were forward 5'-CCTCTTCATCCTGCTGCT-3' and reverse 5'-AACTGAAAGCCAAACAGTG-3'. The PCR cycling program consisted of an initial denaturation step at 95 $^{\circ}$ C for 10 s, followed by 40 amplification cycles of 95 $^{\circ}$ C for 10 s, 60 $^{\circ}$ C for 10 s, 72 $^{\circ}$ C for 10 s, and 79 $^{\circ}$ C for 35 s, and then one cycle of 95 $^{\circ}$ C for 15 s, 60 $^{\circ}$ C for 60 s, and 95 $^{\circ}$ C for 15 s. The inhibition ratio of HBV DNA was calculated as: (control-treatment)/control \times 100%.

HBV antigen detection

HepG2.2.15 cell culture supernatants at days 12, 14 and 16 from each experimental group were collected and centrifuged at $118 \times g$ for 10 min to remove cellular debris and then transferred to clean tubes and stored at -20 $^{\circ}$ C until antigen measurement. The titers of hepatitis B surface antigen (HBsAg) and hepatitis B e antigen (HBeAg) were measured using a commercial enzyme-linked immunosorbent assay (ELISA) kit (Kehua, Shanghai, China) according to the manufacturer's instructions.

Cell counting kit-8 assay

After treatment for 10 d according to the protocols, cells were seeded at 3×10^4 /well in 100 μ L medium in 96-well plates and incubated overnight to allow cell adherence. Cells were then exposed to lamivudine and/or TNF- α + IFN- γ for 6 d. Ten microliters of 2-(2-methoxy-4-nitrophenyl)-3-(4-nitrophenyl)-5-(2,4-disulphophenyl)-2H-tetrazolium, monosodium salt (Dojindo, Kumamoto, Japan) was added to each well, and the culture plate was incubated at 37 $^{\circ}$ C

for 1 h. Absorbance was measured at 450 nm. The percent cell viability was calculated as: (value after treatment-blank)/(control-blank) \times 100.

Statistical analysis

All data are expressed as the mean \pm SD from three different experiments. Statistical analysis was performed with analysis of variance using SPSS 17.0 software. $P < 0.05$ was considered statistically significant.

RESULTS

Sequential treatment has a stronger suppressive effect on HBV cccDNA replication than treatment with lamivudine alone

The level of HBV cccDNA is an important parameter for determining the outcome of anti-HBV therapy. Both sequential treatment (51.50% \pm 0.17%) and cytokine treatment (49.66% \pm 0.06%) showed a stronger inhibition of HBV cccDNA compared to lamivudine alone (22.63% \pm 0.12%) (51.50% \pm 0.17% *vs* 22.63% \pm 0.12%, $P = 0.034$; 49.66% \pm 0.06% *vs* 22.63% \pm 0.12%, $P = 0.041$). The difference between the sequential and cytokine groups was not statistically significant ($P = 0.88$) (Figure 1A).

Sequential treatment has a weaker inhibitory effect on HBV DNA replication than treatment with lamivudine alone

The effect of the three different treatments on HBV DNA was investigated with real-time PCR. The sequential group (67.47% \pm 0.02%) showed lower inhibition of HBV DNA than the lamivudine group (82.48% \pm 0.05%) ($P = 0.014$). The inhibitory effect on HBV DNA between the sequential (67.47% \pm 0.02%) and cytokine groups (57.45% \pm 0.07%) was not significantly different ($P = 0.071$) (Figure 1B).

Sequential treatment causes the greatest reduction in HBsAg and HBeAg

Secretion of HBsAg and HBeAg into cell media at days 12, 14 and 16 during the treatment period was detected with a commercial ELISA kit. After 16 d of treatment, we observed statistically significant decreases in the levels of HBsAg and HBeAg with sequential treatment compared to the other groups [HBsAg: 3.48 \pm 0.04 (control), 3.09 \pm 0.08 (lamivudine), 2.55 \pm 0.13 (cytokine), 2.32 \pm 0.08 (sequential), $P = 0.042$ for each between-group comparison; HBeAg: 3.48 \pm 0.01 (control), 3.08 \pm 0.08 (lamivudine), 2.57 \pm 0.15 (cytokine), 2.34 \pm 0.12 (sequential), $P = 0.048$ for each between-group comparison] (Figure 2).

Sequential treatment suppresses TNF- α + IFN- γ -mediated cellular toxicity

The effect of each treatment on HepG2.2.15 cell viability was quantified with a CCK-8 assay. The viability in the cytokine group was reduced to 58.03% \pm 8.03% compared with control cells (100%, $P = 0.000$). Lamivudine pretreatment significantly reduced TNF- α + IFN- γ -mediated toxicity of HepG2.2.15 cells [85.82% \pm 5.43% (sequential) *vs* 58.03% \pm 8.03% (cytokine), $P = 0.002$] (Figure 3).

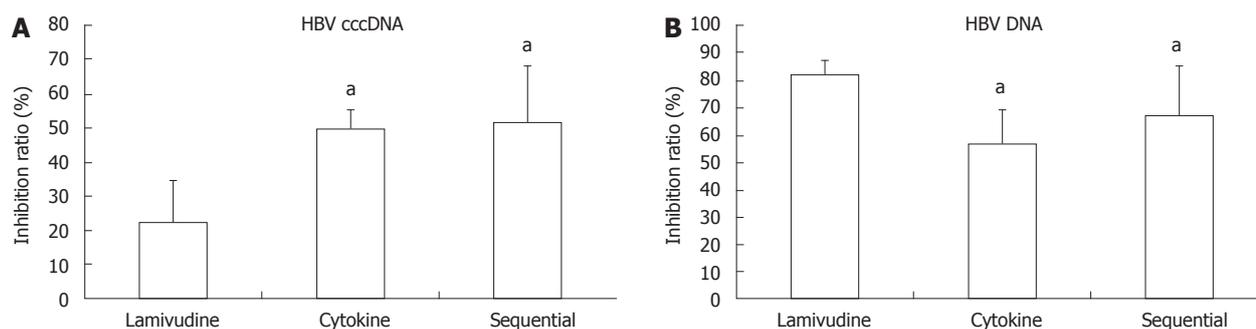

Figure 1 Inhibition ratio of hepatitis B virus covalently closed circular DNA (A) and DNA (B) following different treatments of HepG2.2.15 cells. A: Hepatitis B virus covalently closed circular DNA (HBV cccDNA) was quantified with real-time polymerase chain reaction; B: Hepatitis B virus DNA (HBV DNA) was quantified with real-time polymerase chain reaction. Data are expressed as the mean \pm SD from three individual experiments. ^a $P < 0.05$ vs lamivudine group.

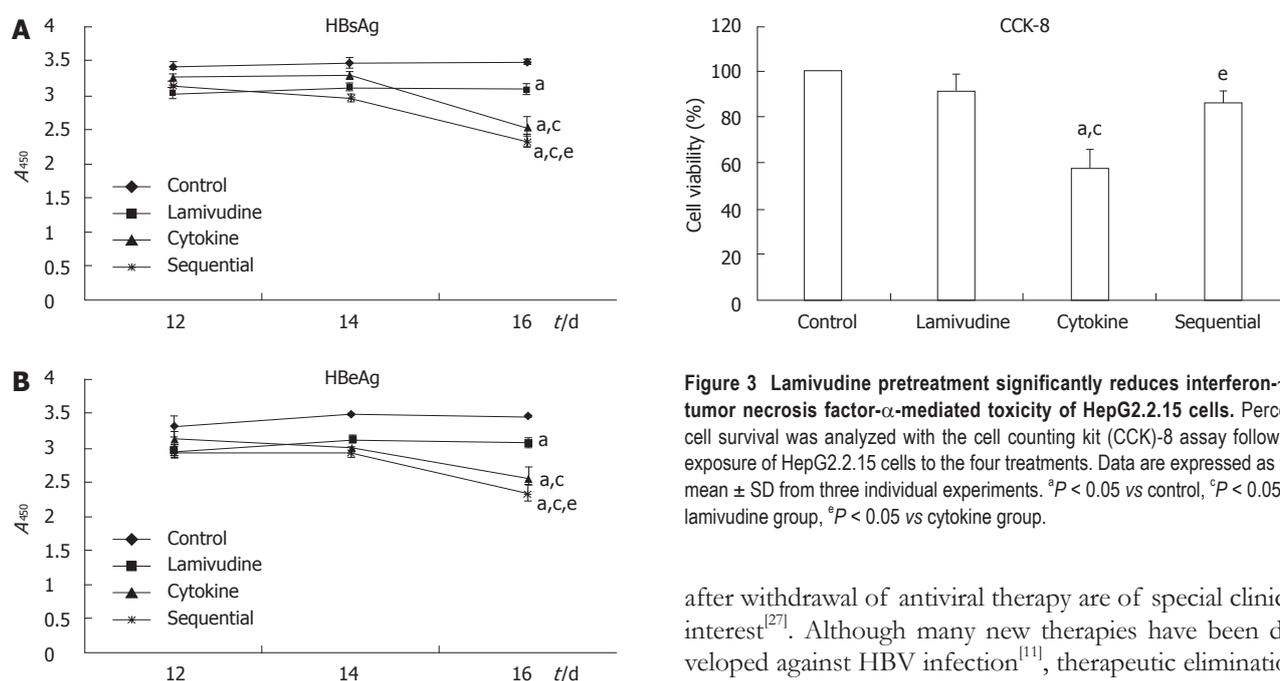

Figure 2 Levels of hepatitis B surface antigen and hepatitis B e antigen following different treatments of HepG2.2.15 cells. Sequential treatment reduced the levels of hepatitis B surface antigen (HBsAg) (A) and hepatitis B e antigen (HBeAg) (B) most strongly at 16 d in the treatment period. ^a $P < 0.05$ vs control group, ^c $P < 0.05$ vs lamivudine group, ^e $P < 0.05$ vs cytokine group.

Figure 3 Lamivudine pretreatment significantly reduces interferon- γ + tumor necrosis factor- α -mediated toxicity of HepG2.2.15 cells. Percent cell survival was analyzed with the cell counting kit (CCK)-8 assay following exposure of HepG2.2.15 cells to the four treatments. Data are expressed as the mean \pm SD from three individual experiments. ^a $P < 0.05$ vs control, ^c $P < 0.05$ vs lamivudine group, ^e $P < 0.05$ vs cytokine group.

DISCUSSION

HBV infection affects about 350 million people globally and is a leading cause of end-stage liver disease, hepatocellular carcinoma, and mortality^[24]. HBV primarily infects hepatocytes by a single pathway, although the exact mechanism remains poorly understood. After endocytosis, nucleocapsids are released into the cytoplasm, and the relaxed circular DNA genome is transported to the nucleus where it is converted into cccDNA^[25]. Persistence of HBV cccDNA in hepatocytes plays a key role in viral persistence, reactivation of viral replication after cessation of antiviral therapy, and resistance to therapy^[20,26]. Thus, prevention of the formation of cccDNA and elimination of cccDNA to prevent reactivation of viral replication

after withdrawal of antiviral therapy are of special clinical interest^[27]. Although many new therapies have been developed against HBV infection^[11], therapeutic elimination of HBV cccDNA remains a major challenge in curing chronic HBV infections. Novel approaches to improving current therapy for HBV infection are demanding but remain a global health priority.

IFN- γ and TNF- α are important immune mediators in host defense against HBV infection^[28,29]. Synergistic antiviral activity of murine IFN- γ and murine TNF- α on HBV gene expression was previously demonstrated in an HBV-Met transgenic hepatocyte cell line^[30]. IFN- γ and TNF- α abolished HBV gene expression and replication without killing the hepatocytes^[31,32]. Nevertheless, IFN- γ and TNF- α also play a role in apoptotic cell death. IFN- γ inhibits large HBV surface protein storage disease and the ground-glass hepatocyte appearance, but it exacerbates inflammation and apoptosis in HBV surface protein-accumulating transgenic livers^[33]. IFN- γ has been proposed to act as a pro-apoptotic regulator, triggering death receptors and other mediators^[34]. HBV X protein (HBx) sensitizes cells to apoptosis by TNF- α ^[35]. We previously reported that IFN- γ and TNF- α play a role in cell death of HBV-expressing HepG2.2.15 cells. Expression of HBV sensitizes the cells to IFN- γ + TNF- α -mediated

apoptosis. Increased expression of genes encoding interferon regulatory factor 1, c-myc and caspase 7 may be responsible for the synergistic induction of apoptosis by IFN- γ and TNF- α ^[16]. Cell death mediated by both IFN- γ and TNF- α may help eradicate the virus by eliminating residually infected cells. In patients with high levels of HBV DNA, however, aggressive immune-mediated processes involving IFN- γ and TNF- α may contribute to HBV-associated fulminant hepatic failure^[16].

To achieve effective suppression of HBV replication and elimination of HBV cccDNA and also avoid aggressive immune-mediated hepatitis and liver damage, we combined the two established strategies of clearance of HBV cccDNA. We found that sequential treatment with lamivudine followed by IFN- γ and TNF- α had a stronger suppressive effect on HBV cccDNA replication and antigen expression compared to the lamivudine-only group. Although the differences between the sequential and cytokine groups in the inhibition ratio of both HBV cccDNA and HBV DNA were not statistically significant, sequential treatment showed stronger inhibition of antigen expression than cytokines only. More importantly, lamivudine pretreatment significantly reduced IFN- γ + TNF- α -induced cytotoxicity of HepG2.2.15 cells.

Our *in vitro* findings suggest that sequential treatment with IFN- γ and TNF- α following lamivudine not only overcame the lower ability of lamivudine alone to inhibit HBV cccDNA by cytokine treatment but also precluded the aggressive immune-mediated cytotoxicity involving IFN- γ and TNF- α by decreasing the viral load with lamivudine pretreatment. This novel treatment suggests a new strategy for treating HBV infection and may shorten the course of antiviral therapy, minimize the emergence of drug-resistant mutants, and reduce the financial burden of patients. Because our present work was carried out *in vitro*, and HBV cccDNA was not eliminated in the relative short study period, further *in vivo* studies are warranted to evaluate the sequential treatment protocol to combat HBV infection.

COMMENTS

Background

Hepatitis B virus (HBV) infection affects about 350 million people globally and is a leading cause of end-stage liver disease, hepatocellular carcinoma, and mortality. Although many new therapies have been developed against HBV infection, therapeutic elimination of HBV covalently closed circular DNA (cccDNA) remains a major challenge in curing chronic HBV infections. Novel approaches to improve current therapy for HBV infection are demanding but remain a global health priority.

Research frontiers

Current knowledge suggests that clearance of HBV cccDNA occurs mainly through two pathways: The first is long-term and potent antiviral therapy, which effectively depletes the mature cytoplasmic nucleocapsid pool available for

conversion into cccDNA. The second involves two immune mechanisms: A cytotoxic T lymphocyte (CTL)-dependent cytolytic mechanism by which infected cells are eliminated and replaced with non-infected cells and a non-cytolytic cytokine-dependent mechanism. These processes are mediated by inflammatory cytokines such as interferon- γ (IFN- γ) and tumor necrosis factor- α (TNF- α), which are secreted by CTLs following antigen recognition in the liver. Nevertheless, IFN- γ and TNF- α have been reported to play a role in cell death of HBV-expressing HepG2.2.15 cells. Increased expression of genes encoding interferon regulatory factor 1, c-myc, and caspase 7 may be responsible for the synergistic induction of apoptosis by IFN- γ and TNF- α .

Innovations and breakthroughs

To achieve effective suppression of HBV replication and elimination of HBV cccDNA and also to avoid aggressive immune-mediated hepatitis and liver damage, the authors combined the two established strategies of clearance of HBV cccDNA. HBV-expressing HepG2.2.15 cells were initially treated with lamivudine to inhibit viral replication and reduce HBV levels, and then the cells were treated with IFN- γ and TNF- α , two important immune mediators, to achieve a synergistic effect on elimination of HBV. Based on the results, the authors found that sequential treatment with lamivudine followed by IFN- γ and TNF- α not only overcame the lower ability of lamivudine alone to inhibit HBV cccDNA by cytokine treatment but also precluded the aggressive immune-mediated cytotoxicity involving IFN- γ and TNF- α by decreasing the viral load with lamivudine pretreatment.

Applications

This novel treatment suggests a new strategy for treating HBV infection and may shorten the course of antiviral therapy, minimize the emergence of drug-resistant mutants, and reduce the financial burden of patients. Further *in vivo* studies are warranted to evaluate the sequential treatment protocol for combating HBV infection.

Terminology

HBV cccDNA: During HBV infection, HBV cccDNA accumulates in cell nuclei where it persists as a stable episome and acts as a template for the transcription of viral genes. Persistence of HBV cccDNA in hepatocytes plays a key role in viral persistence, reactivation of viral replication after cessation of antiviral therapy, and resistance to therapy. The elimination of cccDNA is necessary for curing HBV infection.

Peer review

The authors assessed the effect of sequential treatment with lamivudine followed by IFN- γ and TNF- α on HBV in HepG2.2.15 cells. It was observed that sequential treatment not only overcame the lower ability of lamivudine alone to inhibit HBV cccDNA but also precluded the aggressive immune-mediated cytotoxicity involving IFN- γ and TNF- α . The methodology is sound and the results obtained in cell culture studies have useful potential to be used in humans.

Abstract

The incidence of colonic diverticulosis with or without diverticulitis has increased in the Japanese population due to the modernization of food and aging. The rate of diverticulitis in colon diverticulosis ranges from 8.1% to 9.6%. However, few cases of stenosis due to diverticulitis have been reported. These reports suggest that the differentiation between sigmoid diverticulitis and colon cancer is difficult. This report describes two cases of colon stenosis due to diverticulitis that were difficult to differentiate from colon cancer. Case 1 was a 70-year-old woman with narrowed stools for 1 month who underwent colonofiberscopy (CFS). CFS revealed a diverticulum and circumferential stenosis in the sigmoid colon. Barium enema revealed a marked, hourglass-shaped, 2-cm circumferential stenosis in the sigmoid colon. Fluorodeoxyglucose (FDG)-positron emission tomography computed tomography (CT) revealed an increased FDG uptake at the affected portion of the sigmoid colon. Sigmoid colon cancer was suspected,

and laparoscopic sigmoidectomy was performed. Pathological examination demonstrated active inflammation with no evidence of malignancy. Case 2 was a 50-year-old man who presented to a nearby clinic with reduced stool output despite the urge to defecate. CFS detected severe stenosis in the sigmoid colon approximately 25 cm from the dentate line. Contrast-enhanced abdominal CT revealed multiple diverticula, wall thickening, and swelling of the lymph nodes around the peritoneal aorta and the inferior mesenteric artery. A partial sigmoidectomy was performed. Pathological examination of the resected specimen revealed no changes in the mucosal epithelial surface, but a marked infiltration of inflammatory cells was observed.

INTRODUCTION

The incidence of colonic diverticulosis with or without diverticulitis has increased in the Japanese population due to the modernization of food and aging^[1].

The rate of diverticulitis in colon diverticulosis ranges from 8.1% to 9.6%. However, few cases of stenosis due

to diverticulitis have been reported. These reports suggest that the differentiation between sigmoid diverticulitis and colon cancer is difficult.

No causal relationship between colonic diverticulosis and colon cancer has been established^[2], but a significant correlation between these two conditions has been identified^[3]. Barium enema^[4], positron emission tomography-computed tomography (PET-CT), and magnetic resonance imaging-diffusion weighted imaging (MRI-DWI) are useful for the differential diagnosis between inflammation and cancer in the large intestine. This report describes and discusses two cases of sigmoid stenosis due to sigmoid diverticulitis that were difficult to differentiate from colon cancer using colonofiberscopy (CFS), barium enema, and PET-CT.

CASE REPORT

Case 1 was a 70-year-old woman with narrowed stools for 1 month who underwent CFS of the lower gastrointestinal tract at a nearby clinic. CFS revealed a diverticulum and circumferential stenosis in the sigmoid colon. The mucosa at the stenotic site was discolored, and the scope could not be advanced beyond the stenosis (Figure 1A). Biopsy showed no evidence of malignancy, and laboratory tests revealed no abnormal findings, including tumor markers [carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9)]. Contrast-enhanced abdominal CT revealed a marked thickening in the sigmoid colon wall. Barium enema revealed a marked, hourglass-shaped, 2-cm circumferential stenosis in the sigmoid colon (Figure 1B). Fluorodeoxyglucose [¹⁸F] (FDG)-PET CT revealed an increased FDG uptake at the affected portion of the sigmoid colon (Figure 2). Sigmoid colon cancer was suspected, and laparoscopic sigmoidectomy was performed. Pathological examination of the resected specimen revealed active inflammation characterized by a marked thickening of the muscularis propria, fibrous thickening of interstitial tissue, and a marked infiltration of inflammatory cells with no evidence of malignancy (Figure 3). The patient was diagnosed with inflammatory thickening and stenosis of the sigmoid colon due to sigmoid diverticulitis. The patient had a favorable postoperative course, and she was discharged from the hospital.

Case 2 was a 50-year-old man who presented to a nearby clinic with reduced stool output despite the urge to defecate. Abdominal X-ray revealed mild gas accumulation from the ascending colon to the transverse colon but no evidence of ileus. The patient was placed under observation; however, six months later, he was admitted to our hospital with a lack of bowel movement and lower abdominal pain with increased body temperature. Laboratory tests after admission indicated severe inflammation, including a white blood cell count of 13 520 cells/ μ L and C-reactive protein of 13.5 mg/dL but no abnormal tumor markers (CEA and CA 19-9). Barium enema revealed a segmental stenosis of approximately 10 cm, mucosal wall thickening, and cobblestone-like mucosa in the sigmoid colon (Figure 4). CFS detected severe stenosis in

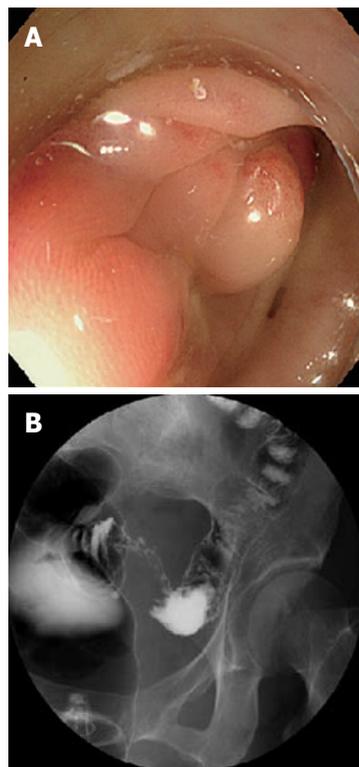

Figure 1 Colonofiberscopy and Barium enema revealed a marked, hourglass-shaped, 2-cm circumferential stenosis in the sigmoid colon. A: Colonofiberscopy; B: Barium enema.

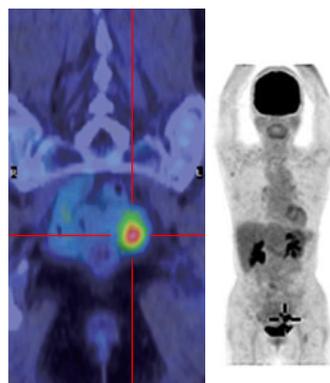

Figure 2 Fluorodeoxyglucose-positron emission tomography computed tomography imaging. A fluorodeoxyglucose-positron emission tomography computed tomography scan showing increased fluorodeoxyglucose (FDG) uptake in the affected portion of the sigmoid colon (maximum standardized uptake value: 5.6 in the early phase and 7.4 in the late phase), but no increase in FDG uptake was observed in the surrounding lymph nodes or distant organs.

the sigmoid colon approximately 25 cm from the dentate line, and the scope could not be advanced further. Mucosal surfaces in the visible range were edematous and red with a partial polyposis-like appearance (Figure 5). Biopsy suggested the presence of inflammation only. Contrast-enhanced abdominal CT revealed multiple diverticula, wall thickening, an increase in surrounding fat tissue, and swelling of the lymph nodes around the peritoneal aorta and the inferior mesenteric artery. FDG-PET also revealed wall thickening, lumen narrowing, and abnormal

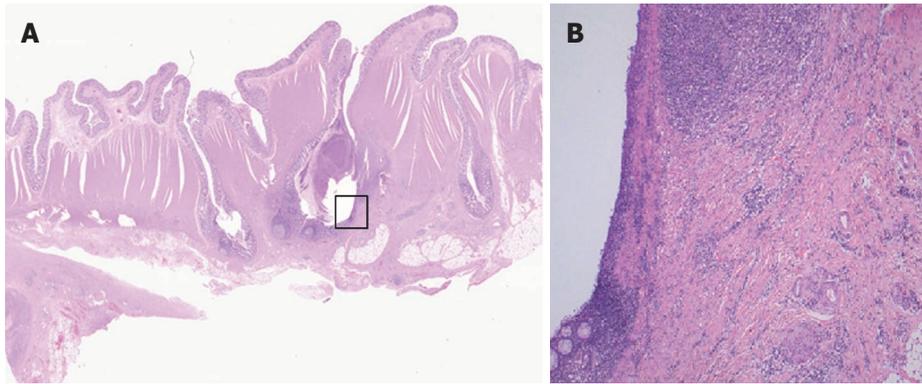

Figure 3 Magnified pathological image of resected specimen. A: A magnified pathological image of the resected specimen reveals some diverticula in the sigmoid colon (HE stain, 10 ×); B: A magnified pathological image of the marked square in Figure 4A (diverticulosis) shows active inflammation characterized by a marked thickening of the muscularis propria, fibrous thickening of interstitial tissue, and a marked infiltration of inflammatory cells with no evidence of malignancy (100 ×).

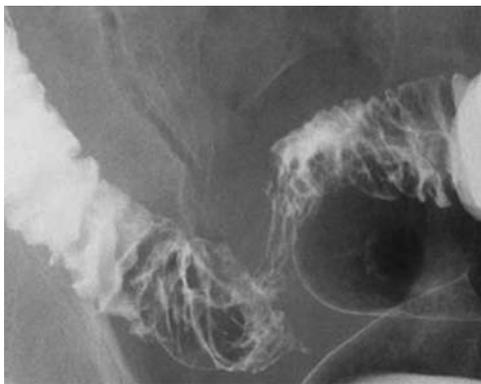

Figure 4 Barium enema revealed a segmental stenosis approximately 10 cm long, mucosal wall thickening, and cobblestone-like mucosa in the sigmoid colon.

Figure 5 Colonofiberscopy detected severe stenosis in the sigmoid colon approximately 25 cm from the dentate line, and the scope could not be advanced further. Mucosal surfaces in the visible range were edematous and red with a partial polyposis-like appearance.

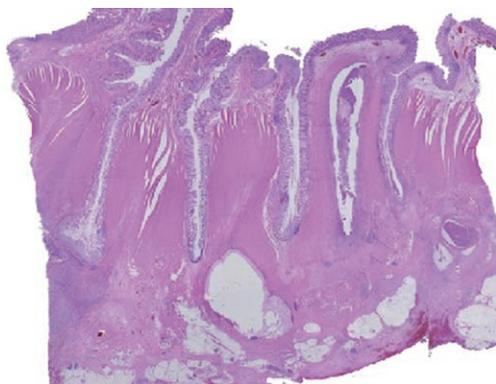

Figure 6 Pathological examination of the resected specimen. Pathological examination of the resected specimen revealed no change in the mucosal epithelial surface, but multiple diverticula penetrated the muscularis propria with a marked thickening of the muscularis propria, fibrous thickening of interstitial tissue, severe infiltration of inflammatory cells, and a cystic change that contained inflammatory exudate and abscess formation.

FDG uptake in the affected portion of the sigmoid colon. A marked increase in FDG uptake was also observed in the surrounding lymph nodes, which suggested a metastasis of the sigmoid cancer to para-aortic lymph nodes (T3N1M1). Partial sigmoidectomy was performed. Patho-

logical examination of the resected specimen revealed no changes in the mucosal epithelial surface, but a marked infiltration of inflammatory cells was observed (Figure 6). The patient was diagnosed with sigmoid diverticulitis, which led to circumferential stenosis due to severe and chronic inflammation.

DISCUSSION

Colonic diverticulosis is generally asymptomatic, but it can lead to diverticulitis, diverticular hemorrhage, and other complications in rare cases. A colonic diverticulum is a false diverticulum without muscularis propria, and the occurrence of diverticulitis leads to the spread of inflammation beyond the intestine. Only 0.09% of patients with diverticulosis develop diverticulitis and subsequent stenosis, which occurs more frequently in the left colon^[5].

The two cases in this study presented difficult preoperative differential diagnoses, which included benign lesions, such as intestinal tuberculosis and metastatic colon cancer, and malignancies with minimal tumor exposure on the mucosal surface, such as diffusely infiltrating colon cancer. However, no characteristic macroscopic findings were obtained, and biopsies did not provide a definitive diagnosis.

Benign lesions such as intestinal tuberculosis do not require immediate diagnosis because these lesions are post-healing changes. However, malignancies such as colon cancer require early diagnosis. The criteria for the differentiation of diverticulitis and cancer using barium enema X-ray results have been reported by Berman and Kirsner^[4]. The cases in this report could have been diagnosed as malignant using these criteria due to the stenosis length, the presence of an hourglass-shaped circumferential stenosis, clear borders and steep margins, despite their almost normal mucosal appearances. PET-CT was performed to differentiate between benign and malignant lesions, and an increased uptake was observed in both cases.

A delayed PET-CT reveals an increased uptake during active inflammation, which is a malignant pattern. However, the PET-CT of lung lesions reveals malignant lesions with higher maximum standardized uptake value levels than inflammatory lesions^[6]. A greater increase in F-FDG uptake at 60 s has been demonstrated in malignant tumors compared to inflammatory lesions in animals^[7].

Cut-off value for a malignant diagnosis using FDG has not been established. **Colon cancer arising from colonic diverticulum** has been reported previously, but Haubrich *et al.*^[2] demonstrated no correlation between colonic diverticulum and colon cancer. Conversely, a significantly higher prevalence of colon cancer in patients with and without multiple sigmoid diverticula was observed in a study conducted with a population of Japanese patients by Mihara *et al.*^[8]. Patients with colonic diverticulosis who develop colon cancer tend to develop diverticulitis at the same site^[9]. Therefore, a diagnosis of colon cancer should be considered in a patient with low levels of FDG uptake on PET-CT.

A lower false-positive rate for the diagnosis of inflammatory lesions has been demonstrated using MRI-DWI compared to PET in animals, but the sensitivity and specificity of MRI-DWI were similar to PET-CT^[10]. These results suggest that MRI-DWI is a useful diagnostic tool when the differentiation between colon cancer and inflammation is difficult.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the “priority” and “copyright” of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers’ names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homoge-

neous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically

for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

Instructions to authors

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A...; B...; C...; D...; E...; F...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of *P* values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be la-

beled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (<http://www.wjgnet.com/1007-9327/office/>). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

The metabolic syndrome is common after liver transplant being present in approximately half of recipients. It has been associated with adverse outcomes such as progression of hepatitis C and major vascular events. As the United States population ages and the rate of obesity increases, prevention of the metabolic syndrome in the post-transplant population deserves special consideration. Currently, the metabolic syndrome after transplant appears at least two times more common than observed rates in the general population. Specific guidelines for patients after transplant does not exist, therefore prevention rests upon knowledge of risk factors and the presence of modifiable elements. The current article will focus on risk factors for the development of the metabolic syndrome after transplant, will highlight potentially modifiable factors and propose potential areas for intervention. As in the non-transplant population, behavioral choices might have a major role. Opportunities exist in this regard for health prevention studies incorporating lifestyle changes. Other factors such as the need for immunosuppression, and the changing characteristics of wait listed patients are not modifiable, but are important to know in order to identify persons at higher risk. Although immunosuppression after transplant is unavoidable, the contribution of different agents to the development of components of

the metabolic syndrome is also discussed. Ultimately, an increased risk of the metabolic syndrome after transplant is likely unavoidable, however, there are many opportunities to reduce the prevalence.

INTRODUCTION

Liver transplantation is a life saving and life changing procedure for patients with advanced chronic liver disease, hepatocellular carcinoma and acute liver failure. The exceptional liver transplant recipient has normal fitness^[1] and can literally climb mountains^[2]. However, the more typical patient has impaired fitness^[3], gains weight^[4-6] and develops the metabolic syndrome^[7-10]. In fact, the prevalence of the posttransplant metabolic syndrome (PTMS) ranges from 44%-58%^[7-10], much higher than the 23% observed in the United States population^[11]. Is the high prevalence of the metabolic syndrome after liver transplant an unavoidable consequence driven by factors such as immunosuppression? Or is it a reflection of behavioral

tendencies in liver transplant recipients that can be modified to prevent illness? Although a definite conclusion is not likely, data can be found to support both possibilities. After a brief overview of the scope of the problem, the current manuscript will examine the factors which contribute to the PTMS and potential means of prevention.

PROBLEM DEFINED

The National Cholesterol Education Program Adult Treatment Panel III (NCEP-ATP III)^[12] defined the components of the metabolic syndrome as follows; (1) impaired fasting glucose (≥ 100 mg/dL); (2) Abdominal obesity (> 102 cm in men, > 88 cm in women); (3) hypertriglyceridemia (≥ 150 mg/dL or drug therapy for triglycerides); (4) low levels of high density lipoprotein (HDL) (< 40 mg/dL in men, < 50 mg/dL in women or drug treatment for low HDL); and (5) elevated blood pressure ($\geq 130/85$ mmHg or drug treatment for hypertension). The presence of 3 or more of these components defines the metabolic syndrome. Complications of advanced liver disease can confound the diagnosis of the metabolic syndrome in the pretransplant setting. The presence of ascites alters waist circumference. Vasodilation and decreased effective circulating volume found with portal hypertension results in lowered systemic blood pressure. Synthetic dysfunction observed with end stages of liver disease immediately prior to transplant can result in lowered serum glucose and lipid values. A study evaluating the metabolic syndrome prior to liver transplantation found a rate of 5.4%^[10]. Pretransplant rates for hypertension were 9%-19%^[8-10,13], diabetes, 10%-22%^[7-10,13], dyslipidemia, 3%-43%^[9,10] and obesity, 11%-38%^[7,10].

Studies of the metabolic syndrome after transplant are summarized in Table 1. The rate of the metabolic syndrome may be underestimated in some reports as diabetes is substituted for impaired fasting glucose, hypertension is substituted for elevated blood pressure and body mass index (BMI) is substituted for elevated waist circumference. The presence of the metabolic syndrome after transplant was associated with more rapid progression of hepatitis C^[8] and an increased rates of major vascular events^[9,10]. Although no prospective data are available, it would be reasonable to expect that the metabolic syndrome might contribute to graft loss and patient death.

PRETRANSPLANT RISK FACTORS

The transplant population has been changing with regard to indication and recipient characteristics. Hepatitis C is declining as an indication for transplant while non-alcoholic fatty liver disease (NAFLD) is increasing and the average age of transplant candidates is rising. With these changes, risk factors for the metabolic syndrome are becoming more common in liver transplant candidates and are important predictors of PTMS development. Although studies evaluating risk factors to predict PTMS

are relatively small, certain factors identified were consistent across multiple series. A summary of risk factors is presented in Table 2. Obesity before transplant is a key factor in predicting the metabolic syndrome after transplant. Both pretransplant weight^[9] and BMI^[7,10,14] were correlated with post transplant metabolic syndrome. Not surprisingly, persons who were obese prior to transplant were often obese after transplant^[7]. The rate of obesity in wait-listed patients varies by transplant indication. Persons awaiting transplant with cryptogenic cirrhosis, which often results from NAFLD, were found to be more commonly obese than age and gender matched controls^[15]. NAFLD has increased annually as an indication for liver transplantation and is projected to become the most common indication for transplantation over the next 10-20 years^[16,17]. Review of Scientific Registry of Transplant Recipients data showed recipients characterized as other/unknown causes, which includes NAFLD, has steadily increased in the past 10 years currently representing 23.6% of recipients, almost equaling the percentage of recipients with hepatitis C^[18]. The proportion of obese persons awaiting transplant will presumably increase with the indication for transplant changing to a higher proportion of recipients with NAFLD. Compounding the effect of obesity, transplant for cryptogenic cirrhosis was found to be a risk factor for PTMS when controlling for other factors including pretransplant BMI^[9,10].

Other risk factors for the PTMS have been identified. Pretransplant diabetes was found to predict PTMS in multiple series^[7,10,14]. In fact, in one study, persons with pretransplant diabetes had nearly a 6 fold higher odds of having the metabolic syndrome after transplant^[10]. Age was additionally predictive of the metabolic syndrome after transplant^[9,10]. This is particularly important as the recipient population in the United States is aging. In 2009, nearly 75% of transplant recipients were above the age of 50, compared to 1993 where only 42% of recipients were 50 years of age or greater^[18]. Other pretransplant factors that were associated with the development of the metabolic syndrome after transplant in at least one series include hypertriglyceridemia^[10], low HDL^[10] and transplantation for hepatitis C or alcohol cirrhosis^[9].

A ROLE FOR PREVENTION PRIOR TO TRANSPLANT?

A preventive intervention could target persons with chronic liver disease, before they require transplant. The long term benefit of weight loss in an obese patient with cirrhosis is not known. In limited series from weight loss surgery, fibrosis improvement in cirrhotic patients after weight loss was inconsistent^[19-21]. However, in selected persons with compensated cirrhosis, diet and weight loss are reasonable recommendations. The potential for a weight loss intervention in reducing future need for transplant in obese persons with cirrhosis is an area in need of study. An exercise program in persons with advanced cirrhosis awaiting transplant may have additional

Table 1 Studies examining the prevalence of the metabolic syndrome after liver transplant

benefits. Sarcopenia^[22] and decreased functional capacity measured by a six-minute walk test^[23] was associated with mortality in persons with cirrhosis. Clearly, increasing physical activity in cirrhotic patients at various degrees of synthetic dysfunction has potential utility and deserves further study.

Existing data indicate that as liver disease progresses to the point of needing transplant, participation in life-style modification becomes increasingly limited by malnutrition, muscle loss and reduced exercise capacity. Protein calorie malnutrition is common, and occurs more frequently with advanced liver disease^[24]. In cirrhosis, a shift toward a catabolic state with utilization of stored fat as a primary energy source during rest and exercise has been observed^[25,26]. The catabolic state induced by an overnight fast in a cirrhotic patient is roughly equivalent to a 36 h fast in a healthy subject^[27]. In a state of protein malnutrition, there is no rationale for a calorie restricted diet in a patient that is potentially requiring transplant. Alterations in physical activity are additionally vital for clinically significant weight loss, with a recent recommendation of greater than 250 min/wk^[28]. There are limitations for cirrhotic patients to achieve this goal. In health-related quality of life measures, persons awaiting liver transplant reported decreased scores relating to physical functioning^[29]. Oxygen consumption during peak exercise is often severely impaired in liver transplant candidates, and is correlated with disease severity^[30]. Additionally, cirrhotic patients develop anaerobic metabolism at low work loads, an effect that also becomes more pronounced as liver dis-

ease progresses^[31]. Studies have shown decreased muscle mass^[22] and strength^[31] in cirrhotic patients which may further limit the ability to exercise. The increase in portal pressure which can occur during exercise could potentially increase the risk of complications such as variceal bleeding is another barrier to exercise^[32].

POST TRANSPLANT RISK FACTORS FOR METABOLIC SYNDROME

As obesity prior to transplant is a risk factor for PTMS, it is intuitive that weight gain after transplant might predict the metabolic syndrome. However, data are mixed. The overall change in BMI after transplant was associated with the metabolic syndrome in one series^[7] but not in another^[9]. It is possible that ascites pre transplant may have resulted in the underestimation of weight gain post transplant in the later series. Weight gain after transplant is well described, however. In one series, the proportion of overweight and obese persons after transplant was 57% compared to 38% prior to transplant^[7]. In a large series of almost 600 liver transplant recipients, the median weight gain at 1 years and 3 years was 5.1 kg and 9.5 kg, respectively^[6]. In studies with longitudinal data, it appears that most weight gain occurs within the first year after liver transplant^[5,33,34]. Data from our center echoes these findings and is shown in Figure 1^[35]. Weight gain after transplant should be viewed in the context of persons returning to health after illness. Aggregate data from three studies which measured the rate of an elevated waist circumference after transplant totaled 36.9%^[7,10,35]. Although the populations are not matched, the absolute number is strikingly similar to the 38.6% rate reported for the United States population^[11]. In a study comparing rates of obesity, the standard prevalence ratio was not significantly higher in persons after liver transplant compared to the general United States population^[36].

Despite the weight gain over time after transplant, time since transplant was not associated with the prevalence of PTMS^[7,9,10]. This finding suggests factors resulting in PTMS develop soon after transplant and factors in addition to obesity require further scrutiny. Immunosuppression is one such factor. The overall contribution of immunosuppression to the development of the metabol-

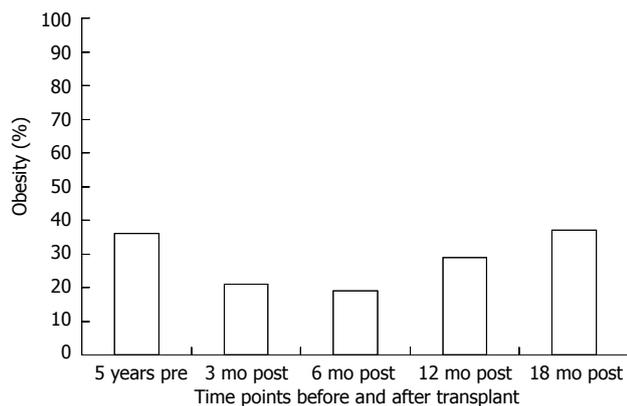

Figure 1 The prevalence of obesity at time points before and after liver transplant.

ic syndrome after transplant is difficult to measure, since immunosuppression is unavoidable. Although, the choice of calcineurin inhibitor (CNI) was not associated with the development of the metabolic syndrome^[7,8], different immunosuppressive agents have been shown to increase risk for various components of the metabolic syndrome. With regard to weight gain after transplant, one series found more weight gain with cyclosporine in the first year^[6]. However, the effect was not seen at 2 years. Another series found a higher overall BMI in cyclosporine treated patients, but no difference in rates of elevated waist circumference^[7]. Weight loss occurred in a majority of liver transplant recipients after switching to tacrolimus from cyclosporine^[37]. Although corticosteroids are often associated with weight gain, this effect after transplant was found in some^[5,38], but not all series^[6,34].

Post transplant diabetes

When compared to the general population, a higher prevalence of posttransplant diabetes mellitus (PTDM) has been observed in liver transplant recipients^[36]. Much of this risk can be related to immunosuppression with both calcineurin inhibitors and steroids playing a major role. Both CNIs have been associated with decreased insulin sensitivity and reduced insulin release^[39]. The reduced insulin release might result from CNI induced damage to pancreatic beta cells^[40]. Comparing the CNIs, most studies show higher rates of PTDM with tacrolimus use compared to cyclosporine^[41-46]. New onset PTDM was found in 27% of recipients on tacrolimus compared to 22% on cyclosporine [hazard ratio (HR) 1.24, 95% confidence interval: 1.07-1.43] in an analysis of over 15 000 recipients from United Network for Organ Sharing data^[45]. Switching tacrolimus to cyclosporine was found to improve PTDM^[47]. However, the absolute rates may not tell the entire story. Lowered serum levels of tacrolimus were associated with better glycemic control^[48]. Corticosteroid use with CNIs has an influence on PTDM rate. Corticosteroid use increases the risk of diabetes through decreasing insulin production and peripheral sensitivity and increasing hepatic gluconeogenesis^[49]. Avoidance of

corticosteroids and the use of induction therapy played an important role in decreasing rates of PTDM^[45,50-57]. In steroid free regimens using tacrolimus and an induction agent, PTDM was seen in less than 10% of recipients^[50,53]. Other series showed that patients receiving cyclosporine are more likely to require corticosteroids^[38,58]. Tacrolimus was associated with less graft loss and rejection^[43] potentially lessening the need for concomitant immunosuppressive agents such as steroids. Further studies are needed to compare rates of PTDM between the two CNIs used with induction therapy.

There are multiple studies examining risk factors in addition to immunosuppression for PTDM. Impaired glucose tolerance prior to transplant consisting of abnormal glucose levels^[59,60] or pretransplant diabetes^[7,44,61], was shown to be associated with post transplant diabetes. Hepatitis C as the transplant indication was linked to higher rates of PTDM in multiple series^[7,41,45,60-63]. Furthermore, eradication of hepatitis C led to improved glycemic control^[62]. In addition to hepatitis C, alcohol cirrhosis was additionally associated with PTDM^[7,44]. The number of episodes of acute cellular rejection^[64,65] and the number of steroid boluses^[62] were tied to higher rates of PTDM. Other factors correlated with PTDM include male gender^[44,61,66], older age^[41,45,67], African American race^[45] and a BMI > 25 kg/m²^[45,60]. Donor factors including age and diabetes were additional risk factors for PTDM^[45]. Insulin resistance after transplant was associated with a pretransplant BMI > 30 kg/m², older age, increased triglycerides, HCV infection and steroid boluses^[10].

Post transplant hypertension

Hypertension is another metabolic component with a higher standardized prevalence ratio in liver transplant recipients compared to the general population^[36]. Immunosuppression appears to have a profound effect in this setting. CNIs are known to increase sympathetic tone, result in vasoconstriction and cause sodium dependent volume expansion^[68]. Hypertension was observed less often with tacrolimus than with cyclosporine^[37,38,56,58,69]. Additionally, changing CNIs from cyclosporine to tacrolimus resulted in decreased rates of hypertension^[70,71]. Hypertension is observed with corticosteroid use^[49]. However, decreasing rates of hypertension with steroid sparing immunosuppression regimens were seen in a series using cyclosporine^[54,57] but not observed in series using tacrolimus^[50,51].

Post transplant dyslipidemia

Unlike diabetes and hypertension, the rate of hyperlipidemia was not found to be higher in persons after liver transplant compared to the general population^[36]. The definition of hyperlipidemia varied widely in studies and few used NCEP-ATP III definitions for dyslipidemia. This is important as one study found the rate of hypertriglyceridemia to be higher than that of elevated cholesterol after transplant^[72]. Although the absolute rate of hyperlipidemia after transplant may not be elevated compared to the general population, various risk factors

and choice of immunosuppressive agent may influence the prevalence of hyperlipidemia. Pretransplant hepatocellular disease and posttransplant renal dysfunction were found to be associated with hypertriglyceridemia after transplant^[72]. With regard to immunosuppressive agent, cyclosporine was associated with more hyperlipidemia^[38,56,69,73,74] and hypertriglyceridemia^[38] compared to tacrolimus. Additionally, changing from cyclosporine to tacrolimus improved hyperlipidemia in multiple series^[37,70,71]. The reason for this effect with cyclosporine could be related to inhibition of bile salt synthesis resulting in hyperlipidemia^[75]. Long term corticosteroid use may additionally contribute to hyperlipidemia^[57,76]. Steroid free or sparing regimens were associated with improved lipid levels^[52,53], including less hypertriglyceridemia in one series^[51]. Sirolimus, an agent used either in conjunction or in place of a CNI, is associated with high rates of dyslipidemia. With sirolimus, dyslipidemia was observed in 55% of patients, the majority of which required therapy^[77]. This finding observed with sirolimus use might result from changes in insulin signaling pathways resulting in excess triglyceride production and secretion^[78]. Rates of dyslipidemia were less when sirolimus was combined with tacrolimus compared to cyclosporine^[79].

In summary, it appears that higher rates of the metabolic syndrome after transplant compared to the general population might be attributed to increased rates of PTDM and hypertension. Although obesity does not appear more prevalent in post transplant populations, weight gain after transplant is pervasive. These findings could lead to a two-fold plan to reduce the metabolic syndrome after transplant. The first would be prevention of excess weight gain through behavioral changes that could start before transplant and continue afterward. The second would be focusing on immunosuppressive strategies to lower rates of diabetes, hypertension and hyperlipidemia after transplant, especially in persons with multiple risk factors present prior to transplant.

PREVENTION AFTER TRANSPLANT

After transplant, patients have an improved functional capacity and can perform tasks independently^[80]. The use of a structured exercise program increased exercise capacity and fitness for the first six months after transplant followed by a plateau^[81]. The improvement in fitness was three times greater than expected in a sedentary person undergoing a similar training regimen. Multiple studies have shown that although exercise performance improved after transplant, it remained lower than predicted values for age matched controls^[5,81,82]. Despite the improvement in fitness and quality of life, many persons after transplant remain sedentary^[81,83]. Only a quarter of persons were found to be physically active after transplant, and those that were physically active had less hypertension and decreased BMI^[83]. Clearly there is a role for programs dedicated to increase physical activity after transplant. There are little data regarding nutritional composition

and caloric intake after transplantation. Up to two thirds of subjects were found to have more than recommended energy intake^[84]. Overall, more data is required to assess the contribution of caloric intake to weight gain after transplant.

There is very limited data regarding behavioral changes and exercise therapy after liver transplantation. A single randomized trial evaluated the effects of exercise and dietary counseling after transplantation. An improvement in cardiorespiratory fitness and quality of life was reported in the intervention group, but no changes were noted in body composition or muscle strength^[82]. There was a trend toward improved body composition in the 37% of subjects that adhered to the intervention^[82]. There are no data regarding the impact of an exercise program on the prevalence of the metabolic syndrome or singular components after transplant. Behavioral therapy after transplant represents an area with vast potential for important research. It is additionally important to note that the primary goal of intervention in this setting should be the prevention of weight gain immediately after transplant as opposed to the treatment of the metabolic syndrome once present.

Additional therapies for weight loss have been tried after transplant. A study using orlistat found a reduction in waist circumference, but not body mass index in a small group of patients^[85]. Concern over interference with the absorption of immunosuppression limited the use of this agent. Bariatric surgery at the time of transplant and in the post transplant period was described in case reports^[86,87]. However, bariatric surgery should be done in a way that preserves access to the biliary system and to minimize interference with the absorption of immunosuppression. As a result of these obvious pitfalls, bariatric surgery during and after liver transplant has not been widely performed.

CONCLUSION

The transplant population is aging and, consistent with the overall population, becoming more often overweight or obese. Immunosuppression likely contributes to an increased prevalence of the metabolic syndrome in liver transplant recipients, especially through increased rates of diabetes and hypertension. These features make it likely that the metabolic syndrome after transplant will become more prevalent. A number of preventative measures could be considered to reduce the burden of the metabolic syndrome in liver transplant recipients.

Patients should be screened for risk factors for post transplant metabolic syndrome at the time of transplant evaluation. Consistent risk factors include diabetes, obesity and cirrhosis from NAFLD. When assessing obesity, screening for the highest lifetime BMI may be beneficial. Identification of at risk patients will allow special focus on preventive effort after transplant.

Although there are no data supporting a definitive increase in risk resulting from the choice in calcineurin

inhibitor, immunosuppression is modifiable. Minimization of corticosteroid use, possibly in conjunction with induction agents, appears to be beneficial in reducing components of the metabolic syndrome. The choice of CNI could be individualized based on the presence of components of the metabolic syndrome prior to transplant. For example, tacrolimus may be a better agent for someone with long standing pretransplant hypertension.

Consideration should be given for early eradication of hepatitis C, especially in those persons at risk for post-transplant diabetes.

Preventative efforts through behavioral changes should be made before and after transplant. At minimum, improved fitness prior to transplant is associated with better survival. After transplant, a multidisciplinary approach with increased activity, diet modifications and behavioral therapy should be explored. Since the metabolic syndrome develops early after transplant, intervention should begin as soon as medically feasible.

Abstract

Fibrosis is a chronic and progressive process characterized by an excessive accumulation of extracellular matrix (ECM) leading to stiffening and/or scarring of the involved tissue. Intestinal fibrosis may develop in several different enteropathies, including inflammatory bowel disease. It develops through complex cell, extracellular matrix, cytokine and growth factor interactions. Distinct cell types are involved in intestinal fibrosis, such as resident mesenchymal cells (fibroblasts, myofibroblasts and smooth muscle cells) but also ECM-producing cells derived from epithelial and endothelial cells (through a process termed epithelial- and endothelial-mesenchymal transition), stellate cells, pericytes, local or bone marrow-derived stem cells. The most important soluble factors that regulate the activation of these cells include cytokines, chemokines, growth factors, components of the renin-angiotensin system, angiogenic factors, peroxisome proliferator-activated receptors, mammalian target of rapamycin, and products of oxidative stress. It soon becomes clear that although inflammation is responsible for triggering the onset of the fibrotic proc-

ess, it only plays a minor role in the progression of this condition, as fibrosis may advance in a self-perpetuating fashion. Definition of the cellular and molecular mechanisms involved in intestinal fibrosis may provide the key to developing new therapeutic approaches.

INTRODUCTION

Fibrosis is a chronic and progressive process characterized by an excessive deposition of extracellular matrix (ECM) components, such as collagens. It is believed to follow chronic tissue inflammation and ultimately leads to organ scarring and subsequent loss of function. Fibroproliferative disease may affect almost all tissues and organs, including the skin, kidneys, lungs, cardiac and vascular systems, eyes, liver, pancreas and intestine. Tissue fibrosis is a leading cause of morbidity and mortality. It has been estimated that 45% of deaths in the United States can be attributed to fibrotic disorders^[1].

Intestinal fibrosis is usually considered to be a com-

mon complication of several enteropathies with distinct initiating pathophysiology, such as inflammatory bowel disease (IBD), radiation enteropathy, graft-versus-host disease, collagenous colitis, eosinophilic enteropathy, drug-induced enteropathy, sigmoid diverticulitis, solitary rectal ulcer, cystic fibrosis, intra-peritoneal fibrotic adhesions, desmoplastic reaction in gastrointestinal tumors (familial adenomatous polyposis-FAP), desmoid tumors, gastrointestinal (GI) stromal tumors (GISTs) and post-surgical intestinal adhesions and strictures leading to intestinal stenosis and obstruction^[1-3].

Of these enteropathies, IBD is the main cause of intestinal fibrosis since this disease is characterized by a persistent immuno-mediated intestinal inflammation. In IBDs, both ulcerative colitis (UC) and Crohn's disease (CD), fibrosis follows the distribution and location of inflammation. In UC, the deposition of ECM is restricted to the mucosal and submucosal layers of the large bowel. In CD, fibrosis can involve the entire bowel wall of the GI tract including the mucosa, submucosa, muscularis mucosa, muscularis propria and serosa layers^[2]. The increase of ECM in the tissue, with collagens and fibronectins being the major components, can ultimately lead to development of intestinal strictures and obstruction. Fibronectin has been shown to co-localize with aggregations of fibroblasts^[2]. Intestinal strictures may be composed of a combination of fibrosis and inflamed tissue. In CD, these may occur anywhere in the GI tract, but most frequently affect the terminal ileum. The increased rate of clinical complications related to small bowel fibrosis in CD is likely related to the smaller diameter of the bowel lumen, rather than to more severe fibrosis.

Intestinal injury is almost invariably followed by an acute inflammatory response. This is usually followed, in turn, by physiologic healing of the damaged tissue and restoration of the normal structure and function of the intestine. If this does not occur, chronic inflammation can develop, characterized by continuous events of injury and repair that may lead to the development of fibrosis. Injury to the intestine is not an uncommon phenomenon, even in otherwise healthy individuals. In most instances, wound healing leads to normal restitution and resolution of the tissue damage. In IBD, it is still unclear which factor triggers the road to chronicity. In addition, once intestinal inflammation is chronic, it is not yet understood what sets the stage for the later development of intestinal strictures.

In contrast to the intensive investigations focusing on the immunological mechanisms related to the early phases of intestinal inflammation and repair, the pathophysiology of chronic mucosal wound healing and the late events of repair leading to fibrosis remain largely unexplored.

It appears to be widely accepted that chronic intestinal inflammation invariably leads to fibrosis. However, this process does not occur in all patients. Chronic intestinal inflammatory diseases exist, such as celiac disease or lymphocytic colitis, that are not complicated by fibrosis and stricture formation. These findings indicate that

distinct mechanisms of inflammation and restitution/fibrosis exist. It is crucial to explore this area since various pathways could be targeted separately, which would thus allow tailored treatment for wound healing abnormalities, especially in IBD.

Several lines of evidence suggest that inflammation is necessary to trigger the onset of the fibrotic process, but subsequently plays a minor role in progression of the disease^[1]. Anti-inflammatory treatment in IBD and in other chronic inflammation-associated fibrotic conditions in various organs (lung, liver, kidney) does not prevent evolution of fibrosis once the process of excessive ECM deposition has started. Mechanisms that regulate fibrosis, therefore, appear to be distinct from those regulating inflammation. The lack of efficient and well-tolerated anti-fibrotic drugs is partly due to the fact that the main and specific cellular and molecular pathways leading to fibrosis remain to be identified.

Various findings suggest that innate and adaptive immune mechanisms acting in chronic inflammation may divert the healing process towards fibrogenesis. A potential mechanism has been attributed to plasticity of the adaptive CD4 T cell immune response. Although CD4 T helper (Th) 1 and Th2 cells are reasonably stable after differentiation occurs, mature Th17 and Foxp3 regulatory T cells (Tregs) can transform into other subsets, i.e., exhibit plasticity^[4]. This appears to be driven by the transcription factors related orphan receptor (ROR) γ t for Th17 cells and Foxp3 for Treg cells. A potential escape mechanism could be the micro RNA system: small sequences of RNA that interact with genes and alter their transcription^[5]. Changes in microRNA expression, induced by biological treatment, may result in non-response to the therapeutic agents.

Fibrogenesis is a "physiological process" triggered by the onset of inflammation that may lead either to tissue repair or fibrosis depending on the balance between production of ECM proteins and enzymatic degradation. Intestinal fibrosis is related to the abnormal function of activated intestinal mesenchymal cells (proliferation, migration, contraction, ECM production) namely, ECM-producing cells or myofibroblasts. Myofibroblasts are activated by a variety of mechanisms including paracrine signals derived from immune and non-immune cells, autocrine factors secreted by myofibroblasts, and pathogen-associated molecular patterns (PAMPs) derived from micro-organisms that interact with pattern recognition receptors such as the toll-like receptors (TLRs)^[1]. The most investigated soluble factors that regulate the activation of the ECM-producing cells include cytokines [interleukin (IL)-6, IL-13, IL-17, IL-21, tumor necrosis factor (TNF)- α], chemokines [monocyte chemoattractant protein (MCP)-1, macrophage inflammatory protein (MIP)-1], growth factors [transforming growth factor (TGF)- β 1, connective tissue growth factor (CTGF), platelet derived growth factor (PDGF), insulin-like growth factor (IGF)-1 and 2, epidermal growth factor (EGF)], components of the renin-angiotensin (ANG) system (RAS), angiogenic

factors [e.g., vascular endothelial growth factor (VEGF)], peroxisome proliferator-activated receptors (PPARs), mammalian target of rapamycin (mTOR), and products of oxidative stress^[1]. All these molecules are being investigated as potential targets of anti-fibrotic drugs. Pharmacological modulation of tissue ECM deposition by reducing activated ECM-producing cells and their profibrogenic effects (proliferation, motility, contraction, ECM production) could be useful in the prevention and treatment of intestinal fibrosis^[1].

ECM degradation is mediated by the matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs). The fine balance between MMPs and TIMPs appears to be disturbed in chronically impaired wound healing in IBD. It is unclear which specific MMPs and TIMPs are involved and how they are regulated in this process. Nevertheless, effective pharmacological modulation of the MMP/TIMP-system could be helpful in the reversal of already established tissue fibrosis^[6].

In IBD, current therapeutic agents, mainly corticosteroids, aminosalicylates, immunosuppressants (e.g., azathioprine and methotrexate), and even the more recent biologic drugs, such as anti-TNF antibodies, can improve intestinal inflammation but seem unable to significantly improve fibrosis^[7-9]. Surgical correction, by means of intestinal resection or stricturoplasty, is necessary in up to 75% of CD patients during the course of their disease^[10-12]. However, surgical resection is associated with a high rate of recurrent stricturing disease and the need for repeated surgery is high; therefore, exploration of new therapeutic approaches has now become mandatory^[11,13,14].

RELATIONSHIP BETWEEN INFLAMMATION AND FIBROSIS

Wound healing is an important biological process that allows the replacement of dead or damaged cells after tissue injury and involves a *regenerative phase*, where injured cells are replaced by cells of the same type, thus leaving no evidence of damage, and a phase known as *fibroplasia*, where normal parenchymal tissue is replaced by the deposit of new ECM components^[1].

In physiological conditions, the normal turnover of ECM, in each tissue, is regulated by several factors that influence synthesis and degradation. Indeed, under normal physiological conditions, continuous ECM remodeling occurs consisting of the production and balanced degradation of ECM components^[15]. Myofibroblasts are the predominant mucosal cells that synthesize components of the ECM and ECM breakdown is mediated by proteolytic enzymes derived from various cell types of which the MMP family represent a large and important component^[15,16].

Fibrosis is progressive but considered reversible. Several studies have shown that fibrosis may progress independently of inflammation^[1,15].

The inflammatory process may be acute or chronic based on its duration and the cells involved. Acute in-

flammation is a rapid response to injurious agents while chronic inflammation is a process of prolonged duration in which the inflammatory cascade lasts for weeks or months and under certain circumstances a lifetime^[15].

During a chronic inflammatory process, the physiological sequence of events related to inflammation (coagulation cascade, inflammatory response, and fibroproliferative response) is activated for a prolonged time period. If the network of negative feedback mechanisms that terminate the proliferative and fibrotic response fails to operate, the healing process can become pathologic causing continuous activation of the fibroproliferative response and excess of ECM deposit that progressively leads to substantial changes in normal tissue architecture with loss of organ function^[1,15,17].

Inflammation is induced and sustained by an infiltrate of immune cells, such as T cells, macrophages and neutrophils in the intestinal mucosa, which determine tissue damage characterized through a loss of epithelial cells and degradation of ECM in the lamina propria leading to the formation of ulcerations. Subsequently, release of inflammatory mediators from damaged epithelial and/or endothelial cells leads to an anti-fibrinolytic-coagulation cascade and formation both of blood clots and a provisional ECM^[15,17,18].

Clotting releases thrombin, a potent inducer of platelet degranulation through which a vast store of bioactive mediators (including thromboxanes, prostaglandins, chemokines and cytokines) are secreted promoting further clot formation and stimulation of the inflammation process. Another consequence of platelet degranulation is the release of potent chemotactic and growth-promoting cytokines at the site of inflammation which enhances inflammatory responses by recruitment of immune cells and activation of immune and non-immune cells and the release of oxygen radicals, cathepsins and ECM-degrading enzymes. Neutrophils are the first cell type recruited and represent the most abundant inflammatory cell in the early stages of wound healing. Activated neutrophils degranulate, releasing inflammatory and pro-fibrogenic cytokines, and subsequently die followed by the recruitment of macrophages. During this initial leukocyte migration phase, the activated macrophages and neutrophils eliminate tissue debris, dead cells, and any invading organisms. They also produce cytokines and chemokines, which initiate and amplify the wound-healing response. These factors are also mitogenic and chemotactic for endothelial cells, which surround the injury and form new blood vessels as they migrate toward the center of the ulceration^[18].

When inflammation becomes chronic it induces myofibroblast activation that can determine an excessive accumulation of ECM, which promotes the formation of a permanent fibrotic scar. ECM consists of several molecular components including collagens (I-VI), elastin, glycoproteins, glycosaminoglycans and proteoglycans (Table 1). ECM is not an inactive structure, but directly regulates the inflammatory response and the process of healing and fibrosis by focal adhesion with immune and

non-immune cells as well as myofibroblasts^[19].

In summary, the events triggered by chronic injury that are involved in fibrogenesis are: (1) immediate damage to the epithelial/endothelial barrier; (2) release of chemokines and cytokines; (3) recruitment of inflammatory cells (immune and non-immune); (4) release of reactive oxygen species (ROS) and pro-fibrogenic cytokines and growth factors; (5) activation of ECM-producing cells; and (6) accumulation of ECM proteins.

Innate immune mechanisms

The causes leading to chronic intestinal inflammation in IBD are unknown. It has been suggested that, in genetically predisposed subjects, it could be the result of a dysregulated immune response to intra-luminal antigens, such as resident luminal bacteria, bacterial products, or dietary antigens: in a chronic defective mucosal barrier, the continuous exposure of lamina propria immune cells to the luminal antigens may trigger, amplify and maintain the local inflammation.

Genetic factors and luminal microbes, in addition to their role in triggering the IBD, are also directly, or indirectly, involved in the development of intestinal fibrosis in IBD.

The luminal bacteria express PAMPs, including lipopolysaccharide (LPS) components of bacterial cell walls, bacterial DNA, and double-stranded RNA, able to bind to pattern recognition receptors expressed by a wide variety of immune and non-immune cells, such as the extracellular TLRs and the intracellular nucleotide oligomerization domain/caspase recruitment domain (NOD/CARD)-like receptors^[20].

TLRs are expressed on immune cells as well as non-immune cells, and are involved in innate immunity by recognizing specific patterns of microbial components.

The TLR family, comprised of 10 members, are able to act as primary sensors of microbial products triggering a host defence response against invading pathogens and activating signaling pathways that induce the expression of immune and pro-inflammatory genes^[20].

Bacterial components induce the activation of an intracellular signaling cascade *via* TLRs that involves the preserved intra-cytoplasmic Toll/interleukin-1R (TIR) domain and TIR domain-containing adaptors, such as MyD88. A MyD88/interleukin-1 receptor-associated kinase signaling is thus generated, which regulates innate immunity and can strongly influence the course of the inflammatory response. An increased mucosal expression of TLRs in the intestine of patients with IBD has been reported^[21,22]. The TLR activation can be considered a pivotal event in the immunological response in IBD patients^[21], suggesting that over-expression of certain TLRs could be one of the underlying mechanisms leading to the abnormal host reaction to commensal bacteria, as seen in IBD^[22]. Another important aspect of this defective immune tolerance to commensal bacteria seems to be TLR polymorphisms. Various studies have demonstrated the correlation between *TLR4* polymorphisms, at Asp299Gly and Thr399Ile, and the development of IBD^[23,24]. Indirect evidence also suggests the involvement of an aberrant innate immune response in intestinal fibrogenesis. Antibodies directed against microbial peptides represent good serological markers that could help in the identification of fibrotic CD. Patients with a stronger immune response to microbial peptides are more likely to develop earlier complicated CD, including the earlier occurrence of fibrotic CD^[25,26].

Nevertheless, the exposure of subepithelial cells to bacterial ligands seems not only to lead to immune-mediated inflammation, but also to direct mesenchymal cell activation.

Studies performed on animal models of IBD have demonstrated not only the presence of TLRs in intestinal fibroblasts and the role of PAMPs in their activation, but have also revealed a close correlation between pathogen-mediated fibroblast activation and the progression of fibrosis. The TLR ligands could directly lead to differentiation of fibroblasts into activated myofibroblasts and TLR expression in non-immune cells can be considered another key event leading to tissue scarring and to the development of fibrosis^[27-29].

The role of TLRs in the fibrosis-promoting signals has been frequently observed in the liver in which hepatic stellate cells (HSCs), the main precursors of ECM-producing cells, are sensitized by TLR4 activation; this receptor is functionally expressed by HSCs and directly stimulates myofibroblasts to enhance TGF- β signaling^[30]. An increase of LPS during hepatic fibrogenesis induces a TLR4-mediated downregulation of bone morphogenetic protein and activin membrane-bound inhibitor (BAMBI), a pseudoreceptor that decoys TGF- β by lacking an intracellular kinase domain^[30,31]. Thereby, the TLR4-MyD88-dependent downregulation of BAMBI induces an unrestricted activation of the TGF- β pathway in HSCs. The LPS-TLR4-MyD88 signaling cascade results are thus closely linked with TGF- β -mediated collagen deposition and promotion of liver fibrosis^[29,30].

The role of TLRs has been investigated in the dam-

aged tissue of several organs, including the intestine, even if their involvement in fibrogenic progression has not been completely elucidated.

An increased expression of TLR 2, 3, 4, 6 and 7 has been observed in the intestinal fibroblasts isolated from patients with CD^[21,22,32]. These receptors are activated by their respective microbial ligands and promote the differentiation of fibroblasts into collagen-producing myofibroblasts to induce a fibrogenic response^[32]. In addition, an increased production of fibronectin and upregulated levels of α -smooth muscle actin (α -SMA) in human intestinal myofibroblasts exposed to TLR ligand have been reported, thus confirming the pro-fibrogenic activity of TLRs and the direct link between bacterial innate immunity and intestinal fibrosis in IBD in man^[33]. Furthermore, TLR activation of gut myofibroblasts induces an increased secretion of CXC chemokine ligand 8, a ligand that was initially characterized as a neutrophil chemotactic factor, but seems to exhibit both an angiogenic and angiostatic activity that can lead to the progression of intestinal fibrosis^[34].

Another key factor able to activate an innate immune response by intracellular recognition of PAMPs of selected microorganisms is NOD2, an intracellular peptidoglycan receptor for muramyl dipeptide encoded by the *NOD2/CARD15* gene present on chromosome 16. *NOD2/CARD15* polymorphisms seem to be, in part, involved in the pathogenesis of CD. Considerable evidence confirms, indeed, a relationship between the mutation of *NOD2/CARD15* genes and CD, either alone or in combination with mutation of *TLR* (especially *TLR4*) or *ATG16L1* (an autophagy gene)^[35].

The major *NOD2/CARD15* polymorphisms associated with CD are Arg702Trp, Gly908Arg and Leu1007fsinsC and these appear to produce defects in the host defence response against invading bacteria that can lead to a persistent intracellular infection with chronic stimulation of inflammatory cells^[36]. NOD2 is present in several cell types such as monocytes and macrophages where it seems to decrease the TLR-induced production of pro-inflammatory Th1 cytokines^[37]. NOD2 is also expressed in Paneth cells. A correlation between *NOD2/CARD15* mutations and the downregulation of mucosal α -defensin has been repeatedly proven^[38,39]. Furthermore, NOD2 can induce autophagy by recruiting the critical autophagy protein ATG16L1 on the plasma membrane during bacterial internalization.

In addition, there is a growing body of evidence proving that the main *NOD2/CARD15* variants are closely related to ileal disease, a stenosing phenotype and to a greater need for abdominal surgery in CD patients^[26]. Cells carrying *NOD2* variants show an enhanced pro-inflammatory response to various intestinal microbes and lead to an increased TGF- β production and collagen deposition by T cells^[40]. All these findings provide evidence that may encourage the clinical use of *NOD2/CARD15* genotyping, both as a marker of CD and as a prognostic factor of the need for early surgery due to stricturing and

fibrostenosing disease^[26].

IBD, however, is a polygenetic disease. The development of genome-wide association scanning technologies has led to the discovery of more than 100 confirmed IBD loci^[41-43]. Some, such as the Th 17 pathway genes (*IL23R*, *IL12B*, Janus kinases 2 (*JAK2*), signal transducers and activators of the transcription 3 (*STAT3*), are shared between CD and UC, others are phenotype-specific (autophagy genes such as *ATG16L1*, *IRGM* and *NOD2* for CD; epithelial barrier genes *HNF4a*, *E-Cadherin*, *LAMB1* and *IL-10* for UC). Variants of some of these genes would also be excellent candidates involved in the development of fibrosis in IBD^[44-46].

Most studies have focused on the involvement of non-immune cell types in the progression of fibrosis in IBD, including mesenchymal cells (smooth muscle cells, fibroblasts, myofibroblasts), epithelial cells, nerve cells and platelets^[47-49]. In addition, mucosal microvascular cells play a central role in the microcirculation regarding the onset and maintenance of IBD^[47]. Much evidence indicates that neoangiogenesis, the growth of blood vessels from those already present, plays a crucial role in IBD^[48]. The microcirculation and endothelial cells perform a crucial task in intestinal immune homeostasis: endothelial cells regulate the type and the number of leukocytes that migrate from the blood flow to the interstitial space and specialized vascular cells, such as those found in the endothelium of venules, control selectively the influx of a specific subset of T-cells^[49].

Despite the evidence regarding the role of endothelial cells and neoangiogenesis in the inflammatory process, very limited data are available on their role in intestinal fibrosis.

CELLULAR MECHANISMS

The key event that leads to the development of intestinal fibrosis is not only recruitment of immune and inflammatory cells, but also the exposure of mesenchymal cells to a variety of inflammatory mediators that are able to maintain these cells in a persistent state of trans- and de-differentiation between fibroblasts, myofibroblasts and smooth muscle cell phenotypes. All mesenchymal cell types can directly or indirectly contribute to intestinal fibrosis by producing large amounts of ECM proteins with different architectural and barrier functions, and are able to regulate several growth factors acting in a paracrine and autocrine fashion^[50-52]. Each single mesenchymal cell type can be identified by the expression of specific cellular markers, as reported in Table 2.

Several conditions (such as ischemia, radiation, chemicals, microbes, products of oxidative stress, drugs, autoimmunity and allergies) promote the release of inflammatory mediators during tissue injury, leading to activation of mesenchymal and non-mesenchymal cells that produce ECM, also referred to as ECM-producing cells (Figure 1).

Cellular processes that lead to abnormal wound healing are mainly represented by activation (proliferation,

Table 2 Cell types involved in intestinal fibrosis

Cell type	Positive markers
Fibroblasts	Vimentin, FSP-1, N-cadherin (high), collagen type I, prolyl 4-hydroxylase
Intestinal subepithelial myofibroblasts	Vimentin, α -SMA, cadherin-11, FSP-1, collagen type I
Interstitial cells of Cajal	Vimentin, c-Kit receptor
Smooth muscle cells	Vimentin (low), α -SMA, Desmin, collagen type I
Stellate cells	Vitamin A, GFAP, α -SMA
Pericytes	α -SMA, desmin (low), MCSP, RGS5, PDGFR- β , CD80, CD86, CD 13, CD90
Epithelial cells	ANG I and II, ET-1, collagen type I
Endothelial cells	E-cadherin, cytokeratins, CD31, vWF, VE-cadherin, N-cadherin (low), vimentin (low)
Bone marrow stem cells	
Hematopoietic stem cells	CD45, CD34, CD14
Mesenchymal stem cells	CD105, CD73, CD44, CD71, CD90
Fibrocytes	CD45, CD34, CD11, CD13, CD14, CD80, CD86, collagen type I, α -SMA

FSP-1: Fibroblast specific protein 1; MCSP: Melanoma chondroitin sulfate proteoglycan; RGS5: Regulator of G protein signaling-5; GFAP: Glial fibrillary acidic protein; α -SMA: α -smooth-muscle actin; VE-cadherin: Vascular endothelial cadherin; vWF: von Willebrand factor; cKit: Tyrosine-protein kinase kit or CD117; ANG I and II: Angiotensin I and II; ET-1: Endothelin-1; CD: Cluster of differentiation. High and low indicate level of expression.

migration, contraction, ECM production) of fibroblasts and myofibroblasts. Nevertheless, it has become clear that the cellular source of the ECM proteins not only involves mesenchymal cells, such as fibroblasts, myofibroblasts and smooth muscle cells, but also other cell populations, such stellate cells, pericytes, as well as bone-marrow and intestinal stem cells^[15,50]. Recently, it has also been observed that myofibroblasts may derive from non-mesenchymal cell transformation such as epithelial-to-mesenchymal transition and endothelial-to-mesenchymal transition^[51].

Fibroblasts

Fibroblasts are a heterogeneous population of cells present in the interstitium of all normal tissues and organs where they play a pivotal role in maintaining structural integrity, regulating matrix homeostasis and taking part in healing and regenerative processes and/or in pathogenesis of scarring.

An acute injury or acute inflammation can launch activation of fibroblasts driving them towards a fibrogenic phenotype. This activated fibroblast can be engaged either in normal wound healing or fibrosis. Fibroblast activation is characterized by a post-transcriptional or post-translational up-regulation of ECM secretion.

Fibroblasts co-express vimentin, fibroblast-specific protein 1 (FSP-1, S100A4), N-cadherin, and prolyl 4-hydroxylase (Table 2).

The increase in the resident fibroblast population is

a pivotal mechanism for the development of intestinal fibrosis. Several growth factors found in the inflamed gut, such as IGF- I , basic fibroblast growth factor (bFGF), EGF, CTGF, PDGF, and pro-inflammatory cytokines, such as interleukins (IL-1 β , IL-6) and TNF- α , increase their proliferation rate^[27].

TGF- β 1, one of the most potent profibrogenic factors, shows a bifunctional role in fibroblast proliferation with either growth stimulation or growth inhibition and blocking of cell differentiation depending upon the concentration used or the organ from which the cells are derived^[51,52]. TGF- β 1 can also act in an indirect mode by up-regulation of the PDGF receptor, increasing synthesis of CTGF and promoting expression of IGF- I , all factors that directly affect proliferation^[15,53,54].

Another mechanism that further increases the number of activated fibroblasts is the migration from non-affected tissue areas into and through the surrounding ECM, under the effect of a chemotactic gradient (chemotaxis) or with active random movement (chemokinesis) to the wound area. In the intestine, the cell migration is generally an essential factor for physiological wound repair, and is a fundamental process during the progression of pathological conditions such as fibrosis in IBD. Migration of fibroblasts can be induced by autocrine stimuli, like fibronectin, and paracrine factors, such as PDGF-AB, IGF- I , EGF and TGF- β 1, all of which appear to be fibronectin-dependent^[51,55,56]. Mediators of active inflammation, such as TNF- α , IFN- γ or PGE2, can inhibit fibroblast migration further indicating distinct mechanisms of inflammation and fibrogenesis^[57,58].

Myofibroblasts

Myofibroblasts represent a highly contractile cell type that is thought to be critical for tissue repair and the pathogenesis of fibrogenetic diseases^[59,60]. These cells exhibit a “hybrid” phenotype between fibroblasts and smooth muscle cells and, when activated, synthesize high levels of ECM, particularly collagen, glycosaminoglycans, tenascin and fibronectin^[61]. Besides their normal activities in growth and differentiation of tissues, the myofibroblasts play a central role in wound healing. During normal wound repair of a tissue injury, a closely regulated sequence is induced, including activation and proliferation of myofibroblasts that are present in the wound bed where they play essential roles in wound contraction and connective tissue restoration, e.g, through the production of ECM and basement membrane molecules^[11,15,17].

Myofibroblasts can also play a role in the up- or down-regulation of the inflammatory response by the secretion both of chemokines and cytokines^[11,17]. When these processes are not controlled, deranged, or repeated, as occurs in several fibroproliferative diseases, the normal resolution stages are abrogated and the proliferation of myofibroblasts continues, inducing excessive accumulation of the ECM and leading to alterations in the tissue architecture and ultimately to organ failure. Therefore, fibrotic disease is a major pathological end point of activated and proliferating

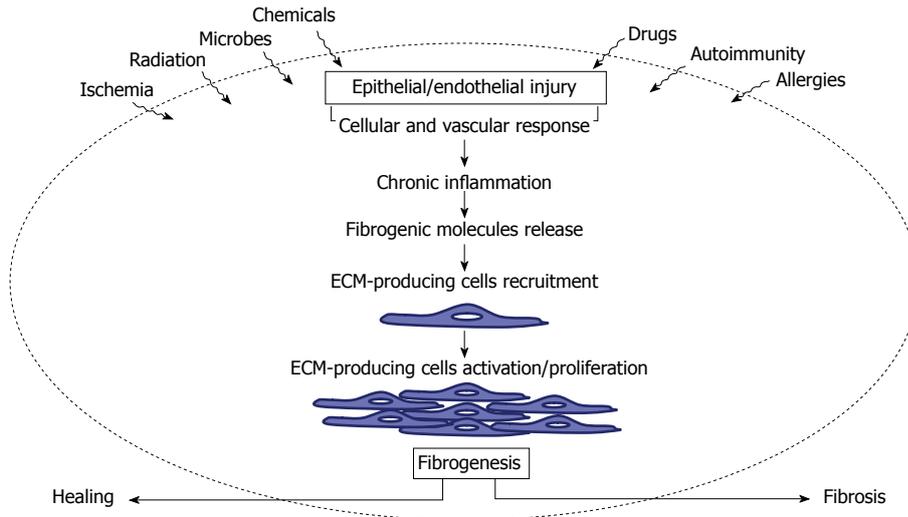

Figure 1 Mechanisms of fibrogenesis. Inflammatory response to tissue damage promotes the release of fibrogenic molecules. These molecules increase activation and proliferation of ECM-producing cells. ECM: Extracellular matrix.

erating myofibroblasts in most, if not all, tissues^[1,17].

Myofibroblastic cells contain smooth muscle cytoskeletal markers (in particular α -SMA) together with three filaments (vimentin, desmin or myosin), with variable expression depending on tissue, species and environmental factors^[61,62]. Based on immunohistochemical staining of these filaments in a given tissue, a classification system has been proposed^[61,62]. Myofibroblasts that express only vimentin (V-type myofibroblasts), those that express vimentin and desmin (VD-type), those that express vimentin, α -SMA and desmin (VAD-type), those that express vimentin and α -SMA (VA-type), and those that express vimentin and myosin (VM-type)^[61,62].

Two types of myofibroblasts are present in the intestinal mucosa in physiological conditions, the interstitial cells of Cajal (ICC) and the intestinal sub-epithelial myofibroblasts (SEMFs)^[61,62].

ICC are located in the submucosa and muscularis propria in association with the smooth muscle layer of the gut, while SEMFs are mainly located at the base of the intestinal crypts in the lamina propria. ICC are pacemaker cells which regulate gastrointestinal smooth muscle motility, facilitate the propagation of electrical events and modulate neurotransmission^[63]. ICC express vimentin and the c-Kit receptor (Table 2).

SEMFs, also called pericryptal fibroblasts, are a syncytium of α -SMA-positive mesenchymal cells, which reside subjacent to the basement membrane of the small and large intestines^[61,62]. SEMFs form a three-dimensional network and are in connection with each other by gap and adherent junctions, but also maintain connections with epithelial cells through fenestrations in the basement membrane; they also interact with intestinal macrophages. SEMFs express α -SMA and vimentin suggesting that they are members of the VA class of myofibroblasts. They may also express smooth muscle myosin (and thus may be referred to as VAM-type myofibroblasts), although the expression of myosin is less than that ob-

served in the corresponding smooth muscle cells in the same tissue^[61,62].

It is unknown whether SEMFs and ICC differentiate from a common precursor. Instead, it has been clearly demonstrated that mediators which act on myofibroblasts, promoting their proliferation and ECM production, are numerous and include: PDGF, EGF, IGF-1 and 2, CTGF, IL-1, IL-13, stem cell factor (SCF), endothelins (ET-1, -2, -3), ANG II, TGF- α , TGF- β , bFGF and PPAR γ ; these factors are all relevant for the transdifferentiation of fibroblasts to myofibroblasts^[15].

Smooth muscle cells

In physiological conditions when there is a need for replacement of connective tissue following injury, the production of collagen is devolved to cells of mesodermal origin. Other cells do not synthesize collagen or may produce only minute quantities; however, under abnormal stimuli collagen expression may become considerably enhanced in these cells^[61,62]. Airway smooth muscle cells (SMCs) appear to play an important role in controlling and perpetuating airway inflammation and fibrosis in chronic airway diseases^[64].

SMCs are one of the three interrelated cell phenotypes into which intestinal mesenchymal cells can differentiate (the other two being fibroblasts and myofibroblasts) and are mainly identified by α -SMA, desmin and collagen type I^[27] (Table 2).

Several studies have shown that SMCs are an important cellular component of IBD. In UC, their behavior leads to a considerable thickening of the muscularis mucosa and, in CD, to a remarkable thickening of the bowel wall, with subsequent stricture formation and obstruction. These cells actively contribute to the development of fibrosis in IBD by inducing production of collagen and MMPs in response to several inflammatory mediators, such as TGF- β and IL-1 β . SMCs are also able to release significant amounts of IL-6, contributing to the

inflammatory process^[65].

Stellate cells

Stellate cells were initially described in the liver as mesenchymal cell precursors important in retinoic acid metabolism, where they represent the site of fat or vitamin A storage. Thereafter, the important contribution of these cells to hepatic and pancreatic fibrosis has been shown^[66,67].

These cells are identified through the expression of vitamin A, glial fibrillary acidic protein (GFAP) and α -SMA (Table 2).

In the liver, it has been clearly shown that HSCs are the main contributors to fibrogenesis. Acute or chronic inflammation can promote activation of HSCs through transdifferentiation from quiescent vitamin A-rich cells into myofibroblast-like cells with strong proliferative, fibrogenic and contractile ability. Moreover, the presence of stellate cells has been detected also in other organs, such as the pancreas, gut, lung, uterus, kidney and deferent duct, even if their functions remain to be fully elucidated^[51,66,67].

Interestingly, there is very limited information regarding intestinal stellate cells, although recently these have been isolated and cultured from the human intestinal mucosa^[51]. In IBD, these cells show a higher proliferation rate, faster differentiation into myofibroblasts, and an earlier and higher collagen production than those from the normal non-IBD mucosa^[51].

Pericytes

Pericytes are cells derived from non-differentiated mesenchymal cells. They surround the endothelial cells of capillaries and small blood vessels.

Pericytes stain positive for α -SMA, desmin, melano-ma chondroitin sulphate proteoglycan, platelet-derived growth factor receptor (PDGFR)- β , and regulator of G protein signaling-5. Pericytes also express costimulatory molecules such as CD80, CD86, CD13 and CD90, suggesting that they may be replenished by circulating fibrocytes. Furthermore, pericytes can express ANG I and II, endothelin-1 and collagen type I (Table 2). The pattern of these pericyte markers differs according to the type of vessel, organ and also pathological condition.

Pericytes control endothelial cell differentiation, endothelial signaling, angiogenesis and ECM degradation. These multiple functions can be exerted due to their location between the interstitium and endothelium^[68]. Moreover, on account of their intermediate phenotype between vascular-SMC and fibroblasts, pericytes represent a useful reserve of fibroblasts during wound healing and are, therefore, considered an excellent contributor to inflammation-associated fibrosis on account of their ability to differentiate into collagen-producing fibroblast-like cells^[51]. Pericytes increase the deposition of ECM proteins in proximity to the blood vessels during the initial phase of fibrotic processes. In addition, the involvement of pericytes in intestinal fibrogenesis has been recently

highlighted, even if their contribution remains to be defined^[51].

Epithelial and endothelial cell transformation

The main fibrogenic cells (fibroblasts, myofibroblasts) may also derive from non-mesenchymal cells, including epithelial and endothelial cells, *via* transformation.

Epithelial-to-mesenchymal transition (EMT) or endothelial-to-mesenchymal transition (EndoMT) is a key process in tissue development, carcinogenesis and organ fibrosis, and is characterized by dramatic changes in cell phenotype and function. Both are a consequence of disruption of the local basement membrane, loss of epithelial cell adhesion, reprogramming of the signaling machinery, *de novo* synthesis of α -SMA, rearrangement of cytoskeletal proteins and transmigration of the epithelial cells through the basement membrane into the interstitial space^[69]. Epithelial or endothelial cells assume a spindle-shape morphology, lose classical cell markers and gain typical fibroblast or myofibroblast markers, such as FSP-1, α -SMA or vimentin, and show the capacity to produce interstitial collagens and fibronectin (Table 2). All these changes are due to the high plasticity of epithelial and endothelial cells. Therefore, these cell types can be considered a multipotent progenitor tissue, which can display alternative developmental pathways following injury.

Recent data on the contribution of EMT and EndoMT in intestinal fibrosis are now available. It has been shown in animal models and in human primary cells that EMT and EndoMT can contribute to intestinal fibrogenesis^[70,71].

Bone marrow and intestinal stem cells

Stem cells are a non-differentiated cell type that do not increase in number but generate a range of differentiated progeny that may continue to be divided *via* a process of clonal growth. They are also defined as non-specialized cells that reside in a particular tissue and renew themselves thus becoming capable of producing all the specialized cell types of the tissue^[72].

Reserves of adult stem cells include the bone marrow, blood stream, cornea and retina, dental pulp, liver, skin, gastrointestinal tract and pancreas. Bone marrow contains hematopoietic and mesenchymal stem cells, which are able to migrate to the majority of organs and differentiate into various cell types. These cells may represent a source of fibroblasts during inflammatory and fibrotic disease; indeed, stem cells can migrate from the bone marrow to sites of injury, during pathological conditions, and differentiate to mesenchymal cells able to express tissue connective proteins^[73].

While HSCs give rise to 3 classes of blood cells (leukocytes, erythrocytes and thrombocytes), and are characterized by several specific markers, including CD45, CD34 and CD14, the mesenchymal stem cells (MSCs) are multipotent and can differentiate into several cell types such as osteoblasts, chondrocytes, myocytes and myofibroblasts. MSCs express CD105, CD73, CD44, CD71 and CD90. Both HSCs and MSCs express vimentin, che-

mokines and chemokine receptors, adhesion molecules and integrins^[74].

A class of bone marrow-derived cells that become progenitors for mesenchymal cells is represented by fibrocytes that circulate in the peripheral blood. These cells appear to be involved in intestinal repair and fibrosis in IBD^[50,51,73,74]. Fibrocytes express hematopoietic markers (CD45, CD34, CD11, CD13, CD14, CD80, CD86), as well as collagen I and α -SMA^[27,51,74-76] (Table 2).

The ability of fibrocytes to differentiate into fibroblasts and contractile myofibroblasts has been highlighted. This leads to the production of ECM components and ECM-modifying enzymes by differentiated fibrocytes that migrate to the affected tissues during both normal tissue repair and inflammatory fibrotic processes. Under physiological conditions, fibrocytes, after their maturation in the bloodstream, may contribute to the local population of macrophages and dendritic cells, whereas during an inflammatory process, numerous fibrocytes differentiate into mesenchymal cells synthesizing ECM. This behavior demonstrates the close relationship between fibrocyte proliferation, migration and differentiation, as well as tissue fibrogenesis^[27].

Fibrocyte functions that lead to tissue fibrosis are modulated by IL-1, TGF- β and serum amyloid P (SAP), a serum protein that inhibits the maturation process in the circulation but promotes differentiation of fibrocytes within the tissue^[75]. Furthermore, fibrocytes themselves produce growth factors, such as CTGF and TGF- β , inflammatory cytokines and chemokines, that in turn promote the proliferation of resident fibroblasts and their differentiation into myofibroblasts^[75].

The contribution of fibrocytes to tissue damage and progression of fibrosis has been shown in several pathological conditions, including asthma, nephrogenic fibrosis, systemic sclerosis, atherosclerosis, chronic pancreatitis, chronic cystitis and tumor-associated stromal reactions^[77].

Another aspect of intestinal fibrosis under investigation is the presence and the involvement of local stem cells in the fibrotic process. Undifferentiated intestinal stem cells (ISCs) give rise to daughter or progenitor cells, which can subsequently differentiate into mature cell types such as columnar cells, goblet cells, neuroendocrine cells and Paneth cells^[72,74,76].

Differentiation of ISCs is induced by various transduction pathways and appears to be involved in the pathogenesis of IBD^[78]. It has been highlighted that a potential mechanism linked to the development and progression of Crohn's disease is the differentiation of ISCs into Paneth cells^[78]. These cells produce different broad spectrum antimicrobial peptides, principally the α -defensins HD-5 and HD-6. In small intestinal Crohn's disease, both these Paneth cell products are specifically reduced. Mechanisms for defective antimicrobial Paneth cell function are complex due to the impaired functions of various pathways including the NOD2, Wnt pathway transcription factor TCF7L2 (also known as TCF4), autophagy factor ATG16L1, endosomal stress protein XBP1, toll-like receptor TLR9,

calcium-mediated potassium channel KCNN4, as well as to the inactivation of HD-5.

A better understanding of all these mechanisms may lead to the development of new therapeutic approaches for the prevention and/or treatment of intestinal fibrosis progression.

MOLECULAR MECHANISMS

Intestinal fibrosis results from the activation of a large variety of cell types that act synergistically and are exposed to an extremely complex microenvironment, under the control of various biological mediators, such as growth factors, cytokines, chemokines, proteolytic enzymes, complement components, vasoactive amines and peptides. The most important of these molecules include, specifically, TGF- β , activins, CTGF, PDGF, IGF-1 and 2, EGF, ET-1, -2, -3, RAS, various cytokines such as IL-1, -4, -6, -13, -17, -21, -22, -23, TNF- α , ROS, PPAR γ , mTOR, MMPs and TIMPs. All these molecules play an important role in the activation of the acute and chronic inflammatory response. In addition, they also regulate the fibrogenic processes stimulating ECM accumulation, independently of inflammation^[1,15,27], acting in autocrine, paracrine, or endocrine pathways. All these profibrotic molecules may be considered as a target for new antifibrotic treatment approaches.

TGF/Smad proteins

Studies on transgenic mice over-expressing TGF- β have revealed the development of fibrosis in several organs, including skin, kidney, lung, heart, blood vessels, liver, pancreas and intestine^[15].

TGF- β is a multifunctional polypeptide hormone acting in essentially all cells, influencing distinct functions including proliferation, differentiation, apoptosis, immunoregulation, regulation of the inflammatory response, restitution and healing, as well as fibrosis^[79]. At a cellular level, TGF- β affects virtually all stages of the chronic inflammatory and fibrotic disease processes.

The profibrotic effects of TGF- β are numerous, including influx and activation of ECM-producing cells, as well as promoting EMT and EndoMT. The biological action of TGF- β that contributes to several fibrotic diseases is the regulation not only of the synthesis but also the breakdown of ECM proteins, including collagens, fibronectins and proteoglycans^[27].

Multicellular organisms present more than 60 TGF- β family members. These include 3 TGF- β s, 5 activins and at least 8 bone morphogenetic proteins (BMPs), all encoded by distinct genes. The three mammalian TGF- β isoforms, TGF- β 1, 2 and 3, are secreted as latent precursor molecules (LTGF- β) containing an amino-terminal hydrophobic signal peptide region, the latency associated peptide (LAP) region and the C-terminal potentially bioactive region. The LTGF- β is usually linked to latent TGF- β -binding proteins (LTBP), requiring activation into a mature form for receptor binding and subsequent

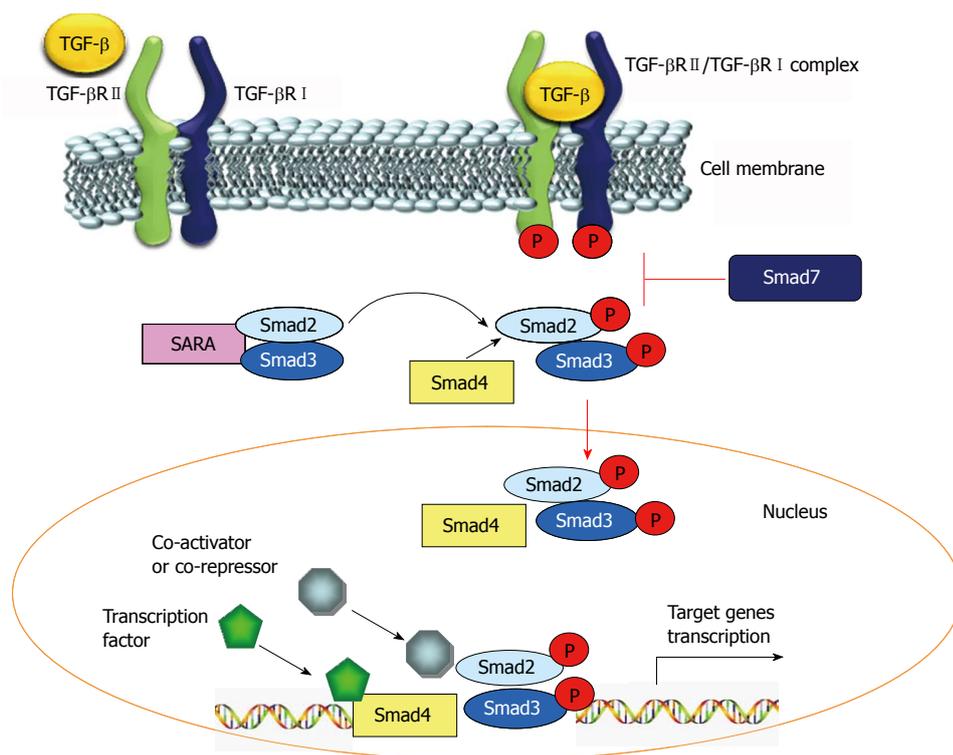

Figure 2 Transforming growth factor- α signaling and induction of gene transcription. Smad: Small mother against decapentaplegic; SARA: Smad anchor for receptor activation; TGF- β : Transforming growth factor β .

activation of signal transduction pathways. The LTBP is removed extracellularly either by proteolytic cleavage by various proteases such as plasmin, thrombin, plasma transglutaminase, or endoglycosidases, or by physical interactions of the LAP with other proteins, such as thrombospondin-1^[80].

The actions of the TGF- β family are mediated through at least three types of TGF- β receptors, TGF- β R I, R II and R III. TGF- β R I and R II are two different transmembrane serine/threonine kinase receptors with single transmembrane domains, which form homo- and heterodimer complexes that bind TGF- β , inducing phosphorylation of a family of proteins designated as Smads that transduce the ligand signal from the cell surface to the nucleus^[80] (Figure 2).

Smads are a family of 8 related proteins, which function as signaling intermediates for the TGF- β superfamily of ligands. Type I receptors specifically recognize and phosphorylate the ligand-specific receptor-activated Smad (R-Smad) and include Smad1, Smad5 and Smad8 (downstream of the BMP), and Smad2 and Smad3 (downstream of TGF- β and activin), that are recruited to activated T β RI by a membrane-bound cytoplasmic protein called Smad anchor for receptor activation (SARA). Upon ligation of TGF- β to its receptors, the phosphorylated Smad2 and 3 form a complex with the common mediator Smad (Co-Smad), such as Smad4. Co-Smad acts as a convergent node in the Smad pathways downstream of the TGF- β superfamily receptors, complexing R-Smad. R-Smad/Smad4 complexes are then translocated into the nucleus by a mechanism involving the cytoplasmic

protein importin; they may then function as transcription factors, binding DNA either directly or in association with other DNA-binding proteins^[80] (Figure 2).

A third group of Smad proteins, the inhibitory Smads such as Smad6 or Smad7, antagonize TGF- β signaling by interfering with the ligation of Smad2/3 to the activated receptor complex^[80].

Using a combined cDNA microarray/promoter transactivation approach, several new Smad gene targets have been identified, among which are *COL1A1*, *COL3A1*, *COL5A2*, *COL6A1*, *COL6A3*, and *TIMP-1*, indicating that the Smad signaling pathway is crucial for the simultaneous activation of several fibrillar collagen genes by TGF- β ^[80]. About 60 other ECM-related genes were also identified as immediate-early gene targets downstream of TGF- β ^[81].

Several studies suggest that disruption of the TGF- β /Smad signaling pathway, either by the loss of Smad3 or the increase of Smad7 expression, prevents the development of tissue fibrosis in various organs, including the skin, kidney, lungs, liver and intestine^[82-84].

Differences in small bowel and colonic morphology, as well as in the expression of collagens I-VI, α -SMA, TGF- β 1, Smad7, and other factors, have been reported in Smad3 knockout mice compared to the littermate wild-type controls^[85]. Using this tool made it possible to define the key role of the TGF- β /Smad signaling pathway in chronic intestinal inflammation and fibrosis^[85]. In fact, a significant reduction of trinitrobenzene sulfonic acid (TNBS)-induced intestinal fibrosis has been reported in knockout mice as compared to wild-type mice^[84].

Smad3 may take part in recruitment of fibroblasts to the site of injury, as well as in differentiation of fibroblasts to myofibroblasts and regulation of collagen synthesis. Furthermore, the loss of Smad3 interferes with the effects of TGF- β on chemotaxis and auto-induction of inflammatory cells^[84,86]. These findings indicate that the TGF- β /Smad signaling pathway is the key element in determining the progressive nature of intestinal fibrosis.

The effects of TGF- β on *ECM* gene expression and subsequent development of tissue fibrosis may be related to additional mechanisms, such as CTGF, the expression of which is controlled by TGF- β in a Smad-dependent manner^[87].

TGF- β preferentially transduces intracellular signaling through Smad proteins, but signal mechanisms that stimulate *ECM* accumulation can also be activated by other molecules such as members of the mitogen-activated protein kinase (MAPK) family including extracellular signal-regulated kinase (ERK), c-Jun N terminal kinase and p38 kinases, as well as members of the JAK and STAT protein family^[88].

Studies on liver fibrosis demonstrate that both MAPK and Smad signaling, independently and in synergy, stimulate HSC activation, thus increasing collagen and α -*SM1* gene expression^[88,89].

The JAK-STAT signaling pathway, activated by TGF- β , is involved in fibrogenesis and can be negatively regulated on multiple levels^[90]. Suppressors of cytokine signaling may inhibit STAT phosphorylation by binding and inhibiting JAKs or competing with STATs for phosphotyrosine binding sites^[91]. Protein inhibitors of activated STATs (PIAS) may act directly in the nucleus on STAT proteins. PIAS1 and PIAS3 inhibit transcriptional activation by STAT1 and STAT3, respectively, by binding and blocking their access to the DNA sequences^[92].

TGF- β 1 may also influence the imbalance between enhanced production and deposition and impaired degradation of *ECM* components. In IBD, the tissue expression of MMP-1, 2, 3 and 9 is increased in relation to that of TIMP-1 and 2, compared with controls^[92]. How the balance of MMPs and TIMPs is regulated is still not clear, but blocking TGF- β 1 in cultures of intestinal biopsies upregulated the expression of MMP-3 but not of TIMP-1, thus suggesting a new role for TGF- β 1 in IBD tissue remodeling^[93].

Activins

The activins are members of the TGF- β superfamily with broad and complex effects on cell growth and differentiation. The activins interact with heterodimeric serine/threonine kinase receptor complexes to activate Smad transcription factors and the MAP kinase signaling pathways. Important functions of activins, in particular of activin A, in tissue inflammation, repair and fibrosis of several organs, including the intestine, have been reported^[94-96].

Activin is a dimeric protein consisting of β_A and β_B subunits connected by disulfide linkages resulting in three different configurations with similar functions: the ho-

modimeric activin A ($\beta_A\beta_A$) and activin B ($\beta_B\beta_B$), and the heterodimeric activin AB ($\beta_A\beta_B$).

Their action is mediated by two heteromeric receptor complexes consisting of two transmembrane receptors (type I or II) with intrinsic serine/threonine kinase activities, similar to the TGF- β mechanism of signal transduction, while its biological effects seem to be inhibited by another activin-binding protein, namely follistatin^[94].

Several studies have shown an increase in activin levels in IBD and in many other inflammatory diseases, thus giving rise to the hypothesis that it plays a significant role in the inflammatory response as well as in fibrosis^[95].

Munz *et al.*^[96] reported an increase in the expression of activin, particularly the activin β_A -subunit, in surgical specimens from the gut of patients with IBD, showing a strong correlation with the degree of inflammation. *In situ* hybridization studies revealed the highest levels of activin mRNA in the mucosa and submucosa of highly inflamed areas. These findings suggest that activins play a novel and important role during the inflammatory processes of the gut^[96].

CTGF

TGF- β has been regarded as a pivotal growth factor in the formation and maintenance of connective tissues but it has been clearly proven that the effects on *ECM* gene expression and subsequent development of tissue fibrosis are related to other factors, such as CTGF, the expression of which is controlled by TGF- β in a Smad-dependent manner. Northern blot and *in situ* hybridization studies have demonstrated that CTGF is co-expressed with TGF- β in principally every fibrotic disorder and CTGF has been considered a possible key determinant of progressive fibrosis^[97].

CTGF is a cysteine-rich mitogenic peptide that binds heparin and is secreted by fibroblasts after activation with TGF- β . In the adult mammal, CTGF acts as a downstream mediator of TGF- β action on connective tissue cells, where it stimulates cell proliferation and *ECM* synthesis. It does not appear to act on epithelial cells or immune cells. Since the biological actions of TGF- β are complex and affect several different cell types, CTGF may serve as a more specific target for selective intervention in processes involving connective tissue formation during wound repair or fibrotic disorders^[97].

CTGF is an interesting molecule for future anti-fibrotic therapies as it is possible that inhibition of CTGF might block the pro-fibrotic effects of TGF- β , without affecting TGF- β 's immunosuppressive and anti-inflammatory effects. In addition to TGF- β , a number of other regulators of CTGF expression have been identified, including VEGF, TNF- α , shear stress, cell stretch and static pressure, hydrogen peroxide (H_2O_2), superoxide (O_2^-), hydroxyl radical ($HO\cdot$) and nitric oxide (NO)^[98].

Outlining the mechanisms that underlie *CTGF* gene regulation in normal and fibrotic cells might help in the design of future intervention strategies aimed at targeting specific interference with CTGF expression at sites

of progressive fibrosis. In addition, forms of treatment targeting CTGF effects have been proposed which might lead to a favorable outcome of wound repair.

PDGF

PDGF consists of two related peptide chains, PDGF-A or PDGF-1 (16 kDa, 124 amino acids), and PDGF-B or PDGF-2 (14 kDa, 140 amino acids) linked by disulfide bonds. All possible isoforms, i.e., PDGF-AA, PDGF-BB and PDGF-AB, are biologically active. More recently, two additional PDGF genes and proteins have been identified, namely PDGF-C and PDGF-D^[99].

PDGF is synthesized mainly by megakaryocytes. It is stored in the α granules of platelets from which it is released after platelet activation. Other cell types also synthesize PDGF, including macrophages, endothelial cells, fibroblasts, glial cells, astrocytes, myoblasts, smooth muscle cells, and a number of tumor cell lines. Several factors induce PDGF synthesis, including hypoxia, thrombin and several cytokines and growth factors such as IL-1, IL-6, TNF- α , TGF- β , FGF- β and EGF^[100].

Two tyrosine kinase receptors, called PDGFR α and PDGFR β , have been described. Binding of the ligand leads to receptor dimerization, which initiates signaling. Ligand configuration and pattern of receptor expression influence the formation of different receptor dimers. Generally, mesenchymal cell expression of PDGFRs is low in normal conditions, but increases dramatically during inflammation.

PDGF plays crucial roles during development. Increased PDGF activity has been linked with several diseases and pathological conditions. Its expression is significantly increased in the inflamed intestine of patients with IBD. Intestinal fibroblasts, intestinal subepithelial myofibroblasts and the interstitial cells of Cajal are activated and proliferate in response to the PDGF family (mainly PDGF-BB)^[51]. PDGF also enhances migration of fibroblasts, and its effects seem to be fibronectin-dependent. Increased activity of PDGF is also responsible for an excessive deposition of ECM in fibrotic processes within several organs, including the intestine.

IGFs

IGFs (IGF- I and -II) are polypeptides composed of a single chain of 70 and 67 amino acids, respectively. They are potent mitogens since they have stimulatory effects on proliferation and inhibitory effects on apoptosis in epithelial cells. IGF- I is the predominant post-natal IGF, whereas IGF- II is a predominantly fetal IGF. IGF- I interacts with IGF- I receptor type I (IGF- I R) on the cell surface. Subsequent phosphorylation by a receptor tyrosine kinase initiates the intra-cellular signaling process. IGF- II also interacts with a receptor type II (mannose-6-phosphate IGF- II R)^[101].

In the intestine, IGF- I interacts principally with fibroblasts and epithelial and endothelial cells. The entire GI tract expresses IGF- I and -II and their respective receptors, the latter being localized in both the mucosal

and muscularis layers. Expression of insulin-like growth factor binding protein (IGFBP)-6 in the intestine has also been described; IGFBPs are proteins that, by binding to IGF, are able to modulate its bioavailability and activity.

Expression of IGF- I is locally increased in several bowel diseases. During bowel inflammation, pro-inflammatory cytokines are able to induce IGF- I expression by mesenchymal cells. The IGF- I, in turn, could regulate the proliferation of these or other cell types acting in a paracrine manner on epithelial cells or in an autocrine manner on intestinal mesenchymal cells^[102]. IGF- I plays a relevant role in the deposition of collagen and fibrosis. It has been shown to be up-regulated in the bowel of animals with experimental intestinal fibrosis and of patients with CD^[102]. In an experimental model of rat colitis, an up-regulated IGFBP and collagen expression and down-regulated collagenase expression were shown, confirming the important role of IGF- I in collagen synthesis in colitis, mediated by IGFBPs^[103]. It has been hypothesized, moreover, that IGF- I, through IGFBP-5, is able to modulate proliferation of fibroblasts/myofibroblasts and collagen synthesis^[104].

In addition, in contrast with the local expression, the circulating levels of IGF- I and IGFBP-3 seem to be reduced in patients with IBD^[105].

EGF

EGF is the prototype member of a family comprising different peptides with a similar primary structure that bind to a family of EGF receptors and have similar biological effects: they are potent mitogens and are also able to modify several properties of non-proliferating cells^[106].

Several tyrosine kinase receptors are now known for EGF family members, such as human EGF receptors 1-4 (HER1, HER2, HER3 and HER4). Since these receptors can heterodimerize, they can form at least 10 different dimers that likely bind to distinct EGF-like molecules and deliver different signaling when activated^[106].

Binding of EGF induces the phosphorylation of several intracellular proteins regulating transcription, translation, cell architecture, cell proliferation, and the production of inflammatory mediators.

EGF is a 53-residue peptide and is also known as urogastrone, since it was initially isolated from urine and was found to inhibit gastric acid secretion^[107]; it is expressed in exocrine pancreas, duodenum, breast milk, colostrum and gastric juice^[108].

EGF can be isolated from the lumen of the intestine; its receptors have been detected in the bowel, especially on monocytes and myofibroblasts.

EGF has numerous functions within the GI tract: it stimulates cell proliferation, inhibits gastric acid secretion, up-regulates intestinal electrolyte and nutrient transport, induces expression of several enzymes, enhances epithelial restitution and stimulates angiogenesis.

EGF stimulates fibroblast proliferation and ECM production in idiopathic pulmonary fibrosis; moreover, it stimulates a more pronounced ECM production in inter-

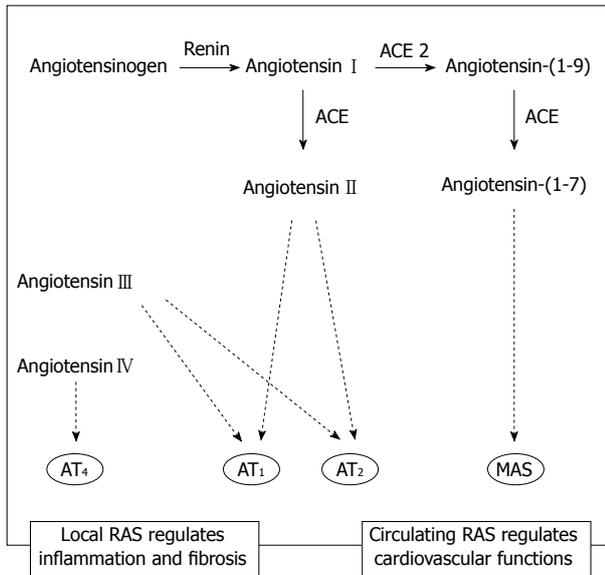

Figure 3 Components and effects of the renin-angiotensin system. ACE: Angiotensin-converting enzyme; AT1: Angiotensin II type 1 receptor; AT2: Angiotensin II type 2 receptor; AT4: Angiotensin II type 4 receptor; MAS: Mas receptor; RAS: Renin-angiotensin system.

stitial pneumonia fibroblasts than in normal fibroblasts, thus suggesting an important role of this growth factor in fibrotic processes^[109].

The role of EGF in IBD is not clear. EGFR expression is generally upregulated in TNBS-induced colitis^[110]. EGF administered intraperitoneally and subcutaneously reduces the severity of TNBS-induced colitis in rats^[110]. EGF appears to be involved in the regulation of migration of human colonic fibroblasts and myofibroblasts^[111,112]. Further studies are needed to fully elucidate the role of EGF and EGFR in IBD and intestinal fibrosis.

Endothelins

Endothelins are a group of polyfunctional cytokines. So far, four endothelins [(ET)-1, ET-2, ET-3 and ET-4]) and two endothelin receptors (ET_A and ET_B) have been recognized.

Endothelins strongly induce vasoconstriction and may provoke local ischemia. They can also induce the release of pro-inflammatory cytokines, alter the intestinal permeability and stimulate leukocyte adhesion in submucosal venules of the intestine, probably through up-regulation of cell adhesion molecules on the endothelium and leukocytes^[113-115].

Adhesion of circulating leukocytes to the endothelium could be one of the initial steps in the pathogenesis of IBD, since adhesion is a crucial event in the recruitment of leukocytes to the inflamed tissue. In addition, several of the pro-inflammatory cytokines playing a key role in IBD, such as IL-1 β and TNF- α , can remarkably increase endothelin production^[116,117].

It has been shown that bosentan, a non-selective endothelin receptor antagonist, reduces intestinal inflammation in a murine model of IBD^[118]. Probably the reduction of inflammation induced by this drug was due to a reduction in adherent leukocytes leading to a reduction of the

mucosa infiltrate of inflammatory cells.

In vivo studies performed on cardiac, renal and pulmonary tissue have shown the role of endothelins in fibrosis^[119]. ET1 stimulates colonic myofibroblast activation (differentiation, migration and contraction), effects prevented using an ET-1 antagonist^[120]. These findings suggest a possible role for ET1 also in the development of intestinal fibrosis.

RAS

The relevance of the renin-ANG system, usually viewed as an endocrine system regulating physiological and vital cardiovascular processes, has expanded in the last decade to include independently regulated local systems in several tissues, new functions of the RAS and new active products of ANG II^[121,122] (Figure 3).

Besides circulating RAS, local RASs also exist in various organs and tissues, such as the heart, blood vessels, kidney, liver, pancreas, intestine, nervous system, reproductive system, as well as lymphatic and adipose tissue^[123-125]. It has been reported that the ANG converting enzyme (ACE) produces the decapeptide ANG I and octapeptide ANG II, respectively. In addition, alternative enzymes to renin and ACE generate a number of bioactive peptides from ANG I and/or ANG II, such as ANG III, ANG IV and ANG-(1-7). ANG II, together with these bioactive peptides, mediates their specific functions *via* the respective cellular receptors of target tissues and organs^[123]. In the last few years, the understanding of the RAS function has changed considerably, following the discovery of other ANG forms [such as ANG III, IV or (1-7)], additional enzymes involved in their generation (such as ACE2, aminopeptidase A or prolyl endopeptidase) and receptors (such as ANG II type 4 receptor and Mas). RAS, therefore, is not represented by a simple linear proteolytic cascade, but by a series of extremely complex reactions (Figure 3). All components of the RAS exist in the large bowel in adults^[126]. In the colon, many cells, such as epithelial cells, vascular endothelial cells, mesenchymal cells and inflammatory cells, express ANG II receptors.

Local RAS has novel functions including the regulation of cell growth, differentiation, proliferation and apoptosis, generation of ROS, expression of cytokines (such as IL-6, TNF- α), activation of endothelial cells, as well as tissue inflammation, ECM production and fibrosis^[123].

These different roles make some of the RAS components attractive therapeutic targets in various chronic diseases, including fibrosis.

ANG II, moreover, plays a role in the pathogenesis of chronic fibrogenetic diseases of various organs, including kidney, heart, lung, pancreas, liver and intestine, through the regulation of both inflammatory and fibrotic processes^[127,128]. In such conditions, fibrosis is mediated, at least in part, through ANG II induction of TGF- β ^[13].

Several components of RAS are over-expressed in the fibrotic liver, both in human and animal models^[129]. In particular, it would appear that ANG II is able to induce proliferation of myofibroblasts and stellate cells,

to stimulate inflammatory cells and to induce the release of several profibrotic molecules, such as TGF- β , CTGF and IL-1 β ^[130]. Blocking RAS, by using ACE inhibitors or ANG II type I (AT1) receptor antagonists, reduces hepatic fibrosis^[131].

In human lung fibroblasts, ANG II is able to modify PDGF-D, IL-4 and IL-7 expression and to induce higher levels of collagen and elastin. Using candesartan, an inhibitor of AT1 receptor, these effects have been shown to be suppressed^[132].

In experimental models of kidney damage, RAS inhibitors (ACE inhibitors and AT1 antagonists) have shown beneficial effects on proteinuria, cell growth, inflammation and fibrosis, thus suggesting that ANG II could be involved in the fibrotic process activating mononuclear cells, increasing proinflammatory mediators and regulating matrix degradation^[132].

New insights into the role of RAS in the development and modulation of chronic intestinal inflammation and related fibrosis have been reported^[133]. The direct effect of ANG II on the pathogenesis of immune-mediated colitis was assessed using mice genetically deficient in angiotensinogen (*Ang*^{-/-}), which is the precursor of ANG II^[133]. TNBS-induced acute colitis was less severe in the *Ang*^{-/-} mice compared to wild-type (*Ang*^{+/+}) mice.

Both ANG II and TGF- β 1 are overexpressed in intestinal fibrosis and stenosis, particularly in Crohn's disease^[134,135]. The production of TGF- β 1, indeed, is strongly stimulated by the local activation of ANG II^[13]. An up-regulation of ANG II in the colon of rats and mice with experimentally induced colitis also supports the role of RAS in intestinal inflammation and fibrosis^[13,136].

Daily administration of the ACE inhibitor captopril in rats with chronic TNBS-induced colitis significantly reduced the macroscopic and microscopic pattern of both colonic inflammation and fibrosis, decreased the colon collagen content, and reduced TGF- β 1 mRNA levels by about 60%. The antifibrotic mechanism of captopril could be related to the inhibition of ANG II-mediated TGF- β 1 overexpression, and/or to a direct downregulation of TGF- β 1 transcripts^[13]. Likewise, the use of losartan, a specific AT1 receptor antagonist, significantly improved the macro- and microscopic scores of experimentally-induced colorectal fibrosis and reduced TGF- β 1 concentration, thus suggesting that this drug has a preventive effect on colorectal fibrosis complicating TNBS-induced chronic colitis by a downregulation of TGF- β 1 expression^[137].

In view of these data, RAS could be considered as a future target for new antifibrotics in IBDs.

Cytokines

Cytokines regulate the inflammatory process, mediating the interactions between activated immune cells and non-immune cells. They can enhance an inflammatory response or reduce inflammation and promote healing.

IBDs are mainly characterized by an enhanced CD4⁺ T cell proliferation and trafficking into the intestinal

mucosa and by alterations in the cytokine profile of the main activated Th cells, resulting in a disturbed balance between pro- and anti-inflammatory cytokines. The abnormal lamina propria T-cell activation and the consequent resistance to apoptosis are, indeed, considered as key events in the pathogenesis of IBD.

Upon activation, naïve CD4⁺ T cells can differentiate into different subsets depending on the surrounding cytokine milieu. CD4⁺ Th cells are currently divided into four major subsets, based on their expression profile of transcription factors and secreted cytokines: Th1, Th2, Th17 and Treg.

Th1 cells are characterized by the secretion of interferon γ (INF- γ). The differentiation of Th1 cells is mainly induced by IL-12 and can be further enhanced by INF- γ . Th1 cells express the transcription factors T-bet and STAT4. INF- γ is a pro-inflammatory cytokine which together with IL-12 induces the differentiation of macrophages and the production of other pro-inflammatory cytokines, such as IL-1 β , IL-6, IL-8, granulocyte-macrophage colony-stimulating factor (GM-CSF) and TNF- α ^[138].

Th2 cells produce primarily IL-4, IL-5 and IL-13. Th2 cells develop in the presence of IL-4 and require the transcription factors GATA3 and STAT6.

Th1 and Th2 negatively regulate each other through their specific cytokine actions: IL-12 represses the induction of Th2 cells, whereas IL-4 inhibits Th1 cell development.

Microarray experiments have established that the various gene-expression profiles associated with different pathological conditions are strongly influenced by Th1- and Th2-polarization of the chronic inflammatory responses^[139].

The Th1 response seems to be involved mainly in CD, whereas the Th2 response occurs mainly in UC^[140]. However, during the late stages of IBD, both Th1 and Th2 cytokines play a pivotal role in the progression of intestinal fibrosis. Several findings have demonstrated that IL-1 β and TNF- α , two Th1 pro-inflammatory cytokines, stimulate fibroblast proliferation and collagen deposition, whereas the development of a Th2 cell response, and particularly IL-4 and IL-13, upregulates the expression of several genes including those that encode procollagen-I, procollagen-III, MMP-2 and MMP-9 as well as TIMP-1^[139,141].

In addition, the other two subsets of CD4⁺ T cells, represented by the Th17 and Treg cells, are involved in the development of intestinal fibrosis in alternate ways^[142].

Th17 cells, which are strongly associated with autoimmune pathology, are characterized by the production of IL-17A, IL-17F, IL-21, IL-22 and TNF- α ^[142]. Differentiation of Th17 cells needs the combined action of TGF- β , IL-6 and IL-21 in mice, whereas IL-6 and IL-21 can be replaced by IL-23 or IL-1 β in humans. These cytokines induce the transcription factors ROR γ t (mice) or RORc (human) and STAT3. Development of Th17 cells is suppressed by INF- γ and IL-4, which promote Th1 and Th2

Table 3 Predominant pro-fibrotic cytokines

Cytokines	Role in fibrosis	Ref.
IL-1/IL-33	Activate myofibroblasts	[144,146]
	Stimulate TGF expression	[145]
	Regulate chemokines, cytokines and MMPs secretion	[144]
IL-4/IL-13	Activate myofibroblasts	[147]
	Increase deposition of collagen I, III and IV	[148]
	Induce production of latent TGF- β and activate TGF- β	[152,153]
IL-6	Promote fibrocyte differentiation	[154]
	Stimulates proliferation of fibroblasts	[157]
	Modulates TGF- β and TGF- β R II	[156]
IL-21/IL-22	Its neutralization improves fibrosis	[155]
	Stimulate the expression of IL-4, IL-13 and IL-17	[159]
	Increase secretion of ECM degrading enzymes	[160]
IL-17/IL-23	Maintain the integrity of the epithelial barrier	[161]
	Inhibit deposition of collagen	[163]
	Maintain chronic inflammation in the gut	[143]
TNF α	Induce activation and proliferation of myofibroblasts	[165]
	Stimulate deposition of collagen	[164]
	Stimulates intestinal myofibroblast proliferation	[170]
IL-17/IL-23	Stimulates deposition of collagen	[171]
	Inhibits collagen degradation through TIMP-1 induction	[172,173]

TNF: Tumor necrosis factor; ECM: Extracellular matrix; IL: Interleukin; TGF- β : Transforming growth factor- β ; TIMPs: Tissue inhibitors of metalloproteinases; MMPs: Matrix metalloproteinases.

cells, respectively. Once Th17 cells have developed, IL-23 is needed for stabilization and further expansion of these cells. Also, IL-1 β and IL-6 can act to enhance the development and expansion of these cells. The intestine of patients with IBD presents higher IL-17 levels than in healthy subjects. There is emerging evidence that IL-17 strongly interacts with IL-23, the expression of which is considerably increased in the inflamed intestine; its selective depletion with monoclonal antibodies has been demonstrated to greatly attenuate T-cell mediated colitis in mice^[143].

Treg cells, which control effector T-cell responses, produce the anti-inflammatory cytokines IL-10 and TGF- β . The differentiation of Treg is induced by TGF- β but inhibited in the presence of pro-inflammatory cytokines. Treg are characterized by the expression of the transcription factor Foxp3 and STAT5 and the expression of CD25 on their surface.

There is a growing body of evidence proving that the inflammatory cascade which influences the progression of intestinal fibrosis can involve many Th1, Th2, Th17 and Treg cytokines, such as IL-1 β , IL-4, IL-6, IL-13, IL-17, IL-21, IL-22, IL-23, IL-33 and TNF- α (Table 3). Consequently, the use of biological therapies antagonizing these cytokines could be of value in the treatment of intestinal fibrosis and, therefore, may represent the targets of new antifibrotic drugs.

IL-1 and IL-33: IL-1 belongs to a family of proinflammatory cytokines that are rapidly expressed following tissue damage. Besides its role in acute and chronic inflammation, IL-1 is involved in tissue remodeling following chronic inflammation in various organs.

IL-1 contributes to the development of fibrosis during chronic intestinal inflammation through various mechanisms, such as regulating intestinal myofibroblast activation, the induction of chemokines (e.g., IL-8, MCP-1) and MMP secretion, and the turnover of ECM^[144]. Furthermore, IL-1, in combination with TNF and INF- γ , is able to increase the TGF- β -induced epithelial-mesenchymal transition (EMT), an important cellular process of fibrogenesis^[145].

Recently, it has been reported that IL-33, a novel member of the IL-1 family, induces mucosal pathology *in vivo* and may lead to the development of fibrosis and angiogenesis^[146]. TLR-3 is one of the strongest promoters inducing IL-33, which activates myofibroblasts and pericytes.

IL-4 and IL-13: Some Th-2 cytokines (IL-4 and IL-13) are present in elevated levels in fibrotic processes and induce activation and differentiation of fibroblasts to myofibroblasts and also induce production of collagens^[1,17,159].

IL-4 appears to be involved in the development of pulmonary fibrosis; in particular, activation of the IL-4R α pathway in macrophages seems to be fundamental in silica-induced pulmonary fibrosis^[147]. Furthermore, it was demonstrated that IL-4 increases the mRNA expression of collagen I, III and IV in cultured human hepatic fibroblasts; these effects require STAT-6 activation^[148]. IL-4 level, finally, correlated with cardiac fibrosis in patients with heart failure^[149].

Inhibition of IL-13 reduces hepatic and skin fibrosis^[150,151]. In experimental studies a marked reduction of hepatic fibrosis by IL-13 blockade has been reported^[150,151]. IL-13 signaling through the corresponding receptor IL-13R α induces production of latent TGF- β (TGF- β bound to LAP) in macrophages and, indirectly, contributes to its activation by stimulating the synthesis of enzymes, such as MMPs and cathepsins, able to remove LAP^[152]. In TNBS-induced colitis, fibrosis development is dependent upon IL-13 binding to the IL-13 receptor to induce TGF- β ^[153]. In the same way, if IL-13 signaling is inhibited TGF- β is produced in reduced amounts and fibrosis does not occur^[153]. Soluble IL-13R α 2-Fc is a highly effective decoy receptor of IL-13 which can reduce the progression of established fibrotic disease. IL-10 has also been shown to inhibit fibrosis in numerous experimental models^[1]. The IL-13 decoy receptor and IL-10, by suppressing collagen deposition, act as endogenous factors that slow the progression of fibrosis.

Both IL-4 and IL-13 appear to be responsible for promoting fibrocyte differentiation from CD14+ peripheral blood monocytes, without induction of their proliferation. In dermal fibroblasts, IL-4 and IL-13 stimulate ERK1/2 pathways, which are involved in the modulation

of collagen gene expression^[154].

IL-6: In addition to a potent proinflammatory action, IL-6 may also have a relevant role in the development of fibrosis. In the cardiac allograft model, IL-6 neutralization improved graft fibrosis^[155]. The role of IL-6 in fibrosis has been further confirmed by the finding of its ability to modulate TGF- β and TGF- β R II mRNA and protein levels in mouse skin^[156] and to strongly stimulate proliferation in normal and keloid fibroblasts, as well as increase levels of STAT-3, which contributes to several processes including collagen production^[157]. IL-6 is markedly increased in CD where it appears to stimulate fibrogenetic mesenchymal cells^[158].

IL-21 and IL-22: IL-21 appears to be related to IBD-associated intestinal fibrosis. IL-21 promotes fibrosis by enhancing the development, survival and migration of Th2 cells. Moreover, it stimulates the expression of IL-4 and IL-13 receptors in macrophages, inducing their activation^[159], stimulates the secretion of ECM-degrading enzymes by fibroblasts and the secretion of the T cell chemoattractants by epithelial cells^[160]. IL-21 is produced in excess in CD compared to controls. IL-21 together with IL-6 is critical in the development of Th17 cells.

IL-22, primarily produced by Th17 cells, presents bi-functional characteristics, pro- and anti-inflammatory, depending on the local milieu. In the intestine, it is involved both in mucosal defense and in wound healing processes. IL-22 plays a protective role in IBD by enhancing barrier integrity and epithelial immunity of the intestinal tract^[161]. A mouse model of UC has, in addition, demonstrated that IL-22 is able to activate the innate immune pathway by enhancing STAT3 activation, particularly within colonic epithelial cells, and by inducing both the restitution of mucus-producing goblet cells and the STAT3-dependent expression of mucus-associated molecules. These studies might, therefore, suggest a protective role for this cytokine in intestinal inflammation^[162]. The involvement of IL-22 in the regulation of fibrotic processes has been shown in a mouse model of hypersensitivity pneumonitis (that generally progresses to lung fibrosis), in which direct blockade of IL-22 enhanced the deposition of collagen in the lung. These findings reveal a protective pathway of this cytokine in the development of lung fibrosis and could suggest an analogous role also in the intestine^[163].

IL-17 and IL-23: The IL-23/IL-17 axis plays a role in normal intestinal homeostasis, although the precise actions of these cytokines remain to be fully elucidated. In the normal intestine, constitutive production of small amounts of both IL-23 and IL-17 may act to protect the epithelial layer fortifying tight junction formation between epithelial cells and inhibiting bacterial colonization. In inflammation, activated dendritic cells produce large amounts of IL-23, which could activate innate immune cells to produce pro-inflammatory cytokines such as IL-1 β , TNF- α and IL-6. IL-23 also induces an in-

creased production of IL-17 and INF α , both by T cells and non-T cells. Recently, it has been shown that targeting IL-23 by employing a p40 peptide-based vaccine improves TNBS-induced acute and chronic murine colitis with a significant decrease in collagen deposition^[164]. The main action of IL-17 may be to promote the production of chemokines that recruit and activate granulocytes, further increasing inflammation^[143]. IL-17 was also found to be a potent activator of mesenchymal cells, especially of myofibroblasts^[165].

In vivo, fibrotic models show enhanced IL-17A expression and activation of IL-17A-associated signaling pathways. Studies performed on pulmonary fibrosis models showed evidence that IL-17A increased synthesis and secretion of collagen and induced epithelial-mesenchymal transition in alveolar epithelial cells in a TGF- β 1-dependent manner^[166].

Moreover, it has been demonstrated that IL-1 β -mediated pulmonary fibrosis is IL-17A-dependent^[167] and that IL-17A blocking is able to attenuate myocarditis-induced cardiac fibrosis and ameliorate ventricular function; further confirming its role in the fibrogenetic process^[168].

A study on Th17 cells in human peripheral blood demonstrated that the expansion of IL-23R+ CD4+ cells was promoted by the combination of IL-7 and IL-12, which are also able to increase the secretion of IFN- γ , while IL-12 alone stimulated these cells to secrete predominately IL-17^[169]. On the basis of these data, IL-7 and IL-12 have similarly been identified as anti-fibrotic cytokines, even if their effective role in the fibrotic process remains to be established.

TNF- α

Another central mediator of the fibrotic process in IBD is TNF- α , a proinflammatory cytokine with important immunomodulatory properties, abundantly expressed in the intestine of patients with CD and UC. This cytokine is produced from various cells such as monocytes/macrophages, adipocytes and T cells, and has different effects including further macrophage and T cell activation, stimulation of granuloma formation and expression of adhesion molecules in endothelial cells with consequent recruitment of neutrophils and other immune cells at the site of inflammation.

TNF- α is able to induce intestinal fibrosis by up-regulating collagen accumulation; moreover, it has mitogenic effects in intestinal myofibroblasts and is able to extend the inflammatory state thus increasing the expression of other inflammation mediators, such as IL-6 and IL-1 β , and activating NF κ B-dependent pathways, a transcription factor that increases the expression of cytokines, enzymes and adhesion molecules^[170].

TNF- α acts by binding to two immunologically distinct TNF- α receptors of approximately 55 kDa (TNF-R1) and 75 kDa (TNF-R2). Studies performed on intestinal myofibroblasts have shown that TNFR2 is essential for TNF- α -induced cell proliferation and collagen synthesis^[171].

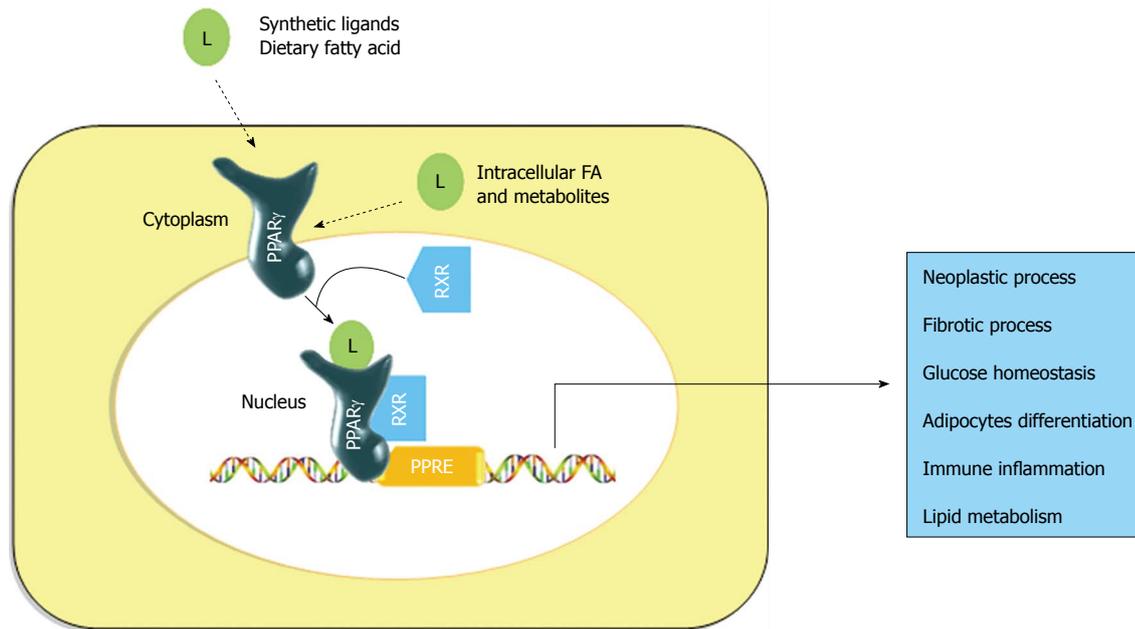

Figure 4 Activation of the peroxisome proliferator activator receptor- γ pathway. Regulation of several genes involved in fibrogenesis. PPAR- γ : Peroxisome proliferator activator receptor- γ ; PPRE: PPAR response elements; RXR: Retinoid X receptors; L: Ligand; FA: Fatty acids.

Furthermore, TNF- α induces TIMP-1 expression and reduces MMP-2 activity and collagen degradation. Inhibition of collagen degradation, through TIMP-1, and induction of collagen gene transcription are responsible for the effects of TNF- α on total collagen accumulation; moreover, TNF- α also appears to have additional effects on collagen synthesis when combined with IGF- I , a growth factor implicated as a key pro-fibrogenic mediator during intestinal inflammation *in vivo*. IGF- I and TNF- α synergistically stimulate intestinal myofibroblast proliferation and collagen production^[172,173].

The role of TNF- α in IBD was confirmed by the therapeutic benefits of anti-TNF- α monoclonal antibodies. In several clinical trials, anti-TNF- α drugs, such as infliximab, adalimumab and certolizumab pegol, induced clinical remission and healing of mucosal lesions in about one third of patients with CD^[174-176].

There is not strong evidence regarding the effectiveness of anti-TNF- α drugs to reduce intestinal fibrosis in IBD.

ROS

Infiltrating leucocytes in the inflamed mucosa produce a large amount of ROS. ROS include various species ($O_2^{\cdot -}$, H_2O_2 , $HO\cdot$) and are involved in several processes, such as regulation of signal transduction, activity of phagocytes, oxidative damage of proteins, lipids and nucleic acids^[177].

Superoxide is mainly generated from the uncoupling of the mitochondrial electron-transport system and from several enzymes including NADPH oxidases, cyclooxygenases, lipoxygenases and nitric oxide synthases. Hydrogen peroxide is directly obtained from oxygen, spontaneously or enzymatically (through the action of the enzyme superoxide dismutase); it can also be the result of lipid

metabolism in peroxisomes. In the presence of metals, hydrogen peroxide can be involved in $HO\cdot$ formation^[178].

ROS, moreover, can negatively affect cell signaling by altering the transcription process and phosphorylation of proteins, including transcription factors.

ROS are involved in acute and chronic inflammatory processes that include a neutrophil or macrophage infiltrate, such as acute and chronic infections, autoimmune conditions such as IBD, arthritis and other inflammatory conditions^[179]. In several pathological states the increase of ROS depends on an over-expression or increased activity of enzymes involved in their production. Increased activity of the NADPH oxidase enzyme is associated with pulmonary, cardiac, hepatic and intestinal fibrosis^[179].

Patients with idiopathic pulmonary fibrosis have a lower antioxidant capacity compared to healthy subjects^[180-182]. It has been reported that antioxidants protect rats against experimental pulmonary fibrosis^[183,184]. It is thus likely that attenuating oxidative stress in tissues could prevent fibrosis caused by ROS.

A recent study showed that mice with NADPH oxidase deficiency had phagocytes which did not produce ROS and they did not develop lung fibrosis induced by bleomycin^[185]. Inhibition of ROS production in this experimental model was associated with alterations in IL-6 levels and in the MMP-9/TIMP-1 ratio, molecules involved in pulmonary fibrosis and remodeling^[185].

The role of ROS has been widely studied in liver fibrosis and substantial data suggest its importance in the transformation of HSCs into activated collagen-producing cells^[186]; ROS appear to be a key mediator in collagen gene regulation^[187].

ROS could also be involved in intestinal fibrosis. It has been shown that inhibition of oxygen radical secre-

tion improves experimental colitis in mice^[188].

PPAR-γ

Novel molecules involved in IBD and in tissue fibrogenesis appears to be PPARs^[189]. Three different isoforms of PPARs have been identified, termed PPAR-α, PPAR-γ and PPAR-δ, each one encoded by specific genes and with distinct patterns of tissue distribution but with similar structure and function. PPARs are nuclear receptors, which regulate gene transcription by binding to retinoid X receptors (RXR) as functional heterodimers in response to a variety of endogenous and exogenous ligands. The PPAR/RXR complex modulates gene target expression by binding to the PPAR response elements (PPREs) in the gene promoter^[190]. These nuclear receptors present three main domains: the N-terminal domain containing a ligand-independent transactivation function; the DNA-binding domain containing two zinc-finger motifs responsible for binding on PPREs to regulate transcription of PPAR-responsive genes; the ligand-binding domain (LBD) containing a ligand-dependent activation function. The LBD shows the presence of a wide hydrophobic region which could explain the increased ability of PPARs to bind a wide variety of natural and synthetic ligands^[191,192] (Figure 4).

In particular, the PPAR-γ isoform, identified mainly in the colorectal mucosa but also in adipocytes, the liver, vascular tissue and several inflammatory cells (monocytes and macrophages, dendritic cells, B and T cells), seems to be involved in several physiological processes, such as differentiation of adipocytes, glucose homeostasis, lipid metabolism, inflammatory and immune processes, as well as fibrosis^[189,190]. Several ligands, either natural, such

as arachidonic acid metabolites (15-d-PGJ₂) and some eicosanoids, or synthetic, such as thiazolidinediones and some non-steroidal anti-inflammatory drugs, appear to be responsible for the activation of PPAR-γ (Figure 4).

PPAR-γ activation seems to be strongly related to the TGF-β/Smads pathway. The stimulation of PPAR-γ with specific ligands, indeed, interferes with the Smad3 pathway by directly antagonizing Smad3 or downregulating the CTGF expression that promotes TGF-induced synthesis of collagen^[189,193]. PPAR-γ agonists inhibit fibroblast migration and proliferation^[194] as well as the transdifferentiation of epithelial and mesenchymal cells in activated myofibroblasts^[195], one of the key points in fibrosis development. PPAR-γ ligands repress TGF-β-induced myofibroblast differentiation and activation by targeting the PI3K/Akt and Smad3 pathways, respectively^[196,197]. Overexpression of PPAR-γ prevents the development of tissue fibrosis, whereas its loss increases susceptibility to fibrosis^[198,199]. All these findings could explain the ability of PPAR-γ to interfere in multiple phases of the tissue fibrotic processes. Therefore, PPAR-γ should be regarded as providing innate protection from excessive fibrogenesis and as a potential new target for the development of novel compounds with anti-fibrotic properties^[200]. Several PPAR-γ ligands with selective activity are under development. Experimental studies have shown that PPAR-γ agonists attenuate fibrosis in various organs including lung, kidney, pancreas, liver and intestine, antifibrotic effects that are abolished by the use of PPAR-γ selective antagonists^[201-206]. The PPAR-γ coding gene is considered a potential susceptibility gene for IBD^[189].

Mammalian target of rapamycin

In the 1970s, during a discovery programme for novel anti-microbial agents from natural sources, a soil sample from Easter Island (known as Rapa Nui) was found to contain *Streptomyces hygroscopicus*, a bacterium that produces a potent antifungal metabolite; the antibiotic was isolated and called rapamycin (Rapa + mycin). TOR was originally identified in *Saccharomyces cerevisiae* and, in subsequent biochemical studies, also in mammals and therefore was named the mTOR.

mTOR is a 289 kDa phosphatidylinositol 3-kinase-related kinase^[207]. mTOR signaling is activated by hormones, growth factors, amino acid levels, stress and alterations in cellular energy status^[208] (Figure 5). Among the signal inputs, growth factor- and hormone-induced mTOR activation is the best characterized and is believed to be mediated through the PI3K pathway and PKB/Akt.

mTOR forms at least two distinct complexes. mTOR complex 1 (mTORC1) is composed of mTOR, GβL and Raptor and is responsible for sensing the nutrient; mTORC2 consists of mTOR, GβL and Rictor and is involved in the organization of actin. mTORC1 is sensitive to rapamycin whereas mTORC2 is insensitive to rapamycin.

The best characterized downstream targets of mTORC1 are S6K1 and 4E-BPI which control protein synthesis and cell growth and proliferation, respectively, as

well as autophagy, angiogenesis and fibrosis^[208] (Figure 5). Rapamycin induces a translational arrest by preventing phosphorylation of S6K-1 and 4E-BPI by mTOR^[209].

It has been demonstrated that mTOR strongly enhances expression of hypoxia-inducible factor (HIF)1- α , a subunit of HIF which is a transcription factor that mediates expression of several genes, the products of which play a considerable role in inducing angiogenesis^[210]. Two of the key gene products induced by HIF are VEGF and angiopoietin-2, which represent the main driving factors of neo-angiogenesis.

It has been shown that mTOR signaling is required for angiogenesis and plays a key role in endothelial cell proliferation in response to hypoxia. Hypoxia, indeed, rapidly promotes and sustains mTOR phosphorylation, whereas mTOR inhibition by rapamycin specifically abrogates hypoxia-mediated amplification of endothelial proliferation and angiogenesis^[211,212]. Moreover, it has been recognized that mTOR-dependent HIF1- α expression is sensitive to rapamycin. Inhibition of mTOR with rapamycin can reduce the process of angiogenesis by blocking VEGF, TNF- α and PDGF α production through inhibition of HIF1- α expression and its transcriptional activation^[213-215]. mTOR might, therefore, play an important role in the abnormal angiogenesis associated with IBD. It has been reported that mTOR is an effector of EGFR- and ANG type 1 receptor-induced fibrosis^[216,217].

mTOR signaling is considered an attractive target for antifibrotic intervention. mTOR inhibitors constitute a relatively new category of immunosuppressive and anti-neoplastic drugs^[218]. These share a unique mechanism of action that is focused on the inhibition of the mTOR. Their clinical applications have recently expanded significantly to cover a wide spectrum of immune and non-immune-mediated disorders, including IBD as well as solid organ transplantation, various solid organ and hematological malignancies, metabolic problems such as diabetes mellitus and obesity, and even fibrotic conditions, including skin, pulmonary, renal, hepatic and intestinal fibrosis^[215-217,219-223].

It has been reported that rapamycin exerts direct antifibrotic activities both by reducing the number of fibroblasts and myofibroblasts and by down-regulating the production of fibrogenic cytokines, such as IL-4, IL-6, IL-17 and TGF- β 1, and the synthesis of type I and III collagen^[224-226]. Application of rapamycin to cultures of fibroblasts dose- and time-dependently downregulates the expression of cytoplasmic PCNA, cyclin D1, α -SMA, fibronectin and collagen^[227]. Rapamycin may improve the defective autophagy associated with fibrostenotic CD^[26,35,42,207].

mTOR might, therefore, also play important roles in IBD-associated fibrosis. Combined immunosuppressive and anti-fibrotic actions of rapamycin and its analogues may result in a promising treatment approach to fibrotic chronic enteropathies such as CD. This has been confirmed by two case reports in which two patients with severe refractory CD were successfully treated

with two different analogues of rapamycin: sirolimus and everolimus^[228,229]. In addition, a recent clinical trial demonstrated the effectiveness of everolimus to maintain steroid-induced remission in patients with moderate-to-severe active CD^[230].

MMPs

An increased turnover of ECM components leads to an intensive remodeling of connective tissue. A delicate balance exists between synthesis and degradation of ECM components. Disturbance of this balance may result either in progressive organ destruction, as seen in formation of ulcers and fistulae, or excessive deposition of collagen, resulting in fibrosis^[231-233]. Degradation of all ECM components is regulated by the enzymatic activity of the predominant and large family of MMPs. In addition to playing a central role in ECM turnover, MMPs proteolytically activate or degrade a variety of non-matrix substrates including chemokines, cytokines, growth factors and junctional proteins. Thus, they are increasingly recognized as critical players in inflammatory response and fibrogenesis^[231-233].

MMPs are a group of calcium-activated and zinc-dependent endopeptidases that are secreted as proforms (inactive zymogens)^[231-233]. They are produced by various cell types, including mesenchymal cells, T-cells, monocytes, macrophages and neutrophils, in response to inflammatory stimuli, such as IL-1, TNF- α , or TGF- β 1^[233]. The MMP family consists of at least 25 distinct members^[234], which can be subclassified according to their substrate specificities: collagenases (e.g., MMP-1, -8, -13, -18), gelatinases (MMP-2, -9), stromelysins (MMP-3, -7, -10, -11), elastase (MMP-12), membrane types (MMP-14, -15, -16, -17, -24, -25) and others (MMP-19, -20, -23, -26, -27, -28). All MMPs become activated *via* proteolytic cleavage and are regarded as the major enzyme group capable of degrading ECM components such as collagens, laminins and fibronectins, including basement membranes. Once one type of MMP is activated it can catalyze activation of other MMP proforms.

MMP activity is controlled by specific and non-specific inhibitors such as TIMPs and α 2-macroglobulin, respectively^[16,232,233]. TIMPs are produced by the same cell types as MMPs and form a 1:1 complex with activated MMPs. The fine balance between MMPs and TIMPs regulates the turnover of ECM both under physiological conditions and in tissue remodeling during inflammation and wound healing. Thereby, the imbalance, due to reduced MMP activity and/or increased expression of TIMPs, may lead to excessive deposition of ECM proteins driving fibrogenesis^[115,30,51].

In IBD, overexpression of several MMPs has been reported, which might lead to inflammation and tissue injury, facilitating the migration and invasion of fibroblasts into the bowel wall, ultimately leading to fibrosis^[235-238]. Addition of recombinant MMP-3 to an *ex vivo* gut model caused extensive tissue injury, and inhibition of MMPs almost completely abolished tissue destruction^[239]. The expression of MMP-1, -3, -7 and -13, as well as TIMP-3,

was increased in the wound edges of ulcerated tissue in UC and CD^[240]. Levels of MMP-1, -2, -3 and -9 relative to TIMP-1 and -2 are increased in inflamed, compared to non-inflamed, IBD tissue homogenates, regardless of the presence of fibrosis^[92,231].

TGF- β 1 may lead to fibrosis by creating an imbalance of TIMP1/MMP expression in favor of TIMP-1^[241]. Stricture-derived myofibroblasts in CD overexpress TIMP-1^[242] and the expression of TGF- β 1 and TIMP-1 is increased in the mucosa overlying strictured compared to non-strictured intestine, while MMP-3 and -12 are down-regulated^[243]. In support of this notion, blocking TGF- β 1 in cultures of intestinal biopsies upregulates the expression of MMP-3, but not of TIMP-1^[93]. In a murine model of chronic inflammation, fibrosis is associated with an increase in TIMP-1^[244].

A possible genetic basis has been explored: SNPs in genes encoding MMPs and TIMPs have been reported. An SNP at the TIMP-1 site is associated with increased susceptibility for CD, and an SNP at the MMP-3 site may increase the chance of stenotic complications^[245].

An imbalance in MMP:TIMP expression and enhanced levels of the messages for fibrogenic cytokines and ECM proteins were also reported in late radiation enteritis and *Schistosoma mansoni*-induced chronic colitis^[246,247]. Despite the fact that the expression of collagens, MMPs and TIMPs simultaneously increased, quantification of net collagen deposition showed an overall accumulation of collagen. These findings indicate that the intestine affected by chronic inflammation is subjected to an active process of fibrogenesis as well as fibrolysis, with a balance toward fibrogenesis. This demonstrates that established fibrotic tissue is not scarred fixed tissue but is subjected to a dynamic remodeling process.

Taken together, all these data strongly support the hypothesis that an imbalance of tissue-degrading enzymes and their inhibitors may cause intestinal fibrosis^[232,233,248]. MMPs and TIMPs may, therefore, be considered as targets for new anti-fibrotic treatment approaches.

CONCLUSION

Intestinal fibrosis is a highly complex process involving the dynamic actions of numerous molecules which are able to regulate activation of ECM-producing cells during tissue damage and repair. The specific molecules determining the balance between physiologic repair following acute inflammation *versus* the excessive accumulation of ECM leading to fibrosis remain to be identified.

Strong evidence indicates that inflammation triggers fibrosis, which, once established, may progress independently. Available anti-inflammatory drugs have been shown to be ineffective in the prevention and treatment of the fibrosis. It is critical to elucidate the cellular signals promoting fibrogenesis that act independently of inflammatory pathways and immuno-inflammatory response.

Definition of the cellular and molecular mechanisms involved in intestinal fibrosis will represent the key to the

development of new therapeutic approaches for the treatment of fibro-stenosing enteropathies, particularly CD.

ACKNOWLEDGMENTS

The authors are grateful to Mrs Marian Shields for help in editing the manuscript.

Abstract

Esophageal atresia (EA) with or without tracheoesophageal fistula (TEF) is the most common congenital anomaly of the esophagus. The improvement of survival observed over the previous two decades is multifactorial and largely attributable to advances in neonatal intensive care, neonatal anesthesia, ventilatory and nutritional support, antibiotics, early surgical intervention, surgical materials and techniques. Indeed, mortality is currently limited to those cases with coexisting severe life-threatening anomalies. The diagnosis of EA is most commonly made during the first 24 h of life but may occur either antenatally or may be delayed. The primary surgical correction for EA and TEF is the best option in the absence of severe malformations. There is no ideal replacement for the esophagus and the optimal surgical treatment for patients with long-gap EA is still contro-

versial. The primary complications during the postoperative period are leak and stenosis of the anastomosis, gastro-esophageal reflux, esophageal dysmotility, fistula recurrence, respiratory disorders and deformities of the thoracic wall. Data regarding long-term outcomes and follow-ups are limited for patients following EA/TEF repair. The determination of the risk factors for the complicated evolution following EA/TEF repair may positively impact long-term prognoses. Much remains to be studied regarding this condition. This manuscript provides a literature review of the current knowledge regarding EA.

INTRODUCTION

Thomas Gibson first described esophageal atresia (EA) associated with tracheoesophageal fistula (TEF) in 1697. However, it was not until 1941 that Cameron Haight performed the first successful surgical repair of this anomaly following innumerable attempts by other surgeons^[1-3].

EA with or without TEF remains the most common congenital anomaly of the esophagus. Although EA with or without TEF is a relative rare condition, this complex anomaly is still a challenging problem in pediatric surgery^[1,2]. In developing countries, many infants that present with EA with TEF exhibit pneumonitis due to late referral, and these patients usually have a low birth weight.

The overall incidence of EA/TEF ranges from one in every 2500 to 4500 live births^[1-9]. The vast majority of cases are sporadic, although the incidence is higher in twins. It has been reported that the relative risk for EA/TEF in twins was 2.56 higher than in singletons^[6-8].

An improvement in survival has been observed over the most recent decades. This finding is likely multifactorial and largely attributable to advances in neonatal intensive care, neonatal anesthesia, ventilatory and nutritional support, antibiotics, surgical materials and techniques^[3,5,9,10]. Indeed, mortality is currently limited to those cases with coexistent severe life-threatening anomalies. It should be noted that the care and treatment of EA is a measure of the surgical expertise and facilities available in a particular center or country. Despite an increased number of patients with severe associated anomalies, survival rates as high as 95% have been reported in centers offering the best neonatal care^[11]. Today, practically all patients without concomitant severe malformation survive. Moreover, the high mortality of very low birth weight patients, patients with severe cardiac malformation and of infants with long-gap defects has significantly decreased. Because of this increase in survival, morbidity associated with EA/TEF repair has become an important issue during the follow-up of these children.

There are a limited number of reports concerning the long-term outcome of patients with EA. Relationships between esophageal dysmotility, gastroesophageal reflux, esophagitis and epithelial metaplastic changes, including esophageal cancer, should be studied further^[3,5,8,9]. The present manuscript provides gastroenterologists with a literature review focused on EA with the aim of providing recent data regarding the embryology, diagnosis, therapeutic approaches, complications and outcomes of this very common congenital anomaly.

CLASSIFICATION

The classification of EA anomalies is determined by the location of the atresia and the presence of any associated fistula to the trachea. In this respect, five different variants have been clinically described. The first classification was published by Vogt in 1929 and was modified by Gross in 1953. Thus, two classifications are used today. The primary types of congenital EA are EA with distal TEF (85%, Vogt IIIb, Gross C), isolated EA without TEF (8%, Vogt II, Gross A), TEF without atresia or H-type TEF (4%, Gross E), EA with proximal TEF (3%, Vogt III, Gross B) and EA with proximal and distal TEF

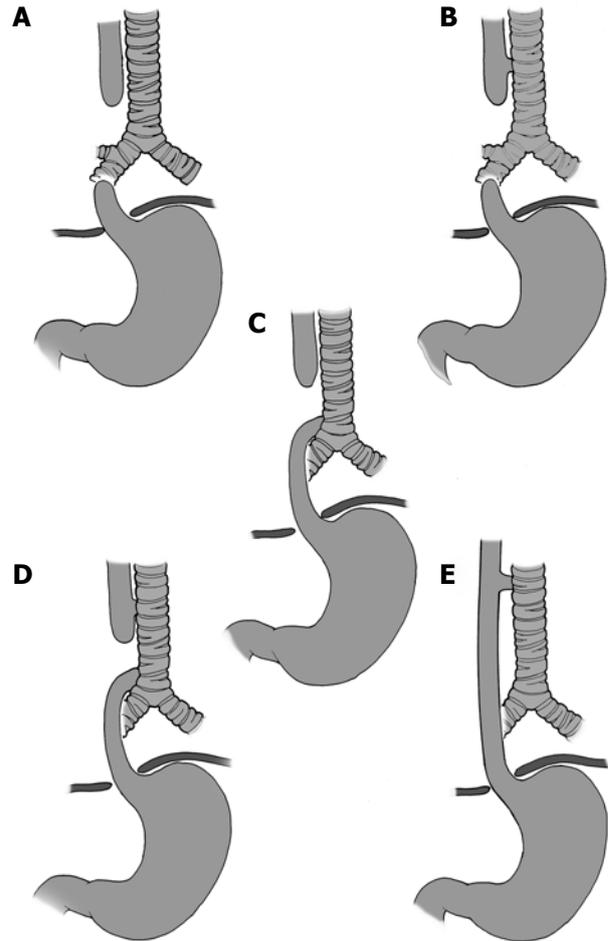

Figure 1 Classification of esophageal atresia/tracheoesophageal fistula. A: Esophageal atresia (EA) without tracheoesophageal fistula (TEF); B: Proximal TEF with distal EA; C: Distal TEF with proximal EA; D: Proximal and distal TEF; E: TEF without EA or "H"-type TEF.

(< 1%, Vogt IIIa, Gross). Figure 1 illustrates the EA classification scheme. An understanding of these anatomical variants is important to aid in medical and surgical management^[1,4,5,12,13].

EMBRYOLOGY

Successful treatment of esophageal anomalies requires knowledge of their embryological origin. Although significant improvements in clinical treatment have been made in recent years, our understanding of the etiology of these defects is still incomplete^[14-17].

The primitive digestive tube (PDT) emerges from the primitive endoderm and subsequently gives rise to the esophagus and trachea. There are three primary theories that attempt to explain this phenomenon^[6,14-19]. The first theory postulates that the evagination of a tracheal diverticulum begins with the PDT, which grows rapidly in the caudal direction, resulting in the separation of the trachea and esophagus (what remains of the PDT). In the context of this developmental mechanism, tracheoesophageal malformations result from tracheal growth failure^[14].

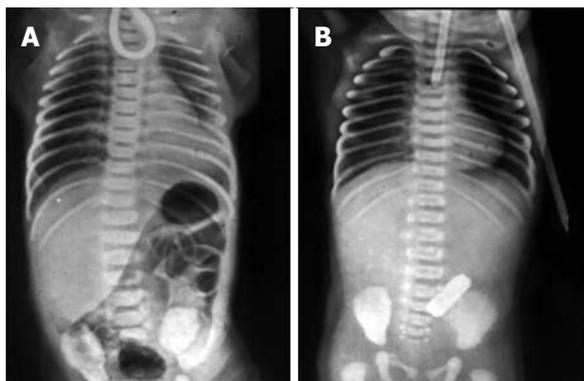

Figure 2 Plain X-rays of the chest and abdomen of two neonates with esophageal atresia. A: The non-progression of an orogastric catheter in the blind esophageal pouch and the presence of air in the stomach diagnose esophageal atresia with distal tracheoesophageal fistula; B: The radiopaque tube in the blind esophageal pouch and the absence of air in the stomach identify esophageal atresia without tracheoesophageal fistula.

Another theory suggests that the formation of a mesenchymal septum in the coronal plane of the PDT, separating the trachea ventrally and the esophagus dorsally from the distal to the proximal ends of PDT. A failure in this process would then result in a tracheoesophageal malformation^[14]. In these two theories, the origin of EA is a cellular rearrangement of the remaining, distal PDT^[14].

The third theory combines elements of the first two and suggests that rapid growth of the tracheal diverticulum occurs in concert with a mesenchymal septation of the PDT, separating the trachea from the esophagus. Unlike the previous theories, however, in this proposed mechanism, EA is believed to result from the loss of a portion of the previously formed tube due to regression toward the main part of the embryo^[14].

Although syndromic cases of EA/TEF are rare, examining the specific genetic anomalies involved may provide valuable information regarding the abnormal developmental processes leading to EA/TEF. Many genes and genetic pathways have been implicated in the development of EA/TEF, but few have been shown to be involved in humans, animals, or both^[15].

There are also molecular and morphogenetic factors related to EA, such as apoptosis, the Sox2, Shh, Gli-2, Gli-3, Pcsk5 and FOX genes and the transcription factors Nkx2.1 and Tbx4^[4,5,15-19]. A failure in the expression of these genes or in the apoptotic programs that they regulate is responsible for EA. However, a whole understanding of these processes remains incomplete^[4,15]. In addition, environmental factors have been suggested to increase the risk for the development of tracheoesophageal anomalies^[15]. Further studies are required for a universally accepted explanation for the pathophysiology of EA/TEF.

DIAGNOSIS

The diagnosis of EA is most commonly made during the first 24 h of life but may be made either antenatally or

may be delayed^[1,5,7-9,20].

Ultrasound (US) scanning is currently a routine method used in prenatal care between the 16th and 20th week of gestation. The suspicion of EA is based on the presence of polyhydramnios and the absence of the gastric bubble, but these are non-specific criteria^[7,21]. US features highly suggestive of EA/TEF are only observed in a small minority of fetuses with EA/TEF (< 10%) on prenatal scans. The combination of polyhydramnios and the absence of a stomach bubble in two previous reports of small patient series gave modest positive predictive values of 44% and 56%, respectively^[7,21].

Dilatation of the blind fundus of the upper segment of the atresic esophagus, the “upper pouch sign”, may also be observed during fetal deglutition at approximately the 32nd gestational week^[7,21]. Moreover, an upper pouch sign may not be detected even with specific examination^[7].

The diagnostic criterion of EA through the use of magnetic resonance imaging is the non-visualization of the intra-thoracic portion of the esophagus. This imaging modality is complementary to ultrasound due to a high percentage of false positives when images are analyzed in an isolated fashion^[21,22]. Even with advances in technological imaging, no ideal prenatal diagnostic method for EA exists.

In the delivery room, the primary sign of EA is the impossibility of the passage of an orogastric catheter beyond 11 or 12 centimeters^[23]. In the nursery, the most important clinical signs are abundant salivation, episodes of cyanosis and suffocation during breastfeeding^[1,4,7]. The confirmation of the diagnosis of EA should be made with a simple chest X-ray using air as contrast in the proximal pouch to avoid aspiration of contrast fluid. If a distal TEF is present, air in the stomach will be present on X-ray films and abdominal distension may be evident^[24]. Figure 2 shows the plain X-rays of two neonates with different forms of EA.

Tracheobronchoscopy has been proposed as an imaging method to detect EA during the preoperative period^[3,22,25]. This technique is used to determine the anatomy of the TEF with respect to the carina, to identify other airway anomalies and to occlude the TEF with a balloon, facilitating mechanical ventilation and avoiding both gastric distension and gastroesophageal reflux. In cases of presumed isolated EA, bronchoscopy also helps to rule out the presence of the less common proximal TEF^[5,22].

PREOPERATIVE PERIOD

Once the diagnosis of EA has been established, the infant needs to be transferred to a regional pediatric surgical center with intensive care support facilities. The aim of the preoperative treatment of EA is to improve the general state of the newborn so that definitive surgery can be carried out under the best possible conditions^[1,4,5].

Classification and risk factors

There are three primary classifications of preoperative

risks regarding EA: the Waterston, Montreal and Spitz classifications^[1,3,10,11,26,27].

According to Waterston, the risk factors to be considered are birth weight (BW), the presence or absence of pneumonia and complications from associated congenital anomalies. In this classification scheme, patients are categorized into group A (BW > 2500 g, with no other complications), group B (BW between 1800 g and 2500 g with no other complications or BW > 2500 g with moderate pneumonia/congenital anomaly) or group C (BW < 1800 g, with no other complications or BW > 2500 g with severe pneumonia/severe congenital anomaly)^[1,3,11,27].

In the Montreal classification scheme for EA, factors such as dependence on mechanical ventilation (MV) and associated congenital anomalies are considered to be of high prognostic significance^[1,11]. Patients are classified into group I (isolated major anomaly, isolated dependence on MV or the presence of non-significant anomalies) and group II (presence of severe congenital anomalies or dependence on MV associated with one major anomaly).

Spitz drafted the most recent classification method by associating BW and cardiac anomalies (CA) as risk factors for EA. In this classification scheme, patients are divided into group I (BW > 1500 g, without CA), group II (BW < 1500 g or the presence of CA) and group III (BW < 1500 g with CA)^[11,21,26,27].

These classification systems serve as guides for the determination of the type of treatment for each case of EA. Some authors no longer consider BW to be a risk factor^[26].

Associated congenital anomalies

What is perhaps of major clinical importance is the high frequency of anomalies associated with EA, with a frequency of over 50%, which may greatly impact both treatment and outcome. In addition to the high frequency of anomalies, their unequal distribution between patients is also important from a clinical perspective. Patients with isolated EA without TEF exhibit anomalies in as many as 65% of cases, while a much lower frequency is observed in patients with TEF without atresia (10%)^[1,7,28].

The most common associated malformation occurs in the cardiovascular system (23% of cases), followed by musculoskeletal malformations (18%), anorectal and intestinal malformations (16%), genital-urinary malformations (15%), anomalies of the head and neck (10%), mediastinal anomalies (8%) and chromosomal anomalies (5.5%)^[5]. Of the observed cardiac anomalies, the most common are ventricular septal defects and tetralogy of Fallot.

A concurrence of congenital anomalies unassociated with a genetic disturbance is referred to as VACTERL [vertebral, anal, cardiac, tracheal, esophageal, renal, and limb (pattern of congenital)] association, which is diagnosed if the patient with EA has 2 or more anomalies of the vertebral, anorectal, cardiac (excluding patent ductus arteriosus and patent foramen ovale), renal/genitourinary, or limb systems. Cardiac anomalies are the most common ones. This broad spectrum of anomalies suggests an al-

teration during the early stages of embryogenesis related to a deficiency in the regulation of the *Sbb* gene^[29]. The CHARGE (coloboma, heart, atresia choanal, retarded growth, genital hypoplasia, ear deformities) association may also include EA^[7].

Life-threatening anomalies, including Potter's Syndrome (bilateral renal agenesis, pulmonary hypoplasia, typical dysmorphic facies), cerebral hypoplasia and chromosomal anomalies, such as trisomy of chromosomes 13, 14 and 18, may be present. These severe conditions directly predict adverse outcomes^[5]. Similarly, infants with totally uncorrectable major cardiac defects or with grade IV intraventricular hemorrhage should be considered for non-operative management^[11].

Nasr *et al.*^[30] demonstrated in 2010 that normal clinical and radiologic examination predicts the absence of significant cardiac abnormalities on echocardiography in 100% of cases. Therefore, these authors conclude that routine pre-surgical echocardiography may not always be necessary, but should be reserved for infants with abnormal clinical and/or radiologic findings.

Vascular components are often overlooked in the investigation of anomalies associated with EA^[31]. The presence of the right aortic arch in association with EA is most often discovered during the surgical intervention for EA correction. According to Babu *et al.*^[32], this condition occurs in 2.5% to 5% of cases of EA, with a greater frequency in males. The method of choice for detecting this anomaly is echocardiography, although this technique is not routinely employed during the investigation of EA. Following the discovery of this anomaly, a left thoracotomy should be performed to correct the EA^[32].

The persistence of the left superior vena cava (LSVC), which results from the persistence of the left inferior cardinal vein, is observed in nearly 10% of infants with EA. Depending on the trajectory of the LSVC, complications may occur, such as thrombosis of the coronary sinus and arrhythmia^[31,33].

Antibiotic prophylaxis

Colonization by bacterial flora of the digestive tract in newborns with EA is related to the establishment of enteral nutrition. However, strains of *Pseudomonas* and *Serratia* have been isolated in the portion of the esophagus that is present in these infants. Antibiotic prophylaxis using amoxicillin and clavulanate is therefore indicated in such patients^[1,3,34].

Neonatal care

Neonatal care includes stabilization of the infant's respiratory status with avoidance of endotracheal intubation; suction tube drainage of the blind, proximal esophageal pouch; semi-prone positioning of the child to minimize the risk of gastroesophageal reflux; and aspiration *via* the occult fistula of the distal trachea^[5]. Monitoring of vital signs and vascular access should also be performed as precautionary measures.

SURGICAL TREATMENT

The surgical treatment of EA is considered urgent but not an emergency, except in premature infants with respiratory distress^[1,3].

Anesthetic care has focused on minimizing ventilation through the fistula, usually by placing the end of the endotracheal tube distal to the fistula, preventing gastric distension/perforation and/or ventilator compromise^[1,7,25]. However, if the fistula is located at the level of the carina, distal placement of the endotracheal tube is impossible. Gastric distention can complicate the ventilation of patients with large TEFs. Gastric distension can also result in the aspiration of gastric contents or in elevation of the diaphragm, leading to decreased tidal volumes, decreased venous return, cardiovascular collapse and ultimately perforation. This results in tension pneumoperitoneum^[1,7,25].

The semi-prone position is the position of choice, with the right side elevated at 45° and the right arm placed over the head. Anesthesia is maintained during the surgical procedure with a volatile anesthetic agent. The patient is ventilated with positive-pressure MV and hydrated with a crystalloid solution^[34].

The primary correction of EA and TEF is the best treatment option in the absence of severe malformations^[35-38]. Standard right posterolateral extrapleural thoracotomy below the tip of the scapula is extremely useful and allows the repair of other complex anatomic variants^[2]. If a right-sided aortic arch is observed on preoperative echocardiography, a left thoracotomy must be performed and the chest is entered through the fourth intercostal space. Care should be taken to avoid entry into the pleura. Extrapleural dissection proceeds posteriorly and superiorly to identify the azygos vein. Division of the azygos vein arch allows for full exposure of the posterior mediastinum. The TEF and vagus nerve are often encountered beneath the azygos arch. This procedure begins with the closure of the fistula. The TEF is divided near the trachea and sewn with fine non-absorbable sutures, which is followed by the correction of the EA. The upper atresic esophageal pouch is identified with downward tension on an oro-esophageal tube, and its dissection is facilitated by the placement of a traction suture at the end of the pouch. Blunt and sharp dissection can mobilize the proximal pouch to the level of the thoracic inlet. Esophageal continuity is accomplished using a single-layer, end-to-end anastomosis with monofilament absorbable sutures^[5]. With respect to unstable patients, however, the procedure should be performed in steps^[35].

There is limited evidence to support the use of a trans-anastomotic tube. The majority of surgeons do not routinely use an intercostal catheter if the repair is extrapleural. Alabbad *et al*^[39] observed that a trans-anastomotic feeding tube may lead to a shorter total parenteral nutrition duration and decreased cholestasis. It was also demonstrated that central venous catheters tended to be removed earlier when trans-anastomotic tubes were used, decreasing the risk of future infection. Furthermore,

hospital stays tended to be shorter^[39]. However, this study provides only preliminary evidence of the benefits of trans-anastomotic tubes. Larger prospective studies will be required to conclusively demonstrate these benefits and to ensure that this technique does not increase anastomotic leaks.

No ideal replacement for the esophagus is available. Nonetheless, the substitute should function as similarly as possible to the original tissue^[35-37]. The reconstruction of the esophagus using only its atresic portions is preferable to the use of any other material, even in cases of long-gap EA^[40-46]. However, a number of authors do not agree with this procedure^[47,48].

Long-gap EA still presents a challenge to pediatric surgeons. A long gap between the two ends of the esophagus in cases of EA has been defined as a gap longer than 3 cm or greater than the height of 2 vertebral bodies^[49].

The historical treatment of EA has included a gastrostomy, the estimation of the extent of the gap between the proximal and distal esophagus and proximal pouch decompression. These measures allow time for potential lengthening of the esophagus with linear patient growth. Delayed surgical intervention is accomplished at approximately three months of age with attempts at achieving a primary anastomosis. Failed attempts at primary anastomosis may then be addressed with colonic interposition, reverse or antegrade gastric tube interposition, gastric transposition, or free jejunal graft interposition. Alternatively, these approaches have been attempted during the neonatal period as a primary repair^[5,50-52].

The ideal surgical treatment for patients with long-gap EA has not been determined, and the topic is still very controversial. In fact, it remains somewhat difficult to determine which surgical procedure achieves the best results. The infant's own functional esophagus is superior to any esophageal replacement. Familiarity with different techniques used to preserve this tissue is therefore important. A number of techniques are proposed for the treatment of long-gap EA. One is the dissection and mobilization of the distal esophageal stump using circular myotomy^[41]. Some authors believe that this technique can be used without vascular impairment of the esophagus due to the abundant irrigation of the esophagus, and that it is preferable to surgery under tension^[41]. Others believe that this technique may result in necrosis of the distal stump and consequent leaking of the anastomosis^[47].

Suboptimal results with these strategies have led to the development of techniques that attempt to elongate the esophagus sufficiently to bridge the gap. This principle was the basis of the technique described by Foker *et al*^[43]. The so-called Foker technique consists of the use of external traction sutures to elongate the esophageal portions and to approximate one stump to the other prior, thus completing the anastomosis. As the esophagus exhibits spontaneous growth during the first three months of life, the technique is performed following this period to ensure that the esophagus has the necessary thickness

to support the traction. This procedure is extremely beneficial despite the requirement for a second thoracotomy, and its success is ensured by esophageal mobilization and the secondary anastomosis^[43,44,53]. A complication that may occur with this technique is the undesired cutting of the esophagus by the sutures^[43]. To avoid this outcome, a modification of the Foker technique has emerged, in which small tubes of silastic are attached to the terminal portions of the two esophageal stumps and the thoracic wall, where the tension is applied^[43].

Nagaya *et al.*^[54] proposed a method for assessing the tension of the anastomosis by placing a metal clip in the trachea at the site of the TEF and assessing the distance between this clip and both the site of anastomosis and the esophago-gastric junction. This method is based on the notion that the stretching of the esophagus is directly related to the tension of the anastomosis and that this information can predict possible postoperative complications. Stretching of up to 5 mm is considered well tolerated^[54].

Tamburri *et al.*^[55] showed that Kimura's technique^[56] is a useful surgical option for a select group of patients with (1) a complex long-gap EA that requires a primary esophagostomy; or (2) any type of EA with the development of severe complications following a primary repair and that required a secondary esophagostomy. The operative procedure consists of an initial cutaneous esophagostomy, multistaged extrathoracic esophageal elongation (ETEE), and definitive esophageal anastomosis. The ETEE includes the mobilization and dissection of the esophagus up to the cricoid cartilage level, with the opening placed on the previously made superior clavicle surgical scar. Variable elongation of the esophagus is achieved following completion of the dissection. The esophagus is again exteriorized as an esophagostomy at a level of a few centimeters below the previous esophagostomy site^[55,56].

More recently, Stringel *et al.*^[57] reported another technique used to repair long gap EAs without anastomosis. This technique consisted of suture approximation and subsequent endoscopic and fluoroscopic placement of string for guided dilations^[57].

In addition to techniques that employ the patient's own esophagus, there are those that use pedicle grafts from the jejunum or colon, which are indicated when the motility of the esophagus does not allow adequate oral feeding and gastric transposition^[5,36,47,48]. The creation of a jejunal graft involves a cross-sectional cut proximal to the ligament of Treitz, separating the first two mesenteric arteries from the peripheral arch. A second cut is made at the level of the third mesenteric artery. The distal portion of the proximal jejunum is removed and transferred to the thorax, leaving on the proximal portion of the jejunum. An anastomosis is then made between the esophageal stumps and the graft. The justification for this technique is that the peristalsis remains in the jejunal graft, but it does not have a tendency to elongate^[48]. With respect to the colon pedicle technique for esophago colic anastomosis, the graft is chosen from the portion of the colon irrigated by the left colic artery and transferred to

the thorax posterior to the mediastinum. The colon also needs to be attached to the muscles of the neck. This technique should only be employed after four months of life to ensure adequate vascularization of the colon^[36,58]. The advantage of using the colon is the presence of long marginal arches, which allows for ample mobilization of extensions to the cervical region. Another advantage is the graft's extreme resistance to gastric fluid due to the continuous production of mucus. The most feared complication is necrosis of the transposed loop^[36,58].

A number of authors prefer gastric transposition^[1,3,37]. This technique has the advantages of being simple, of using the vascularization of the stomach and of easily raising the stomach to the neck for the anastomosis. The primary disadvantages are respiratory distress and late-onset gastric leakage^[37].

For thoracoscopic repair of EA, the patient is placed in a 3/4 prone position and the trocars are inserted at the angle of the scapula in the right axillary region and between the vertebra and the angle of the scapula at the 7th to 8th right intercostal space. The azygos vein and TEF are linked, maintaining the separation between the portions of the esophagus until the mobilization of the proximal stump to avoid retraction of the distal stump toward the diaphragm^[34,59]. A preferentially termino-terminal anastomosis is performed between the esophageal portions, beginning with the posterior wall of the esophagus^[34]. Thoracoscopy is not indicated for the correction of long-gap EA, as this defect requires more invasive dissection and there may be difficulty with the anastomosis of the proximal and distal portions of the esophagus, leading to an increased surgical time, which does not justify the minimally invasive repair^[34].

Cases of "H-type" TEF without EA (Type E) are unique in their presentation and repair^[5]. Infants with this anomaly often present with a long-standing history of recurring aspiration and multiple episodes of pneumonia. The diagnosis is often made following a contrast esophagram or an upper gastrointestinal series by observing the fistula at the lower cervical esophagus or by bronchoscopy. The operative approach for these cases begins with a rigid bronchoscopy and attempts to cannulate the fistula with a small feeding tube or Fogarty catheter. This approach will often aid fistula identification at the time of the operation. The fistula is approached through a right lateral, oblique cervical incision with the neck extended. Dissection begins anterior to the sternocleidomastoid muscle with lateral reflection of the carotid sheath. Exposure of the esophagus continues into the upper mediastinum with identification of the fistula. Primary repair of the tracheal and esophageal portions of the fistula are performed with interrupted sutures. Separation of the adjacent suture lines is aided by interposition of mobilized strap muscles^[5].

Some infants require respiratory support, especially those who are premature; those with associated cardiac anomalies; those in whom the diagnosis was initially missed; and in those with a splinted diaphragm secondary

to gastric distension^[1,7]. In infants requiring respiratory support, great care should be taken during intubation and in supervising ventilation. This challenging and potentially rapidly fatal situation appears to be best managed by an emergency ligation of the distal fistula with a transpleural approach. In the majority of cases, ligation of the fistula improves respiratory status. The thoracotomy is closed pending resolution of respiratory distress over the subsequent few days. Endoscopic placement of a Fogarty balloon catheter, while conceptually an elegant temporizing maneuver, requires a high degree of expertise and has not been proven to be a successful approach in most centers^[1,7].

POST-OPERATIVE PERIOD

In most centers, the infant returns to the neonatal intensive care ventilated and with the neck flexed to reduce anastomotic tension. When the esophageal anastomosis has been performed under tension, the infant is electively paralyzed and mechanically ventilated for 5-7 d postoperatively. If the surgeon has inserted an transanastomotic feeding tube, feeding through the tube should progress slowly, usually beginning 48 h following the surgery^[39]. When the infant can swallow saliva, oral feeding may be started. A routine contrast study appears unnecessary in many cases, but if there is any doubt regarding the integrity of the anastomosis, a water-soluble contrast study should be performed^[1,7].

The primary complications during the postoperative period are leak and stenosis of the anastomosis, gastroesophageal reflux (GER), esophageal dysmotility, fistula recurrence, scoliosis, deformities of the thoracic wall and respiratory disorders^[1-5,7,37,47,60-65].

The outcome following EA/TEF repair is variable. Some patients have an uneventful postoperative period, while others experience several esophageal or respiratory complications that can significantly affect their health through adulthood and can predict the patient's ability to develop adaptive behaviors^[7,49,62-65].

Anastomotic leaks

Anastomotic leaks are considered minor or major. These leaks occur in 15%-20% of patients but are a significant disruption to recovery in less than a third of these cases^[1-5,7,37,38]. Leaks result from the small, friable lower segment, ischemia of the esophageal ends, excess anastomotic tension, sepsis, poor suturing techniques, the type of suture, excessive mobilization of the distal pouch and increased gap length^[66].

Minor leaks are spontaneously reabsorbed by the body, with the vast majority healing within a few days. These leaks are nonetheless associated with a greater incidence of subsequent stricture development. Alternatively, major leaks may cause tension pneumothorax and require the placement of a drain or an early thoracotomy. The thoracotomy is carried out with the intention of repairing the anastomosis. However, if there has been a complete

disruption that precludes any attempt at re-anastomosis, the repair includes a cervical esophagostomy, the closure of the distal esophagus and a subsequent esophageal replacement. Antibiotics and continuous suctioning of the upper pouch may be instituted to reduce saliva egress from the esophagus. The institution of either parenteral nutrition or trans-anastomotic tube feeding is also recommended. A contrast study prior to oral feeding should be performed at the discretion of the surgeon^[1-5,7,37].

A close association exists between anastomotic leakage and the tension of the anastomosis on the suture line^[66]. Uchida *et al*^[67] demonstrated the efficacy of postoperative elective ventilatory support for leakage protection in primary anastomoses of EAs.

Esophageal strictures

Anastomotic strictures are the most common cause of recurrent surgery in children with EA/TEF, and the incidence varies between 30%-40% of cases. The majority of these cases respond to one or two dilatations^[1,2,66,68]. Risk factors that have been implicated in stricture formation include anastomotic tension, anastomotic leakage and GER. With meticulous handling of the esophageal ends, the preservation of the blood supply and careful inclusion of mucosa in each suture of the anastomosis, strictures can be kept to a minimum^[1]. The occurrence of stenosis of the anastomosis is more common in patients with long-gap EA, which is thought to be due to the fact that the repair is under tension^[7,48,59].

The definition of a stricture, however, is not universally accepted as a mild radiological narrowing on a contrast esophagram. Occasionally, this finding may not have any clinical relevance to the physician or to the patient, who may be able to swallow satisfactorily^[2].

Treatment may require successive endoscopic dilatations under general anesthesia^[1,40]. Most strictures respond to dilatation, but it is crucial that reflux is aggressively treated to diminish the impact of acid reflux on recurrent stricture formation^[2]. There is disagreement as to whether dilatation should be performed in a prophylactic or therapeutic fashion. According to Koivusalo *et al*^[69], therapeutic dilatation has the advantages of requiring fewer procedures, shorter hospitalization times and lower costs when compared to prophylactic dilatation.

GER

GER is extremely common among infants following EA repair and may affect between 40% and 65% of patients^[2]. The presence of significant GER is generally believed to be due in part to an intrinsic deficiency in the motor function of the esophagus itself. However, it is likely that GER is exacerbated by the surgical repair and gastrostomy, causing an alteration of the anatomical gastro-esophageal junction and the angle of His^[2]. GER is more common following tension anastomosis^[1,37,70,71]. The symptoms include acute or chronic respiratory problems, regurgitation, recurring vomiting and growth failure^[4]. The diagnosis is made primarily through esophagoscopy,

a 24 h pH probe, intraluminal impedance or a contrast swallow^[2,72].

The treatment of GER can be either clinical or surgical, the latter constituting approximately 28% of cases. The clinical treatment of GER includes dietary modification, adequate positioning of the infant and medication^[5]. The most frequently recommended drug is omeprazole, the effective dose of which is 1.9 mg/kg to 2.5 mg/kg per day, until resolution of the GER and stenosis^[54,73-75].

Surgical treatment consists of Nissen fundoplication, in which the closure of the esophageal hiatus occurs with the approximation of the diaphragm pillars. This is followed by the construction of anti-reflux valves using the gastric fundus to completely envelop the abdominal esophagus^[1,5]. Unfortunately, however, a significant number of infants (> 40%) develop recurrent GER, which may be due in part to the inherent dysmotility of the esophagus^[2].

Long-standing GER is associated with considerable morbidity, resulting in chronic esophageal inflammation and contributing to recurrent pulmonary infections and abnormalities of pulmonary function in a significant number of patients. Moreover, GER is associated with the development of columnar metaplasia that may undergo dysplastic changes, giving rise to esophageal adenocarcinoma through a metaplasia-dysplasia-carcinoma sequence^[37,76-82].

It has been shown that symptoms of GER and histologic findings are poorly correlated. Therefore, long-term endoscopic and pH-metric follow-up of all patients following repair of an EA is warranted. Endoscopic follow-up is recommended for all patients following EA repair irrespective of symptoms. The endoscopic follow-up of children with completely normal esophageal biopsies can be discontinued at the age of 3 years. In patients with mild esophagitis, routine follow-up should be extended to at least 6 years of age^[83-85]. Patients who have undergone anti-reflux surgery should also be followed long-term^[85].

Esophageal dysmotility

Esophageal dysmotility is a very common long-term finding in children with EA/TEF and has been demonstrated in 75% to 100% of patients post-EA/TEF repair. Likewise, in patients who have had some form of esophageal replacement, dysmotility with symptoms such as aspiration, dysphagia, or food bolus obstruction is often reported^[2]. Esophageal dysmotility can be caused by abnormal neural development of the esophagus or may result from complications of EA repair, resulting in deficient peristalsis and uncoordinated contractions of the distal portion of the reconstructed esophagus^[37,86-91]. Esophageal emptying is therefore achieved primarily by gravity. Esophageal and gastric dysmotility can be considered causes of GER^[1,37,86-89]. Scintigraphy and manometry exams are used to diagnose esophageal dysmotility^[86,87,92].

Deformities of the thoracic wall and scoliosis

Chest wall and spinal deformities can be very disfiguring

for patients and may be inadvertently overlooked from a pediatric surgeon's perspective, as these deformities may only become apparent later in life. These anomalies may then be referred to a different specialty, such as orthopedics or plastic surgery. Open thoracotomy can result in significant musculoskeletal morbidity if care is not taken to ensure proper muscle-sparing surgical techniques^[93]. Associated vertebral anomalies can contribute to chest wall or spinal deformities by directly affecting the ribs and vertebral column^[94,95]. A "winged" scapula secondary to neuromuscular injury to the latissimus dorsi muscle has been reported in 24% of patients undergoing a standard posterolateral thoracotomy for EA/TEF repair, with up to 21% of patients exhibiting scoliosis^[2]. Scoliosis is more common in patients who have undergone more than one thoracotomy or division of portions of the serratus anterior and latissimus dorsi muscle groups or their nerve supplies^[2]. Deformities of the thoracic wall are more common in patients who have undergone multiple thoracotomies but can be avoided or diminished with the use of thoracoscopy.

Respiratory disorders

The etiological factors involved in respiratory problems are thought to be retained secretions caused by tracheomalacia, aspiration related to impaired esophageal peristalsis and esophageal stricture and recurrence of TEF or GER. Primary respiratory complications, such as recurrent bronchitis, pneumonias, wheezing illnesses, daily coughing and bronchiectasis are common in patients with repaired EA, but become less frequent with time^[96-102].

Tracheomalacia is due to a structural and functional weakness in the wall of the trachea, resulting in partial and occasionally complete obstruction of the tracheal lumen. This condition results from abnormal tracheal rings, deficiencies in cartilage, and an increase in length of the transverse muscle. Tracheomalacia is a consistent finding in most if not all children with TEF, but is reported to be clinically significant in only 10%-20% of patients and tends to improve with age^[1,7,37]. Approximately half of symptomatic patients require surgical correction, the aortopexy. This repair is reserved for those with near-death episodes or recurrent pneumonia. Success rates of 35% to 88% have been reported^[2].

Bronchoscopy is the gold standard for the diagnosis of tracheomalacia. The severity of tracheomalacia is based on a macroscopic estimation. It is considered severe when the anteroposterior collapse is $\geq 75\%$ with cough or expiration, moderate when the collapse is 50% to 75%, and mild when the collapse is $< 50\%$ ^[96].

CONCLUSION

Improvements have been made in the treatment of EA over the years^[44-49,55]. However, there is no ideal surgical procedure for this congenital anomaly. The search for simpler, less burdensome, more efficient methods for the treatment of EA is closely tied to the difficulty in obtain-

ing sophisticated equipment and qualified personnel for the follow-up of these patients. Long-term outcomes and follow-up data are limited for post-EA/TEF repairs. GER affects these children at the five-year follow-up and gradually declines in children followed for over ten years. Additional long-term morbidities include recurrent respiratory infections, tracheomalacia, dysphagia and choking episodes. Each of these afflictions diminishes over long-term follow-up, but morbidity from esophageal dysmotility may be a life-long problem. Indeed, although EA primarily affects patients during the neonatal period, postoperative complications may lead to common gastroenterological disorders that require long-term follow-up by gastroenterologists. Therefore, determining the risk factors of the complicated evolution of a EA/TEF repair can positively impact the long-term prognosis of these patients, likely avoiding relevant gastroenterological symptoms during adulthood. Knowledge of these risk factors will allow the identification of patients who may benefit from a more intensive follow-up program. Much remains to be understood about EA. Meanwhile, in order to treat patients with individualized care, it is necessary for physicians to stay current regarding treatments for EA.

Abstract

AIM: To investigate the clinicopathological features of intraductal neoplasm of the intrahepatic bile duct (INiHB).

METHODS: Clinicopathological features of 24 cases of INiHB, which were previously diagnosed as biliary papillomatosis or intraductal growth of intrahepatic biliary neoplasm, were reviewed. Mucin immunohistochemistry was performed for mucin (MUC)1, MUC2, MUC5AC and MUC6. Ki-67, P53 and β -catenin immunoreactivity were also examined. We categorized each tumor as adenoma (low grade), borderline (intermediate grade), and malignant (carcinoma *in situ*, high grade including tumors with microinvasion).

RESULTS: Among 24 cases of INiHB, we identified 24 tumors. Twenty of 24 tumors (83%) were composed of a papillary structure; the same feature observed in intraductal papillary neoplasm of the bile duct (IPNB). In contrast, the remaining four tumors (17%) showed both tubular and papillary structures. In three of the four tumors (75%), macroscopic mucin secretion was limited but microscopic intracellular mucin was evident. Histologically, 16 tumors (67%) were malignant, three (12%) were borderline, and five (21%) were adenoma. Microinvasion was found in four cases (17%). Immunohistochemical analysis revealed that MUC1 was not expressed in the borderline/adenoma group but was

expressed only in malignant lesions ($P = 0.0095$). Ki-67 labeling index (LI) was significantly higher in the malignant group than in the borderline/adenoma group (22.2 ± 15.5 vs 7.5 ± 6.3 , $P < 0.01$). In the 16 malignant cases, expression of MUC5AC showed borderline significant association with high Ki-67 LI ($P = 0.0622$). Nuclear expression of β -catenin was observed in two (8%) of the 24 tumors, and these two tumors also showed MUC1 expression. P53 was negative in all tumors.

CONCLUSION: Some cases of INihB have a tubular structure, and are subcategorized as IPNB with tubular structure. MUC1 expression in INihB correlates positively with degree of malignancy.

INTRODUCTION

Mucin-producing tumors arising from the bile duct have been reported previously^[1-5], but as a disease category, consensus has not yet been reached. Recently, Shibahara *et al*^[6] and Zen *et al*^[7] have contributed to the development of the concept of papillary tumors in the bile duct that resemble intraductal papillary mucinous neoplasm of the pancreas (IPMN-P) and pancreatic intraepithelial neoplasia. These bile duct tumors show papillary proliferation in the bile duct with mucin secretion, and are considered as intraductal papillary neoplasm of the bile duct (IPN-B), that is, the biliary counterpart of IPMN-P^[8,9]. Recent studies have indicated that IPN-B could be subcategorized according to the results of mucin immunohistochemistry^[6,7], and the similarity of IPNB and IPMN-P has also been described.

In our current study, we conducted histological and immunohistochemical re-examination of 24 cases of intraductal neoplasm of the intrahepatic bile duct (INihB), which were previously reported as biliary papillomatosis or intraductal growth type of intrahepatic biliary neoplasm^[10-13].

MATERIALS AND METHODS

Definition of INihB

We defined INihB as a tumor that (1) was localized in the liver; (2) arose within the intrahepatic bile duct; (3) had a major lesion that was noninfiltrative and showed an intraductal proliferation pattern; and (4) clinicopathologically communicated with the surrounding bile duct.

Tissue samples

We identified 24 cases of INihB from the medical record at Kurume University Hospital and affiliated institutions. These cases were previously diagnosed as intraductal intrahepatic biliary neoplasm or biliary papillomatosis^[13]. Tissue sections of 4 μ m thickness were prepared from paraffin-embedded tissue samples, and stained with hematoxylin and eosin (HE) in the usual manner. The slides were reviewed by the three pathologists (YN, HK and ON).

Degree of malignancy of intrahepatic bile duct

HE-stained sections were reviewed and each tumor was categorized into three groups according to the degree of malignancy by using the criteria in IPMN-P^[8]: adenoma (low grade), borderline (intermediate grade), and malignant (carcinoma *in situ* and high grade). Tumors with microinvasion were categorized as malignant.

Immunohistochemistry

Paraffin-embedded, 4- μ m-thick sections on a coated glass slides were stained by using the BenchMark XT (Ventata Automated Systems, Inc., Tucson, AZ, United States) with the following antibodies: mucin (MUC)1 (mouse monoclonal, Ma695, dilution 1:100; Novocastra, Newcastle, United Kingdom); MUC2 (mouse monoclonal, Ccp58, dilution 1:100; Novocastra); MUC5AC (mouse monoclonal, CLH2, dilution 1:100; Novocastra); MUC6 (mouse monoclonal, CLH5, dilution 1:50; Novocastra); p53 (mouse monoclonal, DO-7, dilution 1:200; Novocastra); β -catenin (mouse monoclonal, β -catenin-1, dilution 1:200; Dako, Glostrup, Denmark); and Ki-67 (mouse monoclonal, MIB-1, dilution 1:100; Dako). This automated system uses the streptavidin-biotin complex method with DAB as a chromogen (Ventana iVIEW DAB Detection Kit).

Regarding the MUC profile, we evaluated cytoplasmic and luminal surface staining by referring to the method of Shibahara *et al*^[6], and the cells were considered positive when either one or both of the two components were stained. The percentage of positively stained neoplastic cells was also calculated and graded as follows: -, < 5% of the neoplastic cells were stained; +, $\geq 5\%$ and < 20% were stained; 2+, $\geq 20\%$ and < 50% were stained, and 3+, $\geq 50\%$ were stained. These evaluations were conducted by three pathologists (YN, HK and ON). Positivity of p53 and β -catenin were defined by distinct and diffuse nuclear staining among the neoplastic cells. Ki-67 staining was counted on a minimum of 1000 tumor cells and Ki-67 labeling index (LI) was calculated as the per-

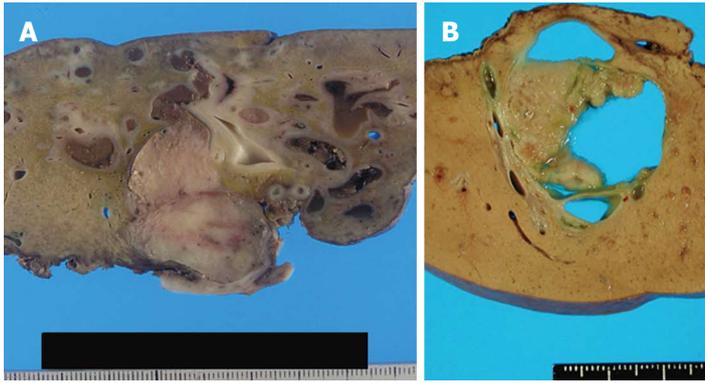

Figure 1 Gross findings. A: Duct-ectatic type. Tumor filled the dilated intrahepatic bile duct. Surrounding bile duct was also dilated; B: Cystic type. Cystic dilatation of intrahepatic bile duct. Papillary tumor was found in the dilated intrahepatic bile duct. Significant retention of mucin was observed.

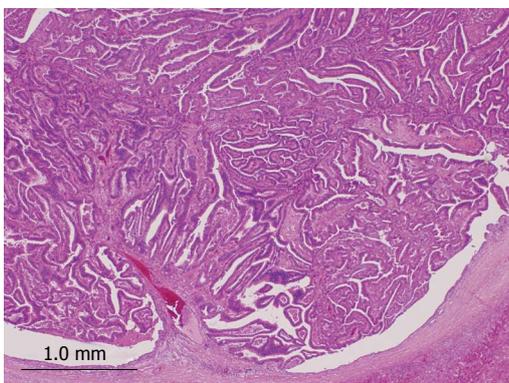

Figure 2 Histopathology of intraductal neoplasm of the intrahepatic bile duct. Tumor shows papillary proliferation within the dilated bile duct (hematoxylin and eosin stain, $\times 20$).

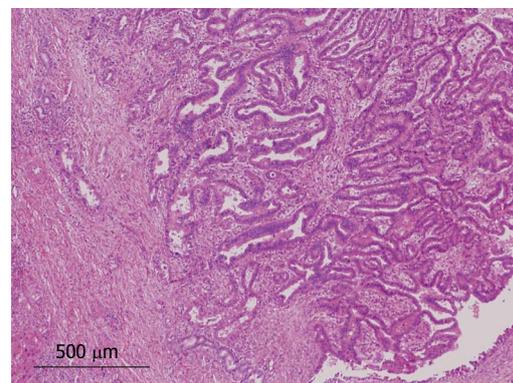

Figure 3 Microinvasion of tumor. Tumor cells infiltrating into the bile duct wall (hematoxylin and eosin stain, $\times 40$).

centage of positively stained cells to total cells.

Statistical analysis

Associations of Ki-67 LI and expression of MUC family (0, 1+ or 2+, 3+) with the degree of malignancy (adenoma, borderline or malignant), and association between Ki-67 LI and MUC profile were examined using the Kruskal-Wallis test and Fisher's exact test. To apply Fisher's exact test, we classified MUC profile into two categories of 0 or 1+ and 2+ or 3+. Association was considered significant when $P < 0.05$. All the statistical analyses were conducted by SAS version 9.12 (SAS Institute Inc., Cary, NC, United States) and R version 2.9.0.

RESULTS

Patients with INihB

We identified 24 tumors in 24 patients. Clinical findings are summarized in Table 1. Median age at the initial diagnosis was 64 years (mean: 63.0 ± 8.1), and the male:female ratio was 1:1. Sixteen tumors (67%) were located in the left lobe. Nineteen tumors (79%) were cystic type associated with mucin hypersecretion, and five tumors (21%) were duct-ectatic type without mucin hypersecretion (Figure 1). Twenty tumors (83%) had papillary struc-

tures in the bile duct as IPNB (Figure 2). The remaining four tumors (17%) presented the following features: the tumor was localized and proliferated in the bile duct, and the tumor showed both tubular and papillary structures. In three of the four tumors (75%), macroscopic mucin secretion was limited but microscopic intracellular mucin was evident. Histologically, 16 tumors (67%) were malignant, three (12%) were borderline, and five (21%) were adenoma. Microinvasion was found in four tumors (21%) (Figure 3), and these were categorized as malignant. There was no ovarian-like stroma in any cases.

Four tumors (17%) were composed of both papillary and tubular structures (Table 2). Histological findings of four patients were similar to those of intraductal tubulopapillary neoplasm (ITPN-P)^[14] or intraductal tubular neoplasm of the pancreas (ITN-P)^[15]. One of these four cases was previously reported as a biliary papillomatosis by Taguchi *et al.*^[13], and the tumor spread from the intrahepatic to extrahepatic bile duct. Another two cases also showed extension of tumor with bile duct dilation. However, the remaining tumor was cystic type and macroscopic mucin hypersecretion was evident. Among tubular structures, a pyloric gland-like structure (Figure 4) was prominent. Three cases were not malignant, but one tumor showed cytological atypia, such as enlarged nuclei with pleomorphism, and was considered as malignant (Figure 5). Atypi-

Table 1 Clinicopathological features of 24 patients with intraductal neoplasm of the intrahepatic bile duct

Age (yr), median (mean ± SD)	64.0 (63.0 ± 8.1)
Gender, <i>n</i> (%)	
Male	12 (50)
Female	12 (50)

Absent	20 (83)

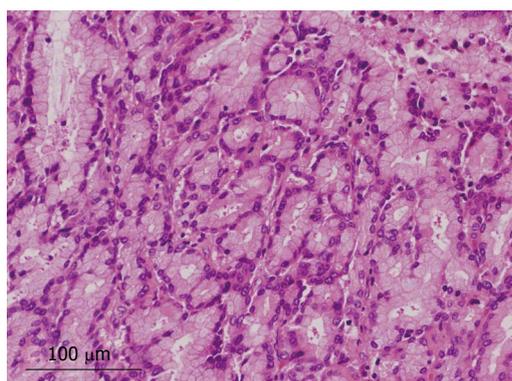

Figure 4 Tubular structure within intraductal neoplasm of the intrahepatic bile duct. Cells with intracellular mucin and mild atypia forming a pyloric gland-like structure (hematoxylin and eosin stain, × 200).

cal cells lining the tubular structure were cuboidal or columnar with little or no cytoplasmic mucin. None of these four cases were associated with tumor invasion.

Immunohistochemical analysis of INihB

Immunohistochemical findings are shown in Table 3. MUC1 was not expressed in the borderline/adenoma group but was expressed in malignant lesions ($P = 0.0095$). No specific pattern of expression was observed for other MUC family members. The Ki-67 LI was significantly higher in the malignant group than in the borderline/adenoma group (22.2 ± 15.5 vs 7.5 ± 6.3 , $P < 0.01$, Figure 6A). In the 16 malignant tumors, there was an association of borderline significance between expression of MUC5AC and higher Ki-67 LI ($P = 0.0622$, Figure 6B). Expression of β -catenin was found in two of the 24 tumors (8%, Figure 7), and these two tumors were also positive

Table 2 Clinicopathological findings of intraductal neoplasm of the intrahepatic bile duct with papillary and tubular structure in four patients

	Case 1	Case 2	Case 3 ¹	Case 4

β -catenin nuclear expression (17%) ³	2 (13)	0

¹MUC1 expression was exhibited only in the malignant group ($P = 0.0095$); ²Ki-67 was significantly higher in malignant cases than in borderline/adenoma patients ($P < 0.01$); ³ β -catenin expression was observed only in the cases with MUC1 expression. LI: Labeling index.

for MUC1. P53 was negative in all 24 tumors.

DISCUSSION

Many studies have been conducted on IPMN-P, and histomorphological criteria for diagnosis have been determined^[8]. Regarding similar lesions in the bile duct, the definition of IPNB^[7] and mucin-producing bile duct tumors^[6] is proposed as a new conceptual framework

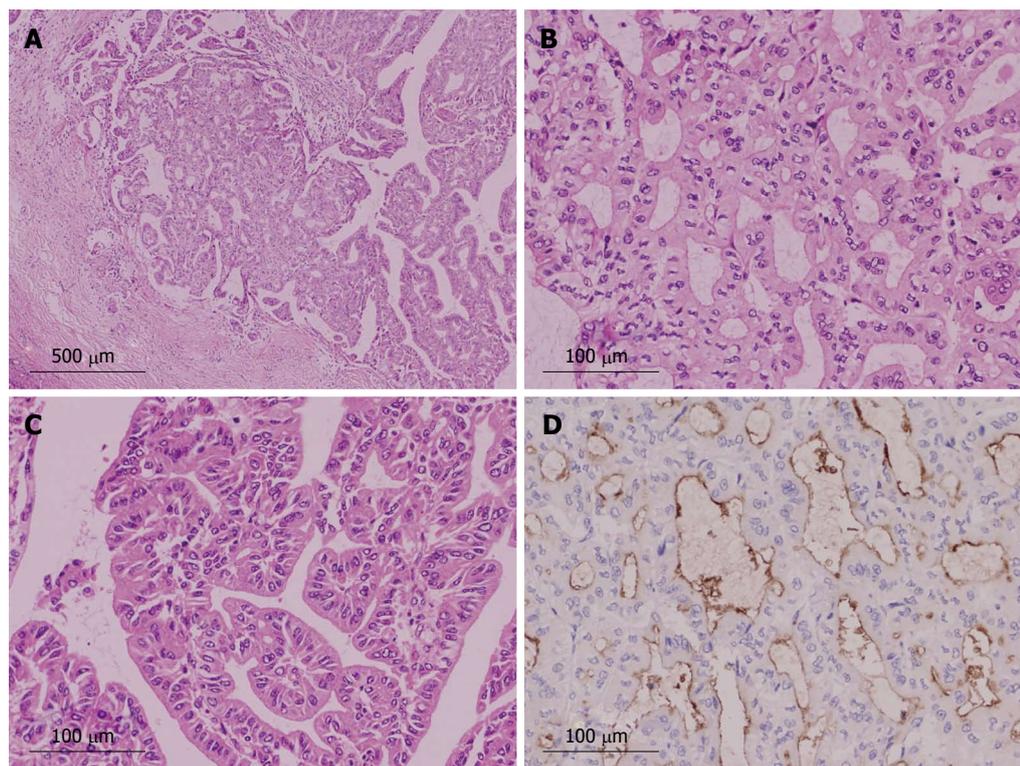

Figure 5 Histology of intraductal neoplasm of the intrahepatic bile duct with papillary and tubular structure (case 1). A: Histological structure was mainly tubular, but papillary structure was also present [hematoxylin and eosin (HE) stain, × 40]; B: Tubular structure (HE stain, × 200); C: Papillary structure (HE stain, × 200); D: Tumor cells were positive for mucin (MUC)1 immunohistochemistry (MUC1 stain, × 200).

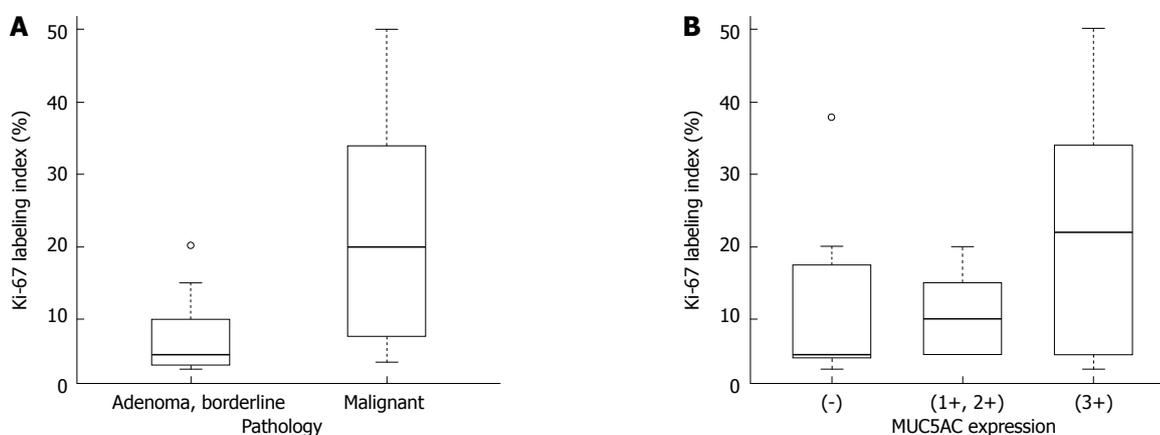

Figure 6 Box plot for Ki-67 labeling index by histological degree of malignancy and MUC5AC expression. A: The Ki-67 labeling index (LI) was significantly higher in the malignant group than in the benign/borderline group; B: There was an association with borderline significance between MUC5AC expression and Ki-67 LI ($P = 0.0622$). MUC: Mucin.

of biliary intraductal neoplasms. These biliary lesions present the same histological features of IPMN-P, and Zen *et al*^[16,17] divided them into four categories, namely, pancreaticobiliary type, intestinal type, gastric type, and oncocytic type. In contrast, Shibahara *et al*^[6] subclassified the lesions into two distinct categories, namely, columnar type and cuboidal type. Columnar type resembles intestinal type, and cuboidal type resembles pancreaticobiliary type or intraductal oncocytic papillary neoplasm, and they hypothesized that these two categories could be the biliary counterparts of IPMN-P.

Among our 24 cases of INihB, 19 cases (79%) were the cystic type that was proposed by Shibahara *et al*^[6], and this type is known as a biliary cystic tumor. Devaney *et al*^[18] reported that ovarian-like stroma was observed in 85% of the adenoma and 28% of the adenocarcinoma tumors. However, none of our cases had ovarian-like stroma. The presence or absence of ovarian-like stroma is an important factor for the classification of IPNB. Recently, Zen *et al*^[17] proposed that biliary cystic tumor could be a cystic variant of IPNB, having bile duct communication and absence of ovarian-like stroma. Based on our

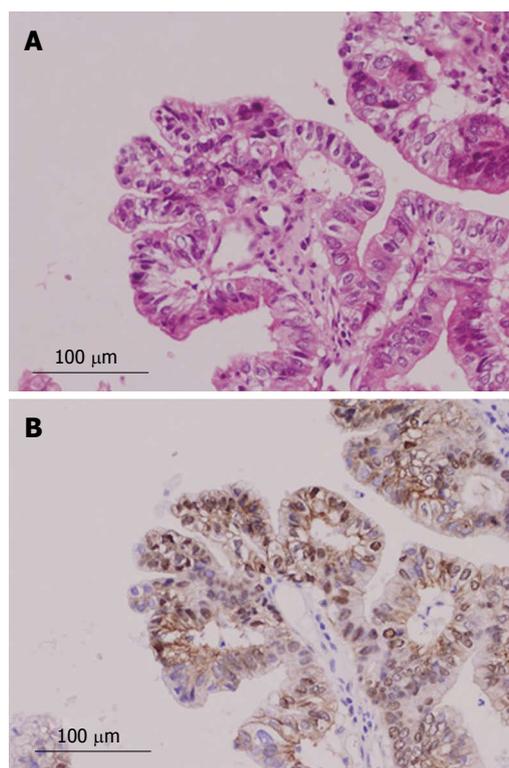

Figure 7 Nuclear expression of β -catenin in pancreaticobiliary type. A: Hematoxylin and eosin stain, $\times 200$; B: β -catenin stain, $\times 200$.

findings, the cystic type reported by Shibahara *et al.*^[6] and biliary cystic variant of IPNB reported by Zen *et al.*^[16] are the most common type among INihB, and they can be recognized by their characteristic macroscopic findings, that is, a cystic change with mucin hypersecretion, even though the tumors have ovarian-like stroma.

In our current study, 20 of 24 INihB tumors (83%) showed purely papillary proliferation that is a morphological feature of IPMN-P, and we diagnosed them as IPNB. In contrast, both papillary and tubular structures were present in the remaining four tumors (17%), and three of these four tumors were duct-ectatic type without macroscopic mucin secretion. These features are common findings in ITN-P or ITPN-P, which are rare diseases^[15,19-24]. These tubulopapillary tumors can be distinctly subcategorized in INihB based on their characteristic macroscopic and histological findings. Intraductal neoplasms with a tubular structure have been reported in the pancreatic area. Albores-Saavedra *et al.*^[19] reported that tumors with a tubular structure included: (1) glands resembling pyloric glands; (2) glands lined by cells with no cytoplasmic mucin and with mild nuclear atypia; and (3) glands lined by pink oncocytic cells. Recently, Yamaguchi *et al.*^[14] proposed the concept of ITPN-P and defined nine diagnostic criteria. Similarly, some authors have described intraductal lesions in which IPNB with formation of the tubular structure is regarded as intraductal tubular neoplasm of the bile duct (ITNB)^[25,26]. In our four cases, we observed morphological similarity with ITN-P or ITPN-P. In particular, Case 1 consisted mainly

of a tubular structure and some papillary patterns, and the neoplastic cells were markedly atypical. In addition, immunohistochemical results were MUC1(+) and MUC5AC(-), which were different from ITN-P. Our case 1 was considered as an ITPN-B subcategory. As discussed above, IPNB contained IPNB with a tubular structure, although small in number, and there might be cases with similar characteristics to ITN-P or ITPN-P.

We also examined Ki-67 and p53 immunoreactivity in the 24 cases of INihB. Ki-67 expression differed significantly between malignant and borderline/adenoma (22.2 ± 15.5 vs 7.5 ± 6.3 , $P < 0.01$), but P53 was negative in all cases. Based on these data, Ki-67 LI correlates with the degree of malignancy in INihB. Shibahara *et al.*^[6] reported significantly high Ki-67 expression and poorer prognosis in the columnar type than in the cuboidal type. In this study, we also investigated the relationship between MUC1/MUC5AC immunostaining and malignant potential. Some studies have reported that the pancreaticobiliary type IPMN-P, which is positive for MUC1, is highly malignant^[8]. Other studies have suggested that MUC1 contributes significantly to tumor growth and metastasis, and that downregulation of MUC1 protein expression decreases the metastatic potential of pancreatic adenocarcinoma^[27]. The association between MUC1 and malignant potential has also been suggested in cholangiocarcinoma^[28]. Although we did not find a significant association between MUC5AC expression and the degree of malignancy or cell proliferation potential, there was a borderline association between the higher expression of MUC5AC and the higher Ki-67 LI in the malignant group. Some authors also have reported that MUC5AC is more strongly expressed in advanced tumors^[17,28]. Thus, we suggest that expression of MUC1 and MUC5AC is related, MUC1 more strongly so than MUC5AC, to the degree of malignancy in INihB.

Nuclear expression of β -catenin was found in 8% of INihB (2/24), and MUC1 was also positive in these cases. β -catenin is a mediator in the canonical Wnt signal transduction pathway^[29] and activation of the Wnt pathway is associated with high proliferation and dedifferentiation in human biliary tumors^[30]. Nuclear accumulation of β -catenin was reported in 15% of intrahepatic cholangiocarcinomas (Sugimachi *et al.*^[31]); 25% of IPN-B, 20% of IPN-B associated with intrahepatic cholangiocarcinoma, and 0% of biliary intraepithelial neoplasms (Itatsu *et al.*^[32]); and 25% of IPN-B (Abraham *et al.*^[33]). The Wnt signaling pathway is frequently activated in biliary neoplasms^[32]. We believe when dealing with INihB one should consider performing immunohistochemical staining for MUC1 and β -catenin, in addition to histomorphological examination, to evaluate malignant potential of the tumor.

In conclusion, we propose the concept of INihB that includes IPNB and IPNB with tubular structure subcategories, that is, ITNB and intraductal tubulopapillary neoplasm of the bile duct. IPNB with tubular structure is rare, and (1) is mostly duct-ectatic without macroscopic mucin hypersecretion; and (2) histologically, has both

papillary and tubular structures. In INihB, MUC1 expression correlates positively with the degree of malignancy and cell proliferation potential. MUC5AC expression also correlates with the degree of malignancy, although the relationship is less robust. Further pathological and molecular studies are necessary to clarify the characteristics of INihB.

COMMENTS

Background

The clinicopathological characteristics of intraductal neoplasm of the intrahepatic bile duct (INihB) remains unclear. In this article, the authors present the clinicopathological features of 24 cases of INihB.

Research frontiers

Some studies have reported that the pancreatobiliary-type intraductal papillary mucinous neoplasm (IPMN-P), which is positive for mucin (MUC)1 expression, is highly malignant, and other studies have suggested that MUC1 contributes significantly to tumor growth and metastasis, and that downregulation of MUC1 protein expression decreases the metastatic potential of pancreatic adenocarcinoma. The association between MUC1 and malignant potential has also been suggested in cholangiocarcinoma. Some authors have reported that MUC5AC is more strongly expressed by advanced tumors. In this study, the authors demonstrated that MUC1 and MUC5AC expression may be related to the malignant potential of INihB.

Innovations and breakthroughs

Recent reports have highlighted the relationship between MUC profile and malignancy potential. In particular, the authors investigated the relationship between MUC1/MUC5AC immunohistochemical staining and Ki-67 labeling index.

Applications

This study offers a better understanding of clinicopathological characteristics of INihB and a potential strategy to predict tumor behavior for better patient care.

Terminology

MUC1/MUC5AC are mucin proteins in the pancreatobiliary/gastric epithelium, respectively. It has been suggested that these proteins play an important role in tumor growth and metastasis in pancreatobiliary disease.

Peer review

Immunohistochemical analysis revealed that Ki-67 expression in the 24 INihBs was significantly high in the malignant group. MUC staining showed that MUC1 was not expressed in the borderline/adenoma group but was expressed only in malignant lesions, and the Ki-67 labeling index was significantly higher in the malignant group than in the borderline/adenoma group. These results may represent a mechanism of MUC protein in tumor growth, that is, malignant potential of the tumor.

Abstract

AIM: To further investigate the role of human B7 homolog 1 (B7-H1) in the mechanism of persistent hepatitis B virus (HBV) infection.

METHODS: Peripheral and intra-hepatic B7-H1 expression were compared by flow cytometry and immunohistochemical staining between two distinct groups, one

being chronic HBV tolerance patients (CHB-T) and the other being acute hepatitis B patients (AHB). B7-H1 mRNA expression level was also compared by real time polymerase chain reaction between CHB-T and AHB patients. The location of intra-hepatic B7-H1 and CD40 expression were analyzed by immunofluorescence. The levels of B7-H1 and CD40 expression on cultured myeloid dendritic cells (mDCs) with or without hepatitis B surface antigen (HBsAg) treatment were analyzed dynamically by flow cytometry. Intracellular interferon- γ (IFN- γ) staining and the stimulatory capacity of mDC of cultured mDC with or without HBsAg treatment were also compared by flow cytometry.

RESULTS: Peripheral B7-H1 expression on mDCs was increased significantly in AHB compared to CHB-T patients ($P < 0.05$). In the liver tissues from CHB-T patients, B7-H1 positive cells were almost absent despite a persistently elevated serum HBsAg load. In contrast, there were indeed increased B7-H1-positive cells *in situ* in the liver tissue from AHB. *In vitro* analysis showed the parallel upregulation of B7-H1 and CD40 on CD11c+ mDCs after the onset of stimulation. Addition of recombinant hepatitis B surface antigen (rHBsAg) significantly decreased CD40 expression ($P < 0.05$ at 16 h, 20 h and 24 h time points). B7-H1 expression was also inhibited by rHBsAg, and the inhibition rate of CD40 was greater than that of B7-H1. This preferential inhibition of CD40 expression on mDCs by rHBsAg resulted in the dysfunction of mDCs and T cells in the mixed leucocyte reaction (MLR) system. With rHBsAg pretreatment, in a carboxyfluorescein diacetate succinimidyl ester (CFSE) labeled MLR system at a ratio of 1:5 responder cell-stimulator cell (R/S), the CFSE^{dim} percentage of T cells decreased from 85.1% to 25.4% and decreased from 30.3% to 12.0% at 1:10 R/S. IFN- γ production by CD8+ T cells, in the MLR system, was reduced significantly by HBsAg pretreatment. At ratios of 1:5 R/S, the percentage of IFN- γ and CD8 dual positive T cells decreased from 55.2% \pm 5.3% to 15.1% \pm

3.1% ($P < 0.001$), and decreased from $35.0\% \pm 5.1\%$ to $7.3\% \pm 2.7\%$ at ratios of 1:10 R/S ($P < 0.001$).

CONCLUSION: B7-H1 is not a signature of immune dysfunction, but an inflammation marker. HBsAg regulate immune response by tipping the balance between B7-H1 and CD40.

INTRODUCTION

Patients with self-limited acute hepatitis B (AHB) can develop appropriate virus-specific immune responses, however these immune responses are insufficient to eliminate the virus in chronic hepatitis B patients and eventually lead to chronic hepatitis B virus (HBV) tolerance (CHB-T). To date, the mechanisms underlying this defect of the HBV specific immune response have not been fully elucidated. T-cell exhaustion, lack of CD4+ T-cell help, induction of T-cell tolerance and viral variation may contribute to HBV persistence^[1-8]. However, it is also possible that the antigen presenting cells (APCs) of hepatitis B patients fail to prime an appropriate T-cell response^[9-13].

Dendritic cells (DCs) are professional APCs that are specialized for the initiation and regulation of T-cell immunity. The efficiency of DCs in activating T cells is determined by many factors. DCs express high levels of positive co-stimulatory molecules, [B7.1 (CD80), B7.2 (CD86), and CD40] which interact with receptors on T cells to mediate T cell activation^[14]. On the other hand, DCs also express negative molecules such as human B7 homolog 1 (B7-H1) and human B7 homolog DC (B7DC), which bind to programmed death 1 (PD1) to deliver a co-inhibitory signal to T cells, thus leading to T-cells tolerance^[14]. Based on these studies, the balance between positive and negative co-stimulatory molecules is viewed as a key factor for determining the outcome of HBV infection^[15,16].

Previous studies have indicated that the B7-H1/PD-1 pathway plays a key role in myeloid dendritic cells (mDCs) dysfunction and T-cell exhaustion when these cells are exposed to high HBV or hepatitis C virus (HCV) antigen loads. In addition, blockade of the PD-1/B7-H1 interaction can restore the allostimulatory ability of mDCs and

the function of HBV and HCV-specific CD8+ T cells with increased proliferation, cytotoxicity and cytokine production^[2,17-19]. Some studies have reported that B7-H1 and PD1, which are expressed in circulating mDCs and HBV specific T cells respectively, were significantly up-regulated in chronic hepatitis B patients. The specificity of this upregulation to HBV or HCV infection was determined by the lack of a significant increase in B7-H1 and PD1 in cytomegalovirus, Epstein-Barr virus and influenza A infected patients^[20-22]. Based on these studies, relatively high levels of B7-H1/PD-1 expression were viewed as the signature of impairments in the HBV- and HCV- specific immune response. Both HBV and HCV might exploit the B7-H1/PD1 pathway to facilitate persistent infection.

On the other hand, recent studies revealed that B7-H1 and PD1 expression are significantly upregulated in the early phase of AHB infection, and successful viral clearance is correlated with a decrease in PD1 expression^[12,23]. These results are in line with reports showing that B7-H1 and PD1 expression is upregulated in liver nonparenchymal cells during the acute phase of inflammation to limit an over-vigorous inflammatory response^[24].

Our clinical observation revealed that chronic HBV infection was composed of 2 different components. On one hand, the CHB-T condition is characterized by active HBV-DNA replication, but shows no serum alanine aminotransferase (ALT) upregulation. The other component is a fluctuating inflammation condition that shows repeated inflammation flare-ups with fluctuating levels of serum ALT and HBV-DNA.

To examine the role of B7-H1 in the mechanism of HBV tolerance, we compared B7-H1 expression between AHB and CHB-T patients.

The results showed that peripheral and intra-hepatic expression of B7-H1 was more significant in AHB than that in CHB-T patients. In the liver tissue of CHB-T subjects, B7-H1 was almost absent despite a persistently elevated hepatitis B surface antigen (HBsAg) load. *In vitro* analysis showed that CD40 and B7-H1 were upregulated synchronously after the onset of stimulation, and CD40 was preferentially inhibited by recombinant hepatitis B surface antigen (rHBsAg), which impaired the allostimulatory capacity of mDCs and interferon- γ (IFN- γ) production by CD8+ T cells in the mixed leucocyte reaction (MLR) system.

Our findings showed that the analysis of B7-H1 expression alone is not sufficient to elucidate the mechanism of HBV immune tolerance. B7-H1 is an inflammatory marker, but not an absolute indicator of HBV-specific immune tolerance. The preferential inhibition of CD40 expression by rHBsAg can be considered as part of a mechanism by which HBV impairs the immune response and results in persistent infection in CHB-T patients.

MATERIALS AND METHODS

Subjects

This study examined 27 adults with HBV infection (18

Table 1 Clinical data of these patients at the time of the first physician consultation

	Male/female	ALT	HBsAg	HBV-DNA load
AHB (<i>n</i> = 15)	10/5	296 ± 110	404 ± 98 ng/mL	(2 - 7) × 10 ⁴ (<i>n</i> = 4), (3 - 6) × 10 ⁵ (<i>n</i> = 5), (1 - 6) × 10 ⁶ (<i>n</i> = 4), (1 - 2) × 10 ⁷ (<i>n</i> = 2)
CHB-T (<i>n</i> = 12)	8/4	Normal (10-40 μ/mL)	363 ± 58 ng/mL	(3 - 7) × 10 ⁵ (<i>n</i> = 6), (1 - 5) × 10 ⁶ (<i>n</i> = 5), (1.1) × 10 ⁷ (<i>n</i> = 1)
AIH (<i>n</i> = 3)	0/3	301 ± 79.3	Negative	Negative
HC (<i>n</i> = 5)	3/2	Normal (10-40 μ/mL)	Negative	Negative

men, 9 women) from August 2008 to August 2010 that were hospitalized in our unit. None of the patients were treated with steroids before sampling. Concurrence of HCV and human immunodeficiency virus infections were excluded from enrolled individuals. The study protocol was approved by the Ethics Committee of our unit, and informed consent was obtained from each subject. The patients were assigned to 2 distinct groups based on plasma HBV DNA loads and ALT levels. The first group (*n* = 12) was formed by CHB-T with HBV-DNA replication and HBs-Ag production, but normal ALT levels (normal range: 10-40 U/L). The other group (*n* = 15) was composed of AHB patients with active HBV replication and significantly elevated serum ALT levels. For comparison, 5 uninfected healthy controls (HC) and 3 patients with autoimmune hepatitis (AIH) were enrolled as controls. The clinical data of these patients at the time of the first physician consultation are summarized in Table 1.

Human B7-H1 expression in circulating mDCs

B7-H1 expression on circulating mDCs was measured using 1 mL of fresh heparinized peripheral blood. Cells were lysed with fluorescence-activated cell sorter (FACS) lysing solution (BD Pharmingen) to remove red blood cells and then incubated with antibodies against B7-H1-Phycoerythrin (PE) and CD11c-fluorescein isothiocyanate (FITC) for 20 min at room temperature. After washing twice with phosphate buffered saline (PBS), the cells were analyzed by flow cytometry on a FACSCalibur (BD Biosciences).

Preparation of mDCs and T cells

Peripheral blood mononuclear cells (PBMC) were isolated from whole blood of healthy donors by Ficoll density gradient centrifugation. PBMCs were then plated (5 × 10⁶ cells/well) into a 6-well plate and incubated at 37 °C for 2 h. T-cell-enriched and T-cell-depleted fractions were prepared by adherence to plastic in complete RPMI 1640 medium. The immature dendritic cells (iDCs) were prepared from the T-cell-depleted fraction by culturing cells in the presence of granulocyte macrophage colony-stimulating factor (50 ng/mL) and interleukin 4 (IL-4) (50 U/mL) for 5 d.

MDCs culture and CD40-, and human B7-H1 expression

iDCs were prepared from PBMC and incubated in a 24-well plate in RPMI 1640 medium containing 10%

FCS and treated with or without rHBsAg-adr (1 μg/mL). (r)HBsAg adr was purified from transfected Chinese Hamster Ovary (CHO) cells. Cell lysates of CHO without HBsAg transfection served as a negative control. After 5 d, these cells were stimulated by 20 μg poly (I: C), and then collected at 4 h, 8 h, 16 h, 20 h, and 24 h after stimulation. The cells were incubated with anti-B7-H1-PE and CD40-FITC antibodies for 20 min at room temperature. After washing three times with PBS, the expression of B7-H1 and CD40 was analyzed by flowjo7.6.

RNA preparation and real-time polymerase chain reaction

Total RNA from liver tissues was isolated using RNeasy kits (Qiagen). Reverse transcription of RNA was performed using a SuperScript One-Cycle cDNA kit (Invitrogen). The cDNA served as a template in real-time polymerase chain reaction (PCR). The human B7-H1 primers for RT-PCR were used as follow: 5'-TTTACTGTACGCGTTCCC-3' (sense) and 5'-TGTTCTTATCCTCCATTTC-3' (antisense); human glyceraldehyde-3-phosphate dehydrogenase (GAPDH) primers, 5'-CTGCCCCCTCTGCTGATG-3' (sense) and 5'-TCCACGATACCAAAGTTGTTCATG-3' (antisense). All reactions were performed in triplicate. The B7-H1 mRNA expression of different specimens was normalized to GAPDH. Relative mRNA levels are presented as unit values of 2^{-ΔΔCt}, where Ct is the threshold cycle value defined as the fractional cycle number at which the target fluorescent signal passes a fixed threshold above baseline.

Immunochemical staining

Acetone-fixed liver tissue cryosections (7 μm) were incubated with anti B7-H1 antibodies (Abcam) at 4 °C overnight. After DAB peroxidase staining, positive cells (brown color) were counted in 3 different fields by 2 independent observers. To determine B7-H1, CD40, CD68, macrophage inflammatory protein (MIP3) α, secondary lymphoid tissue chemokine (SLC), CD11c, chemokine (C-C) receptor (CCR) 7 and HBsAg expression, immunofluorescence double staining was performed. Briefly, liver tissues were incubated for 12 h at 4 °C with diluted primary Abs followed by diluted secondary Abs for 1 h at room temperature. The following primary antibodies were used for CD11c, CD40, B7-H1, CD68, SLC, MIP3α, CCR7 and HBs-Ag: mouse antihuman CD40,

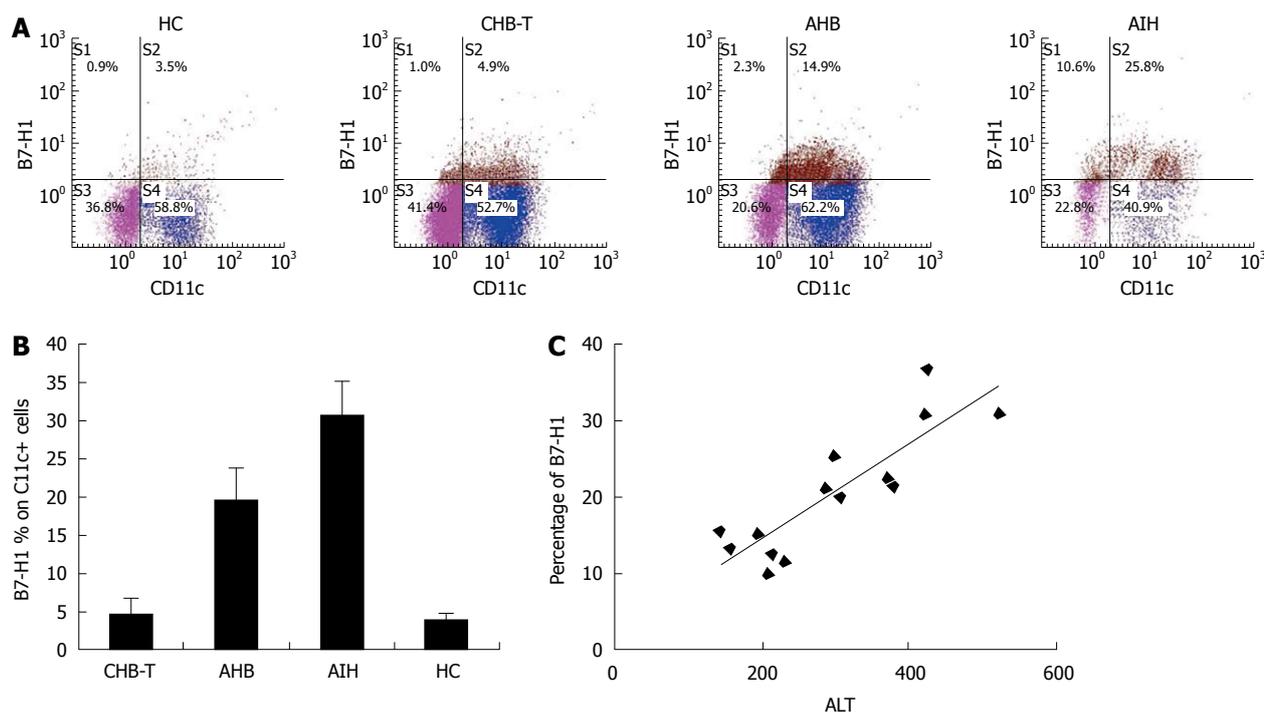

Figure 1 Circulating human B7 homolog 1 expression comparison among acute hepatitis B, chronic hepatitis B virus tolerance and autoimmune hepatitis patients. A: Representative dot plots of double measurements of fifteen independent experiments; B: B7 homolog 1 (B7-H1) expression level on circulating myeloid dendritic cells (mDCs) of acute hepatitis B (AHB) patients was significantly higher than that in chronic hepatitis B virus tolerance (CHB-T) patients ($n = 12$, $P < 0.05$). Autoimmune hepatitis (AIH) patients exhibited the highest levels of B7-H1 expression on circulating mDCs among these groups ($n = 3$, $P < 0.05$); C: In AHB patients, there was significant, positive correlation between B7-H1 expression on mDCs and serum alanine aminotransferase (ALT) levels in AHB patients ($r = 0.809$). HC: Healthy controls.

CD68 and CD11c (diluted 1:100; Santa Cruz Biotechnology, Inc., Santa Cruz, CA, United States), and-, goat antihuman B7-H1, MIP3 α , SLC, CCR7 (diluted 1:100; Santa Cruz). As secondary antibodies, a rabbit anti-goat IgG PE-conjugated antibody (diluted 1:100; Santa Cruz), a rat anti-mouse IgG FITC-conjugated antibody, and a rat anti-mouse IgG rhodamine-conjugated antibody were used.

Allogeneic mixed leukocyte reaction

Purified mDCs with or without HBsAg treatment were matured for 24 h in a 96-well flat-bottom culture plate (at 1×10^5 cells/200 μ L) in culture medium containing poly (I:C) (20 μ g/mL; Sigma). On the following day, mDCs were treated with mitomycin C and were added at different concentrations (1/5 and 1/10) into purified T cells from a normal healthy volunteer (1×10^5 cells/200 μ L) and labeled with carboxyfluorescein diacetate succinimidyl ester [CFSE (1 mmol/mL); Molecular Probes, Eugene, OR] for 5 d. T-cells proliferation was assessed by the loss of CFSE analyzed by flow cytometry. Flow cytometric data were analyzed by CellQuest (Becton Dickinson). All measurements were performed in triplicate.

Intracellular IFN- γ staining

Next, IFN- γ staining during these MLRs was measured. T cells were collected after 5 d of mixed culture, phorbol myristate acetate (1 μ g/mL), ionomycin (0.1 mg/mL; T cell receptor-bypassing reagents) and 0.1 mg/mL monomycin

(Sigma-Aldrich) were added into a mixed culture system 4 h before analysis. T cells were then washed in PBS, stained with anti-CD8 (FITC) mAb and then permeabilized and fixed according to the manufacturer's instructions. After a further wash in PBS, cells were stained with anti-IFN- γ -PE mAb at room temperature for 20 min. After 2 additional washes, cells were fixed and acquired immediately on flow cytometry on a FACSCalibur (BD Biosciences).

Statistical analysis

All experimental conditions were pair analyzed against their controls. Data on co-stimulatory molecules, and cytokine and B7-H1 mRNA expression were analyzed by the Student's *t* test. The correlation between ALT levels and B7-H1 expression obtained by FACS was assessed by Pearson's correlation analysis. Data corresponding to the expression of co-stimulatory molecules and cytokine production are expressed as mean \pm SE. A *P* value of < 0.05 was considered statistically significant.

RESULTS

The expression of human B7-H1 on circulating mDCs was significantly upregulated in AHB patients and AIH

The levels of B7-H1 expression were detected on circulating CD11c + DCs from AHB, CHB-T, and AIH patients, and HC (Figure 1A). B7-H1 expression on circulating CD11c + DCs from enrolled patients was generally

increased, in particular in AHB patients, who expressed higher levels of B7-H1 than CHB-T individuals ($P < 0.05$, Figure 1B). In CHB-T patients, B7-H1 expression also increased, but was not significantly different from that in HC. AIH patients exhibited the highest levels of B7-H1 expression on CD11c + DCs among these groups (all $P < 0.05$, Figure 1B). Correlation analysis revealed that there was a significant, positive correlation between B7-H1 expression on circulating CD11c + DCs and serum ALT levels in AHB patients ($r = 0.809$, Figure 1C).

Intra-hepatic human B7-H1 expression is much higher in AHB than in CHB-T patients

Immunohistochemical staining performed to analyze intrahepatic B7-H1 expression showed an increased number of B7-H1-positive cells *in situ* in the livers of AHB patients. In contrast, B7-H1-positive cells were almost completely absent in the livers of CHB-T subjects and healthy donors (Figure 2A). Immunofluorescence double staining revealed that almost all CD11c + DCs, CD123 + DCs and Kupffer cells expressed B7-H1 molecules in the liver tissue from AHB patients (Figure 2B-D), while in liver tissue from CHB-T patients, B7-H1 positive cells were almost completely absent despite extensive HBsAg expression (Figure 2E). These results were in line with data obtained with circulating CD11c + DCs. In addition, in the liver tissue from AHB patients, B7-H1 was always co-expressed with the positive co-stimulatory molecule CD40 (Figure 2F).

Human B7-H1 mRNA expression is upregulated in liver tissue from AHB patients

B7-H1 mRNA expression levels in liver tissues were further compared between AHB and CHB-T patients by real-time PCR. As show in Figure 3, B7-H1 mRNA expression levels were significantly higher in AHB than in CHB-T liver tissue. The highest relative B7-H1 mRNA expression level in AHB liver tissue showed a 12-fold increase over the CHB-T level. The lowest B7-H1 mRNA level showed a 2-fold increase in AHB compared to CHB-T liver tissue (Figure 3).

Inflammatory markers showed significant expression in the liver tissue from AHB patients with significant human B7-H1 expression

Peripheral and intrahepatic B7-H1 expression in AHB patients was far more significant than that of CHB-T. These results suggest that B7-H1 is a marker of AHB. To further confirm this conclusion, serially sectioned liver tissues from AHB patients were examined for the markers of inflammatory response, including DCs, lymphocytes infiltration and chemokines expression by immunofluorescence double staining. Liver tissue with significant B7-H1 expression showed significant infiltration of CD11c+ and CD8+-positive cells. Chemokines such as MIP3 α and SLC were also expressed extensively by CD11c + DCs (Figure 4A and B). Mature mDCs expressing CCR7 and activated CD8+ lymphocytes expressing PD1 were recruited to the liver lobe (Figure 4D). In contrast, in liver

tissue from CHB-T patients with significant HBsAg but no B7-H1 expression, CD11c+ and CD8+ infiltration cells were predominantly localized in fibrous septa rather than in the sinusoidal area (Figure 4E). These results suggest that B7-H1 was preferentially expressed at the site of AHB.

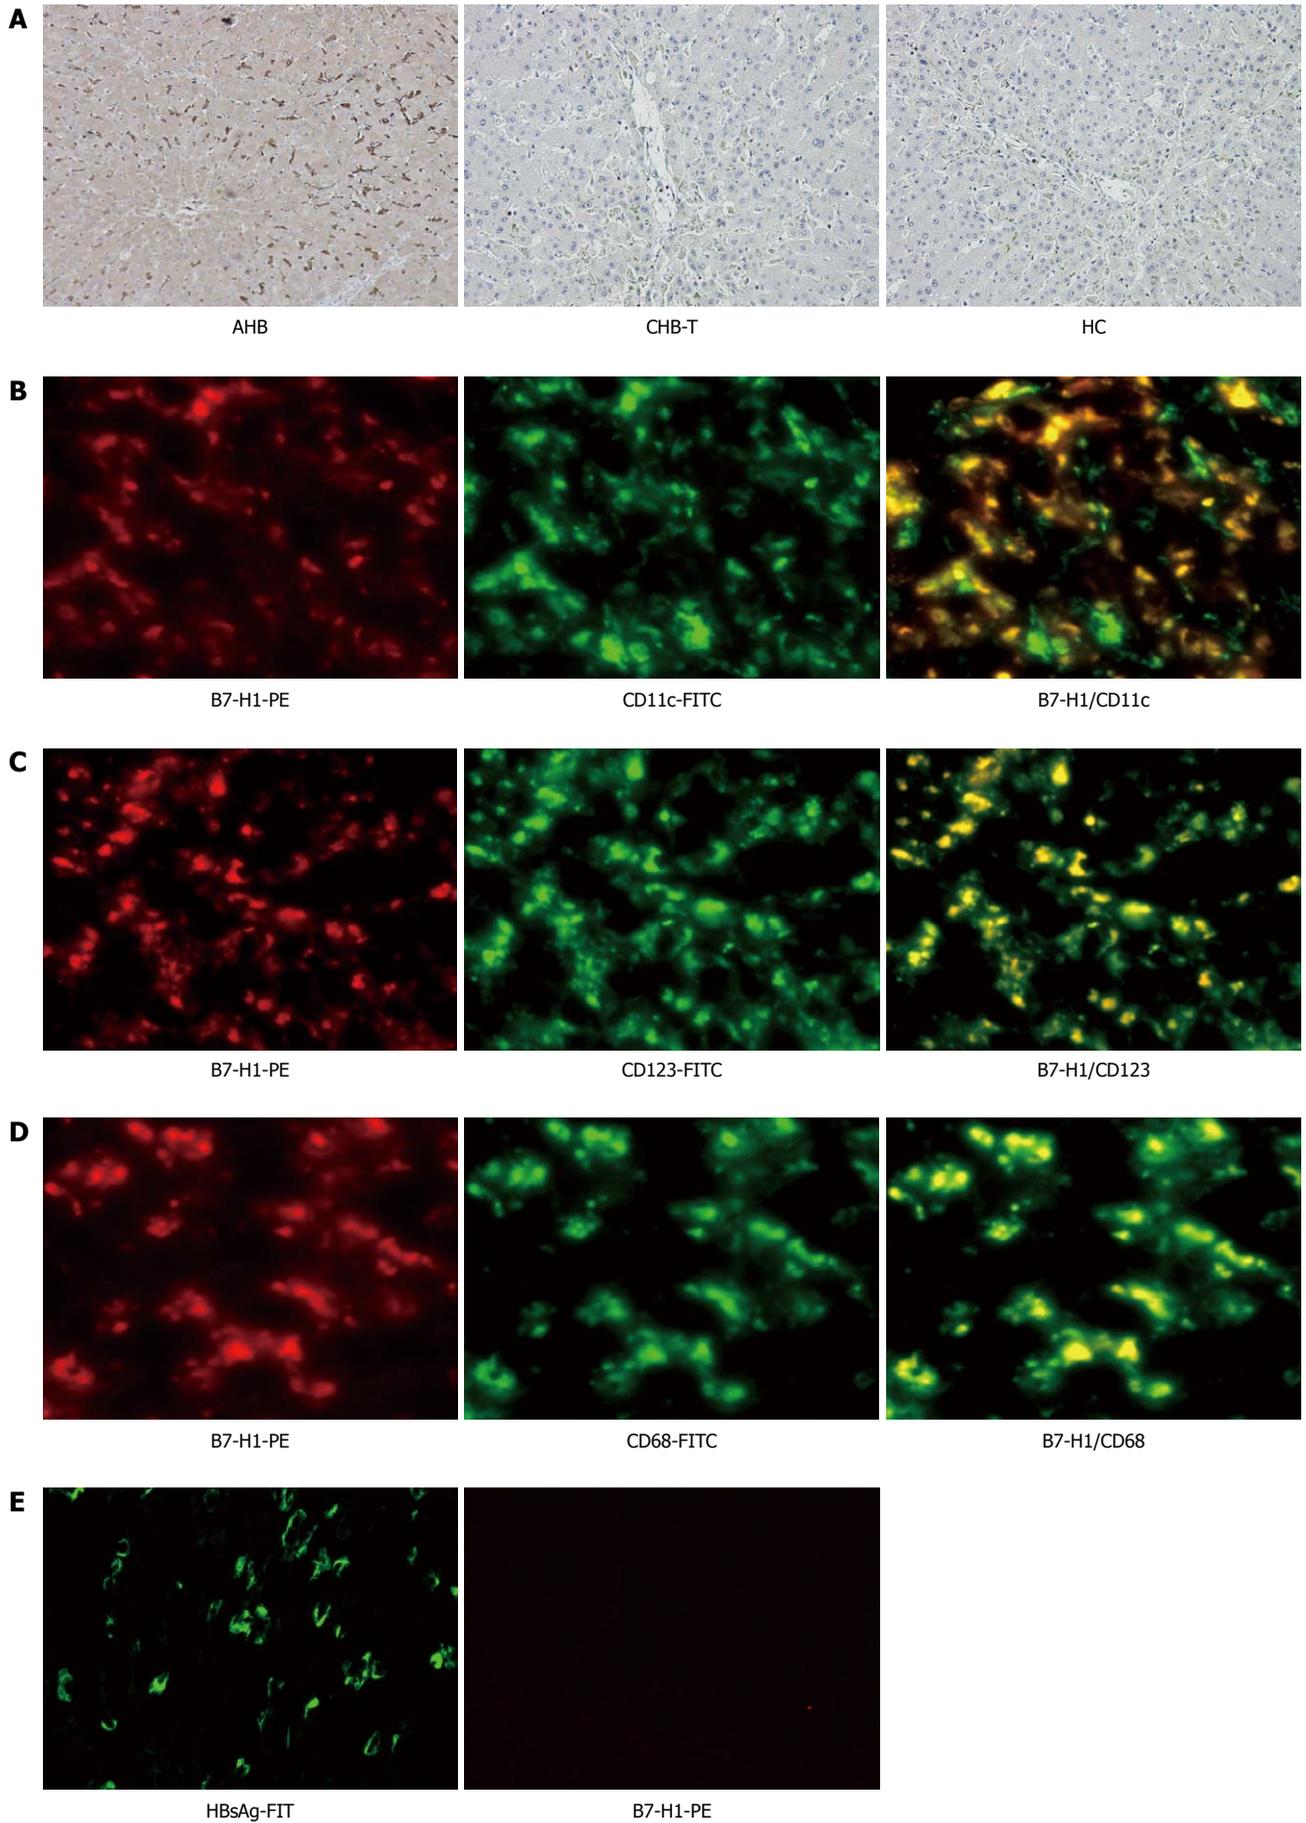

Human B7-H1 expression levels increased during the acute hepatitis phase and decreased with a reduction in inflammation

The correlation between B7-H1 expression and the degree of inflammation in hepatitis was analyzed by detecting B7-H1 expression on circulating mDCs during a follow-up period ranging from 1 mo to 6 mo. In AHB patients, the suppression of HBV replication after anti-viral treatment was accompanied by a decrease in serum HBsAg and ALT levels, and followed by a gradual decrease in B7-H1 expression on circulating mDCs (Figure 5A and B). Two or three mo after the ALT level returned to normal range, the percentage of B7-H1 positive cells decreased within CD11c positive cells from 21.3 ± 5.6 to 6.1 ± 1.4 (Figure 4C). B7-H1 expression levels, as assessed by mean fluorescence intensity (MFI), were also reduced (data not shown). The level of B7-H1 expression increased during the period of acute hepatitis and decreased when inflammation was reduced; supporting the conclusion that B7-H1 is an inflammatory marker. Notably, B7-H1 expression levels remained relatively high (13.2 ± 3.3) when ALT returned to normal range at 16 wk (Figure 5C). Two or three months after the return of serum ALT level to normal, B7-H1 expression further decreased to 6.1 ± 1.4 , approaching healthy control levels (Figure 5B and C). Longitudinal correlation analysis revealed a positive correlation between B7-H1 expression and serum ALT levels in AHB patients (Figure 5D). In CHB-T patients, although serum HBV-DNA and HBS-Ag load remained high, peripheral B7-H1 expression levels did not increase significantly (Figure 5C).

As mentioned above, chronic HBV infection had two different components, namely the CHB-T condition and the chronic active hepatitis status, which was characterized by repeated inflammation flare ups. Detection of peripheral B7-H1 expression in 3 chronic active hepatitis B patients during the inflammatory flare up phase with increasing serum ALT and HBV-DNA level showed that B7-H1 expression on circulating CD11c positive cells increased significantly in all three patients (Figure 6).

High HBsAg loads inhibited the upregulation of CD40 and human B7-H1 on mDCs

The above data showed that the intra and extra-hepatic HBs-Ag load remained persistently high in CHB-T subjects, while B7-H1 and CD40 expression were nearly absent. To further explore the relationship between HBsAg load and B7-H1 and CD40 expression, the effects of HBsAg towards B7-H1 and CD40 expression were analyzed *in vitro*. Population of mDCs with and without HBsAg pretreatment in PBMCs was determined by flow cytometry.

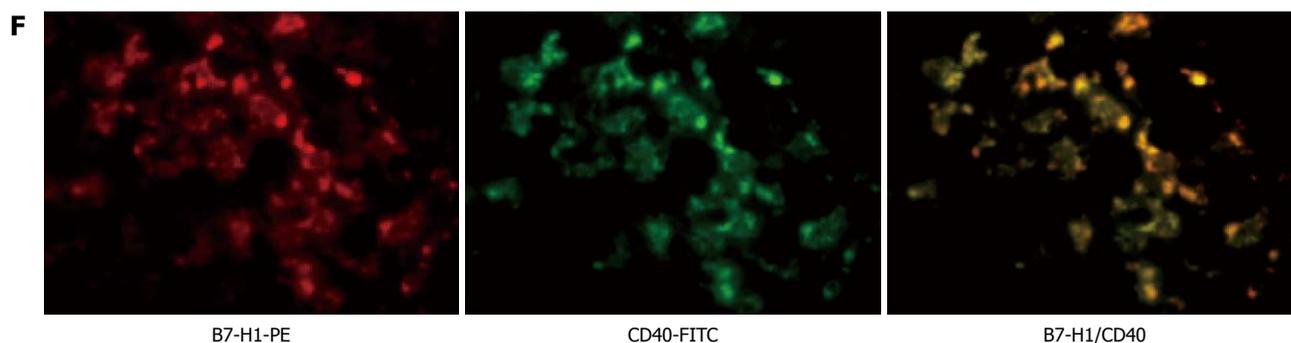

Figure 2 Analysis of intrahepatic human B7 homolog 1 expression among acute hepatitis B and chronic hepatitis B virus tolerance patients. A: Immunohistochemical staining for intrahepatic B7 homolog 1 (B7-H1)-positive cells in acute hepatitis B (AHB), chronic hepatitis B virus tolerance (CHB-T) and healthy controls (HC). Intra-hepatic B7-H1 expression was up-regulated significantly in AHB patients, but was almost absent in both CHB-T and HC subjects. Original magnification $\times 200$; B-D: Co-localization of B7-H1 with CD11c, CD123 and CD68 were shown by immunofluorescence double staining in liver biopsy specimens of AHB patients. B7-H1 (red) is co-localized with CD11c (green) positive mDCs (B), CD123 (green) positive pDCs (C) or CD68 (green) positive Kupffer cells (D). The 2-color merged panels were shown with co-localization visible in yellow. Original magnification $\times 200$; E: Hepatitis B surface antigen (HBsAg) and B7-H1 expression was detected by immunofluorescence stain in the liver tissue of CHB-T patients. Original magnification $\times 200$; F: Colocalization of B7-H1 with CD40 is showed by immunofluorescence double staining in liver biopsy specimens of AHB patients. B7-H1 (red) is colocalized with CD40 (green). The 2-color merged panels were shown with colocalization visible in yellow. Original magnification $\times 200$. Figure 3 Quantitative real-time reverse transcription-polymerase chain reaction was performed in 5 acute hepatitis B and hepatitis B virus tolerance patients. Acute hepatitis B (AHB) and chronic hepatitis B virus tolerance (CHB-T) patients were matched freely. B7 homolog 1 (B7-H1) mRNA expression level was significantly higher in AHB than in CHB-T liver tissue ($n = 5$, $P < 0.01$). PCR: Polymerase chain reaction.

etry. The forward scatter (FSC) and side scatter (SSC) of mDCs with rHBsAg pretreatment were not altered significantly compared to those without rHBsAg pretreatment (Figure 7A). This result suggests that the vitality of mDCs with or without HBsAg pretreatment is similar.

The kinetics of CD40 and B7-H1 expression on poly (I:C)-stimulated mDCs with or without rHBs-Ag pretreatment were analyzed *in vitro*. The expression of B7-H1 and CD40 on mDCs was upregulated synchronously in response to poly (I:C) stimulation. The expression of CD40 was detected on the surface of mDCs at 1h and gradually increased to peak level at 24 h after the onset of stimulation. During the same period, B7-H1 also increased gradually, reaching the highest expression level after 24 h of stimulation. In addition, when rHBs-Ag was added during the period of DC maturation at a final concentration of $1 \mu\text{g}/\text{mL}$, the up-regulation of CD40 and B7-H1 was inhibited simultaneously (Figure

7B-D). The rate of CD40 and B7-H1 inhibition was calculated using the following equation: inhibition rate = $1 - (\text{MFI from mDCs with HBsAg pretreatment} / \text{MFI from mDCs without HBsAg pretreatment})$. It is noteworthy that the inhibition rate of CD40 was greater than that of B7-H1 (Figure 7E).

The T-cell stimulatory capacity of mDCs pretreated by HBsAg was impaired significantly

Since the inhibition rate of CD40 was greater than that of B7-H1, we further investigated whether the T-cell stimulatory capacity of mDCs pretreated by HBs-Ag was impaired. The mDC was stimulated by poly (I:C) for 20 h with or without HBs-Ag pretreatment, and co-cultured at 1:5 and 1:10 ratios with HLA-mismatched allogeneic T cells labeled with cytoplasmic dye CFSE. After 5 d of incubation, T-cell proliferation was assessed by the dilution of CFSE. In the allo-MLR system pretreated by HBsAg, with 1:5 and 1:10 responder cell-stimulator cell (R/S) ratios, approximately 25.4% or 12.0% of the responder T cells were CFSE^{dim} proliferating blasts, respectively (Figure 8A). In the allo-MLR system without HBsAg pretreatment, the percentage of CFSE^{dim} proliferating T cells was 85.1% in the 1:5 R/S ratio and 30.3% in the 1:10 R/S ratio, respectively (Figure 8B). The results showed that mDCs pretreated by HBsAg were less efficient at inducing T-cell proliferation at ratios of 1:5 and 1:10 compared with mDCs without HBsAg pretreatment.

Intracellular IFN- γ staining

In correlation with T-cell proliferation, the intracellular IFN- γ produced in these MLRs was measured after 5 d of co-culture. In the MLRs system at ratios of 1:5 and 1:10 R/S, without HBsAg pretreatment, the percentage of IFN- γ positive cells in CD8⁺ T cells was greater than $55.2\% \pm 5.3\%$ and $35.0\% \pm 5.1\%$ respectively. In the MLRs system, with HBsAg pretreatment, the percentage of IFN- γ positive cells in CD8⁺ T cells decreased to

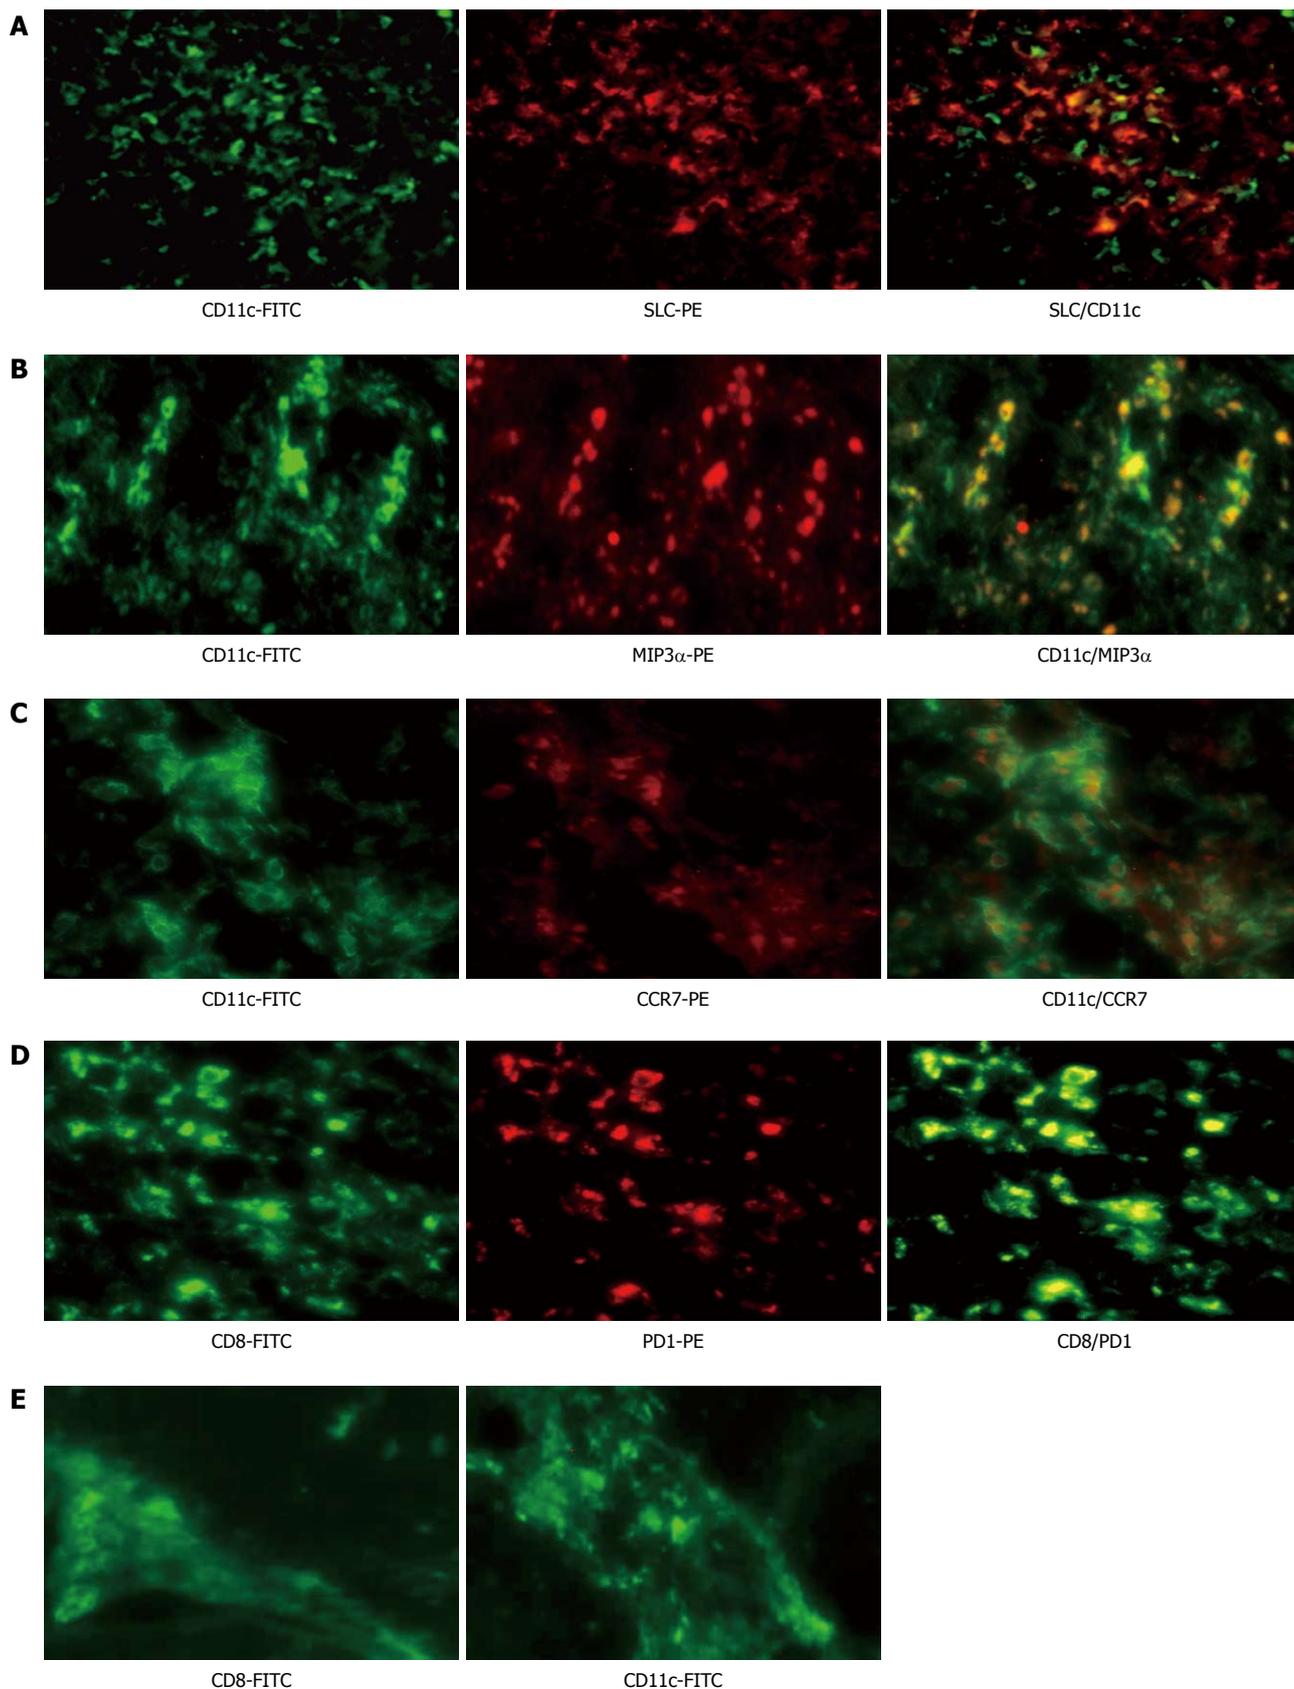

Figure 4 Localization of CD11c and programmed death 1 in liver tissue from acute hepatitis B and chronic hepatitis B virus tolerance patients. A-C: Colocalization of CD11c with SLC, MIP3 α and CCR7 by immunofluorescence double staining in liver biopsy specimens of acute hepatitis B (AHB) patients. CD11c (green) is co-localized with SLC (red) (A), MIP3 α (red) (B) and CCR7 (red) (C). The 2-color merged panels were shown with colocalization visible in yellow. Original magnification $\times 200$; D: Colocalization of CD8 with programmed death 1 (PD1) by immunofluorescence double staining in liver biopsy specimens of AHB patients. CD8 (green) is co-localized with PD1 (red). Original magnification $\times 200$; E: Inflammatory cells, such as CD8 and CD11c positive cells, can be observed mainly in fibrous septa in the liver tissue of chronic hepatitis B virus tolerance patients. FITC: Fluorescein isothiocyanate; PE: Phycoerythrin; SLC: Secondary lymphoid tissue chemokine; MIP3 α : Macrophage inflammatory protein 3 α ; CCR: Chemokine (C-C) receptor.

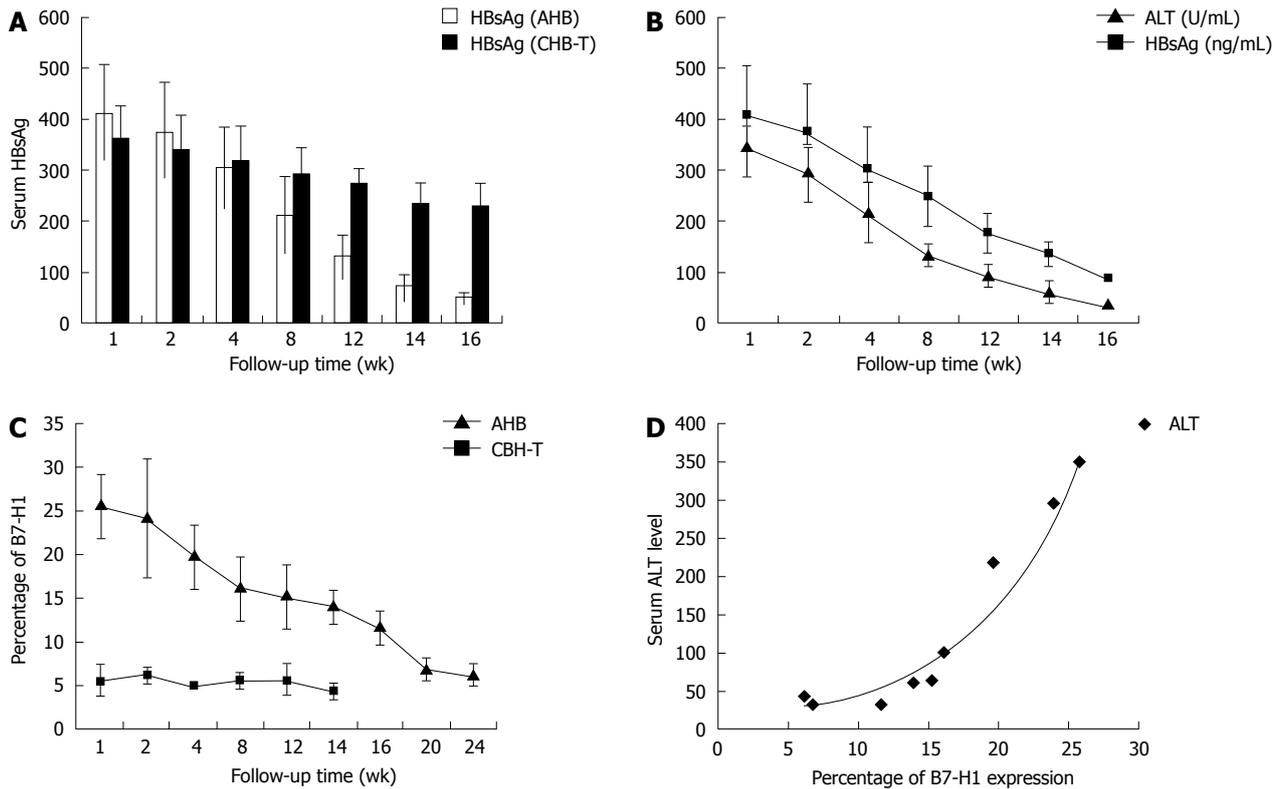

Figure 5 Longitudinal analysis of serum hepatitis B surface antigen, alanine aminotransferase levels and human B7 homolog 1 expression in acute hepatitis B and chronic hepatitis B virus tolerance patients. A: In acute hepatitis B (AHB) patients, serum hepatitis B surface antigen (HBsAg) levels decreased significantly from 404 ± 98.3 ng/mL at the 1st week to less than 30 ng/mL at the 16th week. In chronic hepatitis B virus tolerance (CHB-T) patients, serum HBsAg load remained more than 231 ± 38.6 ng/mL at the 16th week; B: In AHB patients, accompanied by a decrease in serum HBsAg level, serum alanine aminotransferase (ALT) level decreased significantly from 346.5 ± 62.3 at the 1st week to 41.8 ± 82 at the 16th week; C: In AHB patients, followed by a decrease in serum HBsAg and ALT level, the percentage of B7 homolog 1 (B7-H1) positive cells decreased significantly from 25.7 ± 4.0 at the 1st week to 6.3 ± 1.37 at the 24th week. In CHB-T patients, B7-H1 expression levels were not increased significantly during the follow-up period; D: In AHB patients, positive correlation between B7-H1 expression on circulating CD11c + DCs and serum ALT levels was revealed by longitudinal correlation analysis ($r = 0.902$).

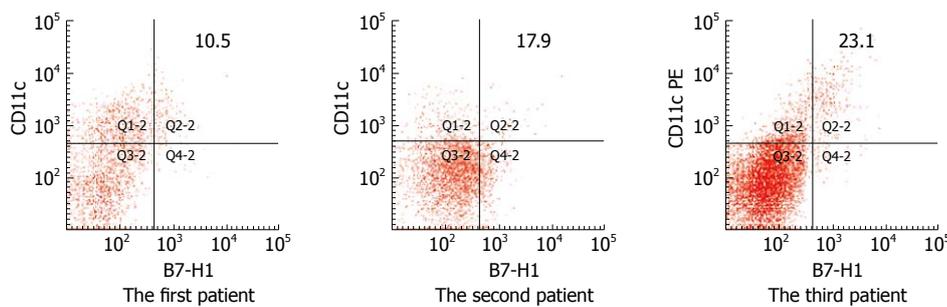

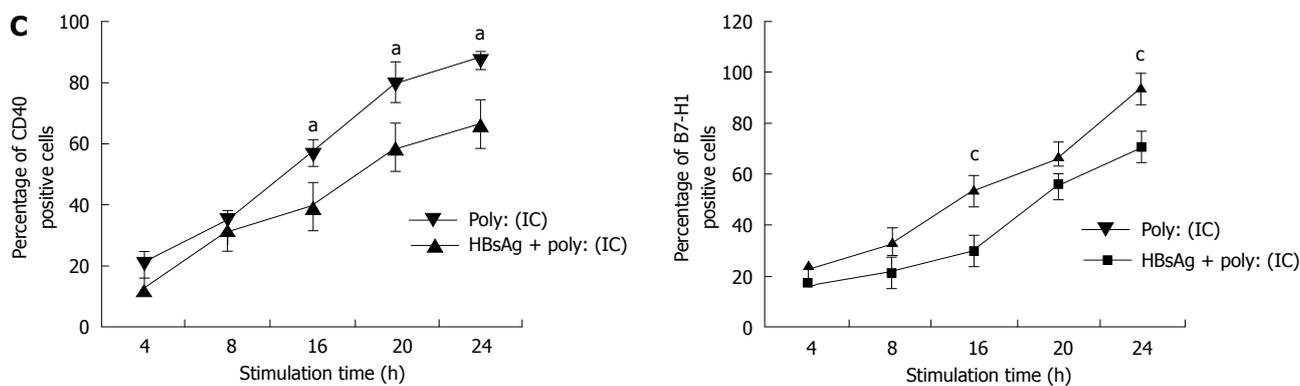

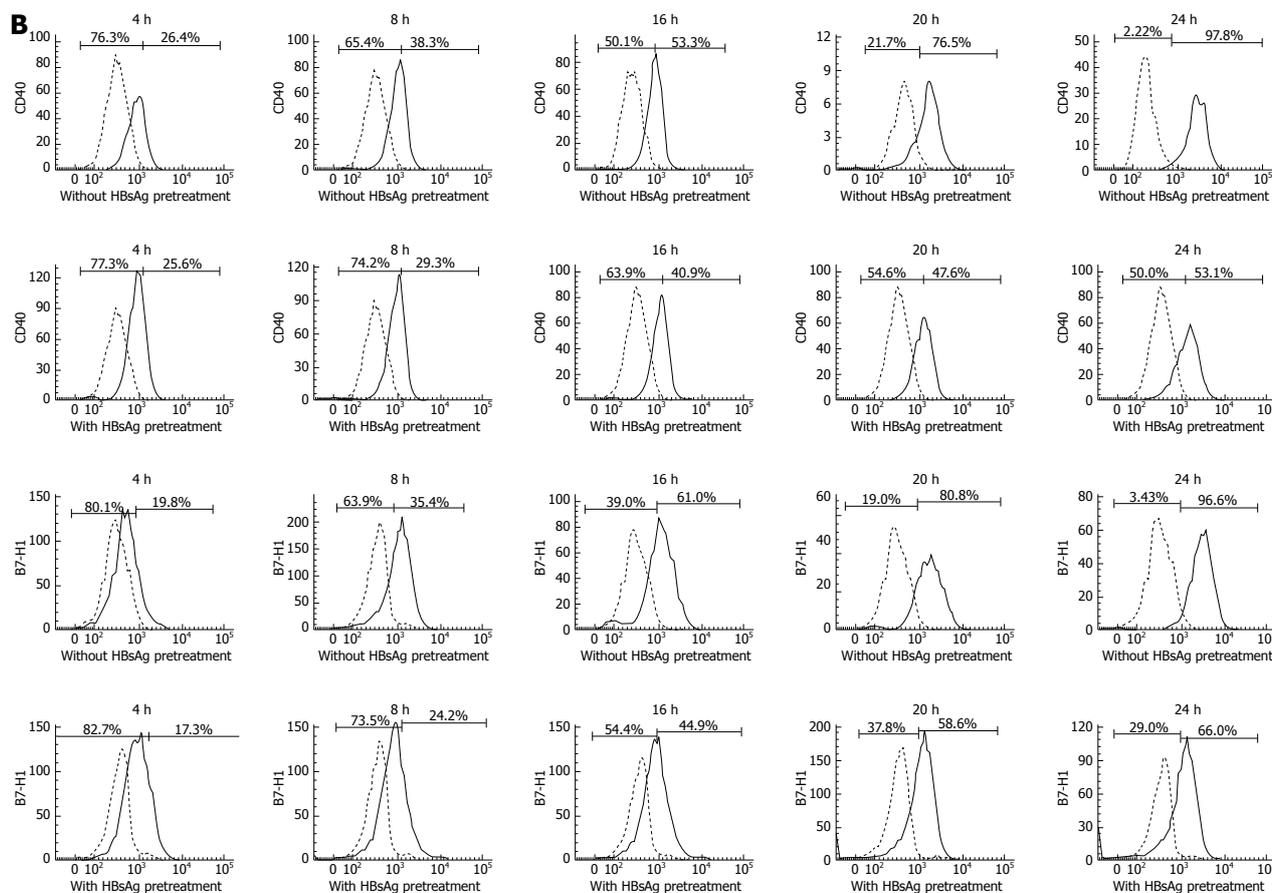

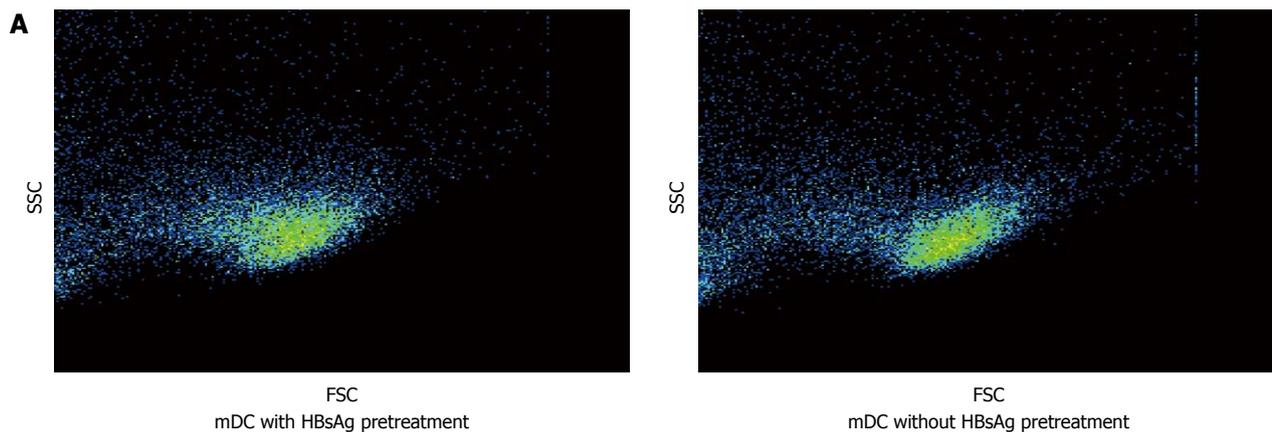

Figure 6 Human B7 homolog 1 expression on circulating CD11c positive cells in three chronic active hepatitis B patients during the inflammatory flare phase. The percentage of B7 homolog 1 (B7-H1) expression on circulating CD11c+ cells increased significantly in all three patients during the inflammatory flare phase. The numbers in the upper right quadrants indicate the percentage of B7-H1 positive CD11c+ dendritic cells. PE: Phycoerythrin.

$15.1\% \pm 3.1\%$ at a 1:5 R/S ratio and $7.3\% \pm 2.7\%$ at a 1:10 R/S ratio, respectively (Figure 9A and B). These results showed that IFN- γ production by CD8+ T cells was reduced significantly in the HBsAg pretreated MLRs system.

DISCUSSION

Recent studies have shown that functional defects in DCs may play a pivotal role in viral persistence during chronic HBV infection. However, the molecular mechanism by

which the impaired mDCs induce HBV-specific T cell immune tolerance remains elusive. Previous studies implicated increased B7-H1/PD-1 signaling in DC malfunction and viral-specific T-cell exhaustion in persistent HBV or HCV infections, which were associated with disease progression. *In vitro* blockade of B7-H1 signaling not only enhanced the mDC mediated allostimulatory capacity, but also up-regulated IL-12 production^[17-22]. Based on these data, B7-H1 was viewed as a signature of impairments in HBV-specific immune response.

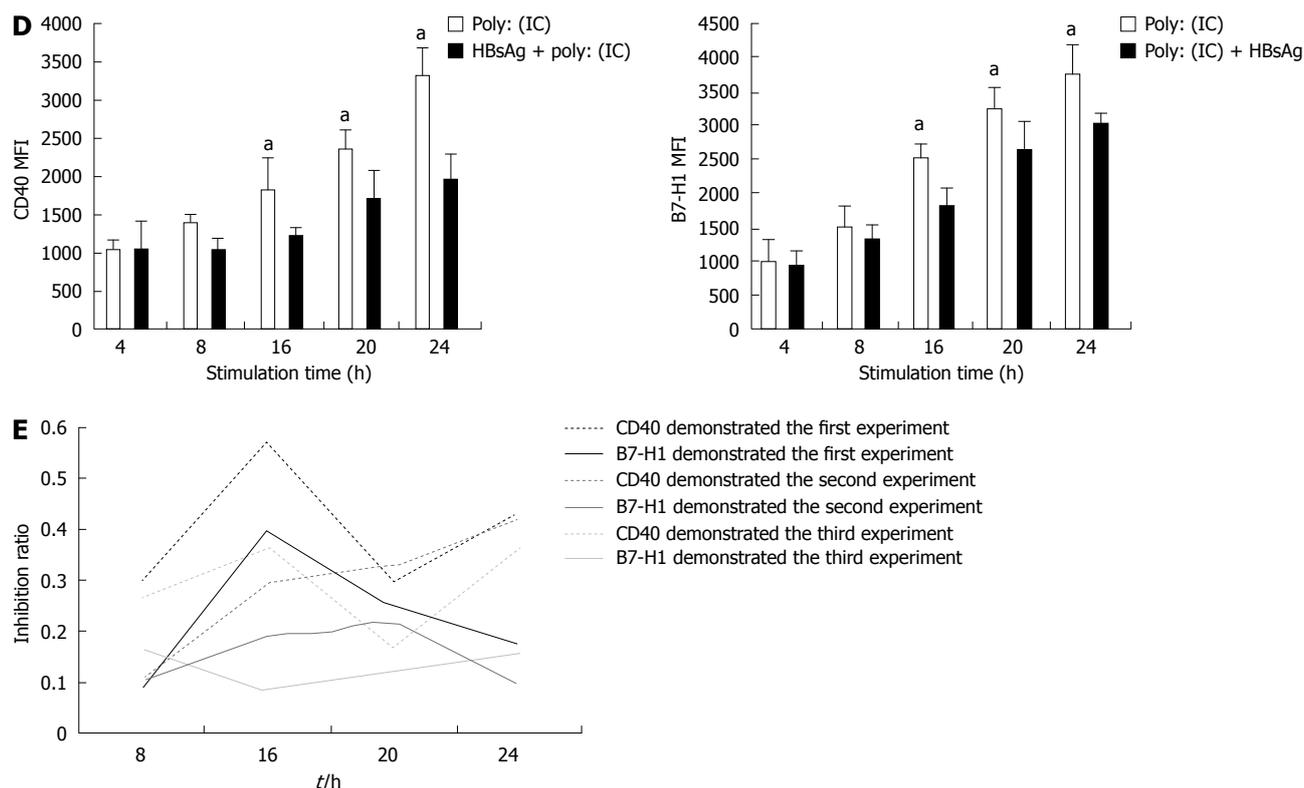

Figure 7 *In vitro* kinetic analysis of CD40 and human B7 homolog 1 expression on myeloid dendritic cells, with or without hepatitis B surface antigen pretreatment, stimulated by poly (I:C). A: The FSC and SSC of myeloid dendritic cells (mDCs) with r hepatitis B surface antigen (HBsAg) pretreatment were not altered significantly compared to those without rHBsAg pretreatment. This result suggests that the vitality of mDCs with or without HBsAg pretreatment is similar; B: Representative plots of CD40 and B7 homolog 1 (B7-H1) expression on mDCs with or without HBsAg pretreatment. Values in the upper right quadrant indicate the percentage of CD40 or B7-H1 positive cells; C: With HBsAg pretreatment, the percentage of CD40 (left) and B7-H1 (right) positive cells within mDCs were decreased significantly at 16 h, 20 h and 24 h time points (for CD40, $^aP < 0.05$ at 16 h, 20 h and 24 h time point; for B7-H1, $^aP < 0.05$ at 16 h and 24 h time point, $n = 10$); D: With HBsAg pretreatment, the MFI of CD40 (left) and B7-H1 (right) were decreased significantly at 16 h and 20 h time points (for CD40 and B7-H1, $^aP < 0.05$ at 16 h, 20 h and 24 h time point, $n = 10$); E: The inhibition rate was calculated using following equation: 1-MFI of CD40 or B7H1 with HBsAg pretreatment / MFI of CD40 or B7H1 without HBsAg pretreatment. The results showed that at 8 h, 16 h, 20 h and 24 h time point, the inhibition rate of CD40 was greater significantly than that of B7H1 ($P < 0.05$ at 8 h time point, $P < 0.01$ at 16 h time point, $P < 0.05$ at 20 h time point, $P < 0.01$ at 24 h time point). MFI: Mean fluorescence intensity; FSC: Forward scatter; SCC: Side scatter.

The present data indicate that B7-H1 is not a signature of HBV immune malfunction, but rather an inflammatory marker of acute hepatitis. Firstly, AIH patients, who did not possess viral etiology, exhibited the highest levels of B7-H1 expression on mDCs among the groups studied. Secondly, B7-H1 expression at protein and mRNA levels was more significant in AHB patients, who were characterized by high levels of serum ALT, than in CHB-T subjects. Thirdly, in AHB patients, despite significant upregulation of intra-hepatic B7-H1 expression, the inflammatory response in liver tissues was vigorous, while in the liver tissues from CHB-T subjects, markers of inflammation were not observed in liver lobe. Only a few inflammatory cells were located in fibrous septa, and B7-H1 molecules were mostly absent despite extensive HBsAg expression. Finally, longitudinal analysis revealed that the level of B7-H1 expression increased during the period of acute hepatitis and decreased when the inflammation was reduced.

Based on our clinical observations, chronic hepatitis B was divided into 2 different components, namely the immune tolerant HBV condition (characterized by active HBV-DNA replication, but with no serum ALT level upregulation) and the chronic active hepatitis condition

(which show repeated inflammation flare ups).

In the present study, B7-H1 expression was also analyzed on circulating mDCs in chronic active hepatitis subjects during the hepatitis flare-up period, and the results showed that B7-H1 expression on circulating mDCs was up-regulated to the same extent as in AHB subjects. These data further demonstrate that B7-H1 is a marker of hepatitis.

The current longitudinal analysis revealed that B7-H1 expression on circulating mDCs remained relatively high when serum ALT returned to normal range on week 16, but decreased to near normal level after serum ALT had remained within normal range for 2 mo or 3 mo, indicating a lag phase between the decrease of serum ALT and the return of B7-H1 expression to normal levels. If the blood sample was acquired within the lag phase, B7-H1 expression was higher than in HC.

In the liver tissue of AHB patients, the majority of B7-H1-positive cells co-expressed CD40, indicating that B7-H1 is always expressed on activated APCs. These results are in line with previous findings showing that B7-H1 was significantly increased by proinflammatory cytokines, including IFN- γ and tumor necrosis factor- α .

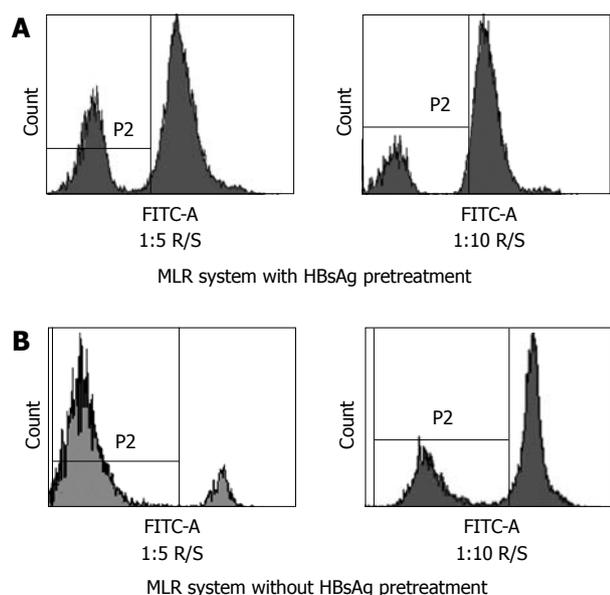

Figure 8 The analysis of the effects of hepatitis B surface antigen on T cell proliferation by carboxyfluorescein diacetate succinimidyl ester labeled mixed leucocyte reaction. A: Myeloid dendritic cells (mDCs) with hepatitis B surface antigen (HBsAg) pretreatment are weak stimulators in the mixed leucocyte reaction (MLR). Approximately 25.4% of T cells are carboxyfluorescein diacetate succinimidyl ester (CFSE)^{dim} in 1:5 R/S ratio and 12.0% in 1:10 R/S ratio respectively; B: mDCs without HBsAg pretreatment are potent stimulators in the MLR. Approximately 85.1% of the T cells are CFSE^{dim} in 1:5 R/S ratio and 30.3% in 1:10 R/S ratio respectively. FITC: Fluorescein isothiocyanate. R/S: Responder cell-stimulator cell.

(TNF- α)^[12,23]. The present results also show the presence of markers of inflammation such as infiltrating inflammatory cells and elevated chemokine expression in the liver tissue from AHB patients, with significant B7-H1 expression. On the other hand, in the liver lobes of CHB-T subjects, both B7-H1 molecules and other inflammatory characters were almost absent. Correlation analysis revealed a positive correlation between B7-H1 expression and liver damage, reflected by the levels of serum ALT, both cross-sectionally and longitudinally. Based on these data, we concluded that B7-H1 expression can be induced by inflammatory microenvironment and that the level of B7-H1 expression can serve as a marker of the degree of inflammation.

In vitro analysis showed that the expression of B7-H1 and CD40 on mDCs was upregulated synchronously in response to poly (I:C) stimulation. This result suggested that a delicate balance between the positive and negative co-stimulate molecules may exist in activated mDCs. The B7-H1/ PD1 interaction may be involved in weakening the positive stimulatory signal, limiting the immune response to avoid an extensive inflammatory response. This concept is in line with several studies supporting the conclusion that the B7-H1/PD-1 pathway may assist the liver in protecting itself from immune-mediated destruction^[24-28]. Zhang *et al.*^[23] reported that the delayed expression of B7-H1 or PD1 lead to fulminant hepatitis. In conclusion, the up-regulation of B7-H1 may contribute to maintaining immune response under the upper limit to

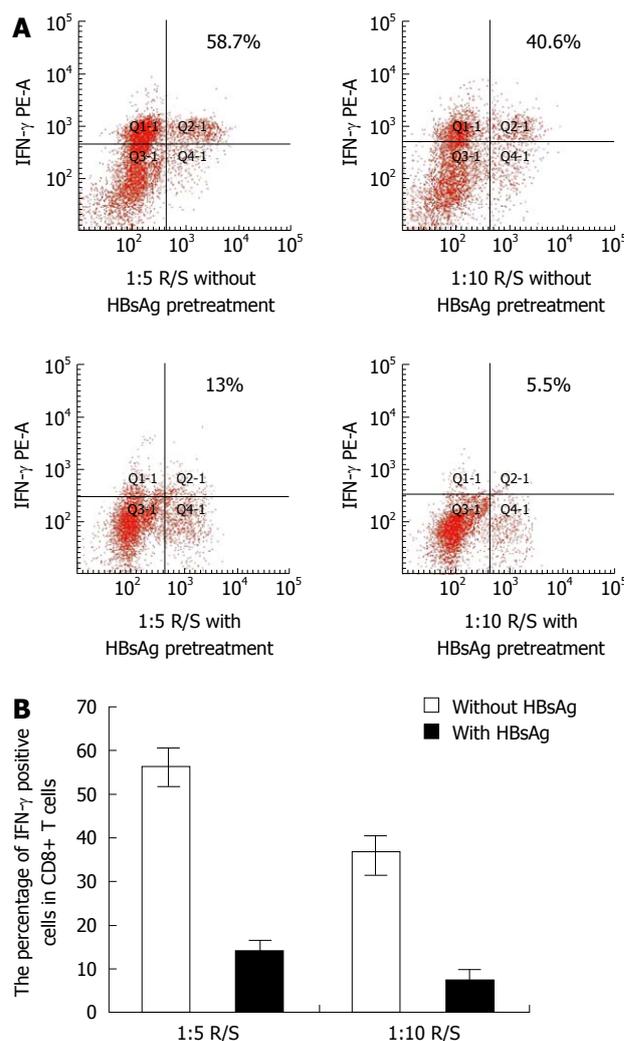

Figure 9 The analysis of the effects of hepatitis B surface antigen on intracellular interferon- γ production. A: Representative plots of intracellular interferon- γ (IFN- γ) produced by CD8+ T cells in mixed leucocyte reaction (MLRs) with or without hepatitis B surface antigen (HBsAg) pretreatment. Values in the upper right quadrant indicate the percentage of IFN- γ positive CD8+ T cells; B: In MLRs system at ratios of 1:5 and 1:10 R/S, IFN- γ production by CD8+T cells was reduced significantly by HBsAg pretreatment (at ratios of 1:5 and 1:10 R/S, $P < 0.001$, $n = 3$). R/S: Responder cell-stimulator cell.

avoid severe immune mediated liver damage during acute HBV infection. In CHB-T patients, immune responses were not elicited and B7-H1 expression was not elevated. These phenomena are consistent with the rule of immune regulation, which states “no activation, no inhibition”.

Previous data revealed that the HBV antigen has immunoregulatory abilities. Studies have reported that exposure to higher level of HBsAg load may lead to mDC dysfunction^[29,30]. Op den Brouw *et al.*^[10] and Loirat *et al.*^[31] reported that both HBsAg and HCsAg have the ability to suppress CD40 or HLA-DR expression and thus contribute to HBV or HCV persistence. Loirat *et al.*^[31] reported that recombinant HBsAg interacts with monocytes through the lipopolysaccharide (LPS) receptor CD14, resulting in diminished LPS-induced monocyte activation. HBsAg was shown to reduce LPS-induced TNF- α production through interference with the activation of

extracellular regulated protein kinases-1,2 and c-Jun NH₂-terminal kinase-1,2^[32,34]. These reports suggest that HBsAg and HBsAg have the ability to weaken the immune response.

The results of the present study revealed that HBsAg load was maintained at a high level in liver tissue as well as in peripheral blood from CHB-T subjects with no significant B7-H1 upregulation. Based on these previous data and the present results, we speculated that B7-H1 expression may also be inhibited by HBsAg, followed by CD40 suppression. To confirm this, the kinetic B7-H1 and CD40 expression in isolated mDCs stimulated by poly (I:C) with or without HBsAg pretreatment were analyzed. The results showed that the upregulation of CD40 and B7-H1 were significantly inhibited by HBsAg. Interestingly, HBsAg displayed a preferential inhibitory effect towards CD40 upregulation. The inhibition rate of CD40 was significantly greater than that of B7-H1, suggesting that HBsAg has the ability to regulate the balance between the CD40 and B7-H1.

Several previous studies have shown the activation of DCs after HBsAg impulsion, but either uric acid or cytokines were added in these investigations to active DCs^[35,36]. Horiike *et al.*^[36] reported that an alum adjuvant was needed in the HBsAg vaccine to active DCs during vaccine therapy. Proof of the low immunogenicity of HBsAg was shown in the research by Reignat *et al.*^[37] and Webster *et al.*^[38] which demonstrated that HBsAg specific CD8⁺ T cells are characterized by an HBV-tolerant phenotype.

Whether the preferential inhibition of CD40 resulted in the impairment of T cell proliferation by mDCs remains unclear. To elucidate this aspect, we compared the T cell stimulatory capacity of mDCs with or without HBsAg pretreatment by MLR. The results showed that T cell proliferation at 1:5 and 1:10 (R/S) ratio was significantly decreased in the HBsAg pretreated MLR system. In addition to T cells proliferation, we examined whether antiviral ability of T cells was affected. Because IFN- γ plays a key role in the control virus infection, the intracellular content of IFN- γ produced during these MLRs was analyzed by flow cytometry. We found that in the HBsAg-pretreated MLR system, IFN- γ production by CD8⁺ T cells decreased significantly. Only 15% of CD8⁺ T cells were IFN- γ positive, while more than 50% were IFN- γ positive in the MLR without HBsAg pretreatment. These results suggested that HBsAg has the ability to regulate the immune response by regulating the balance between CD40 and B7-H1, leading to a reduction in T-cell proliferation and IFN- γ production.

Our results indicated that B7-H1 is an inflammatory marker. It is induced by the inflammatory microenvironment and can serve as a marker of the degree of inflammation. The increase in B7-H1 expression correlated with the expression of positive co-stimulatory molecules to weaken the activation signal for T cells and generate a balance between co-inhibitory and co-stimulatory signal. HBsAg has the ability to tip this balance through preferential inhibition of CD40 expression, leading to a

reduction in T cell proliferation and IFN- γ production. In CHB-T subjects, maintenance of high HBsAg load may impair HBV immunity through the regulation of the balance between CD40 and B7-H1 expression.

Based on our results, we speculated that the outcome of hepatitis B depends on 2 factors. The first is the level of HBV antigen load and HBV replication. The second is the upper limit of the HBV specific immune response set by co-inhibitory molecules such as B7-H1. If the HBV antigen and HBV-DNA are eliminated successfully by the immune response under this upper limit, the hepatitis B patient should recover. The higher the upper limit, the better the chance of HBV elimination.

COMMENTS

Background

Patients with self-limited acute hepatitis B (AHB) can develop appropriate virus-specific immune responses, however these immune responses are insufficient to eliminate the virus in chronic hepatitis B patients and eventually lead to chronic hepatitis B virus (HBV) tolerance. Previous studies have shown that the programmed death 1 and human B7 homology 1 (PD1/B7-H1) interaction impairs HBV-specific immune response and facilitates HBV specific immune tolerance. HBV persistent infection was always attributed to the up-regulation of PD1 and B7-H1 expression. To date, the mechanisms underlying this defect of the HBV specific immune response have not been fully elucidated.

Research frontiers

Studies have indicated that the B7-H1/PD1 pathway plays a key role in myeloid dendritic cells (mDCs) dysfunction and T-cell exhaustion when these cells are exposed to high HBV or hepatitis C virus (HCV) antigen loads. The blockade of the PD1/B7-H1 interaction can restore the allostimulatory ability of mDCs and the function of HBV and HCV-specific CD8⁺ T cells with increased proliferation, cytotoxicity and cytokine production. Some studies have reported that the B7-H1 and PD1 expression were significantly upregulated in chronic hepatitis B patients. The specificity of this upregulation to HBV or HCV infection was determined by the lack of a significant increase in B7-H1 and PD1 in cytomegalovirus, Epstein-Barr virus and influenza A-infected patients. Based on these studies, relatively high levels of B7-H1/PD1 expression were viewed as the signature of impairments in the HBV- and HCV- specific immune response. Both HBV and HCV might exploit the B7-H1/PD1 pathway to facilitate persistent infection. On the other hand, recent studies revealed that B7-H1 and PD1 expression is significantly upregulated in the acute phase of hepatitis B. The upregulation of B7-H1 and PD1 expression protects tissue from severe immune mediated liver damage during AHB. These results are in line with reports showing that B7-H1 and PD1 expression is upregulated in liver nonparenchymal cells during the acute phase of inflammation to limit an over-vigorous inflammatory response.

Innovations and breakthroughs

In this article, the authors reached the conclusion that co-inhibitory molecules, such as B7-H1, are always upregulated during AHB. This phenomenon suggests that co-inhibitory molecules set the upper-limit to immune response to avoid severe liver damage by an over-vigorous immune response. If HBV antigen and HBV-DNA are successfully eliminated by the immune response under this upper limit, the hepatitis B patient should recover. The higher the upper limit, the better the chance of HBV elimination.

Applications

Previous studies attributed malfunction of HBV specific immune response to higher expression levels of PD1 and B7-H1. Based on our data, the authors reached the conclusion that B7-H1 is always upregulated during AHB. Increasing co-inhibitory signals, such as PD1/B7-H1, set the upper-limit to the immune response. If HBV were eliminated under the upper limit of immune response, the hepatitis B patient should recover. This study provides new insight into a co-inhibitory signal pathway function during the clinical course of AHB.

Peer review

Due to simultaneous expression of CD40 and B7-H1, the authors supposed that an upper threshold of the immune response set by co-inhibitory molecules

may exist. HBV antigens should be eliminated efficiently before the immune response reached the upper threshold level, otherwise acute HBV infection may turn into a chronic infectious state. The design of this study is reasonable; the results and conclusion of this paper are reliable; and the notion about an "upper threshold of HBV specific immune response" is somewhat attractive.

Abstract

AIM: To investigate the mechanism of interleukin (IL)-6 secretion through blocking the IL-17A/IL-17A receptor (IL-17RA) signaling pathway with a short hairpin RNA (shRNA) in hepatic stellate cells (HSCs) *in vitro*.

METHODS: HSCs were derived from the livers of adult male Sprague-Dawley rats. IL-6 expression was evaluated using real-time quantitative polymerase chain reaction and enzyme linked immunosorbent assay. The phosphorylation activity of p38 mitogen activated protein kinases (MAPK) and extracellular regulated protein kinases (ERK) 1/2 upon induction by IL-17A and suppression by IL-17RA shRNA were examined using Western blotting.

RESULTS: IL-6 expression induced by IL-17A was significantly increased compared to control in HSCs ($P < 0.01$ in a dose-dependent manner). Suppression of IL-17RA using lentiviral-mediated shRNA inhibited IL-6 expression induced by IL-17A compared to group with only IL-17A treatment (1.44 ± 0.17 vs 4.07 ± 0.43 , $P < 0.01$). IL-17A induced rapid phosphorylation of p38 MAPK and ERK1/2 after 5 min exposure, and showed the strongest levels of phosphorylation of p38 MAPK and ERK1/2 at 15 min in IL-17A-treated HSCs. IL-6 mRNA expression induced by IL-17A (100 ng/mL) for 3 h exposure was inhibited by preincubation with specific inhibitors of p38 MAPK (SB-203580) and ERK1/2 (PD-98059) compared to groups without inhibitors preincubation (1.67 ± 0.24 , 2.01 ± 0.10 vs 4.08 ± 0.59 , $P < 0.01$). Moreover, lentiviral-mediated IL-17RA shRNA 1 inhibited IL-17A-induced IL-6 mRNA expression compared to random shRNA in HSCs (1.44 ± 0.17 vs 3.98 ± 0.68 , $P < 0.01$). Lentiviral-mediated IL-17RA shRNA 1 inhibited phosphorylation of p38 MAPK and ERK1/2 induced by 15 min IL-17A (100 ng/mL) exposure.

CONCLUSION: Down-regulation of the IL-17RA receptor by shRNA decreased IL-6 expression induced by IL-17A *via* p38 MAPK and ERK1/2 phosphorylation in HSCs. Suppression of IL-17RA expression may be a strategy to reduce the inflammatory response induced by IL-17A in the liver.

INTRODUCTION

Hepatic stellate cells (HSCs), also known as fat-storing cells, are a major cell type involved in liver fibrosis. Activation and proliferation of HSCs are associated with liver injury^[1]. Activated HSCs accumulate excess extracellular matrix and produce a variety of pro-inflammatory cytokines, including macrophage inflammatory protein-2, monocyte chemo-attractant protein-1, interleukin (IL)-6, IL-8, and transforming growth factor- β 1 (TGF- β 1)^[2-3]. These pro-inflammatory cytokines can eventually lead to liver fibrosis.

IL-17A is the founding member of the IL-17 cytokine family, which now includes six major isoforms, IL-17A, -B, -C, -D, -E, and -F^[4]. The original "IL-17" has been designated IL-17A and is considered a T cell (Th17 cells)-specific cytokine^[5]. The IL-17A receptor (IL-17RA) is expressed on many cell types in the human body^[6]. IL-17A exerts pro-inflammatory, pro-apoptotic, and pro-mitogenic effects *via* binding to IL-17RA^[6,7].

In this study, we constructed a highly efficient lentiviral short hairpin RNA (shRNA) targeting IL-17RA to study the level of IL-6 secretion in the absence of IL-17RA in activated HSCs and the underlying mechanism(s). Our results showed that the silencing effect of IL-17RA shRNA eliminated IL-6 secretion in activated HSCs. We suggest that secretion of IL-6 involves the mitogen activated protein kinases (MAPK) signaling pathway through phosphorylation of p38 MAPK and extracellular regulated protein kinases (ERK) 1/2. Our finding may provide a novel interventional therapy against hepatic inflammatory responses and hepatic fibrosis.

MATERIALS AND METHODS

Reagents

Recombinant murine IL-17A was purchased from Pe-protech (Princeton Business Park, NJ). Anti-IL-17R (sc-1902, dilution factor 1:200) was purchased from Santa Cruz Biotechnology (Santa Cruz, CA). PD-98509 (inhibitor of MEK1) and SB-203580 (inhibitor of p38 MAPK) were obtained from Sigma-Aldrich (Saint Louis, MO). The p38 MAPK antibody (dilution factor 1:200), phospho-p38 MAPK rabbit mAb (dilution factor 1:200), ERK1/2 MAPK rabbit mAb (dilution factor 1:250), and phospho-ERK1/2 MAPK rabbit mAb (dilution factor 1:250) were obtained from Cell Signaling Technology (Beverly, MA).

shRNA design and plasmid constructs

Candidate sequences targeting rat IL-17RA mRNA (GenBank Accession NM 001107883) were designed using the Dharmacon siDESIGN Center procedure. Two complementary single-strand oligonucleotides containing the target sequences were synthesized chemically and annealed. The double-stranded oligonucleotides were inserted between *Age*I and *Eco*RI restriction sites in the pGCL-green fluorescent protein (GFP) small interfering RNA (siRNA) vector that contains a cytomegaviruses-driven enhanced green fluorescent protein reporter gene. The ligated plasmid was transformed into *Escherichia coli* DH5 α competent cells for pGCSIL/IL-17RA shRNA plasmid amplification.

shRNA lentivirus transduction

Plasmids containing the IL-17RA shRNA lentivirus were transfected into 293T cells using the ViraPower packaging mix (pGCSIL/IL-17RA shRNA plasmids, pHelper 1.0, and pHelper 2.0) and Lipofectamine 2000 (Invitrogen). After 48 h, the harvested viral supernatant was used to infect HSCs at a multiplicity of infection of 10 for 24 h. Cells with the GFP label were harvested after 48 h, and total RNA was extracted. The interference efficiency of IL-17RA shRNA was determined using real-time quantitative polymerase chain reaction (qPCR), and the most efficient silencing sequence of IL-17RA shRNA was selected for subsequent studies.

Isolation and culture of rat HSCs

Adult male Sprague-Dawley rats (body weight, 400-500 g) were used for HSC isolation as described previously^[8]. The liver tissues were digested with collagenase IV (0.5 g/L) and deoxyribonuclease I (0.03 g/L) before fractionation on a discontinuous gradient of iodixanol. HSCs were harvested from the 11.5% medium interface, washed, and seeded in tissue culture plates. Cells were cultured in Dulbecco's modified Eagle's medium (DMEM; Gibco, United States) with 10% fetal bovine serum (Sijiqing Bio. Co. Hangzhou, China), 100 U/mL penicillin, and 100 μ g/mL streptomycin. Culture medium was changed every third day. All experiments were performed with cells from passage numbers 3-6.

Identification of primary HSCs and activated HSCs

The harvested primary HSCs were studied at days 1, 2, and 5 after isolation. Primary d1 HSCs showed intrinsic fluorescence of lipid droplet and desmin expression (Boster, Wuhan, China) under a fluorescence microscope. Nuclei cells were stained with DAPI. After the first sub-culture passage, activated HSC purity was assessed using α -smooth muscle actin (α -SMA, dilution factor 1:100; Boster) and immunocytochemical staining.

IL-6 secretion

Cells cultured in 6-well plates were exposed to different concentrations of IL-17A for 24 h. The amount of IL-6

in supernatants was determined using enzyme linked immunosorbent assay kits purchased from R and D Systems (Minneapolis, MN).

Western blotting analysis

Cells exposed to IL-17A in the presence or absence of inhibitors for the indicated time period were extracted with lysis buffer containing a phosphatase inhibitor cocktail and a protease inhibitor cocktail. The protein concentration was measured using the Bradford assay. Proteins from each sample were loaded equally and separated on a 6% or 10% sodium dodecyl sulfate-polyacrylamide gel electrophoresis gel. Proteins were electrophoretically transferred onto polyvinylidene fluoride membranes, which were then incubated with primary antibodies at 4 °C overnight. On the following day, membranes were incubated with horseradish peroxidase-conjugated secondary antibodies at 37 °C for 2 h and then signals were detected using chemiluminescence (ECL Plus, GE Healthcare). Glyceraldehyde-3-phosphate dehydrogenase [(GAPDH); dilution factor 1:2000, Santa Cruz Biotechnology] was used as a loading control.

RNA extraction and gene expression analysis

Real-time qPCR was used to examine the expression of IL-17RA and IL-6 in HSCs. Total RNAs were isolated from HSCs using the Trizol reagent following the manufacturer's protocol and reverse-transcribed using a cDNA synthesis kit (Promega). SYBR Green detection was used and the values were normalized using GAPDH. Real-time qPCR was performed with a DNA Engine (ABi 7500) using SYBR GREENER qPCR UNIVERSAL. Primer sequences were: IL-17RA (forward) 5'-TG-GCGGTTCTCCTTCAGTC-3' and IL-17RA (reverse) 5'-CGGTGTAGTCATCTTCATCTCC-3', IL-6 (forward) 5'-CGTTTCTACCTGGAGTTTGTG-3' and IL-6 (reverse) 5'-ATTAGGAGAGCATTGGAAGTTGG-3', and GAPDH (forward) 5'-TTCAACGGCACAGT-CAAGG-3' and GAPDH (reverse) 5'-CTCAGCACCAG-CATCACC-3'. Relative expression levels of each primer set were normalized to GAPDH expression.

Statistical analysis

Data were expressed as mean \pm SD. The statistical signifi-

cance of changes was determined using the *t*-test. *P* values < 0.05 were considered to indicate statistical significance.

RESULTS

IL-17RA shRNA lentiviral construction and transduction

The sequences of IL-17RA shRNAs 1, 2, 3, and 4 and random shRNA are shown in Table 1. The recombinant plasmid of pGCSIL/IL-17RA shRNA 1 was confirmed by sequence analysis (Figure 1A) and titers were approximately 1×10^9 TU/mL. The interference efficiency of IL-17RA shRNAs 1, 2, 3, and 4 are shown in Figure 1B. The relative expression of IL-17RA mRNA for IL-17RA shRNAs 1, 2, 3, and 4 were 0.253 ± 0.011 , 0.643 ± 0.022 , 0.673 ± 0.051 , and 0.444 ± 0.043 , respectively. IL-17RA shRNA 1 exhibited a significant silencing effect, with 74.7% interference efficiency. Figure 1C shows HSC morphology with successfully transduced GFP-labeled IL-17RA shRNA 1 using a fluorescence or light microscope ($\times 200$) after 72 h.

Isolation and culture of rat HSCs

Primary HSC culture after isolation on days 1, 2, and 5 are shown in Figure 2A. The cultured HSCs were assessed for intrinsic fluorescence of lipid droplet and desmin expression (Boster; Figure 2B). The purity of activated HSCs was confirmed using immunocytochemical staining for α -smooth muscle actin (Boster; Figure 2C); the purity reached > 98%.

IL-17A induces IL-6 expression

HSCs were incubated with increasing concentrations of IL-17A for 24 h, and the levels of IL-6 secretion in the supernatant were measured by ELISA. As shown in Figure 3A, IL-17A-induced IL-6 secretion increased in a dose-dependent manner. The expression level of IL-6 mRNA by IL-17A was quantified using real-time qPCR (Figure 3B). A rapid increase in IL-17A-induced IL-6 mRNA expression reached a maximum level at 3 h of IL-17A exposure. However, the level of IL-6 mRNA expression decreased gradually after 3 h exposure.

IL-17A induces activation of MAPKs

In various cells, the MAPK family has been shown to

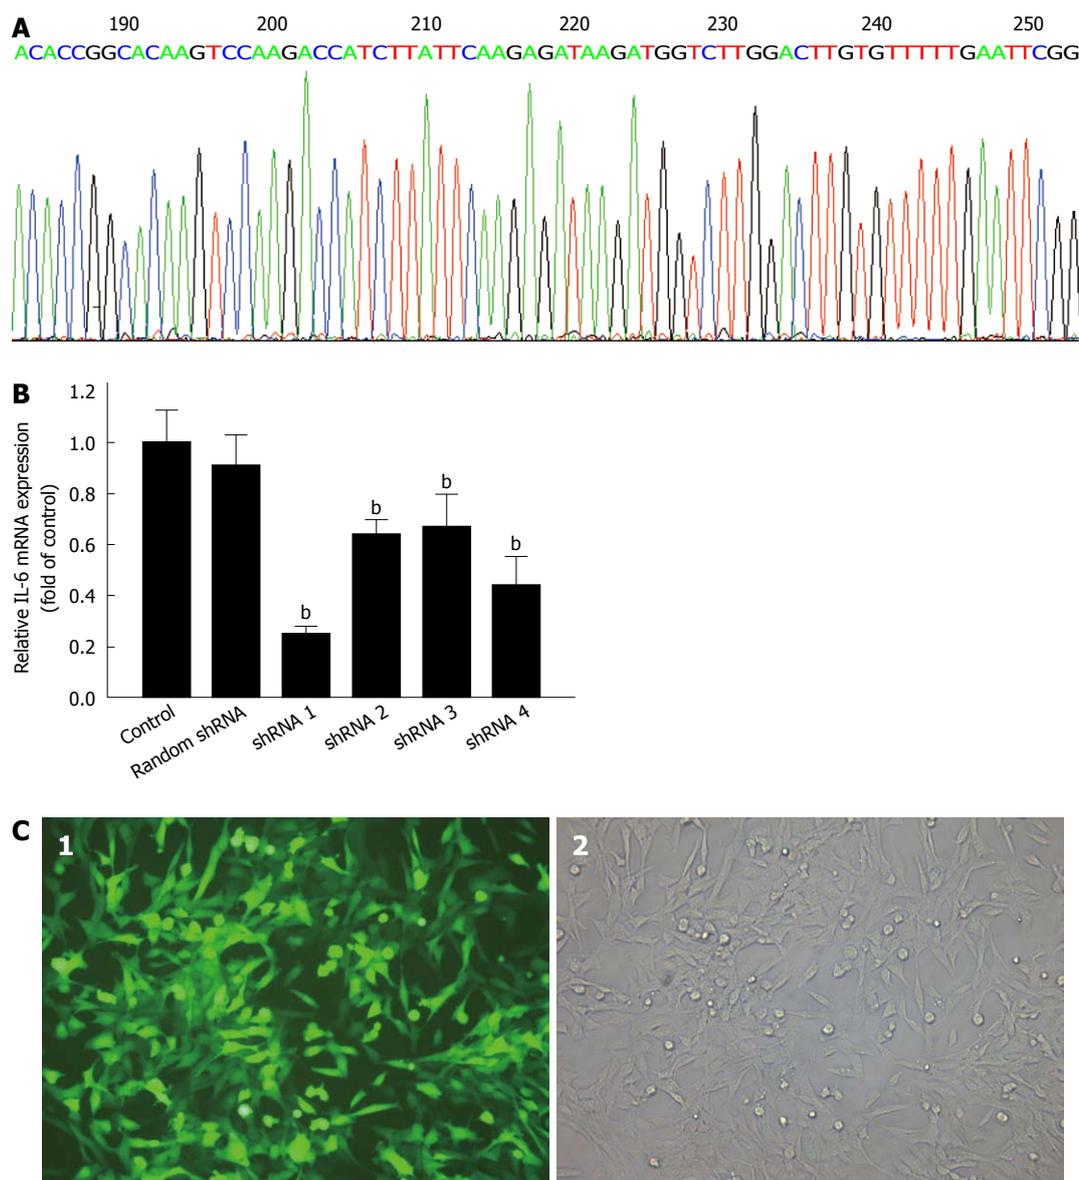

Figure 1 Short hairpin RNA design, interference efficiency assay, and lentivirus transduction. play an important role in regulating gene expression in response to inflammatory mediators^[7]. To investigate whether IL-17A induced activation of p38 MAPK and ERK1/2 in HSCs, phosphorylation of p38 MAPK and ERK1/2 in HSCs were evaluated after IL-17A stimulation. IL-17A induced rapid phosphorylation of p38 MAPK and ERK1/2 after 5 min, and showed the strongest levels of phosphorylation of p38 MAPK and ERK1/2 at 15 min (Figure 3C). However, IL-17A did not affect the expression of total p38 MAPK or ERK1/2. This result indicated that IL-17A enhanced p38 MAPK and ERK1/2 phosphorylation in HSCs.

MAPK inhibitors suppress IL-6 expression

To further assess the phosphorylation of p38 and ERK1/2

induced by IL-17A, two specific inhibitors, SB-203580 (p38 MAPK) and PD-98059 (ERK1/2), were used. As shown in Figure 3D, SB-203580 inhibited p38 MAPK phosphorylation and PD-98059 blocked phosphorylation of ERK1/2 induced by IL-17A in HSCs. SB-203580 and PD-98059 were used to further evaluate the roles of p38 MAPK and ERK1/2 in IL-6 mRNA expression induced by IL-17A in HSCs. Both inhibitors reduced IL-17A-induced IL-6 mRNA expression significantly (Figure 3E).

shRNA suppresses IL-17RA and IL-6 expression

Western blotting and real-time qPCR were performed to study the silencing effect of lentiviral-mediated shRNA on IL-17RA-induced IL-6 expression in HSCs. The protein levels of IL-17RA in shRNA 1-treated HSCs were

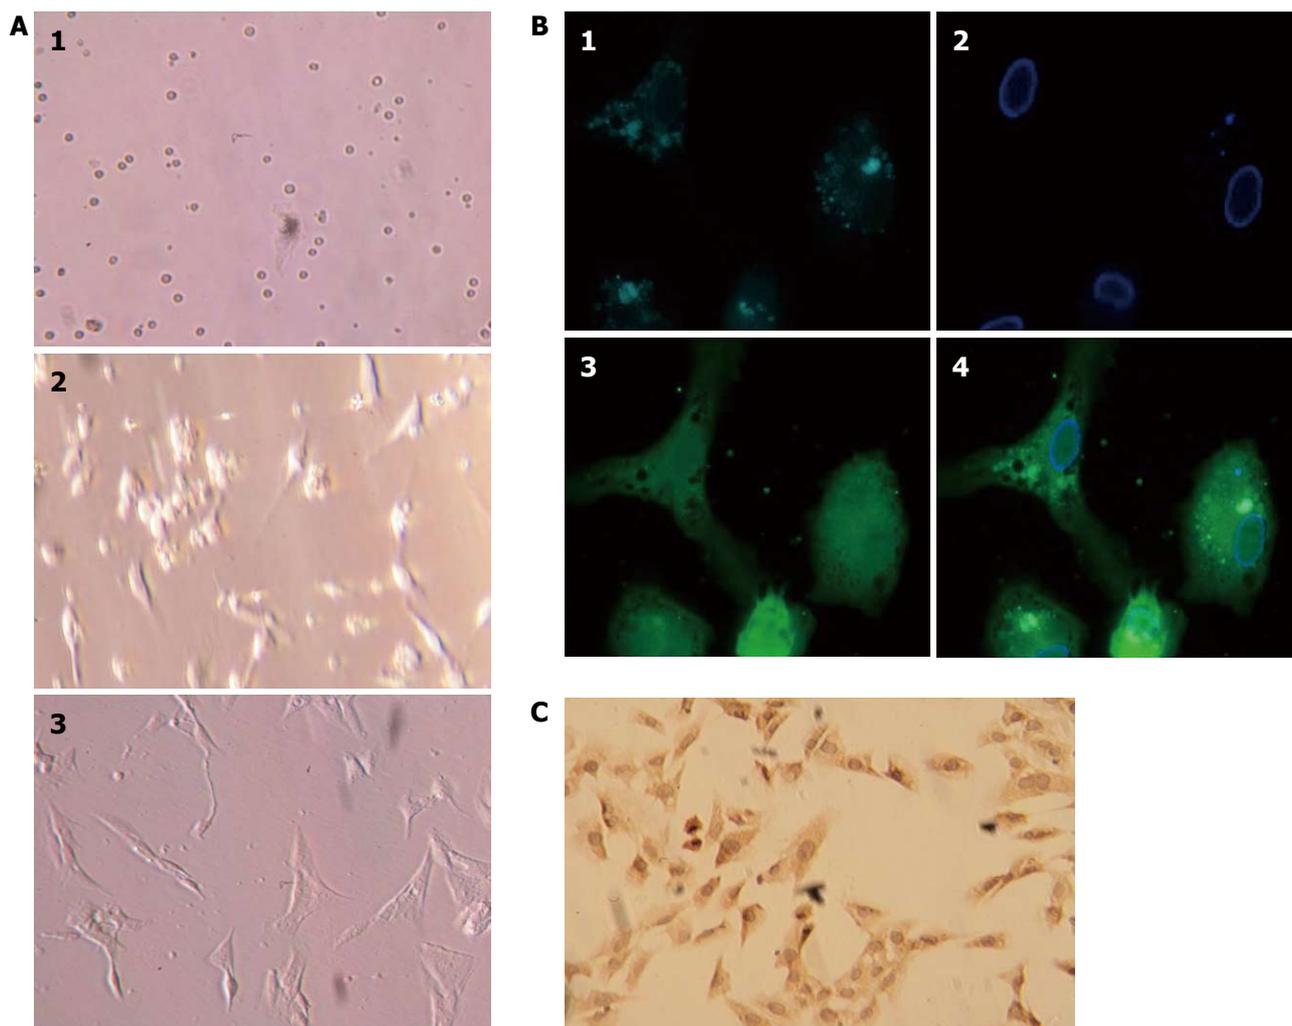

Figure 2 Isolation, culture, and identification of primary rat hepatic stellate cells. A: Primary rat hepatic stellate cells (HSCs) on days 1, 2, and 5 after isolation and plated in culture; B: HSCs isolated from Sprague-Dawley rats showed characteristic multiple lipid droplets with a rapid fade of the blue-green autofluorescence at 328 nm. 1: Lipid droplets; 2: Cell nucleus; 3: Cell body. 4: Merged images; C: HSC culture after the first passage and stained with anti- α -smooth muscle actin antibody.

reduced, compared with random shRNA and control (Figure 4A). HSCs treated with IL-17A alone or IL-17A with random shRNA showed increased IL-6 mRNA expression, whereas, IL-6 mRNA expression in HSCs pretreated with IL-17RA shRNA 1 was decreased significantly (Figure 4B).

shRNA suppresses phosphorylation of p38 and ERK1/2

IL-17A induced IL-6 expression *via* p38 MAPK and ERK1/2 phosphorylation. In Figure 4C, we show that HSCs treated with IL-17A transduced with shRNA 1 exhibited reduced protein levels of phosphorylation of p38 MAPK and ERK1/2, compared with IL-17A alone and IL-17A transduced with random shRNA group. Phosphorylation of p38 MAPK and ERK1/2 was blocked in the group treated with lentiviral-mediated IL-17RA shRNA 1, whereas there was almost no change in the IL-17A alone or IL-17A transduced with random shRNA groups.

DISCUSSION

IL-17A is a pro-inflammatory cytokine secreted by a subset of T helper cells, named Th17 cells. IL-17A signals exert miscellaneous effects through binding to the IL-17A receptor, which is expressed on a variety of cells and tissues^[9,10]. The IL-17A pathway plays important roles in the human inflammatory and autoimmune diseases and tumor progression^[11,12]. Clinical studies have shown that high levels of IL-17A and other cytokines related to the IL-17A pathway are seen in sera or tissues of patients with diseases such as psoriasis, multiple sclerosis, systemic sclerosis, ankylosing spondylitis, and juvenile idiopathic arthritis^[13-17]. The IL-17RA is found on hepatocytes, Kupffer cells, HSCs, biliary epithelial cells, and sinusoidal endothelial cells^[18]. Thus, IL-17A function in liver diseases has attracted much attention. Previous studies indicated that IL-17A is elevated in various liver diseases, including liver autoimmunity and inflammatory diseases, alcoholic liver disease (ALD), and hepatocellular carcinoma^[19].

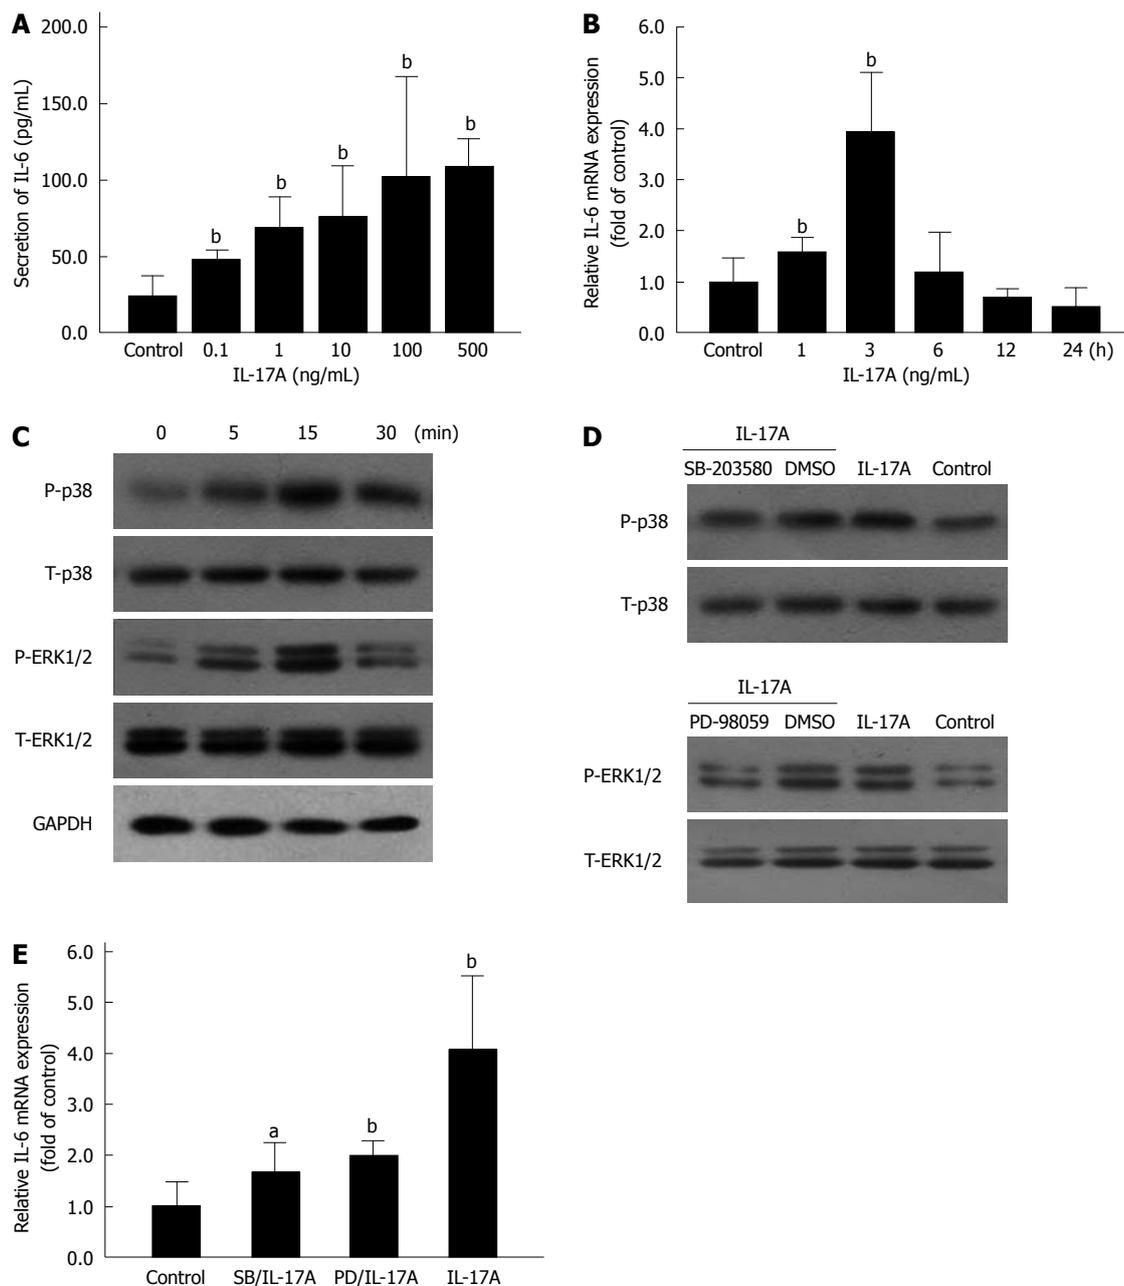

Figure 3 Mitogen activated protein kinases pathway involved in interleukin 17A induced interleukin 6 expression. A: Secretion of interleukin (IL)-6 in hepatic stellate cells (HSCs) induced by interleukin 17A (IL-17A) was determined using enzyme-linked immunosorbent assay. ^b*P* < 0.01 vs control; B: IL-6 mRNA expression in HSCs induced by IL-17A (100 ng/mL) was measured by polymerase chain reaction. ^b*P* < 0.01 vs control; C: Phosphorylation of p38 MAPK and ERK1/2 induced by IL-17A (100 ng/mL) in HSCs was detected using Western blotting; D: Phosphorylation of p38 MAPK and ERK1/2 induced by IL-17A (100 ng/mL) for 15 min was blocked by preincubation with MAPKs inhibitors, SB-203580 (1 μ mol/L in DMSO, 30 min) and PD-98059 (10 μ mol/L in DMSO, 1 h); E: IL-6 mRNA expression induced by IL-17A (100 ng/mL) for 3 h exposure was inhibited by preincubation with SB-203580 (SB) and PD-98059 (PD) for the same time period as above. ^a*P* < 0.05, ^b*P* < 0.01 vs control. T: Total; P: Phosphorylation; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase; MAPK: Mitogen activated protein kinases; ERK: Extracellular regulated protein kinases.

Studies based on acute hepatic injury (AHI) and hepatitis C virus (HCV) showed that patients with AHI and HCV have significantly higher serum IL-17A levels than controls^[20-22]. Furthermore, percentages of circulating Th17 cells and Th17-associated cytokines, including IL-17A, IL-6, and IL-23, were increased markedly in peripheral blood and in liver tissues of chronic hepatitis B patients compared with controls^[23,24]. Recent studies indicate that patients with ALD had significantly higher plasma levels of IL-17A compared with healthy subjects. Moreover, the

number of liver Th17 cells was correlated positively with hepatocellular damage and the severity of the disease in a cohort study of patients with ALD^[25].

HSCs are the major source of extracellular matrix in liver fibrosis^[26] and participate in modulating liver inflammation during liver fibrogenesis^[27]. IL-17RA is expressed on HSCs, and thus blockade of IL-17A/IL-17RA signal transduction in HSCs may be a strategy to interfere with hepatic inflammatory processes in chronic liver diseases. In our study, we sought to investigate the secretion of

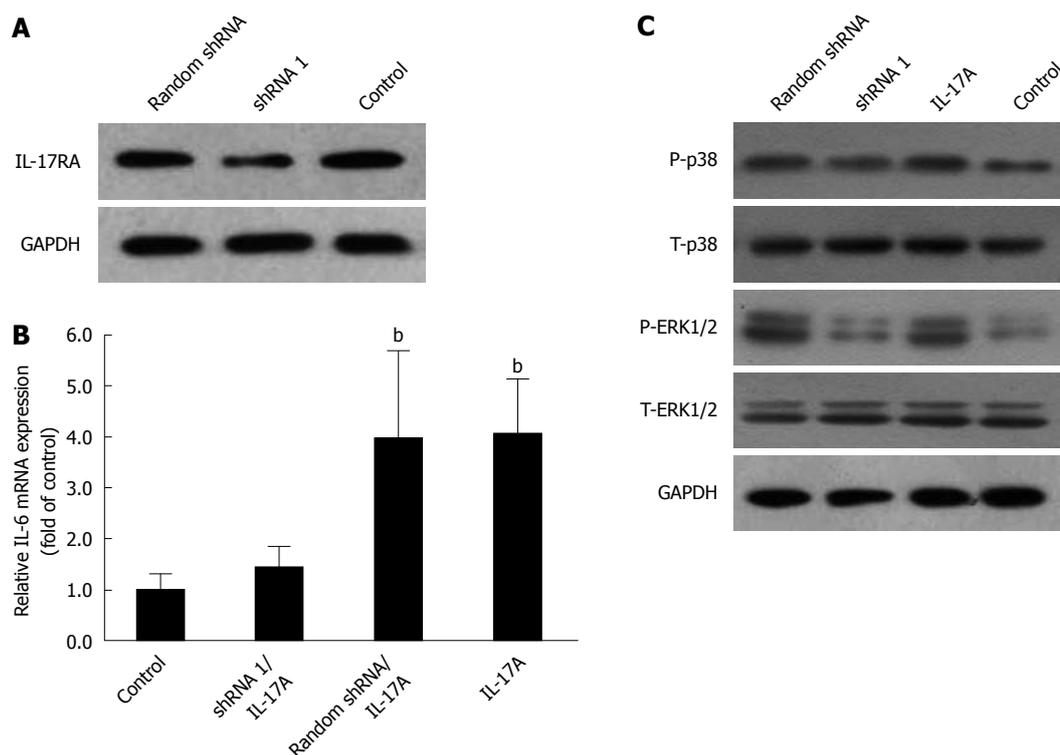

Figure 4 Lentiviral-mediated interleukin 17A receptor short hairpin RNA arrested interleukin 6 expression, partly through suppressing phosphorylation of p38 mitogen activated protein kinases and extracellular regulated protein kinases 1/2. A: Lentiviral-mediated interleukin (IL)-17A receptor short hairpin RNA (shRNA) 1 [at multiplicity of infection (MOI) = 10 for 72 h] inhibited the expression of IL-17RA in hepatic stellate cells (HSCs); B: Lentiviral-mediated IL-17RA shRNA 1 inhibited IL-17A-induced IL-6 mRNA expression in HSCs. HSCs were infected with IL-17RA shRNA 1 or random shRNA lentivirus at MOI = 10 for 72 h, and followed by 3 h exposure to IL-17A (100 ng/mL). ^a*P* < 0.01 vs control; C: Lentiviral-mediated IL-17RA shRNA 1 inhibited phosphorylation of p38 MAPK and ERK1/2. HSCs were transduced with IL-17RA shRNA 1 or random shRNA lentiviral at MOI = 10 for 72 h, and followed by 15 min exposure to IL-17A (100 ng/mL). T: Total, P: Phosphorylation; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

IL-6, one of the major cytokines in various liver injuries^[28-30], stimulated by IL-17A in HSCs. Our data show that IL-17A induces a large amount of IL-6 secretion (68.96 ± 8.30 pg/mL) even at a low concentration of IL-17A treatment (1 ng/mL). With increasing concentrations of IL-17A, the secretion of IL-6 also increased. Surprisingly, a higher concentration of IL-17A (500 ng/mL) induced only moderate expression of IL-6 (109.16 ± 6.91 pg/mL). This may suggest that there is saturation of binding between IL-17A and IL-17RA at a particular concentration or that there may be a negative feedback response on IL-6 expression on IL-17A induction. Our data further show that the IL-6 mRNA expression detected in real-time qPCR reached a maximum level after 3 h exposure to IL-17A and declined thereafter. These results are based on data obtained from the expression of IL-6 protein in HSCs supernatants and indicate that IL-17A induces IL-6 expression *in vitro*. We made a lentivirus-mediated IL-17RA shRNA construct to repress endogenous IL-17RA in HSCs. As a result, we found that IL-6 mRNA expression was notably reduced. Our results further suggest that the MAPK pathway in IL-6 expression is induced by IL-17A in HSCs. We showed that the phosphorylation of p38 MAPK and ERK1/2 is increased after 15 min exposure to IL-17A, and lentivirus-mediated IL-17RA shRNA decreased the phosphorylation of p38 MAPK and ERK1/2. Moreover, use of specific inhibi-

tors further revealed the importance of the MAPK pathway in IL-17A-induced IL-6 mRNA expression in HSCs. The imidazole compound SB-203580, a specific inhibitor of p38 MAPK, caused a significant decrease in IL-17A-induced IL-6 mRNA expression. Additionally, PD-98059, a specific inhibitor of MEK1 that is the directly upstream protein kinase of ERK1/2, promotes marked suppression of IL-17A induced IL-6 mRNA expression. Thus, we conclude that the p38 MAPK and ERK1/2 pathways are involved in IL-6 mRNA expression induced by IL-17A in HSCs. Hot *et al*^[31] indicated that IL-17A stimulated IL-6 secretion by inducing activation of all three MAPKs (ERK, p38, JNK). Inhibition of IL-17RA expression *via* siRNA lead to near complete abrogation of IL-6 expression mediated by IL-17A.

IL-6 is an important cytokine in regulating different inflammatory responses in liver diseases and is a marker in the diagnosis of symptoms of liver cirrhosis^[32-34]. Previous studies have described that IL-6, in conjunction with TGF- β , promotes Th17 cell differentiation and drives IL-17A production^[35,36]. On the other hand, IL-17A can also stimulate IL-6 expression^[37] and IL-6 is a key downstream target gene for IL-17A in non-immune cells, such as fibroblasts^[38]. IL-17A triggers a positive feedback loop of IL-6 signaling and forms the "IL-6 amplifier"^[37,38]. IL-17A plays a pivotal role in immune and non-immune tissues^[37]. The IL-6 amplifier exerts its ef-

fects through activation and phosphorylation of both NF- κ B and STAT3 proteins. It is also known that HSCs are involved in extracellular matrix degradation and maintenance, imbalances in which lead to liver fibrosis, as a result of unmatched levels of metalloproteinases, inhibitors of fibrillary collagen, and tissue inhibitors of metalloproteinase-1 and -2^[2]. Thus, it is important to examine the role of the IL-17A/IL-6 pathway in HSCs. Zhao *et al.*^[39] indicated that IL-17A induced IL-6 expression *via* the MAPK signaling pathway in hepatocytes, which, in turn, may further stimulate Th17 cells and forms a positive feedback loop. They concluded that Th17 cells and the IL-17A signaling pathway played an important role in targets for AIH. Yan *et al.*^[40] demonstrated that acute Con A-induced liver injury was reduced in mice treated with an adenovirus vector encoding a soluble IL-17R immunoglobulin (Ig)G fusion (AdIL-17R:Fc) that neutralized the interaction between IL-17A and IL-17RA. This supported the key role of IL-17A/IL-17RA signaling in Con A-induced hepatitis. Blockade of the IL-17A/IL-17RA signaling pathway may provide a novel therapeutic target in human autoimmune-related hepatitis. Genovese *et al.*^[41] also reported that IL-17A neutralization can achieve positive results in rheumatoid arthritis.

Consistent with previous reports in other cells, our data indicate that IL-17A induces IL-6 expression in HSCs. Suppression of IL-17RA with lentivirus-mediated IL-17RA shRNA inhibited IL-6 expression and blocked IL-17A-triggered positive-feedback loop of IL-6 signaling. Additionally, phosphorylation of p38 MAPK and ERK1/2, induced by IL-17A, was blocked in the presence of IL-17RA shRNA. Negative regulation of MAPK signaling using two specific inhibitors (SB-203580 and PD-98059) for p38 MAPK and ERK1/2, respectively, significantly attenuated IL-6 mRNA expression. These results indicated that blocking IL-17RA expression may be an alternative strategy to reduce the inflammatory response induced by IL-17A in the liver. Further, this study allows us to further understand the function of IL-17RA in HSCs. We would like to examine more potential target substrates that may be affected by the IL-17A/IL-17RA signaling pathway in the future and to further examine the underlying mechanism of HSCs in liver fibrosis.

ACKNOWLEDGMENTS

The study protocol and animal care were approved by the Animal Care and Use Committee of Wenzhou Medical College.

COMMENTS

Background

Liver fibrosis results from chronic damage to the liver in accompany with repeated chronic liver inflammation and evenly evolves into liver cirrhosis. Following chronic injury, Hepatic stellate cells (HSCs) activate, migrate and accumulate at the sites of tissue repair, acquiring contractile, proinflammatory, and fibrogenic properties. Activated HSCs secrete large amounts of extracellular matrix (ECM) and regulate ECM degradation. HSCs are also involved in modulating liver inflammation in liver fibrogenesis. But the mechanism involved in the secretion of interleukin (IL) 6 (which is a crucial cytokine in regulating different inflammatory

responses in liver diseases and is a marker to diagnose symptoms of liver cirrhosis) mediated by IL-17 stimulation in HSCs is not understood totally.

Research frontiers

IL-17A is a pro-inflammatory cytokine secreted by a new subset T help cells named Th17 cells. IL-17A signals exert miscellaneous effects through binding to the IL-17A receptor (IL-17RA) which is expressed in a variety of cells and tissues. In recently years, Clinical studies have shown that high levels of IL-17A and other cytokines related to IL-17A pathway exhibit various liver diseases including liver autoimmunity and inflammatory diseases, viral hepatitis, alcoholic liver disease and hepatocellular carcinoma. The research hotspot is how to reduce liver injury by modify liver inflammatory response, and then inhibit or postpone liver fibrosis and cirrhosis.

Innovations and breakthroughs

The present study indicated that IL-17A induces IL-6 secretion *via* p38 MAPK and ERK1/2 pathway by binding to IL-17RA in HSCs. Suppression of IL-17RA using lentiviral-mediated IL-17RA shRNA inhibits IL-6 secretion.

Applications

The study results suggest that IL-17 could stimulate IL-6 secretion *via* p38 MARK and ERK1/2 pathway in HSCs. Downregulation of IL-17RA receptor by Lentiviral vector-mediated IL-17RA shRNA decreases IL-6 expression induced by IL-17A *via* p38 MAPK and ERK1/2 Phosphorylation in HSCs. Suppression of IL-17RA expression may be an optional strategy to impair the inflammation response induced by IL-17A in the liver. This suggests that modulating IL-17RA expression might be a strategy to interfere with hepatic inflammatory processes in various liver diseases.

Terminology

HSCs are the main ECM-producing cells in the injured liver. In the normal liver, HSCs reside in the space of Disse and are the major storage sites of vitamin A. Following chronic injury, HSCs activate or transdifferentiate into myofibroblast-like cells, acquiring contractile, proinflammatory, and fibrogenic properties. Activated HSCs migrate and accumulate at the sites of tissue repair, secreting large amounts of ECM and regulating ECM degradation. If the hepatic injury persists, then eventually the liver regeneration fails, and hepatocytes are substituted with abundant ECM, including fibrillar collagen. As fibrotic liver diseases advance, disease progression from collagen bands to bridging fibrosis to frank cirrhosis occurs.

Peer review

The manuscript is addressing clearly the objective of the study. The results sustain the conclusion obtained and the experiments are performed properly. The novelty is enough to be an interesting paper.

Abstract

AIM: To describe endoscopic treatment of bile leaks in these patients and to identify risk factors in these patients which can predict the development of bile leaks.

METHODS: Retrospective case-control study examining consecutive patients who underwent partial hepatectomy for polycystic liver disease (PLD) and developed a postoperative bile leak managed endoscopically over a ten year period. Each case was matched with two controls with PLD who did not develop a postoperative bile leak.

RESULTS: Ten cases underwent partial hepatectomy with fenestration for symptoms including abdominal distention, pain and nausea. Endoscopic retrograde cholangiopancreatography (ERCP) showed anatomic abnormalities in 1 case. A biliary sphincterotomy was performed in 4 cases. A plastic biliary stent was placed

with the proximal end at the site of the leak in 9 cases; in 1 case two stents were placed. The overall success rate of ERCP to manage the leak was 90%. There were no significant differences in age, gender, comorbidities, duration of symptoms, history of previous surgery or type of surgery performed between cases and controls.

CONCLUSION: ERCP with stent placement is safe and effective for management of post-hepatectomy bile leak in patients with PLD.

INTRODUCTION

Polycystic liver disease (PLD) is a rare inherited disorder characterized by multiple cysts in the liver, often associated with autosomal dominant polycystic kidney disease (ADPKD)^[1,2]. The cysts develop as progressive dilation of biliary microhamartomas^[3,4] which communicate with the hepatic sinusoids and the portal tree. Mature cysts

do not communicate with the biliary tree but are lined by biliary epithelium^[5]. These cysts grow slowly but can become large and produce massive hepatomegaly. Most patients with PLD are asymptomatic until significant hepatomegaly develops. The commonest symptoms are abdominal pain, dyspnea from diaphragmatic compression, and lower extremity edema. Medical therapy is largely ineffective for the management of these symptoms and therefore, surgical treatment aimed at reduction in hepatic volume is the treatment of choice. These modalities include surgical fenestration or unroofing of cysts, partial hepatectomy or a combination.

Bile leaks are a common complication of surgical management of PLD and occur in 6%^[6] to 15%^[7] of patients. Management of bile leaks can be conservative, surgical, or by the use of endoscopic retrograde cholangiopancreatography (ERCP) with placement of a biliary stent with or without a biliary sphincterotomy. Although ERCP has been reported to be used successfully to manage bile leaks in patients without PLD following hepatectomy^[8-12] there are no reports on endoscopic management of biliary leaks in patients with PLD following surgery. Hence, we hope to define the use of ERCP in these patients.

In this report, we describe endoscopic treatment of bile leaks following surgical management of PLD. We also sought to determine if there were patient or procedural factors in patients with PLD which can predict the development of bile leaks.

MATERIALS AND METHODS

IRB consent was obtained from the Mayo Clinic Institutional Review Board prior to initiation of the study. We performed a retrospective case control study. All patients with PLD undergoing surgical treatment between January 1, 1998 and September 30, 2008 were identified. These patients were referred for surgery because they were symptomatic from the PLD, with the commonest symptoms being abdominal pain and early satiety. Patients were included only if they underwent fenestration and/or hepatectomy or wedge resection to address these symptoms. PLD was defined as having at least 20 simple cysts larger than 1 cm in diameter in the liver excluding any infectious, parasitic or traumatic causes. Only patients with research authorization were then further studied. Cases were defined as patients having a clinical diagnosis of bile leaks as identified by review of the medical record. Controls were defined as patients who underwent a similar surgery for PLD, matched by date of surgery within 4 months before or after the surgery of the case, without development of a post-operative bile leak. Two controls were chosen for each case. Demographic data including age and gender were abstracted. Charlson score^[13] was assessed for each patient as also the duration of disease at the time of surgery. Surgical procedural details including type of surgery performed, hepatic lobe(s) removed, and concomitant surgeries performed such as cholecystectomy were noted. The exact classification of hepatic

resection was limited because of anatomic distortion in the livers of patients with PLD^[7]. The need for ERCP was decided by the surgeon in consultation with the performing endoscopist based upon clinical symptoms and presence and/or volume of ongoing bile leakage from surgical or percutaneous drains. Endoscopic procedural details including time between surgery and ERCP, the leak site identified, performance of a sphincterotomy or placement of a biliary stent, and development of complications were identified. The outcome of ERCP was assessed from chart review and resolution of symptoms, removal of drains, follow-up non-invasive imaging studies or by follow-up ERCP.

Statistical analysis

Descriptive statistics were used to describe the case patient characteristics and ERCP outcomes. For comparative statistics for the case control portion of the study, a standard unpaired *t*-test or Mann Whitney *U* test was used to compare parametric and nonparametric continuous variables respectively, and the Fischer's exact test was used to compare dichotomous variables. A *P* value ≤ 0.05 was considered statistically significant.

RESULTS

Case series description

10 patients developed a post-operative bile leak after surgery for symptomatic PLD treatment between between January 1, 1998 and September 30, 2008 and were treated endoscopically (Table 1). Of these 10 patients, all were women, with a mean age of 48.3 ± 9.7 years. The median duration of symptoms prior to the index surgery was 12 years (range 2-30 years), and 3 had had previous fenestration or alcohol sclerosis of cysts. All patients underwent partial hepatectomy with fenestration for symptoms including abdominal distention, pain and nausea. The exact classification of hepatic resection was limited because of anatomic distortion in the livers of patients with PLD^[7]. Half had right hepatectomy and half had left hepatectomy. All the surgeries were performed by one highly experienced surgeon (David M Nagorney). All were open laparotomy and at least 1 percutaneous drain was placed. Seven patients had concomitant cholecystectomy.

Bile leak was diagnosed and ERCP performed after a mean of 17^[12] postoperative days. Bile leak was suspected when persistent bilious drainage was noted from the percutaneous drains. Computed tomography confirmation was obtained in two cases. ERCP showed the exact site of leak in 5 (50%) cases and in three more cases a leak of contrast was noted to communicate with the surgical drain but the exact site could not be determined. In two patients, no leak was seen. Leaks occurred from the common hepatic duct and the right intrahepatic ducts in one patient each and the other three arose from the left intrahepatic ducts. None of the patients had a previous sphincterotomy; biliary sphincterotomy was performed in 4 (40%) cases. A 10 French plastic biliary stent was placed

Table 1 Characteristics of 10 patients with polycystic liver disease who underwent endoscopic retrograde cholangiopancreatography management of post-hepatectomy bile leaks

Patient	Duration of diagnosis prior to surgery (yr)	Surgery performed in addition to fenestration	Cholecystectomy performed?	Time to ERCP (d)	Leak site	Sphincterotomy performed?	Outcome
1	30	Extended left hepatectomy ¹	Yes	8	Not specified ²	No	Success on repeat ERCP
2	2	Extended right hepatectomy	Yes	16	Common hepatic duct	No	Died 10 d after ERCP
3	17	Right hepatectomy	Yes	21	Left intrahepatic	No	Success clinically
4	6	Extended right hepatectomy	No	28	Left intrahepatic	No	Success clinically
5	8	Right hepatectomy	Yes	7	No leak seen	No	Success clinically
6	4	Left hepatectomy	Yes	20	Not specified	No	Success clinically
7	4	Right hepatectomy	Yes	15	Left intrahepatic	Yes	Success on repeat ERCP
8	26	Left hepatectomy	No	43	Not specified	Yes	Success clinically
9	30	Extended left hepatectomy	Yes	4	No leak seen	Yes	Success on repeat ERCP
10	20	Left hepatectomy	No	6	Right intrahepatic	Yes	Success on repeat ERCP

¹Extended included removal of segments 4A and/or 4B of the liver; ²Leak noted into percutaneous drain, but no specific site identified. ERCP: Endoscopic retrograde cholangiopancreatography.

Table 2 Risk factors for bile leak development

	Cases (n = 10)	Controls (n = 20)	Effect	P value
Age (yr) (mean ± SD)	48.3 ± 9.7	52.2 ± 9.2	-3.9	0.30
Duration of symptoms (yr) (mean ± SD)	14.7 ± 11.3	13.4 ± 7.6	1.3	0.71
Previous surgery (Y/N) n (%)	3 (30)	4 (20)	OR: 1.71, 95% CI: 0.3-9.78	0.66
Charlson score median (range)	1.5 (0-4)	1.5 (1-5)	No difference	0.60
Wedge resection n (%)	2 (20)	10 (50)	OR: 0.25, 95% CI: 0.04-1.48	0.24

Concomitant cholecystectomy n (%)	7 (70)	17 (85)	OR: 0.41, 95% CI: 0.07-2.56	0.37

OR: Odds ratio; CI: Confidence interval; Y/N: Yes/no.

with the proximal end at the site of the leak when identified or into the common bile duct in 9 (90%) cases; in 1 (10%) case two stents were placed. None of the patients developed post-ERCP complications. A repeat ERCP was performed in 5 patients after a mean (range) of 26 (8-47) d, 4 of which had resolved the leak. The one patient who in who the leak had not resolved underwent a second ERCP 8 d later for worsening jaundice and suffered fatal fulminant hepatic failure 3 d later. One more patient (20% total) died of liver failure after clinical resolution of bile leak but prior to repeat ERCP. Three cases were lost to follow up in terms of removal of the biliary stent but clinically did well with regards to the bile leak, and in one case the stent passed spontaneously without complication. Overall, 9 of the 10 patients (90%) were deemed to have successful treatment of the bile leak by ERCP management. The patient who died of hepatic decompensation with an ongoing leak was counted as a failure of therapy though

death was not directly related to the bile leak or treatment.

Risk factors for bile leak development

In order to determine if there were any patient or procedural factors predictive of developing a post-operative bile leak, the above 10 cases were matched retrospectively 1:2 to control patients with PLD who underwent similar surgical procedures within 4 mo of the matched case patient, but who did not develop a post-operative bile leak. All the controls were female and all but three underwent fenestration along with hepatectomy; one patient had only fenestration performed and two had fenestration with wedge resections. When comparing cases to controls, there was no significant difference in age (48.3 ± 9.7 years *vs* 52.2 ± 9.2 years, *P* = 0.30), duration of symptoms (14.7 ± 11.3 years *vs* 13.4 ± 7.6 years, *P* = 0.70), history of previous surgical resection [odds ratio (OR): 1.71, 95% confidence interval (CI): 0.30-9.78, *P* = 0.66], Charlson score [median 1.5 (range: 0-4) *vs* 1.5 (range: 1-5), *P* = 0.61], performance of wedge resection (OR: 0.25, 95% CI: 0.04-1.48, *P* = 0.24), number of post-operative drains [median 1 (range: 1-2) *vs* 1 (range: 1-2), *P* = 0.67] or concomitant cholecystectomy (OR: 0.42, 95% CI: 0.07-2.56, *P* = 0.37) (Table 2). All the surgeries were performed by a single highly experienced surgeon (David M Nagorney). Thus, no factors could be identified that would predict development of a bile leak in patients with PLD undergoing surgical fenestration of hepatectomy.

DISCUSSION

PLD is a disease where multiple cysts develop in the liver and grow with age. When these cysts are significantly enlarged, they cause symptoms including abdominal pain, shortness of breath, and early satiety with resultant adverse affect on quality of life. Surgical manage-

ment of symptomatic cysts includes fenestration of the cysts, wedge resection of the most affected areas of the liver (for limited cystic involvement) or hepatectomy to remove the most enlarged areas. Bile leaks are the commonest complication from hepatectomy and it can be surmised that patients with PLD who have distorted anatomy because of the presence of cysts might be at an even higher risk for this complication. In fact, the risk of biliary complications in patients with PLD undergoing surgery is as high as 15%^[7]. The incidence of biliary complications following hepatectomy in patients without PLD is 4.8% to 8.1%^[14].

Traditionally, management of post-hepatectomy bile leaks in patients with PLD has been exploratory laparotomy or conservative management. However, a laparotomy significantly increases morbidity and costs. Conservative management results in a much longer recovery process^[14] and is not always successful^[8]. Nagano *et al.*^[14] reported that patients who underwent biliary drainage with a nasobiliary tube had markedly shorter healing times compared to those who did not (30 d *vs* 179 d). However, nasobiliary tubes are more cumbersome for patients and technically more difficult to place than indwelling biliary stents. Endoscopic therapy has been used successfully to treat biliary leaks that occur after cholecystectomy^[15] and also in patients without PLD following liver surgery^[16]. However, there are no data to support its use in patients with PLD where theoretically, bile leaks may be more difficult to treat given the altered anatomy. Thus, our aim was to publish experience with ERCP in the treatment of post-hepatectomy bile leaks.

Our findings show that ERCP may be an effective therapy for post-hepatectomy bile leaks in patients with PLD. Nine of 10 patients had successful healing of bile leaks. The patient who died with a persistent leak died of hepatic failure, not as a result of complications from the leak.

Bile leaks were treated with and without endoscopic biliary sphincterotomy based upon endoscopist preference. A 10 French biliary stent was used in all cases and the proximal end was placed in the branch of the hepatic duct where the leak was seen to originate. No complications including pancreatitis, perforation or bleeding occurred after ERCP.

The case-control comparison was performed to determine if patient or procedural factors could predict the risk of post-operative bile leak. Previous studies in patients without PLD have determined that age, gender, cut surface area and other operative factors, presence of hepatitis B or C, baseline laboratory studies and the presence of cirrhosis can affect the risk of development of a bile leak^[14]. In our cohort of patients with PLD, all the cases and controls were women, of similar ages, had no other liver disease or cirrhosis. PLD causes symptoms by mechanical effect and therefore laboratory studies were mostly normal. There is a risk of hepatic decompensation following large hepatectomy because the remaining liver volume may be insufficient though synthetic function

is not affected at baseline. There was also no significant difference between cases and controls in duration of disease, whether right or left hepatectomy was performed, and whether a wedge resection was performed.

There are several limitations to the study. Because of its retrospective nature, there is inherent selection bias. Also, the numbers of patients are small. This is not unusual given that the prevalence of symptomatic PLD is low. The case-control comparison may not be sufficiently powered to detect a difference in risk factors but over 10 years, only 10 patients were identified with clinically important bile leaks. Also, operative details were not prospectively collected and hence not available for review in all cases. Certain operative details such as difficulty of resection, amount of blood loss, and intra-operative damage and repair of bile ducts could have impacted the risk of developing a bile leak.

In summary, we conclude that ERCP with placement of an internal biliary stent is a safe and effective treatment for post-hepatectomy bile leaks in patients with PLD. ERCP should be considered as a therapeutic option when bile leak is suspected clinically due to persistent biliary drainage from percutaneous tubes in these patients. No patient factors can be identified as risk factors to predict development of bile leaks in these patients. Further prospective studies could be performed to assess risk factors.

COMMENTS

Background

Polycystic liver disease (PLD) is a rare inherited disorder characterized by multiple cysts in the liver, and surgical treatment aimed at reduction in hepatic volume is the treatment of choice. Bile leaks are a common complication of surgical management of PLD. Here, the authors describe the use of endoscopic retrograde cholangiopancreatography (ERCP) to manage bile leaks in these patients.

Research frontiers

In the area of management of bile leaks in polycystic liver disease, the research hot spot is in determining the safest and most effective modality of treatment, whether medical, surgical or endoscopic.

Innovations and breakthroughs

Previously, endoscopic therapy had been used successfully to treat biliary leaks that occur after cholecystectomy, and also in patients without PLD following liver surgery. The innovation described in this report is in the successful use of endoscopic therapy in a novel patient population.

Applications

The study demonstrates that ERCP may be an effective therapy for post-hepatectomy bile leaks in patients with PLD.

Terminology

PLD is a disease where multiple cysts develop in the liver and grow with age. When these cysts are significantly enlarged, they cause symptoms including abdominal pain, shortness of breath, and early satiety with resultant adverse effect on quality of life.

Peer review

Although the endoscopic treatment in patients with biliary leaks after hepatectomy is a well recognized procedure, the authors report their experience, as case series, concerning a subset of patient with hepatic cysts.

Abstract

AIM: To clarify the association between physical activity and gastroesophageal reflux disease (GERD) in non-obese and obese people.

METHODS: A Swedish population-based cross-sectional survey was conducted. Participants aged 40-79 years were randomly selected from the Swedish Registry of the Total Population. Data on physical activity, GERD, body mass index (BMI) and the covariates age, gender, comorbidity, education, sleeping problems, and tobacco smoking were obtained using validated questionnaires. GERD was self-reported and defined as heartburn or

regurgitation at least once weekly, and having at least moderate problems from such symptoms. Frequency of physical activity was categorized into three groups: (1) "high" (several times/week); (2) "intermediate" (approximately once weekly); and (3) "low" (1-3 times/month or less). Analyses were stratified for participants with "normal weight" (BMI < 25 kg/m²), "overweight" (BMI 25 to ≤ 30 kg/m²) and "obese" (BMI > 30 kg/m²). Multivariate logistic regression was used to calculate odds ratios (ORs) with 95% confidence intervals (CIs), adjusted for potential confounding by covariates.

RESULTS: Of 6969 eligible and randomly selected individuals, 4910 (70.5%) participated. High frequency of physical activity was reported by 2463 (50%) participants, GERD was identified in 472 (10%) participants, and obesity was found in 680 (14%). There were 226 (5%) individuals with missing information about BMI. Normal weight, overweight and obese participants were similar regarding distribution of gender and tobacco smoking status, while obese participants were on average slightly older, had fewer years of education, more comorbidity, slightly more sleeping problems, lower frequency of physical activity, and higher occurrence of GERD. Among the 2146 normal-weight participants, crude point estimates indicated a decreased risk of GERD among individuals with high frequency of physical activity (OR: 0.59, 95% CI: 0.39-0.89), compared to low frequency of physical activity. However, after adjustment for potential confounding factors, neither intermediate (OR: 1.30, 95% CI: 0.75-2.26) nor high (OR: 0.99, 95% CI: 0.62-1.60) frequency of physical activity was followed by decreased risk of GERD. Sleeping problems and high comorbidity were identified as potential confounders. Among the 1859 overweight participants, crude point estimates indicated no increased or decreased risk of GERD among individuals with intermediate or high frequency of physical activity, compared to low frequency. After adjustment for confounding, neither intermediate (OR: 0.75, 95% CI: 0.46-1.22) nor high frequency of physical activity were

followed by increased or decreased risk of GERD compared to low frequency among nonobese participants. Sleeping problems and high comorbidity were identified as potential confounders for overweight participants. In obese individuals, crude ORs were similar to the adjusted ORs and no particular confounding factors were identified. Intermediate frequency of physical activity was associated with a decreased occurrence of GERD compared to low frequency of physical activity (adjusted OR: 0.41, 95% CI: 0.22-0.77).

CONCLUSION: Intermediate frequency of physical activity might decrease the risk of GERD among obese individuals, while no influence of physical activity on GERD was found in non-obese people.

INTRODUCTION

Gastroesophageal reflux disease (GERD) is a public health concern defined by troublesome and frequent symptoms of heartburn or regurgitation^[1,2], affecting up to 20% of the adult population in the western world^[3]. GERD is associated with a negative impact on health-related quality of life (HRQL), increased risk of esophageal adenocarcinoma, and great costs for patients and society^[3-8]. Established risk factors for GERD are overweight, tobacco smoking, low socioeconomic status, and heredity^[9-15], while the potential role of physical activity is complex and intriguing. Intense physical activity is known to trigger reflux symptoms^[16], but physical activity has many positive effects on health in general, and some data indicate that high physical activity might also prevent GERD in a long-term perspective^[17,18]. Two population-based studies have assessed associations between physical activity and reflux; our twin study from Sweden indicated that high physical activity at work was related to an increased risk of GERD, while recreational physical activity decreased this risk^[17], and our nested case-control study from Norway has sug-

gested a protective effect of physical activity on the risk of GERD^[18]. Few studies have addressed this issue and the available results are partly conflicting, thus, more research is required before any preventive effect of physical activity on GERD can be established. Obesity is strongly linked with both physical activity and GERD, therefore, for this study, we aimed to test the hypothesis that the association between frequency of physical activity and GERD differs between non-obese and obese people^[11]. The occurrence of GERD and frequency of physical activity might change with time, therefore, we conducted a cross-sectional study assessing both variables at the same time, enabling us to investigate whether a higher frequency of physical activity is associated with an increased risk of GERD in an unselected general population.

MATERIALS AND METHODS

Design

A population-based, cross-sectional study was performed between April and June 2008 in Sweden. Participants aged 40-79 years were randomly selected from the Swedish Registry of the Total Population; a registry that contains information of all Swedish residents regarding vital status, gender, age, place of residence, with a maximum of 2 wk delay. Eligible individuals received a postal questionnaire assessing physical activity, body weight, height, and GERD, together with socio-demographic variables, concurrent disease, and lifestyle factors. By completing and returning the questionnaires, participants consented to their data being used for research purposes. Up to two reminder letters were sent to non-responders. Participants were not offered any inducement for participation.

Study variables

Physical activity: The questionnaire assessed physical activity by asking "How often do you perform a physically demanding activity lasting at least 30 min? For example running, cycling, swimming". Frequency of physical activity was categorized into three groups: (1) "high" (several times per week); (2) "intermediate" (approximately once per week); and (3) "low" (1-3 times per month, or less often).

GERD: Information regarding GERD was collected on a 5-point Likert scale for frequency and symptom severity. In line with the implementation of the Montreal definition of GERD^[19], individuals were categorized as having GERD or not (yes or no). Participants were categorized as having GERD if they reported heartburn or regurgitation occurring at least once a week, and having at least moderate problems from such symptoms. Participants reporting use of medications for heartburn or regurgitation at least once weekly were also included in the group fulfilling the criteria for GERD, irrespective of symptom severity.

Covariates: The socio-demographic information included

¹Two hundred and twenty-six persons had missing information about body mass index. Percentages not adding up to 100 are explained by missing data in some variables; ²Low: 1-3 times per month or less often; Intermediate: approximately once per week; and High: several times per week; ³Definition of GERD^[19]: heartburn or regurgitation occurring at least once a week and at least having intermediate problems from heartburn or regurgitation. Persons reporting use of medications for heartburn or regurgitation at least once weekly were also included in the group fulfilling the criteria for GERD, irrespective of their severity of the problem. GERD: Gastroesophageal reflux disease.

gender, age, years of formal education, and marital status. The questionnaire further assessed diseases confirmed by a physician (yes or no), including angina, heart failure, atrial fibrillation, myocardial infarction, hypertension, stroke, chronic obstructive pulmonary disease, asthma, diabetes, rheumatoid arthritis, osteoarthritis, kidney failure requiring dialysis, chronic pain, depression under treatment, and cancer. Data on sleeping problems during the past week were assessed with the validated EORTC QLQ-C30^[20] questionnaire. Tobacco smoking was assessed by asking if the person had been smoking during the past 3 mo (yes or no). For calculation of body mass index (BMI), the questionnaire assessed adult height and current weight, and participants were categorized as normal weight (BMI < 25 kg/m²), overweight (BMI 25 to ≤ 30 kg/m²) or obese (BMI > 30 kg/m²).

Statistical analysis

Sample characteristics were described by standard de-

scriptive statistics. In order to examine the associations between frequency of physical activity and presence of GERD, odds ratios (ORs) with 95% confidence intervals (CIs) were calculated using logistic regression with multivariate adjustment for potential confounders. Analyses were stratified for participants with normal weight (BMI < 25 kg/m²), overweight (BMI 25 to ≤ 30 kg/m²), or obese (BMI > 30 kg/m²). Potential confounders were: (1) gender (male or female); (2) age (as a continuous variable); (3) education level (< 9 years, 10-12 years, or > 12 years); (4) number of concurrent diseases (0, 1, 2 or > 2); (5) sleeping problems (“none”, “a little”, “quite a bit” or “very much”); and (6) current tobacco smoking (yes or no). A weighting factor was applied to ensure that the characteristics of the study sample conformed to independently estimated national distributions by age, gender and region. The statistical package STATA 12 for Windows (STATA Corp, College Station, Texas, United States) and SAS (SAS Institute, Cary, NC, United States) were used for the analyses.

RESULTS

Study participants

Of 6969 eligible individuals, 4910 (70.5%) participated. Some characteristics of the participants are presented in Table 1. High physical activity was reported by 2463 (50%) of all participants, GERD was identified in 472 (10%) participants, and obesity was found in 680 (14%) of the participants. Missing information about BMI was found in 226 individuals. Normal weight, overweight and obese participants were similar regarding distribution of gender and tobacco smoking status, while obese participants were on average slightly older, had fewer years of education, a greater number of comorbidities, slightly more sleeping problems, lower frequency of physical activity, and higher occurrence of GERD.

Frequency of physical activity and GERD in normal weight participants

Among normal weight participants (BMI < 25 kg/m²), crude point estimates indicated a decreased risk of GERD among individuals with high frequency of physical activity (OR: 0.59, 95% CI: 0.39-0.89), compared to low frequency of physical activity. After adjustment for confounding variables, neither intermediate (OR: 1.30, 95% CI: 0.75-2.26) nor high (OR: 0.99, 95% CI: 0.62-1.60) frequency of physical activity was followed by a decreased risk of GERD compared to low frequency of physical activity among normal weight participants (Table 2). Sleeping problems and a high number of comorbidities were identified as potential confounders, since they had a major impact in the multivariable model.

Frequency of physical activity and GERD in overweight participants

Among overweight participants (BMI 25 to ≤ 30 kg/m²), crude point estimates indicated no increased or decreased

Table 2 Association between frequency of physical exercise and occurrence of gastroesophageal reflux disease

¹Definition of GERD^[9]: Self-reported heartburn or regurgitation occurring at least once a week and at least having moderate problems from heartburn or regurgitation. Persons reporting use of medications for heartburn or regurgitation at least once weekly were also included in the group fulfilling the criteria for GERD, irrespective of their severity of the problem; ²Adjusted for gender, age, education level, number of diseases, sleeping problems and tobacco smoking; ³Low = 1-3 times per month or less often, Intermediate = approximately once per week, and High = several times per week. Association between frequency of physical exercise and occurrence of gastroesophageal reflux disease in normal weight people in a random sample of 4910 people from the Swedish general population (226 participants had missing information on BMI). Presented as OR: with 95% CI. GERD: Gastroesophageal reflux disease; BMI: Body mass index; CI: Confidence interval; OR: Odds ratio.

risk of GERD among individuals with intermediate or high frequency of physical activity, compared to low frequency of physical activity. After adjustment for confounding variables, neither intermediate (OR: 0.75, 95% CI: 0.46-1.22) nor high frequency of physical activity were followed by an increased or decreased risk of GERD compared to low frequency of physical activity among overweight participants (Table 2). Identified potential confounders were sleeping problems and a high number of comorbidities, because they had a major impact in the multivariate model.

Frequency of physical activity and GERD in obese participants

In obese individuals (BMI > 30 kg/m²), crude ORs were similar to the adjusted ORs and no particular confounding factors were identified. Intermediate frequency of physical activity was associated with a decreased occurrence of GERD compared to low frequency of physical activity (adjusted OR: 0.41, 95% CI: 0.22-0.77). A non-significantly decreased risk of GERD was found among obese individuals with high frequency of physical activity compared to low frequency of physical activity (adjusted OR: 0.83, 95% CI: 0.50-1.35).

DISCUSSION

This study indicated that intermediate frequency of physical activity was associated with a lower occurrence of GERD among obese individuals, while no such association was found among normal weight or overweight individuals.

The strengths of the present study include the population-based design with random selection of participants, the high participation rate, and the large sample size. Moreover, symptoms of GERD were measured with a well-validated questionnaire^[21], fulfilling the consensus criteria for GERD^[1]. Furthermore, it was possible to adjust the results for several potential confounding factors. Limitations include an inherent uncertainty about the accuracy of self-reported data and lack of validation of the

assessment of frequency of physical activity, BMI, as well as information about previous surgical interventions for GERD. Also, because this was a cross-sectional study, it is not possible to know if participants with a self-detected association between reflux and physical exercise may have changed their behavior, resulting in reverse causality.

The decreased risk of GERD in people participating in physical activity is in line with previous population-based studies assessing an association between physical activity and GERD within the general population^[17,18]. However, none of the previous studies conducted stratified analyses for BMI categories; meaning that the decreased risk of GERD limited to obese individuals is a first-time observation.

A potential biological mechanism underlying increased risk of reflux among obese persons is through increased extrinsic gastric compression by surrounding adipose tissue and anatomical disruption of the gastroesophageal junction^[8,22]. This is also thought to be the mechanism when physical activity triggers reflux symptoms^[16]. It has also been argued that physical exercise might cause GERD by decreasing the gastrointestinal blood flow and changing the esophagogastric motor function. On the other hand, physical activity might strengthen striated muscles in the diaphragmatic crurae and thereby reinforce the antireflux barrier^[16,23-25]. Furthermore, both intensity and type of physical exercise might pose different risks for GERD^[16,23,26]. Should the present results be confirmed in future research, the findings from this study might be important for the prevention and treatment of GERD and its complications.

In conclusion, this large population-based study indicates decreased occurrence of GERD in obese people who report intermediate frequency of physical activity, while no influence of frequency of physical activity on GERD was identified in non-obese people.

COMMENTS

Background

Gastroesophageal reflux disease (GERD) is a public health concern defined by

troublesome and frequent symptoms of heartburn or regurgitation, affecting up to 20% of the adult population in the western world. Established risk factors for GERD are overweight, tobacco smoking, low socioeconomic status, and heredity, while the potential role of physical activity is complex and intriguing.

Research frontiers

GERD is very common and bothersome for people experiencing this disease. All types of risk factors and possible treatments and interventions to reduce symptoms are of relevance.

Innovations and breakthroughs

Two population-based studies have assessed associations between physical activity and reflux; the twin study from Sweden indicated that high physical activity at work was related to an increased risk of GERD, while recreational physical activity decreased this risk, and the nested case-control study based on data from Norway suggested a protective effect of physical activity on the risk of GERD.

Applications

To summarize the actual application values, the implications for further application and modification, or the perspectives of future application of the outcome of the study. Further studies are necessary to determine the direction of causation between physical exercise and GERD in obese patients.

Terminology

GERD is defined by troublesome and frequent symptoms of heartburn or regurgitation. Body mass index (BMI), is calculated by dividing height in meters by the square root of weight in kilograms.

Peer review

The study was well-designed and the results add to current knowledge about GERD and its relieving and aggravating factors.

Abstract

AIM: To study if and how physicians use the irritable bowel syndrome (IBS) diagnostic criteria and to assess treatment strategies in IBS patients.

METHODS: A questionnaire was sent to 191 physicians regarding IBS criteria, diagnostic methods and treatment. Furthermore, 94 patients who were diagnosed with IBS underwent telephone interview.

RESULTS: A total of 80/191 (41.9%) physicians responded to the survey. Overall, 13 patients were diag-

nosed monthly with IBS by specialists in gastroenterology (SGs) and 2.5 patients by general practitioners (GPs). All the SGs knew of the criteria to diagnose IBS, as did 46/70 (65.7%) GPs. Seventy-nine percent used the patient's history, 38% used a physical examination, and 38% exclusion of other diseases to diagnose IBS. Only 18/80 (22.5%) physicians used specific IBS criteria. Of the patients interviewed, 59/94 (62.8%) knew they had experienced IBS. Two out of five patients knew IBS and had seen a physician because of IBS symptoms. Half of those received a diagnosis of IBS. A total of 13% were satisfied with treatment. IBS affected daily activities in 43% of cases.

CONCLUSION: Half of the patients with IBS who consulted a physician received a diagnosis. Awareness and knowledge of diagnostic criteria for IBS differ between SGs and GPs.

INTRODUCTION

Irritable bowel syndrome (IBS) is a common functional gastrointestinal disorder. The prevalence of IBS is estimated to range from 3% to 28% depending on the country studied^[1-4]. The prevalence of IBS in the western countries is estimated to be 10%-15%^[2]. However, ascertaining prevalence is based on various approaches in studies using different diagnostic criteria.

The criteria that have been used to identify IBS patients are the Manning criteria^[5], Rome I^[6], Rome II^[7] and the most recent Rome III criteria^[8,9]. The Rome criteria are more refined than the Manning criteria and include the duration of symptoms as part of the definition of IBS^[10]. Studies have also shown that the Manning criteria are relatively sensitive but lack specificity^[11] (Table 1).

It has been questioned whether the Rome criteria are sensitive enough to diagnose patients in general practice. The current lack of interest in these criteria, especially among general practitioners (GPs), is unlikely to change unless they can be considerably improved^[12]. The challenges and uncertainties for diagnosis of IBS have been listed as follows^[13,14]: (1) there is currently no consistent biological marker of IBS, leaving clinicians to rely on patient symptoms alone to make the diagnosis; (2) symptoms of IBS are often difficult to quantify objectively; (3) symptoms can vary among individuals with IBS; and (4) many organic conditions can masquerade as IBS.

With these uncertainties, many physicians approach IBS as a diagnosis of exclusion^[14]. A recent study concluded that: (1) the best practise diagnostic guidelines have not been uniformly adopted in IBS, particularly among primary care providers; (2) most community providers believe IBS is a diagnosis of exclusion (this belief is associated with increased diagnostic resource use); and (3) despite the dissemination of guidelines regarding diagnostic testing in IBS, there remains extreme variation in beliefs among both experts and non-experts^[14].

Patients diagnosed with IBS exhibit a higher use of outpatient visits, inpatient stays, outpatient prescriptions, and number of hospitalizations than those not diagnosed with IBS^[15-17]. A recent study showed that knowledge and use of the Rome criteria or their positive predictive values for IBS did not correlate with reduced use of diagnostic tests^[18]. The cost for outpatient visits, drugs and diagnostic testing has been shown to be 51% higher for IBS patients than for others^[15-17]. IBS patients have been shown to lose time from work more often than others and are less productive while at work^[19]. This may reflect the morbidity in this relatively benign disorder, although up to 70% of IBS patients in the United States do not consult a health care provider regarding their symptoms^[20]. IBS patients are often reluctant to consult a physician, often because they think their symptoms do not warrant a visit to a physician or are afraid that they have a serious life-threatening illness^[2,19]. United States family practitioners have problems with IBS patients, which include difficulties in satisfying patients and difficulties in

making a strategy decision and finding the time required, and their lack of knowledge could interfere with patient care^[21]. No specific treatment options for IBS are available. In clinical practice, the decision to treat is up to the discretion of the physician^[19]. While some physicians recommend lifestyle modification or trials with over-the-counter products, others recommend antispasmodics and antidepressants.

In our study, we aimed to analyze IBS from the physicians' and patients' point of view. The specific aims of this study were: First, physician study, to assess if and how physicians [GPs and specialists in gastroenterology (SGs)]: (1) use the diagnostic criteria to identify IBS; (2) diagnose patients with IBS, and which symptoms of IBS they identify; and (3) which treatment they recommend; and Second, patient study, to assess how patients with IBS are diagnosed and treated by physicians, as well as studying the ideas that patients have about IBS. The results of a parallel study based on the same database but focusing on functional dyspepsia, stability of IBS and heartburn have been published^[22-24].

MATERIALS AND METHODS

Patient study

Participants and setting: In 1996, an epidemiological study of gastrointestinal diseases was performed in Iceland^[25] among 2000 inhabitants aged 18-75 years. The individuals were randomly selected from the National Registry. Equal distribution of sex and age was secured in each age group. In 2006, we attempted to contact all the individuals from 1996, as well as adding 300 new individuals in the 18-27 years age group, who were also randomly selected from the National Registry of Iceland. A questionnaire was mailed to individuals at baseline and the study questionnaire and an explanatory letter mailed to all eligible individuals. Reminder letters were mailed at 2 wk, 4 wk and 7 wk, using the Total Method of Dillman^[26]. Individuals who indicated at any point that they did not want to participate in the study were not contacted further.

Questionnaire: The Bowel Disease Questionnaire (BDQ)^[27,28] was translated from English into Icelandic and modified for this study. The questionnaire was translated by two gastroenterologists and a pharmacist. A specialist in the Icelandic language at the University of Iceland made linguistic modifications. The questionnaire was piloted within a small group of IBS patients diagnosed by a gastroenterologist. The questionnaire was designed as a self-report instrument to measure symptoms experienced over the previous year and to collect the participants' past medical history^[29].

The Icelandic version of the BDQ questionnaire addressed 47 gastrointestinal symptoms and 32 items that measured past illness, health care use, and sociodemographic and psychosomatic symptoms, together with a valid measure of non-gastrointestinal somatic complaints, the Somatic Symptom Checklist (SSC)^[30]. The SSC consisted of 12 non-gastrointestinal and five gastrointestinal

Table 1 Manning, Rome I, II and III criteria for irritable bowel syndrome^[5-7,9]

Manning
Pain eased after BM
Looser stools at onset of pain
More frequent BM at onset of pain
Abdominal distension
Mucus throughout rectum
Feeling of incomplete emptying
Rome I criteria
3 mo or more of continuous or recurrent symptoms
Abdominal pain or discomfort
Relieved with defecation; and/or
Associated with a change in frequency of stool; and/or
Associated with a change in consistency of stool; and
Two or more of the following, at least 25% of occasions or days
Altered stool frequency (> 3 BMs/d or < 3/wk)
Altered stool form (lumpy/hard or loose/watery stool),
Altered stool passage (straining, urgency, tenesmus)
Passage of mucus
Bloating or feeling of abdominal distension
Rome II criteria
At least 12 wk (which need not be consecutive)
In the preceding 12 mo, of abdominal discomfort or pain that has two out of three features
Relieved with defecation; and/or
Onset associated with a change in frequency of stool, and/or
Onset associated with a change in form (appearance) of stool
Rome III criteria
Recurrent abdominal pain or discomfort at least 3 d/mo
In the last 3 mo association with two or more of the following:
Improvement with defecation
Onset associated with a change in frequency of stool
Onset associated with a change in form (appearance) of stool

BM: Bowel movement.

symptoms or illnesses. Individuals were instructed to indicate, on a 5-point scale, how often each symptom appeared and how bothersome it was. There were only a few changes in the 2006 questionnaire, which addressed 51 gastrointestinal symptoms and 33 items that measured past illness, health care use, and sociodemographic and psychosomatic symptoms. The 2006 questionnaire furthermore addressed 17 items to identify heartburn and symptoms related to heartburn.

Telephone survey: In the questionnaire, patients were asked to write down their telephone number and give their permission to participate in a telephone survey. Subjects who were diagnosed with IBS based on the Manning criteria and/or the Rome III criteria and had written down their telephone number were called and interviewed.

Physician study

In Iceland (population approximately 300 000), there are 177 physicians working in general practice and 17 SGs (three physicians who were involved in carrying out this study were excluded). A questionnaire was sent to these 191 physicians regarding awareness and application of the three sets of criteria used to diagnose IBS (Table 1), as well as diagnostic methods and treatment of this dis-

Table 2 Awareness of the disorder, diagnosis and treatment in interviewer-diagnosed patients *n* (%)

	All patients (<i>n</i> = 94)
Diagnosed with IBS	20 (22.2)
Knowledge of IBS	37 (39.4)
Seen a physician because of IBS symptoms	37 (39.4)
Satisfied with treatment for IBS	12 (12.8)
IBS affects daily activities	40 (42.6)
Think they will be cured of IBS	29 (30.9)
Think they will always suffer from IBS	27 (28.7)

order. We assessed the knowledge of validated symptom-based criteria for IBS.

Statistical analysis

Tables were constructed for frequency and percentage. Categorical data were analyzed using the χ^2 test. The type I error protection rate was set at 0.05. The exact *P* values are listed in the tables and text. All the research data were imported into SPSS software.

Ethics

The National Bioethics Committee of Iceland and The Icelandic Data Protection Authority (Personuvernd) gave their permission for the research.

RESULTS

Patient study

A total of 94 patients underwent telephone interview (29.8% male, 70.2% female) with a mean age of 47 years. All these had IBS according to the Manning criteria and 56.0% according to the Rome III criteria (the Rome III criteria being more refined and stricter than the Manning criteria). When patients were asked if they had experienced IBS (self-assessed), 62.8% reported yes and 21.3% said they had received an IBS diagnosis from a physician; 60% of these had a Rome-III-based diagnosis, and 100% had a Manning-based diagnosis.

Table 2 shows the awareness of IBS. Two out of five patients had heard of IBS and the same number had seen a physician because of IBS symptoms, but only half of those had received a diagnosis of IBS. Only 12/94 (12.8%) IBS patients were satisfied with the treatment they had been given. IBS did affect daily activities in approximately 43% of the cases (Table 2). One third of the IBS patients thought they would be cured of IBS but a similar proportion thought they would always suffer from IBS (Table 2). IBS patients were found to use more non-traditional medication than prescribed drugs. More than half of patients believed that dietary modification was important for treatment of IBS (Table 2).

Three out of five IBS patients were diagnosed by a

gastroenterologist and two out of five by a GP. Most IBS patients reported abdominal pain (73.7%), bloating (21.1%), constipation (5.3%) and diarrhea (10.5%) as the symptom that led to the diagnosis. More than half (57.9%) of the IBS patients who received management for their IBS symptoms were satisfied.

Physician study

An anonymous questionnaire was sent to a total of 191 physicians in Iceland in the fields of primary care, or to SGs (excluding three physicians involved in carrying out this study). A total of 80 physicians (41.9%) replied (83% male, 17% female) and completed the questionnaire. Of those who answered, 70/175 were GPs and 9/15 were SGs.

On average, 13 patients were estimated to be diagnosed with IBS monthly by SGs and 2.5 by GPs. Physicians reported how they diagnosed patients with IBS (Table 3). Two thirds of all the physicians knew that special diagnostic criteria exist for defining and diagnosing IBS (Figure 1).

When physicians were asked if they knew of the IBS diagnostic criteria, 71% said yes (64% of GPs, 100% of SGs). Despite the fact that 64% of GPs claimed they knew that diagnostic criteria existed, only 10% had heard of the Manning criteria, 27% of Rome I, and 17% of Rome II (Figure 1).

Physicians stated that abnormal bowel movements such as diarrhea and constipation, abdominal pain and bloating were the most commonly reported symptoms of IBS (Table 4).

Physicians reported in most cases that they would give advice on diet and education about IBS as a treatment for IBS symptoms. Both GPs and SGs gave their patients mebeverine in most cases. Psyllium was frequently used by SGs and chlordiazepoxide, and clidinium was in some cases used by both GPs and SGs (Table 5).

DISCUSSION

Most physicians have used the method of exclusion when diagnosing patients with IBS. Most community providers also believe IBS is a diagnosis of exclusion rather than using positive criteria to support the diagnosis^[14]. This approach-or lack of one-has therefore been time consuming and costly for the health care system. The importance of a precise diagnostic tool to diagnose IBS

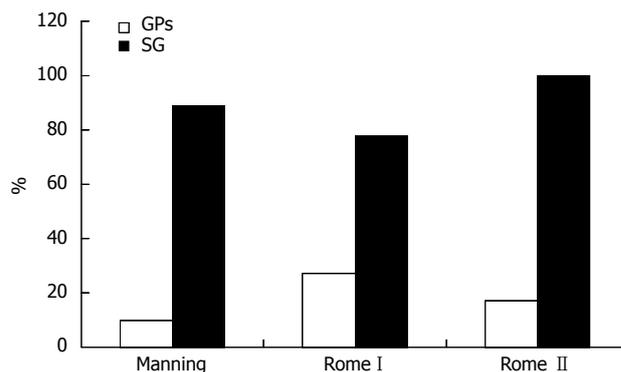

Figure 1 Number of physicians knowing about each set of diagnostic criteria. SG: Specialists in gastroenterology; GP: General practitioners.

is therefore very important. In recent years, the development of diagnostic criteria for IBS has been ongoing, leading to the recent introduction of the Rome III criteria. There is no doubt that diagnostic criteria constitute a useful and important tool to help physicians make a positive diagnosis of IBS without resorting simply to excluding other diseases. This study has revealed the proportion of Icelandic physicians in two fields of medicine who are aware of the criteria for diagnosing the disease. The study has addressed not only the question of how informed physicians are of the criteria for diagnosing IBS, but also the importance of consensus about the diagnosis of the disease. This study has also addressed the IBS patients' perspective, how many sought physicians, and how they

experienced the disease.

According to the results of this study, most IBS patients were seen by GPs, and this is most likely also the case in other countries, underlining the importance of awareness and knowledge of IBS on the part of the GPs. Although 64% of all GPs reported that they were aware of the fact that special criteria to identify IBS existed, most of them (81%) did not know the criteria and therefore did not rely on them in practice. Most of them seem to make a positive diagnosis of IBS without the use of endoscopy. A United States study showed that only 30% of family practitioners knew that the Manning, Rome and Rome II criteria are used to diagnose IBS, which is in line with the results of the current study^[21]. GPs are more likely than hospital specialists to perceive functional gastrointestinal disorders as having a psychological basis, are far less likely to be familiar with diagnostic criteria, and are more likely to use other methods to make such diagnoses^[31]. However, physicians are aware of and use the most common IBS symptoms such as abnormal bowel movements, abdominal pain and bloating in their diagnostic approach, and these were the most common symptoms IBS subjects in the present study.

In the current study, physicians reported in most cases that they gave advice on diet and education on IBS as a treatment of IBS symptoms; this finding underlines the importance of providing reliable and useful information on IBS to patients, as well as the fact that there are no specific treatment options for IBS that are useful for all patients.

It is of interest that among interviewer-diagnosed IBS patients, only one out of five was diagnosed with IBS, even though more than half of the IBS patients saw a physician because of their symptoms. These results were irrespective of whether the patients fulfilled the Manning or Rome III criteria for IBS. This was also interesting because the majority of IBS patients reported that IBS affected daily activities. This emphasises the question of whether IBS patients reveal to the physicians the low quality of life caused by IBS. It is also conceivable that physicians do not recognize IBS as a disorder that leads to impaired quality of life. The absence of positive diagnosis of IBS might lead to lack of relevant treatment for specific symptoms of IBS such as abdominal pain. There is a need for a simple, practical and reliable diagnostic tool to be used in everyday clinical practice to diagnose IBS more accurately; a tool that will encourage physicians to be able to make a reliable diagnosis and to provide effective treatment^[32,33].

The limitation of this study was the relatively low response rate in the physician study, which raises the question as to whether the level of awareness and knowledge of diagnostic criteria might be even lower than the result obtained. The strengths of the study, however, were that all physicians in Iceland in the relevant fields of general practice and gastroenterology were invited to participate, and the fact that all IBS patients who were contacted by telephone participated in the survey.

In conclusion, in this study, only half of the IBS patients who saw a physician received a diagnosis of IBS. Knowledge of IBS is limited among IBS patients. This study suggests that few physicians use IBS criteria and that awareness and knowledge of diagnostic criteria for IBS differed between SGs and GPs. One out of four physicians used a diagnosis of exclusion.

More widespread knowledge and use of the diagnostic criteria among physicians can be expected to support a more accurate diagnosis of IBS.

COMMENTS

Background

Irritable bowel syndrome (IBS) is a common functional gastrointestinal disorder. The prevalence of IBS in western countries is estimated to be 10%-15%. The criteria that have been used to identify IBS patients are the Manning criteria and Rome I, II and III criteria. It has been questioned whether the Rome criteria are sensitive enough to diagnose patients in general practice. Many physicians approach IBS as a diagnosis of exclusion. Patients diagnosed with IBS have a higher number of outpatient visits, inpatient stays, outpatient prescriptions, and hospitalizations than those not diagnosed with IBS. IBS patients are often reluctant to consult a physician, often because they think their symptoms do not warrant a visit to a physician, or they are afraid that they have a serious life-threatening illness. United States family practitioners have problems with IBS patients, which include difficulties in satisfying patients and treatment decision making, and finding the time required, and their lack of knowledge could interfere with patient care.

Research frontiers

The prevalence of IBS in the general population is high and physicians often lack the tools to diagnose and treat IBS. It is important for IBS patients as well as the physicians to understand each other and the IBS symptoms, and to improve knowledge of IBS. The aim of the present study was to analyze IBS from the physicians' and IBS patients' points of view. The specific aims of this study were: First, physician study, to assess if and how physicians [general practitioners (GPs), specialists in gastroenterology (SGs)]: (1) use the diagnostic criteria to identify IBS; (2) diagnose patients with IBS, and which symptoms of IBS they identify; and (3) which treatment they recommend; and Second, patient study, to assess how patients with IBS based on criteria are diagnosed and treated by physicians and which treatment they receive, as well as studying the ideas that patients have about IBS.

Innovations and breakthroughs

The prevalence of IBS is high in Iceland. The awareness of IBS is low among patients with IBS and two out of five of those saw physicians because of IBS symptoms. Only half of the IBS patients who saw a physician received a diagnosis of IBS. Knowledge of IBS is limited among patients. This study suggests that few physicians use IBS criteria and that awareness and knowledge of the diagnostic criteria for IBS differed between SGs and GPs. One out of four physicians used a diagnosis of exclusion.

Applications

IBS patient and physician points of view are important for understanding IBS. It is important for the physicians to understand IBS patients and to know that many who seek medical care will not receive a diagnosis. This study creates a database for further studies and hopefully stimulates studies in other countries. International awareness and knowledge of IBS diagnosis and treatment can contribute towards better understanding of IBS.

Peer review

The prevalence of IBS in Western countries is estimated to be 10%-15% and is associated with extensive health care expenses and diminished quality of life. Studies that examine IBS from the patients and physicians point of view are important and there is a need to document secular trends and compare various countries.

Abstract

AIM: To determine the effective hospitalization period as the clinical pathway to prepare patients for endoscopic submucosal dissection (ESD).

METHODS: This is a retrospective observational study which included 189 patients consecutively treated by ESD at the National Cancer Center Hospital from May 2007 to March 2009. Patients were divided into 2 groups; patients in group A were discharged in 5 d and patients in group B included those who stayed longer than 5 d. The following data were collected for both groups: mean hospitalization period, tumor site, median tumor size, post-ESD rectal bleeding requiring urgent endoscopy, perforation during or after ESD, abdominal pain, fever above 38 °C, and blood test results positive

for inflammatory markers before and after ESD. Each parameter was compared after data collection.

RESULTS: A total of 83% (156/189) of all patients could be discharged from the hospital on day 3 post-ESD. Complications were observed in 12.1% (23/189) of patients. Perforation occurred in 3.7% (7/189) of patients. All the perforations occurred during the ESD procedure and they were managed with endoscopic clipping. The incidence of post-operative bleeding was 2.6% (5/189); all the cases involved rectal bleeding. We divided the subjects into 2 groups: tumor diameter ≥ 4 cm and < 4 cm; there was no significant difference between the 2 groups ($P = 0.93$, χ^2 test with Yates correction). The incidence of abdominal pain was 3.7% (7/189). All the cases occurred on the day of the procedure or the next day. The median white blood cell count was 6800 ± 2280 (cells/ μ L; \pm SD) for group A, and 7700 ± 2775 (cells/ μ L; \pm SD) for group B, showing a statistically significant difference ($P = 0.023$, t -test). The mean C-reactive protein values the day after ESD were 0.4 ± 1.3 mg/dL and 0.5 ± 1.3 mg/dL for groups A and B, respectively, with no significant difference between the 2 groups ($P = 0.54$, t -test).

CONCLUSION: One-day admission is sufficient in the absence of complications during ESD or early post-operative bleeding.

INTRODUCTION

Conventional laparotomy is the standard treatment for early colon cancer. Subsequently, endoscopic mucosal resection (EMR) was developed for small polyps^[1]. Analysis of surgically resected specimens revealed that in cases of early colon cancer with a depth of invasion of < 1000 μm into the submucosal layer (SM 1), no lymphatic invasion, no vascular involvement, or without a poorly differentiated adenocarcinoma component, curative resection can be obtained by endoscopic treatment^[2,3].

Endoscopic submucosal dissection (ESD) is an advanced technique, compared with EMR, by which higher *en-bloc* resection and lower rates of tumor recurrence are achieved when treating large tumors > 20 mm in diameter^[4-11].

In our institution, gastric ESD has been performed since 1996, and in 2002, a clinical pathway (CP) was introduced to standardize this form of intervention. This CP included a set period of hospitalization to prepare patients and to determine any sign of post-procedure complications. The efficacy of the CP in gastric ESD was then reported^[12]. A similar CP was introduced for colon ESD, which involves a 5 d hospital admission, including a 1 d pre-procedure for bowel preparation. In this study, we examined the appropriateness of this hospitalization period as the CP to prepare patients for ESD and to determine any sign of post-procedure complications.

MATERIALS AND METHODS

In our institution, colon ESD was introduced in 2007, and the CP was implemented in May 2007. All 189 consecutive patients who had colon ESD from May 2007 to March 2009 were included in this study. All used data were recorded in the ESD database.

Patients were divided into 2 groups: group A included patients who were discharged in 5 d and group B included patients who stayed longer than 5 d. The following data were collected for both groups: mean hospitalization period, tumor site, median tumor size, post-ESD rectal bleeding requiring urgent endoscopy, perforation during or after ESD, abdominal pain, fever above 38 °C, and blood test results positive for inflammatory markers before and after ESD.

Perforation during colon ESD was diagnosed when the abdominal cavity could be observed owing to injury of the muscle layer. Cases with no perforation, but with a deep separation of the submucosal layer, enabling the

endoscopist to observe the muscle layer directly were recorded as “exposure of the muscle layer”. Late-onset bleeding was defined as the occurrence of rectal bleeding after ESD, if confirmed by urgent endoscopy. Abdominal pain was defined as the presence of tenderness following examination by a physician or by patient request for analgesia. Late-onset perforation was defined as the finding of free air on abdominal computed tomography or plain X-ray, performed owing to the complaint of abdominal pain. All complications were defined in advance and recorded in the ESD database.

Patients are admitted 1 d before the procedure at noon, and receive a low-fiber diet for lunch and dinner. For bowel preparation on the day of ESD, patients drink 3000 mL of intestinal lavage fluid [polyethylene glycol; (PEG)] over a period of 2 h in the morning. Then, the ward nurse checks their stools. If the bowel preparation is poor, patients will drink an additional 500 mL to 1000 mL of PEG. Otherwise, no food or drink is allowed on the day of the procedure or the following day. The procedure starts in the afternoon after achieving successful bowel preparation. We provide prophylactic antibiotic (cefmetazole 1.0 g, intravenously) just before the procedure.

In general, the ESD procedure is performed using a bipolar needle knife (Xeon Medical Co., Tokyo, Japan), insulation-tipped (IT) knife (Olympus Co., Tokyo, Japan), HemoStat-Y (bipolar forceps for hemostasis, PENTAX, Tokyo, Japan), water jet scope (Olympus Co.), distal attachment (short ST hood, Fujifilm Co., Tokyo, Japan)^[13], and a CO₂ insufflation system (Olympus Co.) for all patients. The high-frequency wave device used is ICC200 (ERBE, Tübingen, Germany); to set the output power, an Endo Cut 50 W/Forced 40 W bipolar needle knife/IT knife is used; a bipolar 25 W is used for the HemoStat-Y.

Conscious sedation is performed to allow positional changes to patients during the procedure. Sedation with midazolam and pentazocine is usually started with 2 mg and 15 mg doses intravenously, respectively, and if required, additional dosing will be provided perioperatively based on the operator’s assessment. Hyoscine butylbromide (Buscopan) (10 mg, intravenously) is administered immediately before the procedure and another 10 mg can be given later if needed.

The morning after the ESD, routine peripheral blood and biochemistry tests are performed. Providing there are no signs or symptoms of complications, patients will start to drink water on day 1 and have meals (rice porridge) on day 2. Patients can only walk to the restroom as they should maintain bed rest the whole day of the ESD procedure. On the next day, they can walk within the hospital ward. If there is no concern with the clinical progression, patients are allowed home on day 3. Patients are instructed to refrain from ingesting alcohol or performing exercise during the first week after hospital discharge.

The ESD procedure is performed by 6 endoscopists, all of whom began performing colon ESD after first experiencing gastric ESD cases.

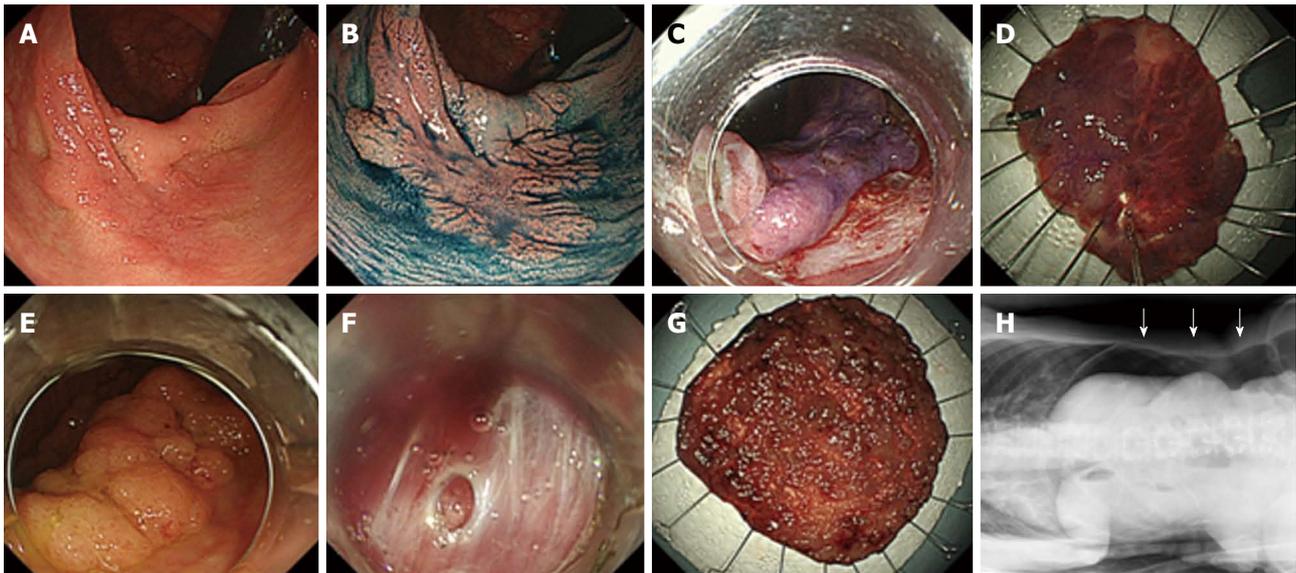

Figure 1 Case without complications and with perforation. A: Tumor located in the ascending colon; B: Image of dye spraying (indigo carmine). The macroscopic type is 0-IIa (LST-NG). The size is 35 mm; C: Treatment by endoscopic submucosal dissection (ESD); D: *En-bloc* resection was performed; E: Tumor located in the cecum. The macroscopic type is 0-IIa (LST-G). The size is 65 mm; F: Perforation occurred during ESD. It was closed by endoscopic clipping; G: *En-bloc* resection was performed by ESD; H: Prominent free air was observed in the abdominal cavity with the patient lying on the left side. The free air is indicated in the Figure by an arrow. LST-NG: Laterally spreading tumors-non-granular; LST-G: Laterally spreading tumors-granular.

Table 1 Results of the patients reviewed

	Group A	Group B	Total or average
Number	156	33	189
Average hospitalization period (d)	4.94	6.67	5.81
Location of lesion			
Colon (%)	108 (69.2)	23 (70.0)	131 (69.0)
Rectum (%)	48 (30.8)	10 (30.3)	58 (31)
Median size of lesion (mm)	34.5	35	35
Hemorrhage (%)	1 (0.6)	4 (12.1)	5 (2.6)
Perforation (%)	1 (0.6)	6 (18.2)	7 (3.7)
Abdominal pain (%)	2 (1.3)	5 (15.2)	7 (3.7)
Fever > 38.0 °C (%)	2 (1.3)	2 (6.1)	4 (2.1)
WBC (cells/ μ L; median)	6800 ^a	7700	7000
Hemoglobin level change pre-/post-ESD > 2.0 (%)	5 (3.2)	1 (3.0)	6 (3.2)
CRP (mg/dL; mean)	0.4 ^b	0.5	0.4

^a $P = 0.023$, ^b $P = 0.54$ vs group B. ESD: Endoscopic submucosal dissection; CRP: C-reactive protein; WBC: White blood cell.

RESULTS

Case presentations

Case without complications: This is the case of a 74-year-old male patient. The tumor was of the macroscopic type, grade 0-IIa laterally spreading tumors-non-granular (LST-NG) with a diameter of 35 mm, located in the ascending colon. *En-bloc* resection was achieved by ESD. The total length of hospital stay was 5 d. Histological examination revealed a well-differentiated adenocarcinoma, low-grade atypia with no lymphatic-vascular invasion, and the lateral and horizontal margins were negative. Curative resection was achieved (Figure 1).

Case with perforation: This is the case of a 58-year-old

female patient. The tumor was of the macroscopic type, grade 0-IIa laterally spreading tumors-granular (LST-G) with a diameter of 65 mm, located in the cecum. *En-bloc* resection was achieved by ESD. A small perforation occurred during the ESD, which was closed by endoscopic clipping immediately after submucosal dissection around the perforation site. Abdominal X-ray showed a small amount of free air, but no abdominal pain was reported or high-grade fever (suggesting peritonitis) observed, so the patient was managed conservatively and stayed for a total of 10 d in the hospital. Histological examination revealed a well-differentiated adenocarcinoma, low-grade atypia with no lymphatic-vascular invasion, and the lateral and horizontal margins were negative. Curative resection was achieved and no surgical treatment was necessary (Figure 1).

Of all the patients, 83% (156/189) could be discharged from the hospital on day 3 post-ESD (group A). On the other hand, the remaining 17% (33/189) of patients required prolonged hospitalization (group B) (Table 1). Complications were observed in 12.1% (23/189) of patients. Perforation was the most commonly observed complication, occurring in 3.7% (7/189) of patients. All the perforations occurred during the ESD procedure and none were of late-onset. They were managed with endoscopic clipping and no patient required surgical intervention. Six out of 7 patients with perforations (86%) were required to stay for more than 5 d.

The incidence of post-operative bleeding was 2.6% (5/189); all the cases involved rectal bleeding. Five cases required hemostatic intervention and 3 of them were in-patient admissions. The period of hospitalization needed to be prolonged for 4 out of the 5 (80%) cases. Two patients had to be re-admitted to undergo emergency

endoscopy due to bleeding which occurred after hospital discharge (post-discharge days 4 and 6); however, bleeding did not recur after that.

To analyze the rates of late-onset bleeding and tumor size, we divided the subjects into 2 groups: one with a tumor diameter < 4 cm (118 patients) and the other with a tumor diameter \geq 4 cm (71 patients). The incidence of post-ESD bleeding was compared. The rates were 5.6% (4/71) for a tumor diameter < 4 cm and 4.2% (5/118) for a tumor diameter \geq 4 cm. There was no significant difference between the 2 groups ($P = 0.93$, χ^2 test with Yates correction).

The incidence of abdominal pain was 3.7% (7/189). All the cases occurred on the day of the procedure or the next day. Of all the patients who had abdominal pain, 70% (5/7) stayed for more than 3 d post-procedure, based on the attending physician's assessment. The most common causes of delayed discharge from the hospital were late-onset bleeding and social reasons (7 patients each). Other complications were as follows: perforation (6 patients), exposure of the muscle layer (6 patients), abdominal pain (5 patients), fever (2 patients), and increased inflammatory reaction (1 patient).

Serum inflammatory markers were also assessed. On the day after ESD, the median white blood cell (WBC) count was 6800 ± 2280 (cells/ μ L; \pm SD) for group A, and 7700 ± 2775 (cells/ μ L; \pm SD) for group B, showing a statistically significant difference ($P = 0.023$, t -test). The mean C-reactive protein (CRP) values the day after ESD were 0.4 ± 1.3 and 0.5 ± 1.3 mg/dL for groups A and B, respectively, with no significant difference between the 2 groups ($P = 0.54$, t -test).

DISCUSSION

The introduction of the CP for colon ESD was demonstrated to be useful for maintaining the safety of ESD and post-procedure care^[12,14-16]. Seventy-nine percent of the patients were discharged on day 3 post-procedure; they had no complications or adverse events requiring medical attention. Three percent had complications, but they did not need to stay any longer. One percent of patients were readmitted 1 week post-procedure due to bleeding.

Looking at the breakdown of the 17% of patients with CP deviation (those who stayed for more than 5 d), it was observed that most cases were due to social reasons. Taking the above into consideration, we conclude that, in the absence of complications during ESD or early post-operative bleeding, the period of admission can be safely shortened to 1 d. However, we have to consider patients' circumstances and traveling requirements. Patients certainly need to be educated before ESD on appropriate ways of responding if symptoms of complications (particularly post-operative bleeding) occur. They may need to be advised to stay in a hotel nearby if they live far away from the endoscopy center. We have no local evidence that inpatient preparation is better than outpatient prepara-

tion. However, to avoid failure of the procedure, and patient dissatisfaction, we have included 1 d hospital stays for these reasons within our CP, particularly since the cost is very low here in Japan. On the other hand, reports from the United States and the United Kingdom have shown no differences between inpatient and outpatient preparation, and the latter situation may even be preferable^[17]. Therefore, a 1 d admission for bowel preparation may not be necessary under all conditions. Omitting this admission would minimize the cost of the procedure.

As mentioned previously, the indications for colon ESD are 0-Is+IIa (LST-G) exceeding 30 mm, LST-NG exceeding 20 mm, IIc and non-lifting sign positive intramucosal lesions, and residual recurrent lesions that cannot be resected by EMR^[18]. This is because the rate of SM invasion of LST-NG lesions is comparatively high, and 27% of them are multifocal invasions, making it difficult to identify the region of invasion before the procedure. Thus, accurate pathological evaluation by reliable *en-bloc* resection is necessary^[3]. In LST-G, 84% of cases of SM invasion are in the macro-nodular area, and if the same area can be resected *en-bloc*, endoscopic piecemeal mucosal resection (EPMR) is also allowed. However, with a 0-Is+IIa (LST-G) exceeding 30 mm, if EPMR is eventually performed, there is the possibility that the pathological assessment of the macro-nodular component will be inaccurate; such lesions are also treated by ESD as a relative indication.

The bowel preparation for colon ESD at our institution consists of domperidone (10 mg) and mosapride citrate hydrate (15 mg) administered with 3000 mL to a maximum of 4000 mL of PEG. This is a more rigorous bowel preparation than that used for conventional colonoscopy. This is to ensure a good field of view during ESD and to prevent diffuse peritonitis due to the discharge of fecal fluid in case perforation occurs^[19].

Currently, there are no fixed guidelines for antibiotics that can be administered prophylactically in colon ESD. In the field of gastroenterological surgery, there is evidence that prophylactic administration of antibiotics is useful in the prevention of wound infection, and broad-spectrum antibiotics are commonly used immediately before surgery. In the field of therapeutic endoscopy of the colon, Ishikawa *et al.*^[20] reported that if the high risk of infectious endocarditis and bacteremia are considered, the administration of antibiotics depended on the type of treatment procedure. This report was on conventional snare polypectomy and hot biopsy. With colon ESD, the risk of perforation is slightly higher than in the above procedures; therefore, we considered it appropriate to provide some form of prophylactic treatment. However, as changes in WBC and CRP level are minimal, there is the possibility that such treatment can be omitted.

We consider the bipolar system (B-knife), which is mainly used in the colon ESD procedure, to be safe^[21]. Although the monopolar system is available as a backup, the IT-knife with an insulated tip that enhances safety is being used^[22,23]. In other institutions, there are those that

mainly use a dual-knife (Olympus Co.) with the monopolar system. Differences between such devices can create differences in the rate of complications and the method of post-ESD management.

The colon ESD performed at our institution has the indications mentioned above and is discussed in the context of the CP. The purpose of this study was to investigate the appropriateness and effectiveness of the 5 d hospitalization period, including 1 d for bowel preparation, as the CP to prepare patients for ESD and to determine any sign of post-procedure complications. However, the attending physician mainly judged the prolongation of the hospitalization period. Although there is no particularly clear standard, the attending physician usually orders the prolongation under any of the following circumstances: (1) when complications, such as perforation and bleeding, are observed; (2) when an ablation on the intrinsic muscle layer at the time of ESD is judged as invasive; and (3) when there may be problems with blood sampling or physical findings the following day. It became clear that in such a case, the time to restart ingestion of water and food was commonly prolonged. At our institution, the incidence of post-ESD bleeding following gastric ESD is approximately 5% and the CP for gastric ESD is 7 d (patients discharged on day 5 after ESD). With the introduction of the CP for colon ESD, the incidence of post-ESD bleeding was lower than gastric ESD bleeding; thus, the period of hospitalization was set at 5 d and safety could be maintained for many patients. The lesions, method and bowel preparation in colon ESD differ according to the institution; therefore, the risks of complications during and after ESD are likely to differ. Hereafter, to stratify the risks in the CP, addition of the status after resection (complete suturing) and the site of the lesion (rectum or colon) as parameters should increase safety.

Limitations

There is no doubt that a 5 d hospitalization period may not be possible in many countries for financial reasons. A randomized control trial would be the best method to evaluate the necessity of post-procedure hospital admission. However, we would like to share our findings from this retrospective observational study which confirm the safety of discharging ESD patients without any complications 1 d after the procedure.

COMMENTS

Background

Conventional laparotomy is the standard treatment for early colon cancer.

Subsequently, endoscopic mucosal resection (EMR) was developed for small polyps. Analysis of surgically resected specimens revealed that in cases of early colon cancer with a depth of invasion of < 1000 μm into the submucosal layer (SM 1), no lymphatic invasion, no vascular involvement, or without a poorly differentiated adenocarcinoma component, curative resection can be obtained by endoscopic treatment.

Research frontiers

Endoscopic submucosal dissection (ESD) is an advanced technique, compared with EMR, by which higher *en-bloc* resection and lower rates of tumor recurrence are achieved when treating large tumors > 20 mm in diameter.

Innovations and breakthroughs

This is a retrospective observational study which included 189 patients consecutively treated by ESD at the National Cancer Center Hospital from May 2007 to March 2009. The following data were collected for both groups: mean hospitalization period, tumor site, median tumor size, post-ESD rectal bleeding requiring urgent endoscopy, perforation during or after ESD, abdominal pain, fever above 38 $^{\circ}\text{C}$, and blood test results positive for inflammatory markers before and after ESD. Each parameter was compared after data collection.

Applications

The lesions, method and bowel preparation in colon ESD differ according to the institution; therefore, the risks of complications during and after ESD are likely to differ. Hereafter, to stratify the risks in the clinical pathway, addition of the status after resection (complete suturing) and the site of the lesion (rectum or colon) as parameters should increase safety.

Peer review

The paper covers an important topic related to the ESD procedure: the length of the hospital stay and the quality of the monitoring of the patient after the procedure. The clinical problem is well exposed, the picture is impressive and the paper opens a new area of discussion on colonic ESD.

Abstract

AIM: To establish methods for quantitative polymerase chain reaction (PCR) for hepcidin using RNAs isolated from paraffin-embedded sections and *in situ* hybridization of hepatocellular carcinoma (HCC).

METHODS: Total RNA from paraffin-embedded sections was isolated from 68 paraffin-embedded samples of HCC. Samples came from 54 male and 14 female patients with a mean age of 66.8 ± 7.8 years. Quantitative PCR was performed. Immunohistochemistry and *in situ* hybridization for hepcidin were also performed.

RESULTS: Quantitative PCR for hepcidin using RNAs isolated from paraffin-embedded sections of HCC was

performed successfully. The expression level of hepcidin mRNA in cancer tissues was significantly higher than that in non-cancer tissues. A method of *in situ* hybridization for hepcidin was established successfully, and this demonstrated that hepcidin mRNA was expressed in non-cancerous tissue but absent in cancerous tissue.

CONCLUSION: We have established novel methods for quantitative PCR for hepcidin using RNAs isolated from paraffin-embedded sections and *in situ* hybridization of HCC.

INTRODUCTION

Hepcidin is a key regulator of iron metabolism, binding to the iron-exporter ferroportin and triggering internal-

ization and degradation^[1]. Because both iron deficiency and overload are toxic for the human body, iron concentration is tightly regulated, and hepcidin plays a major role in this process.

Hepcidin was discovered initially as an anti-microbial peptide^[2,3], and a recent study has indicated that hepcidin functions as an acute inflammatory molecule^[4]. Furthermore, the roles of hepcidin in other diseases, including cancer, have been extensively studied^[5,6]. We have previously reported that the expression of hepcidin mRNA is suppressed in hepatocellular carcinoma (HCC)^[7]. In the present study, we isolated RNAs from fresh surgical specimens. There have been no previous reports describing the isolation of RNA from paraffin-embedded sections and quantitative reverse-transcriptional polymerase chain reaction (RT-PCR). It would be valuable if quantitative RT-PCR could be performed using RNAs isolated from paraffin-embedded sections. However, it is well known that hepcidin is a difficult molecule to analyze in this way. Here we report a simple way to isolate hepcidin RNA for RT-PCR from paraffin-embedded sections, and also in situ hybridization for hepcidin.

MATERIALS AND METHODS

Patients

A total of 68 paraffin-embedded samples of HCC were used in this study. The sections were taken from areas that were clearly in the border zone between cancerous and non-cancerous tissues. The mean age of the patients was 66.8 ± 7.8 years, and there were 54 males and 14 females. Liver cirrhosis was observed in 42 patients and chronic hepatitis was diagnosed in 21; only 5 patients lacked chronic hepatitis or liver cirrhosis. Tumor stage was determined based on the classification of the Liver Cancer Study Group of Japan.

Isolation of RNAs from paraffin-embedded sections

Isolation of total RNA from paraffin-embedded sections was performed using an Agencourt Formapure Kit (Beckman-Coulter, Beverly, MA). Briefly, tissue sections were moistened with 20 μ L of lysis buffer, and cancerous and non-cancerous parts were separately cut off with a scalpel and transferred to a 96-well plate (IWAKI, Tokyo, Japan). The removed samples were heated at 72 °C for 60 min, then 20 μ L proteinase K was added, followed by incubation at 55 °C for 60 min. After 2 min of cooling, the lysates were mixed with 150 μ L of Bind I buffer and 320 μ L of Bind II buffer, and incubated at 55 °C for 5 min. The plate containing the digests was placed on a magnetic sheet for 5 min, and then the supernatants were removed. The RNA and bead complexes were washed twice, and the complexes were resuspended with 70% ethanol. The plate was then placed back on the magnetic sheet and the supernatant was again removed. Then, the plate was removed from the magnetic sheet and 100 μ L of DNase solution was added. After 15 min of incubation at 37 °C, 550 μ L of Wash Buffer was added and the plate was left at room

temperature for 5 min. It was then placed again on the magnetic sheet for 10 min, and the supernatant was again removed. The plate was then removed from the magnetic sheet and 750 μ L of 70% ethanol was added, followed by replacement on the magnetic sheet. After 5 min, the supernatant was removed, the plate was taken from the magnetic sheet, and the complex was resuspended in 500 μ L of 90% isopropanol. The plate was then incubated at 70 °C for 3 min, followed by removal from the magnetic sheet and aspiration of the supernatant. The complex was resuspended in 750 μ L of 70% ethanol and the plate was placed back on the magnetic sheet for 5 min, followed by removal of the supernatant. The complex was then air-dried for 10 min and resuspended in 80 μ L nuclease-free water. The plate was then incubated at 65 °C for 30 s, placed back on the magnetic sheet for 1 min, and the supernatant containing RNA was obtained.

Real-time PCR

Reverse transcription reactions were performed using a Rever Tra Ace α -First Strand cDNA Synthesis Kit (Toyobo, Osaka, Japan). Briefly, 1 μ g of total RNA, oligo dT-primer, and dNTPs were incubated at 65 °C for 5 min, then 10 μ L of a cDNA synthesis mixture was added and the mixture was incubated at 50 °C for 50 min. The reaction was terminated by adding 1 μ L of RNaseH and incubating the mixture at 37 °C for 20 min.

Real-time PCR was performed with an ABI Prism 7700 sequence detector (Applied Biosystems, Warrington, United Kingdom). The PCR reaction was carried out in a final volume of 2 μ L cDNA, 12.5 μ L 2 \times SYBR Green (Applied Biosystems), 0.5 μ L of 25 nmol/L sense and antisense primers, and H₂O up to 25 μ L. The PCR conditions consisted of 40 cycles at 95 °C for 30 s and 60 °C for 30 s. The sequences of the primers were as follows: GAPDH: sense-primer 5'-CCACCCAGAAGACTGTGGAT-3', anti-sense 5'-TTCAGCTCAGGGATGACCTT-3'; β -actin: sense-primer 5'-GTCGTACCCTGGCATTGTG-3', anti-sense 5'-CCATCTCTTGCTCGAAGTCC-3'; hepcidin 1: sense-primer 5'-CACAACAGACGGGACAACCTT-3', anti-sense 5'-CGCAGCAGAAAATGCAGATG-3'; hepcidin 2: sense-primer 5'-GACCAGTGGCTCTGTTTTCC-3', anti-sense 5'-CACATCCCACACTTTGATCG-3'. The primer sets for GAPDH, β -actin, and hepcidin 2 were designed using Primer 3 software (ver. 4.0), and that for hepcidin 1 was based on the previous report^[8].

The level of expression was calculated using the formula: Relative expression (t) = (Copy number of target molecule/Copy number of GAPDH)^[8]. Samples were assayed in triplicate. Means and standard deviations were calculated from the data obtained. The *t* value was calculated from the mean of three different assays.

Immunohistochemistry

The tissues were fixed with Tissue Fixative (Genostaff), and then embedded in paraffin, and sectioned at 6 μ m. Tissue sections were deparaffinized with xylene and

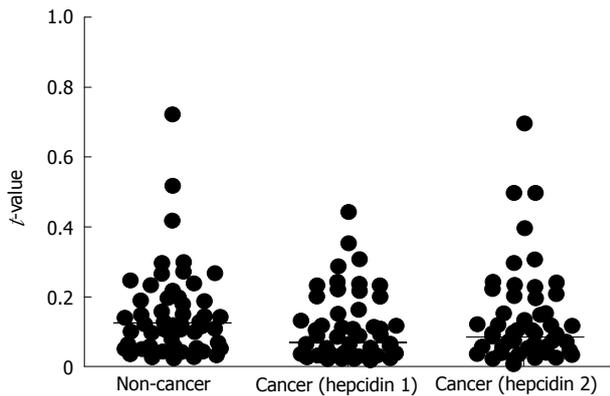

Figure 1 Expression of hepcidin mRNA in hepatocellular carcinoma. Expression of hepcidin mRNA, extracted from paraffin-embedded sections, was suppressed in cancer tissue. The median *t*-values for non-cancer, and cancer tissues with hepcidin 1 and hepcidin 2 primers, were 0.124 (0.021-3.433), 0.067 (0.009-2.063), and 0.0825 (0.007-2.1), respectively. The *t*-values for cancer tissues were significantly higher than that for non-cancer tissues ($P = 0.0057$).

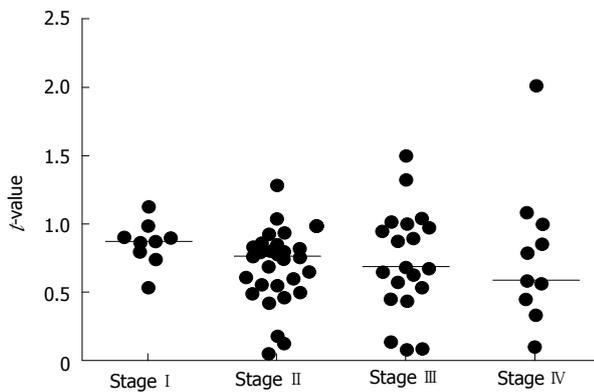

Figure 2 Ratio of hepcidin expression in non-cancer relative to cancer tissues, according to tumor stage. The median *t*-values for stages I, II, III and IV were 0.874 (0.537-1.127), 0.754 (0.052-1.286), 0.678 (0.069-1.494), and 0.579 (0.090-2.013), respectively ($P = 0.3381$, one-way analysis of variance).

rehydrated through an ethanol series and Tris-buffered saline (TBS). Antigen retrieval was performed by microwave treatment for 10 min at 500 W in 1 mmol/L ethylenediaminetetraacetic acid (EDTA) buffer, pH 9.0. Endogenous peroxidase was blocked with 3% H₂O₂ in methanol for 15 min, followed by incubation with Protein Block (DAKO). The sections were incubated with anti-hepcidin-25 antibody (HEPC13-S, Alpha Diagnostic International, San Antonio, TX) at 4 °C overnight. After washing with TBS, the sections were treated with a Biotin Blocking System (DAKO) and biotin-conjugated goat anti-rabbit Ig (DAKO) diluted 1:600, for 30 min at room temperature, followed by addition of peroxidase-conjugated streptavidin (Nichirei) for 5 min. Peroxidase activity was visualized using diaminobenzidine. The sections were counterstained with Mayer's hematoxylin (Muto), dehydrated, and then mounted with Malinol (Muto). Some sections were also stained with hematoxylin-eosin.

In situ hybridization

The tissue sections were dewaxed with xylene and rehy-

drated through an ethanol series and phosphate buffered saline (PBS). The sections were then fixed with 4% paraformaldehyde in PBS for 15 min and washed with PBS. The sections were treated with 15 µg/mL proteinase K in PBS for 30 min at 37 °C, washed with PBS, refixed with 4% paraformaldehyde in PBS, washed again with PBS, and placed in 0.2 mol/L HCl for 10 min, followed by acetylation by incubation in 0.1 mol/L triethanolamine-HCl, pH 8.0, and 0.25% acetic anhydride for 10 min. After a wash with PBS, the sections were dehydrated through an ethanol series. Hybridization was performed with digoxigenin-labeled RNA probes at a concentration of 100 ng/mL in Probe Diluent (Genostaff Co., Ltd., Tokyo, Japan) at 60 °C for 16 h. After hybridization, the sections were washed in 5 × HybriWash (Genostaff Co., Ltd.), equal to 5 × SSC, at 60 °C for 20 min and then in 50% formamide, 2 × HybriWash at 60 °C for 20 min, followed by RNase treatment in 50 µg/mL RNaseA in 10 mmol/L Tris-HCl, pH 8.0, 1 mol/L NaCl and 1 mmol/L EDTA. Then the sections were washed twice with 2 × HybriWash at 60 °C for 20 min, twice with 0.2 × HybriWash at 60 °C for 20 min and once with TBS containing 0.1% Tween 20 (TBST). After treatment with 0.5% blocking reagent (Roche) in TBST for 30 min, the sections were incubated with anti-DIG alkaline phosphatase (AP) conjugate (Roche) diluted 1:1000 with TBST for 2 h. The sections were washed twice with TBST and then incubated in 100 mmol/L NaCl, 50 mmol/L MgCl₂, 0.1% Tween 20, and 100 mmol/L Tris-HCl, pH 9.5. Coloring reactions were performed with BM purple AP substrate (Roche) overnight and then washed with PBS. The sections were counterstained with Kemechtrot stain solution (Muto), dehydrated, and then mounted with Malinol (Muto). The DNA fragment used for the probes was a 246-bp fragment corresponding to nucleotide positions 72-317 of human hepcidin (GenBank accession number NM_021175).

RESULTS

Real-time PCR

Using the method described in Materials and Methods, quantitative RT-PCR was performed for all samples. The median *t*-values for non-cancer and cancer tissues with the hepcidin 1 and hepcidin 2 primers were 0.124 (0.021-3.433), 0.067 (0.009-2.063), and 0.0825 (0.007-2.1), respectively. The *t*-values for cancer tissues were significantly higher than those for non-cancer tissues ($P = 0.0057$) (Figure 1). The assays were repeated using primers for β-actin, and the results were the same as those shown in Figure 1. Figure 2 shows the ratio of *t*-values for non-cancer to cancer tissues according to tumor stage. The median ratio of *t*-values for stages I, II, III and IV were 0.874 (0.537-1.127), 0.754 (0.052-1.286), 0.678 (0.069-1.494), and 0.579 (0.090-2.013), respectively ($P = 0.3381$; one-way analysis of variance).

Figure 3 shows a representative result of *in situ* hybridization for hepcidin. Positive staining for hepcidin was observed in non-cancerous tissues by immunohisto-

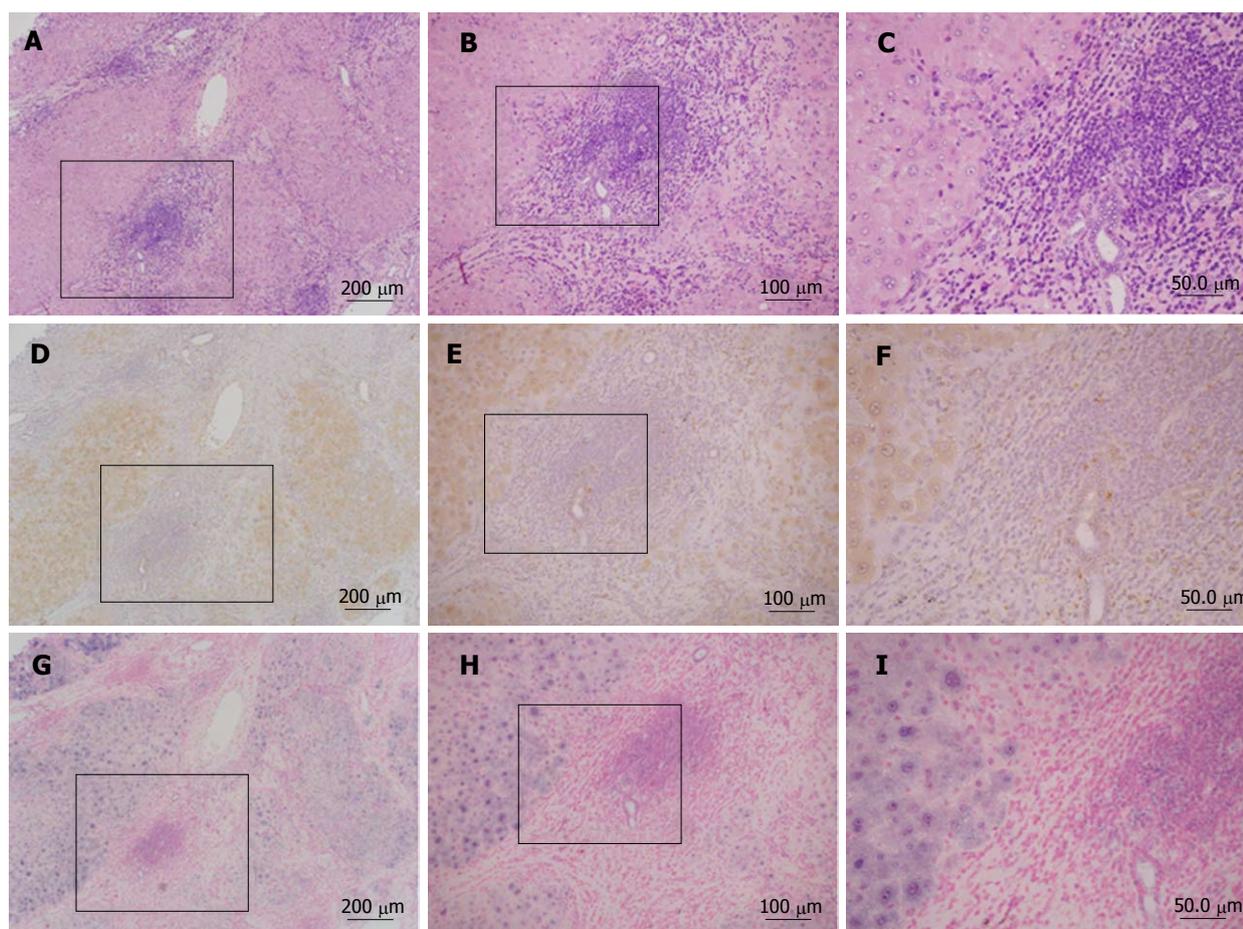

Figure 3 *In situ* hybridization for hepcidin. A surgical specimen was stained with hematoxylin-eosin (A: $\times 100$, B: $\times 200$, C: $\times 400$), and also subjected to immunohistochemistry (D: $\times 100$, E: $\times 200$, F: $\times 400$) and *in situ* hybridization (G: $\times 100$, H: $\times 200$, I: $\times 400$). Hematoxylin-eosin staining shows cancer tissues surrounded by non-cancerous hepatic lobules. Immunohistochemistry shows positive staining for hepcidin in the non-cancerous hepatic lobules (indicated as yellow in the figures). *In situ* hybridization for hepcidin shows clear expression of hepcidin mRNA in non-cancerous tissues (blue in the figures). Squares represent magnified areas.

chemistry (Figure 3D-F). Accordingly, by *in situ* hybridization, hepcidin mRNA was expressed in non-cancerous tissue but was absent in cancerous tissue (Figure 3G-I).

DISCUSSION

As we have reported previously, hepcidin gene expression was decreased in HCC^[7]. In the previous study, we extracted RNAs from freshly resected surgical specimens. This time, however, we aimed to investigate hepcidin gene expression using RNAs obtained from paraffin-embedded sections. However, for reasons that are unclear, this was not an easy process. We finally succeeded in isolating hepcidin RNA using the method described here. The expression of hepcidin mRNA was lower in cancerous than in non-cancerous tissues in most of the samples, and although not statistically significant, the ratios of the level of hepcidin mRNA in non-cancer to cancer tissues tended to be lower in poorly differentiated than in well differentiated HCCs.

Visualizing the expression of hepcidin is very important when analyzing which types of cells express or

do not express the molecule. For this purpose, *in situ* hybridization is an ideal approach, but so far no studies have succeeded with *in situ* hybridization for hepcidin. As shown in Figure 3, hepcidin mRNA was clearly detected in non-cancerous tissue, and not in cancerous tissue. Thus, the present *in situ* hybridization technique should contribute to investigations of the role of hepcidin in HCC.

COMMENTS

Background

Hepcidin is a key regulator of iron metabolism, binding to the iron-exporter ferroportin and triggering internalization and degradation. Hepcidin functions as an acute inflammatory molecule. The authors have previously reported that the expression of hepcidin mRNA is suppressed in hepatocellular carcinoma (HCC). In the present study, the authors isolated RNAs from fresh surgical specimens. There have been no previous reports describing the isolation of RNA from paraffin-embedded sections and quantitative reverse-transcriptional polymerase reaction (RT-PCR). It would be valuable if quantitative RT-PCR could be performed using RNAs isolated from paraffin-embedded sections. However, it is well known that hepcidin is a difficult molecule to analyze in this way. In the present study, the authors devised a simple way to isolate hepcidin RNA for RT-PCR from paraffin-embedded sections, and also performed *in situ* hybridization for hepcidin.

Research frontiers

There have been no previous reports of isolation of RNA from paraffin-embedded sections and quantitative RT-PCR. It would be valuable if quantitative RT-PCR could be performed using RNAs isolated from paraffin-embedded sections.

Innovations and breakthroughs

The authors established novel methods for quantitative PCR for hepcidin using RNAs isolated from paraffin-embedded sections and *in situ* hybridization of HCC.

Applications

The methods described in this paper will help to clarify the role of hepcidin in various disorders.

Peer review

This technical report relates to the analysis of hepcidin expression in the liver tissues of paraffin sections from patients with hepatocellular carcinoma using *in situ* hybridization and quantitative polymerase chain reaction. It is a nice technical note and well written, and should be relevant to other investigators in general.

Abstract

AIM: To evaluate the clinical outcomes of double-layered self-expanding metal stents (SEMS) for treatment of malignant esophageal obstruction according to whether SEMS crosses the gastroesophageal junction (GEJ).

METHODS: Forty eight patients who underwent the SEMS insertion for malignant esophageal obstruction were enrolled. Patients were classified as GEJ group

(SEMS across GEJ, 18 patients) and non-GEJ group (SEMS above GEJ, 30 patients) according to SEMS position. Double layered (outer uncovered and inner covered stent) esophageal stents were placed.

RESULTS: The SEMS insertion and the clinical improvement were achieved in all patients in both groups. Stent malfunction occurred in seven patients in the GEJ group and nine patients in the non-GEJ group. Tumor overgrowth occurred in five and eight patients, respectively, food impaction occurred in one patient in each group, and stent migration occurred in one and no patient, respectively. There were no significant differences between the two groups. Reflux esophagitis occurred more frequently in the GEJ group (eight vs five patients, $P = 0.036$) and was controlled by proton pump inhibitor. Aspiration pneumonia occurred in zero and five patients, respectively, and tracheoesophageal fistula occurred in zero and two patients, respectively.

CONCLUSION: Double-layered SEMS are a feasible and effective treatment when placed across the GEJ for malignant esophageal obstruction. Double-layered SEMS provide acceptable complications, especially migration, although reflux esophagitis is more common in the GEJ group.

Double layered self-expanding metal stents for malignant esophageal obstruction, especially across the gastroesophageal junction. *World J Gastroenterol* 2012; 18(28): 3732-3737 Available from: URL: <http://www.wjnet.com/1007-9327/full/v18/i28/3732.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i28.3732>

INTRODUCTION

Despite recent developments in diagnosis and treatment, more than 50% of malignancies involving the esophagus are inoperable and the 5-year survival rates are < 10% at present^[1,2]. In advanced or metastatic patients, therapy is usually palliative in nature, with the major aims being relief of dysphagia, maintenance of nutrition, or closure of the tracheoesophageal fistula. Self-expanding metal stents (SEMS) are widely used for the relief of patients with dysphagia, providing rapid, safe, and effective symptomatic relief in most patients^[3-6]. However, placing a stent across the gastroesophageal junction (GEJ) face several limitations due to anatomic features leading to a higher migration rate and gastroesophageal reflux^[7-10].

Covered stents are now the most commonly used type in esophageal obstruction to prevent tumor ingrowth. But, covered stents are more likely to migrate than uncovered stents, especially in the region of the GEJ. Therefore, uncovered stents should be considered to prevent migration in those cases. However, considering the risk of stent obstruction owing to tumor in-growth and stent migration in GEJ tumors, a newly designed stent with advantages of uncovered (low migration) and covered (low tumor in-growth) stents should be considered^[11-13].

Although several studies have reported the efficacy of SEMS in malignant esophageal obstruction, there are only limited data about stenting across the GEJ^[14-16]. Because placement of SEMS across the GEJ has a tendency of higher migration, we evaluated the clinical outcomes of double-layered SEMS for treatment of malignant esophageal obstruction according to whether SEMS crossed the GEJ.

MATERIALS AND METHODS

Patients

Between February 2005 and June 2010, we enrolled a consecutive series of 48 patients with malignant esophageal obstruction who underwent SEMS placement. All patients had pathologically proven esophageal or gastric cardiac carcinoma. None were candidates for curative surgical treatment because of advanced or metastatic disease or poor functional status. Informed consent for stent placement was obtained from each patient before

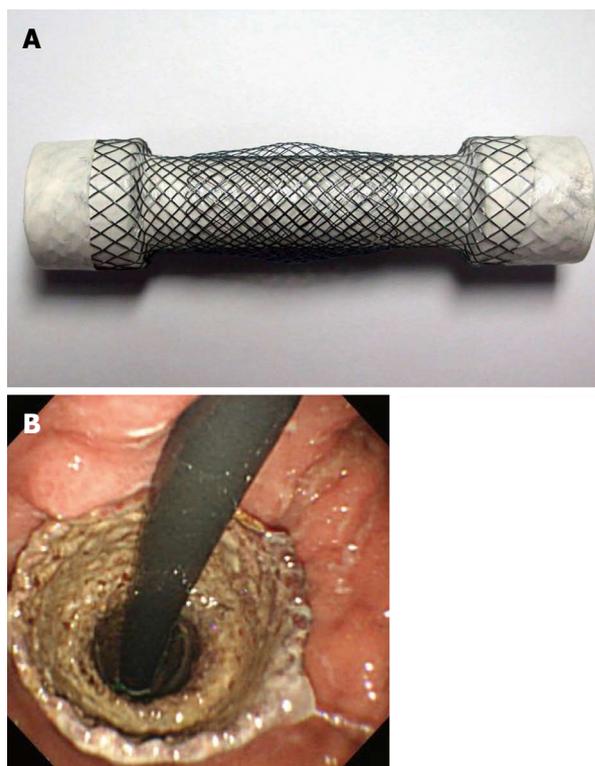

Figure 1 Niti-S double layered stent and endoscopic finding. A: Niti-S double layered esophageal stent, consisting of an inner polyurethane membrane layer and an outer uncovered nitinol wire; B: Endoscopic view of an expanding Niti-S stent, seen from the stomach.

SEMS placement.

SEMS construction and placement

Double-layered stent (Niti-S double layered esophageal stent; Taewoong, Seoul, South Korea) was used throughout the study. The double-layered stent was designed to have the advantages of both uncovered (low migration rate) and covered (low in-growth rate) stents to resolve some of the disadvantages of preexisting metal stents. The stents consist of an inner polyurethane membrane covered stent to prevent tumor ingrowth and an outer uncovered stent to reduce migration. The outer uncovered stent overlapped in the central portion of the covered stent (Figure 1). Because there is space between the covered and uncovered stent in the central portion, this space permits tissue and tumor growth throughout. Thus, the double-layered stent becomes anchored to the esophageal wall.

Patients were consciously sedated with intravenous midazolam during the procedure. Under fluoroscopic and endoscopic visualization, the length of the stricture was measured. A stent 2-4 cm longer than the length of the stricture was chosen to allow for a 1-2 cm extension above and below the proximal and distal tumor margin, respectively. After the guidewire was inserted through the stricture, the delivery system of the stent was gently introduced. After the stent placement, the positioning of the stent was assessed both radiographically and endoscopically.

	Overall (<i>n</i> = 48)	GEJ obstruction (<i>n</i> = 18)	Non-GEJ obstruction (<i>n</i> = 30)	<i>P</i> value

GEJ obstruction, distal esophageal and gastroesophageal junction obstruction; Non-GEJ obstruction, middle and upper esophageal obstruction. GEJ: Gastroesophageal junction; SEMs: Self-expanding metal stents.

Assessment of clinical outcomes and complications

The technical success of stent placement was defined as adequate positioning and deployment of the stent with complete bridging of the stricture. For the assessment of clinical improvement, we used a dysphagia score: score 0, ability to eat a normal diet; score 1, ability to eat some solid food; score 2, ability to eat some semisolids only; score 3, ability to swallow liquids only; score 4, complete inability to swallow^[17]. This was measured before and 1–2 weeks after the stent placement. We evaluated stent malfunction due to tumor overgrowth, stent migration, or food impaction and other complications including reflux esophagitis, aspiration pneumonia, or fistula.

Statistical analysis

Differences between categorical variables were examined statistically using the χ^2 test. Dysphagia scores before and after the stent placements were analyzed by the paired-*t* test. The incidence of complications was compared between two groups using the χ^2 test. All statistical analyses were performed with SPSS 12.0 (SPSS, Chicago, IL). A *P* value < 0.05 was considered statistically significant.

RESULTS

The clinical characteristics of the patients are shown in Table 1. Forty eight patients (39 men, mean age 68.4 years, range 45–86 years) with esophageal obstruction underwent SEMs placement. The histological types were squamous cell carcinoma in 32 patients (66.6%) and adenocarcinoma in 16 (33.4%). The location of obstruction was in the GEJ in 18 patients (37.5%) and non-GEJ in 30 patients (62.5%). In our study, GEJ obstruction meant that the location of obstruction was in the far distal esophagus and GEJ. Non-GEJ obstruction meant that the location of obstruction were in the upper, middle, and proximal distal esophagus. Before stent placement, 39.6% (19/48) of patients received anticancer treatments

Outcomes	Overall (<i>n</i> = 48)	GEJ obstruction (<i>n</i> = 18)	Non-GEJ obstruction (<i>n</i> = 30)

Mean dysphagia score postprocedure (mean ± SD)	1.77 ± 0.77	1.77 ± 0.73	1.76 ± 0.81
Change dysphagia score (paired- <i>t</i> test) (<i>P</i> value)	< 0.001	< 0.001	< 0.001

GEJ obstruction, distal esophageal and gastroesophageal junction obstruction; Non-GEJ obstruction, middle and upper esophageal obstruction. GEJ: Gastroesophageal junction.

such as chemotherapy (*n* = 11, 22.9%), radiation therapy (*n* = 7, 14.6%) or chemoradiation therapy (*n* = 1, 2.1%). The remaining (*n* = 29, 60.4%) patients received supportive care. Patients were classified as GEJ (18 patients including distal esophageal cancer and GEJ cancer patients) and non-GEJ groups (30 patients) according to SEMs position. In GEJ group, SEMs placed across GEJ and distal flange portion of SEMs did not anchor to the esophageal wall but was free in the cardia portion. Baseline characteristics are similar except for histologic types.

The placement of esophageal stents was technically successful in all patients. Clinical success rates for malignant esophageal obstruction were 100%. The mean dysphagia score improved from 3.20 ± 0.68 to 1.77 ± 0.77 (*P* < 0.001) by stent placement. The mean dysphagia score improved from 3.05 ± 0.63 to 1.77 ± 0.73 (*P* < 0.001) and 3.30 ± 0.70 to 1.76 ± 0.81 (*P* < 0.001) in GEJ obstruction and in non-GEJ obstruction, respectively (Table 2). Most patients complained of mild foreign body sensation or pain immediately after the stent placement and were getting better and free of these symptoms after several days. There was no procedure-related mortality within 24 h of the intervention.

Stent malfunctions developed in 16 (33.3%) patients [seven (38.9%) for GEJ group and nine (30.0%) for non-GEJ group], the causes of which consisted of tumor overgrowth (13 patients, 27%), stent migration (one patient, 2.1%) and food impaction (two patients, 4.2%). Tumor overgrowth, stent migration, and food impaction occurred in five (27.8%) and eight (26.7%) patients, zero (5.6%) and zero patient, and one (5.6%) and one (3.3%) patient in the GEJ and non-GEJ obstruction, respectively (Table 3). There was no significant difference between GEJ and non-GEJ groups.

Twenty patients (41.6%) showed complications such as reflux esophagitis (13 patients, 27.1%), aspiration pneumonia (five patients, 10.4%), and tracheoesophageal fistula (two patients, 4.2%). Only reflux esophagitis occurred more frequently in GEJ group [eight (44.4%) *vs* five (16.7%), *P* = 0.036]. Aspiration pneumonia and tracheoesophageal fistula occurred in zero and five (16.7%) and zero and two (6.7%) patients in the GEJ and non-GEJ

Table 3 Complications and causes of stent malfunctions *n* (%)

	Overall (<i>n</i> = 48)	GEJ obstruction (<i>n</i> = 18)	Non-GEJ obstruction (<i>n</i> = 30)	<i>P</i> value
Causes of stent malfunctions

GEJ obstruction, distal esophageal and gastroesophageal junction obstruction; Non-GEJ obstruction, middle and upper esophageal obstruction. GEJ: Gastroesophageal junction.

group, respectively. These complications were managed successfully with administration of proton pump inhibitors, antibiotics, or another covered stent, respectively.

DISCUSSION

Given the increased incidence of carcinoma involving the distal esophagus and gastric cardia, SEMs are increasingly being deployed across the gastroesophageal junction. Although endoscopic placement of SEMs has become an easy and safe palliative treatment for malignant esophageal obstructions, placing a stent across the GEJ still has several problems associated with anatomic location, such as stent migration and reflux esophagitis^[10]. However, little data has been published focusing on esophageal stenting across the GEJ.

In the present study, SEMs were shown to be a safe and effective treatment for malignant GEJ obstruction, providing a technical and clinical success rate of 100% and no procedure-related major complications. In comparison to another study^[18], our technical and clinical success rate was similar.

Stent placement in GEJ is especially vulnerable to migration, because the distal portion of the stent projects freely into the gastric fundus without fixation to the esophageal or gastric wall^[9]. In other studies, migration rates for covered stents have varied considerable, from 7% to as high as 50%^[18-22]. Especially, migration rates for covered stent placement in GEJ was reported as 20%^[18]. But, another study of migration rates for double layered stent placement in GEJ was reported as 4.7%^[11]. In our study, stent migration developed in one (5.6%) patient in the GEJ group. It has been recognized that stent design may play a role in reducing migration. The double layered stent was designed to reduce stent migration (Figure 1). This device combines two specific characteristics. First, it flares to 24-28 mm at both ends; this size was chosen to minimize the risk of stent-related esophageal complications. Second, it has a double-layered configuration, consisting of an inner silicone membrane layer and an outer uncovered nitinol wire to allow the mesh of the stent to embed itself in esophageal wall. So, our low migration

seems to be associated with outer uncovered stent portion. A central uncovered stent makes space between the uncovered and covered stent in the central portion of double layered SEMs. Adjacent tumor or normal tissue invades through mesh and anchor SEMs firmly to the esophageal wall. Furthermore, inner covered stent resists to tumor in-growth. So, double layered SEMs placement in GEJ is effective for prevention of stent migration with advantage of covered stent.

Overall 27% of patients experienced a symptomatic reflux esophagitis, which is similar to incidence of other studies (27%)^[10,19]. Placement of the stent across the GEJ eliminates the sphincter function of esophagus and permits free reflux of gastric contents into esophagus. Patients experience reflux from an increase in intraabdominal pressure and also passive reflux when gravity is eliminated^[23]. Thus, stenting across the GEJ seems to lead gastroesophageal reflux and even aspiration pneumonia. Weston *et al*^[24] reported gastroesophageal reflux disease, including cases of aspiration and death, in 27% of patients who had SEMs placed across the GEJ. Valbuena also reported cases of heartburn and coughing spells in 27% of patients in whom a standard open stent was used for palliative treatment of GEJ cancer^[25]. It is widely known that reflux esophagitis is more common westerners than asians. But, in our study, reflux esophagitis (44.4%) was more frequent developed by SEMs insertion in GEJ obstruction, compared to other studies (27%). Because our study was retrospective in nature, reflux esophagitis might be overestimated and multiple post-procedure symptoms could be considered as reflux esophagitis symptoms. For example, not only heartburn and regurgitation, but also chest pain and epigastric pain could be regarded as reflux esophagitis symptoms. Asians complain of atypical reflux esophagitis symptoms more frequently than westerners^[26] and 30% of atypical reflux esophagitis symptoms are related chest pain and epigastric pain^[27].

As reported on another study^[28], proton pump inhibitors were effective for controlling gastroesophageal reflux disease symptoms in most cases. Although several anti-reflux stents have been developed to prevent reflux, the results are conflicting^[29-31]. These stents also have demerits of higher rates of migration and gas bloating after meals^[32]. As our and Sabharwal *et al*^[33] results, conventional SEMs placement with a proton pump inhibitor seems to be useful alternative to manage reflux in patients with stenting across GEJ.

Our study has several limitations. First, since our study was a retrospective study, bias in evaluation of reflux esophagitis might be involved. Second, we did not take into consideration of anticancer treatment including chemotherapy and/or radiation therapy before SEMs placement. It is possible that these may cause different clinical outcomes in stent patency according to the oncologic outcomes of anticancer treatments. Consequently, such differences might have affected results of our study.

In conclusion, double-layered SEMs are feasible and

effective treatment when placing SEMS across GEJ for malignant esophageal obstruction. Double-layered SEMS provide acceptable complications, especially migration, although reflux esophagitis is more common in GEJ group.

COMMENTS

Background

There is not yet few data focusing esophageal stenting across gastroesophageal junction (GEJ). Because placement of self-expanding metal stents (SEMS) across the GEJ has a tendency of higher migration, the authors evaluated the clinical outcomes of double-layered SEMS for treatment of malignant esophageal obstruction according to whether SEMS across gastroesophageal junction.

Research frontiers

Placing a stent across the GEJ have several limitations due to anatomic features leading to a higher migration rate and gastroesophageal reflux. Double-layered SEMS provide acceptable complications, especially migration, although reflux esophagitis is more common in GEJ group.

Innovations and breakthroughs

The double-layered stent has the advantages of both uncovered (low migration rate) and covered (low in-growth rate) stents. The authors demonstrated the effectiveness of double-layered SEMS for treatment of malignant esophageal obstruction.

Applications

Double-layered SEMS are feasible and effective treatment when placing SEMS across GEJ for malignant esophageal obstruction.

Terminology

Double layered SEMS means that the stent consists of an outer uncovered and an inner covered stent. Dysphagia score is defined as follows: score 0, ability to eat a normal diet; 1, ability to eat some solid food; 2, ability to eat some semisolids only; 3, ability to swallow liquids only; and 4, complete inability to swallow.

Peer review

The paper is well structured and the results are presented and discussed in a good way.

Abstract

AIM: To assess vitamin D (Vit D) abnormalities in hepatitis C infected patients and their relationship with interleukin (IL)-17, IL-23 and N-terminal propeptide of type III pro-collagen (P^{III}NP) as immune response mediators.

METHODS: The study was conducted on 50 Egyptian patients (36 male, 14 female) with hepatitis C virus (HCV) infection, who visited the Hepatology Outpatient Clinic in the Endemic Disease Hospital at Cairo University. Patients were compared with 25 age- and sex-matched healthy individuals. Inclusion criteria were based on a history of liver disease with HCV genotype 4 (HCV-4) infection (as new patients or under follow-up). Based on ultrasonography, patients were classified into four subgroups; 14 with bright hepatomegaly; 11 with perihepatic fibrosis; 11 with hepatic cirrhosis; and 14 with cirrhosis and hepatocellular carcinoma (HCC).

Total Vit D (i.e., 25-OH-Vit D) and active Vit D [i.e., 1,25-(OH)₂-Vit D] assays were carried out using commercial kits. IL-17, IL-23 and P^{III}NP levels were assayed using enzyme linked immunosorbent assay kits, while HCV virus was measured by quantitative and qualitative polymerase chain reaction.

RESULTS: Levels of Vit D and its active form were significantly lower in advanced liver disease (hepatic cirrhosis and/or carcinoma) patients, compared to those with bright hepatomegaly and perihepatic fibrosis. IL-17, IL-23 and P^{III}NP levels were markedly increased in HCV patients and correlated with the progression of hepatic damage. The decrease in Vit D and active Vit D was concomitant with an increase in viral load, as well as levels of IL-17, IL-23 and P^{III}NP among all subgroups of HCV-infected patients, compared to normal healthy controls. A significant negative correlation was evident between active Vit D and each of IL-17, IL-23 and P^{III}NP ($r = -0.679, -0.801$ and -0.920 at $P < 0.001$, respectively). HCV-infected men and women showed no differences with respect to Vit D levels. The viral load was negatively correlated with Vit D and active Vit D ($r = -0.084$ and -0.846 at $P < 0.001$, respectively), and positively correlated with IL-17, IL-23 and P^{III}NP ($r = 0.951, 0.922$ and 0.94 at $P < 0.001$, respectively). Whether the deficiency in Vit D was related to HCV-induced chronic liver disease or was a predisposing factor for a higher viral load remains to be elucidated.

CONCLUSION: The negative correlations between Vit D and IL-17, IL-23 and P^{III}NP highlight their involvement in the immune response in patients with HCV-4-related liver diseases in Egypt.

INTRODUCTION

Hepatitis C virus genotype 4 (HCV-4) is the most common variant of hepatitis C virus (HCV) in the Middle East and Africa, particularly Egypt. This region has the highest prevalence of HCV worldwide, with > 90% of infections due to HCV-4, which is considered a major cause of chronic hepatitis, liver cirrhosis, hepatocellular carcinoma (HCC), and liver transplantation in the country^[1]. HCV-4 has recently spread beyond its strongholds in Africa and the Middle East to several western countries, particularly in Europe, due to variations in population structure, immigration and routes of transmission. However, the features of this genotype and management strategies for patients infected with this genotype are not well developed^[2].

HCV is remarkably efficient at establishing persistent infections. This suggests that HCV has evolved one or more strategies to evade the host immune response, among which are effects upon T-lymphocyte responses, including interferon (IFN)- γ production; documented by the severely suppressed T-lymphocyte responses in patients with chronic HCV infections^[3].

Vitamin D (Vit D) is a critical regulator of immunity, playing a role in both innate and cell-mediated immune responses^[4]. Vit D suppresses production of T-helper (Th)-1 lymphocyte type cytokines, such as IFN- γ and interleukin (IL)-2, and consequently leads to an enhanced production of Th-2 cytokines, such as IL-4 and IL-5, thereby promoting humoral immune responses. Vit D also endorses innate immunity by directly inducing gene expression of antimicrobial peptides, such as cathelicidin and β -defensin 2, in various human cell types^[5-8]. Vit D deficiency has been shown to associate several immune-mediated diseases, as well as to increase susceptibility to both infections and cancer. Specifically, a 25(OH)-Vit D concentration < 50 nmol/L (i.e., 20 ng/mL) is accepted as a marker of deficiency, whereas a concentration of 51-74 nmol/L (21-29 ng/mL) indicates insufficiency^[8,9].

Chronic hepatic cirrhotic patients with HCV genotype 1 have low serum 25(OH)-Vit D levels, and a low Vit D status is linked to severe fibrosis and a low sustained virological response (SVR) during IFN- α -based

therapy^[10,11]. Moreover, there is interesting preliminary data that indicate that 1,25-(OH)₂ Vit D suppresses Th-17 driven cytokine responses and the differentiation and maturation of B lymphocytes, while it induces formation/activation of T-regulatory lymphocytes, stimulates IL-4 production (Th-2), and enhances natural-killer-T-cell functions^[12,13].

It has also been shown that treatment with Vit D receptor (VDR) agonists inhibits T-lymphocyte production of IL-17, which is a potent mediator of delayed-type reactions. It achieves this effect (in a manner similar to IFN γ) by elevating chemokine production in various tissues that, in turn, leads to recruitment of monocytes and neutrophils to the site of inflammation. Furthermore, IL-17 acts synergistically with tumor necrosis factor (TNF)- α and IL-1^[14] to stimulate immune functions, and its production is sustained by IL-23, an IL-12 family member, the latter of which is strongly inhibited by VDR agonists^[15]. IL-23, in conjunction with IL-6 and transforming growth factor (TGF)- β , also stimulate the differentiation of Th-17 cells with the subsequent production of IL-17^[16].

The aim of the work was to assess Vit D status in HCV-4-infected patients and its relationship to levels of IL-17 and IL-23, as well as the N-terminal propeptide of type III pro-collagen (PIII^{NP}), the direct serologic marker of collagen turnover, as immuno-inflammatory mediators.

MATERIALS AND METHODS

Subjects

Prior to initiation, this study received approval by the Ethical Committee of the Faculty of Medicine, Cairo University. The study recruited 50 patients with HCV-related chronic liver disease (minimum duration of 7 years; group I) who visited the Hepatology Outpatient Clinic in the Endemic Disease Hospital at Cairo University. Inclusion criteria were based on a history of liver disease with HCV-4 infection (as new patients or under follow-up). Patients with hepatitis B virus (HBV) or co-infection with HBV and human immunodeficiency virus were excluded. All included patients underwent tests for liver function and abdominal ultrasonography, and were tested for the presence of HCV antibodies. When fulfilled, the investigated patients included 36 men and 14 women, ranging in age from 30 to 55 years (mean age = 42.5 years). Twenty-five age- and sex-matched healthy individuals were then recruited as a control group (group II). The controls had normal liver functions and abdominal ultrasonography and negligible HCV antibody levels. Informed consent was obtained from the patients and controls regarding all the procedures. All patients were subjected to a thorough history taking.

Based on ultrasonography results, patients were classified into four subgroups: 14 with bright hepatomegaly; 11 with perihepatic fibrosis; 11 with hepatic cirrhosis; and 14 with cirrhosis and HCC. After subclassification, venous blood samples (5 mL) were obtained (after overnight fast-

HCC: Hepatocellular carcinoma; IL: Interleukin.

ing) from all patients/controls. Samples were allowed to clot and sera were then separated by centrifugation (3500 rpm, 20 min, 25 °C) and then stored at -20 °C until used for analysis of the various parameters outlined below.

Assessment of Vit D, active Vit D, IL-17, IL-23 and P^{III}NP levels

Total Vit D (i.e., 25-OH-Vit D) assay was carried out using a commercial solid phase radioimmunoassay kit (Medgenix Diagnostics SA Zoning Industrial, Fleurus, Belgium) according to the method of Mawer^[17]. The active Vit D (i.e., 1,25-[OH]₂-Vit D) assay was carried out according to Hollis^[18] using a commercial kit from Incstar Corporation (Stillwater, MN, United States). IL-17, IL-23 and P^{III}NP levels were assayed using enzyme linked immunosorbent assay kits obtained from Biosource Europe SA (Nivelles, Belgium). The sensitivity of the 25-OH-Vit D, 1,25-(OH)₂-Vit D, IL-17, IL-23 and P^{III}NP kits were 2.4 ng/mL, 5.5 pg/mL, 10 pg/mL, 5 pg/mL, and 10 pg/mL, respectively.

Assessment of HCV levels

Quantitative reverse transcription polymerase chain reaction (RT-PCR) for HCV was done using TaqMan technology according to the method of Scott and Gretch^[19], and only HCV-4-infected patients were included in the study. Typically, an RT-PCR has a limit of quantification (LOQ) of 25 IU/mL and a limit of detection (LOD) of 10-15 IU/mL; in the assays used here for HCV-RNA testing, the LOQ was 24 IU/mL and the LOD 12 IU/mL.

For genotyping, HCV type-specific primers designed by Okamoto *et al.*^[20] were utilized. Assessments of genotype burdens required three steps: (1) RNA virus was extracted from patient samples using a Tripure Method (Roche, Mannheim, Germany); (2) isolated RNA was converted to cDNA using random hexamers and Moloney Murine Leukemia Virus Reverse Transcriptase enzymes from Promega (Madison, WI, United States); and (3) the product cDNA was amplified using an allele-specific PCR method. The PCR program was set for 1 cycle at 96 °C for 6 min, then for 40 cycles at 95 °C for 1 min, 60 °C for 1 min, and 72 °C for 1 min, and a final extension cycle of 72 °C for 10 min. For each patient,

two vials containing primer specific for virus types 1a/1b and for 2a and 3a were used. A positive control for each genotype (supplied by the kit manufacturer) was also run in parallel with each set of samples. In addition, HCV viral load was also determined using an Artus Real Art PCR Kit (Qiagen, Valencia, CA, United States). For both assays, a LightCycler[®] 480 real-time PCR System (Roche) was used. The slope of each reaction was between 3.2 and 3.4, and the error < 0.002. All results of the quantitative HCV analyses were expressed as IU/mL.

Statistical analysis

All data are expressed as mean ± SD. All analyses utilized SPSS for Windows version 15.0 (SPSS, Chicago, IL, United States). Analysis of variance was employed for comparisons of means of the different parameters, with Tukey-Kramer test as the post hoc test. $P < 0.05$ was accepted as statistically significant. Correlation analyses were done using Pearson's correlation.

RESULTS

Table 1 demonstrates significantly decreasing levels of Vit D and active Vit D [1,25-(OH)₂-Vit D], along with the progressive hepatic state induced by chronic HCV infection, ranging from bright hepatomegaly and perihepatic fibrosis to hepatic cirrhosis and further HCC. Levels of Vit D and active 1,25-(OH)₂-Vit D were significantly lower in advanced liver disease (i.e., hepatic cirrhosis and/or carcinoma), compared to bright hepatomegaly and perihepatic fibrosis. A similar pattern was seen for the levels of IL-17, IL-23 and P^{III}NP and the viral load, for which the levels were significantly elevated in hepatic cirrhosis and/or carcinoma, compared to bright hepatomegaly and perihepatic fibrosis. Only the IL-17, P^{III}NP and the viral load of patients with HCC were significantly higher than in cirrhotic patients. The decrease in Vit D and active Vit D was concomitant with increases in viral load, as well as levels of IL-17, IL-23 and P^{III}NP among all subgroups of HCV-infected patients, compared to normal healthy controls.

Vit D insufficiency (21-29 ng/mL) was detected in 14 (28%) HCV patients and three (12%) controls, while Vit

Table 2 Vitamin D, its active form, interleukin-17, interleukin-23, N-terminal propeptide of type III pro-collagen and viral load in male and female subgroups of hepatitis C virus-infected patients

Item	Male group (n = 36)	Female group (n = 14)	P value
Vit D (ng/mL)	10.30 ± 2.12	10.00 ± 2.60	1.00
Active Vit D (ng/mL)	12.10 ± 2.80	12.40 ± 2.60	0.96
Viral load (IU/mL)	198.00 ± 38.10	199.00 ± 31.10	0.93
IL-17 (ng/mL)	133.80 ± 32.50	134.90 ± 32.60	0.90
IL-23 (ng/mL)	241.00 ± 28.10	243.00 ± 26.50	0.92
P ^{III} NP (μg/L)	226.57 ± 346.54	227.94 ± 36.45	0.90

Values shown are means ± SD of data for both male and female hepatitis C virus-infected subjects. Values shown include group 1c (liver cirrhosis) and 1d (hepatocellular carcinoma) subjects. Significant difference is determined at $P < 0.05$. IL: Interleukin; Vit: Vitamin.

D deficiency, defined as serum level < 20 ng/mL, was present in 36 (72%) of the HCV-infected patients and none of the controls. Lastly, Vit D deficiency was seen in all 25 cirrhotic patients and 10 (40%) of the non-cirrhotic HCV-infected patients.

The parameters studied in HCV-infected patients when classified into two subgroups according to sex are shown in Table 2. HCV-infected men and women showed no differences with respect to Vit D levels. There were significant correlations between different parameters in HCV-infected patients and controls. There was a significant negative correlation between Vit D and IL-17, IL-23 and P^{III}NP. Viral load was negatively correlated with Vit D and active Vit D levels ($r = -0.084$ and -0.846 at $P < 0.001$, respectively), and positively correlated with IL-17, IL-23 and P^{III}NP ($r = 0.951$, 0.922 and 0.94 at $P < 0.001$). The significant negative correlations between active Vit D and IL-17 ($r = -0.679$), IL-23 ($r = -0.801$), and viral load ($r = -0.84$), are illustrated in Figure 1.

DISCUSSION

The liver plays a central role in Vit D metabolism, and its inadequacy is common in non-cholestatic chronic liver diseases and correlates with disease severity^[21]. The current study showed a significant reduction of Vit D and its active metabolite in HCV-4-infected patients compared to healthy controls. HCV-infected patients were classified according to sonar finding into four groups with progressive hepatic states; bright hepatomegaly and perihepatic fibrosis to hepatic cirrhosis and further HCC. The reduction of the levels of Vit D and its active form was more prevalent and severe in cirrhotic patients (versus non-cirrhotic patients), and much lower in patients with HCC; these differences were each highly significant. This is consistent with previous studies in patients with HCV genotype 1, which showed that Vit D deficiency is universal (92%) among patients with chronic liver disease, and at least one-third of the patients have severe Vit D deficiency^[21-23].

A significant negative correlation was reported between viral load and Vit D and active Vit D. Vit D is an impor-

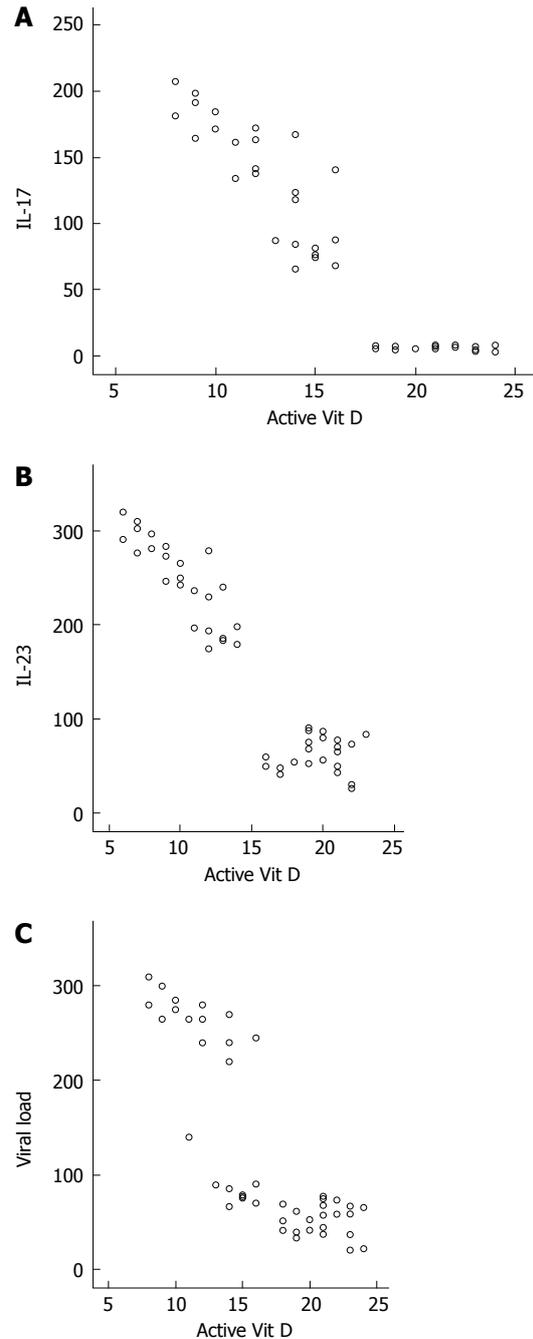

Figure 1 Correlation between active vitamin D levels and interleukin-17, interleukin-23 and viral load. A: Correlation between active Vit D levels and interleukin (IL)-17, revealing a negative correlation ($r = -0.679$); B: Correlation between active Vit D levels and IL-23, revealing a negative correlation ($r = -0.801$); C: Correlation between active Vit D levels and viral load, revealing a negative correlation ($r = -0.846$). Vit: Vitamin.

tant immune modulator and preliminary data have indicated associations between Vit D deficiency and failure to achieve SVR rates in HCV patients^[24]. It has been reported that the reduced (25-OH Vit D) levels and CYP27-1260 promoter polymorphism lead to reduced [1,25-(OH)₂ Vit D] levels, and are associated with failure to achieve an SVR in patients infected with HCV genotypes 1, 2 or 3^[14,25]. The patients in the present study with HCV-4 need further follow-up to confirm the effect of Vit D deficiency upon

their responses to treatment.

Furthermore, the present study showed that IL-17 and IL-23 were markedly increased in HCV-infected patients in comparison to controls. The difference in viral load among these groups may explain, in part, the differences noted in levels of inflammatory cytokines in the patients in the current study. Regulation of Th1 and Th17 responses in HCV-infected individuals has previously been studied^[25], and it has been reported that TGF- β and IL-6 promote differentiation of naïve murine CD4⁺ T lymphocytes into IL-17-secreting Th17 lymphocytes. In addition, it has been reported that other innate cytokines, including IL-1, IL-23, TNF- α and IL-21, in different combinations or with TGF- β , are also involved in the differentiation, amplification, or stabilization of the Th17 phenotype^[26]. A significant negative correlation between Vit D and both IL-17 and IL-23 was a prominent finding in the current investigation. Previous studies in mice have shown that Vit D is a strong inhibitor of Th17 polarization and Th17 cytokine expression by splenic CD4⁺ T lymphocytes. Furthermore, Th17 differentiation from naïve T lymphocytes is affected by Vit D. These data imply a regulatory effect on Th17 cells by Vit D, through the reduction of retinoic acid-related orphan receptor (ROR) γ t expression^[22]. The effect of Vit D on the behavior of Th17 cells has been investigated in different diseases and Vit D suppresses the expression of IL-17 and IL-23^[27-32], as documented in the current study.

We reported a positive correlation between IL-17 and IL-23 and viral load; a finding that supports our hypothesis regarding a link between Vit D and both IL-17 and IL-23 in immunoregulation of HCV-4-related chronic liver disease, and may explain how Vit D deficiency plays a role in increasing liver fibrosis. Our results also revealed no significant differences between HCV-infected men and women with respect to Vit D status. In contrast, Arteh *et al.*^[33] have reported that African American women with chronic liver disease are at higher risk of Vit D deficiency.

During the process of liver fibrosis, type III procollagen is converted to type III collagen by cleavage of its amino terminal and carboxy terminal propeptides. Serum levels of PIII^{NP}, which are direct serologic markers of collagen turnover in liver fibrosis, are elevated in both acute and chronic liver diseases; and further reflect the histologic stage of hepatic fibrosis in various chronic liver diseases^[34]. There was a significant increase (in comparison to controls) in the serum levels of PIII^{NP} in patients with all grades of hepatic disease; results that are in agreement with Walsh *et al.*^[34]. However, Panasiuk *et al.*^[35] have reported a decrease in PIII^{NP} levels in cirrhotic patients in comparison to controls, and have not shown any inflammatory process in the cirrhosis, hence more studies are needed to resolve this point of controversy. The results of the current study also revealed a significant negative correlation between Vit D and PIII^{NP} levels, supporting a role for decreased Vit D in inflammation and fibrosis; a relationship that has not previously been

investigated in patients with hepatic disease. Interestingly, Zehnder *et al.*^[36] have reported that reduction of the Vit D hormonal system in kidney diseases is associated with increased renal inflammation and fibrosis. These investigators have also reported a significant negative correlation between Vit D and PIII^{NP} levels. Logistic regression analysis with urinary PIII^{NP}, as a binary outcome, has shown that a 10-U increase in serum 1,25(OH)₂-D or 25-OH-Vit D resulted in lower renal inflammation^[37].

In conclusion, Vit D deficiency is prevalent in HCV-4-infected patients and the viral load is negatively correlated with Vit D status. In view of the role of Vit D in maintaining optimal immune function, Vit D status may be assessed and supplements may be considered to achieve an SVR during IFN- α -based therapy. The negative correlation between Vit D and IL-17, IL-23 and PIII^{NP} levels appears to highlight, at least in part, how these cytokines are involved with Vit D in immune responses in HCV-4-related liver disease, and could explain how Vit D deficiency plays a role in liver fibrosis.

COMMENTS

Background

Hepatitis C virus (HCV) infects primarily the hepatocytes, leads to the development of fibrosis or cirrhosis of the liver, and is a significant risk factor for the development of hepatocellular carcinoma (HCC). The cell-mediated immune response plays a central role in hepatocellular necrosis and in the immunopathogenic mechanisms involved in viral clearance and persistence in liver disease of viral etiology, such as HCV-related chronic liver disease. In this context, cytokines modulate the immune system and exert direct antiviral activity by cytopathic and non-cytopathic mechanisms. T-cell immunoregulatory cytokines influence the persistence of HCV chronic infection and the extent of liver damage.

Research frontiers

Vitamin (Vit D) abnormalities are well documented in patients with chronic liver disease, but the association of the degree of Vit D abnormality with the progressive hepatic necroinflammatory state has not been thoroughly investigated. Furthermore, the proinflammatory cytokine profile in patients infected with HCV genotype 4 (HCV-4) needs further study. The research hotspot is how to determine/assess the extent of Vit D abnormality in HCV-4-infected patients and determine its relationship with proinflammatory markers, namely, interleukin (IL)-17, IL-23, and the N-terminal propeptide of type III pro-collagen (PIII^{NP}) as immune response mediators.

Innovations and breakthroughs

A plethora of studies has investigated the association of Vit D abnormalities with individual liver diseases, including hepatitis B, alcoholic hepatitis, autoimmune hepatitis, and HCC. Nevertheless, the role of Vit D abnormalities in the progression of HCV to cirrhosis and then to HCC remains to be elucidated. To this end, this study sought to investigate the potential association between levels of Vit D and IL-17, IL-23 and exacerbation of hepatic damage in chronic HCV patients. The results showed that levels of Vit D and its active form were significantly lower in patients with advanced liver disease (hepatic cirrhosis and/or carcinoma), compared to those with bright hepatomegaly and perihepatic fibrosis. IL-17, IL-23 and PIII^{NP} levels were markedly increased in HCV patients and correlated with progression of hepatic damage. The decrease in Vit D and its active form was concomitant with increases in viral load, as well as levels of IL-17, IL-23 and PIII^{NP} among all subgroups of HCV-infected patients, com-

pared to normal healthy controls. The negative correlation between Vit D and IL-17, IL-23 and PIII^{NP} may highlight, at least in part, how these cytokines are involved with Vit D in the immune response to HCV-4-related liver disease, and may explain how Vit D deficiency plays a role in the progression of liver fibrosis. In view of the role of Vit D in maintenance of immune function, its status may be assessed and supplements should be considered to achieve a sustained virological response during therapy.

Applications

The actual role of Vit D in the context of hepatic inflammatory process is still not fully elucidated. Given the major significance of the inflammatory response in mediating HCV clearance, as well as the anti-inflammatory actions displayed by Vit D *in vitro*, Vit D could have a positive influence on HCV infection. Further studies are needed to explain which stages of HCV infection require higher levels of Vit D and the mechanism of Vit D supplementation for these patients.

Terminology

Hepatitis C is a chronic liver infection that can be complicated by liver failure and liver cancer. In the liver, cytokines coordinate physiological and pathological processes such as liver growth and regeneration, inflammatory processes including viral liver disease, liver fibrosis and cirrhosis. T-cell immunoregulatory cytokines may play a key role in influencing the persistence of HCV infection and the extent of liver damage. IL-6 and transforming growth factor β , as the differentiation factors for Th17 cells, both cytokines together induce massive amounts of IL-17 from naïve T cells. Vit D has an important role in the treatment of different bacterial and viral infections; this vitamin is synthesized in the skin by absorption of ultraviolet light from the sun. The mechanism of action of this vitamin is unknown, but it may improve the activities of immune cells that are important in the eradication of HCV.

Peer review

This article reveals the importance of Vit D and/or its active form in HCV-4 infection, which is the most common form of hepatitis C in Egypt. The study also showed that this deficiency progresses with disease deterioration. This may indicate that Vit D supplements could be efficient in early stages of the disease.

Abstract

AIM: To assess the significance of phosphatidylinositol 3-kinase (PI3K) in colorectal cancer (CRC) and toxicity of LY294002 in CRC cells with different metastatic abilities.

METHODS: Sixty formalin-fixed and paraffin-embedded CRC tumor specimens were investigated. Adjacent normal colonic mucosa specimens from 10 of these cases were selected as controls. PI3K protein was detected by immunohistochemistry and PIK3CA mutations were investigated by gene sequencing analysis. A flow-cytometry-based apoptosis detection kit was used to determine PI3K inhibitor-induced apoptosis in CRC cell lines SW480 and SW620. Expression of phosphorylated protein kinase B in CRC cell lines was detected by Western blotting.

RESULTS: There was a significant difference in the proportion of primary lesions (30%, 18/60) vs metastatic lesions (46.7%, 28/60) that were positive for PI3K ($P < 0.05$). Mutations were detected in exon 9 (13.3%) and

exon 20 (8.3%). Out of 60 cases, seven mutations were identified: two hotspot mutations, C.1633G>A resulting in E545A, and C.3140A>G resulting in H1047R; two novel missense mutations C.1624G>A and C.3079G>A; and three synonymous mutations (C.1641G>A, C.1581C>T and C.3027T>A). Exposure of SW480 cells to PI3K inhibitor for 48 h resulted in a significant increase of apoptotic cells in a dose-dependent manner [3.2% apoptotic cells in 0 $\mu\text{mol/L}$, 4.3% in 5 $\mu\text{mol/L}$, 6.3% in 10 $\mu\text{mol/L}$ ($P < 0.05$), and 6.7% in 20 $\mu\text{mol/L}$ ($P < 0.05$)]. Moreover, PI3K inhibitor induced a similar significant increase of apoptotic cells in the SW620 cell line for 48 h [3.3% apoptotic cells in 0 $\mu\text{mol/L}$, 13.3% in 5 $\mu\text{mol/L}$ ($P < 0.01$), 19.2% in 10 $\mu\text{mol/L}$ ($P < 0.01$), and 21.3% in 20 $\mu\text{mol/L}$ ($P < 0.01$)].

CONCLUSION: High PI3K expression is associated with CRC metastasis. PI3K inhibitor induced apoptosis in CRC cells and displayed strong cytotoxicity for highly metastatic cells. PI3K inhibition may be an effective treatment for CRC.

Zhu YF, Yu BH, Li DL, Ke HL, Guo XZ, Xiao XY. PI3K expression and PIK3CA mutations are related to colorectal cancer metastases. *World J Gastroenterol* 2012; 18(28): 3745-3751 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i28/3745.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i28.3745>

INTRODUCTION

Colorectal cancer (CRC) is the second leading cause of cancer-related death in the United States. The majority

of these deaths are due to metastatic disease^[1]. There is at least a 25-fold variation in occurrence of CRC worldwide, although rates are generally increasing. In high-risk areas, such as Europe, the rates are gradually increasing. The incidence tends to be low in Africa and Asia and intermediate in southern parts of South America^[2]. However, in China, the incidence of CRC is increasing rapidly^[3]. The phosphatidylinositol 3-kinase (PI3K)/protein kinase B (AKT) signaling pathway is activated in multiple cancers and it is an important regulator of cell growth, metabolism, proliferation, survival, motility, and invasion^[4-7]. Highlighting the importance of the PI3K signaling pathway in human cancers, genetic alterations have been reported in various tumors including amplification of AKT1 and PIK3CA^[8], somatic mutations of PIK3CA and AKT^[9,10], and deletion of PTEN^[11]. Somatic mutations in the catalytic subunit of PIK3CA have been found in a significant fraction of breast carcinomas, in which PIK3CA exon 20 mutation is associated with poor prognosis^[12]. However, the different significance of PIK3CA mutations in primary CRC *vs* metastatic lesions has not been explored. Mutations in PIK3CA have been reported to occur in 13.6%-31.6% of CRC, making it one of the most frequently mutated genes^[13,14]. A majority of mutations have been identified in the helical (exon 9) and kinase (exon 20) domains of PIK3CA. Expression of cancer-derived PIK3CA mutants in cultured human-derived CRC cells increases kinase activity, invasion, and resistance to apoptosis, suggesting that mutant PIK3CA plays a role in the initiating steps of CRC tumorigenesis^[15,16]. In addition, the higher frequency of PIK3CA mutations in other advanced stage invasive tumors suggests a putative role in tumor progression^[4,17].

Alongside genetic, molecular biological, and biochemical studies, chemical inhibitors have been valuable as tools in PI3K research^[18-21]. They are helpful in understanding the role of PI3K enzymes in signal transduction and downstream physiological and pathological processes, as well as to assist validation of PI3Ks preclinically as therapeutic targets^[18]. The earliest and still widely utilized inhibitors are wortmannin and LY294002. We utilized the PI3K inhibitor LY294002 in this study.

Based on PIK3CA data in other malignancies, we hypothesized that mutations resulting in the activation of the PIK3CA pathway may play a role in the progression of CRC. To test this hypothesis, we analyzed expression of PI3K protein in both primary and metastatic lesions; the mutational status of the two hotspot regions of PIK3CA (exons 9 and 20) in CRC; and the effect of PI3K inhibitor on cell apoptosis and AKT phosphorylation using two CRC cell lines.

MATERIALS AND METHODS

Samples and cell lines

Formalin-fixed and paraffin-embedded tumor specimens were obtained from surgical specimens from Shanghai Xuhui District Center Hospital. Specimens were from

sporadic patients with colorectal adenocarcinoma who had not received preoperative radiotherapy, chemotherapy, or immunotherapy. All tumors were reviewed and confirmed by two senior pathologists using the World Health Organization classification of tumors of the digestive system^[22]. Among the 60 patients with CRC, 33 were male and 27 were female. Their mean age was 52 years, ranging from 24 years to 78 years. There were 58 cases in stage III and two in stage IV according to the tumor, nodes, metastasis system. Lymph node metastasis was seen in 58 cases and liver metastasis in two. Twenty-six cases occurred in the colon and 34 in the rectum. Adjacent normal colonic mucosa specimens from 10 of these cases were selected as controls. Human colon cell lines SW480 and SW620 (Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences); annexin V-fluorescein iso-thiocyanate (FITC) Apoptosis Detection kit (BioVision, Palo Alto, CA, United States); and the detergent-compatible protein assay kit and ECL Plus Western blotting Detection System (Bio-Rad Laboratories, Hercules, CA, United States) were also used.

Immunohistochemistry

Paraffin-embedded blocks of CRC primary and metastatic tissue specimens were cut into 5 μ m thick sections. One section from each block was stained with hematoxylin and eosin as a control. Known positive biopsies were used as positive controls, while specimens treated with phosphate buffered saline (PBS) instead of primary antibody were used as negative controls. All further steps were performed in strict accordance with the Envision two-step method instructions. PI3K (p110 α) rabbit anti-human monoclonal antibody (Cell Signaling Technology, Beverly, MA, United States) was diluted 1:50. Envision Kit and DAB color kit (Zhongshan Biotechnology Company, Beijing, China) were used. PI3K presence was expressed in the cytoplasm as brown-yellow or brown granules. We observed the distribution of PI3K protein and scored the specimens^[23]. The score was 0 if no positive tumor cells were found; 1 if positive tumor cells were < 10%; and 2 if positive tumor cells were > 10%. Tissues with scores of 0 or 1 were considered negative; those with scores of 2 were considered positive.

Polymerase chain reaction and sequencing

Genomic DNA was extracted from all samples using phenol-chloroform and ethanol precipitation. The DNA concentration of each sample was measured using NanoVue ultraviolet spectrophotometer. Exons 9 and 20 of PIK3CA were amplified using previously described polymerase chain reaction (PCR) primers^[24]. The exon 9 forward and reverse primers were respectively 5'-GATTG-GTTCTTTCCTGTCTCTG-3' and 5'-CCACAAATATCAA TTTACAACCATTG-3', and yielded a 487-bp expected product. The exon 20 forward and reverse primers were respectively 5'-TGGGGTAAAGGGAAT-CAAAAG-3' and 5'-CCTATGCAATCGGTCTT TGC-3', and yielded a 525-bp expected product. The PCR

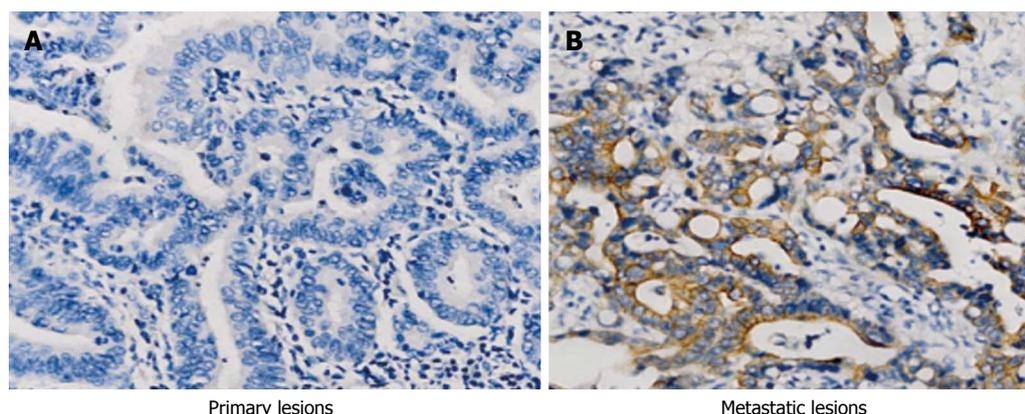

Figure 1 Expression of phosphatidylinositol 3-kinase in colorectal cancer by immunohistochemistry staining (enVision $\times 400$).

mixture contained 150 ng DNA, 5 pmol/L each primer, 2.5 nmol/L each dNTP, and 1.25 U Taq DNA polymerase in 20 μ L buffer with 0.04 μ mol/L Mg^{2+} . After an initial denaturation step at 94 $^{\circ}C$ for 5 min, 35 PCR cycles were performed, which included 45 s for denaturation at 94 $^{\circ}C$, 30 s for annealing at 60 $^{\circ}C$, and 45 s for extension at 68 $^{\circ}C$. PCR products were analyzed by 2% agarose gel electrophoresis. After observing clear and accurately sized bands, amplification products were then purified and directly sequenced on an ABI Prism 3730 sequence detection system (Applied Biosystems, Foster City, CA, United States).

Cells apoptosis analysis

SW480 and SW620 cells were cultured in Dulbecco's Modified Eagle's Medium supplemented with 10% fetal bovine serum, 100 U/mL penicillin, and 100 μ g/mL streptomycin. All cell lines were incubated in 5% CO_2 at 37 $^{\circ}C$. PI3K-inhibitor-induced apoptosis in SW480 and SW620 cells was determined by flow cytometry using the annexin V-FITC Apoptosis Detection kit following the manufacturer's instructions. Briefly, 3×10^5 cells were treated with PI3K inhibitor (0 μ mol/L, 5 μ mol/L, 10 μ mol/L, and 20 μ mol/L) for 24 h. The cells were then harvested, washed in PBS, and incubated with annexin V and propidium iodide for staining in binding buffer at room temperature for 10 min in the dark. The stained cells were analyzed using the fluorescence-activated cell sorting (FACS) Aria instrument (BD Biosciences, CA, United States).

Western blotting

Whole cell lysates were generated with cell lysis solution for Western blotting. After centrifugation, the supernatant fraction was collected for Western blotting. Proteins were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and transferred onto a nitrocellulose membrane. After blocking with 5% nonfat milk in blocking buffer [20 mmol/L tris-buffered saline (pH 7.5) containing 0.1% Tween 20], the membrane was incubated with the primary antibody at 4 $^{\circ}C$ overnight and then incubated with appropriate horseradish peroxidase (HRP)-conjugated secondary antibody. The immunoreac-

tive bands were visualized using the ECL Plus Western Blotting Detection System. The level of β -actin for each sample was used as a loading control. PI3K (p110 α) rabbit anti-human monoclonal antibody was purchased from Cell Signaling Technology. β -actin (1-19) and the secondary antibodies (HRP-linked anti-mouse IgG) were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, United States).

Statistical analysis

The statistical analysis software package SPSS 11.5 was used to conduct the Fisher's exact test and χ^2 test. $P < 0.05$ was considered to be statistically significant.

RESULTS

Expression of PI3K protein in CRC

PI3K protein was localized in the cytoplasm of CRC tumor cells; brown granules were detected within the cytoplasm. The expression of PI3K in primary and metastatic lesions in the same patient is shown in Figure 1A and B. The positive PI3K rates were significantly lower in the primary tumors than in the associated metastases: 30% (18/60) *vs* 46.7% (28/60) ($P < 0.05$). Moreover, the positive rate of 10% (1/10) in normal mucosa was significantly lower than in cancer tissue ($P < 0.05$).

Mutational analysis of PIK3CA exon 9 and exon 20 in CRC

PCR products of PIK3CA exon 9 and exon 20 were analyzed by 2% agarose gel electrophoresis (Figure 2). After observing clear and accurately sized bands, amplification products were then purified and directly sequenced on an ABI Prism 3730 sequence detection system. Mutational analysis of PIK3CA was done in 60 primary CRC and 10 normal tissues (Figure 3). Mutation rates of PIK3CA exon 9 and exon 20 were 13.33% (8/60) and 8.33% (5/60) in CRC, respectively. A total of eight mutations were identified (Table 1). All the mutations were not detected in corresponding normal tissues, therefore, these mutations were confirmed as somatic mutations. Of these 13 mutations, eight were clustered in exon 9 and the remain-

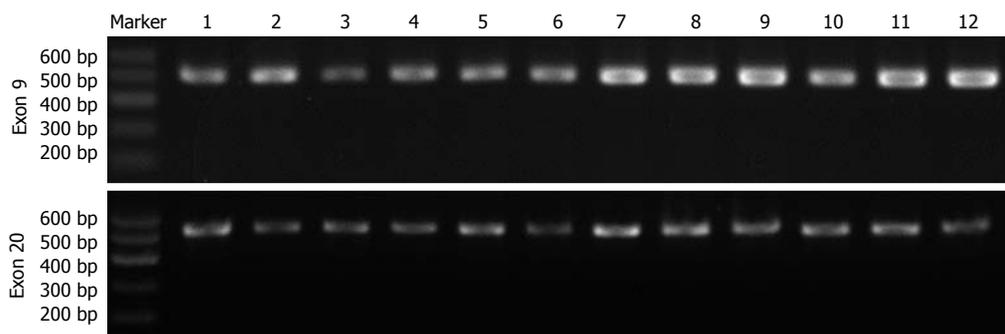

Figure 2 Representative examples (1-12) of 2% agarose gel electrophoresis results of PIK3CA (exon 9) and PIK3CA (exon 20) polymerase chain reaction products.

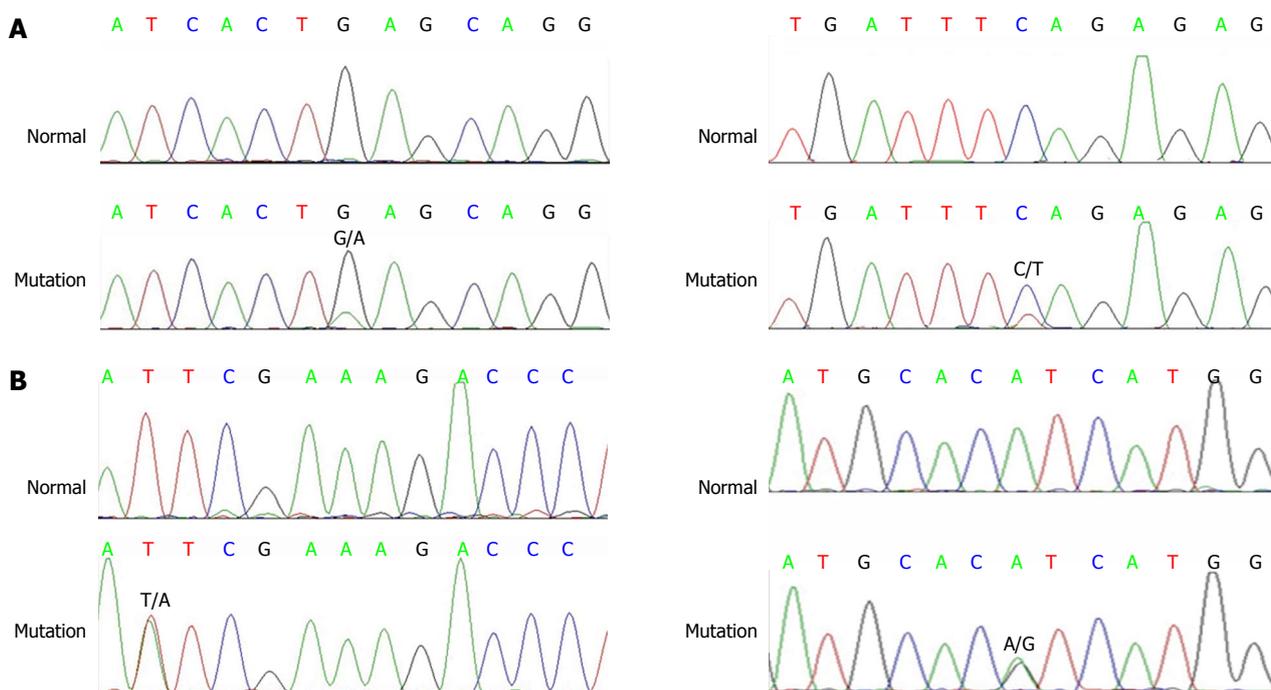

Figure 3 Sequencing traces are shown for exon 9 (A) and exon 20 (B) with cancer mutant sequence (bottom) and normal wild-type sequence (top).

Analysis of PI3K-inhibitor-induced apoptosis in human CRC cells with different metastatic activities

To determine whether the PI3K inhibitor (LY294002)-induced growth inhibition in human CRC cells was associated with metastasis of CRC, SW480 and SW620 cells were treated with PI3K inhibitor. The numbers of apop-

totic cells were assessed using the annexin V-FITC Apoptosis Detection kit by the FACS Aria instrument. Exposure of SW480 cells to PI3K inhibitor for 48 h resulted in a significant increase of apoptotic cells in a dose-dependent manner [3.2% apoptotic cells in 0 μmol/L, 4.3% in 5 μmol/L, 6.3% in 10 μmol/L (*P* < 0.05), and 6.7% in 20 μmol/L (*P* < 0.05)]. Inhibition was also obtained when the SW620 cell lines were exposed to the same PI3K inhibitor for 48 h [3.3% apoptotic cells in 0 μmol/L, 13.3% in 5 μmol/L (*P* < 0.01), 19.2% in 10 μmol/L (*P* < 0.01), and 21.3% in 20 μmol/L (*P* < 0.01)] (Figure 4). PI3K inhibitor, at a concentration of 20 μmol/L, induced apoptosis to a greater extent in SW620 cells, which have higher metastatic potential than SW480 cells.

Effect of PI3K inhibition on AKT phosphorylation in CRC cells with different metastatic activities

To determine the potential effect of PI3K inhibition on AKT phosphorylation, phosphorylated AKT (pAKT)

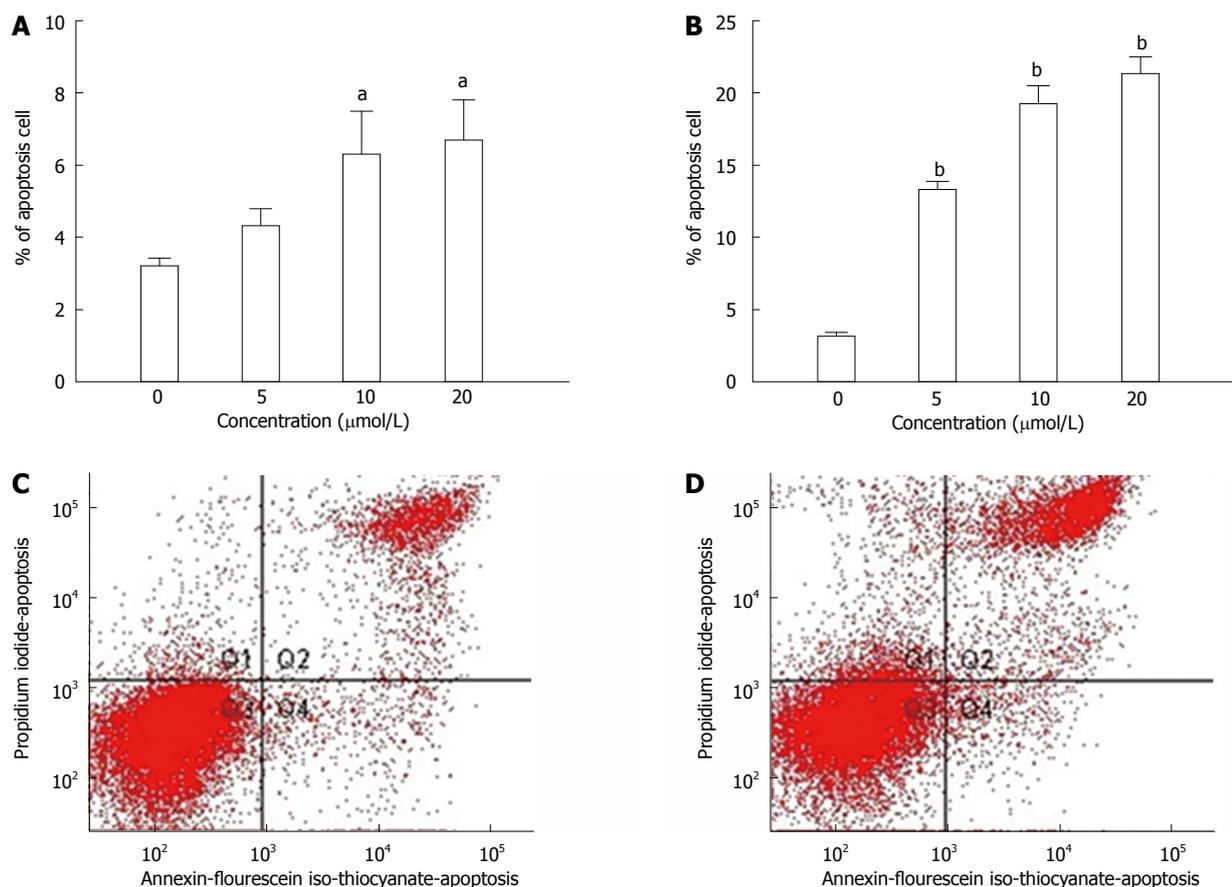

Figure 4 LY294002 induced apoptosis in human colorectal cancer cells with different metastatic activities. Induction of apoptosis in human colorectal cancer cells SW480 (A) and SW620 (B) by LY294002. Cells were exposed to various concentrations of LY294002 for 48 h followed by examination with annexin V-flourescein iso-thiocyanate Apoptosis Detection kit. SW620 cells were exposed to 5 μmol/L (C) and 20 μmol/L (D) LY294002 and analyzed by flow cytometry. All assays were done in triplicate [^a*P* < 0.05, ^b*P* < 0.01 vs control group (0 μmol/L)].

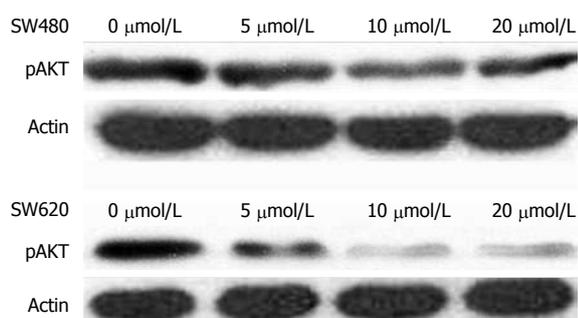

Figure 5 Effect of phosphatidylinositol 3-kinase inhibitors on protein kinase B phosphorylation in colon cancer cells.

was detected using different concentrations of PI3K inhibitors by Western blotting in two colon cancer cell lines with different metastatic activities. As shown in Figure 5, pAKT was detected in cells with 0 μmol/L inhibitor concentration, indicating the constitutive activation of AKT in two colon cancer cell lines. In SW620 and SW480 cells, the level of pAKT gradually decreased as inhibitor concentration gradually increased from 5 μmol/L to 10 μmol/L and 20 μmol/L. In SW620 and SW480 cells, pAKT at high inhibitory concentration was lower than that at low inhibitory concentration. In addition, pAKT

was marginally lower in SW620 than SW480 cells at the same inhibitory concentration. These findings confirmed that this PI3K inhibitor was strongly cytotoxic for highly metastatic CRC cells.

DISCUSSION

It is well known that tumors are often genetically influenced and somatic mutations of oncogenes and tumor suppressor genes are the initiators of the carcinogenic process. The PI3K/AKT signaling pathway has previously been implicated in tumorigenesis; evidence over the past several years suggests a vital role for the PI3K catalytic subunit PIK3CA in human cancers^[25,26]. In this study, we found that the expression of PI3K protein differed between primary and metastatic lesions in CRC. The positive rate of PI3K was higher in metastatic than in primary tumors, indicating that PI3K might be involved in CRC development, progression and metastases. The exact molecular mechanism deserves further study.

To probe the mechanism of PI3K high expression, we investigated the frequency of PIK3CA mutations in CRC and normal tissue adjacent to cancer. Due to the limited number of metastatic samples, PIK3CA mutations in metastases could not be evaluated. Instead, two

previously characterized mutational hotspots, exon 9 and exon 20, were analyzed. PIK3CA mutations were identified in 21.67% of the tumor tissues. No mutations were detected in corresponding normal tissues, therefore, these mutations were confirmed as somatic mutations. We also found that the PI3K mutation rate was less than the expression rate of PI3K protein, indicating that PI3K mutations were not the sole cause of the high expression of PI3K protein in CRC samples.

Of these 13 mutations, eight were clustered in exon 9 and five in exon 20. In the two previously reported hotspots, we identified the point mutations c.1633G>A and c.3140A>G, which resulted in the amino acid substitutions E545A and H1047R, respectively^[27,28]. Previous studies have also shown that mutations are more common in exon 9 in CRC^[14]. We also explored associations between any PIK3CA mutation and other variables, as well as interactions between histological groups, and found no significant correlation with mutation frequency. This does not agree with previous studies^[29], which might be related to the small number of cases in the present study. However, some similar reports have been found in breast cancer research. Dupont Jensen *et al.*^[30] have reported that PIK3CA mutations may be discordant between primary and corresponding metastatic disease in breast cancer, and PIK3CA mutation was detected in 45% of the primary tumors; and there was a net gain in mutation in metastatic disease, to 53%. Nonetheless, there were instances where metastases were wild type in patients with PIK3CA mutant primary tumors. Thus, we believe that PIK3CA is altered between primary and metastatic disease, and it is necessary to assess the PIK3CA status in the metastatic lesions to select patients that would benefit from PIK3CA inhibitor treatment.

To remedy the problem that PIK3CA mutations in metastases were not evaluated due to the limited number of metastatic samples, we further investigated the effect of PI3K inhibitor on human CRC cells with different metastatic activities. We found that PI3K inhibitor (LY294002) induced growth inhibition in human CRC cells, which was associated with the induction of apoptosis. The number of apoptotic cells in SW620 cell line was obviously increased compared with that in SW480 after LY294002 (20 $\mu\text{mol/L}$) treatment. Other research has confirmed that LY294002 has a strong sensitizing effect similar to boswellic-acid-induced apoptosis in colon cancer cells, and inhibits bone-morphogenetic-protein-2-induced epithelial-mesenchymal transition and invasion^[31,32]. Our results indicate that PI3K inhibitor induced different levels of apoptosis in cell lines with various metastatic capabilities, which suggests that PI3K is involved in the process of CRC metastasis. PIK3CA mutation and subsequent activation of the AKT pathway play an important role in colorectal carcinogenesis^[29]. Therefore, we also investigated the influence of LY294002 on AKT activation in our study. We found that LY294002 (5 $\mu\text{mol/L}$, 10 $\mu\text{mol/L}$ or 20 $\mu\text{mol/L}$) inhibited the phosphorylation of AKT significantly in two colon cancer cell lines, SW620 and SW480. PI3K inhibitor may have

potential for the treatment of metastatic CRC. It is worth investigating further the relationship among the death receptors Fas, tumor necrosis factor-related apoptosis-inducing ligand receptor (TRAILR)1, TRAILR2 and PI3K. These experiments are planned in our future work.

In summary, our results suggest that activation of the PI3K pathway plays an important role in colorectal tumor metastasis, and PI3K mutation is likely to be involved in promoting tumor invasion. However, PI3K mutation rate was not in accordance with the expression rate of PI3K protein, indicating that PI3K mutations were not the unique cause leading to the high expression of PI3K protein in CRC samples. PI3K inhibitors might become a new therapeutic method for CRC metastasis. However, the association between exon 9 and exon 20 mutations and the risk of CRC progression needs further investigation of a larger number of samples. In addition, the upstream and downstream genes of the PI3K/AKT pathway including insulin-like growth factor 1 receptor and ligand, phosphatidylinositol-3,4,5-triphosphate (PIP3), phosphatase and tensin homolog deleted on chromosome 10 (PTEN), mammalian target of rapamycin complex 2 and pyruvate dehydrogenase kinase warrant further study.

COMMENTS

Background

Colorectal cancer (CRC) is the second leading cause of cancer-related death in the United States. The majority of these deaths are due to metastatic disease. The phosphatidylinositol 3-kinase (PI3K)/protein kinase B signaling pathway is an important regulator of cell growth, metabolism, proliferation, survival, motility, and invasion. This pathway is activated in multiple cancers. It is of important to identify expression of PI3K protein in both primary and metastatic lesions to understand better the molecular mechanism of CRC, and evaluate PI3K inhibitors as a new treatment method for metastatic CRC.

Research frontiers

The expression of PI3K in primary CRC and metastatic tissues remains unclear. The differential effects of PI3K inhibition in CRC cell lines with various metastatic capabilities have been less well reported.

Innovations and breakthroughs

This is an important study that validates the hypothesis that activation of the PI3K pathway might play a role in CRC metastasis, and PI3K inhibitors should be evaluated as new candidates for the treatment of metastatic CRC.

Applications

These results suggest that the PI3K/AKT signaling pathway plays an important role in colorectal tumor metastasis. However, the PI3K mutation rate was not in accordance with the expression rate of PI3K protein, indicating that PI3K mutations were not the unique cause of the high expression of PI3K protein in CRC. PI3K inhibitor was strongly cytotoxic for cells with high metastatic ability, making PI3K targeting a new therapeutic candidate for the treatment of CRC metastasis. Further bioinformatics and functional studies using a large number of patient specimens will further determine the significance of these genes in CRC pathogenesis.

Terminology

Flow cytometry (FCM) is a technique used to analyze cells rapidly and individually, and it allows for the quantitative analysis of distributions of a property or properties in a population. FCM has been a fundamental tool for biological dis-

covery in recent years. It offers many advantages over conventional measurements for the analysis of biological cells, and it is a generally accepted tool to analyze apoptotic cells.

Peer review

The intention of the authors is to focus on the PI3K/AKT pathway. This pathway is indeed very interesting concerning oncogenesis.

Abstract

AIM: To evaluate the efficacy and safety of a hybrid bioartificial liver (HBAL) system in the treatment of acute liver failure.

METHODS: Canine models with acute liver failure were introduced with intravenous administration of D-galactosamine. The animals were divided into: the HBAL treatment group ($n = 8$), in which the canines received a 3-h treatment of HBAL; the bioartificial liver (BAL) treatment group ($n = 8$), in which the canines received a 3-h treatment of BAL; the non-bioartificial liver (NBAL) treatment group ($n = 8$), in which the canines received a 3-h treatment of NBAL; the control group ($n = 8$), in which the canines received no additional treat-

ment. Biochemical parameters and survival time were determined. Levels of xenoantibodies, RNA of porcine endogenous retrovirus (PERV) and reverse transcriptase (RT) activity in the plasma were detected.

RESULTS: Biochemical parameters were significantly decreased in all treatment groups. The TBIL level in the HBAL group was lower than that in other groups ($2.19 \pm 0.55 \mu\text{mol/L}$ vs $24.2 \pm 6.45 \mu\text{mol/L}$, $12.47 \pm 3.62 \mu\text{mol/L}$, $3.77 \pm 1.83 \mu\text{mol/L}$, $P < 0.05$). The prothrombin time (PT) in the BAL and HBAL groups was significantly shorter than the NBAL and control groups (18.47 ± 4.41 s, 15.5 ± 1.56 s vs 28.67 ± 5.71 s, 21.71 ± 3.4 s, $P < 0.05$), and the PT in the HBAL group was shortest of all the groups. The albumin in the BAL and HBAL groups significantly increased and a significantly higher level was observed in the HBAL group compared with the BAL group (27.7 ± 1.7 g/L vs 25.24 ± 1.93 g/L). In the HBAL group, the ammonia levels significantly decreased from 54.37 ± 6.86 to 37.75 ± 6.09 after treatment ($P < 0.05$); there were significant difference in ammonia levels between other the groups ($P < 0.05$). The levels of antibodies were similar before and after treatment. The PERV RNA and the RT activity in the canine plasma were all negative.

CONCLUSION: The HBAL showed great efficiency and safety in the treatment of acute liver failure.

bioartificial liver based on a multi-layer flat-plate bioreactor. *World J Gastroenterol* 2012; 18(28): 3752-3760 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i28/3752.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i28.3752>

INTRODUCTION

The mortality associated with acute liver failure or acute-on-chronic liver failure remains dismally high^[1]. Orthotopic liver transplantation is a unique and effective treatment for acute liver failure^[2]. However, many patients still die while waiting for liver transplantation due to a persistent scarcity of donors. Therefore, many investigators have attempted to develop diversified extracorporeal liver assist devices as a bridge for patients until recovery or liver transplantation^[3-5]. Extracorporeal liver assist devices can be classified into artificial systems and bioartificial systems. An effective liver assist device should include three primary functions: detoxification, biosynthesis and regulation. The main functions of artificial systems include the removal of toxins (e.g., aromatic amino acids and ammonia), but does not include the synthesis of products that take place in the liver. Bioartificial systems could be the ideal replacement therapy in the long run. However, bioartificial liver systems have not reached their full efficiency yet, since enhancing the viability and functions of hepatocytes in the bioreactor remains a difficult problem, and the function of detoxification is inadequate^[6-8]. For these reasons, we consider the application of artificial systems in combination with bioartificial liver systems presents a potential method for aiding patients waiting for liver transplantation.

In this study, we first developed a newly bioartificial liver system based on multi-layer flat-plate bioreactor with co-cultured pig hepatocytes and bone marrow mesenchymal stem cells, so as to mimic the microenvironment *in vivo*. We then combined this newly bioartificial liver system with an anionic resin adsorption column to form a novel hybrid bioartificial liver (HBAL) system. The efficacy and safety of this novel HBAL system was evaluated *via* treatment of canines with acute liver failure.

MATERIALS AND METHODS

Animals and reagents

Outbred white pigs with a weight of 15-20 kg, as well as dogs with a weight of 10-15 kg, received humane care. All animal procedures were performed according to institutional and national guidelines and approved by the Animal Care Ethics Committee of Nanjing University and Nanjing Drum Tower Hospital. RPMI 1640 were purchased from GIBCO (United States). Lactobionic acid and chitosan (low molecular weight, Brookfield viscosity 20 000 cps, 85% deacetylation) were purchased from Sigma-Aldrich (Saint Louis, United States). N-Hydroxysuccinimide was purchased from Thermo-Pierce (Rockford,

United States). 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide and N, N, N', N'-tetramethylethylenediamine were obtained from TCI (Tokyo, Japan). Polyethylenoxid (M_w ≈ 10⁶) was supplied by Guoren Chemical Co. (Beijing, China). All other reagents were of analytical reagent grade.

Cell isolation and culture

Porcine mesenchymal stem cells were isolated by bone marrow aspirates from the iliac crest of pigs, as described previously, with slight modification^[9]. Briefly, mononuclear cells were collected by gradient centrifugation over a Ficoll Histopaque layer (20 min, 400 g, density 1.077 g/mL) and seeded at a density of 1 × 10⁶ cells/cm² in growth medium containing low-glucose Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum, penicillin (100 IU/mL) and streptomycin (100 µg/mL). The non-adherent cells were removed after the first 24 h and changed every 3 d to 4 d thereafter. The primary pig hepatocytes were then harvested by a two-step *in situ* collagenase perfusion technique^[10]. The viability of the isolated primary hepatocytes, determined by trypan blue exclusion, was more than 95%.

Non-bioartificial liver system

Whole blood was removed at a rate of 30 mL/min from the jugular vein of the canine and separated to plasma by a plasma separator (Bellco, Italy) at a rate of 30 mL/min. The separated plasma was pumped into an anionic resin adsorption column (Aier, China) where the toxic substances were absorbed, and then reconstituted with red blood cells and returned to the canine *via* the venous cannula (Figure 1A).

Bioartificial liver system

Bioreactor configuration: The multi-layer bioreactor consisted of housing, a hollow column stent, and stacked flat plates, all of which were made of polycarbonate. The fully assembled bioreactor contained a stack of 65-layer round flat plates, on which galactosylated chitosan nanofiber scaffolds were electrospun for hepatocyte immobilization and aggregation. The diameter and thickness of each plate were 10.4 cm and 1 mmol, respectively. There was a hole with a diameter of 1 cm in the center of each plate, which was used to fix them onto the stent. The channel height between every two neighboring plates was maintained at 0.5 mmol with the spacers attached to the bottom of each plate. The stent was open on the top and closed at the bottom, with four vertical-side holes on the lateral wall, which were broken up into eyelets between every two plates. The last component was housing, which was a cylindrical container with an outlet on the bottom. When the stacked plates were fixed onto the stent, they were put into the housing, and the lid with an O-ring was screwed onto the housing in order to provide a water tight seal. The culture medium entered the bioreactor from the top opening of the stent, then flowed onto the surface of each flat plate through the eyelets, and

finally flowed out from the outlet of housing. The height of this bioreactor was about 10 cm, and the effective volume was 480 mL.

The multi-layer flat-plate bioartificial liver consists of a cell circuit and a blood circuit. Freshly isolated porcine

hepatocytes (approximately 10^{10}) were pre-mixed in 480 mL RPMI 1640 culture medium containing 10% BSA, 0.5 mg/mL insulin, 10 mmol NaHCO_3 , 50 mg/mL penicillin and streptomycin, and 100 mg/mL neomycin. The medium was then filled into the bioreactor by a peristaltic pump (JHBP-2000B, Guangzhou, China). The whole bioreactor was incubated for 1 h at 37 °C and 5% CO_2 until the cells were adhered onto the surface of plates. The culture medium was pumped through an oxygenator (Affinity, United States) via Fresenius silicone tubing (Fresenius, Germany) by a peristaltic pump before flowing into the bioreactor, and then circulated into a blood component exchange column (Asahi Kasei Corporation, Japan) at 25 mL/min, which constitute the cell circuit. As for the blood circuit, whole blood was removed at a rate of 30 mL/min from the jugular vein of the canine and separated to plasma by a plasma separator (Bellco, Italy) at a rate of 15 mL/min. The separated plasma was pumped into the blood component exchange column where the plasma component and culture medium component exchanged, and then reconstituted with red blood cells and returned to the canine via the venous cannula (Figure 1B).

HBAL system

We combined the bioartificial liver system with an anionic resin absorption column to form a novel HBAL system. This HBAL system differs from the bioartificial liver system in that the separated plasma was pumped into an anionic resin adsorption column where the toxic substances were absorbed, and then passed through the blood component exchange column (Figure 1C).

Canine models of acute liver failure and treatment groups

The canines were injected intravenously with D-galactosamine to induce acute liver failure and then randomly divided into 4 groups: the HBAL system treatment group ($n = 8$), in which the canines received a 3 h treatment of HBAL system (as described above) 24 h after the administration of the drug; the bioartificial liver system treatment group ($n = 8$), in which the canines received a 3 h treatment of bioartificial liver system; the non-bioartificial liver system (artificial support system) treatment group ($n = 8$), in which the canines received a 3 h treatment of artificial support system; the control group ($n = 8$), in which the canines received no additional treatment.

Blood biochemistry and survival rate

Blood samples were measured with an automatic analyzer (Hitachi 7600, Tokyo, Japan) for alanine aminotransferase (ALT), aspartate aminotransferase (AST), lactate dehydrogenase (LDH), total bilirubin (TBIL), albumin (ALB), ammonia, and prothrombin time (PT). Survival was observed for 7 d.

Safety evaluation

Levels of xenoantibodies (IgG, IgM) were detected by

enzyme linked immunosorbent assay (ELISA) kit (Alpha Diagnostic International Inc., United States). To identify the transmission of porcine endogenous retroviruses (PERVs), the PERV RNA and reverse transcriptase (RT) activity in the plasma was detected with reverse transcription-polymerase chain reaction (RT-PCR) and RT activity assay kits (Cavidi-Tech, Uppsala, Sweden), respectively.

Statistical analysis

All values were expressed as the mean ± SD. The two-tailed unpaired Student's *t*-test or one-way analysis of variance was used to evaluate the statistical significance of differences, which were set with a *P* value < 0.05. The survival rates were analyzed using the Kaplan-Maier method and compared using a log-rank test.

RESULTS

Common conditions

After treatment, hepatic encephalopathy was significantly improved in all treatment groups; most of the canines could stand, eat and drink by themselves. However, the canines in the control group became gradually worse, progressing into a coma and eventually death. Body temperature was stable in all treatment groups (38 ± 0.5 °C in non-bioartificial liver (NBAL) group; 37 ± 1 °C in bioartificial liver (BAL) group; 38 ± 0.8 °C in HBAL group); however, the canines in the control group became lower than other groups.

Liver function parameters

Several laboratory parameters have been determined,

such as ALT, AST, LDH, TBIL, ALB, PT and ammonia. As Table 1 and Figure 2 show, there was no significant difference between any of the groups before treatment. In all treatment groups, ALT, AST, LDH, TNIL and ammonia were shown to be statistically decreased compared to the control group. Moreover, the TBIL level in the HBAL group was lower than that in the other groups (2.19 ± 0.55 μmol/L *vs* 24.2 ± 6.45 μmol/L, 12.47 ± 3.62 μmol/L, 3.77 ± 1.83 μmol/L, *P* < 0.05). There was no significant difference in PT and ALB between the NBAL and control groups. On the contrary, the PT in the BAL and HBAL groups was significantly shorter than in the NBAL and control groups (18.47 ± 4.41 s, 15.5 ± 1.56 s *vs* 28.67 ± 5.71 s, 21.71 ± 3.4 s, *P* < 0.05), and the PT in the HBAL group was the shortest of all the groups. The ALB in the BAL and HBAL groups significantly increased and a significantly higher level was observed in the HBAL group compared with the BAL group (27.7 ± 1.7 g/L *vs* 25.24 ± 1.93 g/L). In the HBAL group, ammonia levels significantly decreased from 54.37 ± 6.86 to 37.75 ± 6.09 after treatment (*P* < 0.05); there were significant differences in ammonia levels between the other groups (*P* < 0.05).

Animal survival

Analysis of survival curves (Figure 3) showed that the 7 day survival rate was 37.5% (3/8) in the control group, 50% (4/8) in the NBAL group, 62.5% (5/8) in the BAL group and 87.5% (7/8) in the HBAL group. Survival time was significantly prolonged by HBAL treatment (*P* = 0.028). However, the results showed there was no significant difference between the other groups.

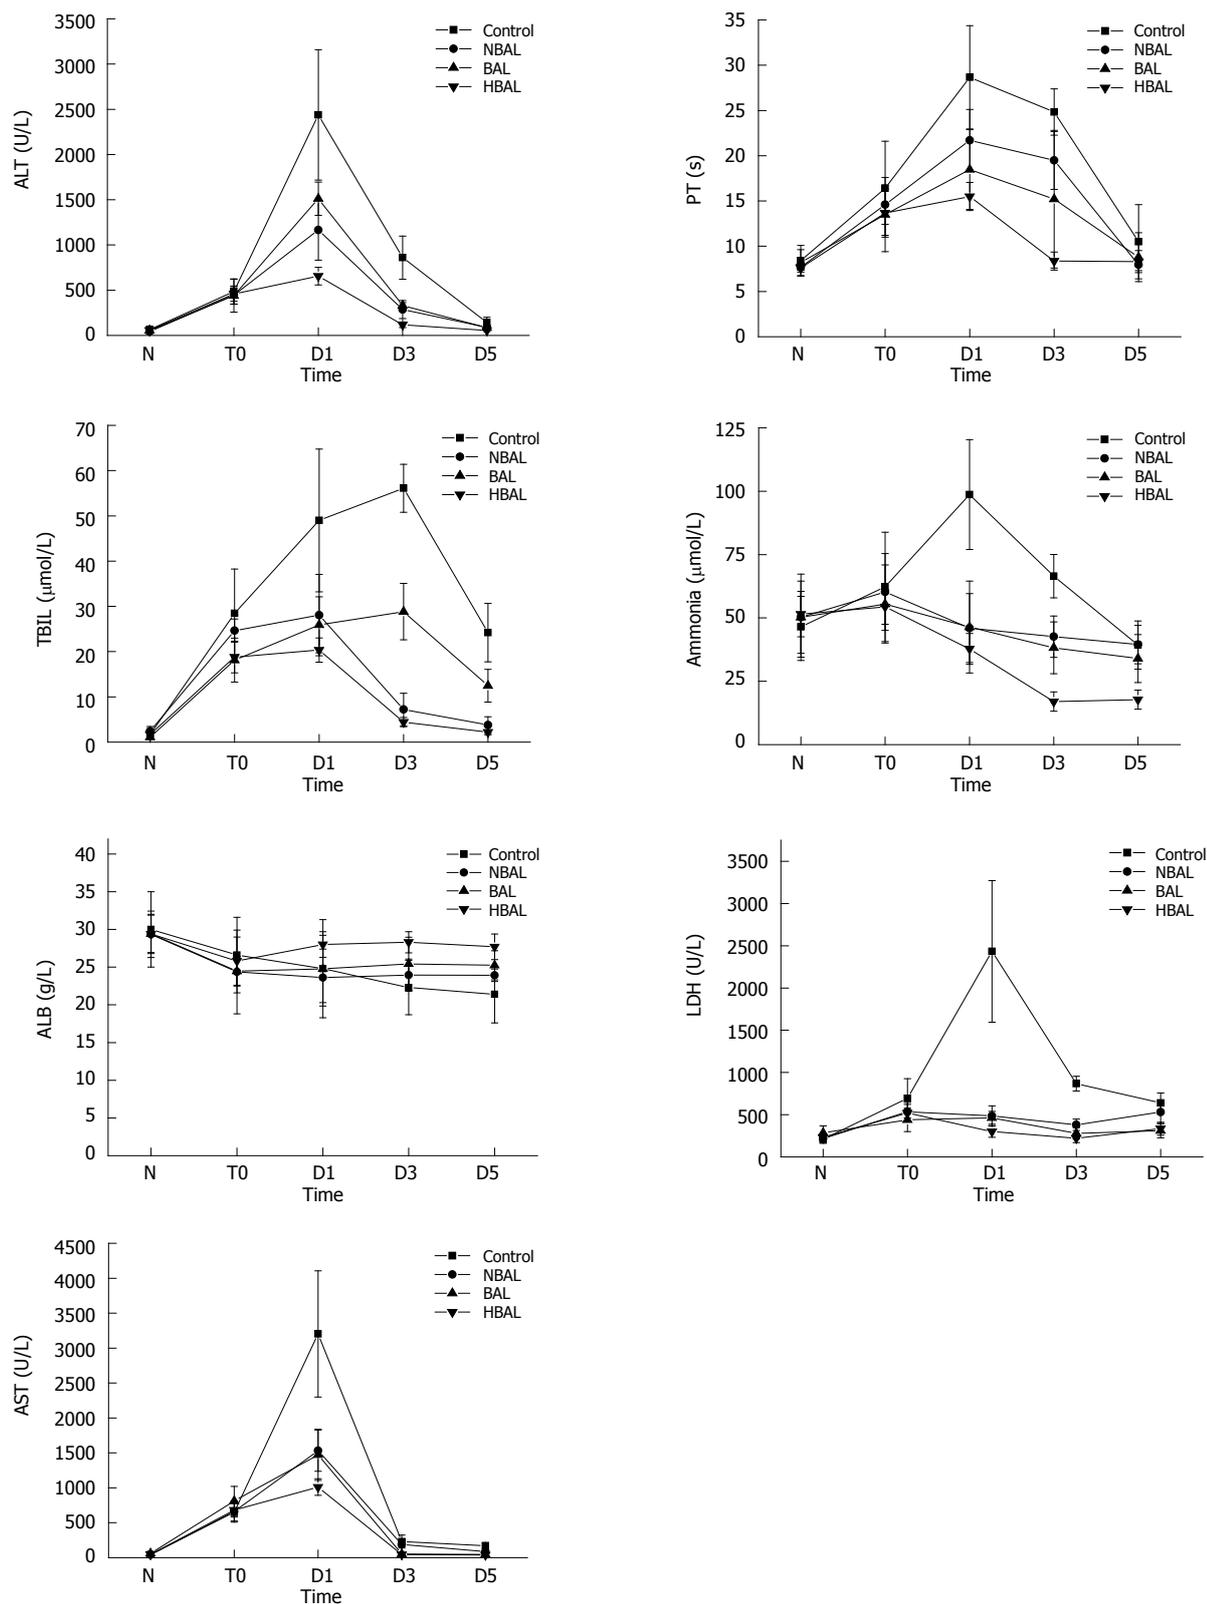

Figure 2 Comparisons of biochemical index between the treatment groups and the control group. Safety evaluation

To evaluate the humoral immune response in canine models after treatment with BAL, we examined the levels

of antibodies. The levels of antibodies were measured by ELISA in canine plasma obtained before and after BAL. As shown in Figure 4A, immediately after the first

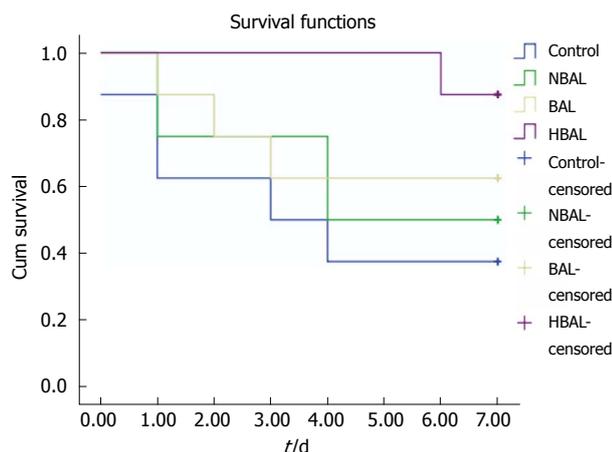

Figure 3 Kaplan-Meier analysis of survival of two groups. HBAL: Hybrid bioartificial liver; BAL: Bioartificial liver; NBAL: Non-bioartificial liver.

BAL treatment, the levels of IgG and IgM were suitable before and after treatment. All results of RT-PCR with the RNA from collected plasma were negative (Figure 4B). In addition, the RT activity in the canine plasma was negative as well.

DISCUSSION

In recent years, extracorporeal liver assist devices have been developed and widely used to bridge the gap between for patients until liver transplantation or a spontaneous recovery of liver function. There are currently two types of liver assist devices: artificial and bioartificial livers. Artificial liver systems include conventional plasmapheresis with plasma exchange, hemodialysis using large pore membranes and hemoperfusion using exchange resin columns or activated charcoal^[11-13]. These systems could remove toxic substances (e.g., ammonia, endotoxin, mercaptans and endogenous inhibitor neurotransmitters) but also some helpful cytokines, such as interleukin-6, hepatocyte growth factor. Moreover, these devices could not replace the synthetic and metabolic functions, nor could they prolong patient survival time. Bioartificial liver systems could replace the primary and most important liver functions, such as oxidative detoxification, biotransformation, excretion and synthesis. However, there are still many problems holding back the development of bioartificial livers in a clinical setting. How to maintain the functions of hepatocytes and mimic cell microenvironment *in vitro* remains a difficult problem. In addition, plasma from patients with acute liver failure have some toxic factors, which are harmful to the hepatocytes in the bioreactor. In the present study, to resolve these problems, we first developed a new bioartificial liver system based on a multi-layer flat-plate bioreactor with co-cultured pig hepatocytes and bone marrow mesenchymal stem cells.

Due to the short-term viability and rapid phenotypic de-differentiation of primary hepatocytes *in vitro*, mimicking the three-dimensional microenvironment of

Figure 4 Safety evaluation. liver sinusoid *in vitro* should be important for reconstruction of tissue architectures and restoration of isolated hepatocyte functions. Recent studies have shown that functions of primary hepatocytes can be maintained by co-culturing with non-parenchymal cells^[14,15]. The interaction between cells and the extracellular matrix (ECM) provides direct regulatory signals to cells through adhesion. In addition, various soluble factors secreted

by mesenchymal cells have been shown to be important in maintaining hepatocyte phenotypes. In our previous study, we confirmed that the morphology and functionality of co-culturing such heterotypic cells were well-maintained and improved over hepatocytes homo-culture^[16,17]. Therefore, in this study, we adopted co-cultured porcine hepatocytes and bone marrow mesenchymal stem cells as the cell resource.

Hepatocytes *in vivo* are exposed to sinusoidal endothelial cells mediated by Disse space filled with ECM, which consists of a complex topography in the nanometer range and functional proteins that provide signals regulating cellular functions through cell surface receptors. In order to mimic the topography of ECM, various materials have been fabricated into nanometer materials and proven to affect cell migration, adhesion, proliferation and other cellular behaviors^[18]. In the past decade, nanometer scaffolds have been widely applied in various areas of tissue engineering. In our previous study, galactosylated chitosan nanofiber scaffolds could adequately mimic the topography of ECMs *in vitro* and increase the contact sites between cells and materials, thus enhancing the signal transduction between cells, promoting cell functions, and the pseudopod of hepatocytes could be formatted on the scaffolds, which further facilitated cells to adhere tightly to the nanofiber surface, and enhance cell adhesion and viability. Moreover, the galactose group grafted onto the scaffold could selectively adhere to the asialoglycoprotein receptors on the surface of hepatocytes, which could then induce the formation of hepatocyte aggregates and exhibit higher levels of liver-specific functions^[19,20]. Based on these results, we introduced galactosylated chitosan nanofiber scaffolds into the bioreactor to mimic the topography and biochemical environment of ECMs.

Bioreactors can be divided into four types: (1) hollow fibers (e.g., the HepatAssist system and the Extracorporeal Liver Assist Device, which suffer from oxygen substrate limitations^[21-23], and so a large proportion of hepatocytes may be anoxic and lose their functions); (2) beds or scaffolds (the major disadvantage of which is the direct contact between plasma and porcine liver cells, and so there is no barrier for porcine pathogens^[24,25]); (3) suspension and encapsulation chambers; and (4) flat plate and monolayer cultures. As one classical type of bioreactor, flat-plate bioreactors have many advantages^[26-28]. Firstly, the cells can adhere to the plates evenly and therefore making the microenvironment homogeneous. Secondly, the culture medium/plasma can make contact with seeded cells adequately, which allows sufficient material exchange. Thirdly, the bioreactor can be easily scaled up by adjusting the flat plates to meet the clinical requirements. Finally, the structure of multi-layer flat plates is similar to that of hepatic plates of a normal liver, which is crucial for the long-term maintenance of liver functions.

A successful liver support system is likely to depend on the viability and functions of the hepatocytes in the bioreactor. Previous research has shown that the toxic

substances of acute liver failure plasma can damage the hepatocytes^[29]. In our study, in order to reduce the damage to the hepatocytes caused by the toxic substances in acute liver failure plasma and improve the efficacy of the treatment, we combined bioartificial liver system with an anionic resin absorption column to form a novel HBAL system. An anionic resin absorption column was used before the bioreactor, which may not only protect the co-culture cells in the bioreactor from toxic effect of acute liver failure plasma, but also improve the effect of plasma detoxification.

In this study, we found that the ALT, AST, LDH, TBIL and ammonia in HBAL group appeared to be statistically decreased compared to the control group. Furthermore, the TBIL level in the HBAL group was lower than that in other treatment groups. In addition, the ALB in the BAL and HBAL groups significantly increased, and a significantly higher level was observed in the HBAL group as compared with the BAL group. The survival rate of the HBAL group was higher than in the other treatment groups and the control group. This result suggests that HBAL significantly prolonged the survival time of the canine models with acute liver failure. These data indicate that the performance of this novel HBAL system may be superior to that of the simple BAL systems.

The main recognized disadvantages of the use of porcine hepatocytes are the risk of infection of PERV and immunological rejection. Previous reports have shown that PERV successfully infected a variety of human cells *in vitro*, such as endothelial cells, fibroblasts and bone marrow stromal cells^[30-32]. Moreover, Wilson found that implanted porcine islets may lead to PERV infection in non-obese diabetic severe combined immunodeficiency mice^[33]. On the other hand, elevated titers of xenoantibodies have been found after treatment with porcine-based BAL systems, indicating that host exposure to porcine antigens occurs^[34]. In our study, the PERV RNA and RT activity in the canine plasma were all negative. No direct evidence of severe immunological complications were observed. Our results were similar to other reports^[35,36].

In conclusion, This novel HBAL system showed great efficiency and safety in the treatment of canines with acute liver failure and seemed to be applied in a clinical setting.

COMMENTS

Background

Orthotopic liver transplantation is a unique and effective treatment for acute liver failure. However, due to severe donor-liver shortage, high cost and exacerbation of disease, many patients die before they can receive the operation. Therefore, bioartificial livers have been proposed as temporary liver support for patients awaiting liver transplantation. However, bioartificial liver systems have not reached their full efficiency yet, since a method to enhance the viability and functions of hepatocytes in the bioreactor remains a difficult problem, and the function of detoxification is inadequate.

Research frontiers

Nowadays, various types of bioartificial liver are applied in clinic, and obtain

satisfactory curative effects. However, in a bioartificial liver, the problem remains as to how it would be possible to enhance the viability and functions of hepatocytes in the bioreactor.

Innovations and breakthroughs

In this study, the authors first developed a new bioartificial liver system based on a multi-layer flat-plate bioreactor with co-cultured pig hepatocytes and bone marrow mesenchymal stem cells so as to mimic the microenvironment *in vivo*. They then combined this new bioartificial liver system with an anionic resin absorption column to form a novel hybrid bioartificial liver (HBAL) system. An anionic resin absorption column was used before the bioreactor, which may not only protect the co-culture cells in the bioreactor from toxic effect of acute liver failure plasma, but also improve the effect of plasma detoxification.

Applications

The study results suggest that the HBAL showed great efficiency and safety in the treatment of acute liver failure.

Terminology

BAL: An artificial extracorporeal supportive device in which patient plasma is circulated extracorporeally through a bioreactor. The bioreactor houses metabolically active liver cells (hepatocytes) between artificial plates or capillaries. The functions of the liver are principally carried out by hepatocytes. The goal is to develop bioartificial liver devices in which hepatocytes are optimally maintained so that they carry out as many activities as possible.

Peer review

This is a good descriptive study in which authors evaluate the efficacy and safety of a HBAL system in the treatment of acute liver failure. The results are interesting and suggest that the HBAL could be used in the treatment of acute liver failure.

Abstract

Type IV-A choledochal cysts (CCs) are a congenital biliary anomaly which involve dilatation of the extrahepatic and intrahepatic bile ducts. We present the case of a 30-year-old woman with type IV-A CC, on whom three-dimensional computed tomography (3D CT) and virtual endoscopy were performed. 3D CT revealed partial dilatation in the posterior branch of the intrahepatic bile duct and a relative stricture between it and the extrahepatic bile duct. Virtual endoscopy showed that this stricture was membrane-like and separated from the surrounding blood vessels. Based on these image findings, complete cyst resection, bile duct plasty for the stricture, and hepaticojejunostomy were safely performed. To the best of our knowledge, there are no reports of imaging by virtual endoscopy of the biliary tract which show the surrounding blood vessels running along the bile duct.

INTRODUCTION

Choledochal cysts (CCs), namely, congenital bile duct dilatation, are high-risk factors for biliary tract cancer^[1,2]. Almost all cases of type I and type IV-A CCs are associated with pancreaticobiliary maljunction, and preventative diversion surgery is performed even without the presence of cancer^[3]. Type IV-A CCs involve dilatation of the extrahepatic and intrahepatic bile ducts, and relative stricture at the junction of both is often observed. If this stricture is left alone, several complications, including cholangitis, hepatolithiasis, and cholangiocarcinoma may occur after surgery. Therefore, bile duct plasty for stricture or bile duct resection which includes the stricture site is required^[4,5]. Moreover, if the stricture or cyst is present in the intrahepatic bile duct, hepatectomy is required to remove these lesions^[4,6]. Accordingly, for type IV-A CCs, a thorough examination of the biliary tract is necessary before surgery. Recently, three-dimensional (3D) imaging and virtual endoscopy based on computed tomography (CT) or magnetic resonance images have often been used for the evaluation of biliary tract anatomy and disease detection^[7-10]. Here, we report a case of type IV-A CC in which the condition of the bile duct stricture and blood

Figure 1 Percutaneous transhepatic bile duct drainage cholangiography demonstrating a cystic dilatation of the common bile duct and relative stricture (arrow) between the extrahepatic and intrahepatic bile ducts.

vessels running along the CC were confirmed by 3D CT imaging and virtual endoscopy, and surgery was safely performed.

CASE REPORT

A 30-year-old woman was admitted to a local hospital because of cholangitis during late pregnancy. Since marked dilatation of the common bile duct and jaundice were observed, she underwent percutaneous transhepatic bile duct drainage (PTCD). She was given a diagnosis of type IV-A CC with pancreaticobiliary maljunction and was transferred to our department for surgery. We performed cholangiography by injecting a contrast medium *via* a PTCD tube, and imaging data at 1 mm intervals obtained by multislice CT was evaluated using a 3D image analytic system (Synapse Vincent FN-7941; Fuji Film Medical Co., Ltd., Tokyo, Japan).

PTCD cholangiography and endoscopic retrograde cholangiopancreatography (ERCP) revealed marked cystic dilatation in the common bile duct (Figure 1). The end of the common bile duct was obstructed, and communication between the bile duct and the side of the papilla was not observed. Moreover, stricture was found in the transition site, which was assumed to be between the left hepatic duct and the intrahepatic bile duct. On a 3D image of the biliary tract, no dilatation in the anterior branch or the lateral branch of the intrahepatic bile duct, and no relative stricture of the extrahepatic bile duct were observed. However, the posterior branch showed partial dilatation in the transition site from the extrahepatic bile duct, and relative stricture was observed in the transition site, but with no stricture or dilatation in the peripheral bile duct (Figure 2).

A virtual endoscopic image of the biliary tract showed no stricture in the orifice of the anterior branch, but the presence of a membrane-like stricture in the orifice of the posterior branch was confirmed (Figure 3A). Furthermore, when this image was overlapped with blood vessel images obtained by 3D imaging, the distribution of a blood vessel system around the biliary tract was clearly

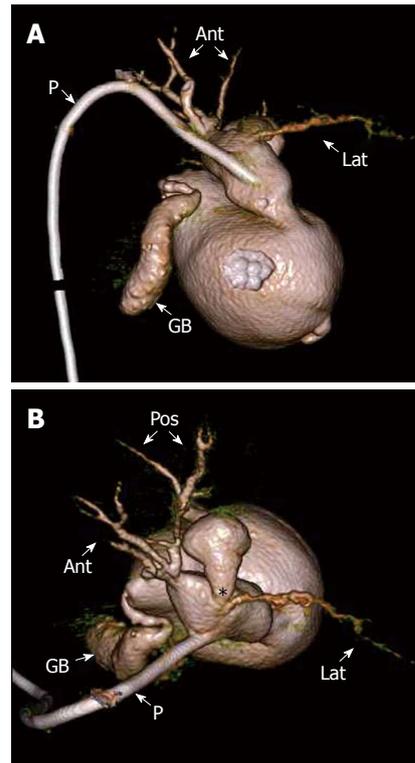

Figure 2 Three-dimensional image. A: Three-dimensional (3D) frontal image demonstrating no stricture or dilatation of the anterior and lateral branches of the bile duct; B: 3D head image showing a relative stricture (*) and partial dilatation of the posterior branch of the bile duct. P: Percutaneous transhepatic bile duct drainage tube; GB: Gallbladder; Ant: Anterior branch; Pos: Posterior branch; Lat: Lateral branch.

observed. This image showed that blood vessels did not run in the membrane-like stricture (Figure 3B).

During surgery, the gallbladder and dilated extrahepatic bile duct were removed. Next, the membrane-like stricture of the posterior branch was cut by several mm, and each cut end was sutured with 2 stitches of 5-0 absorbable sutures. This alleviated the relative stricture, and the orifice of the posterior branch expanded sufficiently (Figure 4). Finally, the bile ducts on the hepatic side and jejunum were anastomosed. In the histopathological findings of the resected specimen, chronic inflammation and hyperplasia of the gallbladder and bile duct were observed, but no malignancy was observed. One year after surgery, no complications, including cholangitis or hepatolithiasis, have been observed.

DISCUSSION

3D imaging and virtual endoscopy based on reconstructed CT images have been performed since the early 1990s, and have been applied in various fields. Initially, the images obtained were comparatively rough because they were taken from helical CT^[7], but with the introduction of multislice CT, it has become possible to obtain images almost as clear as those obtained in cholangioscopy^[8]. This imaging modality has 93% sensitivity in visualizing the biliary tract, 90% sensitivity in visualizing CCs, and 93%

Figure 3 Virtual cholangioscopy. Figure 4 Operative findings. A: A membrane-like stricture, which was cut along the arrow line; B: Bile duct plasty was safely performed.

sensitivity in the diagnosis of lithiasis^[11]. Conventionally, ERCP is considered to be the best imaging modality for CCs, but its application has become less with the appearance of virtual endoscopy^[11]. One reason for this is that ERCP is invasive and poses the risk of complications including bleeding, cholangitis or pancreatitis. Moreover, if there is partial or complete obstruction of the bile duct, imaging of the peripheral bile duct may also be poor. Furthermore, since a high volume of contrast medium is needed to visualize CCs, there is a risk of missing small lesions in the biliary mucosa. In the present case, since the end of the common bile duct was completely obstructed, neither ERCP nor direct cholangioscopy could be performed. PTCD cholangiography revealed that there was a relative stricture in the transition site, which was assumed to be present between the left hepatic duct and the intrahepatic bile duct, but was clearly shown in the posterior branch of the bile duct by 3D imaging and virtual endoscopy. These results indicate that 3D imaging and virtual endoscopy can be very useful in understanding the anatomy of the biliary tract.

The basic surgical treatment for type IV-A CCs is as follows^[4,12]: (1) the gallbladder and extrahepatic bile duct portions with high carcinogenetic risk are completely removed; (2) if the transition site of the extrahepatic bile

duct and intrahepatic bile duct is narrow, bile duct plasty for stricture is performed; (3) if stricture or dilatation is observed in the intrahepatic bile duct, hepatectomy is also performed; and (4) during hepaticoenterostomy, a wide anastomotic stoma is formed to prevent cholangitis due to anastomotic stricture. In the present case, the posterior branch of the bile duct showed partial dilatation from the transition site from the extrahepatic bile duct, and a relative stricture was observed in the transition site. Moreover, according to the virtual endoscopic findings, this was a membrane-like stricture, and bile duct plasty was performed. There was no other stricture or dilatation in the intrahepatic bile duct, thus hepatectomy was not required. In the present case, by confirming blood vessels running around the bile duct using virtual endoscopy, the risk of mistakenly cutting the blood vessels by bile duct plasty could be avoided. To the best of our knowledge, there are no reports considering the overlapping of surrounding blood vessels running on the same image through observation of the bile duct by virtual endoscopy. Since the hepatic artery, and often the portal vein, may become displaced by a dilated cyst, caution is required in performing surgery of CCs. The present results clearly show that CT virtual endoscopy greatly contributes to the diagnosis and treatment of CCs.

Abstract

Double-balloon enteroscope (DBE)-assisted endoscopic retrograde cholangiopancreatography (ERCP) is an effective endoscopic approach for pancreatobiliary disorders in patients with altered gastrointestinal anatomy. Endoscopic interventions *via* DBE in these postoperative settings remain difficult because of the lack of an elevator and the use of extra-long ERCP accessories. Here, we report the usefulness of direct cholangioscopy with an ultra-slim gastroscope during DBE-assisted ERCP. Three patients with choledocholithiasis in postoperative settings (two patients after Billroth II gastrojejunostomy and one patient after Roux-en-Y gastrojejunostomy) were treated. DBE was used to gain access to the papilla under carbon dioxide insufflation, and endoscopic sphincterotomy was performed with a conventional sphincterotome. For direct cholangioscopy, the entero-

scope was exchanged for an ultra-slim gastroscope through an incision in the overtube, which was inserted directly into the bile duct. Direct cholangioscopy was used to extract retained bile duct stones in two cases and to confirm the complete clearance of stones in one case. Bile duct stones were eliminated with a 5-Fr basket catheter under direct visual control. No adverse events were noted in any of the three cases. Direct cholangioscopy with an ultra-slim gastroscope facilitates subsequent treatment within the bile duct. This procedure represents another potential option during DBE-assisted ERCP.

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP)-related maneuvers are difficult in patients with altered gastrointestinal (GI) anatomy due to previous abdominal surgery. ERCP success rates using conventional methods

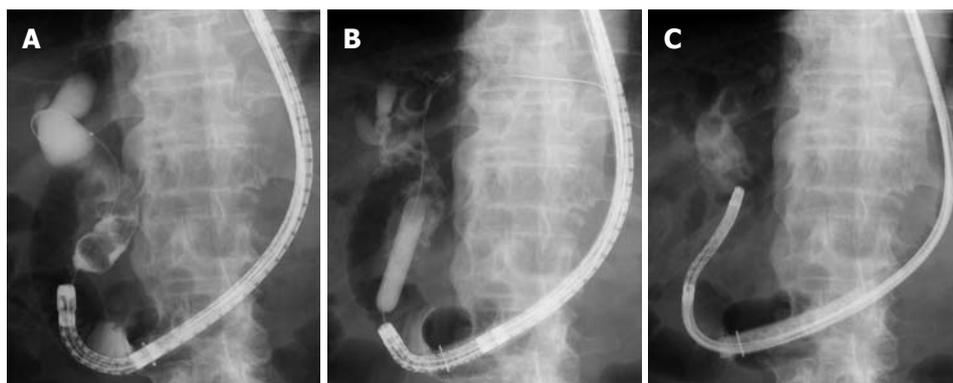

Figure 1 X-ray images. A: Cholangiography revealed a dilated bile duct and multiple stones piled up at the lower to middle part of the bile duct; B: Papillary dilation using a large balloon catheter; C: An ultra-slim gastroscope was introduced directly into the bile duct.

in patients after Billroth II gastrojejunostomy, Whipple pancreatoduodenectomy and Roux-en-Y gastrojejunostomy are reported to be as low as 52%^[1,2], 51%^[3], and 33%^[2], respectively. If the papilla or biliary anastomosis in the afferent loop cannot be reached by an ordinary duodenoscope because of excessive intestinal length and/or sharp angulation of the anastomosis, it has recently become possible to use a double-balloon enteroscope (DBE) for ERCP. There are several hurdles for this technique, including reaching the papilla or biliary anastomosis, selective duct cannulation, and accomplishment of the treatment. The enteroscope is advanced through the overtube into the afferent jejunal loop using the push-and-pull double balloon technique. Identifying the opening of the afferent loop and coping with sharp angulation of the anastomosis are the keys for the successful endoscope insertion. Once the papilla or biliary anastomosis is reached, however, endoscopic interventions *via* DBE in these postoperative settings remain the most difficult ERCP manipulations because of the lack of an elevator and the use of extra-long ERCP accessories.

Here, we report three cases with choledocholithiasis treated with DBE-assisted ERCP and demonstrate the usefulness of direct cholangioscopy with an ultra-slim gastroscope for subsequent treatment.

CASE REPORT

Case 1

An 80-year-old man was referred for the treatment of choledocholithiasis. He had undergone partial gastrectomy with Roux-en-Y gastrojejunostomy for gastric carcinoma five years before. With the DBE (EC-450BI5; Fujinon, Osaka, Japan) with a 152 cm working length and a 2.8 mm instrumental channel, the papilla could be reached *via* the Roux-en-Y anastomosis under carbon dioxide insufflation. Cannulation of the papilla and cholangiography revealed a dilated bile duct and multiple stones (maximum size 20 mm) piled up at the lower to middle part of the bile duct (Figure 1A). Endoscopic sphincterotomy (EST) was performed with a conventional sphincterotome, placing the papilla of Vater at the

6 o'clock position. After mechanical lithotripsy with a 7-Fr crusher catheter (Xemex crusher catheter; Zeon Medical, Tokyo, Japan), stone extraction was attempted with a basket catheter but frequently failed because the catheter was inserted into the dilated cystic duct. Because the same attempt was performed unsuccessfully during another session, the enteroscope was exchanged for an ultra-slim gastroscope (EG-530NW; Fujinon, outer diameter 5.9 mm), leaving the overtube with its balloon inflated. The ultra-slim endoscope was introduced through an incision in the overtube, which was made at a point 100 cm from its tip. The ultra-slim endoscope was advanced through the overtube up to the papilla and was directly inserted into the bile duct after papillary dilation using a large balloon catheter (CRE balloon dilator; Boston Scientific Japan, Tokyo, Japan) (Figure 1B and C). Cholangioscopy showed multiple stones inside the dilated bile duct and the cystic duct. The stones were all removed with a 5-Fr basket catheter (Basket catheter, diamond type; MTW Endoskopie, Wesel, Germany) under direct visual control (Figure 2). The patient had a good clinical course after the procedure, and no adverse events occurred.

Case 2

An 89-year-old man developed acute cholangitis with choledocholithiasis. He had undergone partial gastrectomy with Billroth II gastrojejunostomy for gastric carcinoma 21 years before. Because of the long afferent loop, the DBE (EC-450BI5; Fujinon, Osaka, Japan) was used to gain access to the papilla under carbon dioxide insufflation. Cannulation of the papilla and cholangiography showed two bile duct stones (maximum size 15 mm) at the middle part of the bile duct. After EST with a conventional sphincterotome, a smaller stone located distally was extracted with a basket catheter (Figure 3). Another stone could not be removed despite all possible efforts because of its impaction. The enteroscope was then exchanged for an ultra-slim gastroscope as described above. The endoscope was inserted directly into the bile duct, revealing an impacted stone inside the duct. The stone was removed successfully with a 5-Fr basket catheter under direct visual control, and the proximal bile duct was

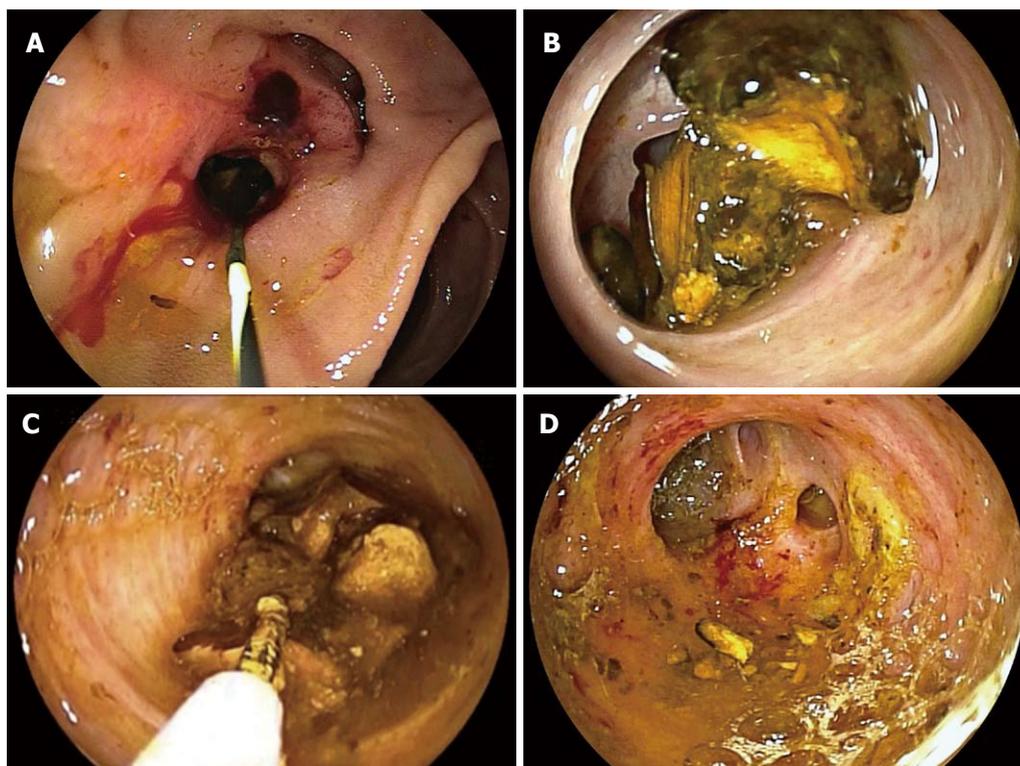

Figure 2 Endoscopic images. A: The papilla of Vater after balloon dilation; B: Cholangioscopy showed multiple stones inside the bile duct; C, D: The stones were all removed with a 5-Fr basket catheter under direct visual control.

Figure 3 Cholangiography. A smaller stone located distally was extracted with a basket catheter. Another stone was impacted inside the bile duct (arrow).

also investigated (Figure 4A-C). The patient had a good clinical course after the procedure, and no adverse events occurred.

Case 3

A 73-year-old man was referred because of cholestasis and suspected choledocholithiasis. He had undergone partial gastrectomy with Billroth II gastrojejunostomy for gastric ulcer 43 years before. The DBE (EC-450BI5; Fujinon, Osaka, Japan) was first inserted into the efferent loop and was then introduced up to the papilla *via* Braun's anastomosis under carbon dioxide insufflation. Cannulation of the papilla and cholangiography revealed several small stones (5 mm in size) inside the bile duct. After

EST with a conventional sphincterotome, the stones were extracted with a basket catheter and a retrieval balloon (Figure 5A-C). An ultra-slim gastroscope was then introduced into the bile duct as described above. Cholangioscopy confirmed complete clearance of the stones inside the bile duct (Figure 6A and B). The patient had a good clinical course after the procedure, and no adverse events occurred.

DISCUSSION

Since the first report^[4] of a successful DBE-assisted cholangiography in a pediatric case with late biliary stricture of choledochojejunostomy after living donor liver transplantation, many case series^[5-17] have reported the effectiveness of DBE-assisted ERCP for pancreatobiliary disorders in various postoperative settings. In most previous reports^[6-8,10-12,15,16], the therapeutic enteroscope, which has a 200-cm working length and a 2.8-mm instrumental channel, has been used for DBE-assisted ERCP. Recently, the single-balloon enteroscope (SBE) system (Olympus Medical Systems, Tokyo, Japan), which consists of an enteroscope without the balloon at the tip of the endoscope and an overtube equipped with a balloon, has also been used for ERCP in patients with altered postsurgical anatomy with similar technical success rates^[18-20].

The maneuverability of these enteroscopes is rather poor and only limited ERCP accessories are available for these endoscopes because of the long working length. To overcome these drawbacks, Fährndrich *et al*^[9] reported a

Figure 4 Direct cholangioscopy with an ultra-slim gastroscope. A: Cholangioscopy revealed an impacted stone inside the bile duct; B: The stone was removed with a 5-Fr basket catheter under direct visual control; C: The proximal bile duct was also investigated.

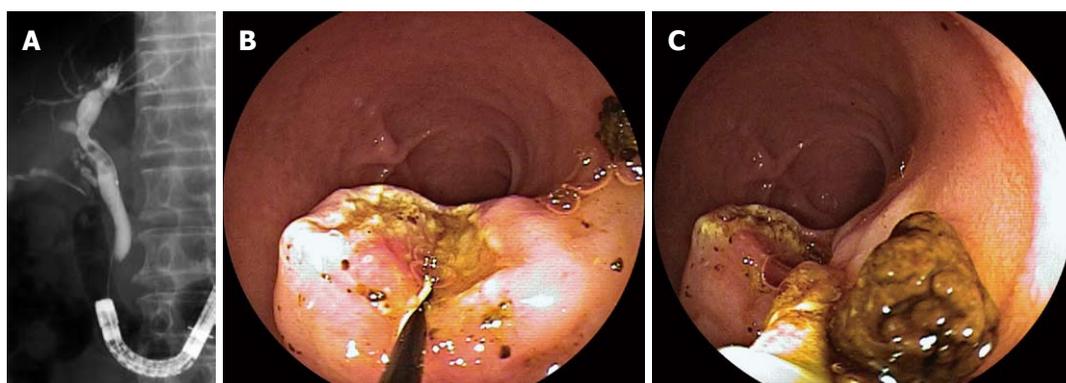

Figure 5 X-ray and endoscopic images. A: Cholangiography revealed several small stones inside the bile duct; B: The papilla of Vater after endoscopic sphincterotomy; C: The bile duct stones were extracted with a basket catheter and a retrieval balloon.

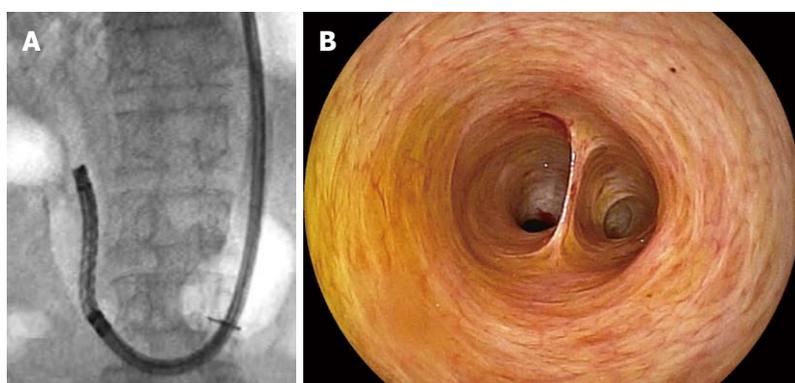

Figure 6 Direct cholangioscopy. A: An ultra-slim gastroscope was introduced directly into the bile duct after removal of bile duct stones; B: Cholangioscopy confirmed complete clearance of the duct.

facilitated method for endoscopic interventions at the bile duct during DBE-assisted ERCP that involved exchanging the enteroscope with an ordinary gastroscope after incision of the overtube once the papilla or the biliary anastomosis was reached. This technique is favorably performed in our country when the SBE or the “long” DBE is used for ERCP because long-length ERCP accessories are not commercially available in Japan. Alternatively, the DBE, which has a 152 cm working length and a 2.8 mm instrumental channel, can be used. This instrument is the “short” DBE for which conventional ERCP accessories are available. With this enteroscope, Shimatani *et al*^[13]

performed DBE-assisted ERCP and related therapeutic maneuvers in 68 patients with altered GI anatomies with an extremely high success rate.

Another disadvantage of DBE-assisted ERCP is that the enteroscope is forward-viewing. The lack of an elevator and the absence of the side-viewing perspective reduce the success rate of cannulation or sphincterotomy. Moreover, additional treatment becomes difficult in cases such as the retained bile duct stones described here, even if access to the biliary duct is obtained. Direct visualization of the bile duct with an ultra-slim gastroscope expands the options for therapy inside the duct

because the endoscope has a 2 mm instrumental channel for which 5-Fr accessories (including the biopsy forceps, the basket catheter, the laser lithotripsy probe, and the argon plasma coagulation probe) are available. The ultra-slim endoscope was introduced through incision of the overtube. The overtube was incised for three-quarters of its circumference on the side opposite of the pressure line, as described by Fährndrich *et al*^[9]. Care was taken not to damage the pressure line of the overtube to maintain the inflation of the balloon. Although this technique is only possible when the intact papilla or biliary anastomosis is reached with (at most) 100 cm of the enteroscope introduced, it is easy to advance the ultra-slim endoscope into the bile duct through the papilla treated with EST or balloon dilation because the approach is from the distal side of the afferent loop.

We did not encounter any adverse events in this case series. However, care must be taken because DBE-assisted ERCP can potentially cause serious complications, such as perforation, bleeding, or pancreatitis, during or after the scope insertion and ERCP procedures. Although no serious complications of direct cholangioscopy with an ultra-slim endoscope have been reported^[21,22], there is still a risk of air embolism; pneumobilia is often recognized after EST. Carbon dioxide insufflation during the DBE procedure may be effective in preventing this complication.

In conclusion, DBE-assisted ERCP appears to be a promising method; however, this technique still has several disadvantages. Direct cholangioscopy with an ultra-slim gastroscope compensates for drawbacks of the enteroscope and facilitates subsequent treatment within the bile duct. This procedure may represent another option during DBE-assisted ERCP.

Abstract

A 75-year old man had been diagnosed at 42 years of age as having polycythemia vera and had been monitored at another hospital. Progression of anemia had been recognized at about age 70 years, and the patient was thus referred to our center in 2008 where secondary myelofibrosis was diagnosed based on bone marrow biopsy findings. Hematemesis due to rupture of esophageal varices occurred in January and February of 2011. The bleeding was stopped by endoscopic variceal ligation. Furthermore, in March of the same year, hematemesis recurred and the patient was transported to our center. He was in irreversible hemorrhagic shock and died. The autopsy showed severe bone marrow fibrosis with mainly argyrophilic fibers, an observation consistent with myelofibrosis. The liver weighed 1856 g the spleen 1572 g, indicating marked hepatosplenomegaly. The liver and spleen both showed extramedullary hemopoiesis. Myelofibrosis is often complicated by portal hypertension and is occasionally associated with gastrointestinal hemorrhage due to esophageal varices. A patient diagnosed as having myelofibrosis needs to

be screened for esophageal/gastric varices. Myelofibrosis has a poor prognosis. Therefore, it is necessary to carefully decide the therapeutic strategy in consideration of the patient's concomitant conditions, treatment invasiveness and quality of life.

INTRODUCTION

Myelofibrosis is a disease resulting in extensive diffuse fibrosis involving the bone marrow and is characterized by hepatosplenomegaly, leukoerythroblastosis and so on.

Portal hypertension reportedly occurs as a complication in 10%-17% of patients^[1] and may be accompanied by gastroesophageal variceal hemorrhage^[2]. Herein, we present a patient diagnosed with myelofibrosis who died 3 years later due to repeated ruptures of esophageal varices, associated with massive ascites. Autopsy findings of this case are described with a discussion of the relevant literature.

CASE REPORT

The patient was a 75-year-old man. Increases in 2 blood

cell lines, white and red blood cells, had been detected by medical examination at age 42 years, and polycythemia vera was diagnosed at another hospital. Blood hemoglobin (Hb) at this time was approximately 19 g/dL. Thereafter, the patient had been monitored without treatment, but blood Hb gradually decreased from 2005 onward. Thus, the patient was referred to the Department of Hematology of our center in October 2009.

The white blood cell count was 29 700/ μ L, the red blood cell count $641 \times 10^6/\mu$ L, showing an increase in 2 blood cell lines, and juvenile cells were noted (Table 1).

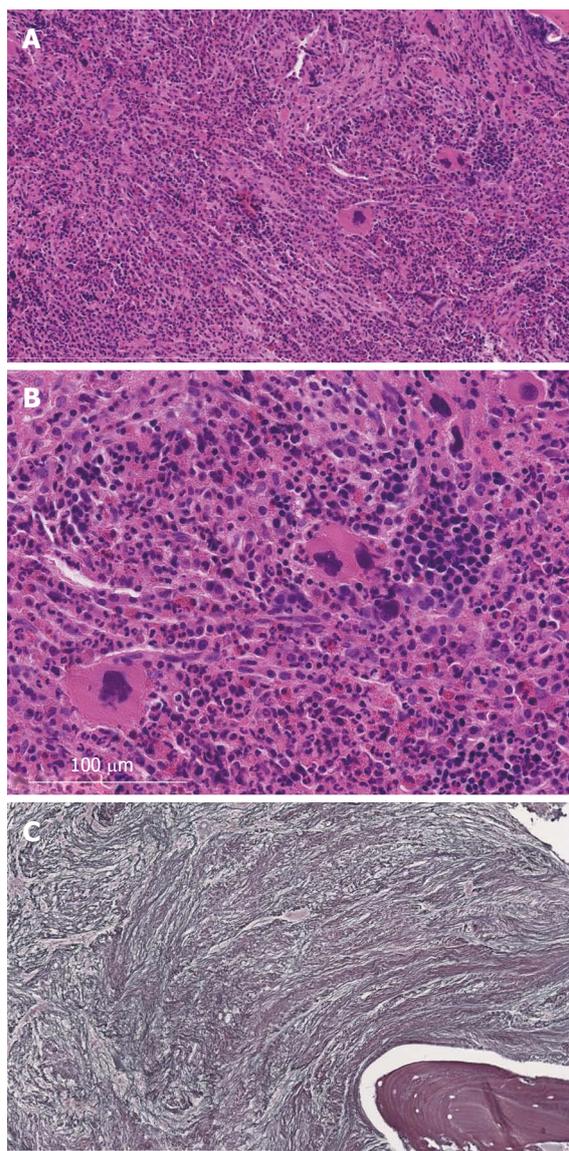

Figure 2 Microscopic findings on autopsy on bone marrow biopsy. A: Hematoxylin and eosin, $\times 20$; B: Hematoxylin and eosin, $\times 40$; C: Silver, $\times 40$. Adipocyte disappearance and markedly decreased hematopoietic cells.

Abdominal computed tomography scan revealed a large quantity of ascites in the peritoneal cavity, and marked spleen enlargement and dilatation of the splenic vein were seen (Figure 1). There were no abnormalities of the liver or other organs. No obvious blood clot formation was seen in the main blood vessels.

Bone marrow aspiration was attempted to evaluate the disease state but the tap was dry. Therefore, bone marrow biopsy was conducted from the ilium (Figure 2). Adipocytes were completely absent and hematopoietic cells markedly decreased. Thus, secondary myelofibrosis was diagnosed. There were no findings of progression to leukemia, and the patient was thus monitored by our hematology department.

The patient was urgently transported to our center due to hematemesis in January 2011. Urgent endoscopy was conducted, and esophageal varices of Lm, F2, and

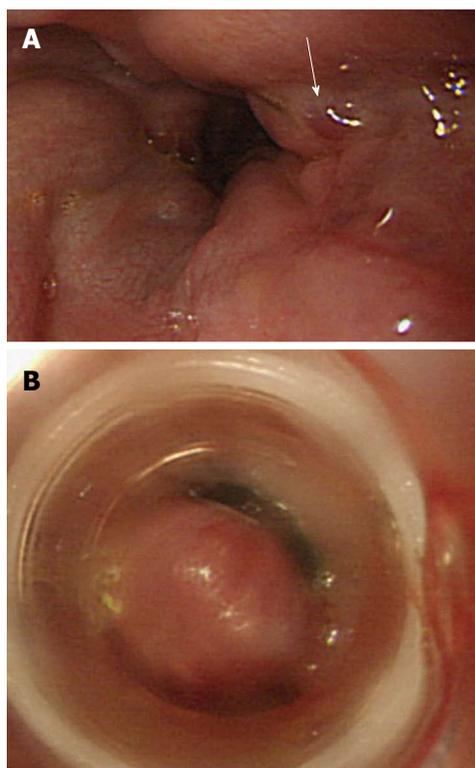

Figure 3 Endoscopic image in the lower esophagus. A: Showing a hemocystic spot by the white arrow; B: Endoscopic variceal ligation was thus conducted.

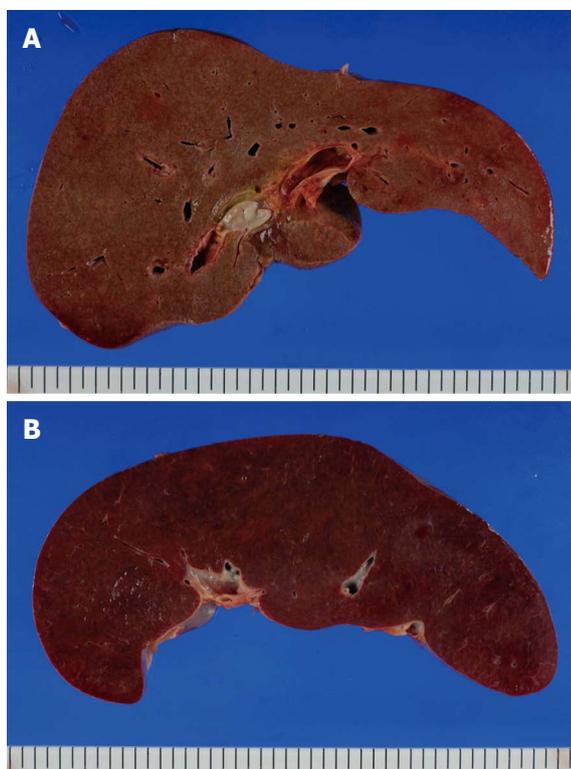

Figure 4 Macroscopic findings on autopsy. A: The liver weighed 1856 g; B: The spleen 1572 g indicating hepatosplenomegaly.

Cb and the red color sign (hemocystic spot) in the

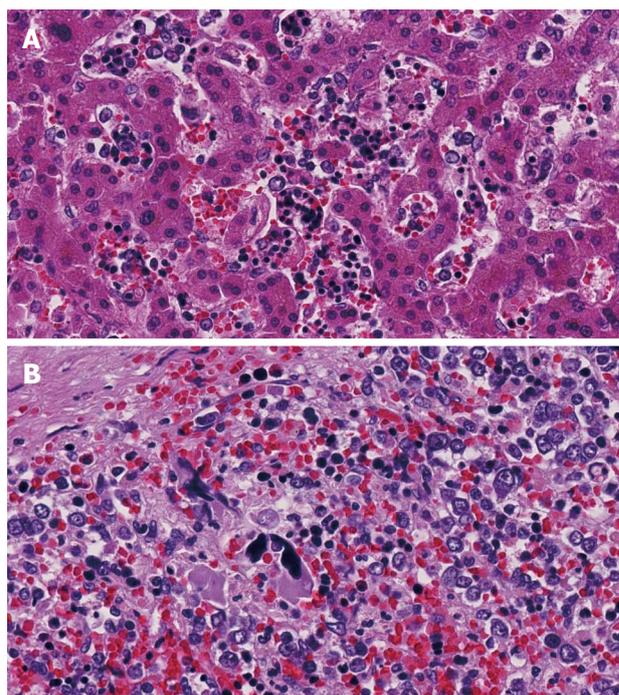

Figure 5 Microscopic findings on autopsy stained with hematoxylin and eosin. A: Liver; B: Spleen. Both the liver and the spleen showed extramedullary hemopoiesis.

lower esophagus were found (Figure 3). Therefore, endoscopic variceal ligation (EVL) was conducted. A large quantity of poorly controlled ascites was observed, and the patient's activities of daily living (ADL) were poor. Thus, no additional treatment such as endoscopic injection sclerotherapy was conducted, and the patient was discharged from the hospital. He had hematemesis in February of the same year, and bleeding was again stopped with EVL. However, no additional treatment was conducted for similar reasons. Furthermore, the patient had hematemesis again in March of the same year and was emergently transported to our center. Urgent endoscopy was conducted; however, because there was a large quantity of fresh blood in the stomach and esophagus, it was difficult to identify bleeding points. Blood pressure became unstable during the examination. Therefore, we abandoned EVL and inserted a Sengstaken-Blakemore tube. The patient was hospitalized at this time. However, the hemorrhagic shock was irreversible and he died 20 h after emergency transport. With informed consent from his family, autopsy was conducted the same day.

Autopsy findings

The enlarged liver weighed 1856 g but there were no obvious abnormalities on histopathological observation of the portal area or in hepatocytes. Extramedullary hemopoiesis was seen mainly in sinusoids. The spleen weighed 1572 g, indicating marked splenomegaly, and obscuration of white matter and the presence of bone marrow cells with splenic red pulp were the main features noted (Figures 4 and 5). In addition to these findings, small

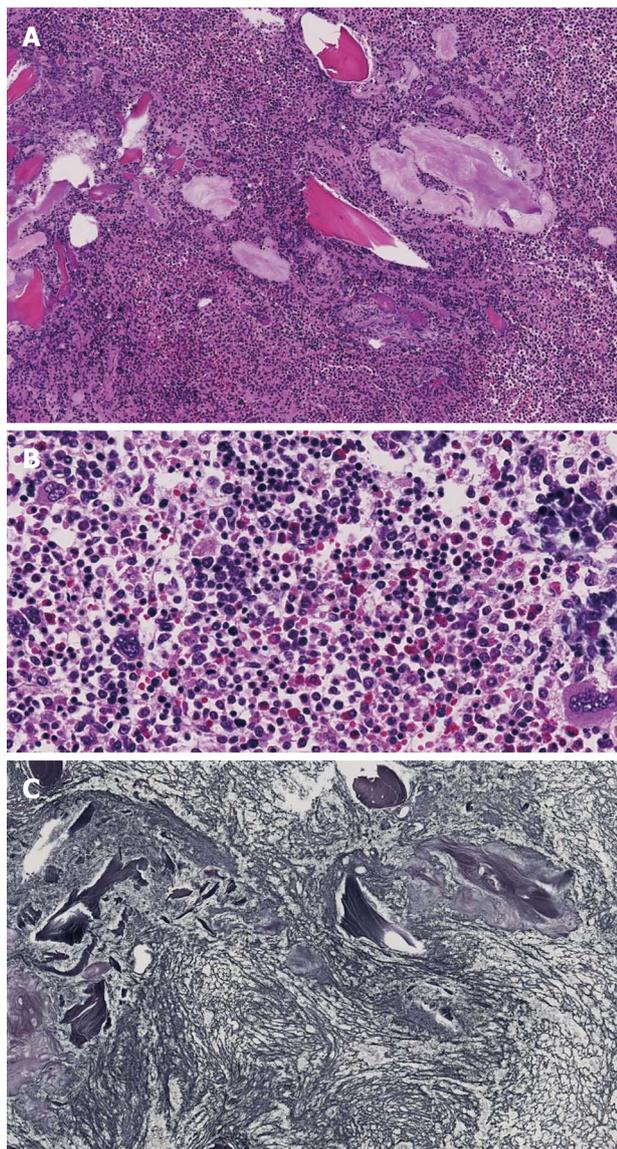

Figure 6 Microscopic findings on autopsy (bone marrow). A: Hematoxylin and eosin (HE), $\times 10$; B: HE, $\times 40$; C: Silver, $\times 10$. Adipocyte disappearance and 3-lineage differentiation were seen. Silver staining showed severe fibrosis with mainly argyrophilic fibers.

numbers of foci of extramedullary hematopoiesis were detected in the lungs, kidneys and lymph nodes around the pancreas. In bone marrow, adipocytes had completely disappeared, and 3-line cellular growth was seen. Severe fibrosis with mainly argyrophilic fibers was revealed by silver staining, and this finding was consistent with myelofibrosis (Figure 6).

DISCUSSION

Polycythemia vera is a myeloproliferative tumors resulting in absolute increases in the red blood cell count and circulating blood volume due to an acquired genetic abnormality of hematopoietic stem cells. Survival without treatment averages 18 mo, and the leading causes of death are reportedly thrombosis, progression to leukemia,

myelodysplastic syndrome or myelofibrosis, hemorrhage, and so on^[3,4].

The present case was diagnosed as having polycythemia vera, and then showed a disease shift to secondary myelofibrosis approximately 30 years later. The histology of both biopsy and autopsy osseous samples showed increased cells in the 3-lineage differentiations. Since there was no morphological abnormality in them and limited proliferation of immature cells, it was considered that malignant lymphoma and leukemia could be ruled out.

Three years thereafter, the patient repeatedly suffered rupture of esophageal varices and ultimately died of this complication. Non-cirrhotic portal hypertension has various causes. Myeloproliferative tumors are often accompanied by marked splenomegaly and can cause portal hypertension due to increased portal vein flow^[5,6]. Furthermore, Shaldon *et al*^[7] reported that pre-sinusoidal blood flow resistance increases, in association with extramedullary hemopoiesis in hepatic sinusoids. Even if the increase in blood flow is mild, impaired blood flow can be regarded as the cause of increased pressure. Other than this, portal vein thrombosis within and outside of the liver and venous thrombosis can be causes in some cases. Liver histology in the present case showed mild fibrosis in the portal area and extramedullary hemopoiesis in hepatic sinusoids but no inflammatory cell infiltrate or reconstruction of hepatic lobules.

At autopsy, extramedullary hemopoiesis was not considered to be severe enough to have resulted in impaired blood flow. In addition, no obvious portal vein thrombosis or venous thrombosis was seen, while spleen weight was markedly increased as compared with that of the liver. These findings and splenic vein enlargement were consistent with portal hypertension. Thus, portal hypertension may have been caused by the increased blood flow associated with splenomegaly in our present case.

Myelofibrosis is often associated with splenomegaly, and we advocate paying close attention to myelofibrosis that may be accompanied by portal hypertension clinically. Patients with concomitant gastroesophageal varices can reportedly be treated effectively with splenectomy, splenic embolization, and transjugular intrahepatic portal-hepatic venous shunting^[2,8].

The massive ascites in our present case was considered to have been caused by pre-sinusoidal lymphatic blockade due to extramedullary hemopoiesis; however, ascites was refractory to treatments such as the administration of diuretics. Therefore, we considered the possibility that transjugular intrahepatic portal-hepatic venous shunting would be effective.

The ADL of the present case were poor, and ascites was poorly controlled at the time of the initial hospitalization. Treatments for portal hypertension were thus considered to be too invasive and difficult; thus, they were not administered. When a patient is diagnosed as having myelofibrosis, screening endoscopy for esophageal and gastric varices should be conducted regularly, keeping in mind that portal hypertension may develop. When risk of

rupture is considered, prophylactic endoscopic therapy or endovascular treatment should be considered while the patient's general condition is good. However, the average survival period for myelofibrosis patients ranges from 3 to 7 years, and no more than 20% can expect a median survival of 10 years as this disease has a poor prognosis^[2]. Therapy should be carefully selected in full consideration of invasiveness, as it impacts quality of life and prognosis.

Events Calendar 2012

January 13-15, 2012 Asian Pacific <i>Helicobacter pylori</i> Meeting 2012 Kuala Lumpur, Malaysia	March 12-14, 2012 World Congress on Gastroenterology and Urology Omaha, NE 68197, United States	Meeting Madrid, Spain	Neurogastroenterology and Motility Meeting Bologna, Italy
January 19-21, 2012 American Society of Clinical Oncology 2012 Gastrointestinal Cancers Symposium San Francisco, CA 3000, United States	March 17-20, 2012 Mayo Clinic Gastroenterology and Hepatology Orlando, FL 32808, United States	April 28, 2012 Issues in Pediatric Oncology Kiev, Ukraine	September 7-9, 2012 The Viral Hepatitis Congress Frankfurt, Germany
January 19-21, 2012 2012 Gastrointestinal Cancers Symposium San Francisco, CA 94103, United States	March 26-27, 2012 26th Annual New Treatments in Chronic Liver Disease San Diego, CA 92121, United States	May 3-5, 2012 9th Congress of The Jordanian Society of Gastroenterology Amman, Jordan	September 8-9, 2012 New Advances in Inflammatory Bowel Disease La Jolla, CA 92093, United States
January 20-21, 2012 American Gastroenterological Association Clinical Congress of Gastroenterology and Hepatology Miami Beach, FL 33141, United States	March 30-April 2, 2012 Mayo Clinic Gastroenterology and Hepatology San Antonio, TX 78249, United States	May 7-10, 2012 Digestive Diseases Week Chicago, IL 60601, United States	September 8-9, 2012 Florida Gastroenterologic Society 2012 Annual Meeting Boca Raton, FL 33498, United States
February 3, 2012 The Future of Obesity Treatment London, United Kingdom	March 31-April 1, 2012 27th Annual New Treatments in Chronic Liver Disease San Diego, CA 92121, United States	May 17-21, 2012 2012 ASCRS Annual Meeting- American Society of Colon and Rectal Surgeons Hollywood, FL 1300, United States	September 15-16, 2012 Current Problems of Gastroenterology and Abdominal Surgery Kiev, Ukraine
February 16-17, 2012 4th United Kingdom Swallowing Research Group Conference London, United Kingdom	April 8-10, 2012 9th International Symposium on Functional GI Disorders Milwaukee, WI 53202, United States	May 18-19, 2012 Pancreas Club Meeting San Diego, CA 92101, United States	September 20-22, 2012 1st World Congress on Controversies in the Management of Viral Hepatitis Prague, Czech
February 23, 2012 Management of Barretts Oesophagus: Everything you need to know Cambridge, United Kingdom	April 13-15, 2012 Asian Oncology Summit 2012 Singapore, Singapore	May 18-23, 2012 SGNA: Society of Gastroenterology Nurses and Associates Annual Course Phoenix, AZ 85001, United States	October 19-24, 2012 American College of Gastroenterology 77th Annual Scientific Meeting and Postgraduate Course Las Vegas, NV 89085, United States
February 24-27, 2012 Canadian Digestive Diseases Week 2012 Montreal, Canada	April 15-17, 2012 European Multidisciplinary Colorectal Cancer Congress 2012 Prague, Czech	May 19-22, 2012 2012-Digestive Disease Week San Diego, CA 92121, United States	November 3-4, 2012 Modern Technologies in Diagnosis and Treatment of Gastroenterological Patients Dnepropetrovsk, Ukraine
March 1-3, 2012 International Conference on Nutrition and Growth 2012 Paris, France	April 18-20, 2012 The International Liver Congress 2012 Barcelona, Spain	June 2-6, 2012 American Society of Colon and Rectal Surgeons Annual Meeting San Antonio, TX 78249, United States	November 4-8, 2012 The Liver Meeting San Francisco, CA 94101, United States
March 7-10, 2012 Society of American Gastrointestinal and Endoscopic Surgeons Annual Meeting San Diego, CA 92121, United States	April 19-21, 2012 Internal Medicine 2012 New Orleans, LA 70166, United States	June 18-21, 2012 Pancreatic Cancer: Progress and Challenges Lake Tahoe, NV 89101, United States	November 9-13, 2012 American Association for the Study of Liver Diseases Boston, MA 02298, United States
	April 20-22, 2012 Diffuse Small Bowel and Liver Diseases Melbourne, Australia	July 25-26, 2012 PancreasFest 2012 Pittsburgh, PA 15260, United States	December 1-4, 2012 Advances in Inflammatory Bowel Diseases Hollywood, FL 33028, United States
	April 22-24, 2012 EUROSON 2012 EFSUMB Annual	September 1-4, 2012 OESO 11th World Conference Como, Italy	
		September 6-8, 2012 2012 Joint International	

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the “priority” and “copy-right” of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers’ names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homoge-

neous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically

for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

Instructions to authors

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of “To investigate/study/...”; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of *P* values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be la-

beled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, “Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]”. If references are cited directly in the text, they should be put together within the text, for example, “From references^[19,22-24], we know that...”.

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (<http://www.wjgnet.com/1007-9327/office/>). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

ACKNOWLEDGMENTS I Acknowledgments to reviewers of *World Journal of Gastroenterology*

APPENDIX I Meetings
I-VI Instructions to authors

ABOUT COVER Digestive Disease Week, May 19-22, 2012, Lian-Sheng Ma, President and Editor-in-Chief (first left) with *World Journal of Gastroenterology* Editorial Board Members, Carlos J Pirola (first right), PhD, FAHA and Silvia Sookoian (middle), MD, PhD, both from Argentina

AIM AND SCOPE *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, DOI: 10.3748) is a weekly, open-access, peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.
The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

factors such as obesity, insulin resistance (IR), high blood pressure, and dyslipidemia were associated with several metabolites, including branched-chain amino acids, other hydrophobic amino acids, tryptophan breakdown products, and nucleotide metabolites. In addition, the authors found a significant association of IR traits with glutamine, glutamate and the glutamine-to-glutamate ratio. These data provide new insight into the pathogenesis of MS-associated phenotypes and introduce a crucial role of glutamine-cycling pathway as prominently involved in the development of metabolic risk. We consider that the hypothesis about the role of abnormal glutamate metabolism in the pathogenesis of the MS is certainly challenging and suggests the critical role of the liver in the global metabolic modulation as glutamate metabolism is linked with aminotransferase reactions. We discuss here the critical role of the "liver metabolism" in the pathogenesis of the MS and IR, and postulate that before fatty liver develops, abnormal levels of liver enzymes, such as alanine and aspartate aminotransferases might reflect high levels of hepatic transamination of amino acids in the liver.

Abstract

Although new research technologies are constantly used to look either for genes or biomarkers in the prediction of metabolic syndrome (MS), the pathogenesis and pathophysiology of this complex disease remains a major challenge. Interestingly, Cheng *et al* recently investigated possible pathways underlying MS by high-throughput metabolite profiling in two large and well characterized community-based cohorts. The authors explored by liquid chromatography and mass spectrometry the plasma concentrations of 45 distinct metabolites and examined their relation to cardiometabolic risk, and observed that metabolic risk

Sookoian S, Pirola CJ. Alanine and aspartate aminotransferase and glutamine-cycling pathway: Their roles in pathogenesis of metabolic syndrome. *World J Gastroenterol* 2012; 18(29): 3775-3781 Available from: URL: <http://www.wjgnet.com>

INVITED COMMENTARY ON HOT ARTICLES

The metabolic syndrome (MS), a complex disorder associated with several metabolic disturbances and mostly characterized by insulin resistance (IR) in several tissues, results from a complex interplay between genetic and environmental factors^[1]. Among the environmental factors, decreased physical activity, increased nutrient availability and over nutrition, play an important role and are also largely considered to be responsible for the modern epidemic of MS-related phenotypes, such as obesity, arterial hypertension and type 2 diabetes (T2D). Moreover, the pathogenesis of IR is strongly associated with the ability of the liver to suppress endogenous glucose production, suggesting that this organ is a key player in the pathophysiology of the MS. Some metabolic disturbances in the hepatic tissue, such as abnormal triglycerides accumulation observed in fatty liver, have been suggested as the trigger events and perhaps the causative factors of IR^[2,3]. As such, nonalcoholic fatty liver disease (NAFLD) is now considered to be an additional component of the MS strongly associated with cardiovascular disease (CVD)^[1,4-6].

Although significant efforts have been made in the last years and new research technologies are constantly used to look for either genes or biomarkers in the MS prediction, the pathogenesis and pathophysiology of this complex disease remains a major challenge.

We read with great interest the article by Cheng *et al*^[7] recently published in *Circulation*. Interestingly, Cheng *et al*^[7] investigated possible pathways underlying MS by high-throughput metabolite profiling in two large and well characterized community-based cohorts, including 1015 individuals from the Framingham Heart Study and 746 from the Malmö Diet and Cancer Study. By liquid chromatography and mass spectrometry, the authors explored the plasma concentrations of 45 distinct metabolites and examined their relation to cardiometabolic risk, and found that metabolic risk factors such as obesity, IR, high blood pressure, and dyslipidemia were associated with several metabolites, including branched-chain amino acids (BCAA), other hydrophobic amino acids, tryptophan breakdown products, and nucleotide metabolites. In addition, the authors observed a significant association of IR traits with glutamine, glutamate and the glutamine-to-glutamate ratio in individuals from both cohorts. They described for the first time that a high glutamine-to-glutamate ratio is associated with a lower risk of incident diabetes mellitus. The authors also followed up these findings by a dietary-intervention study in mice, and observed that administration of glutamine led to both increased glucose tolerance and decreased blood pressure^[7]. Hence, the authors conclude

that individuals with metabolic risk factors have higher circulating concentrations of glutamate and BCAA, and lower concentrations of glutamine, and suggest that glutamate may contribute to the development of the MS. Moreover, the authors observed that circulating levels of BCAA are not only associated with obesity and impaired glucose tolerance but also with dyslipidemia and blood pressure.

What can this metabolomic data tell us about the pathogenesis of MS?

These data open new perspectives about the pathogenesis of MS-associated phenotypes and introduce a crucial role of glutamine-cycling pathway as prominently involved in the development of metabolic risk.

Actually, the role of glutamine-cycle in the regulation of metabolic syndrome-related phenotypes was postulated many years ago, as Hermanussen *et al*^[8] showed that chronic hyperglutamatemia may intoxicate arcuate nucleus neurons, thereby disrupting the hypothalamic signaling cascade of leptin action, causing hyperphagia, obesity and hyperleptinaemia. Surprisingly, glutamate has also been associated with metabolic programming and it was postulated that the thrifty phenotype, the epidemiological association between poor fetal and infant growth and the subsequent development of the MS, may be the consequence of fetal hyperglutamatemia^[8].

In addition, previous evidences from a human study, including a metabolic profiling performed on 74 obese and 67 lean subjects, identified a cluster of obesity-associated changes in specific amino acid, acylcarnitine, and organic acid metabolites in obese compared to lean subjects that was associated with IR^[9]. Newgard *et al*^[9] tested the effect of supplementation of high fat diet with BCAA in an experimental study, and showed that this model was associated with decreased levels of circulating α -ketoglutarate and increased levels of glutamate, and speculated that the accumulation of glutamate increases the transamination of pyruvate to alanine, leading to the development of obesity-associated IR. Newgard *et al*^[9] in fact extended this reasoning to that the increase in alanine, a highly gluconeogenic amino acid, contributes to the development of glucose intolerance in obesity, as circulating alanine levels are elevated in obese subjects.

Furthermore, a recent human study exploring metabolite predictors of deteriorating glucose tolerance in two Finnish population-based studies consisting of 1873 individuals and reexamination of 618 individuals after 6.5 years in one of the cohorts showed that alterations in BCAA metabolism precede hyperglycemia^[10]. In addition, alanine, lactate, and pyruvate were predictive of post-challenge glucose^[10]. A candidate gene association study in 9369 non-diabetic or newly diagnosed T2D Finnish men that explored the association of glycemia and 43 genetic risk variants showed that hyperglycemia and a variant of glucokinase (hexokinase 4) regulator (*GCKR*) are associated with the levels of eight amino acids, including alanine, leucine, isoleucine, tyrosine,

Table 1 Overview about liver aminotransferases alanine and aspartate

<p>ALT or GPT Catalyzes the reversible transamination¹ between alanine and 2-oxoglutarate to form pyruvate and glutamate: L-alanine + 2-oxoglutarate = pyruvate + L-glutamate ALT has both degradative and biosynthetic roles in the glutamate cycling ALT participates in cellular nitrogen metabolism and also in liver gluconeogenesis starting with precursors transported from skeletal muscles ALT is present in tissues including liver, kidney, heart, and skeletal muscle. AST or GOT Catalyzes the reversible transamination between L-aspartate and 2-oxoglutarate to form oxaloacetate and glutamate: L-alanine + 2-oxoglutarate L-aspartate + 2-oxoglutarate = oxaloacetate + L-glutamate Cytosolic AST (GOT 1 catalyzes the reversible reaction of oxaloacetate and glutamate to form aspartate and 2-oxoglutarate (alpha-ketoglutarate) AST has two isoforms: cytoplasmatic and mitochondrial</p>
--

¹Transaminase: A subclass of enzymes that catalyze the transfer of an amino group from a donor (generally an amino acid) to an acceptor (generally 2 keto acid) in a cyclic process using pyridoxal phosphate as a cofactor. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GPT: Glutamate pyruvate transaminase; GOT: Glutamate oxaloacetate transaminase.

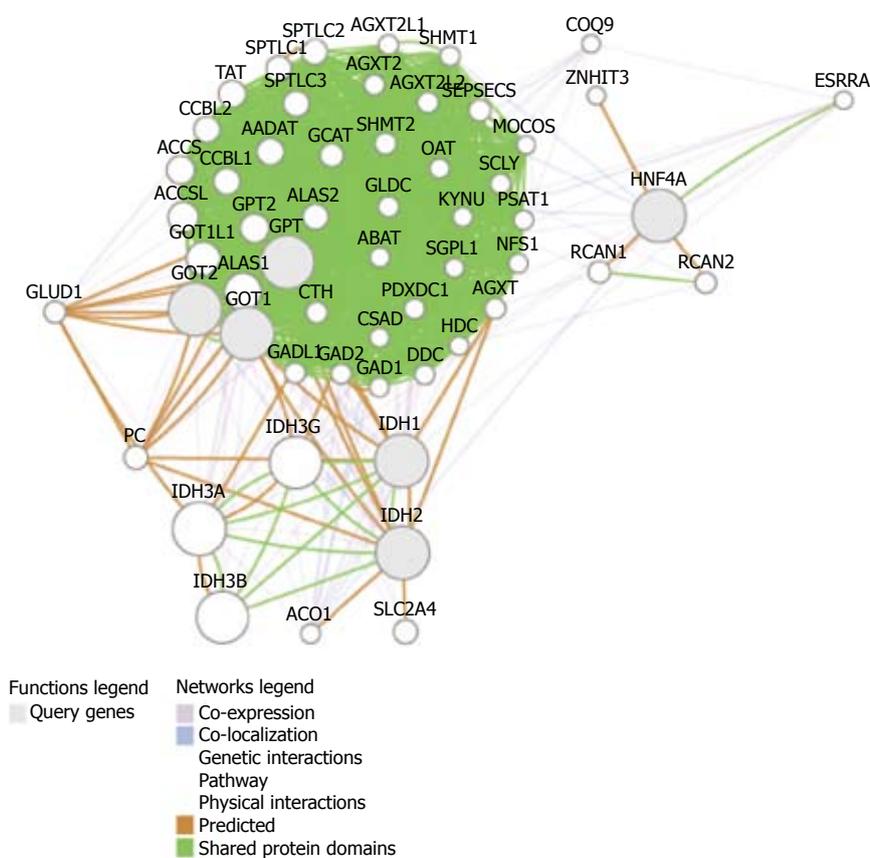

Figure 2 Integrated functional association analysis of protein and genetic interactions on alanine and aspartate. Pathways, co-expression, co-localization, and protein domain similarity were analyzed by the bioinformatics resource GenMANIA (genemania.org) for the 5 candidate genes [alanine also known as glutamate pyruvate transaminase (GPT) and GPT2], aspartate [also known as glutamate oxaloacetate transaminase (GOT)1 and GOT2, (Table 1)], isocitrate dehydrogenases 1 (IDH1), IDH2 and HNF4 (gray circles) and the predicted related genes by systems biology (open circles). List of gene symbol and gene function is shown in Table 2. Predicted functional pathways and Q values are shown in Table 3.

analyses^[14]. There was also a significant interaction between body mass index and ALT levels, and the follow-up study of these overweight and obese participants with highest ALT levels for 20 years showed a 30-fold increased risk for developing T2D^[14].

The association of ALT with the risk of development MS was also evaluated in 1097 subjects from the population-based cohort of Caucasian men and women (Hoorn Study), and ALT was significantly associated with fasting plasma glucose at follow-up^[15]. The 10-year risk of all-cause mortality, fatal and non-fatal CVD in relation to ALT was also assessed in 1439 subjects participating in the Hoorn Study, and the predictive value of ALT for coronary events, seems independent of tra-

ditional risk factors^[16].

Moreover, findings from the Western Australian Health Department data linkage system, an Australian population-based cohort study, support a strong association between ALT levels and the MS independent of insulin resistance^[17].

An overview about the epidemiological evidence of liver enzymes and cardiovascular outcomes was recently published^[18].

In spite of the epidemiological evidences mentioned above, the research community is still inconclusive about the pathobiological meaning of the elevated ALT levels and CV risk. In fact, the question of whether abnormalities in ALT levels precede the development of MS, or

whether the MS components themselves can lead to the increase of ALT levels is still unanswered^[14]. Hence, the biological mechanisms responsible for the association between liver enzymes and the MS-related phenotypes are still poorly understood, and much of the speculations focus on the putative liver injury associated with

fatty liver that frequently coexists with the MS.

The metabolomic data presented by Cheng *et al*^[7] not only raised new questions about the role of glutamate-glutamine cycle in the pathogenesis of the MS, but also suggested a dramatic change in the paradigm of the meaning of elevated aminotransferase levels in the context of MS-

Q value stands for the *P* value corrected for multiple testing. In addition, number of genes in the network and in the whole genome belonging to the biological process is depicted. The candidate genes are listed in Table 2, which are involved in functional enrichment analysis using the GeneMANIA tool (genemania.org).

related phenotypes. Thus, we speculate that abnormal levels of ALT and AST are associated with a deregulation of normal amino acid metabolism in the liver, including aromatic amino acid, and then special compounds such as glutamate are released into the general circulation. This hypothesis attempts to illustrate the critical role of the “liver metabolism” in the pathogenesis of the MS and IR, and postulates that before the liver becomes fatty, abnormal levels of liver enzymes might reflect high levels of hepatic transamination of amino acids in the organ.

Is there any experimental evidence for this? Stegink *et al*^[19] have demonstrated that if a large proportion of glutamate is ingested, portal glutamate increases and this elevation results in increased hepatic glutamate metabolism, leading to release of glucose into systemic circulation, a physiopathogenic event that may perpetuate hyperglycemia.

Systems biology also provides a rational evidence for the association between liver transaminases and the metabolic abnormalities observed by Cheng *et al*^[7].

We performed a functional association analysis that included protein and genetic interactions, pathways, co-expression, co-localization, and protein domain similarity using the bioinformatics resource GenMANIA^[20]. Interestingly, several genes are regarded as direct “neighbors” of liver transaminases (GPT and GOT1/2, as described in Table 1), but including isocitrate dehydrogenases 1 (IDH1) and 2 (IDH2) and the transcription factor hepatic nuclear factor 4 alpha, because they are involved in the regulation of liver transaminases and glutamine synthetase^[21] (Figure 2). Interestingly, the predicted genes (Table 2) belong to pathways that explain most of the findings of Cheng *et al*^[7], such as glutamine family amino acid metabolic process, indolalkylamine catabolic process, indole-containing compound catabolic process, tryptophan catabolic process, tryptophan metabolic process, indolalkylamine metabolic process, indole-containing compound metabolic process, cellular biogenic amine catabolic process, among others (Table 3).

Clinical perspective

To conclude, liver transaminases should not be considered as mere biomarkers of liver damage but central players in the pathophysiology of the NAFLD in particular or the MS components in general. Further research has to be done to define whether the elevation of these enzymes is an adaptive or a causative process of the disease.

In particular, because many confounding issues are implied in a pathogenetic relationship with liver, heart and kidney, it is time to look at multi-organ pathogenetic interactions, as recently revised by Bonora *et al*^[22].

Finally, mutations in *IDH1* and *IDH2* seem to be critically involved in the generation of certain types of cancers because they create “neoenzymes” that produce 2-hydroxyglutarate, which are required for tumor cell growth from α -ketoglutarate (α -KG)^[23]. α -KG is derived from glutamine through its conversion to glutamate by glutaminase. This process may explain the glutamine dependency of the cancer cell growth^[24]. Then, it is tempting to speculate that glutamate excess as observed in the MS and NAFLD is an appropriate milieu for cancer development, which may explain the high prevalence of hepatocellular carcinoma in these patients^[25], which offers, at the same time, new avenues for its treatment.

Abstract

Nonalcoholic fatty liver disease (NAFLD), defined by excessive liver fat deposition related to the metabolic syndrome, is a leading cause of progressive liver disease, for which accurate non-invasive staging systems and effective treatments are still lacking. Evidence has shown that increased ferritin levels are associated with the metabolic insulin resistance syndrome, and higher hepatic iron and fat content. Hyperferritinemia and iron stores have been associated with the severity of liver damage in NAFLD, and iron depletion reduced insulin resistance and liver enzymes. Recently, Kowdley *et al* demonstrated in a multicenter study in 628 adult patients with NAFLD from the NAFLD-clinical research network database with central re-evaluation of liver histology and iron staining that the increased serum ferritin level is an independent predictor of liver damage in patients with NAFLD, and is useful to identify NAFLD patients at risk of non-alcoholic steatohepatitis and advanced fibrosis. These data indicate that

incorporation of serum ferritin level may improve the performance of noninvasive scoring of liver damage in patients with NAFLD, and that iron depletion still represents an attractive therapeutic target to prevent the progression of liver damage in these patients.

INVITED COMMENTARY ON HOT ARTICLES

We read with interest the article by Kowdley *et al*^[1] reporting an association between serum ferritin and the severity of liver damage in patients with nonalcoholic fatty liver disease (NAFLD), and strongly recommend it to the readers.

NAFLD is defined by the presence of liver fat deposition related to systemic insulin resistance and the metabolic syndrome^[2]. In susceptible individuals, NAFLD is associated with oxidative hepatocellular damage, inflammation, and activation of fibrogenesis, i.e., non-alcoholic steatohepatitis (NASH)^[3], with potential progression towards cirrhosis and hepatocellular carcinoma (HCC)^[4], whereas simple steatosis is believed to represent a relatively benign condition^[5]. Due to the epidemic of obesity and the metabolic syndrome, NAFLD is now the most common liver disease and the leading cause of altered liver enzymes in Western countries^[6,7], and it is supposed to become the leading cause of end-stage liver disease, liver transplantation and HCC within the next 10-20 years. Considering the high prevalence of the NAFLD (20%-34% of Western population) two key clinical challenges are expected: the development of noninvasive methods for the diagnosis, staging and follow-up of NASH, and effective treatment strategies counteracting disease progression. Although the gold standard for diagnosis is still liver biopsy, it would be impossible to perform in such a large population at risk, whereas algorithms to predict steatohepatitis and liver fibrosis are still inefficient, need validation, and leave a large grey area^[5]. In addition, although promising results have been shown for anti-oxidants^[8], no therapeutic trial has yielded convincing results in the progression of liver damage^[9], and no pharmacologic therapy is yet approved for NASH.

Over the last years, there has been accumulating evidence about a strong association between hyperferritinemia and mild iron overload unrelated to hereditary hemochromatosis and manifestations of the metabolic syndrome^[10-12], including NAFLD^[13-18], as recently reviewed by our group^[19]. Increased ferritin level was detected in about 30% of unselected patients with NAFLD^[20], which has been associated with increased hepatic iron, as determined by histological and radiological assessment, and by quantitative phlebotomy^[15,20-22]. However, it is likely that inflammation, cytokines, oxidative and endoplasmic reticulum stress, and the genetic background contribute to ferritin induction by compartmentalization of iron in macrophages in a subset of NAFLD patients without histologically detectable iron stores^[19,22-26]. Does hyperferritinemia reflect a subclinical increase in hepatic iron also in this latter subgroup? Very recent data, which have been generated thanks to the availability of magnetic resonance imaging protocols for reliable estimates of tissue iron concentration, confirmed a close link between hepatic iron stores, steatosis, and metabolic diseases. Haap *et al.*^[27] reported that in healthy non-diabetic subjects, serum ferritin is strongly associated with hepatic iron stores, and hepatic iron stores are independently associated with insulin sensitivity and hepatic fat accumulation. On the other hand, Zheng *et al.*^[28] reported that in Chinese subjects, subclinical hepatic iron overload is more frequent (60%) in subjects with pre-diabetes and diabetes than in those with normal glucose tolerance, and hepatic iron concentration explains

> 40% of glycated hemoglobin variance. Furthermore, in patients with steatosis, body iron stores have been linked to a higher risk of metabolic complications, such as insulin resistance and diabetes^[29-31], and to the faster progression of cardiovascular diseases^[32-35].

Our group first reported an association between hyperferritinemia, NASH, and the severity of liver damage^[13], which was later confirmed by other groups, even if evidence was still controversial^[1,14,19,36]. Histological evidence of hepatic iron accumulation has also been associated with an increased risk of fibrosis in large multicenter studies in patients with NAFLD both from Europe and the NASH Clinical Research Network (NASH-CRN) in the United States^[15,37], whereas *beta-globin* mutations, the best predictor of parenchymal iron overload in the Mediterranean area, were associated with an almost double risk of severe fibrosis^[16]. Furthermore, iron overload has also been associated with HCC in Italian patients with NASH-related cirrhosis^[38]. Recent data obtained in animal models are also consistent with a synergistic interaction between liver fat and iron in the pathogenesis of liver damage, which may be related to the induction of iron-dependent cell death (ferroptosis)^[39,40]. A schematic presentation of the hypothesized mechanisms underlying hepatic iron accumulation and the role of iron in the progression of liver damage in NAFLD is shown in Figure 1.

Most importantly, iron overload represents also a treatable condition. Experimental evidence suggests that iron depletion induced by chelators induces glucose uptake and utilization in hepatocytes *in vitro* and in the liver *in vivo*, increasing insulin receptor binding activity and signaling^[41].

Several reports indicate that iron depletion, most frequently achieved by phlebotomy, may be beneficial in patients with mild iron overload associated with NAFLD. Iron depletion has been first reported to improve insulin sensitivity in a short term in patients with NAFLD with and without increased ferritin levels in two pilot studies in patients with impaired glucose tolerance^[42] and normal glucose tolerance^[43], and it led to decreased HbA1c levels, heightened insulin secretion and insulin sensitivity in a randomized controlled study in a small number of patients with type 2 diabetes and increased ferritin levels^[44]. Both venesection therapy and dietary therapy improved serum ferritin, metabolic parameters and liver function in a controlled study in patients with hepatic iron overload associated with the metabolic syndrome^[45]. However, in a matched case-control study in 128 patients with diet-resistant NAFLD, iron depletion reduced insulin resistance more than lifestyle modifications alone, independently of other confounding factors^[21]. Finally, in an observational study in 198 NAFLD patients without diabetes with adjustment for propensity score, iron depletion was associated with a higher probability of normalization not only of insulin resistance, but also of liver enzymes during follow-up compared with lifestyle modifications alone^[46].

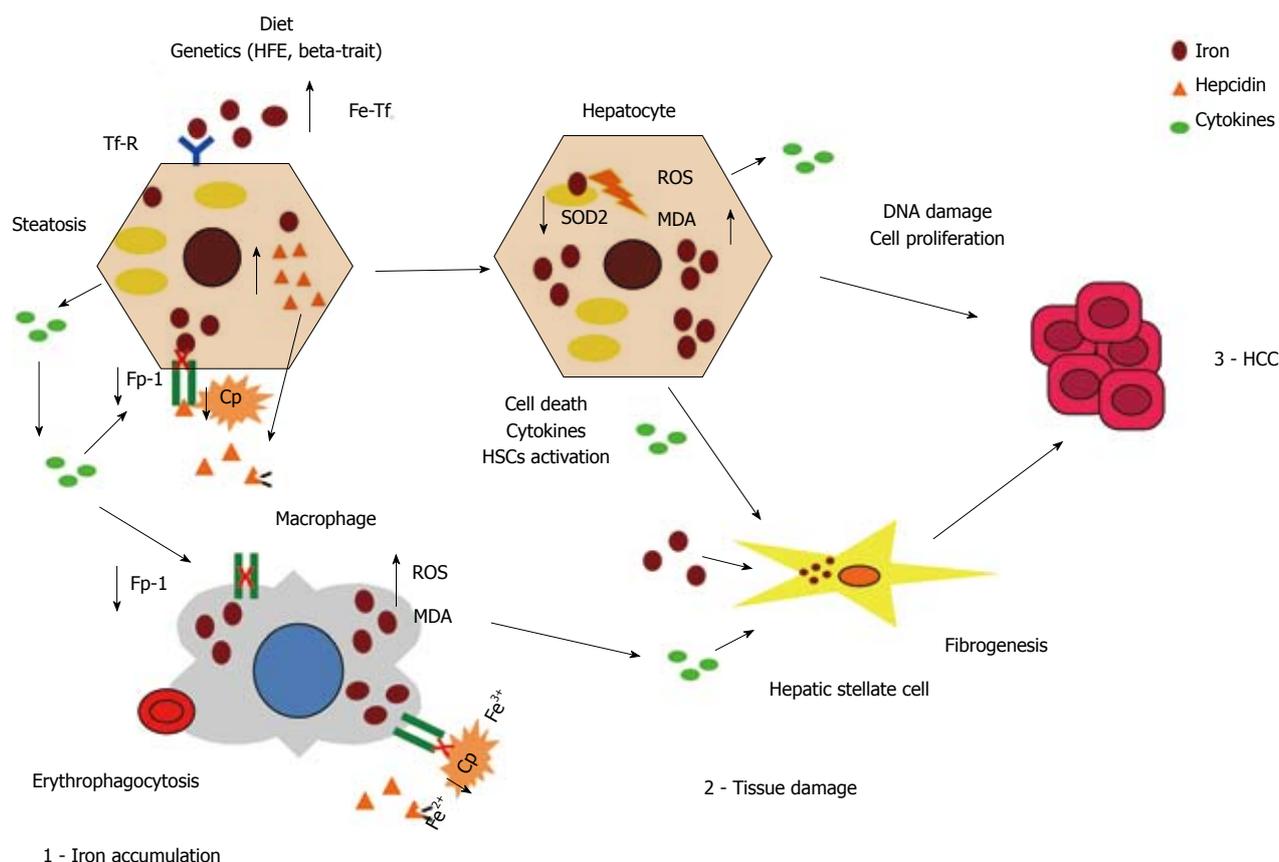

Figure 1 Proposed mechanisms explaining iron induced liver damage associated with steatosis and hepatic iron overload in hepatocytes (brown), macrophages (grey), and hepatic stellate cells (yellow). Cp: Ceruloplasmin; Fe-Tf: Ferric-transferrin; Fp-1: Ferroportin-1; HCC: Hepatocellular carcinoma; HFE: Hemochromatosis gene; HSCs: Hepatic stellate cells; MDA: Malonyl-dialdehyde; ROS: Reactive oxygen species; SOD2: Mn superoxide dismutase; Tf-R: Transferrin receptor. Modified from Dongiovanni *et al*^[9].

Within this context, the novel findings reported by Kowdley *et al*^[11] provided significant insight into this field. In this study, the authors assessed the relationship between elevated serum ferritin levels (defined as > 1.5 times the upper normal limit) and NAFLD severity in a multicenter study in 628 adult patients with NAFLD from the NAFLD-CRN database with central re-evaluation of liver histology and iron staining. Despite that the upper normal limits were specific for gender, hyperferritinemia was observed more frequently in males (25% *vs* 17%), and was strongly associated with other indices of iron stores including serum iron, transferrin saturation, and hepatic iron staining. Different from what observed in a previous study by our group^[15], hyperferritinemia was also associated with alanine and aspartate aminotransferases, but in line with our results^[15] with lower platelets, suggesting increased liver fibrosis^[47]. Histological features of NAFLD, including steatosis, hepatocellular ballooning, diagnosis of NASH, and fibrosis, were more severe in patients with increased serum ferritin, and at multivariate logistic regression analysis, hyperferritinemia remained significantly associated with advanced hepatic fibrosis [odds ratio (OR): 1.66, 95% CI: 1.05-2.62] and increased NAFLD activity score (OR: 1.99, 95% CI: 1.06-3.75). Based on these results, it is concluded that serum ferritin is associated with hepatic deposition and

worsened histological activity in patients with NAFLD, and it is a useful variable to identify NAFLD patients at risk of NASH and advanced fibrosis. An important finding, in view of the previously cited debate about significance of increased ferritin in patients without iron overload, is that hyperferritinemia was associated with enhanced histological activity even in patients without histologically detectable iron deposition.

Although a significant proportion of patients included in the NASH-CRN database had to be excluded due to the lack of ferritin measurement at the time of liver biopsy, important strengths of this study include the analysis of a large multicenter series of patients with histological evaluation, the inclusion of a large percentage of patients with moderate to severe liver fibrosis, and the availability of semiquantitative evaluation of iron stores by Perls' staining and determination of mutations in the hemochromatosis gene of hereditary hemochromatosis in the majority of patients, with concomitant exclusion of patients affected by hereditary hemochromatosis.

Therefore, adding to the previous literature^[15,19], this elegant and solid confirmation of the association between hyperferritinemia and severe hepatic fibrosis/NASH has two major implications. The first one and most scientifically grounded is that, whatever its cause (iron overload or altered compartmentalization, inflammation, cellular

stress), in patients with NAFLD, hyperferritinemia is very frequently and strongly associated with liver damage. Since serum ferritin evaluation is widely available in clinical practice and relatively inexpensive, the next step is to test its inclusion in noninvasive prognostic scores of liver damage related to NAFLD to improve their predictive power^[1,5,37]. Interestingly, a score incorporating increased ferritin levels, called the “National Association of Fraternal Insurance Counselors score” has already been developed and validated in a large series of Japanese patients, and although the evaluation of a serum marker such as the collagen IV 7S domain is required, that is not easily available outside Japan clinically, it showed a superior predictive power for NASH and severe fibrosis compared with other noninvasive scores^[48], and other authors have confirmed the predictive power of ferritin on liver damage in NAFLD^[49].

Secondly, but not less important, more clues, that link with increased hepatic iron stores or altered iron compartmentalization in macrophages with steatosis, insulin resistance, and progressive liver disease, are being found^[19,50]; and while the results of a small pilot randomized controlled trial evaluating the effect of iron depletion on the progression of histologically evaluated liver damage in patients with NAFLD and increased iron stores (NCT 00658164) are being expected, the accumulated available evidence allows to validate the effect of iron depletion on the prevention of hepatic, metabolic and cardiovascular complications of NAFLD.

Abstract

It is well known that perioperative hyperglycemia is the main cause of infectious complications after surgery. To improve perioperative glycemic control, we wish to highlight and comment on an interesting paper published recently by the *Annals of Surgery* entitled: "Early postoperative hyperglycemia is associated with postoperative complications after pancreatoduodenectomy (PD)" by Eshuis *et al.* The authors concluded that early postoperative glucose levels more than 140 mg/dL was significantly associated with complications after PD. Since we recommend that perioperative tight glycemic control (TGC) is an effective method to prevent postoperative complications including surgical site infection after distal, proximal, and total pancreatic resection, we support strongly this conclusion drawn in this article. However, if early postoperative glucose control in patients undergoing PD was administrated by conventional method such as sliding scale approach as described in this article, it is difficult to maintain TGC. Therefore, we introduce a novel perioperative glycemic control using an artificial endocrine pancreas against pancreatogenic diabetes after pancreatic resection including PD.

Hanazaki K. Tight glycemic control using an artificial endocrine pancreas may play an important role in preventing infection after pancreatic resection. *World J Gastroenterol* 2012; 18(29): 3787-3789 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i29/3787.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i29.3787>

INVITED COMMENTARY ON HOT ARTICLES

It is well known that perioperative hyperglycemia is the main cause of infectious complications after surgery^[1]. Figure 1 shows the relationship between hyperglycemia and postoperative infection (POI). Glucose toxicity is caused by surgical stress induced hyperglycemia such as a level of more than 200 mg/dL. Glucose toxicity leads to the leukocyte deficiencies, granulocyte adherence, impaired phagocytosis, delayed chemotaxis, and depressed bactericidal capacity. These abnormalities are the principal causes of POI and they can be improved by appropriate glycemic control^[1]. However, optimal blood glucose range to prevent postoperative infectious complications

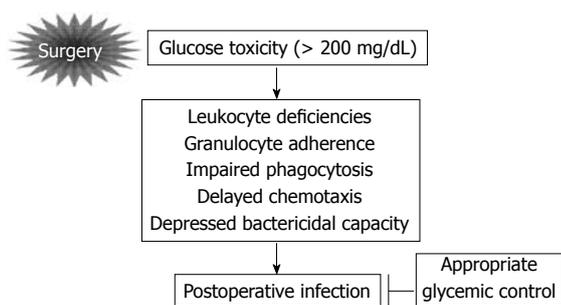

Figure 1 Relationship between hyperglycemia and postoperative infection.

remains unclear in various surgical settings^[1]. To improve the methods for perioperative glycemic control, we would like to recommend an interesting paper published recently on this topic^[2]. At the same time, we will introduce a novel perioperative tight glycemic control (TGC) using an artificial pancreas (AP) in patients undergoing pancreatic resection aimed to reduce postoperative infectious complications including surgical site infection (SSI).

We read with great interest the article published in *Annals of Surgery* entitled “Early postoperative hyperglycemia is associated with postoperative complications after pancreatoduodenectomy” by Eshuis *et al*^[2]. Among 330 consecutive patients undergoing pancreatoduodenectomy (PD), the average glucose levels were controlled at 135 mg/dL (preoperative), 133 mg/dL (intraoperative) and 142 mg/dL (early postoperative). Pre- and intraoperative glucose levels were not associated with postoperative complications. However, early postoperative glucose levels more than 140 mg/dL was significantly associated with complications after PD^[2]. Recent reports indicate that postoperative hyperglycemia increases the risk of postoperative infectious complications and prolongs hospital stay^[3-5]. Since we recommend that perioperative TGC is an effective method to prevent postoperative complications including SSI after distal, proximal, and total pancreatic resection^[6,7], we support strongly the conclusion drawn in this article^[2]. Undoubtedly, this is a significant paper in our understanding of the efficacy of strict perioperative glucose control for patients undergoing PD. However, if early postoperative glucose control in patients undergoing PD was administrated by conventional method such as sliding scale approach as described in this article^[2], it seems to be difficult to maintain strict glycemic control with less variability of blood glucose concentration recommended by the authors, including the targeting blood glucose zone of less than 140 mg/dL because pancreatogenic diabetes after pancreatic resection is likely to occur, either hypoglycemia or hyperglycemia, so called brittle diabetes^[8,9]. Therefore, we would like to share our opinions regarding more effective and safe TGC against pancreatogenic diabetes after pancreatic resection including PD.

In 2005, we reported that perioperative glycemic control using a closed-loop AP for total pancreatectomized dogs could maintain a stable blood glucose near the normoglycemia^[10]. Based on this experimental study,

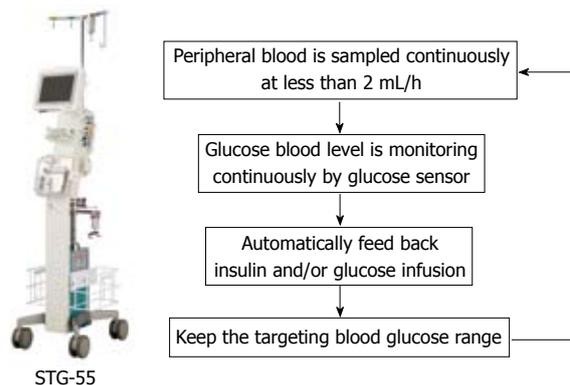

Figure 2 STG-55, a bedside-type artificial endocrine pancreas with closed-loop system.

since 2006, we have introduced clinically perioperative glycemic control using an AP^[8,11]. As described previously^[8,11,12], the Nikkiso Company (Tokyo, Japan) developed a bed-side type AP with closed-loop glycemic control system as STG-22 in conventional device^[8] and STG-55 in current device^[12] (Figure 2). Detailed mechanisms and characteristics of STG-22 and/or STG-55 were reported previously^[8,11,12]. Briefly, peripheral venous blood for glucose monitoring was sampled continuously at less than 2 mL/h. STG-55 (Figure 2)^[12] is capable of measuring continuously the blood glucose with its glucose sensor, and automatically infuses insulin and/or glucose to adjust the blood glucose level in accordance with a target blood glucose value, which is the so called closed-loop system^[13].

As a result in the clinical surgical settings, our previous report^[7] suggested that perioperative TGC using an AP (targeted blood glucose zone of 80-110 mg/dL) in patients undergoing pancreatectomy decreased significantly SSI as compared with that of conventional glycemic control by sliding scale method (targeted blood glucose zone of 150-200 mg/dL). In the sliding scale group, postoperative blood glucose levels rose initially before reaching a plateau of approximately 200 mg/dL between 4 and 6 h after pancreatectomy. The levels remained high for 18 h postoperatively. In the AP group, blood glucose levels reduced steadily, reaching the target zone (80-110 mg/dL) by 6 h after surgery. The total insulin dose administered per patient during the first postoperative 18 h was significantly higher in the AP group (mean \pm SD, 107 \pm 109 IU) than the sliding scale group (8 \pm 6 IU; $P < 0.01$). Neither group showed hypoglycemia^[7]. In addition, this novel glycemic control provided for high achievement of targeting blood glucose levels with stable blood glucose concentration^[7,8,14]. Moreover, surprisingly, we have never observed occurrence of hypoglycemia less than 40 mg/dL in more than 400 patients undergoing general surgery^[12]. Up to dates, we have performed perioperative TGC with target blood glucose levels of 80-110 mg/dL using an AP in more than 100 pancreatectomized patients including more than 50 PD and 10 total pancreatectomies. Of note, every pancreatec-

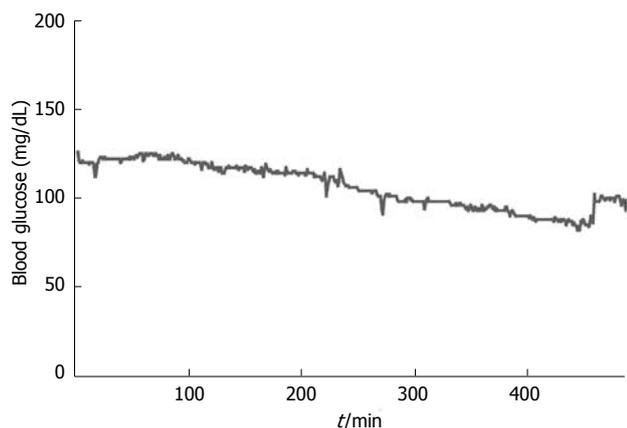

Figure 3 Continuous perioperative blood glucose levels in a case after total pancreatectomy.

tomized patient had stable perioperative blood glucose near the normoglycemia not only without hyperglycemia and/or hypoglycemia but also with less variability of blood glucose concentration, even in a total pancreatectomized patient (Figure 3) who often presented with the most serious pancreatogenic diabetes^[9]. Based on these findings from our experimental and clinical studies, we suggest that the AP helps us accomplish an effective and safe perioperative TGC in patients undergoing pancreatic resection.

Interestingly, this article^[2] suggests that an early postoperative level of at least more than 140 mg/dL is not recommended for improvement of morbidity after PD. Unfortunately, however, the ideal blood glucose range to reduce mortality and morbidity after PD remains unclear. Therefore, we promote a prospective randomized clinical trial to compared targeted blood glucose range of 80-110 mg/dL group and that of 140-180 mg/dL group in patients undergoing distal, proximal, and total pancreatic resection. Primary end point of this study is incidence of SSI and secondary end points are other postoperative complications and mortality (data not shown). We believe that this novel perioperative glucose control using AP is an easy and a reliable method to maintain targeted blood glucose zone, such as 80-110 mg/dL, 110-140 mg/dL and 140-180 mg/dL, which can be determined freely even in patients undergoing pancreatic resection. In the future perspectives, it is essential to find the optimal blood glucose range to improve morbidity and mortality in patients undergoing pancreatic resection, and then AP will be a useful device to maintain the range.

In conclusion, we suggest that the TGC using an artificial endocrine pancreas with a closed-loop system may play an important role in the effective control of in-

fection after pancreatic resection. This novel perioperative glycemic control will enable us to improve surgical outcome by reducing the postoperative infectious complications due to surgical stress induced hyperglycemia.

Abstract

Inflammatory bowel diseases (IBD), including ulcerative colitis (UC) and Crohn's disease (CD), are chronic, progressive and disabling disorders. Over the last few decades, new therapeutic approaches have been introduced which have led not only to a reduction in the mortality rate but also offered the possibility of a favorable modification in the natural history of IBD. The identification of clinical, genetic and serological prognostic factors has permitted a better stratification of the disease, thus allowing the opportunity to indicate the most appropriate therapy. Early treatment with immunosuppressive drugs and biologics has offered the opportunity to change, at least in the short term, the course of the disease by reducing, in a subset of patients with IBD, hospitalization and the need for surgery. In this review, the crucial steps in the natural history of both UC and CD will be discussed, as well as the factors that may change their clinical course. The methodological requirements for high quality studies on the course and prognosis of IBD, the true impact of environmental and dietary factors on the clinical course of IBD, the clinical, serological and genetic predictors of the IBD course (in particular, which of these are rel-

evant and appropriate for use in clinical practice), the impact of the various forms of medical treatment on the IBD complication rate, the role of surgery for IBD in the biologic era, the true magnitude of risk of colorectal cancer associated with IBD, as well as the mortality rate related to IBD will be stressed; all topics that are extensively discussed in separate reviews included in this issue of *World Journal of Gastroenterology*.

INTRODUCTION

Inflammatory bowel diseases (IBD), including ulcerative colitis (UC) and Crohn's disease (CD), are chronic, progressive and relapsing inflammatory disorders of unknown etiology that may cause disability over time. Genetic, environmental and intestinal microbial factors have been reported to play a role in the etiology and pathogenesis of IBD^[1]. IBD represents a life-long disorder that may occur at any time from early childhood to late adulthood, although over 80% of cases are cur-

rently diagnosed in the second or third decade of life. UC is characterized by inflammation and ulcerations in the large bowel mucosa and submucosa, whereas CD is a trans-mural inflammatory disorder that may involve various sites of the gastrointestinal tract: in 40%-70% of cases the terminal ileum. Approximately 50% of the patients with IBD present a slight evolutive disease with a low prevalence of relapses, hospitalizations, and complications^[2,3]. Other patients have a more severe course and may develop complications that require surgery. In UC, the main complications include toxic megacolon, massive hemorrhage or colon perforation, while strictures and fistulas are uncommon. In CD, intestinal strictures, internal or perianal fistulas or abscesses are frequent, being reported in approximately one-third of patients.

A better understanding of the natural history of this chronic disabling disorder provides valid opportunities: (1) by better defining etiological factors and pathology, it may allow the set up of new strategies of disease prevention; (2) by identifying the relevant clinical subsets in which disease prognosis can be stratified by initial clinical, serological or genetic features, it may be useful in the choice of the most appropriate management of these patients; and (3) by understanding the evolution and the time course of the disease, it may help to define the best end points for clinical trials designed to test drugs modifying disease course^[4] (Figure 1).

Questions regarding the natural history and prognosis of IBD are among the most prominent concerns both for patients and clinicians. Unfortunately, most data regarding the course of IBD are obtained from a limited number of cohorts and not all studies focusing on the course and prognosis are of high quality. Adequate knowledge of the methodological requirements of studies focused on prognosis is crucial for interpreting the results of observational studies and for applying these results in clinical practice. In this issue of *World Journal of Gastroenterology* (WJG), these methodological aspects have been critically discussed by Modesto *et al.*^[5]. In particular, they stressed the criteria for an excellent cohort study of prognosis: population-based, use of standard diagnostic criteria for UC and/or CD, start of follow-up already at inception, complete follow-up (80% or more), and use of survival methods to evaluate results.

The crucial steps in the natural history of IBD include the occurrence of lesions, the manifestation and severity of symptoms, the development of complications, the need for surgery, the disability and the mortality (Figure 2). In order to achieve a favorable modification in the disease course, an effective intervention must be carried out at the right time and with a specific therapeutic endpoint (Figure 1). The main outcomes considered include disease activity and relapse, corticosteroid therapy, hospitalizations, complications, surgery, post-operative recurrence, and mortality. More recently, mucosal healing (MH) has been included^[6,8]. Early treatment is advisable, before the development of severe bowel damage and impaired functioning^[6,8]. There is probably a difference between early disease and long-lasting disease, the control of the disease process being more difficult and unstable in the latter situ-

ation^[6]. Immunological status of the patients may change over the course of the disease; a stable remission will usually be more difficult to obtain in long-lasting disease and the disease will be more treatment-dependent^[6,9].

RISK AND PROGNOSTIC FACTORS

As far as the approach to the treatment of IBD is concerned, it must take into consideration the potential impact of environmental factors (e.g., dietary factors, smoking, psychological stress, drugs and infections) on the clinical course. Clinical, serologic and genetic factors have been reported to be associated with a different clinical course, but their relevance in everyday clinical practice is still controversial^[10].

Two reviews in this issue of WJG deal with prognostic factors in IBD^[11,12].

In the first, Cabré *et al.*^[11] critically review the role of environmental and dietary factors on the clinical course of IBD. Smoking is the only well established risk and prognostic factor in IBD, with a different impact on CD and UC. In CD, there is consistent evidence that active smoking is a risk factor for post-operative disease recurrence^[13,14] but the impact of smoking on the response to therapy is still controversial. In CD patients, the beneficial effect of giving up smoking can be observed; conversely, some patients with refractory UC may even benefit from taking up smoking again^[13,15,16]. Based on these observations, therapeutic trials with transdermic nicotine have been performed but with inconclusive results.

The role of dietary habits and dietary manipulation on the clinical course of IBD is far from being well established; therefore, IBD patients are usually encouraged to follow a free diet. As far as concerns the possible therapeutic role of some dietary components, enteral nutrition appears to be effective in CD, particularly in the pediatric population and a low-fat diet seems to be particularly useful even in adult patients^[17-20].

With regard to the relationship between psychological stress and IBD, a recent systematic review of 18 prospective studies examining stress as a risk factor for disease exacerbations showed a significant association, and coping behaviors appeared to modulate the effect of stress^[21]. Furthermore, it has been reported that approximately 50% of IBD patients had experienced some type of stress; family stress was the most commonly reported form, followed by work or school and financial stress^[22].

As far as drugs are concerned, nonsteroidal anti-inflammatory drugs (NSAIDs) are generally considered to potentially affect the IBD course. This concept is not supported by consistent evidence, although in a subset of susceptible patients, NSAID-induced IBD flares appear to occur early after NSAID administration^[23]. Current evidence does not support the role of antibiotics and vaccines as a prognostic factor in IBD, albeit antibiotic use is included in the predisposing factors of IBD etiology^[24].

Intestinal infections due to enteropathogens have been associated with IBD relapse and the response to therapy^[25]. In particular, associated *Clostridium difficile* in-

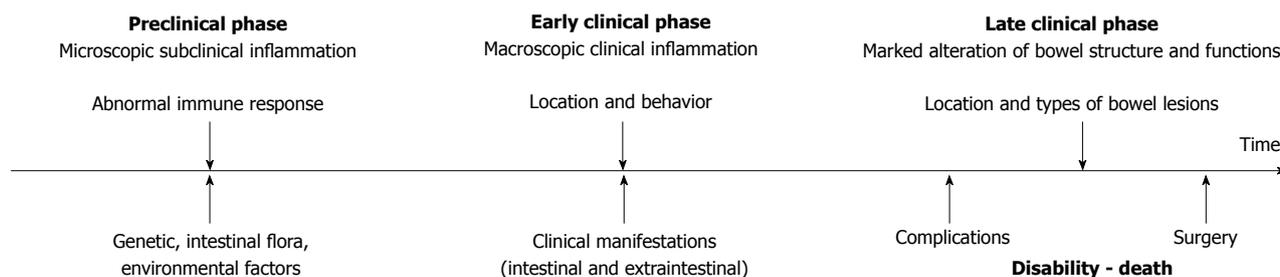

Figure 1 Longitudinal course of inflammatory bowel disease.

fection (which is more frequent in UC than CD) has been reported to have a negative effect on IBD outcome, and to lead to longer hospitalization time, as well as high rates of surgery and a high mortality rate^[26]. The role of cytomegalovirus reactivation in the colon of patients with refractory colitis remains to be fully elucidated^[27].

In the second paper, Beaugerie *et al.*^[12] review the role of clinical, serological and genetic predictors of the IBD course and discuss their potential role in clinical practice. This aspect appears to be particularly relevant: there is a need for predictors of a benign or unfavorable clinical course, in order to avoid over-treatment of patients who will experience a mild clinical course and under-treatment of those patients who will experience an aggressive and progressive disorder.

In CD, age under 40 years, perianal disease, ileal lesions and need of steroids at diagnosis have been consistently associated with an unfavorable medium- and long-term clinical course^[28-31]. In the post-operative setting, smoking, history of previous resection and severity of early post-operative endoscopic recurrence are the strongest predictors of symptomatic recurrence. In UC, extensive colitis, high disease activity, younger age and female gender are associated with poor outcome in most population-based studies^[32-34].

Genetic factors and luminal microbes, besides their role in triggering the IBD, may also be directly, or indirectly, involved in the clinical course of IBD^[35,36].

Identifying genetic prognostic factors in IBD is very attractive as they are already present at the onset of the disease and remain stable over time, which is not the case for clinical and serologic parameters. However, despite the growing number of identified susceptibility loci in both CD and UC, only very few have been associated with disease outcomes. The development of genome-wide association scanning techniques has led to the discovery of more than 100 confirmed IBD loci^[35-38]. Some of these loci, such as the Th 17 pathway genes (*IL23R*, *IL12B*, *JAK2*, *STAT3*), are shared between CD and UC, others are phenotype-specific (autophagy genes such as *ATG16L1*, *IRGM* and *NOD2* for CD; epithelial barrier genes *HNF4a*, *E-Cadherin*, *LAMB1* and *IL-10* for UC). Variants of some of these genes would be excellent prognostic factors^[39].

There is a growing body of evidence proving that in CD, the main *NOD2/CARD15* variants are closely related to ileal disease, a stenosing phenotype, an earlier need

for first surgery and a reduced post-operative disease-free interval^[10]. All of these findings provide evidence that may encourage the clinical application of *NOD2/CARD15* genotyping both as a marker of CD and as a prognostic factor of the need for early surgery due to stricturing and fibrostenosing disease^[10].

Certain genetic factors appear to influence the response to medical treatments. Polymorphisms in multi drug resistant-1, migration inhibitory factor, tumor necrosis factor (TNF) and apoptosis genes have been associated with a higher risk of treatment failure (steroids, cyclosporine, infliximab) in CD and UC^[40-45].

Antibodies directed against microbial peptides represent good serological markers that could help in the prediction of the clinical course of IBD^[10,46]. Patients with a stronger immune response to microbial peptides are associated with early disease onset of CD, fibrostenosing and penetrating disease, and need for early small bowel surgery^[10,46]. In pediatric CD patients, baseline anti-*Saccharomyces cerevisiae* antibody (ASCA) reactivity is associated with earlier complications, relapsing disease and need for additional surgery^[10,46]. The frequency of disease complications increases with reactivity to increasing numbers of microbial antigens (ASCA, anti-I2, anti-OmpC, and anti-CBir1). High levels of perinuclear anti-neutrophil antibody are associated with the risk of subsequent chronic pouchitis in UC patients undergoing ileal pouch-anal anastomosis^[47].

Overall, these data suggest that serological markers of microbial peptides may be useful predictors of IBD complications. In future, genetic and serological markers will be associated with clinical findings to obtain more reliable and useful predicting tools.

INTESTINAL LESIONS, CLINICAL MANIFESTATIONS AND DISEASE PROGRESSION

Progression of intestinal lesions may range from weeks to decades; however, it can be slowed down, stopped, or reversed spontaneously or by means of medical therapy^[2,3] (Figure 2). Superficial mucosal lesions are most prone to heal, whereas deep ulcers or transmural fissures may heal with more difficulty; fibrotic strictures are usually definitive. IBD becomes symptomatic when lesions are extensive or distal, associated with a systemic inflam-

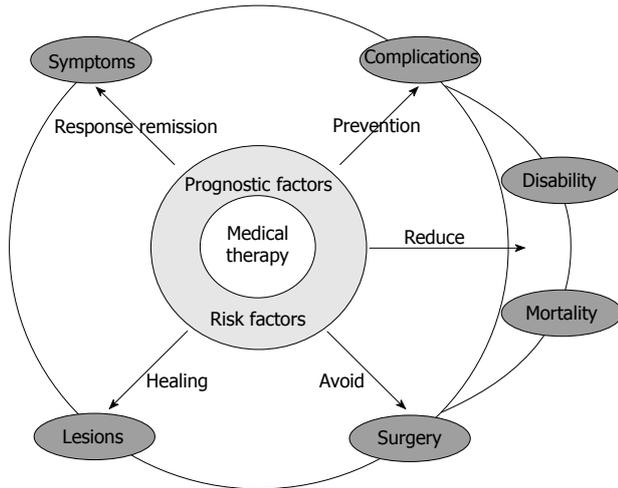

Figure 2 Potential effects of medical therapy on the natural history of inflammatory bowel disease.

matory response, or when associated with local complications such as dilatation (toxic megacolon), massive hemorrhage, strictures, perforation (abscesses and fistulas) and cancer^[2,3]. Colorectal lesions usually present more and early symptoms, whereas small bowel lesions may remain latent for several years^[2,3]. The disease course is generally characterized by a sequence of flares and remission of varying duration, while approximately one-fifth of these patients undergo a chronic, active, continuous disease course. Abdominal pain, abnormal bowel functions and rectal bleeding are the patients' main complaints that significantly alter their quality of life. Since UC is a pathological disorder that affects the mucosa and submucosa, while CD is a transmural inflammation, the anatomic evolution of the lesions and the disease progression are different, and will therefore be considered separately.

UC involves the rectum and colon and extends proximally in a continuous fashion. Upon presentation, lesions are limited to the rectum (proctitis) in 30%-35% of patients, to the splenic flexure (left-sided colitis) in 30%-45% and to the cecum (pancolitis) in 20%-25%^[2,3]. During the course of the disease, after 20 years, the rate of pancolitis may increase reaching 50% of cases. Pancolitis may be associated with inflammation of the terminal ileum ("back wash ileitis"); children do not always have rectal lesions. Mucosal lesions are usually diffuse and superficial, and deep ulcerations are present only in patients with severe disease. Perianal disease may develop in rare cases of UC. Diagnosis may change from UC to CD in 5%-10% of adult patients and in 15%-40% of pediatric patients^[2,3,32,48]. UC appears to be particularly severe in younger patients (especially in children), with a higher frequency of flares that do not respond to medical treatment. Severity of flares and their response to therapy vary and are difficult to predict. Disease activity tends to decrease over time, with 40%-50% of patients in prolonged remission and about 30% with active disease. Clinical remission is usually associated with MH^[8,49]. Extra-intestinal manifestations are observed in one-third of UC patients^[50].

In CD, the lesions can involve any segment of the digestive tract, from the mouth to the anus, but mainly affect the distal ileum and the colon. At the time of diagnosis, approximately 40% of patients present with ileocolonic disease, about 30% have isolated ileal disease, and another 30% have a pure colonic disease^[2,3]. Approximately 5%-15% of patients have associated upper gastrointestinal lesions and 20%-30% present perianal lesions^[2,3,51,52]. The localization of the lesions changes only minimally over time, with only 10%-15% of patients presenting a change in lesion localization 10 years after diagnosis^[53-55].

Although the location remains relatively stable, the clinical behavior of CD shows a dynamic evolution with striking changes over the course of the disease^[53-55]. During the first few years of CD, the non-penetrating/non-stricturing (inflammatory) form predominates, whereas most patients develop complications during follow-up and are then classified as having a penetrating or a stricturing disease. These two forms may co-exist in the same patient, since internal fistulae may complicate longstanding intestinal stenosis. Disease evolution is related to lesion localization, the development of complications (abscess, fistula, stricture) being more frequent and rapid when the small bowel is involved, whereas when the disease is localised in the colon, it may remain inflammatory and uncomplicated for many years. There is no relationship between symptoms and progression of the intestinal lesions, since strictures and fistulae may develop for several years with only mild symptoms or, in some cases, without any symptoms at all^[5]. Approximately 50% of CD patients have only a slight evolutive disease and, therefore, overtreatment should be avoided^[28-30,56]. The remaining patients present a more aggressive and evolutive disease with high rates of relapse, complications, hospitalization and surgery, all conditions that considerably affect the patients' everyday life and long-term projects. For these patients, sustained control of disease activity and progression is clearly warranted. Taken together, these data obviously indicate the need for strategies aimed at interrupting or delaying the natural evolution of this pathological condition. Current treatment options (antibiotics, steroids, immunosuppressive drugs, biological therapies) may relieve the inflammatory symptoms, but do not improve fibrostenotic obstruction^[57-63]. The results of medical treatment aimed at stricturing or penetrating CD are poor, since 64% of these patients ultimately require surgery within one year^[64]. This situation should be taken into consideration (and discussed with the patient) when planning medical treatment. It is likely that progression to a stricturing or penetrating disease phenotype is an end-stage sequel of CD associated with either irreversible fibrosis or severe inflammation that will not abate despite optimal medical therapy introduced at too late a stage^[65].

IMPACT OF MEDICAL THERAPY

The advancements in knowledge of IBD over the past few years have modified the treatment goals. While, in the

past, the aim of medical treatment was an improvement in IBD symptoms, the current objective is to achieve a deep remission, defined, both in UC and CD, as clinical remission [Mayo score for UC activity < 2 and Crohn's disease activity index (CDAI) < 150] with MH (Mayo endoscopic score for UC < 1 and simple endoscopic score for CD < 2) and cessation of steroid administration^[6-8,65-67] (Figure 2). Therefore, treatment should modify the course of the disease by avoiding the disabling condition and irreversible tissue damage. The treatment strategy in IBD should, therefore, be tailored according to the risk that each patient runs in developing a disabling disease. In this issue of *WJG*, the review by Reenaers *et al*^[68] focuses on the impact of treatment on the natural history of IBD.

Clinical and endoscopic remission is the best result that one can hope to reach and every effort should be made to maintain this condition for as long as possible. Healing of the mucosa, therefore, appears to be an obvious endpoint of treatment. MH can be considered appropriate for UC which is a disease of the mucosa, whereas the term intestinal healing would be more correct for CD which is a transmural disease^[67]. Complete assessment of intestinal healing in CD can be obtained only by using both endoscopy and cross-sectional imaging techniques (magnetic resonance, computed tomography, ultrasonography). In CD, it is not uncommon to find healed mucosa covering symptomatic intestinal stenotic segments. Another crucial point is the timing of endoscopic evaluation which was seen to differ (range: 4-52 wk) in studies evaluating the MH^[7,8,67]. Many studies have been performed investigating the relationships between clinical symptoms and intestinal lesions but, to date, MH has been evaluated as the primary clinical end point in a single randomized clinical trial^[69]. Efficacy of adalimumab (anti-TNF α antibody) for induction and maintenance of MH in 135 adults with moderate-to-severe ileocolonic CD was evaluated in this trial^[69]. Twenty-seven percent of patients receiving adalimumab had MH at week 12 (the primary end point) *vs* 13% given placebo ($P = 0.056$). At week 52, rates of MH were 24% and 0%, respectively ($P < 0.001$). Clinical remission rates (CDAI < 150) were 52% for adalimumab and 28% for placebo at week 12 ($P = 0.006$) and 28% and 3%, respectively, at week 52 ($P < 0.001$). Despite the lack of data to confirm an impact of MH induced by anti-TNFs on outcomes in CD, the issue of potential benefits is widely debated. Furthermore, scientific evidence that MH may change the natural course of IBD needs to be proved in long-term studies^[6-8,65-67].

The current medical armamentarium for treating moderate-severe IBD consists of corticosteroids, immunosuppressants and biologics (anti-TNF α antibodies), but for most of these medications it is unclear whether treating patients more aggressively will actually slow down disease progression^[67,70,71].

In UC, the percentage of patients achieving MH appears to be of the same order for treatment with immunosuppressants (53%-68%)^[8,72,73] and biologics (30%-71%)^[8,74-76]; albeit, it is obtained more rapidly with the latter agents.

Complete restoration of the mucosal architecture may be achieved when acute UC is of short duration and a prompt response to medical therapy has been reached.

In CD, anti-TNF α antibody therapy has been reported, during 54 wk trials, to reduce the need for CD-related hospitalization and surgery^[77-80]; however, the duration of these effects is unknown. Although biological therapies have shown disease-modifying characteristics in other pathological conditions, more data are necessary before it can be confirmed whether they can influence the long-term natural history of CD^[65,66,81]. There is no doubt that these agents work best when introduced early in the course of the disease, when they could reasonably be expected to change the course of CD. The fact is that they are not: the median duration of disease when this practice is adopted is almost 10 years. It is these patients, who are not frequently found in clinical practice but represent the majority, upon whom attention is focused: new therapeutic agents may add even more delay and ultimately be associated with a higher burden of disease.

It is interesting to note that the overall percentage of CD patients achieving MH with anti-TNF α antibodies (29%-73%)^[8,67,77,82-84] is of the same order as that reported with immunosuppressants (35%-73%)^[8,67,85-89]. Efficacy of infliximab monotherapy, azathioprine monotherapy, and the two drugs combined in adults with moderate-to-severe CD was evaluated by the Study of Biologic and Immunomodulator Naïve Patients in Crohn's Disease (SONIC study)^[83]. At week 26, MH had occurred in 43.9% of patients receiving combination therapy, as compared with 30.1% of patients receiving infliximab ($P = 0.06$) and 16.5% of patients receiving azathioprine ($P < 0.001$ for the comparison with combination therapy and $P = 0.02$ for the comparison with infliximab). In a recent prospective comparative study on CD, the MH rate achieved with azathioprine (50%) was not statistically different from that obtained with infliximab (60%)^[90]. On the other hand, another recent study showed that only non-complicated inflammatory CD behavior and long-term anti-TNF treatment were associated with a lower risk of the need for surgery, whereas azathioprine only slightly reduced this risk^[91].

A crucial point is the timing of commencement of early treatment. In clinical practice, early CD is usually considered as a newly diagnosed case, and this does not always correspond to onset of the early purely inflammatory form of the disease. Approximately 50% of patients already present a stricturing or penetrating disease at the time of diagnosis^[55], thus indicating a late disease which is more resistant to treatment both with immunosuppressants and biological agents.

SURGERY

Surgery plays an important role in the management of IBD. Up to 75% of CD patients will require an operation at some point in the course of the disease^[92], and, although surgery is not curative, it appears to be the most efficacious treatment in inducing prolonged remission^[93].

Therefore, surgery should not be dismissed as the end of the road after all medical options have failed, but should be considered a valid part of the overall management strategy^[63]. Nevertheless, in the biological era, avoiding surgery is becoming an emerging and interesting therapeutic endpoint. Considering that biological agents are claimed to induce MH in a large percentage of cases, a substantial reduction in the need for surgery would be expected. Although data from RCTs and observational studies^[94] suggest that biological use may reduce the need for surgery in the short term, the real impact of biologics on the lifetime risk of surgery remains to be established. Recent data from population-based cohorts have shown that in the pre-biologic era, the rate of surgery ranged between 27% and 61% within 5 years after diagnosis, and, in the era of anti-TNF α , ranged between 25% and 33%^[95], thus suggesting that the need for surgery also remains high in the era of biologics. Moreover, an analysis of secular trends of hospitalization and surgery rates in the United States, from 1990 to 2003, showed stable rates of bowel resection surgery for CD despite advances in treatment^[96]. In this issue of *WJG*, de Buck van Overstraeten *et al*^[97] discuss the need for surgery in randomized trials as well as the need for surgery in population studies (the real world).

In UC, the cumulative probability of colectomy within 10 years after diagnosis appears to be lower than previously reported^[98], but with considerable geographical variations (up to 25% in Denmark and 3.9% in Southern Europe, thus reflecting the different policies in approaching surgery)^[99]. In severe UC, colectomy is a life-saving intervention in patients refractory to intravenous steroids; prompt surgery, when necessary, is probably the major determinant of the improved outcome of severe UC in the past 30-40 years^[100,101]. During the last 20 years, medical rescue therapy with cyclosporine, and, more recently, with infliximab and tacrolimus, has received growing interest on account of its high efficacy in avoiding colectomy, in the short term, in severe steroid-refractory UC. However, the overall impact of rescue therapies on the outcome of severe UC remains to be defined: the short-term colectomy rate has remained stable over the last 30 years, despite the introduction of cyclosporine^[102] and the long-term efficacy of infliximab remains to be defined. In this issue of *WJG*, Dayan *et al*^[103] discuss, in detail, the role of surgery in severe UC in the era of medical rescue therapy.

RISK OF COLORECTAL CANCER

There is general consensus that the risk of colorectal cancer (CRC) is increased in IBD. Duration and extent of colitis, persistent inflammatory activity, family history of sporadic CRC and concomitant primary sclerosing cholangitis are well established risk factors. Although CRC risk has been studied more extensively in UC^[104], recent data suggest that CD carries a similar risk^[105]. However, the exact magnitude of the risk is controversial. In a meta-analysis published in 2001 which included

116 studies, a cumulative probability of CRC in UC of 2% by 10 years, 8% by 20 years, and 18% by 30 years has been reported^[104]. These results are in contrast with data from population-based studies from Scandinavia and the United States which report a 30-year cumulative probability of CRC in UC as low as approximately 2% with an overall risk of CRC among UC patients similar to that expected in the general population^[106,107].

Although geographical variations in the risk of developing CRC can play a role, differences in the methodology of individual studies (population-based *vs* referral center based) and different clinical approaches in the management of patients and follow-up (cumulative proctocolectomy rate, maintenance treatment with aminosalicylates, close follow-up evaluation of patients and surveillance programs) can explain the high variability in the risk. The exact definition of the risk appears to be crucial when planning “reducing-risk strategies”, for example, an endoscopic surveillance program, chemoprevention or both. In fact, the cost-effectiveness of any strategy aimed at reducing the risk of CRC is affected primarily by the baseline risk. Currently there is no strong evidence to support a chemoprophylactic role for 5-aminosalicylic acid, as well as for other drugs used in the treatment of IBD^[108-110].

An exhaustive discussion of the molecular biology and all the potential risk factors of IBD-associated CRC is reported by Dyson *et al*^[111] in this issue of *WJG*.

MORTALITY

Mortality is the most relevant clinical endpoint in studies focusing on the natural history of a chronic disease. In UC, mortality has continuously decreased over the last 50 years. This time trend probably results from improved medical and surgical management. Data from population-based studies suggest that the overall mortality in UC is not different from that of the background population. However, subgroups of patients, particularly those with extensive disease in the first few years after diagnosis, may be at greater risk of dying^[112]. Conversely, CD is associated with a small, but nevertheless significantly increased, risk of death compared to the general population^[113].

Although a slight decrease in the standardized mortality ratios has been observed over the last 30 years, this decrease is not statistically significant. This would appear to suggest that the overall prognosis of CD has not really changed despite the improvement in medical and surgical management over the last 30 years.

It will be interesting to see the trend in mortality due to CD in the near future. Preliminary data suggest that in-hospital mortality for CD is reduced in centers with a very large number of admissions for IBD^[114], thus suggesting that specialist care could improve outcomes. Besides the reduction in mortality related to the disease, we will, in the near future, also be facing more severe side-effects, including mortality, related to the more aggressive medical treatment.

CONCLUSION

Onset of IBD usually occurs in young adulthood and lasts throughout the patient's life. Despite the enormous progress that has been made in the understanding of these pathological conditions, the etiology remains unknown and no definite cure is yet available^[1-3]. The incidence of IBD is increasing worldwide, including also developing countries. UC and CD both have a negative effect on the quality of life and the capacity for work, and, furthermore, increase disability^[115]. Disease progression and prognosis have greatly benefited from the use of steroids introduced in the 1950s, immunosuppressants in the 1970s and biological agents in the 1990s. Although these treatments appear to be effective in the management of disease activity in the majority of patients, and to improve the quality of life, it is still not clear whether they are able to modify the natural history of IBD^[3,65-67]. There is evidence that new approaches aimed at optimizing immunosuppressants and biological agents by using them as early as possible could prevent disease progression and have a positive effect on the natural history of IBD.

ACKNOWLEDGMENTS

Authors are grateful to Mrs Marian Shields for help in editing the manuscript.

Abstract

Inflammatory bowel diseases (IBDs) are characterized by a chronic course with an alternation of relapses and remissions. Questions about prognosis are important for the patient who wants to know how the disease will affect his/her life and also for clinicians to make management decisions. Correct selection of the patients is the basis for good methodological studies on the course of IBD. A great proportion of data on the course of IBD is derived from a limited number of cohort studies. Studies help to define the endpoints for clinical trials and to identify subsets of patients in whom the prognosis of the disease can be stratified according to clinical features. Specific scientific requirements for high-quality studies on prognosis are the following: use of inception cohort, description of referral patterns, completeness of follow-up, objective outcome criteria, blind outcome assessment, adjustment for extraneous prognostic factors and statistical issues. We analyzed each of these requirements in studies on IBDs. To date, prospective and population-based cohort studies are the standard for an unbiased assessment of prognosis. A better knowledge of the

course of disease of chronic disorders ideally requires: (1) data from population-based studies, to avoid selection bias from referral centers in which patients with a more severe disease are usually treated; (2) inclusion of patients seen at the onset of the disease excluding misdiagnosed cases; and (3) follow-up from the onset of the disease to the end without dropouts.

INTRODUCTION

Inflammatory bowel diseases (IBDs) are characterized by an alternate course of relapses and remissions. A better knowledge of the course of a chronic disease permits us to answer correctly the questions about the response to therapy, disability, the rate of surgery and mortality, and to identify subsets of patients in whom disease prognosis can be stratified according to clinical features. Finally, studies of the course may increase our knowledge of disease pathology and etiological factors, possibly result-

ing in the prevention of disease.

Until 1970, the course and prognosis of the IBDs were derived initially from tertiary referral centers showing high morbidity and mortality, because they concerned more severe and complicated diseases. Subsequently, several cohort studies have been carried out showing better prognosis than previously described. In fact, for prognosis studies, it is preferable to analyze an unselected group of patients, ensuring the reliability of study results.

Since 1950, drug therapies for IBDs have been introduced, so it is impossible to have any long-term natural history data even if the placebo arms of the clinical trials can be utilized as a source of data on short-term natural history.

According to Sackett *et al*¹¹, natural history is the course of a disease from its biological onset to its recovery or permanent disability or death. In the spectrum of the course of the disease, we can identify different phases: (1) biological onset, “the initial interaction between man, environment and casual factors”; actually it is not certain what the initial event is; and (2) preclinical phase, interval between biological onset and clinical manifestations. To date, we do not know of any specific markers of disease that allow early diagnosis in this phase. The importance of an early diagnosis is also questionable because of the lack of specific treatment, which can alter the natural history of the disease if initiated in a preclinical phase.

In these first two phases, we deal with natural history because patients have not been treated. However, in all the population studies it is better to use the terminology “course of disease” more than “natural history”. The following phases deal with the course of disease: (1) clinical diagnosis that does not correspond to the onset of symptoms (often there is a long gap between the onset of the disease and the time of diagnosis, which represents an important source of bias); and (2) outcome: recovery, permanent disability, mortality. In chronic disease, the interim outcomes (i.e., complications, cancer, impairment of the quality of life, the need of immunosuppression) also represent relevant endpoints in prognostic studies.

In this review, we emphasize the methodological requirements for high-quality studies on the course and prognosis of IBDs. According to Sackett *et al*¹¹, specific scientific requirements for high-quality studies on prognosis are the following: (1) use of inception cohort; (2) description of referral patterns; (3) completeness of follow-up; (4) objective outcome criteria; (5) blind outcome assessment; (6) adjustment for extraneous prognostic factors; and (7) statistical issues. We analyzed each of these requirements within the studies on IBDs.

INCEPTION COHORT

To evaluate the prognosis of a disease in a cohort of patients, it is important to start the follow-up at a common point; preferably as early as possible in the course of the

disease (i.e., onset of symptoms or clinical diagnosis). For this reason, inception cohorts, preferably prospective, now represent the standard design to minimize bias. Bias in cohort studies can create apparent differences when they do not actually exist in nature.

The most frequent selection biases in conducting studies on prognosis are as follows. (1) Prevalence-incidence bias: when mild or asymptomatic cases, for example, proctitis, as well as fatal short disease episodes, such as severe colitis, are missed when studies are performed late in the disease process. It could result in an overestimation of the severity of the disease if the patients with a mild disease are missed, and in a more favorable prognosis if the mortality is not included in the prevalent group; (2) Lead time bias: occurs when the outcomes such as survival, as measured from the time of diagnosis, may be increased not only, because the patients live longer, but because screening permits an early diagnosis (i.e., for the availability of a new diagnostic test). This results in an apparent prolongation of the time to a predefined event (i.e., death, time to surgery or time to relapse), when instead it only results in an earlier diagnosis when compared to traditional methods [i.e., detection of asymptomatic colon cancer during screening endoscopy in patients with ulcerative colitis (UC) could result in an apparent prolongation of survival]; and (3) Length time bias: screening tends to detect a disease that is destined to progress slowly and, therefore, has a good prognosis. Also, advances in diagnostic techniques allow an earlier diagnosis, in an asymptomatic phase of the diseases with less aggressive course. Length time bias occurs when the patients, whose disease is discovered by screening, may also appear to do better, or live longer, than people whose disease is clinically diagnosed with symptoms. For example in patients with IBDs, before the introduction of endoscopy, mild colonic or distal disease, which are often mildly symptomatic, were often missed. This distortion is called technical bias and is related to the length time bias; together with the therapeutic bias (concerning the advance in therapy) it concurs to determine the temporal bias.

DESCRIPTION OF REFERRAL PATTERNS

In a study of prognosis, it is of great importance to use unselected patients to obtain more realistic results and for a wider applicability of study results. However, it is important to describe the referral pattern, which occurs when the characteristics of patients differ between one setting (e.g., primary care) and another setting that includes only referred patients (e.g., secondary or tertiary care). Studies from referral centers include more severe and complicated cases and usually result in poor prognosis.

Another relevant bias is the diagnostic/therapeutic access bias that occurs when studies made between populations with a different access to diagnostic facilities or therapy are compared. For example, in a tertiary center, patients have more opportunities to access biological ther-

apy, allowing a better course of disease in severe patients.

The outcome could also be influenced by the different health insurance or government programs across countries, as is the limit which exists in some countries (i.e., the United Kingdom) on the maximum duration of anti-tumor necrosis factor (TNF) therapy. Few data are available on the relationship between the length of maintenance therapy with anti-TNF α and the natural history of the disease, or with the achievement of mucosal healing, which actually seems to be the main outcome correlated with the maintenance of remission. The best study is the population study in which all the incident cases in a well-defined area are identified and followed up regularly with a clear protocol.

COMPLETENESS OF FOLLOW-UP

According to Sackett *et al.*^[1], in an accurate study of prognosis, at least 90% of the population should complete follow-up. This statement results from the evidence that a study with many patients lost during follow-up (usually > 20%) leads to distorted results. For example, if patients are lost during follow-up, for poor compliance, it could result in a better prognosis of the cohort. If they are affected by mild disease (like proctitis in UC) and therefore omit control visits, this can result in an overestimation of poor outcomes. However, for any degree of loss during follow-up, the validity of the study could be diminished. In addition to this, the length of follow-up is also important if one is evaluating some specific outcomes like survival. In that case, the follow-up time should be long enough so that about two-thirds of the patients will have suffered the events under study at the end of the observation period. In other cases, when the outcome evaluated is more frequent and rapid in occurrence (i.e., postsurgical recurrence or response to therapy), the follow-up could be shorter.

OBJECTIVE OUTCOME CRITERIA AND BLIND ASSESSMENT

The most important outcomes to assess in a prognosis study are disease activity, intestinal complications, surgery, cancer risk and mortality. One of the most relevant problems in the study of prognosis of IBDs is the difficulty of identifying an objective outcome because of the lack of an agreement in the definition of some important outcome measures that are open to possible differences in the results.

Disease activity

For example, analyzing some of the most important studies of prognosis, the definition of disease activity is variable. Below, we report some examples of this variability in cohort studies of IBDs.

Remission or no activity: (1) In the Copenhagen study^[2-7] for Crohn's disease (CD) no activity was defined as no

more than two stools per day and no blood or pus in the stools, no abdominal pain and no systemic symptoms such as fever or weight loss; and (2) in the Olmsted County study^[8-11], remission or no medication state was defined as a patient who required no medication for CD, excluding antidiarrheals.

Mild disease: (1) In the Copenhagen study^[2-7], mild disease activity was defined as ≥ 2 and ≤ 4 bowel movements and/or blood or pus in the stools and/or mild abdominal pain less than daily and no systemic symptoms; and (2) in the Olmsted county study^[8-11], mild disease was defined according to therapy; a patient with mild disease was a patient on sulfasalazine, 5-acetylsalicylic acid, antibiotics, or topical therapy.

Severe disease: (1) In the Copenhagen study^[2-7], moderate/high activity was defined as more than four stools daily and/or blood or pus daily and or abdominal pain either severe or daily, with or without systemic symptoms; and (2) in the Olmsted study^[8-11] the authors distinguished severe disease drug responsive and severe disease drug refractory; in the former, they referred to a patient on oral corticosteroids or immunosuppressive therapy lasting > 6 mo, with documented improvements; in the latter definition they included patients on oral corticosteroids or immunosuppressive therapy with no documented improvements within 2 mo for corticosteroids or within 3 mo for immunosuppressive medications.

In another important study, as in the European collaborative study on inflammatory bowel disease^[12-17], there was not a clear definition of disease activity; the course of the disease was assessed comparing the activity in a given point during the follow-up with the initial status. Any of these definitions involves subjective judgment and blind outcome assessment, one of the requirements, is not usually feasible and the study results are difficult to compare. Probably the CD activity index^[18] and Mayo Clinic score^[19] for UC are a more objective outcome to evaluate disease activity or response to therapy in clinical trials, but owing to their complexity, they are not often used in clinical practice.

Complications

Another bias that occurs when collecting data retrospectively, in evaluating intestinal and extraintestinal complications or need of surgery, is referral bias, which occurs when the appearance of complications has triggered the visit. Thus, it is essential that data on the occurrence of complications in IBDs are collected prospectively and in unselected samples, and the diagnostic measures are well defined. It is important to define the diagnostic and therapeutic protocol for complications because a different approach among centers influences the course of the disease. For example, endoscopic dilation is an approach adopted in stricturing postsurgical recurrence in CD in some centers, whereas in others, surgery is the preferred option and this different choice may influence prognosis.

Cancer risk and mortality

In the evaluation of cancer risk, an important concern is represented by the influence of surveillance bias. Surveillance bias, what some texts call detection bias, occurs when one group is followed more closely than another. This could lead to an outcome being diagnosed more often in the more closely followed group, but not because it really occurred more often in that group. Of course, cancer risk is linked to the surgical policy of the single center. A center that proposes early intervention may have a lower risk of cancer in long-term follow-up. It is mandatory that the cancer risk is evaluated in an incident cohort and in a population study. Another relevant requirement is the presence of a cancer registry in the area where the cohort is followed-up.

Another important outcome in prognosis studies is mortality. A recognized method to assess mortality is the calculation of standardized mortality ratio (SMR). SMR is the ratio between the observed number of deaths in a study population and the number of would-be-expected deaths, based on the age- and sex-specific rates in a standard population and the age and sex distribution of the study population. If the ratio of observed/expected deaths is > 1.0 , there is said to be “excess deaths” in the study population. It is, however, a very efficient stratification method and also permits one to use retrospective data. The results of studies with good methodological requirements have been summarized in a meta-analysis^[20], and give a reliable measure of this outcome correcting for differences among centers. Of course, meta-analysis should include studies with the same methodological standards. Small differences will only be detected if the studied group is very large. At the same time, if the baseline risk of an outcome (i.e., cancer or mortality) is very low, few events in the study population can identify an apparent relevant risk difference (i.e., the risk of Hodgkin lymphoma identified in the Florence cohort^[21,22]).

ADJUSTMENT FOR EXTRANEOUS PROGNOSTIC FACTORS

Examining the effects of specific factors on prognosis, it is important to adjust for extraneous variables, for the potential effect of associated factors on the results, thus unmasking a possible erroneous association. These confounding factors can also influence data from different population-based inception cohort studies. Even population-based inception cohorts could be difficult to compare because of the presence of different sources of bias, such as temporal, diagnostic access and therapeutic. Thus, it is important always to give information about the distribution of potential confounding prognostic factors.

In UC, it is important to know the extent of the distribution of the disease (pancolitis, left-side colitis, or proctitis) at diagnosis and the duration of disease because of the known major risk of cancer in pancolitis

and in long disease duration.

In CD, many relevant prognostic factors have been identified that should always be included in a multivariate analysis, such as smoking habits, age, site of disease, and extent of disease. Prognostic factors should be evaluated in incident cohorts prospectively.

An example of a possible bias in the evaluation of the prognostic factor is the study by Beaugerie *et al.*^[23]. Among 1526 patients diagnosed with CD between 1985 and 1998, those operated upon within the first month of the disease, patients with inadequate data, and patients with severe chronic nondigestive disease were excluded. The authors identified age < 40 years, perianal disease, and initial use of steroids as predictive factors for subsequent 5-year disabling. The authors suggested that referral bias could have distorted the results and a further study in a population setting was advocated. Of course, the prognostic model identified in an incident cohort should be applied in another independent cohort (the test sample).

STATISTICAL ISSUES

To date, to evaluate survival in prognosis studies, life-table-based methods have been used to minimize the difficulty in interpreting crude rates deriving from studies with different lengths of follow-up. During a follow-up period, a decrease in the number of patients makes it easier to detect differences in the early stages of follow-up. Some problems could derive from the lack of study power, and caution should be exercised when the effects are examined over different intervals of time. Rare events, such as lymphoma, risk being overestimated because the baseline risk in the general population is low. Finally, it would be desirable that data on the number of patients under observation at a given time are reported as confidence intervals. Cox's proportional hazard analysis is a type of multivariable analysis used when the outcome is the time to obtain the event. When data on important prognostic factors are not available, sensitivity analysis is a useful tool, assuming various degrees of maldistribution between groups, and seeing how it affects the results.

CONCLUSION

The validity of prognosis studies on IBDs is based on the presence of the above-mentioned methodological requirements. An excellent cohort study must fulfill the following criteria: (1) start of follow-up at inception; (2) population-based, or near to population-based; (3) use of standard diagnostic criteria for UC and/or CD; (4) use of survival methods; and (5) complete or near to complete follow-up ($\geq 80\%$).

Better knowledge of the course of chronic disorders ideally requires: (1) data from population-based studies to avoid selection bias from referral centers where patients with more severe disease are usually treated; (2)

UC: Ulcerative colitis; CD: Crohn's disease; SMR: Standardized mortality ratio; EC-IBD study: European collaborative study on inflammatory bowel disease; IBSEN: Inflammatory bowel south-eastern Norway; NA: Not available. Number of cases may vary between various reports from same centers.

inclusion of patients seen at the onset of the disease excluding misdiagnosed cases; and (3) follow-up from the onset of the disease to the end without dropouts.

The more relevant cohort studies are summarized in Table 1 (prospective and retrospective)^[2-7,12-17,23-41], which have been followed up for a long period and in which the methodological requirements listed above are satisfied. Two main outcomes are included in the table to show the variation between both types of study, despite the same methodology being adopted. Prospective cohort studies are a more relevant source of information. Although there was wide variation in the rate of surgery, which depends on the therapeutic policy adopted in different areas, mortality was homogeneous in the three main studies.

Abstract

Patients with extensive or complicated Crohn's disease (CD) at diagnosis should be treated straightaway with immunosuppressive therapy according to the most recent guidelines. In patients with localized and uncomplicated CD at diagnosis, early use of immunosuppressive therapy is debated for preventing disease progression and limiting the disabling clinical impact. In this context, there is a need for predictors of benign or unfavourable subsequent clinical course, in order to avoid over-treating with risky drugs those patients who would have experienced spontaneous mid-term asymptomatic disease without progression towards irreversible intestinal lesions. At diagnosis, an age below 40 years, the presence of perianal lesions and the need for treating the first flare with steroids have been consistently associated with an unfavourable subsequent 5-year or 10-year clinical course. The positive predictive value of unfavourable course in patients with 2 or 3 predictors ranges between 0.75 and 0.95 in population-based and referral centre cohorts. Consequently, the use of these predictors can be integrated into the elements that influence individual decisions. In the CD postoperative context, keeping smoking and history of prior resection are the stron-

gest predictors of disease symptomatic recurrence. However, these clinical predictors alone are not as reliable as severity of early postoperative endoscopic recurrence in clinical practice. In ulcerative colitis (UC), extensive colitis at diagnosis is associated with unfavourable clinical course in the first 5 to 10 years of the disease, and also with long-term colectomy and colorectal inflammation-associated colorectal cancer. In patients with extensive UC at diagnosis, a rapid step-up strategy aiming to achieve sustained deep remission should therefore be considered. At the moment, no reliable serological or genetic predictor of inflammatory bowel disease clinical course has been identified.

INTRODUCTION

The lifelong risk of developing inflammatory bowel disease (IBD) exceeds one percent in industrialized countries^[1]. Such diseases are considered as chronic, with a small trend towards spontaneous long-term extinction in ulcerative colitis (UC)^[2], but not in Crohn's disease (CD)^[3]. Despite an increasing use of immunosuppressive thera-

py, the long-term risk of intestinal resection and permanent ileostomy in CD is approximately 80% and 10%, respectively^[1]. In UC, the actuarial risk of colectomy is about one percent per year in population-based cohorts of Northern Europe^[4]. To reverse these unfavourable figures that have not significantly changed during the last five decades^[5], the early use of aggressive therapy, such as the combination of thiopurines and anti-tumor necrosis factor (TNF) therapy^[6], is considered both in CD and UC, with the aim of bringing patients into deep and sustained remission. However, some CD patients present at diagnosis with localized and uncomplicated (no perforation, no stricture) disease, and some UC patients present at diagnosis without disabling symptoms, biological abnormalities or severe endoscopic lesions. In those patients, the early and prolonged use of immunosuppressive therapy, with its associated risk of serious infections^[7] and cancers^[8,9], is questionable because the spontaneous evolution of the disease could have been benign. The risk of over-treating patients could be reduced in theory with the use of clinical, biological or endoscopic factors present at diagnosis and able to predict the subsequent course of IBD. In CD, there is also a need for predictors after complete resection of intestinal lesions when considering the postoperative preventive use of immunosuppressive therapy for limiting the risk of clinical recurrence. We review here the literature on clinical, serological and genetic predictors of IBD course, and discuss which predictors can be potentially useful in clinical practice.

CD

Clinical predictors of CD course

Prediction at diagnosis of unfavourable 5-year or 10-year clinical course: This question has been specifically studied in two referral centre cohorts^[10,11] and two population-based cohorts^[12-14], with fixed 5-year or 10-year study period and complete follow-up in most patients (Table 1). Markers of unfavourable CD course were either a single event (first clinical recurrence^[14] or surgical operation^[12,13]) or the presence of at least one element of a composite definition of disabling disease^[10,11]. Whatever the definition, age below 40 years and presence of perianal disease at diagnosis were identified in most studies as predictors of subsequent unfavourable evolution. Need for steroids for treating the first flare and presence of upper gastrointestinal lesions were associated with a poor outcome in two studies. Finally, in two single studies, terminal ileal location and ileo-colonic lesions were predictive of first surgical operation and disabling disease, respectively. Of note, active smoking status, which is an established transient worsening factor of CD course^[15,16], was not shown to be an independent predictor of unfavourable short and mid-term CD course in these studies.

Other studies: As a general feature, clinical predic-

tors of unfavourable CD course identified in the above dedicated 5-year and 10-year studies have been confirmed in other studies with various design, follow-up time and endpoints. In the historical national cooperative CD study, perianal disease was an independent predictor of unfavourable outcome among 1084 patients^[17]. In a Portuguese referral centre cohort testing CD outcome according to Vienna classification and other clinical markers, earlier age at diagnosis, penetrating lesions (including perianal fistulas and abscesses) and ileo-colonic location were associated with unfavourable outcome^[18]. In the Olmstedt population-based study, young age was predictive of surgery, irrespective of smoking status^[19]. In the Maastricht population-based cohort, young age, small bowel location and stricturing lesions were predictive of first surgery in 476 patients with a mean follow-up of 7 years^[20]. In a referral centre population from Boston, early surgery (within 3 years of diagnosis) was associated with active smoking status, ileal location and need for early steroids in 345 patients followed for at least 3 years^[21].

Whether childhood- and adult-onset CD courses differ in terms of severity has been recently questioned^[22,23]. Patients with childhood-onset disease tend to have more extensive intestinal involvement, more active disease requiring more immunosuppressive therapy, and more rapid disease progression. By contrast, CD patients with a family history of IBD do not exhibit a more severe disease course in population-based studies^[24] as well as in referral centre populations^[12]. Finally, erythema nodosum and pyoderma gangrenosum, at diagnosis or later in the disease, are not predictive of more severe CD course^[25].

Clinical predictors of long-term CD course: There are very scarce data on predictors of the long-term evolution of CD. In the Saint-Antoine cohort, predictors of 15-year CD course were characterized in 600 patients^[1]. Non-severe evolution was defined as clinically inactive disease for greater than 12 years, less than one intestinal resection without permanent stoma and no death. Factors independently associated with a non-severe 15-year clinical course were non-smoking status, rectal sparing, high educational level, older age and longer disease duration.

Clinical predictors of postoperative recurrence:

Literature on clinical predictors of postoperative recurrence is abundant and has been extensively reviewed recently^[26-28]. In brief, postoperative active smoking status appears in most studies as a strong predictor of postoperative recurrence: the risk of clinical recurrence and reoperation is approximately doubled in smokers^[29], with an increase in the risk according to the number of cigarettes smoked per day among smokers^[30]. The other independent undisputed predictor of postoperative recurrence is a history of prior resection. The positive predictive value of penetrating disease behaviour, short disease duration prior to surgery, non-colonic disease location, long duration and extensive bowel resection has been evidenced

Table 1 Clinical predictors of unfavourable course of Crohn's disease and ulcerative colitis

Study	Cohort type	No. of patients	Definition or marker of unfavourable course	Independent predictors of unfavourable course, present at diagnosis

Henriksen <i>et al</i> ^[12] , 2007	Population-based (IBSEN)	454	Relapse during the study period	Female gender Younger age
Within the first 10 yr after diagnosis				
Langholz <i>et al</i> ^[12] , 1994	Population-based (county of Copenhagen)	1161	Relapsing or chronic active course Colectomy	Less systemic symptoms (fever, weight loss) Extensive colitis High disease activity (including systemic symptoms)
Höie <i>et al</i> ^[56] , 2007	Population-based (EC-IBD)	771	Frequent relapse	Female gender Younger age Non-smoking status
Höie <i>et al</i> ^[57] , 2007	Population-based (EC-IBD)	781	Colectomy	Extensive colitis
Solberg <i>et al</i> ^[14] , 2009	Population-based (IBSEN)	423	Colectomy	Extensive colitis

¹One or more of the following criteria: more than 2 steroid courses, steroid dependence, hospitalization for disease flare or complication, disabling chronic symptoms, need for immunosuppressive therapy, intestinal resection or surgical operation for surgical disease; ²According to Vienna classification. IBSEN: A population-based inception cohort study; EC-IBD: European collaborative study group of inflammatory bowel disease.

less consistently. Finally, the roles of young age at onset and family history remain controversial.

Serological predictors of CD course

The search for serologic markers in IBD has led to the discovery of specific antibodies. Perinuclear anti-neutrophil antibody (pANCA) is associated with UC or UC-like CD whereas anti-*Saccharomyces cerevisiae* antibody (ASCA, glycan antibody) is mostly associated with CD^[31,32]. Three other markers linked to immune response towards bacteria have been identified; antibodies to the *Escherichia coli* outer-membrane porin C (OmpC), the *Pseudomonas fluorescens* CD-related protein [anti-CD related bacterial sequence (I2)] and the CBir1 flagellin^[33,34].

Many studies have been performed to assess the predictive value of these serological markers. Reactivity to ASCA, OmpC, anti-I2 and CBir1 has been associated with early disease onset CD, fibrostenosing and penetrating disease and need for early small bowel surgery^[34-36]. In paediatric CD patients, baseline ASCA reactivity has been associated with earlier complications, relapsing disease and need for an additional surgery^[37]. The frequency of disease complications increases with reactivity to increasing numbers of antigens (ASCA, anti-I2, anti-OmpC,

and anti-CBir1)^[38]. pANCA has been shown to be associated with less severe disease, UC-like disease and to be negatively associated with small bowel complication^[36,39]. ASCA positivity has been associated with CD of the pouch after ileal pouch-anal anastomosis (IPAA)^[40].

Genetic predictors of CD course

Before the era of genome-wide association studies, the role of genetic factors in IBD severity had been looked for by comparing familial and sporadic IBD. Although having a relative with IBD increases the risk for CD, the severity of CD is unaffected by family history^[24]. A family history of CD increases the risk of subsequent CD after IPAA. Identifying genetic prognostic factors in IBD is a very attractive option as they are already present at the onset of the disease and actually even earlier. Their main advantage is their long-term stability, which is not the case for many other potential predictive factors such as clinical parameters or serologic markers. However, despite a growing number of identified susceptibility loci in both CD and UC^[41], only very few have been associated with disease outcome. The presence of *NOD2* polymorphism has been associated with a more aggressive clinical course of CD; i.e., higher risk of intestinal strictures,

Table 2 Validation of the positive predictive value of Saint-Antoine predictors

¹Age < 40 years and perianal lesions at first presentation, need for steroids for treating the first flare; ²Unfavourable clinical Crohn's disease course (one or more of the following criteria: more than 2 steroid courses, steroid dependence, hospitalization for disease flare or complication, disabling chronic symptoms, need for immunosuppressive therapy, intestinal resection or surgical operation for surgical disease) within the 5 years following diagnosis.

earlier need for first surgery and reduced postoperative disease-free interval^[42-44]. Some studies have also tried to identify genetic factors associated with response to treatment. Polymorphisms in multi-drug resistant 1 (*MDR1*), *TNF* and migration inhibitory factor genes have been associated with corticosteroid refractoriness or sensitivity in CD and UC^[45-47]. *MDR1* polymorphism has also been associated with a higher risk of cyclosporine failure in patients with steroid-resistant UC^[48]. The efficacy of infliximab is partly due to the induction of apoptosis in activated T lymphocytes. A research group in Leuven has analyzed infliximab-treated patients and found polymorphisms in apoptosis genes predicting response to infliximab therapy in luminal and fistulizing Crohn's disease^[49]. Other studies suggest that genetic polymorphisms might be useful to predict anti-TNF therapeutic responsiveness in paediatric IBD^[50].

Despite their attractiveness, genetic markers will probably never be able to fully predict IBD behaviour and complications, because of the major role of environmental factors in the disease pathogenesis. On the other hand, they could be associated with other factors, such as clinical or microbiological data, in order to build relevant composite predicting tools.

Relevance and potential use of predictors in CD

Saint-Antoine clinical predictors at diagnosis and early use of immunosuppressive therapy: In the Saint-Antoine cohort, patients were considered as having an unfavourable ("disabling") clinical course in the first five years after diagnosis if they met at least one of the following criteria during the study period: more than 2 steroid courses, steroid dependence, hospitalization for disease flare or complication, disabling chronic symptoms, need for immunosuppressive therapy, intestinal resection or surgical operation for perianal disease. Among the 1123 patients studied, the rate of unfavourable course was 85%. By multivariate analysis, initial need for steroid use, age below 40 years and perianal disease at diagnosis were the three independent predictors of subsequent 5-year unfavourable course. The positive predic-

tive value of unfavourable course in patients with two or three predictors was 0.91 and 0.93, respectively.

The Saint-Antoine clinical predictors are the only predictive factors that have been tested subsequently in independent population samples (Table 2). In a subsequent group of 302 patients from the Saint-Antoine centre, the positive predictive value of unfavourable course in patients with two or three predictors was 0.84 and 0.91, respectively^[10]. The Saint-Antoine predictors were subsequently evaluated in two independent cohorts, using the same definition of unfavourable CD course as in the reference study. In the Liege referral population, the positive predictive value of unfavourable course in patients with two or three predictors was 0.67^[11]. This rate was 0.74 in the Olmstedt population^[51]. In conclusion, using the three Saint-Antoine predictors at diagnosis, the prediction of subsequent 5-year unfavourable CD course is accurate in more than two-thirds of patients from various populations. It is plausible that prediction accuracy holds true for the 5 to 10-year CD clinical course, since a strong homology has been demonstrated between the course pattern of CD in the first 3 years of the disease and the 7 subsequent years^[5,52].

In the literature, the proportion of patients exhibiting unfavourable clinical course in the first 5 years of the disease, whatever the definition (disabling disease, frequent clinical relapses, chronic disabling symptoms, need for surgery, *etc.*) exceeds 50%, with an expected trend towards higher prevalence in referral centre cohorts than in population-based studies^[53]. In clinical practice, patients presenting at diagnosis with irreversible penetrating or stricturing lesions, requiring (or not) immediate operation, can be considered as having complicated disease at diagnosis requiring early aggressive therapy (Figure 1). In the second recent European Crohn's and Colitis Organisation (ECCO) CD consensus, patients with upper gastrointestinal lesions or extensive (> 100 cm) lesions at diagnosis are also considered as having severe disease at presentation which justifies immediate use of immunosuppressive therapy^[54]. In the remaining patients, the need for treating moderate to severe flares

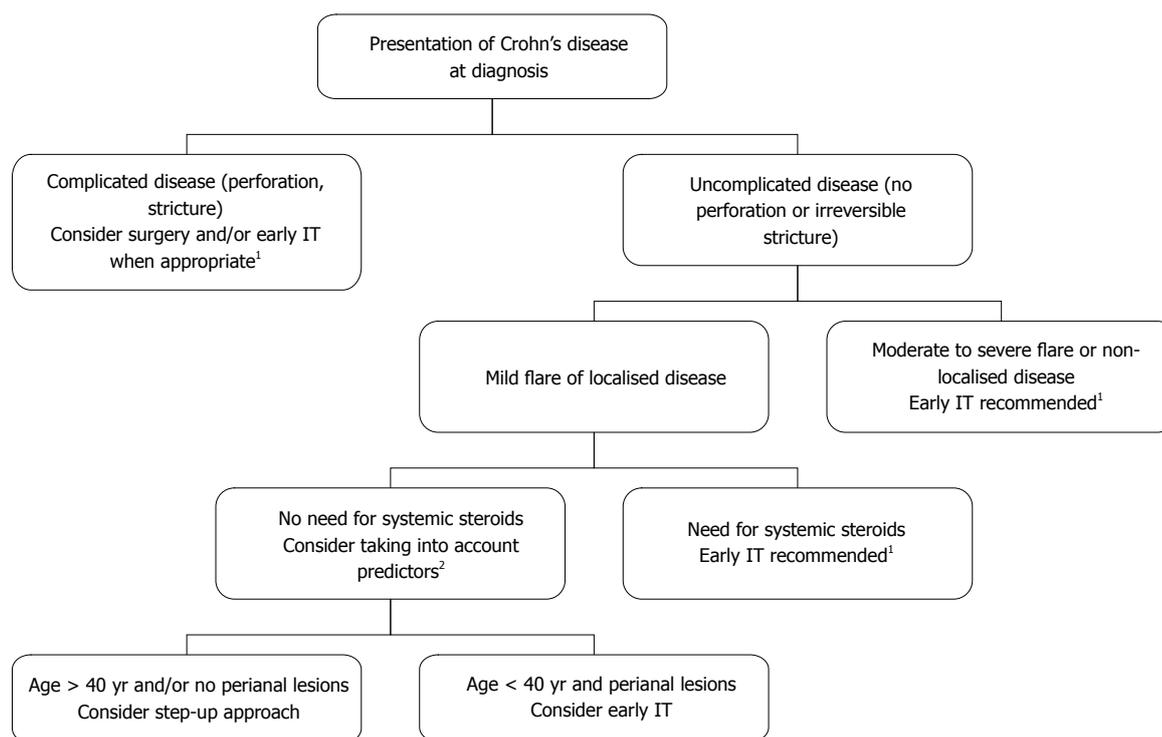

Figure 1 Indication for early immunosuppressive therapy. Thiopurines and/or anti-tumor necrosis factor therapy, according to presentation of Crohn's disease at diagnosis, ¹European Crohn's and Colitis Organisation guidelines and ²Saint-Antoine predictors (2 or 3 of the following items at diagnosis are predictive for subsequent 5-year unfavourable course: Age < 40 years, need for systemic steroids and presence of perianal lesions). IT: Immunosuppressive therapy.

with systemic steroids is increasingly considered as an indication for concurrent initiation of immunosuppressive therapy^[54], taking into account, for instance, the high rate of recurrence within the year after steroid discontinuation^[55]. Among the patients treated with systemic steroids from diagnosis, it must be noted that those who are younger than 40 years and/or have perianal lesions at diagnosis have *ipso facto* at least two predictors of unfavourable subsequent disease. Finally, patients with first disease flare not requiring systemic steroids often have localised^[28] (< 30 cm) continuous intestinal disease with mild symptoms. In this context of true initial benign disease only, Saint-Antoine predictors may be helpful for the decision: in particular, young patients with perianal lesions could be considered for early immunosuppressive therapy, given the high risk of subsequent unfavourable course. However, if early immunosuppressive therapy is not decided on and if patients go rapidly into clinical remission, subclinical inflammatory lesions can now be monitored using blood C-reactive protein, magnetic resonance imaging and faecal calprotectin evaluations, limiting the risk of subclinical progression of intestinal lesions towards irreversible damage without appropriate change in maintenance treatment.

Clinical predictors at surgery of postoperative recurrence and choice of the postoperative maintenance treatment: After intestinal resection, all previous smokers are strongly encouraged to quit smoking. For guiding the choice of the immediate postoperative treat-

ment, in the absence of a validated predictive index, the members of the ECCO consensus group have selected some of the predictors reported in the literature series^[28]. In addition to the two undisputed predictors of early recurrence (keeping smoking and prior resection), penetrating disease behaviour, perianal disease and extensive small bowel resection have been proposed as risk factors. In patients with at least one risk factor, thiopurines are proposed as the drug of choice for preventing early recurrence. However, it is also recommended to perform during the first postoperative year an ileocolonoscopy in order to assess the presence and severity of endoscopic perianastomotic lesions. These endoscopic findings are unanimously considered as the gold standard predictor of subsequent clinical evolution^[26,27], so that the definite choice of the postoperative prophylactic treatment should be based on the severity of endoscopic lesions^[28]. As a consequence, the choice of immediate therapy based on (insufficiently) validated clinical predictors *vs* tailored treatment initiated according to endoscopic findings has a limited impact since, in all patients, the final choice of the mid-term prophylactic treatment is based on endoscopic findings.

UC

Clinical predictors of UC course

Prediction at diagnosis of unfavourable 5-year or 10-year clinical course: This question has been specifically studied in five population-based studies (Table

1)^[2,4,12,56,57]. Young age at diagnosis and female gender were associated in two studies with a trend towards more frequent relapses^[12,56]. Active smoking status was associated with reduced number of relapses within 10 years after diagnosis in one cohort only^[56], but many other studies on the natural history have established the relationship between sustained non-smoking status and less active disease course^[1], with reversion of this impact when resuming smoking^[15]. However, of course, patients with UC are not encouraged to smoke. Finally, in the Danish cohort, a high level of systemic clinical symptoms at presentation (fever, weight loss) was associated at the same time with a trend towards infrequent relapses and chronic disease but higher risk of colectomy. Since proctocolectomy is no longer considered as the end of the medical problems in most operated patients, the risk of colectomy is a good marker of overall severity in patients with UC. Extensive colitis at presentation (defined as upper limit of macroscopic lesions proximal to the splenic flexure) has consistently been evidenced as an independent predictor of colectomy within the 10 years after diagnosis.

Serological and genetic predictors of UC course

Serological and genetic predictors have been far less studied in UC than in CD and only a few clinical settings have been investigated. As in CD, the severity of UC does not seem to be affected by family history of IBD^[12,58]. In the pre-colectomy situation, high levels of pANCA have been associated with the risk of subsequent chronic pouchitis in UC patients undergoing IPAA^[59]. pANCA might also be useful to predict response to anti-TNF therapy since negative status has been independently associated with early response to this treatment^[60]. Some genetic factors might also be useful to predict response to treatment in the future. A recent study by a German group suggests that homozygous carriers of IBD risk-increasing *IL23R* variants are more likely to respond to infliximab than are homozygous carriers of IBD risk-decreasing *IL23R* variants^[60]. It is also possible that a genetic scoring system taking into account several single nucleotide polymorphisms might be able to identify medically refractory UC patients^[61]. As in CD, serological and genetic markers will probably be useful in future composite predicting tools.

Relevance and potential use of predictors in UC

Compared with CD, individual natural history of patients is harder to predict than in CD^[1], and the clinical relevance of clinical predictors of 10-year UC severity has not been validated in independent cohorts. However, extensive colitis at diagnosis consistently appears as a predictor of subsequent colectomy. In addition, extensive colitis is strongly associated with the risk of long-term colorectal cancer^[62,63], and persisting colonic mucosal inflammation (macroscopic^[64] and microscopic^[65]) also contribute independently to the risk. Finally, the IBSEN group also demonstrated that obtaining mucosal

healing in the short-term in patients with UC is associated with a reduced risk of subsequent colectomy^[66]. In this context, it is reasonable to suggest considering a more aggressive therapeutic strategy (for instance, faster step-up approach) in patients with extensive colitis at diagnosis.

In conclusion, at the moment no reliable genetic or serological predictor of IBD course can be used in clinical practice. Saint-Antoine clinical predictors of subsequent unfavourable CD course may be taken into account in the decision about early immunosuppressive therapy in selected patients, and extensive colitis at diagnosis should influence individual therapeutic strategy in UC. However, we are aiming now towards the primary therapeutic goal of obtaining sustained deep remission (including mucosal healing) rather than simple sustained clinical remission. Consequently, we will need to identify predictors at diagnosis of subsequent sustained deep remission. Given the growing research in genetics and pharmacogenomics, we can imagine that sensitive and reliable predictors will be available in the near future.

Abstract

Besides their possible effects on the development of inflammatory bowel disease (IBD), some environmental factors can modulate the clinical course of both ulcerative colitis (UC) and Crohn's disease (CD). This review is mainly devoted to describing the current knowledge of the impact of some of these factors on the outcome of IBD, with special emphasis on smoking and diet. Although the impact of smoking on the susceptibility to develop CD and UC is firmly established, its influence on the clinical course of both diseases is still debatable. In CD, active smoking is a risk factor for postoperative recurrence. Beyond this clinical setting, smoking cessation seems to be advantageous in those CD patients who were smokers at disease diagnosis, while smoking resumption may be of benefit in ex-smokers with resistant UC. The role of dietary habits on the development of IBD is far from being well established. Also, food intolerances are very frequent, but usually inconsistent

among IBD patients, and therefore no general dietary recommendations can be made in these patients. In general, IBD patients should eat a diet as varied as possible. Regarding the possible therapeutic role of some dietary components in IBD, lessons should be drawn from the investigation of the primary therapeutic effect of enteral nutrition in CD. Low-fat diets seem to be particularly useful. Also, some lipid sources, such as olive oil, medium-chain triglycerides, and perhaps omega-3 fatty acids, might have a therapeutic effect. Fermentable fiber may have a role in preventing relapses in inactive UC.

INTRODUCTION

Despite the advances in uncovering genetic risk for Crohn's disease (CD) and ulcerative colitis (UC) over the past decade, the etiopathogenesis of inflammatory bowel diseases (IBDs) cannot be explained only in terms of genetic susceptibility. In fact, a vast number of possible environmental risk factors for the development of IBD have

been investigated, including smoking, dietary factors, psychological stress, use of non-steroidal anti-inflammatory drugs (NSAIDs) and oral contraceptives, appendectomy, breastfeeding, as well as infections and other events related to the so-called “hygiene hypothesis” in childhood^[1].

In addition to their putative effects on the development of IBD, some environmental factors can play a role in modulating the clinical course of both UC and CD. This review is mainly devoted to describing the current knowledge of the impact of some of these factors on the clinical outcome of IBD, with special emphasis on smoking and diet. The role of microbial factors (namely, the commensal microflora, and pathogens such as *Mycobacterium avium* *ssp.* paratuberculosis) in the pathogenesis of IBD will be not discussed.

SMOKING

Tobacco is the best established environmental factor affecting the susceptibility to develop IBD^[2] and maybe its clinical course, with opposite effects in CD and UC. However, most of the published studies assessing the impact of smoking on the long-term clinical outcomes of IBD are retrospective, often leading to controversial results.

Role of smoking on the clinical course of CD

Beyond the higher incidence of CD among smokers, several studies suggest that continuing to smoke leads to worse clinical outcomes^[3]. The underlying mechanisms of this deleterious effect are not well understood, but it has been reported that tobacco glycoprotein may be responsible for promoting a Th1 cell response^[4]. Moreover, tobacco increases production of reactive oxygen species and impaired antioxidant capacity has been shown in smokers^[5].

Smoking has been associated with a higher risk of relapse^[6,7] and increased need for immunomodulators^[8], but the strongest evidence of the deleterious effect of smoking upon the course of CD lies in the beneficial consequences of smoking cessation^[9]. Cosnes *et al.*^[10] demonstrated that patients who stop smoking for at least 6 mo are at a lower risk of relapse in the following 12-18 mo, as compared to non-quitters.

The negative impact of active smoking may not be the same in all CD patients and it has been suggested that it may depend, at least, on gender and disease location. The effect of smoking has been reported to be more marked in women^[8,10]. While the natural history of colonic CD seems to be the same in smokers and non-smokers, the rates of relapse^[11] and intestinal resection are higher among smokers with ileal disease^[6]. In addition, smoking has been associated with a lower prevalence of inflammatory (non-stricturing, non-penetrating) behavior of the disease, thus suggesting that tobacco facilitates progression towards complicated disease^[12-14]. Nevertheless, this may only reflect a greater proportion of smokers among patients with ileal involvement^[15].

The negative effects of tobacco seem to be dose-dependent, and some studies pointed to an increased risk

of surgery and persistent inflammatory activity in those patients smoking over 10 cigarettes/d^[12,16]. Conversely, a recent study reported non-detrimental effects of active smoking on CD course, but passive smokers needed immunosuppressants and infliximab more frequently than non-passive smokers^[17]. Although seldom assessed, genetic background may also play a role, as suggested by the lack of association between smoking and CD in Jewish patients in Israel^[18].

The worse clinical evolution among smokers might also be explained by a lesser response to drug therapies. Despite initial data suggesting a decreased likelihood of response to infliximab for luminal CD in smokers^[19,20], larger studies failed to find any association between smoking and infliximab response^[21-23]. We assessed the influence of smoking on the response to thiopurines in steroid-dependent IBD and, although no differences between smokers and non-smokers were found, CD responders who continued smoking had a higher rate of relapses during follow-up. Surprisingly, we found that smoking was an independent predictor for the need of thiopurine discontinuation because of side effects, leading to a lower treatment efficacy among CD patients (as compared to UC) when evaluated by intention-to-treat analysis^[24].

Postsurgical recurrence is the clinical scenario in which active smoking has better proven to worsen CD prognosis both in the short- and long-term^[25]. Smoking has been reported to be an independent risk factor for endoscopic, clinical, and surgical recurrence^[26-28]. We have recently reported the results of the first prospective study assessing risk factors for endoscopic recurrence in a series of 152 CD patients undergoing ileo-colic resection^[29]. Smoking was independently associated with significant postoperative recurrence as defined by the development of clinical recurrence and/or Rutgeerts grade 3 or 4 of endoscopic recurrence, whereas the only independent protective factor was the use of thiopurines^[29]. Of interest, postoperative recurrence has been reported to be much more marked among heavy smokers (> 10 cigarettes/d)^[26,29]. In spite of the fact that it has been suggested that the harmful effect of tobacco in CD might be neutralized by the use of immunomodulators^[10], this does not seem to be the case in postoperative recurrence where two different studies identified both azathioprine use and active smoking as independent predictors for both endoscopic and surgical recurrence^[26,29].

Role of smoking on the clinical course of UC

There is strong evidence pointing to a protective effect of tobacco on the susceptibility to develop UC^[2]. Early studies, performed before the widespread use of calcineurinic drugs and infliximab, suggested higher rates of flares, hospitalizations, and even colectomy for UC among non-smokers^[30-33], but these findings were not confirmed in most recent studies^[34,35]. Conflicting results have been obtained about the effect of tobacco on retrograde progression of distal forms of UC^[31,36-38].

Some authors reported a worsening in clinical out-

comes among UC patients who quit smoking^[30,39], while improvement of disease activity has been noticed in ex-smokers who returned to smoke^[40,41]. A number of trials show the efficacy of nicotine for inducing remission in active UC, although with a high rate of mild side effects^[42]. In fact, some authors still propose “mild smoking” as an alternative therapy in patients with resistant UC^[43].

DIET

Along with microbiota, dietary products are the most common luminal antigens in the bowel and may influence intestinal inflammation. Possible mechanisms include a direct antigenic effect, alteration of gene expression, modulation of inflammatory mediators (e.g., eicosanoids), changes in the composition of the enteric flora, and effects on gut permeability. Thus, the role of dietary habits on the development of IBD has been extensively investigated in case-control retrospective studies subject to different biases^[44,45]. In a recent systematic review of these studies, high intakes of total fat, omega-6 fatty acids and meat were associated with increased risk of developing IBD, while high vegetable and fruit intake decreased the risk for these diseases^[45]. A recent case-control study suggests that increased intake of refined sugars may facilitate the development of CD and UC^[46]. Prospective studies are necessary to confirm the role of dietary factors on the development of IBD.

Role of diet on the clinical course of IBD

For decades, physicians based dietary counseling for IBD patients on restrictive criteria. This was because the so-called “bowel rest” was considered as a sine qua non to induce disease remission. However, controlled trials clearly demonstrated that drug-induced IBD remission was not influenced by the type of nutritional support (i.e., enteral, parenteral or oral conventional foods)^[47-49]. Thus, the concept of “bowel rest” has been abandoned, and IBD patients are now advised to eat a diet as unrestricted as possible.

Food intolerance: Does it have a role in dietary management of IBD? IBD patients often complain of food intolerance. In a prospective study, 65% out of 130 patients who completed a food questionnaire reported to be intolerant to some food item, as compared to only 14% out of 70 healthy controls ($P < 0.0001$)^[50]. A more recent study in 187 UC patients confirms these findings: 50% of patients avoided some foodstuff (mainly dairy foods, fruits and vegetables)^[51]. However, 22% of patients ate supplemental amounts of these food items because they had the perception that these improved their symptoms^[51].

Despite its high prevalence, food intolerance is quite inconsistent in IBD patients. Pearson *et al.*^[52] sequentially introduced single conventional foods in 28 CD patients who had gone into remission with an elemental diet.

Twenty patients reported intolerance to some of these foods, but seven of them were tolerant to it after a rechallenge. Of interest, one patient who was also intolerant to this rechallenge, could tolerate the “offending” food after a second blinded rechallenge, and someone even had opposite responses to two blinded rechallenges with the same food item^[52].

These data well illustrate how difficult it is to prove food intolerances in IBD patients. From this perspective, avoiding every food that causes patient’s upset is an unwise strategy. In a large series of patients with inactive UC, dietary changes based on the patient’s self-perceptions did not have any influence on the relapse rate^[51]. Therefore, bearing in mind the fact that protein-energy malnutrition and other nutritional deficiencies are frequent in IBD, patients with UC or CD should be advised to avoid only those food items which repeatedly and systematically worsen their symptoms. In this setting, two groups of foods often raise concerns both among patients and doctors: dairy foods and dietary fiber.

None of the milk components has been proven to play a role in promoting bowel inflammation, causing the disease or triggering a flare. In contrast, it is well known that dairy foods are the main dietary source of calcium, which is necessary to prevent metabolic bone disease in these patients. However, it is also true that a significant proportion of healthy people (mainly in the Mediterranean basin) have lactase deficiency. Unabsorbed lactose reaching the colon may cause diarrhea and/or bloating in a dose-dependent manner. This phenomenon, which does not depend on the fact of suffering from IBD, may occur in lactase-deficient patients with these diseases, thus worsening their symptoms. Studies performed in our laboratory suggest that the prevalence of lactose malabsorption (as assessed by hydrogen breath test) is not higher in IBD patients than in healthy controls^[53]. Therefore, IBD patients should not limit their milk intake during flares unless it clearly worsens diarrhea. Moreover, even in these cases, dairy foods with lower lactose contents (i.e., yogurt) may be well tolerated.

Prescribing a low-residue diet - that is, devoid of insoluble fiber - may be advisable during acute flares of IBD, particularly in patients with stricturing CD or severe UC attacks. Soluble fiber generates much less residue than insoluble fiber, and is fermented by colonic microflora yielding several products such as short-chain fatty acids (SCFA) - mainly butyrate - than can be of benefit in IBD. Butyrate is the preferred fuel for colonic epithelial cells. Decreased fecal levels of SCFA have been reported in patients with UC in relation to the severity of inflammation^[54], and impaired beta-oxidation of butyrate could be demonstrated in patients with active and even inactive UC^[55,56]. Experimental work suggests that butyrate is able to down-regulate the production of proinflammatory cytokines, and also nuclear factor kappa B (NF- κ B) activation^[57].

Soluble fiber may be particularly useful in inactive UC. In a randomized controlled trial, *Plantago ovata* husks (a source of slowly fermentable soluble fiber) were as

effective as mesalazine for preventing disease relapse in patients with quiescent UC^[58]. In active UC, however, the use of soluble fiber might be potentially detrimental. The presence of intraluminal blood (and, hence, oxygen), and a lower intraluminal pH during active disease may favor the growth of lactic acid-producing bacteria (*Lactobacilli* and *Streptococci*). Lactic acid directly damages the bowel mucosa. Indeed, increased levels of fecal lactic acid have been reported in patients with active UC^[59].

The usefulness of “exclusion diets” in CD has been supported by several authors due to their potential capacity to prevent clinical relapses and spare steroids. To date, only one prospective randomized controlled trial assessing the role of exclusion diet in preventing relapse in inactive CD has been published^[60]. Seventy-eight patients, who had gone into remission with an elemental diet, were randomized to receive an exclusion diet (i.e., sequential introduction of foods, with exclusion of those that elicited symptoms) or prednisolone (40 mg/d, with tapering dose until discontinuation by week 12) (control group)^[60]. Treatment of a control group is hard to justify, since it is well-known that steroids are not useful as maintenance therapy in CD. Anyway, the two-year cumulative probability of relapse was lower in the group treated with the exclusion diet than in the control group (62% *vs* 79%, *P* = 0.048)^[60]. However, 62% is a high relapse rate, suggesting that exclusion diets benefit only a minority of CD patients.

Food components as primary treatment for CD: In the last three decades, the possibility that enteral nutrition could be used as primary treatment (i.e., able, *per se*, to induce remission) in active CD has been a matter of debate.

To date, four meta-analyses of the trials comparing enteral nutrition *vs* corticosteroids in active CD have been published^[61-64]. All of them agree that steroids are better than enteral nutrition in inducing remission but they also indicate that, as a whole, enteral nutrition is able to induce remission in about 50%-60% of patients, a remission rate substantially higher than that obtained with placebo in active CD, which barely achieves 30%. This suggests that enteral nutrition (or, at least, some enteral formulas) would have a primary therapeutic effect in active CD (or, at least, in some subsets of patients). The primary therapeutic effect of enteral nutrition in CD is particularly relevant for children, as confirmed by two meta-analyses of pediatric trials which conclude that enteral nutrition is as effective as steroids in inducing remission in children^[65,66]. In addition to its role in active CD, enteral nutrition is suggested to be useful for preventing relapse both in children^[67] and adults^[68]. Recent data suggest that it could also have a role in preventing postoperative recurrence^[69].

The mechanisms whereby enteral nutrition exerts its primary therapeutic effect in CD remain obscure. The hypothesis that elemental (i.e., amino acid-based) diets would be particularly useful by virtue of their low antigenicity was challenged by the results of meta-analyses of

randomized trials comparing elemental *vs* non-elemental (i.e., peptide- or whole protein-based) diets, which showed that both types of diets were equally effective in inducing remission^[61,64].

To date, the amount and/or the type of dietary fat are major candidates for the therapeutic effect of enteral nutrition in CD. Recent meta-analysis suggests very low fat (i.e., less than 3 g/1000 kcal) diets could be particularly effective^[64]. Early studies pointed out that olive oil-based diets were better than diets based on seed oils (corn, safflower, sunflower, soybean), suggesting that oleic acid would be better than linoleic acid in reducing inflammation^[70]. Experimental data also support this view^[71,72]. However, this hypothesis could not be confirmed in a trial comparing linoleic acid- and oleic acid-based diets, where the latter performed particularly badly^[73]. As the oleic acid source in this trial was not olive oil but synthetic triolein, it cannot be ruled out that other components of olive oil (e.g., antioxidants) could exert anti-inflammatory actions in these patients.

Although coconut oil-derived medium-chain triglycerides (MCT) are traditionally considered as a mere easy-to-oxidize energy source, recent data support the idea that they can also exhibit immunomodulatory properties. In fact, there is growing experimental evidence that MCT are able to improve bowel damage both in spontaneous and induced animal models of intestinal inflammation^[74-77]. There are also some clinical data suggesting that replacing part of dietary fat with MCT would contribute to the primary therapeutic effect of enteral nutrition in CD^[78-80].

Surprisingly, fish oil-derived omega-3 fatty acids - the paradigm of anti-inflammatory lipids - have been scarcely assessed in the setting of enteral nutrition formulas for CD. Several randomized trials have been published, however, on the role of fish oil supplements as therapy for both active and inactive CD and UC, which have been systematically reviewed^[81-83]. Overall, available data do not allow supporting the use of omega-3 fatty acid supplementation for the treatment of both active and inactive IBD. Negative results are quite consistent in trials assessing the use of omega-3 fatty acids to maintain disease remission, particularly UC, and to a lesser extent CD. Trials on their use in active disease do not allow us to draw firm conclusions, mainly because of the heterogeneity of their design (UC) or their small number (CD). In most trials, the appropriateness of the selected placebo is questionable^[83].

NSAIDs

Since it is known that NSAIDs can induce gastrointestinal mucosal inflammation, it has been suggested that they might trigger disease exacerbation in IBD patients. Several potential mechanisms for this phenomenon have been proposed such as cyclooxygenase (COX) inhibition, leukotriene shunting or inhibition of NF- κ B activity, although none of them has been firmly demonstrated^[84].

Most (but not all) retrospective, uncontrolled or cross-sectional studies evaluating the impact of NSAID use on IBD relapse agree on the potential deleterious effect of these drugs on quiescent IBD^[84,85]. In the only prospective controlled study assessing disease relapse with the use of different NSAIDs as compared to acetaminophen in IBD patients without arthritic complaints, a significantly increased risk of relapse with NSAIDs was reported^[86]. Interestingly, patients who tolerated NSAIDs for a week did not seem to be at risk for relapse, suggesting that drug-induced IBD flares occur early after starting NSAID use and only in a subset of susceptible patients. It is also still debated whether selective COX-2 inhibitors are safer than conventional NSAIDs for patients with IBD. The only prospective, randomized, double-blind, controlled trial performed to date showed no increase in UC flares as compared to placebo^[87], but most authors conclude that further randomized, double-blind trials are needed to address this issue^[84,85].

INTESTINAL INFECTIONS

Intestinal infections by enteropathogens have been associated with both IBD onset and IBD relapses, and stool microbiological studies are usually advised in patients with IBD flares. Several prospective and retrospective studies show that intestinal infections assessed by stool cultures occur in less than 10% of IBD flares, mainly in those patients with extensive colonic involvement^[88-93]. However, the clinical relevance of such infections on IBD course has not been appropriately assessed, and no study has specifically addressed the effect of adding antibiotic therapy in patients with active IBD and a positive stool culture. Baliellas *et al.*^[89] reported that only half of the patients with active IBD and positive stool cultures achieved symptomatic remission after antibiotic therapy alone, despite stool cultures becoming negative in all of them.

Clostridium difficile infection (CDI) has become in recent years a worldwide epidemic phenomenon also affecting IBD patients. In the last two decades, the prevalence of CDI increased two-fold in UC and almost three-fold in CD^[94]. As for enteropathogen intestinal infections, IBD patients with colonic involvement seem to be those at higher risk for CDI^[95-97]. In addition to the risk factors for CDI in the general population, increasing age and steroid use seem to be particularly relevant in IBD patients, with no conclusive data about the role of other immunosuppressants^[98]. Several studies have reported that CDI worsens IBD outcome, with higher rates of surgical procedures, longer hospital stay, and higher mortality, as compared to patients admitted to the hospital with IBD or CDI alone^[94,95,97,99].

Finally, many studies have been published addressing the role of intestinal cytomegalovirus (CMV) infection in IBD, mainly in UC^[100]. Two prospective studies demonstrated that this infection was a reactivation of CMV carriers that occurs almost exclusively in active, steroid-

refractory UC patients^[101,102]. However, the small number of patients included in both studies does not allow ascertaining whether CMV reactivation is the cause of refractoriness or the consequence of steroid use, and also whether it worsens UC outcome or if it is only an innocent bystander.

OTHER ENVIRONMENTAL FACTORS

Breastfeeding

Breastfeeding is a protective factor against several immunologically-based diseases. In fact, breast milk is relevant for acquiring tolerance against bacterial microflora and dietary antigens. Most studies investigating the role of breastfeeding on the development of either UC or CD have shown a protective effect, as concluded in a meta-analysis of 14 case-control studies published in 2004^[103]. Subsequent studies confirmed these results (especially for those infants breastfed for more than six months)^[46], while others suggest that breastfeeding could promote CD in childhood, rather than protecting from its development^[104].

Obesity

IBD, particularly CD, has been traditionally associated with protein-energy malnutrition and other nutritional deficiencies. However, in recent years the prevalence of obesity among IBD patients has been increasing^[105] in parallel with the obesity epidemics in the general population of developed countries. Case-control studies suggest that obese CD patients are more prone to perineal disease^[106] and early surgical treatment^[107].

Vaccinations

The role of vaccinations - mainly attenuated measles-containing vaccines - in the development of IBD is a matter of debate, with studies reporting a positive^[108], negative^[109] or no association^[110,111] with IBD. A recent case-control study reported that vaccinations against pertussis and polio increase the odds of suffering IBD^[46]. The exact role, if any, of vaccinations with regard to IBD is far from being elucidated.

Oral contraceptive pills

A meta-analysis conducted in 2008 showed that the use of oral contraceptives was associated with an increased risk of both CD and UC^[112]. The risk increased with the time of exposure and reversed after pill discontinuation^[112]. The effect of oral contraceptives on the risk of IBD appears to be related to estrogens. Estrogen acts as an immune enhancer and may increase the production of tumor necrosis factor by macrophages. Also, estrogen may induce microthrombotic phenomena in the bowel due to its thrombogenic potential.

Appendectomy

Appendectomy is associated with a lower risk of suffering from UC, particularly in children who are operated

before the age of 10, as shown in a meta-analysis of 17 case-control studies^[113]. Investigations on the relationship between appendectomy and CD are less conclusive, in spite of the fact that a recent meta-analysis showed an increased risk of CD in appendectomized subjects^[114]. However, this association was particularly strong for those appendectomies performed within one year before CD diagnosis, and almost null for those performed five years before CD^[114], suggesting that this is a circumstantial rather than causative relationship.

Psychological stress

Psychological stress has been hypothesized to play a role both in the pathogenesis of IBD and as a triggering factor for disease relapse as well. However, retrospective observational studies have yielded conflicting results^[115,116].

Abstract

Crohn's disease and ulcerative colitis are progressive diseases associated with a high risk of complications over time including strictures, fistulae, perianal complications, surgery, and colorectal cancer. Changing the natural history and avoiding evolution to a disabling disease should be the main goal of treatment. In recent studies, mucosal healing has been associated with longer-term remission and fewer complications. Conventional therapies with immunosuppressive drugs are able to induce mucosal healing in a minority of cases but their impact on disease progression appears modest. Higher rates of mucosal healing can be achieved with anti-tumor necrosis factor therapies that reduce the risk of relapse, surgery and hospitalization, and are associated with perianal fistulae closure. These drugs might be able to change the natural history of the disease mainly when introduced early in the course of the disease. Treatment strategy in inflammatory bowel diseases should thus be tailored according to the risk that each patient could develop disabling disease.

INTRODUCTION

The natural history of Crohn's disease (CD) is the progression to chronic complications including strictures, penetrating fistulae^[1,2] or complex perianal disease^[3], leading to the need for surgery and hospitalization^[4]. This leads to the concept of cumulative tissue damage for which a quantitative score is currently under development^[5]. Coloproctectomy due to chronic refractory disease or acute severe colitis is a major complication of ulcerative colitis (UC) and develops in 20%-25% of patients after 25 years. An increased risk of colorectal cancer (CRC) in long-standing colitis is a second major complication in UC^[6], but also in Crohn's colitis, with a relative risk of 2.5 compared to the general population. The aim of medical therapies was the improvement of inflammatory bowel disease (IBD) symptoms 20 years ago, however, the current objective is to achieve deep remission, including cessation of corticosteroids, and mucosal healing. Therefore, treatments should modify the course of the disease by avoiding disabling disease and irreversible tissue damage. This review focuses on the impact of treatment on the natural history of IBD.

MUCOSAL HEALING

Mucosal healing (MH) has become a major goal of treatment of IBD because it has been correlated with fewer complications^[7,8], fewer relapses after surgery^[9], and drug

withdrawal^[10]. There is no validated definition of MH in IBD. Mucosal healing is usually assessed by endoscopy in CD and UC and defined as the absence of ulcers^[10]. Although poorly studied, MH is achievable with thiopurine analogs in active CD. In earlier uncontrolled studies, among azathioprine (AZA) clinical responders, 74% achieved MH after a mean of 2 years^[11,12]. However, in a more recent controlled trial (SONIC) studying infliximab (IFX), AZA, or combination therapy for immunosuppressive-naïve CD patients^[13], only 16% of CD patients in the AZA arm achieved mucosal healing at week 26. Few data are available about the efficacy of methotrexate (MTX) in inducing MH. A preliminary study^[14] of 11 CD patients treated with MTX 25 mg weekly intramuscular injection showed MH and histological healing in five and four patients, respectively, after 12 wk. No MH was observed in UC, although 5/7 patients had a clinical response with histological improvement. A recent prospective study showed MH in only 11% of CD patients in clinical remission on MTX, compared to 50% on AZA and 60% on IFX^[15]. A possible bias in this study may have been the small size of the groups, the more refractory disease, and the shorter treatment duration in the MTX group. Anti-tumor necrosis factor (TNF) treatments have changed the management of IBD since the late 1990s. A subanalysis of a Crohn's disease clinical study evaluating infliximab in a new long-term treatment regimen (ACCENT1) trial demonstrated that MH on IFX was associated with fewer relapses^[16]. A retrospective single center study has shown that, among IFX responders, 68% had MH (45% complete MH) and MH was associated with fewer relapses (64% *vs* 40%)^[17]. In the step-up top-down study, 71% of patients with MH at 2 years were still in remission 2 years later, compared to patients who had endoscopic signs of activity^[18]. At week 26 of the SONIC trial, IFX was more effective to induce MH than AZA, (16.5%), either in mono- (30.1%) or combination therapy with AZA (39.5%). In the prospective ACT1/ACT2 trials studying IFX for induction and maintenance therapy in UC, IFX efficacy in inducing MH was also demonstrated with 62%/60% of MH at week 8 compared to 32%/30% in the placebo group. Adalimumab (ADA) was also more effective than placebo in inducing and maintaining clinical remission in patients with moderate-to-severe UC^[19], and MH was achieved more frequently in the ADA arm compared to placebo (25% *vs* 15% at week 52).

In CD, mucosal healing has also been consistently described as more frequently achieved when an anti-TNF was started earlier in the disease course^[20].

SURGERY AND HOSPITALIZATION

CD is a chronic condition that leads to tissue damage and complications requiring surgery in 70%-80% of patients at 20 years^[4,8]. In UC, the cumulative probability of colectomy after 25 years varies from 20% to 30%^[21,22]. In 2005, Cosnes *et al*^[23] demonstrated that immunosuppressive

drugs (AZA and MTX) were introduced more frequently and earlier in the course of the CD over the past 25 years but the percentage of patients requiring intestinal surgery each year remained stable. These results should be interpreted with caution because < 10% of the patients included in this study received AZA before surgery. Recent contradictory data have demonstrated that increased immunosuppressant prescriptions, from 11% to 45% over 25 years, have decreased the rate of intestinal resection from 59% to 25% 5 years after diagnosis^[24]. Early introduction of thiopurine was a protective factor. French results recently have demonstrated that AZA is associated with less surgery in patients newly diagnosed with CD but the benefit was modest compared to IFX^[25]. In UC, Ardizzone *et al*^[26] have demonstrated higher rates of clinical response in patients treated with AZA compared to 5-aminosalicylic acid, but the colectomy rate was similar in both groups (8%). The ACCENT 1 and 2 trials have reported a decreased risk of surgery in patients on IFX scheduled therapy at week 54 (3% *vs* 7% with IFX episodic therapy)^[27,28]. Schnitzler *et al*^[17] have demonstrated less intra-abdominal surgery (14%) and hospitalization (42%) for active CD in patients achieving MH on scheduled IFX compared to those who had endoscopically active disease (38% and 59% respectively). Lower colectomy rates in IBD were also associated with MH in a retrospective Norwegian population-based study^[29]. Recently, IFX given for at least 16 mo was reported as a protective factor against surgery in active CD^[25]. Jones *et al*^[30] have reported a stable rate of surgery in CD from 1993 to 2004, but these data should be interpreted with caution because they concern a period when IFX was mainly prescribed as episodic therapy, which is clearly a suboptimal strategy and does not represent the current practice. In the Crohn's Trial of the Fully Human Antibody Adalimumab for Remission Maintenance (CHARM) trial, CD patients treated with scheduled ADA had less hospitalization at 3 mo (1.6%) and 12 mo (5.9%) compared to placebo (7.3% and 13.9% respectively)^[31]. Surgery at 1 year also decreased from 3.8% in the placebo group to 0.6% in the ADA groups. These results were confirmed at 2 years follow-up^[32]. A sub-analysis of the ACT1 and ACT2 trials demonstrated a 10% cumulative incidence of colectomy in UC through 54 wk in the IFX group compared to 17% in the placebo group. Less UC-related hospitalization was reported in the IFX group^[33]. Moreover, the degree of MH after 8 wk IFX was correlated with less colectomy^[34].

PERIANAL COMPLICATIONS OF CD

Perianal fistulae occur in 21%-26% of CD patients after 20 years^[5]. Anti-TNF antibodies have dramatically improved the ability to heal fistula with medical therapy. After 54 wk of scheduled IFX treatment for active CD fistulae, partial response was observed in 46% of patients *vs* 23% in the placebo group and 36% had a complete response compared to 19% with placebo^[28]. After primary drainage, high rates of clinical response (85%)

and remission (74%) at week 14 were also reported in patients with severe active perianal CD treated with three infusions of IFX followed by MTX as maintenance therapy (25 mg weekly intramuscular or subcutaneous). Fifty percent of patients were still in remission from their perianal disease at 1 year, but this strategy failed to achieve a prolonged remission of luminal disease in the majority of patients^[35]. No other prospective studies have investigated the efficacy of MTX in perianal CD. In the CHARM trial that studied the long-term efficacy of ADA in CD, 33% of active fistulae achieved complete healing on ADA after 56 wk compared to 13% in the placebo group^[31]. This effect was globally maintained over 3 years follow-up^[32]. Fistula healing in a substantial proportion of patients under ADA was also confirmed in a large European open label trial mimicking routine practice^[36]. In this trial, full fistula closure was achieved in 26% of patients after 20 wk. The impact of thiopurine on fistula closure was poorly studied. A meta-analysis showed a complete closure or an improvement of the fistulae in 54% of the patients compared to 21% in the placebo group. However, these results should be interpreted with caution because fistula closure was not the primary endpoint of this study^[37].

CANCER

Chronic colitis predisposes to CRC over time, with cumulative estimated incidence rates of 2%, 8% and 18% at 10, 20 and 30 years of evolution, respectively^[6]. This risk was however reported as lower in more recent cohorts^[38], with a relative risk around 2.0 over disease course. The risk of CRC in CD has also been reported^[39]. Risk factors for CRC in chronic colitis are extensive location, long duration of the disease, familial history of CRC, and associated primary sclerosing cholangitis^[40]. Few studies have addressed the severity of colonic inflammation over time as an independent risk factor for progression to neoplasia. Rutter *et al.*^[41,42] have demonstrated a highly significant correlation between colonic inflammation scores and the risk of CRC in UC. Only association with histological inflammation was significant in the multivariable analysis [odds ratio (OR): 4.7]. In the case of normal colonoscopy, the 5-year risk of CRC was the same as that of the matched general population (OR: 0.38). Gupta *et al.*^[43] also have demonstrated that the severity of microscopic inflammation is an independent risk factor for dysplasia in patients with longstanding UC. Such data are not yet available in CD. Due to the ability of medical treatment to maintain tissue healing in IBD, we can speculate on the potential impact of these treatments on the risk of cancer. Mesalazine is effective at maintaining clinical remission in UC and remains the main drug in this disease. In retrospective studies and meta-analyses, a significant decrease in CRC in UC has been described with mesalazine. More intriguingly, this has also been suggested for ileal cancer in CD^[44]. More recently, in the Cesame cohort, a potential decrease in

CRC was also suggested in extensive longstanding UC treated with purine analogs^[45]. No data are available yet with anti-TNF agents.

CONCLUSION

In conclusion, anti-TNFs and to a lesser extent immunosuppressants, can induce MH, which is associated with long-term clinical remission, closure of perianal fistulae, less hospitalization and surgery, suggesting an impact of these medications on the natural history of the disease. The benefit might be higher if MH is achieved earlier in the course of the disease. Histological remission is also associated with a reduced risk of CRC in UC. Although immunosuppressive treatments with thiopurine or MTX are able to induce MH, their benefit on the complications of IBD appears more modest. Many questions remain open, including the degree of MH achievement (complete *vs* partial) required to improve the prognosis, when and how often in the course of the disease should this healing be assessed, and how to adapt the treatment according to MH. Prospective randomized clinical trials are ongoing to answer these questions. Furthermore, the validation and the further use of a tissue damage score in CD (Lemann score) will be an important step to assess adequately the ability of treatment strategies to change natural history.

Abstract

Crohn's disease (CD) is a chronic inflammatory bowel disease that can affect the entire gastrointestinal tract. Ultimately, up to 70% of all patients will need surgery, despite optimized medical therapy. Moreover, about half of the patients will need redo-surgery because of disease recurrence. The introduction of anti-tumor necrosis factor (TNF) drugs (Infliximab in 1998) revolutionized the treatment of CD. Different randomized trials assessed the efficacy of anti-TNF treatment not only to induce, but also to maintain, steroid-free remission. Furthermore, these agents can rapidly lead to mucosal healing. This aspect is important, as it is a major predictor for long-term disease control. Subgroup analyses of responding patients seemed to suggest a reduction in the need for surgery at median-term follow up (1-3 years). However if one looks at population surveys, one does not observe any decline in the need for surgery since the introduction of Infliximab in 1998. The short follow-up term and the exclusion of patients with imminent surgical need in the randomized trials could bias the results. Only 60% of patients respond to induction of anti-TNF therapy, moreover, some patients will actually develop resistance to biologicals.

Many patients are diagnosed when stenosing disease has already occurred, obviating the need for biological therapy. In a further attempt to change the actual course of the disease, top down strategies have been progressively implemented. Whether this will indeed obviate surgery for a substantial group of patients remains unclear. For the time being, surgery will still play a pivotal role in the treatment of CD.

INTRODUCTION

Crohn's disease (CD) is a chronic inflammatory disorder which can affect the complete gastrointestinal tract. Only a minority of patients (10%-15%) will experience a prolonged relapse-free interval after initial diagnosis; most patients develop a mild chronic disease pattern^[1]. This relapsing inflammation results in progressive bowel occlusion and/or fistula and abscess formation. A large majority of patients (70%-80%) will require surgical treatment within a time frame of 10 years^[2,3]. The type of surgery is dictated by the anatomic location and/or the related complication(s). Depending on the localization of the disease, CD tends to have a different clinical

phenotype. Indeed, ileocolonic and small bowel involvement is more prone to develop occlusive disease than colonic affection^[2,4]. Thus, small bowel or ileocolic distribution will increase the rate of surgery compared to Crohn's colitis. Intractable inflammation is a rather seldom indication for surgery. Penetrating anal disease often leads to surgery in order to control sepsis and drain fistulas. Unfortunately, surgery in CD is not curative and the majority of patients will have early endoscopic relapse, despite clinical remission^[5]. Over time, symptomatic recurrence demands medical treatment, and up to 40% of patients will eventually need secondary surgery^[2]. This explains the tendency to avoid 'too early' surgery. If surgery is needed, the focus should be on bowel sparing and minimally invasive surgical techniques.

Progressive understanding of the pathogenesis of CD resulted in significant changes and improvements in its medical treatment. The use of immunomodulators (such as azathioprine and methotrexate) has not decreased the need for surgery, nor has it decreased hospitalization rates either^[2,6]. The introduction of anti-tumor necrosis factor (TNF) treatment in 1998 revolutionized the treatment paradigms. TNF antagonists proved to induce a rapid clinical remission in about 60% of the cases^[7,8]. In randomized controlled trials, anti-TNF therapy seemed to maintain remission in contrast to steroid regimens^[9-12]. Moreover, mucosal healing has even been obtained in a subset of patients, which could support a sustained clinical remission^[13-15]. Therefore, one could expect that, in the long run, fewer patients would need to undergo major abdominal surgery. This paper reflects on some aspects of the impact of anti-TNF treatment on the rates of surgery in CD patients.

NEED FOR SURGERY IN THE MARGIN OF LARGE RANDOMIZED TRIALS

Several randomized controlled trials have analyzed the maintenance of clinical remission in CD comparing patients who received anti-TNF agents or placebo^[9-12]. Besides an initial response rate of about 60%, a majority of patients will show sustained remission with anti-TNF therapy. Steroid discontinuation was also significantly better in the treatment groups. Moreover, an endoscopic substudy of a Crohn's disease clinical study evaluating infliximab in a new long-term treatment regimen demonstrated that about 50% of patients with a clinical response will also have mucosal healing^[14]. Considering that control of inflammation and induction of mucosal healing is predictive for long-term disease activity and bowel preservation, one could expect an effect of anti-TNF treatment on the rate of surgery^[13]. Feagan *et al*^[16] evaluated the influence of maintenance adalimumab therapy on the rate of hospital admissions and surgery in a post-hoc analysis of the Crohn's Trial of the Fully Human Antibody Adalimumab for Remission Maintenance trial. The authors came to the conclusion that adalimumab maintenance therapy significantly reduced hospitaliza-

tions and surgery for CD amongst the enrolled patients. Mucosal healing seems a promising surrogate marker of deep and prolonged clinical remission. This alteration in disease course should lead to a reduced need for surgery. More predictors are needed, not only to select those patients who will develop an aggressive and complicated disease pattern to enable early installment of immunosuppressive therapy, but also to select patients for "early" surgery to obtain a prolonged clinical remission.

One year after primary surgery, as many as 72% of the patients had already developed endoscopic recurrence, mainly at the anastomosis. Clinical manifestations of the disease are, however, often absent in this early postoperative stage^[17]. About one half of patients will need redo-surgery over a 20-year period^[2]. Although a high recurrence-rate is observed after surgery, there is no consensus about the postoperative therapy regimen. Considering the high amount of endoscopic recurrences, one could wonder if prophylactic medical therapy after surgery can play a role. Studies have been conducted to find the best prophylactic regimen. Aminosalicylates regimens seem to have modest effects on the postoperative recurrence rate. It is therefore not recommended to use them in a postoperative setting^[18,19]. Nitromidazole and ornidazole have demonstrated a significant drop in recurrence, but at the expense of important side effects, making these therapies not longer suitable for prophylactic use. Budenoside has no long term effect, but is indicated to suppress acute relapse. Azathioprine and 6-Mercaptopurine have already been used in randomized controlled trials to assess the effect on rate of recurrence after surgery. Because there was a high drop-out rate during the follow-up period, no convincing results have been found in these series^[20,21]. The advent of anti-TNF agents and their demonstrated effect on mucosal healing in the preoperative setting has given hope to care providers that relapses can be avoided when administered postoperatively. Regarding this important clinical question, two randomized controlled trials have been published so far. Twenty-four patients were randomized after ileocaecal resection to receive infliximab or a placebo for one year^[22]. The endoscopic and histologic recurrence rate after one year was significantly lower in the infliximab group. There was no significant difference in clinical recurrence rate, though more patients showed relapse after one year in the placebo group. Another study randomized 26 postoperative patients with proven endoscopic recurrence six months after receiving mesalamine in three different groups: one received infliximab, another azathioprine and the last group continued mesalamine^[23]. Control of endoscopic inflammation was improved in the infliximab group compared to the azathioprine and mesalamine group, demonstrating the clear suppressive effect of infliximab. In these two small trials, the positive impact of infliximab in avoiding postoperative recurrence has been demonstrated. These conclusions have to be interpreted with the greatest caution considering the small sample sizes and the short follow-up periods. No conclusion can be made about the usefulness of infliximab to

prevent recurrences. Large prospective randomized trials with a long follow-up have to be designed to assess the benefit of anti-TNF agents on postoperative recurrence. Moreover, one could wonder if it is reasonable to give prophylactic treatment after resection, considering the high costs and the number of patients who will be treated that would not develop recurrence. It is more likely to stratify the risk factors of every patient to assess the need of postoperative medical treatment. One of the most powerful methods for assessing patients is performing a colonoscopy six to twelve mo after resection. Rutgeerts *et al*^[51] demonstrated the predictive value of endoscopic recurrence. Indeed, patients with severe endoscopic recurrence within one year after surgery are at greater risk of developing clinical recurrence.

Approximately one third of all CD patients will develop perianal disease, including skin tags, ulcers, low and high fistulas, rectovaginal fistulas, perianal abscesses, anorectal strictures and cancer^[24]. Complex perianal fistulas are challenging to treat and can lead to destruction of the anal sphincters with intractable incontinence as a result. Twenty-five percent of patients with anal CD will eventually need a proctectomy^[25]. The classical medication used for CD, like antibiotics and immunomodulators, have not demonstrated any beneficial effect in the treatment of fistulizing CD^[26-28]. In contrast, infliximab maintenance therapy seems to reach superior durable and complete fistula closure, even in patients not responding to other medical treatments^[29,30]. This seems to have an impact on the surgery rate and hospital stay^[31]. There is, however, some concern about treatment with infliximab inducing healing of the external opening and suppressing the inflammatory reaction around the fistula tract without eradicating the tract^[32]. Magnetic resonance imaging of patients in clinical remission after infliximab treatment still showed inflammation and subsisting fistula tracts. Some are concerned about the possibility of fistula recurrence after withdrawal of treatment. More extensive investigation will be needed to test this hypothesis.

NEED FOR A WIDE SURGERY POPULATION (THE REAL WORLD)

In view of the aforementioned randomized controlled trials, it may be possible to change the course of the disease in patients treated with biologicals, perhaps leading to a decreasing need for resectional surgery. Other large population based series, however, are less convincing. Lazarev *et al*^[33] showed that, despite the increasing use of infliximab, the rate of small bowel resection has remained unchanged over the years in a large referral centre in Pittsburgh. Moreover, the relative frequency of stricturizing and penetrating disease did not change over time. Bewtra *et al*^[34] analyzed hospitalization and surgery trends for inflammatory bowel disease from 1990 to 2003. They observed a steady rate in the number of surgical interventions for CD with a significant increase in hospitalization rate, despite the introduction of inflix-

imab in 1998. Jones *et al*^[35] concluded in their series that surgery for penetrating small bowel disease increased with 60% from 1993 to 2004 despite the increasing use of infliximab.

In contrast, two population-based series reported a significant decrease in hospitalization and surgery rate^[36,37]. In a series from Wales, stoma formation and the long-term need for steroids are likely to have been influenced by the use of infliximab, but only 16% of patients had been prescribed anti-TNF agents in this series. Moreover, 614 consecutive patients responding to induction therapy with infliximab were observed to evaluate the long term clinical benefit of this anti-TNF agent^[38]. Two thirds of these patients seemed to have a sustained benefit of this therapy regimen. There seemed to be a decreased rate of surgery for patients responding to medication. Loss of response was inadvertently associated with an increased risk of surgery. This study demonstrated that infliximab could have an impact on disease course in responding patients. However, this group was not compared to patients not receiving anti-TNF agents. More recently it has been shown that the use of infliximab, and to a lesser extent of azathioprine, seems to be associated with a decreased risk of surgery^[39]. Interestingly, in this retrospective cohort study including 296 patients with CD between 2000 and 2008, the median follow-up was 57 mo, which was much longer than in the randomized controlled trials.

DISCUSSION

The introduction of anti-TNF agents significantly changed clinical practice and treatment algorithms. Optimized medical treatment should not only achieve symptomatic relief and clinical remission, but also aim to reduce the need for hospitalization and surgery. The use of these agents evolved over time and is mainly based on evidence from different large clinical trials on the efficacy for induction and maintenance treatment. The achievement of mucosal healing in a subgroup of patients raised the expectation that anti-TNF treatment could lead to a decrease in disease-related complications and the ultimate need for surgery. Biological therapies have shown to alter the natural history of psoriatic arthritis and ankylosing spondylitis^[40]. Indeed, anti-TNF therapy has been shown to reduce the need for surgery in different randomized clinical trials. Medium follow-ups of those trials have been rather limited, and the question remains whether the natural history of CD can be changed. Population-wide studies during the anti-TNF era have not yet demonstrated a decrease in the need for hospitalization and surgery. Different reasons can explain this discrepancy: firstly, the selection criterion for the randomized trials excluded patients with an imminent need for surgery and therefore contains a selection bias. Secondly, not all patients respond to anti-TNF therapy and the presence of a stricture and/or penetrating disease at the time of diagnosis is highly predictive for the need of surgery and

conservative treatment failure. Thirdly, most experience has been gained with the use of infliximab. The immunogenicity of the drug will lead to a substantial loss of response over time^[41,42]. Finally, a genuine resistance (irrespective to immunogenicity) to anti-TNF drugs has been observed. This will lead to a drop-out of 10% of patients per year. Results of recent top-down strategies clearly demonstrate the beneficial effect of early “aggressive” treatment of luminal inflammation^[43]. The medium-term benefits with regard to clinical remission and the need for surgery seem to indicate that a disease modification can indeed be obtained in a subset of patients. This concept therefore needs to be further explored and implemented into clinical practice.

The face of surgery has also evolved over time. Today, most patients can benefit from a minimally invasive approach (laparoscopy and single site laparoscopy). Furthermore, isoperistaltic stricturoplasty has demonstrated its safety and long-term efficacy in the treatment of long strictures of the small bowel and reduces the ultimate risk for intestinal failure^[44]. The implementation of enhanced recovery protocols further expedites patient rehabilitation after surgery. These aspects open a more attractive alternative to protracted medical treatment. Surgical-recurrence free survival at 5 years after primary ileocaecal resection is as high as 91% (own unpublished data). However early endoscopic and symptomatic disease recurrence hampers the enthusiasm for an early surgical approach. In patients with anorectal CD, surgery remains an essential, and often first, step in the treatment algorithm. Anal examination under anesthesia and drainage of perianal abscess precedes maintenance medical treatment. This combined approach is essential to safeguard anorectal function in the maximum number of patients, and to avoid definitive proctocolectomy and stoma formation.

The introduction of anti-TNF agents in the 1990s changed treatment algorithms in CD and has the potential to alter the natural history of the disease. Randomized data show a significant decrease in the development of complications and the need for surgery. Sustained mucosal healing seems a good predictor for fewer complications and surgery in the long-term. No reduction in the need for surgery has been documented in population-based surveys. This discrepancy is multifactorial. Further evolution and implementation of top-down treatment strategies should eventually lead to a genuine reduction in the need for surgery. For the time being, surgery still plays a pivotal role in a large subset of patients in order to obtain long-term disease remission and improvement of patient quality of life. However, the evolving concept of disease modification will certainly alter the role and need for surgery in the future. Optimal treatment of CD remains a joint effort of dedicated physicians and surgeons.

Abstract

Despite the growing use of medical salvage therapy, colectomy has remained a cornerstone in managing acute severe ulcerative colitis (ASC) both in children and in adults. Colectomy should be regarded as a life saving procedure in ASC, and must be seriously considered in any steroid-refractory patient. However, colectomy is not a cure for the disease but rather the substitution of a large problem with smaller problems, including fecal incontinence, pouchitis, irritable pouch syndrome, cuffitis, anastomotic ulcer and stenosis, missed or de-novo Crohn's disease and, in young females, reduced fecundity. This notion has led to the widespread practice of offering medical salvage therapy before colectomy in most patients without surgical abdomen or toxic megacolon. Medical salvage therapies which have proved effective in the clinical trial setting include cyclosporine, tacrolimus and infliximab, which seem equally effective in the short term. Validated predictive rules can identify a subset of patients who will eventually fail corticosteroid therapy after only 3-5 d of steroid therapy with an accuracy of 85%-95%. This accuracy is sufficiently high for initiating

medical therapy, but usually not colectomy, early in the admission without delaying colectomy if required. This approach has reduced the colectomy rate in ASC from 30%-70% in the past to 10%-20% nowadays, and the mortality rate from over 70% in the 1930s to about 1%. In general, restorative proctocolectomy (ileoanal pouch or ileal pouch-anal anastomosis), especially the J-pouch, is preferred over straight pull-through (ileo-anal) or ileo-rectal anastomosis, which may still be considered in young females concerned about infertility. Colectomy in the acute severe colitis setting, is usually performed in three steps due to the severity of the inflammation, concurrent steroid treatment and the generally reduced clinical condition. The first surgical step involves colectomy and constructing an ileal stoma, the second - constructing the pouch and the third - closing the stoma. This review focuses on the role of surgical treatment in ulcerative colitis in the era of medical rescue therapy.

INTRODUCTION

Acute severe colitis (ASC) is one of the few emergencies in gastroenterology. The mortality rate from ASC dropped from over 70% in 1933 to 20%-25% in the 1950s when the importance of timely urgent colectomy was first recognized^[1,2]. Subsequently, the mortality rate was further reduced to 7% with the introduction of corticosteroids, and eventually to about 1% nowadays^[3-5].

Truelove *et al*^[3], in their landmark clinical trial in 1955, defined severe disease as the passage of at least six daily bloody stools, erythrocyte sedimentation rate > 30, temperature > 37.8 °C, pulse rate > 90/min and hemoglobin < 10.5 g/dL. These criteria remain the most common classification of ASC in adults. In a systematic review of cohort studies on ASC, 20 of 29 studies used the Truelove and Witts classification^[5]. However, of these 20 studies, 12 required the fulfillment of all of the five items, and 8 applied various more liberal modifications. More recently, the European Crohn's and Colitis Organization (ECCO) issued guidelines on managing ASC defining severe attack as ≥ 6 bloody diarrhea per day with at least *one* of the other four bullets^[6]. In children, severe disease has been robustly defined using the Pediatric Ulcerative Colitis Activity Index (PUCAI) with a score of at least 65 points yielding high sensitivity and specificity^[7,8]. Pediatric onset ulcerative colitis (UC) is often more extensive than in adults^[9], and since disease severity has been consistently associated with disease extent, children are especially susceptible to refractory severe attacks. Nearly one third of children with ulcerative colitis will experience at least one severe exacerbation before turning into adult care^[10].

PREDICTING THE NEED FOR SALVAGE THERAPY

The only factor associated with a major surgical complication among 80 adults who underwent urgent colectomy in Oxford for ASC, was longer duration of medical therapy before colectomy^[11]. It is of great importance to recognize those who are likely to fail intravenous corticosteroid early during the admission and to introduce timely rescue therapy. This approach may reduce morbidity and mortality and avoid futile toxic medical therapy.

Several clinical predictive indices have been proven to perform well in identifying those who require salvage therapy after only 3-5 d of admission. In a prospective study, Travis *et al*^[12] from Oxford suggested that a stool frequency of > 8/d or 3-8/d and C-reactive protein (CRP) > 45 mg/dL on the third day of corticosteroid therapy should be sufficient for initiating rescue therapy. Lindgren *et al*^[13] developed the fulminant colitis index ($n = 97$) based on the same variables as the Oxford index - stool frequency/d + 0.14 \times CRP mg/L. Ho *et al*^[14] based the Scottish index on stool frequency, presence of colonic dilatation, and hypoalbuminemia. Others have also shown some predictive ability of their indices^[15,16].

In children, a predictive rule based on the PUCAI score at days three and five of steroid therapy has been validated^[10,17] and incorporated in the combined ECCO and European Society for Paediatric Gastroenterology Hepatology and Nutrition recent guidelines on pediatric ASC^[8]. A PUCAI score of > 45 points on day 3 should dictate planning of second-line therapy and > 65-70 points on day 5 should prompt execution of the planned therapy. All aforementioned indices are based on the consistently reproduced fact that the likelihood for responding to medical corticosteroids is inversely associated with the degree of disease severity even before treatment has been initiated.

Despite the significant improvement in patient care with the implementation of indices-based management schemes, their accuracy is still imperfect. The positive predictive value (PPV) of the Oxford index in predicting steroid failure is 85% for colectomy and the sensitivity and specificity of the Scottish index is 85% and 75%, respectively. The PPV of the fulminant colitis index at a cutoff score of > 8 at day 3 is 69%-72%^[13,18]. The PUCAI successfully identifies those for whom the likelihood of failing corticosteroids is 92%. These indices should be perceived as accurate enough for initiating salvage medical therapy (i.e., infliximab or calcineurin inhibitors) but probably not for early irreversible colectomy (Table 1).

SALVAGE MEDICAL THERAPY

Medical rescue therapy should be utilized as the first-line treatment in ASC before colectomy in most corticosteroid-failed patients who do not present with surgical abdomen or toxic megacolon. During the last 20 years, cyclosporine has been widely used^[19] and more recently also infliximab^[18], and tacrolimus^[20]. These medications reduced the short-term colectomy rate from 30%-70%^[3,5,21,22] to approximately 10%-20% nowadays^[17,23]. The increasing use of second-line medical therapy before colectomy has been based on the high effectiveness of these drugs and the notion that colectomy is not a cure for the disease, but rather the substitution of one large problem with several smaller problems.

Experience with cyclosporine showed that, although the short-term response rate reaches 70%-80%^[5,9], approximately 50% of responders will eventually require colectomy when the drug is discontinued, typically after 4 mo^[5,21,24-26]. The likelihood of colectomy is reduced if cyclosporine is used as a bridging medication to thiopurines^[27]. The other calcineurin inhibitor, tacrolimus (FK-506), has recently been proved effective as a second-line regimen in the clinical trial setting, while aiming at high trough levels of 10-15 ng/mL^[20]. It seems that tacrolimus is as effective as cyclosporine for salvage therapy in ASC, both in adults and children^[21,28,29]. Tacrolimus, a more expensive medication, has a better bioavailability than cyclosporine, allowing for oral treatment. The toxicity profile is more appealing but there are fewer published studies to support its use.

Table 1 Prediction rules for corticosteroid failure in patients with acute severe ulcerative colitis

Prediction rule	Study	Measure	Prediction accuracy
Oxford index	Travis <i>et al</i> ^[12] , prospective; Turner <i>et al</i> ^[10] , retrospective	Stool frequency of > 8/d or 3-8/d and CRP > 45 mg/L (on day 3 of IVCS)	Adults: PPV = 85% Children: Sens = 38%, Spec = 100%, PPV = 88%, NPV = 75%

Infliximab has been established as an effective regimen for moderate to severe ulcerative colitis, including ASC. The ACT-1 and ACT-2 randomized controlled trials assessed the ability of infliximab to induce and maintain remission in moderate to severe ulcerative colitis^[30,31]. A total of 728 adult patients received placebo or infliximab (5 or 10 mg/kg) through week 46 (ACT-1) or 22 (ACT-2). In the ACT-1 and 2 trials respectively, 61% and 69% of infliximab-treated subjects had a short-term clinical response compared with 29% and 37% of those who received placebo. In steroid-refractory ASC, infliximab is effective as salvage medical therapy in approximately 70%-80% of children and adults, reducing short- and long-term colectomy rate^[17,18,32]. In the Jarnerot trial, the colectomy-free rate was 12/24 (50%) after 3 years^[33]. Combining the data of both ACT trials has shown that the 1-year colectomy rate in the infliximab-treated arm was 10% *vs* 17% in the placebo arm^[34]. It should be emphasized that the ACT trials did not include patients who were refractory to intravenous steroid in the setting of ASC.

In the recent steroid-refractory severe attacks of ulcerative colitis trial, 116 adults with ASC who did not respond to a 5-d course of intravenous steroids were randomized to receive intravenous cyclosporine or infliximab using standard doses and protocols, both combined with azathioprine^[35]. Both the 7-d response rate (85.4% *vs* 85.7%) and treatment failure rate through day 98 (60% *vs* 54%) were similar between the cyclosporine and the infliximab arms, suggesting that the two regimens are equally viable alternatives to colectomy in steroid-refractory ASC. Similar effectiveness has also been suggested in a systematic review of non-randomized studies in children^[21]. In contrast, a nonrandomized study showed that 52% of patients receiving cyclosporine proceeded to colectomy by discharge, *vs* 18% of those administered infliximab^[36].

SURGERY

Although, in general, medical rescue therapy should be regarded as the first-line treatment in steroid-refractory ASC, colectomy is still a cornerstone of the management scheme. Colectomy is indicated in ASC not responding to medical therapy, toxic megacolon, perforation, and uncontrolled colorectal bleeding (rare)^[37,38]. Colectomy in steroid-refractory ASC cases may be considered before medical salvage therapy in chronic active UC previously resistant to thiopurines and infliximab, since no maintenance therapy would be available after discontinuing the calcineurin inhibitor. Surgery is usually the preferred therapeutic option in patients with toxic megacolon, a life threatening event. However, a 24-48 h trial of conservative treatment (i.e., bowel rest, broad spectrum antibiotics and rectal tube) may be cautiously attempted in the non-severe cases in specialized centers only while under intense monitoring. Sequential therapy of calcineurin inhibitors followed by infliximab or vice versa may be successful in approximately 25%-40% of adult patients, but is associated with significant morbidity and even mortality^[39-42]. Therefore, most recommend timely referral for colectomy after failing one medical salvage therapy, rather than attempting another regimen^[6,8]. Expected response to calcineurin inhibitors and infliximab is roughly 1-2 wk and colectomy should not be withheld in non-responders.

Although in the past ileoanal straight anastomosis has been the procedure of choice, now the ileal pouch-anal anastomosis (IPAA) (also known as "restorative proctocolectomy") is the most commonly practiced surgery, also in children. In some centers, ileo-rectal anastomosis is practiced but limited data are available to support this surgery. High early failure rates have been reported with this surgery and a life-long follow-up of the retained rectal stump is required. The ileoanal

pouch procedures are likely superior to the straight pull through (i.e., ileoanal anastomosis) as they are associated with a lower early stool frequency and better long-term continence while maintaining acceptable early complication rates. However, the IPAA procedure is associated with pouchitis in approximately 45%-60%^[43-45], of whom 60% will suffer from recurrent episodes and 5%-10% will develop chronic pouchitis^[45]. The probability of pouch failure has been found to be 9% at 10 years^[43]. Daytime and nighttime incontinence occurred in 7%-10% and 12%-24% of patients, respectively, over a 10-15 year period^[43,44]. The risk for female infertility after IPAA seems to be a major concern with an increase from approximately 10% in the average population to 25%-30%^[8,46]. The role of ileo-rectal anastomosis is controversial, but may be considered in females who are primarily concerned about the reduced fecundity associated with IPAA. The apparent advantages of the IPAA procedure must be seriously balanced against the potential adverse events which should be discussed openly with the families.

IPAA can be performed in one, two or three stages. A two-stage procedure (colectomy with pouch construction and a temporary protecting loop ileostomy to be closed in the second stage) is the most frequent procedure in stable ambulatory patients. The one step procedure (restorative proctocolectomy without protecting ileostomy) may be safe in selected ambulatory patients without any risk factors (e.g., steroids treatment, malabsorption and hypoalbuminemia) in highly trained centers^[8]. A three-stage approach (colectomy with temporary ileostomy in the first stage, pouch construction in the second stage and ultimately ileostomy closure) should be performed in patients with steroid-refractory acute severe colitis, those on high dose steroids and/or suffering from malnutrition, and those in whom Crohn's disease has not been excluded^[8]. With any chosen procedure, a laparoscopic-assisted procedure is feasible and safe^[47,48], also in children^[49,50]. The overall complication rate was higher in open surgery, compared with laparoscopic surgery (55% *vs* 39%, $P = 0.004$)^[48] with longer hospital stay. Patients who had an ileal pouch created through the laparoscopic approach had fewer occurrences of pouchitis^[49]. There were no significant differences between the two groups regarding daytime and night continence, or sexual function^[47].

In a meta-analysis, pouch failure rate was found to be 4.3% (95% CI: 3.5-6.3) and pelvic sepsis 7.5% (95% CI: 6.1-9.1)^[51]. Pouch failure was lower by 2.5% in recent studies *vs* those published prior to 2000. Functional outcome remained stable over time, with a 24-h defecation frequency of 5.9 (95% CI: 5.0-6.9), regardless of the technical aspects of the surgery^[51]. Preoperative steroid therapy (> 20 mg in adults), hypoalbuminemia and malnutrition are associated with increased surgical complications^[52]. Pre-operative high dose steroids and probably also infliximab^[53] are associated with increased surgical complications (especially in combination with other immune suppressants), while thiopurines and calcineurin

inhibitors are not.

AMBULATORY SURGERY

The most frequent indication for colectomy in ambulatory children with UC is chronic ongoing disease, at times- steroid dependent, whereas in adults- dysplasia is also a common indication^[54]. The points outlined above for ASC should also be followed in the decision-making of elective colectomy. In general, thiopurines and infliximab should be strongly considered in most cases before referral to colectomy in ambulatory mild-moderate UC. While cyclosporine should be initially administered in the hospital setting only, tacrolimus may be used in selected ambulatory patients as a bridge to thiopurines. In those losing response to infliximab, adalimumab may be considered before colectomy, given the recent evidence in adults showing its moderate effectiveness in ambulatory UC^[55,56]. Colectomy should be discussed as a viable alternative in children who suffer from ongoing symptoms despite multiple immunosuppressive medications, especially in steroid dependency.

CONCLUSION

Colectomy, a potentially lifesaving procedure in ASC, is associated with several long-term unwanted consequences. On the other hand, medical rescue therapy, including cyclosporine, tacrolimus and infliximab, are highly effective in steroid-refractory ASC. Therefore, medical salvage therapy should be offered before colectomy in most patients who do not present with surgical abdomen or toxic megacolon. Validated predictive rules can identify a subset of patients who will eventually fail corticosteroid therapy after only 3-5 d of steroid therapy with an accuracy of 85%-95%. This accuracy is sufficiently high for initiating medical therapy early in the admission without delaying colectomy if required. Families may elect to proceed to early colectomy before attempting medical rescue therapy, especially in chronic active disease. Therefore, whenever considering second-line medical therapy, colectomy should always be openly discussed. In patients failing one medical rescue therapy, colectomy should be regarded as the next therapeutic step.

Abstract

The association between inflammatory bowel disease (IBD) and colorectal cancer (CRC) has been recognised since 1925 and still accounts for 10%-15% of deaths in IBD. IBD-associated CRC (IBD-CRC) affects patients at a younger age than sporadic CRC. The prognosis for sporadic CRC and IBD-CRC is similar, with a 5-year survival of approximately 50%. Identifying at risk patients and implementing appropriate surveillance for these patients is central to managing the CRC risk in IBD. The increased risk of colorectal cancer in association with IBD is thought to be due to genetic and acquired factors. The link between inflammation and cancer is well recognised but the molecular biology, immune pathobiology and genetics of IBD-CRC are areas of much ongoing research. This review examines the literature relating to IBD-CRC, focusing on the incidence of IBD-CRC and examining potential risk factors including age at diagnosis, gender, duration and extent of colitis, severity of inflammation, family history of sporadic CRC and co-existent primary sclerosing cholangitis (PSC). Confirmed risk factors for IBD-CRC are duration, severity and extent of colitis, the presence of

co-existent PSC and a family history of CRC. There is insufficient evidence currently to support an increased frequency of surveillance for patients diagnosed with IBD at a younger age. Evidence-based guidelines advise surveillance colonoscopy for patients with colitis 8 to 10 years after diagnosis, with the interval for further surveillance guided by risk factors (extent of disease, family history of CRC, post-inflammatory polyps, concomitant PSC, personal history of colonic dysplasia, colonic strictures). There is a move away from using random colonic biopsies towards targeted biopsies aimed at abnormal areas identified by newer colonoscopic techniques (narrow band imaging, chromoendoscopy, confocal microendoscopy).

Dyson JK, Rutter MD. Colorectal cancer in inflammatory bowel disease: What is the real magnitude of the risk? *World J Gastroenterol* 2012; 18(29): 3839-3848 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i29/3839.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i29.3839>

INTRODUCTION

Crohn^[1] first described colorectal cancer (CRC) in association with inflammatory bowel disease (IBD) in 1925 and colorectal cancer still accounts for 10%-15% of deaths in patients with IBD^[2]. The incidence of IBD

has two peaks; between 15 and 30 years, and between 50 and 80 years^[3]. Due to this younger age peak, the mean age for developing IBD-associated CRC (IBD-CRC) is lower than that seen in sporadic CRC^[4]. A meta-analysis of 116 studies found the mean age of IBD-CRC diagnosis to be 43.2 years^[5]. Lakatos *et al*^[6] found the average age of IBD-CRC diagnosis to be 10 to 15 years younger than sporadic CRC in Eastern Europe (50.9 years *vs* 62.2 years). The prognosis for sporadic CRC and IBD-CRC is similar with a 5-year survival of approximately 50%^[7]. Identifying at risk patients and implementing appropriate surveillance for these patients is central to managing the CRC risk in IBD.

The increased risk of colorectal cancer in association with IBD is thought to be due to genetic and acquired factors^[8]. The link between inflammation and cancer is well recognised but the molecular biology, immune pathobiology and genetics of IBD-CRC are areas of much ongoing research. The role of the immune system for both tumour promotion and prevention is being examined. Studies indicate that immune cells are important in tumour promotion, with leucocyte infiltration and inflammatory mediators found in association with tumours^[9,10].

Genome-wide association studies have now identified approximately 99 susceptibility loci/genes relating to IBD. The better understanding of the genetics of IBD gives us more insight into disease pathogenesis. Some of the key themes identified are the role of interleukin (IL)-23/IL-17 signalling in IBD, defective barrier function in ulcerative colitis (UC) and defective processing of intracellular bacteria in Crohn's disease^[11]. Overlap of these loci/genes is seen with many diseases including CRC: E-cadherin (CDH1) has been associated with CRC^[12], UC^[13], and possibly Crohn's disease^[14].

MOLECULAR BIOLOGY OF IBD-CRC

IBD-CRC and sporadic CRC both have a dysplasia-cancer sequence and require multiple mutations to result in carcinoma^[7]. Sporadic CRC usually occurs as the end point of the adenoma-carcinoma sequence. Multiple molecular alterations occur within this sequence: chromosomal instability, microsatellite instability, hypermethylation^[15,16]. However, there are often differences in the timing and frequency of these events between sporadic and IBD-CRC. The molecular and genetic alterations occur more rapidly in IBD-CRC and in an unconventional sequence^[17]. It is suggested that the inflammation occurring in colitis results in a cascade of abnormal epithelial proliferation in addition to the genetic alterations that occur^[18]. In sporadic CRC, loss of the adenomatous polyposis coli gene function occurs early and p53 mutations occur late. The timing of these events is frequently reversed in IBD-CRC. It is also notable that in IBD-CRC, p53 mutations may be found within non-dysplastic mucosa. This is markedly different from sporadic CRC where p53 mutations are seen in morphologically aggressive lesions^[19].

The dysplasia-cancer sequence is a useful concept but it is more complex in IBD-CRC. There is not always a clear, stepwise transition from normal, through low and high grade dysplasia (HGD), to cancer^[17]. However, low grade dysplasia (LGD) can clearly progress to more advanced lesions and there is varying evidence as to the size of this risk. The 5-year cumulative risk has been shown to be as high as 33%-54% in a number of studies^[20-23]. This is in contrast to a 2%-10% risk of CRC over 10 years found by other groups^[24,25].

Cancer can occur without preceding detection of dysplasia, and LGD can regress or progress directly to cancer without the intermediate HGD^[26]. The high rate of synchronous and metachronous cancers associated with finding high grade dysplasia in biopsies usually leads to proctocolectomy^[27]. In a review of 10 prospective trials, 42% of patients undergoing colectomy for HGD had a synchronous CRC^[28]. Low grade dysplasia is an independent risk factor for CRC and often found in flat lesions which are difficult to see endoscopically. This is in contrast to sporadic CRC where dysplasia occurs within raised polypoid lesions. The concern is that flat LGD may be accompanied by HGD or cancer elsewhere in the colon. Studies suggest that 16%-27% of patients undergoing colectomy for LGD have synchronous CRC^[20,22,28]. Opinions differ as to how LGD should be managed: colectomy versus colonoscopic surveillance. Informed patient choice is important here. If surveillance is pursued colonoscopy should be repeated in 3 to 6 mo. The presence of multifocal LGD is a much stronger argument for colectomy.

QUANTIFYING THE RISK

It is important to quantify the risk of CRC in association with IBD. The reported risk varies widely between studies. This is partly due to the different methodology used in studies. Data comes from a mixture of tertiary referral centres, district general hospitals and population-based studies. Information from tertiary centres is likely to include patients with severe disease who are at greater risk of IBD-CRC. Early studies included patients who had already been referred with a diagnosis of CRC and those admitted to hospital with IBD, rather than gold-standard population-based studies which have a lower proportion of patients with severe or extensive colitis.

Eaden *et al*^[5] performed a meta-analysis of 116 studies including 54 478 UC patients with 1698 cases of IBD-CRC. The analysis included studies from a wide variety of centres: tertiary referral centres, population-based studies and hospital-based centres, and from different geographical areas. Studies from the United Kingdom and United States found a higher incidence [4 and 5 per 1000 person-years duration (pyd), respectively] than those from Scandinavia (2 per 1000 pyd). They found the overall prevalence of CRC in UC to be 3.7%, increasing to 5.4% in those with pancolitis.

Ekbom *et al*^[29] undertook a population-based cohort

study of 3117 patients with UC who were diagnosed between 1922 and 1983. Ninety one patients were found to have IBD-CRC giving a standardised incidence ratio of 5.7 (95% CI: 4.6-7.0) as compared with the expected incidence of CRC in the general population.

Söderlund *et al*^[30] undertook a population-based study of 7607 patients with IBD who were diagnosed between 1954 and 1989 for a total of 198 227 person-years. A total of 196 cases of CRC occurred in 188 patients, giving an overall incidence of 85 (95% CI: 82-109) cases per 100 000 person-years. This corresponds to a standardised incidence ratio of 2.3 (95% CI: 2.0-2.6) as compared with the general population.

Other population-based studies have suggested a much lower risk of IBD-CRC. Palli *et al*^[31] followed 689 patients with UC over 14 years (1978-1992) and found 10 cases of IBD-CRC, equating to an annual crude incidence of 0.13%. A study in Olmsted County followed 378 patients with UC for a total of 5567 person-years (1940-2004) and found 6 cases of IBD-CRC. They calculated the annual crude incidence to be 0.10% and the cumulative risk of CRC at 30 years to be as low as 2%. They found no statistically significant increase in the standardised mortality ratio (SMR) for CRC between IBD and non-IBD populations and concluded that the risk of CRC is only increased in patients with extensive colitis^[32]. Bernstein *et al*^[33] retrospectively examined 2672 patients with UC over a total of 19 665 person-years between 1984 and 1997. They found the annual risks to be 0.16% for colon cancer and 0.06% for rectal cancer.

Rutter *et al*^[20] followed 600 patients with extensive UC (as shown by barium enema or colonoscopy) for 5932 person-years as part of a colonoscopic surveillance programme (1970-2001). Data was gathered prospectively. Ninety-one patients (163 episodes) were found to have dysplasia or CRC. They calculated the cumulative probability of IBD-CRC to be 7.6% and a decreasing incidence over the period studied.

A Hungarian population-based study followed 723 UC patients for a total of 8564 person-years (1974-2004) and found 13 cases of IBD-CRC. They calculated the cumulative risks according to disease duration: 0.6% after 10 years, 5.4% after 20 years and 7.5% after 30 years^[6]. Hungary has a high rate of sporadic CRC and a low rate of colectomy for non-CRC reasons; factors which might have been expected to result in a higher rate of CRC.

Winther *et al*^[34] followed 1160 patients with UC over 22 290 person-years (1962-1987) and found 13 cases of IBD-CRC, giving an annual crude incidence of 0.06% and cumulative risk of 2.1% at 30 years. They found no statistically significant increase in the SMR for CRC between IBD and non-IBD populations. This study is from Denmark where the colectomy rate is one of the highest in the world: a fact that may affect the results and underestimate the risk of IBD-CRC.

The increased risk of CRC in UC has been long established. More recently, data has shown that Crohn's colitis

carries a similar magnitude of risk for the same disease extent. A Canadian cohort study matched a population-based IBD database to a cancer registry in North America between 1984 and 1997. There were 2857 cases of Crohn's disease and 2672 of UC. There was an increased incidence of CRC for patients with Crohn's [risk ratio (RR) 2.64; 95% CI: 1.69-4.12] or UC (RR 2.75; 95% CI: 1.91-3.97) as compared to the general population but no statistically significant difference between the two IBD diagnoses^[33]. They found the risk of rectal cancer to be increased in UC (RR 1.90; 95% CI: 1.05-3.43) but not in Crohn's colitis (RR 1.08; 95% CI: 0.43-2.70). A limitation of this study was the lack of definition of disease site or extent.

Ekblom *et al*^[35] also studied the risk of CRC in Crohn's disease. In a cohort study of 1655 patients in Sweden, patients with terminal ileal Crohn's had the same risk of CRC as the general population but those with colonic Crohn's had a RR of 5.6 (95% CI: 2.1-12.2).

CHANGING INCIDENCE OVER TIME

Eaden *et al*^[5] examined how the incidence of IBD-CRC is changing over time by plotting the cancer risk against the mid-point for each study. Although the incidence had increased between 1995 and 2001 the change was not statistically significant (slope 0.003, $P = 0.80$).

Rutter *et al*^[20] looked at the changing incidence of CRC over time within their 30-year colonoscopic surveillance program. They found a statistically significant decrease in CRC incidence ($r = -0.40$, $P = 0.04$), specifically for cancers proximal to the splenic flexure ($r = -0.54$, $P = 0.005$) and early cancers since 1975 (Dukes' A or B; $r = -0.4$, $P = 0.04$). However, there was not a statistically significant change in incidence for distal cancers ($r = 0.11$, $P = 0.59$) or advanced cancers (Dukes' C or D; $r = -0.05$, $P = 0.79$).

Jess *et al*^[32] examined a population-based cohort from Minnesota diagnosed between 1940 and 2001. They followed 692 patients with IBD for a total of 10 470 person-years. They analysed the incidence of CRC and the year that IBD was diagnosed. All their patients were diagnosed with CRC before 1980. The standardised incidence ratio for CRC diagnosed before 1980 was 1.6 (95% CI: 0.6-3.4) in comparison to 0 for those diagnosed after 1980. However, this difference between calendar periods was not statistically significant. They suggested that use of maintenance therapy and surveillance colonoscopy may be responsible for the absence of CRC seen in this cohort.

Söderlund *et al*^[30] examined the relative risk of CRC across calendar periods in their population-based study of 7607 patients with IBD who were diagnosed between 1954 and 1989. This cohort was followed up until 2004. After adjusting for type and extent of IBD, gender, age, and time since IBD diagnosis, the RRs were 1.7 (95% CI: 0.6-4.4) from 1960 to 1969, 1.3 (95% CI: 0.7-2.6) from 1970 to 1979, 1.2 (95% CI: 0.7-2.2) from 1980 to

1989, 1.1 (95% CI: 0.7-1.8) from 1990 to 1999, and 1.0 from 2000-2004. Although there was a trend towards decreasing incidence of CRC this did not reach statistical significance.

RISK FACTORS

Duration of colitis

A longer duration of colitis is associated with an increased risk of IBD-CRC; it is relatively rare before 8 years of colitis. However, Lutgens *et al*^[36] conducted a retrospective, nationwide database search to identify patients with IBD-CRC in the Netherlands between 1990 and 2006. For the 149 patients identified, they calculated the time interval between the diagnoses of IBD and cancer. They found that 22%-28% of patients developed cancer before the starting points for surveillance (8-10 years for extensive colitis and 15-20 years for left-sided disease). When the time interval from onset of symptoms to CRC diagnosis was used, 17%-22% would have developed cancer prior to surveillance endoscopy.

Identifying when the risk increases is central to guiding timing of surveillance strategies. Patients may also have colitis for a time before the diagnosis is made. This means they are exposed to cancer risk for a longer period if diagnosis is delayed.

In the meta-analysis by Eaden *et al*^[5], 41 studies reported colitis duration and 19 of these stratified duration into 10 year intervals. The overall incidence of IBD-CRC in any patient with UC was 3 per 1000 pyd. The cumulative incidence of IBD-CRC in patients with UC was 2% at 10 years, 8% at 20 years, and 18% after 30 years of disease. In the 61 studies that reported duration of colitis at the time of IBD-CRC diagnosis the mean was 16.3 years (95% CI: 15.0-17.6).

Lakatos *et al*^[6] retrospectively examined data relating to 723 patients within their 30-year database of IBD patients. They found 13 cases of IBD-CRC in 8564 person-years. They examined the incidence of CRC according to disease duration and found the cumulative risk to be 0.6% at 10 years (95% CI: 0.2-1.0), 5.4% at 20 years (95% CI: 3.7-7.1), and 7.5% at 30 years (95% CI: 4.8-10.2).

The prospective surveillance data from Rutter *et al*^[20] found the median duration of UC at diagnosis of CRC to be 23.5 years (range 11-48 years). The cumulative incidence of CRC was 0% at 10 years, 2.5% at 20 years, 7.6% at 30 years, 10.8% at 40 years, and 13.5% at 45 years (from onset of colitis). This lower incidence of IBD-CRC is particularly interesting given that the data comes from a specialist centre with a low colectomy rate and might have been expected to show a higher incidence. Data being obtained from a surveillance programme may in itself be responsible for the lower incidence of CRC, and regular colonic examination should prompt treatment measures to gain disease control.

Age at diagnosis

There is conflicting evidence as to whether younger age

at diagnosis of IBD is an independent risk factor for IBD-CRC. This evidence is not easy to evaluate as children tend to have more extensive and severe colitis than those diagnosed as adults, and younger people have the potential for longer colitis duration, which is itself a risk factor.

An important question is whether patients studied actually develop colitis at a younger age or whether they are diagnosed late after a period of undiagnosed inflammation. Eaden *et al*^[5] included 21 studies in their meta-analysis that examined age at onset of UC (over 20 years old). They excluded studies that reported the age at diagnosis of UC due to potential delay in diagnosis. They found a negative trend between younger age at onset (in adulthood) and increased risk of CRC but this was not statistically significant ($\chi = -1.61$, $P = 0.11$). They also analysed 12 studies looking at the incidence of IBD-CRC in children with UC (average age at onset of UC was 10 years old), only 5 of which commented on the duration of follow up. They found the overall incidence to be 6 per 1000 pyd and the cumulative risk of CRC to be 5.5% at 10 years, 10.8% at 20 years, and 15.7% at 30 years; higher than the corresponding rates for adults. However, these studies did not report incidence according to 10 yearly intervals so they assumed the log incidence rate to be constant. The small number of studies in children necessitates cautious interpretation of results.

Ekbom *et al*^[29] conducted a population-based cohort study of 3117 patients who were diagnosed with UC between 1922 and 1983 in Sweden. CRC was identified in 91 patients. They found age at diagnosis to be an independent risk factor for CRC. After adjusting for the extent of disease, they found the relative risk of CRC decreased by about half (adjusted standardized incidence ratio = 0.51; 95% CI: 0.46-0.56) for each increase in age group at diagnosis (under 15 years, 15-29 years, 30-39 years, 40-49 years, 50-59 years, and over 60 years). For those with extensive disease, after 35 years of disease, the cumulative risk for IBD-CRC was 40% if diagnosed under 15 years and 25% if diagnosed between 15 and 39 years of age.

Other studies have not confirmed this association. Greenstein *et al*^[37] found that the CRC risk was higher in patients diagnosed with IBD above 30-40 years of age compared with those diagnosed below 20 years old. Data from the 30-year study of Rutter *et al*^[20] showed that patients who developed CRC had a higher median age of onset of disease than those not developing cancer. This suggests that early onset is not an independent risk factor for IBD-CRC. Winther *et al*^[34] found the time between onset of colitis and the development of IBD-CRC to be the same in young and old patients.

Karvellas *et al*^[38] undertook a retrospective audit of adult patients with UC who were diagnosed with CRC between 1991 and 2002 in Edmonton, Alberta. They found that patients diagnosed with UC over the age of 40 years developed CRC more quickly than younger patients. The median disease duration at the time of CRC

diagnosis was 22 years in patients under 40 years, and 10 years for those over 40 years [odds ratio (OR): 11.5; 95% CI: 2.41-20.16; $P = 0.00029$].

Extent of colitis

The greater the disease extent, the greater the risk of CRC. Patients with proctitis and proctosigmoiditis are at the lowest risk, left-sided colitis carries moderate risk and those with pan-colitis are at the highest risk of CRC^[39,40].

How we measure the extent of disease is important; macroscopic versus radiological versus histological. Ekbohm *et al.*^[29] assessed IBD-CRC risk in UC according to extent of disease; proctitis versus left-sided colitis versus pancolitis. The extent was determined from barium enema and colonoscopy reports. The relative risk for CRC was 1.7 for proctitis, 2.8 for left-sided colitis, and 14.8 for pancolitis, as compared with the general population.

Söderlund *et al.*^[30] examined the risk of CRC according to extent of colitis in their population-based study. They found the relative risks of CRC to be 2.7 for all patients with UC (95% CI: 2.3-3.2), 5.6 for pancolitis (95% CI: 4.0-4.7), 2.1 for Crohn's colitis (95% CI: 1.2-3.4) and 1.7 for proctitis (95% CI: 1.2-2.4).

Severity of inflammation

IBD-CRC is thought to occur in the context of inflammation and anti-inflammatory treatments are felt to decrease the risk of CRC. Recent studies have focused on this association.

Rutter *et al.*^[20] conducted a case-control study of patients with colorectal neoplasia identified within a surveillance program between 1988 and 2002 ($n = 68$). They found a significant correlation between both colonoscopic (OR: 2.5; $P < 0.001$) and histological (OR: 5.1; $P < 0.001$) inflammation and the risk of neoplasia. When multivariate analysis was performed, histological inflammation remained a significant risk factor (OR: 4.7; $P < 0.001$). In a follow-up study from this work, Rutter *et al.*^[41] found that mucosal healing may decrease the risk of neoplasia; macroscopically normal mucosa appears to return the CRC risk to that of the general population.

Gupta *et al.*^[42] retrospectively studied a cohort of 418 patients undergoing colonoscopic surveillance for UC. They found a significant relationship between histological inflammation over time and progression to advanced neoplasia (hazard ratio 3.0; 95% CI: 1.4-6.3) which remained an independent risk factor in multivariate analysis. This is in contrast to other studies showing that those with quiescent disease have a similar risk of developing CRC as those with active disease^[6,43].

Post-inflammatory polyps have been associated with an increased risk of CRC. They do not in themselves have malignant potential^[44]. It is possible that multiple post-inflammatory polyps increase the miss rate of dysplastic lesions or that their presence is evidence of more severe previous inflammation. A retrospective study using the Mayo Clinic centralised diagnostic index identified 188 patients with UC-associated CRC and matched them

to 1528 gender and disease-extent matched controls. The presence of post-inflammatory polyps remained statistically associated with CRC even after adjusting for surveillance and anti-inflammatory treatments^[45]. In the follow-up case-control study by Rutter *et al.*^[41], cases of CRC were significantly more likely to have post-inflammatory polyps than the controls (OR: 2.14; 95% CI: 1.24-3.70).

Gender

In their population-based study, Söderlund *et al.*^[30] looked specifically at the gender-related risk of IBD-CRC by identifying those diagnosed with CRC between 1960 and 2004. They compared their results with the general population using standardised incidence ratios and data obtained from national health and census registers. There were 196 cases of IBD-CRC giving an overall incidence of 110 cases per 100 000 person-years. The relative risk in males was 2.6 (95% CI: 2.2-3.1) and in females 1.9 (95% CI: 1.5-2.4) compared to the general population. The cumulative incidence at 40 years after the diagnosis of IBD was 8.3% in males and 3.5% in females.

Ekbohm *et al.*^[29,35] found a similar relative risk for IBD-CRC in men and women whether they have UC (5.6 in men and 5.9 in women) or Crohn's disease (2.8 in men and 2.1 in women).

Family history of sporadic colorectal cancer

Patients with IBD who have a family history of sporadic CRC are at increased risk. The magnitude of the risk has been found to be a 2-3 fold increase in both case control and population-based studies. Askling *et al.*^[46] undertook a population-based cohort study of 19 876 patients with UC or Crohn's disease born between 1941 and 1995. They found that a family history of CRC was associated with a more than 2-fold risk of IBD-CRC (adjusted RR 2.5; 95% CI: 1.4-4.4) and those with a 1st-degree relative diagnosed with CRC before 50 years of age had a higher risk (RR 9.2; 95% CI: 3.7-23). In a retrospective cohort study, Velayos *et al.*^[45] also found family history of CRC to be an important risk factor for IBD-CRC in patients with UC (OR: 3.7; 95% CI: 1.0-13.2)^[47].

Co-existent primary sclerosing cholangitis

Smith *et al.*^[43] first identified a link between UC and primary sclerosing cholangitis (PSC) in 1965. The association between Crohn's disease and PSC was identified by Atkinson and Carroll in 1964^[48]. It has since been shown that the risk of IBD-CRC is greater in the presence of co-existent PSC. The adjusted relative risk for dysplasia or cancer is reported as 3.15 (95% CI: 1.37-7.27) for patients with PSC and UC as compared to those with UC alone^[49]. Kornfeld *et al.*^[50] found the cumulative risk was 33% at 20 years and 40% at 30 years from the diagnosis of UC. Causative theories include that a high concentration of bile acids in the lumen of the colon may contribute to the increased risk^[51]. Lundqvist *et al.*^[52] suggest that patients with PSC often have a longer duration of colitis and this in itself may explain the increased risk of CRC.

However, patients with PSC seem to have more quiescent colitis^[53]. Sokol *et al.*^[53], also found that patients with co-existent IBD and PSC receive more 5-aminosalicylic acid (5-ASA) treatment than patients with IBD alone. Given the importance of the severity of inflammation in the aetiology of IBD-CRC this points to the existence of PSC itself having a carcinogenic effect.

Soetikno *et al.*^[54] conducted a meta-analysis of 11 studies to establish whether the risk of CRC is increased in patients with concomitant UC and PSC. They found that patients with UC-PSC are at increased risk of colorectal dysplasia and carcinoma compared with patients with UC alone (OR: 4.79; 95% CI: 3.58-6.41) and the risk is still increased if CRC is considered alone (OR: 4.09; 95% CI: 2.89-5.76). Broomé *et al.*^[55] studied 120 patients in Stockholm; 40 with UC-PSC and 80 with UC alone. They found that those with concomitant UC and PSC have a significantly higher risk of developing CRC.

CLINICAL MANAGEMENT

Chemoprevention

As with all pathology, prevention is better than cure. By focussing on the risk factors predisposing people to IBD-CRC it is hoped we can reduce the incidence of dysplasia and cancer. Any chemoprevention strategy must be acceptable to patients and physicians, in terms of safety, efficacy and cost. Ongoing colonic inflammation has been accepted as one of the causative factors behind IBD-CRC. Studies have focussed on using maintenance anti-inflammatory medications to prevent the development of dysplasia and cancer.

5-ASA compounds are used as maintenance therapy in colitis. *In vitro* studies found that they inhibit the nuclear factor kappa B pathway which is involved in tumour survival and sustaining chronic inflammation^[4,56,57]. Due to the widespread use of 5-ASA compounds for maintenance therapy, prospective randomised trials are lacking with respect to chemoprevention. Velayos *et al.*^[58] undertook a meta-analysis of 9 studies which included a total of 1932 patients with UC. They found a protective effect of 5-ASA against colorectal cancer (OR: 0.51; 95% CI: 0.37-0.69) and colorectal cancer/dysplasia as a combined end point (OR: 0.51; 95% CI: 0.38-0.69). They did not find an association between 5-ASA use and a lower risk of dysplasia (OR: 1.18; 95% CI: 0.41-3.43) although they make the point that only 2 of the studies looked at this endpoint.

Terdiman *et al.*^[59] have reached a different conclusion with their observational study looking at the association between 5-ASA and IBD-CRC. They found that exposure to 5-ASA compounds during the 12 mo prior to the diagnosis of IBD-CRC was not associated with a decreased cancer risk (OR: 0.97; 95% CI: 0.77-1.23). They also found a non-statistically significant trend between a lower risk of IBD-CRC and an increased number of 5-ASA prescriptions in the previous year. Their conclusion was that 5-ASA compounds do not have

a protective effect against IBD-CRC when assessed over a short period. The important factor here seems to be the time period studied. Any preventative strategy has to be seen as a long term management approach. By using chemoprevention we are trying to prevent the genetic alterations which occur in the context of inflamed mucosa. The relationship between 5-ASA compounds and any protective effect must surely be assessed over a longer time period in order to discount it. The design of this study is too short and the results should be interpreted with caution.

The link between IBD-CRC and co-existent PSC is well established. The presence of additional bile acids in the colonic lumen is felt to contribute to this increased risk. Ursodeoxycholic acid (UDCA) decreases the amount of bile acids and studies have suggested treatment with UDCA may reduce the risk. Tung *et al.*^[60] found a strong relationship between UDCA and a decreased risk of colonic dysplasia (OR: 0.18; 95% CI: 0.05-0.61). The relationship remained after adjusting for gender, age at diagnosis of colitis, duration of colitis, duration of PSC, severity of liver disease, and sulfasalazine use. Pardi *et al.*^[61] also found a relative risk of 0.26 for colorectal dysplasia or cancer using UDCA when compared to placebo. These studies are in patients with colitis and PSC. The potential for using UDCA for patients with colitis only has not been explored. There are concerns about the side effects of using the medication in patients without PSC.

Given the potential benefit with suppression of inflammation, interest has been shown in other anti-inflammatory treatments. The role of steroids as chemopreventive agents has been explored. Evidence suggests a reduction in CRC risk with systemic and topical steroids^[45,62]. However, the significant complications that occur with long-term steroid treatment make this strategy unacceptable. No chemopreventive effect has been shown with azathioprine or 6-mercaptopurine^[63].

Other suggested therapies include folic acid and statins. Patients with IBD are at risk of folate deficiency. Studies have shown a protective trend against CRC but the effect is not statistically significant^[64,65]. Potack *et al.*^[66] suggest that given that folate is safe and inexpensive, supplementation should be considered for risk reduction. A study in Israel suggested statin therapy is associated with a risk reduction in sporadic CRC and a 94% risk reduction in patients with IBD^[67]. This potential benefit needs further investigation.

Surveillance

As described above, the quoted risk of developing cancer in colitis varies greatly from study to study. More recent population-based studies suggest a much lower risk than the earlier cohort studies. Methodological differences, the more recent widespread use of anti-inflammatory treatments and the advent of surveillance colonoscopy programmes may account for these differences. There is insufficient evidence to support the discontinuation

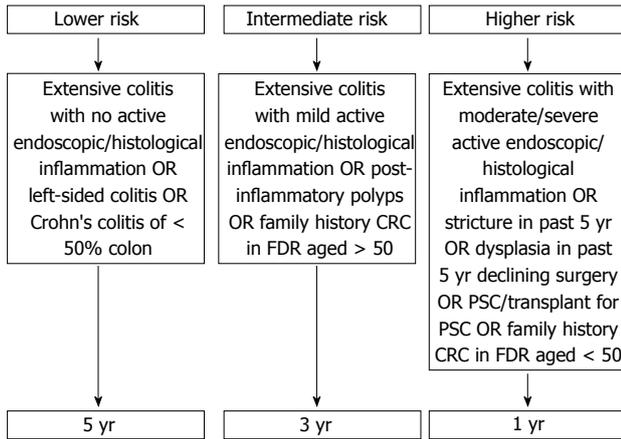

Figure 1 Surveillance recommendations for patients with colitis. OR: Odds ratio; CRC: Colorectal cancer; PSC: Primary sclerosing cholangitis; FDR: First degree relative.

of surveillance programmes and IBD is still believed to expose patients to an increased risk of CRC.

The aim of any screening or surveillance programme must be to identify early lesions to enable treatment and prevention before the development of invasive cancer. Prophylactic proctocolectomy eliminates the risk of CRC but this strategy is not acceptable to most patients or physicians. A surveillance programme must be acceptable to patients and practically possible to implement. The success of such programmes relies on patients engaging with follow up; they must understand the risks of not being tested and also that no surveillance strategy is without a miss rate.

Equally, physicians must implement the guidelines effectively. Many current guidelines advocate random quadrantic biopsies every 10 cm throughout the entire colon. This approach only visualises less than 1% of colonic mucosa. Rubin *et al.*⁶⁸ found the probability of detecting dysplasia was 90% if 33 and 95% if 56 biopsies were taken. Studies have shown that clinicians do not take sufficient biopsies^{69,70}.

The distinct differences between sporadic CRC and IBD-CRC are important for surveillance strategies. Bowel cancer screening in the general population relies on identification of adenomatous lesions which can be resected before they transform into carcinoma. IBD-CRC poses different challenges: dysplastic lesions do not follow the adenoma-carcinoma sequence, they can be difficult to see (flat lesions), difficult to resect completely, and multifocal. A meta-analysis of 1225 patients with UC found the likelihood of finding concurrent cancer at the time of colectomy for high or low grade dysplasia was 42% and 19%, respectively²⁸.

Due to the increased risk, patients diagnosed with PSC who are not previously known to have IBD should have a screening colonoscopy. For patients diagnosed with UC already, yearly surveillance colonoscopy should be performed from the point of diagnosis with PSC.

There has been increased focus on targeted biopsies and methods to improve identification of dysplastic le-

sions. Chromoendoscopy involves spraying dye (indigo carmine or methylene blue) on to the colonic mucosa to enable more detailed examination. Rutter *et al.*⁷¹ compared consecutive, random and indigo carmine targeted biopsies. Chromoendoscopy found 7 dysplastic lesions in 157 targeted biopsies, compared to no dysplasia in 2904 non-targeted biopsies. Hurlstone *et al.*⁷² conducted a prospective case-controlled study of 700 patients and also found a higher yield of dysplasia using indigo carmine chromoendoscopy as compared to conventional colonoscopy with random biopsies. They found 69 dysplastic lesions using chromoendoscopy and only 24 lesions with random biopsies ($P < 0.001$). These results are supported by Kiesslich *et al.*⁷³, who found a statistically significantly higher rate of neoplasia detection with methylene blue chromoendoscopy.

Narrow band imaging (NBI) is available on most colonoscopes. It uses optical filter technology to improve the visibility of vessels, pit pattern and other soft tissue structures. Dekker *et al.*⁷⁴ performed a prospective, randomised trial to compare NBI and conventional colonoscopy. They did not find a statistically significant difference between the two methods; a similar number of dysplastic lesions were identified and missed using both methods.

Confocal laser endomicroscopy visualises the histology of the mucosa in real time. This is useful for characterising lesions rather than finding the lesion in the first place. Kiesslich *et al.*⁷⁵ compared confocal chromoscopic endomicroscopy with conventional colonoscopy with random biopsies in a randomised controlled trial. They found the yield of neoplasia was increased 4.75 times using the new approach ($P = 0.005$) using 50% less biopsies. Hurlstone *et al.*⁷⁶ compared confocal chromoscopic endomicroscopy to chromoendoscopy alone in a prospective, randomised controlled trial. They found that endomicroscopy increased the diagnostic yield of neoplasia 2.5 times.

However, it is already well known that there is significant inter-observer variability between even expert gastrointestinal pathologists when interpreting dysplasia. The use of confocal endomicroscopy requires the endoscopist to have the ability to interpret histological findings. For this modality to be widely used endoscopists would require extensive training to enable accuracy.

The best technique for surveillance is evolving. There is a move away from using random colonic biopsies towards targeted biopsies aimed at abnormal areas identified by newer colonoscopic techniques (chromoendoscopy, confocal microendoscopy). There has been concern regarding the specialist training needed for endoscopists to use chromoendoscopy effectively. Nevertheless, the 2010 guidelines from the British Society of Gastroenterology (BSG) recommend the use of chromoendoscopy with targeted biopsies for colitis surveillance⁷⁷.

Current guidance from the BSG advises all patients with IBD should have a screening colonoscopy approximately 10 years from symptom onset (ideally when in remission) with pancolonic dye spraying and targeted

biopsies of abnormal areas. The risk of IBD-CRC is estimated based on duration and extent of disease, co-existent risk factors (PSC, family history of sporadic CRC), and the endoscopic and histological findings at colonoscopy. The surveillance intervals are based on this assessment of risk (Figure 1)^[77].

In conclusion, confirmed risk factors for IBD-CRC are duration, severity and extent of colitis, the presence of co-existent PSC and a family history of CRC. There is insufficient evidence currently to support an increased frequency of surveillance for patients diagnosed with IBD at a younger age. Evidence-based guidelines advise surveillance colonoscopy for patients with colitis 8 to 10 years after diagnosis, with the interval for further surveillance guided by risk factors (extent of disease, family history of CRC, post-inflammatory polyps, concomitant PSC, personal history of colonic dysplasia, colonic strictures)^[78-80].

Abstract

AIM: To investigate the reciprocal modulation between microRNA (miRNA) and DNA methylation *via* exploring the correlation between miR-373 and methyl-CpG-binding domain protein (MBD)2.

METHODS: MiR-373 expression was examined using the TaqMan miRNA assay. Methylation of *miR-373* was investigated using methylation-specific polymerase chain reaction, and recruitment of methyl binding proteins was studied using the chromatin immunoprecipitation assay. Mutation analysis was conducted using the QuikChange™ Site-Directed Mutagenesis kit. The activity of *miR-373* gene promoter constructs and targeting at MBD2-three prime untranslated region (3'UTR) by miR-373 were evaluated by a dual-luciferase reporter gene assay.

RESULTS: In hilar cholangiocarcinoma, miR-373 decreased and was closely associated with poor cell differentiation, advanced clinical stage, and shorter survival. The promoter-associated CpG island of miR-373 gene was hypermethylated and inhibited expression of miR-373. MBD2 was up-regulated and enriched at the promoter-associated CpG island of miR-373. Methylation-mediated suppression of miR-373 required MBD2 enrichment at the promoter-associated CpG island, and miR-373 negatively regulated MBD2 expression through targeting the 3'UTR.

CONCLUSION: MiR-373 behaves as a direct transcriptional target and negative regulator of MBD2 activity through a feedback loop of CpG island methylation.

Mutual regulation between microRNA-373 and methyl-CpG-binding domain protein 2 in hilar cholangiocarcinoma. *World J Gastroenterol* 2012; 18(29): 3849-3861 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i29/3849.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i29.3849>

INTRODUCTION

Hilar cholangiocarcinoma, known as Klatskin tumor^[1], is an uncommon cancer with an incidence of 0.01% to 0.2% per year^[2]. Although it is relatively rare, hilar cholangio-

carcinoma displays a highly aggressive malignancy and is considered to be an incurable and rapidly lethal disease despite recent progress in diagnostic and therapeutic techniques. The 5-year overall survival after curative resection ranges from 15% to 35%, but the 10-year survival is almost zero^[3]. Patients with inoperable, recurrent, or metastatic disease can only be treated with palliative therapy, such as endoscopic, percutaneous biliary drainage in combination with radiotherapy and chemotherapy. However, hilar cholangiocarcinoma is not sensitive to chemotherapy and radiotherapy, and the median survival rate of those cases is only about 5.8 mo^[4].

Studies have established a direct link between aberrant DNA methylation and regulation of gene expression in human cancer^[5]. Once a given sequence becomes methylated, it can directly repress transcription by either impeding recognition of transcriptional activators to DNA sequences^[6], or by recruiting methyl-CpG binding domain proteins (MBPs) to modify chromatin compaction and control gene silencing^[7]. The MBP family consists of five isoforms, including Mecp2, methyl-CpG-binding domain protein (MBD1), MBD2, MBD3, and MBD4. With the exception of MBD4, which is primarily a thymine glycosylase involved in DNA repair^[8], all MBPs are implicated in transcriptional repression mediated by DNA methylation. Mecp2, MBD1, and MBD2 have been demonstrated to be involved in methylation-based gene repression and also affect chromatin structure^[9-11]. MBD3 lacks a functional MBD, but is an integral subunit of the histone deacetylase Mi2-NuRD complex that is recruited through MBD2^[12].

MicroRNAs (miRNAs) are non-coding, single-stranded RNAs of 18 to 24 nucleotides in length that constitute a novel class of gene regulators^[13]. In general, miRNAs negatively regulate gene expression by targeting the three prime untranslated region (3'UTR), which consequently triggers mRNA degradation or translational suppression^[14,15] on the basis of complementary value. miRNAs have recently been shown to play important roles in cancers, as more than 50% of miRNA genes reside in cancer-associated genomic regions, and their expression has been found to be dysregulated in various cancers^[16]. Depending on the target genes, miRNAs can function as tumor suppressor genes or oncogenes^[17].

Mature miRNAs are transcribed from *miRNA* genes by RNA polymerase II. Hence, the expression of miRNAs share the same genetic and epigenetic regulation of gene function including methylation^[18]. Although only subsets of miRNA genes harbor CpG islands in their promoter regions or are embedded in CpG islands, DNA methylation-mediated down-regulation of miRNAs have been reported by a number of groups^[19]. Moreover, miRNA interference with DNA methylation through DNA methyltransferases (DNMTs) 3a, 3b, and DNMT1, have been observed^[20-22]. These results suggest that miRNA and DNA methylation regulate one another. However, the literature has only revealed a one-way effect of miRNA on DNA methylation or miRNA modification by promoter methylation^[23]. We speculate that a particular miRNA may

act as a bidirectional regulator by not only impacting DNA methylation, but also *via* regulation by methylation itself.

In this study, we demonstrate that miR-373 functions as a negative regulator of MBD2 by targeting the 3'UTR. Inversely, miR-373 is restrained by MBD2 enrichment at the methylated promoter-associated CpG island. We functionally demonstrate the fact that miR-373 serves as a one directional transcriptional target and negative regulator of MBD2 through a feedback loop of CpG methylation in hilar cholangiocarcinoma.

MATERIALS AND METHODS

Patients and samples

A total of 48 patients with both tumor and normal bile duct tissues, which were successfully obtained from operations conducted from January 2005 to December 2008 at Tongji Hospital in the Tongji Medical College of the Huazhong University of Science and Technology (China), were used in this study. The fresh tissues were harvested immediately after surgery, washed twice with chilled phosphate buffered saline, and immediately stored in liquid nitrogen and at -80 °C in our tissue bank until further use. The detailed clinical data of these patients is provided in Table 1. Written informed consent was obtained from each patient before sample collection. Ethical approval

was obtained from the Cancer Center Research Ethics Committee of Tongji Medical College and Hospital.

Cell lines and epigenetic treatment

The QBC₉₃₉ cell line, originating from human common bile duct adenocarcinoma, was kindly provided by Dr. Shuguang Wang from Southwest Hospital of the Third Military Medical University (China)^[24]. The HEK293 cell line was purchased from the Cell Bank of Chinese Academy of Sciences (China). Cells were cultured in RPMI 1640 medium supplemented with 10% fetal bovine serum (Gibco-BRL; Carlsbad, CA, United States). For the epigenetic study, QBC₉₃₉ cells were treated with 5.0 μmol 5-Aza-2-CdR for 5 d, and 200 nmol trichostatin A (TSA; Sigma-Aldrich; St. Louis, MO, United States) was added on day 5.

Taqman miRNA assay

RNA was extracted using the mirVana™ miRNA Isolation Kit (Applied Biosystems, Carlsbad, CA, United States). cDNA synthesis and analysis of miR-373 expression were performed according to the TaqMan MicroRNA Assay protocol (Applied Biosystems). U6 (RUN6B) was used as an endogenous control. Polymerase chain reaction (PCR) was conducted in three independent replicates for each sample. Expression of miR-373 was normalized to U6, and fold change was calculated based on the $2^{-\Delta\Delta C_t}$ method.

Genomic DNA bisulfate modification

Genomic DNA was isolated from tissues and cells using the DNeasy® Blood and Tissue Kit (Qiagen, Valencia, CA, United States). For DNA methylation detection, 1.5 μg of genomic DNA was modified with sodium bisulfite using the EpiTect Bisulfate Kit (Qiagen). CG Genome Universal Unmethylated DNA and CG Genome Universal Methylated DNA (mDNA) (Millipore, Darmstadt, Germany) were also modified for use as positive and negative controls, respectively (100% values).

DNA methylation analysis

Methylation-specific PCR (MSP) and MethySYBR^[25,26] quantitative methylation-specific PCR (qMSP) were performed with primers specific for fully methylated and fully unmethylated CpG island sequences (MmiR-373, UmiR-373). Primers for converted (ActB) and unconverted (ActG) β-actin special sequences containing no CpG sites were used as a control to correct *C_r* values and for efficiency of bisulfite conversion, respectively. *C_r* values of samples MmiR-373, UmiR-373, and ActB were calculated using corresponding standard curves, after which they were corrected to DNA amount with ActB values. The sum of percent of fully methylated reference (PMR) and percent of unmethylated reference (PUR) DNA sample amounts (MmiR-373 + UmiR-373 = 100%) was calculated.

Chromatin immunoprecipitation assay

The Chromatin immunoprecipitation (ChIP) assay was

performed with the ChIP-IT™ Express kit (Active Motif, Carlsbad, CA, United States) according to the manufacturer's instructions using 2 μg ChIP-validated antibodies (Mecp2, MBD2, and mouse IgG, Active Motif; MBD1, Invitrogen, Carlsbad, CA, United States). The presence of target proteins at DNA segment were validated with primers (5'-AGATCGAGACCATCCTGGCTAACA-3'; 5'-TGAGAATGAGTCTTGCTCTGTCCG-3') to a product of 201 base pairs (bp) in size, and the enrichment of RNA polymerase II on the glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) gene (116 bp in size) was quantified as the endogenous control. ChIP-qPCR reactions were performed using SYBR® GreenER™ Assay (Invitrogen) in a genomic DNA model. Protein enrichment was expressed as the ratio of immunoprecipitated DNA (IP-DNA) to the total amount of DNA in the chromatin sample (input). Fold change was calculated as the ratio of IP-DNA/input (target) to IP-DNA/input (RNA polymerase II), and was then normalized to the control.

Vectors

The promoter luciferase reporter plasmid harboring the CpG island of *miR-373* gene was constructed according to a previously described approach^[27] and designated pGL4-373-Prom. In brief, the *miR-373* gene locus was screened in the database (<http://genome.ucsc.edu/>), a 5-kb fragment upstream of the pre-*miR-373* sequence was analyzed (http://www.fruitfly.org/seq_tools/promoter) to figure out the putative promoter and transcriptional start site (TSS), and a CpG island was predicted using Methprimer software (<http://www.urogene.org/methprimer/>). The results showed 402 bases of putative CpG islands spanning -251 to +150 bp and containing 26 CpG dinucleotides in the 5'-flank region of the human *miR-373* gene (predicted TSS is recognized as +1).

A 726 bp fragment of the *miR-373* gene (GenBank accession no. NR_029866) was amplified from QBC939 cell genomic DNA using the following PCR-specific primers: 5'-CGATGGTACCTGGAAAGTGCTGCGA-CATTT-3' (sense), which contains an artificial *Kpn* I site, and 5'-TCATGCTAGCAGAGGTTGGCCTCCAAT-CAT-3' (antisense), which contains an artificial *Nhe* I site and four protective bases. The PCR-amplified fragments were digested with *Kpn* I/*Hne* I and then inserted into the pGL4.22-basic plasmid (Promega, Madison, WI, United States) to generate the *miR-373* gene promoter luciferase reporter plasmid designated pGL4-373-Prom.

Precursor miR-373 clones (miRNA Accession: MI0000781), a scrambled control clone, wild-type MBD2 3'UTR vector pEZX-MBD2-3'UTR (Gene Accession: NM_004992.3), a scrambled control, and full-length cDNA expression vector of MBD2 (pDONR™_MBD2), were purchased from GeneCopoeia company (GeneCopoeia, Rockville, MD, United States). The potential binding sequences of miR-373 on the MBD2 3'UTR were mutated using the QuikChange™ Site-Directed Mutagenesis Kit (Stratagene, La Jolla, CA, United States). Silencer® Select siRNA for MBD2 and the scrambled control were

purchased from Applied Biosystems (siRNA ID: s17081, Target RefSeq Number: NM_003927). The recombinants were confirmed by full-length sequencing.

siRNA knock-down study

For protein knock-down by RNAi, 5×10^6 freshly elutriated HEK293 cells were transfected with targeting MBD2-siRNA or scrambled control at a final concentration of 200 nmol, using HiPerfect Transfection Kit (Qiagen) according to the manufacturer's instructions. Seventy-two hours after transfection, the cells were harvested.

In vitro DNA methylation

pGL4-373-prom was methylated *in vitro* using M. Sss I (4 U/ μ g DNA) (New England Biolab, Ipswich, MA, United States) in the presence of 160 μ mol S-adenosylmethionine (SAM) for 16 h. The mDNA, re-designed as pGL4-m373-prom, was digested with either Sal I (blocked by M. Sss I) or Bam I (not blocked by M. Sss I) restriction enzymes. Sensitivity to Sal I and resistance to Bam I indicated efficient DNA methylation.

Establishment of stable cell line

pGL4-m373-prom or pGL4-u373-prom were transfected into HEK293 cells in 35-mm dishes using Lipofectamine™ LTX and Plus Reagent (Invitrogen). Twenty-four hours post-transfection, cells were plated into 100-mm dishes at various densities and incubated in RPMI 1640 medium containing 2.0 μ g/mL of puromycin for 7 d, followed by maintenance with 1.0 μ g/mL puromycin. The stable cell line established was designated HEK-m373-prom and HEK-u373-prom.

Luciferase reporter gene assay

For promoter luciferase activity assay, pGL4-m373-prom or pGL4-u373-prom were transfected into HEK293 cells; pRL-TK was cotransfected as an endogenous control, and methylated and unmethylated pGL4-control were also used as controls. For the 3'UTR luciferase reporter assay, vectors containing WT-3'UTR or MUT-3'UTR were cotransfected with precursor miR-373 or pre-miR-neg. Cells were harvested 72 h after transfection, and luciferase activity was quantified using the Dual-Luciferase® Reporter Assay System (Promega, Madison, WI, United States) according to the manufacturer's protocol.

Western blotting

Proteins (50 μ g) were analyzed by Western blotting with primary antibodies against Meccp2 (1:500, Sigma-Aldrich), MBD1 (1:1000, Millipore, Darmstadt, Germany) and MBD2 (1:1000, Millipore), which produced a signal of approximately 75 kDa, 61 kDa, and 50 kDa, respectively. GAPDH (1:5000, abcam, Cambridge, MA, United States) was used as a loading control.

Statistical analysis

Data analysis was performed using SPSS for windows version 14.0 (Chicago, IL, United States). Student's test,

one-way analysis of variance, and Pearson were used according to the data characteristics. Duration of hilar cholangiocarcinoma recurrence and death measured from the date of surgery was referenced against disease-free survival and overall survival time. Survival duration was calculated *via* the Kaplan-Meier method. The log-rank test was employed for comparison of cumulative survival rate and disease-free survival in the patient group. *P* values < 0.05 were considered statistically significant.

RESULTS

Down-regulation miR-373 is associated with poor cell differentiation, advanced clinical stage, and shorter survival

In patients with hilar cholangiocarcinoma, significant down-regulation of miR-373 was observed in QBC₉₃₉ cells and 35 (72.92%) tumors, including seven undetectable samples (*P* < 0.01) (Figure 1A). Fold-change analysis showed a 2.94-fold decrease in the tumor group compared to the control (*P* < 0.01, Figure 1B). In regard to the correlation between miR-373 expression and clinicopathological factors, miR-373 showed low expression in specimens with poor cell differentiation (*P* = 0.031) and advanced clinical stages (stage III, IV *vs* I, II) (*P* = 0.017) (Table 1), while no association was observed with age, gender, tumor size, different pathological types, Bismuth classification, or lymphatic metastasis (*P* > 0.05). Further studies were conducted to evaluate the correlation between miR-373 expression and survival. Kaplan-Meier analysis showed that down-regulation of miR-373 correlated with decreased overall survival (Figure 1C, *P* < 0.05, log-rank test) and disease-free survival (Figure 1D, *P* < 0.05, log-rank).

Promoter-associated CpG island of miR-373 is hypermethylated in hilar cholangiocarcinoma

According to the literature, the CpG island is a region of at least 200 bp, a GC percentage greater than 50%, and an observed/expected CpG ratio greater than 60%. A 402 base canonical CpG island spanning -251 to +150 bp and containing 26 CpG dinucleotides encompasses the transcription start site (TSS, recognized as +1, Figure 2A). Methylation of the promoter-associated CpG island was investigated with standard MSP and MethylSYBR. In standard MSP, methylation was present in 38 (38/48, 79.17%) tumors, including 26 homozygous and 12 heterozygous samples, which are indicated by a single methylation band or by both methylation and unmethylation bands, respectively (Figure 2B). Heterozygous methylation was also observed in five control tissues. These results were validated by qMSP and a fluorescent signal was detected in same samples. The value of PMR and PUR was 87.4% and 14.7% in the tumor and control groups, respectively (Figure 2C, *P* < 0.01).

To determine the correlation between promoter methylation and miR-373 expression, we divided methylation into four groups according to the following PMR values:

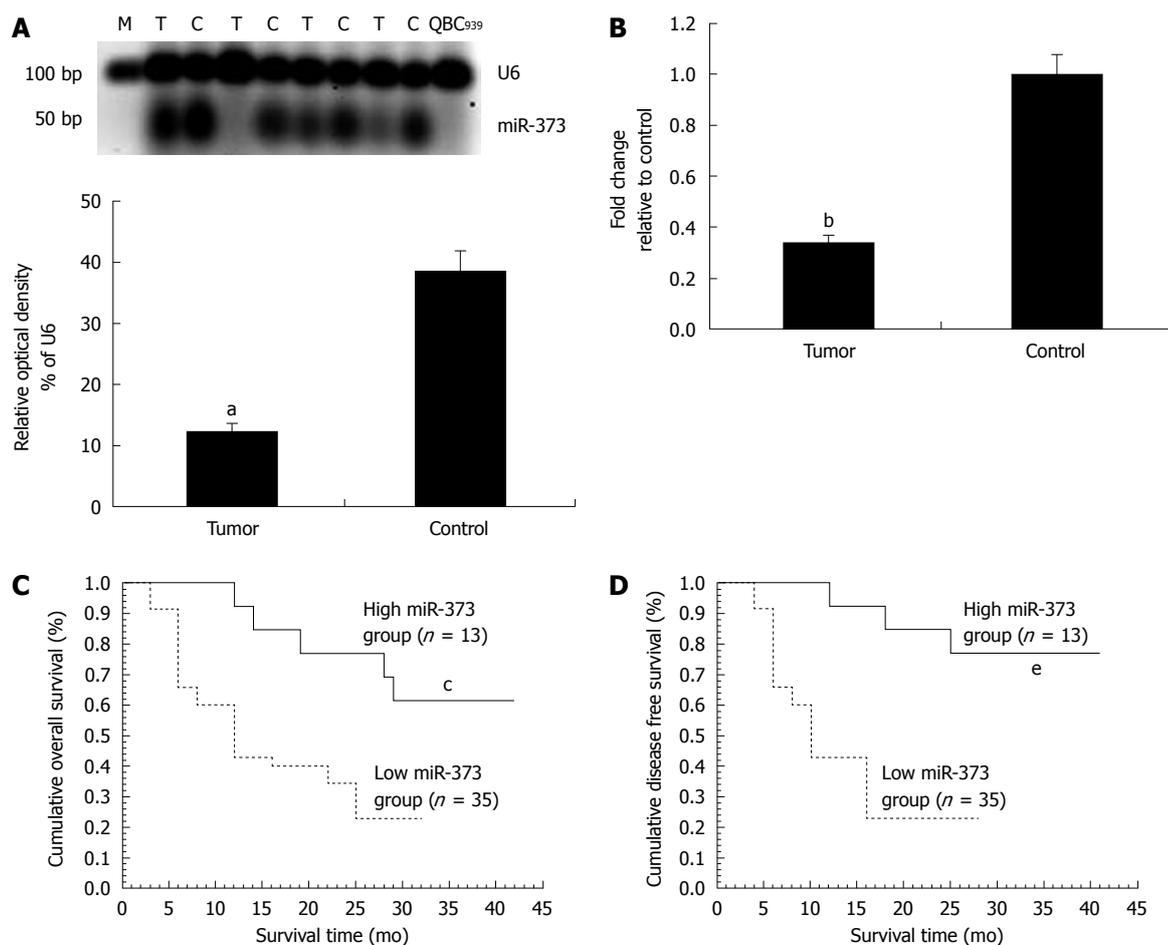

Figure 1 Expression of miR-373 and the association with clinicopathological factors in patients with hilar cholangiocarcinoma. A: Representative expression of miR-373 decreased in tumor and in QBC₉₃₉ detected by RT-PCR ($^{\circ}P < 0.05$ vs control); B: Taqman microRNA assay of miR-373 displayed 2.94-fold down-regulation in tumor group ($^{\circ}P < 0.01$ vs control); C: Relationship between miR-373 expression and overall survival in the patients with hilar cholangiocarcinoma. The median overall survival time was 16.3 mo and 29.7 mo in low- and high- miR-373 group, respectively ($^{\circ}P < 0.05$ vs high-group); D: Kaplan-Meier disease-free survival, the median disease-free survival time were 11.2 mo, 23.4 mo in low- and high- miR-373 group, respectively ($^{\circ}P < 0.05$ vs high-group).

(PMR above 90.00%), hypermethylation (PMR range from 42.00% to 89.99%), standard methylation (PMR range from 20.00% to 41.99%), and hypomethylation (PMR below 20.00%). Compared to its counterparts, miR-373 expression distinctly decreased in 88.5% (23/26) supermethylated samples ($P < 0.01$). There was a comparative reduction in seven hypermethylated samples ($P < 0.05$), and a dramatic increase was seen in 10 hypomethylated tumors and 43 control tissues ($P < 0.01$); no difference was detected in five standard methylated samples ($P > 0.05$). Interestingly, three supermethylated tumors were characterized by relatively high miR-373 expression (samples 14, 18, and 44). Despite these three extra tumors, promoter methylation demonstrated an inverse relationship with miR-373 expression in hilar cholangiocarcinoma (Figure 2D).

For further study on the contribution of promoter-associated CpG island methylation and inhibition of miR-373, pGL4-373-prom was constructed and methylated *in vitro* followed by transfection into HEK293 cells. As shown in Figure 3A, the relative luciferase activity in pGL4-u373-prom presented a higher level and decrease

significantly in pGL4-m373-prom ($P < 0.01$). This phenomenon was also proven by data showing reactivation of miR-373 with epigenetic treatment of QBC₉₃₉ cells. A 3.4-fold increase in miR-373 in cells treated with 5-Aza-2'-CdR and a 3.1-fold increase in cells treated with 5-Aza-2'-CdR and TSA were detected (Figure 3B). These results suggest that the promoter-associated CpG island acts as a cis-element of *miR-373* gene transcription, and its function can be abrogated by methylation in hilar cholangiocarcinomas and QBC₉₃₉ cells.

MBP 2 is up-regulated and enriched at the promoter-associated CpG island of miR-373

Among the MeCPs, Mecp2, MBD1, and MBD2 have been established to be involved in the methylation-dependent repression of transcription. Therefore, we explored protein expression using antibodies directed against Mecp2, MBD1, and MBD2. Compared to the control, a 2.9-fold increase in MBD2 expression was found in tumors while no difference in MBD1 and Mecp2 expression were detected (Figure 4A).

The presence of Mecp2, MBD1, and MBD2 in the

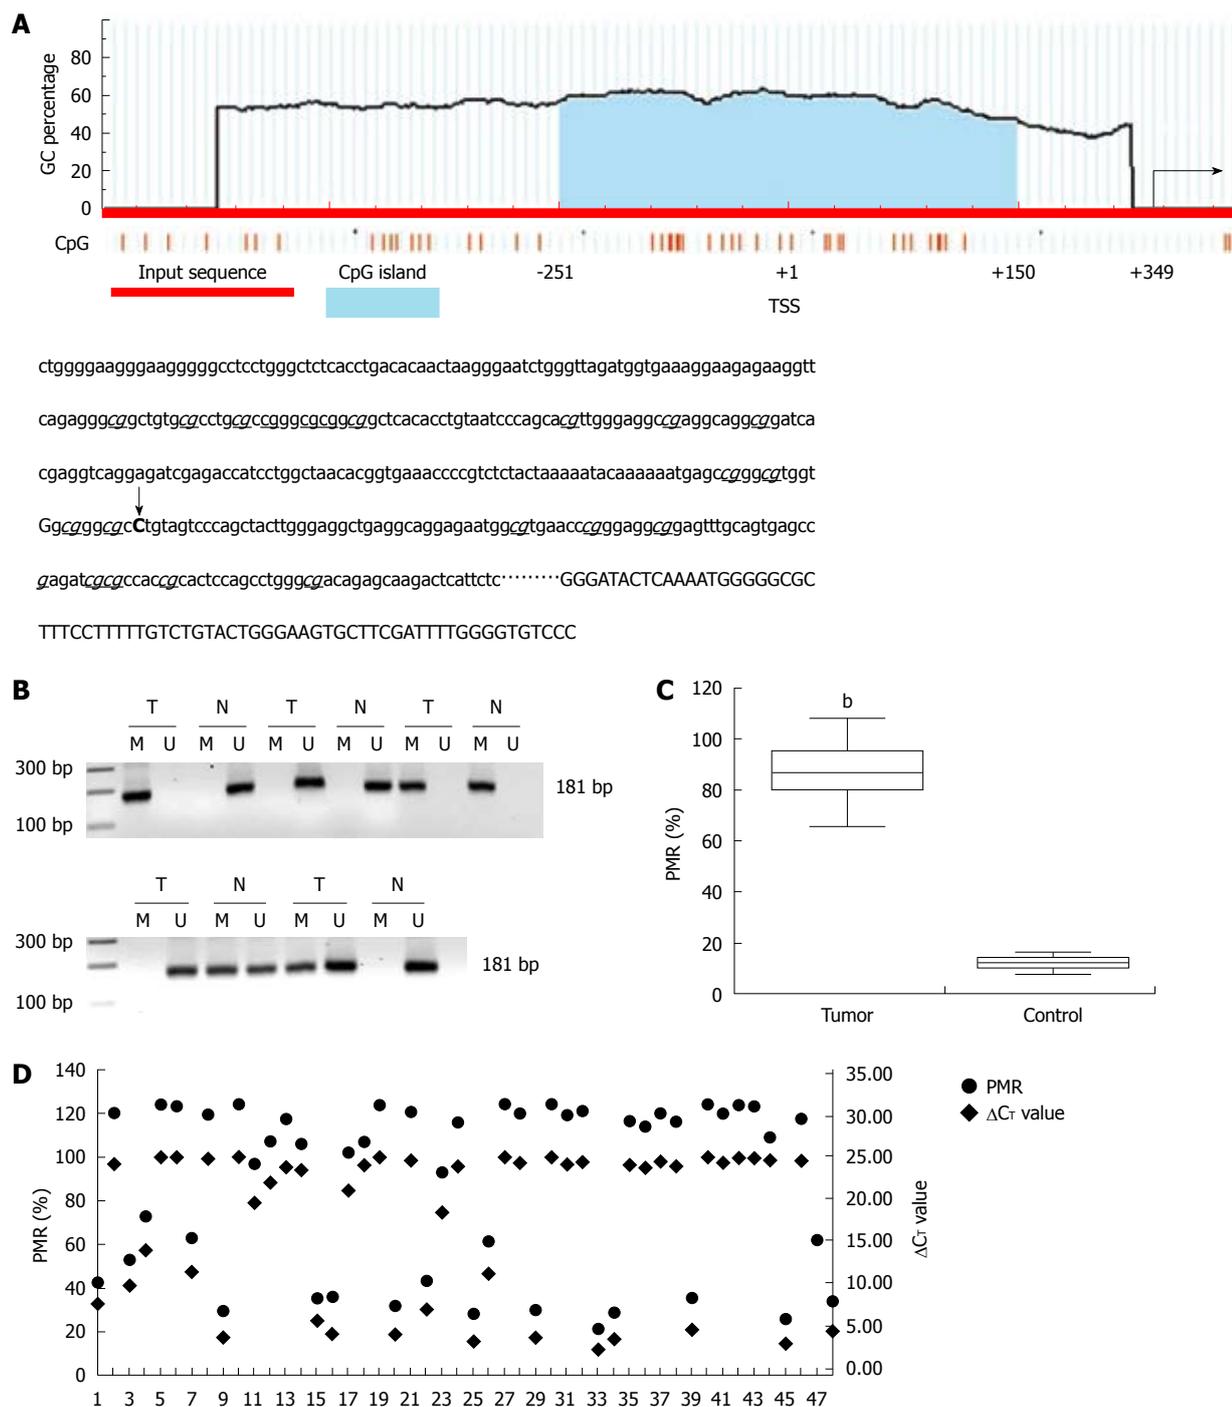

Figure 2 Methylation of miR-373 promoter-associated CpG island in hilar cholangiocarcinoma. A: Top panel, a schematic drawing of the putative CpG island in the 5'-flank region of *miR-373* gene; Bottom panel, sequence information of *miR-373* gene including partial 5'-flank region. The transcriptional start site (TSS) in boldface uppercase indicated by black arrow, 26 CpG dinucleotides are underlined and italic, pre-miR-373 sequences are capitalized; B: DNA methylation detected by methylation-specific polymerase chain reaction (MSP). Five representative cases were shown to indicate homozygous methylation (cases 1, 3), heterozygous methylation (cases 4, 5) and unmethylated (case 2), respectively. Lanes labeled M and U denote products amplified by primers recognizing methylated and unmethylated sequences; C: Percent of methylated reference (PMR) of miR-373 promoter-associated CpG island in tumor group is significant higher than control ($P < 0.01$ vs control); D: Relationship between CpG island methylation and miR-373 expression in hilar cholangiocarcinoma. A reverse correlation between PMR values and miR-373 expression could be observed (high ΔC_t value indicated low expression) excluding 3 extra samples displayed high PMR values and high mRNA expression (samples 14, 18 and 44).

region of the promoter-associated CpG island was assessed by the ChIP assay using ChIP-validated antibodies (Figure 4B). In hilar cholangiocarcinoma, the amount of CpG island fragment immunoprecipitated by MBD2 was greater than the input. ChIP-qPCR analysis showed

0.03-fold, 0.11-fold, and 0.79-fold for Mecn2, MBD1, and MBD2 compared to the endogenous control of RNA polymerase II enrichment of GAPDH, respectively ($P < 0.01$, Figure 4B, bottom panel). These findings indicate that the fraction of promoter-associated

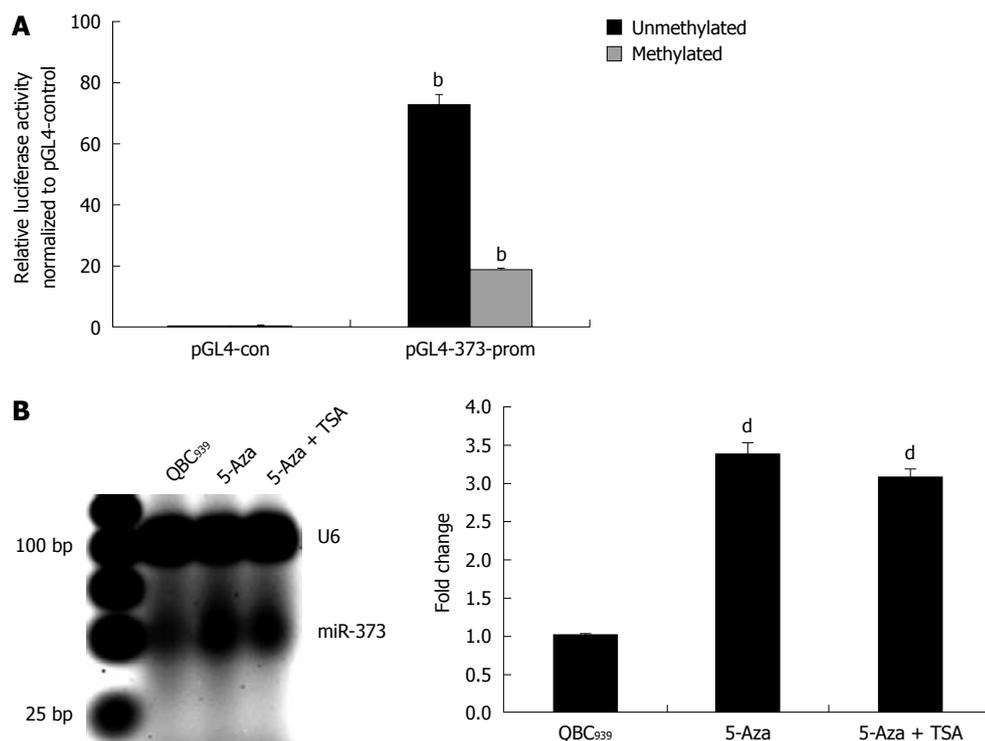

Figure 3 Methylation of CpG island regulates the expression of miR-373. A: Promoter luciferase reporter gene assay for miR-373. Prior CpG methylated resulted in dramatic decrease of luciferase activity of pGL4-m373-prom compared with pGL4-u373-prom ($^*P < 0.01$ vs control); B: miR-373 expression was reactivated by epigenetic reagents of 5'-Aza-2-CdR or combination with trichostatin A (TSA). $^{\#}P < 0.01$ vs untreated QBC₉₃₉.

CpG island is selectively immunoprecipitated by MBD2, but not by Mecp2 and MBD1. In addition, fold enrichment analysis showed a remarkable correlation between miR-373 promoter methylation and MBD2 enrichment in four groups with different frequencies of methylation ($P < 0.01$, Figure 4C).

Methylation-mediated suppression of miR-373 requires MBP 2 enrichment at promoter-associated CpG island

In QBC₉₃₉ cells and hilar cholangiocarcinoma, we evaluated whether inhibition of miR-373 was closely related to hypermethylation and enrichment of MBD2 at the promoter-associated CpG island. Specifically, to unravel whether the enrichment of MBD2 is critical for inactivation of miR-373, exogenous MBD2 expression was induced in stable cell lines of HEK-u373-prom or HEK-m373-prom. The ChIP assay was performed 72 h post-transfection, and fold change analysis showed a 6.2-fold enrichment of MBD2 in pGL4-m373-prom compared to wild-type HEK293 cells, while no change was found in the pGL4-u373-prom group (Figure 5A, $P < 0.01$).

Further knock-down studies in QBC₉₃₉ were performed to reduce endogenous MBD2 by a specific siRNA. A 4.3-fold increase in miR-373 expression was observed in knock-down cells compared to wild-type QBC₉₃₉ cells (Figure 5C). Sequential ChIP assay revealed that knock-down of MBD2 resulted in depletion of MBD2 enrichment at the CpG island (Figure 5B). Furthermore, knock-down of MBD2 was not compensated by the binding of MBD1 or Mecp2. In addition, in

MBD2 knock-down QBC₉₃₉ cells, 5-Aza-2-CdR and TSA treatments had an innocent effect on MBD2 enrichment (Figure 5D). These findings suggest that the enrichment of MBD2 is specific to the methylated region of miR-373 promoter-associated CpG island, MBD2 likely mediates CpG methylation-dependent inhibition of miR-373 in hilar cholangiocarcinomas.

miR-373 negatively regulates MBPs 2 expression by targeting the 3'UTR

One putative miR-373 binding site was predicted to have greater specificity to MBD2 3'UTR, ranging from dinucleotide 295 to 301 bp, as predicted by four algorithms (TargetScan, PicTar, miRanda, miRbase Target) (Figure 6A). To investigate whether the 3'UTR of MBD2 is a functional target of miR-373, wild-type MBD2-3'UTR vector was transfected into HEK293 cells with pre-miR-373, which led to a decrease of 55.8% reporter activity compared to the pre-miR-neg (Figure 6B, $P < 0.001$). After the conserved targeting regions for miR-373 recognition were mutated, relative luciferase activity of the reporter gene was also restored (Figure 6B). These observations suggest that the predicted complementary sequence in MBD 3'UTR is a functional element of miR-373.

On the contrary, enhanced expression of miR-373 by transfecting pre-miR-373 into QBC₉₃₉ cells resulted in a significant reduction of MBD2 protein (Figure 6C). Furthermore, reactivation of miR-373 expression in epigenetic-treated QBC₉₃₉ cells (Figure 3B) led to an inhibition

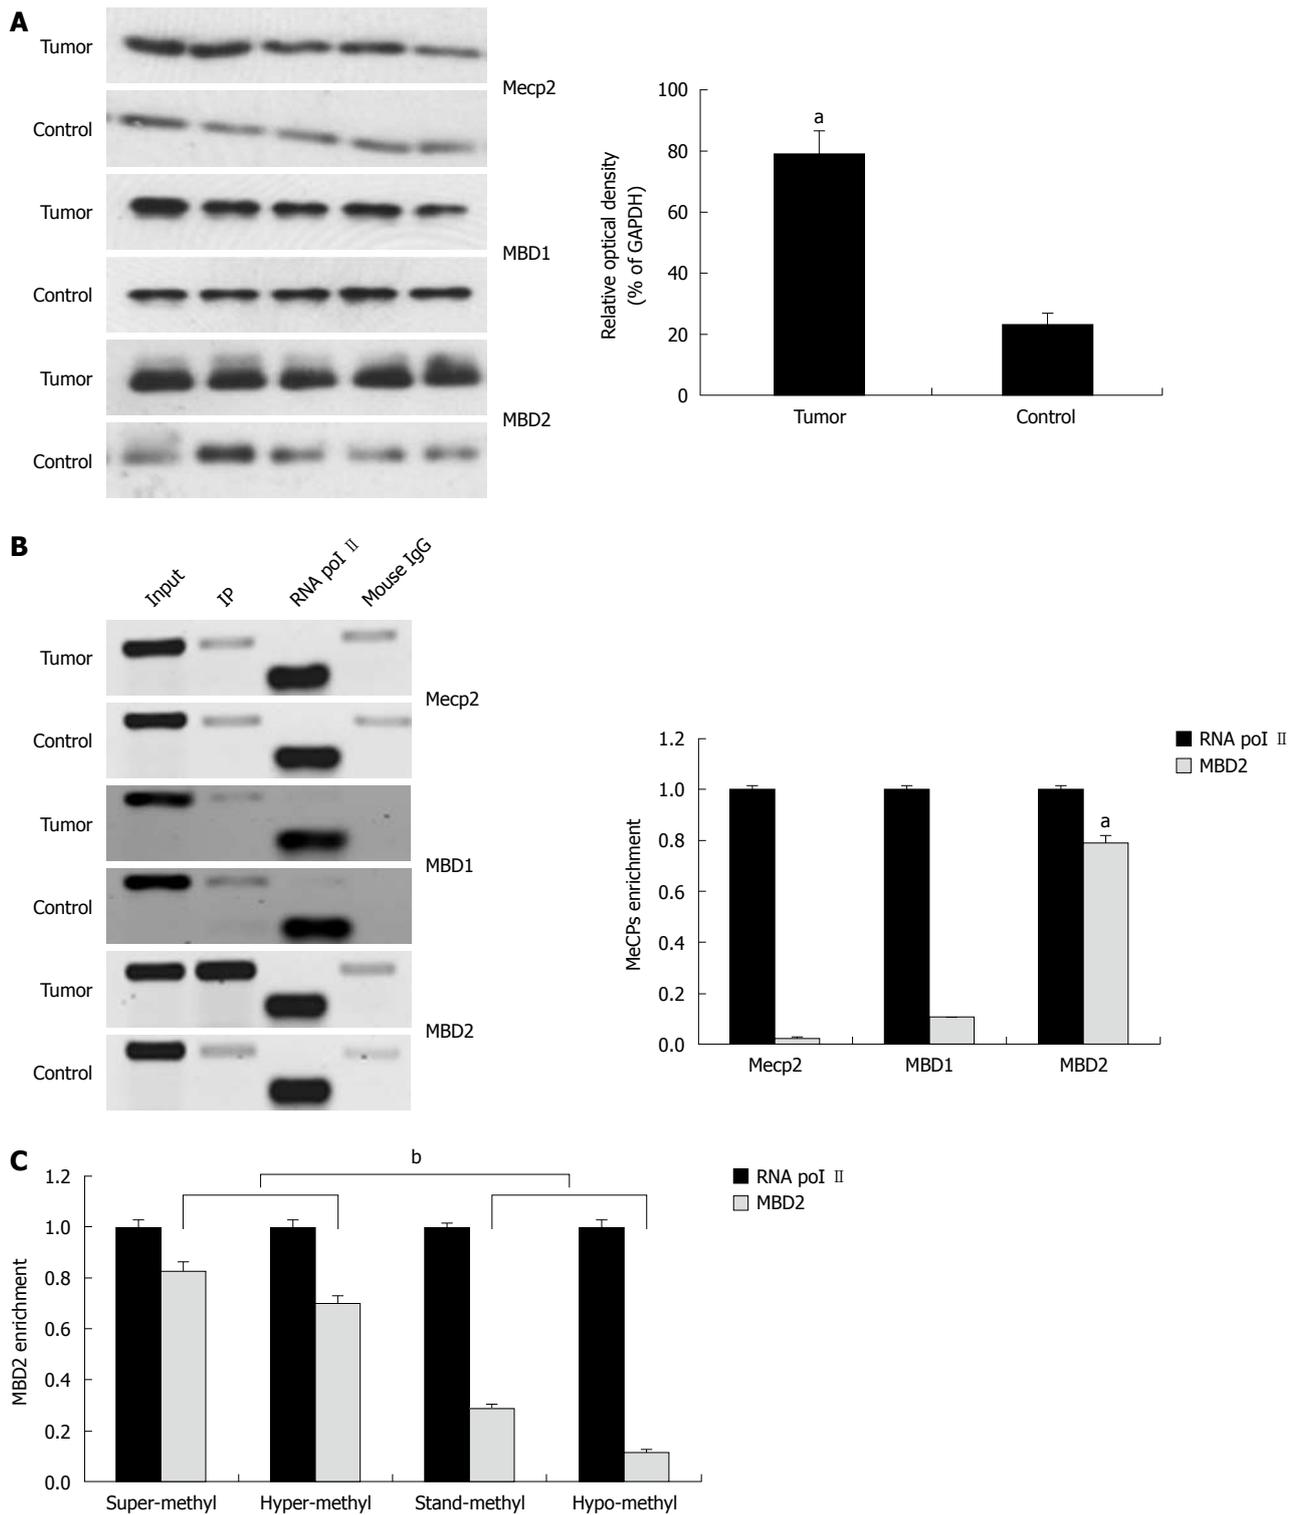

Figure 4 Methyl-CpG binding domain proteins expression and enrichment in fragment of promoter-associated CpG island. A: Expression methyl-CpG binding domain proteins (MBPs) in hilar cholangiocarcinoma. Compared to control, 2.9-fold increase of methyl-CpG-binding domain protein (MBD)2 was found while no difference of MBD1 and Mecp2 were detected; B: Chromatin immunoprecipitation (ChIP)-polymerase chain reaction analysis showed selective enrichment of MBD2 at region of CpG island; C: Correlation between MBD2 enrichment and different frequency of CpG island methylation. Remarkable difference was observed between super-/hyper-methylation and stand-/hypo-methylation group (^a*P* < 0.05, ^b*P* < 0.01 vs control). GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

of MBD2 protein (Figure 6D). Taken together, these findings suggest that MBD2 3'UTR carries a miR-373 regulatory site, and miR-373 can negatively regulate MBD2 through binding to the miRNA locus of MBD2 3' UTR.

DISCUSSION

In previous studies, miR-373 has displayed controversial characteristics in different cancers. In testicular germ cell tumors^[27], esophageal cancer^[28], and breast cancer^[29],

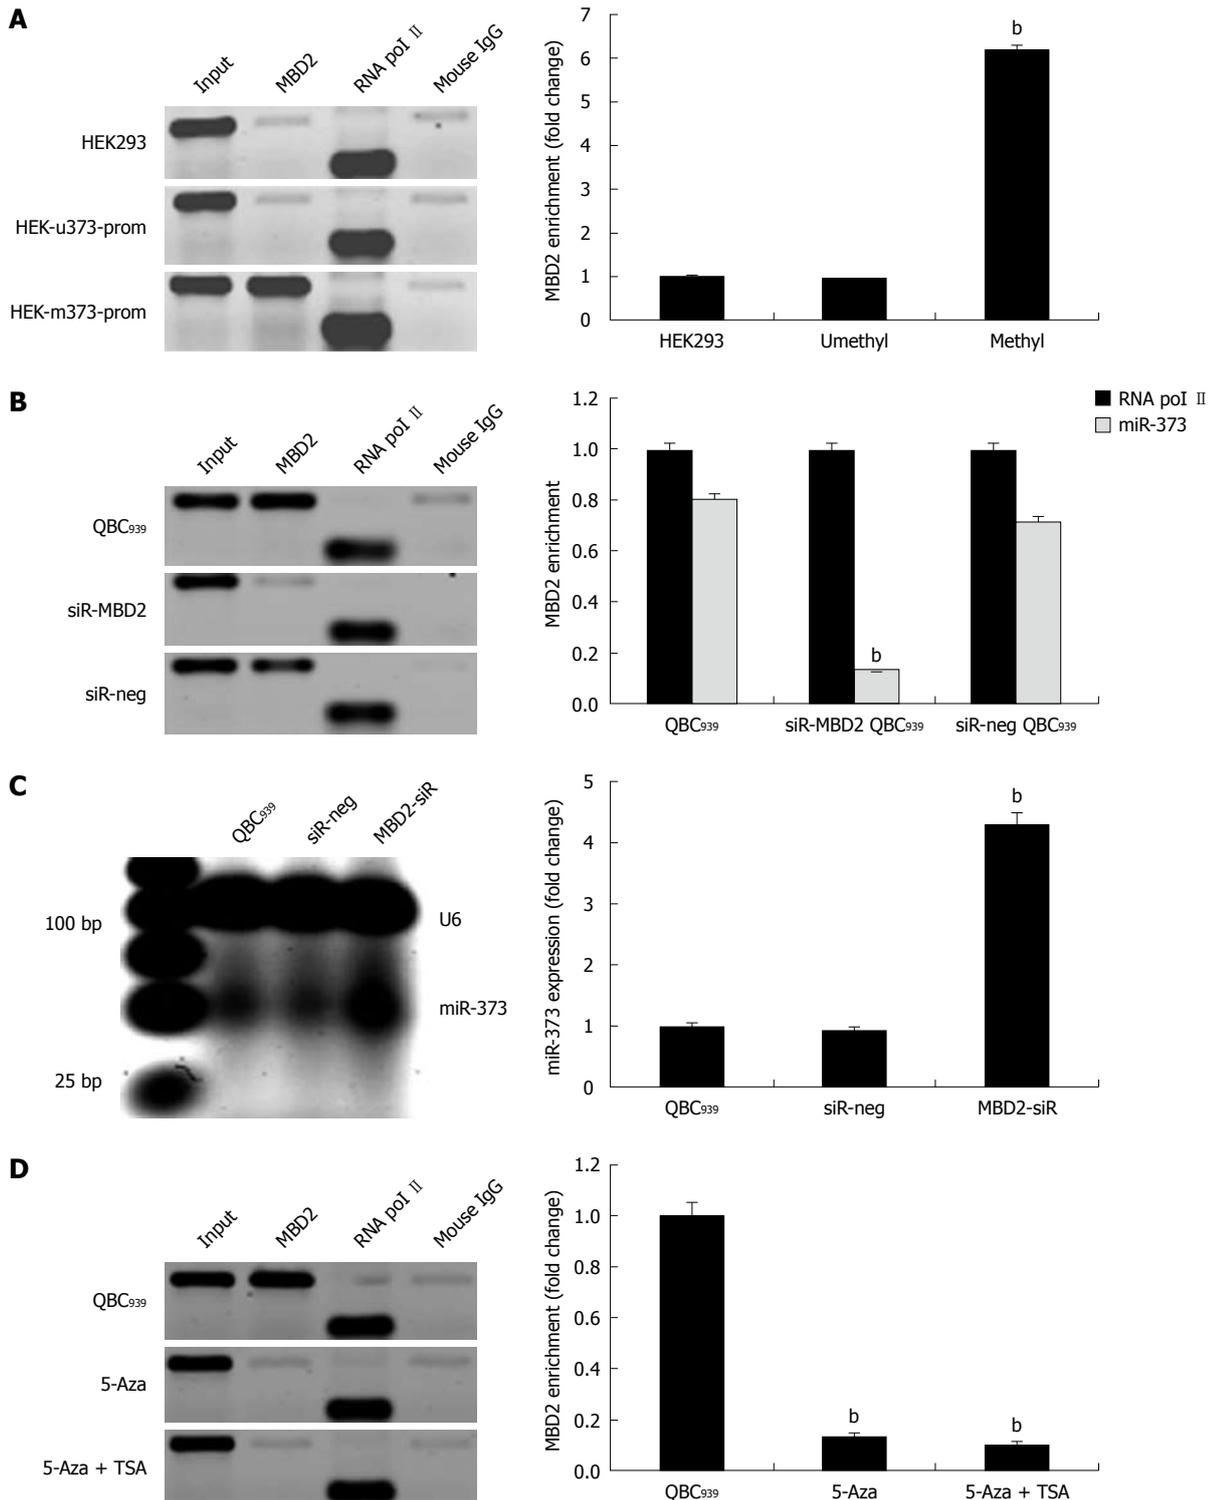

Figure 5 Enrichment of methyl-CpG-binding domain protein 2 at CpG island region is essential for methylation-mediated silencing of *miR-373* gene. A: Enrichment of methyl-CpG-binding domain protein (MBD)2 in fragment of CpG island in HEK-m373-prom stable cells showed 6.2-fold increase compared to control and no significant change was detected in HEK-u373-prom cells; B: MBD2 enrichment in MBD2-siRNA QBC₉₃₉ cells presented dramatically deduction compared to QBC₉₃₉ cells; C: Knock-down of MBD2 induced a increase of *miR-373* expression in QBC₉₃₉ cells; D: Epigenetic treatment of QBC₉₃₉ cell with 5-Aza-CdR or combination with trichostatin A (TSA) eliminated the recruitment MBD2 at the region of *miR-373* promoter-associated CpG island. ^b*P* < 0.01 vs background.

miR-373 behaves as a novel oncogene. Whereas in prostate cancer^[30] and malignant cholangiocytes, including the extrahepatic cholangiocarcinoma cell line^[31], *miR-373* shows characteristics of a tumor suppressor. Regardless of this divergence, it has been well established that

miR-373 participates in tumorigenesis, invasion, and metastasis by mediating gene expression.

In this study, we show that *miR-373* is dramatically down-regulated in hilar cholangiocarcinoma, and correlates closely with poor cell differentiation, advanced

miR-373 binding Mecp2 3'UTR

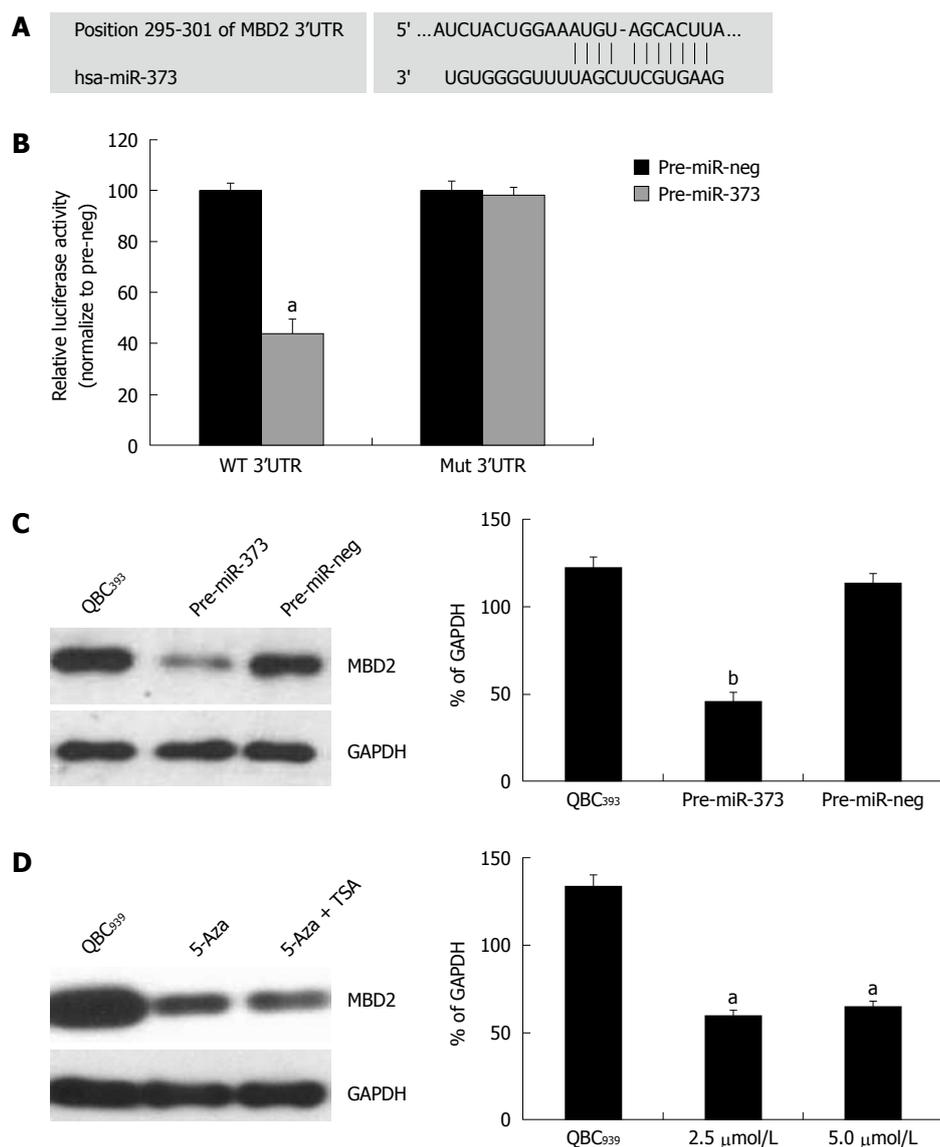

Figure 6 miR-373 negatively regulates methyl-CpG-binding domain protein expression through binding to three prime untranslated region. A: miRNA target prediction screened one computative miR-373 binding site at methyl-CpG-binding domain protein (MBD)2-three prime untranslated region (3'UTR); B: 3'UTR luciferase reporter assay showed a reduction of relative luciferase activity of wild-type MBD2 3'UTR by pre-miR-373 in HEK293 cells; C: Exogenous miR-373 down-regulates MBD2 protein in QBC₉₃₉; D: Epigenetic treatment of QBC₉₃₉ cells inhibits MBD2 protein following reactivation of miR-373 (Figure 3A). ^a*P* < 0.05, ^b*P* < 0.01 vs background. TSA: Trichostatin A; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

clinical stages, shorter overall survival, and disease-free survival. Our findings are in agreement with the last two reports. Although it is difficult to definitively explain these directly opposing results, the expression pattern of individual miRNAs with strict tissue- and clinical-feature-specificity^[32], and the different target genes involved in the unique regulation network of various cancers, could lead to these discrepancies.

Epigenetic dysregulation of miRNAs in human cancer constitutes an emerging mechanism implicated in the development of cancer^[33]. Great effort has been devoted to understanding the relevance of aberrant CpG methylation patterns, and their roles in gene transcription. The inverse correlation between miR-373 expression and hilar cholangiocarcinoma progression prompted us to study

the molecular mechanisms underlying *miR-373* gene inhibition. In the present study, miR-373 promoter-associated CpG island was found to be hypermethylated in tumor tissues and QBC₉₃₉ cells. Reciprocal assays were performed with demethylation of the CpG island by treatment of QBC₉₃₉ cells with 5-aza-CdR in the absence or presence of combination with TSA, which contributes to the reactivation of miR-373. In addition, pre-methylation of pGL4-373-prom *in vitro* inhibited luciferase activity. Together, the results presented here provide evidence that promoter-associated CpG island methylation is a major cause of *miR-373* gene suppression in hilar cholangiocarcinoma.

Promoter-associated CpG-methylation, along with MBPs and HDACs, has been identified as a major epi-

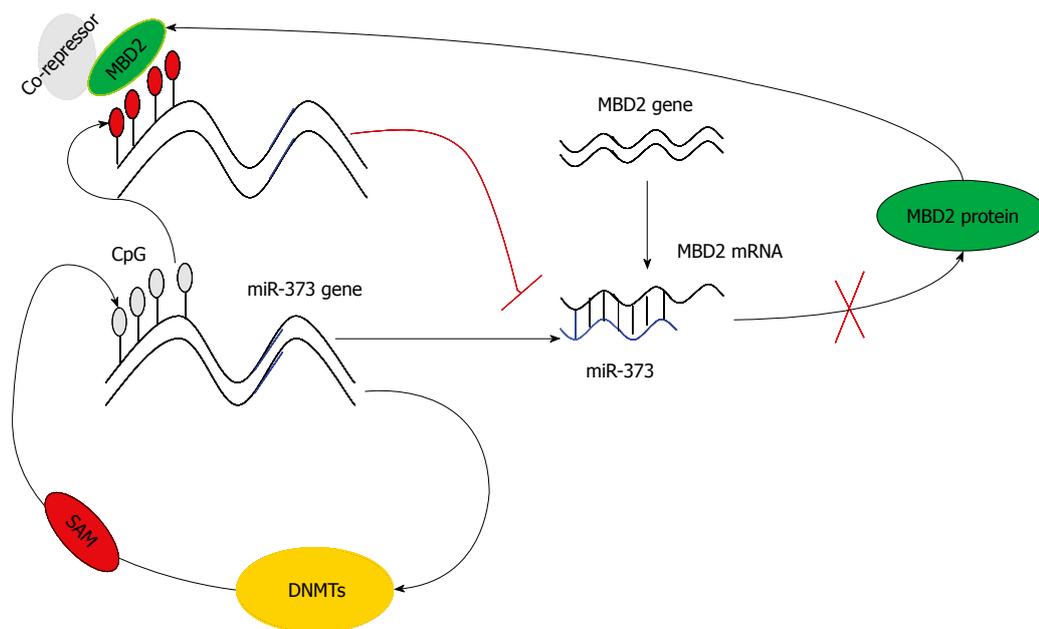

Figure 7 Dual regulation between miR-373 and methyl-CpG-binding domain protein 2. miR-373 is one direct transcriptional target and negative regulator to methyl-CpG-binding domain protein (MBD)2 through a feedback loop of CpG methylation. SAM: S-adenosylmethionine; DNMTs: DNA methyltransferases.

genetic event in the loss of gene expression during tumor progression^[34]. In this study, we further investigated the involvement of MBPs in methylation-mediated suppression of miR-373 in hilar cholangiocarcinoma. MBD2 is an exclusive MBP that is aberrantly expressed in hilar cholangiocarcinoma. ChIP assays showed that MBD2 selectively bound to methylated CpG sequences. Moreover, silencing conferred by DNA methylation and MBD2 enrichment in QBC₉₃₉ cells was reversed by treatment with 5-aza-CdR and TSA. These findings indicate that MBD2 plays an important role in recruiting transcription-repressive machinery to the methylated promoter, thereby suppressing transcriptional activation of miR-373. Confirming these findings, siRNA knock-down of MBD2 triggered a stimulation of miR-373 in QBC₉₃₉ cells. Taken together, these data suggest that MBD2 is an important factor in methylation-mediated inhibition of miR-373.

The reciprocal correlation of expression between miR-373 and MBD2 encouraged us to explore whether miR-373 is a negative regulator of MBD2. To this end, four algorithms were used to predict the alignment of miR-373 with MBD2 3'UTR. In consensus, the seed region of miR-373 matched nucleotides 295-301 of the MBD2 3'UTR, suggesting the ability of miR-373 to directly bind to MBD2 mRNA. However, not all miRNAs identified in this manner are likely to be functional since factors such as steric hindrance may render them inaccessible to the mRNA^[35]. Hence, functional validation experiments including transfection of miR-373 precursors showed that miR-373 can down-regulate the relative luciferase activity of MBD 3'UTR reporter vectors and MBD2 protein in QBC₉₃₉ cell lines. These findings indicate that miR-373 functionally regulates the expression of MBD2 by targeting the 3'UTR.

In this study, several interesting observations were made. First, the heterozygous methylation of miR-373, as indicated by both methylated and unmethylated bands in MSP, was detected in 12 cancers and five normal bile duct tissues. This is contrary to the 'all-or-none' manner of DNA methylation in regulating gene expression. Although the mechanism is unclear, there are several points to keep in mind: (1) *miR-373* gene exhibits allele-specific DNA methylation (ASM) which means that only one allele is methylated and the other one is unmethylated^[36]. ASM has been documented in a number of cancer cases except imprinted regions and X chromosomes; (2) samples contain normal and malignant cells although multiple efforts have been adapted to obtain purified tissues; and (3) miR-373 displays discrepant methylation in various differentiated cells. Secondly, in primary samples, three supermethylated tumors were characterized with relatively high miR-373 expression. The relevant mechanism underlying transcription that escapes methylation-mediated suppression is unknown, but whether MBPs bind effectively to the methylated CpG dinucleotides may determine the expression level.

Based on these findings, we conclude that due to the hypermethylation of the promoter-associated CpG island and enrichment of MBD2, the function of miR-373 is restrained rendering it unable to inhibit MBD2. As a result, the expression of MBD2 is predominantly enhanced, leading to a strong inhibitory effect on miR-373 (Figure 7). This dysregulation ultimately results in the promotion of tumorigenesis and the development of hilar cholangiocarcinoma. In conclusion, our study proves that miRNA-373 behaves as a direct transcriptional target and negative regulator of MBD2 through a feedback loop of CpG methylation in hilar cholangiocarcinoma.

COMMENTS

Background

Both DNA methylation and microRNAs (miRNAs) are epigenetic and play vital roles in tumorigenesis and development of human malignance. DNA methylation represses transcription by impeding recognition of transcriptional activators to DNA sequences or recruiting methyl-CpG binding domain proteins (MBPs) to modify chromatin compaction and control gene silencing. miRNAs regulate gene expression mainly by binding to the three prime untranslated region of target mRNAs, leading to mRNA degradation or translation inhibition. Many studies have reported that the expression of miRNAs gene is regulated by DNA methylation, and in addition, DNA methyltransferases and MBPs are regulated by miRNAs.

Research frontiers

Hilar cholangiocarcinoma displays highly aggressive malignancy. Many studies have reported miRNA expression and DNA methylation in hilar cholangiocarcinoma. In this study, the authors report evidence of the role of miR-373 in hilar cholangiocarcinoma. In particular, they show that miR-373 behaves as a direct transcriptional target and negative regulator of methyl-CpG-binding domain protein (MBD)2 through a feedback loop of CpG methylation in hilar cholangiocarcinoma.

Innovations and breakthroughs

It has been well established that miR-373 participates in tumorigenesis, invasion, and metastasis by mediating gene expression. In this study, the authors demonstrate that miR-373 is dramatically down-regulated in hilar cholangiocarcinoma, and closely correlates with poor cell differentiation, advanced clinical stage, shorter overall survival, and disease-free survival. The authors show that due to the hypermethylation of the promoter-associated CpG island and enrichment of MBD2, function of miR-373 is restrained, rendering it unable to inhibit MBD2. As a result, MBD2 expression is predominantly enhanced and has a strong inhibitory effect on miR-373. This dysregulation finally promotes the tumorigenesis and development of hilar cholangiocarcinoma.

Applications

This study provides the first evidence showing that miR-373 behaves as a direct transcriptional target and negative regulator of MBD2 through a feedback loop of CpG methylation in hilar cholangiocarcinoma. These results shed light on the mutual regulation between miRNA-373 and MBD2, which may eventually serve as useful biomarkers as well as therapeutic targets.

Peer review

This study demonstrates the role of miR-373 in cholangiocarcinoma. In particular, the authors showed that miR-373 acts through a feedback loop of CpG methylation. This study is well designed and performed, and is of great interest for its novelty and impact in the field.

Abstract

AIM: To establish if the juice of *Moro*, an anthocyanin-rich orange, may improve liver damage in mice with diet-induced obesity.

METHODS: Eight-week-old mice were fed a high-fat diet (HFD) and were administered water or *Moro* juice for 12 wk. Liver morphology, gene expression of lipid transcription factors, and metabolic enzymes were assessed.

RESULTS: Mice fed HFD displayed increased body weight, insulin resistance and dyslipidemia. *Moro* juice administration limited body weight gain, enhanced insulin sensitivity, and decreased serum triglycerides and total cholesterol. Mice fed HFD showed liver steatosis associated with ballooning. Dietary *Moro* juice markedly improved liver steatosis by inducing the expression of peroxisome proliferator-activated receptor- α and its target gene *acylCoA-oxidase*, a key enzyme of lipid oxidation. Consistently, *Moro* juice consumption suppressed the expression of liver X receptor- α and its target gene fatty acid synthase, and restored liver glycerol-3-phosphate acyltransferase 1 activity.

CONCLUSION: *Moro* juice counteracts liver steatogenesis in mice with diet-induced obesity and thus may represent a promising dietary option for the prevention of fatty liver.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is a chronic

metabolic disorder with significant impact on cardiovascular and liver-related mortality^[1,2]. NAFLD is closely associated with obesity, dyslipidemia, diabetes and the full spectrum of the metabolic syndrome^[3,4], with insulin resistance as a common pathophysiological determinant^[5]. Lifestyle, that is, dietary habits and physical activity, plays a pivot role in the pathogenesis of the metabolic syndrome^[6]. Likewise, dietary factors have been shown to exert a major role in the development of fatty liver^[7]. Recently, the consumption of foods and beverages containing fructose has been identified as a risk factor for NAFLD^[8]. Nonetheless, despite their fructose content, fruits are also rich in different polyphenolic compounds that exert several beneficial effects on health, mainly by modulating expression of key enzymes involved in glucose sensitivity and lipid homeostasis^[9].

Anthocyanins (ACNs) are water-soluble plant polyphenolic pigments that confer a typical blue, red or purple color, and are contained especially in berries, blood oranges and pigmented corn and potato^[10]. ACNs have been attributed several putative therapeutic roles, including beneficial effects on obesity and related metabolic complications^[11]. In this respect, Tsuda *et al.*^[12] firstly showed that ACN from purple corn prevented obesity, dyslipidemia and visceral fat inflammation in mice fed a high-fat diet (HFD). Recently, a further demonstration of the putative hepatoprotective properties of ACN has been provided by Liu *et al.*^[13], who observed that administration of protocatechuic acid, the major *in vivo* metabolite of the main ACN cyanidin-3-O- β -glucoside, reduced gene expression of lipogenic enzymes in the liver, thus leading to a decreased hepatic lipid accumulation. *In vitro* and *in vivo* experiments suggest that ACNs can modulate gene expression of several adipocytokines and regulate the pathways involved in lipogenesis and fat accumulation^[12,14]. ACNs are contained also in blood oranges, a variety of sweet orange (*Citrus sinensis*) with an intense red pigmentation^[15]. A recent study has demonstrated that blood orange consumption inhibits fat accumulation in mice^[16] and may represent a promising dietary tool for the treatment of obesity.

In the current study, we aimed at clarifying whether consumption of the juice of *Moro*, a blood orange cultivated in Sicily, Italy, improved liver steatosis in mice fed HFD; a physiological model of NAFLD and metabolic syndrome.

MATERIALS AND METHODS

Animals and treatments

All procedures fulfilled the Italian Guidelines for the Use and Care of Laboratory Animals. Eight-week-old male C57BL6/J mice were purchased from Charles River Laboratories (Calco, Italy). Animals were maintained in a temperature- and light-controlled facility for 12 wk. Diets were obtained by Harlan Teklad (Madison, WI, United States). The standard diet (SD) provided 3.3 kcal/g with 60% carbohydrates, 23% proteins and 17%

fat. The HFD provided 5.2 kcal/g with 60% fat, 20% proteins and 20% carbohydrates. Mice were distributed in three groups: group I included six mice fed SD and permitted *ad libitum* consumption of water (SD + water); group II comprised six mice fed HFD and permitted *ad libitum* consumption of water (HFD + water); group III comprised six mice fed HFD and permitted *ad libitum* consumption of *Moro* orange juice instead of water (HFD + *Moro*). *Moro* fruits were collected in the experimental farm of the Research Center for Citric Culture and Mediterranean Crops (Acireale, Italy). Fruits were immediately stored at 4 °C and squeezed a few days later; the juice obtained was pre-filtered and stored at -20 °C in aliquots of 0.5 L. Every 2 d, frozen juice aliquots were thawed, filtered and put in the bottle of each cage. Fruit juice analysis was performed as previously described^[16]. Food and beverage consumption was recorded twice weekly; body weight was recorded weekly. After sacrifice by CO₂ asphyxiation, blood and liver samples were obtained, processed and stored for further analysis.

Histopathology

Formalin-fixed paraffin-embedded liver sections were stained with haematoxylin-eosin and Masson's trichrome, using standard procedures. Liver injury was blindly evaluated according to the NAFLD activity score.

Biochemical analysis

Serum glucose, total cholesterol, triglycerides and alanine aminotransferase (ALT) were measured using Reflotron Plus system from Roche Diagnostic (Milan, Italy). Liver triglycerides content was measured using a serum/tissue triglyceride colorimetric kit (Biovision, Mountain View, CA, United States). Insulin tolerance test (ITT) was performed on 5-h starved mice, and glycemia was measured immediately before and 15, 30 and 60 min after intraperitoneal injection of 0.4 U/kg recombinant human insulin. The total amount of ACN in *Moro* juice was determined as previously described^[16]. Glycerol-3-phosphate acyltransferase 1 (GPAT1) activity was assayed as previously described^[17].

RNA extraction and real-time polymerase chain reaction

Total RNA was extracted by homogenizing snap frozen liver samples in TRIzol reagent (Invitrogen, Milan, Italy). Quantitative real-time polymerase chain reaction (PCR) was performed in 7900HT Fast Real-Time PCR System Applied Biosystems (Applied Biosystems, Foster City, CA, United States), using the EXPRESS SYBR GreenER™ qPCR SuperMix with Premixed ROX (Invitrogen).

Reactions were performed in a 20 μ L mixture containing cDNA, specific primers of each gene, and the SYBR GreenER™ qPCR SuperMix. The specific PCR products were detected by the fluorescence of SYBR Green, the double-stranded DNA binding dye. The relative mRNA expression level was calculated by the threshold cycle (Ct) value of each PCR product and normalized with that of glyceraldehyde-3-phosphate de-

hydrogenase by using comparative $2^{\Delta\Delta Ct}$ method. Primer sequences are shown in Table 1.

Statistical analysis

Statistical analysis was performed by GraphPad Prism software (San Diego, CA, United States). Data are the results of three independent experiments. All results were expressed as mean \pm SE. One-way analysis of variance with Bonferroni post-hoc analysis was used for parametric data. Kruskal-Wallis test was used for non-parametric data. *P* values < 0.05 were considered significant.

RESULTS

Moro juice improves dyslipidemia and enhances insulin sensitivity

Moro juice had an ACN content of 85 mg/L. Food intake was identical among the three experimental groups (SD + water, 3.1 ± 0.5 g/d *vs* HFD + water, 3.0 ± 0.8 g/d *vs* HFD + *Moro*, 3.1 ± 0.7 g/d). The amount of *Moro* juice intake (4.1 ± 0.75 mL/d) did not differ from the amount of water intake in the control groups (4.0 ± 1.2 mL/d). All mice had similar body weight at the start of the experiment, and after 12 wk, mice fed HFD + water had higher body weight compared with SD mice (Figure 1A). Strikingly, mice fed HFD + *Moro* had the same body weight gain as mice fed SD. This effect on body weight gain occurred despite the fact that mice fed HFD + *Moro* received a 10% higher energy intake, due to the sugar content of the juice, as compared to mice fed HFD + water (Figure 1A). Obese mice had increased serum total cholesterol, triglycerides and ALT as compared to the SD group (Figure 1B-D). *Moro* juice decreased serum total cholesterol and triglycerides, and reduced serum ALT to the levels of lean controls (Figure 1B-D). Furthermore, orange juice consumption significantly enhanced insulin sensitivity, as demonstrated by the area under curve derived from ITT, which was 8685 ± 516 in mice fed HFD + water and was reduced to 7225 ± 718 in the HFD + *Moro* group (Figure 2).

Moro juice induces liver peroxisome proliferator-activated receptor- α and inhibits liver lipogenesis

Liver sections of mice fed HFD + water showed moderate steatosis with a panacinar pattern (Figure 3B), mild lobular inflammation, and diffuse hepatocyte ballooning.

In the HFD + *Moro* group, steatosis was almost absent (Figure 3C). Consistently, lobular inflammation and ballooning degeneration was less pronounced throughout the hepatic parenchyma. Fibrosis, assessed by Masson's trichrome, was not found in any mice after 12 wk HFD (data not shown). Biochemical analysis confirmed that *Moro* juice induced a marked decrease of liver triglyceride content in mice fed HFD (Figure 3D).

HFD was associated with impaired expression of key transcription factors and metabolic enzymes involved in lipid homeostasis. In particular, we found a decrease in the gene expression of peroxisome proliferator-activated receptor (PPAR)- α (Figure 4A) and acyl-CoA oxidase (AOX) (Figure 4B) and a significant increase in the expression of liver X receptor (LXR)- α (Figure 4C), fatty acid synthase (FAS) (Figure 4D) and hydroxy methylglutaryl (HMG)-CoA reductase (Figure 4E). *Moro* juice markedly decreased the mRNA levels of LXR- α , FAS and HMG-CoA reductase but augmented the mRNA levels of PPAR- α and AOX (Figure 4A-E). Consistent with gene expression findings, GPAT1 activity was restored to the levels of lean animals by *Moro* juice consumption (Figure 4F).

DISCUSSION

In this study, we explored the effect of the consumption of the juice of *Moro*, an ACN-rich orange cultivated in the Mediterranean region, on liver steatosis in mice with diet-induced obesity. In previous experiments in mice fed SD, we observed that C57BL6 mice and other strains tolerated the substitution of drinking water with orange juice as the only drinking source, had similar food intake, and did not show any behavioral abnormality. Here, we demonstrated that *Moro* juice drinking reversed most of the metabolic abnormalities exhibited by obese mice, including fatty liver.

Our results are in agreement with previous experimental data suggesting that ACNs from different fruits and vegetables are able to exert beneficial effects on several metabolic aspects related to obesity^[11]. One common effect of ACN administration both in diet-induced and genetic models of obesity is the reduction of body weight and of visceral fat. In this respect, Kwon *et al*^[18] showed that ACN extracted from black soybean led to improvement in dyslipidemia and a decrease in visceral

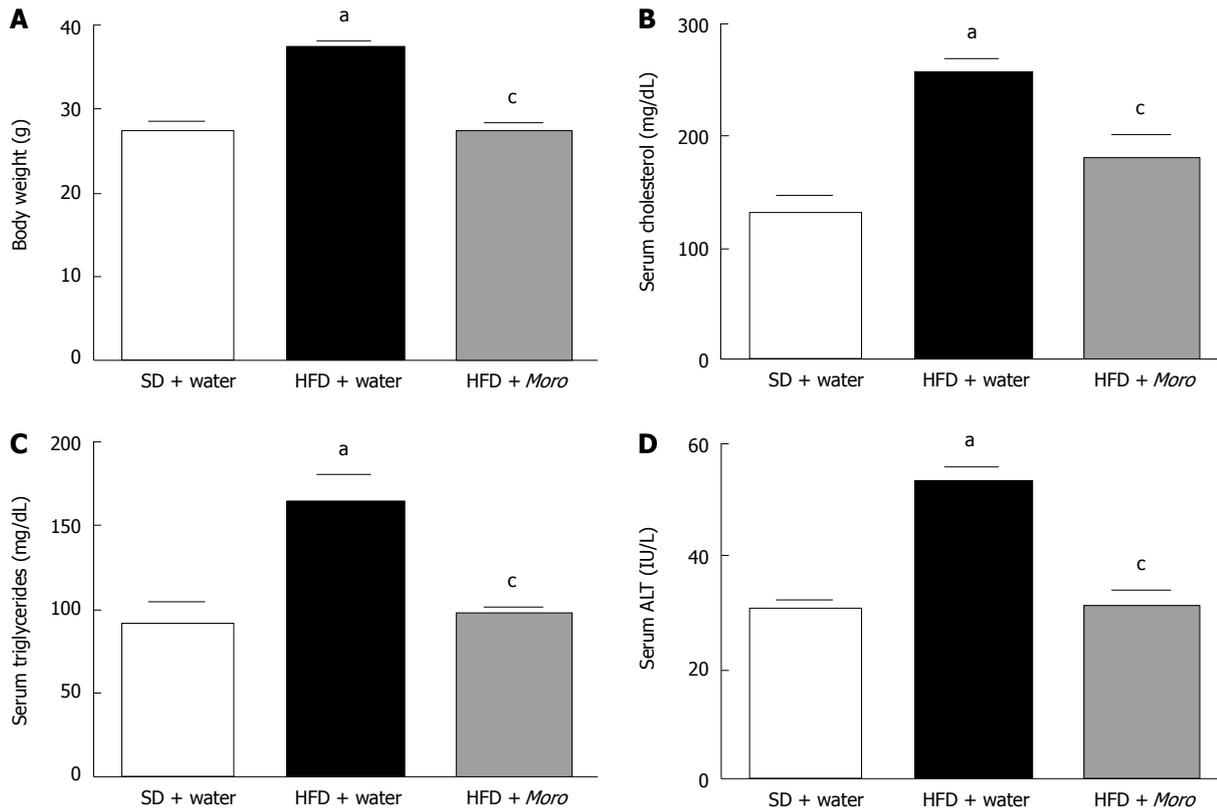

Figure 1 Effects of *Moro* juice on body weight and serum parameters. A: Body weight was markedly increased in mice fed high-fat diet (HFD) and was decreased to the levels of lean mice by *Moro* juice; B: Serum total cholesterol was significantly reduced in mice drinking *Moro*; C and D: Serum triglycerides (C) and alanine aminotransferase (ALT) (D) were restored to the levels of lean mice. ^a $P < 0.05$ vs standard diet (SD) + water; ^c $P < 0.05$ vs HFD + water.

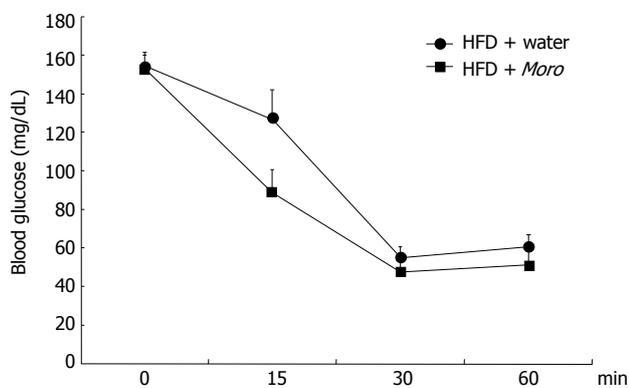

Figure 2 Effects of *Moro* juice on insulin sensitivity. Insulin tolerance test was performed with 0.4 U/kg recombinant human insulin in the two groups of mice fed high-fat diet (HFD); area under curve of blood glucose was 8685 ± 516 in mice fed HFD + water and was reduced to 7225 ± 718 in HFD + *Moro* ($P < 0.05$).

adiposity in rats fed HFD. Similarly, extracts from tart cherries ameliorate dyslipidemia and decrease liver fat content in genetically insulin-resistant rats^[19], as does cyanidin 3-glucoside in db/db mice^[20].

As regards the molecular events underlying the effects of *Moro* on liver lipid metabolism, we demonstrated that a major mechanism is induction of PPAR- α . PPAR- α is a key transcription factor promoting lipolysis and lipid oxidation in different tissues^[21]. Mice lacking PPAR- α develop obesity and liver steatosis^[22]; similarly,

the hepatic levels of PPAR- α are decreased in patients with NAFLD^[23], and pharmacological agonists are able to improve liver steatosis^[24]. Previous studies have suggested that PPAR- α induction is involved in the antisteatotic effect of extracts containing ACNs in different models of obesity^[19,20]. Along with the promotion of lipid oxidation, *Moro* juice consumption induced the inhibition of lipogenesis. In this respect, a major mechanism for the antisteatotic effect is the reversion of LXR- α expression. LXR- α is a nuclear hormone receptor that promotes lipogenesis^[25], which is increased in the liver of patients with NAFLD^[26]. LXR- α stimulates lipogenesis through upregulation of enzymes of *de novo* lipogenesis such as FAS^[25]. Suppression of LXR- α expression and activity exerts potent antisteatotic effects in the liver^[27]; some flavonoids have been shown to inhibit LXR- α ^[28].

Besides the effects on lipid homeostasis, the beneficial impact of *Moro* on insulin sensitivity is also noteworthy. Insulin resistance is the metabolic hallmark of patients with NAFLD^[29]. Studies using the hyperinsulinemic-euglycemic clamp coupled with infusion tracers have demonstrated that hepatic fat content is directly related to insulin resistance in the liver, skeletal muscle, and adipose tissue of obese subjects^[5]. In contrast, recent findings have demonstrated that liver triglyceride content, not visceral adipose tissue volume, predicts the impairment of insulin sensitivity and of very low density lipoprotein secretion in patients with obesity^[30,31].

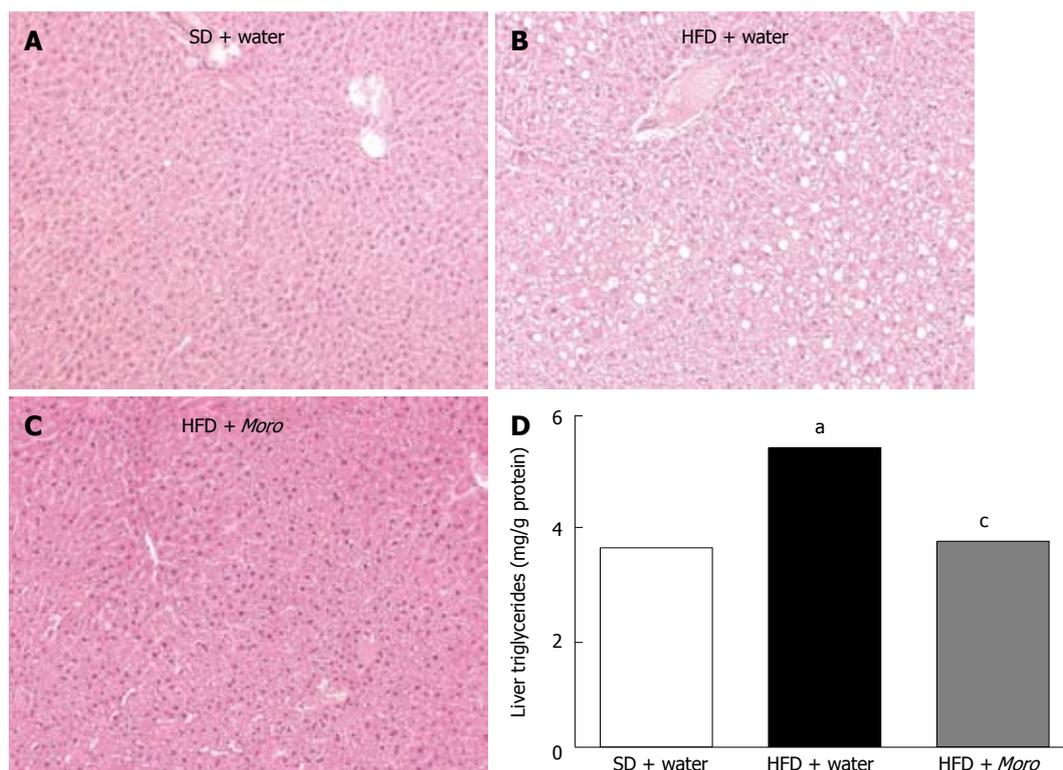

Figure 3 Effects of *Moro* juice on liver histology and liver triglycerides content. A: Hematoxylin-eosin-stained liver sections showing normal histology in lean mice; B: Moderate panacinar steatosis and hepatocyte ballooning in mice fed high-fat diet (HFD); C: Liver sections of mice fed HFD + *Moro* showing absence of steatosis and ballooning; D: Liver triglycerides content was significantly decreased in mice drinking orange juice. ^a*P* < 0.05 vs standard diet (SD) + water, ^c*P* < 0.05 vs HFD + water. Magnification: 10 ×.

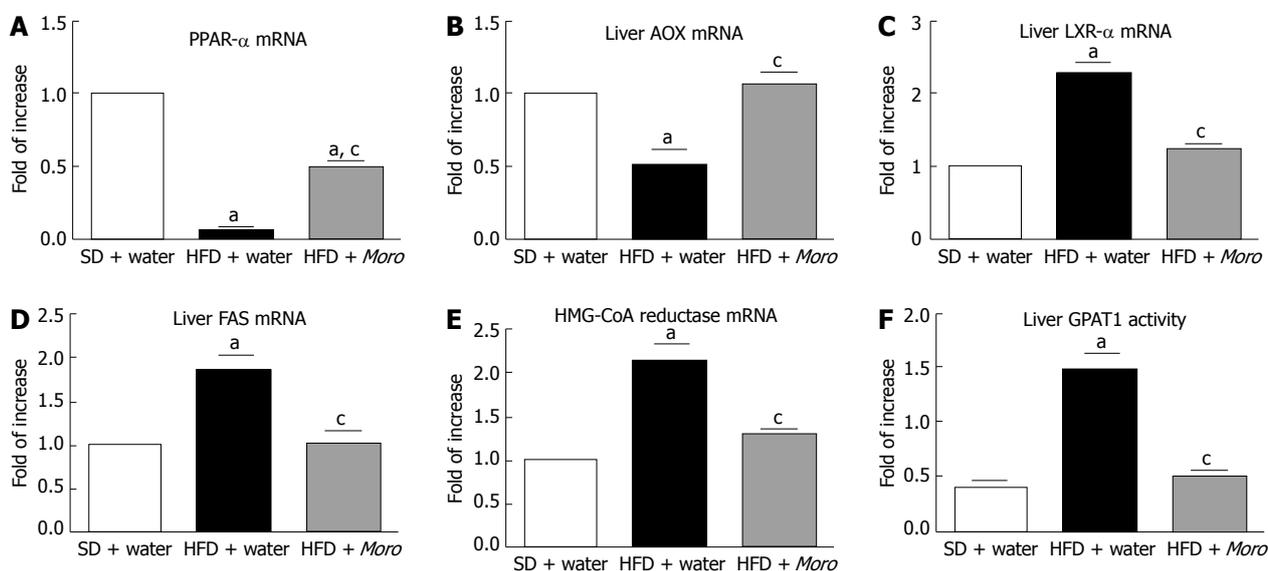

Figure 4 Effects of *Moro* juice on liver lipid homeostasis. Gene expression of (A) peroxisome proliferator-activated receptor (PPAR)-α and (B) acyl-CoA oxidase (AOX) was significantly increased in mice fed high-fat diet (HFD) + *Moro*, whereas gene expression of (C) liver X receptor (LXR)-α, (D) fatty acid synthase (FAS) and (E) hydroxy methylglutaryl (HMG)-CoA reductase was markedly reduced by orange juice; Liver glycerol-3-phosphate acyltransferase 1 (GPAT1) was increased in mice fed HFD + water and was restored to control levels in mice drinking *Moro* juice (F). ^a*P* < 0.05 vs standard diet (SD) + water, ^c*P* < 0.05 vs HFD + water.

Although mice drinking *Moro* juice remained hyperglycemic, probably because of the sugar content, the ITT unequivocally revealed that *Moro* juice exerted insulin-sensitizing activity. An insulin-sensitizing effect has been

demonstrated for ACN-rich extracts from bilberry in genetically obese mice^[32], and for dietary blueberry in mice fed HFD^[33].

In conclusion, in this study, we demonstrated that the

juice of *Moro* exerts metabolic hepatoprotective effects due to changes in the expression of several enzymes involved in lipid homeostasis. Thus, the dietary administration of this food may be effective in preventing liver steatosis, and may be considered as a nutritional approach for the prevention of NAFLD. Clinical trials are now warranted.

COMMENTS

Background

Nonalcoholic fatty liver disease (NAFLD) is a chronic metabolic disorder with significant impact on cardiovascular and liver-related mortality. Lifestyle, that is, dietary habits and physical activity, plays a pivot role in the pathogenesis of NAFLD.

Research frontiers

Anthocyanins (ACNs) are water-soluble plant polyphenolic pigments that confer a typical blue, red or purple color, and are contained especially in berries, blood oranges, and pigmented corn and potato. ACNs have been attributed several putative therapeutic roles, including beneficial effects on obesity and related metabolic complications. Diet enriched with ACNs may provide a useful tool to counteract liver steatogenesis.

Innovations and breakthroughs

ACNs are contained in blood oranges, a variety of sweet orange (*Citrus sinensis*) with an intense red pigmentation. A recent study has demonstrated that blood orange consumption inhibits fat accumulation in mice. Furthermore, the administration of protocatechuic acid, the major *in vivo* metabolite of ACN, reduces the activity of lipogenic enzymes in the liver, thus leading to decreased hepatic lipid accumulation. The data in this article demonstrated for the first time that *Moro* juice counteracted liver steatogenesis in mice with diet-induced obesity, through modulation of enzymes involved in lipogenesis and lipid oxidation. Thus, *Moro* juice consumption may represent a promising dietary option for prevention of fatty liver.

Terminology

ACNs are water-soluble pigments that belong to the family of flavonoids. They are contained in berries, blood oranges, and pigmented corn and potato. They are able to modulate lipid and glucose metabolic pathways in humans.

Peer review

It is interesting to readers and may be effective dietary supplements for NAFLD. The manuscript described an interesting finding about the protective effect of this orange juice on the development of fatty liver induced by a high-fat diet in mice.

Abstract

AIM: To study the short-term outcome of patients treated with laparoscopic right colectomy and how intracorporeal anastomosis has improved the outcome.

METHODS: We retrospectively examined all patients affected by colorectal cancer who underwent a laparoscopic right colectomy between January 2006 and December 2010 in our department. Our evaluation criteria were: diagnosis of colorectal carcinoma at presurgical biopsy, elective surgery, and the same surgeon. We excluded: emergency surgery, conversions from laparotomic colectomy, and other surgeons. The endpoints we examined were: surgical time, number of lymph nodes removed, length of stay (removal of nasogastric tube, bowel movements, gas evacuation, solid and liquid feeding, hospitalization), and major complications. Seventy-two patients were divided into two groups: intracorporeal anastomosis (39 patients)

and extracorporeal anastomosis (33 patients).

RESULTS: Significant differences were observed between intracorporeal vs extracorporeal anastomosis, respectively, for surgical times (186.8 min vs 184.1 min, $P < 0.001$), time to resumption of gas evacuation (3 d vs 3.5 d, $P < 0.001$), days until resumption of bowel movements (3.8 d vs 4.9 d, $P < 0.001$), days until resumption of liquid diet (3.5 d vs 4.5 d, $P < 0.001$), days until resuming a solid diet (4.6 d vs 5.7 d, $P < 0.001$), and total hospitalization duration (7.4 d vs 8.5 d, $P < 0.001$). In the intracorporeal group, on average, 19 positive lymph nodes were removed; in the extracorporeal group, on average, 14 were removed ($P < 0.001$). Thus, intracorporeal anastomosis for right laparoscopic colectomy improved patient outcome by providing faster recovery of nutrition, faster recovery of intestinal function, and shorter hospitalization than extracorporeal anastomosis.

CONCLUSION: Short-term outcomes favor intracorporeal anastomosis, confirming that a less traumatic surgical approach improves patient outcome.

INTRODUCTION

Over the last decades, colorectal laparoscopic surgery has outachieved traditional surgery for safety and oncological radicality. Some studies such as COST^[1], CLAS-ICC^[2], Barcelona^[3], and COLOR^[4] have shown short-term postoperative advantages without compromising long-term oncological results. For right colectomy, laparoscopic surgery was established later because of technical difficulties related to anatomic and vascular variability^[5]. The re-establishment of intestinal transit with ileocolic anastomosis can be performed with two techniques: extracorporeal anastomosis and intracorporeal anastomosis. In extracorporeal anastomosis, also called “laparoscopic-assisted colectomy”, stitching (manual or mechanical) and vascular resection are done extracorporeally by externalizing the bowel through a cutaneous mini-incision. On the other hand, the other type of anastomosis is totally intracorporeal, and the stitching is often performed mechanically. A case-control study showed that laparoscopic right colectomy performed with intracorporeal anastomosis is considered one of the most difficult surgeries after transverse resection, rectum resection, and recanalization after Hartmann’s resection. However, the ligation of ileocolic vessels and the medial-to-lateral dissection of the right mesocolon intracorporeally are more oncologically safe in terms of the number of lymph nodes removed and cancer management. Nevertheless, extracorporeal anastomosis is the most popular as the literature shows, although it has some limitations in terms of the number of accesses and complications after bowel externalization^[6-11].

We evaluated the short-term outcome of patients with colorectal cancer who underwent a laparoscopic right colectomy, and we showed that intracorporeal anastomosis improved patient outcome (shorter hospitalization, fewer postoperative complications, and better oncological radicality). Finally, we considered the influence of the “learning curve” on these surgical techniques.

MATERIALS AND METHODS

We retrospectively examined all patients with colorectal cancer who underwent a laparoscopic right colectomy between January 2006 and December 2010 in our department. Our evaluation criteria were elective surgery and the same surgeon as the first operator. We excluded patients undergoing emergency surgery, conversions from laparotomic colectomy, and other surgeons as the first operator. Patients were divided into two groups: the first included those who underwent a right colectomy with intracorporeal anastomosis, and the second included those who underwent a right colectomy with extracorporeal anastomosis. Patient data included age, gender, body mass index (BMI), American Society of Anesthesiology (ASA) class, and surgical history. We also obtained other data concerning the operation including the surgical time, preoperative diagnosis, and number of lymph nodes removed. We noted parameters of post-

Table 1 Homogeneous groups

surgery hospitalization including removal of nasogastric tube, resumption of bowel movements, resumption of gas evacuation, time to consumption of solid and liquid feeding. We also considered major complications in terms of post-surgery time and hospitalization.

We obtained data from medical records, surgical cards, and databases. We used JMP software 7a Version [SAS Institute Inc. (1989-2007), Cary, NC, United States] for electronic data processing. Descriptive variables were expressed as mean, standard deviation, mode, median, number of events, patients, and percentage. According to the different features of these variables, we used the χ^2 test, *F* test, and Student’s *t* test as appropriate, and considered *P* < 0.05 to indicate statistical significance.

RESULTS

In this study, 72 patients were divided into two groups: intracorporeal anastomosis (*n* = 39) and extracorporeal anastomosis (*n* = 33). There were no significant differences in age, gender, BMI (Table 1), or ASA class between the two groups (*P* = 0.8645 for ASA).

Twenty patients in the intracorporeal group had a positive abdominal surgical history (51.3%), whereas 21 patients in the extracorporeal group had such a history (63.6%; *P* = 0.8433, Table 2). There were also no significant differences in the diagnosis from the pre-surgery biopsy (Figure 1).

In the intracorporeal group, we performed additional surgical procedures in seven patients during surgery, i.e., one nefrectomy, five colecistectomies, and one intraoperative coloscopy, whereas in the extracorporeal group, we performed two colecistectomies, one intraoperative coloscopy, and one polypectomy.

In the intracorporeal group, we removed an average of 19 lymph nodes (range: 7-36), whereas in the extracorporeal group we removed an average of 14 lymph nodes (range: 2-29, *P* < 0.0001).

The average surgical time was 186.8 min (range: 105-280 min) in the intracorporeal group and 184.1 min in the extracorporeal group (range: 115-285 min, *P* = 0.6549).

Gas evacuation was shorter in the intracorporeal

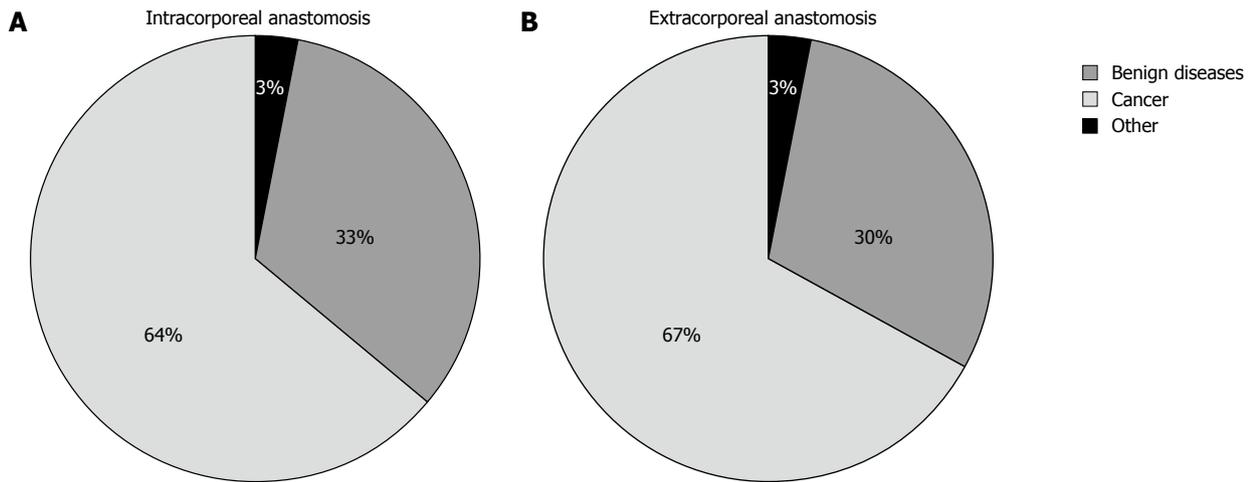

Figure 1 Intracorporeal anastomosis and extracorporeal anastomosis were no significant differences in the diagnosis from the pre-surgery biopsy. A: Intracorporeal anastomosis; B: Extracorporeal anastomosis.

group than in the extracorporeal group (3 ± 1.05 d vs 3.5 ± 1.1 d, range: 1-6 d, $P < 0.0001$). Bowel movements occurred earlier in the intracorporeal group (3.8 ± 1.4 d, range: 1-7 d vs 4.9 ± 1.5 d, range: 2-8 d, $P < 0.0001$). In addition, the NGT was removed sooner in the intracorporeal group than in the extracorporeal group (1.8 d and 3 d, respectively, $P < 0.0001$).

Resumption of a liquid diet occurred an average of (3.5 ± 2.2 d, range: 2-12 d, $P < 0.0001$) after intracorporeal anastomosis and (4.5 ± 1.7 d, range: 2-10 d, $P < 0.0001$) after extracorporeal anastomosis. Resumption of a solid diet occurred (4.6 ± 2.1 d, range 2-12 d) and after intracorporeal and extracorporeal anastomosis, respectively (5.7 ± 1.7 d, range: 3-11 d, $P < 0.0001$).

Total hospitalization time was significantly less after intracorporeal anastomosis (average of 7.4 ± 3.2 d, range: 4-19 d) than after extracorporeal anastomosis (average of 8.5 ± 3.9 d, range: 5-25 d, $P < 0.0001$; Table 3).

Major complications occurred in 10.2% of patients undergoing intracorporeal anastomosis, i.e., three patients: one with severe anemia, one with anastomotic dehiscence, and one with enterocutaneous fistula. In the extracorporeal group, 12.1% of patients had major complications, i.e., five patients: two with severe anemia, one with occlusion, one with anastomotic dehiscence, and one with enterocutaneous fistula.

NS: Not significant.

DISCUSSION

Our study shows that intracorporeal anastomosis for right laparoscopic colectomy improved patient outcome compared with patients who underwent extracorporeal anastomosis. With intracorporeal anastomosis, we found faster recovery of nutrition, faster recovery of intestinal function, and shorter hospitalization. However, there was no difference in average surgery time between the two groups.

According to the inclusion and exclusion criteria, we obtained two homogeneous and comparable groups without significant differences in age, gender, BMI (Tables 1 and 4), ASA class, or abdominal surgical history (Table 2). In laparoscopic right colectomy with extracorporeal anastomosis (laparoscopic-assisted colectomy), the bowel is externalized through a lateral mini-incision. With this approach, bowel mobilization and ligation of vessels is usually laparoscopic, whereas resection of the specimen and creation of the anastomosis is extracorporeal. On the other hand, in laparoscopic right colectomy with intracorporeal anastomosis (totally laparoscopic

BMI: Body mass index.

colectomy), bowel mobilization, ligation of vessels, resection of the specimen, and creation of the anastomosis are totally intracorporeal.

In our experience, right colectomy with intracorporeal anastomosis has been standardized step by step: first, ileocolic vessels are isolated, secured between clips, and divided near their origin. Then, the right mesocolon is dissected medial-to-lateral, and the small bowel mesentery is divided to reach the edge of the terminal ileum. Then, the specimen is resected with an Endo-GIA stapler. The end the Endo-GIA stapler is deployed through the bowel openings to form a side-to-side anastomosis. The last step is specimen extraction and wound closure. We did not standardize the right colectomy with extracorporeal anastomosis; in 36.4% of cases, the ligation of vessels was performed after partial bowel mobilization, whereas in 63.6% of cases, it was the first step of the surgical procedure. Finally, the anastomosis was realized manually, lateral-to-lateral, in a double layer.

Both techniques are oncologically safe; according to the latest Union for International Cancer Control Tumor Node Metastasis classification, removal of at least 12 lymph nodes is fundamental to guarantee sufficient oncological radicality^[12]. To achieve this goal, the arterial vessels must be ligated at the origin from the superior mesenteric artery. When vascular ligation is extracorporeal, it is very difficult to obtain an adequate number of lymph nodes^[13]. Bergamaschi *et al*^[14] showed that extracorporeal vascular oncologic ligation is very difficult through a small cutaneous incision, and the bowel undergoes a hard traction with this technique. Hellan *et al*^[15] emphasized that the limitations of extracorporeal vascular ligation include poor exposure of the ileocolic pedicle through the small incision. Difficult exposure of the base of the mesentery could compromise the oncological result. That is why some surgeons propose the technique of

intracorporeal high-vessel ligation combined with extracorporeal anastomosis^[16-19].

Regarding oncological radicality, we found significant differences in the number of lymph nodes removed. We removed an average of 19 lymph nodes from the intracorporeal group and 14 lymph nodes from the extracorporeal group. In particular, in the first group we removed more than 15 lymph nodes in 60% of patients, 12 to 15 lymph nodes in 18.2% of patients, and fewer than 12 lymph nodes in 21% of patients. In the extracorporeal group, we removed more than 15 lymph nodes in 46.7% of patients, 12 to 15 lymph nodes in 6.6% of patients, and fewer than 12 lymph nodes in 46.7% of patients (Table 4). Thus, our experience shows that there is an important difference in the number of positive lymph nodes removed in the intracorporeal group, and also on the percentage of patients in which more than 12 lymph nodes were removed ($P < 0.0001$). The explanation for this difference is the missed ligation of vessels before the mobilization of the right colon. We believe that is very difficult to obtain an adequate number of lymph nodes when vessel division is not the first step in laparoscopic right colectomy.

In the literature, some authors have reported no differences in safety, whereas others noted that the only advantage was a smaller incision^[20,21]. On the other hand, other studies affirmed the safety of intracorporeal anastomosis, with the same complication rate as for extracorporeal anastomosis^[22,23].

Because intracorporeal anastomosis is considered more difficult, only a few surgeons have used this kind of technique; however less mobilization is required, and less tension is applied to the bowel and mesentery because the bowel does not need to reach the anterior abdominal wall for externalization. Furthermore, the excessive tension on the mesentery during the mobilization is associated with an increased risk of mesenteric or portal vein thrombosis^[24].

Concerning surgical times, we did not find a significant difference in surgical time between the two groups.

Patients in the intracorporeal group had a shorter hospitalization duration. In some cases, the hospitalization duration was longer possibly because of age (43.2% of patients in the intracorporeal group and 33.4% in the extracorporeal group were over 80 years old). Our results showed a significantly shorter average hospitalization stay in the intracorporeal group (Table 4). These data agree with a recent Spanish study^[25], although this difference was not significant ($P = 0.5424$) because hospitalization duration is influenced by many patient factors. On the other hand, we found that 71.4% of patients in the intracorporeal group went home within 7 d, and 54.7% of patients in the extracorporeal group went home within this period ($P = 0.0001$, Figure 2).

Concerning the recovery of intestinal function, our results found significantly shorter average times for resumption of gas evacuation after 3 d in the intracorporeal group compared to after 3.8 d in the extracorporeal

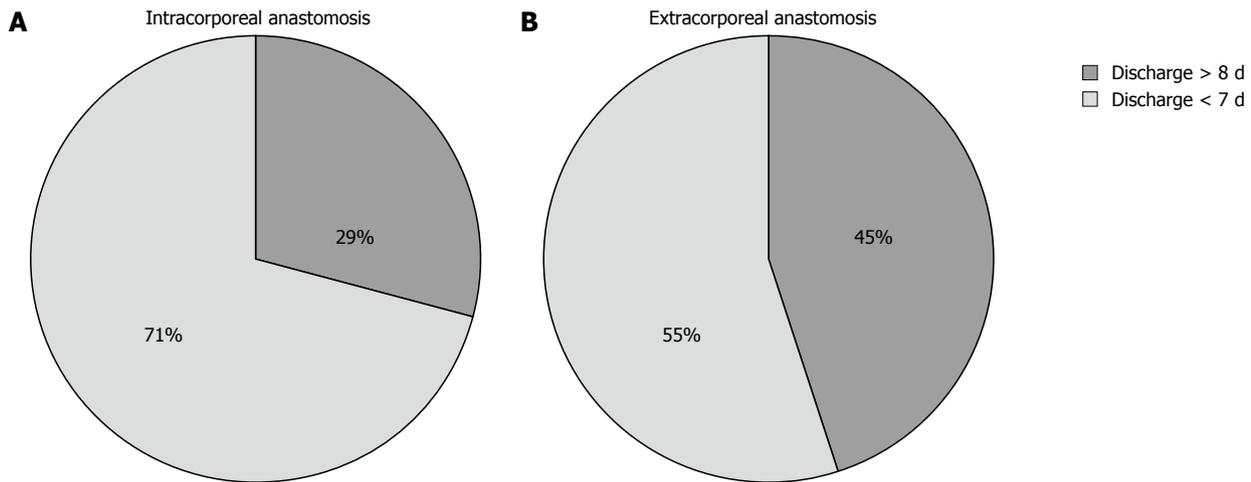

Figure 2 Patients in the intracorporeal group and extracorporeal group went home within 7 d. A: Intracorporeal group; B: Extracorporeal group.

group. Bowel movements occurred after an average of 4.9 d in the intracorporeal group. In the intracorporeal group, the nasogastric tube was removed after 1.8 d, whereas it was removed after 3 d in the extracorporeal group. This difference can be explained by an increased percentage of paralytic ileum in the second group, which is due to the traction of the right colon and terminal ileum through the mini-incision on the pancreas and duodenum^[26]. This approach allowed a more rapid recovery of liquid and solid nutrition consumption.

We analyzed major complications, which included severe anemia, occlusion, anastomotic dehiscence, and enterocutaneous fistulae. There were no significant differences between the two groups.

In conclusion, our study clearly shows that laparoscopic right colectomy with intracorporeal anastomosis improves patient outcome. We found that intracorporeal anastomosis resulted in faster recovery of nutrition consumption, faster recovery of intestinal function, and shorter hospitalization duration. The higher number of lymph nodes removed seems to be related to vascular division as the first surgical step as a rule. This confirms that a mini-invasive approach improves patient outcome.

COMMENTS

Background

A lot of studies have demonstrated the benefits of laparoscopic right colectomy, proving the short-term outcome of patients. The aim of this study is to show how intracorporeal anastomosis in laparoscopic right colectomy has further improved patient outcome.

Research frontiers

In the area of mini-invasive surgery, intracorporeal anastomosis, confirm that a less traumatic surgical approach improves patient outcome.

Innovations and breakthroughs

Based on a large series, this study describes the outcome of patients treated with laparoscopic right colectomy and is a reference for comparison in future studies.

Applications

The study results show how laparoscopic right colectomy with intracorporeal anastomosis improves patients outcome. This study suggests that all patients treated with intracorporeal anastomosis have faster recovery of nutrition consumption,

faster recovery of intestinal function, and shorter hospitalization duration.

Peer review

This paper demonstrated the outcomes of patients treated with laparoscopic right colectomy with intracorporeal anastomosis.

Abstract

AIM: To establish an animal model with human hepatocyte-repopulated liver for the study of liver cancer metastasis.

METHODS: Cell transplantation into mouse livers was conducted using alpha-fetoprotein (AFP)-producing hu-

man gastric cancer cells (h-GCCs) and h-hepatocytes as donor cells in a transgenic mouse line expressing urokinase-type plasminogen activator (uPA) driven by the albumin enhancer/promoter crossed with a severe combined immunodeficient (SCID) mouse line (uPA/SCID mice). Host mice were divided into two groups (A and B). Group A mice were transplanted with h-GCCs alone, and group B mice were transplanted with h-GCCs and h-hepatocytes together. The replacement index (RI), which is the ratio of transplanted h-GCCs and h-hepatocytes that occupy the examined area of a histological section, was estimated by measuring h-AFP and h-albumin concentrations in sera, respectively, as well as by immunohistochemical analyses of h-AFP and human cytokeratin 18 in histological sections.

RESULTS: The h-GCCs successfully engrafted, repopulated, and colonized the livers of mice in group A (RI = 22.0% ± 2.6%). These mice had moderately differentiated adenocarcinomatous lesions with disrupted glandular structures, which is a characteristics feature of gastric cancers. The serum h-AFP level reached 211.0 ± 142.2 g/mL (range, 7.1-324.2 g/mL). In group B mice, the h-GCCs and h-hepatocytes independently engrafted, repopulated the host liver, and developed colonies (RI = 12.0% ± 6.8% and 66.0% ± 12.3%, respectively). h-GCC colonies also showed typical adenocarcinomatous glandular structures around the h-hepatocyte-colonies. These mice survived for the full 56 day-study and did not exhibit any metastasis of h-GCCs in the extrahepatic regions during the observational period. The mice with an h-hepatocyte-repopulated liver possessed metastasized h-GCCs and therefore could be a useful humanized liver animal model for studying liver cancer metastasis *in vivo*.

CONCLUSION: A novel animal model of human liver cancer metastasis was established using the uPA/SCID mouse line. This model could be useful for *in vivo* testing of anti-cancer drugs and for studying the mechanisms of human liver cancer metastasis.

INTRODUCTION

Tumor metastasis, which is defined by a process in which tumor cells originating from an organ invade another anatomically distant organ, is the leading cause of cancer-related mortality^[1,2]. One of the major target organs for cancer metastasis is the liver^[1-3], and therefore there is increasing need for animal models that accurately mimic the pathophysiological situations in human liver and are suitable for investigating the mechanisms of hepatic cancer metastasis. In fact, several studies have attempted to transplant metastatic h-tumor cells into the livers of the immuno-compromized mice, such as athymic nude mice^[4], which cannot generate T cells, severe combined immunodeficient (SCID) mice that lack mature B and T cells^[5-7], and NOD/SCID/ c^{null} (NOG) mice^[8,9], which are deficient in T, B, and natural killer cells, and have impaired dendritic cells. In these animal models, the transplanted h-tumor cells invade the hepatic parenchyma, which is composed of mouse hepatocytes that are phylogenetically distant from h-hepatocytes and are known to exhibit biological and pathological features that are different from the human counterpart.

Heckel *et al*^[10] established transgenic mice expressing urokinase type plasminogen activator (uPA) under the control of the albumin (Alb) enhancer/promoter and found that the m-hepatocytes were constitutively damaged due to constant exposure to the expressed uPA. In another study, a mouse line possessing a humanized liver (chimeric mouse) was generated by transplanting healthy and normal h-hepatocytes into the liver of the immuno- and liver-compromized mouse, which was created by mating the uPA-Tg mouse with the SCID mouse (uPA/SCID mouse)^[10,11].

We previously developed chimeric mice where the liver was stably and reproducibly replaced with h-hepatocytes and found that the occupancy ratio or replacement index (RI) in the parenchyma was quite high (> 90%) in best cases^[12]. Human hepatocytes in the chimeric m-liver have been intensively and extensively characterized based on normal hepatic phenotypes, such as expres-

sion profiles of cytochrome P450, the major xenobiotic-metabolizing enzymes, drug-metabolizing capacities, and hepatitis virus infectivity^[11,13-15]. Based on these studies, which indicate that a chimeric m-liver can appropriately recapitulate the characteristics of h-liver, we hypothesized that the chimeric mouse as an animal model can be used to investigate the underlying mechanisms of tumor metastasis into the liver where the parenchyma is largely composed of normal and healthy h-hepatocytes.

In the present study, we established a chimeric mouse as a novel experimental model that sufficiently mimics the pathophysiological micro-environment in h-liver for studying liver cancer metastasis.

MATERIALS AND METHODS

This study was approved by the Ethics Committee of the National Hospital Organization, Nagasaki Medical Center, the Hiroshima Prefectural Institute of Industrial Science and Technology Ethics Board, and the Phoenix-Bio Ethics Board. This study was conducted in accordance with their guidelines.

Animals

The uPA/SCID mice were generated and used as transplant hosts once they reached an age of 24-32 d old as previously described^[14,15]. The mice were maintained in the laboratory in a specific pathogen-free environment in accordance with the guidelines of the Hiroshima Prefectural Institute of Industrial Science and Technology Ethics Board as well as the PhoenixBio Ethics Board.

Cancer cells

Human gastric cancer cells (h-GCCs) were purchased from the Japanese Collection of Research Biosources (Osaka, Japan) and used as liver metastatic cancer cells. These cells are adenocarcinoma cells derived from human gastric cancer cells that produce alpha-fetoprotein (AFP) and have a high affinity for liver tissue^[16-18]. The cells were maintained in Dulbecco's modified Eagle's medium (Sigma Chemical Co., St. Louis, MO, United States) containing 10% fetal bovine serum (Sigma Chemical Co., St. Louis, MO, United States) in an atmosphere of 95% air and 5% CO₂ at 37 °C.

Cell transplantation into the uPA/SCID

Human GCCs were suspended at a concentration of 1×10^7 cells/mL and placed on ice until transplantation. Cryopreserved h-hepatocytes derived from a 6-year-old African female were purchased from BD Biosciences (San Jose, CA, United States), thawed in a 37 °C water bath, rapidly diluted with culture medium at 4 °C, and washed twice to remove the cryopreservation solution. The cell viability was assessed by a trypan blue exclusion test. The uPA/SCID mice were anesthetized with ether and then were intrasplenically injected with the h-hepatocytes as previously described^[12]. Blood samples, 5 μ L each, were periodically collected from the host tail-vein for

Table 1 Serum concentrations of human albumin and human alpha-fetoprotein in host mice at 56 d post-transplantation

Experimental groups	Transplanted cells	No. of animals	Serum concentration	
			h-Alb (mg/mL)	h-AFP (mg/mL)
A	h-GCCs	4	UD	7.1-324.2 (211.0 ± 142.2)
B	h-GCCs and h-hepatocytes	6	0.03-9.1 (3.1 ± 3.5)	0.3-126.1 (54.3 ± 60.7)

The numerals represent the range of the concentrations and those in the parentheses indicate the mean ± SD. h-GCCs: Human gastric cancer cells; h-Alb: Human albumin; h-AFP: Human alpha-fetoprotein; h-hepatocytes: Human hepatocytes; UD: Undetectable.

determining concentrations of human albumin (h-Alb) and human AFP (h-AFP) using an h-Alb enzyme-linked immunosorbent assay quantification kit (Bethyl Laboratories Inc., Montgomery, TX) and an h-AFP enzyme immunoassay test kit (Hope Laboratories, Belmont, CA, United States), respectively.

Histological and immunohistochemical evaluation of the m-liver

Liver tissue specimens were removed from the transplanted mice, paraffin-embedded, sectioned at a 4 μm thickness, and stained with hematoxylin and eosin (H and E). Human hepatocyte-colonies were identified by staining the sections with mouse monoclonal antibodies against human-specific cytokeratin 18 (h-CK18) (DAKO, Glostrup Denmark). Human GCCs in the m-liver were identified by h-AFP staining with a polyclonal Ab (Novocastra Laboratories Ltd, United Kingdom). The sections were treated with a biotinylated, goat anti-rabbit IgG for h-CK18 and rabbit anti-m-IgG (DAKO, Glostrup Denmark) for h-AFP. All of the tissue specimens or cells were counterstained with H and E.

Determination of h-hepatocytes and h-GCCs repopulation of the uPA/SCID m-liver

Serial liver sections were double immunostained for h-CK18 and h-AFP to identify h-hepatocytes/h-GCCs and h-GCCs, respectively. The extent of repopulation of h-hepatocytes and h-GCCs in the chimeric mouse liver was determined as the RI, which is the occupational ratio of the transplanted cells in the examined area of histological sections, as previously described^[12]. The RI of h-hepatocytes (RI_{h-hepatocytes}) in the uPA/SCID m-liver was determined using h-CK18 as a maker to histologically identify h-hepatocytes. When appropriate, the RI for h-GCCs (RI_{h-GCCs}) was referred to as the metastatic index (MI_{h-GCCs}) in this study. Human hepatocytes and h-GCCs were identified on histological sections as the h-CK18-positive (h-CK18⁺) and h-AFP-negative (h-AFP⁻) cells and the h-CK18⁺ and h-AFP⁺ cells, respectively. The RI_{h-hepatocytes} and MI_{h-GCC} of the m-livers were calculated as the ratio of the “h-CK18⁺/h-AFP⁻” and “h-CK18⁺/h-AFP⁺” areas to the entire examined area of the sections, respectively.

Experimental groups

The uPA/SCID mice were divided into two groups (A and B groups). Four uPA/SCID mice in group A were each injected with 1×10^6 h-GCCs. Six mice in group B were co-transplanted with 7.5×10^5 h-hepatocytes and h-GCCs each. The blood h-Alb and h-AFP concentrations were periodically monitored after cell transplantation. The mice were euthanized at the termination of the experiments and their livers, spleens, and lungs were microscopically examined to identify any metastasis of h-GCCs.

RESULTS

Group A experiment

Human GCCs were transplanted into the livers of uPA/SCID mice and euthanized 56 d after transplantation. Human GCC colonies were macroscopically distinguishable from the host m-liver cells as brown colored regions (Figure 1A). Histological examinations showed that these areas contained h-GCC colonies and host m-liver cells composed of m-parenchymal and m-nonparenchymal cells (Figure 1B). The whitish or pale regions observed in Figure 1A were composed of only m-liver cells. The specimens were also stained for h-AFP to define h-GCCs (Figure 1C and D). Human GCCs formed colonies with well-developed glandular structures, which is a characteristic feature of gastric cancer. The serum concentrations of h-AFP increased to 211.0 ± 142.2 g/mL (range 7.1-324.2 g/mL, Table 1), which reflected the repopulation of h-GCCs in the liver, since serum h-AFP was undetectable in uPA/SCID mice without transplantation of h-GCCs (data; not shown). The MI of h-GCCs (MI_{h-GCC}) was $22.0\% \pm 2.6\%$ at the termination of the experiment 56 d post-transplantation.

Group B experiment

Both h-hepatocytes and h-GCCs were simultaneously transplanted into six uPA/SCID mice. The serum concentrations of h-Alb and h-AFP monitored after the cell transplantation (Figure 2). These protein levels were variable among individual mice, and three mice (No. 1-3) had substantially elevated h-Alb levels over the 56-d study. In addition, these mice exhibited RI_{h-hepatocytes} > 70% based on the correlation graph between h-Alb concentrations and RI_{h-hepatocytes}^[12]. These hosts also had markedly elevated h-AFP concentrations. In particular, mice No. 1 and 2 showed the highest h-Alb levels (approximately 9.1 mg/mL) and h-AFP concentrations (approximately 126.1 mg/mL) at 56 d post-transplantation (Table 1; Figure 2). As shown in Figure 3A, mouse 1 had the highest h-Alb and h-AFP levels, and the liver was composed of brown and whitish regions indicated by the thick and the thin arrows, respectively, which corresponded to the colonies composed of both h-hepatocytes and h-GCCs or m-liver cells, respectively. The brown region in the liver shown in Figure 3A was sectioned and stained with H and E (Figure 3B), anti-h-CK18 Abs to identify both h-hepatocytes and

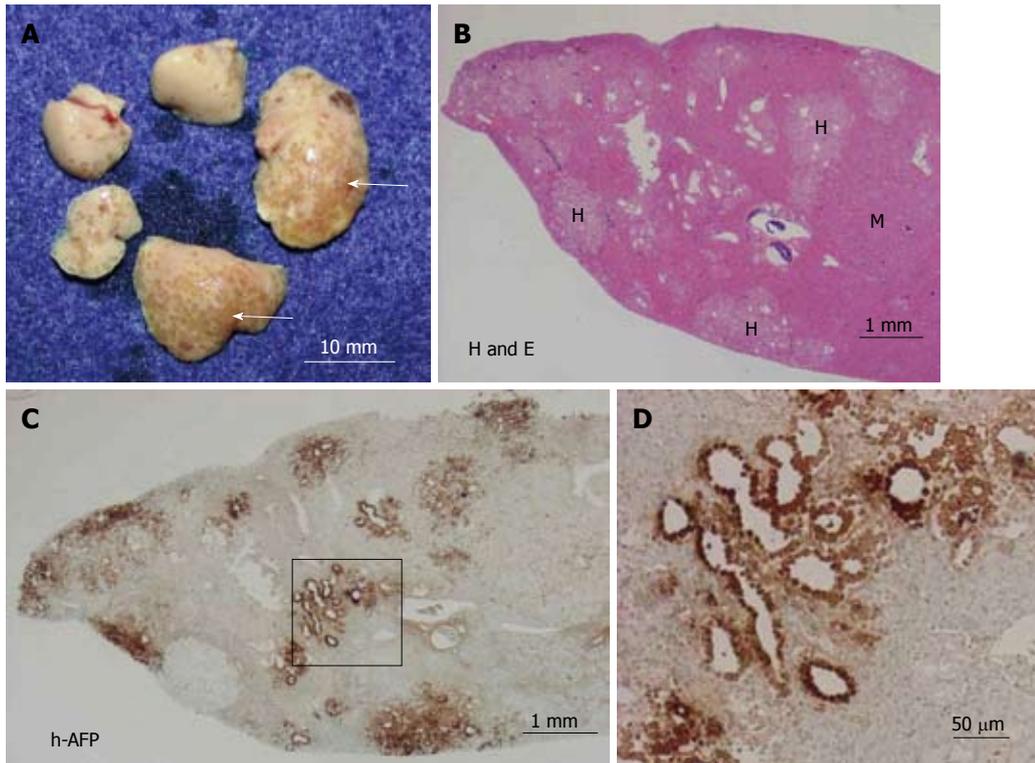

Figure 1 Macro- and microscopic images of the liver from group A mice. A: The urokinase-type plasminogen activator/severe combined immunodeficient mouse were transplanted with human gastric cancer cells (h-GCCs) and euthanized 56 d later, at which time the livers were isolated and photographed; B: The arrows in A point to concentrated regions of h-GCC colonies, and the sections were stained with hematoxylin and eosin (H and E). H and M in B represent h-GCC colonies and m-liver cell regions, respectively; C: The sections were stained with anti-human alpha-fetoprotein (h-AFP) antibodies; D: The square region in C is enlarged and shown.

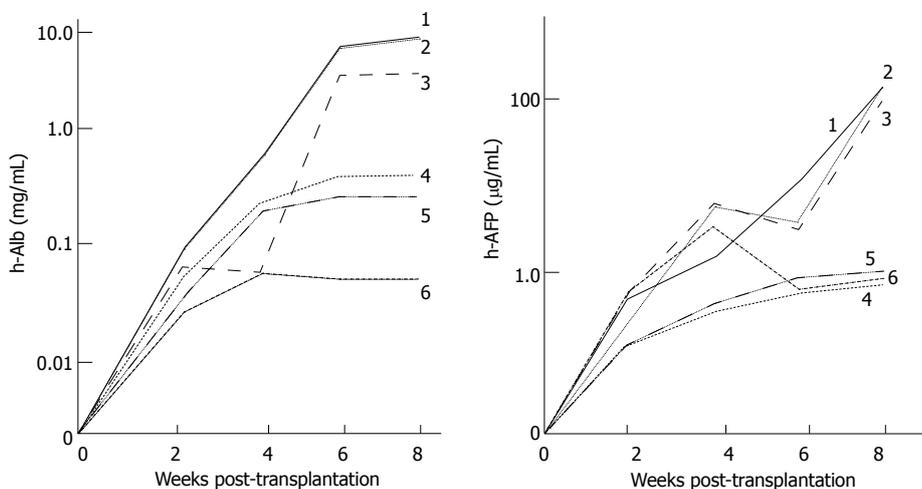

Figure 2 Changes in the serum concentrations of human albumin and human alpha-fetoprotein in group B-mice. Six mice (No.1-6) were co-transplanted with h-hepatocytes and human gastric cancer cells. The serum levels of human albumin (h-Alb) (left panel) and human alpha-fetoprotein (h-AFP) (right panel) were periodically monitored after the cell transplantation.

h-GCCs (Figure 3C), and the anti-h-AFP Ab to identify h-GCCs (Figure 3D). A comparison of Figure 3B and C showed that most of the section from Figure 3B was occupied with h-CK18⁺ cells, which corresponded to the cells in the less eosinophilic areas of the H and E section. Human CK18⁺ m-liver cells were located in eosinophilic areas in the H and E section, which were sporadically distributed as clusters with variable forms among large engrafted h-cell colonies. Human-AFP⁺ h-GCC-colonies were distinguished by comparing Figure 3B-D. These colonies were surrounded with less eosinophilic

h-hepatocytes (Figure 3D) that were swollen and clearer (Figure 3B and C). Magnified views of the brown area obtained from another serial sections of the liver shown in Figure 3A are shown in Figure 4A (H and E) and Figure 4B (h-AFP-stain). Human GCCs formed moderately differentiated adenocarcinomas with disrupted glandular structures, which is a characteristic feature of gastric cancer. Morphometric analyses using these h-CK18- and h-AFP-stained serial sections indicated that the RI_{h-hepatocyte} and MI_{h-GCC} in group B mice was 66.0% ± 12.3% (*n* = 6) and 12.0% ± 6.8% (*n* = 6), respectively. The mice in

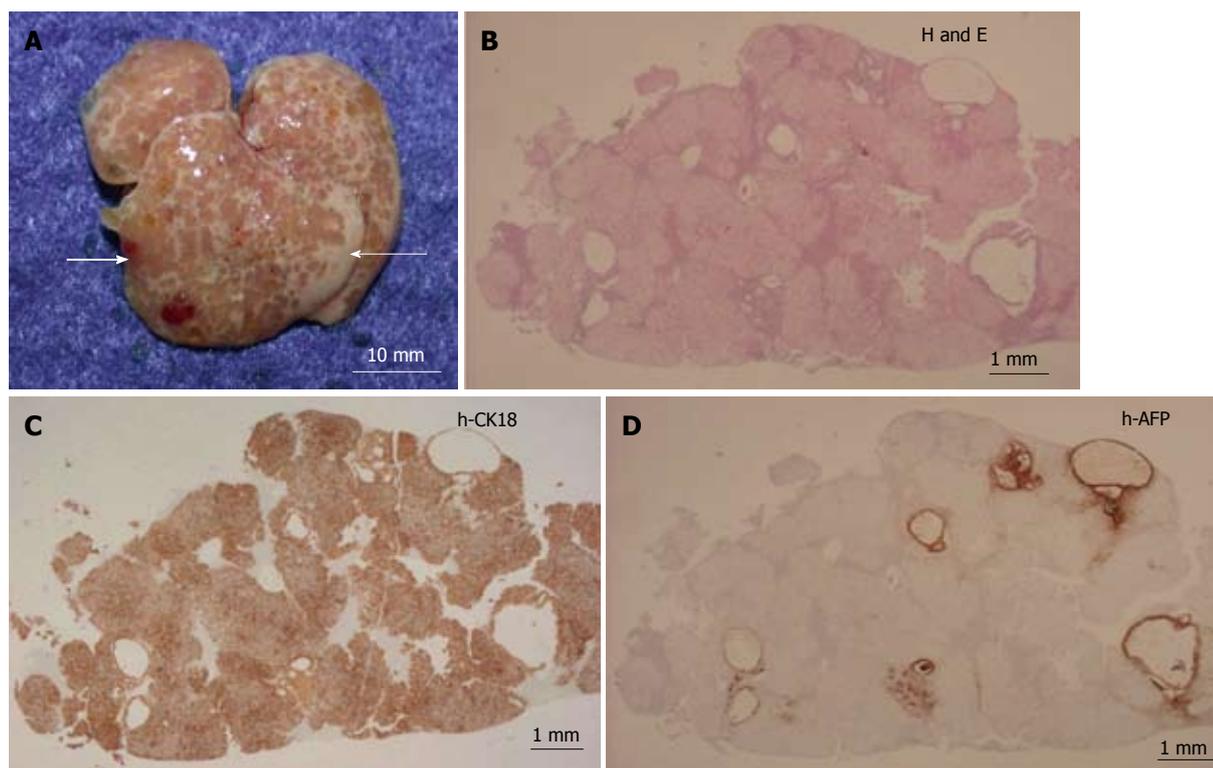

Figure 3 Macroscopic image of the liver of mouse No. 1 from Figure 2 at 56 d post-transplantation. A: The thick and thin white arrows point to h-cells [human hepatocytes (h-hepatocytes) and human gastric cancer cells (h-GCCs)] and m-liver cell regions, respectively; B: The liver was sectioned and stained with hematoxylin and eosin (H and E); C: The liver was sectioned and stained with anti-h-CK18; D: The liver was sectioned and stained with anti-human alpha-fetoprotein (h-AFP) antibodies. The h-AFP + (h-GCC) colonies were surrounded by less eosinophilic h-hepatocytes.

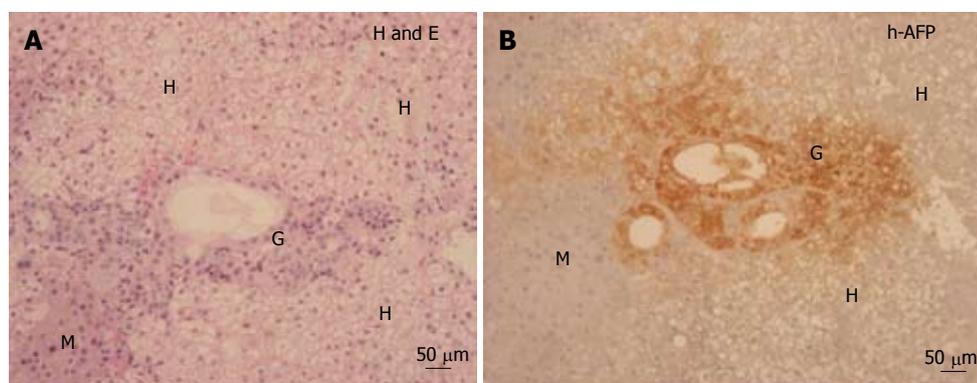

Figure 4 Magnified images of hepatic histology from group B mice. A: A serial section of the liver in Figure 3 was subjected to hematoxylin and eosin (H and E); B: A serial section of the liver in Figure 3 was subjected to human alpha-fetoprotein (h-AFP) staining. H, G and M represent the areas occupied by human-hepatocytes, human gastric cancer cells (h-GCCs), and host m-liver cells, respectively. h-GCCs composed moderately differentiated adenocarcinoma with disrupted glandular structures.

group B survived for the entire 56 d study. Extrahepatic sites and organs, such as the peritoneal cavity and kidney, were also examined for the presence of metastatic h-GCC lesions. The metastatic h-GCCs were not found in the extrahepatic regions during the observational period, indicating that the cells did not metastasize to any other regions.

DISCUSSION

An ideal animal model for liver metastasis of h-cancer

cells should possess at least two key features. First, the transplanted cancer cells need to invade and colonize in the host liver. Second, the liver of the host model has to provide the human cells with appropriate pathophysiological microenvironments that recapitulate the h-liver *in vivo*. Most of the conventional models to date manifest the first feature, but none of them have been able to sufficiently recapitulate the microenvironment of the h-liver^[4-6]. In the present study, we established a unique and novel that possessed both of these features.

In our study, we successfully engrafted the liver with

h-GCCs in the group A mice, and the cells formed relatively large colonies, with the MI as high as 25% at 56 d post-transplantation. However, such a considerably high MI could be a result of effects from either the donor or host side of the model. We chose h-AFP⁺ h-GCCs as a metastatic cancer cell line, since previous studies reported that patients with AFP⁺ gastric cancer showed a higher liver MI than those with AFP⁻ cells; more than 70% of the patients developed liver metastasis^[18,19]. These AFP⁺ cancer cells express c-Met^[19], which is the receptor for human hepatocyte growth factor (HGF), and therefore it is plausible that the cells have a high affinity for liver tissues under conditions where the levels of activated HGF in these tissues become high^[20]. In the present study, we utilized the uPA/SCID mice as hosts, which possessed a uPA transgene product that continuously damages the hepatocytes. In this model, the host hepatocytes generate pro-inflammatory environments in the liver, which stimulates the mobilization and expression of HGF in the liver tissues, including hepatocytes.

The role of uPA is an important aspect in this model. The host m-hepatocytes express unusually high levels of uPA, which is thought to induce severe damage in the replicative ability of m-hepatocytes through the activation of plasminogen, fibrinogen, and other proteins within the rough endoplasmic reticulum (RER) involved in proteolysis that lead to functional defects of the RER^[21]. In addition, uPA is secreted from m-hepatocytes into the plasma^[10], indicating that it circulates to liver tissues through sinusoidal capillaries and activates the conversion of blood plasminogen to plasmin. Therefore, the host liver tissue may provide h-GCCs with a pro-metastatic-like microenvironment. In fact, previous studies have indicated that uPA and its receptor (uPAR) play critical roles in the extravasation of tumors^[22-24]. Therefore, the injected h-GCCs are prone to extravasate liver tissues through the portal vein and sinusoid because of the uPA-induced fragility of vascular and sinusoidal endothelia and subsequently engraft liver tissues through an affinity for c-Met. Once the h-GCCs invade liver tissues, they can relatively easily propagate due to c-Met signaling in the host parenchyma, and can consequently replace m-hepatocytes as a result of the uPA-mediated damage. These conditions are also convenient for engraftment and proliferation of normal, healthy h-hepatocytes, as shown in this study when co-transplanted with h-GCCs.

The co-transplantation of h-hepatocytes with h-GCCs also resulted in the development of metastatic colonies in the mice similar to the transplantation of h-GCCs alone. In this type of transplantation experiment, large variances in serum concentrations of replacement marker proteins (h-Alb and h-AFP) were observed. The h-AFP kinetic curves were different from those of h-Alb and exhibited an increase of the serum level through "three steps": initial increase, followed by a plateau or decline, and then a sharp increase. This complex h-AFP kinetic pattern suggests the presence

of interactions between the invading cancer cells and the accepting host cells. There seemed to be two groups of animals within the experimental groups, one that more easily accepted xenogeneic cells and another that demonstrated resistance. However, we have consistently observed similar variances in h-Alb levels among individual mice when we generated h-hepatocyte chimeric mice^[12], though inbred mice were used as hosts. These variances are accidental in nature and might originate from some differences in manipulation procedures for transplantation as well as uncontrollable differences in the phenotypes of the uPA Tg mice^[10]. Despite these variances at the individual level, experimental group B of this study clearly demonstrated that we were able to reproducibly create mice whose livers were co-repopulated with healthy, normal h-hepatocytes and h-GCCs. Both h-hepatocytes and h-GCCs have high affinities for liver tissue, which drives engraftment of the liver and results in the generation of a humanized liver with metastatic cancer cells. We also found that the RI_{h-hepatocyte} (66.0% ± 12.3%) was significantly higher than MI_{h-GCC} (12.0% ± 6.8%), which may be a reflection of the difference in the inherent replication rates of the cells and adaptability to the host liver tissues. Our results indicate that h-hepatocytes are, as a whole, superior to h-GCCs in colony growth.

Relevant and reproducible animal models are indispensable tools for deducing the mechanisms of liver metastasis and pharmacokinetics of anti-cancer drugs, and several models have been developed to meet these practical needs, though they are quite limited^[2,25-30]. Preclinical tests of anti-cancer drugs for their effectiveness and toxicity in relevant animal models are required prior to application in humans^[31]. Toxicity data from non-primate species have been quite poor at predicting outcomes in subsequent human clinical trials, since there are significant differences in the metabolic activities of the hepatocytes between humans and rodent^[32-34]. Therefore, animal models with a humanized liver are more physiologic and will provide better tools for analyzing the pharmacokinetics of anti-cancer drugs as well as studying cancer metastasis^[35-37]. To our knowledge, no intrahepatic metastatic cancer model with a humanized liver has been available to date^[25,30,35-37]. The m-liver in the present study was chimeric and was composed of normal h-hepatocytes and m-hepatocytes. Previous studies have reported that the h-hepatocytes in these chimeric livers are functional and secreted a variety of hepatic proteins, such as Alb, -1 antitrypsin, apolipoprotein A, apolipoprotein E, several clotting factors, and complement proteins present in h-plasma^[38]. Transplanted h-hepatocytes also retain normal pharmacological responses, which makes the chimeric mouse model useful for studying the metabolism of compounds that cannot be easily administered to healthy volunteers^[14,15]. *In vivo* studies using these mice showed their utility in evaluating the metabolism of drugs catalyzed by both phase I and phase II enzymes^[13-15,39,40]. Since the liver functions of

the chimeric mice described in this study have not yet been characterized, future studies are needed to assess the model for anti-cancer drug testing. Taking together, the h-hepatocyte-chimeric mice may provide a useful bridge for studying human liver-related diseases because of the similarities with humans in physiological function and drug kinetics.

In conclusion, we have established a unique and novel animal model for studying liver cancer metastasis. The chimeric liver of the uPA/SCID mouse containing both human cancer cells and hepatocytes could be utilized as an appropriate model for *in vivo* testing of the efficacy and human-type metabolisms of candidate drugs for anti-cancer treatment as well as studying the mechanisms of liver cancer metastasis.

COMMENTS

Background

One of the major target organs for cancer metastasis is the liver, and therefore, there has been increasing needs for animal models that can sufficiently mimic the pathophysiological situation in human liver and that are suitable for investigating the mechanisms of hepatic cancer metastasis.

Research frontiers

An ideal animal model for liver metastasis of human cancer cells should possess at least two key features. First, the transplanted cancer cells need to invade and colonize the liver of the host. Second, the liver of the host model has to provide the human cells with appropriate pathophysiological microenvironments that recapitulate the human liver *in vivo*. In the present study, the authors established a unique and novel animal model with both of these features.

Innovations and breakthroughs

A liver-humanized mouse was generated by transplanting healthy and normal h-hepatocytes into urokinase type plasminogen activator/severe combined immunodeficient (uPA/SCID) mice (immuno- and liver- compromised mice), and the liver was stably and reproducibly replaced with human hepatocytes. This is the first report of a novel experimental model that sufficiently mimics the pathophysiological situation of human liver.

Applications

The chimeric liver of the uPA/SCID mouse containing both human cancer cells and hepatocytes could be utilized as an appropriate model for the *in vivo* testing of anti-cancer drugs as well as studying the mechanisms of liver cancer metastasis.

Terminology

The uPA/SCID mouse is a transgenic mouse line that expressed uPA under the control of the albumin enhancer/promoter which constitutively damages the hepatocytes due to constant exposure to uPA. A liver-humanized mouse (chimeric mouse) was generated by transplanting healthy and normal human hepatocytes into mouse liver of the uPA/SCID mouse (immuno- and liver-compromised mouse), which had been generated by mating the uPA-Tg mouse with the SCID mouse. This mouse model sufficiently mimics the pathophysiological situation in human liver.

Peer review

This study tries to establish an animal model with h-hepatocyte-repopulated liver for *in vivo* study of liver cancer using uPA/SCID mouse, which could be useful for studying liver cancer metastasis. The authors transfected uPA/SCID mouse either with human gastric cancer cells (h-GCCs) or h-GCCs with h-hepatocytes and observed that both colonies can repopulate mouse liver. The study is well conducted, the manuscript is well-written and the figures are of good quality.

pancreatitis (LPSP) and idiopathic duct-centric pancreatitis (IDCP) mentioned in the International Consensus Diagnostic Criteria and examined if these findings make a contribution to the differential diagnosis of type 1 and type 2 AIP. A disposable 22-gauge needle was used for EUS-FNA.

RESULTS: Adequate specimens including pancreatic tissue for differentiating AIP from cancer were obtained from 43 of 47 patients who underwent EUS-FNA. EUS-FNA was performed from the pancreatic head in 21 cases, which is known to be technically difficult when performed by core biopsy; there was no significant difference in the results compared with pancreatic body-tail. Nine of 47 patients met level 1 findings of LPSP and 5 patients met level 2 findings of LPSP. No one met level 1 findings of IDCP, but 3 patients met level 2 findings of IDCP. Of 10 seronegative cases, 2 cases were diagnosed with "definitive type 1 AIP", and 3 cases were diagnosed with "probable type 2 AIP" when considering both the level 2 histological findings and response to steroids.

CONCLUSION: EUS-FNA is useful in the differentiation of type 1 and type 2 AIP, particularly in seronegative cases.

Abstract

AIM: To investigate the usefulness of endoscopic ultrasound-guided fine needle aspiration (EUS-FNA) in the differentiation of autoimmune pancreatitis (AIP).

METHODS: We retrospectively reviewed 47 of 56 AIP patients who underwent EUS-FNA and met the Asian diagnostic criteria. On 47 EUS-FNA specimens, we evaluated the presence of adequate material and characteristic features of lymphoplasmacytic sclerosing

Key words: Autoimmune pancreatitis; Endoscopic ultrasound-guided fine needle aspiration; Idiopathic duct centric pancreatitis; Lymphoplasmacytic sclerosing pancreatitis; Pancreatic cancer

INTRODUCTION

Recently, the International Consensus Diagnostic Criteria (ICDC) for autoimmune pancreatitis (AIP) was proposed by Shimosegawa *et al.*^[1]. According to these criteria, AIP is classified into 2 types^[2]. The histological substance of type 1 AIP is known as lymphoplasmacytic sclerosing pancreatitis (LPSP)^[3-6], and type 2 AIP is characterized by a distinct histology called idiopathic duct centric pancreatitis (IDCP)^[7-10]. Type 2 AIP patients are generally seronegative and lack other organ involvement (OOI) in contrast to type 1 AIP. However, the absence of serological abnormalities or lack of OOI in patients with AIP does not necessarily imply the diagnosis of type 2, as type 1 also can be seronegative and without OOI. Taking these findings into consideration, ICDC made separate diagnostic criteria for type 1 and type 2 AIP, and histological differentiation is becoming more important for diagnosing AIP.

Endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) is now widely accepted as a safe and effective modality for obtaining pancreatic tissue samples^[11-14]. There are reports on the usefulness of EUS-FNA in the diagnosis of AIP^[15,16] but only negative reports on the differentiation between LPSP and IDCP using specimens obtained by EUS-FNA^[17,18]. The findings of expert panel deliberations at the AIP International 2009 Honolulu Meeting reached a uniform consensus that essential histological features of LPSP can only be obtained or evaluated in tissues with preserved architecture, i.e., either a surgical resection specimen or a core biopsy but not FNA^[19]. However, a surgically resected specimen can only be obtained from a patient misdiagnosed with pancreatic cancer^[20-22], and a core biopsy device may not function properly when used in the duodenum. We thus investigated the usefulness of EUS-FNA in the differentiation of type 1 and type 2 AIP using EUS-FNA with a 22-gauge needle.

MATERIALS AND METHODS

Patients

We retrospectively reviewed 47 patients who underwent EUS-FNA of 56 AIP patients who met the Asian Diagnostic Criteria^[23] at our institute between July 2003 and July 2011. Forty-two men and 5 women with a mean age of 62.1 ± 13.6 years (range, 28-86 years) and a mean follow-up period of 839.8 ± 722.7 d (range, 19-2506 d) were included. The mean serum immunoglobulin G4 (IgG4) levels were 626.1 ± 1004.6 mg/dL (range of 4-5850 mg/dL), and 10 patients were seronegative. On

47 EUS-FNA specimens, we evaluated the presence of adequate material and characteristic features of LPSP [lymphoplasmacytic infiltration, storiform fibrosis, obliterative phlebitis, and abundant (> 10 cells per high-power field) IgG4-positive cells] and IDCP [granulocytic infiltration of the duct wall (GEL) or granulocytic acinar infiltrate] mentioned in the histological criteria for ICDC (Table 1). Adequate material indicated an adequate specimen including pancreatic tissue for differentiating AIP from cancer. EUS-FNA was performed from the pancreatic head in 21 cases, an approach that is known to be technically difficult when performed by core biopsy. The histological findings according to the locations of EUS-FNA were also evaluated. Using the results of EUS-FNA, we examined whether these findings make a contribution to the differential diagnosis of type 1 and type 2 AIP. Patients with jaundice or abdominal pain underwent steroid therapy with oral prednisolone (PSL). The initial dose of PSL was 30-40 mg/d, and it was tapered down to the maintenance dose (2.5-5 mg/d) within 12 wk. Relapse was defined as exacerbation of the pancreatic lesion or OOI morphology or emergence of new OOI. OOI include cholangitis^[24] [proximal (hilar/intrahepatic) or proximal and distal bile stricture], sialadenitis, nephritis^[25], inflammatory bowel disease (IBD), and retroperitoneal fibrosis.

EUS-FNA

After receiving written informed consent, the patients were submitted to conscious sedation with intravenous diazepam under appropriate cardiorespiratory monitoring. EUS-FNA was performed by expert endosonographers with experience of more than five thousand EUS cases. The apparatus used was a convex-type EUS, GF-UCT 240 (OLYMPUS Co., Ltd., Tokyo, Japan) and Pro-sound $\alpha 10$ (ALOKA Co., Ltd., Tokyo, Japan) with a frequency of 7.5 MHz. The needle used for EUS-FNA was a disposable 22-gauge needle (EZ shot; OLYMPUS Co., Ltd., Tokyo, Japan). After detailed evaluation of the pancreas with the B-mode and confirmation that no vessels were present in the puncture route in the color Doppler mode, EUS-FNA was performed from the stomach to puncture the pancreatic body or tail and from the duodenum to puncture the pancreatic head.

Statistical analysis

Statistical analyses were performed using SPSS Statistics 17.0 (SPSS Inc., Chicago, IL, United States). The χ^2 test and Fisher's exact test were used to compare categorical parameters between the groups. Continuous parameters were presented as the mean \pm SD and/or median (range), and Student's *t* test was used. A *P* value of less than 0.05 was considered statistically significant.

RESULTS

EUS-FNA

The number of FNA passes ranged from 1 to 4 with a

Table 1 Histological criteria for International Consensus Diagnostic Criteria		
	Level 1	Level 2
Type 1 AIP		
Histology of the pancreas	LPSP (core biopsy/resection) At least 3 of the following: (1) Periductal lymphoplasmacytic infiltrate without granulocytic infiltration (2) Obliterative phlebitis (3) Storiform fibrosis (4) Abundant (> 10 cells/HPF) IgG4-positive cells	LPSP (core biopsy) Any 2 of the following: (1) Periductal lymphoplasmacytic infiltrate without granulocytic infiltration (2) Obliterative phlebitis (3) Storiform fibrosis (4) Abundant (> 10 cells/HPF) IgG4-positive cells
Type 2 AIP		
Histology of the pancreas (core biopsy/resection)	IDCP Both of the following: (1) GEL with or without granulocytic acinar inflammation (2) Absent or scant (0-10 cells/HPF) IgG4-positive cells	Both of the following: (1) Granulocytic and lymphoplasmacytic acinar infiltrate (2) Absent or scant (0-10 cells/HPF) IgG4-positive cells

AIP: Autoimmune pancreatitis; LPSP: Lymphoplasmacytic sclerosign pancreatitis; IDCP: Idiopathic duct-centric pancreatitis; GEL: Granulocytic infiltration of the duct wall; IgG4: Immunoglobulin G4; HPF: High power field.

IgG4: Immunoglobulin G4; FNA: Fine needle aspiration.

mean of 2.00 ± 0.48. One pass included approximately 15 to 20 back-and-forth movements in the target lesions. Adequate sample material was obtained from 43 of 47 patients who underwent EUS-FNA as well as 17 of 21 cases from the pancreatic head and all 26 cases from the body and tail. Sixteen of 47 EUS-FNA specimens showed lymphoplasmacytic infiltration, and 34 showed storiform fibrosis, but obliterative phlebitis could not be detected in any of the cases. Abundant IgG4-positive plasmacyte infiltration was shown in 10 of 28 patients who underwent immunostaining. Although GEL was not detected in any of the cases, three cases showed granulocytic acinar infiltrate. No significance was seen in the results of EUS-FNA between those performed at the pancreatic head and those obtained at the body-tail. There were no complications from EUS-FNA (Table 2).

On comparing the histological results of EUS-FNA against ICDC (Figure 1), 9 of 47 patients met level 1 findings of LPSP (Figure 2), and 5 patients met level

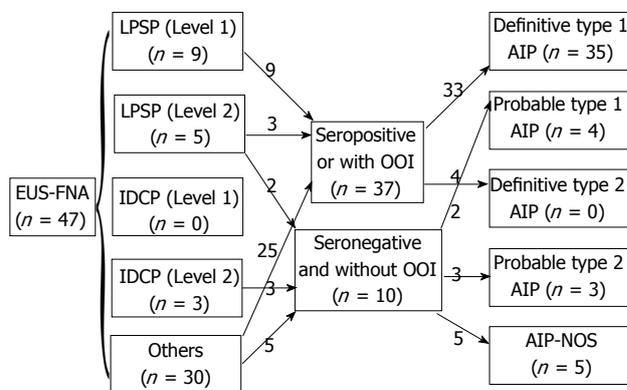

Figure 1 Comparison of endoscopic ultrasound-guided fine needle aspiration with International Consensus Diagnostic Criteria. EUS-FNA: Endoscopic ultra-sound-guided fine needle aspiration; LPSP: Lymphoplasmacytic sclerosing pancreatitis; IDCP: Idiopathic duct-centric pancreatitis; OOI: Other organ involvement; AIP: Autoimmune pancreatitis; NOS: Not otherwise specified.

2 findings of LPSP. Two of 5 patients who met level 2 findings of LPSP were seronegative and without OOI and were finally diagnosed with “definitive type 1 AIP” after considering both the level 2 histological findings and response to steroids (Table 3). No one met level 1 findings of IDCP (GEL), but 3 patients met level 2 findings of IDCP. All 3 patients were relatively young, seronegative, and had no OOI, including IBD. They were diagnosed with “probable type 2 AIP” (Figure 3) after considering the level 2 histological findings and response to steroids. They have shown improvement without relapse on radiological findings following steroid therapy thus far (Table 4).

DISCUSSION

EUS-FNA is an established and widely used technique to evaluate pancreatic masses. The diagnostic accuracy of EUS-FNA for pancreatic cancer is reported to be between 60% and 90%^[26-28], but conclusive diagnosis of

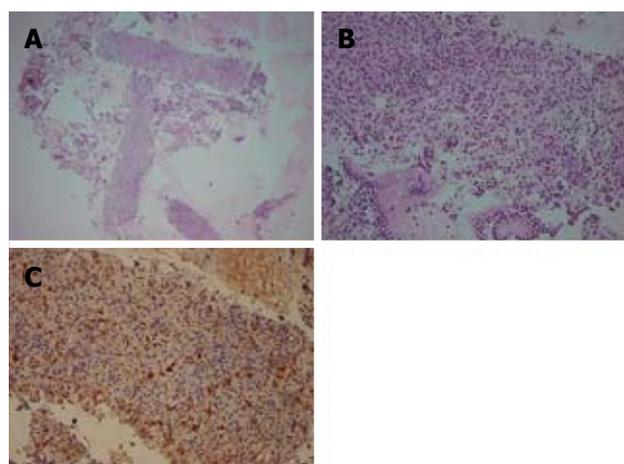

Figure 2 Endoscopic ultrasound-guided fine needle aspiration specimen of "definitive type 1 autoimmune pancreatitis". A, B: Hematoxylin and eosin staining of a resected pancreas specimen obtained by endoscopic ultrasound-guided fine needle aspiration shows replacement of the acinar structure by lymphoplasmacytic infiltration and fibrosis; C: Numerous plasma cells show positive immunoreactivity for immunoglobulin G4.

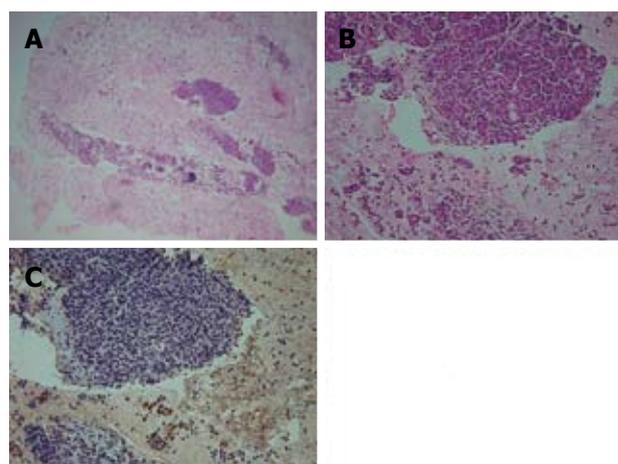

Figure 3 Endoscopic ultrasound-guided fine needle aspiration specimen of "probable type 2 autoimmune pancreatitis". A, B: Hematoxylin and eosin staining of a resected pancreas specimen obtained by endoscopic ultrasound-guided fine needle aspiration shows the infiltration of neutrophils in addition to lymphocyte infiltration and fibrosis; C: Immunostaining for immunoglobulin G4 is negative.

2	Female	71	364	Diffuse	(+)	Cholangitis	Definitive type 1 AIP
3	Male	54	230	Focal	(+)	Sialadenitis	Definitive type 1 AIP
4	Male	47	104	Focal	(+)	None	Definitive type 1 AIP
5	Male	57	46	Focal	(+)	None	Definitive type 1 AIP

IgG4: Immunoglobulin G4; OOI: Other organ involvement; AIP: Autoimmune pancreatitis.

AIP is often difficult due to the small size of specimens obtained by FNA. Recently, there have been several reports on the usefulness of EUS-guided tru-cut biopsy (EUS-TCB) for the diagnosis of AIP^[29-31]. Tru-cut biopsy needles have been developed to acquire samples while preserving tissue architecture, thus allowing histological examination^[32,33]. Previous reports describe the safety and the technical feasibility of performing EUS-TCB from a transgastric approach. However, the TCB device may not function properly when used in the second portion of the duodenum, and there is also some difficulty when using the TCB device from the duodenal bulb and along the greater curvature of the antrum^[29,34]. Moreover, because a 19-gauge needle is used for EUS-TCB, the risk of bleeding is higher compared with EUS-FNA using a 22-gauge needle, indicating that reexamination of safety is required. We previously reported^[35,36] the feasibility of EUS-FNA using a 22-gauge needle for the histological evaluation of gastrointestinal submucosal

Table 4 Patients with level 2 histological findings of idiopathic duct-centric pancreatitis

Case	Sex	Age, yr	IgG4 (mg/dL)	Location	Response to steroid	OOI	Follow-up, d	Relapse	Diagnosis
1	Male	28	69	Diffuse	(+)	(-)	973	(-)	Probable type 2 AIP
2	Female	31	43	Diffuse	(+)	(-)	425	(-)	Probable type 2 AIP
3	Male	30	23	Focal	(+)	(-)	120	(-)	Probable type 2 AIP

IgG4: Immunoglobulin G4; OOI: Other organ involvement; AIP: Autoimmune pancreatitis.

tumors, and we believe that this method can also be applied to pancreatic lesions. In our study, adequate material for differentiating cancer from AIP was obtained in 43 of 47 cases (91.4%), and no significant difference in EUS-FNA results was seen between those obtained from the pancreatic head and body-tail. Nine of 47 patients (19.1%) met 3 of 4 characteristic features of LPSP and were diagnosed with "definitive type 1 AIP" based on histological findings alone. Detailed analysis of 8 patients who showed level 2 histological findings of type 1 or type 2 AIP revealed that 3 patients with level 2 findings of type 1 were seropositive and/or with OOI and could be diagnosed with "definitive type 1 AIP" without histological findings, but the other 5 patients were seronegative and without OOI and diagnosed with "definitive type 1 AIP" or "probable type 2 AIP" based on combination of the level 2 histological findings and the response to steroid treatment. Therefore, out of 10 seronegative cases, 2 cases were diagnosed with "definitive type 1 AIP", and 3 cases were diagnosed with "probable type 2 AIP" using the histological findings of EUS-FNA. As mentioned earlier, type 1 AIP often can be di-

agnosed without histology, but it is difficult to differentiate type 1 and type 2 AIP when results are seronegative and without OOI. We believe histological evaluation of EUS-FNA is rather important in such cases.

In conclusion, EUS-FNA is useful in diagnosing AIP even when performed from the pancreatic head and may also provide complementary histological information to distinguish type 1 and type 2 AIP, particularly in seronegative cases.

COMMENTS

Background

Recently, the International Consensus Diagnostic Criteria (ICDC) for autoimmune pancreatitis (AIP) was proposed. ICDC made separate diagnostic criteria for type 1 and type 2 AIP, and histological differentiation is becoming more important for diagnosing AIP. There have been reports on the usefulness of endoscopic ultrasound-guided fine-needle aspiration (EUS-FNA) in the diagnosis of AIP but only negative reports on the differentiation between type 1 and type 2 AIP using specimens obtained by EUS-FNA.

Research frontiers

In the area of AIP, the research hotspot is how to obtain sufficient materials from AIP patients and differentiate type 1 and type 2 AIP correctly.

Innovations and breakthroughs

Adequate specimens including pancreatic tissue for differentiating AIP from cancer were obtained from 43 of 47 patients who underwent EUS-FNA. EUS-FNA was performed from the pancreatic head in 21 cases, which is known to be technically difficult when performed by core biopsy; there was no significant difference in the results compared with pancreatic body-tail. Of 10 seronegative cases, 2 cases were diagnosed with "definitive type 1 AIP," and 3 cases were diagnosed with "probable type 2 AIP" when considering both the level 2 histological findings and response to steroids.

Applications

The study results suggested that EUS-FNA (instead of core biopsy) was useful in diagnosing AIP even when performed from the pancreatic head and may also provide complementary histological information to distinguish type 1 and type 2 AIP, particularly in seronegative cases.

Terminology

Type 1 and type 2 AIP: The histological substance of type 1 AIP is known as lymphoplasmacytic sclerosing pancreatitis, and type 2 AIP is characterized by a distinct histology called idiopathic duct centric pancreatitis. Type 2 AIP patients are generally seronegative and lack other organ involvement (OOI) in contrast to type 1 AIP. However, the absence of serological abnormalities or lack of OOI in patients with AIP does not necessarily imply the diagnosis of type 2, as type 1 also can be seronegative and without OOI.

Peer review

The authors reported the usefulness of EUS-FNA in the diagnosis of type 1 and type 2 AIP and also stressed the importance of this method for the differential diagnosis between AIP and pancreatic cancer especially in the cases with negative results of serology and absence of other organ involvement. The content is clear and the discussion is straightforward. This paper is useful for understanding the ICDC and the classification of type 1 and 2 AIP.

Abstract

AIM: To use leptin-deficient (*ob/ob*) mice with demonstrated differences in steatosis levels to test a new diagnostic method using the acoustical structure quantification (ASQ) mode and the associated analytical parameter, "focal disturbance ratio" (FD-ratio).

METHODS: Nine *ob/ob* mice, at 5, 8, and 12 wk of age ($n = 3$ in each age group), were used as models for hepatic steatosis. Echo signals obtained from ultrasonography in the mice were analyzed by ASQ, which uses a statistical analysis of echo amplitude to estimate inhomogeneity in the diagnostic region. FD-ratio, as calculated from this analysis, was the focus of the present study. FD-ratio and fat droplet areas and sizes were compared between age groups.

RESULTS: No fibrosis or inflammation was observed in any of the groups. The fat droplet area significantly ($P < 0.01$) increased with age from $1.25\% \pm 0.28\%$ at 5 wk to $31.07\% \pm 0.48\%$ at 8 wk to $51.69\% \pm 3.19\%$ at 12 wk. The median fat droplet size also significantly ($P < 0.01$) increased with age, from 1.33 (0.55 - 10.52) μm at 5 wk, 2.82 (0.61 - 44.13) μm at 8 wk and 6.34 (0.66 - 81.83) μm at 12 wk. The mean FD-ratio was 0.42 ± 0.11 at 5 wk, 0.11 ± 0.05 at 8 wk, and 0.03 ± 0.02 at 12 wk. The FD-ratio was significantly lower at 12 wk than at 5 wk and 8 wk ($P < 0.01$). A significant negative correlation was observed between the FD-ratio and either the fat droplet area ($r = -0.7211$, $P = 0.0017$) or fat droplet size ($r = -0.9811$, $P = 0.0052$).

CONCLUSION: This tool for statistical analysis of signals from ultrasonography using the FD-ratio can be used to accurately quantify fat *in vivo* in an animal model of hepatic steatosis, and may serve as a quantitative biomarker of hepatic steatosis.

Non-invasive determination of hepatic steatosis by acoustic structure quantification from ultrasound echo amplitude. *World J Gastroenterol* 2012; 18(29): 3889-3895 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i29/3889.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i29.3889>

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is a clinically important disease that occurs in subjects with underlying conditions such as obesity or insulin resistance, and is frequently accompanied by metabolic syndrome, including diabetes, hyperlipidemia and/or hypertension^[1-5]. Non-alcoholic steatohepatitis (NASH) is the most extreme form of NAFLD, and is regarded as a major cause of cirrhosis of the liver of unknown cause^[6-10]. Methods for early detection and assessment of NAFLD through quantitative measurement of steatosis are needed to achieve earlier intervention and avoid the progression to cirrhosis.

The gold standard for quantitative assessment of steatosis has been considered to be liver histology^[11]. However, liver biopsy shows various limitations, such as potential sampling error, difficulties repeating the procedure because of ethical concerns, and complications including bleeding^[12]. Non-invasive alternatives to liver biopsy thus need to be established.

Several methods have recently been established for non-invasively quantifying steatosis using imaging techniques. Non-invasive modalities such as ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) have been employed for the assessment of hepatic steatosis^[13-15]. However, using these modalities for the repeated evaluation of NAFLD is difficult, because CT involves radiation exposure and MRI is expensive to perform. From these perspectives, ultrasonography represents an excellent examination modality that is minimally invasive, inexpensive, and can be performed repeatedly with no risk to the patient. Furthermore, ultrasonography is known to be highly sensitive for detecting fat accumulation in the liver^[16]. However, the diagnostic performance of ultrasonography depends on the empirical and qualitative reading skills of the examiner, and quantitative methods to evaluate liver lipogenesis have yet to be established.

In recent years, Yamaguchi *et al.*^[17,18] have reported that diffuse pathological changes in the liver tissue can be quantitatively evaluated based on the statistical deviation of ultrasound signals compared to normal liver. Generally, ultrasonographic images of parenchymal organs such as the liver are designated as having a “speckle pattern” consisting of numerous fine echo spots. The speckle pattern is constructed by ultrasonic interference of scattered ultrasound waves generated by innumerable reflexive objects that are distributed closer than the ultrasonic wavelength^[17-19]. Image analysis of speckle patterns has been used to identify tissue characteristics associated with chronic liver diseases, because the pattern changes according to the structural characteristics of the medium. One such analytical method, the probability density function (PDF) of the echo amplitude of a speckle pattern, has been reported to be approximated by a function called the Rayleigh distribution. Moreover, Toyoda *et al.*^[20] proposed the acoustical structure quantification (ASQ) method and reported the possibility of quantifying diffuse liver disease or monitoring regression/progression in cases of liver fibrosis and during treatment. However,

no reports have yet described assessments of hepatic steatosis in NAFLD patients using this tool for the statistical analysis of ultrasonic signals.

The present study aimed to validate a quantitative imaging technique used to detect and measure steatosis with statistical information from ultrasound echo signals with the focal disturbance ratio (FD-ratio) as a parameter in leptin-deficient (*ob/ob*) mice, a pure NAFLD model.

MATERIALS AND METHODS

This study was a collaborative effort between Iwate Medical University and Toshiba Medical Systems. However, no direct financial support was received from Toshiba Medical Systems for this study.

Animals

The animal research protocols for this prospective study were approved by our institutional research animal resource center. Nine 5 wk old (at the start of the study) male *ob/ob* mice were purchased from Charles River Laboratories (Yokohama, Japan) and maintained on conventional food and water throughout the experiment. These mice were divided into 3 groups ($n = 3$ each) that underwent the experiment described below at 5, 8 and 12 wk old, respectively.

General anesthesia was induced in mice by intraperitoneal administration of 40-50 mg/kg pentobarbital sodium (Ovation Pharmaceutical, Deerfield, IL), and underwent laparotomic ultrasonography, prior to having the liver extracted for histological examination.

Ultrasonographic imaging

An AplioXG ultrasound scanner (Toshiba Medical Systems, Otawara, Japan) was combined with a 12 MHz linear transducer (PLT-1204BT) for ultrasonographic investigations in this study. The scan mode was harmonic B-mode imaging (T: 6.0/R: 12.0 MHz). Display depth and transmit focus were fixed at 15 mm and 7.5 mm, respectively, and cross-sectional images of the hepatic parenchyma were recorded digitally with raw data, consisting substantially of the linear amplitudes without any cosmetic image processing. Raw data were uploaded to a personal computer in the DICOM format. FD-ratio was determined using ASQ software (details described in the next section). A region of interest (ROI) was set to a fixed depth of 2.5 mm to the liver surface (Figure 1). FD-ratio was measured 10 times in succession, and the mean value (after excluding outliers) was used as the final result. In parallel, mean echo intensity of the hepatic parenchyma was measured using Image-J image analysis software (NIH, United States).

Analytical method

The principles of the ASQ method^[20] are as follows. When echo signals are generated from very small, dense scatters located beyond the limit of spatial resolution, the pattern of the ultrasound image is constructed based on the interference of the sound waves (speckle noise). In that

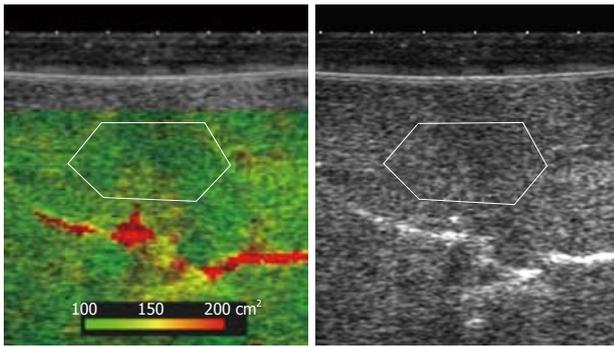

Figure 1 Acoustic structure quantification imaging. In parametric imaging, the intensity distribution can be visualized and displayed on a split screen by color coding. The large-region of interest was set at a fixed depth of 2.5 mm from the liver surface.

case, the PDF of the echo amplitude can be approximated using the Rayleigh distribution function^[21]. In normal liver parenchyma, such statistical results are not described by the Rayleigh distribution due to the existence of structures such as vessel walls. Results for livers with either nodules or fibrosis, i.e., liver cirrhosis, are even less similar to the Rayleigh distribution. We hypothesized that in the case of progression of fat drops, these scatters would generate wave interference or mask the original small structures, which would change the PDF to more closely resemble a Rayleigh distribution.

Once the examiner sets a comprehensive ROI (hereinafter referred to as a large-ROI) on the image, several hundred small ROIs (small-ROIs hereinafter) are automatically set therein to calculate the PDF (Figure 2A). The essential parameter, C_m^2 , in the analysis is defined by the equation:

$$C_m^2 = \frac{\sigma_m^2}{\sigma_R^2(\mu_m)} = \left(\frac{\pi}{4 - \pi} \right) \frac{\sigma_m^2}{\mu_m^2}$$

where μ and σ^2 are the average and variance of the echo amplitude in a small-ROI, respectively. The $\sigma_R^2(\mu)$ is a variant if the Rayleigh distribution is estimated from the measured average. Multiple results for small-ROIs in a large-ROI are displayed as an occurrence histogram of C^2 (real line in Figure 2B). If samples consist of speckle noise, the C^2 histogram will gather to 100 with narrow variance, while structural information will make the average value larger and variance wider.

FD-ratio is calculated in the following manner. First, C_m^2 is defined as:

$$C_m^2 = \frac{\sigma_m^2}{\sigma_R^2(\mu)} = \left(\frac{\pi}{4 - \pi} \right) \frac{\sigma_m^2}{\mu^2}$$

where σ_m is the variance calculated from limited samples less than $\mu + 4\sigma$. If the ratio C^2/C_m^2 is larger than the threshold α , the result of C_m^2 is eliminated from the histogram (real line), but added to the alternative histogram (dotted line). The FD-ratio is the ratio of the area under the curve (AUC) for these two histograms: $R_{FD} = [\text{AUC (real)}]/[\text{AUC (dotted)}]$.

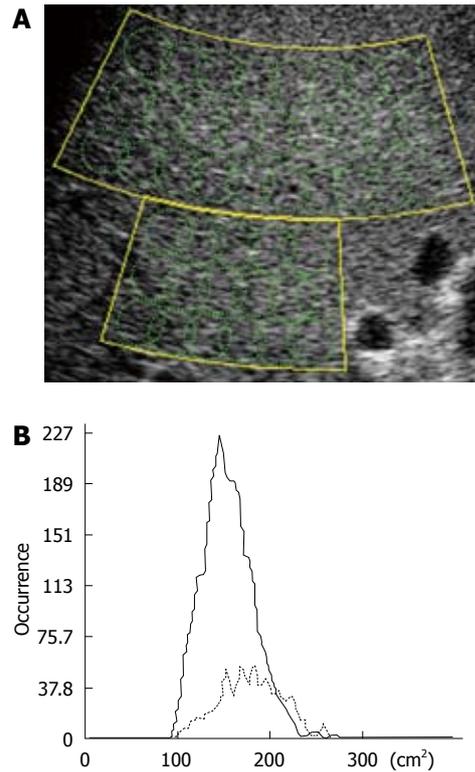

Figure 2 Schematic of region of interests used for statistical analysis of the radio frequency signal with the acoustic structure quantification method, and the C_m^2 -histogram. A: The set large-region of interest (ROI) actually consists of several hundred small ROIs used to calculate multiple C_m^2 (intensity or amplitude) values; B: Results are shown as the occurrence in the C_m^2 histogram.

Here, the threshold α was set to 1.2, so $R_{FD} = 0$ when the samples show a Rayleigh distribution for the PDF, and has a positive value in the presence of tiny structural changes.

The ASQ software also has an imaging function that reconstructs the 2-dimensional color map of the C^2 measured for each position (parametric image).

Histopathological analysis

Histopathological examinations were performed by an experienced pathologist certified by the Japanese Society of Pathology. Images from liver biopsy samples were recorded using the JPEG format. Using Image-J software, the percentage fat area was calculated from the ratio between total fat tissue area and total specimen area, and the mean value was used to denote the fat droplet area. In addition, again using Image-J software, the maximum diameter of fat droplets in 8 and 12 wk old mice was measured, and median values were used to denote the size of fat droplets. The fat droplet area and size obtained in this manner were compared with the FD-ratio.

Statistical analysis

Values are shown as mean \pm SD, or median (range) according to the distribution of values. Stat View software (version 5.0; SAS Institute, Cary, NC, United States) was used for all statistical analysis. The Spearman rank-order

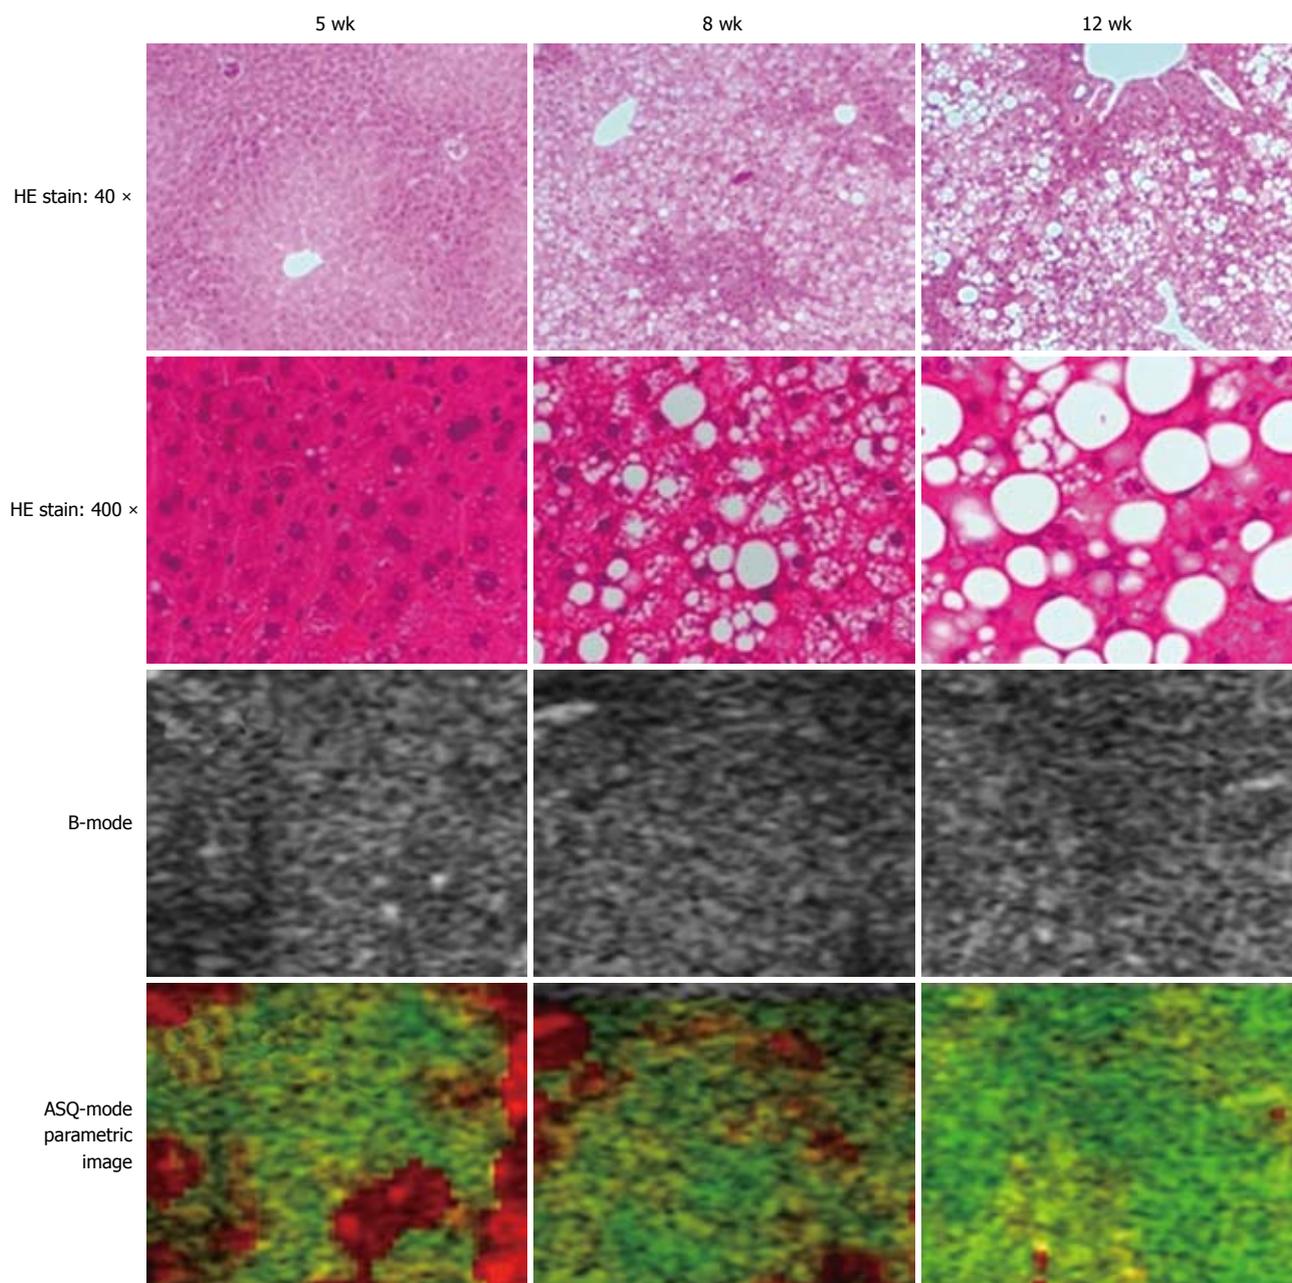

Figure 3 Representative histological findings, B-mode images and acoustic structure quantification-mode images for each group. No fibrosis or inflammation was observed in any groups. Large fat droplets were mainly observed at 12 wk old. In parametric imaging, red and green existed together at 5 wk, and red decreased and green was more abundant at 12 wk. ASQ: Acoustical structure quantification.

correlation test was used to study correlations between two variables, with a significant correlation considered to exist for values of $P < 0.05$, and for correlation coefficient $r \geq 0.40$. The Tukey-Kramer method was used for multiple comparison tests, and values of $P < 0.05$ were considered to indicate a significant difference.

RESULTS

Comparison of histological findings and liver echogenicity

No fibrosis or inflammation was observed in any groups. Large fat droplets were mainly observed at 12 wk

(Figure 3). Fat droplet area increased significantly ($P < 0.01$ each) with age from $1.25\% \pm 0.28\%$ at 5 wk to $31.07\% \pm 0.48\%$ at 8 wk, and to $51.69\% \pm 3.19\%$ at 12 wk. Median fat droplet size also increased significantly ($P < 0.01$ each) with age, from $1.33 \mu\text{m}$ (range: $0.55\text{-}10.52 \mu\text{m}$) at 5 wk to $2.82 \mu\text{m}$ (range: $0.61\text{-}44.13 \mu\text{m}$) at 8 wk and $6.34 \mu\text{m}$ (range: $0.66\text{-}81.83 \mu\text{m}$) at 12 wk (Figure 4). Mean Gray values in each group were 65.31 ± 22.52 at 5 wk, 65.95 ± 19.41 at 8 wk and 91.32 ± 21.83 at 12 wk (Figure 5). Although no differences were observed between the 5 and 8 wk old groups, mean gray value was significantly elevated in the 12 wk old group, with an increase observed in the brightness of the hepatic parenchyma.

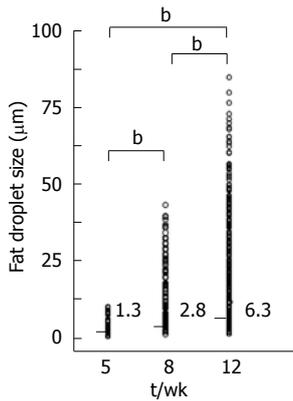

Figure 4 Comparison of fat droplet size. Median fat droplet size increased significantly ($^bP < 0.01$) with age, from 1.33 μm (range: 0.55-10.52 μm) at 5 wk, to 2.82 μm (range: 0.61-44.13 μm) at 8 wk and 6.34 μm (range: 0.66-81.83 μm) at 12 wk.

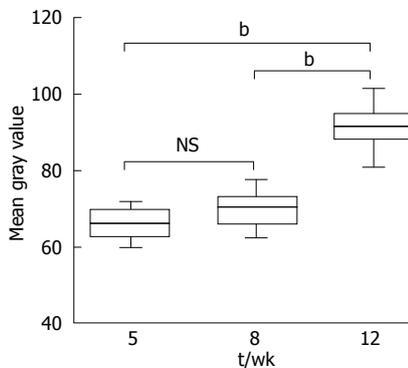

Figure 5 Comparison of liver echogenicity. Mean gray values in each group were 65.31 ± 22.52 at 5 wk, 65.95 ± 19.41 at 8 wk, and 91.32 ± 21.83 at 12 wk. Although no difference was apparent between the 5 and 8 wk old groups, mean gray value was significantly elevated in the 12 wk old group, with increased brightness of the hepatic parenchyma. $^bP < 0.01$. NS: Not significant.

Relationship between FD-ratio and fat droplet area or size

Mean FD-ratio was 0.42 ± 0.11 at 5 wk, 0.11 ± 0.05 at 8 wk, and 0.03 ± 0.02 at 12 wk. The FD-ratio was significantly lower at 12 wk than at 5 or 8 wk ($P < 0.01$ each). In parametric imaging, red and green existed together at 5 wk, and the red had decreased and green was more abundant at 12 wk (Figure 3). A significant negative correlation was observed between FD-ratio and both fat droplet area ($r = -0.7211$, $P = 0.0017$) (Figure 6A) and fat droplet size ($r = -0.9811$, $P = 0.0052$) (Figure 6B).

DISCUSSION

The results of this study demonstrated a close correlation between FD-ratio and the degree of histologically evaluated fat accumulation in the liver. These data suggest that ASQ analysis of liver ultrasonography and its representative parameter, FD-ratio, may offer a reliable new clinical modality for the assessment of liver steatosis.

With regard to the ultrasonographic diagnosis of fatty liver disease, Joseph *et al*^[16] advocated the bright liver pat-

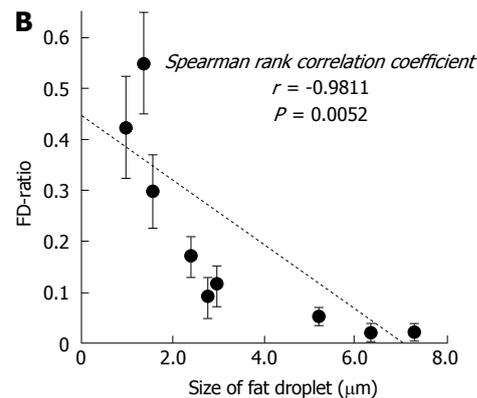

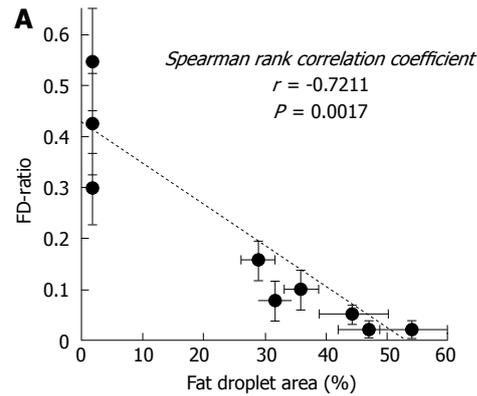

Figure 6 Relationship between “focal disturbance ratio” and fat droplet area or size of fat droplets. A: Significant negative correlations were observed between focal disturbance ratio (FD-ratio) and either fat droplet area ($r = -0.7211$, $P = 0.0017$); B: Fat droplet size ($r = -0.9811$, $P = 0.0052$).

tern, and attempts to quantify the hepatosplenic contrast or hepatorenal contrast were subsequently proposed^[22-24]. Although findings of a bright liver pattern and hepatorenal contrast are widely accepted as sensitive, reliable findings for the presence of fatty liver disease, no quantitative method to evaluate the severity of hepatic fat accumulation has previously been established. The difficulties in ultrasonographic diagnosis may originate from the fact that image information obtained by conventional ultrasonography lacks an objective or quantitative nature, unlike the X-ray absorbance in CT. In contrast, ASQ analysis generate objective data and provide a quantitative assessment of liver histology with respect to fat accumulation. Taking into account the non-invasive and inexpensive nature of ultrasonography, ASQ analysis could become a mainstay in the diagnosis of fatty liver disease and evaluations of disease severity and response to treatment. In addition, these studies of tissue characterization using ASQ analysis could lead to the development of methods for the quantitative diagnosis of other diffuse liver diseases, including fibrosis or inflammation, thus decreasing the need for liver biopsies.

With regard to the ASQ method, procedures are undertaken to analyze the RF signals for each of a large number of small-ROIs set up within a large ROI, for the purpose of improving analytical precision^[17-19]. The assumption is that in small-ROIs with a high degree of de-

viation from the Rayleigh distribution, the strength of the signals contained therein would be non-homogeneous. We also assumed the presence of two kinds of inhomogeneous samples, i.e., diffuse inhomogeneity and focal inhomogeneity, and by placing our focus on the small-ROIs with a high degree of deviation from the Rayleigh distribution resulting from a focally inhomogeneous structure, we established FD-ratio as a parameter.

Conversely, a bright liver pattern and vascular blurring are observed in fatty livers, due to reflection and scattering of the ultrasound waves and physical pressure on small blood vessels by ballooning hepatocytes induced by the fat droplets. We predicted that, due to the large number of fat droplets assembled densely (and thereby enveloping structures such as small blood vessels and bile ducts), the brightness of the hepatic parenchyma would be increased, and hepatic vein walls would become blurred, thus resulting in homogenization of the signal strength in each small-ROI and a decrease in the number of focally inhomogeneous small-ROIs. As a result, we believed that, as the area and diameter of fat droplets increased, the FD-ratio would decrease. Interestingly, no significant difference was seen in the brightness of hepatic parenchyma between 5 and 8 wk old mice, while FD-ratios were lowest in 8 wk old mice. We can therefore infer that a tool for the statistical analysis of ultrasonic signals may detect, beyond a qualitatively oriented reading ability, small changes in the speckle pattern caused by steatosis.

In conclusion, a novel tool for the statistical analysis of ultrasonic signals using FD-ratio as a parameter would be useful for the quantitative evaluation of liver steatosis. FD-ratio can therefore be used as a non-invasive biological marker for the early detection and quantitative evaluation of hepatic steatosis.

We wish to thank Ms. Yuriko Mikami for her invaluable technical assistance with ultrasonography.

COMMENTS

Background

Non-alcoholic fatty liver disease (NAFLD) is the most common cause of chronic liver disease. The gold standard for quantitative assessment of steatosis has been considered to be liver histology. However, liver biopsy shows various limitations and repeating the procedure is difficult because of ethical concerns. Non-invasive alternatives to liver biopsy are thus needed.

Research frontiers

Non-invasive modalities such as ultrasonography, computed tomography, and magnetic resonance imaging have been employed for the assessment of hepatic steatosis. Researchers have recently reported that diffuse pathological changes in liver tissue can be quantitatively evaluated as the statistical deviation of ultrasound signals compared to normal liver. However, no reports have described the assessment of hepatic steatosis in NAFLD patients using this tool for the statistical analysis of ultrasonic signals.

Innovations and breakthroughs

This study validated a quantitative imaging technique used to detect and measure hepatic steatosis with statistical information from ultrasound echo signals using focal disturbance ratio (FD-ratio) as a parameter in an animal model.

Applications

FD-ratio can be used as a non-invasive biological marker for the early detection and quantitative evaluation of hepatic steatosis.

Peer review

The authors present some pilot data from their research on the diagnostic utility of a new ultrasound technique in an animal model of fatty liver.

Abstract

AIM: To analyze the epidermal growth factor receptor pathway substrate 8 (EPS8) expression status and role in colorectal carcinogenesis given that EPS8 has a conserved actin barbed-end capping function that is required for proper maturation in intestinal cells.

METHODS: We studied 8 colon cancer cell lines and 58 colorectal tumors (19 adenomas and 39 carcinomas). We performed expression microarray analysis of colon cancer cell lines followed by loss of heterozygosity (LOH)

analysis and immunohistochemistry for EPS8 expression in colon tumors. Subsequently, we performed mutation analysis by direct sequencing and methylation analysis by bisulfite sequencing and methylation-specific polymerase chain reaction assays.

RESULTS: Expression microarray analysis of colon cancer cell lines showed overexpression of EPS8 transcript in all lines but RKO. Genome wide loss of heterozygosity (LOH) analysis of colon tumors, showed considerable LOH at the *EPS8* gene locus. Immunohistochemically, EPS8 was constitutively expressed in normal colonic mucosa with a dot-like supranuclear localization with accentuation at the luminal surface supporting its proposed role in epithelial maturation. Nineteen colon tumors (4 adenoma, 15 carcinoma) out of 51 (37%) showed strikingly tumor specific EPS8 protein loss. Of the remaining tumors, 5/51 (2 adenoma, and 3 carcinoma, 10%) showed marked overexpression, while 27/51 tumors (53%) showed retained expression. Mutation analysis revealed a missense mutation (c.794C>T, p.R265C) in exon 8 in RKO. The *EPS8* promoter was also methylated in RKO, but there was no significant methylation in other cell lines or carcinoma specimens.

CONCLUSION: The loss of EPS8 expression in colorectal adenomas and carcinomas suggests that down regulation of this gene contributes to the development of a subset of colorectal cancers, a finding which could have applications in diagnosis and treatment.

INTRODUCTION

Epidermal growth factor receptor pathway substrate 8 (EPS8) is a 97-kDa protein that is tyrosine phosphorylated following stimulation of receptor tyrosine kinases (RTK)^[1]. EPS8 plays a role in signal transduction from RTK and PI3K^[2,3] leading to Rac-mediated actin remodeling, ruffle formation and cell motility^[4]. In *Caenorhabditis elegans* (*C. elegans*), *eps-8* knockdown animals were zygotic lethal due to major defects in the gut, and the isoform EPS-8A was shown to be required for proper apical morphogenesis in the intestinal cells. This phenotype was correlated with an actin barbed-end capping activity, which is present in the C terminus of the EPS-8A isoform and is required for coordinately terminated elongation of the microvillar actin bundle core^[5]. This function of EPS8 protein is conserved throughout evolution^[6].

EPS8 was recently shown to be overexpressed in advanced stage human cancers including colon cancer cell lines and specimens^[7]. Our expression microarray analysis of colon cancer cell lines confirmed this overexpression. Interestingly, there was a strikingly low level of *EPS8* in RKO, a colon cancer cell line with a marked lack of constitutive β -catenin regulated transcription^[8], which prompted us to conduct a comprehensive immunohistochemical, genetic, and epigenetic analysis of *EPS8* alterations in colorectal cell lines and patient specimens.

MATERIALS AND METHODS

Patients and samples

We studied 8 colon cancer cell lines (RKO, HCA7, KM12, LoVo, DLD1, HCT116, SW48, LIM1215) and 58 colorectal tumors (19 adenomas and 39 carcinomas) of which 21 tumors (4 adenomas and 17 carcinomas) belong to a well characterized series of familial colon cancer type X (FCC-X). 15 adenomas and 22 carcinomas were sporadic. Clinicopathological characteristics of these cohorts are available in our previous publications^[9-11]. The FCC-X originated from 19 cancer families clinically indistinguishable from Lynch syndrome (hereditary non-polyposis colon cancer), but screening negative for the known predisposing genes by multiple techniques^[12]. We identified distinct molecular features in these tumors including high frequency of genomically stable carcinomas with membranous β -catenin, however, the predisposing defects in these families remain elusive^[9]. The sporadic colorectal tumors were selected from a larger cohort with the aim to include equal numbers of tumors with membranous *vs* nuclear β -catenin.

Fresh frozen and/or paraffin derived specimens of tumor and matching normal tissues were collected from pathology departments of different hospitals and used for immunohistochemical analysis and DNA extraction according to standard protocols. All human specimens were obtained after informed consent and approvals from the appropriate institutional review boards of the Helsinki University Central Hospital.

mRNA expression analysis by microarrays

Analyses were performed using HG-U133 Plus 2.0 array (Affymetrix, Santa Clara, CA, United States). The protocols for HG-U133 Plus 2.0 arrays were as described by the manufacturer (Affymetrix, Santa Clara, CA, United States). Briefly, total RNA was extracted from cell lines by RNeasy (Qiagen, Valencia, CA, United States). An aliquot of each RNA sample was run on a 2100 Bioanalyzer (Agilent Technologies, Palo Alto, CA, United States) to visualize and quantify the degree of RNA integrity. Double-stranded cDNA was synthesized from 5 μ g of total RNA using the GeneChip One-Cycle cDNA synthesis kit, followed by cleanup with the GeneChip Sample Cleanup Module, *in vitro* transcription (IVT) and Biotin labeling reaction using the GeneChip IVT Labeling kit, and clean-up and quantification of the biotin-labeled cRNA yield by spectrophotometric analysis. All kits were from Affymetrix. Fragmentation of the 8 μ g cRNA and hybridizations to test chips and the HG-U133 Plus 2.0 array were carried out according to Affymetrix protocols, and microarrays were processed by the Affymetrix Fluidics Station 450 and scanned with an Affymetrix GeneChip Scanner 7G. Captured images were analyzed using Microarray Suite version 5.0 algorithm (Affymetrix). All quality control criteria recommended by Affymetrix were observed in the "Test" chips and sample chips.

The hybridization data were pre-processed using Robust Multi-array Average (RMA^[13]), designed to enhance the comparability of expression measures between separate arrays. RMA pre-processing produces a single expression measure for each probe set in the Affymetrix array which can be readily used in subsequent analyses. As duplicate arrays were available for each cell line, the median of the two RMA values was used as the expression value. Gene assignments of the probes were extracted from the Affymetrix annotation files and genes with ambiguous information about the physical location were excluded from the analysis.

EPS8 loss of heterozygosity analysis

For the *EPS8* loss of heterozygosity (LOH) analysis we chose two microsatellite markers spanning the *EPS8* gene locus at Ensembl cytogenetic band 12p12.3 and surrounding the gene from both directions (<http://www.ensembl.org>). The physical distances between loci in mega-bases according to Ensembl are given in parentheses: pter D12S1580 - (2.4 Mb) - EPS8 - (0.4 Mb) - D12S1728 qter. The polymerase chain reaction (PCR) amplification primers were from Généthon Microsatellite Maps at <http://>

www.genlink.wustl.edu/genethon_frame. The forward primers were fluorescently labeled with carboxyfluorescein and PCR fragments were run on the ABI3730 sequencer/genotyper and results analyzed using GeneMapper v3 software (Applied Biosystems, Forster City, CA, United States) as described previously^[9]. A sample was scored as showing LOH, if one of the alleles had decreased 40% or more, and borderline LOH or allelic imbalance, if the decrease was 25%-39% for one allele.

Microsatellite instability analysis

Microsatellite instability status was determined using the Bethesda panel of 5 microsatellite markers and additional markers as described^[9,14,15]. Tumors with two or more unstable markers were considered to have high-degree microsatellite instability (MSI-H), while those with one unstable marker had low-degree microsatellite instability (MSI-L) and those with no unstable markers were microsatellite stable (MSS). MSI-H cancers were mostly excluded from this study cohort to enable the LOH study.

Immunohistochemical analysis

Four-micrometer sections from formalin-fixed paraffin-embedded tissues were mounted on silanized slides (Dako, Glostrup, Denmark) and air-dried overnight at 37 °C. After de-waxing and re-hydration in distilled water, sections were subject to heat-induced target retrieval in 1 mmol/L ethylenediaminetetraacetic acid buffer pH 8.0 for 5 min at 750 W followed by 5 min at 450 W in a microwave oven. After cooling, the slides were washed in Tris-buffered saline pH 7.2 and subsequent staining steps were performed manually with the Dako EnVision+ System, Peroxidase (DAB), according to the manufacturer's instructions (Dako, Glostrup, Denmark). In addition, after blocking endogenous peroxidase activity, and prior to incubation with the primary antibody, the sections were incubated with 10% normal (non-immune) goat serum (Dako, Glostrup, Denmark) for 30 min. The primary antibodies were purified rabbit polyclonal anti EPS8 Antibody (C-terminal, clone RB4006, Abgent, San Diego, CA, United States) and purified mouse monoclonal anti- β -catenin antibody (clone 14, BD Transduction Laboratories, Ermbodegem, Belgium). Paired tumor and normal mucosa were in the same section and the normal tissues were used as an internal reference for evaluation of staining results. β -catenin immunohistochemical staining for identification of its sub-cellular localization and the interpretation of results were performed as described^[9]. β -catenin expression was considered aberrant if there was nuclear staining of more than 10% or cytoplasmic staining of more than 50% of tumor cells (not observed in the matching normal tissue). For approximately half of the tumors, β -catenin data were available from our earlier studies^[9], while for the rest, these results were generated in the present investigation.

EPS8 mutation analysis

All coding exons of the *EPS8* gene were examined

by direct sequencing. The primer sequences and PCR conditions are given in Table 1. *EPS8* sequences were compared to that of GenBank accession number RefSeq NC_000012.10, and exon information was from Ensembl ENST00000389337. DNA mutation numbering is based on cDNA sequence where +1 corresponds to the A of the ATG translation initiation codon and the initiation codon is codon 1. Sequence changes reported here were present in sequence tracing from both the forward and reverse direction and were reproducibly found in 2 independent PCR products from cases of interest.

EPS8 methylation analysis

To search for CpG islands in the *EPS8* promoter, the EMBOSS CpG Plot program was used with default definitions (<http://www.ebi.ac.uk/emboss>). Two adjacent CpG islands were identified, together spanning 750 bp within and upstream of the untranslated exon number 1. This area was divided into two overlapping segments to screen cell lines and normal lymphocytes for methylation by bisulfite sequencing. The primers for the distal region were, forward, 5'-gggagatttttagggatttgatgg-3' and reverse, 5'-ccaaattatcaaaaccacaatcaaaatc-3', and for the proximal region (closest to and in part including the untranslated exon 1), forward, 5'-ttagttagttttgtagggatttttgg-3' and reverse, 5'-ctaactactacataaaatctaaacc-3'. Only the distal region showed any evidence of methylation, which is why we focused on this region when designing methylation-specific PCR (MSP) assays for the studies of patient specimens.

MSP^[11] was performed to separately amplify either methylated or unmethylated alleles from the distal region of the *EPS8* promoter (see above). Two alternative pairs of primers (MF1 + MR1, or MF3 + MR3) were used for the methylated reaction, and primers UF1 + UR1 for the unmethylated reaction. The primer sequences were: MF1, 5'-tggtattatagatgcggttttggttgc-3', MR1, 5'-gtataaaaacttcgccccgcagc-3'; MF3, 5'-ggtgttgaattgagcgttttttc-3', MR3, 5'-aacgtataaaaacttcgccccgc-3'; and UF1, 5'-ttggttagatgtgttttggttt-3', UR1 5'-ccaacaaaataaacacccccaaaca-3'. DNA (1 μ g) was modified with sodium bisulfite treatment (CpGenome DNA Modification kit, Chemicon) and subjected to MSP. MSP was performed in a volume of 25 μ L containing 24 ng of bisulfite-modified template per reaction with HotStarTaq DNA polymerase (Qiagen). Cycling conditions were according to the manufacturers' standard cycling protocol for HotStarTaq DNA polymerase, with 35 cycles. Annealing temperatures were 58 °C for the methylated reaction MF1 + MR1, 64 °C for the methylated reaction MF3 + MR3, and 58 °C for the unmethylated reaction. MSP products were run through 2%-3% agarose gel, stained with ethidium bromide, and visualized with ultraviolet transillumination. All sodium bisulfite modifications and MSP runs were repeated at least twice. A negative control without template was included in each MSP run.

RESULTS

RKO is a special colon cancer cell line as it lacks constitu-

EPS8: Epidermal growth factor receptor pathway substrate 8; PCR: Polymerase chain reaction; F: Forward; R: Reverse.

tive β -catenin regulated transcription compared to other colon cancer cell lines^[8]. To detect genes that show the most remarkable differential expression in the RKO cell line compared to all the other cell lines (HCA7, KM12, LoVo, DLD1, HCT116, SW48, and LIM1215, each being mismatch repair-deficient like RKO), maximum deviance in signal between RKO and the remaining lines was calculated for each Affymetrix probe. When identifying putative over-expressed genes, the deviance was defined as the difference between the signal in RKO and the maximum signal in the other cell lines. In the case of under-expressed genes, the deviance was defined as the difference between the signal in RKO and the minimum signal in the other cell lines. The Affymetrix probe “202609_at” corresponding to the *EPS8* gene showed remarkable reduction in the RKO cell line when compared to the other cell lines. The signal detected in RKO was 118, whereas the other cell lines showed signals of 1454, 1361, 3792, 429, 683, 758 and 1804 (Log2 ratio-3.53).

Most patient samples were MSS apart from 5/43 (12%) which showed the MSI phenotype. By immunohistochemical analysis of clinical specimens, normal colonic mucosa showed dot-like supranuclear cytoplasmic expression pattern of EPS8 protein (Figure 1A). In some cases we noticed a gradient of expression with more intense staining at the luminal surface that faded away towards the intestinal crypts (Figure 1B). Colorectal adenomas and carcinomas showed three patterns of expression compared to their matching normal mucosae. 19 (4 adenoma, 15 carcinoma) out of 51 tumors (37%) showed tumor specific EPS8 protein loss, 5 (2 adenoma, and 3 carcinoma) out of 51 (10%) showed marked overexpression, while 27/51 tumors (53%) showed retained expression comparable to what was observed in the matching normal mucosae (Table 2, Figure 1C-F). However, there was no significant correlation between EPS8 expression pattern and β -catenin subcellular localization (in contrast to the finding in the RKO cell line), or tumor stage and location within the colon.

Table 2 Analysis of epidermal growth factor receptor pathway substrate 8 gene status and protein expression in uncultured tumor specimens *n* (%)

	Total number	Membranous β -catenin	LOH ¹	EPS8 protein loss	EPS8 mutation ²	Methylation ³
Sporadic carcinomas	22	10/22 (45)	7/19 (37)	11/22 (50)	0/11	0/7
Sporadic adenomas	15	4/10 (40)	6/15 (40)	4/14 (29)	0/4	ND
FCC-X	21	11/18 (61)	7/17 (41)	4/15 (27)	ND	ND
Total	58		20/51 (39)	19/51 (37)	0/15	0/7

¹Based on informative (i.e., constitutionally heterozygous) cases; ²Cases with protein loss by immunohistochemistry and/or presence of loss of heterozygosity (LOH) were selected for this analysis; ³Cases were selected on the basis of immunohistochemical protein loss without LOH. ND: Not done; FCC-X: Familial colon cancer type X; EPS8: Epidermal growth factor receptor pathway substrate 8.

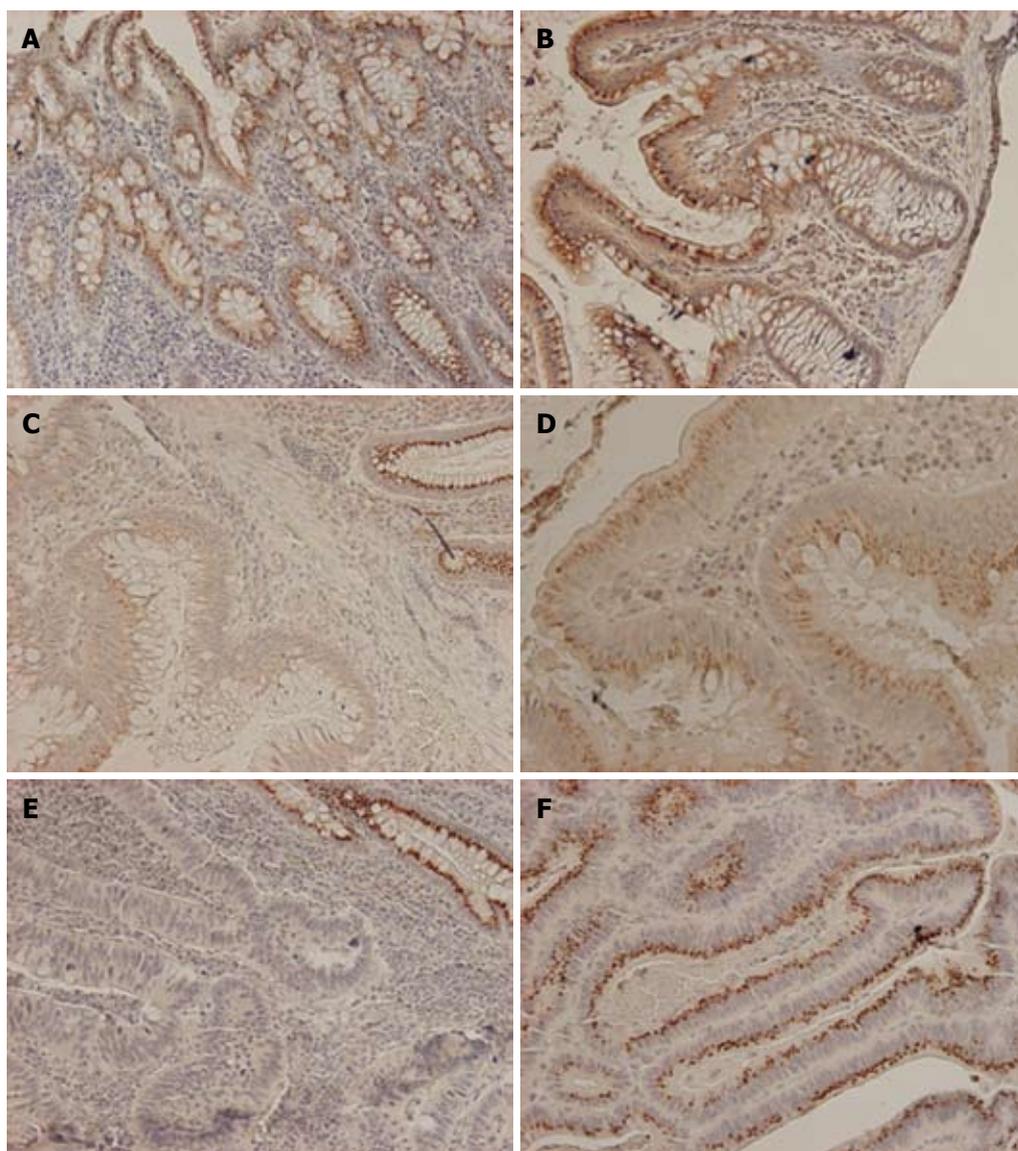

Figure 1 Epidermal growth factor receptor pathway substrate 8 immunohistochemistry. A: Normal colon mucosa with dot-like, supranuclear expression; B: Normal colon mucosa with clear gradient of expression stronger at the luminal aspect compared to the crypt bases; C: Marked reduction to complete loss of epidermal growth factor receptor pathway substrate 8 (EPS8) expression in adenoma (lower left) compared to normal mucosa (upper right); D: EPS8 positive adenoma; E: Marked reduction to complete loss of EPS8 expression in carcinoma (lower left) compared to normal mucosa (upper right); F: EPS8 positive carcinoma.

As possible mechanisms underlying expression changes, LOH, mutation, and promoter methylation were evaluated. We report LOH at EPS8 locus if, at least, one of the two markers D12S1580 and D12S1728 showed a clear cut

LOH (40% or more reduction) while borderline-LOH (ratio reduction ranging from (25%-39%) at one marker only was ignored. Overall, 20/51 (39%) tumors showed *EPS8* locus LOH with similar frequencies in adenomas (40%)

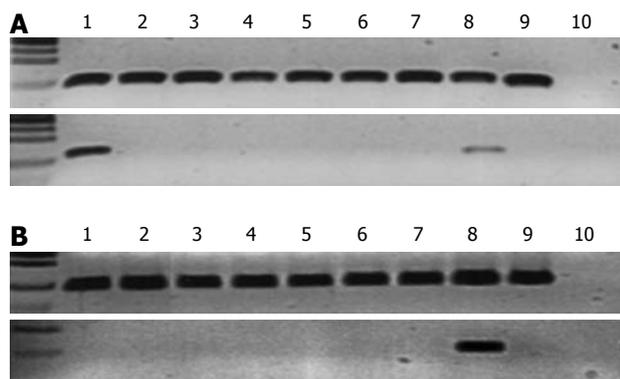

Figure 2 Methylation-specific polymerase chain reaction assays for epidermal growth factor receptor pathway substrate 8 gene. A: Cell lines analysis; upper panel is the unmethylated (UF1 + UR1) reaction and lower panel is the methylated (MF1 + MR1) reaction. Sample order in both panels from left to right is 1, RKO; 2, LoVo; 3, LIM1215; 4, HCA7; 5, HCT116; 6, KM12; 7, HCT15; 8, TK6 (a lymphoblastoid cell line); 9, unmethylated (negative) control; 10, water; B: Primary uncultured colon cancer analysis; upper panel is the unmethylated reaction and lower panel is the methylated reaction (MF3 + MR3). Sample order in both panels from left to right is 1-7, uncultured colon cancer specimens; 8, RKO (used as methylated control); 9, unmethylated (negative) control; 10, water.

and carcinomas (37%-41%) (Table 2). LOH was observed in 6/16 (38%) of informative tumors with absent *EPS8* protein *vs* 9/39 (23%) of cases with retained or elevated protein expression ($P = 0.53$).

All coding exons and flanking intronic regions of the *EPS8* gene were examined by direct sequencing. The focus of this analysis was the cell line RKO and tumors with loss of *EPS8* expression and/or LOH. We also included one of the control cell lines (HCA7 because of other special features^[16]). We identified only one tumor specific missense mutation c.794C>T (p.R265C) in exon 8 in the RKO cell line. Since the matching normal tissue for the RKO cell line was not available, we further analyzed more than 100 normal DNA samples and none of them showed this change. To our knowledge, this nucleotide change is also not reported in any sequence or single nucleotide polymorphism (SNP) database. The nature of the amino acid change suggests that this is not likely to be a SNP since Arginine (R) is a positively charged, large polar amino acid that mostly prefers to substitute for the other positively charged amino acid Lysine, although in some circumstances it will also tolerate a change to other polar amino acids, but substitution with the small amino acid cysteine (C) is not tolerated in any cellular location^[17]. We tested this particular substitution using the SIFT program (<http://blocks.fhcrc.org/sift/SIFT.html>) that sorts intolerant from tolerant amino acid substitutions based on evolutionary conservation, and cysteine substitution was regarded as intolerant.

Regarding *EPS8* methylation analysis, our very first observation was that the well-established human lymphoblastoid cell line TK6 was methylated in the distal region of the *EPS8* promoter, which indicated that the promoter was sensitive to methylation in general (Figure 2A). *EPS8* promoter methylation was examined by bisulfite sequencing in all cancer cell lines. These included

cell lines in which the *MLH1* promoter was known to be methylated (RKO, KM12, HCA7) as well as cell lines with unmethylated *MLH1* promoter (HCT15, HCT116, LoVo, LIM1215)^[11]. Only RKO was methylated (Figure 2A). Encouraged by *EPS8* methylation in RKO, we designed MSP reactions to investigate *EPS8* methylation status in patient specimens of colorectal cancer. We focused on those cases that had no LOH at chromosome 12 markers (including cases that were uninformative for LOH), yet *EPS8* protein was reduced or lost by immunohistochemistry, suggesting that there had to be alternative mechanisms for inactivation. There was no methylation in any of the seven tumor specimens analyzed, including five MSS tumors and two with MSI (Figure 2B). Given the lack of methylation in these samples of perhaps the highest interest, we did not extend these analyses to additional specimens.

DISCUSSION

Our data shed light on the role of *EPS8* in tumorigenesis in several important respects. *EPS8* is involved in actin dynamics through its actin barbed-end capping activity and its ability to modulate Rac activity. Accordingly, *EPS8* is crucial for the formation of actin networks that support cellular structures such as lamellipodia, filopodia, stress fibers and focal adhesions^[18]. It appears that this is the most significant function of *EPS8* in carcinogenesis also, since it did not colocalize with epidermal growth factor receptors but colocalized with F-actin in circular ruffles and at the leading edge of pancreatic cancer cells^[19]. The data presented here support an important role of *EPS8* in maturation and differentiation of the normal human colonic mucosa since normal colonic mucosa showed strong constitutive supranuclear cytoplasmic expression of *EPS8* with increasing intensity towards the luminal surface away from the crypt base. These data are consistent with the well established role of *EPS8* in the maturation of intestinal epithelium in *C. elegans*^[5] and the previously described expression pattern in pancreatic ductal cells^[19]. Potential roles of *EPS8* in normal colonic epithelium might include the migration of proliferating cells from the bases of the crypt to the colonic luminal surface and/or stabilization of cell-cell junctions, as *EPS8* was shown to be involved in cell-cell junction stability in fibroblasts^[20], and *EPS8* knockdown impaired actin cell-cell junction in confluent pancreatic cancer cells^[19].

Regarding colon carcinoma, we noticed high levels of *EPS8* mRNA in all cell lines except RKO. However, immunohistochemical analysis of *EPS8* protein in uncultured tumor biopsies showed that only around 10% of uncultured patient biopsies showed protein overexpression. This discrepancy between the cell line mRNA approach and patient biopsies' protein expression was consistent with the observation in pancreatic ductal adenocarcinomas^[19] and may be explained by the apparent need of the cell lines to over-express motility and invasion markers. We are currently undertaking studies to ex-

plore the role of miRNA in posttranscriptional regulation of EPS8 protein expression. However, studies showed good correlation between mRNA and protein levels within the same tumor model^[21].

The remarkable finding in this work was loss of EPS8 protein expression in subsets of colon adenoma and carcinoma. This finding is intriguing given the large number of published reports on EPS8 upregulation in different types of cancers, including those of the colon^[7,19,22-24]. We also noted this upregulation at the levels of mRNA and protein expression in some tumors as discussed above. A careful analysis of the published reports shows, however, that most cases of EPS8 upregulation were characteristic of advanced stage and metastatic cancers^[7,19,23,24]. The published literature suggests that EPS8 is most likely to be upregulated at the stage of metastasis. This hypothesis is best highlighted by the finding of EPS8 upregulation in the metastatic cell line SW620 as compared to its primary colon cancer cell line SW480^[7]. These two cell lines are a well established model that have been used to study the markers associated with metastasis in colon carcinomas^[25,26]. Similarly, the metastatic HN12 cells expressed high levels of EPS8 compared to its primary squamous cell carcinoma-derived cell line HN4^[22]. In pancreatic cancer, cell lines from primary tumors had low levels of *EPS8* mRNA expression; cell lines from pancreatic cancer metastases had medium levels of *EPS8* mRNA expression; and a cell line derived from malignant ascites (AsPC-1) had high levels of *EPS8* mRNA expression^[19]. These data could explain the apparent lack of mutation in our study, particularly in those tumors with loss of EPS8 protein which should leave a space for upregulation and overexpression at later stages; since reversion mutations are known to be extremely rare. In this regard, epigenetic and other regulatory mechanisms that could be easily reversed would be a preferable mode for controlling this gene expression status. Consistent with this, we noted the susceptibility of the *EPS8* promoter to methylation in the lymphoblastoid TK6 cells (Figure 2A) and its methylation in the RKO cell line associated with EPS8 mRNA underexpression. This is in agreement with RKO being a prototype of CpG island methylator phenotype that is usually observed in combination with MSI tumors^[27]. We, however, did not observe promoter methylation in the primary tumors considered to have the highest a priori likelihood for methylation, suggesting that *EPS8* inactivation in these tumors occurred by other, as yet unknown mechanisms.

In conclusion, we report EPS8 loss of expression in colorectal adenomas and carcinomas and propose that EPS8 downregulation plays a role in the development of these tumors.

Esa Perkiö is thanked for help in methylation analyses, Saira Saarinen for expert technical assistance throughout this work and Sanna Heino and Tiina Wirtanen for technical advice through the microarray experiment.

COMMENTS

Background

Epidermal growth factor receptor pathway substrate 8 (EPS8) is a 97-kDa protein that is required for intestinal cell maturation. EPS8 was recently shown to be overexpressed in advanced stage human cancers including colon cancer cells. In this study, the authors analyzed EPS8 status in colorectal cancers.

Research frontiers

This work applies multiple approaches to gain insight into the expression status of EPS8 in colorectal cancer cell lines and primary tumors. Furthermore, it sheds light on the possible mechanisms of the observed expression alterations.

Innovations and breakthroughs

The remarkable finding in this work was loss of EPS8 protein expression in colorectal adenoma and carcinoma. This finding is intriguing given the previously published reports on EPS8 upregulation in different types of cancers, including those of the colon. Thus, the results show, for the first time, that EPS8 downregulation plays a role in the development of subsets of colorectal tumors.

Applications

The current findings could have applications in diagnosis and treatment of a subset of colon tumors. The observed expression differences of EPS8 here raise a note of caution about generalization of the previously reported findings of EPS8 overexpression in some tumors and re-emphasize the significance of personalized medicine in the treatment of cancer patients.

Peer review

It is an interesting study worth to be considered.
