Abstract

AIM: To investigate the significance of the surgical approaches in the prognosis of hepatocellular carcinoma (HCC) located in the caudate lobe with a multivariate regression analysis using a Cox proportional hazard model.

METHODS: Thirty-six patients with HCC underwent caudate lobectomy at a single tertiary referral center between January 1995 and June 2010. In this series, left-sided, right-sided and bilateral approaches were used. The outcomes of patients who underwent isolated caudate lobectomy or caudate lobectomy combined with an additional partial hepatectomy were compared. The survival curves of the isolated and combined resection groups were generated by the Kaplan-Meier method and compared by a log-rank test.

RESULTS: Sixteen (44.4%) of 36 patients underwent isolated total or partial caudate lobectomy whereas 20

(55.6%) received a total or partial caudate lobectomy combined with an additional partial hepatectomy. The median diameter of the tumor was 6.7 cm (range, 2.1-15.8 cm). Patients who underwent an isolated caudate lobectomy had significantly longer operative time (240 min *vs* 170 min), longer length of hospital stay (18 d *vs* 13 d) and more blood loss (780 mL *vs* 270 mL) than patients who underwent a combined caudate lobectomy ($P < 0.05$). There were no perioperative deaths in both groups of patients. The complication rate was higher in the patients who underwent an isolated caudate lobectomy than in those who underwent combined caudate lobectomy (31.3% *vs* 10.0%, $P < 0.05$). The 1-, 3- and 5-year disease-free survival rates for the isolated caudate lobectomy and the combined caudate lobectomy groups were 54.5%, 6.5% and 0% and 85.8%, 37.6% and 0%, respectively ($P < 0.05$). The corresponding overall survival rates were 73.8%, 18.5% and 0% and 93.1%, 43.6% and 6.7% ($P < 0.05$).

CONCLUSION: The caudate lobectomy combined with an additional partial hepatectomy is preferred because this approach is technically less demanding and offers an adequate surgical margin.

INTRODUCTION

The caudate lobe is a segment of the liver that is surgically difficult to approach because of its deep location in the hepatic parenchyma^[1-3]. The anatomic relationship of the caudate lobe to the hepatic vasculature was initially described by Couinaud. The caudate lobe is located anterior to the inferior vena cava (IVC), which may envelop this structure circumferentially. It extends to the hilum of the liver just posterior to the bifurcation of the portal vein. Cephalad, the caudate lobe lies posterior to the confluence of the left and middle veins as they enter the IVC on the left^[4].

The caudate lobe is generally divided into three regions: the left Spiegelian lobe, the process portion and the paracaval portion. As these regions are supplied by different vasculobiliary branches of the portal triad and they are drained separately by branches of the hepatic veins, each region can be resected independently, thus making partial caudate lobectomy possible^[5].

Caudate lobectomy is commonly indicated for hepatocellular carcinoma (HCC). It has been performed infrequently in the past, partly because of technical difficulties and the inadequate understanding of the anatomy^[5-7]. Precise anatomic knowledge of the caudate lobe, and improvement in perioperative care and the surgical techniques have resulted in more performance of caudate lobectomies. However, caudate lobectomy remains a technical challenge, even for experienced hepatic surgeons. Caudate lobectomy is classified as total or partial lobectomy, and as isolated caudate lobectomy or caudate lobectomy combined with an additional partial hepatectomy. This study aimed to evaluate the surgical outcomes of caudate lobectomy and the optimal surgical approach for HCC in the caudate lobe.

MATERIALS AND METHODS

Study subjects

Thirty-six patients with HCC underwent caudate lobectomy at the Department of Hepatobiliary Surgery and Liver Transplantation Surgery, Navy General Hospital between January 1995 and June 2010. Informed consent was obtained from each patient. Surgical outcomes for patients who underwent isolated caudate lobectomy or caudate lobectomy combined with an additional partial hepatectomy were compared. The data were collected prospectively and analyzed retrospectively.

Procedure

The surgeries of this series were completed over the past

15 years. The choice of approach mainly depended on the prevailing conditions and surgeon's experience. Surgery was performed through a bilateral subcostal incision in eight patients, while a Mercedes-Benz incision was used in 28 patients. After an exploratory laparotomy, the liver was fully mobilized from all its peritoneal attachments. The liver was then assessed with intraoperative ultrasound. We carefully searched the abdominal cavity for the extent of local disease, extrahepatic metastases and peritoneal seedings. In this series, three approaches were used^[8,9]: (1) a left-sided approach for tumors situated mainly in the Spiegelian lobe, or when a caudate lobectomy was combined with a left hepatectomy; (2) a right-sided approach for tumors situated mainly in the caudate process or paracaval portion, or when a caudate lobectomy was combined with a right hepatectomy; and (3) a bilateral approach for tumors situated in the whole caudate lobe. Although we started with one particular surgical approach in most patients, we had to combine different approaches to facilitate the caudate lobectomy. The suprahepatic and infrahepatic IVC was slung with vascular loops. Resection began with a pringle maneuver in cycles of 15/5 min of clamp/unclamp times. Total vascular exclusion was used only when patients had excessive bleeding from a lacerated IVC or hepatic vein. Liver resection was carried out by a clamp crushing method.

Statistical analysis

The survival curves of the isolated and combined resection groups were generated by the Kaplan-Meier method and compared with a log-rank test. To investigate the prognostic significance of the operative procedure, we performed a multivariate regression analysis with a Cox proportional hazard model, using a variable-selection method by a backward-elimination procedure. $P < 0.15$ was set as the cutoff for elimination. In the multivariate analysis, we chose 12 factors as potential confounders, considering their clinical significance and the results of previous reports^[10,11]. Because any factors that are of potential importance can be incorporated into a multivariate analysis, whether or not they are statistically significant^[12], we entered some nonsignificant factors in the univariate analysis into the model of the multivariate analysis in the present study. The 12 factors included: age (older *vs* younger than 65 years), sex, preoperative serum total bilirubin level (more *vs* less than 1 mg/dL), Child-Pugh class (A *vs* B), background liver status (cirrhosis *vs* noncirrhosis) as assessed histologically, tumor size (larger *vs* smaller than 30 mm), cancer spread (present or absent), tumor cell differentiation (well *vs* moderate or poor), serum-fetoprotein level (more *vs* less than 100 ng/mL), history of red blood cell transfusion (yes *vs* no), surgical margin (greater *vs* smaller than 5 mm) and tumor exposure (yes *vs* no). The Mann-Whitney U test and χ^2 test were used for the continuous and categorical data, respectively. All statistical analysis were performed using statistical software (SPSS 11.5 for Windows, SPSS, Inc., Chicago, IL). $P < 0.05$ was considered to be statistically significant.

RESULTS

During the study period, 36 patients (28 males and 8 females) underwent caudate lobectomy for HCC. The median age was 49 years (range 31-74 years), and 66.7% of the patients had liver cirrhosis. The median diameter of the tumor was 6.7 cm (range 2.1-15.8 cm). Tumors were present in all three parts of the caudate lobe in 11 patients, in the Spiegel lobe in five patients, in the paracaval portion in five patients, in the caudate process in three patients, in the paracaval portion and caudate process in five patients, and in the Spiegel and paracaval portion in 7 patients. The comparative data are shown in Table 1.

Surgical procedures

The operative procedures are listed in Table 2. Sixteen patients (44.4%) received an isolated complete or partial caudate lobectomy, whereas 20 (55.6%) underwent a

complete or partial caudate lobectomy combined with an additional partial hepatectomy. Five patients required a partial resection and repair of the IVC because of tumor invasion into the anterior wall of the IVC. The left-sided, right-sided and bilateral approaches were used in 6, 4 and 26 patients, respectively.

Surgical outcomes

The surgical outcomes were compared between isolated caudate lobectomy and caudate lobectomy combined with an additional partial hepatectomy. The median operating time was 198 min (range 150-310 min) and the median blood loss was 620 mL (range 150-1470 mL). Patients that underwent an isolated caudate lobectomy had significantly longer operative time, length of hospital stay and blood loss than patients who underwent caudate lobectomy combined with an additional partial hepatectomy ($P < 0.05$). There were no perioperative deaths in both groups of patients. Patients that underwent an isolated caudate lobectomy had a higher complication rate than those who underwent caudate lobectomy combined with an additional partial hepatectomy (31.3% *vs* 10.1%, $P < 0.05$, Table 3).

The 1-, 3- and 5-year disease-free survival rates for the isolated caudate lobectomy and the combined caudate lobectomy groups were 54.5%, 6.5% and 0% and 85.8%, 37.6% and 0%, respectively ($P < 0.05$, Figure 1A). The corresponding overall survival rates were 73.8%, 18.5% and 0% and 93.1%, 43.6% and 6.7% ($P < 0.05$, Figure 1B). Multivariate analysis identified combined resection as significantly influencing the overall survival rate and the disease-free survival rate (Table 4).

DISCUSSION

Although studies on caudate lobectomies have been increasingly reported, most of them were single case reports or small series reports^[13-15]. Some series contained cases of caudate lobectomy carried out for microscopic involvement of hilar cholangiocarcinoma^[16]. Comparative studies are very rare.

Caudate lobectomy is classified as a total or partial resection, and is also classified as an isolated or combined resection^[17]. Several approaches have been described for caudate lobectomy, including the left-sided approach, right-sided approach, combined left- and right-sided approach and the anterior transhepatic approach. Peng *et al.*^[18] also described the retrograde approach for resecting tumors in the caudate lobe that had invaded the IVC. The selection of an appropriate surgical approach is essential for a safe caudate lobectomy. When the tumor is large or the IVC and/or major hepatic vein is compressed by the tumor, caudate lobectomy is technically very difficult and the resection has to be carried out using a combination of different approaches^[19].

In an isolated caudate lobectomy, especially for a bulky tumor, it is important to recognize the danger of tearing the middle hepatic vein posteriorly when the caudate lobe is dissected away from this vein. To prevent major hemorrhage from a torn middle hepatic vein, the common trunk of the middle and left hepatic veins should be isolated and slung with a vascular loop before any attempt is made to dissect the caudate lobe within the tunnel formed by the IVC and the hepatic veins^[20]. In a caudate lobectomy that is combined with either a right or left hepatectomy, a caudate lobectomy can be performed with little danger of bleeding from the middle hepatic vein since this vessel is usually controlled extrahepatically, or it can be sacrificed and resected together with the

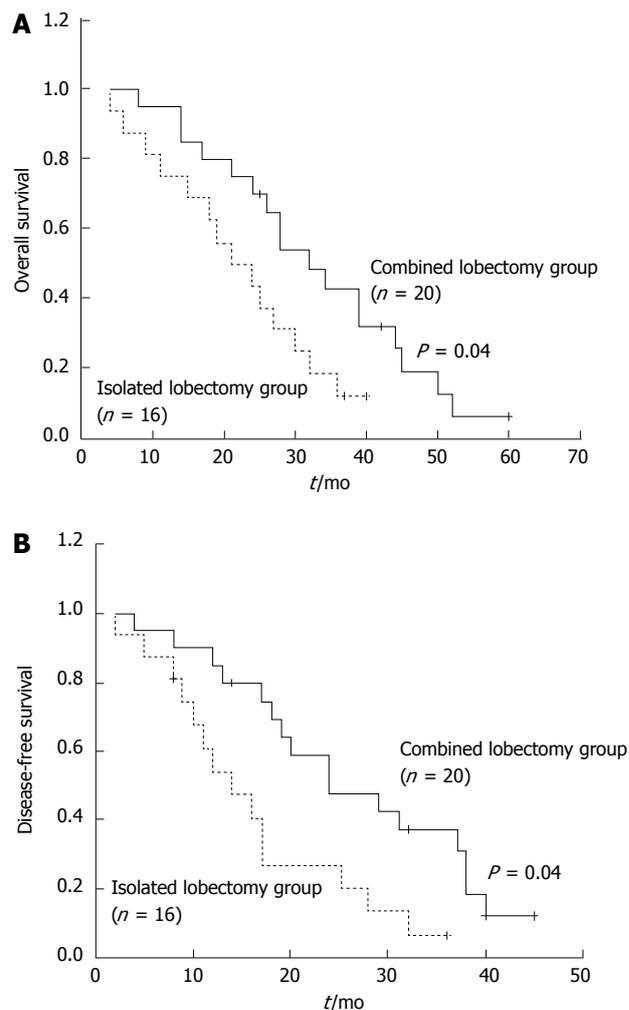

Figure 1 Overall survival rate curves and disease-free survival rate curves after isolated and combined resections for hepatocellular carcinoma originating from caudate lobe. A: Overall survival rate curves after isolated and combined resections for hepatocellular carcinoma originating from caudate lobe; B: Disease-free survival rate curves after isolated and combined resections for hepatocellular carcinoma originating from the caudate lobe.

specimen. Thus, an isolated caudate lobectomy is technically more difficult than a caudate lobectomy combined with either a right or a left hepatectomy.

The choice of isolated or combined resection is based primarily on the extent of HCC invasion and liver function reserve. The group that had an isolated resection of the tumor was characterized by well-differentiated, capsule intact, and poor liver function reserve, which could be easily removed. On the contrary, the group that had a combined resection of the tumor was characterized by poorly-differentiated, capsule incomplete, and better liver function reserve, which could be ablated with an extended resection to achieve the purpose of a complete resection.

We found that the isolated resection group had a worse long-term prognosis than the combined resection group. The main reasons were related to the following factors. First, the caudate lobe HCC was very close to the other lobe with limited growth space. Especially when the tumor was located in the paracaval part, it often infil-

Table 4 Multivariate analysis

¹Cancer spread was defined by presence of microscopic vascular invasion and/or intrahepatic metastasis.

trated the other lobe, such as segment IV, V, VI, VII or VIII. Due to the unclear boundary, an isolated resection of the tumor could not achieve a complete resection. Second, the caudate HCC was often close to the main branch of the main portal and hepatic veins, which increased the likelihood of vascular invasion leading to an inadequate surgical margin. A caudate lobe resection combined with the other lobe could obtain a clear exposure and acquire a more adequate surgical margin. Third, from the no-touch point of view, repeated over-turning and pulling on the caudate lobe can cause HCC cells to transfer to other locations along the portal vein and hepatic vein, increasing the possibility of metastasis in the isolated resection. Although the anterior approach can avoid this problem, its application is limited by varying degrees of liver cirrhosis. The anterior approach required segment IV resection, which prolonged the operation time and increased the amount of bleeding^[21]. Obtaining a negative margin may not be easy particularly in large and very large HCC, especially for those located in the caudate lobe^[22-24]. Therefore, the style of the combined resection can solve the above problem, which is an optimal method. We advocate that the caudate lobe should be ablated from the combined adjacent lobe to get an adequate margin and reduce the stretching and compression of the tumor, thereby achieving a good long-term prognosis.

If confounders in a multivariate analysis are limited only to the significant factors in a univariate analysis, some factors, which are not significant despite their potential importance, may be excluded. Therefore, according to Tralhão *et al.*^[25], we chose 12 factors as confounders, after weighing their clinical importance, whether or not they were significant in the univariate analysis. Indeed, this method was also adopted in a previous study^[26,27]. The present study indicated that anatomic resection would be a suitable option of choice for HCC. Our multivariate analysis showed that liver function was an important prognostic factor for the overall survival, though the Child-Pugh class between the two groups showed no difference. In the other study, we found that segmentectomy or lobectomy might be recommended as an initial treatment for patients with good hepatic func-

tion and a solitary hepatic nodule because such patients have a chance of achieving long-term survival and wider surgical resections could minimize the chance of microscopic residual tumors or occult metastases^[28-32].

Approaches to a caudate lobectomy thus depend largely on the size and location of the lesion and liver functional reserve. For patients with sufficient liver functional reserve, partial or complete caudate lobectomy combined with other partial hepatic resections is preferred because such an operation is technically less demanding. For patients with a poor liver function, we are left with no choice but to carry out an isolated caudate lobectomy. HCC originating from the caudate lobe is relatively rare. As the study sample is small, a more accurate conclusion requires a multi-center randomized controlled study to confirm our results.

COMMENTS

Background

The caudate lobe is a segment of the liver that is surgically difficult to approach because of its location deep in the hepatic parenchyma, which is surrounded by branches of the porta hepatis, the hepatic veins and the inferior vena cava (IVC). Caudate lobectomy is commonly indicated for hepatocellular carcinoma (HCC). Currently, caudate lobectomy remains a technical challenge, even for experienced hepatic surgeons. This study gives some instructions for hepatectomy for HCC located in the caudate lobe, with the choice of isolated or combined lobectomy.

Research frontiers

Caudate lobectomy is classified as total or partial lobectomy; it is also classified as isolated caudate lobectomy or caudate lobectomy combined with an additional partial hepatectomy. The selection of an appropriate surgical approach is essential for a safe caudate lobectomy.

Innovations and breakthroughs

Although increasing numbers of studies on caudate lobectomy have been reported in the medical literature, most are single case reports or small series studies. Some series contained cases of caudate lobectomy carried out for microscopic involvement of hilar cholangiocarcinoma. Comparative studies are very rare. In this paper, 36 patients with HCC underwent caudate lobectomy at a single tertiary referral center between January 1995 and June 2010. The surgical outcomes of patients who underwent isolated caudate lobectomy or caudate lobectomy combined with an additional partial hepatectomy were compared. For patients with sufficient liver functional reserve, caudate lobectomy combined with an additional partial hepatectomy is preferred because such an approach is technically less demanding and offers an adequate surgical margin. For patients with a marginal liver functional reserve, the viable surgical option is an isolated caudate lobectomy.

Applications

This study showed that, in patients with sufficient liver functional reserve, a caudate lobectomy combined with an additional partial hepatectomy is preferred because such an approach is technically less demanding and achieves adequate surgical margin. However, for patients with marginal liver functional reserve, the viable surgical option is an isolated caudate lobectomy.

Terminology

Caudate lobectomy is classified as total or partial resection, and is also classified as an isolated or combined resection. Several approaches have been described for caudate lobectomy, such as the left-sided approach, right-sided approach, combined left- and right-sided approach and the anterior transhepatic approach. Recently, a retrograde approach for resecting tumors in the caudate lobe that have invaded the IVC has also been described.

Peer review

This manuscript emphasizes the optimal surgical approach for HCC in the caudate lobe. The manuscript sections are very clearly described and the conclusion is an opened door for further investigation. They observed that the 16 patients who underwent isolated lobectomy had longer operative times, greater blood loss, a higher complication rate, longer hospital stays and higher mortality. They concluded that, in patients with adequate functional reserve, combined hepatectomy is the preferred choice.

Abstract

AIM: To evaluate pretreatment serum carcinoembryonic antigen (CEA) as a predictor of survival for patients with locally advanced gastric cancer receiving perioperative chemotherapy.

METHODS: We retrospectively studied a cohort of 228 gastric cancer patients who underwent D2 gastrectomy combined with chemotherapy at the Sun Yat-sen University Cancer Center between January 2005 and December 2009. Among them, 168 patients received 6-12 cycles of oxaliplatin-based adjuvant (post-operative) chemotherapy, while 60 received perioperative chemotherapy (2 cycles of FOLFOX6 or XELOX before surgery and 4-10 cycles after surgery). Serum CEA was measured using an enzyme immunoassay. The follow-up lasted until December 2010.

RESULTS: In the group that had elevated serum CEA, the difference in survival time between patients receiving perioperative chemotherapy and those receiving adjuvant chemotherapy had no statistical significance ($P > 0.05$). However, in the group that had normal serum CEA, patients receiving perioperative chemotherapy had a longer survival time. In multivariate analysis, T staging and lymph node metastatic rate were independent prognostic factors for the patients. Perioperative chemotherapy improved the overall survival of patients who had a normal pretreatment CEA level ($P = 0.070$).

CONCLUSION: Normal pretreatment serum CEA is a predictor of survival for patients receiving perioperative chemotherapy.

INTRODUCTION

Gastric cancer is one of the most common cancers worldwide. It is the second leading cause of cancer deaths in the world^[1-3], and most of those patients are diagnosed at an advanced stage of disease^[4,5]. Surgery is the main

treatment for gastric cancer. Many meta-analyses have demonstrated that adjuvant (post-operative) chemotherapy can improve the prognosis for gastric cancer patients^[6-8], and in some prospective clinical trials, adjuvant chemotherapy has improved the prognosis of patients with locally advanced gastric cancer^[9-11]. The Cunningham trial showed for the first time that perioperative chemotherapy (treatment both before and after surgery) is superior to surgery alone in treating gastric cancers. Further studies showed that preoperative chemotherapy combined with chemoradiotherapy provided substantial responses that improved the prognosis^[12-14].

Carcinoembryonic antigen (CEA) was first identified in 1965 by Gold and Freedman in human colon cancer tissue extracts^[15]. In the last two decades, CEA has been widely used as a tumor marker in the diagnosis and monitoring of some malignancies^[16]. Since the 1990s, tumor markers including CEA, carbohydrate antigen 19-9, and others have been widely used to monitor gastric cancer progression and even to assess the prognosis of gastric cancer patients, although their specificities have not been satisfactory^[17-20]. The controversial conclusions resulting from the use of these biomarkers are therefore understandable^[21]. In the present study, we retrospectively evaluated the predictive value of pretreatment serum CEA in patients with late-stage gastric cancer in China.

MATERIALS AND METHODS

Patient inclusion and exclusion criteria

Inclusion criteria: (1) age: 20 to 75 years; World Health Organization performance status 0 to 1; (2) histologically proven adenocarcinoma of the stomach; T3 or T4 tumor based on endoscopic ultrasound; no evidence of distant metastases or of disease considered nonresectable by endoscopic ultrasonography, computed tomography (CT), or extended diagnostic laparoscopy; (3) no prior gastric surgery; (4) no previous radiotherapy or other treatments, including immunotherapy or Chinese traditional medicine; (5) no uncontrolled infectious or cardiac disease; adequate hepatic and renal functions; and (6) no synchronous or metachronous cancers.

Exclusion criteria: (1) age: older than 75 years or younger than 20 years; (2) hepatic, renal, pulmonary, or cardiac dysfunction; and (3) severe postoperative complications, such as anastomosis leakage or anastomosis stenosis, that may cause malnutrition or make the patients intolerant to postoperative chemotherapy.

Patient characteristics

We included 228 patients who underwent D2 gastrectomy at the Sun Yat-sen University Cancer Center between January 2005 and December 2009. Among them, 173 patients had a normal pretreatment serum CEA (≤ 5 ng/mL) and 55 patients had elevated pretreatment serum CEA (> 5 ng/mL). Sixty patients among both CEA groups (43 with normal serum CEA and 17 with

elevated serum CEA) received oxaliplatin-based perioperative chemotherapy, with 2 cycles before surgery and 4-10 cycles of the same regimen after surgery. The exception was 6 patients suffering from progressive disease who received second-line chemotherapy for 4-6 cycles (see Treatment section). Among both CEA groups, 168 patients received only adjuvant chemotherapy (Figure 1). The clinicopathological characteristics of all patients are presented in Table 1.

Treatment

The two cycles of preoperative chemotherapy included the XELOX and FOLFOX regimens. All the chemotherapy regimens were used under standard protocols. The XELOX regimen consisted of oxaliplatin at 130 mg/m² (i.v. drip, day 1) and capecitabine at 1000 mg/m² (oral,

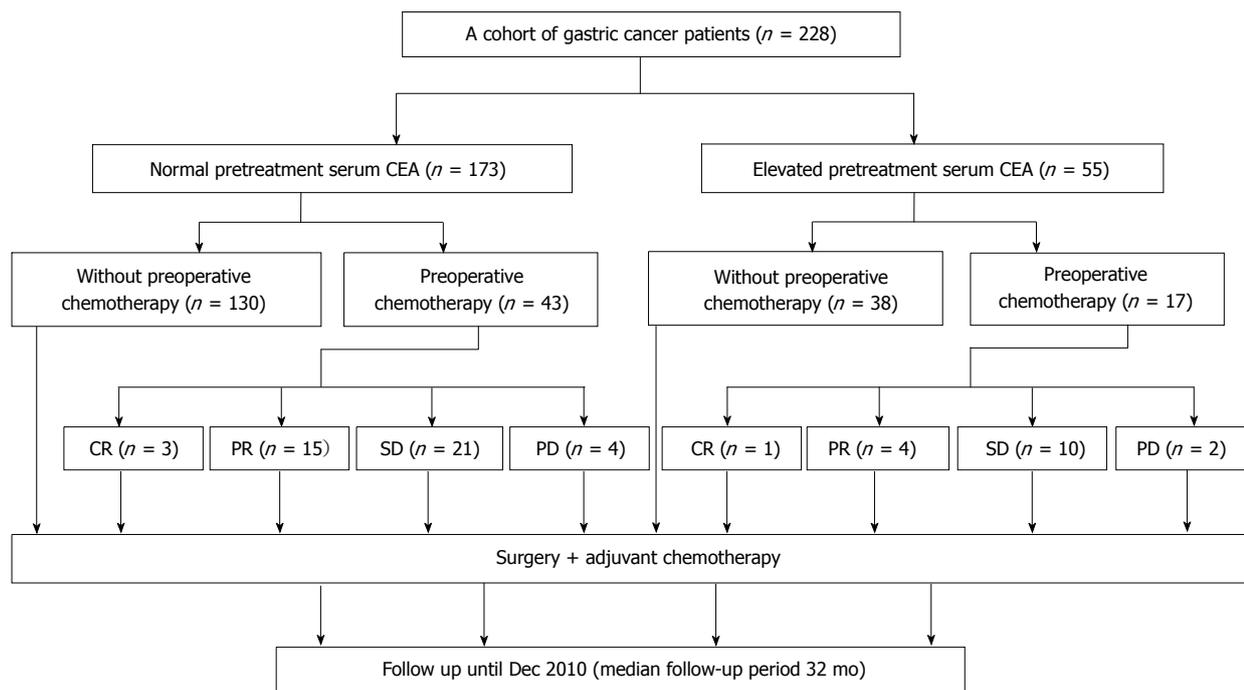

Figure 1 The treatment subgroups of the cohort of 228 patients in this retrospective study. CEA: Carcinoembryonic antigen; CR: Complete response; PR: Partial response; SD: Stable disease; PD: Progressive disease.

day 1-14), followed by one week of no treatment. Starting on day 22, the cycle was repeated, and surgery took place between day 43 and 47.

The FOLFOX6 regimen started on day 1 with oxaliplatin at 100 mg/m² (i.v. drip) with folic acid at 400 mg/m² (racemic) or 200 mg/m² (L-form), plus 5-fluorouracil (5-FU) as a 400 mg/m² bolus, followed by 2400 mg/m² of 5-FU as a continuous 46 h infusion. When the infusion was completed, there was no further treatment through day 14. On day 15, the cycle was repeated, with surgery taking place between day 30 and day 33.

After surgery, all of the patients received adjuvant chemotherapy starting within 2-4 wk. The median number of cycles for each regimen was 9 for FOLFOX6 (range: 7-12) and 7 for XELOX (range: 6-8). The six progressive disease patients received paclitaxel plus 5-FU (1 patient), docetaxel plus 5-FU (2 patients), or S-1 oral administration (3 patients) chemotherapy; these patients received a median of 5 cycles (range: 4-6).

Chemotherapy response evaluation

Assessment of the response to preoperative chemotherapy was based on the reduction of primary tumor size (as measured by endoscopic ultrasonography and CT scan) and the Response Evaluation Criteria in Solid Tumors criteria.

Complete response: Disappearance of all target lesions. Any pathological lymph nodes (whether target or non-target) must have a reduction of the short axis to less than 10 mm.

Partial response: At least a 30% decrease in the sum of diameters of target lesions, taking as a reference the baseline sum of diameters.

Stable disease: Neither sufficient shrinkage to qualify as a partial response nor sufficient increase to qualify as progressive disease.

Progressive disease: At least a 20% increase in the sum of diameters of target lesions, taking as reference the smallest sum in the study (which may include the baseline sum). The sum must also show an absolute increase of at least 5 mm.

Patient follow-up

After treatment, the patients were monitored every 3 mo for the first 2 years, then every 6 mo thereafter. Telephone calls and letters were used to assess patients who could not be physically present. Complete data were collected from all 228 patients until December 2010. The follow-up period ranged from 8 mo to 59 mo (median, 32 mo). The total follow-up times are shown in Figure 2A.

Statistical analysis

The χ^2 test was used to compare categorical variables between the normal and elevated serum CEA groups. Univariate survival analysis was performed using the Kaplan-Meier method. Survival curves were compared with the log-rank test. Multivariate statistical survival analysis was performed using Cox regression. Analysis were performed with SPSS software version 16.0 for Windows

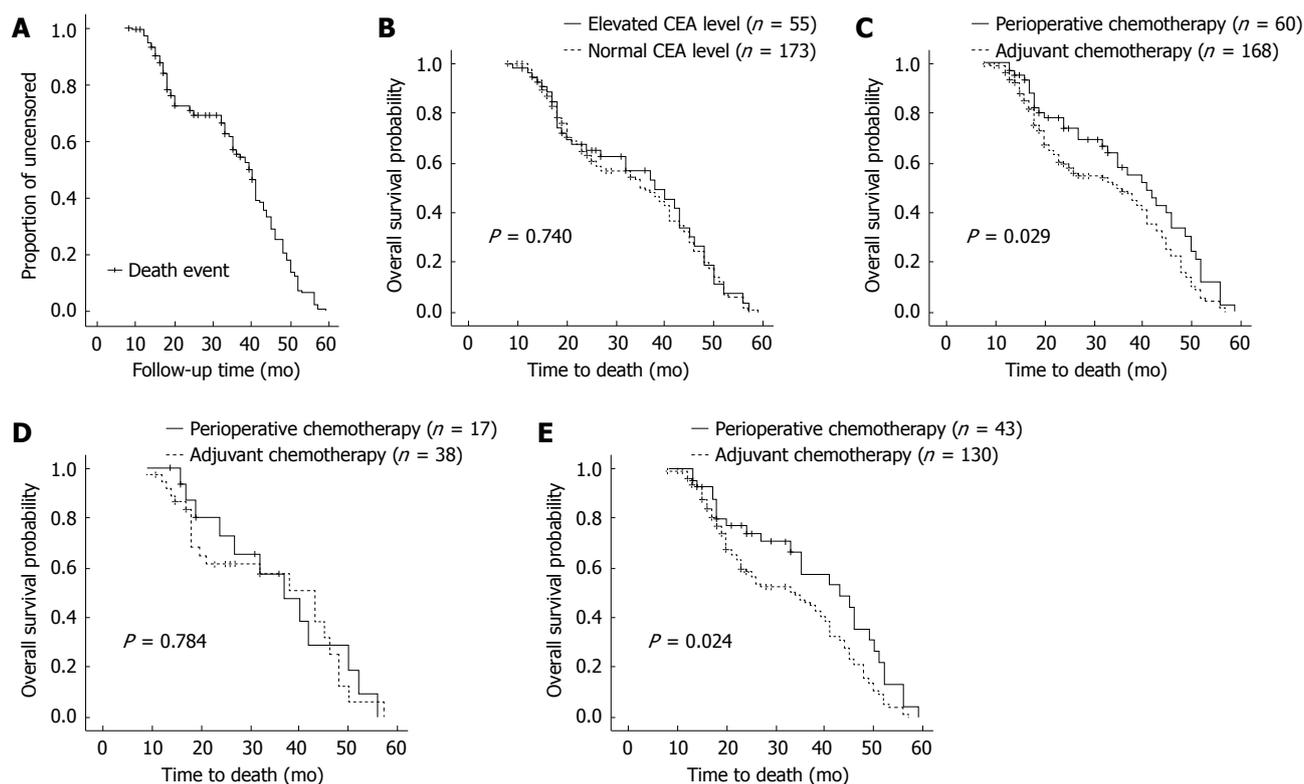

Figure 2 Survival curves for carcinoembryonic antigen patients with different treatments. A: The 228 patients in follow-up over this study; follow-up times ranged from 8 to 59 mo (median, 32 mo); B: Survival curves for the elevated carcinoembryonic antigen (CEA) patients and the normal CEA patients, with two-year survival rates of 57% and 51%, respectively, and no statistically significant difference between the groups ($P = 0.740$); C: Survival curves for patients receiving perioperative chemotherapy or adjuvant chemotherapy, with two-year survival rates of 58% and 50%, respectively. The difference is statistically significant ($P = 0.029$); D: Survival curves for the elevated CEA patients who received perioperative or adjuvant chemotherapy, with two-year survival rates of 58% and 58%, respectively, with no statistical significance ($P = 0.784$); E: Survival curves for normal CEA patients who received perioperative or adjuvant chemotherapy, with a two-year survival rate of 59% and 48%, respectively. The difference is statistically significant ($P = 0.024$).

(SPSS, Inc., Chicago, IL, United States). Statistical significance was defined as $P < 0.05$.

RESULTS

There was no statistically significant difference in overall survival between the normal CEA group ($n = 173$) and the elevated CEA group ($n = 55$). The survival curves are shown in Figure 2B.

The efficacy of preoperative chemotherapy was evaluated. Among these 60 patients, 4 (6.67%) had complete clinical response and 19 (31.7%) had partial clinical response, yielding an overall response rate of 40.0%. The response rates of the patients who had normal pretreatment serum CEA *vs* those who had elevated CEA were not significantly different, although patients with normal CEA had a higher response rate (complete response + partial response) (41.9% *vs* 29.4%). These results are shown in Table 2.

The 60 patients who received perioperative chemotherapy (i.e., preoperative plus adjuvant) had a significantly better overall survival rate than the 168 who received only adjuvant chemotherapy, with median survival time of 41 mo for the perioperative group *vs* 35 mo for the adjuvant group ($P = 0.029$). The survival curves are shown in Figure 2C. For the patients with elevated se-

rum CEA, there was no significant difference in overall survival rate between perioperative chemotherapy ($n = 17$) and adjuvant chemotherapy ($n = 38$, $P = 0.784$, Figure 2D). For the patients with normal serum CEA, the overall survival rate was significantly better in the perioperative group ($n = 43$) and the median survival time was 43 mo *vs* 34 mo for the adjuvant group ($n = 130$, $P = 0.024$). The survival curves are shown in Figure 2E.

In univariate analyses, perioperative chemotherapy, T staging, and the lymph node metastasis rate significantly correlated with overall survival (Table 3). In multivariate analysis, T staging and the lymph node metastatic rate were independent prognostic factors. Perioperative chemotherapy improved the overall survival of patients who had normal pretreatment serum CEA (Table 4).

DISCUSSION

Perioperative chemotherapy, although it is a large physical and psychological burden, has been proven to be effective for some gastric cancer patients. The European Organization for Research and Treatment of Cancer Randomized Trial 40 954 showed no survival benefit from preoperative chemotherapy compared with surgery alone for locally advanced cancer^[22]. However, this study had low statistical power; a high number of proximal

gastric cancers (which involved the gastroesophageal junction and were different from most of the cases in endemic areas); and an increased R0 resection rate, indicating a better outcome in those patients suffering from early-stage gastric cancer. In China, most gastric cancer patients are diagnosed as having locally advanced disease, suggesting that different treatments should be considered for increasing the survival of the patients. However, there is no reliable marker to determine which patients with advanced gastric cancer can benefit from perioperative chemotherapy. The goal of the present study was to determine whether the pretreatment serum CEA level could be used as a marker to select patients for this aggressive treatment.

Our study revealed that perioperative chemotherapy can improve overall survival in patients with advanced gastric cancer. Dividing the patients in two groups based

CEA: Carcinoembryonic antigen.

on their pretreatment serum CEA, we found that perioperative chemotherapy improved the survival rate only for patients with a normal level of pretreatment serum CEA.

Although the biological functions of CEA are not fully known, the close correlation of CEA with cancer aggressiveness has been known for decades. Higher preoperative CEA correlates with more aggressive gastric cancer and a lower patient survival rate^[23]. Our findings imply that patients with elevated CEA might have gastric cancers more resistant to chemotherapy, resulting in no survival benefit even from aggressive chemotherapy. CEA has been reported to have roles in homotypic adhesion and cellular aggregation^[24], and it cooperates with Myc and Bcl-2 in cellular transformation^[25]. In colon cancer, CEA is up-regulated in the microadenoma stage in the colon of patients with APC mutations^[26], and CEA plays antiapoptotic and prometastatic roles in colon cancer cells^[27]. Overexpression of CEA can protect tumor cells from apoptosis induced by loss of cell contact with the extracellular matrix (anoikis)^[28].

Interestingly, those gastric cancer cells expressing alpha-fetoprotein (which is another oncofetal antigen) show P-glycoprotein overexpression and drug resistance in both animal models and human cancer^[29,30]. In some case reports, drug-resistant patients always had elevated serum CEA^[31,32], and CEA overexpression was observed in multidrug-resistant breast carcinoma cell lines^[33]. The CEA promoter (AdCEAIacZ) can increase the IC50 of ganciclovir against gastric cancer cell lines by improving CEA production^[34]. All of these pieces of evidence suggest that CEA may induce or promote drug resistance in cancer cells.

This study is retrospective, with its own weaknesses such as confounding factors and low persuasiveness. The cycles of adjuvant chemotherapy were different among the patients, and there were two main chemotherapy regimens: XELOX and FOLFOX6. We believe that the study would be more convincing if there had been a standard regimen, although most investigators report the efficacy of these two regimens as having no statistically significant difference in gastric cancer patients. Thus, more randomized controlled trials are needed to confirm

that pretreatment serum CEA can be used as a marker to select patients for the aggressive perioperative treatment or to find other markers for assigning patients to an appropriate treatment.

To our knowledge, there is no strong evidence that CEA is a marker of drug resistance in gastric cancer. More experiments and clinical trials are needed to validate whether CEA levels can predict such drug resistance. In summary, our study showed that only patients with normal pretreatment serum CEA obtained a survival benefit from cytotoxic perioperative chemotherapy. The role of CEA in the drug resistance of gastric cancers warrants further exploration.

COMMENTS

Background

Perioperative chemotherapy has been proven to be effective for some gastric cancer patients. However, there is no reliable marker for determining which patients with advanced gastric cancer can benefit from perioperative chemotherapy.

Research frontiers

In the last two decades, carcinoembryonic antigen (CEA) has been widely used as a tumor marker in the diagnosis and monitoring of some malignancies. The research hotspot is to determine whether pretreatment serum CEA can be used as a marker to select patients for this aggressive perioperative treatment.

Innovations and breakthroughs

The study revealed that perioperative chemotherapy can improve overall survival in patients with advanced gastric cancer. After dividing the patients in two groups based on their pretreatment serum CEA, the authors found that perioperative chemotherapy improved the survival rate only for patients with a normal level of pretreatment serum CEA.

Applications

The study results suggest that normal pretreatment serum CEA is a predictor of survival benefit for the patients receiving perioperative chemotherapy.

Peer review

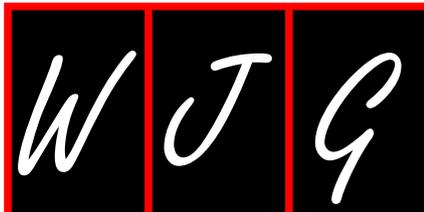

This is an interesting paper aimed to evaluate the role of pretreatment serum CEA level as a predictor of survival for patients with locally advanced gastric cancer receiving neoadjuvant chemotherapy. This retrospective study is well conducted and well written.

Abstract

Here we present the case of a 79-year-old woman who complained of acute abdominal pain, vomiting and diarrhoea. Laboratory exams demonstrated a severe metabolic imbalance. Abdominal X-rays showed bowel overdistension and pneumatosis of the stomach wall. Abdominal tomography revealed infarction of the stomach, duodenum and small bowel due to thrombosis of the celiacomesenteric trunk. Exploratory laparotomy revealed ischemia of the liver, spleen infarction and necrosis of the gastro-intestinal tube (from the stomach up to the first third of the transverse colon). No further surgical procedures were performed. The patient died the following day. To our knowledge, this is the first reported case about severe gastro-intestinal ischemia due to thrombosis of the celiacomesenteric trunk, a rare anatomic variation of the gastrointestinal vascularisation.

INTRODUCTION

The majority of the blood supply of the gastrointestinal tract is provided by the anterior branches of the abdominal aorta: celiac trunk and superior mesenteric artery. Usually, the aforementioned branches arise independently from the abdominal aorta, the first one at the level of the twelfth thoracic vertebra, the second one at the level of the first lumbar vertebra. Anomalies of vascularisation of the gastro-intestinal tract are frequent, but the presence of the celiacomesenteric trunk (derived by common origin of celiac trunk and superior mesenteric artery) is rare. The injury of the trunk can have lethal effects on the organism. Here we describe the first reported case of severe ischemia of the gastrointestinal tract due to thrombosis of the celiacomesenteric trunk.

CASE REPORT

In September 2011, a 79-year-old woman arrived at the emergency department of San Biagio hospital with severe and diffuse abdominal pain and tenderness, more marked in the lower abdominal quadrants, with signs of peritoneal irritation. The area of hepatic dullness was

Figure 1 Abdominal X-rays. Gaseous overdistension of the small bowel. The arrow points the pneumatosis of the stomach wall.

present at percussion and intestinal peristalsis was diminished. The patient was afebrile and eupneic at rest. Laboratory analyses demonstrated increased inflammatory markers (neutrophilic leukocytes, polymerase chain reaction), acute renal failure (creatinine: 5.85 mg/dL) and severe metabolic acidosis. No pathological signs were found at chest X-rays, whereas abdominal X-rays revealed gaseous overdistension of the small bowel and pneumatosis of the stomach wall (Figure 1).

The radiological findings were subsequently confirmed by computed tomography of the abdomen performed without iodinated contrast due to renal failure of the patient. Tomography demonstrated pneumatosis of the wall of the stomach, duodenum and small bowel. Air was also present within the superior mesenteric and portal veins with intraparenchymal distribution to ventral portions of the left liver and fourth segment (Figure 2A), because of the advanced stage of arterial infarction. The axial scan evidenced the thrombosis of the celiacomesenteric trunk, which justified the radiological findings (Figure 2B); no further arterial vessel directed to the gastro-intestinal tract was identified by tomography.

Exploratory laparotomy showed ischemia of the liver, spleen infarction and necrosis of the stomach, duodenum, small bowel and large intestine (from the caecum to the first third of transverse colon). No further surgical procedures were performed. The patient died the following day.

DISCUSSION

The celiac trunk and superior mesenteric artery supply the majority of the blood to the gastrointestinal tract. Usually, the celiac trunk is a short artery that arises from the anterior wall of the abdominal aorta at the level of the twelfth thoracic vertebra; it divides almost immediately into three branches: left gastric, splenic and common hepatic artery.

The left gastric artery courses upwards to the left toward the cardias, where it turns downward and, following the lesser gastric curvature, descends to the right toward the pylorus. The left gastric artery forms an ar-

In the detail: common origin of celiac trunk (CT) and superior mesenteric artery (SMA) from the CMT.

cing anastomotic loop with the right gastric artery, a branch of the common hepatic artery and, less frequently, of the gastroduodenal artery.

The splenic artery from its origin takes a short loop to the right and then runs along the cephalic border of the pancreas to supply the spleen. The splenic artery gives rise to several branches directed to the pancreas (dorsal pancreatic artery, arteria pancreatica magna, caudal pancreatic arteries) and to the stomach (left gastro-epiploic artery, short gastric arteries).

The common hepatic artery arises on the right side of the celiac trunk and runs to the right reaching the first part of duodenum, where it gives rise to a branch called the gastroduodenal artery and continues into the hepatic artery proper (some authors don't utilise this definition, but they call this branch of celiac trunk the common hepatic artery "before" or "after" the origin of the gastroduodenal artery). At the porta hepatis it divides into right and left hepatic arteries. The common hepatic artery emerges partially or entirely from the superior mesenteric artery in approximately 18% of the population.

The celiac trunk supplies the liver, stomach, pancreas and superior part of the duodenum^[1,2].

The superior mesenteric artery arises from the ante-

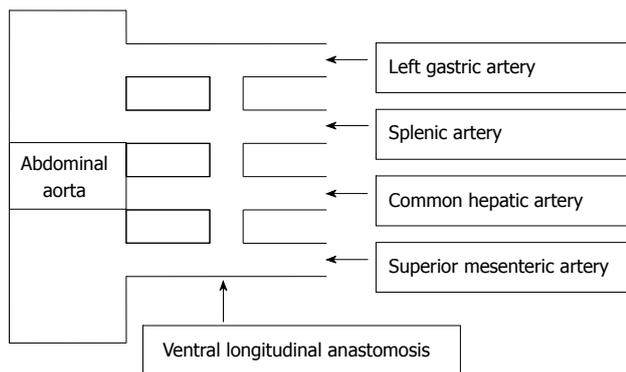

Figure 3 Primitive splanchnic vascularisation. Ventral longitudinal anastomosis (Lang's anastomosis) between four primitive splanchnic roots arising from the abdominal aorta.

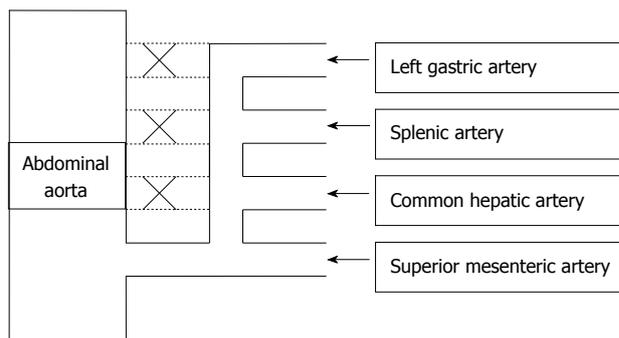

Figure 4 Celiacomesenteric trunk. Retention of the ventral longitudinal anastomosis higher than the fourth root keeps one or more celiac trunk branches with the superior mesenteric artery, disappearance of the first or fourth root causes a common celiacomesenteric trunk.

rior wall of the abdominal aorta at the level of the first lumbar vertebra. It runs down behind the head of the pancreas and ahead of the uncinat process of the pancreas and the third part of the duodenum. It descends anteriorly into the mesentery of the small intestine. Its right branches are inferior pancreatico-duodenal (this vessel forms an anastomosis with the superior pancreatico-duodenal artery, branch of the gastroduodenal artery), right colic, middle colic and ileo-colic; its left branches are 4-6 jejunal and 9-13 ileal arteries.

The superior mesenteric artery supplies the pancreas, duodenum (from the second to the fourth part), small bowel and colon from the caecum to the right half of the transverse colon^[1,2].

Variations of the normal vascularisation described above may be caused by the retention or disappearance of the roots of the primitive arterial plexus, as indicated by Tandler^[3] in 1908. The fetal digestive tube is supplied by four primitive splanchnic roots which arise from the abdominal aorta. There is a ventral longitudinal anastomosis (Lang's anastomosis) between these branches (Figure 3): the closure of the longitudinal anastomosis between the third and the fourth root and the disappearance of the central two roots lead to normal anatomy. Retention of the ventral longitudinal anastomosis higher than the fourth root keeps one or more celiac trunk branches with the superior mesenteric artery; disappearance of the first or fourth root causes a common celiacomesenteric trunk^[2,4,5]. Moreover, the simple arboriform scheme of the gastroduodenal and hepatobiliary vasculature is profoundly altered by the growth of the liver and pancreas, and by the assumption of a curved form in the stomach and duodenum. These factors operate to complicate the branching of the coeliac axis and the superior mesenteric artery^[6].

In our case, the celiacomesenteric trunk was formed by an anomalous separation of the ventral longitudinal anastomosis, with the common hepatic, left gastric and splenic arteries joining with the fourth root, as shown in Figure 4.

The celiacomesenteric trunk is one of the most striking among the different variations of the normal vascularisation of the gastro-intestinal tract^[1,2,4-7]: it is found in 1%-2% of all anomalies involving the coeliac axis^[1,8-10].

Full comprehension of the topics as knowledge of the different anatomical variations of the arterial supply of the gallbladder, liver, stomach and colon is crucial in cholecystectomy, hepatobiliary and gastro-intestinal surgical procedures^[6]. Without knowledge of the arterial architecture of the patient in this critical region, surgery may lead to a considerable risk of errors occasionally leading also to lethal complications^[11].

Different classifications of these anatomical variations are present in the literature; however the most widely used are those indicated by Morita^[12], Michels^[13] and Olry *et al*^[14]. The present case belongs to type P'b of Morita's classification and to type 6 of the Michels's classification.

The discovery of a celiacomesenteric trunk is often fortuitous during autoscopic dissections^[15-17] or can be accidentally detected by angiography or abdominal computed tomography scanning^[5,8,10]. It can accompany different clinical situations, such as aneurysm^[7,10,18], chronic occlusive disease^[9,18], compression by abdominal aorta aneurysm or aortic dissection^[18], celiac compression syndrome^[9,19], but the large gastrointestinal infarction caused by thrombosis of the celiacomesenteric trunk, to our knowledge, has never been previously reported.

In the current case, the celiacomesenteric trunk arose at the level of the first lumbar vertebra and then, after a stretch of about one centimetre, it divided in two branches, superior (hepato-gastro-splenic trunk or celiac trunk) and inferior (superior mesenteric artery). The thrombosis of the origin of the celiacomesenteric trunk had a lethal effect on the patient because it caused the full stoppage of the splanchnic arterial supply and consequent ischemia. In fact, in this rare situation a single artery is the sole source of vascularisation of the supramesocolic organs and collateral flow is only possible from the inferior mesenteric, phrenic, oesophageal and retroperitoneal arteries^[1]. Evidently, the condition of generalized atherosclerosis has prevented any collateral flow.

In conclusion, the present clinical report describes a

rare anomaly involving the celiac axis and, especially, the dramatic consequences related to the complete thrombosis of the celiacomesenteric trunk. This condition has important wide-ranging clinical implications because it compromises the blood supply of a large portion of the gastrointestinal tract and it may put at severe risk most of the abdominal viscera.

Abstract

I read with great interest the recent article by Chen *et al* in a recent issue of your esteemed journal. The article is highly thought provoking. One emerging therapeutic alternative for opioid induced constipation is the emergence of opioid/naloxone prolonged release combinations. For instance, naloxone when administered in a 1:2 ratio with oxycodone reverses the inhibitory effect of oxycodone on the gastrointestinal tract. The advantage of oxycodone/naloxone prolonged release (OXN) is that while its anti-nociceptive efficacy is equivalent to that of oxycodone prolonged release (OXC), it significantly decreases the "Bowel Function Index" thereby ameliorating symptoms of opioid induced constipation to a large extent. Schutter *et al* in a recent study have reported a decrease in the bowel function index from 38.2 to 15.1. Similarly, Löwenstein *et al* in another recent study have reported that following a month of therapy, complete spontaneous bowel movements per week is increased from one in OXC therapy to three in OXN therapy.

TO THE EDITOR

I read with great interest the article by Chen *et al*^[1] in a recent issue of your esteemed journal. The article is highly thought provoking. One emerging therapeutic alternative for opioid induced constipation is the emergence of opioid/naloxone prolonged release combinations.

For instance, naloxone when administered in a 1:2 ratio with oxycodone reverses the inhibitory effect of oxycodone on the gastrointestinal tract^[2]. The advantage of oxycodone/naloxone prolonged release (OXN) is that while its anti-nociceptive efficacy is equivalent to that of oxycodone prolonged release (OXC), it significantly decreases the "Bowel Function Index" thereby ameliorating symptoms of opioid induced constipation to a large extent. Schutter *et al*^[3] in a recent study have reported a decrease in the bowel function index from 38.2 to 15.1. Similarly, Löwenstein *et al*^[4] in another recent study have reported that following a month of therapy, complete spontaneous bowel movements per week is increased from one in OXC therapy to three in OXN therapy.

In fact, the colonic transit time is reduced by almost two hours with OXN 20/10 mg combination therapy^[5]. This is further affirmed by the fact that in patients receiving OXN therapy the mean laxative use is decreased by almost 20% while the stool consistency as measured by the "Bristol

Stool Form Scale” is improved from type 2 to type 5^[6,7].

In addition, in a recent study, the quality of life was accentuated by 47% following OXN therapy for management of chronic severe neuropathic pain^[8]. Similarly, a low mean Brief Pain Inventory Short Form “sleep interference” score is maintained with OXN therapy and is comparable to OXC therapy^[9].

Clearly, OXN therapy is highly effective in mitigating the symptoms of opioid induced constipation and provides a safe and efficacious alternative to methylnaltrexone.

Acknowledgments to reviewers of World Journal of Gastroenterology

Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of *World Journal of Gastroenterology*. The editors and authors of the articles submitted to the journal are grateful to the following reviewers for evaluating the articles (including those published in this issue and those rejected for this issue) during the last editing time period.

Hussein M Atta, MD, PhD, Professor, Department of Surgery, Faculty of Medicine, Minia University, Misr-Aswan Road, El-Minia 61519, Egypt

Giedrius Barauskas, Professor, Department of Surgery, Kaunas University of Medicine, Eiveniu Str. 2, Kaunas, LT-50009, Lithuania

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the “priority” and “copy-right” of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers’ names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t* test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homoge-

neous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/1007-9327/office>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically

for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

Instructions to authors

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of “To investigate/study/...”; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of *P* values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be la-

beled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, “Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]”. If references are cited directly in the text, they should be put together within the text, for example, “From references^[19,22-24], we know that...”.

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (<http://www.wjgnet.com/1007-9327/office/>). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1300 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Gastric cancer and liver cancer are among the most common malignancies and the leading causes of death worldwide, due to late detection and high recurrence rates. Today, these cancers have a heavy socioeconomic burden, for which a full understanding of their pathophysiological features is warranted to search for promising biomarkers and therapeutic targets. Osteopontin (OPN) is overexpressed in most patients with gastric and liver cancers. Over the past decade, emerging evidence has revealed a correlation of OPN level and clinicopathological features and prognosis in gastric and liver cancers, indicating its potential as an independent prognostic indicator in such patients. Functional studies have verified the potential of OPN knockdown as a therapeutic approach *in vitro* and *in vivo*. Furthermore, OPN mediates multifaceted roles in the interaction be-

tween cancer cells and the tumor microenvironment, in which many details need further exploration. OPN signaling results in various functions, including prevention of apoptosis, modulation of angiogenesis, malfunction of tumor-associated macrophages, degradation of extracellular matrix, activation of phosphoinositide 3-kinase-Akt and nuclear factor- κ B pathways, which lead to tumor formation and progression, particularly in gastric and liver cancers. This editorial aims to review recent findings on alteration in OPN expression and its clinicopathological associations with tumor progression, its potential as a therapeutic target, and putative mechanisms in gastric and liver cancers. Better understanding of the implications of OPN in tumorigenesis might facilitate development of therapeutic regimens to benefit patients with these deadly malignancies.

Osteopontin as potential biomarker and therapeutic target in gastric and liver cancers. *World J Gastroenterol* 2012; 18(30): 3923-3930 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i30/3923.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i30.3923>

INTRODUCTION

Gastric and liver cancers are among the most common malignancies and leading causes of death worldwide,

which carries a heavy socioeconomic burden. Until now, surgical resection has remained the frontline treatment for patients with early stage gastric and liver cancers. Nevertheless, the majority of such patients have poor prognosis due to high rates of tumor recurrence as well as lymph node (LN) and systemic metastases. Therefore, a full understanding of gastric and liver cancers is crucial to develop useful prognostic markers and therapeutic targets. During the past decade, emerging evidence has refined the value of osteopontin (OPN) as a candidate biomarker and target for cancer therapy^[1]. OPN is a secretory extracellular matrix (ECM) protein that is involved in a series of physiological and pathophysiological processes including but not limited to cell attachment, migration, invasion, proliferation, tissue remodeling, bone formation and even inflammation^[1-4]. OPN is frequently overexpressed in human cancers and contributes to tumor formation and progression^[5,6]. OPN belongs to the small integrin binding ligand N-linked glycoprotein family, which consists of members serving as markers of early cancer progression, due to their capabilities in modulating the activity of matrix metalloproteinases (MMPs)^[7]. OPN participates in the interactions between cancer cells and tumor stroma, which plays a pivotal role in malignant cancer phenotype. A more thorough understanding of the functional role of OPN in the tumor microenvironment is warranted. There have been many reports on OPN and gastric and liver cancers, therefore, this review aims to summarize recent findings on clinical implications of OPN, its potential as a therapeutic target, and its related mechanisms in these two types of cancer. Further understanding on the role of OPN in gastric and liver cancers may facilitate development of therapeutic strategies in such patients.

OPN GENE AND PROTEIN STRUCTURE

OPN is a matrix glycoprotein secreted by a variety of cell types including osteoclasts, endothelial cells, epithelial cells, and activated immune cells such as macrophages and T cells^[8]. It is also known as bone sialoprotein I, early T lymphocyte activation 1 and secreted phosphoprotein 1^[9-11]. Human *OPN* gene is located on chromosome 4q21-q25, spans approximately 11 kb, and consists of seven exons encoding the OPN protein with 314 amino acid residues^[12]. It contains several highly conserved structural elements, including arginine-glycine-aspartate and Ser-Val-Val-Tyr-Gly-Leu-Arg domains for integrin binding, a calcium binding site and a heparin binding domain for CD44 receptor binding^[13] (Figure 1). Alternative splicing produces three OPN isoforms, OPN-a, OPN-b and OPN-c, which probably display different expression profiles and functional heterogeneity in a tumor-specific manner^[14,15]. Moreover, OPN protein is subjected to a series of post-translational modifications including serine/threonine phosphorylation, glycosylation and tyrosine sulfation, resulting in molecular variants ranging from 25 to 75 kDa^[16]. These modifications are cell type specific and depend on physiological and pathophysiological factors, which likely affect both OPN structure and functions^[17].

ological factors, which likely affect both OPN structure and functions^[17].

OPN OVEREXPRESSION AND CLINICAL VALUE IN PATIENTS WITH GASTRIC CANCER

OPN expression is significantly elevated in most gastric cancer patients at both transcriptional and translational levels^[18-24]. OPN protein is overexpressed in both primary gastric cancer and metastatic lesions, mildly expressed in the epithelial cells in chronic atrophic gastritis that is a precancerous lesion for gastric cancer, and negatively in normal gastric mucosa, which indicates that OPN may play a role and serve as a potential biomarker in the formation and progression of gastric cancer^[18-20]. Moreover, Wu *et al*^[19] have found higher OPN plasma level in gastric cancer patients as compared with healthy individuals, suggesting that OPN plasma level may also be a biomarker for gastric cancer, and is of particular clinical interest because plasma-derived biomarkers are more convenient in clinical application than biomarkers from tissues. In gastric cancer tissues, OPN protein is diffusely located in the cytoplasm of tumor cells as well as tumor-associated macrophages (TAMs), which is in line with its implications in the interactions between cancer cells and tumor stroma.

Until now, the diagnostic and prognostic values of OPN have been implicated in gastric cancer patients. Microarray studies have identified gene signatures including OPN in gastric cancer patients^[18]. OPN overexpression is significantly associated with clinicopathological parameters in gastric cancer such as low apoptotic index, high proliferative index, low grade, high stage, LN and vascular invasion, and distant metastasis^[20-24]. In addition, OPN overexpression is an independent predictor of poor prognosis and tumor recurrence in patients with gastric cancer^[21,22]. Dai *et al*^[22] have suggested that patients with OPN-positive gastric cancer have poorer outcome than OPN-negative cases. Multivariate analysis has revealed OPN expression as an independent prognostic indicator of poor disease-free and overall survival in patients with gastric cancer, particularly for survival in cases in tumor, node, metastasis (TNM) stage II and III. The prognostic value of the marker combinations of OPN with conventional biomarkers has also been explored in gastric cancer patients. Zhang *et al*^[24] have found the combination of OPN and caudal-related homeobox gene 2 (*CDX2*) as a survival predictor of advanced gastric cancer patients. OPN plasma level is commonly elevated in patients with gastric cancer, and is significantly associated with the clinicopathological features including late stage, serosal invasion, LN and vascular invasion, and liver metastasis^[19]. High OPN plasma level is inversely correlated with poor prognosis in gastric cancer patients, especially in those with invasive phenotypes. Thus, elevated OPN plasma level may serve as an independent risk factor for poor survival in gastric cancer patients.

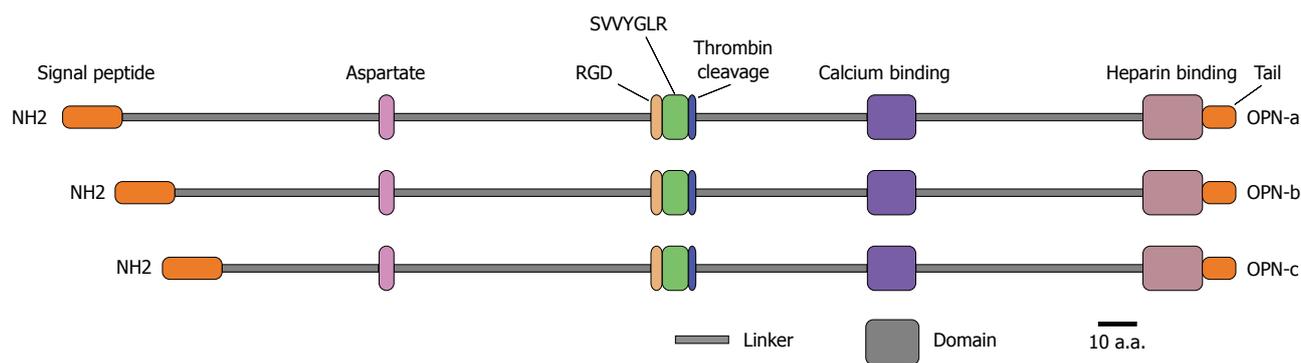

Figure 1 Structural features of osteopontin isoforms. Three isoforms of osteopontin (OPN), OPN-a, OPN-b and OPN-c, are known. All of them possess identical domains [aspartate domain, arginine-glycine-aspartate domain, Ser-Val-Val-Tyr-Gly-Leu-Arg (SVVYGLR) domain, thrombin cleavage domain, calcium binding domain and heparin binding domain] that are linked together with various linkers. These isoforms distinguish themselves by having a variable length of the linker between signal peptide and aspartate domain. RGD: Arginine-glycine-aspartate.

OPN OVEREXPRESSION AND CLINICAL VALUE IN PATIENTS WITH LIVER CANCER

OPN is positive in most hepatocellular carcinoma (HCC) patients at both transcriptional and translational levels^[25-35]. Yuan *et al.*^[28] demonstrated OPN mRNA overexpression in 79 (51%) of 156 primary HCC patients. Kim *et al.*^[35] disclosed that OPN protein was expressed in 92 (32.3%) of 285 tumors. The expressions of OPN mRNA and protein display a positive correlation^[29]. In HCC, OPN is secreted by both cancer cells and TAMs, and secreted by bile duct epithelium and stellate cells, but not by normal hepatocytes or Kupffer cells, in normal liver conditions^[34,35]. OPN⁺ cancer cells are often dispersed in the periphery of cancer nodules and are adjacent to stromal cells^[34,35]. In addition, OPN plasma level is also significantly elevated in HCC patients, especially in those with cirrhosis or in advanced stages^[35-39]. Kim *et al.*^[35] determined that OPN plasma level in HCC patients was significantly higher than in patients with chronic liver diseases or healthy controls (954 ng/mL *vs* 381 ng/mL; 954 ng/mL *vs* 155 ng/mL). Zhang *et al.*^[36] also found that OPN plasma level of HCC patients was significantly higher than that of healthy controls (176.90 ng/mL *vs* 63.74 ng/mL). These data propose that elevated OPN plasma level can serve as a potential biomarker for HCC.

Meanwhile, several microarray studies have identified OPN-containing gene signatures of HCC patients^[30-32]. Ye *et al.*^[31] have identified *OPN* as a leading gene in the gene signature that was relevant to tumor metastasis and patient survival. Luo *et al.*^[32] have found that overexpressed *OPN* gene belongs to a specific gene signature in HCC. In addition, many studies have established a significant correlation between OPN overexpression and clinicopathological features of HCC, including the severity of liver damage according to Child-Pugh class, high grade, late stage, LN/vascular/bile duct/capsular invasion, and intrahepatic or distant metastases^[26-30,40-44]. Until now, OPN overexpression has been revealed as an independent prognostic factor for poor overall and disease-free survival in HCC patients^[25-28,33,42-47]. In 2010, Weber

et al.^[42] performed a meta-analysis and found that OPN level correlated with poor overall and disease-/relapse-free survival, and as a biomarker for stage, grade, and early tumor progression in HCC. Chen *et al.*^[25] disclosed that OPN expression was a prognostic marker for HCC patients at TNM stage I. Furthermore, novel biomarker combinations are evaluated to predict patient outcome in HCC, since classical parameters cannot provide exact information. The biomarker combinations, OPN and α -fetoprotein (AFP), or OPN and CD44s, are revealed to have better prognostic value than the classical diagnostic biomarkers^[29,44]. Huang *et al.*^[48] have suggested that the combination of OPN and caspase-3 can be an effective indicator for HCC patients after curative resection. However, because the published data are conflicting in many cases, further large-scale studies are necessary to confirm their clinical value^[49].

Tumor recurrence is a persistent issue after surgical resection. A number of studies have suggested OPN as a useful marker for predicting early recurrence in HCC patients^[25-27,33,44-46,50]. OPN polymorphisms and the combination of OPN and CD44 are potential predictors of tumor recurrence in HCC^[45,46]. OPN overexpression is associated with early recurrence of hepatitis C virus (HCV)-related HCC^[50]. Chen *et al.*^[25] found that OPN expression was correlated with early postoperative recurrence in patients at stage I. Sieghart *et al.*^[33] have revealed that OPN is an independent predictor of tumor recurrence and survival in HCC patients beyond Milan criteria undergoing orthotopic liver transplantation. Thus, OPN may be able to help determine the patients who need adjuvant therapy to prevent early recurrence after surgical resection.

At present, many serum biomarkers are under evaluation for the detection of HCC, but none of them has sufficient sensitivity and specificity to be considered in the guidelines. OPN plasma level increases significantly with advanced Child-Pugh class, large tumor size, high grade, and late stage^[35,38]. OPN plasma level is suggested as an adverse prognostic factor for both overall survival, disease-free survival and relapse-free survival in hepatitis

Table 1 Osteopontin as a potential therapeutic target for gastric and liver cancers

Cell lines	Mouse model	Method of study	Resultant effects	Possible mechanisms
Gastric cancer SGC7901	Nude mice	siRNA knockdown	Reduced angiogenesis <i>in vitro</i> and <i>in vivo</i>	Decreasing microvessel density
BGC-823	Nude mice	Transient/stable siRNA knockdown	Inhibited cell growth, anchorage-independent growth, migration and invasion <i>in vitro</i> , and suppressed tumor growth and prolonged survival <i>in vivo</i>	Inhibition of MMP-2 and uPA expression, NF- κ B DNA binding activity, and Akt phosphorylation
SGC7901	Nude mice implanted with SGC-OPN-cells	Lentivirus-mediated stable depletion	Suppressed metastases and prolonged survival time <i>in vivo</i>	Reducing expression of VEGF
HCC MHCC97-L, MHCC97-H, HCC-LM3		siRNA knockdown	Decreased cell invasion and cell cloning number <i>in vitro</i>	
HuH1/4/7, MHCC97, SMMC7721, SK-Hep-1, Hep3B, CCL13, HCCLM3	Nude mice of lung metastasis	OPN-neutralizing antibody	Blocked invasion of SK-Hep-1 and Hep3B cells <i>in vitro</i> , inhibited pulmonary metastasis of HCC-LM3 cells <i>in vivo</i>	
HCC-LM6	Nude mice implanted with HCC-LM6	Antisense knockdown	Suppressed migration and invasion <i>in vitro</i> , decreased lung metastases <i>in vivo</i>	Inhibiting MMP-2 and uPA expression
HCC-LM3	Nude mice implanted with Lenti OPNi-transfected HCC-LM3 cells	Stable depletion using lentiviral vectors encoding miRNA against OPN	Inhibited both <i>in vitro</i> proliferation, invasion and <i>in vivo</i> tumor growth and lung metastasis	Inhibiting MAPK and NF- κ B pathways, and MMP-2 and suppressing uPA expression
HCC-LM3 HepG2	Nude mice	shRNA gene silencing	Inhibited HCC cell growth, adhesion and invasion <i>in vitro</i> , and suppressed tumorigenicity and lung metastasis <i>in vivo</i> , enhanced sensitivity of HCC cells to chemotherapeutic drugs	Suppressing α , β 1, β 3 integrin expression, blocking NF- κ B activation, inhibiting apoptosis

HCC: Hepatocellular carcinoma; OPN: Osteopontin; siRNA: Small interfering RNA; MAPK: Mitogen-activated protein kinase; NF: Nuclear factor; MMP: Matrix metalloproteinase; VEGF: Vascular endothelial growth factor; uPA: Urokinase-type plasminogen activator; shRNA: Short hairpin RNA; Akt: Protein kinase B; miRNA: microRNA.

B virus (HBV)- or HCV-related HCC patients^[36,38,51]. In addition, OPN plasma level may be a potential diagnostic biomarker for HCC in the surveillance of patients with HBV or HCV infection. Sun *et al*^[51] have suggested that preoperative plasma level of OPN and AFP can be used as a prognostic marker for early stage HCC. A recent study conducted by Shang *et al*^[52] has also identified serum OPN as a novel marker for early HCC diagnosis because OPN was found clearly elevated 1 year before diagnosis in a pilot prospective study including 22 patients. In another two studies, a greater area under curve value of OPN than AFP was observed, suggesting superior diagnostic accuracy of OPN for HCC^[58]. HCC patients whose pretreatment OPN serum level is low and declines following transarterial chemoembolization exhibit better tumor response and longer survival^[37]. These data suggest that OPN plasma level can be used, either independently or coupled with AFP, for predicting clinical outcome in HCC patients.

OPN AS A POTENTIAL THERAPEUTIC TARGET FOR GASTRIC AND LIVER CANCERS

OPN as a therapeutic target has been explored in various tumors including cancers of breast, lung, head and neck, stomach, colon and liver. Promising results have been achieved in a series of studies^[53-57]. The strategies often

utilize OPN antibody to block its binding to receptors so as to inhibit the downstream signal transduction related to tumor growth and invasion, and deliver the small interfering RNA (siRNA) targeting OPN to tumor cells to decrease directly the expression of OPN to abrogate the effects triggered by elevated OPN.

At present, OPN-knockdown-induced tumor suppression in gastric cancer has been shown through RNA interference (RNAi)^[58-60]. *In vitro* and *in vivo* studies have demonstrated OPN-RNAi-induced inhibition of tumor growth, migration and invasion in gastric cancer^[58,59]. Moreover, Wang *et al*^[60] silenced OPN expression in gastric cancer cell line SGC7901 using lentiviral-OPN siRNA technology, and found reduced detectable tumors, fewer metastases, and longer survival time in mice implanted with OPN-SGC7901 cells. These data suggest that targeting OPN and its related signaling network is likely to provide an effective therapeutic approach for gastric cancer (Table 1).

In recent years, efforts have also been made to inhibit HCC progression and metastasis by interfering OPN^[27,31,61-63]. OPN knockdown significantly suppresses migration and invasion of HCC cells *in vitro* and decreases lung metastases *in vivo*, which is associated with decreased angiogenesis in HCC cells^[61,62]. Besides, OPN-specific antibody can effectively block HCC cell invasion *in vitro* and inhibit lung metastasis of HCC cells *in vivo*^[31]. In addition, Zhao *et al*^[63] have demonstrated that short hairpin RNA-mediated OPN depletion enhances sensitivity of HCC cells

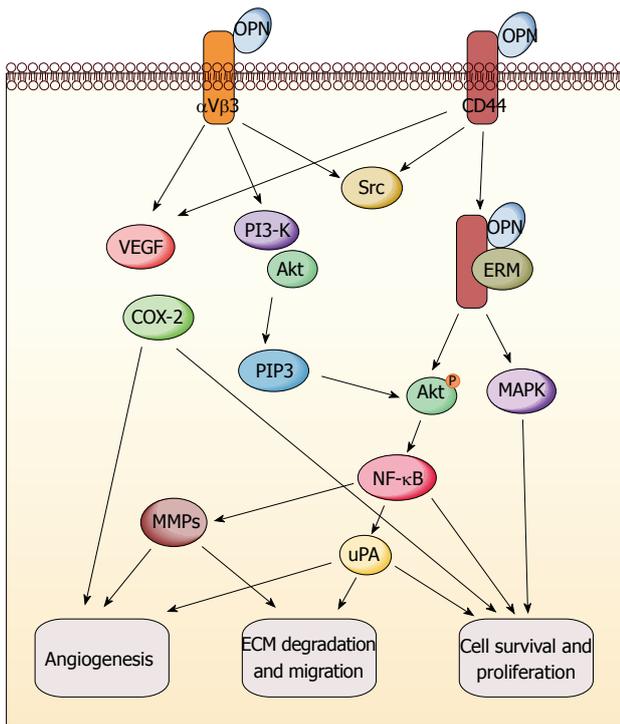

Figure 2 Molecular mechanisms of osteopontin in gastrointestinal cancers. Osteopontin (OPN) signaling leads to gastrointestinal cancer growth and metastasis through activation of various pathways, including cell survival and proliferation, angiogenesis, and extracellular matrix (ECM) degradation. VEGF: Vascular endothelial growth factor; PI3-K: Phosphoinositide 3-kinase; COX-2: Cyclooxygenase-2; MAPK: Mitogen-activated protein kinase; NF: Nuclear factor; uPA: Urokinase-type plasminogen activator; MMP: Matrix metalloproteinase; ERM: Ezrin/radixin/moesin; Akt: Protein kinase B.

to chemotherapeutic drugs through blockade of nuclear factor (NF)- κ B activation. Thus, targeting OPN and its related signaling network is likely to help develop novel therapeutic regimens for HCC (Table 1).

MOLECULAR MECHANISMS OF OPN IN GASTRIC AND LIVER CANCERS

The multifunction of OPN has been revealed in promoting tumor formation and progression (Figure 2). It exerts these functions through direct binding to integrin and/or CD44. The subsequent activation of various pathways leads to increased malignant phenotype^[64,65]. Various signaling transduction pathways triggered by OPN molecule have been reported in different cancer models such as breast cancer, melanoma, lung cancer, myeloma, prostate cancer and gastrointestinal cancers. The results indicated that OPN exerts the tumor-related functions through a complicated signaling network^[65]. Here, we only summarize the reported signaling pathways of OPN relevant to gastric and liver cancers; some of which are commonly overlapped with other cancers, but some are specific in these two types of cancers. It has been suggested that phosphoinositide 3-kinase (PI3-K)/protein kinase B (Akt) pathway and hypoxia-inducible factor-1 are involved in the tumor-promoting function of OPN,

which induces pro-survival and anti-apoptosis signaling in gastric and liver cancers after the survival pathway is activated^[63,66]. Mitogen-activated protein kinase pathway (MEK/ERK1/2) can also be triggered by OPN protein in liver cancer to promote tumor growth and metastasis, while the effect can be reversed through OPN knock-down^[62]. The NF- κ B pathway is crucial to keep cell survival through initiating the gene expression of antiapoptotic proteins, and is often induced by chemotherapeutic drugs and contributes to resistance to chemotherapy^[59,62]. Relevant tumor-promoting functions of OPN are found to be highly associated with NF- κ B pathway activation in gastric and liver cancers^[59,62,63]. The MMP family is responsible for ECM degradation and remodeling, which plays an important role in tumor invasion and metastasis. OPN-induced metastasis of gastrointestinal cancers is also involved in several MMP members such as MMP-2, MMP-9, MMP-7 and other famous invasion-related proteins such as vascular endothelial growth factor (VEGF) and urokinase-type plasminogen activator (uPA)^[54,59,62,67,68]. Recently, Lee *et al.*^[66] illustrated that OPN can enhance the survival of gastric cancer through the interaction with CD44 variant isoforms. The underlying mechanism involves Src kinase signaling upon OPN binding to CD44, followed by “inside-out” integrin activation. In addition, there may be a positive correlation between OPN and cyclooxygenase-2 (COX-2). OPN, VEGF and COX-2 could synergistically induce angiogenesis and metastasis in gastric cancer^[69]. On the other hand, the antitumor activity of COX-2 inhibitors in intestinal cancer is probably mediated through downregulation of OPN, which results from blockade of nuclear receptor subfamily 4, group A, member 2 (NR4A2) and Wnt/ β -catenin signaling, two important components of the OPN regulatory network^[70].

Several mechanisms regulating *OPN* gene expression have been revealed, but many details remain to be elucidated. *OPN* is a transcriptional target of aberrant Wnt/ β -catenin signaling^[70-72], and is also regulated by other molecules including specificity protein 1, v-ets erythroblastosis virus E26 oncogene homolog 1, runt-related transcription factor 2, v-myb myeloblastosis viral oncogene homolog, CDX2, deleted in liver cancer 1, late SV40 factor (LSF), epidermal growth factor (EGF), NR4A2 and NO^[24,73-79]. Interestingly, the activation of several downstream targets of OPN, such as Akt, LSF, NO, EGF and thrombin, can enhance OPN expression in turn, suggesting a positive feedback regulation of *OPN* gene expression^[68,73,78-82]. Moreover, the modulation of OPN mRNA stability also influences OPN expression in HCC^[83,84]. In addition, miRNA-181a decreased OPN expression in HCC cell lines, suggesting that miRNA is involved in the regulation of *OPN* gene expression^[85]. Furthermore, the expression of OPN is also affected by COX-2 and 30-kDa Tat-interacting protein^[70,86,87].

In short, OPN signaling could result in the activation of anti-apoptosis and pro-survival pathways *via* PI3-K-Akt and NF- κ B signaling molecules, angiogenesis modulation *via* VEGF induction, ECM degradation *via* MMPs

and uPA secretion, leading to tumor growth and metastasis in gastric and liver cancers.

CONCLUSION

OPN overexpression occurs frequently in patients with gastric cancer and liver cancer. Previous studies have revealed its clinicopathological correlation with tumor formation and progression in these two types of cancer, indicating its potential as an independent indicator for predicting outcome in such patients. Functional studies have shown the potential of OPN as a therapeutic target in gastric and liver cancers both *in vitro* and *in vivo*. OPN mediates multifaceted roles in the interaction between cancer cells and tumor microenvironment, in which many details need to be further explored. The various mechanisms of OPN signaling in gastric and liver cancers including evasion of apoptosis, modulation of angiogenesis, ECM degradation, activation of PI3-K-Akt and NF- κ B pathways, might induce the development and progression of gastric and liver cancers. However, no clinical trial targeting OPN is in progress for tumor treatment, although the importance of OPN has been widely investigated and demonstrated in various cancers, and many patents including antibodies or peptides against OPN have been filed to treat different tumors. OPN is an important cytokine to mediate normal physiological functions. Blocking OPN possibly results in severe adverse effects due to interference with normal OPN roles. Therefore, further understanding of the implications and roles of OPN in various tumors including gastric and liver cancers could help develop better therapeutic strategies for such patients. On the other hand, OPN as a secreted plasma protein seems to have a greater potential to be utilized as a diagnostic or prognostic marker for in relevant cancers in combination with other biomarkers or alone.

Abstract

Metastasis is the main reason for cancer-related death. S100A4 is one of the key molecules involved in this event. Several studies have shown that overexpression of S100A4 in non-metastatic cancer cells can make them become metastatic, and knockdown of S100A4 in metastatic cancer cells can curtail their invasive nature. A study by Chen *et al*^[2] published in the *World J Gastroenterol* 18(9): 915-922, 2012 is a typical example. This study showed *in vitro* and *in vivo* evidence that S100A4 expression level determines the invasiveness of esophageal squamous carcinoma. Considering the fact that more than half of the cancer-related deaths are caused by malignancies derived from the digestive system and esophageal cancer is the 4th top contributor to this fraction, this study warrants more attention.

INVITED COMMENTARY ON HOT ARTICLES

Cancer is the second leading cause of death in the world (18%), after heart disease (21%). Among about 18 million new cases of cancers diagnosed each year, about one third is skin cancer. However, 95% of skin cancer is either basal cell carcinoma or squamous cell carcinoma, which has a mortality of less than 0.5%. The majority of cancer-related deaths are actually caused by malignancies derived from the digestive system, including esophagus, stomach, small intestine, colon, rectum, anus, liver, gallbladder and pancreas^[1]. The main feature that makes these cancers deadly is metastasis, a process that cancer cells break off from their original location and invade other parts of the organ. The majority of skin cancers do not have this capacity; therefore, they can be easily treated before becoming life threatening. Esophageal cancer, on the other hand, is highly metastatic. Therefore, understanding the molecular mechanisms behind its metastasis is of great values for developing better treatment strategies. A study by Chen *et al*^[2] published in the *World J Gastroenterol* 18(9): 915-922, 2012 examined the role of S100A4, one of the well-known cancer metastatic markers, in esophageal squamous cell carcinoma (ESCC) *in vitro* and *in vivo*, in animal models as well as in clinical human specimens, and clearly demonstrated a reliance of the invasiveness of esophageal cancer on this small calcium-binding protein^[2].

A little biography of S100A4: Short but hot

S100A4 was discovered in the mid 1980s by several laboratories independently. One of these laboratories be-

longed to Daniel Nathans, MD (10/30/1928-11/16/1999) (Figure 1), the Nobel Prize winner in Physiology/Medicine 1978 for his landmark discovery of restriction enzymes. In 1983, one of his post-doctoral fellows, Daniel I Linzer, PhD, was constructing a cDNA library from serum-stimulated mouse 3T3 fibroblasts and found that a clone named 18A2 was highly up-regulated by serum exposure^[3]. There seemed to be many laboratories in the late 70s and early 80s of the 20th century which were interested in the effect of serum on gene expression. That was also how and when serum response factor (SRF) was discovered^[4,5]. In the following year, Linzer took a job at Northwest University in Illinois (now he is the Provost of this school) and continued his study on 18A2. He determined that 18A2 coded for a calcium binding protein of 101 amino acids^[6], much similar to the members of S100 family, a group of small peptides that are known to be 100% soluble in saturated ammonia sulfate. He also compared the sequence of 18A2 with 2A9, a human clone that was published a year earlier^[7], and found a 57% nucleotide and 62% amino acid homology between them. It might be due to the difference of species origin, Linzer was pretty sure that these two sequences represented different genes. Around that time and shortly thereafter, several other laboratories also published similar sequences and each of which was given a different name, including p9Ka from rat mammary cells^[8], 42A from rat neuronal cells^[9], pEL98 from mouse fibroblasts^[10], CAPL from *Aplysia* neurons^[11], mts1 from metastatic tumor cells^[12], and FSP1 from mouse fibroblasts^[13]. Despite the individuality of each of these studies, there were some common features shared among their discoveries: (1) serum inducibility; (2) around 100 amino acids; and (3) similarity to S100 calcium binding proteins. Although all of these sequences eventually turned out to be for a single molecule - S100A4, each of these studies made unique contributions to our knowledge today about S100A4. The last two studies warrant an extra attention, because one established the connection between S100A4 and cancer metastasis and the other associated it to fibroblast phenotype. Now we know that S100A4 is a prognostic marker for metastatic cancers as well as a marker for epithelial-mesenchymal transition. However, both of these studies went a little bit too far by calling this molecule metastatic-specific and fibroblast-specific, respectively. Now we know that is not entirely true, a lot of other cells (e.g., epithelial cells, endothelial cells, lymphocytes, smooth muscle cells, *etc.*) also express S100A4, just as our study reported^[14].

Functions of S100A4: Motivation to move

Up to date, S100 family includes 25 members with common characteristics such as low molecular weight, two calcium binding sites of the helix-loop-helix ("EF-hand type") conformation, and complete solubility in ammonium sulfate at pH 7. They have been implicated in regulation of protein phosphorylation, transcription factor activation, calcium homeostasis, cytoskeleton reorganization, cell migration, cell growth and death^[15].

Figure 1 Daniel Nathans, MD, Nobel Laureate (10/30/1928-11/16/1999), Department of Molecular Biology and Genetics, the Johns Hopkins University School of Medicine Baltimore, Baltimore, MD 21205, United States.

S100A4 is naturally expressed in various cell types including both cancer and normal cells, and its elevation is usually associated with cell motility. It appears that wherever cell migration is required, such as wound healing^[16], angiogenesis^[17] and cancer metastasis^[18], S100A4 is activated. Like other members of S100 family, S100A4 works like a calcium sensor. Upon calcium binding, S100A4 goes through a series of conformational changes, which allow the molecule to interact with its targets, such as nonmuscle myosin heavy chain (MHC II A) and liprin β 1, to facilitate cell migration^[19,20]. For this reason, in motile cells, S100A4 is often found in complex with these cytoskeletal components at the migrating front where a high level of calcium is accumulated. It is interesting to know that S100A4 knock-out mice do not display developmental abnormalities in the postnatal period, but 10% of them develop tumors at age of 10-14 months, possibly due to destabilization of the tumor suppressor p53^[21], as S100A4 has been shown capable to bind to the C-terminal of p53 and repress its transcriptional activity^[22,23].

Yet, the story of S100A4 is not as straightforward as it might have been anticipated. In addition to being a cytoskeletal regulator in the cytoplasm, S100A4 has also been localized to the nucleus and extracellular matrix. How it gets there and what it does in these locations remain unclear. Nevertheless, its association with transcription factors like p53 might explain some of its roles in the nucleus. It has been postulated that S100A4 binding to the tetramerization domain of p53 favors p53 oligomerization and thereby facilitates p53 nuclear translocation^[23]. On the other hand, extracellular S100A4 has been demonstrated to stimulate MMP-13 expression in chondrocytes in a receptor for advanced glycation end products (RAGE)-dependent manner^[24], while its inductivity on neuron growth was found to be RAGE irrelevant^[25]. More complicatedly, S100A4 has been found in association with cell death in a conflict way, it inhibits apoptosis in pancreatic cancer^[26] but promotes it in osteosarcoma cells^[27].

S100A4 in cancers: A facilitator, not a generator

Elevation of S100A4 has been found in almost every metastatic cancer known, including breast^[28], ovarian^[29], prostate^[30], urinary bladder^[31], lung^[32], esophageal^[33], gastric^[34], colon^[35], pancreatic^[36], liver^[37], gallbladder^[38] and

thyroid carcinomas^[39]. More direct evidence for the essential role of S100A4 in cancer metastasis perhaps comes from *in vitro* studies and animal models, which have shown that overexpression of S100A4 in non-metastatic tumor cells confers a metastatic phenotype, just as demonstrated in the study by Chen *et al*^[2] as well as several others^[40,41]; whereas, knockdown of S100A4 in metastatic tumor cells curtails their invasive capability^[2,42,43].

It should be pointed out though that S100A4 is not an oncogene product. As shown by transgenic studies^[17,44], mice carrying extra copies of *S100A4* gene develop normally as wild-type and have no increased risk of cancer. However, when these mice mated with cancer mice, their offspring showed increased number of tumors distant from their primary location^[45]. Therefore, S100A4 is not a cancer generator but a metastatic facilitator.

S100A4 has been studied extensively in other cancers, especially in breast cancer. In esophageal cancer, there are about a dozen of publications so far, mostly focusing on squamous cell carcinoma. The earliest study that can be found was done by a Japanese group^[33], showing an elevated expression of S100A4 protein in surgically resected ESCC, and a possible association with esophageal cancer progression. However, a later study reported an opposite result, showing that 11 out of 16 S100 family members examined, including S100A4, were down-regulated at transcriptional level in tumor tissues compared with adjacent normal tissues^[46]. In 2010, a Chinese research team used RNA interference technology to knock down S100A4 in metastatic esophageal tumor cells and grafted them in nude mice^[47]. They noticed that tumor growth was significantly inhibited by S100A4 deficiency, and E-cadherin expression was reciprocal to the level of S100A4. Unfortunately, the study had little impact because it was published in a local journal in Chinese. However, the idea of xenografting has recently advanced to a new cancer treatment strategy - the "avatar" mice. Principally, it is to take tumor tissue from a patient and graft it in nude mice to create a personalized colony of mice carrying exact that patient's cancer, and then test every potential treatment combinations in mice before selecting the best one to treat that patient. Manuel Hidalgo, the Director of the Spanish National Cancer Research Center in Madrid, has been practicing this approach for pancreatic cancer patients over years and showed a clear advantage in drug responses^[48,49], and now more and more researchers believe that this idea holds a great promise in cancer treatment in the future.

In the study by Chen *et al*^[2], the research team cleverly used two ESCC cell lines, EC109 (highly invasive) and TE13 (non-invasive), and successfully made these cells switch characters by down-regulation of S100A4 in EC109 and up-regulation of S100A4 in TE13. They provided *in vitro* and *in vivo* evidence that the level of S100A4 determines the metastatic status of the cancer.

There are two main subtypes of esophageal cancer: ESCC and esophageal adenocarcinoma (EAC). Although nearly 95% of esophageal cancer is ESCC, EAC has been rising by 6-fold annually in Americans and now its in-

crease rate exceeds the rate for any other type of cancers. Overexpression of S100A4 was also reported in EAC and its correlation with lymph node metastasis was found significant^[50].

Although the exact molecular mechanisms how S100A4 promotes cancer metastasis still need to be further examined, based on various studies, one possible explanation could be that S100A4 binding to liprin $\beta 1$ inhibits its phosphorylation^[19], and thereby prevents its interaction with liprin $\alpha 1$. As a result, liprin $\alpha 1$ fails to recruit leukocyte common antigen-related (LAR) protein^[51], a phosphatase, to focal adhesions. Without LAR to dephosphorylate β -catenin^[52], β -catenin becomes activated to leave E-cadherin and results in the collapse of adherens junctions, allowing cells to migrate. As found in our study, the dissociation of β -catenin from E-cadherin causes E-cadherin ubiquitination and degradation^[53], which might at least in part explains why S100A4 elevation is often found in association of E-cadherin loss, as shown in the study by Chen *et al*^[2].

S100A4 in normal situation: An innocent bystander

As discussed above, S100A4 is expressed wherever cell migration is required, regardless normal or pathological situation. However, most of S100A4 studies focus on its bad side, such as cancer metastasis and organ fibrosis. Its good side has been continually overlooked. If we go back to the story that S100A4 was discovered in an experiment of serum stimulated fibroblasts, we know that S100A4 is innocent. Cells, including fibroblasts, in our body normally do not come into a direct contact with serum unless there is an injury. Therefore, when cells are suddenly exposed to serum, as the experiment done in Nathans' lab, they naturally interpret it as a signal of a wound. Therefore, a transcriptional program for wound healing gets activated immediately to battle against injury. S100A4 is just one of the players in this battle. So is SRF, and so are many SRF-regulated genes (e.g., C-FOS, EGR-1, CCN1, CTGF, FGF10, *etc.*)^[54]. All these genes contain a common regulatory element CArG box, which SRF recognizes to bind. *S100A4* gene also contains such element in its promoter region^[55], suggesting a possible regulation by SRF. *In vivo*, S100A4 activation has been found in various wound healings, and its contributions to tissue repair and modification are indisputable^[16,56].

Abstract

Acute pancreatitis is the most common and the most fearful complication of endoscopic retrograde cholangiopancreatography (ERCP). Prevention of post-ERCP pancreatitis has therefore been of great interest to endoscopists performing ERCP procedures. So far, only pancreatic duct stenting during ERCP and rectal administration of a non-steroidal anti-inflammatory drug (NSAID) prior to or immediately after ERCP have been consistently shown to be effective for prevention of post-ERCP pancreatitis. This commentary focuses on a short discussion about the rates, mechanisms, and risk factors for post-ERCP pancreatitis, and effective means for its prevention with emphasis on the use of NSAIDs including a recent clinical trial published in *The New England Journal of Medicine* by Elmunzer *et al*^[11].

INVITED COMMENTARY ON HOT ARTICLES

Acute pancreatitis is the most common complication of endoscopic retrograde cholangiopancreatography (ERCP)^[1,2]. It is important to distinguish between acute pancreatitis and hyperenzymemia after ERCP. Hyperenzymemia, defined as asymptomatic elevation of serum levels of amylase and lipase, is estimated to occur in more than 75% of patients undergoing ERCP and by itself does not have any clinical consequences^[3]. Acute pancreatitis, on the other hand, is less common and can have significant clinical consequences. Although both conditions are characterized by elevation of serum levels of amylase and lipase, diagnosis of acute pancreatitis requires an additional factor, either pancreatic type pain or cross-sectional imaging confirming pancreatic inflammation^[4].

Proposed underlying mechanisms that alone or in combination can induce post-ERCP pancreatitis (PEP) are prolonged manipulation around the papillary orifice causing edema, enzymatic injury from intestinal contents or contrast, hydrostatic injury from over-injection of the pancreatic duct, and thermal injury from electrocautery. There are probably other mechanisms involved that are yet to be recognized.

In most patients, the risk of PEP is in the range of 1%-10%. In high-risk cases, the risk can be as high as 30%^[1]. Factors that convey a high risk for PEP can be

classified as patient-related, procedure-related, operator-related, and disease- or indication-related. Patient-related factors associated with a higher risk of PEP are younger age, female gender, and a normal serum bilirubin level. Procedure-related factors that have been suggested to be related to a higher risk of PEP include difficult cannulation, balloon dilatation of the biliary sphincter, and injection of contrast into the pancreatic duct particularly when acinarization occurs. Operator-related factors include lack of a good technique, lack of experience, and low case volume. The disease or indication for the ERCP is also important. For example, while the risk of PEP in patients undergoing ERCP for chronic calcific pancreatitis is very low, nearly one in 3 patients with type 3 sphincter of Oddi dysfunction undergoing ERCP will develop PEP.

Acute pancreatitis after ERCP is not a uniform disorder and varies in intensity^[1,3]. Most cases of PEP are mild and resolve with proper treatment without any permanent sequela. A minority of the cases, however, is severe. Severe PEP is a feared complication of ERCP and can result in significant morbidity and mortality. Prevention of PEP has therefore been of major interest to endoscopists and significant time and effort have been devoted to finding endoscopic or pharmacologic means of preventing PEP.

So far, only pancreatic duct stenting and use of non-steroidal anti-inflammatory drugs (NSAIDs) consistently have been shown to be effective for PEP prophylaxis.

The first randomized trials assessing pancreatic duct stenting at the time of ERCP for PEP prevention were conducted in the 1990s^[1]. Subsequent studies confirmed the effectiveness of this approach in decreasing the rate and severity of PEP, especially in high-risk patients.

Use of NSAIDs for PEP prophylaxis is relatively new. The rationale of NSAIDs administration for PEP prevention lies in their ability to inhibit substances such as prostaglandins, phospholipase A2 and neutrophil-endothelial interaction, which are believed to play an important role in severe inflammatory processes including acute pancreatitis^[6]. The first clinical trial assessing the efficacy of a rectally administered NSAID for PEP prevention was reported in 2003 by a British group^[7]. In that study, pancreatitis occurred in 6.4% of patients in the NSAID group compared to 15.5% in the placebo group. Two subsequent clinical trials by two independent Iranian research teams found that rectally administered NSAIDs were effective for PEP prevention^[8,9]. A Mexican study confirmed those results^[10].

The most recent clinical trial on use of a rectally administered NSAID for prevention of post-ERCP pancreatitis was published a few weeks ago^[11]. In this clinical trial, 602 patients at elevated risk for post-ERCP pancreatitis were randomly assigned to receive a single dose of rectal indomethacin or placebo immediately after ERCP. The incidence of post-ERCP pancreatitis was significantly reduced among those receiving rectal indomethacin (9.2%) compared to those in the placebo group (16.9%).

In conclusion, based on the current literature, two prevention modalities have proven effective for PEP prophylaxis: (1) endoscopic placement of a pancreatic duct

stent during ERCP; and (2) rectally administered NSAID immediately before or after ERCP.

Endoscopic pancreatic duct stenting for PEP prophylaxis in high-risk patients is a well-accepted strategy and is being used as a routine practice in most ERCP centers.

Although still not adopted as a routine practice, there is enough evidence to support the routine use of NSAIDs for PEP prevention at least in high-risk patients.

Although use of endoscopic and pharmacological means such as pancreatic duct stenting or rectally administered NSAIDs can decrease the rate and severity of PEP, they cannot, and should not replace the common sense. The best strategy for prevention of post-ERCP pancreatitis has been and remains avoiding unnecessary procedures. Other strategies for PEP prophylaxis include proper training of the endoscopists and assistants; adequate case volume to maintain proficiency; avoiding repeated injection to the pancreatic duct if evaluation of the pancreatic duct is not required; and referral of high-risk cases to specialized ERCP centers.

Abstract

Primary biliary cirrhosis (PBC) is a progressive autoimmune liver disease of unknown etiology that affects almost exclusively women. Ursodeoxycholic acid (UDCA) is currently the only approved drug by Food and Drug Administration for patients with PBC. Although the precise pathogenesis of PBC remains unclear, it has been postulated that many cell populations, including B cells, are involved in the ongoing inflammatory process, which implicates, not surprisingly, a potential therapeutic target of depleting B cell to treat this disorder. Rituximab is a chimeric anti-CD20 monoclonal antibody that has been approved for the treatment of lymphoma and some autoimmune diseases such as rheumatoid arthritis. Whether it is effective in the treatment of PBC has not been evaluated. Recently, Tsuda *et al*^[1] demonstrated that B cell depletion with rituximab significantly reduced the number of anti-mitochondrial antibodies (AMA)-producing B cells, AMA titers, the plasma levels of immunoglobulins (IgA, IgM and IgG) as well as serum alkaline phosphatase, and it was well tolerated by all the treated patients with no serious adverse events. This observation provides a novel treatment option for

the patients with PBC who have incomplete response to UDCA.

INVITED COMMENTARY ON HOT ARTICLES

We read with interest the recently published paper by Tsuda *et al*^[1] describing an open-label study of rituximab treatment in six patients with primary biliary cirrhosis (PBC) who had an incomplete response to ursodeoxycholic acid (UDCA). We believe this observation provides a novel treatment option for the patients with PBC who have incomplete response to UDCA and would recommend it to the readers.

PBC is a cholestatic liver disease characterized by serological findings of anti-mitochondrial antibodies (AMA) and pathological non-suppurative destruction of biliary epithelial cells^[2,3]. PBC may lead to liver failure or

even death. However, UDCA is the only Food and Drug Administration-approved drug and its efficacy is far from satisfaction in a large proportion of patients^[4]. Recent studies have demonstrated that B cells are involved in immune mechanisms of the pathogenesis of non-suppurative cholangitis and the destruction of bile ducts in PBC^[5-7]. These findings implicate a potential treatment efficacy of B cell depletion in patients with PBC^[8-10].

Rituximab is a mouse-human chimeric anti-CD20 monoclonal antibody designed for B cell depletion in human. Its safety and efficacy as a single therapeutic agent has been demonstrated initially in the treatment of non-Hodgkin B cell lymphoma and chronic lymphocytic leukemia^[11,12]. In addition, there were also clinical trials demonstrating that rituximab significantly induced clinical remission in a number of autoimmune diseases such as granulomatosis with polyangiitis, microscopic polyangiitis, and rheumatoid arthritis (RA)^[13-15].

In the field of PBC, there were several studies in murine models investigating the treatment effect of B-cell depletion. Dhirapong *et al.*^[8] reported that B cell-depleted mice developed more aggressive PBC-like liver disease with increased infiltration of inflammatory cells around the damaged bile canaliculi in portal areas. Whereas Moritoki *et al.*^[16] showed that anti-CD20 therapy had no effect on adult dominant-negative transforming growth factor (TGF)- β R II mice (age range: 20-22 wk to 36-38 wk), and it neither alleviated liver inflammation nor exacerbated colitis. But in younger dominant-negative TGF- β R II mice aged 4-6 wk, anti-CD20 treatment significantly alleviated the liver inflammation and reduced the bile duct damage, suggesting that anti-CD20 treatment might be beneficial for patients with PBC of early disease stage.

Tsuda *et al.*^[11] used rituximab to treat six patients with PBC who had suboptimal biochemical response to UDCA. After B-cell depletion, they observed a reduction in the number of AMA-producing B cells, AMA titers, the plasma levels of immunoglobulins (IgA, IgM and IgG) as well as serum alkaline phosphatase (ALP) at week 24. As the levels of immunoglobulins, AMA titers and ALP returned to baseline levels at week 36, repeated anti-CD20 treatment was suggested to maintain the treatment effect. The necessity of repeated treatment with rituximab was also demonstrated by recent clinical trials on other autoimmune diseases such as RA and systemic lupus erythematosus, and this treatment strategy did not lead to permanent remission^[17-19]. It is noteworthy that there was also study reporting that repeated treatment with rituximab could potentially compromise host protective immune response and might cause severe infection in RA patients^[20]. In Tsuda's study on PBC patients^[11], two patients (2/6, 33.3%) experienced reactivation of varicella zoster and upper respiratory infection after the first infusion of rituximab. Though it might be arbitrary to ascribe these infections exclusively to rituximab infusion, infections remain the major concern when treating patients with anti-CD20 antibodies. In PBC and other autoimmune diseases, it remains controversial if repeated anti-CD20 treatment is beneficial in terms of safety and

efficacy, and if so, when is the optimal time for repeated therapy.

A high titer of serum AMA can be detected in 83%-95% of patients with PBC^[21]. Most studies have shown that there is no correlation between the level of serum AMA and the severity of PBC, and AMAs positivity does not predict the patient's response to treatment with UDCA^[22-25]. However, there were also some studies suggesting that AMA-positive PBC patients had more severe bile duct destruction than PBC patients with negative AMA^[26]. AMAs could induce the caspase activation of the biliary epithelial cells and subsequent cell death and bile duct damage^[27]. Tsuda *et al.*^[11] found that in the PBC patients, together with the number of peripheral B cells, the plasma levels of immunoglobulins and ALP, the level of AMA also decreased after treatment with rituximab and returned to baseline levels 36 wk after cessation of rituximab. They suggested that the depletion of the AMA-secreting plasma cells by rituximab could potentially reduce hyperactive B cell immune response and lead to the amelioration of the bile duct destruction in PBC, even though it is too early to jump to the conclusion that the level of serologic AMAs is a predicting factor for the efficacy of rituximab therapy.

Although B cell is one of the pivotal inflammatory cells in the immunopathogenesis of PBC, its precise role and the adverse events associated with B cell-depletion remain unclear^[28]. A study reported that the morbidity of severe side effects of B cell-depletion is low but not insignificant^[29]. There were also studies reporting new onset cases of inflammatory bowel disease that may be attributed to the B cell depletion in up to 40% patients with PBC^[30,31]. In dominant negative TGF- β R II mice, Moritoki *et al.*^[16] found that anti-CD20 treatment induced up-regulation of interleukin 6, which could lead to exacerbation of colitis. Paradoxically, in some studies on murine models, B cells might play a protective role in PBC and B cell depletion exacerbated the biliary pathology and caused more aggressive PBC-like liver diseases^[8,26,28]. There was also a case report showing that, after rituximab treatment, PBC developed with a high AMAs titer, intrahepatic cholestasis and steatorrhea in a RA patient^[32], though it is not exactly understood if PBC was caused by immuno-mechanism underlying RA or by rituximab itself. In Tsuda's study on PBC patients^[11], however, there was no evaluation of inflammatory bowel diseases and biliary pathology during follow-up. It should also be noted that, in their study, the number of enrolled patients and the duration of follow-up were not enough and the level of other biochemical parameters and PBC-40 scores remained unaltered. The long-term efficacy and prognosis could be the most important concern of rituximab treatment.

In conclusion, the study by Tsuda *et al.*^[11] suggests that B cell depletion with rituximab is potentially a promising treatment regimen for the PBC patients who do not have good response to UDCA. B cell depletion merits further investigation in human PBC to illuminate its safety and efficacy.

Abstract

Hepatocellular carcinoma (HCC) is a leading cause of cancer-related death worldwide. The recurrence of HCC after curative treatments is currently a major hurdle. Identification of subsets of patients with distinct prognosis provides an opportunity to tailor therapeutic approaches as well as to select the patients with specific sub-phenotypes for targeted therapy. Thus, the development of gene expression profiles to improve the prediction of HCC prognosis is important for HCC management. Although several gene signatures have been evaluated for the prediction of HCC prognosis, there is no consensus on the predictive power of these signatures. Using systematic approaches to evaluate these signatures and combine them with clinicopathologic information may provide more accurate prediction of HCC prognosis. Recently, Villanueva *et al.*^[13] developed a composite prognostic model incorporating gene expression patterns in both tumor and adjacent tissues to predict HCC recurrence. In this commentary, we summarize the current progress in using gene signatures to predict HCC prognosis, and discuss the importance, existing issues and future research directions in this field.

INVITED COMMENTARY ON HOT ARTICLES

Hepatocellular carcinoma (HCC) is the sixth most common cancer type and the third leading cause of cancer-related death worldwide^[1]. The major risk factor of HCC is chronic infection with hepatitis B virus (HBV) and/or hepatitis C virus (HCV)^[2]. So far, curative treatments for HCC include orthotopic liver transplantation, surgical resection and percutaneous ablation. However, the recurrence rates remain high and long-term survival is poor.

There are two types of HCC recurrence: early recurrence and late recurrence with different mechanisms. Early recurrence (< 2 years after the treatment) is mostly caused by metastasis and dissemination of primary HCC; while late recurrence (\geq 2 years after the treatment) mainly

results from *de novo* tumors, as a consequence of field effect in diseased liver which is closely associated with high viral loads and hepatic inflammatory activities^[3,4]. The treatment after curative therapy varies greatly, depending on individual's profile^[5]. The traditional prognostic markers of HCC include vascular invasion (both macroscopic and microscopic) which is the most significant factor, tumor size, number of nodules, α -fetoprotein level, degree of differentiation, and satellites^[6]. Recent advancement in the field has shown that viral factors and inflammation-related conditions are apparently associated with HCC prognosis. Viral load, genotype C, viral mutations, and expression of inflammatory molecules in HBV-related HCC tissues are significantly associated with poor prognosis. Host-inflammation-related factors such as imbalance between intratumoral CD8⁺ T lymphocytes and regulatory T lymphocytes, T helper (Th)1 and Th2 cytokines in peritumoral tissues are also predictors of HBV-related HCC^[7,8]. In addition, non-coding RNA also plays a significant role in HCC progression^[9]. However, even after incorporating viral and other factors, the prediction power can not be optimized. Therefore, it is crucial to identify new prognostic markers to better approach opportunities for individualized therapeutics for HCC patients.

The application of high-throughput methods has provided new opportunities for analyzing the diversity and heterogeneity of cancers. Studies of microarray-based gene expression profiling in breast cancer have shown a great success and led to a working model for a breast cancer molecular taxonomy^[10]. Gene expression signatures succeeded in prognosis prediction and treatment responses for HCC^[11], and they are promising in developing personalized cancer medication^[12]. Gene expression profiles may add new and important prognostic information beyond those provided by the standard clinical predictors. It is important to incorporate molecular information to more accurately predict early and overall recurrence of HCC.

We read with great interest the recent article by Villanueva *et al.*^[13]. In this article, the authors developed an integrated prognostic model combining genomic and clinicopathologic data to improve outcome prediction in single-nodule early HCC patients. They analyzed the prognostic power of 22 previously reported gene signatures in a cohort of 287 early-stage HCC patients. The analysis showed that the proliferation signature was the most prevalent prediction (number of patients identified with the signature/number of total patients); and there was a substantial association among three groups of signatures: (1) signatures related to increased cell proliferation, progression in cell cycle and activation of specific pathways; (2) signatures generated in the adjacent tissues; and (3) cytokeratin-19 gene signature. They found that G3 (tumoral) signature and poor-survival (non-tumoral) signature, along with satellites were independent predictors of early tumor recurrence and overall recurrence. They also reported that genomic profiles of tumor and adjacent tissues were complementary in refining the prediction.

Advanced imaging techniques such as computed to-

mography and magnetic resonance imaging have been used to detect vascular invasion and conduct satellite evaluation before surgery, which are helpful in the pre-operative prediction of HCC prognosis. Genomic profiling using tumor and adjacent tissues obtained by fine-needle biopsy may provide complementary and/or confirmative information, thus having a great potential when combined with imaging findings in the clinical practice. Many studies have used array-based gene expression profiling obtained from tumoral or non-tumoral tissues to predict HCC prognosis. However, the number and heterogeneity of the signatures hinders their further application. The study of Villanueva *et al.*^[13] attempted to address these issues. They evaluated the prognostic predictive power of previously reported gene signatures in an independent cohort, and then developed a "composite genomic-based prognostic model". They further validated the stability of the model using samples from different sites of the same tumor nodule to test whether the genomic signature was consistent throughout different sites of a tumor^[13]. This study presents a unified approach to systematically evaluate and independently validate HCC prognostic gene signatures; and the procedure developed in this study is conducive to the future studies of other complex disease.

Cancer gene signatures may indicate specific biological traits of heterogeneous tumor sub-phenotypes that cannot be identified by traditional methods. They may be associated with tumor biology and tumor microenvironment such as chromosomal instability, wounded stroma, or invasiveness, and possibly also linked to certain signaling pathways^[14]. Gene signatures may have functional implications and may be predictive of response to specific therapeutic agents such as antiviral medications. Signatures identified in the study of Villanueva *et al.*^[13] (tumoral G3-proliferation signature and nontumoral poor-prognosis signature) reflect highly relevant biological events for outcome prediction and point out possible pathways to search for biomarkers as therapeutic targets. If used appropriately, gene signatures should be important complementary methods to current clinicopathological risk stratification systems^[15]. Integrating gene signatures in HCC prognosis prediction may potentially improve patient outcomes, obtain a better understanding of the underlying HCC biology, and identify effective therapeutic options for an individual patient.

HCC is not a single disease at the molecular level. Using gene signatures to classify HCC into molecular subtypes with similar prognostic implication can guide clinical decision-making, particularly regarding therapy. However, these signatures lack prognostic power. The assignment of a given patient to a subgroup is strongly dependent on the gene signature used and the results from studies of a specific/single gene signature cannot necessarily be generalized. Furthermore, there are few genes overlapped among gene expression signatures which reflect common cellular phenotypes and yield similar predictions. Therefore, it is not appropriate to use overlapping in gene identity to measure the reproducibility of gene-expression profiles^[16]. Thus, systematic evaluation of different gene

expression datasets and validation in independent cohorts provide basis for identifying true genomic signatures that are associated with oncogenic pathway, tumor biology and its microenvironment. Nevertheless, there are problems of using gene signatures to classify sub-phenotypes and predict HCC prognosis. In the following section, we take the paper of Villanueva *et al.*^[13] for an example to discuss several imposing issues in the field.

First, the paper does not mention whether evaluation on the quality of the different gene signatures was used. These signatures were generated from different samples with different biological background. Different studies may vary greatly in study quality, such as patient selection criteria, RNA quality, follow-up criteria, definition of prognosis, treatment after surgery, *etc.* Patient differences including different staging and underlying conditions may reflect etiological differences, thus resulting in the heterogeneity of gene signatures. Prognostic accuracy might differ in tumors with different stages. Additionally, multiple end points, such as overall recurrence, early recurrence, late recurrence, overall survival, or metastasis-free survival, used in the analyses are also the source of heterogeneity. There is also the possibility of stromal contamination, namely, gene signatures derived from analysis of tumor specimens with a high proportion of adjacent tissue contamination, and vice versa. The general reproducibility of these signatures stands out as an important issue.

Second, it is inappropriate to directly combine datasets from different platforms and different experiments because of the non-biological experimental variation or batch effects. In the study of Villanueva *et al.*^[13], gene expression data were obtained from 3 high-throughput genomic platforms, and these datasets cannot be readily put together because of their heterogeneity. Again, the authors did not mention whether any standardization procedures were applied. In addition, the method used for integration and/or standardization of different platforms is also a challenge. How to choose a robust normalization method according to the features of the dataset to reduce the batch effect is essential for further computational analyses^[17].

Third, the authors did not describe whether they applied the gene mapping procedure. Gene database updates with time, with the accumulation of information, the platform used several years ago may not be comparable to the gene database in service now. Without mapping, the genes in the 22 signatures produced at different time points may not correspond well. Accurately mapping and matching a gene across different signatures generated by different platforms at different time points is an important quality control step to enable the finding of true signatures.

Last but not least, the quality of survival analyses used to generate these signatures differs. The frequently used statistical methods, such as the significant analysis of microarray tool, the trend filter tool, and Cox's proportional Hazard model, may contribute to the great variety of gene expression signatures^[17]. Different studies also vary in terms of follow-up information collected, covariates

adjusted in multivariate analysis, and non-informative censoring. These directly affect the gene signatures generated.

For gene signatures to be used in clinical practice to accurately predict HCC prognosis, the following procedures are required. For a start, there should be a standardization of tissue composition. Without appropriate and standardized samples, the further experiments to determine a robust signature will be difficult. For example, the variable selection procedure is crucial in developing reliable and reproducible gene signature because pre-analytical variables such as stromal component and tissue processing will directly affect gene expression profiles. In addition, to enable the usage of data by different researchers and future investigators, a detailed description of data processing and analytical methods is required. A further step is to establish unified high criteria for generating gene expression signatures. Moreover, it is also important to identify gene signatures to predict early and late recurrence of HCC. HCCs are a group of diverse and heterogeneous diseases. Gene expression patterns can provide a basis to distinguish sub-phenotypes within the heterogeneity subgroups characterized by conventional clinicopathological variables, and also present important information about individualization of therapy^[18]. Viral mutations in the preS and the basal core promoter regions of HBV are significantly associated with HCC risk^[19-23]. The HBV mutations including A1762T/G1764A, preS deletion at nt.107-141, and preS2 mutations in adjacent hepatic tissues and the HCV mutation such as M91L are significantly associated with poor prognosis of HCC^[24-26]. The viral mutations should be reasonably integrated into the HCC prognosis-related gene signature.

To summarize, this paper drew our interests because gene expression signatures have shown great promise in classifying cancer subtypes and predicting prognosis. The Villanueva team has introduced an effective approach to systematically integrate different types of data for HCC prognosis prediction. With the increasing amount of data produced, there is an urgent need of standardized methods in systems biology to integrate descriptive data from cohort studies and other sources such as clinicopathological features, massive DNA and RNA parallel sequencing, and proteomics, along with functional data to guide therapeutic decisions. In addition, data on vascular features of HCC from imaging techniques may help select and validate true gene expression signatures associated with HCC prognosis. Future studies should also correlate these two non-invasive and innovative methods. It is still premature to use the current gene signatures for predicting HCC prognosis in the context of clinical practice. There is enormous work to be done for these gene signatures to be used in routine clinical practice and treatment decision making.

Abstract

High prevalence of non-alcoholic fatty liver disease (NAFLD) and very diverse outcomes that are related to disease form and severity at presentation have made the search for noninvasive diagnostic tools in NAFLD one of the areas with most intense development in hepatology today. Various methods have been investigated in the recent years, including imaging methods like ultrasound and magnetic resonance imaging, different forms of liver stiffness measurement, various biomarkers of necroinflammatory processes (acute phase reactants, cytokines, markers of apoptosis), hyaluronic acid and other biomarkers of liver fibrosis. Multicomponent tests, scoring systems and diagnostic panels were also developed with the purposes of differentiating non-alcoholic steatohepatitis from simple steatosis or discriminating between various fibrosis stages. In all of the cases, performance of noninvasive methods was compared with liver biopsy, which is still considered to be a gold standard in diagnosis, but is by itself far from a perfect comparative measure. We present here

the overview of the published data on various noninvasive diagnostic tools, some of which appear to be very promising, and we address as well some of still unresolved issues in this interesting field.

INTRODUCTION

Finding a means to noninvasive diagnosis of non-alcoholic fatty liver disease (NAFLD) and its entities has been the aim of many research efforts since recently, and seems to remain a very much needed goal among many clinicians and researchers in the field of hepatology. Why is it that way?

NAFLD is today considered to be the most common liver disease in adults. The prevalence of NAFLD in general population is very high, in the range of 15%-30% according to various studies, and is even increasing, due to

the rising prevalence of diabetes and obesity^[1]. Spectrum of NAFLD includes two entities with very different natural course and prognosis: simple steatosis, which mostly has a benign non-progressive course and good prognosis, and non-alcoholic steatohepatitis (NASH), which demonstrates progression of fibrosis in about 30%-40% of patients and has a proven potential to eventually lead to cirrhosis and end-stage liver disease including hepatocellular carcinoma^[2-4]. NASH seems to be present in a surprisingly high proportion of NAFLD patients, including 40% to 75% of cases with elevated aminotransferase levels, those data coming from recent studies using current histological definitions and including substantial number of patients^[2,5,6]. In studies of liver biopsy findings from apparently healthy living liver donor candidates, the proportion of NASH among patients with newly discovered NAFLD was about 30%^[7]. Even in patients with normal aminotransferase levels, proportion of NASH among NAFLD cases seems to be almost the same, and the whole spectrum of NAFLD including advanced fibrosis and cirrhosis has been observed in patients with completely normal laboratory findings^[6,8,9].

Liver biopsy is still considered the gold standard in diagnosis and the only reliable tool for distinguishing NASH from simple steatosis and for grading and staging the disease, providing important information about severity of steatosis, lobular inflammation, hepatocellular ballooning, and degree of fibrosis^[10]. Minimal histological criteria for NASH include steatosis, hepatocyte injury (in the form of ballooning or apoptosis) and lobular inflammation. Similarly to other chronic liver diseases, fibrosis is usually divided histologically in four stages: perisinusoidal fibrosis (F1), perisinusoidal and periportal fibrosis (F2), bridging fibrosis (F3) and cirrhosis (F4). Liver biopsy also has several negative aspects: it is invasive, unpleasant for patients, it usually includes hospitalization and a day or two lost at work, and the adequate interpretation of the specimen requires a pathologist with expertise in hepatopathology, which altogether makes it a costly and time-consuming procedure. Another significant drawback of liver biopsy, and in medical terms the most important one is its substantial sampling variability, which has been consistently proven for several chronic liver diseases including NAFLD. In a well-designed study by Ratziu *et al*^[11], the negative predictive value of a single biopsy for the diagnosis of NASH was calculated to be only 74%.

Considering the mentioned high prevalence of NAFLD in the general population, and the fact that every patient with NAFLD including the one with normal aminotransferases can potentially have NASH, we come to the conclusion that it would be necessary to perform liver biopsy in about one fourth of the whole Western population. This is clearly not feasible, but is it necessary? Until recently, many have advocated against the routine use of liver biopsy for patients with NAFLD because fatty liver is still considered by many to be a benign condition—although many studies have now clearly indicated a progressive course in a proportion of patients with NASH. Another reason for avoiding biopsy and definite diagno-

sis was the lack of established pharmacological treatment options which would have proven efficacy in preventing progression or leading to regression of disease.

Although there are still no generally approved treatments for NASH, several treatment options have demonstrated efficacy in various clinical trials, and for example recently published results of the randomized multicenter pioglitazone *vs* vitamin E *vs* placebo for the treatment of nondiabetic patients with nonalcoholic steatohepatitis (PIVENS) trial have provided substantial evidence for the previously suggested efficacy of vitamin E (and to a lesser extent pioglitazone) in inducing histologic improvement of NASH^[12]. Hopefully, we could soon expect to have several efficient treatment options available. All of this pretty much eliminates the validity of approach where NASH remains undiagnosed, which currently does happen in many clinical settings, e.g., in patients with accidental ultrasonographic finding of fatty liver and even patients with mildly elevated transaminase levels and known NAFLD risk factors who are very often not investigated any further.

The necessity of diagnosing NASH and the proportion of the population affected lead to a logical conclusion that a need for a reliable noninvasive tool in NAFLD diagnosis is highly urgent. Ideal noninvasive tool would be able to distinguish NASH from simple steatosis and allow for grading and staging of disease, which would largely facilitate screening of population at risk. Development of noninvasive tools would also enable monitoring of disease course and progression and evaluation of response to therapy, both in routine practice and in the setting of clinical trials, which is currently only possible with a follow-up liver biopsy. Another very important, and somewhat disregarded point, is that an efficient biomarker or set of biomarkers would accurately reflect the inflammatory and fibrotic processes on the level of the whole of liver parenchyma, thereby increasing the diagnostic accuracy and resolving the problem of sampling variability intrinsic to liver biopsy, which represents only about 1/50.000 part of the organ which is not homogeneously affected by disease features.

In the text below, we present the current level of knowledge and progress regarding the noninvasive diagnostic tools that have been studied in the context of NAFLD (Table 1).

ROUTINE LABORATORY TESTS

Patients with NAFLD are mostly asymptomatic and the disease is usually suspected based on either hyperechoic liver appearance on abdominal ultrasound or mild to moderate increases in liver enzyme levels. These are usually the only aberrations that can be encountered in this patient population (apart from signs of associated conditions like elevated glucose or lipid levels), and a large proportion of patients has completely normal laboratory findings. Hypoalbuminemia, prolonged prothrombin time, and hyperbilirubinemia are parameters of impaired liver function and occur only in patients who have already de-

veloped cirrhosis. Most commonly elevated enzymes are alanine aminotransferase (ALT) and γ -glutamyltransferase (GGT), while aspartate aminotransferase (AST) elevation is less frequent and when pronounced may indicate presence of advanced fibrosis^[13]. Many studies have tried to correlate liver enzyme levels with histological severity and progression of disease, and various results have been obtained. In some cases ALT, in other AST or GGT levels demonstrated best correlation with severity of inflammation or fibrosis and their progression/regression on follow-up biopsies^[4,14-16]. Equally important, the full spectrum of NAFLD including severe inflammation and fibrosis was proven to occur with almost similar frequency in patients with completely normal liver enzymes^[8,9].

IMAGING METHODS

Imaging modalities frequently used in the diagnosis of NAFLD include ultrasound, computed tomography and magnetic resonance imaging (MRI). While they are all very sensitive (80%-100%) and specific in detection of steatosis, none of them can effectively distinguish simple steatosis from NASH or determine the degree of fibrosis^[17]. Nevertheless, MRI is more sensitive than ultrasound in detecting lesser degrees of hepatic steatosis, and new techniques in MRI are constantly being developed that

provide additional data on different tissue parameters. One of them is magnetic resonance (MR) elastography, which estimates liver tissue stiffness by imaging the propagation of induced shear waves with a modified phase-contrast MR sequence. This technique was shown to have an excellent predictive value for excluding fibrosis, while sensitivity and specificity for discriminating between mild and more severe fibrosis was around 85%^[18]. A recent study investigated the performance of MR elastography in 58 patients with NAFLD and demonstrated very high accuracy with under the receiver operated curve (AUROC) of 0.93 for discriminating patients with NASH and those with simple steatosis, with a sensitivity of 94% and a specificity 73% by using a threshold of 2.74 kPa^[19]. The future advances in MRI technology including hepatic flow parameters and diffusion-weighted MRI may hopefully provide more MR-based tools for liver fibrosis detection. Ultrasound has also demonstrated the potential for improvement in diagnosis of NAFLD and NASH. Apart from ultrasound-based elastography, use of ultrasound contrast agents has been studied in this scenario, and signal intensity after contrast administration was shown to be significantly lower in NASH when compared with simple steatosis and normal liver^[20].

LIVER STIFFNESS MEASUREMENT

Transient elastography (FibroScan[®], EchoSens, Paris, France) is a relatively novel technique which measures liver tissue elasticity by measuring the speed of propagation of probe-induced vibrations through parenchyma by ultrasound. Elasticity shows significant correlation with degree of liver fibrosis, and FibroScan is considered to produce a reliable prediction of higher degrees of liver fibrosis. The method was first assessed in population of patients with hepatitis C, and after evaluation in multiple studies it has been introduced into clinical practice. A survey performed four years ago in France showed that about a third of hepatologists was using it (mostly in evaluation of patients with hepatitis C), and the method is now gaining increasing popularity in other countries as well^[21]. More recent studies have assessed transient elastography in population of patients with NAFLD, and obtained results that are similar to those from studies in hepatitis C^[22-24]. A consistent increase in liver stiffness with increasing fibrosis stage was observed, and the largest study, performed by Wong *et al*^[22], obtained AUROC values of 0.93 for advanced fibrosis and 0.95 for cirrhosis. When the liver stiffness cut-off was set at 7.9 kPa, negative predictive value for advanced fibrosis was excellent (97%), and could be applied to 60% of the population. On the other side, positive predictive value of having advanced fibrosis or cirrhosis was at best only 72.4%, at the 9.6 kPa cut-off. Accuracy of FibroScan in detecting significant fibrosis (defined as at least perisinusoidal and portal/periportal fibrosis) was poor, as was expected from previous experience.

Several meta-analyses have assessed performance of transient elastography in fibrosis detection, consisting

mostly of studies on hepatitis C patients. They have shown generally very good diagnostic accuracy in detecting cirrhosis and somewhat lesser precision in excluding advanced fibrosis, while they demonstrated substantial heterogeneity in diagnosis of significant fibrosis ($F \geq 2$)^[25,26]. Importantly, variation in cut-off values of liver stiffness has been large and these values still require validation. In conclusion, due to the relatively low specificity, the value of transient elastography seems to remain in ruling out cirrhosis and advanced fibrosis in patients with low liver stiffness values, while patients with intermediate values would still require liver biopsy for correct classification, and the proportion of patients with high stiffness values who are misclassified is not negligible. It is also important to take into account that the population of patients that is usually encountered in clinical practice does not have advanced fibrosis or cirrhosis in large proportions, and diagnosis of lesser degrees of fibrosis is equally important in estimating the risk for liver-related morbidity and mortality. A large study that evaluated frequency and reasons of failure to obtain the elasticity measurement found that FibroScan was feasible in over 95% of the patients, and the only factor associated with failure was body mass index greater than 28^[27]. Failure occurs due to the elastic and ultrasound wave attenuation by subcutaneous fat, and while this may not be a significant issue in other chronic liver diseases, it is an important limitation in patients with NAFLD, considering the prevalence of obesity in this population. In the study by Wong *et al.*^[22], measurement could not be obtained in over 10% of cases, which significantly reduced diagnostic accuracy when the 'intention-to-diagnose' analysis was performed.

Another noninvasive method of assessing tissue stiffness, acoustic radiation force impulse (ARFI) shear wave imaging, was recently assessed in a couple of studies with NAFLD patients^[28,29]. This ultrasound-based technique estimates the tissue stiffness by measuring transient tissue deformations of several microns which are induced in the liver parenchyma by acoustic radiation force. In a study on 172 NAFLD patients by Palmeri *et al.*^[29], ARFI imaging distinguished low (Stages 0-2) from high (Stage 3-4) fibrosis stages with a sensitivity and a specificity of around 90% (AUROC of 0.90). Body mass index over 40 kg/m² was not a limiting factor for ARFI imaging, which overcomes part of the problems associated with FibroScan. When compared to FibroScan, ARFI imaging demonstrated similar diagnostic performance^[28,30].

BIOMARKERS OF NECROINFLAMMATION

Most intense research is now being focused on biomarkers, measurable serum parameters that reflect the intensity of inflammatory processes and hepatocyte necrosis, as well as the ones that reflect extracellular matrix remodeling and collagen deposition. Ideally, an excellent biomarker would be specific for liver and accurately reflect the underlying pathogenetic processes on the level of whole organ, and thus be an even more precise indicator of the

disease than liver biopsy, which is prone to sampling variability and interpretation biases as described earlier.

Cytokeratin 18 fragments

Apoptosis is an important mechanism in pathogenesis of NASH, and its initiation leads to activation of caspase family of intracellular proteases which then cleave different intracellular proteins including cytokeratin 18 (CK-18), the major intermediate filament protein in hepatocytes. By measurement of CK-18 fragments hepatocyte apoptosis can be quantified, and this method was tested as a noninvasive tool in NASH diagnosis in several studies. Initial results were very promising, as Wieckowska *et al.*^[31] demonstrated a striking increase in serum CK-18 fragment levels in patients with definitive NASH, as well as their high diagnostic accuracy for differentiating between NASH and simple steatosis or normal liver, with AUROC of 0.93 and positive and negative predictive value of 95.0% and 89.5%, respectively. However, this study included only 39 patients, and the larger validation study that was subsequently undertaken and included 139 patients obtained less favourable results: median CK-18 fragment levels in NASH cases were now only 335 U/L (compared to 765 U/L in the first study, and to about 200 U/L in non-NASH cases in both studies), and diagnostic performance was expectedly poorer (calculated AUROC was 0.83 and sensitivity for diagnosing NASH was at best 77%, with the specificity rising above 90% only at the highest tested cut-off value)^[32]. Nevertheless, CK-18 fragment levels showed very good correlation with NASH, fibrosis and NAS (NAFLD activity score), and similar results were reported from other groups as well, supporting its potential role as a noninvasive tool in NAFLD^[33-35]. Even more importantly, in the study by Diab *et al.*^[35,36] on 99 patients who underwent bariatric surgery, CK-18 fragment levels showed a significant decrease 6 mo postoperatively, and in another study changes in CK-18 fragment levels closely paralleled changes in NAS on follow-up biopsy. These findings indicate the potential use of CK-18 fragment levels in the follow-up of patients with NASH, including evaluation of response to therapy. This certainly requires further attention, as it could possibly lead us closer to the goal of eliminating the need for second liver biopsy and thus facilitating design and conductance of clinical trials, as well as enhancing patient follow-up in clinical practice.

High-sensitivity C-reactive protein

C-reactive protein (CRP) is an acute-phase reactant produced by the liver in many inflammatory conditions, and based on the hypothesis that NASH is associated with low-grade systemic inflammation, several studies have compared high-sensitivity CRP levels in patients with NAFLD. Two studies found that hs-CRP levels were significantly higher in cases with NASH compared to those with simple steatosis, and hs-CRP also correlated well with presence of advanced fibrosis^[37,38]. However, a study performed earlier concluded that measurement of hs-CRP

was not useful in predicting the histological severity of NAFLD, as there was no relationship between the levels of hs-CRP and the grades of steatosis, necroinflammation or fibrosis^[39]. Further investigation including testing of diagnostic accuracy is needed before definite conclusions can be reached about usefulness of this marker in NAFLD.

Interleukin-6 and C-C chemokine ligand 2

Interleukin-6 (IL-6) is a proinflammatory cytokine that is involved in NAFLD pathogenesis, and Wieckowska *et al*^[40] demonstrated a markedly increased IL-6 expression in liver tissue of patients with NASH as compared to simple steatosis or normal liver, with a positive correlation with severity of inflammation and fibrosis. Plasma IL-6 levels that were parallelly measured in this study correlated well with liver IL-6 expression. In another study, IL-6 was among several serum markers evaluated in 47 NAFLD patients and 30 controls, and it was significantly increased in patients with NAFLD as compared to controls, but not in NASH compared to simple steatosis^[41]. This study also evaluated serum levels of C-C chemokine ligand 2 (CCL2), a chemokine responsible for monocyte/macrophage infiltration of liver and maintaining hepatic inflammation and fibrogenesis, and found that it was significantly elevated in patients with NASH compared to simple steatosis, but diagnostic performance of CCL2 levels was not tested. In a recent study, pharmacological inhibition of CCL2 had an effect on reduction of hepatic steatosis in a murine model, and CCL2 will presumably see some further investigation in the context of NAFLD^[42].

Plasma pentraxin 3

Plasma pentraxin 3 is a novel marker of systemic inflammation from pentraxin family of acute-phase proteins that is produced by diverse cell types in response to pro-inflammatory cytokines^[43]. Yoneda *et al*^[44] have evaluated pentraxin 3 levels in 70 patients with NAFLD, and found that they were significantly higher in cases with NASH compared to non-NASH, with the AUROC value of 0.75 for NASH detection. Pentraxin 3 levels also correlated well with the stage of fibrosis. These findings should provide basis for additional evaluation of this marker in other NAFLD patient cohorts.

Oxidative stress

Oxidative stress is one of the key mechanisms in NASH pathogenesis, and several studies have measured systemic markers of oxidative stress status in NAFLD patients and compared them between cases with NASH and controls^[45-47]. Different methods for measurement of oxidative stress have been used (measurement of levels of lipid peroxidation products, levels of antioxidant defence systems like vitamin E, glutathione peroxidase and superoxide dismutase activities, antioxidant capacity of the plasma and total plasma peroxide concentrations), and studies produced disparate results. Based on the current data, there is no doubt that oxidative stress is present in

NASH, but the utility of its measurement as a noninvasive tool in NAFLD diagnosis probably does not have any clinical value.

Tumor necrosis factor- α and adiponectin

Tumor necrosis factor (TNF)- α and adiponectin are cytokines which have been proven to play important roles in NAFLD pathogenesis, and the serum levels of these cytokines were determined in patients with NAFLD and correlated to disease severity in multiple studies^[48-52]. However, diagnostic accuracy in discerning NASH from simple steatosis and the potential for noninvasive use in diagnosis were generally not evaluated, and the data on diagnostic performance of these cytokines are not available. As of the published results, most of the studies demonstrated correlation of lower adiponectin levels with presence of NAFLD compared to healthy controls, presence of NASH compared to simple steatosis, and with histological severity of the disease, while levels of TNF- α and its soluble receptor were most often not significantly different between patients with NASH and patients with simple steatosis or controls. Thus, the potential for clinical use of these cytokines as noninvasive tools for diagnosis of NASH is questionable.

Insulin resistance

Insulin resistance state leads to increased lipolysis and free fatty acid flux to the liver, and elevated plasma glucose and insulin levels promote *de novo* fatty acid synthesis and impair β -oxidation, contributing to the development of hepatic steatosis. Although it is not clear whether insulin resistance causes hepatic steatosis or the liver fat accumulation represents the primary event leading to peripheral insulin resistance, there is no doubt that it plays an important role in the pathogenesis of NAFLD. Large population studies have shown that almost all of the NAFLD patients were insulin resistant according to the homeostasis model assessment of insulin resistance (HOMA-IR)^[53]. Additionally, the potential of insulin resistance measurement as a noninvasive diagnostic tool was also evaluated. In a study by Shimada *et al*^[54], the authors tested the diagnostic performance of adiponectin, insulin resistance measured by HOMA-IR, and type IV collagen 7S in discriminating NASH from simple steatosis. While performance of each of these markers individually wasn't great, sensitivity of the combination of three markers was 94%, with a specificity of 74%.

Although insulin resistance has been usually associated with type 2 diabetes, it can also be present in type 1 diabetic patients^[55]. The euglycemic insulin clamp technique which represents the gold standard for identifying type 1 diabetic patients who are insulin resistant is impractical for routine clinical use, and insulin resistance in type 1 diabetic patients was often recognized only by higher insulin requirements. Recent introduction of a validated method for estimated glucose disposal rate (eGDR) measurement based on clinical parameters has allowed its easier assessment in a clinical setting^[56]. A recently pub-

lished study demonstrated that NAFLD markers were associated with insulin resistance measured by eGDR in type 1 diabetic patients. NAFLD associated markers (ALT, AST, alkaline phosphatase, GGT and ferritin) worsened in parallel with the decline in insulin sensitivity and after adjustment for covariates, ALT, AST and alkaline phosphatase were independent predictors of insulin resistance^[57].

Multicomponent tests

There have been several attempts at constructing a panel of clinical and laboratory parameters that would, when combined using a formula or a scoring system, result in a value that enables distinguishing between NASH and simple steatosis. The most advanced attempt was a study by the French group specialized at developing diagnostic models for various liver conditions, who constructed a complex test (NashTest) which combines 13 parameters (age, sex, height, weight, triglycerides, cholesterol, α 2-macroglobulin, apolipoprotein A1, haptoglobin, GGT, ALT, AST and bilirubin) into a patented algorithm^[58]. Their design and validation study included 257 patients and 383 controls, and the NashTest had AUROC of 0.79 [95% confidence interval (CI) 0.69-0.86], with sensitivity for NASH (using criteria by Kleiner *et al.*^[59]) of only 33% and positive predictive value of 66%. The results were somewhat better when subgroups with borderline NASH and NASH were combined, the sensitivity rising to 88% and positive predictive value to 74%. In another study, a clinical scoring system was developed based on the results of multivariate analysis in a group of morbidly obese patients that underwent intraoperative liver biopsy at bariatric surgery^[60]. The proposed NASH Clinical Scoring System for Morbid Obesity included 6 clinical variables (hypertension, diabetes, AST, ALT, sleep apnea and non-black race) and was used to stratify morbidly obese into 4 groups regarding the risk for presence of NASH (low, intermediate, high and very high). In the studied group, the proportion of patients with low-risk score who had NASH was 13%, while it was 80% in those with very high-risk score. Recently, Miele *et al.*^[61] measured several markers of liver fibrosis in a cohort of 46 patients with NAFLD, and constructed a mathematical model based on the results of multivariate analysis that included age, hyaluronic acid and tissue inhibitor of metalloproteinase 1 levels. A specific cut-off value identified patients with NASH with 86% sensitivity, and negative and positive predictive values of 96% and 60%. This model could potentially be useful in excluding patients with negative values from liver biopsy consideration if these findings are confirmed in larger independent studies.

BIOMARKERS OF FIBROSIS

As with other chronic liver diseases, the most important indicator of severity and progression of liver damage in NAFLD is the presence and degree of liver fibrosis. Estimation of fibrosis is therefore essential in the diag-

nostic workup of patients with NAFLD, and it remains one of the major reasons for performing liver biopsy in this population. After a large number of studies was undertaken in hepatitis C patients that tried either to design tests and scoring systems using combinations of readily available clinical and biochemical parameters, or to find specific biomarkers of fibrosis processes that would adequately correspond to liver biopsy findings, similar attempts were made as well in populations of patients with NAFLD. Generally, while showing good accuracy in detection of advanced fibrosis or cirrhosis, all of these tests demonstrate significantly lower sensitivities in predicting the presence of mild or moderate fibrosis. The problem lies in the fact that this is exactly the group of patients that would benefit most from therapeutic interventions, before significant fibrosis has already developed, and they therefore require early diagnosis.

Hyaluronic acid and other markers of extracellular matrix turnover

Hyaluronic acid is a component of the extracellular matrix that can be measured in serum, where it partially enters through lymphatics. Serum levels are dependent on production, which increases with increased collagen synthesis, as well as degradation, which takes course in liver sinusoidal endothelial cells after binding to specific receptors. With progression of liver fibrosis, both increased production of collagen and decreased function of sinusoidal endothelial cells lead to elevation of hyaluronic acid serum levels.

Several groups have so far evaluated the potential use of hyaluronic acid levels in diagnosis of NASH-related fibrosis. Suzuki *et al.*^[62] investigated the potential of hyaluronic acid for use in diagnosing fibrosis in a cohort of 79 patients with NAFLD and various degrees of fibrosis. The hyaluronic acid serum levels demonstrated good correlation with the degree of hepatic fibrosis, and significant difference was noted especially when comparing mild to moderate (Stages 0-2) with severe fibrosis or cirrhosis (Stages 3-4). The calculated AUROC for severe fibrosis was 0.89 (95% CI 0.81-0.97), and at the optimal cut-off value of 46.1 ng/mL sensitivity was 85% (95% CI 62%-97%) and specificity 80% (95% CI 67%-89%). When a prevalence of severe fibrosis among NAFLD patients was assumed to be 20% (approximate of usual patient population at referral centers), the corresponding positive predictive value was 51% (95% CI 39%-68%) and negative predictive value 95% (95% CI 91%-100%). Accuracy for diagnosing mild fibrosis (Stage 1) was low and the number of patients with moderate fibrosis (Stage 2) was inadequate for valid analysis. Another study evaluated hyaluronic acid and laminin levels in 50 patients with NASH, of whom 23 had some degree of fibrosis and 27 had no fibrosis on liver biopsy^[63]. Subjects with NASH and fibrosis had significantly higher hyaluronic acid and laminin levels than those without fibrosis, and AUROC and diagnostic performance of both of these markers was calculated for differentiating between presence and

absence of fibrosis, showing excellent diagnostic accuracy of hyaluronic acid at the cut-off value of 148.8 ng/mL (reported sensitivity and specificity was over 95%). In the fibrosis group, levels of hyaluronic acid significantly increased with rising fibrosis stages, however the accuracy for distinguishing different fibrosis stages was not tested due to small patient numbers. Sakugawa *et al.*^[64] investigated the levels of hyaluronic acid and type VI collagen 7S domain in a population of 112 patients with NAFLD, of whom 70 were classified as NASH. On regression analysis, both markers were independently associated with the presence of NASH or severe fibrosis, but demonstrated sensitivity and specificity for severe fibrosis in the range of 70%-80%. However, if both markers were negative in a given patient, severe fibrosis was highly unlikely to be present (negative predictive value 95.2%).

Although some of these results look very promising, studies are still lacking in power, and the proposed cut-off values and calculated diagnostic accuracies are quite heterogeneous, which may be due to other factors in addition to difference in sample size, like difference in measurement methods and studied populations. Another important aspect of clinical usefulness of hyaluronic acid and other serum markers of fibrosis that hasn't yet been investigated is the question of sensitivity to longitudinal changes in fibrosis of liver parenchyma, which could potentially enable noninvasive patient follow-up and evaluation of treatment effects.

Multicomponent panels

FibroTest is a copyrighted panel developed by the French group who originally conceived it for diagnosis of liver fibrosis in hepatitis C, where it has subsequently been extensively studied. It includes 5 biochemical parameters (α 2-macroglobulin, apolipoprotein A1, haptoglobin, total bilirubin and GGT) that are incorporated into a patented formula. More recently, the authors of the panel conducted a study that thoroughly evaluated diagnostic performance of FibroTest in the setting of NAFLD by including 267 patients and a large number of healthy controls^[65]. Fibrosis stage was determined according to Kleiner *et al.*^[59], and advanced fibrosis included stages F2-F4 (perisinusoidal and portal/periportal fibrosis, bridging fibrosis and cirrhosis). Mean FibroTest value steadily increased with increasing fibrosis stage, and calculated AUROC for advanced fibrosis was 0.86 (95% CI 0.77-0.91), while it was 0.92 (95% CI 0.83-0.96) for bridging fibrosis or cirrhosis (F3-F4). A FibroTest cut-off score of 0.30 had 77% sensitivity and 90% negative predictive value, and score of 0.70 had 98% specificity and 76% positive predictive value for advanced fibrosis. As expected, performance was even better in detection of F3-F4, with 92% sensitivity and 98% negative predictive value. In addition to one third of patients having the value that fell between these two cut-offs and thus a nondiagnostic test result, other causes of FibroTest failure were analyzed and included Gilbert's syndrome, acute inflammation, and abnormal apolipoprotein A1 that was related to dyslipidaemia.

Another large multicenter study by a different group was undertaken and included a total of 733 patients divided in 2 groups in an attempt to develop and validate a noninvasive scoring system that would separate NAFLD patients with and without advanced liver fibrosis^[66]. The score was named NAFLD fibrosis score and included a formula with 6 variables (age, hyperglycemia, body mass index, platelet count, albumin and AST/ALT ratio), selected based on results of multivariate analysis. Biopsy was also scored according to Kleiner *et al.*^[59], but the diagnostic goal of advanced fibrosis included only Stages F3 and F4. AUROC values were 0.88 in estimation and 0.82 in validation set, and two cut-off points were determined similarly to the previously mentioned study. Using the low cut-off point, negative predictive value of the score was 93% in estimation group and 88% in validation group, while with the high cut-off point positive predictive value was 90% in estimation group and 82% in validation group. Only 25% of patients had score values between the cut-offs and would thus be considered as "indeterminate" and still require liver biopsy after this noninvasive test was performed.

After the European Liver Fibrosis Group developed an algorithm that included age, tissue inhibitor of matrix metalloproteinase 1, hyaluronic acid and aminoterminal peptide of pro-collagen III and tested its performance in diagnosing significant fibrosis in a large cohort of patients with various chronic liver diseases, another study was undertaken more recently that investigated performance of this panel specifically in NAFLD patients^[67,68]. The original panel was modified by excluding age and naming it enhanced liver fibrosis panel (ELF), and its diagnostic performance was tested in a cohort of 192 patients. The ELF panel had very good performance in distinguishing severe fibrosis (Stage F3-F4) with an AUROC of 0.90 (95% CI 0.84-0.96), while AUROC for detecting moderate and severe fibrosis together (F2-F4) was 0.82 (95% CI 0.75-0.88). Diagnostic accuracy varied with various cut-off points tested, and if cut-offs with 90% sensitivity and specificity for severe fibrosis detection were selected, 86% of study patients would have avoided a liver biopsy, with 76% correctly classified. The study also suggested that the addition of simple parameters, the ones included in previously mentioned NAFLD fibrosis score, could augment the diagnostic performance of the ELF panel, although additional studies with larger sample size would be required to confirm this.

CONCLUSION

Due to the very high prevalence of the disease and numerous difficulties related to establishing the diagnosis, NAFLD remains undiagnosed or incompletely defined in a large number of cases. Therefore, the search for the means to noninvasive diagnosis of different forms of NAFLD is a matter of uttermost importance. It is gaining even greater significance in the light of recent advances in the treatment of NASH, as the research efforts are finally starting to provide us with definite treatment

options. Recently published study with vitamin E and pioglitazone, as well as other current treatment trials place the necessity of establishing a correct diagnosis and not missing NASH in a whole different perspective^[12]. Furthermore, given the proportion of population with fatty liver and the fact that the presence of NASH in a given patient is often not linked with elevation in liver enzymes, the number of patients in need of a screening becomes daunting. After the insight in all of the aforementioned studies, we can see that some have indeed come very close and demonstrated very good diagnostic performance of certain noninvasive tools. However, the gold standard used in almost all of the studies is liver biopsy, and the question that remains is whether we are actually able to accurately assess the performance of noninvasive methods when the gold standard by itself has significant flaws. These flaws were very clearly demonstrated in a study of sampling variability in NAFLD by Ratziu *et al*^[11]. One can also pose the question: have we maybe found an excellent noninvasive tool already, but are ignorant of the fact due to our incapability to actually see “the absolute truth”? This question has been addressed in a study by Mehta *et al*^[69], who calculated the AUROC for a hypothetical liver histology surrogate marker against the biopsy for a range of possible performances of both tests. The authors found that an ideal marker (99% accuracy) could in the best possible setting (sensitivity and specificity of biopsy 90%, prevalence of significant disease 40%) have an AUROC of not more than 0.90. This may mean that, unless an alternative gold standard is found, we might as well be in pursuit of something that isn't there.

Abstract

AIM: To determine whether expression of certain enzymes related to 5-fluorouracil (5-FU) metabolism pre-

dicts 5-FU chemosensitivity in cholangiocarcinoma (CCA).

METHODS: The histoculture drug response assay (HDRA) was performed using surgically resected CCA tissues. Tumor cell viability was determined morphologically with hematoxylin and eosin- and terminal deoxynucleotide transferase-mediated dUTP nick-end labeling-stained tissues. The mRNA expression of thymidine phosphorylase (TP), orotate phosphoribosyl transferase (OPRT), thymidylate synthase (TS), and dihydropyrimidine dehydrogenase (DPD) was determined with real-time reverse transcriptase-polymerase chain reaction. The levels of gene expression and the sensitivity to 5-FU were evaluated.

RESULTS: Twenty-three CCA tissues were obtained from patients who had been diagnosed with intrahepatic CCA and who underwent surgical resection at Srinagarind Hospital, Khon Kaen University from 2007 to 2009. HDRA was used to determine the response of these CCA tissues to 5-FU. Based on the dose-response curve, 200 µg/mL 5-FU was selected as the test concentration. The percentage of inhibition index at the median point was selected as the cut-off point to differentiate the responding and non-responding tumors to 5-FU. When the relationship between TP, OPRT, TS and DPD mRNA expression levels and the sensitivity of CCA tissues to 5-FU was examined, only OPRT mRNA expression was significantly correlated with the response to 5-FU. The mean expression level of OPRT was significantly higher in the responder group compared to the non-responder group (0.41 ± 0.25 vs 0.22 ± 0.12 , $P < 0.05$).

CONCLUSION: OPRT mRNA expression may be a useful predictor of 5-FU chemosensitivity of CCA. Whether OPRT mRNA could be used to predict the success of 5-FU chemotherapy in CCA patients requires confirmation in patients.

INTRODUCTION

Cholangiocarcinoma (CCA), a bile duct epithelial tumor, has poor prognosis owing to the absence of an early diagnostic method and effective treatments. The only curative therapy is surgical resection, but most CCA patients are diagnosed at an unresectable stage. Therefore, chemotherapy is the only practical treatment^[1].

5-fluorouracil (5-FU) is one of the most common anticancer agents and is used to treat a variety of solid tumors. 5-FU alone or 5-FU-based regimens are widely used to treat CCA patients. As reviewed by Thongprasert^[2], the overall response rate and median survival time following treatment with 5-FU for CCA are 10% and 6.5 mo, respectively. In addition, a combination of 5-FU and leucovorin yields a response rate of 32% and a median survival time of 6 mo^[2]. Combination therapy of 5-FU with cisplatin consistently yields response rates of 10%-40%, and median survival times are better than those observed with 5-FU alone^[2]. Combinations of 5-FU with taxanes or etoposide, however, have not shown convincing superiority over 5-FU alone for CCA treatment^[3,4]. Thus, data obtained from these clinical studies revealed relatively poor response rates of CCA to 5-FU-based regimens.

After entering cells, 5-FU is converted to 5-fluorodeoxyuridine monophosphate (FdUMP) through intermediary molecules by thymidine phosphorylase (TP) and orotate phosphoribosyl transferase (OPRT)^[5-7]. FdUMP then forms a complex with thymidylate synthase (TS), leading to inhibition of DNA synthesis^[5]. In addition, 5-FU can be phosphorylated by OPRT to form 5-fluorouridine monophosphate, and then to 5-fluorouridine triphosphate, which is subsequently incorporated into RNA, resulting in RNA dysfunction^[8]. In the degradation pathway, 5-FU is metabolized by dihydropyrimidine dehydrogenase (DPD) to an inactive metabolite, 5-fluorodihydrouracil, and subsequently excreted in the urine^[9]. The resistance of several cancer types to 5-FU may be due to alterations in the expression of several genes that are involved in the metabolism and action of this drug^[10]. Moreover, the expression and activities of these enzymes

have been proposed as markers to predict the response to 5-FU of several cancers such as gastric cancers and metastatic colorectal cancer^[11-14].

Because 5-FU is the main chemotherapeutic agent for treatment of CCA, elucidating the molecular mechanism involved in the response to 5-FU may be useful for the treatment of CCA. In the present study, we examined the correlation between mRNA expression of target genes involved in 5-FU metabolism and the chemosensitivity of cancer tissues to 5-FU in 23 CCA patients.

MATERIALS AND METHODS

Chemicals

Hank's balanced salt solution (HBSS), RPMI 1640 medium, fetal bovine serum, penicillin, and streptomycin were purchased from GIBCO BRL (Grand Island, NY, United States). Collagen gel sponges were purchased from Pharmacia and Upjohn (Kalamazoo, MI, United States). 5-FU was provided by Fresenius Kabi Oncology Ltd. (Hayarna, India). The DeadEnd Colorimetric Terminal deoxynucleotide transferase-mediated dUTP nick-end labeling (TUNEL) system was purchased from Promega (Madison, WI, United States). TRIzol reagent was purchased from Invitrogen (Carlsbad, CA, United States). The TaqMan[®] gene expression assay kit and TaqMan Universal polymerase chain reaction (PCR) master mix with AmpErase UNG were purchased from Applied Biosystems (Foster City, CA, United States).

CCA tissues

Twenty-three samples of CCA tissues were obtained from patients who had been diagnosed with intrahepatic CCA and who underwent surgical resection at the Department of Surgery, Srinagarind Hospital, Khon Kaen University between 2007 and 2009. The histological types of the CCA tissues were classified according to the World Health Organization classification. Of these patients, 69.6% were men. The median age of the CCA patients was 61 years (range: 42-70 years). Written informed consent was obtained from all patients before the collection of tumor tissues. The study protocol was approved by the Khon Kaen Ethics Committee for Human Research, Khon Kaen University, Thailand (HE500501).

Histoculture drug response assay

After surgery, the tumor tissues were immediately transferred to the laboratory in HBSS containing 100 IU/mL penicillin and 100 µg/mL streptomycin. Histoculture drug response assay (HDRA) was performed as described^[13] with some modifications. Cubes of collagen gel sponge (1 cm³) were immersed in 1 mL RPMI 1640 containing 20% fetal bovine serum, 100 IU/mL penicillin, 100 µg/mL streptomycin, and 5-FU at final concentrations of 100, 200, and 400 µg/mL in a 24-well plate. After washing six times in HBSS, the tumor tissues were aseptically cut into small pieces using biopsy punches (3 mm diameter), placed on the collagen gel sponges, and cultured at 37 °C for 4 d

in a 5% CO₂ atmosphere. Duplicate tissue cultures were performed for each drug concentration. Wells containing culture medium without 5-FU were used as controls.

After 4 d of culture, the viability of tumor cells in the cultured tissues was examined with histology. Hematoxylin and eosin (HE) and TUNEL staining were used to assess cell viability^[15]. In brief, tissues were fixed in 4% formaldehyde and embedded in paraffin, and 4- μ m tissue sections were cut. Deparaffinized sections were rehydrated, stained with HE and TUNEL, and examined under a microscope. *In situ* TUNEL was carried out according to the manufacturer's instructions. TUNEL-positive cells were quantified in at least four high-power fields ($\times 40$) of randomly selected tissue sections. The total live tumor cells showing anaplastic characteristics with hyperchromatic nuclei/cytoplasm were counted and scored as the percent of the total tumor cells. TUNEL-stained tumor cells were identified as dead cells. The efficacy of 5-FU was calculated and expressed as the inhibition index (% I.I.) using the following formula: % I.I. = $(1 - \% \text{ living tumor cells in 5-FU-treated tumor tissue} / \% \text{ living tumor cells in control tissue}) \times 100$. The % I.I.s at various concentrations of 5-FU ranging from doses of 100-400 μ g/mL were determined.

Determination of mRNA expression

The mRNA expression of target genes including those encoding TS, DPD, TP, OPRT and glyceraldehyde 3-phosphate dehydrogenase (GAPDH) in CCA tissues was determined by reverse transcription and quantitative real-time PCR. In brief, total RNA of each CCA tissue was isolated using TRIzol reagent according to the manufacturer's protocol. Reverse transcription was performed as described^[16].

The mRNA expression of the target gene was determined using the TaqMan[®] gene expression assay kit according to the manufacturer's instructions. Real-time PCR was performed in 20- μ L PCR reactions containing TaqMan Universal PCR master mix, target-specific primers, one TaqMan[®] MGB FAM[™] dye-labeled probe, and 50 ng cDNA. Each PCR was carried out in duplicate. The PCR conditions were 50 °C for 2 min and 95 °C for 10 min, followed by 40 cycles at 95 °C for 15 s and 60 °C for 1 min. All data were analyzed using the ABI PRISM 7500 Real-time PCR system sequence detection software v.1.4 (Applied Biosystems). The quantity of target cDNA or GAPDH PCR product was calculated using the corresponding standard curve, and the amount of target cDNA in a given sample was normalized to that of GAPDH cDNA.

Statistical analysis

The Student's *t*-test was used to compare the % I.I. values between the responder and non-responder groups.

RESULTS

Microscopic examination of CCA tissues after HDRA

HE- and TUNEL-stained sections of control and 5-FU treated CCA tissues are shown in Figure 1. After 4 d of culture on the collagen gel sponge, the CCA tissue archi-

tecture including cell-to-cell contact was well maintained. Most of the tumor cells were alive and showed anaplastic characteristics with hyperchromatic nuclei/cytoplasm (short arrows). On the other hand, cells with eosinophilic cytoplasm, shrunken (condensed) nuclei (pyknotic nuclei), and fragmented nuclei (karyorrhexis, indicated by long arrows) were found in 5-FU-treated cells. TUNEL-stained tumor cells were identified as dead cells. The mean percentage of living tumor cells in control tissues at day 4 was $83.3\% \pm 14.2\%$ of those observed at day 0. In addition, the proportion of viable tumor cells in control condition gradually decreased on days 5, 6 and 7 of culture; therefore HDRA of CCA tissues was performed for 4 d.

Response of CCA tissues to 5-FU

The responses of CCA tissues to various concentrations of 5-FU ranging from 100-400 μ g/mL were determined using CCA tissues obtained from five patients. Dose-dependent responses of CCA tissues to 5-FU were observed (Figure 2). From these results, a 5-FU concentration of 200 μ g/mL was selected as the test concentration. The % I.I. values for 5-FU (200 μ g/mL) treatment of 23 CCA tissues are shown in Figure 3. The median % I.I. value was selected as the cut-off to classify CCA tissues as responders or non-responders (Figure 3).

Relationship between the expression of target genes and the sensitivity to 5-FU

For each CCA tissue, mRNA expression was quantified with real-time PCR using specific TaqMan probes for genes encoding enzymes involved in the 5-FU metabolic pathway, including TS, DPD, TP and OPRT. Moderate variability in the expression levels of TS, TP and OPRT mRNA normalized to GAPDH expression among individual samples was observed (24-fold, range: 0.05-1.22; 33-fold, range: 0.13-4.27, and 17-fold, range: 0.06-1.02, respectively), whereas high variability was observed for DPD expression (135-fold, range: 0.05-6.76).

Scattered, overlapping expression levels of these genes were observed in the responder and non-responder groups. However, the mean expression level of OPRT was significantly higher in the responder group compared to the non-responder group (0.41 ± 0.25 vs 0.22 ± 0.12 , $P < 0.05$, Figure 4). The mean expression levels of TS, DPD, and TP appeared higher in the responder group compared to the non-responder group, but the differences were not statistically significant (0.26 ± 0.32 vs 0.18 ± 0.12 , $P = 0.43$; 1.73 ± 1.96 vs 0.74 ± 0.50 , $P = 0.12$; and 1.60 ± 1.16 vs 1.02 ± 0.72 , $P = 0.16$, respectively; Figure 4).

DISCUSSION

5-FU is phosphorylated in cells to become an active metabolite that inhibits DNA synthesis and induces RNA dysfunction^[5,8]. Intra-tumoral gene expression and activities of several enzymes related to 5-FU metabolism correlate with sensitivity to this drug for the treatment of several cancers^[11-14]. Of the genes we studied, OPRT seems to have predictive power and may be a promising

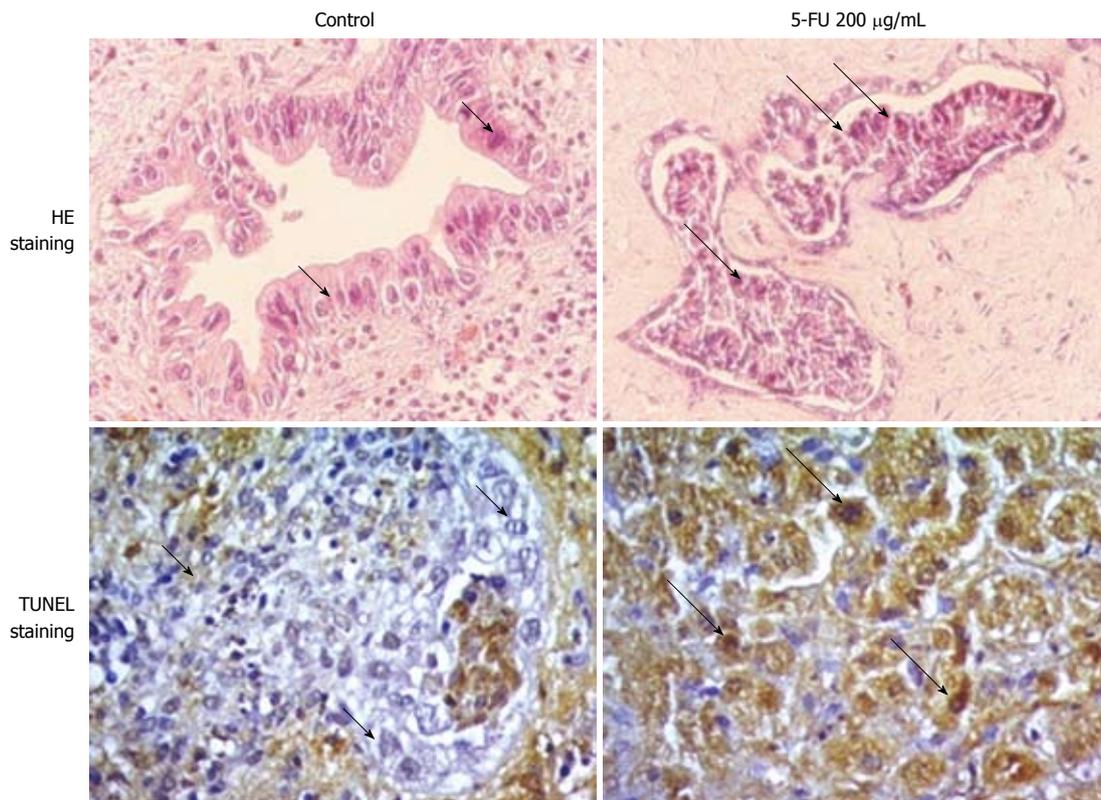

Figure 1 Photomicrographs (40 ×) of hematoxylin and eosin-stained and terminal deoxynucleotide transferase-mediated dUTP nick-end label-stained sections of cholangiocarcinoma tissues cultured on collagen gel sponges for 4 d in the absence or presence of 5-fluorouracil. Tumor cells with anaplastic characteristics showing hyperchromatic nuclei/cytoplasm are indicated with short arrows. Cells with eosinophilic cytoplasm with shrunken (condensed) nuclei (pyknotic nuclei) and fragmented nuclei (karyorrhexis) are indicated with long arrows. 5-FU: 5-fluorouracil; HE: Hematoxylin and eosin; TUNEL: Terminal deoxynucleotide transferase-mediated dUTP nick-end label

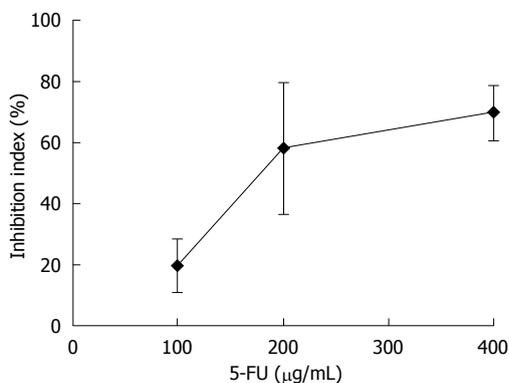

Figure 2 Dose-response-curve of cholangiocarcinoma tissues to 5-fluorouracil. Sensitivities of five cholangiocarcinoma tissues to 5-fluorouracil (5-FU) are shown as the percent of inhibition index (% I.I.), which was evaluated at doses of 100 µg/mL, 200 µg/mL, and 400 µg/mL using histoculture drug response assay. Data are the mean ± SD of two independent experiments.

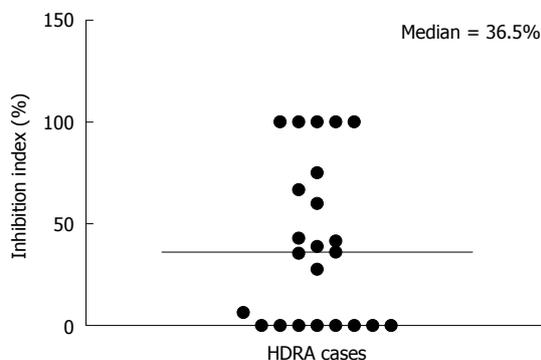

Figure 3 Distribution of percent of inhibition index of 23 cholangiocarcinoma tissues to 200 µg/mL 5-fluorouracil. Sensitivities of 23 cholangiocarcinoma (CCA) tissues to 5-fluorouracil (5-FU) were evaluated at 200 µg/mL 5-FU using histoculture drug response assay (HDRA). The median value of % I.I. (36.5%) was selected as the cut-off for classifying these tissues as responders and non-responders. Each circle represents one CCA sample. The median is shown by the long, thin horizontal line.

marker. High enzymatic activity of OPRT in tumor tissues is associated with high sensitivity of urinary bladder cancer^[17] and colorectal cancer^[18] to 5-FU. In addition, OPRT mRNA or the ratio of OPRT/DPD mRNA is associated with prolonged survival of metastatic colon cancer patients receiving oral tegafur-uracil and leucovorin^[11] and colorectal liver metastasis patients receiving intra-arterial chemotherapy with 5-FU^[19]. In addition, combined

expression of OPRT and TS in pre-chemotherapeutic fresh-frozen samples obtained from primary tumors may predict the response to S-1, an oral DPD-inhibiting fluoropyrimidine, in metastatic gastric cancer patients^[20]. Consistent with the previous studies, we observed here that intratumoral expression of OPRT mRNA in the responder group was significantly higher than expression

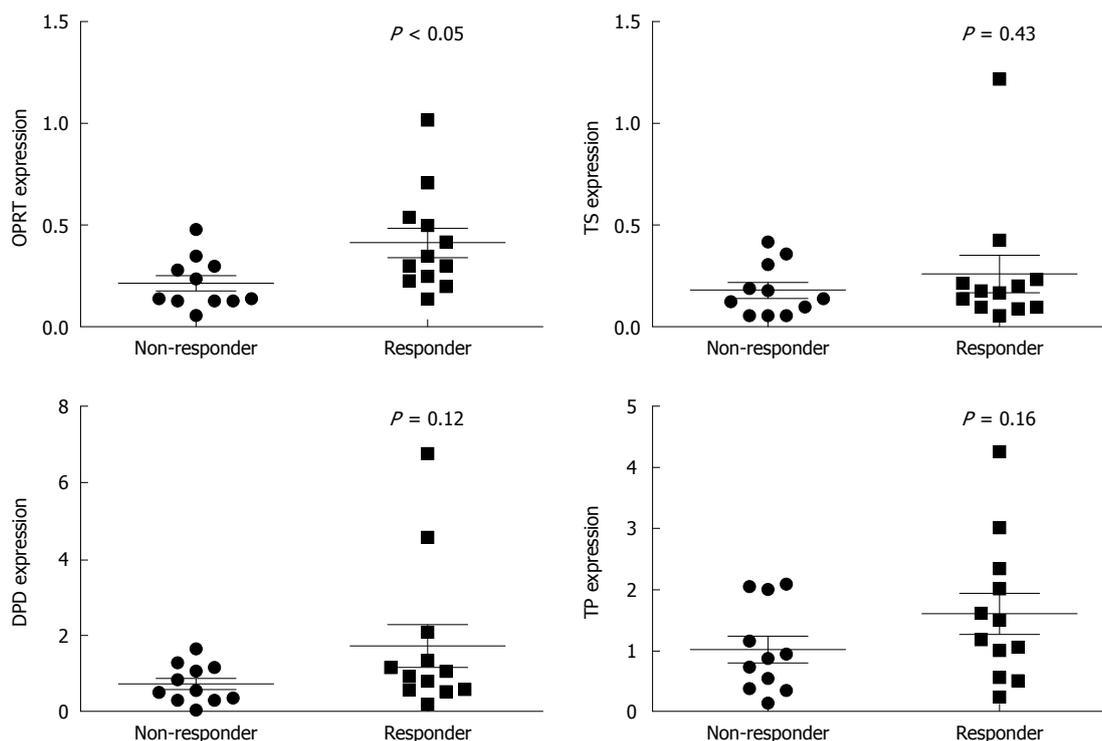

Figure 4 Relationship between chemosensitivity to 5-fluorouracil and mRNA expression of thymidine phosphorylase, orotate phosphoribosyl transferase, thymidylate synthase, and dihydropyrimidine dehydrogenase in 23 cholangiocarcinoma tissues. Chemosensitivity to 5-fluorouracil (5-FU) and mRNA expression were analyzed for 23 cholangiocarcinoma (CCA) tissues using histoculture drug response assay and quantitative real-time reverse transcription-polymerase chain reaction. The responders and non-responders were classified using the median value of the % I.I. as the cut-off point. The mRNA expression of orotate phosphoribosyl transferase (OPRT) was significantly higher in the responder ($P < 0.05$) group. The mRNA levels of thymidylate synthase (TS), and dihydropyrimidine dehydrogenase (DPD) and thymidine phosphorylase (TP) in the non-responder and responder groups, however, were not significantly different. The long, thin lines represent the mean, and the error bars represent the SD values. Each symbol (circles and squares) represents one CCA tissue sample.

in the non-responder group. These results suggest that the OPRT mRNA level in CCA tissues may be a promising predictor of an *in vitro* sensitivity to 5-FU using the HDRA technique. It should be noted that we observed overlapping expression levels of each gene among responder and non-responder tumors.

We observed moderate variability in the expression levels of TS, TP, and OPRT mRNA among individual samples (24-fold, 33-fold and 17-fold, respectively). The moderate differences in OPRT and TS expression levels observed in the present study were similar to those previously observed in gastric carcinoma and colorectal tissues^[21,22]. Similar to the variability reported in colorectal^[22] and esophageal carcinoma^[23], we observed high variability in the expression of DPD among CCA tissues. Genetic polymorphisms of genes encoding TP, DPD, TS and OPRT are well known^[24-27]. Variable expression of DPD, TP, TS and OPRT may explained by genetic polymorphisms in these genes.

TP is the first enzyme involved in the metabolic activation pathway of 5-FU to 5-fluorodeoxyuridine (FdUR), which can be phosphorylated by thymidine kinase to form FdUMP^[28]. In this study, no relationship was found between the intratumoral expression of TP mRNA and the sensitivity to 5-FU. In addition to TP, that the rate of conversion of 5-FU to FdUR could be influenced by the availability of the TP cofactor, deoxyribose-1-phosphate

(dRib-1-P) in cells^[29]. It has been previously demonstrated that the addition of dRib-1-P greatly increases the incorporation of thymidine into DNA and increases the potency of the growth-inhibitory actions of 5-FU^[30]. Thus, it may be possible that the amount of dRib-1-P in CCA tissues may be limited. Similar observations have been reported in colorectal tumor that there was no relationship between TP expression and 5-FU sensitivity^[31,32].

TS is a key enzyme that catalyzes the methylation of deoxyuridine monophosphate to deoxythymidine monophosphate, an important step in DNA synthesis^[33]. Colon cancer patients with high TS expression are reportedly un-responsive to 5-FU and show poor prognosis^[34]. In contrast, tumoral expression of TS mRNA is associated with response to protracted infusions of 5-FU-based chemotherapy and survival in patients with disseminated colorectal cancer^[35]. Consistent with a report on colorectal tumors^[36], no relationship between TS expression and sensitivity to 5-FU in CCA *in vitro* was observed in our present study.

DPD is a major enzyme in the metabolism of 5-FU to an inactive metabolite. Some reports have suggested a negative correlation between 5-FU sensitivity and DPD activity in human stomach cancer cells^[37]. In patients with advanced colorectal cancer treated with 5-FU/leucovorin, patients who responded to the treatment exhibited low levels and a narrow distribution range of DPD mRNA

expression compared to the non-responder group^[32]. In the present study, DPD mRNA expression was apparently higher in the responders than in the non-responders. However, no clear relationship was found between DPD mRNA expression and 5-FU sensitivity.

In conclusion, we developed HDRA as an *in vitro* screening of the response of CCA tissues to 5-FU. We found that the level of OPRT mRNA may be a promising predictor of CCA sensitivity to 5-FU. Whether the OPRT mRNA level could be used as a predictor of the success of 5-FU chemotherapy in CCA patients needs to be confirmed further in patients.

ACKNOWLEDGMENTS

The authors sincerely thank Professor Will J, University of Wisconsin, United States and Professor Nawa Y, Visiting Professor, Faculty of Medicine, Khon Kaen University for reviewing the manuscript.

COMMENTS

Background

Cholangiocarcinoma (CCA) has a poor prognosis owing to the absence of effective treatments. Data from clinical studies have revealed that the response rate of CCA to 5-fluorouracil (5-FU) or 5-FU-based regimens is relatively poor. Therefore, a method to identify patients who may benefit from 5-FU is required.

Research frontiers

The histoculture drug response assay (HDRA) was used to determine the response of 23 CCA tissues to 5-FU. By determining the relative expression levels of several genes involved in the action and metabolism of 5-FU, they found that the orotate phosphoribosyl transferase (OPRT) mRNA level was significantly correlated with the response of CCA to 5-FU.

Innovations and breakthroughs

This is the first report to show a relationship between OPRT mRNA expression and the sensitivity of CCA tissues to 5-FU.

Applications

The HDRA may be useful as an *in vitro* test for determining the sensitivity of CCA tissues to anticancer agents. Based on the results from this study, OPRT mRNA expression may be a useful predictor of the chemosensitivity of CCA to 5-FU.

Peer review

This is a good descriptive study in which authors analyze whether expression of certain enzymes related to 5-FU metabolism predicts 5-FU chemosensitivity in CCA. This is an interesting paper of the basic research data of CCA using HDRA.

Abstract

AIM: To investigate the expression of chondroitin sulphate proteoglycans (CSPGs) in rat liver tissues of hepatocellular carcinoma (HCC).

METHODS: Thirty male Sprague Dawley rats were randomly divided into two groups: control group ($n = 10$) and HCC model group ($n = 20$). Rats in the HCC model groups were intragastrically administered with 0.2% (w/v) N-diethylnitrosamine (DEN) every 5 d for 16 wk, whereas 0.9% (w/v) normal saline was administered

to rats in the control group. After 16 wk from the initiation of experiment, all rats were killed and livers were collected and fixed in 4% (w/v) paraformaldehyde. All tissues were embedded in paraffin and sectioned. Histological staining (hematoxylin and eosin and Toluidine blue) was performed to demonstrate the onset of HCC and the content of sulphated glycosaminoglycan (sGAG). Immunohistochemical staining was performed to investigate the expression of chondroitin sulphate (CS)/dermatan sulphate (DS)-GAG, heparan sulphate (HS)-GAG, keratan sulphate (KS)-GAG in liver tissues. Furthermore, expression and distribution of CSPG family members, including aggrecan, versican, biglycan and decorin in liver tissues, were also immunohistochemically determined.

RESULTS: After 16 wk administration of DEN, malignant nodules were observed on the surface of livers from the HCC model group, and their hepatic lobule structures appeared largely disrupted under microscope. Toluidine blue staining demonstrated that there was an significant increase in sGAG content in HCC tissues when compared with that in the normal liver tissues from the control group [0.37 ± 0.05 integrated optical density per stained area (IOD/area) and 0.21 ± 0.01 IOD/area, $P < 0.05$]. Immunohistochemical studies demonstrated that this increased sGAG in HCC tissues was induced by an elevated expression of CS/DS (0.28 ± 0.02 IOD/area and 0.18 ± 0.02 IOD/area, $P < 0.05$) and HS (0.30 ± 0.03 IOD/area and 0.17 ± 0.02 IOD/area, $P < 0.01$) but not KS GAGs in HCC tissues. Further studies thereby were performed to investigate the expression and distribution of several CSPG components in HCC tissues, including aggrecan, versican, biglycan and decorin. Interestingly, there was a distinct distribution pattern for these CSPG components between HCC tissues and the normal tissues. Positive staining of aggrecan, biglycan and decorin was localized in hepatic membrane and/or pericellular matrix in normal liver tissues; however, their expression was

mainly observed in the cytoplasm, cell membranes in hepatoma cells and/or pericellular matrix within HCC tissues. Semi-quantitative analysis indicated that there was a higher level of expression of aggrecan (0.43 ± 0.01 and 0.35 ± 0.03 , $P < 0.05$), biglycan (0.32 ± 0.01 and 0.25 ± 0.01 , $P < 0.001$) and decorin (0.29 ± 0.01 and 0.26 ± 0.01 , $P < 0.05$) in HCC tissues compared with that in the normal liver tissues. Very weak versican positive staining was observed in hepatocytes near central vein in normal liver tissues; however there was an intensive versican distribution in fibrosis septa between the hepatoma nodules. Semi-quantitative analysis indicated that the positive rate of versican in hepatoma tissues from the HCC model group was much higher than that in the control group (33.61% and 21.28%, $P < 0.05$). There was no positive staining in lumican and keratan, two major KSPGs, in either normal or HCC liver tissues.

CONCLUSION: CSPGs play important roles in the onset and progression of HCC, and may provide potential therapeutic targets and clinical biomarkers for this prevalent tumor in humans.

INTRODUCTION

Proteoglycans (PGs) are remarkably complex macromolecules consisting of one or more glycosaminoglycan (GAG) chains, which are covalently attached to different core proteins. Depending upon the structures of their GAG side-chains, PGs can be categorized as different groups such as heparan sulphate PGs (HSPGs), chondroitin/dermatan sulphate PGs (CS/DS PGs) and keratan sulphate PGs (KSPGs)^[1]. According to their different structures of the core proteins, CS/DS PGs can be further categorized as large aggregating PGs (aggrecan, versican), and small leucine-rich PGs (biglycan and decorin), which have been found to be widely expressed in many tissues including liver.

CS/DS PGs are major components of the cell surface and extracellular matrix (ECM)^[1,2]. They perform

a myriad of functions ranging from structural roles in the ECM to control of growth factor gradients and the regulation of certain cell processes such as cell adhesion, growth, receptor binding, migration, and interactions with other ECM constituents^[3-5]. These, especially the latter two functions, are largely mediated through specific interactions between their charged GAG chains and proteins such as growth factors, cytokines, chemokines, proteinases and their inhibitors^[6,7]. In addition, emerging data have revealed that the core proteins of PGs can also form complexes with other proteins, such as integrins and regulate their signaling^[7]. Because CS/DS PGs are at the crossroads of many signaling events and the abilities to regulate cell behaviors, they are being extensively investigated for their potential as therapeutic targets for cancers. What has become clear to date is that the functional effects of CS/DS PGs on cancers can range from stimulatory to inhibitory influences^[5], depending on the core protein and GAG structures^[1,8], the types and stages of cancers and the localizations of the tumors^[9].

PGs have been found widespread and abundant in liver tissues^[10]. Interestingly, in rats, fetal and early neonatal liver exhibits a completely different PG expression pattern when compared with adult liver tissues, where the synthesis of heparan sulphate (HS) comprises more than 80% and CS less than 5% of total GAGs^[11]. In contrast, CS is the major type of GAG synthesized in fetal liver, representing above 50% of total sulfated GAG (sGAG). Moreover, the overall PG production in fetal liver is enhanced two-fold when compared with that in the adult liver tissues. Thus, the synthesis of CS is elevated nearly 30-fold in fetal liver as compared with the adult counterpart^[12]. Immediately after birth CS formation decreases rapidly to the adult levels between the 10th and 15th day of postnatal life^[13], whereas the production of HS is almost unchanged during perinatal liver development due to a relatively low fractional synthesis of HS GAG in fetal liver^[12]. This phenomenon illustrates that CSPG synthesis and expression in liver tissues are cell-type dependent, and the undifferentiated liver cells trend to produce more CSPGs compared with the differentiated hepatocytes in the adult liver tissues.

Interestingly, the expression patterns of PGs including HSPGs and CSPGs are markedly changed under pathological conditions^[14]. For example, PGs are abnormally expressed in a wide variety of malignant tumors^[9]. In liver, hepatocellular carcinoma (HCC) and hepatic parenchyma adjacent to tumor contain abnormally higher concentrations of CS GAGs than the corresponding healthy tissues, but only with mild alteration in HS expression, indicating that the increase in CS GAGs is a characteristic abnormality in HCC tissues^[15-17]. This indicates that the expression of CSPGs plays a pivotal role in the occurrence, progression and metastasis of HCC, and therefore CSPG expression may be a potential marker and treatment target for HCC.

In this study, the expression patterns of different CSPGs including aggrecan, versican, decorin, biglycan in

the liver tissue from a rat HCC model established using N-diethylnitrosamine (DEN) were investigated using histological and immunochemical staining analyses.

MATERIALS AND METHODS

All chemicals were obtained from Xi'an Chemical Reagent Factory (Xi'an, China) unless otherwise stated and were of analytical grade or better.

Animal model preparation

The rat HCC model experimentation was approved by the Animal Ethics Committee, Medical School of Xi'an Jiaotong University. Use of animals in this study was in accordance with the China National Institute of Health publication 85-23 "Guide for Care and Use of Laboratory Animals" (National Research Council, 1996). Thirty male Sprague Dawley rats weighing 248.18 ± 12.32 g (3-4 mo old) were purchased from the Laboratory Animal Center of Medical School, Xi'an Jiaotong University. Rats were acclimated for 7 d before experimentation. Rats were randomly divided into two groups: control group ($n = 10$) and HCC model group ($n = 20$). Rats in the HCC model group were intragastrically administered with 0.2% (w/v) DEN (Sigma, United State) in saline (10 ng DEN per gram body weight) every 5 d for 16 wk, whereas 0.9% (w/v) normal saline was administered to the rats in the control group. All the rats had free access to distilled water. Electrolyte balance between the two groups was maintained through their common dietary food intake.

Sample collection

The weights of the rats were measured every week. After 16 wk from the initiation of the experiment, all the rats were killed under general anesthesia. Hepatic tissues were collected and fixed in 4% (w/v) paraformaldehyde in phosphate buffered saline (PBS, 0.16 mol/L NaCl, 0.003 mol/L KCl, 0.008 mol/L Na_2HPO_4 , 0.001 mol/L KH_2PO_4 , pH 7.3) immediately. The tissues were embedded in paraffin and sectioned at 8 μm thickness.

Histological staining

Sections were deparaffinized and hydrated and either stained with hematoxylin and eosin or Toluidine blue as previously described^[18]. After dehydration, sections were mounted using DPX mounting medium (Thermo Fisher Scientific, Loughborough, United Kingdom). Representative regions were photographed under bright field optics using a Leica DMRB light microscope (Leica, Wetzlar, Germany) equipped with digital image acquisition.

Immunohistochemical staining

Immunohistochemical staining was performed using Mouse on Mouse™ Vectastain® Elite® ABC Kits (Vector labs, Peterborough, United Kingdom) according to the manufacturer's protocols. Briefly, sections were incubated with 0.3% (v/v) hydrogen peroxide for 30 min at room temperature to quench endogenous peroxidase activity. After blocking

with mouse immunoglobulin (Ig) blocking reagent for 1 h at room temperature, sections were incubated with rat anti-Versican (Abcam, Cambridge, United Kingdom), mouse anti-Aggrecan, mouse anti-Decorin, mouse anti-Keratocan, mouse anti-Lumican, mouse anti-Biglycan (in house) primary antibodies^[19] for 60 min, respectively. For the negative control, the primary antibody was replaced by PBS or 2 $\mu\text{g}/\text{mL}$ mouse or rat IgG (DAKO, Ely, United Kingdom). Sections were then incubated with biotinylated goat anti-mouse or rat IgG for 30 min at room temperature. After washing, sections were incubated with Mouse on Mouse™ ABC reagent for 5 min. Sections were then visualized using Vector® NovaRED™ kit (Vector labs, Peterborough, United Kingdom) according to the manufacturer's protocols. Cell nucleuses were counterstained with hemotoxylin. After dehydration, sections were mounted using DPX mounting medium. Representative regions were then photographed under bright field optics using a Leica DMRB bright field microscope (Leica, Wetzlar, Germany) equipped with digital image acquisition.

Semi-quantitative analysis for versican positive rate in liver tissues

Positive staining rate for versican in liver tissue sections was quantitatively analyzed. Sections of 4 liver tissues from 4 individual rats in each experimental group were taken for analysis. For each liver tissue specimen, three sections were randomly selected, and the positive and negative stained cells in these sections were counted using Image J software (NIH, United States). The percentage of positive cells was then calculated using the equation below: the percentage of positive cells = (positive stained cells)/(positive stained cells + negative stained cells) \times 100%.

Semi-quantitative analysis for the intensity of positive staining in tissues

The intensity of positive staining in tissue sections was analyzed by integrated optical density (IOD) using the Image-Pro Plus 5.1 software (Media Cybernetics, United States) as described previously^[20] with minor modification. Briefly, four 20 \times TIFF-format images from four individual rats in each group were analyzed in a blinded manner. All of the images were taken using the same microscope and camera sets. Image-pro Plus software was used to calculate the average IOD per stained area (μm^2) (IOD/area) for positive staining.

Statistical analysis

Data were presented as mean \pm SE, with samples derived from 4 animals in each group. D'Agostino and Pear omnibus normality test was used for normality and equal variances test. Student *t* test plus Bonferroni's post-test was carried out using GraphPad Prism 4.0 software (GraphPad Software Inc., California, United States). The comparisons of the staining results were performed only between rats from the HCC model and the control groups, but not between the tumor nodules and its adjacent normal liver

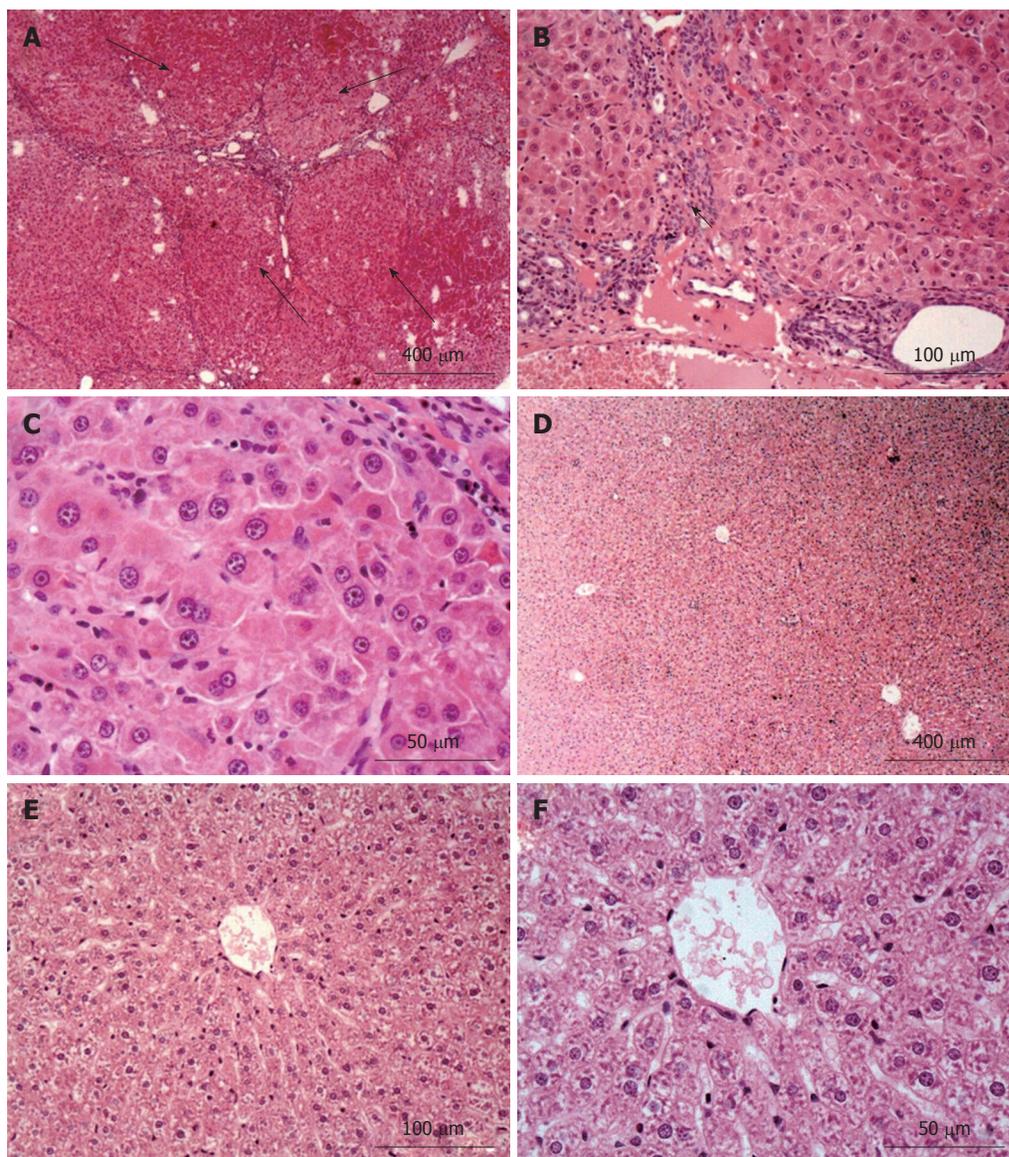

Figure 1 Hematoxylin and eosin staining results for liver tissues from the hepatocellular carcinoma model (A-C) and the control group (D-F). Normal liver structure and cell morphology were observed in the control group. However, apparent hepatoma nodules (long black arrows, A) and fibrosis (short black arrow, B) in the hepatocellular carcinoma model group were observed when compared with that in the control group.

tissues of rats from the same group. Differences were considered significant at $P < 0.05$.

RESULTS

Rat HCC model establishment

After 16 wk administration of DEN, malignant nodules were observed on the surface of the livers in the HCC model group but not in the control group. The average number of macroscopic nodules bigger than 3 mm and 5 mm on the surface of a single liver was 33.4 and 4.9, respectively, with the biggest nodule being approximately 1.5 cm × 1.0 cm × 0.8 cm (Table 1). H and E staining was used to identify and classify the cancerous nodules pathologically according to Edmondson *et al*^[21]. As expected, the normal hepatic lobule structure was disrupted and hepatoma nodules (long black arrows) were evident in the tis-

Table 1 Number and size of malignant nodules in rat livers

Group	<i>n</i>	Nodules ≥ 3 mm	Nodules ≥ 5 mm	The biggest nodule (mm ³)
Control group	10	0	0	0
Model group	14	33.4 ± 7.9	4.9 ± 1.9	122.8

sues from the HCC model group (Figure 1A), which were separated by fibrosis septa (short black arrows, Figure 1B), suggesting fibrosis formation around the tumors. The differentiation of HCC cells was also investigated according to method described by Edmondson. All of the cancer cells in the HCC model group were classified as grade III, and there was no hepatic plate-like structure present in the tumor tissues (Figure 1C). In contrast, there was no evidence of macroscopic tumor nodules in the livers from

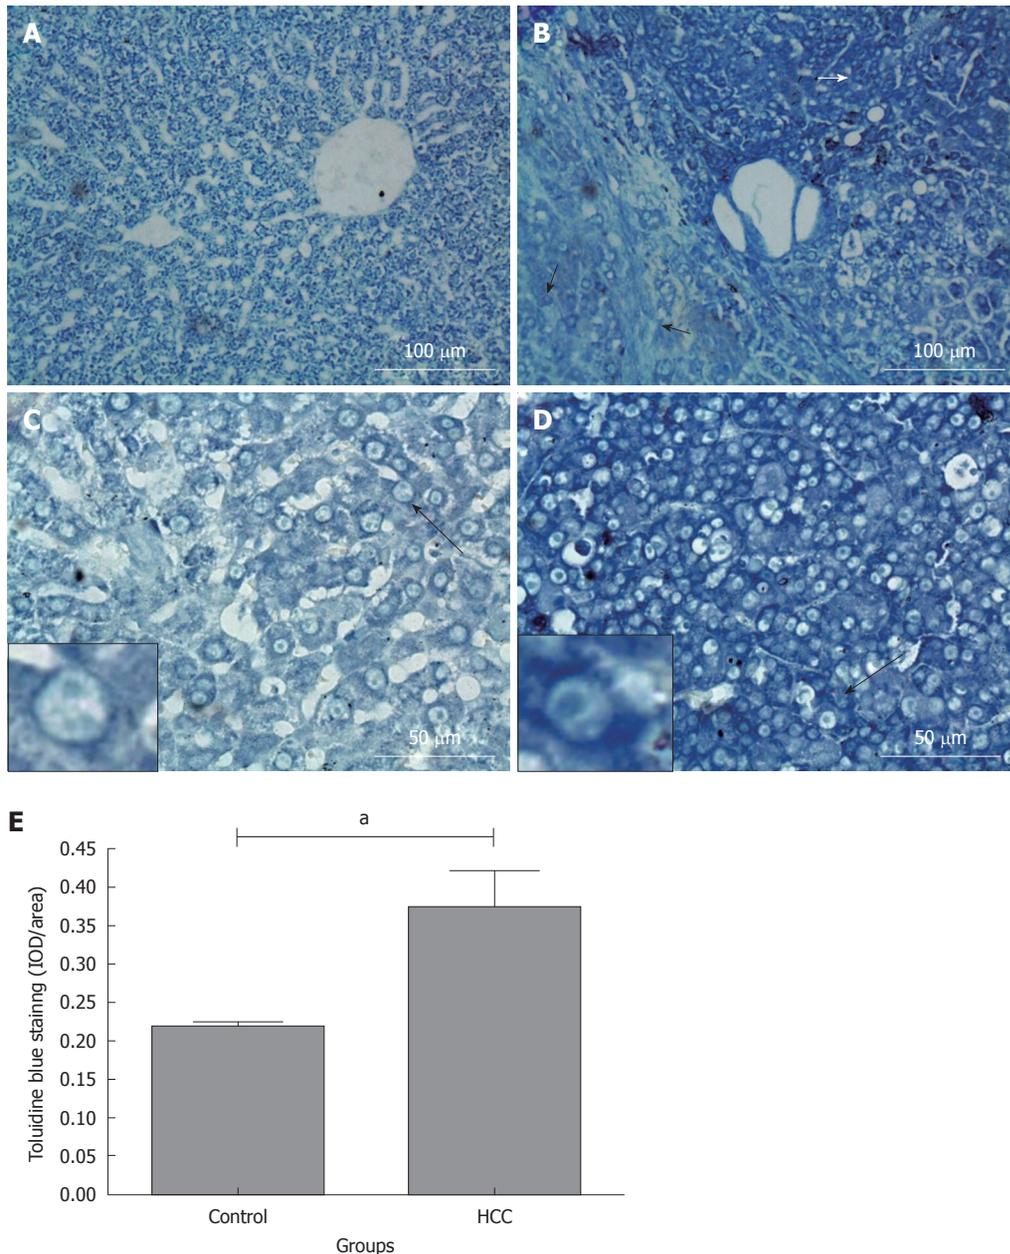

Figure 2 Toluidine blue staining in rat liver tissue sections. Rats were treated with N-diethylnitrosamine for 16 wk to establish a hepatocellular carcinoma (HCC) animal model. Sulphated glycosaminoglycan content in tissues were stained with Toluidine blue. A and C: Control group; B and D: HCC model group. Long black arrows: The cells are magnified in the small boxes. Short white arrow: Hepatoma tissues with intensive Toluidine blue staining; short black arrow: Weaker Toluidine blue staining fibrosis and “relative normal” liver tissues adjacent to the hepatoma nodules; E: Comparison of average integrated optical density (IOD) of toluidine blue staining in liver tissue between control and HCC model group ($^*P < 0.05$). IOD/area: Integrated optical density per stained area.

rats in the control group (Figure 1D), where a normal morphology was observed for hepatic cells, composing a normal liver tissue structure (Figure 1E and F). These results indicated the successful establishment of HCC in rats treated with DEN.

Increased sGAG content in HCC tissues

The contents of sGAG were investigated using Toluidine blue staining, which was evident in liver tissues from both control (Figure 2A and C) and HCC model groups (Figure 2B and D). Positive staining was found in the cytoplasm, cell membrane and/or pericellular matrix

(Figure 2C and D; the cells identified by long black arrows are magnified in the small boxes). Noticeably, Toluidine blue staining in hepatoma tissues (white short arrow, Figure 2B) was stronger than that in the fibrosis and “relative normal liver tissue” (black short arrows, Figure 2B) adjacent to the tumor nodules. Semi-quantitative IOD analysis indicated that there was more Toluidine blue positive staining in the tissues from the HCC model group when compared with the tissues from the control group (0.37 ± 0.05 IOD/area and 0.21 ± 0.01 IOD/area, $P < 0.05$, Figure 2E). This finding demonstrates elevated sGAG content in HCC tissues compared to that in the normal liver tissues. To

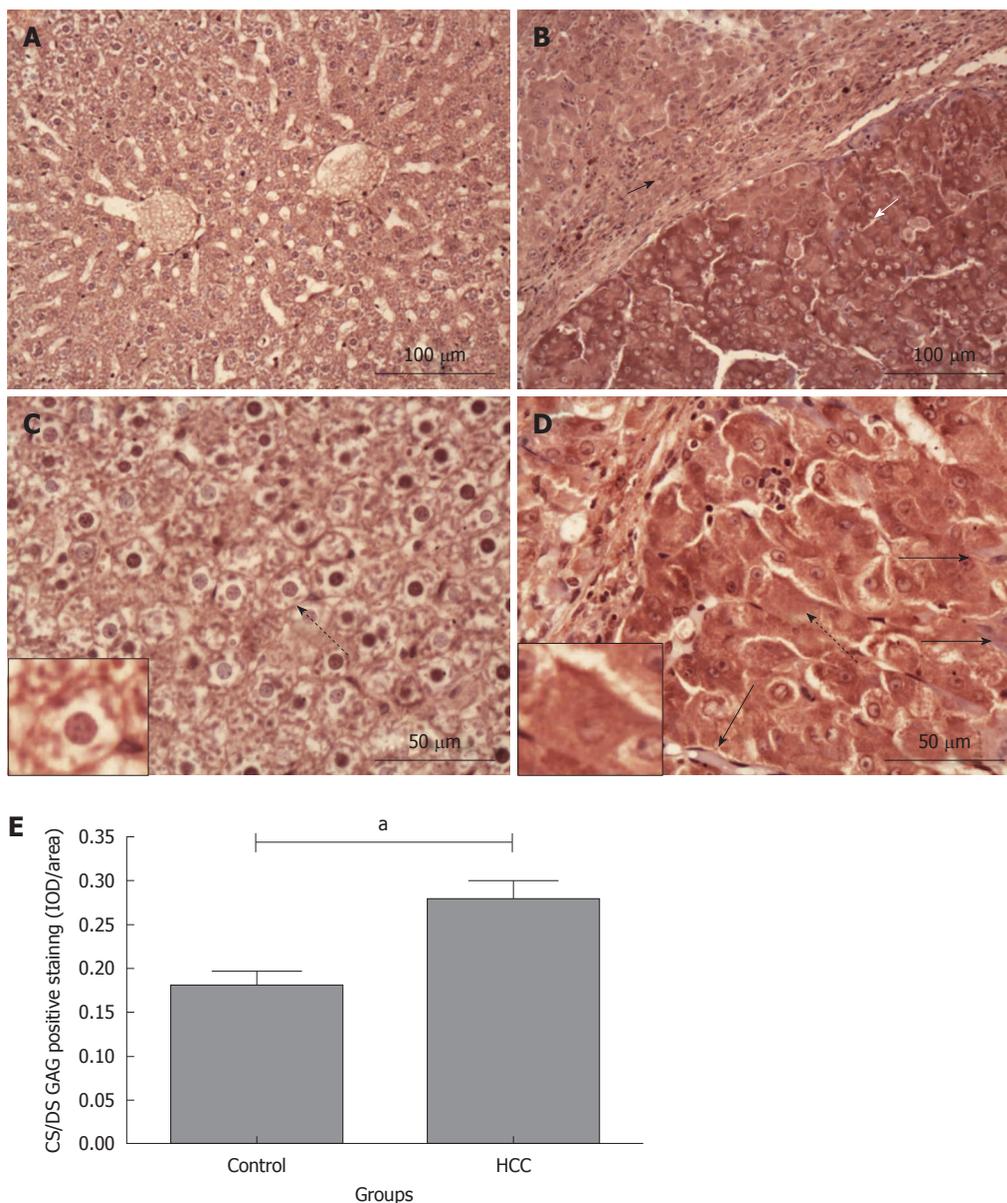

Figure 3 Chondroitin sulphate/dermatan sulphate glycosaminoglycan immunohistochemical staining in rat liver tissues. Chondroitin sulphate (CS)/dermatan sulphate (DS) sulphated glycosaminoglycan (sGAG) content in liver tissues was stained using 2B6 (+) antibody (dark red). A and C: Control group; B and D: Hepatocellular carcinoma (HCC) model group. Long black arrows: Perisinusoidal cells negatively stained by 2B6 antibody; dotted arrows: The cells are magnified in the small boxes; short white arrow: Hepatoma tissues with intensive CS/DS GAG staining; short black arrow: Weaker CS/DS GAG staining in fibrosis and "relative normal" liver tissues adjacent to the hepatoma nodules; E: Comparison of the average integrated optical density (IOD) in CS/DS GAG positive staining in liver tissues between the control and HCC model groups ($P < 0.05$). IOD/area: Integrated optical density per stained area.

further identify the specific expression of sGAG in HCC model tissue, immunohistochemical staining for CS/DS, HS and keratan sulphate (KS) GAG were performed.

Increased CS/DS GAG expression in HCC tissues

The expression of CS/DS GAG chains in normal and HCC tissues was investigated using 2B6 (+) monoclonal antibody^[11,19]. As shown in Figure 3, positive staining for 4-sulphated CS/DS GAGs was observed on cell membranes and/or pericellular matrix in the normal liver tissues from the control group (Figure 3A and C; the cell identified with dotted arrow is magnified in the small box). In contrast, 2B6 (+) positive staining was observed in the cytoplasm, cell membrane and/or pericellular ma-

trix (Figure 3B and D; the cell pointed with dotted arrow is magnified in the small box). The expression of 4-sulphated CS/DS GAGs was variable across the HCC tissues, with a stronger staining in the hepatoma nodules (white short arrow, Figure 3B) but a relative weaker staining in its adjacent tissues such as fibrous septa and relatively normal hepatocytes (black short arrow, Figure 3B). Interestingly, these variable distribution patterns in 4-sulphated CS/DS were also observed inside the hepatoma nodules, i.e., several perisinusoidal cells were negatively stained in CS/DS expression (Figure 3D, black long arrows), although most of the hepatoma cells were positively stained. Semi-quantitative IOD analysis for the intensity of positive staining indicated that there was more 4-sulphated CS/DS expres-

sions in the hepatoma nodules when compared with that in the normal tissues from the control group (0.28 ± 0.02 IOD/area and 0.18 ± 0.02 IOD/area, $P < 0.05$, Figure 3E).

Increased HS GAG staining in HCC tissues

We also investigated the expression of HS GAG chains in the tissues from rats in the control and HCC model groups. Similar to the CS/DS GAG staining, HS positive staining was evenly distributed across the normal liver tissue sections from the control group (Figure 4A and D) and mainly localized on the cell membrane and/or pericellular matrix (Figure 4D; the cell identified with a black short arrow is shown at a higher magnification in the small box). However, this “normal tissue” HS distribution pattern was altered and became uneven in the tissues obtained from rats in the HCC model group. In some hepatoma nodules, intensive HS positive staining was observed in the hepatoma cytoplasm, cell membrane, pericellular matrix and even in cell nuclei (Figure 4E; the cell identified with a black short arrow is shown at a higher magnification in the small box). There was no HS positive staining in the fibrous tissue septa (black long arrows; Figure 4B and E). Semi-quantitative IOD analysis indicated that there was a stronger HS staining in these hepatoma nodules than that in the normal liver tissues from the control group (0.30 ± 0.03 and 0.17 ± 0.02 , $P < 0.01$, Figure 4G). However in some hepatoma nodules, a relative weaker HS positive staining was observed on the hepatoma cell membrane and/or pericellular matrix (Figure 4C and F; the cell identified with a black short arrow is shown at a higher magnification in the small box), similar to that observed in the normal liver tissues from the control group. In this case, there was no significant difference in the average density of HS positive staining between the HCC model and the control groups ($P = 0.1169$).

KS GAG expression was not altered in HCC tissues

KS is another important sGAG side chains attached to the core proteins of several matrix PGs. In contrast to the CS and HS GAG staining described above, the positive staining of KS GAG chains was weak and there was no difference between control and HCC model groups (data not shown).

Collectively, the results described above demonstrate that there is a significant elevation in the expression of CS/DS and HS but not KS GAG chains in the HCC model tissues when compared with the normal liver tissues. Therefore, we further investigated the expression patterns of different PG core proteins with CS GAGs, including aggrecan, versican, biglycan and decorin.

Increased aggrecan expression in HCC tissues

Aggrecan is a common CSPG found in many musculoskeletal tissues especially in hyaline articular cartilage. Interestingly, aggrecan expression in the liver at the gene level has been reported previously^[14,22]. In this study, aggrecan expression in liver tissues was immunohistochemically investigated using a monoclonal antibody [anti-IGD (6B4)]

recognizing the interglobular domain of aggrecan core protein^[19,23]. Positive staining for aggrecan was observed in both control and HCC model groups (Figure 5A and B). However, their distribution patterns were different. In the control group where aggrecan positive staining was mainly localized on cell membrane and/or pericellular matrix (Figure 5C; the cell identified with a black short arrow is magnified in the small box). In contrast, there was more intensive aggrecan positive staining in hepatoma cytoplasm, cell membrane and/or pericellular matrix in the tissues from the HCC model group (Figure 5D; the cell identified with a black short arrow is magnified in the small box). Noticeably, there was no or very weak aggrecan positive staining in the fibrous tissue septa between hepatoma nodules (black long arrows, Figure 5B and D). Interestingly, the differences in staining intensity and patterns for aggrecan described above were also observed between the hepatoma tissues and its adjacent “relative normal liver tissues” (Figure 5E; the areas inside the black or red boxes are magnified on the left column). Semi-quantitative IOD analysis indicated that there was more aggrecan positive staining in the tissues from the HCC model group when compared with that in the control group (0.43 ± 0.01 IOD/area and 0.35 ± 0.03 IOD/area, $P < 0.05$, Figure 5F). These results demonstrated that DEN-induced HCC in rat liver increases the aggrecan expression in cells at the protein level, suggesting that there may be a correlation between HCC and aggrecan expression.

Increased versican expression in HCC tissues

Versican is another member of the large aggregating CSPGs family and its expression in rat liver tissues was also investigated by immunohistochemical staining. In contrast to the aggrecan staining, most of the hepatocytes were negatively stained for versican in the liver tissues from the control group (Figure 6A and D). However, a weak versican positive staining was observed on the cell membrane and/or pericellular matrix of some hepatocytes around the central vein (Figure 6D; the cell identified with a black short arrow is magnified in the small box). In the liver tissues from rats in the HCC model group, versican positive staining was observed in some hepatoma cells (Figure 6B and E), and mainly localized in the cytoplasm, cell membrane and/or pericellular matrix (Figure 6E; the cell identified with a black short arrow is magnified in the small box). Statistical analysis indicated that versican positive staining rate in the HCC model group was much higher than that in the control group ($33.61\% \pm 4.90\%$ and $21.28\% \pm 1.79\%$, $P < 0.05$, Figure 6G), although a large number of cells were still negatively stained. Interestingly, the strongest versican positive staining was observed in the pericellular matrix of fibrous tissue septa and portal areas (Figure 6C and F), indicating a different versican distribution pattern between the control and HCC model groups.

Increased biglycan expression in HCC tissues

In normal liver tissues, a moderate positive staining of biglycan was evenly distributed on hepatic membrane

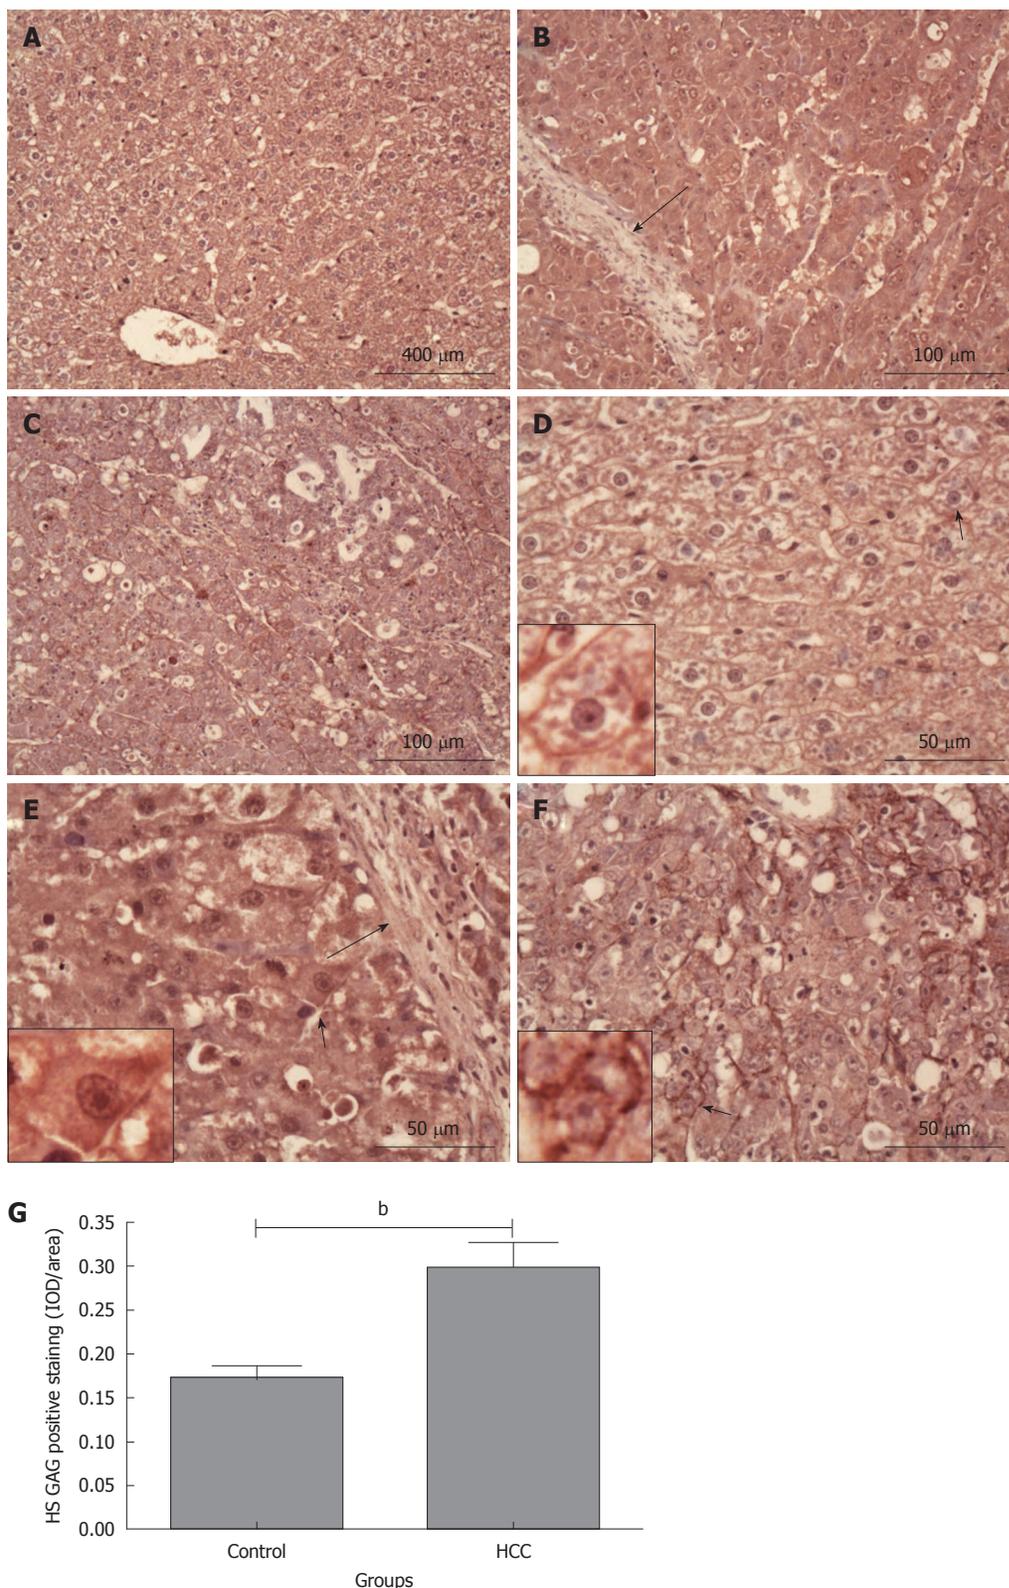

Figure 4 Heparan sulphate glycosaminoglycan staining in rat liver tissues. Heparan sulphate (HS) glycosaminoglycan (GAG) content in tissue was stained using 10E4 antibody (dark red). A and D: Control group; B and E: Hepatocellular carcinoma (HCC) tissues with intensive HS GAG staining; C and F: HCC tissues with relative weaker HS GAG staining. Long black arrows: Fibrous tissue septa; short black arrows: The cells are magnified in the small boxes; G: Comparison of the average integrated optical density (IOD) in HS GAG positive staining in liver tissues between the control and HCC model groups ($P < 0.01$). IOD/area: Integrated optical density per stained area.

and/or pericellular matrix in the liver tissues of rats from the control group (Figure 7A). There was limited positive

staining in hepatocyte cytoplasm and nuclei (Figure 7C; the cell identified with a black short arrow is magnified in

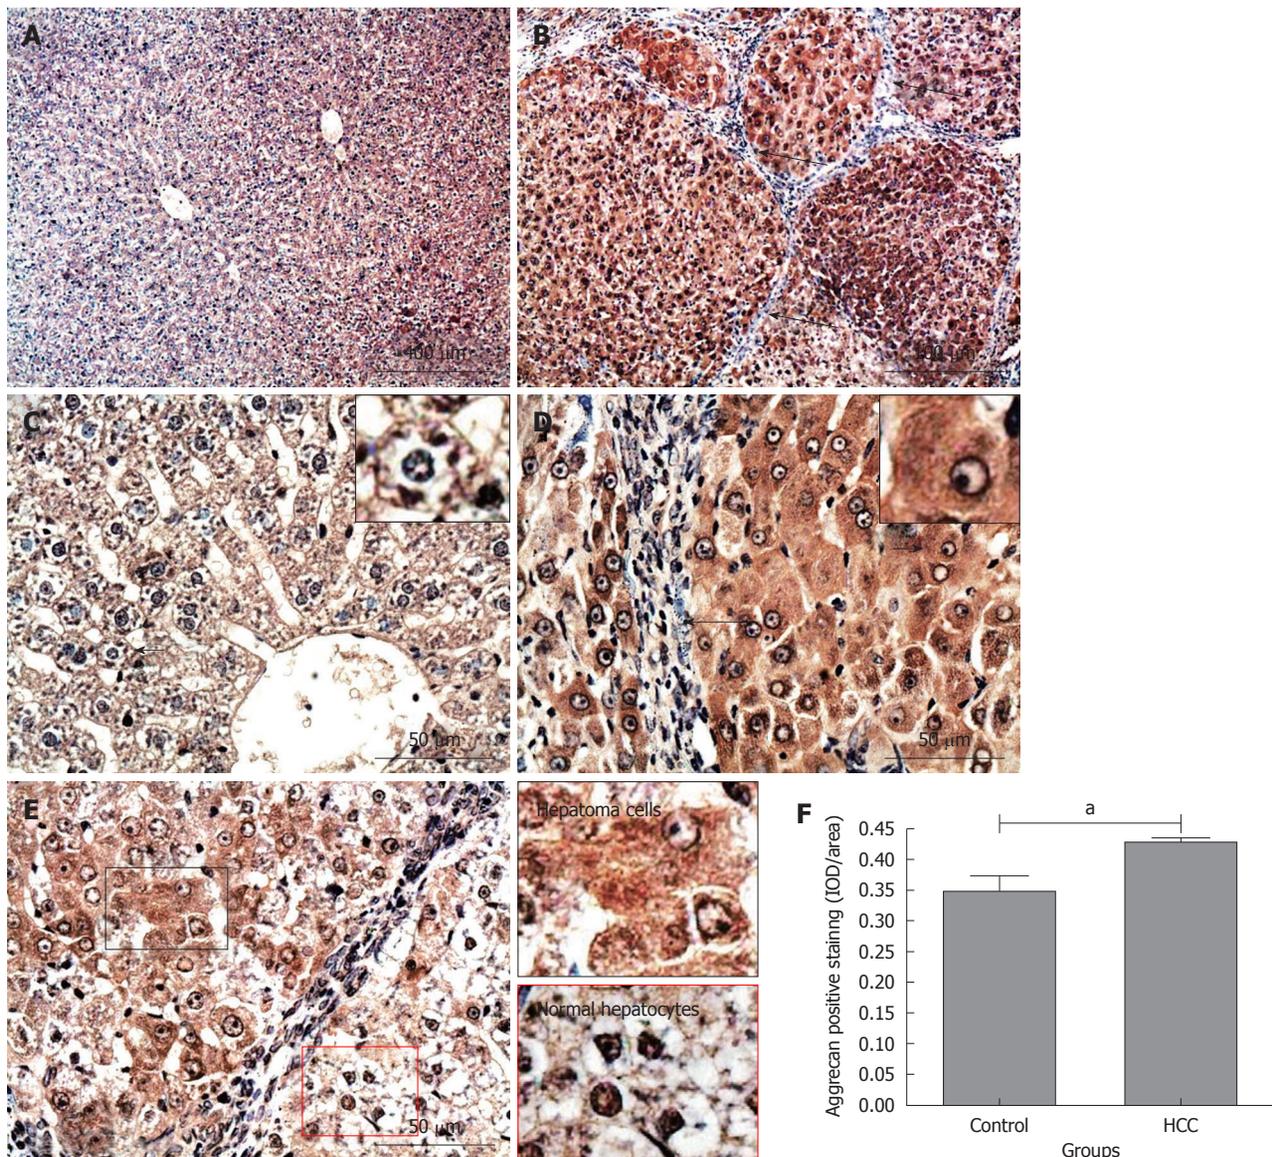

Figure 5 Immunohistochemical staining for aggrecan in rat liver tissues. Aggrecan positive staining was dark red. A and C: Control group; B, D and E: Hepatocellular carcinoma (HCC) model group. Long black arrows: Fibrous tissue septa; short black arrows: The cells are magnified in the small boxes; E: Areas in black and red boxes are magnified in left column; F: Comparison of the average integrated optical density (IOD) in aggrecan positive staining in liver tissues between the control and HCC model groups ($^a P < 0.05$). IOD/area: Integrated optical density per stained area.

the small box). In contrast, strong biglycan staining was observed in almost all hepatoma cells in tumor nodules from the HCC model group (Figure 7B). The staining was not only on the cell membrane and/or pericellular matrix but also in the cytoplasm (Figure 7D; the cell identified with a white short arrow is magnified in the small box). Interestingly, the differences in staining intensity and patterns for biglycan were also observed between hepatoma cells and its adjacent “relatively normal hepatocytes” (Figure 7E; the areas inside the black or red boxes are magnified on the left column). Semi-quantitative IOD analysis showed that there was significantly more biglycan expression in HCC tissues when compared with that in the normal liver tissues (0.32 ± 0.01 and 0.25 ± 0.01 , $P < 0.001$, Figure 7F). There was no intensive biglycan staining in the portal areas and fibrous tissue septa between hepatoma nodules (white long arrow, Figure 7D).

Increased decorin expression in HCC tissues

Similarly to biglycan, decorin positive staining was evenly distributed on hepatic cell membrane and/or pericellular matrix across the whole liver tissue sections from the control group (Figure 8A and C; the cell identified with a black short arrow is magnified in the small box). In the HCC model tissues, intensive decorin positive staining was observed in almost all hepatoma cells (Figure 8B), mainly localized in the cytoplasm, cell membrane and/or pericellular matrix (Figure 8D; the cell identified with a black short arrow is magnified in the small box). This difference described above was also observed between hepatoma cells and its adjacent “relatively normal hepatocytes” (Figure 8E; the areas inside the black or red boxes are magnified on the left column). Semi-quantitative IOD analysis indicated that there was significantly more decorin expression in hepatoma nodules when compared

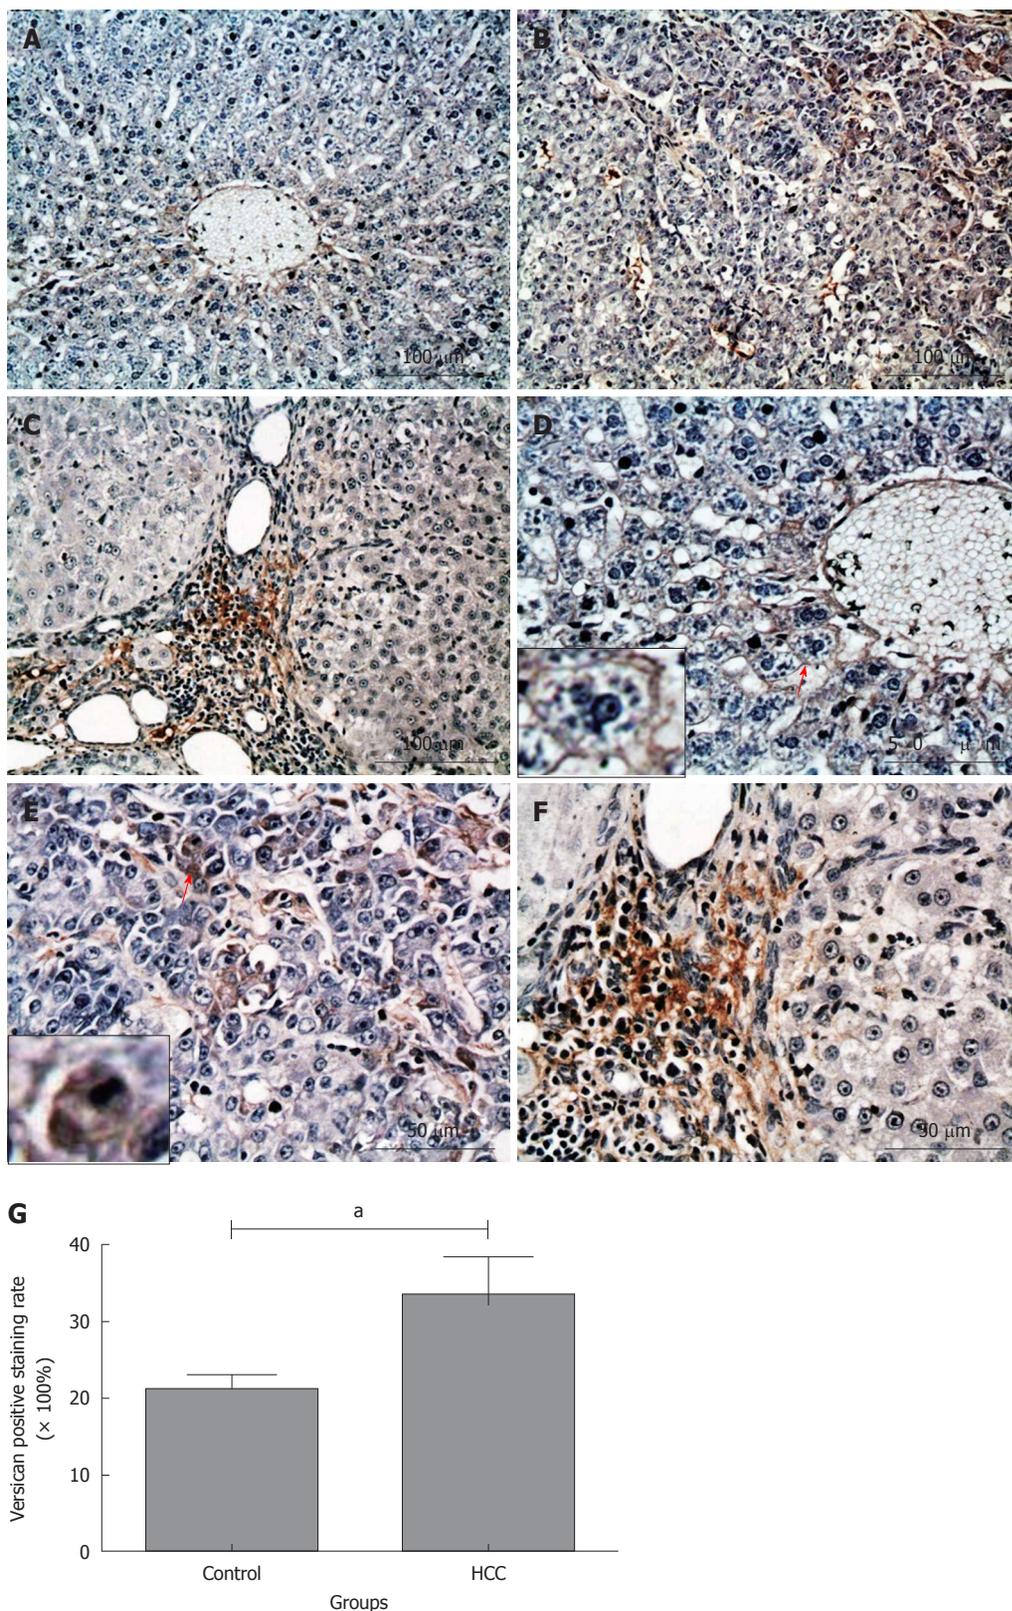

Figure 6 Immunohistochemical staining for versican in rat liver tissues. Versican positive staining was dark red. A-F: Most of hepatocytes were negatively stained in control group (A and D), whereas more hepatoma cells in hepatocellular carcinoma (HCC) nodules were positively stained (B and E); however, the strongest versican positive staining was observed in the fibrosis septa between hepatoma nodules (C and F). Short red arrows: The cells are magnified in the small boxes; G: Comparison of the positive rate for versican staining in liver tissues between the control and HCC model groups. ^aP < 0.05.

with that in the normal liver tissues (0.29 ± 0.01 and 0.26 ± 0.01 , $P < 0.05$, Figure 8F). Interestingly, there was no

decorin positive staining in the portal areas and fibrous tissue septa between the tumor nodules (Figure 8B and D).

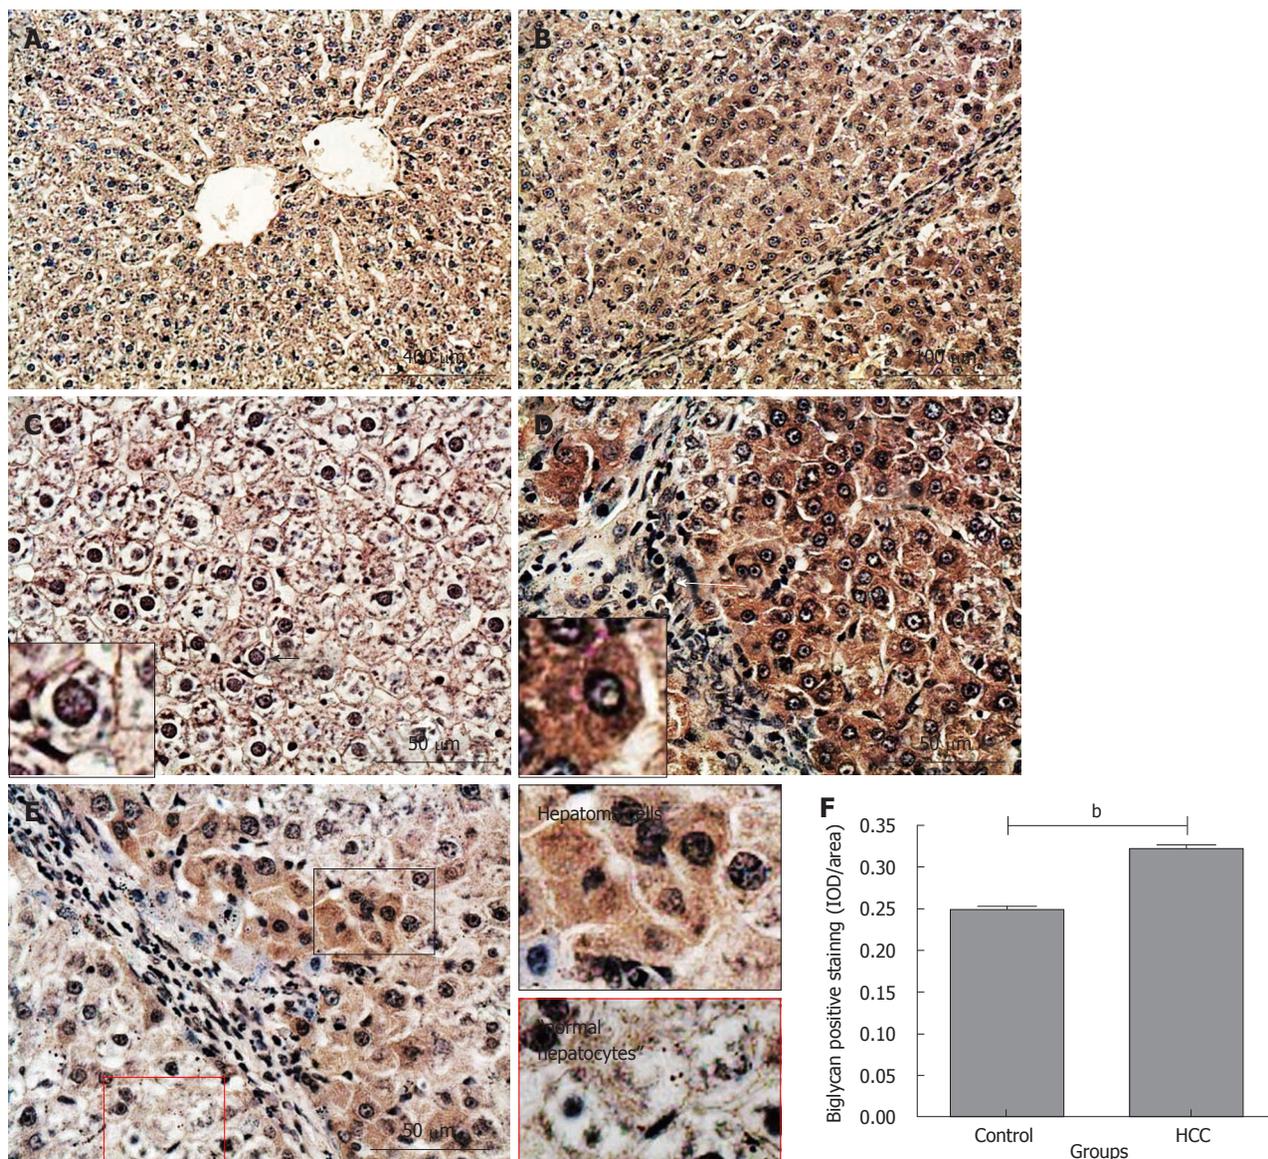

Figure 7 Immunohistochemical staining for biglycan in rat liver tissues. Biglycan positive staining was dark red. A and C: Control group; B, D and E: Hepatocellular carcinoma (HCC) model group. Long white arrow: Fibrous tissue septa; short black and white arrows: The cells are magnified in the small boxes; E: Areas in black and red boxes are magnified in left column; F: Comparison of the average integrated optical density (IOD) in biglycan positive staining in liver tissues between the control and HCC model groups ($^bP < 0.001$). IOD/area: Integrated optical density per stained area.

There was no positive staining for keratocan or lumican in rat liver tissues

The expression of keratocan and lumican was also investigated. Consistent with the KS negative staining results, there was no or very weak keratocan or lumican staining in these liver tissues, either from the control or HCC model group (data not shown).

DISCUSSION

The abnormally high expression of CS GAGs in HCC tissues has been known for a long time^[16,17] although little is known about the biological mechanisms underlying their increased presence. Interestingly, an accumulation of CS GAG expression has also been observed in other physiological and pathological processes involved in liver development and metabolism. For example, in neonatal

liver where premature hepatocytes (hepatic stem cells) still remain as an undifferentiated phenotype, much higher CS GAGs were observed when compared with that in the postnatal liver tissues^[13]. Similarly, there is a transient accumulation of CS GAGs during liver regeneration after partial hepatectomy^[13] and active fibrosis^[24]. All of these examples demonstrate that CSPGs are involved in embryogenesis, regeneration and carcinogenesis of liver. One of the crucial events occurring within these biological processes is the epithelial mesenchymal transition (EMT), a complex molecular and cellular transformation of cell phenotype from differentiated characteristics (mature epithelial cells) to undifferentiated mesenchymal (stem/progenitor cells) features. During this process, cells acquire motility, enhanced migratory capacity/invasiveness^[25], and become more stem cell-like^[26]. Interestingly, increased production of ECM components such as CS

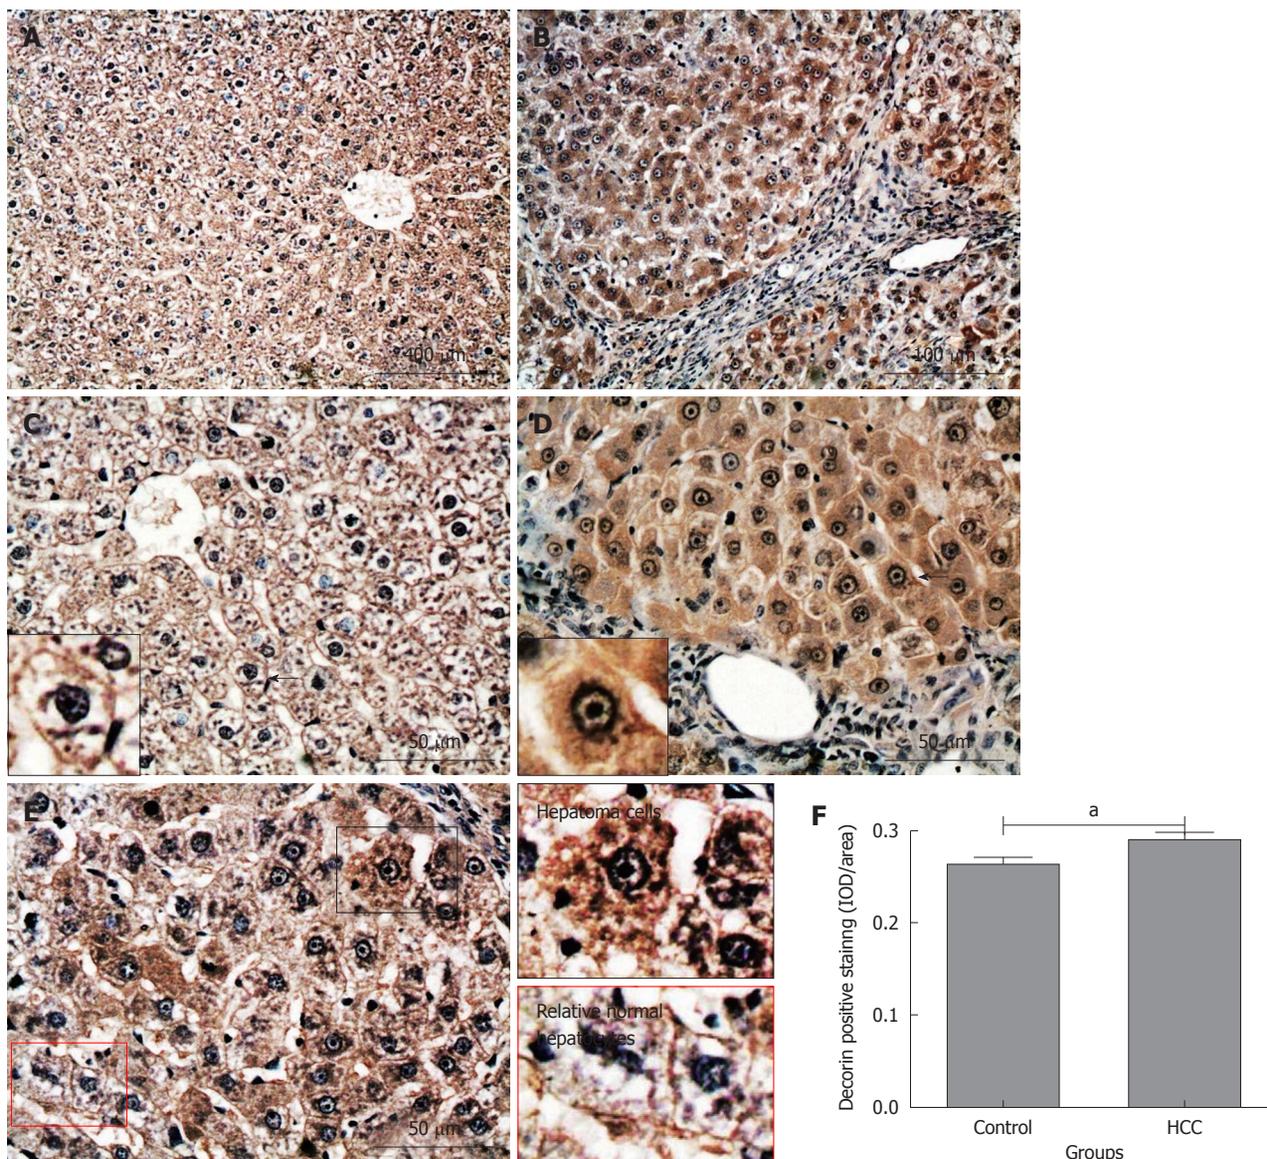

Figure 8 Immunohistochemical staining for decorin in rat liver tissues. Decorin positive staining was dark red. A and C: Control group; B, D and E: Hepatocellular carcinoma (HCC) model group. Short black arrows: The cells are magnified in the small boxes; E: Areas in black and red boxes are magnified in left column; F: Comparison of the average integrated optical density (IOD) in decorin positive staining in liver tissues between the control and HCC model groups ($^*P < 0.05$). IOD/area: Integrated optical density per stained area.

GAGs has been observed during this process^[8,27], demonstrating that *de novo* CSPG expression may play a pivotal role during the cell phenotype transformation, notably initiating the development of HCC. However, it is still unclear what the precise CSPG expression patterns are in the hepatoma cells and their relationship with HCC development.

In this study, the Toluidine blue staining results indicated that there was more sGAG content in HCC tissues than that in the normal liver tissues from the control group, which is consistent with previous studies^[16,17]. Our further immunostaining with CS/DS, HS and KS antibodies demonstrated that there was a significant increase in CS/DS and HS but not KS GAG expression in HCC tissues. The weak expression of KS GAG in both normal liver and HCC tissues is consistent with the very low staining patterns for keratan and lumican, two major

KSPGs expressed in the other tissues. A recent study performed on human HCC tissues^[28], indicated that KSPGs were not involved in HCC development. Therefore, the increased sGAG content in HCC tissues must be induced by the enhanced production and accumulation of CS/DS and/or HSPGs, which is confirmed by our CS/DS and HS GAG staining. Previous studies have reported the expression of several HSPGs including glypican-3^[29], syndecan-4^[30] and perlecan^[31] are increased in HCC tissues, which coincides with our HS staining results. However, little is known for the expression patterns of specific CSPGs in HCC, therefore our following investigation was mainly focused on CSPG expression.

Aggrecan gene expression has been previously reported in liver tissues^[14,22]. Our results demonstrate, for the first time at a protein level, the positive expression of aggrecan in liver tissues, which was mainly localized on

the cell membrane and/or pericellular matrix in normal hepatocytes. However, in the HCC model group there was much stronger aggrecan staining in the cytoplasm, the cell membranes and/or pericellular matrix in HCC hepatoma cells, indicating an elevated aggrecan production and accumulation in HCC tissues. The function of this increased aggrecan presence is not clear but a previous study has suggested that the expression of aggrecan in tumors may be a result of EMT^[27]. Moreover, aggrecan production is mediated by different growth factors such as transforming growth factor β in hepatocytes^[22,32], which has been identified as a promoter for both HCC-related fibrosis and angiogenesis^[32,33]. Interestingly, there was very low aggrecan expression in the fibrous tissue septa between hepatoma nodules, consistent with previous studies showing that the formation of fibrous septa arises from myofibroblasts^[34], which have a low expression of CS/DS PGs^[35].

In contrast to the increased aggrecan expression, versican content in hepatoma cells was variable with the most intensive staining mainly localized in the ECM of fibrous septa between hepatoma nodules. This finding is novel as little is known about versican expression in HCC tissues. Interestingly, versican expression was observed around the central veins and portal areas, illustrating there may be a close relationship between versican and HCC metastases. This is consistent with previous studies, where an elevated expression of versican was observed in the ECM of other tumor tissues including breast^[36] and prostate^[37], and correlated with metastases^[38]. The mechanism as to how versican promotes metastases is not clear. However, the deposition of versican in the tumor stroma, particularly in the hyaluronic acid rich region, will lead to the structural aggregation of tumor matrix and modulation of cellular attachment and motility, therefore supporting cancer cell growth, proliferation, migration and differentiation, all processes vital for tumor development and metastases^[5,36].

Both biglycan and decorin are the members of the small leucine-rich proteoglycan family. They are usually associated with growth factor binding^[4] and collagen fibrillogenesis^[39,40]. Therefore, it is not surprising that an elevated biglycan and decorin expression was observed during liver fibrosis^[10,41,42]. However, our results showed that the major positive staining of decorin and biglycan was localized in the hepatoma cells instead of fibrosis septa between hepatoma nodules, suggesting that the expression of biglycan and decorin may play different roles in HCC occurrence and liver fibrosis. The association between biglycan and HCC has not been previously reported; however, elevated expression of biglycan may correlate with the aggressiveness and poor prognosis of the other cancers^[43]. Varied evidence for the changes in decorin expression in HCC tissues has been previously reported. Kovalszky *et al.*^[17] and Lai *et al.*^[44] have found that decorin expression was elevated in HCC tissues. In contrast, Miyasaka *et al.*^[45] showed that there was a decline in decorin gene expression in HCC. The difference may arise from the different stages of HCC, as previ-

ous studies have showed that decorin can be either pro-angiogenic or anti-angiogenic in tumors^[46]. The precise contributions of biglycan and decorin metabolism during HCC occurrence and metastases have not yet been elucidated. However, the ability of these proteins to interact with the other matrix components and induce ECM remodeling^[47] as well as increasing cell proliferation and migration^[48] highlights them as an important PG subsets involved in tumor formation and metastases. Alternatively, the increased biglycan and decorin expression may also be a consequence of EMT of hepatoma cells, because a recent study reported higher biglycan and decorin expression levels during a Ras-induced EMT in MDCK cells^[49]. Clearly, further studies for the roles of biglycan and decorin in hepatocarcinogenesis are warranted.

Much less is known about the precise role that CSPGs play in the HCC induction and metastases. CSPGs are ubiquitous components of ECM and cell surface, therefore can predominantly interact with a wide variety of key molecules, such as growth factors, cytokines, chemokines, adhesion molecules, and lipoproteins. These interactions regulate biological processes including signaling, cell differentiation, cell-cell or cell-matrix interactions and morphogenesis^[50]. In this study, using histological staining, we found a significant increase in the sGAG content in DEN-induced HCC tissues when compared with the normal rat liver tissues from the control group and this increased sGAG content in tumor tissue was mainly induced by elevated expression in CS/DS and HS but not KS GAGs. We further demonstrated that the expression of several CSPGs including aggrecan, versican, biglycan and decorin was elevated in HCC tissues. To our knowledge, this is the first systematical study demonstrating the elevated CSPGs expression in HCC tissues. The experimental data shown here expands our knowledge of the relationships between CS/DS PGs and HCC, and other liver diseases.

COMMENTS

Background

Proteoglycans (PGs) are macromolecules consisting of one or several polysaccharide chains of the glycosaminoglycan (GAG), which covalently attached to a variety of core proteins. They are widely expressed in cells and extracellular matrix in various tissues including liver. According to the difference in GAG side chains, PGs can be categorized as chondroitin sulphate PG (CSPG) and heparan sulphate PG, etc. PGs have been found to play a critical role in different malignant tumor progression. However, the effect of PGs on cancer is variable, which can range from stimulatory to inhibitory, depending on their core proteins and GAG types, the sources and stages of cancers and the tumor localizations.

Research frontiers

Previous studies have shown that the expression of CS GAG was increased in hepatocellular carcinoma (HCC) tissues, and inhibition of CS GAG expression in HCC cell line partially abrogates cell ability of migration *in vitro*. This illustrated that CSPGs may play a pivotal role in the occurrence, progression and metastasis of HCC and thereby they may be used as potential markers and treatment target for HCC. The hotspot in this area is their temporal and spatial expression and the mechanism how they are involved in the onset, development and metastasis of HCC.

Innovations and breakthroughs

The authors investigated the expression pattern of different CSPGs including aggrecan, versican, decorin, biglycan in the liver tissues from a rat HCC model

established using N-diethylnitrosamine (DEN). This is the first systematical study demonstrating the elevated CSPGs expression in HCC tissues.

Applications

The study results suggest that the CSPGs could be potential therapeutic targets and clinical biomarkers for HCC in humans in the future.

Terminology

PG is a kind of macromolecule units consists of a "core protein" with one or more covalently attached GAG chain(s); GAGs are long unbranched polysaccharides consisting of a repeating disaccharide unit; Chondroitin sulfate is a sulfated GAG composed of a chain of alternating sugars (N-acetylgalactosamine and glucuronic acid).

Peer review

This is a good descriptive study in which authors investigate the expression of PGs in rats with DEN-induced HCC. The results are interesting and suggest that CSPGs are potential therapeutic targets and clinical biomarkers for HCC.

Abstract

AIM: To investigate the mechanisms of *Lactobacillus plantarum* (*L. plantarum*) action on gut barrier in pre-operative and postoperative experimental obstructive jaundice in rats.

METHODS: Forty rats were randomly divided into groups of sham-operation, bile duct ligation (BDL), BDL + *L. plantarum*, BDL + internal biliary drainage (IBD), and BDL + IBD + *L. plantarum*. Ten days after *L. plantarum* administration, blood and ileal samples were collected from the rats for morphological examination, and intestinal barrier function, liver function, intestinal oxidative stress and protein kinase C (PKC) activity

measurement. The distribution and expression of the PKC and tight junction (TJ) proteins, such as occludin, zonula occludens-1, claudin-1, claudin-4, junction adhesion molecule-A and F-actin, were examined by confocal laser scanning microscopy, immunohistochemistry, Western blotting, real-time fluorescent quantitative polymerase chain reaction assay.

RESULTS: *L. plantarum* administration substantially restored gut barrier, decreased enterocyte apoptosis, improved intestinal oxidative stress, promoted the activity and expression of protein kinase (BDL vs BDL + *L. plantarum*, 0.295 ± 0.007 vs 0.349 ± 0.003 , $P < 0.05$; BDL + IBD vs BDL + IBD + *L. plantarum*, 0.407 ± 0.046 vs 0.465 ± 0.135 , $P < 0.05$), and particularly enhanced the expression and phosphorylation of TJ proteins in the experimental obstructive jaundice (BDL vs BDL + *L. plantarum*, 0.266 ± 0.118 vs 0.326 ± 0.009 , $P < 0.05$). The protective effect of *L. plantarum* was more prominent after internal biliary drainage (BDL + IBD vs BDL + IBD + *L. plantarum*, 0.415 ± 0.105 vs 0.494 ± 0.145 , $P < 0.05$).

CONCLUSION: *L. plantarum* can decrease intestinal epithelial cell apoptosis, reduce oxidative stress, and prevent TJ disruption in biliary obstruction by activating the PKC pathway.

Zhou YK, Qin HL, Zhang M, Shen TY, Chen HQ, Ma YL, Chu ZX, Zhang P, Liu ZH. Effects of *Lactobacillus plantarum* on gut barrier function in experimental obstructive jaundice. *World J Gastroenterol* 2012; 18(30): 3977-3991 Available from: URL: <http://www.wjnet.com/1007-9327/full/v18/i30/3977.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i30.3977>

INTRODUCTION

Biliary tract surgery in patients with obstructive jaundice is associated with high a morbidity and mortality rate^[1]. Evidence accumulated over the past several years indicates that the absence of bile in the gastrointestinal tract promotes bacterial overgrowth and increases intestinal permeability, leading to significant translocation of bacteria and endotoxin following bile duct obstruction^[2,3]. The mechanism underlying the increased intestinal permeability in obstructive jaundice has been obscure. However, recent experimental studies have shown that the regional decrease in tight junction (TJ)-associated protein levels in the intestinal epithelium^[4], increased apoptosis of enterocytes in intestinal crypts^[5], and intestinal oxidative stress^[6] are the key factors in the pathogenesis of hepatic and intestinal injury in obstructive jaundice^[7].

Probiotic bacteria have been shown to have beneficial effects in the intestinal barrier function. For example, live *Bifidobacterium lactis* has been shown to inhibit toxic effects in epithelial cell culture^[8]. *Lactobacillus plantarum* (*L. plantarum*) has been found to inhibit epithelial barrier dysfunction and interleukin-8 secretion induced by tumor necrosis factor- α ^[9] and prevent cytokine-induced apoptosis in intestinal epithelial cells^[10]. *L. plantarum* stabilizes the cellular TJ, thereby preventing enteropathogenic *Escherichia coli*-induced redistribution of integral TJ proteins^[11]. Based on the excretion of orally administered ¹⁴C, White *et al.*^[12] demonstrated that enteral administration of the probiotic bacterium *L. plantarum* 299 reduced intestinal hyperpermeability associated with experimental biliary obstruction. However, these authors did not clarify the mechanism for the protective effect of the probiotics on the intestinal barrier in obstructive jaundice. A recent clinical study reported that preoperative oral administration of synbiotics could enhance immune responses, attenuate systemic post-operative inflammatory responses, and improve the intestinal microbial environment after hepatobiliary surgery for obstructive jaundice^[13].

TJs, which represent the uppermost basolateral connection between neighboring enterocytes, are important components of the epithelial barrier^[14]. TJ assembly and paracellular permeability are regulated by a network of signaling pathways that involves different protein kinase C (PKC) isoforms^[15]. A substantial body of experimental

data indicates that PKC regulates paracellular permeability of the epithelial barrier^[16,17]. PKC regulates the assembly of TJ proteins through phosphorylation of zonula occludens-1 (ZO-1)^[15]. Seth *et al.*^[18] suggested that PKC β I activation may be one of the initial events in the probiotic-mediated protection of TJs. PKC ϵ may play a role in the downstream events of the signaling pathway involved in this process. These data suggest that PKC plays a crucial role in the mediation of intestinal epithelial TJ proteins.

This study aims to investigate the effects of *L. plantarum* on the intestinal mucosal barrier, oxidative stress, epithelial TJ-protein structure and phosphorylation, especially its impact on the expression and activity of PKC.

MATERIALS AND METHODS

Reagents

Rabbit polyclonal anti-occludin, rabbit polyclonal anti-junction adhesion molecule (JAM)-A, rabbit polyclonal anti-claudin-1, mouse monoclonal anti-claudin-4, and rabbit polyclonal anti-phosphoserine antibodies were supplied by Zymed (Invitrogen, Carlsbad, CA, United States). Rabbit polyclonal anti-ZO-1 and rabbit polyclonal anti-PKC were obtained from Santa Cruz Biotechnology (Santa Cruz, CA, United States). Fluorescein isothiocyanate (FITC)-phalloidin was obtained from Sigma (St. Louis, United States). FITC-conjugated secondary antibodies were supplied by Zymed (Invitrogen). Biotin-labeled goat anti-rabbit immunoglobulin G (IgG) and horseradish peroxidase (HRP)-labeled streptavidin were supplied by DAKO (Glostrup, Denmark). All other reagents of analytical grade were purchased from Sigma (St. Louis, United States).

L. plantarum

The *L. plantarum* (strain CGMCC No. 1258) used in this study was a gift from Dr. Xiao-Ming Hang (Onlly Institute of Biomedicine, Shanghai Jiao Tong University, Shanghai, China). *L. plantarum* cultures were prepared exactly as described previously^[11].

Animals

Forty male albino Wistar rats weighing 250-320 g were purchased from Fudan University Medical Animal Center (Shanghai, China). They were housed in stainless-steel cages, three rats per cage, at controlled temperature (23 °C) and humidity and with a 12 h/12 h dark/light cycle. They were maintained on a standard laboratory diet with tap water ad libitum, except for an overnight fast before surgery. The study was conducted according to the Guide for the Care and Use of Laboratory Animals published by the National Institutes of Health, and it was approved by the Ethics and Research Committee of Shanghai Sixth People's Hospital, Shanghai, China.

Experimental design

Animals were randomly divided into five groups of eight rats each as described below.

Group I, sham-operation: A 2.0-cm upper midline abdominal incision was made, and the common bile duct (CBD) was freed from the surrounding tissues without ligation or transection.

Group II, bile duct ligation: The CBD was double ligated in its middle third with a 4-0 silk suture and transected between the two ligatures.

Group III, bile duct ligation + *L. plantarum*: After bile duct ligation (BDL), a volume of 10 mL live *L. plantarum* (activity, 2×10^8 CFU/mL) divided into two equal doses was administered daily to the rats by gavage for 10 d. After 10 d, the animals were sacrificed under ketamine anesthesia.

Group IV, BDL + IBD: The CBDs of animals were ligated and isolated. A polyethylene tube PE-10 (American Health and Medical Supply International Corp. Co., Ltd., Scarsdale, New York, United States) was inserted into the proximal CBD in a cephalad direction and fixed. The drainage end was tied and positioned in the right hepatorenal recess. After 5 d of obstructive jaundice, the abdomen was reopened through the previous incision. After releasing the biliary obstruction by transecting the tube, a distal 3-cm segment of the catheter was inserted into the duodenum for internal biliary drainage. The animals were sacrificed after another 5 d.

Group V, BDL + IBD + *L. plantarum*: Ten days after BDL, live *L. plantarum* was infused as described for Group III.

All non-*L. plantarum* control groups, including sham-operation (SHAM), were gavaged with the same volume of the same vehicle (Dulbecco's phosphate buffered saline) used for the *L. plantarum* groups. The animals were sacrificed after 10 d.

All surgical procedures were performed under strict sterile conditions and ketamine anesthesia. At the end of the experiment on day 10, 4-5 mL blood sample was collected from each animal by puncturing the portal vein.

Serum total bilirubin and alanine aminotransferase measurement

The serum total bilirubin and alanine aminotransferase (ALT) levels were determined using a kit (Jiancheng Biological Co., Ltd., Nanjing, China) and a Hitachi Model 7600 series automatic analyzer (Hitachi Co., Tokyo, Japan).

Plasma endotoxin measurement

Endotoxin concentrations were determined using a quantitative chromogenic Limulus Amebocyte Lysate test kit (Shanghai Med. and Chem. Institute, Shanghai, China). Samples were processed according to the manufacturer's instructions^[19].

Plasma D-lactate and plasma diamine oxidase measurement

Plasma D-lactate levels were measured by an enzymatic spectrophotometric assay^[20] using a serum D-lactate quan-

titative colorimetric detection kit according to the manufacturer's instructions (GMS19038.6, Genmed, Boston, MA, United States). Results were expressed as mol/mL. Plasma diamine oxidase (DAO) activities were determined with an enzymatic spectrophotometric assay^[21] using a Serum DAO detection kit according to the manufacturer's instructions (Jiancheng Biological Co., Ltd., Nanjing, China). Results were expressed as U/L.

Plasma reduced glutathione/oxidized glutathione measurement

Plasma glutathione (GSH) and glutathione (GSSG) were determined by an enzymatic spectrophotometric assay^[22] using the GSH and GSSG detection kits according to the manufacturer's instructions (Jiancheng Biological Co., Ltd.). Results were expressed as mol/mL.

Detection of superoxide dismutase and malondialdehyde in the ileum

Superoxide dismutase (SOD) activity was detected using Sun *et al*'s^[23] nitroblue tetrazolium method. Malondialdehyde (MDA) levels were measured using the thiobarbituric acid test according to Ohkawa *et al*'s^[24]. Intestinal tissue samples were thawed, weighed, and homogenized 1:9 (w/v) in 0.9% saline. The homogenates were centrifuged at $3000 \times g$ for 10 min at 4 °C, and the supernatant was removed for the measurement of MDA content, SOD activity, and total protein. Total intestinal protein concentration was determined by a Coomassie blue method, with bovine serum albumin (BSA) as a standard. SOD activity and MDA levels were detected with kits according to the manufacturer's instructions (Jiancheng Bioengineering Ltd., Nanjing, China). Results were expressed as U/mg protein and nmol/mg protein.

Light microscopy

Samples 1 cm in length were collected from the terminal ileum. To avoid mucosal damage, the intestinal lumen was carefully cannulated and gently washed with normal saline before sampling. Specimens were fixed by immersion in 10% buffered formaldehyde solution and embedded in paraffin. Sections (5 µm thick) were cut and stained for routine light microscopy using HE.

Transmission electron microscopy

Samples 3-4 mm in length were collected from the terminal ileum. These samples were longitudinally cut and immersed in 2.5% phosphate-buffered glutaraldehyde solution for 24 h at 4 °C. Specimens were then washed with phosphate-buffered solution (PBS), fixed in 1% osmium tetroxide for 2 h at 4 °C, dehydrated in ethanol and propylene oxide, and embedded in Epon 812 for 48 h. Sections (1 µm thick) were cut and stained with methylene blue. Ultrathin sections were then cut with a diamond knife, stained with uranyl acetate and lead citrate, and observed under transmission electron microscopy (TEM).

Terminal deoxyuridine nick-end labeling assay

Four-µm thick sections were collected on poly-L-lysine-

coated glass slides. The nuclear DNA fragmentation of apoptotic cells was labeled *in situ* by the terminal deoxynucleotidyl transferase nick-end labeling immunohistochemical method^[25] using an ApopTag[®] Plus Peroxidase In Situ Apoptosis Detection Kit (CHEMICON, Billerica, MA, United States) according to the manufacturer's instructions.

Immunofluorescence microscopy

Terminal ileum tissues were fixed in 3% paraformaldehyde for 3 h, washed with PBS, and embedded in paraffin. Sections (5 μ m thick) were cut and attached to glass slides. After deparaffinization and rehydration, sections were permeabilized with 0.2% Triton X-100 in PBS for 20 min. Slides were washed with PBS extensively and blocked with 5% normal goat serum PBS containing 0.05% Tween-20 and 0.1% BSA for 20 min at room temperature. Primary antibodies were added to the slides and incubated overnight at 4 °C in a humidity chamber. After washing, sections were incubated with FITC-conjugated specific secondary antibody (Sigma) at room temperature for 2 h in the dark. The slides were again washed extensively and then mounted with Vectashield mounting medium (Vector Laboratories, Inc., Burlingame, CA, United States). Sections were observed under a confocal laser microscope (LSM 510, Zeiss, Jena, Germany).

Expression of PKC by immunocytochemical staining using labelled streptavidin biotin method

After the rats were sacrificed, terminal ileum tissues were excised and fixed in Bouin's solution and embedded in paraffin. Immunohistochemistry was performed on 5- μ m thick paraffin sections. After deparaffinization and dehydration, endogenous peroxidase was blocked with 30 mL/L H₂O₂ for 15 min. After blocking of nonspecific binding sites with 5% normal goat serum, slides were incubated with specific primary antibody overnight at 4 °C. Primary antibodies were diluted 1:50 (rabbit polyclonal anti-human PKC, Santa Cruz Biotechnology, Inc., United States) in PBS. Next, the slides were washed three times for 5 min each with PBS and incubated with biotinylated goat anti-rabbit IgG at 37 °C for 30 min, washed as before, and developed with HRP-labeled streptavidin. The incubation and the subsequent washing were exactly the same as done before. Finally, diaminobenzidine chromogen, a peroxidase substrate, was added for color development. The reaction was stopped with a tap water rinse. The sections were counterstained with hematoxylin and mounted for examination.

Western blotting analysis

Terminal ileum samples were homogenized in ice-cold radioimmunoprecipitation assay (RIPA) buffer [150 mmol NaCl, 50 mmol Tris·HCl (pH 7.4), 0.5 mmol phenylmethylsulfonyl fluoride, 2.4 mmol EDTA, and 1 mmol sodium orthovanadate with 1% nonidet-40 (NP-40) and Sigma protease inhibitor cocktail (1:100)] for 30 min at 4 °C. After centrifugation at 10 000 \times g for 10 min at 4 °C, the protein concentration of each sample was quantified by the Bradford method. An equal amount of

total protein was separated on 10% sodium dodecyl sulfate (SDS)-polyacrylamide gels and then transferred to a nitrocellulose membrane. After blocked overnight in tris-buffered saline (TBS) containing 0.05% tween (TBS-T) and 5% dry powdered milk, membranes were washed three times for 5 min each with TBS-T and incubated for 2 h at room temperature in primary antibody (rabbit anti-claudin-1, rabbit anti-occludin, rabbit anti-JAM-A, or rabbit anti-ZO-1). After three washes with TBS-T, the membranes were incubated for 1 h with HRP-conjugated secondary antibody. Following two washes with TBS-T and one wash with TBS, the membranes were prepared for visualization of protein by the addition of enhanced chemiluminescence (ECL) reagent (Amersham, Princeton, NJ, United States). Densitometric analysis was performed using an Alpha Imager 1220 system (AlphaImotech Co., San Leandro, CA, United States).

Real-time reverse transcription-PCR

The levels of occludin, ZO-1, claudin-1, claudin-4, JAM-A and UGT1A mRNA were measured by real-time reverse transcription-PCR (RT-PCR) using SYBR1 green^[26]. Total RNA was isolated from terminal ileum samples with the TRIzol reagent (Invitrogen) according to the manufacturer's protocol. Real-time RT-PCR was performed with an ABI prism 7000 Real-Time PCR System (Applied Biosystems, Foster City, CA, United States). The primers were designed using the Primer Express[®] Program (Applied Biosystems). Their sequences are shown in Table 1. The following procedure used 2 μ g of RNA. In a sterile RNase-free microcentrifuge tube, 1 μ L of 20 μ M oligo (dT) 15 primer was added to a total volume of 15 μ L water. The tubes were heated to 70 °C for 5 min, cooled immediately on ice, and spun briefly. The following reagents were added to the annealed primer/template: 5 μ L of 5 \times M-MLV reaction buffer, 1.25 μ L of 10 mmol dNTPs and 25 units of RNasin RNase inhibitor, and 200 units of M-MLVRT RNase H were added to the reagent to yield a 25 μ L total reaction volume. All were mixed gently and then incubated for 60 min at 42 °C before the reaction was terminated at -20 °C.

Glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) gene expression was used as a house-keeping gene control. Separate PCR reactions (25 μ L) were conducted for each transcript and contained 2.0 μ L cDNA, 12.5 μ L of 2 \times SYBR Premix Ex Taq[™] (TaKaRa, Ltd., Shiga, Japan), and 0.5 μ L each of 10 μ mol/L gene-specific forward and reverse primers. PCR conditions were optimized to 95 °C (30 s), followed by 40 cycles (45 s each) at 95 °C, 60 °C (5 s), and 72 °C (30 s), and the reaction was completed at 37 °C for 30 s. Five serial dilutions of cDNA were analyzed for each target gene and used to construct linear standard curves. To compensate for variations in the RNA input and in the efficiency of the real-time RT-PCR, we used a normalization strategy based on the house-keeping gene *GAPDH*.

Immunoprecipitation and immunoblotting assays

The terminal ileum tissues were homogenized and ex-

tracted with the buffer used for Western blotting assays for 30 min at 4 °C. After centrifugation at 10 000 × *g* for 10 min at 4 °C, the protein concentration of each sample was quantified by the Bradford method. The supernatant was treated with protein G plus protein A agarose beads (Sigma) and incubated overnight at 4 °C with rabbit anti-occludin antibody (Zymed) and protein G + protein A agarose beads. The beads were washed with PBS and ice-cold RIPA buffer, and immunoprecipitated proteins were separated on 10% SDS-polyacrylamide gel electrophoresis gels and transferred onto nitrocellulose membranes (Invitrogen). The membranes were blocked with 1% BSA in PBS overnight at 4 °C and then incubated with rabbit anti-phosphoserine antibodies (Zymed) for 2 h at room temperature, followed by HRP-conjugated secondary antibody (Santa Cruz Biotechnology, Inc., United States). The reaction was visualized by an enzyme chemiluminescence kit from Pierce (Rockford, IL, United States). Western blotting was performed with an anti-occludin rabbit polyclonal antibody (Zymed) followed by an anti-rabbit secondary antibody coupled with peroxidase (Santa Cruz Biotechnology, Inc.) and ECL. For Western blotting of *ZO-1*, the same protocol was used with the rabbit polyclonal anti-*ZO-1* antibody and a rabbit anti- β -actin antibody (both from Santa Cruz Biotechnology, Inc.).

PKC activity assay

The PKC activity assay was conducted according to the instructions of the PepTag non-radioactive PKC assay kit (Promega, Madison, WI, United States). Briefly, terminal ileum tissues were homogenized and lysed in cold lysis buffer, containing 20 mmol/L tris-HCl, 0.5 mmol/L ethylene glycol tetraacetic acid, 2 mmol/L ethylenediamine-tetraacetic acid, 2 mmol/L phenylmethanesulfonyl fluoride, and 10 mg/L leupeptin (pH 7.5). Assays were then performed at 30 °C in a total volume of 25 μ L containing 5 μ L PKC reaction 5 × buffer, 5 μ L PLSRTPLSVAAK peptide, 5 μ L PKC activator, 1 μ L peptide protection solution, and 9 μ L sample. Reactions were initiated by the addition of the 9 μ L sample and terminated after 30 min

by incubation of the reaction mixture at 95 °C for 10 min. After added with 1 μ L of 80% glycerol, each sample was separated by 0.8% agarose gel electrophoresis at 100 V for 15 min. The intensity of fluorescence of phosphorylated peptides reflected the activity of PKC. All experiments were carried out in triplicate, with each data point representing the results from a separate culture.

Image analysis

Quantification of the immunohistochemical and immunofluorescence staining was performed on stored images of completely scanned tissue sections. Images were acquired with an AxioCam MRc (Carl Zeiss, Jena, Germany) connected to an Axioplan 2 fluorescence microscope (Carl Zeiss), at × 40 magnification. Each microscopic field was individually autofocused before acquisition. Five fields were selected from each slide and a total of five slides per group were examined. All image acquisition and processing were done using custom-written macros in KS400 image analysis software (version 3.0, Carl Zeiss).

Statistical analysis

Results were presented as mean ± SD of three experiments. The data were analyzed using GraphPad PRISM (GraphPad Software Inc., San Diego, CA, United States) and SPSS 11.0 (SPSS Inc., Chicago, IL, United States). All data were analyzed using one-way analysis of variance with Bonferroni/Dunnett T3 *post-hoc* test for multiple comparisons to determine differences between two experimental groups. *P* values < 0.05 were considered to be significant.

RESULTS

General observations

All animals survived throughout the experiment. Bile duct ligated rats were clinically jaundiced within 3 d. At reoperation on day 3, the ligation and division of the CBD were successful in all cases and resulted in significant dilatation of the CBD remnant proximal to the liga-

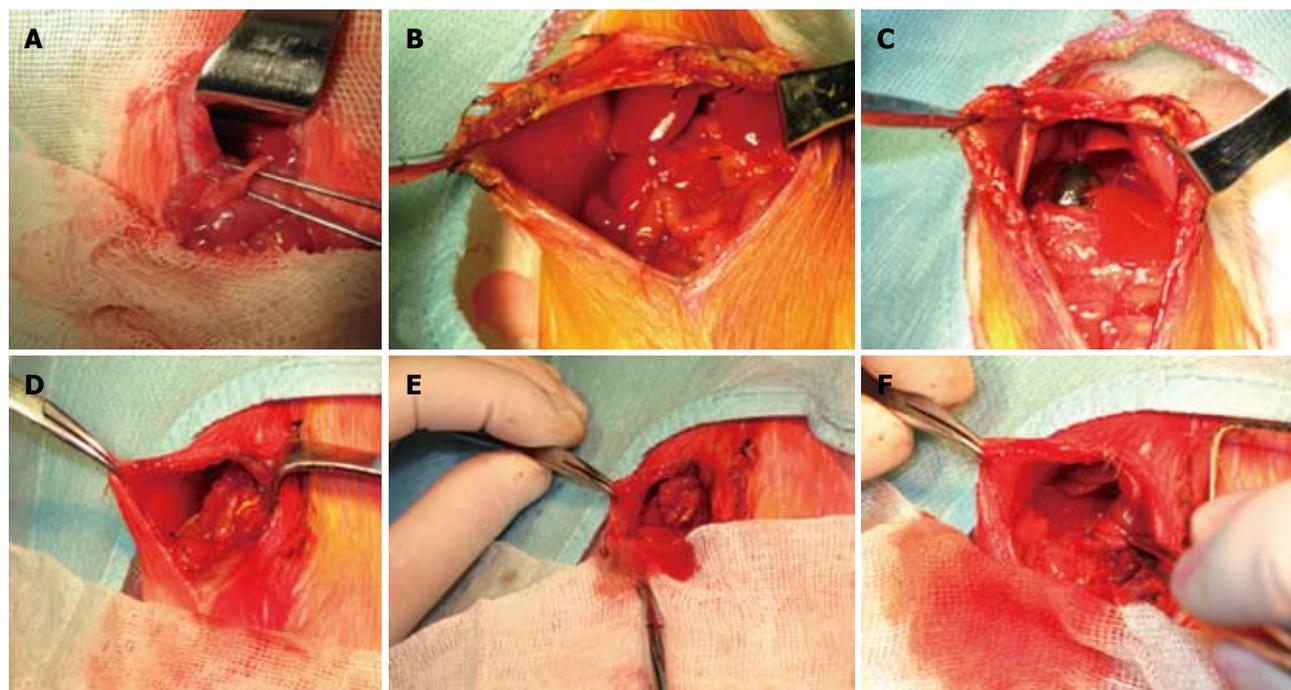

Figure 1 Images of experimental obstructive jaundice and internal biliary drainage. A: Dissection revealing the common bile duct; B: Reoperation after 3 d of common bile duct ligation. Light yellow abdominal ascites were present in the right side of the abdominal cavity; C: The proximal bile duct showed a remarkable expansion (dark blue color) after 3 d of common bile duct ligation; D: The PE-10 polyethylene tube was positioned with the end tied in the right hepatorenal recess; E: Brown bile flowed out while the catheter end was open; F: The distal 3 cm segment of the catheter was inserted into the duodenum for internal biliary drainage.

ture with obvious cholestatic appearance of the liver. At reoperation on day 10, the CBD diameter had returned to a normal size in the BDL + IBD group, and the cholestatic livers also appeared improved visually (Figure 1).

Serum total bilirubin and ALT levels

Obstructive jaundice led to significantly elevated serum levels of total bilirubin [153.73 mmol/L vs 3.0 ± 1.63 mmol/L] and ALT [543.83 U/L vs 60.8 ± 5.69 U/L, *P* < 0.05]. Administration of *L. plantarum* significantly reduced levels of total bilirubin (132 ± 23.9 mmol/L vs 9.0 ± 1.87 mmol/L) and ALT (218.38 ± 91.09 U/L vs 97 ± 10.37 U/L) in the portal serum (Table 2).

Portal endotoxin concentrations

Group II (BDL + *L. plantarum*) animals presented with significantly elevated endotoxin concentrations in portal blood compared with those in Group I (SHAM) (*P* < 0.05). Treatment with *L. plantarum* in the BDL + *L. plantarum* and BDL + IBD + *L. plantarum* groups significantly

reduced endotoxin levels in the portal serum (Table 2).

Plasma D-lactate and plasma DAO measurement

Plasma D-lactate levels increased significantly in the BDL group compared with the SHAM group. Administration of *L. plantarum* significantly decreased the plasma D-lactate levels in the BDL + *L. plantarum* and IBD + *L. plantarum* groups (Table 3).

DAO activity in the BDL group was significantly higher than that in the SHAM group. Plasma DAO activity became significantly lower after the use of probiotics in the BDL + *L. plantarum* and IBD + *L. plantarum* groups (Table 3).

Glutathione redox state

Plasma GSH was significantly reduced in Group II (BDL) animals compared with those in Group I (*P* < 0.05). Administration of *L. plantarum* significantly increased the levels of GSH in the Group IV (BDL + IBD) animals, whereas GSSG was found to be significantly increased in BDL animals. Administration of *L. plantarum* significantly

Images shown represent at least three regions observed on the same slide.

reduced the levels of GSSG in the BDL + IBD group (Table 3).

Intestinal mucosal SOD and MDA

Ileum mucosal MDA was significantly increased in BDL group compared with SHAM. Administration of *L. plantarum* significantly decreased the levels of MDA in the BDL + IBD group. The trend in ileum mucosal SOD levels among the groups was opposite to the results of MDA (Table 3).

Morphological studies

Specimens collected from the terminal ileum in the BDL group showed subepithelial edema and blunting of the villi, mostly located at the tip of the villi, with a large number of lymphocytes and plasma cells infiltrated in the intestinal mucosa (Figure 2). Under TEM, cell ultrastructure was disordered, with loss or disruption of microvilli and large dense secondary lysosomes that resembled partially degraded bacteria within the enterocyte cytoplasm. Inflated vacuolization of the cells, swollen mitochondria with partial or complete absence of interior cristae, disruption of desmosomes and formation of oedematous spaces, and expansion of endoplasmic reticulum were observed. Cells often showed serious damage to the plasma membrane and complete loss of junctional specialization between adjacent cells. Additionally, spherical and rod-shaped bacteria in the ileum were seen near enterocytes. These features are typical of pre-necrotic and necrotic injury of the intestinal mucosa. However, in the BDL +

L. plantarum group, cells were aligned regularly, with less swelling of mitochondria, no expansion of the endoplasmic reticulum, while the morphology was nearly normal in the IBD + *L. plantarum* group (Figure 3).

Apoptosis in the intestinal mucosal epithelium

Apoptotic nuclei were significantly more abundant in the markedly atrophic villi in the BDL group than in the SHAM group. The apoptotic nuclei were mostly distributed at the top of villi (Figure 4A). Administration of *L. plantarum* significantly decreased the number of apoptotic nuclei in the BDL + IBD + *L. plantarum* group (Figure 4B).

Expression of PKC illustrated by immunocytochemistry

PKC appeared as brown spots in the perinuclear structure. Its expression was decreased in the BDL group compared with the SHAM group. Administration of *L. plantarum* significantly enhanced the expression of PKC in the BDL + *L. plantarum* and IBD + *L. plantarum* groups (Figure 5).

Effects of *L. plantarum* on TJ protein localization (fluorescence microscopy)

Confocal imaging was performed to assess the distribution of the TJs in each group. TJ-associated proteins were continuously distributed in bright green or red color along the membrane of the cells. The F-actin staining showed a continuous line at the cell borders and along the cytoskeleton. Their borders were very clear in the SHAM group, where TJ-associated proteins were present at the apical

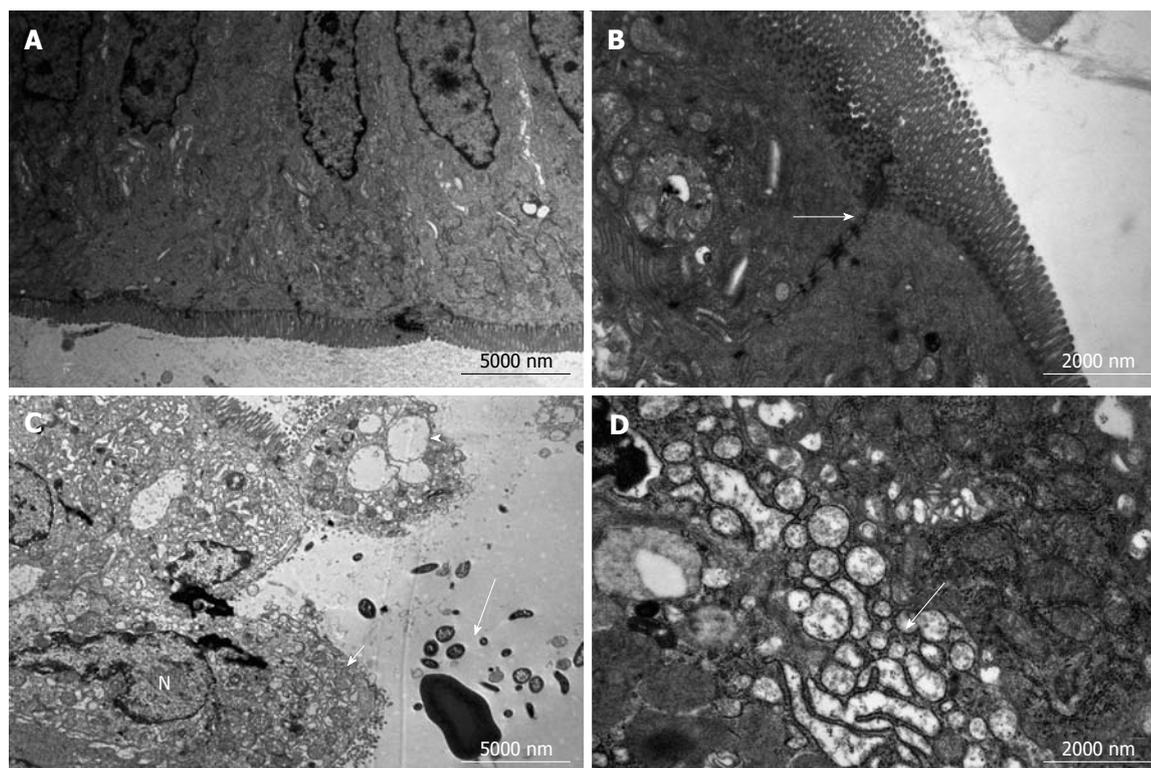

Figure 3 Ultrastructural assessment of enterocytes in the terminal ileum. A: Normal cell ultrastructure; B: The positions of tight junctions (arrow) and desmosomes; C: Enterocytes showed vacuolar degeneration (short arrow) and mitochondrial swelling, disruption of their microvilli (arrowhead), large dense secondary lysosomes, complete loss of the junctional specialization between adjacent cells (long arrow), and karyopyknosis (N); D: Expansion of the endoplasmic reticulum (arrow). Images shown represent at least three regions observed on the same slide. Group I : Sham-operation; Group II : Bile duct ligation (BDL); Group III : BDL + *Lactobacillus plantarum* (*L. plantarum*); Group IV : BDL + internal biliary drainage (IBD); Group V : BDL + IBD + *L. plantarum*.

intercellular borders in a belt-like manner, encircling the cells and delineating the cellular borders. In the BDL group, the fluorescence was dispersed and even became punctate, with loss of membrane fluorescence as against the uniform membrane staining in controls. Administration of *L. plantarum* enhanced the expression of TJ-associated proteins in the BDL + *L. plantarum* and IBD + *L. plantarum* groups (Figure 6).

Effects of *L. plantarum* on TJ and PKC protein levels (Western blotting)

Western blotting analyses were performed to determine the relative protein levels of the target proteins occludin, claudin-1, claudin-4, JAM-A, ZO-1 and PKC in the terminal ileum. The intensity of the whole-cell proteins was determined from ratios of the integrated intensity of the target protein bands to the integrated intensities of the β -actin bands in the same sample. Compared with samples obtained from rats in the SHAM group, levels of target proteins were decreased in protein extracts from ileal mucosal scrapings of rats subjected to BDL. Administration of *L. plantarum* significantly enhanced the expression of TJ-associated proteins in the BDL + *L. plantarum* and IBD + *L. plantarum* groups (Figure 7).

Levels of mRNA in TJ and PKC determined by real-time PCR assays

Intragastric administration of *L. plantarum* resulted in

changes in the levels of occludin, ZO-1, claudin-1, claudin-4, JAM-A and PKC. This result raised the question whether these altered protein levels were a consequence of changes in mRNA levels. We, therefore, used real-time RT-PCR to determine the levels of mRNA in the terminal ileum in each group. The levels of mRNA of occludin, ZO-1, claudin-1, claudin-4, JAM-A, PKC and UGT1A1 were found significantly lower in the BDL group than in the SHAM group. Administration of *L. plantarum* significantly increased the mRNA levels of target proteins in both the BDL + *L. plantarum* and IBD + *L. plantarum* groups (Table 4).

Phosphorylation of occludin and ZO-1

We examined the phosphorylation status of occludin and ZO-1 using immunoprecipitation and immunoblotting assays. Occludin and ZO-1 were phosphorylated at serine residues. BDL lowered p-occludin and p-ZO-1 proteins levels compared with the SHAM group. Administration of *L. plantarum* improved the expression of the p-occludin and p-ZO-1 proteins from the terminal ileum in the BDL + *L. plantarum* and BDL + IBD + *L. plantarum* groups (Figure 8).

Effects of *L. plantarum* on PKC activity

As shown in Figure 9, PKC activity was significantly decreased in the BDL group compared with SHAM group. Intragastric administration of *L. plantarum* partly restored

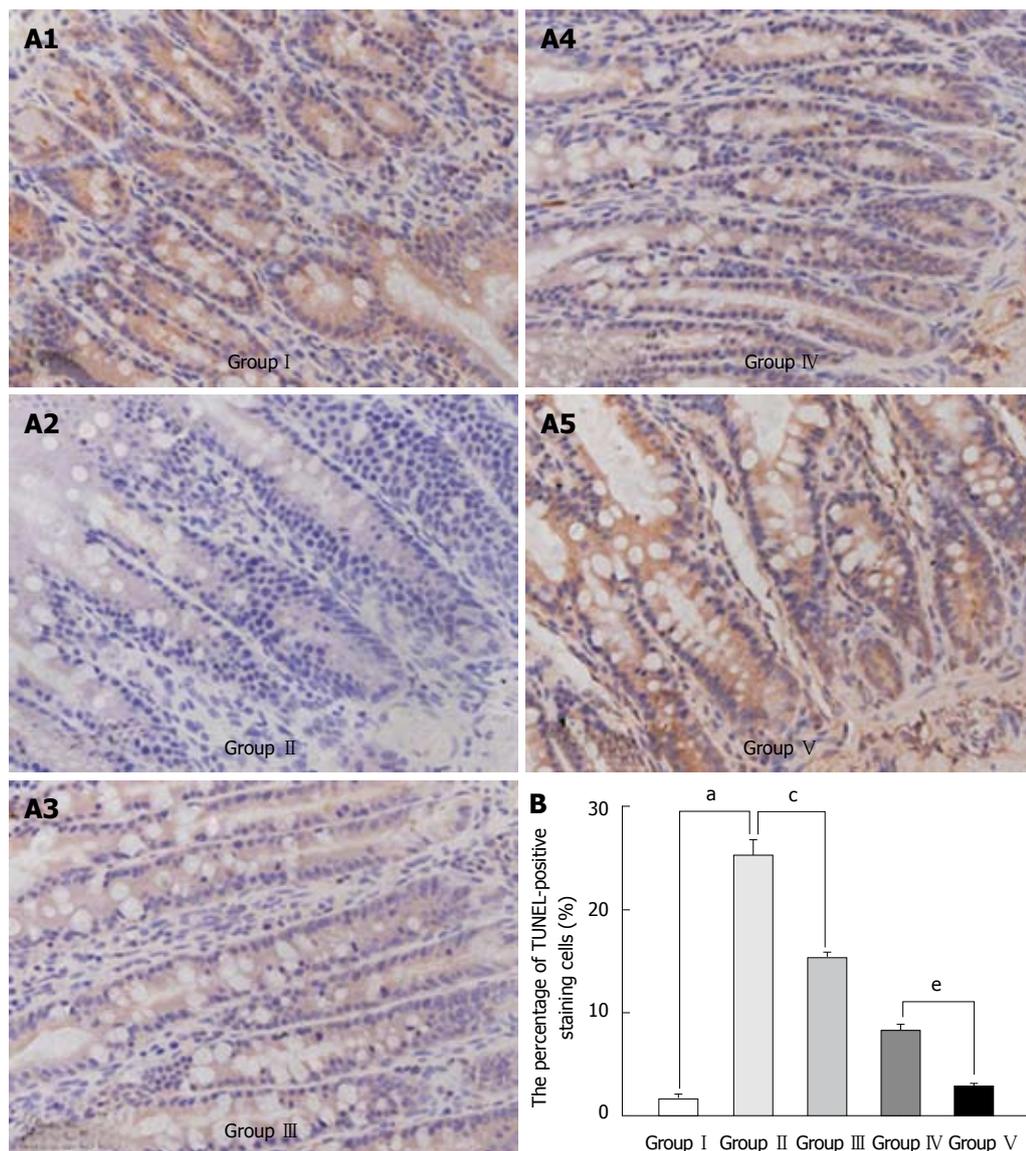

Figure 4 Effects of *Lactobacillus plantarum* on the apoptosis in the intestinal mucosal epithelium. A: Ileum sections from each group stained using the terminal deoxyuridine nick-end labeling (TUNEL) method. TUNEL-positive cells were stained dark brown. A significantly higher number of TUNEL-positive cells was detected in tissues from group II animals compared with group III; and the number of TUNEL-positive cells in group IV was higher than in group V. PKC activity in both the BDL + *L. plantarum* and BDL + IBD + *L. plantarum* groups.

DISCUSSION

The present study demonstrated that oral administration of *L. plantarum* significantly reduced bilirubin, ALT and endotoxin levels in the systemic circulation in an experimental obstructive jaundice animal model with internal biliary drainage for 10 d. Moreover, oral *L. plantarum* administration to the rats in the BDL + *L. plantarum* group and the BDL + IBD + *L. plantarum* group not only reduced the serum endotoxin levels, but also substantially improved liver function. This result is consistent with the conclusions reported in previous literature^[12].

In our study, oral *L. plantarum* administration also

significantly decreased the serum DAO activity and D-lactate level in both the BDL + *L. plantarum* group and the BDL + IBD + *L. plantarum* group. These findings indicate that *L. plantarum* plays an important role in intestinal integrity. Previous *in vitro* studies have confirmed that probiotics exert direct protective effects in intestinal epithelial cell TJJs *via* a PKC-kinase-dependent mechanism and inhibiting epithelial cell apoptosis in cell culture experiments^[11,18,10]. The current experiments focused on *L. plantarum* effects, while several previous studies have reported the protective effects of other lactobacilli and probiotics. For example, Moorthy *et al*^[27] reported that pretreatment with a combination of *Lactobacillus rhamnosus* (*L. rhamnosus*) and *Lactobacillus acidophilus* had a significant protective effect on TJ proteins (claudin-1 and occludin) in a *Shigella dysenteriae* 1 infection rat model. colitis. These studies support the findings that a number of probiotic agents have the protective effects in gastrointestinal tract as described in the current work.

Previous studies, including experimental models and clinical cases of biliary obstruction, have shown that disruption of intestinal barrier integrity in obstructive jaundice is associated with high intestinal oxidative stress, as evidenced by increased lipid peroxidation and oxidation of proteins, non-protein, and protein thiols^[6,30]. Increased intestinal oxidative stress, a factor in cellular injury, may also play a critical role in regulating important cellular alterations of the intestinal mucosa in obstructive jaundice, such as increased apoptosis and altered TJ expression^[5,31]. The results of this study strongly suggest that obstructive jaundice induces oxidative stress in the intestine.

We also found that apoptotic nuclei were significantly more abundant in markedly atrophic villi in the BDL group. Administration of *L. plantarum* significantly decreased apoptosis of the terminal ileum and improved the histology of the terminal ileum, which also was affected by obstructive jaundice. The protective effect of *L. plantarum* may be related to amelioration of oxidative stress. Previous studies of *L. rhamnosus* GG, a member of the same genus as *L. plantarum*, showed that this bacterium attenuated the H₂O₂-induced disruption of barrier function^[18]. Our studies also revealed that administration of *L. plantarum* significantly reduced the levels of GSSG, MDA and SOD in rats of the BDL + *L. plantarum* group and the BDL + IBD + *L. plantarum* group.

Intestinal epithelial TJs prevent diffusion of potential injurious factors from the gastrointestinal lumen into the tissue. TJs located at the subapical aspect of the lateral membranes contain a large number of membrane-associated proteins, including occludin, JAM and claudins, which are responsible for forming the physical connections between cells that confer the basic barrier properties. Using immunohistochemistry and immunoblotting, previous studies have demonstrated that intestinal mucosal barrier dysfunction in obstructive jaundice is associated with a regional loss of occludin expression in the intestinal epithelium^[4,31]. Similarly, our study showed that levels of TJ-associated proteins such as occludin, ZO-1, claudin-1, claudin-4 and JAM-A were reduced in the intestinal epithelium, especially at the upper part of villi. These data support the conclusion that oral *L. plantarum* administration can enhance the expression of TJ-associated proteins.

A significant body of evidence indicates that PKC is involved in the regulation of the integrity of TJs and AJs. Recent studies have shown differences between Tyr-phosphorylation and Ser/Thr-phosphorylation of occludin. Tyr-phosphorylation of occludin is clearly associated with the disruption of TJs. Ser/Thr-phosphorylation may be required for the assembly of occludin into the TJs. PKC- ζ prevents oxidant-induced iNOS upregulation and protects microtubules and gut barrier integrity^[32]. Thus, PKC- ζ appears to be an endogenous stabilizer of the microtubule cytoskeleton and of intestinal barrier function against oxidative injury^[33].

The probiotic bacterium *L. plantarum* has been shown to improve intestinal barrier function in a range of experimental models of colitis, pancreatitis, liver injury and biliary obstruction^[8,34-37]. Recent studies have shed some light on the mechanisms involved in the beneficial effects of probiotics in the gastrointestinal tract. PKC activity may be involved in epidermal growth factor-mediated protection of the intestinal epithelial barrier function against oxidative stress^[38]. Seth *et al.*^[18] suggested that PKC β I activation may be one of the initial events in the probiotic-mediated protection of TJs and AJs. PKC ϵ may play a role in the downstream events of the signaling pathway involved in this process. TJ-protein phosphorylation mediated by PKC may be related to the mechanism of protection by *L. plantarum* in obstructive jaundice. Previous studies have shown that phosphorylation is a key mechanism for regulating the biological function of TJ proteins. Highly phosphorylated occludin molecules are selectively concentrated at TJs, whereas non- or less phosphorylated occludin molecules are localized in the cytoplasm^[39].

To determine whether PKC mediates the disruption of the intestinal barrier in obstructive jaundice, we examined the phosphorylation status of occludin and ZO-1 using Western blotting analysis with antibodies against phosphoserine. We found that obstructive jaundice decreased p-occludin and p-ZO-1 protein levels compared with sham-operation. Our study also demonstrated that obstructive jaundice resulted in a significant decrease in PKC activity. Co-incubation with *L. plantarum* partly restored PKC activity and increased phosphorylation of serine residues on TJ proteins in both the BDL + *L. plantarum* group and the BDL + IBD + *L. plantarum* group. Phosphorylation of these proteins occurred on Ser residues that have been described as substrates for PKC activity^[40-42]. Our results suggest that the PKC pathway is involved in the process of *L. plantarum*-induced TJ redistribution.

In conclusion, administration of probiotics before and after operation in rats with experimental obstructive jaundice can substantially protect the gut barrier. The protective mechanisms of probiotics are associated with decreased intestinal epithelial cell apoptosis, reduction of oxidative stress, and protection of intestinal mucosal TJs. *L. plantarum* can prevent TJ disruption in biliary obstruction by activating the PKC pathway.

COMMENTS

Background

Biliary tract surgery in patients with obstructive jaundice is associated with a high morbidity and mortality rate, and obstructive jaundice increased gut permeability and bacterial translocation. *Lactobacillus plantarum* (*L. plantarum*) has been shown to have beneficial effects on intestinal barrier function. Protein kinase C (PKC) plays a crucial role in the mediation of intestinal epithelial tight junction (TJ) proteins, and *L. plantarum* may prevent TJ disruption in biliary obstruction by activating the PKC pathway. However, there had been few studies about the mechanism for the protective effect of probiotics on the intestinal barrier in obstructive jaundice. This study focused on the effects of *L. plantarum* on the intestinal mucosal barrier, oxidative stress, epithelial TJ-protein structure

and phosphorylation, especially its impact on the expression and activity of PKC.

Research frontiers

Previous *in vitro* studies have confirmed that probiotics could protect intestinal epithelial cell TJs via a PKC-kinase-dependent mechanism and inhibit epithelial cell apoptosis in cell culture experiments. TJ-protein phosphorylation mediated by PKC may be related to the protective effects of *L. plantarum* in obstructive jaundice.

Innovations and breakthroughs

The administration of *L. plantarum* before and after operation in rats with experimental obstructive jaundice could substantially protect the gut barrier. Protective mechanisms of *L. plantarum* are associated with decreased intestinal epithelial cell apoptosis, reduction of oxidative stress, and protection of intestinal mucosal TJs. *L. plantarum* can prevent TJ disruption in biliary obstruction by activating the PKC pathway.

Applications

By understanding the mechanism and effects of *L. plantarum* on the intestinal mucosal barrier, this study may represent a future strategy in the treatment of patients with obstructive jaundice.

Peer review

This is a very well done experimental study for evaluating the effect of *L. plantarum* on the intestinal mucosal barrier, oxidative stress, epithelial TJ protein structure and phosphorylation, with special regard to its impact on the expression and activity of PKC in experimental obstructive jaundice.

Abstract

AIM: To report our experience using a recently introduced anchoring balloon for diagnostic and therapeutic direct peroral cholangioscopy (DPOC).

METHODS: Consecutive patients referred for diagnostic or therapeutic peroral cholangioscopy were evaluated in a prospective cohort study. The patients underwent DPOC using an intraductal anchoring balloon, which was recently introduced to allow consistent access to the biliary tree with an ultraslim upper endoscope. The device was later voluntarily withdrawn from the market by the manufacturer.

RESULTS: Fourteen patients underwent DPOC using the anchoring balloon. Biliary access with an ultraslim upper endoscope was accomplished in all 14 patients. In 12 (86%) patients, ductal access required sphincteroplasty with a 10-mm dilating balloon. Intraductal placement of the ultraslim upper endoscope allowed satisfactory visualization of the biliary mucosa to the level of the confluence of the right and left hepatic ducts in 13 of 14 patients (93%). Therapeutic interventions by DPOC were successfully completed in all five attempted cases (intraductal biopsy in one and DPOC guided laser

lithotripsy in four). Adverse events occurred in a patient on immunosuppressive therapy who developed an intrahepatic biloma at the site of the anchoring balloon. This required hospitalization and antibiotics. Repeat endoscopic retrograde cholangiopancreatography 8 wk after the index procedure showed resolution of the biloma.

CONCLUSION: Use of this anchoring balloon allowed consistent access to the biliary tree for performance of diagnostic and therapeutic DPOC distal to the biliary bifurcation.

Diagnostic and therapeutic direct peroral cholangioscopy using an intraductal anchoring balloon. *World J Gastroenterol* 2012; 18(30): 3992-3996 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i30/3992.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i30.3992>

INTRODUCTION

The value of cholangioscopy for diagnosis and treatment of biliary disorders has been well established^[1]. Diagnostic and therapeutic direct peroral cholangioscopy (DPOC) using an ultraslim upper endoscope offers significant advantages over ductoscopy using dedicated cholangioscopes^[2]. The ultraslim endoscope uses a single-operator platform, provides high-definition digital image quality, allows simultaneous irrigation and therapy,

is not fragile, and has a larger working channel enabling enhanced diagnostic sampling and therapeutic interventions. However, DPOC in its current state has significant limitations. Initial free biliary cannulation is cumbersome, time consuming, and associated with a significant failure rate. Even when access is obtained, intraductal maneuverability and stability may be compromised by looping of the endoscope in the stomach or duodenum. To address these technical challenges, a prototype biliary anchoring balloon has been designed. Feasibility of this system in an animal model has been assessed but human reports are lacking^[2].

We performed a study in 14 patients to assess utility of this device for diagnosis and treatment of various biliary disorders prior to voluntary device withdrawal by the manufacturer. We report our experience using this device for ductal access in all 14 patients.

MATERIALS AND METHODS

Study aims and patients

This was a prospective cohort study of consecutive patients referred to our tertiary care center for endoscopic retrograde cholangiopancreatography (ERCP) and peroral cholangioscopy. The primary aim of the study was to assess the ability to gain access to the bile duct with an ultraslim upper endoscope and visualize the extrahepatic biliary mucosa to the level of the confluence of the left and right hepatic ducts. The secondary aim was to examine the feasibility of performing therapeutic procedures through the endoscope while maintaining intraductal access. This study was approved by The Cleveland Clinic Institutional Review Board. The inclusion criteria were presence of biliary pathology and ability of the patients to give informed consent. The exclusion criteria were coagulopathy, suspicion for acute ascending cholangitis, latex allergy, and biliary ductal diameter < 6 mm.

Anchoring balloon

The anchoring balloon used in this study (Cook Medical, Winston-Salem, NC, United States) had five components. A short stylet located at the most proximal end of the device was used to occlude the air channel after the balloon was inflated. This prevented deflation of the balloon after removal of the handle. Immediately distal to the stylet, there was a handle, which could be detached and removed to allow backloading of the device into an ultraslim upper endoscope while maintaining balloon inflation. The device had a 300-cm long, 4-French catheter with a nitinol stiffening core. At the distal end of the catheter, there was a latex balloon that could be inflated to 15 mm and used as an intraductal anchoring point. A radiopaque loop tip was located at the most distal end of the device and allowed positioning of the balloon in the desired duct under fluoroscopic guidance over a guidewire (Figure 1A).

Cholangioscopy procedure

All procedures were performed by an experienced endos-

copist, under monitored anesthesia care sedation with the patients in the prone position. Endoscopic sphincterotomy was or had been performed previously prior to direct peroral cholangioscopy in all patients. Balloon sphincteroplasty to 10 mm was performed as needed. After completion of ERCP, a 0.889-mm guidewire was placed in one of the intrahepatic ducts. The anchoring balloon was then directed into that intrahepatic duct by placing the loop end of the device over the guidewire. Location of the guidewire and the anchoring balloon was verified by fluoroscopy (Figure 1B). The balloon was then inflated with air to anchor it within the duct. A gentle pull on the balloon catheter confirmed ductal anchoring. If the pull on the catheter led to dislodgment of the balloon, it was deflated and the procedure was repeated to reposition the balloon in another intrahepatic duct followed by inflation of the balloon and pulling to confirm anchoring. Once anchoring of the balloon was confirmed, the air channel of the device was covered with the stylet to keep the balloon inflated. The proximal handle was then detached from the catheter and removed. This was followed by removal of the duodenoscope and the guidewire, leaving the inflated balloon and its catheter behind. An ultraslim upper endoscope was backloaded over the catheter and advanced into the bile duct to the level of the confluence of the right and left hepatic ducts (Figure 1C). The anchoring balloon was then removed in most cases. The bile duct was irrigated through the accessory channel of the ultraslim endoscope with sterile saline solution, followed by slow withdrawal of the endoscope, allowing systematic inspection of the biliary tree. Air insufflation was not used, to avoid potential complications. Routine antibiotic prophylaxis was not administered. The ultraslim endoscopes used in this study included GIF-XP160 (outer diameter 5.9 mm), GIF-XP180 (outer diameter 5.5 mm), and GIF-N180 (outer diameter 4.9 mm) (Olympus Corporation, Center Valley, PA United States). All endoscopes had an instrument channel with an inner diameter of 2 mm.

Statistical analysis

Values are presented as mean (range) or frequency (percentage). R version 2.4.1 software (The R Foundation for Statistical Computing, Vienna, Austria) was used to perform all the analyses.

RESULTS

Patients and indications

Fourteen consecutive patients underwent DPOC using the new anchoring balloon. The mean age of the patients was 65 years (range: 30-92 years). Nine (64%) patients were female. The indications for the procedure, DPOC findings and final diagnosis are presented in Table 1.

Biliary access

Biliary access with an ultraslim upper endoscope was accomplished in all patients. In 12 of 14 (86%) patients, biliary access required sphincteroplasty with a 10-mm

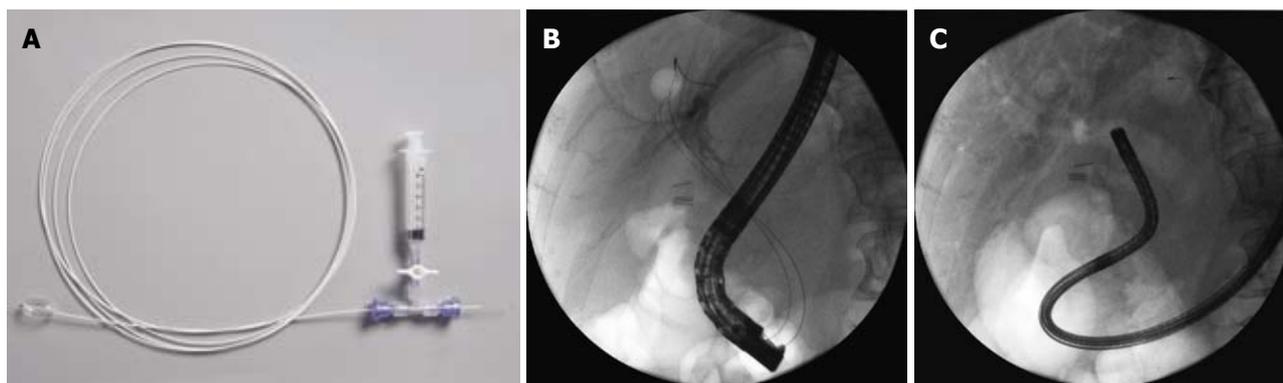

Figure 1 *Ex vivo* and *in vivo* views of the anchoring balloon. dilating balloon over a guidewire. In 13 of 14 (93%) patients, the bile duct mucosa from the bifurcation to the ampulla could be well visualized. In one patient, the common hepatic duct could not be examined due to a sigmoid-shaped main bile duct that prevented passage of the endoscope proximal to the common bile duct. In this patient, only the mucosa of the common bile duct was inspected.

Biliary intervention

Therapeutic measures were attempted in five patients. Four patients underwent removal of difficult-to-remove bile duct stones and one patient had intraductal biopsy.

The four patients with difficult-to-remove stones had at least one prior unsuccessful attempt at stone extraction by ERCP with sphincterotomy, sphincteroplasty, and mechanical lithotripsy. In all cases, laser lithotripsy through

the ultraslim upper endoscope successfully fragmented the stones, with subsequent removal of the fragments (Figure 2). In one of these cases, however, instability of the ultraslim upper endoscope after removal of the anchoring balloon, required passage of the laser probe (SlimLine GI, Lumenis, Santa Clara, CA, United States) into the bile duct alongside the anchoring balloon, while keeping the balloon inflated in one of the intrahepatic ducts to maintain access. Nonetheless, the procedure was successful with excellent views of the biliary mucosa and performance of laser lithotripsy under direct vision with fragmentation and subsequent removal of the stone fragments.

In one patient, DPOC was performed to evaluate an ill-defined filling defect at the biliary confluence with intrahepatic ductal dilatation seen on magnetic resonance imaging. DPOC successfully visualized the filling defect

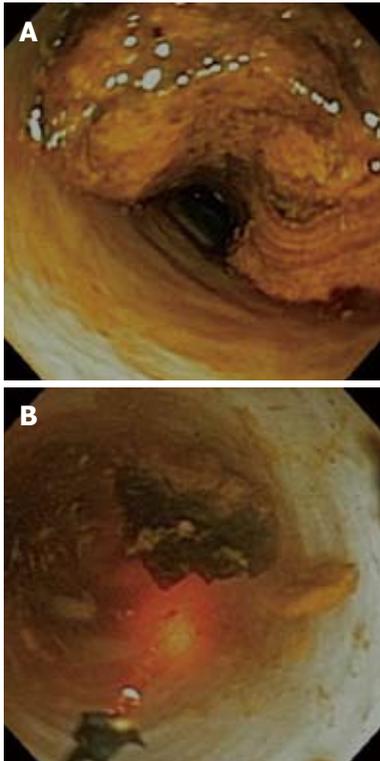

Figure 2 Cholangioscopic view of a large stone. A: The stone could not be removed during prior endoscopic retrograde cholangiopancreatography. A plastic stent was placed and the patient was referred for cholangioscopy-guided laser lithotripsy. Impression of the plastic stent in the stone is clearly visible; B: Cholangioscopic view of the same stone after laser lithotripsy. The laser probe is seen in the left lower corner of the picture.

and showed it to be a tumor projecting into the bile duct lumen (Figure 3). Biopsies of the tumor were obtained through the ultraslim upper endoscope using a regular pediatric forceps (EndoJaw FB-221K; Olympus Corporation, Tokyo, Japan) and showed necrotic tissue. Follow-up imaging studies showed growing intraductal tumor suggesting cholangiocarcinoma.

Adverse events

One patient who had undergone orthotopic liver transplantation 2 years prior to the procedure, and was on immunosuppressive therapy, developed intrahepatic biloma at the site where the balloon was anchored within the duct (Figure 4). She underwent biliary stenting to assure ductal drainage. She also was given an intravenous dose of antibiotics during the procedure and discharged home on oral antibiotics and outpatient follow-up. However, 2 d after discharge she developed fever. She was admitted to the hospital and treated with intravenous antibiotics followed by 2 wk of oral antibiotics after discharge. Repeat ERCP 8 wk after the index procedure showed resolution of the biloma.

DISCUSSION

Despite its many advantages, DPOC is rarely performed in nonacademic settings. The biggest disadvantage of DPOC has been the difficult and time-consuming task

Figure 3 Cholangioscopic image of a tumor in the proximal common hepatic duct. The anchoring balloon catheter is seen in the left lower corner of the picture.

Figure 4 Biloma at the site of the anchored balloon within an intrahepatic bile duct.

of bile duct cannulation with an upper endoscope, often ending in failure. There are several published reports in the endoscopic literature with innovative suggestions on how to achieve this task. Introduction of the endoscope over a guidewire, through a regular overtube, or with the help of a double-balloon overtube are some of the suggestions^[3-6]. However, despite use of these accessories, failure rate remains high^[7].

Different variations of inflatable balloons used as an anchor within the biliary tree have therefore been introduced for easier access^[2,8]. Using such a device, we were able to gain access to the bile duct with an ultraslim upper endoscope in all cases and obtain high-quality images of the biliary mucosa. We were also able to perform necessary interventions such as shock wave lithotripsy or targeted biopsy in all cases in which therapy was attempted. In one of the therapeutic cases, however, the instability of the ultraslim endoscope upon removal of the balloon could only be remedied by keeping the anchoring balloon in position.

Although this device performed well for allowing access to the bile duct for performance of DPOC and assessment and therapy of disorders of the distal biliary system, we found it difficult to maneuver the endoscope and gain access to the ducts proximal to the bifurcation after deflation and removal of the anchoring balloon.

This was mainly due to looping of the endoscope in the stomach or duodenum after removal of the balloon.

The anchoring balloon used in this study was voluntarily withdrawn from the market by the manufacturing company, reportedly because of possible increased risk of air embolism^[9]. The possible increased risk of air embolism is probably due to the ability of the ultraslim upper endoscopes to insufflate the biliary tree with air, while at the same time blocking the escape route of the insufflated air. In this study, we used irrigation with saline rather than air to distend the bile duct and visualize the mucosa of the biliary tree.

One of the patients developed a biloma at the anchoring site of the balloon. Although she had a full recovery with antibiotic therapy, ductal damage at the anchoring site may be another potential adverse event associated with use of anchoring balloons.

One of the main limitations of this study was the small number of patients. However, the primary objective of this study was to assess performance of this device in a limited number of patients. Another limitation was performance of the procedures in a tertiary care referral setting by an endoscopist proficient in all forms of peroral and percutaneous cholangioscopy. This may limit extrapolation of the results to other settings.

In conclusion, our experience suggests that anchoring balloons are effective for consistent access to the bile duct with an ultraslim upper endoscope for performance of diagnostic and therapeutic DPOC distal to the confluence of the right and left hepatic ducts. However, we urge caution with widespread use of anchoring balloons until more information on potential adverse effects is available.

COMMENTS

Background

Direct peroral cholangioscopy (DPOC) in its current state has significant limitations. Initial free biliary cannulation is cumbersome, time consuming, and associated with a significant failure rate. Even when access is obtained, intraductal maneuverability and stability may be compromised by looping of the endoscope in the stomach or duodenum.

Research frontiers

To address the technical challenges associated with DPOC, a prototype biliary anchoring balloon has been designed. Feasibility of this system in an animal model has been assessed but human reports are lacking. This is the first study assessing utility of this prototype anchoring balloon for diagnosis and treatment of various biliary disorders.

Innovations and breakthroughs

Despite its many advantages, DPOC is rarely performed in nonacademic

settings. The biggest disadvantage of DPOC has been the difficult and time-consuming task of bile duct cannulation with an upper endoscope, often ending in failure. There are several published reports in the endoscopic literature with innovative suggestions on how to achieve this task. Introduction of the endoscope over a guidewire, through a regular overtube, or with the help of a double-balloon overtube are some of the suggestions. However, despite use of these accessories, the failure rate remains high. Using an anchoring balloon, the authors were able to gain access to the bile duct with an ultraslim upper endoscope in all cases and obtain high-quality images of the biliary mucosa. They were also able to perform necessary interventions such as shock wave lithotripsy or targeted biopsy in all cases in which therapy was attempted.

Applications

This study suggests that anchoring balloons are effective for consistent access to the bile duct with an ultraslim upper endoscope for performance of diagnostic and therapeutic DPOC distal to the confluence of the right and left hepatic ducts.

Peer review

The authors report clinical experiences of DPOC by using a novel balloon catheter as an assisting accessory. This is a well-written article. However, it is necessary that the authors offer more detailed descriptions and revise several major and minor points.

Abstract

AIM: To describe the clinical and epidemiologic profiles of the disease and to compare the findings with those generated from the previous hospital-based studies.

METHODS: The Gharbiah cancer registry is the only population-based cancer registry in Egypt since 1998. We analyzed the data of all colorectal cancer patients

included in the registry for the period of 1999–2007. All medical records of the 1364 patients diagnosed in Gharbiah during the study period were retrieved and the following information abstracted: age, residence, diagnosis date, grade, stage, topology, clinical characteristics, and histology variables. Egyptian census data for 1996 and 2006 were used to provide the general population's statistics on age, sex, residence and other related demographic factors. In addition to age- and sex-specific incidence rate analyses, we analyze the data to explore the incidence distribution by rural-urban differences among the 8 districts of the province. We also compared the incidence rates of Gharbiah to the rates of the Surveillance Epidemiology and End Results (SEER) data of the United States.

RESULTS: Over the 9 year-period, 1364 colorectal cancer cases were included. The disease incidence under age 40 years was relatively high ($1.3/10^5$) while the incidence in the age groups 40 and over was very low ($12.0/10^5$, $19.4/10^5$ and $21.2/10^5$ in the age groups 40–59 years, 60–69 years and > 70 years, respectively). The vast majority of tumors (97.2%) had no polyps and 37.2% of the patients presented with primary lesions in the rectum. Colorectal cancer was more common in patients from urban (55%) than rural (45%) areas. Regional differences in colon and rectal cancer incidence in the 8 districts of the study province may reflect different etiologic patterns in this population. The registry data of Egypt shows a slightly higher incidence of colorectal cancer than the United States in subjects under age 40 years. The results also shows significantly lower incidence of colorectal cancer in subjects over age 40 years compared to the same age group in the United States SEER.

CONCLUSION: Low rate of polyps, low incidence in older subjects, and high rate of rectal cancer in Egypt. Future studies should explore clinical and molecular disease patterns.

Veruttipong D, Soliman AS, Gilbert SF, Blachley TS, Hablas A, Ramadan M, Rozek LS, Seifeldin IA. Age distribution, polyps and rectal cancer in the Egyptian population-based cancer registry. *World J Gastroenterol* 2012; 18(30): 3997-4003 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i30/3997.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i30.3997>

INTRODUCTION

Colorectal cancer is a common cancer worldwide. In 2008, Globocan estimated there were 663 000 new cases in men and 571 000 new cases in women^[1,2]. With a combined 608 000 deaths worldwide, colorectal cancer represents the fourth most common cause of cancer-related mortality. There is a wide variability in the incidence rates of colorectal cancer, with most incident cases occurring in developed countries^[1]. Incidence rates of colorectal cancer for men range from 4.1/10⁵ in Karunagappally, India, to 59.1/10⁵ in the Czech Republic. In women, incidence rates range from 3.6/10⁵ in Karunagappally, India, up to 39.5/10⁵ in New Zealand^[2]. Rates for the United States are 34.1/10⁵ for men and 25/10⁵ for women^[1].

Westernization is often associated with higher incidence rates of colorectal cancer. Diet and lifestyle factors are implicated risk factors for the disease. Fruit and vegetable-deficient diet, calorie-dense foods, physical inactivity, obesity, and smoking increase the risk for developing colorectal cancer^[2]. While developing countries historically have a low rate of colorectal cancer, the transition to a more Western diet has been associated with increasing rates of disease^[3,4].

Our previous hospital-based studies in Egypt showed low incidence of colorectal cancer and high proportion of young-onset disease^[5]. In comparing rates of Egyptian colorectal cancer to the Surveillance Epidemiology and End Results Program (SEER) of the United States, Egypt had higher rates up to age 30-34 years, at which point Egyptian rates level out while United States rates increase sharply^[5]. Our studies also revealed low rate of polyps, high proportion of rectal cancers among the colorectal cancer tumors, and lack of molecular characteristics of hereditary non-polyposis colorectal cancer (HNPCC) or young-onset or sporadic colorectal cancer in the United States^[5-7]. Our studies have also shown intense environmental exposures such as organochlorine pesticide levels, however, these environmental and genetic factors were not related to the young or old onset of the disease^[8].

Limitations of the previous studies on colorectal cancer in Egypt included their hospital-based nature and relatively small sample size. Therefore, with the establish-

ment of Egypt's only population-based cancer registry and availability of complete data from 1999-2007, it was intriguing to investigate the epidemiologic and clinical profiles of colorectal cancer and examine the previous findings based on the new population-based registry data.

MATERIALS AND METHODS

The Gharbiah province is in the center of the Nile delta region about 90 km north of Cairo with a population of about 4 million individuals^[9]. It has a male:female ratio of 1.02:1 and age structure approximately equivalent to that of the rest of Egypt^[10].

The Gharbiah population-based cancer registry, the only population-based registry in Egypt was founded in 1998^[9]. It actively collects information on all cancer cases in the province from 3 main cancer hospitals; Tanta Cancer Center, the Gharbiah Cancer Society Hospital, and the Tanta University Hospital. In addition, information on cancer patients is collected from all private clinics and laboratories throughout the province^[9]. The registry receives support and training from the National Cancer Institute (NCI) in Bethesda, Maryland through the Middle East Cancer Consortium (MECC). Technical support, training, and quality control of data are periodically conducted by Rollins School of Public Health, the International Agency for Research on Cancer, and NCI to ensure the high quality of the registry data^[9,11].

All colorectal cancers diagnosed from 1999 to 2007 were included in the study. Medical records of 1364 patients were retrieved and the following information abstracted: age, residence, diagnosis date, grade, stage, topology, clinical characteristics and histology variables. Egyptian census data were used to provide the general population's statistics on age, sex, residence, and other related demographic factors. The 1364 cases included in this study over the 9 years from 1999-2007 average out to about 150 cases a year, which is in keeping with the registry's previous preliminary reports^[9,12,13].

The student's *t*-test was used to determine the significance of differences in mean values of the study variables. A χ^2 test for independence was used to determine the significance of differences in frequency distributions and proportions of variables. The cut-off value for statistical significance was *P* value = 0.05. SAS version 9.2 (SAS Institute, Cary, NC) was used.

RESULTS

The results of the study provide a comprehensive profile of colorectal cancer in this population. This profile sheds some lights on the epidemiologic, clinical, and geographic distribution of colorectal cancer in this population. The results also demonstrate the differences in colorectal cancer incidence between the population-based registry of Gharbiah and the SEER registry of the United States.

A total of 1364 cases of colorectal cancer were included in registry from 1999-2007. Table 1 shows the summary characteristics for the colorectal cancer patients.

Table 1 Characteristics of study population and cancer patterns in Gharbiah, Egypt (1999-2007)

Variable	n (%)
Total cases	1364 (100.0)
Gender	
Male	737 (54.0)
Female	627 (46.0)
Residence	
Urban	752 (55.1)
Rural	612 (44.9)
Year of diagnosis	
1999	135 (9.9)
2000	149 (10.9)
2001	144 (10.6)
2002	154 (11.3)
2003	151 (11.1)
2004	137 (10.0)
2005	161 (11.8)
2006	171 (12.5)
2007	162 (11.9)
District of residence	
Tanta	437 (32.0)
El Mehalla	355 (26.0)
Kafr El Zayat	118 (8.7)
Zefta	98 (7.2)
Samanoud	82 (6.0)
El Santa	103 (7.6)
Kotour	78 (5.7)
Basyoon	93 (6.8)

Slightly more than half the cases were males (54%), giving a male:female ratio of 1.2:1. Patients designated as residing in an urban area constituted 55.1% of all patients. In any given year, between 135 -171 new cases of colorectal cancer were included in the registry. The Tanta district of the Gharbiah province had the most cases (32.0%) with the Kotour district seeing the least (5.7%).

The clinical and histopathologic characteristics of the colorectal cancer patients included in the study are illustrated in Table 2. Age and tumor site distribution of cases showed that 22.0% of all cases were under the age of 40 and 62.8% of cases had primary lesions in the colon with 37.2% having primary lesions in the rectum. The majority of tumors were grade II moderately-differentiated tumors (51.5% of cases) followed by 11.4% grade III. About 25.7% cases had no grade information. The vast majority of patients did not present with polyps (97.2%) though of the 38 patients who had polyps, 76.3% were over the age of 40. Mucinous carcinomas were present in only 23.3% of cases and over two-thirds of those patients (67.9%) were patients over the age of 40 years. Adenocarcinoma was the most common histopathologic type of tumors (87.0%).

Table 3 shows colorectal cancer incidence rates and incidence rate ratios by gender and urban-rural status. For both men and women, living in an urban area significantly increased the risk of developing colorectal cancer (either in the colon or the rectum). The same trend was present looking only at primary lesions in the colon and less pronounced for rectal cancers. Older urban men were more likely to develop rectal cancer while young urban men were more likely to develop colon cancer.

NOS: Not otherwise specified.

The comparison of the incidence rates and incidence rate ratios of colorectal cancer across the 8 districts are shown in Table 4 for patients under the age of 40 years and those 40 years and older. Compared to the low rates of the Zefta district, living in Tanta and Basyoon districts was significantly associated with increased risk of developing colorectal cancer for both young and old subjects. Living in El Mehalla and Kafr El Zayat was associated with significantly increased risk of developing colorectal cancer for subjects over 40 years only.

Compared to the low rates of colon or rectal cancers in the Zefta district, living in Tanta and Basyoon districts was associated with significantly increased risk of developing both primary colon and rectal cancers. Living in El Mehalla and Kafr El Zayat districts was significantly associated with increased risk of developing colon but not rectal cancer (Table 4).

gender of the Gharbiah registry and the United States SEER data. Incidence rate of colorectal cancer was 5.5/10⁵ in Gharbiah (6.1/10⁵ for males, 4.9/10⁵ for females). These rates were significantly lower than the colorectal cancer incidence rates seen in the United States of 32.0/10⁵ (37.7/10⁵ for males, 27.4/10⁵ for females). While incidence rate of colorectal cancer for those under age 40 years in Gharbiah was slightly higher than the United States incidence rate for the same age group, the incidence rates for subjects 40 years and older in the United

States were significantly higher than the corresponding rates for the same age groups in Egypt.

DISCUSSION

Analysis of the 1364 cases of colorectal cancer collected at the Gharbiah population-based cancer registry from 1999-2007 revealed the following important findings: First, a relatively high incidence of colorectal cancer in young subjects under age 40 years and significantly low

Table 4 Comparison of incidence rates for colorectal cancer patients in the 8 districts of Gharbiah (1999-2007)

District	Young (< 40 yr)		Old (≥ 40 yr)		Colon		Rectum	
	IR	IRR (95% CI)	IR	IRR (95% CI)	IR	IRR (95% CI)	IR	IRR (95% CI)

IRR: Incidence rate ratio; IR: Incidence rate; 95% CI: 95% confidence interval.

incidence in subjects 40 years and older. Second, high proportion of tumors located in the rectum. Third, a vast majority of tumors (over 97%) did not have polyps. Fourth, living in an urban area was associated with higher rates of colorectal cancer, with variability in rates across the region.

Similar low rates of colorectal cancer in this population in Egypt ($6.9/10^5$ for males and $5.1/10^5$ for females) were reported by the MECC for the short period of 1999-2001^[11]. The low rates were also reported from the Gharbiah cancer registry for the period of 2000-2002, where the age-standardized incidence rates for colorectal cancer was $6.5/10^5$ for males and $4.2/10^5$ for females^[12]. The relatively high rate in subjects under age 40 years was reported by the MECC report in which Egypt had the highest incidence for both genders combined ($1.4/10^5$) and for males ($1.7/10^5$) than the rate in the same age group among Israeli Jewish and Arab populations, Jordanians and Cyprians^[13]. High proportion of young-onset colorectal cancer was also reported in our previous hospital-based studies^[5-7,14] that showed about 1/3 of all Egyptian colorectal cancer patients under age 40 years. It is unclear if the high young-onset rate is due to adoption of a more “westernized” lifestyle and diet, particularly in the younger generation^[6,15] or due to intense environmental exposures with more susceptibility among the younger generations^[15]. While our previous studies showed no familial aggregation among young patients to suggest HNPCC or similar syndromes^[7,16,17], more recent studies of possible mismatch repair gene defects^[18-21] or autosomal recessive inheritance^[22] are warranted in this population, especially in absence of a strong family history and lack of distinct molecular characteristics among young-colorectal cancer patients in Egypt^[7,17].

The high proportion of cancers that are located in the rectum in this study (37.2%) and the low ratio of colon/rectum tumors are characteristic of colorectal cancer in developing countries^[23]. The high proportion of rectal cancer was reported in our previous hospital based studies^[5-7]. However, the proportion of rectal cancer declined from about 50% to 37% perhaps due to the more accurate nature of the population-based studies or the changing life-style with westernization leading to higher proportions of colon than rectal cancers^[23]. How-

Table 5 Age standardized incidence rates by gender in Gharbiah, Egypt and the United States Surveillance Epidemiology and End Results Program

ever, the proportion of primary rectal colorectal cancers in this study is still high compared to Western countries, where only 27.9% of American colorectal cancers are primary rectum^[13]. It is worth noting that recent studies in the United States showed increasing incidence of both young-onset colorectal cancer as well as the proportions of rectal cancers^[24].

The very low rate of polyps reported in this study is unique. The low rate of polyps was also reported in our previous hospital-based studies^[6,7]. It is important to note that pathologists in this population in Egypt report very few polyps in other segments of the resected colon not only in the cancer site. Causes of the very low rate of polyps may be related to diet rich in high fiber, legumes, and green vegetables^[25,26] which is common in this population^[27,28]. Other causes of the low polyp rate may be related to the intake of aspirin or aspirin-like compounds^[29-32] which is also common in this population because of self-medication^[33,34] or other molecular pathways that do not include polyps in the colorectal carcinogenesis in this population.

There are a number of distinctive environmental and possibly genetic factors that may contribute to the variable rates of urban/rural incidence in this population. Intense exposure to pesticides in this predominately agricultural region^[8], industrial pollution^[15,35-37], and high rate of consanguinity and first cousins' marriage^[16,17] may also

lead to this variable cancer incidence and urban/rural rate risk differences.

The higher incidence rate of colorectal cancer in regions of the province may suggest differences in environmental exposures and/or variable access to medical care for colorectal screening or diagnosis. As there is a fairly reliable access to medical care for diagnosis and no screening facilities are available in the province of the registry^[38], differences in risk factors across the region is most likely the cause of the variation in incidence rates. The main occupation in the Gharbiah province is agriculture. Further, pesticide manufacturing in Kafr El Zayat City and textile production in El Mehalla City are also important industries in the province.

This study had the following strengths: (1) the population-based data from the Gharbiah population-based cancer registry and the large sample size give an accurate picture of the state of colorectal cancer in Egypt; (2) the inclusion of key demographic and clinical data allowed for characterization of the clinical profile and suggestions of possible risk factors for colorectal cancer in this population; and (3) previous studies in the same population using hospital-based data were comparable to results from the population-based cancer registry. Weaknesses included inherent nature of population-based cancer registries of limited information on potential risk factors for colorectal cancer, such as diet and lifestyle habits, pesticide exposure, and family history because of lack of interviewing of patients.

In summary this study showed a relatively high incidence of colorectal cancer under age 40 years and a significantly low incidence in the age group of 40 years and older in this population in Egypt. The high proportion of rectal cancers and the vast majority of tumors without polyps are also interesting findings of the study. Regional differences in disease incidence in colon and rectal cancers in the region may reflect different etiologic patterns in this population. Future analytical studies should focus on further understanding of the etiology and pathogenesis of the disease in this population with extensive environmental exposures and possible genetic factors that may modulate the disease risk.

COMMENTS

Background

Previous hospital-based studies in Egypt showed low incidence of colorectal cancer and high proportion of young-onset disease. Egypt has a new reliable resource of a population-based registry in the Gharbiah region of the Nile Delta. The registry data for the period of 1999-2007 was used to examine epidemiologic, clinical and incidence rates of colorectal cancer in this population and to compare that with the results of the United States Surveillance Epidemiology and End Results Program (SEER).

Research frontiers

The vast majority of tumors (97.2%) had no polyps and 37.2% of the patients presented with primary lesions in the rectum. Colorectal cancer was more common in patients from urban (55%) than rural (45%) areas. Regional differences in colon and rectal cancer incidence in the 8 districts of the study province may reflect different etiologic patterns in this population. The registry data of Egypt shows a slightly higher incidence of colorectal cancer than the United States in subjects under age 40 years. The results also shows significantly lower inci-

dence of colorectal cancer in subjects over age 40 years compared to the same age group in the United States SEER.

Innovations and breakthroughs

This study confirms that patients over age 40 years in Egypt have significantly lower incidence of colorectal cancer than subjects in the same age group in the United States. This is the first study on a population-based scale to show the limited proportions of polyps in colorectal cancer patients in Egypt.

Applications

Future clinical and epidemiologic studies should investigate the etiologic factors related to the regional differences of colorectal cancer in this population in Egypt. Studies should also explore clinical and molecular pathways for the district age and polyp distribution of colorectal cancer.

Peer review

The quality of the data set is very important, especially in the population-based cancer registry.

Abstract

AIM: To present a critical discussion of the efficacy of the faecal pyruvate kinase isoenzyme type M2 (faecal M2-PK) test for colorectal cancer (CRC) screening based on the currently available studies.

METHODS: A literature search in PubMed and Embase was conducted using the following search terms: faecal Tumor M2-PK, faecal Tumour M2-PK, fecal M2-PK, faecal M2-PK, fecal pyruvate kinase, faecal pyruvate kinase, pyruvate kinase stool and M2-PK stool.

RESULTS: Stool samples from 704 patients with CRC and from 11 412 healthy subjects have been investigated for faecal M2-PK concentrations in seventeen independent studies. The mean faecal M2-PK sensitivity was 80.3%; the specificity was 95.2%. Four studies compared faecal M2-PK head-to-head with guaiac-based faecal occult blood test (gFOBT). Faecal M2-PK demonstrated a sensitivity of 81.1%, whereas the gFOBT detected only 36.9% of the CRCs. Eight inde-

pendent studies investigated the sensitivity of faecal M2-PK for adenoma ($n = 554$), with the following sensitivities: adenoma < 1 cm in diameter: 25%; adenoma > 1 cm: 44%; adenoma of unspecified diameter: 51%. In a direct comparison with gFOBT of adenoma > 1 cm in diameter, 47% tested positive with the faecal M2-PK test, whereas the gFOBT detected only 27%.

CONCLUSION: We recommend faecal M2-PK as a routine test for CRC screening. Faecal M2-PK closes a gap in clinical practice because it detects bleeding and non-bleeding tumors and adenoma with high sensitivity and specificity.

INTRODUCTION

Colorectal cancer (CRC) is the most frequent malignant disease in Europe according to an estimation of cancer incidence and mortality by the International Agency for Research on Cancer in Lyon, France^[1]. In 2008, 436 000

persons were diagnosed with CRC, followed by breast cancer with 421 000 cases, lung cancer with 391 000 cases and prostate cancer with 382 000 cases. Approximately 212 000 patients died due to CRC that year, which makes it the second most common death from cancer (after lung cancer with approximately 342 000 deaths in 2008)^[1]. Worldwide, in the developed countries about 1.167 million new cases of CRC and about 603 000 deaths due to CRC were estimated for 2007^[2].

However, due to the long process of carcinogenesis in CRC (adenoma-carcinoma sequence), CRC has an overall good prognosis when diagnosed at an early stage. For that reason different CRC screening programs have been developed and are offered in various European countries.

The gold standard for early detection of colorectal neoplasia is colonoscopy. A great advantage of colonoscopy is that adenomas, the potential precursors of carcinogenesis, can be simultaneously detected and removed. However, the acceptance of screening colonoscopy among patients is low. For example, in Germany only 2.7% of insured people exercise their right to a colonoscopy even though it is reimbursed for people over 55 years old^[3]. The most common *in-vitro* diagnostic method for CRC screening is the detection of occult blood in the stool using the guaiac-based faecal occult blood test (gFOBT). This test is based on the peroxidase activity of haemoglobin, which induces an oxidation and blue colouration of guaiac in the presence of hydrogen peroxide. Red meat and a number of vegetables may result in false positive results whereas vitamin C may result in false negative staining. Therefore, dietary restriction is recommended for three days prior to and during testing. A widespread criticism of gFOBT is its low sensitivity for adenomas and carcinomas (13%-50%)^[4-8]. The immunological faecal occult blood tests (iFOBTs) specifically quantify human haemoglobin with antibodies. Comparative evaluations of immunochemical faecal occult blood tests from different manufacturers have revealed great variations in their respective sensitivities for colorectal adenoma detection^[9,10].

The faecal pyruvate kinase isoenzyme type M2 (faecal M2-PK) test recognises a key enzyme controlling the metabolism of cells with a high proliferation rate, such as tumour cells, and thereby detects specific alterations in intestinal cells, such as polyps and CRC, as well as high-risk patients with acute or chronic inflammatory bowel diseases (IBD) (i.e., ulcerative colitis, Crohn's disease).

M2-PK is a special isoenzyme of pyruvate kinase, a key enzyme within glycolysis which catalyzes the ATP-producing conversion of phosphoenolpyruvate (PEP) to pyruvate. Depending upon the metabolic functions of the tissues, different isoenzymes of pyruvate kinase are expressed. During tumour formation the tissue-specific isoenzymes disappear and the pyruvate kinase isoenzyme type M2 is expressed^[11]. In contrast to all other pyruvate kinase isoenzymes (type L, M1 and R) which consist of four subunits, the M2 pyruvate kinase isoenzyme may occur in a highly active tetrameric form as well as in a dimeric form with low activity. The dimeric form is nearly

inactive and favours the channelling of glucose carbons into synthetic processes, such as nucleic acid, amino acid and fatty acid synthesis. The tetrameric form is highly active and favours the energy-regenerating conversion of PEP to pyruvate and lactate (the Warburg effect). In tumour cells, M2-PK is mainly found to be in the dimeric form and has therefore been termed "Tumour M2-PK". The dimerisation of M2-PK is induced by interaction with different oncoproteins, including pp60v-src-kinase, oncogenic fibroblast growth factor1 and human papilloma virus 16 E7^[11].

The dimeric form of M2-PK is released from tumours into the blood and can be quantified by a sandwich enzyme-linked immunosorbent assay (ELISA; ScheBo Biotech AG, Giessen, Germany). About 40 studies have been published on M2-PK concentrations in blood since 1997. These demonstrate a significant increase in M2-PK and correlation with staging for the following tumours: melanoma, thyroid, breast, lung, kidney, oesophageal, gastric, pancreatic, colorectal, ovarian, cervical and renal cell cancer^[12-19]. The long-term determination of M2-PK in EDTA-plasma is used as a tool for follow-up studies to monitor failure, relapse or success during therapy. In CRC and adenoma M2-PK is also released into the patients' faeces. A sandwich ELISA and a lateral flow rapid test (for doctor's office, point-of-care and laboratory use), both based upon two monoclonal antibodies which specifically recognise the dimeric form of M2-PK, are commercially available for the quantification of M2-PK in stool. The potential of the faecal M2-PK test for CRC screening has been evaluated in at least 17 different independent international studies. The objectives of this review were to obtain an overview of the currently available studies with faecal M2-PK and to present a critical discussion of the efficacy of the faecal M2-PK test for CRC screening.

MATERIALS AND METHODS

Search procedure for studies

In order to find the most relevant studies about faecal M2-PK and CRC screening, a literature search in PubMed and Embase was conducted using the following search terms: fecal tumor M2-PK, faecal tumour M2-PK, fecal M2-PK, faecal M2-PK, fecal pyruvate kinase, faecal pyruvate kinase, pyruvate kinase stool, M2-PK stool. In June 2011 this search revealed 34 publications dealing with faecal M2-PK^[7,8,10,18,20-49] (Table 1). The ScheBo faecal M2-PK test was used in 33 publications, whereas one publication used another antibody combination and was therefore excluded. The following were also omitted from the meta-analysis: seven publications which summarized results from previous papers as reviews; three author-replies to questions about an existing published paper; one publication written in Bulgarian; two publications which investigated neither sensitivity nor specificity; seven publications that only referred to IBD (which was outside the scope of our review) (Table 1). The remaining 13 publications were included in the meta-analysis^[7,8,10,30,31,33,35,37,41,44-46,49]. In

Faecal M2-PK: Faecal pyruvate kinase isoenzyme type M2.

addition, three posters from conferences^[50-52] and a German doctoral thesis^[53] known to the authors have been added to the list of relevant studies (Table 1). Hence, 17 published studies in total have been incorporated into the meta-analysis (Tables 1 and 2). For our meta-analysis the sensitivities for CRC and adenoma, positivity rates, as well as the specificities published within the individual papers were summarized in individual tables, together with the number of cases which underlie the calculated sensitivities and specificities. mean ± SD was calculated for the sensitivities and specificities of the combined data from the different studies using the Statistics package of SigmaPlot Version 11.0. The sensitivities for CRC and adenoma in all studies are based upon colonoscopy results.

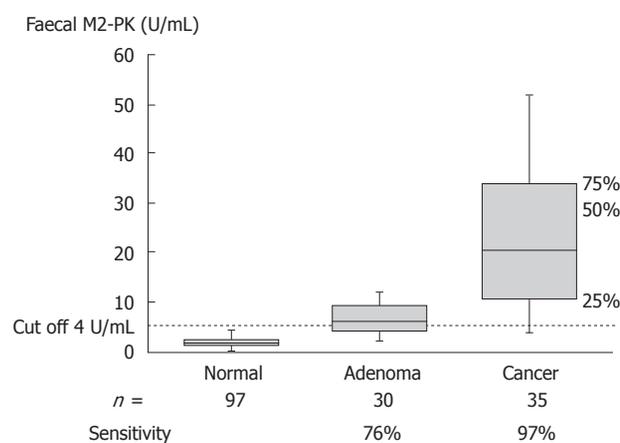

Figure 1 Faecal pyruvate kinase isoenzyme type M2 in healthy controls, patients with colorectal adenoma and colorectal cancer^[51]. Faecal M2-PK: Faecal pyruvate kinase isoenzyme type M2.

Calculated specificities are either based on colonoscopy results or are authors' estimates derived from published prevalence data of CRC and adenoma in screening populations. In the absence of colonoscopies or estimated specificities, only the percentages of test-negative individuals were included in the tables.

Faecal M2-PK test

In all seventeen studies included in our meta-analysis, the M2-PK stool test from ScheBo Biotech AG in Giessen, Germany was used. This test is a sandwich ELISA based on two monoclonal antibodies which specifically recognise the dimeric form of M2-PK.

In accordance with the manufacturer's protocol all studies included a cut-off value of 4 U/mL. One study also included a lower cut-off value (3.33 U/mL^[8]) and another also incorporated additional higher cut off values (5 U/mL and 6 U/mL^[45]) to calculate the resultant sensitivities and specificities. To ensure comparability only those results obtained with the cut-off value of 4 U/mL are included in the meta-analysis.

RESULTS

Sensitivity of faecal M2-PK for colorectal carcinoma

Sensitivity of the faecal M2-PK test for CRC was investigated and calculated in twelve independent studies (Table 3 and Figure 1), which found sensitivities of faecal M2-PK for detection of CRC between 68% and 97%. The mean sensitivity of all twelve studies is 80.3% ± 7.1%. These twelve studies measured faecal M2-PK concentrations in a total of 704 stool samples of patients with CRC, whereby 559 tested positive. Five studies considered the tumor node metastases and/or Dukes classification and showed a close correlation between the sensitivity of the faecal M2-PK test and staging (Table 4). The mean sensitivities ranged from 59% for T1 to 90% for T4 and from 60% for Dukes A to 91% for Dukes D. gFOBT studies from various countries showed much lower sensitivities for CRC which ranged between 13% and 50%^[4-6]. The higher sensitivity of faecal M2-PK compared to gFOBT was confirmed in four studies which measured faecal M2-PK and gFOBT head-to-head in the same patients (Table 5). Combining all four studies, 155 samples from patients with CRC were tested for faecal M2-PK and gFOBT. M2-PK correctly detected 81.1% whereas the gFOBT detected only 36.9%.

Sensitivity of faecal M2-PK for adenoma

More than 90% of colorectal carcinomas evolve from adenoma *via* the adenoma-carcinoma sequence within 10 to 15 years. Therefore, the early detection and removal

of adenoma is an important aspect in the prevention of CRC. The sensitivity of faecal M2-PK for adenoma was investigated in eight studies and ranged between 20% and 76%, whereby a clear dependency with the diameter of the adenoma is described (Table 6). In total, 339 adenomas with a diameter < 1 cm and 117 adenomas with a diameter > 1 cm were investigated. Twenty-five percent of the adenomas < 1 cm in diameter tested positive with the faecal M2-PK test and 44% of the adenomas > 1 cm were correctly detected. Three studies included a total of 98 stool samples from patients with adenoma of unclassified diameter. Faecal M2-PK concentrations above the cut-off were found in 51% of the samples. In direct comparisons of faecal M2-PK with gFOBT, 25% of patients with polyps < 1 cm tested positive with the M2-PK test whereas only 9% were identified by the gFOBT (Table 7). Forty-seven percent of adenomas > 1 cm in diameter tested positive with the M2-PK test whereas the gFOBT detected only 27% (Table 7). One study with adenomas of unclassified diameter revealed a sensitivity of 48% for M2-PK in comparison to 9% for gFOBT. Möslein *et al*^[10] combined adenomas > 1 cm in diameter and CRC to form a group with 55 cases of “advanced neoplasia”. The resultant sensitivity of faecal M2-PK for advanced neoplasia was 27.3% whereas the sensitivity of gFOBT was only 9.1%. This study also included a head-to-head comparison of four iFOBTs from different manufacturers using the same 55 samples of patients with advanced neoplasia. With sensitivities of 7.3%, 8.5%, 18.9% and

20%, respectively, all four iFOBTs were less sensitive than faecal M2-PK.

Specificity of faecal M2-PK for colorectal carcinoma

The specificity of an *in-vitro* diagnostic test reflects the proportion of correctly identified negatives. Consequently, the composition of the control group has a profound effect on the specificity. By its very definition, screening is used in a population to detect a disease in individuals without signs or symptoms of that disease. Therefore, symptoms in the gastrointestinal tract, such as pain, visible blood in the stool or known inflammation are not appropriate for inclusion into the control group of a CRC screening study. In total, seventeen publications calculated specificities for the M2-PK stool test. Nine of these studies included patients from hospitals (clinical settings instead of screening settings) with positive gFOBTs and with inflammation and/or other symptoms in the gastrointestinal tract into the control group and hence these studies have been discounted from our evaluation of the specificity of faecal M2-PK^[7,30,31,35,44-46,50,53]. Eight studies, comprising 11 412 samples in total, had control groups which conformed to the correct composition for screening studies (Table 8, Figures 2 and 3). Ninety one point five percent tested negative which means that about 9% of those tested had a faecal M2-PK value above the cut-off value of 4 U/mL. Colonoscopies were performed in four studies^[8,10,51,41] (Table 8) and revealed specificities of 98% (*n* = 97), 93% (*n* = 42), 100% (*n* = 13) and 89.5%

(*n* = 796). In study 49 with 4854 participants, the authors calculated an estimated specificity of 93.4% based on a prevalence of CRC of 2%. Based on a prevalence of 0.5% for CRC and 18% for advanced adenoma, the authors of study 52 with 2787 participants calculated an estimated specificity for colorectal neoplasia of 97.4%. The screening in study 49 with 4854 participants describes a continuous increase in the percentage of faecal M2-PK positive volunteers with age from 30 years old upwards (Figure 3).

DISCUSSION

With a sensitivity of about 80% for CRC and 44% for adenoma > 1 cm, faecal M2-PK outclasses the gFOBT which has sensitivity between 13% and 50% for CRC (Tables 3-7, and literature^[4-6]). The superiority of faecal M2-PK may be due to the fact that M2-PK is a metabolic biomarker which is characteristic for the metabolic state of tumour cells and their precursors, whereas detection of bowel cancer using the gFOBT is restricted to bleeding tumours and adenoma. Therefore, faecal M2-PK has the advantage that it detects both bleeding as well as non-bleeding tumours and adenoma and will close a gap in clinical practice. Conversely, faecal M2-PK does not have false positive results due to various non-cancerous sources of bleeding, e.g., haemorrhoids and fissures. Screening studies involving a total of more than 11 000 healthy subjects have demonstrated a mean specificity of 95.2% for the detection of CRC/advanced neoplasia with faecal M2-

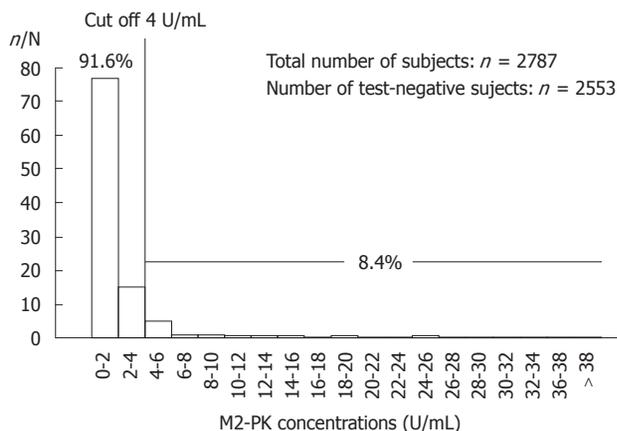

Figure 2 Distribution of faecal pyruvate kinase isoenzyme type M2 concentrations in a screening collective of 2787 participants aged from 45 to 65 years^[52]. n: Number of test negative; N: Total number of subjects; M2-PK: Pyruvate kinase isoenzyme type M2.

PK. The specificities were 100%, 98%, 93% and 89.5%, respectively, in studies which incorporated colonoscopies; 97.4% and 93.4% in studies with estimated specificities; and 90.4% and 78.6% in studies without colonoscopies (Table 8). This demonstrates that specificities were higher in studies with confirmatory colonoscopies in comparison to studies without colonoscopies. Whilst gFOBT specificities $\geq 94\%$ are reported in the literature^[5,6], the authors of a meta-analysis of over 440 000 subjects from six independent studies concluded that more than 80% of the positive gFOBT results are actually false positives^[54]. In most studies the calculated specificities are based on the results of colonoscopy. Colonoscopy is the gold standard for early detection of CRC and polyps and has the advantage that polyps, the potential precursors of carcinogenesis, can be simultaneously detected and removed. However, recent studies have revealed that colonoscopies may have false negative results, e.g., due to suboptimal bowel preparation. For example, a systematic review which summarized six studies totaling 465 patients who had undergone two colonoscopies on the same day revealed a pooled miss rate of 22% for polyps of any size^[55].

IBD may also be a cause of increased faecal M2-PK levels and hence detection of previously undiagnosed patients by faecal M2-PK is another advantage of the test, whereas those patients with known IBD are subject to their own endoscopic monitoring program and are not categorized as suitable for inclusion in a non-invasive CRC screening program.

The cost of one faecal M2-PK ELISA test is about 15-25 US\$. In comparison, based on 2004 data from privately insured beneficiaries, costs were estimated to be about 557 US\$ (range: 150-1112 US\$) for a colonoscopy, 174 US\$ (range: 54-392 US\$) for a flexible sigmoidoscopy and 7 US\$ (range: 2-16 US\$) for a guaiac faecal occult blood test^[56].

In conclusion, faecal M2-PK, either as an ELISA or as a lateral flow rapid test, is a cost-effective and easy-to-perform routine test. In contrast to the gFOBT, only one

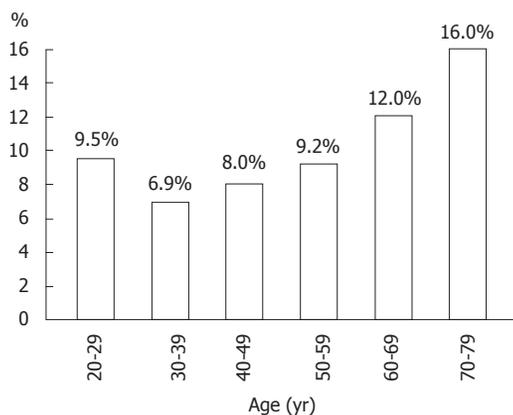

Figure 3 Percentage of faecal pyruvate kinase isoenzyme type M2-positive volunteers by age group (from Tonus *et al.*^[49]).

small stool sample (from a single stool passage), which may be collected with a convenient stool sample device, is necessary and no dietary restrictions are needed. Faecal M2-PK is an appropriately sensitive tool to pre-select those patients who require colonoscopy for further diagnostic confirmation or exclusion of CRC. Based on the current data we recommend the use of faecal M2-PK as a routine *in-vitro* diagnostic test for CRC screening.

COMMENTS

Background

Colorectal cancer (CRC) is the most frequent malignant disease worldwide. The gold standard for early detection of colorectal neoplasia is colonoscopy. However, the acceptance of screening colonoscopy by potential screenees is low. Faecal pyruvate kinase isoenzyme type M2 (faecal M2-PK) is an *in-vitro* diagnostic test which recognizes a specific metabolic characteristic of proliferating cells in 4 mg stool samples. The simplicity of sample collection can encourage participation in CRC screening programs.

Research frontiers

The sensitivity and specificity of faecal M2-PK for CRC screening has been investigated in numerous publications. Here the paper presents a critical discussion of the efficacy of faecal M2-PK for CRC screening based on the accumulated data from currently available studies.

Innovations and breakthroughs

The most established *in-vitro* diagnostic test for CRC screening is the guaiac-based faecal occult blood test (gFOBT). In contrast to the FOBTs, faecal M2-PK detects bleeding and non-bleeding tumors. With a sensitivity of about 80% for CRC and 44% for adenoma > 1 cm, faecal M2-PK outclasses the gFOBT which has a sensitivity between 13% and 50% for CRC.

Applications

This meta-analysis summarizes the results of 17 published studies evaluating the faecal M2-PK test for CRC screening. The data will help to critically assess the efficiency of the faecal M2-PK test in comparison to other *in-vitro* diagnostic tests for CRC screening.

Peer review

This is a meta-analysis about screening CRC with fecal MK-pyruvate kinase.

Abstract

AIM: To assess the symptomatic efficacy of *Lactobacillus plantarum* 299v (*L. plantarum* 299v) (DSM 9843) for the relief of abdominal symptoms in a large subset of irritable bowel syndrome (IBS) patients fulfilling the Rome III criteria.

METHODS: In this double blind, placebo-controlled, parallel-designed study, subjects were randomized to daily receive either one capsule of *L. plantarum* 299v (DSM 9843) or placebo for 4 wk. Frequency and intensity of abdominal pain, bloating and feeling of incomplete rectal emptying were assessed weekly on a visual analogue scale while stool frequency was calculated.

RESULTS: Two hundred and fourteen IBS patients were recruited. After 4 wk, both pain severity (0.68 + 0.53 vs 0.92 + 0.57, $P < 0.05$) and daily frequency (1.01 + 0.77 vs 1.71 + 0.93, $P < 0.05$) were lower with

L. plantarum 299v (DSM 9843) than with placebo. Similar results were obtained for bloating. At week 4, 78.1 % of the patients scored the *L. plantarum* 299v (DSM 9843) symptomatic effect as excellent or good vs only 8.1 % for placebo ($P < 0.01$).

CONCLUSION: A 4-wk treatment with *L. plantarum* 299v (DSM 9843) provided effective symptom relief, particularly of abdominal pain and bloating, in IBS patients fulfilling the Rome III criteria.

Clinical trial: *Lactobacillus plantarum* 299v (DSM 9843) improves symptoms of irritable bowel syndrome. *World J Gastroenterol* 2012; 18(30): 4012-4018 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i30/4012.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i30.4012>

INTRODUCTION

Irritable bowel syndrome (IBS) is one of the most frequent digestive tract disorders encountered by general practitioners and gastroenterologists. IBS is a functional bowel disorder characterized by chronic and relapsing abdominal pain or discomfort associated with altered bowel habits. The primary aim of any treatment is the relief of abdominal pain which can significantly impair the patient's quality of life. According to published guidelines, the main treatment options for abdominal pain include antispasmodics or anti-depressants at low dose while anti-

diarrheal or laxative drugs are given to improve transit disturbances^[1,2]. However, in many cases, all these options remain disappointing for the relief of abdominal pain. The therapeutic efficacy in IBS is probably impacted by the heterogeneous pathogenesis of the disease which includes altered intestinal motility, visceral hypersensitivity, abnormal brain-gut interactions, food intolerance, altered intestinal permeability and post infectious and/or inflammatory changes^[3].

Recently, the deleterious role of qualitative or quantitative alterations of gut microbiota at the onset of symptoms has been emphasized. Therefore, a rationale exists to discuss the therapeutic use of probiotics, which are live microorganisms conferring health benefits to the host when ingested in adequate amounts^[4]. Clinical evidence regarding the efficacy of some probiotic strains to improve IBS symptoms has recently emerged^[5,6], although the mechanism of action of probiotics on IBS symptoms is not completely understood. Some probiotics bind to small and large bowel epithelium and may produce substances with antibiotic properties, while others compete for attachment and thereby reduce invasion by pathogenic organisms^[7]. Probiotics also modulate gastrointestinal luminal immunity by changing the cytokine and cellular milieu from a pro-inflammatory to anti-inflammatory state^[8]. They may also convert undigested carbohydrates into short chain fatty acids, which act as nutrients for colonocytes and affect gut motility^[4].

Lactobacillus plantarum 299v (*L. plantarum* 299v) (DSM 9843) is a probiotic strain able to reside in the human colonic mucosa *in vivo* due to a specific mechanism of mannose adhesion^[7]. *L. plantarum* 299v (DSM 9843) also increases the amount of carboxylic acid, particularly acetic and propionic acids, in the stools of healthy volunteers^[9]. The strain has shown antibacterial activity against several potential pathogenic agents such as *Listeria monocytogenes*, *Escherichia coli*, *Yersinia enterocolitica*, *Enterobacter cloacae* and *Enterococcus faecalis*^[10]. *L. plantarum* 299v (DSM 9843) also has beneficial immunomodulatory activity *via* an increased interleukin-10 synthesis and secretion in macrophages and T-cells derived from the inflamed colon. And recently, an experimental study reported that *L. plantarum* 299v (DSM 9843) increased the transcription and excretion of the mucins MUC2 and MUC3 in goblet cells^[11,12].

Three single-centre studies have tested the clinical efficacy of *L. plantarum* 299v (DSM 9843) in IBS patients^[13-15]. Two trials have demonstrated significant benefits in comparison with placebo on improvement of flatulence scores^[13] and a reduction of abdominal pain^[14] while the results of the third trial, based on only 12 patients, were not conclusive. The aim of the present randomized, double-blind, placebo controlled clinical trial was to assess the symptomatic efficacy of *L. plantarum* 299v (DSM 9843) in a larger subset of IBS patients fulfilling the Rome III criteria.

MATERIALS AND METHODS

Patients

Participants ($n = 214$) were recruited by general practitio-

ners in four clinical centres in India: one in Mumbai, two in Chennai and one in Bangalore. Subjects between 18-70 years of age with IBS according to the Rome III criteria were eligible for inclusion. All subjects had a colonic examination at baseline to exclude any organic disease while an intestinal infection was excluded by stool cultures in any patient in whom this diagnosis was suspected. Subjects with severe chronic medical disease including colorectal and other gastrointestinal diseases were excluded. Pregnant and breast-feeding women and patients with dietary habits which might interfere with the assessment of the study product or patients with known allergy to the study product components were also excluded. Throughout the study, the subjects were not allowed to consume any other probiotic and were encouraged not to change their usual dietary and physical exercise habits.

Study design

This study was designed as a multicentre double blind, placebo-controlled study with parallel groups to assess the beneficial effects of a daily consumption of *L. plantarum* 299v (DSM 9843) on IBS symptoms. Treatment duration was 4 wk with 3 follow-up visits at weekly intervals. The study protocol was conducted in accordance with the Declaration of Helsinki and approved by the local Ethics Committee. All volunteers gave written informed consent prior to participation in the study.

Study products

The test product was a probiotic preparation containing a mixture of freeze-dried lactic acid bacteria and excipients. The lactic acid bacteria strain was *L. plantarum* 299v (DSM 9843). It is deposited at the DSM collection (Deutsche Sammlung von Mikroorganismen und Zellkulturen GmbH) under number DSM 9843. The test product contained 10 billion colony-forming units (cfu) per capsule in a potato starch and magnesium stearate base. The control product contained potato starch (97%) and magnesium stearate (3%). Both the test and control products had a similar appearance, texture and taste. Both products were specifically prepared for the study and provided by the Rosell-Lallemand Institute (Blagnac, France).

Assessments and study endpoints

The primary endpoint was the improvement of the frequency of abdominal pain episodes. Secondary endpoints were changes in severity of abdominal pain, changes in frequency and severity of abdominal bloating and in feeling of incomplete rectal emptying. Both frequency of abdominal pain and feeling of incomplete rectal emptying were assessed weekly using a four-point scale ranging from 1 (only occasional symptom) to 4 (daily symptom). Symptom severity (abdominal pain, abdominal bloating and feeling of incomplete rectal emptying) was rated on a visual analogue scale (VAS 1-10) and converted to a 4 point scale ranging from 0 (No pain, VAS = 0) to 3 (Severe, VAS = 8 to 10).

The daily number of stools and bloating episodes were calculated and registered at each visit. At the end

Table 1 Baseline characteristics of the subjects between the two groups (mean ± SD)

	<i>L. plantarum</i> 299v (DSM 9843) (n = 108)	Placebo (n = 106)	P
Age (yr)	36.53 ± 12.08	38.40 ± 13.13	NS
Men/women	70/38	81/25	NS
IBS duration (yr)	3.4	4.6	NS
Abdominal pain frequency	2.1 ± 1.01	1.98 ± 0.91	NS
Abdominal pain severity	1.24 ± 0.60	1.20 ± 0.63	NS
Bloating severity	1.07 ± 0.62	1.14 ± 0.64	NS
Stool frequency	3.94 ± 1.51	3.69 ± 1.34	NS
Pure vegetarians (%)	30.5	20.2	NS
Daily yoghurt intake (%)	46.7	42.1	NS

No significant differences were found between the groups for all the variables tested. NS: No significant; *L. plantarum* 299v: *Lactobacillus plantarum* 299v.

of the 4-wk treatment period, both the patient’s and the practitioner’s opinion about the overall efficacy of the treatment were recorded using a 4-point scale, from “poor” to “excellent”.

Regarding safety assessment, blood samples were taken at baseline and week 4 in each patient for the assessment of blood cell counts, glycaemia, blood urea nitrogen and liver function tests. Physical examinations and verification of any adverse events were performed at each visit.

Sample size and randomization

The sample-size calculation was based on the main outcome, the frequency of abdominal pain episodes. The trial sample size required to detect a significant difference of 20% between the two groups with an 80% power and 5% statistical significance level was calculated to be at least seventy-nine patients per group. Taking into account that all subjects who withdrew prematurely were not replaced, 214 subjects were randomised according to a computer-generated randomization list in the ratio 1:1. For each site, randomization charts were provided to investigators keeping a 1:1 ratio. All investigators, patients and monitors were blinded throughout the study. To ensure allocation concealment, packaging and labelling were performed by a third party, and the randomization code was kept in a secure place during the study.

Statistical analysis

All the analyses of efficacy were performed with full analysis set (FAS) population. The FAS population corresponds to all randomised subjects who took at least one dose of the study drug and who had at least one post-baseline efficacy assessment. Overall assessment of symptoms were analysed using a repeated-measures analysis of variance (ANOVA) with time, treatment group, interaction time x product and baseline score as fixed factors for each period.

RESULTS

The flow chart of the study is given in Figure 1. A total

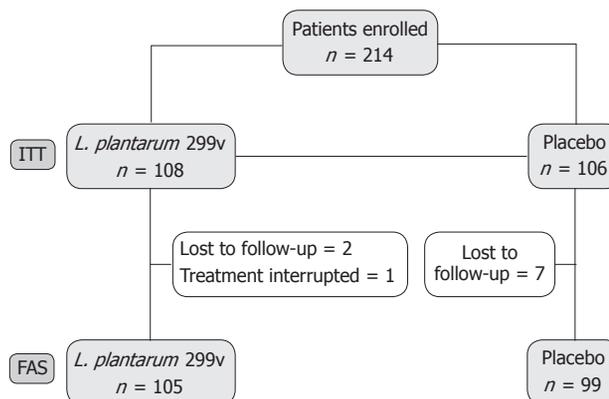

Figure 1 Flow-chart of the study. *L. plantarum* 299v: *Lactobacillus plantarum* 299v; FAS: Full analysis set; ITT: Intention to treat.

of 214 patients were randomized and 108 subjects assigned to receive *L. plantarum* 299v (DSM 9843) group and 106 patients the placebo. Among these 214 subjects, 10 were excluded, either because they did not complete the entire 4-wk double-blind period, or because they did not provide any available data about the treatment period. A majority of patients were IBS-D patients, 63.89% and 60.3% in *L. plantarum* 299v (DSM 9843) and placebo groups, respectively. Baseline characteristics of the two groups are given in Table 1.

Frequency of digestive symptoms

The mean changes over this 4-wk period of the frequency of each digestive symptom are shown in Figure 2. The decrease of abdominal pain frequency was significantly higher in the *L. plantarum* 299v (DSM 9843) group than in the placebo group at weeks 3 and 4. At the end of week 4 the mean frequency was reduced significantly by 51.9% in the *L. plantarum* 299v group in comparison with the 13.6% reduction in the placebo group. Overall reductions in stool frequency, bloating and feeling of incomplete emptying frequency were also significantly greater in the *L. plantarum* 299v (DSM 9843) group when compared with the placebo group over the 4-wk period ($P < 0.05$). The effects of both treatments on stool frequency are shown in Figure 3. A significant reduction of the daily number of stools was observed with *L. plantarum* 299v (DSM 9843) after the second week of treatment.

Severity of digestive symptoms

The change in mean severity of abdominal pain over the 4-wk period was analysed on the VAS. At the end of the 4th week, the mean score was reduced by 45.2% in the *L. plantarum* 299v (DSM 9843) group and reduced by only 23.3% in the placebo group (Figure 2A). The weekly analysis of this score showed significantly lower scores at weeks 2, 3 and 4 in the *L. plantarum* 299v (DSM 9843) group in comparison with placebo. The decrease of the mean scores of severity of abdominal bloating and feeling of incomplete emptying were also statistically higher in the *L. plantarum* 299v (DSM 9843) group when compared to the placebo group at weeks 3 and 4 (Figure 2B and C).

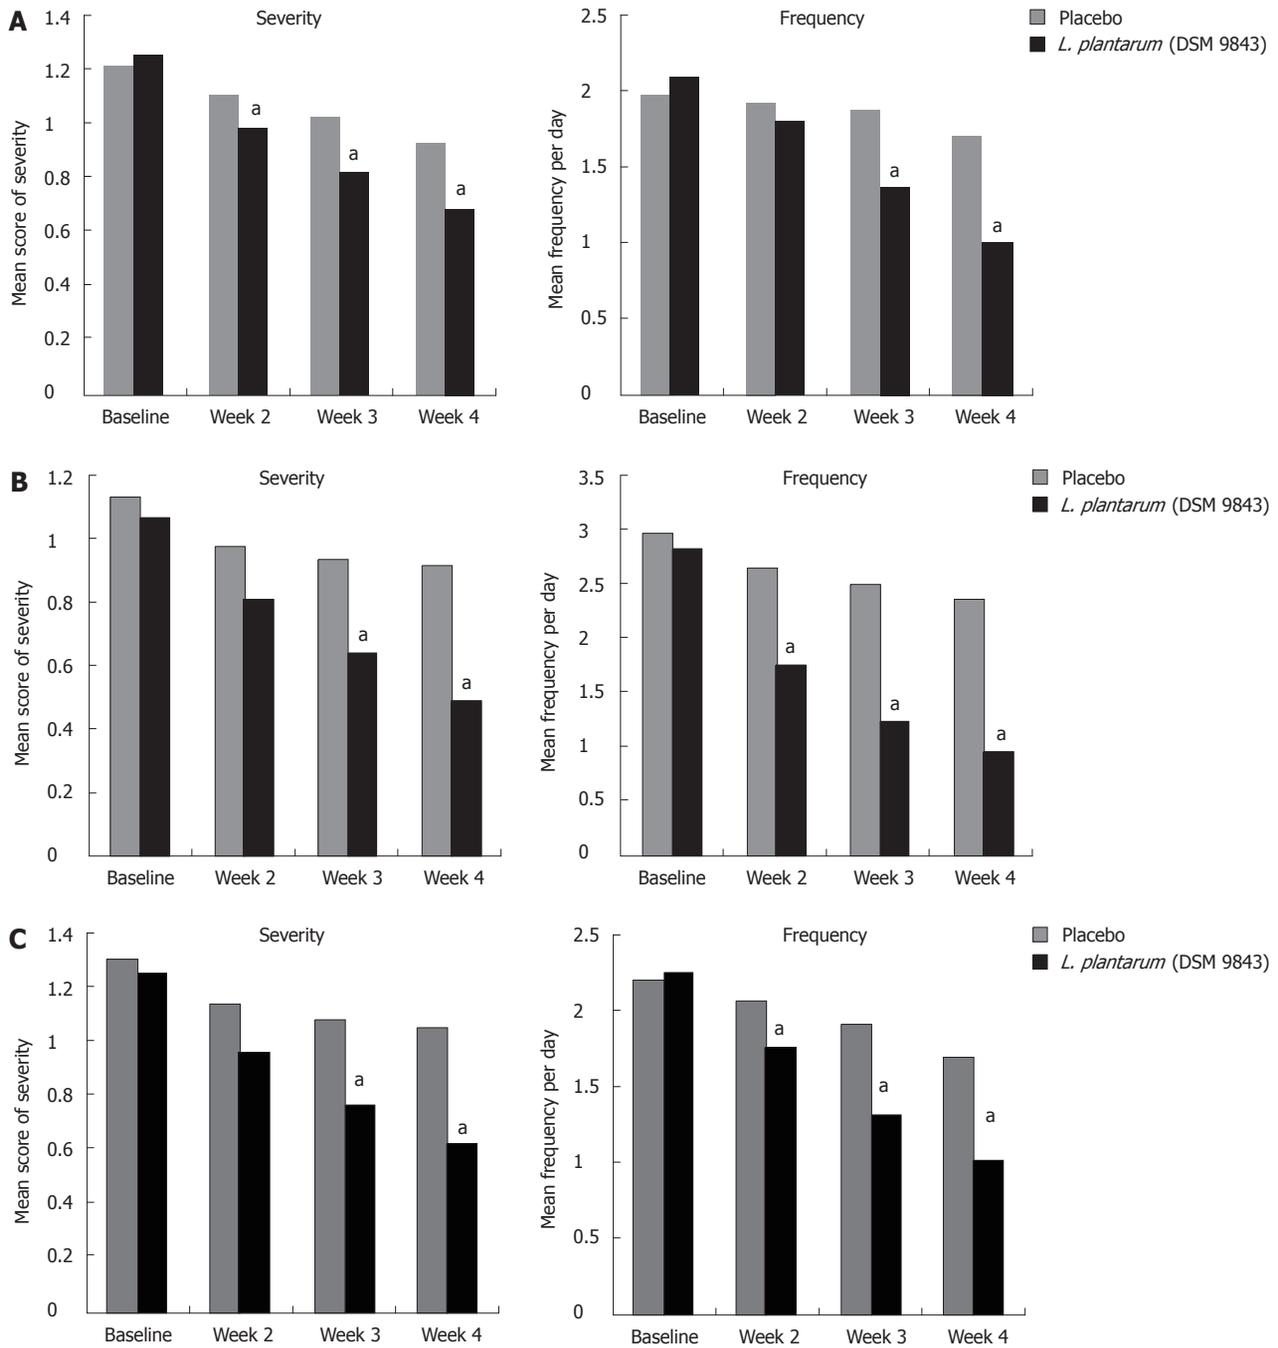

Figure 2 Changes in frequency and severity of symptoms in both groups. A: Abdominal pain; B: Bloating; C: Feeling of incomplete evacuation. *L. plantarum* (DSM 9843): *Lactobacillus plantarum* 299v. ^a*P* < 0.05 vs baseline group.

Overall assessment

The percentage of patients who considered the efficacy of the treatment they received as good or excellent was significantly higher in the *L. plantarum* 299v (DSM 9843) group than in the placebo group (78.1% vs 8.1%) (Figure 4). Similar results were observed when the efficacy was estimated by the investigators (82.8% vs 11.1%) (Figure 4).

Comparative efficacy according to dietary habits

Yoghurt consumption did not affect the results and did not induce any difference between the two arms of treatment (data not shown). The frequency of abdominal pain

was also not different between the two arms when the vegetarian or non vegetarian status was considered. However, the severity of the abdominal pain with *L. plantarum* 299v (DSM 9843) was lower in the vegetarians than in the non-vegetarians at weeks 2, 3 and 4 (*P* < 0.05).

Safety

No significant side-effect was reported in any group during the 4 wk of treatment. The only adverse event reported was a transient vertigo onset by one of the patients who received *L. plantarum* 299v (DSM 9843). No change in blood parameters was detected throughout the study.

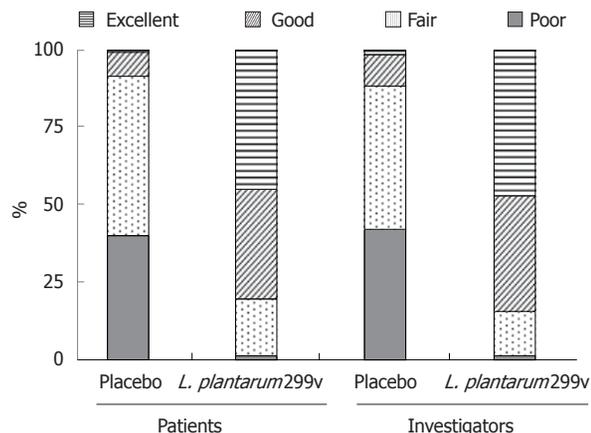

Figure 4 Overall assessment of the treatment efficacy by the patients and by the investigators.

DISCUSSION

The present placebo-controlled trial demonstrated that in an Indian population *L. plantarum* 299v (DSM 9843) is a probiotic strain able to relieve IBS symptoms, particularly abdominal pain and bloating, in IBS patients fulfilling the Rome III criteria. Abdominal pain was chosen as the primary end point because it is the major symptom leading to the seeking of medical advice by IBS patients. This trial was designed for a group of IBS patients of any subtype, complaining of moderate IBS symptoms and recruited by general practitioners. Several trials with probiotics have involved mainly IBS-D patients but microbiological studies have emphasized that qualitative changes of the microbiota exist in all IBS sub-types^[16]. Therefore, we considered that any IBS patient, whatever the subtype, could be eligible to participate. In the present study, the majority of recruited participants were males as compared to previous trials where approximately two-thirds of study subjects were females. The female predominance in IBS patients reported in the West has not been observed in Asian populations, particularly in India. Two major recent community studies reported higher prevalence of IBS in the male population. In Mumbai, male prevalence was 7.9% vs female prevalence of 6.9%, and in a pan-Indian study male prevalence was 4.3% vs female prevalence of 4.0%^[17]. However, other population surveys in the Indian subcontinent have reported an IBS prevalence of 8.5% using the Rome I criteria and demonstrated a female predominance similar to Western countries^[18]. The notable gender difference between the population of this study and that of previously published trials can also be explained by the fact that, in the Indian subcontinent but not in other parts of Asia, men seem to have a greater access to healthcare^[19]. However, data about the consultation behaviour of the community groups are not all in agreement. In the recent large survey conducted by the Indian Society of Gastroenterology Task Force (3000 IBS patients and 4500 community subjects in 18 centres), 33% of men and 38% of women had consulted a doctor in the preceding 12 mo^[20]. Eating behaviours of the patients enrolled in this trial were also somewhat different from that of Western IBS patients

with a high percentage of pure vegetarians and with daily yoghurt consumption in almost half of the cases. Due to the possible interactions between nutrients and bacteria, we cannot exclude that this regimen might have influenced the therapeutic results even if eating behaviours were not different between the two groups. We have even observed that *L. plantarum* results on abdominal pain intensity were better in vegetarian than in non vegetarian IBS patients. This suggests that the symptomatic effect of the strain could be, at least partly, related to interactions between the luminal content and *L. plantarum* or that the strain affects the luminal metabolism of nutrients. However, the design of our study does not allow us to conclude that this is indeed the case.

This trial was performed according to the Rome III guidelines on design of trials for functional GI disorders^[21] in order to demonstrate statistical superiority to placebo with a double-blind, placebo-controlled parallel design and outcome measures including both the effect of the treatment on the main symptom, i.e., abdominal pain, and a global assessment of the treatment efficacy to obtain adequate relief. Several clinical trials testing the symptomatic efficacy of probiotics in IBS were longer than this trial. However, a duration of treatment of 4 weeks follows not only the Rome III guidelines but is also the recommendation of international agencies^[22]. One potential weakness of this study was the choice of a four-point Likert scale to analyze the frequency of symptoms instead of a score such as the IBS symptom severity scale that has been shown to be responsive to treatment effect^[23].

We enrolled patients with moderate abdominal pain. Some studies have suggested that the achievement of a satisfactory relief end-point was significantly influenced by baseline symptom severity^[23,24]. However, the concern that baseline severity compromises the achievement of an end point, such as satisfactory relief, does not appear to affect the current design of clinical trials. For example, trials with 5-HT₃ antagonists^[25] or antidepressant at low dose^[26] or even with a non pharmacological approach^[27] have not confirmed the impact of baseline severity on the

achievement of an adequate relief as a trial end point^[17,28].

In accordance with previous findings in many trials, IBS patients who received placebo exhibited a significant improvement with time. However this improvement was lower than in the *L. plantarum* group and the overall number of patients in the placebo group who considered themselves as improved was low. Furthermore, in the present study, the placebo results were lower than that calculated in a recent meta-analysis of 73 randomized controlled trials (RCTs) reporting a pooled placebo response of 37.5%. But the same meta-analysis of the factors affecting placebo response rate outlined that rates were significantly higher in European RCTs^[29]. The percentage of patients who considered the efficacy of the treatment as good or excellent was very high (78.1%) in the *L. plantarum* 299v (DSM 9843) group and low in the placebo group (8.1%). This result cannot be explained only by the greater effects of *L. plantarum* 299v (DSM 9843) *vs* placebo on each IBS symptom. This satisfaction rate could also be explained by a possible efficacy of the strain on upper abdominal symptoms that are very frequent in Indian IBS patients. Indeed, the Indian Society of Gastroenterology Task Force have outlined that 49% of Indian IBS patients reported epigastric pain, and that 70% complained of upper abdominal fullness or bloating rather than pain^[20].

Three studies using *L. plantarum* 299v (DSM 9843) have been published prior to this trial. In the first study, Nobaek *et al.*^[13] enrolled 60 IBS patients and compared *L. plantarum* 299v to placebo to determine whether endogenous colonic flora could be altered by probiotic consumption. Multiple secondary symptom-based end-points were also evaluated. The active treatment period lasted 4 wk after a 2-wk observation period. Compared with placebo, a statistically significant decrease in flatulence was observed during the second half of the treatment period but only 52/60 patients were included in the analysis of this secondary endpoint. In another study, Niedzielin *et al.*^[14] enrolled 40 IBS patients and assessed abdominal pain and global IBS symptoms as primary and secondary outcomes, respectively. At 4 wk, 20/20 patients in the *L. plantarum* 299v group compared to 11/20 in the control group had complete resolution of their pain ($P = 0.0012$). Moreover, 19/20 patients in the *L. plantarum* 299v group compared to 3/20 patients in the control group also experienced improvement in their global IBS symptoms ($P < 0.0001$). In both trials, no adverse effects were identified. The final study, performed by Sen *et al.*^[15], showed no significant improvement but it was a pseudo-randomized study with only 12 patients with a cross-over design and evaluated changes of a composite score of IBS symptoms. At 8 wk, no significant differences were identified between groups^[15]. Given the significant differences in the enrolled populations, study designs, outcome variables, and statistical analyses, it is difficult to make comparisons across the studies and all three previous studies suffered from multiple design flaws.

In conclusion, the present study shows the potential benefit of a particular strain *L. plantarum* 299v (DSM

9843), in the management of IBS. Further studies are warranted in order to identify the mechanism of the probiotic's potential beneficial effect.

COMMENTS

Background

Lactobacillus plantarum 299v (*L. plantarum* 299v) (DSM 9843) is a probiotic strain able to reside in the human colonic mucosa *in vivo*, with an antibacterial activity against several potential pathogenic agents and an immunomodulatory activity *via* an increased interleukin-10 synthesis and secretion in colonic macrophages and T-cells.

Research frontiers

Recent studies have highlighted disturbances of the relationship between the complex community of the gut microbiota and their host in irritable bowel syndrome. The potential to correct this using probiotics has been suggested but the effective strains need to be determined.

Innovations and breakthroughs

After a treatment of 4 wk, the relief or improvement of irritable bowel syndrome (IBS) symptoms was greater with the *L. plantarum* 299v group than with placebo ($P < 0.05$) leading to greater patient satisfaction.

Applications

L. plantarum 299v (DSM 9843) is a suitable candidate for the relief of moderate symptoms in any IBS patient.

Peer review

Overall this is a well written paper reporting a trial of reasonable methodology. It should be published if authors can revise it in a satisfactory manner.

Abstract

AIM: To evaluate the impact of incidental gallbladder cancer on surgical experience.

METHODS: Between 1998 and 2008 all cases of cholecystectomy at two divisions of general surgery, one university based and one at a public hospital, were retrospectively reviewed. Gallbladder pathology was diagnosed by history, physical examination, and laboratory and imaging studies [ultrasonography and computed tomography (CT)]. Patients with gallbladder cancer (GBC) were further analyzed for demographic data, and type of operation, surgical morbidity and mortality,

histopathological classification, and survival. Incidental GBC was compared with suspected or preoperatively diagnosed GBC. The primary endpoint was disease-free survival (DFS). The secondary endpoint was the difference in DFS between patients previously treated with laparoscopic cholecystectomy and those who had oncological resection as first intervention.

RESULTS: Nineteen patients (11 women and eight men) were found to have GBC. The male to female ratio was 1:1.4 and the mean age was 68 years (range: 45-82 years). Preoperative diagnosis was made in 10 cases, and eight were diagnosed postoperatively. One was suspected intraoperatively and confirmed by frozen sections. The ratio between incidental and nonincidental cases was 9/19. The tumor node metastasis stage was: pTis (1), pT1a (2), pT1b (4), pT2 (6), pT3 (4), pT4 (2); five cases with stage I a (T1 a-b); two with stage I b (T2 N0); one with stage II a (T3 N0); six with stage II b (T1-T3 N1); two with stage III (T4 Nx Nx); and one with stage IV (Tx Nx Mx). Eighty-eight percent of the incidental cases were discovered at an early stage (\leq II). Preoperative diagnosis of the 19 patients with GBC was: GBC with liver invasion diagnosed by preoperative CT (nine cases), gallbladder abscess perforated into hepatic parenchyma and involving the transversal mesocolon and hepatic hilum (one case), porcelain gallbladder (one case), gallbladder adenoma (one case), and chronic cholelithiasis (eight cases). Every case, except one, with a T1b or more advanced invasion underwent IVb + V wedge liver resection and pericholecystic/hepatoduodenal lymphadenectomy. One patient with stage T1b GBC refused further surgery. Cases with Tis and T1a involvement were treated with cholecystectomy alone. One incidental case was diagnosed by intraoperative frozen section and treated with cholecystectomy alone. Six of the nine patients with incidental diagnosis reached 5-year DFS. One patient reached 38 mo survival despite a port-site recurrence 2 years after original surgery. Cases with non in-

cidental diagnosis were more locally advanced and only two patients experienced 5-year DFS.

CONCLUSION: Laparoscopic cholecystectomy does not affect survival if implemented properly. Reoperation should have two objectives: R0 resection and clearance of the lymph nodes.

INTRODUCTION

The widespread use of laparoscopic techniques has led to an increase in referrals for cholecystectomy. As a consequence, the incidental finding of gallbladder cancer (GBC) at an earlier stage has altered the management and the outcome of the disease. However, GBC remains a lethal disease associated with a dismal prognosis. Controversies exist on the optimal treatment of this unexpected finding during routine laparoscopic cholecystectomy. The management is difficult because no guidelines have been established and some authors have reported worse overall prognosis when the patient was not adequately treated during the first operation. If GBC is suspected preoperatively, open cholecystectomy must be performed to enable a complete evaluation of the disease extent and to allow radical resection, if necessary.

Simple cholecystectomy may be adequate treatment only for the earlier stages: T_{is} and T_{1a}. Reoperation is recommended in cases of T₂ tumors and more advanced stages of disease. On the contrary, controversies still exist on the need for more radical resection for T_{1b} GBC. During reoperation it is also unclear what the appropriate extent of hepatic resection is, and whether hepatic resection can prevent liver recurrence.

We report our 10 years experience (19 cases) in the treatment of GBC, and we present a systematic review to evaluate the role of extended surgery in the treatment of the incidental GBC. A Medline search was performed using the keywords "Incidental gallbladder cancer", "laparoscopic cholecystectomy", "lymph nodes dissection" and "hepatic resection".

Reviewing the literature, we focused on the following key points, which are still considered controversial in the management of GBC: (1) How laparoscopy has modified the presentation, the outcome, and the management of the patients with gallbladder cancer? (2) What is an appropriate extent of hepatic resection during reoperation, and can hepatic resection prevent liver recurrence? (3) What is the optimal extent of lymph node dissection? (4) When is resection of the common bile duct necessary? (5) Which type of surgical strategy should be used according to depth invasion? (6) Does laparoscopic cholecystectomy worsen prognosis? (7) Are port-site metastases a real problem? and (8) When is additional radical resection not indicated?

MATERIALS AND METHODS

Ethics

This work was carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. All patients provided informed consent.

Data collection

From 1998 to 2008, in the Department of General Surgery of Catania University Hospital and in the General Surgery Unit of Taormina Hospital, 1490 patients underwent cholecystectomy. Within this group of patients, all the cases of GBC were retrospectively reviewed. Patients' demographic data, as well as type of operation, surgical morbidity and mortality, histopathological classification, and survival data were collected in a database for further analysis. The diagnosis of gallbladder pathology was made by history, physical examination, and laboratory and imaging studies [ultrasonography and computed tomography (CT)].

Disease-free survival analysis

The patients were divided in two groups: incidental diagnosis of gallbladder carcinoma, and known or suspected diagnosis preoperatively. The primary endpoint of the study was disease-free survival (DFS) at different stages of diagnosis. The secondary endpoint was the difference in DFS between patients previously treated with laparoscopic cholecystectomy and patients who had oncological resection as their first intervention. The results are reported in percentages and means.

RESULTS

GBC was diagnosed in 19 patients, 11 women and eight men. The male to female ratio was 1:1.4 and the mean age was 68 years (range: 45-82 years).

According to tumor node metastasis staging of the 6th edition of the American Joint Committee on Cancer (AJCC), our patients were divided into: pT_{is} (1), pT_{1a} (2), pT_{1b} (4), pT₂ (6), pT₃ (4), pT₄ (2); five cases with stage I a (T₁ a-b); two with stage I b (T₂ N₀); one with stage II a (T₃ N₀); six with stage II b (T₁-T₃ N₁); two

with stage III (T4 Nx Nx); and one with Stage IV (Tx Nx Mx). Eighty-eight percent of the incidental cases were discovered at an early stage (\leq II). A preoperative diagnosis was possible only in 10 cases; eight were diagnosed postoperatively during the pathological examination; and one was suspected intraoperatively and then confirmed by frozen sections. The ratio between incidental and nonincidental cases was 9/19, with eight cases discovered after laparoscopic cholecystectomy. The preoperative diagnosis of the 19 patients with GBC was: GBC with liver invasion diagnosed by preoperative CT (nine cases); gallbladder abscess perforated into hepatic parenchyma and involving the transversal mesocolon and hepatic hilum (one case); porcelain gallbladder (one case); gallbladder adenoma (one case); and chronic cholecystolithiasis (eight cases).

Pathological characteristics of the tumors were: one *in situ* cancer; three well-differentiated polypoid adenocarcinoma (G1); one well-differentiated nonpolypoid adenocarcinoma of the gallbladder fundus (G1); seven moderately differentiated polypoid adenocarcinoma (G2-G3); one moderately differentiated nonpolypoid adenocarcinoma (G2); and one and five polypoid and nonpolypoid poorly differentiated GBC (G3), respectively (Table 1).

Every case, except one, with a T1b or more advanced invasion underwent IVb + V wedge liver resection and pericholedochic/hepatoduodenal lymphadenectomy. One patient with stage T1b refused further surgery. Cases with Tis and T1a involvement were treated with cholecystectomy alone. One incidental case was diagnosed by intraoperative frozen section and treated with cholecystectomy alone. Six of the nine patients with in-

cidental diagnosis reached 5-year DFS. Surprisingly, one patient reached 38 mo survival despite a port-site recurrence 2 years after the original surgery requiring further resection. Cases with nonincidental diagnosis were more locally advanced and only two patients experienced 5 years DFS (Tables 2 and 3).

DISCUSSION

How laparoscopy has modified presentation, outcome and management of patients with GBC

Presentation and outcome: The widespread use of laparoscopic cholecystectomy has led to discovery of this deadly disease at an earlier stage, altering the management and the outcome of these patients. GBC is an incidental finding in 0.25%-3% of patients and almost half of these cases are occasionally discovered during or after laparoscopic cholecystectomy for benign disease, such as gallstones and their complications (47% in the series of Memorial Sloan-Kettering Cancer Centre, 50% in the series of Johns Hopkins)^[1,2]. The earlier discovery results in an earlier pathological stage, and consequently, increased long-term survival^[2-4]. Patients with incidental GBC had a significant increase in survival when compared with those who had a preoperative diagnosis (overall 5-year survival 15% *vs* 33%)^[2]. Therefore, the general surgeon should be prepared to deal with GBC suspected or diagnosed incidentally, following a well-established treatment algorithm^[5-8]. It is paramount not to violate oncological principles during the first operation, if a two-stage approach is necessary. For this reason, the surgeon during video-laparoscopic cholecystectomy should always follow these simple rules: (1) perform a thorough preoperative diagnosis; (2) when in doubt, give up the laparoscopy to open access; (3) try to preserve the integrity of the gallbladder, handling it as little as possible; (4) close possible breaches of the wall with clips or endoloops; (5) always use the endobag for the removal of the gallbladder; (6) carefully inspect the gallbladder once extracted; (7) if in doubt, perform a histological examination impromptu; and (8) desufflate the pneumoperitoneum with the trocars *in situ*. During cholecystectomy, accidental opening of the gallbladder is described in 25%-30% of the cases, which clearly have a worse prognosis^[3,9].

Management: The approach to incidental GBC is still controversial because of the difficulty of comparing data deriving from nonuniform case studies. Particularly discordant are the data deriving from western cancer registries with respect to the Japanese ones^[3,4,10-13]. The only constant element seems to be that the prognosis strongly depends on the stage and on the possibility of achieving R0 oncological resection^[3,4]. When incidental GBC is diagnosed afterwards by the pathologist, it is essential to restage the patients carefully by CT, magnetic resonance imaging and positron emission tomography, with a targeted study of the liver bed, peritoneum and of orifices of the trocars^[14,15]. Moreover, a reassessment of

the histological examination has to be performed, with a possible second opinion. This is important in order to: (1) confirm the pT; (2) specify the exact site of the tumor (hepatic side, bottom, infundibulum); (3) have a thorough evaluation of the cystic duct; and (4) evaluate whether the cystic lymph node is included in the histological examination. Today reoperation for incidental GBC should have two fundamental objectives: R0 resection of the liver parenchyma with the other adjacent structures, and clearance of the locoregional lymph nodes^[7,8].

What is an appropriate extent of hepatic resection during reoperation and can hepatic resection prevent liver recurrence?

Hepatic resection for GBC must have two main aims: resect the tumor that has directly invaded the liver from the gallbladder bed, and prevent micrometastases that may recur around the gallbladder bed^[3]. However, it remains unclear what an appropriate extent of hepatic resection is, and whether hepatic resection can prevent liver recurrence. Generally, operative procedures for incidental GBC include: extended cholecystectomy or Glenn resection (i.e., cholecystectomy plus partial resection of liver segments 4 and 5, approximately 2-3 cm from the gallbladder bed); anatomic resection of liver segment 5 and lower part of segment 4 when GC invades the liver bed to a depth of 2 cm or more; right hepatectomy when GC invaded the right Glisson capsule^[3,7,8].

As noted in the literature, the preference today is for

parenchyma-sparing operations, such as no anatomical wedge resection^[1,3]. Araida *et al*^[16] showed in a multi-center retrospective study, that there was no significant differences in survival and in recurrence rates of liver metastasis between patients that underwent resection of the gallbladder bed, anatomical segmentectomy 4b + 5 and hepatectomy for pT2 and pT3 GBC. He also proved that there were no particular preferences of recurrent liver metastasis for segment 4a + 5. Similarly, other authors have reported that there was no association between major hepatectomy and long-term survival, and that there was an increased association between major hepatic surgery and perioperative morbidity^[1,3].

In order to support this, Pawlik *et al*^[5] have proved that patients who had undergone major hepatic resection (anatomical segmentectomy of 4a + 5 or hemihepatectomy) had a similar risk of specific death as patients who underwent hepatic wedge resection, on both univariate and multivariate analyses. Rather than the type of hepatic resection, the most important factor that determines the final outcome is to obtain R0 resection. In fact, R1/R2 margin status is associated with decreased long-term survival^[17].

In conclusion, for gallbladder cancer without hepatoduodenal ligament invasion and without any locoregional liver involvement, the wedge resection of the gallbladder bed (3 cm) is preferable to hepatectomy^[3,5,17]. With regard to GBC that has invaded the gallbladder bed, in order to obtain negative histological margins, the preferred approach is nonanatomical resection of hepatic parenchyma, with a distal clearance of at least 2 cm^[3,5,17].

Optimal extent of lymph node dissection?

In GBC, besides radical R0 resection, another main aim of surgery is to obtain complete clearance of the locoregional lymph nodes. GBC spreads through different pathways: direct locoregional invasion to lymphatic, vascular and neural invasion. The most common route of dissemination is lymphatic diffusion. This is facilitated by lymphatic channels in both the muscular and subserosal layers of the gallbladder. In addition, neoplastic cells, even without evident transmural invasion, often spread superficially to the other lymph nodes along the bile ducts^[18-20]. The lymph nodes involved in the locoregional spread of GC can be divided into three: (1) cystic, pericholedochal and hilar lymph nodes; (2) lymph nodes around the portal vein, the common hepatic artery and periduodenal and peripancreatic lymph nodes; and (3) celiac, superior mesenteric artery and the para-aortic lymph nodes^[18-20].

Although the cystic and pericholedochal lymph nodes are the first key station, the pathways of lymph node involvement from the first site of diffusion to the hepatoduodenal ligament (cystic, pericholedochal and hilar lymph nodes) tend to be highly variable^[21]. In fact, GBC can spread directly to the third level of lymph nodes, along the perivascular soft tissue (celiac, superior mesenteric artery and the para-aortic lymph nodes), according to the three pathways of lymphatic drainage proposed

by Ito *et al*^[21]: cholecysto-retropancreatic pathway (main pathway), cholecysto-celiac and cholecysto-mesenteric pathways (accessory pathways). The incidence of occult lymphatic metastasis discovered during reoperation for incidental GBC can vary from 0% to 85% in relation to the depth of organ invasion (pT).

In fact, the reported incidence of occult lymphatic metastasis by stage is as follows: for T1a 0%-2.5%, for T1b 15%-25%, for T2 30%-50%, for T3 45%-75%, and for T4 > 85%^[5,18,22-26] (Table 4). Similarly to other cancers, lymphadenectomy not only provides important staging information, but more importantly, may decrease the risk of locoregional recurrence. In fact, after tumor resection, the level of lymph node metastasis correlates with overall prognosis within the same pT stage category^[25,26]. Miyakawa *et al*^[27] reported 5-year survival of 60.3% for pN0 patients, 30.0% for pN1, 16.8% for pN2, and 5.9% for pN3. Hence, little controversy exists on the optimal management of T1a GBC. In fact, cholecystectomy alone is sufficient^[3]. On the contrary, controversy still exists on the need for more radical resection in T1b GBC^[24,26]. Moreover, different authors have advocated that not all T1b stages are the same, and treatment should be individualized. In fact, due to the strong correlation between lymphatic invasion and lymph node metastasis, Shibata *et al*^[20] have advocated the use of

Table 4 Residual disease in the lymph nodes after re-resection for each pT (%)

lymphatic invasion as guidance for additional radical resection. However, this remains controversial because the absence of lymph node invasion does not exclude other recurrence such as liver metastases, peritoneal carcinomatosis or recurrence at the port sites, or expression of other forms of diffusion of GBC^[28,29].

Based on our review, we believe that resection of the gallbladder bed with regional lymph node dissection is the best choice for treatment of T1b GBC. In Western countries, lymphadenectomy is usually confined to the hepatoduodenal ligament around the hilar area (N1 lymph nodes: cystic, pericholedochal and hilar lymph nodes). Extended radical lymphadenectomy of N2 lymph nodes (including lymph nodes around the portal vein, common hepatic artery, and periduodenal and peripancreatic lymph nodes) is not routinely advocated^[3,4]. Currently, according to the 7th edition of AJCC staging, N2 involvement is considered as M1 metastasis, and represent a potential contraindication to additional radical surgery^[30].

When is resection of the common bile duct necessary?

Resection of the common bile duct performed at the time of the hepatic resection and lymphadenectomy is controversial^[31-33]. GC has a strong tendency to invade the hepatoduodenal ligament in the form of perineural invasion or lymph node metastasis, therefore, *en bloc* resection of the regional lymph nodes together with excision of the connective tissue around the portal and hepatic artery should be performed, whenever lymph node dissection of the hepatoduodenal ligament is entertained^[34-36]. Dissection of the hepatoduodenal ligament implies a risk of inducing ischemic damage to the common bile duct, therefore, Shimizu *et al.*^[10] proposed routine resection of the extrahepatic bile duct to facilitate lymphadenectomy, avoiding common bile duct ischemia, and increasing the number of lymph nodes harvested. However, these benefits have not been confirmed in other studies^[32,33]. Pawlik *et al.*^[5] showed that the median number of lymph nodes harvested at the time of lymphadenectomy was the same ($n = 3$), regardless of whether the common bile duct was or was not resected concomitantly with lymph node dissection ($P = 0.35$). Araida *et al.*^[31] found that, in patients with advanced GBC, who did not have direct invasion of the hepatoduodenal ligament and/or of the cystic duct, bile duct resection did not result in any differences in terms of recurrence and overall survival, but it only exposes patients to the potential complications of the bilioenteric anastomosis.

In conclusion, bile duct resection should be performed only when the patients have a positive involvement of the cystic duct margins, discovered either on the pathological review of the initial cholecystectomy or through biopsy of the cystic duct at the time of the second operation^[3,32,33]. In fact, microscopic involvement of the cystic duct margin is associated with a residual and/or additional disease in the common bile duct in over one-third of the cases^[32,33].

Type of treatment according to depth invasion

Contrary to other gastrointestinal carcinomas, the depth of invasion of GBC dictates the extent of surgical resection. In cases of carcinoma *in situ* or tumor invading the mucosa (Tis and T1a), simple cholecystectomy with negative surgical margins can be considered as curative surgery^[3,4,23,37].

The 5-year survival after simple cholecystectomy is between 99% and 100%^[23,37]. When the muscularis layer is involved (T1b), a 20%-50% local-regional recurrence can be expected after simple cholecystectomy^[3,6,37] (Table 5). At the time of reoperation, it has been shown that there is a 10% incidence of residual disease in the liver bed associated with a 15%-25% incidence of residual metastatic lymph node involvement^[22,24,26]. The 5-year survival after simple cholecystectomy is between 40% and 50%^[6,23,36-39]. Therefore, the recommended procedure is cholecystectomy associated with resection of at least 3 cm of liver parenchyma (wedge resection), plus adequate lymphadenectomy (Glenn's resection)^[37-39]. When the tumor extends beyond the serosa and invades the liver or an organ or an adjacent structure (T3), there is a 36% incidence of residual disease at the liver level and 45%-75% incidence of lymph node dissemination^[5,22,25,26]. The goal of surgical intervention is to obtain R0 resection, hence, mandatory steps include extended lymphadenectomy and extended hepatic resection, associated with resection of other organs and structures, when necessary^[35]. T3 patients are at high risk of peritoneal metastases, therefore, explorative laparoscopy should be considered in order to avoid unnecessary laparotomy. The 5-year survival after simple cholecystectomy is 0%-15%, and reaches 25%-65% after extended resection^[5,23,36] (Table 5).

Does laparoscopic cholecystectomy worsen prognosis?

More cases of GBC are incidentally diagnosed during laparoscopic cholecystectomy, thus, the question arises whether laparoscopic cholecystectomy worsens the prog-

LC: Laparoscopic cholecystectomy.

nosis of these patients. Drouard *et al*^[40] first described the development of port-site metastases in 1991, and additional proof came in 1994^[41]. This contributed to the loss of interest in approaching malignancy laparoscopically. Furthermore, excessive manipulation of the organ and perforation can cause intraperitoneal spread of malignant cells, resulting in a worse long-term survival^[42]. In fact, the incidence of port-site recurrence increased from 9% in patients without intraoperative perforation to 40% in those in whom perforation could be demonstrated^[43]. Other studies proved that pneumoperitoneum significantly increased tumor cell implantation at trocar sites, and tumor growth in the peritoneum^[44-46]. However, laparoscopic cholecystectomy, if correctly performed, did not influence the long-term prognosis of early stage tumors (T1a, T1b, T2)^[7,8]. Also, radical re-resection, performed several months after laparoscopic cholecystectomy, has similar results to radical resection in one stage, and long-term survival can be achieved in tumors with infiltration of the liver in patients who have previously undergone noncurative surgery^[1,7,8,23]. Survival is strictly related to the depth of parietal invasion of the tumor, but there is no significant difference between patients with incidental GBC discovered during or after cholecystectomy ($P = 0.235$)^[7]. The real problem is to have a clear understanding of how to deal with this eventuality.

Are port-site metastasis a real problem?

Port-site metastasis is the most common form of parietal recurrence (Table 6). It has been reported at all stages of gallbladder carcinoma and at any of the trocar sites. It generally presents after latency, ranging from a few months to 3-4 years. Many factors can contribute to port-site metastasis. One of the most important is intraoperative spillage of bile from gallbladder wall perforation, which has been described in 30% of laparoscopic cholecystectomy cases, and it has been linked to port-site metastasis^[43,44,47,48]. Intraoperative manipulation of the tumor, in the form of tension, dissection and isolation, often leads to the disintegration of a certain proportion of cancer cells, as confirmed by the presence of granular cells in 40% of laparoscopic instruments^[49,50]. The increased intraperitoneal pressure induced by the CO₂ pneumoperitoneum can spread and redistribute cancer cells within the peritoneal cavity and in damaged surfaces. Finally, evidence exists on the immunosuppressive action of CO₂ which would favor the implantation of tumor

cells^[50]. The median survival after port-site metastasis is approximately 1 year, and it is mandatory to perform resection at the time of reintervention in patients previously treated with laparoscopic cholecystectomy^[3,7,8].

Contraindications to additional radical resection

With the primary goal of surgery in mind (R0 resection), the only contraindication to additional surgery is the inability to obtain radical R0 resection. In particular, the presence of peritoneal metastasis, distant metastasis, locally advanced GBC with N2 or M1 (according to the 7th edition of AJCC staging), lymph node invasion along the hepatic artery, portal vein and celiac and mesenteric vessels are all considered contraindications to radical resection^[35,51-53]. On the other hand, the presence of peripancreatic (head only) lymph node disease is not a contraindication to surgical excision, and radical lymphadenectomy and pancreaticoduodenectomy can be carried out together with liver resection^[35,53]. Also, the depth of liver involvement and multiorgan locoregional involvement do not represent a contraindication for additional radical resection^[51,52]. Combined pancreaticoduodenectomy, right hemicolectomy and major hepatectomy are effective treatment for GBC with direct invasion of the adjacent organs (stomach, duodenum, pancreas, colon and liver), but only if potentially curative resection (R0) is feasible. In these cases of multiorgan resection for GBC, given radical R0 resection, the long-term survival will depend on bile duct involvement^[35,51-53]. In fact, stromal invasion of the extrahepatic bile ducts is sometimes a prelude to hepatoduodenal ligament involvement, and is also associated with a higher rate of metastases to para-aortic nodes with a high incidence of residual tumor and poor outcome after surgery^[32].

In conclusion, incidental carcinoma of the gallbladder, as our experience confirms, generally is diagnosed at an earlier stage and carries a better prognosis than non-incidentally found cancer. Laparoscopic cholecystectomy does not affect survival if implemented with proper technique. Simple cholecystectomy may be an adequate treatment only for earlier stage GBC: Tis and T1a. All other stages, starting from T1b should be treated with lymphadenectomy and resection of at least 2-3 cm of liver parenchyma around the liver bed, provided that no residual microscopic cancer (R0) remains. Resection of the main bile ducts could be necessary in hilum-type cancers with positive margins of the cystic duct. More extensive liver resection or performance of multiorgan resection can be pursued in order to achieve R0 resection.

COMMENTS

Background

Gallbladder carcinoma remains a rare, but highly aggressive disease. Its dismal prognosis is associated with the advanced stage of the disease at the time of diagnosis.

Research frontiers

Controversy exists about the optimal management of the disease. In particular, the debate involves the extent of surgical resection of the liver and surrounding organs, the need for resection of the main bile duct, the extent of lymph node removal, and the potential for negative effects of previous laparoscopic cholecystectomy. It is also unclear when surgery is not indicated at all.

Innovations and breakthroughs

Previous studies have proved how simple cholecystectomy is sufficient treatment for early stages of gallbladder carcinoma. Also, it seems that, at more advanced stages, it is paramount to obtain complete gross oncological resection (R0) without the need for anatomical hepatic resection. In order to minimize port-site metastasis, the laparoscopic approach to apparently benign gallbladder disease has to follow specific principles: minimal manipulation of the gallbladder; avoidance of rupture of the gallbladder and bile spillage; extraction of the specimen with a protective bag to avoid contact with the skin; and evacuation of the intraperitoneally insufflated gas via the cannulae.

Applications

The authors conclude that gallbladder cancer can be adequately cured when the diagnosis is early and the treatment is standardized by stage. Incidental carcinoma of the gallbladder is generally diagnosed at an earlier stage and carries a better prognosis than nonincidentally found cancer. Laparoscopic cholecystectomy does not affect survival if implemented with proper technique. Simple cholecystectomy may be adequate treatment only for the earlier stages. All other stages should be treated with lymphadenectomy and resection of at least 2-3 cm of liver parenchyma around the liver bed, provided that no residual microscopic cancer remains. Resection of the main bile ducts could be necessary in cancers with positive margins of the cystic duct. More extensive liver resection or performance of multiorgan resection can be pursued in order to achieve complete resection of the tumor. This research can certainly guide surgeons that encounter this rare entity unexpectedly. In fact, as long as the appropriate referrals are made, the prognosis does not worsen. This can also increase awareness of this rare, but potentially lethal disease.

Terminology

R0 is the surgical removal of all the grossly apparent tumor cells. Port-site metastasis refers to implantation of tumor cells at the skin incisions utilized to place the laparoscopic trocars.

Peer review

The authors present solid experience with a rare disease. Their clinical analysis, along with a thorough review of the literature, provides a clear algorithm to approach the disease at different stages.

Abstract

AIM: To investigate matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) in pouch mucosa of pediatric onset ulcerative colitis (UC).

METHODS: In this cross-sectional study, 28 patients with pediatric onset UC underwent ileal pouch biopsy 13 years (median) after proctocolectomy. Expression of MMPs-3, -7, -8, -9, -12 and -26 and TIMPs-1, -2 and -3 in samples was examined using immunohistochemical methods, and another biopsy was used to evaluate the grade of histological inflammation. Two investigators independently graded the immunohistochemical specimens in a semiquantitative fashion, using a scale marking staining intensity as follows: 0 = less than 20 positive cells; 1 = 20-50 positive cells; 2 = 50-200 positive cells; 3 = over 20 positive cells. Fecal calprotectin and blood inflammatory markers [serum C-reactive protein (CRP) and erythrocyte sedimentation rate] were determined during a follow-up visit to examine correlations between these markers and the expression of MMPs and TIMPs.

RESULTS: Of the 28 patients with pediatric onset UC, nine had not experienced pouchitis, whereas thirteen reported a single episode, and six had recurrent pouchitis (≥ 4 episodes). At the time of the study, six patients required metronidazole. In all of the others, the most recent episode of pouchitis had occurred over one month earlier, and none were on antibiotics. Only four samples depicted no sign of inflammation, and these were all from patients who had not had pouchitis. Two samples were too small to determine the grade of inflammation, but both had suffered pouchitis, the other recurrent. No sample depicted signs of colonic metaplasia. Most pouch samples showed expression of epithelial (e) and stromal (s) MMP-3 (e, $n = 22$; s, $n = 20$), MMP-7 (e, $n = 28$; s, $n = 27$), MMP-12 (e, $n = 20$; s, $n = 24$), TIMP-2 (e, $n = 23$; s, $n = 23$) and MMP-3 (e, $n = 23$; s, $n = 28$) but MMP-8 (e, $n = 0$; s, $n = 1$), MMP-9 (e, $n = 0$; s, $n = 9$) and MMP-26 (e, $n = 0$; s, $n = 3$) and TIMP-1 ($n = 0$, both) were lacking. In samples with low grade of inflammatory activity, the epithelial MMP-3 and MMP-7 expression was increased ($r = -0.614$ and $r = -0.472$, respectively, $P < 0.05$ in both). MMPs and

TIMPs did not correlate with the markers of inflammation, fecal calprotectin, erythrocyte sedimentation rate, or CRP, with the exception of patients with low fecal calprotectin (< 100 µg/g) in whom a higher expression of epithelial MMP-7 was found no differences in MMP- or TIMP-profiles were seen in patients with a history of pouchitis compared to ones with no such episodes. Anastomosis with either straight ileoanal anastomosis or ileoanal anastomosis with J-pouch did depict differences in MMP- or TIMP-expression.

CONCLUSION: The expression of MMPs pediatric UC pouch in the long-term shares characteristics with inflammatory bowel disease, but inflammation cannot be classified as a reactivation of the disease.

Matrix metalloproteinases in the restorative proctocolectomy pouch of pediatric ulcerative colitis. *World J Gastroenterol* 2012; 18(30): 4028-4036 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i30/4028.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i30.4028>

INTRODUCTION

In children, ulcerative colitis (UC) appears to present more aggressively than in adults^[1,2]. The number of pediatric UC cases requiring colectomy within the first decade after diagnosis may reach 24%^[1]. Restorative proctocolectomy with ileoanal anastomosis (IAA) and an ileal pouch-anal anastomosis is the surgical treatment of choice in UC^[2].

In proctocolectomized patients, pouchitis is a common complication, and over two thirds of children undergoing proctocolectomy will suffer at least one episode of pouchitis during the following decade^[2]. Yet, studies on pouchitis in children are limited. Pouchitis is an idiopathic inflammatory condition of the ileal reservoir occurring frequently after colectomy with IAA^[3]. The etiology of pouchitis is poorly understood, but it is associated with risk factors such as extensive colonic disease preoperatively and young age at proctocolectomy^[4]. The incidence of pouchitis is higher in UC than in familial adenomatous polyposis^[5], and pouchitis has been consid-

ered a recurrent form of colitis^[5,6]. Ileal pouch mucosa may acquire colonic characteristics^[7,8], and colonic metaplasia is more pronounced in patients with pouchitis^[9]. This mucosal transformation could have a role in the pathogenesis of pouchitis, possibly allowing the recurrence of inflammatory bowel disease (IBD) and may represent a novel manifestation IBD^[7-9].

Matrix metalloproteinases (MMPs) are a family of 24 zinc-dependent enzymes implicated in mucosal damage in IBD^[10]. MMPs take part in normal mucosal defense, and are capable of degrading extracellular matrix and basement membrane proteins in tissue remodeling processes both in normal and in pathological conditions^[10]. In IBD, MMP-9 is the most abundantly expressed MMP, and it shows increased activity in inflamed UC mucosa^[11]. Other MMPs have also been linked to inflammation severity in IBD, such as MMP-7^[12]. Our group has demonstrated enhanced MMPs-1, -3 and -7 expression in IBD, and shown MMP-10 expression in IBD granulation tissue^[13,14]. In pediatric IBD, we have described increased expression of epithelial MMP-10 and stromal tissue inhibitor (TIMP)-3^[15].

The pathogenesis of pouchitis is unknown, and it is debated whether or not the inflammation is similar to that found in UC, or whether it is inflammation of a novel kind. The management of pouchitis by antibiotics and probiotics is widely accepted. Yet, according to a recent review, antibiotics are not significantly better than a placebo, compared to the high dose probiotics. By altering the endogenous flora and the expression of inflammation parameters, as well as competing with pathogens for receptor binding, nutrients, and growth factors, the high dose probiotics are effective in treatment of pouchitis^[16]. The occurring inflammation and acquisition of colonic characteristics^[7,8] inspires an interest in the MMP and TIMP-profile of pouch. We are aware of only two studies of MMP expression in pouchitis in adults^[17,18]. Expression of MMP-1 and MMP-2 in pouchitis is different from normal ileal mucosa, but is similar to expression in active UC colitis^[17]. We examined the MMP and TIMP profiles of pouch patients who had undergone proctocolectomy in their childhood or adolescence, and to find clues to the type of inflammation appearing in the pouch. It is important to determine whether this inflammation is IBD-like or of a novel kind, to appropriately prevent and manage pouchitis in the future.

MATERIALS AND METHODS

Patients and setting

Between 1985 and 2005, 81 pediatric patients with UC underwent proctocolectomy with ileal anastomosis at Tampere University Hospital or Children's Hospital, Helsinki. Of these colectomized patients, one died of an unrelated cause and one emigrated. Thus, 79 patients were traced from the database of the Population Register Centre and contacted by mail during 2006. Thirty-five patients agreed to participate for a follow up visit described elsewhere

in detail^[2], but seven had been rediagnosed as Crohn's disease (CD). The 28 UC cases were included in this study (Table 1). All proctocolectomies included transanal mucosectomy and a hand-sewn anastomosis. Twenty-one patients had an IAA with J-pouch, and 7 had straight ileoanal anastomosis (SIAA). Patients filled out a questionnaire surveying the current diagnosis, complications, medical therapy and pouchitis. To map the latter two, we asked about medications to control stool frequency, and the history and treatment of pouchitis. During the outpatient visit, biopsy of the pulled through ileum, and stool and blood samples were obtained. The Ethical Committee of the Helsinki University Hospital approved the and the participants (or their guardians) gave informed consent.

Fifteen UC patients had other chronic illnesses: sclerosing cholangitis, active hepatitis, gastroesophageal reflux, gallstones, rheumatoid arthritis, sacroiliac-joint arthritis, knee arthritis, hyperthyroidism, cardiac arrhythmias, psychiatric illness, endometriosis, fibromyalgia, osteoporosis, asthma, atopic skin and contact allergy. Specific medications at the time of the study are shown in Table 2. Post-operatively, 18 (64%) UC patients had received antibiotics

as treatment for pouchitis, and of these, 7 (25%) also had received corticosteroids.

Blood inflammatory markers and fecal calprotectin

Inflammation biomarkers in blood [erythrocyte sedimentation rate, erythrocyte sedimentation rate (ESR), and serum concentration of C-reactive protein (CRP)] and fecal calprotectin (quantitative enzyme immunoassay, PhiCal test, Calpro AS, Oslo, Norway) were routinely determined^[18]. For immunohistochemistry, biopsies from pouch were used. The histological grade of inflammation in the samples was assessed according to the scoring system for pathological changes in the ileal reservoir mucosa^[7,19].

Immunohistochemistry

One biopsy was analyzed for the grade of histological inflammation, the other biopsy was used for MMP immunohistochemistry. Immunohistochemistry was performed using streptavidin-biotin-peroxidase complex technique (DakoCytomation, StreptABComplex/HRP Duet, Mouse/Rabbit, Glostrup, Denmark; and Elite goat Vectastain ABC kit, Vector laboratories, Burlingame, CA, United States) or the antibody-polymer detection technique (ImmPRESS universal reagent, Anti-Mouse/Rabbit IG, Vector laboratories Burlingame, CA, United States). Diaminobenzidine or NovaRED (Vector Laboratories) were used as chromogenic substrates and Mayer's hematoxylin as counterstain. Monoclonal antibodies were used to stain for MMP-7 (1:600, MAB3315, Millipore, Temecula, CA, United States)^[15], MMP-8 (1:100, IM38, Calbiochem, La Jolla, CA, United States)^[15], MMP-9 (1:100, MS-569-P1, Lab Vision Corporation Neomarkers, Fremont, CA, United States)^[15], TIMP-1 (1:50, IM63, Calbiochem)^[15], TIMP-2 (1:600, IM56, Calbiochem) and TIMP-3 (1:300, IM43L, Calbiochem)^[15]. Polyclonal antibodies were used for MMP-3 (1:50, ab32607, Abcam Ltd, Cambridge, United Kingdom), MMP-12 (1:80, sc-12361, Santa Cruz Biotechnology, CA, United States)^[15] and MMP-26 (1:120, a gift from Professor Isaka K, Tokyo Medical University)^[15]. MMP-8 and MMP-9 were pretreated with 1% trypsin solution for 30 min at 37 °C. MMP-3, MMP-7, MMP-26, TIMP-1, TIMP-2 and TIMP-3 were pretreated in a 95 °C water bath for 30 min (Dako retrieval solution pH 6; DakoCytomation). MMP-12 required no pre-treatment. The incubation conditions for the antibodies were: 4 °C overnight for MMPs-7, -9, -12 and TIMPs-1, -2, -3; 1 h 45 min at 37 °C for MMP-8 and 1 h at room temperature for MMP-3 and MMP-26. For negative controls, parallel sections of the same samples were processed using preimmune sera or normal rabbit or mouse immunoglobulin. As positive controls, we used formalin fixed, paraffin embedded sections of hailey-hailey, pyoderma gangrenosum and dermatitis herpetiformis (MMP-3), adenocarcinoma (MMP-7), squamous cell cancer (MMP-8), chronic wounds (MMP-9 and TIMP-2 and -3), foreign body reaction (MMP-12), endometrium (MMP-26), and pyoderma gangrenosum (TIMP-1). Immunohistochemical specimens were graded independently by two different investigators (Mäkitalo L, Piekkala M) in a semiquantitative fashion under a light-

field microscope at $\times 100$ magnification using a scale marking staining intensity as follows: 0 = less than 20 positive cells; 1 = 20-50 positive cells; 2 = 50-200 positive cells; 3 = over 200 positive cells^[15,20]. The identity of the cell types producing each MMP or TIMP was confirmed together with an experienced pathologist (Karikoski R).

Statistical analysis

Non-parametric Mann-Whitney's test, Spearman's correlation test and independent samples t test were performed with the SPSS 17.0 for Windows (Chicago, IL) to investigate the significance of results. A $P < 0.05$ was considered significant.

RESULTS

Of the 28 patients with pediatric onset UC, nine (32.1%) had not experienced pouchitis, whereas 13 (46.4%) reported a single episode, and six (21.4%) had recurrent pouchitis (≥ 4 episodes)^[19]. Six patients were on metronidazole medication at the time of the study (Table 2)

one of them also on a 5-aminosalicylic acid formulation and showed inflammation of grades 1 to 3^[7,20]. In all the others the last episode of pouchitis had occurred more than one month earlier, in most cases several months earlier and they were not on antibiotics. Only four samples (14%) depicted no signs of inflammation, and these were all from patients who had not experienced pouchitis. Of the 19 patients who had experienced pouchitis, 7 showed mild inflammation, 3 depicted moderate and 7 severe inflammation in the biopsy. Two samples were too small to determine the grade of inflammation, but both had suffered pouchitis, the other recurrent. No sample depicted signs of colonic metaplasia.

Expression of MMP-3 was seen in the majority of the samples in the epithelium and in stroma in plasma cells, macrophages and eosinophils (Table 3 and Figure 1A, B). Also, MMP-3 positive endothelium was observed (Figure 1B1, B4). Epithelial MMP-7 was present in all samples, and stromal MMP-7 in 27 samples in plasma cells, macrophages and eosinophils, as well as endothelium (Table 3 and Figure 1C, D). Conversely, stromal MMP-9 was present in 9 samples in macrophages, plasma cells and eosinophils, and in intraepithelial neutrophils, but no positive enterocytes could be found (Table 3 and Figure 2D, E). MMP-12 was found in the majority of the samples in the epithelium and in stroma in macrophages, plasma cells, and eosinophils and intraepithelial neutrophils (Table 3 and Figure 2F, G1). Stromal cells showed positivity for MMP-26 in 3 samples in neutrophils and plasma cells but epithelial cells were negative for this MMP (Table 3 and Figure 2B). MMP-26 positive neutrophils were present in blood vessels (Figure 2B3). TIMP-2 was positive in the majority of samples in the epithelium and in stromal cells including plasma cells, eosinophils and macrophages (Table 3 and Figure 1E, F). TIMP-3 was found in enterocytes in 23 (82%) samples and in all samples in plasma cells and macrophages in stroma (mean 2.39) (Table 3 and Figure 1G). Endothelial cells were also positive for TIMP-3 (Figure 1G1, G2). Expression of MMP-8 and TIMP-1 was generally absent, although a few neutrophils in stroma were positive for MMP-8 and cryptal cells showed positivity for TIMP-1 (Figure 2A, C).

No differences in MMP- or TIMP-profiles were seen when comparing samples from patients that had experienced pouchitis (single or several episodes) ($n = 19$) to ones that had not ($n = 9$). The same was true when performing comparisons related to the frequency of pouchitis (data not shown). When comparing patients with SIAA to those with SIAA with J-pouch, no differences in MMP- and TIMP-expression profiles or the frequency of pouchitis episodes could be found.

MMPs and TIMPs did not generally correlate with inflammation markers fecal calprotectin, ESR and CRP. However, patients considered have no active inflammation (fecal calprotectin $< 100 \mu\text{g/g}$) showed higher expression of epithelial MMP-7 (Figure 1C) in their pouch biopsies compared to samples from those with active inflammation (fecal calprotectin $\geq 100 \mu\text{g/g}$)^[21] (Figure 1D1; means 1.75 *vs* 1.14, $P = 0.020$, respectively).

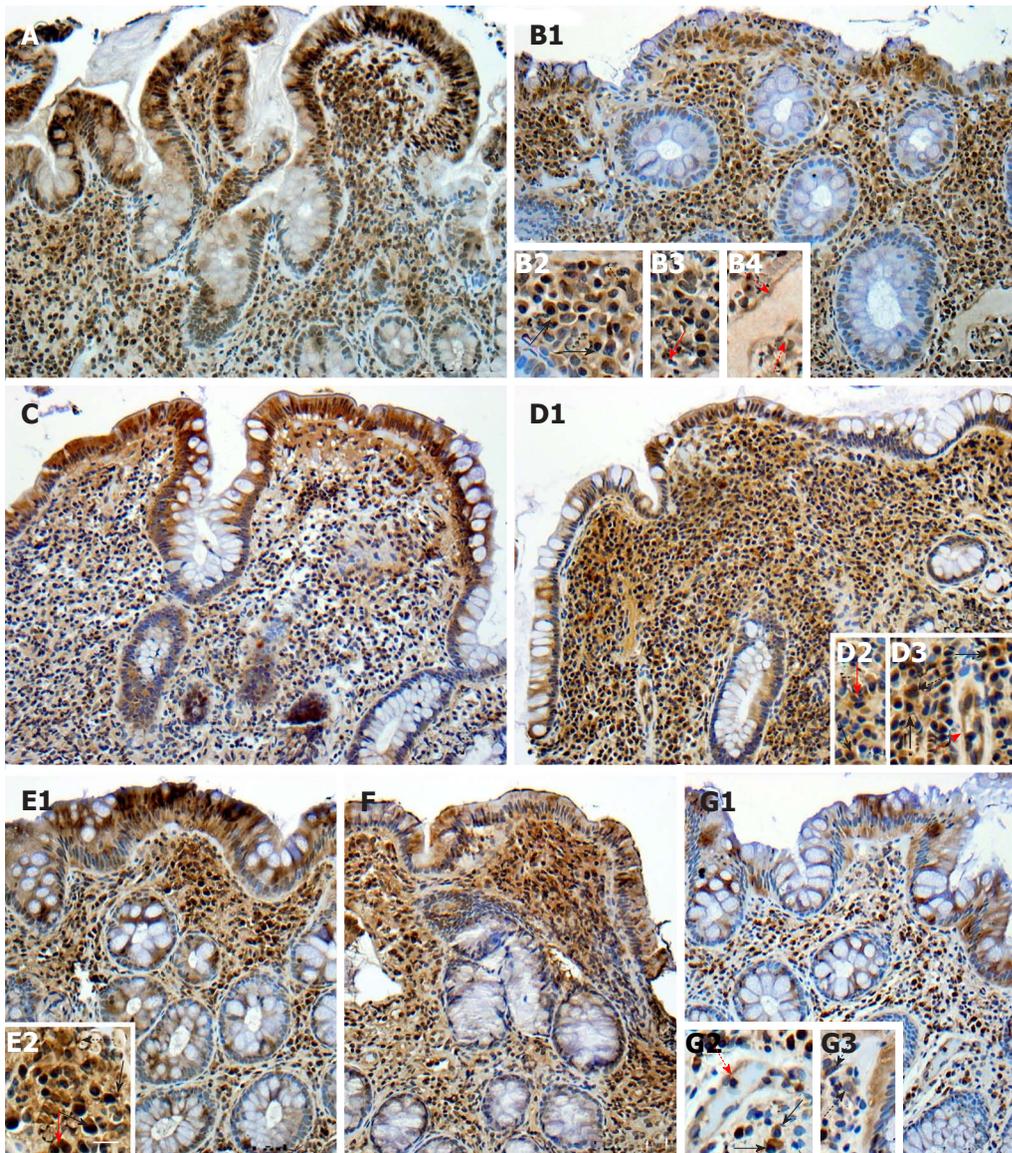

Figure 1 Matrix metalloproteinases-3, matrix metalloproteinases-7 and tissue inhibitor of matrix metalloproteinase-2 in lower (A, C, E1, respectively) and higher grade of inflammation and calprotectin levels (B1, D1, F, respectively), tissue inhibitor of matrix metalloproteinase-3 in pouch (G1). Black solid arrows plasma cells, black dotted arrows macrophages, red solid arrows eosinophils and red dotted arrows endothelium. Scale bars: 15 μm (A, B1, C, D1, E1, F, G1); 7.5 μm (B2-B4, D2, D3, E2, G2, G3). Stainings were performed using diaminobenzidine or NovaRED as chromogenic substrates and Mayer's hematoxylin as counterstain. Images were obtained using a light-field microscope, and edited using Adobe Photoshop 7.0 (Adobe Systems Incorporated).

The grade of inflammation in histological assessment^[7] correlated negatively with epithelial MMP-3 (Table 4) ($r = -0.614, P = 0.002$) (Figure 1A, B1) and MMP-7 ($r = -0.472, P = 0.027$) (Figure 1C, D1).

DISCUSSION

In pediatric patients, these MMPs and TIMPs have not been studied in pouches, and in adults, reports of only MMPs 1-3 and MMP-9 exist^[17,18]. This study reports for the first time expression of MMPs-7, -8, -12, TIMP-2, and TIMP-3 in ileal reservoir mucosa. In long-term, the MMP- and TIMP-profiles in pouch demonstrate similarities with IBD, but profiles in pouch cannot be said to replicate those in UC colon.

In adult inflamed and non-inflamed pouches of UC

patients, MMP-3 activity is considered weak^[18]. Here, MMP-3 was present in all but few samples in epithelium and stroma. In pediatric IBD, MMP-3 is elevated in endoscopically abnormal colon compared to healthy colon^[22]. MMP-3 plays an important role in T-cell- and tumor necrosis factor (TNF)- α -mediated gut injury^[23,24], and IBD gut plasma cells produce more MMP-3 than those of healthy controls^[25]. Here, expression of epithelial MMP-3 associated with the degree of inflammation, complying with animal studies where lack of MMP-3 associated with impaired wound healing^[26]. The present findings suggest that MMP-3 is an important MMP in pouch mucosa, resembling IBD. However, its relationship to the development of pouchitis is unclear. Similar to MMP-3, we found TIMP-3 in a large number of cells in stroma, expression paralleling reports in IBD colon^[15,20].

Table 4 Matrix metalloproteinases and tissue inhibitor of matrix metalloproteinase that correlated with inflammation indicators

Inflammation indicators	Correlation coefficients values				
	MMP-3	MMP-7	MMP-12		TIMP-2
	Epithelium	Epithelium	Epithelium	Stroma	Epithelium
Fecal calprotectin	NS	NS	-0.350	NS	NS
C-reactive protein	NS	NS	NS	-0.422	NS
Grade of inflammation	-0.614	-0.472	NS	NS	-0.420

NS: Not significant; MMPs: Matrix metalloproteinases; TIMP: Tissue inhibitor of matrix metalloproteinase. Correlations were calculated using Spearman's correlation test.

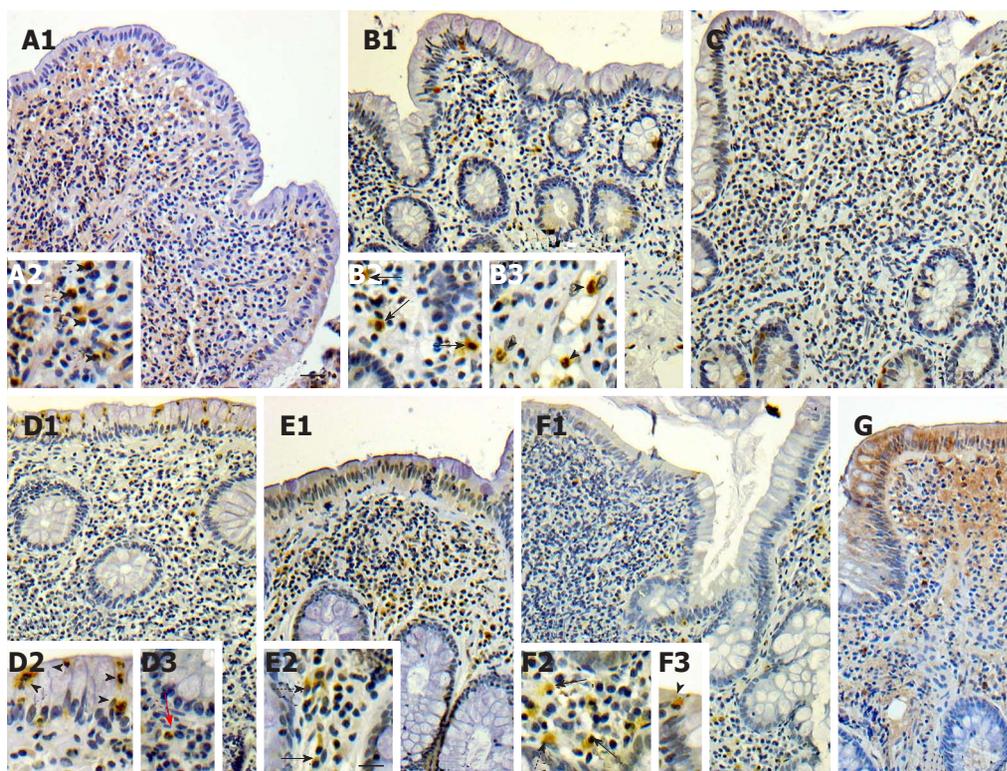

Figure 2 matrix metalloproteinases-8 (A1), matrix metalloproteinases-9 (D1, E1), matrix metalloproteinases-12 (F1, G), matrix metalloproteinases-26 (B1) and tissue inhibitor of matrix metalloproteinase-1 (C) in pouch. Inset g' added to figure from another sample, not shown in here in lesser magnification. Arrowheads depict neutrophils, black solid arrows plasma cells, black dotted arrows macrophages, red solid arrows eosinophils. Scale bars: 15 μ m (A1, B1, C, D1, E1, F1, G); 7.5 μ m (A2, B2, B3, D2, D3, E2, F2, F3). Stainings were performed using diaminobenzidine or NovaRED as chromogenic substrates and Mayer's hematoxylin as counterstain. Images were obtained using a light-field microscope, and edited using Adobe Photoshop 7.0 (Adobe Systems Incorporated).

Our group has noted that in intestinal ulcerations in IBD, TIMP-3 is expressed in a greater number of stromal cells compared to normal intestine^[14]. TIMP-3 inhibits TNF- α ^[27], an important cytokine in IBD inflammation^[28], and elevated TIMP-3 protein is likely to associate with elevated TNF- α -levels as seen in a human colonic cell line^[29]. Also, abundant TIMP-3 expression in stroma in pouch resembles that found in pediatric UC^[15], possibly preventing destructive activity as suggested for other autoimmune diseases^[30].

Of the other MMPs, expression of MMP-7, MMP-8, and MMP-9 was not IBD-like. Unlike MMP-8 and MMP-9, stromal MMP-7 was present in notable numbers of cells in almost all samples. We recently examined MMP-7 expression in pediatric IBD colon, and found weaker expression in epithelium in UC samples^[15]. Here, MMP-7 was found

in a smaller number of epithelial cells in samples with higher grade of histological inflammation and fecal calprotectin levels. This contradicts earlier results in UC^[12,31]. However, MMP-7 contributes to intestinal wound closure but over-expression may delay epithelial wound healing^[32]. Epithelial expression in pouch thus may be due to a regenerative process. MMP-7 has also been suggested to aid the growth of myofibroblasts and their function^[33] and stromal MMP-7 may take part in maintaining mucosal homeostasis. In normal colon, MMP-8 is undetectable^[10] but it may be involved in ulcer formation^[34] as elevated levels are found in ulcer bases of both UC and CD^[10]. We are not aware of previous studies of MMP-8 in pouch mucosa, but in our study, MMP-8 was generally absent from pouches. MMP-9 is important in IBD-related inflammation, and has also been shown to correlate

with disease activity^[10]. We found expression of MMP-9 in only a few samples, not suggestive of IBD-like inflammation.

In our study, MMP-12 was found in almost all pouch samples, although it is not expressed in normal adult ileum^[14,35]. While its role in IBD is unknown, this MMP may take part in macrophage migration and can activate TNF- α ^[10,36]. MMP-12 has been proposed to be a final step in tissue injury in celiac disease^[37] and might have a pathological role in pouch mucosa. Its expression suggests that pouch mucosa is dissimilar to normal ileal mucosa, even in the absence of inflammation.

In the present study, expression of MMP-26 was rare. We have proposed that immunosuppressive drugs modulate disease activity in CD by downregulating MMP-26^[20]. It is found in the colon of pediatric IBD patients^[15], but also in healthy ileum^[38], and expression is not IBD-specific. TIMP-1 is present in greater amount in inflamed adult IBD than in healthy mucosa^[31], whereas in pediatric IBD, we have reported weak TIMP-1 expression^[15]. We found no expression of TIMP-1 in the pouch, but epithelial and stromal TIMP-2 was found in most samples. Structural features of TIMP-2 suggest that it is expressed in constant amount^[39], and it has been reported to be present in normal-appearing IBD mucosa, with no significant increase in inflamed mucosa^[40]. Expression of MMP-26, TIMP-1 and TIMP-2 were inconclusive, neither supporting of contradicting IBD-etiology.

Taken together, earlier studies on MMPs and TIMPs in pouch are scarce, but in adults elevated MMP-1 and MMP-2 have been found in pouchitis mucosa^[17]. Due to small sizes of the biopsy and limited stainable slides, these MMPs were not studied here. The presence of MMP-3 and TIMP-3 in our samples is comparable to findings in IBD. In line with this, MMP-12 is detected in active IBD but not in normal ileum^[14,35,41], and here, expression of MMP-12 in pouch suggests altered mucosa. The lack of proper MMP-8 and MMP-9 expression in the pouch, however, contradicts IBD-related inflammation, as does the expression profile of MMP-7.

The results here are based on immunohistochemistry only, a limitation of this study, and further research using other techniques, e.g., Western blotting and polymerase chain reaction, would be necessary to verify the findings. We could not include a side-by-side analysis of samples from active UC and normal ileum and colon. Parallel analysis of ileal and colonic samples is challenging, as the follow up lasted until early adulthood. It is possible, that the use of medication in some cases may affect the expression of MMPs and TIMPs. It has been put forth, that probiotic use - that seems to elevate interleukin-10 in the gut-might downregulate the expression of MMP activity in the pouch mucosa and alter the expression of other proinflammatory cytokines^[18], but this finding needs more systematic studies. However, due to small sample size, we focused on comparing the expression patterns with established markers depicting the activity of inflammation. Interestingly, we found no differences in MMP or TIMP expression depending on the frequency of

pouchitis, but most samples depicted inflammation with concurrent elevated calprotectin. It seems reasonable that since there was no variation in MMP- or TIMP-profile according to the frequency of pouchitis, that inflammation markers depict very little correlation with MMPs. While even a longer follow-up may be necessary to further investigate the nature of pouch mucosa, the strength of the study is the long follow-up of the patients with pediatric onset disease, up to two decades after surgery.

In conclusion, in long-term, MMP expression in pouch shares characteristics with UC, but inflammation cannot be classified as a reactivation *per se*. Expression of MMP-3 and TIMP-3 in pouch resembles that of IBD, but the lack of MMP-9 contradicts an IBD-like pathomechanism. To the best of our knowledge, this study is the first to show that MMPs-7, -12, and TIMP-2 are also important in pouch mucosa. Further studies on the role of MMP profiles in etiopathology and the development of pouchitis in pediatric onset UC are warranted.

ACKNOWLEDGMENTS

The authors thank Professor Isaka K, University of Tokyo, for MMP-26 antibodies, Ms. Tallqvist A for skilful technical assistance and Ms. Nikkonen A for excellent help in collecting the patient data.

COMMENTS

Background

Approximately 24% of pediatric ulcerative colitis (UC) patients undergo colectomy with ileal pouch anal anastomosis within the first decade after diagnosis. Pouchitis is the most common complication occurring in approximately two thirds of the patients at least once during the following decade. The etiology of pouchitis is unknown and it is debated whether the inflammation is a novel kind or similar to that of found in UC. Matrix metalloproteinases (MMPs) have been linked to both physiological and pathological event in inflammatory bowel disease (IBD) mucosa.

Research frontiers

In pediatric IBD MMP 10 and tissue inhibitor of matrix metalloproteinase (TIMP) 3 have been linked to the colonic inflammation. Most abundantly expressed MMP in IBD-like inflammation is MMP-9 and the MMP-7 is linked to the severity of inflammation. There are no reports of MMP expression in pediatric pouch. Thus, the authors studied the expression of MMPs-3, -7, -8, -9 and -12 and TIMPs-1, -2, and -3 from the biopsies of pediatric UC patients' pouches to find MMPs and TIMPs specific to the pediatric pouchitis.

Innovations and breakthroughs

The expression of MMPs and TIMPs in pediatric pouches has not been studied previously and adult reports of only MMPs-1, -3 and -9 exist. This study, for first time, reports the epithelial and stromal expression of MMP-3, -7 -12, TIMP-2, and -3 and the lack of MMPs-8, -9, -26, and TIMP-1 expression in pediatric ileal reservoirs. The presence of MMPs-3, -12 and TIMP-3 share some similarities with IBD, but the lack of MMP-9 contradicts the IBD-like inflammation.

Applications

By understanding the MMP- and TIMP-profile of pouch mucosa, this study takes part in characterizing molecular environment in pouch, which may in turn aid in finding specific biomolecular targets for treatment of pouchitis.

Terminology

UC is chronic disease of the mucosa of the colon and the rectum characterized by bloody diarrhea, abdominal pain, and weight loss. Pouchitis is the inflammation of the ileal reservoir that is made after colectomy to avoid permanent ostomy. MMPs are a family of 24 zinc-dependent enzymes that are capable to degrade nearly all extracellular matrix and basement membrane proteins and take part to both normal and pathological tissue remodeling. TIMPs inhibit the action

of MMPs but the actions of TIMPs are not restricted to the MMP-inhibition, they also modulate other cellular processes.

Peer review

This is a study on matrix metalloproteinases and their tissue inhibitors in pouch mucosa of pediatric onset UC. This is a good study and the topic is so important because pouchitis is often seen in those who have undergone ileal pouch-anal anastomosis.

Abstract

AIM: To investigate M2 isoform of pyruvate kinase (PKM2) expression in gastric cancers and evaluate its potential as a prognostic biomarker and an anticancer target.

METHODS: All tissue samples were derived from gastric cancer patients underwent curative gastrectomy as a primary treatment. Clinical and pathological information were obtained from the medical records. Gene ex-

pression microarray data from 60 cancer and 19 non-cancer gastric tissues were analyzed to evaluate the expression level of PKM2 mRNA. Tissue microarrays were constructed from 368 gastric cancer patients. Immunohistochemistry was used to measure PKM2 expression and PKM2 positivity of cancer was determined by proportion of PKM2-positive tumor cells and staining intensity. Association between PKM2 expression and the clinicopathological factors was evaluated and the correlation between PKM2 and cancer prognosis was evaluated.

RESULTS: PKM2 mRNA levels were increased more than 2-fold in primary gastric cancers compared to adjacent normal tissues from the same patients (log transformed expression level: 7.6 ± 0.65 vs 6.3 ± 0.51 , $P < 0.001$). Moreover, differentiated type cancers had significantly higher PKM2 mRNA compared to undifferentiated type cancers (log transformed expression level: 7.8 ± 0.70 vs 6.7 ± 0.71 , $P < 0.001$). PKM2 protein was mainly localized in the cytoplasm of primary cancer cells and detected in 144 of 368 (39.1%) human gastric cancer cases. PKM2 expression was not related with stage ($P = 0.811$), but strongly correlated with gastric cancer differentiation ($P < 0.001$). Differentiated type cancers expressed more PKM2 protein than did the undifferentiated ones. Well differentiated adenocarcinoma showed 63.6% PKM2-positive cells; in contrast, signet-ring cell cancers showed only 17.7% PKM2-positive cells. Importantly, PKM2 expression was correlated with shorter overall survival ($P < 0.05$) independent of stage only in signet-ring cell cancers.

CONCLUSION: PKM2 expression might be an adverse prognostic factor for signet-ring cell carcinomas. Its function and potential as a prognostic marker should be further verified in gastric cancer.

INTRODUCTION

Gastric cancer is the second leading cause of cancer-related deaths worldwide^[1]. Although surgery is the standard curative treatment for gastric cancer, relapses occur in many patients even after adjuvant therapy. Gastric cancer patients with the same stage of the disease present different clinical courses and have different prognosis^[2]. This heterogeneity of gastric cancer is present at the molecular level and has a genetic predisposition to it^[3-6]. Therefore, it is important to identify new molecular markers to predict patients' outcomes and personalize treatments according to the individual biology of each cancer.

Cancer cells take up glucose at higher rates than do normal cells but produce energy mainly by glycolysis, rather than by mitochondrial oxidation of pyruvate^[7]. This process, called aerobic glycolysis or the Warburg effect, is very important for tumor growth^[8]. Glycolysis increases lactate production resulting in acidification of the extracellular environment, which is believed to facilitate cell invasion and metastasis^[9]. The M2 isoform of pyruvate kinase (PKM2) was identified as a driver of aerobic glycolysis, and has been shown to be the isoform preferentially overexpressed in tumor cells^[10]. Other isoenzymes of pyruvate kinase (pyruvate kinase type M1, pyruvate kinase type L, pyruvate kinase type R) are expressed depending upon the metabolic responsibilities of the various non-cancerous cells and tissues^[10].

Several studies have shown that PKM2 is selectively stained in cancer cells in immunohistochemical assay^[11,12]. It has been suggested that plasma PKM2 could be a valuable tumor marker for diagnosis or monitoring of lung, pancreas, kidney, breast, tongue, and gastrointestinal cancers^[11-17]. However, little is known about the biological function of PKM2 in cancer and its potential as an anti-cancer target. Previous studies reported that PKM2 protein level was increased in both the tumors and plasma of gastric cancer patients^[17], and that it positively correlated with cisplatin sensitivity in gastric cancer cell lines^[18]. However, clinical and prognostic implications of PKM2 as a marker for gastric cancer are still unclear. Therefore, we decided to analyze whether PKM2 expression is correlated with cancer progression and prognosis in human gastric cancer patients.

MATERIALS AND METHODS

Gene expression microarray data analysis

The previously generated gene expression data from 60 gastric cancer patients is available in the NCBI's GEO public database (microarray data accession number, GSE13861)^[2]. All patients underwent curative gastrectomy as a primary treatment in 2005 at Severance Hospital, Yonsei University College of Medicine, Seoul, South Korea. Clinical and pathologic data were obtained by review of the Severance Hospital medical records. The gene expression data of 60 cancer and 19 non-cancer gastric tissues from 60 gastric cancer patients were analyzed. Class comparison using two sample *t* test (significance $P < 0.001$, 10 000 random permutation) identified gastric cancer specific genes.

Patients and tissues

We selected primary gastric adenocarcinoma patients who had undergone curative gastrectomy as the primary treatment between 1999 and 2007 at Gangnam Severance Hospital, Yonsei University College of Medicine, Seoul, South Korea. Patients were followed up more than 36 mo after surgery or presented recurrence or death within 36 mo after surgery. We obtained paraffin-embedded tissues and clinical data from patients. The demographic details of the cases analyzed are described in Table 1. Clinical and pathological information were obtained from the medical records. Tumors were staged according to the 7th edition of the American Joint Committee Guidelines on cancer staging issued in 2010. Tumor histology was classified as differentiated (well and moderately differentiated adenocarcinoma) and undifferentiated (poorly differentiated adenocarcinoma and signet ring cell carcinoma) type. The median follow-up duration was 70.6 mo (range: 3.6-144.6 mo). A total of 125 (34%) patients did not receive any adjuvant chemotherapy, and most of their cancers were classified as stage I. No radiation was given to any of the patients. The study was approved by the Investigational Review Board of Gangnam Severance Hospital.

Tissue microarray construction and immunohistochemistry

The paraffin-embedded tissue microarray blocks of gastric cancer tissue specimens obtained from 368 patients were used. Each block had a 3-mm core of gastric cancer tissue. Immunohistochemistry was performed on 4 μ m-thick tissue microarray tissue sections on an Enzyme-conjugated polymer backbone: Dextran (EnVision Detection kit, DAKO Cytomation, Glostrup, Denmark) according to the manufacturer's instructions after microwave-based antigen retrieval. Antibody to PKM2 1:500, Cell Signaling, Cambridge, MA, United States) was applied to the sections, which were incubated for 2 h at room temperature. The sections were incubated with secondary antibody (HRP-Rabbit/Mouse) for 15 min at room temperature, and developed using a Nova-RED substrate kit (VECTOR Laboratory, Burlingame,

AJCC: American Joint Committee on Cancer; T: Tumor; N: Node.

CA, United States) and counterstained with Harris hematoxylin. The slides were photographed using a Zeiss microscope. The degree of immunostaining was scored independently by 2 observers based on the proportion of positively stained tumor cells and the intensity of staining. Tumor cell proportion was classified as follows: 0%, 10%-25%, 25%-50%, and > 50% PKM2-positive tumor cells. Staining intensity was classified as none, weak and strong staining.

We measured PKM2 expression in non-cancer gastric epithelial cells and malignant lesions. Tumors with more than 25% PKM2-positive cells were considered tumors with positive PKM2 expression, and those with less than 25% PKM2-positive cells were considered negative for PKM2 expression.

Statistical analysis

The correlation between the immunohistochemical expression scores and patient survival after surgery was estimated using the Kaplan-Meier method, followed by univariate comparison between the groups using the log-rank test. To adjust for potential confounding variables and to single out independent predictors of survival, a multivariate analysis of survival was done using the Cox's proportional hazard model using a forward stepwise mode. Statistical analyses were done with GraphPad Prism 5

(GraphPad Software, San Diego, CA) and PASW Statistics 18.0 (SPSS Inc., Chicago, IL). Association between PKM2 expression and the clinicopathological factors was tested using the χ^2 test. Two-tailed *P* values of 0.05 or less were considered statistically significant.

RESULTS

Upregulation of PKM2 mRNA in primary gastric cancers

From sixty gastric cancer patients, 60 gastric cancer tissues and 19 non-cancer adjacent gastric tissues were used for gene expression microarray analysis. PKM2 was identified as one of 3360 gastric cancer-specific genes by class comparison using the 2-sample *t* test (Data not shown). PKM2 mRNA levels were increased > 2-fold in human primary gastric cancers compared to normal adjacent tissues from the same patients (log transformed expression level: 7.6 ± 0.65 vs 6.3 ± 0.51 , $P < 0.001$, Figure 1A). Among cancer types, differentiated type cancers displayed > 2-fold increase in PKM2 levels compared to undifferentiated type cancers (log transformed expression level: 7.8 ± 0.70 vs 6.7 ± 0.71 , $P < 0.001$, Figure 1B).

Overexpression of PKM2 in primary gastric cancer

To examine whether PKM2 protein upregulation was linked to the clinical characteristics of gastric cancers,

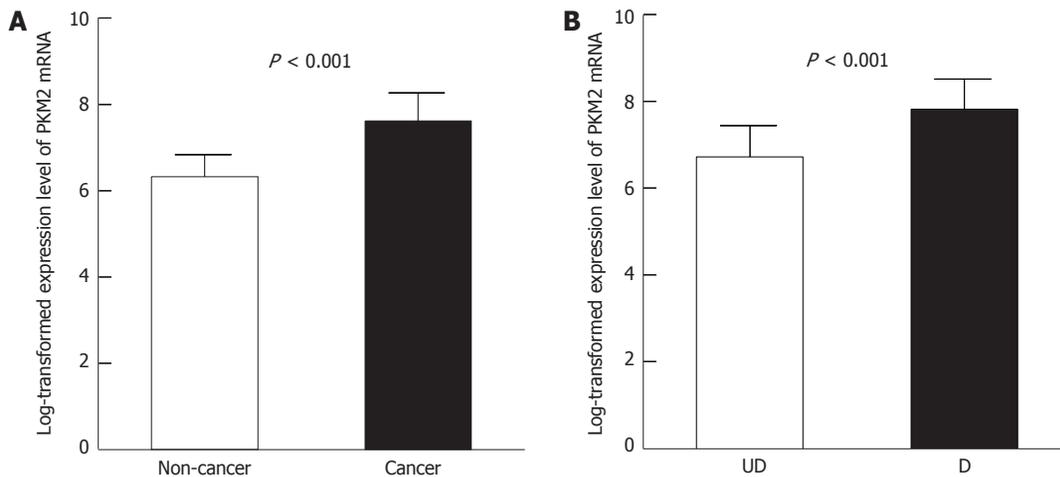

Figure 1 Expression level of the M2 isoform of pyruvate kinase mRNA by gene expression microarray. A: The M2 isoform of pyruvate kinase (PKM2) up-regulation in the 18 primary gastric cancers compared to gastric adjacent noncancerous tissues paired from the same patient ($P < 0.001$); B: PKM2 up-regulation in the 22 differentiated type (D) gastric cancers compared to 27 undifferentiated type (UD) gastric cancers ($P < 0.001$). The column and bar represent mean and standard deviation, respectively.

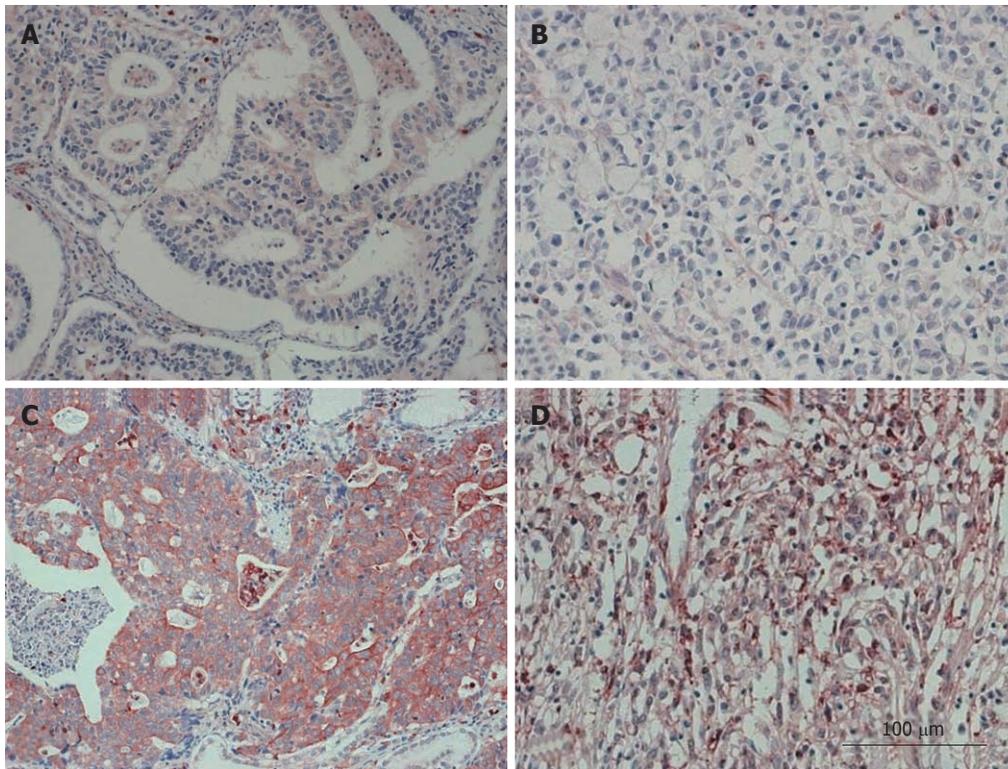

Figure 2 Representative images from immunohistochemistry assays of 368 archived gastric cancer cases at 20×10 magnification. A: Moderately differentiated adenocarcinoma and negative for the M2 isoform of pyruvate kinase (PKM2) expression; B: Signet ring cell carcinoma and negative for PKM2 expression; C: Moderately differentiated adenocarcinoma and positive for PKM2 expression; D: Signet ring cell carcinoma and positive for PKM2 expression.

the following samples were subjected to immunohistochemistry with a human PKM2 antibody: 368 paraffin-embedded, archived gastric cancer tissue samples, including 194 cases of stages I / II and 174 cases of stage III/IV tumors. The results are summarized in Table 1. PKM2 protein was detected in 144 of 368 (39.1%) human gastric cancer cases. Strong cytoplasmic staining of PKM2 was detected in 42 (11.4%) tumors and weak staining was detected in 102 (27.7%) tumors. As shown in Figure 2, PKM2 was mainly localized in the cytoplasm

of primary cancer cells. Diffuse and/or intense cytoplasmic staining was noted in only cancer cells. In contrast, PKM2 was either undetectable or only marginally detectable in the normal epithelial body gland of noncancerous tissues in the adjacent section regions (Figure 2).

Relationship between PKM2 expression and the clinical features of gastric cancers

As shown in Table 1, there was no correlation between stage and PKM2 expression ($P = 0.811$). PKM2 expres-

sion was strongly correlated with gastric cancer differentiation (*P* < 0.001). Differentiated type cancers expressed more PKM2 protein than did the undifferentiated ones. Well differentiated adenocarcinoma showed 63.6% PKM2-positive cells; in contrast, signet-ring cell cancers showed only 17.7% PKM2-positive cells.

Association between PKM2 expression and patient prognosis

We evaluated whether PKM2 expression could be a prognostic factor for gastric cancer. Two out of 368 patients died of non-cancer and were excluded from analysis. Table 2 shows that recurrence-free survival (RFS) and overall survival (OS) are significantly different between patients with different clinical stage (*P* < 0.001), T classification (*P* < 0.001), and N classification (*P* < 0.001). There was no significant difference in prognosis according to PKM2 expression.

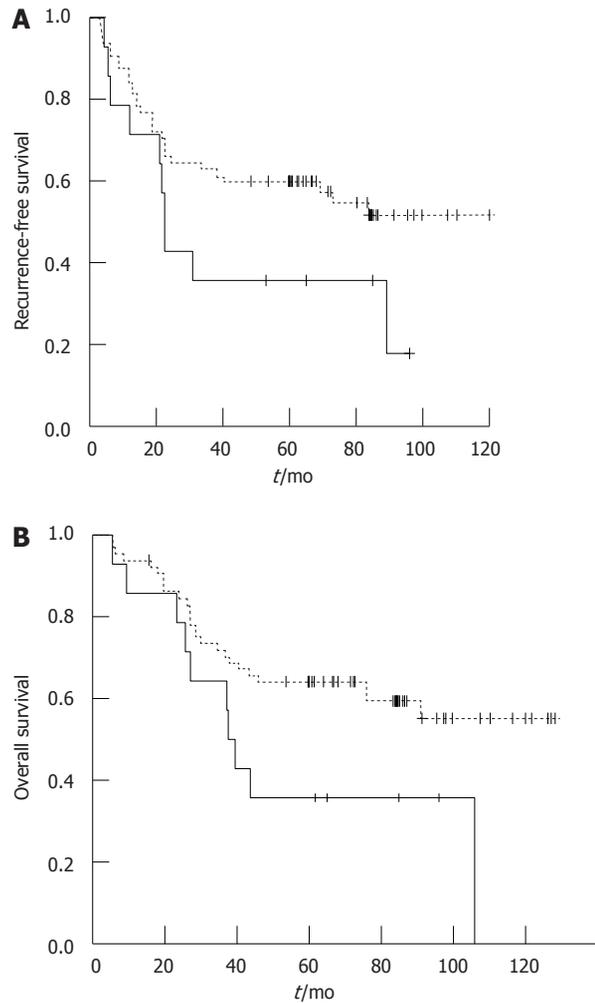

Figure 3 Recurrence-free survival (A) and overall survival (B) curves according to the M2 isoform of pyruvate kinase expression in signet ring cell gastric cancer after curative resection (*n* = 79). Positive M2 isoform of pyruvate kinase (PKM2) expression, real line; Negative PKM2 expression, dotted line.

We performed subgroup analysis at each tumor stage. In stages II or III patients, PKM2 expression showed no significant correlation with RFS or OS. However, in stage I early gastric cancer patients (*n* = 99), PKM2 expression was significantly correlated with poor RFS (*P* = 0.006) and OS (*P* = 0.015). Based on the observation that PKM2 expression rate was remarkably different according to cancer histology (Table 1), the prognostic value of PKM2 expression in patient subgroups was evaluated according to the histology. We found that in signet-ring cell carcinomas PKM2 expression correlated with poor prognosis (*P* = 0.042 for OS, Table 3 and Figure 3). Moreover, univariate and multivariate analyses showed that PKM2 expression, as well as clinical stage, were independent prognostic factors for survival (Table 3).

DISCUSSION

In this study, we report the characterization of PKM2 expression in human gastric cancers, and present its correlation with clinicopathological parameters and patients' prognosis. First, our study revealed that PKM2 is overex-

pressed in gastric cancers both at the mRNA and protein levels compared to normal gastric tissues. Well and moderately differentiated adenocarcinoma showed significantly higher expression of PKM2 (60% PKM2-positive cells); in contrast, signet-ring cell cancers showed only 17.7% PKM2-positive cells (Table 1). Because PKM2 is mainly localized in the cytoplasm of primary cancer cells and signet-ring cells contain a large amount of mucin and scanty cytoplasm, we hypothesize that this might explain the lower levels of PKM2 expression in these cells. This finding might be explained by the different glucose utilization rates of the various gastric cancer subtypes. Fluorine-18 fluoro deoxy-D-glucose positron emission tomography detected glucose uptake of tumor cells, and differentiated gastric cancers showed higher fluoro deoxy-D-glucose uptake rates than did undifferentiated ones^[19].

Second, PKM2 protein expression was found to negatively correlate with survival in signet-ring cell gastric cancer patients, as higher expression of PKM2 is associated with patients' shorter survival time ($P = 0.042$) after curative resection (Figure 3). Signet-ring cell carcinomas have a distinct biology and generally have worse prognosis than do other types of gastric cancer^[20]. A recent study reported that higher glucose uptake was indicative of a more aggressive disease especially in advanced signet-ring cell cancers^[21], although no biological mechanism was proposed to explain it. This finding is in agreement with our results. Thus, our study suggests that higher PKM2 expression, which indicates a higher rate of glycolysis in the tumor, might represent a novel prognostic marker for the clinical outcome of these types of gastric cancers.

PKM2 expression was related with poor prognosis only in stage I gastric cancer patients who did not receive chemotherapy. Only 4 of 99 patients showed relapse after curative gastrectomy, and in all cases, cancer cells were positive for PKM2 expression compared to the 36% patients overall who expressed PKM2. Furthermore, 3 patients had early relapses, within 1 year from the surgery, and all expressed high levels of PKM2 in the resected tissues. As cancer relapse in stage I patients are rare and four recurrent cases in our result are small number, it seems too early to conclude that PKM2 expression correlated with poor prognosis of stage I gastric cancer. However, it is clinical value to expand investigation in large cases. For stages II and III patients, there were no significant differences in survival. In a previous study, PKM2 was shown to positively correlate with the response to cisplatin in human gastric cancer cell lines^[18]. Cisplatin is the main chemotherapeutic agent for gastric cancers as either adjuvant or palliative aim. As cisplatin was administered as adjuvant therapy to 62.8% (147/234) of stages II or III gastric cancer patients after curative gastrectomy, the negative prognostic effect of PKM2 might be cancelled by cisplatin-based chemotherapy.

The possibility of using PKM2 as a target for the development of anti-cancer therapies has been evaluated in the preclinical setting^[22,23]. PKM2 knockdown by short hairpin RNA reduced the ability of human cancer cell lines to form tumors in nude mouse xenografts^[10,24]. If

anti-cancer strategies based on targeting PKM2 treatment are feasible, stage I or signet-ring cell cancer patients with PKM2 expression would be suitable candidates for such treatments.

The molecular function of PKM2 and its role in cancer are not completely understood yet. It was recently shown that PKM2 allows cancer cells to mount an anti-oxidant response and thereby support cell survival under acute oxidative stress^[25] and also induces epidermal growth factor receptor (EGFR)-dependent β -catenin transactivation, which leads to cell proliferation and tumorigenesis^[26]. These data are in agreement with our microarray study in which we also identified EGFR and β -catenin signaling, and hypoxic stress are linked to gastric cancer. Altogether, these studies suggest that the function of PKM2 in gastric cancer is very complex and needs to be further elucidated. In addition, the mechanisms of the regulation of PKM2 expression specifically in gastric tumors should be studied.

In conclusion, this study showed that PKM2 was overexpressed in gastric cancers. Moreover, PKM2 expression is an independent prognostic factor for signet ring cell carcinomas. The biological role of PKM2 in the development of these tumors needs to be further elucidated.

COMMENTS

Background

Gastric cancer is the major cause of cancer-related deaths worldwide. It is important to identify molecular markers to predict patients' outcomes and personalize treatments according to the individual biology. Clinical and prognostic implications of M2 isoform of pyruvate kinase (PKM2) as a marker for gastric cancer were unclear. The authors evaluated whether PKM2 expression is correlated with cancer progression and prognosis in human gastric cancer patients.

Research frontiers

PKM2 was identified as a driver of aerobic glycolysis, and has been shown to be overexpressed in tumor cells. PKM2 was selectively expressed in cancer cells and suggested valuable tumor marker for diagnosis or monitoring of various cancers. The biological function of PKM2 in cancer has been elucidated and PKM2 might be a candidate for anti-cancer target.

Innovations and breakthroughs

This study revealed that PKM2 was overexpressed in gastric cancers both at the mRNA and protein levels compared to normal gastric tissues and was found to negatively correlate with survival in signet-ring cell gastric cancer patients. PKM2 expression might be an adverse prognostic factor for signet-ring cell carcinomas. Its function and potential as a prognostic marker should be further verified in gastric cancer.

Applications

It is plausible to use PKM2 as an adverse prognostic marker of signet-ring cell cancer patients. If anti-cancer strategies based on targeting PKM2 treatment are feasible, signet-ring cell cancer patients with PKM2 expression would be suitable candidates for such treatments.

Terminology

Aerobic glycolysis: Many tumor cells have elevated rates of glucose uptake but reduced rates of oxidative phosphorylation. This persistence of high lactate production by tumors in the presence of oxygen was known as aerobic glycolysis. This metabolic switch may be required to support cell growth. High aerobic glycolysis by malignant tumors is utilized clinically to diagnose and monitor treatment responses of cancers and also to treat cancer using antagonist.

Peer review

This study investigated PKM2 expression in 368 gastric cancers and evaluated its potential as a prognostic biomarker based on relapse and survival data of patients. The results indicate that PKM2 positive expression could be used as an adverse prognostic marker in signet-ring cell gastric cancer.

Abstract

AIM: To investigate the relationship between the function of vagus nerve and peptide YY₃₋₃₆ and ghrelin levels after subtotal gastrectomy.

METHODS: We enrolled a total of 16 patients who underwent subtotal gastrectomy due to gastric cancer. All surgeries were performed by a single skilled surgeon. We measured peptide YY₃₋₃₆, ghrelin, leptin, insulin, growth hormone levels, and body weight immediately before and one month after surgery.

RESULTS: Vagus nerve preservation group showed less body weight loss and less increase of peptide YY₃₋₃₆ compared with vagotomy group (-5.56 ± 2.24 kg vs -7.85 ± 1.57 kg, $P = 0.037$ and 0.06 ± 0.08 ng/mL vs 0.19 ± 0.12 ng/mL, $P = 0.021$, respectively). Moreover, patients with body weight loss of less than 10% exhib-

ited reduced elevation of peptide YY₃₋₃₆ level, typically less than 20% [6 (66.7%) vs 0 (0.0%), $P = 0.011$, odd ratio = 3.333, 95% confidence interval (1.293, 8.591)].

CONCLUSION: Vagus nerve preservation contributes to the maintenance of body weight after gastrectomy, and this phenomenon may be related to the suppressed activity of peptide YY₃₋₃₆.

INTRODUCTION

Body weight loss is a common and serious outcome in patients with gastric cancer who are treated by gastrectomy^[1]. Weight loss is correlated with declines in postoperative quality of life and is the most reliable indicator of malnutrition, which impairs immune function, infection susceptibility, and survival^[2,3]. Postoperative body weight loss can be explained by mechanisms such as reduced food intake, appetite loss caused by the reduced reservoir or delayed gastric emptying^[4,5], diarrhea^[6] and malabsorp-

tion. Malabsorption, in turn, is linked to reduced secretion of gastric acid^[7] and pancreatic insufficiency^[8,9]. In addition, it was recently suggested that alterations of endocrine status, such as reduced gastrin^[8] or ghrelin^[10], and increased cholecystokinin levels^[5,8] might be involved in weight loss after gastrectomy. However, the mechanism of body weight loss after gastrectomy has not been fully clarified.

The 28-amino acid peptide ghrelin is the endogenous ligand for the growth hormone secretagogue receptor 1a, which stimulates the release of growth hormone from the pituitary gland^[11]. The majority of ghrelin is produced by X/A-like endocrine cells of the gastric oxyntic mucosa, and smaller amounts are secreted by other organs, such as the intestine, pancreas, kidney and hypothalamus^[12,13]. Ghrelin has a number of physiologic effects that result in positive energy balance, such as promoting the appetite signal in the hypothalamus as an antagonist to leptin^[14], stimulating gastrointestinal activities such as peristalsis, gastric acid secretion, and pancreatic excretion through the vagal nerves^[15], and regulation of fat metabolism. Peptide YY₃₋₃₆, a 36 amino acid gut-derived hormone, reduces food intake over the short term in animals^[16,17] and in humans^[18] by stimulating hypothalamic neuropeptide Y receptors. Preprandial decreases and postprandial increases in plasma peptide YY₃₋₃₆ concentrations suggest that peptide YY₃₋₃₆ is one of satiety signals. Peptide YY₃₋₃₆ is suggested to be involved in intermediate term inhibition of food intake, in contrast to the classical short term regulators such as cholecystokinin^[16]. Dose-dependent reductions in food intake following peripheral peptide YY₃₋₃₆ administration are observed in both fasting and freely feeding rodents^[16,17,19,20]. In healthy human volunteers, intravenous infusion of peptide YY₃₋₃₆ caused a sustained decrease in appetite and food intake for more than 24 h^[18]. Moreover, gastric bypass results in a more robust peptide YY₃₋₃₆ response to caloric intake, which, in conjunction with decreased ghrelin levels, may contribute to the sustained efficacy of this procedure^[21]. One animal study suggested that peptide YY release is inhibited through a vagal cholinergic mechanism due to significant elevations of basal and food-induced release of peptide YY after truncal vagotomy^[22].

Recently, one study reported that reductions in visceral fat were significantly lower in patients in whom the vagus nerve was preserved than in patients who had undergone vagotomy, and concluded that the vagus nerve locally regulates amounts of intra-abdominal fat tissue^[23]. However, they did not mention the hormonal changes regarding the effect of vagotomy and vagus nerve preservation on body weight loss. Therefore, we aimed to reveal the correlation between the effect of vagus nerve preservation and vagotomy on peptide YY₃₋₃₆ or ghrelin levels after subtotal gastrectomy in relation to body weight loss.

MATERIALS AND METHODS

Patients

Sixteen patients who underwent subtotal gastrectomy at Gospel Hospital, Kosin University College of Medicine,

Busan, South Korea between January 2008 and January 2010 were enrolled in the study. The inclusion criteria were as follows: (1) adenocarcinoma of the stomach confirmed by histopathologic examination; (2) preoperative clinical staging of less than stage IIIA (International Union Against Cancer tumor, node, metastasis stage classification); (3) curative surgical treatment (R0) (i.e., subtotal gastrectomy with D1 or D2 lymph node dissection); and (4) age between 20 and 80 years. The exclusion criteria were the presence of any of the following: (1) cardiopulmonary, liver, or renal dysfunction; (2) active dual malignancy; (3) pregnancy; (4) past history of gastrointestinal surgery; and (5) postoperative complications after subtotal gastrectomy that could affect oral food intake, such as anastomotic leakage, pancreatitis, and mechanical ileus. Sixteen patients were randomized by sealed-envelope selection and divided into two study groups. The random allocation sequence was concealed until interventions were assigned. Nine patients were treated by subtotal gastrectomy with vagus nerve preservation (vagus nerve preservation group), and seven patients underwent both subtotal gastrectomy and vagotomy (vagotomy group). The study was approved by the Kosin University Ethics Committee, and all patients provided written informed consent before study entry in accordance with the Declaration of Helsinki.

Operative procedures

In seven cases, subtotal gastrectomy and bilateral truncal vagotomy were performed with D1 or D2 lymph node dissection followed by Billroth-I or Roux-en-Y reconstruction. The hepatic and celiac branches of the vagus nerve were preserved in nine patients who underwent Billroth-I or Roux-en-Y reconstruction after subtotal gastrectomy with D1 or D2 lymph node dissection. The greater omentum was largely preserved in all cases. All operations were performed by a surgeon with a history of over 1000 gastric cancer operations over the course of 20 years. An ultrasonic knife (Ultracision[®], Ethicon Endo Surgery, Cincinnati, OH, United States) was used to prevent nerve damage in the vagus nerve preservation group. Electrical impulses were produced by a high-frequency ultrasound generator, transferred to a hand piece and converted into mechanical movement at a frequency of 55.5 kHz. This instrument was chosen because of the relatively low temperatures generated, ranging from 50 °C to 100 °C, which limit damage to adjacent tissue compared to conventional diathermy. Diathermy produces temperatures up to 400 °C, resulting in char formation and deleterious thermal effects to a distance of up to 1 cm from the blade, as well as the extensive formation of necrotic tissue.

Body weight and blood sampling for hormone measurement in the fasted state

Peptide YY₃₋₃₆, ghrelin, leptin, insulin, and growth hormone levels as well as body weights were measured 1 d before surgery (day 1) and 1 mo after surgery (day 30). Venous fasting blood samples were taken early in the

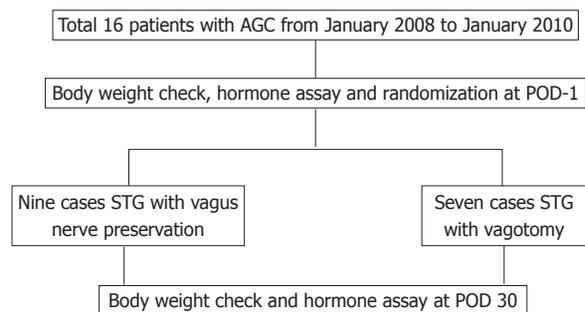

Figure 1 Flowchart for investigating effects of vagus nerve preservation and vagotomy on body weight and hormones such as peptide YY, ghrelin, leptin, insulin and growth hormone after total gastrectomy due to gastric cancer. AGC: Advanced gastric cancer; POD: Postoperative day; STG: Subtotal gastrectomy.

morning on day 1 and day 30 for the measurement of plasma concentrations of the following hormones: peptide YY₃₋₃₆ (enzyme-linked immunosorbent assay, Phoenix Pharmaceuticals Inc., Belmont, CA, United States), total ghrelin (radioimmunoassay, Linco Research Inc., St. Louis, MO, United States), leptin (radioimmunoassay, Linco Research Inc.), insulin (two-site sandwich immunoassay, Siemens Medical Solutions Diagnostics, Los Angeles, CA, United States), and human growth hormone (radioimmunoassay, Packard Instruments Inc., Chicago, IL, United States). Peptide YY₃₋₃₆, insulin, and growth hormone levels were measured with the V-MAX 220 VAC enzyme-linked immunosorbent assay reader (Molecular Devices, Sunnyvale, CA, United States), ADVIA Centaur XP (Siemens, Tarry-town, NY, United States), and COBRA II Gamma counter (PacKard, Waltham, MA, United States), respectively. Ghrelin and leptin were analyzed with the COBRA II Gamma Counter (PacKard, United States). Total protein, albumin, total cholesterol, and triglyceride levels were tested with the ADVIA 2400 (Siemens, Tarry-town, NY, United States).

Statistical analysis

Statistical analysis was performed using the SPSS software (version 16.0, SPSS, Chicago, IL, United States). Differences between the vagus nerve preservation group and the vagotomy group, including sex, age, stages of gastric cancer, body weight, body mass index (BMI), and laboratory values were assessed by Fisher's exact tests and Mann-Whitney *U* test. Wilcoxon signed rank test was used to calculate the changes between pre and post-operative values in body weight, BMI, peptide YY₃₋₃₆, ghrelin, leptin, insulin, growth hormone, and other laboratory profiles of all patients. The differences in body weight, BMI, hormones, and other laboratory values between two groups one month after operation were calculated by Mann-Whitney *U* test. Fisher's exact tests were used to validate the correlation among vagus nerve preservation, body weight loss of less than 10%, and peptide YY₃₋₃₆ level increases of less than 20%. Statistical significance was set at a *P* value of < 0.05.

RESULTS

Patient characteristics

The study flow diagram is summarized in Figure 1. There was no significant difference in age, sex, body weight, BMI, clinical stage of gastric cancer, pathologic types, and laboratory profiles including hormone values between the two groups. Table 1 summarizes the clinical and laboratory background of the 16 patients who completed the study.

Changes of body weight and hormones

All patients demonstrated body weight loss (preoperative body weight: 62.51 ± 9.02 kg *vs* postoperative body weight: 56.02 ± 8.32 kg, *P* < 0.001) with decreased BMI (23.71 ± 2.94 kg/m² *vs* 21.33 ± 2.62 kg/m², *P* < 0.001). All patients have increased peptide YY₃₋₃₆ (0.41 ± 0.09 ng/mL *vs* 0.52 ± 0.15 ng/mL, *P* = 0.020), and decreased ghrelin (787.34 ± 421.33 pg/mL *vs* 506.21 ± 201.10 pg/mL, *P* = 0.007) postoperatively. Insulin levels were significantly increased in most patients (4.59 ± 6.12 mIU/L *vs* 1.86 ± 1.49 mIU/L, *P* = 0.001). There was no correlation between the basal values of peptide YY₃₋₃₆ and the extent of body weight loss. There were no significant changes in leptin and growth hormone levels after surgery. No significant differences were found in albumin, protein, triglyceride, and total cholesterol levels either. Vagus nerve preservation group showed less decrease in

All data were expressed as mean ± SD. ¹95% confidence interval (CI) = -4.445 to -0.157; ²95% CI = -1.902 to -0.103; ³95% CI = -0.224 to -0.022; ⁴95% CI = -0.320 to -0.032. BMI: Body mass index; HOMA: Homeostatic model assessment; NS: Not significant.

body weight (-5.56 ± 2.24 kg *vs* -7.85 ± 1.57 kg, $P = 0.037$) and BMI (-1.91 ± 1.04 kg/m² *vs* -2.91 ± 0.39 kg/m², $P = 0.031$) than vagotomy group. Moreover, less elevation of peptide YY₃₋₃₆ was observed in vagus nerve preservation group (0.06 ± 0.08 ng/mL *vs* 0.19 ± 0.12 ng/mL, $P = 0.021$) than vagotomy group. Total protein, albumin, total cholesterol, and triglyceride levels did not show significant changes between two groups after surgery. These results were presented in Table 2. Vagus nerve preservation group showed significantly lower post-operative peptide YY₃₋₃₆ value than vagus nerve preserved group (0.44 ± 0.07 ng/mL *vs* 0.62 ± 0.17 ng/mL, $P = 0.020$). However, there were no differences in other post-operative values between two groups. These post-operative findings were described in Table 2.

Relationships among vagus nerve preservation, body weight change, and peptide YY₃₋₃₆ change

Patients were separated into groups based on the changes of body weight and peptide YY₃₋₃₆. Body weight loss of less than 10% was more frequently observed in vagus nerve preservation group [6 (66.7%) *vs* 0 (0.0%), $P = 0.011$, odd ratio (OR) = 3.333, 95% confidence interval (95% CI) (1.293, 8.591); Figure 2A]. Increases of peptide YY₃₋₃₆ less than 20% was more frequently noticed in the vagus nerve preservation group after surgery [5 (55.6%) *vs* 0 (0.0%), $P = 0.034$, OR = 2.750, 95% CI (1.258, 6.010); Figure 2B]. Patients with body weight loss of less than 10% exhibited significant correlation with reduced elevation of peptide YY₃₋₃₆ level, typically less than 20% [5 (83.3%) *vs* 0 (0.0%), $P = 0.001$, OR = 11.000, 95% CI (1.697, 71.282); Figure 2C].

DISCUSSION

Weight loss is a common complication after gastrectomy. However, the effects of different surgical procedures associated with gastrectomy on postoperative body weight

loss and hormonal changes are not well understood. In the present study, we examined changes in body weight, peptide YY₃₋₃₆, ghrelin, leptin, growth hormone, and insulin levels in vagus nerve preservation and vagotomy groups.

Although all 16 patients who underwent subtotal gastrectomy exhibited body weight loss, the vagus nerve preservation group demonstrated significantly less decreases in body weight and BMI than the vagotomy group. This study reproduces the findings of Melissas *et al*^[7] who postulated that this phenomenon might be explained by the energy saving function of the vagus nerve as a major parasympathetic nerve innervating visceral organs. The sympathetic nervous system predominates during energy-spending catabolic states, whereas in energy-saving anabolic states the parasympathetic nervous system prevails^[24,25]. Anatomical and physiological studies have demonstrated the innervation of adipose tissue by sympathetic nerves, which in turn accelerate lipolysis of adipocytes^[26,27]. The vagotomy group showed significantly greater visceral fat mass reduction than the vagus nerve preservation group^[7]. In our study, vagus nerve preservation presented 3.333 fold more chance than vagotomy group for body weight loss less than 10% (95% CI from 1.293 to 8.591).

All patients in this study showed increased peptide YY₃₋₃₆ levels after subtotal gastrectomy. A previous study demonstrated that stomach gastrin inhibited peptide YY secretion in rats^[28]. All study patients lost the antrum after subtotal gastrectomy, therefore reducing the effect of stomach gastrin on peptide YY. This is a possible explanation for the elevation of peptide YY levels in these patients. An alternative explanation for this phenomenon is that there is a negative correlation between fasting peptide YY₃₋₃₆ and markers of adiposity^[18,29-31]. In addition, fasting peptide YY levels are significantly higher in anorexia nervosa sufferers than normal weight controls. In rodent studies, mice exposed to a high-fat diet develop

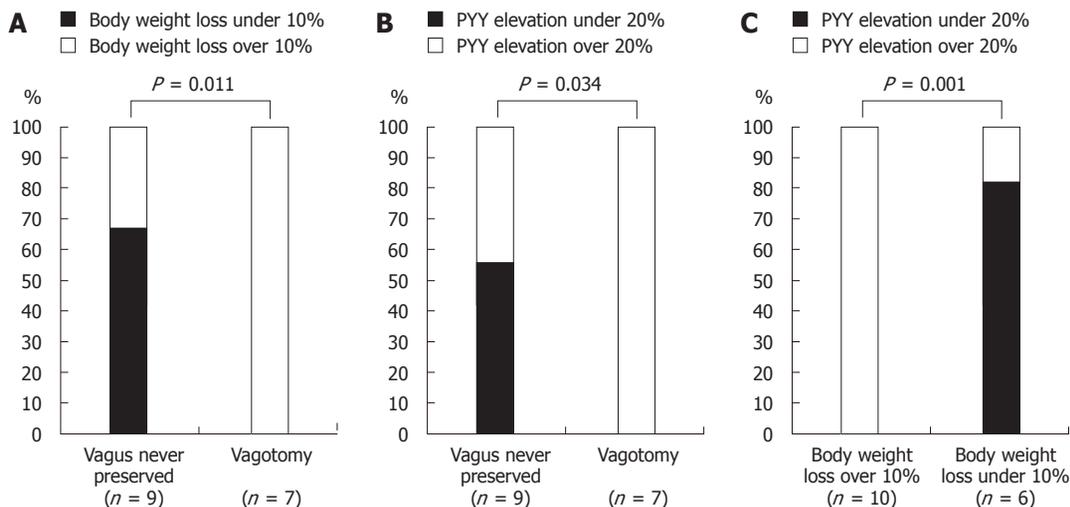

Figure 2 Correlations among vagus nerve preservation, body weight loss and peptide YY₃₋₃₆ increase. A: Vagus nerve preservation was correlated with body weight loss less than 10% [66.7% vs 0.0%, $P = 0.011$, odd ratio (OR) = 3.333, 95% confidence interval (95% CI) (1.293, 8.591)]; B: The vagus nerve preservation group showed significant correlation with peptide YY₃₋₃₆ level increases of less than 20% [55.6% vs 0.0%, $P = 0.034$, OR = 2.750, 95% CI (1.258, 6.010)]; C: Patients with body weight loss of less than 10% exhibited tight correlation with reduced elevation of peptide YY₃₋₃₆ level, typically less than 20% [83.3% vs 0.0%, $P = 0.001$, OR = 11.000, 95% CI (1.697, 71.282)]. PYY: Peptide YY.

obesity and a concomitant reduction in circulating peptide YY^[32,33].

Vagus nerve preservation group demonstrated significantly less increase in peptide YY₃₋₃₆ than vagotomy group in the present study. Moreover, the vagus nerve preservation group demonstrated a tight correlation with increases in peptide YY₃₋₃₆ levels of less than 20%. According to a previous animal study, truncal vagotomy resulted in significant elevations of basal and food-induced release of peptide YY^[22]. This suggests that peptide YY release is inhibited tonically, probably through a vagal cholinergic mechanism. Adrenergic pathways did not participate in food-stimulated peptide YY release. However, electrical stimulation of the splanchnic nerves increased basal levels of peptide YY, suggesting that the sympathetic nervous system affects the release of peptide YY^[22]. This agrees with our finding that the vagus nerve preservation group showed reduced elevation of peptide YY₃₋₃₆ levels in comparison to the vagotomy group, although increased peptide YY₃₋₃₆ levels were observed in both groups. An alternative explanation for more elevation of peptide YY₃₋₃₆ in the vagotomy group could be a compensatory increase in peptide YY₃₋₃₆ secretion in response to reduced peptide YY₃₋₃₆ signaling to the hindbrain *via* the vagus. Thus peptide YY₃₋₃₆ may exert its effects on body weight by acting centrally, *via* vagal stimulation, or both. Many lines of evidence suggest that peptide YY₃₋₃₆ exerts its effects on feeding *via* the hypothalamus; intra-arcuate injection of peptide YY₃₋₃₆ reduces feeding, whereas Y2-antagonist injection has the opposite effect^[34]. Thus, vagotomy, transection of hindbrain-hypothalamic pathways, can cause compensatory increase of peripheral peptide YY₃₋₃₆.

When correlations between body weight loss and increase of peptide YY₃₋₃₆ levels were performed, patients who demonstrated body weight loss of less than 10% ex-

hibited lower increases in peptide YY₃₋₃₆ levels, less than 20%. Because vagus nerve preservation is associated with lower increases in peptide YY₃₋₃₆ levels and reductions in body weight loss, it is not clear whether the lower increase in peptide YY₃₋₃₆ levels actually caused less body weight loss. However, we cannot exclude the possibility that peptide YY₃₋₃₆ levels influence body weight, as peptide YY₃₋₃₆ has been shown to suppress appetite and promote weight loss^[16,17,19,20,35]. In healthy human volunteers, intravenous infusion of peptide YY₃₋₃₆ causes sustained decreases in appetite and food intake for more than 24 h^[18]. Energy intake by obese subjects during a buffet lunch was reduced by 30% after intravenous infusion of peptide YY₃₋₃₆^[18]. Chronic administration of peptide YY₃₋₃₆ inhibits food intake and reduced body weight gain in mice, rabbits, and rhesus macaques^[16,35,36]. In addition, daily food intake, body weight, and body fat are increased in peptide YY knockout mice in comparison to wild-type mice^[32]. Although the number of patients enrolled in the present study was limited, these findings suggest that elevated basal peptide YY₃₋₃₆ levels may contribute to body weight loss after subtotal gastrectomy.

All patients in this present study demonstrated increased plasma insulin after operation. A previous study showed the partial gastrectomy and intestinal resection induced impaired oral glucose tolerance despite normal insulin concentrations^[37]. Increased basal level insulin might reflect the impaired insulin tolerance in the present study although it was not proved by oral glucose tolerance test.

There are five limitations in our study. First, patient appetite was not assessed. Assessing subjects' appetite on a visual analogue scale before and after surgery would have allowed us to evaluate the relationship between changes in peptide YY₃₋₃₆ levels and changes in appetite. Second, unfortunately, this present study did not include

data from meal-stimulated secretions of peptide YY or other hormones such as glucagon like peptide-1, which could have shed more light on the true interaction effects between vagus nerve preservation/vagotomy and gastrointestinal hormonal functions and body weight. Third, we did not evaluate body composition. Evaluating changes in body composition may have helped to elucidate the correlations between vagus nerve preservation, changes in peptide YY₃₋₃₆ levels, and changes in specific body composition, especially visceral fat levels. Fourth, only total ghrelin was measured, since active octanoylated ghrelin is unstable. Although both total and active ghrelin appear to be regulated in a similar and parallel manner, future studies will need to focus on measurement of the biologically active form. Finally, small number of patients was enrolled in the present study.

In summary, body weight loss, increased peptide YY₃₋₃₆ levels, and decreased ghrelin levels were observed in all patients after subtotal gastrectomy. Vagus nerve preservation group showed less decrease in body weight and BMI than vagotomy group. Less increase of peptide YY₃₋₃₆ was observed in vagus nerve preservation group. Moreover, patients with body weight loss of less than 10% exhibited reduced elevation of peptide YY₃₋₃₆ level, typically less than 20%. Based on these results and those of previous studies, we concluded that vagus nerve preservation resulted in reduced body weight loss after subtotal gastrectomy, in direct relation with peptide YY₃₋₃₆ activities and suggest that vagus nerve should be preserved for preventing excessive body weight loss after subtotal gastrectomy due to gastric cancer.

COMMENTS

Background

Body weight loss is a common and serious outcome in patients with gastric cancer who are treated by gastrectomy. Weight loss is correlated with declines in postoperative quality of life and is the most reliable indicator of malnutrition, which impairs immune function, infection susceptibility, and survival. Patients who underwent vagus nerve-preserving procedures lose less body weight than patients treated with vagotomy after gastrectomy.

Research frontiers

Ghrelin has a number of physiologic effects that result in positive energy balance, such as promoting the appetite signal in the hypothalamus as an antagonist to leptin. Peptide YY₃₋₃₆ is suggested to be involved in intermediate term inhibition of food intake, in contrast to the classical short term regulators such as cholecystokinin. Recently, one study reported that reductions in visceral fat were significantly lower in patients in whom the vagus nerve was preserved than in patients who had undergone vagotomy, and concluded that the vagus nerve locally regulates amounts of intra-abdominal fat tissue.

Innovations and breakthroughs

This study is the first to evaluate relationship between the differences in weight loss between patients treated with vagus nerve-preserving procedures and vagotomy and the changes of peptide YY₃₋₃₆ and ghrelin levels after subtotal gastrectomy. Vagus nerve preservation group showed less decrease in body weight and BMI than vagotomy group. Less increase of peptide YY₃₋₃₆ was observed in vagus nerve preservation group. Moreover, patients with body weight loss of less than 10% exhibited reduced elevation of peptide YY₃₋₃₆ level, typically less than 20%. Based on these results, the authors concluded that vagus nerve preservation resulted in reduced body weight loss after subtotal gastrectomy, in direct relation with peptide YY₃₋₃₆ activities

Applications

Present study showed that vagus nerve preservation resulted in less decrease

in body weight and BMI than vagotomy group. Furthermore, this study suggested plausible peptide YY₃₋₃₆ activities in this phenomenon. Considering these findings, the authors cautiously suggest to preserve vagus nerve during subtotal gastrectomy for less body weight loss.

Peer review

This is a good experiment study in which authors analyze the cause of the differences in weight loss between patients treated with vagus nerve-preserving procedures and vagotomy in the view of the changes of peptide YY₃₋₃₆ and ghrelin levels after subtotal gastrectomy. The findings that vagus nerve preservation resulted in reduced body weight loss after subtotal gastrectomy, in direct relation with peptide YY₃₋₃₆ activities suggesting the possible role of peptide YY₃₋₃₆ in this phenomenon.

papilloma virus (HPV) infection and colorectal cancer.

METHODS: Sixty-nine patients with pathologically confirmed primary colorectal cancer including 6 stage I, 24 stage II, 21 stage III, and 18 stage IV patients were enrolled in this study to investigate whether HPV 16 could be involved in colorectal tumorigenesis. Nested-polymerase chain reaction (nested-PCR) was used to detect HPV16 DNA in colorectal tumor tissues and further confirmed by *in situ* hybridization (ISH). In addition, immunohistochemistry analysis was performed to examine the E6 oncoprotein in colorectal tumors. To verify whether E6 could inactivate the p53 transcriptional function, the levels of p21 and Mdm2 mRNA expression were evaluated by real-time reverse transcription (RT)-PCR.

RESULTS: Of the 69 colorectal tumors, HPV16 DNA was detected in 11 (16%) by nested-PCR, and HPV16 DNA was present in 8 of the 11 (73%) tumors which was confirmed by ISH. The presence of HPV16 DNA in colorectal tumors was not associated with patients' clinical parameters including age, gender, smoking status, tumor site; however, HPV16 infection was more common in stage I patients than in late-stages patients (II, III and IV). We next asked whether HPV16 infection could be linked with colorectal cancer development. Immunohistochemical data indicated that 8 of the 11 HPV16 DNA-positive tumors had E6 oncoprotein expression. Moreover, we also observed that the adjacent normal tissues including endothelial cells, lymphocytes, fibroblasts, and gland cells in E6-positive tumors had E6 oncoprotein expression. In addition, 3 of the 4 (75%) E6-positive tumors carrying p53 wild-type had negative immunostaining, but one tumor had less p53 immunostaining. We further examined whether E6-positive and/or p53 mutated tumors reduce p53 transcriptional activity. Real-time RT-PCR analysis indicated that p21 and mdm2 mRNA expression levels in E6/p53-wildtype tumors were significantly lower than in their adjacent

Abstract

AIM: To investigate the association between human

normal tissues; as expected, E6-positive/p53-mutated tumors had lower p21 and mdm2 mRNA expression levels compared with their adjacent normal tissues. These results clearly indicate that the E6 oncoprotein expressed in p53 wildtype tumors may reduce p21 and mdm2 expression *via* p53 inactivation.

CONCLUSION: These results suggest that HPV16 infection may be involved in a subset of colorectal cancer, and we suggest that the transmission of HPV to the colon and rectum might occur through peripheral blood lymphocytes.

Human papilloma virus 16 E6 oncoprotein associated with p53 inactivation in colorectal cancer. *World J Gastroenterol* 2012; 18(30): 4051-4058 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i30/4051.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i30.4051>

INTRODUCTION

A high risk of human papilloma virus (HPV) 16/18 infection has been documented to be involved in the development of cervical and anal genital cancers^[1]. Among non-genital cancers, the association of HPV16/18 infection and oropharyngeal cancer was recently evidenced^[2-4]. However, other non-genital cancers, including lung, breast, and colorectal cancers have not yet been identified^[5-12]. This is due to a lack of clarity as to how HPV transmits to internal organs even though blood circulation has been suggested as a possible route of infection^[13,14].

In the past two decades, a large body of research has demonstrated an association between HPV infection and colorectal cancer^[5,6,15-17]. Studies have shown HPV16 to be the major HPV subtype in colorectal tumors^[16,17]. However, inconsistent conclusions have been drawn on this issue because only HPV DNA detection is used to associate HPV and colorectal cancer; there is no evidence to demonstrate that HPV is involved in colorectal cancer development. It is well known that HPV DNA integration into the host chromosome plays a crucial role in HPV-associated tumorigenesis^[18]. When HPV DNA was spliced at E2, E6 and E7 oncoproteins were expressed which inactivated the p53 and Rb pathways^[18]. Therefore, in the present study, 69 tumors resected from colorectal cancer patients were enrolled to determine the presence

of HPV16 DNA by nested polymerase chain reaction (PCR) and *in situ* hybridization (ISH), and expressions of E6 and p53 proteins were evaluated by immunohistochemistry (IHC) in colorectal tumor paraffin serial sections. We explored whether HPV16 DNA could exist and express E6 oncoprotein to inactivate the p53 pathway in colorectal tumors. We next asked whether HPV16 DNA and E6 oncoprotein could be expressed in adjacent normal tissue cells, such as endothelial cells and lymphocytes, to understand whether colorectal tumors infected with HPV16 could be spread through blood circulation.

MATERIALS AND METHODS

Study subjects

We collected tumor specimens from 69 patients with colorectal cancer. All of these patients, including 34 females and 35 males who were admitted to the Department of Surgery at Chung Shan Medical University Hospital, Taichung, Taiwan between 2000 and 2005, were asked to submit a written informed consent approved by the Institutional Review Board. A series of examinations for pathological stages were conducted for each case by board-certified pathologists based on the criteria in the 7th edition of the American Joint Committee on Cancer. We collected information pertaining to personal characteristics from hospital reports. Smokers were defined as those who were active smokers or previous smokers and nonsmokers were those who had never smoked.

Immunohistochemistry

Formalin-fixed and paraffin-embedded specimens were sectioned at a thickness of 3 μ m. All sections were then deparaffinized in xylene, rehydrated through serial dilutions of alcohol, and washed in phosphate-buffered saline (pH 7.2), the buffer that was used for all subsequent washes. For HPV16 E6 and p53 detection, sections were heated in a microwave oven twice for 5 min in citrate buffer (pH 6.0), and then incubated with a monoclonal anti-human p53 antibody (DAKO, DO7, Denmark; at a dilution of 1:250) for 60 min at 25 °C or with monoclonal anti-HPV16 (Santa Cruz, CA, United States) for 90 min at 25 °C. The conventional streptavidin peroxidase method (DAKO, LSAB Kit K675, Copenhagen, Denmark) was performed to develop signals and the cells were counter-stained with hematoxylin. Negative controls were obtained by leaving out the primary antibody. The intensities of signals were evaluated independently by three observers. The results were evaluated independently by three observers and scored for the percentage of positive nuclei: score 0, no positive staining; score +, from 1% to 10%; score ++, from 1% to 50%; score +++, more than 50% positive cells. Positive control slides for p53 protein detection were purchased from DAKO (Denmark) and the cervical cancer tumor tissues with HPV16 were used as a positive control for HPV16 E6. The antibody dilution buffer replaced the antibodies to serve as a negative control.

Direct sequencing

Mutations in exons 5-8 of the *p53* gene were determined by direct sequencing of PCR products amplified from the DNA of tumor cells isolated by microdissection of the colorectal tumor tissues. DNA lysis buffer was used to lyse cells and then the solution was subjected to proteinase K digestion and phenol-chloroform extraction. Finally, the DNA was precipitated by ethanol. Target sequences were amplified in a 50 μ L reaction mixture containing 20 pmol of each primer, 2.5 units of Taq polymerase (TAKARA Shuzo, Shiga, Japan), 0.5 mmol/L dNTPs, 5 μ L PCR reaction buffer, and 1 μ L genomic DNA as the template. Genomic DNA sequences extracted from the frozen sections were not adequate for an amplification of long fragment DNA sequences, and therefore, PCR products ranging from 200 to 400 bp were amplified for *p53* mutation analysis. Primers for β -actin, which act as an internal control, were included in each amplification reaction. The primers used in the reactions were E5S (5'TGCCCTGACTTTCAACTCTG3') and E5AS (5'GCTGCTCACCATCGCTATC3') for exon 5, E6S (5'CTGATTCCCTCACTGATTGCT3') and E6AS (5'AGTTGCAAACCAGACCTCAGG3') for exon 6, E7S (5'CCTGTGTTATCTCCTAGGTTG3') and E7AS (5'GCACAGCAGGCCAGTGTGCA3') for exon 7, and E8S (5'GACCTGATTTCCCTTACTGCC3') and E8AS (5'TCTCCTCCACCGCTTCTTGT3') for exon 8. An initial cycle was performed for 5 min at 94 °C; followed by 35 cycles of 40 s at 94 °C, 40 s at 54 °C, and 1 min at 72 °C. The PCR products were sequenced using an Applied Biosystems 3100 Avant Genetic Analyzer (Applied Biosystems, Foster City, CA, United States), and the same primers were used for both the PCR and for the DNA sequencing. All *p53* mutations were confirmed by direct sequencing of both DNA strands.

Nested polymerase chain reaction

Genomic DNA was prepared from a tissue section and isolated by conventional phenol-chloroform extraction, ethanol precipitation, and was finally dissolved in 20 μ L of sterile distilled water. HPV viral DNA was first amplified with consensus primers MY09 and MY11^[19] followed by a second round of amplification with type-specific primers flanking the L1 region to identify the subtype. Ten microliters of the final PCR product were loaded onto a 2% agarose gel, stained with ethidium bromide, and visualized under ultraviolet-visible illumination. Appropriate negative and positive controls were included in each PCR reaction. A part of the β -actin gene in all samples was amplified to exclude false-negative results while DNA preparations from the SiHa cell (containing HPV16) were used as positive controls.

ISH

ISH for the detection of HPV type 16 DNA was performed using digoxigenin-labeled (DIG-labeled) oligonucleotide probes and a commercially available hybridization kit (Boehringer Mannheim, Indianapolis, IN). Briefly,

the hybridizing probes were prepared by PCR amplification using HPV 16 type-specific primers with DIG-deoxyuridine triphosphate as a substrate according to the manufacturer's instructions^[19]. The deparaffinized and rehydrated 5 μ m sections were digested with proteinase K, rinsed with PBS, and dehydrated. The hybridization was performed in a humidified chamber at 48 °C for 16 h followed by a wash with sodium chloride-sodium citrate. Thereafter, the detection reagent (anti-DIG antibody conjugated with peroxidase) was applied to the sections and then the sections were incubated in diaminobenzidine solution to allow the signals to develop. After the signal development, the sections were counterstained with hematoxylin, rinsed briefly in absolute ethanol, mounted, and observed for signals under a microscope.

Preparation of RNA and real-time quantitative RT-PCR

Total RNA was extracted from the colorectal tumors after homogenization in 1 mL TRIzol reagent, followed by chloroform re-extraction and isopropanol precipitation. Three micrograms of total RNA from the colorectal tumor tissues were reverse transcribed using SuperScript II Reverse Transcriptase (Invitrogen, CA, United States) and oligo d(T)₁₅ primer. Real-time RT-PCR was performed in a final volume of 25 μ L containing 1 μ L of each cDNA template, 10 pmoles of each primer, and 12.5 μ L of a SYBR-Green master mix. The primers were designed using ABI Prism 7000 SDS Software. Quantification was carried out using the comparative threshold cycle (CT) method and water was used as the negative control. An arbitrary threshold was chosen on the basis of the variability of the baseline. CT values were calculated by determining the point at which the fluorescence exceeded the threshold limit. CT was reported as the cycle number at this point. The average of the target gene was normalized to *18S rRNA* as the endogenous housekeeping gene.

Statistical analysis

Statistical analysis was performed using the SPSS statistical software program (Version 11.0 SPSS Inc., Chicago, IL, United States). The χ^2 test, Fisher's exact test (two tailed), and Mann-Whitney test were applied for statistical analysis.

RESULTS

HPV16 DNA does indeed exist in a subset of colorectal tumors

Sixty-nine colorectal tumors were collected to evaluate HPV16 DNA. As shown in Figure 1, the presence of HPV16 DNA in colorectal tumors was determined by nested PCR using MY09/MY11 and specific primers, and 11 of 69 tumors (16%) possessed positive HPV16 DNA signals. The relationships between HPV16 DNA and clinicopathological features were statistically analyzed (Table 1). Our data showed that HPV16 DNA was present more frequently in stage I tumors than in late-stage tumors (66.7% for stage I vs 12.5% for stage II, 9.5% for stage III,

and 11.1% for stage IV, *P* = 0.017). However, the presence of HPV16 DNA in colorectal tumors was not associated with other clinicopathological features including gender, age, smoking status, and tumor site (Table 1). To further confirm the presence of HPV16 DNA, ISH was conducted to determine the presence of HPV16 DNA in 11 colorectal tumor paraffin sections. ISH data indicated that 8 of the 11 tumors (72.7%) had positive HPV16 DNA signals (Table 2 and Figure 2). Collectively, these results clearly indicate that HPV16 DNA exists in a subset of colorectal tumors, at least in this study population.

E6 oncoprotein is expressed in HPV16 DNA-positive colorectal tumors and related to p53 inactivation

To explore whether HPV16 infection could be linked with colorectal cancer development, HPV16 E6 oncoprotein was evaluated by IHC in HPV16 DNA-positive colorectal tumors. Our data showed that E6 oncoprotein expression was detected in all HPV16 DNA-positive tumors (Table 2). We next examined whether E6 oncoprotein expressed in four p53 wild-type colorectal tumors (P101, P134, P141 and P169) could degrade p53 protein to produce tumors

Table 3 p21 and Mdm2 mRNA expression levels in tumor tissues and adjacent normal tissues of E6-positive colorectal patients

Variable	E6-positive (<i>n</i> = 8)			
	p53 wild-type (<i>n</i> = 4)	<i>P</i>	p53-mutation (<i>n</i> = 4)	<i>P</i>
P21 mRNA		0.025		0.061
Adjacent normal tissues	348.46 ± 143.89		241.12 ± 84.13	
Tumor tissues	49.62 ± 16.58		122.96 ± 45.28	
Mdm2 mRNA		0.032		0.043
Adjacent normal tissues	563.74 ± 252.28		541.50 ± 100.56	
Tumor tissues	111.60 ± 75.99		317.74 ± 137.59	

with p53 negative immunostaining (Figure 2). IHC analysis clearly showed p53 negative immunostaining in three out of four colorectal tumors (P101, P141, and P169), but one tumor (P134) had p53 positive immunostaining (< 10%). The other four E6-positive tumors with p53 mutations (P142, P167, P173 and P200) still had p53 positive immunostaining (Figure 2). To explore whether p53 inactivation could have occurred in p53 wild-type E6-positive tumors, expression levels of the p53-downstream targets Mdm2 and p21 mRNA were decreased compared with adjacent normal tissues. Real-time RT-PCR analysis showed that Mdm2 and p21 mRNA expression levels in these E6-positive tumors with p53 wild-type were significantly lower than in their adjacent normal tissues (*P* = 0.025 for p21 mRNA; *P* = 0.032 for Mdm2 mRNA; Table 3). As expected, both gene mRNA expression levels in E6-positive tumors with p53 mutations were lower than in the adjacent normal tissues (*P* = 0.043 for Mdm2 mRNA); however, p21 mRNA levels were marginally different between tumors and adjacent normal tissues (*P* = 0.061). These results clearly indicate that E6 oncoprotein is expressed in HPV16 DNA-positive colorectal tumors and may be linked with p53 inactivation in these HPV16 DNA positive tumors, which had the p53 wild-type gene.

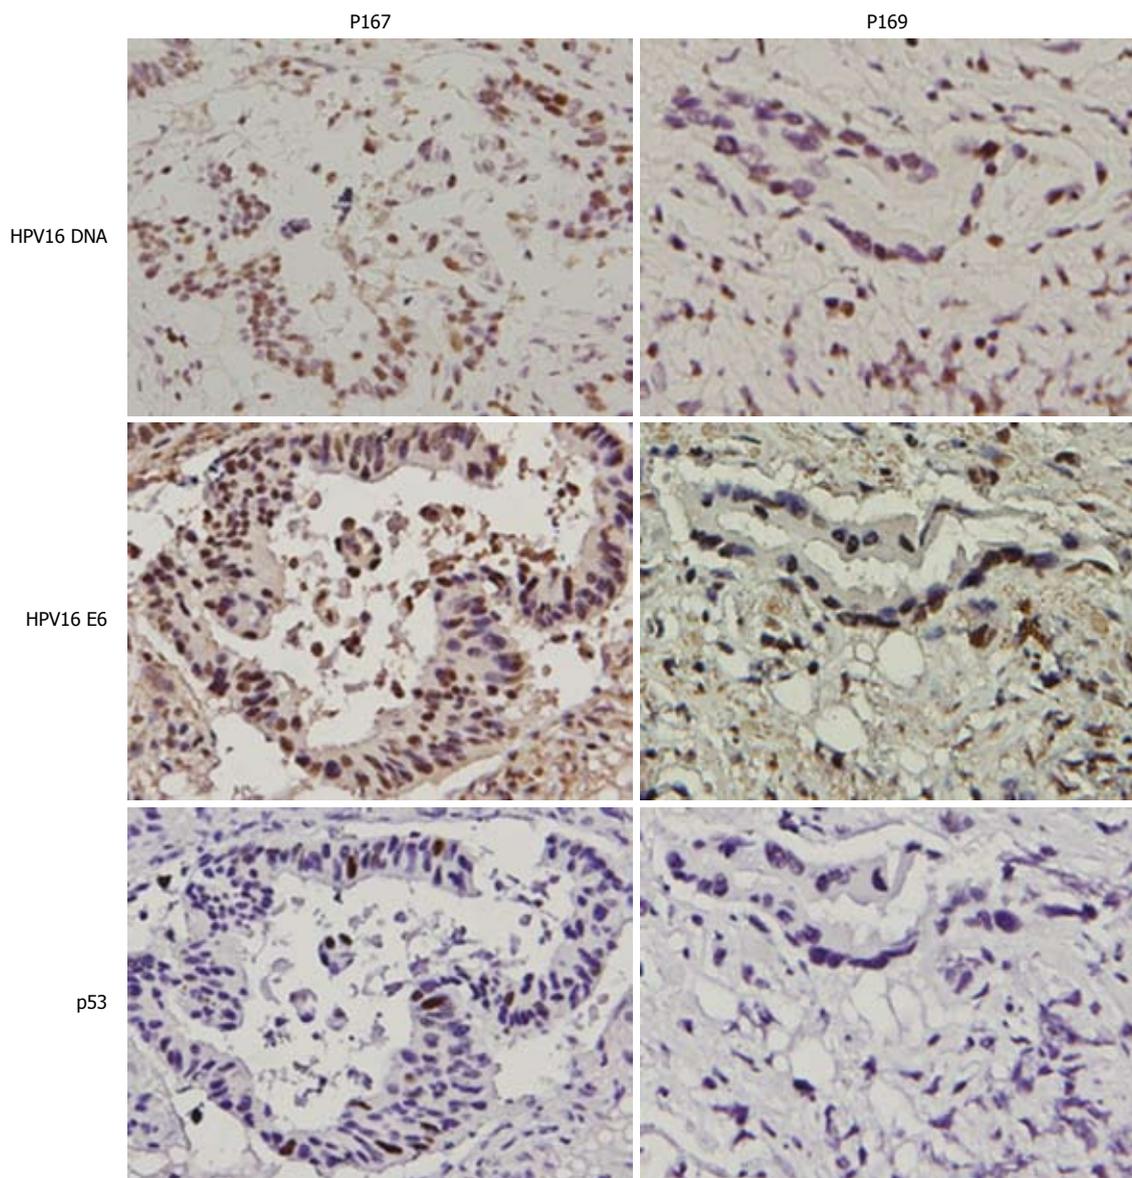

Figure 2 The representative reciprocal relationships between human papilloma virus 16 E6 and p53 immunostainings in human papilloma virus 16-infected colorectal (400 ×). HPV: Human papilloma virus.

E6 oncoprotein is expressed in endothelial cells and lymphocytes of colorectal tumors

To understand whether HPV-infected colorectal tumors could be mediated through blood circulation, E6 oncoprotein expression in normal parts of the colorectal tumors were examined by IHC (Figure 3). Our data showed that E6 oncoprotein is indeed expressed in endothelial cells of blood vessels and in lymphocytes infiltrating colorectal tumors. In addition, E6 oncoprotein was expressed in normal glands and dysplastic glands in colorectal tumors (Figure 3). These results seem to support the possibility that HPV16 infection in colorectal tumors may occur partially through blood circulation.

DISCUSSION

The presence of HPV is commonly detected by nested PCR in human tumors including colorectal tumors. In

previous studies, only one report has shown the concomitant detection of HPV16 DNA in three colorectal tumors by nested-PCR and *in situ* PCR^[15]. In the present study, nested PCR detected 8 of 11 HPV16-positive colorectal tumors and ISH confirmed this finding as well. Detection of HPV DNA by ISH had markedly lower sensitivity than *in situ* PCR, suggesting that the HPV16 DNA copy number in the tumors studied herein could be higher than previously reported^[19]. In the current study, the association between HPV infection and tumor stage was observed; however, only 6 stage I patients were enrolled in this study. Since the sample size of stage I patients is so small, it might be biased to conclude that HPV infection might play a role in the development of colorectal cancer. In addition, among 4 of the 6 stage I tumors with HPV16 DNA, HPV infection was confirmed by ISH in only 2 tumors. Therefore, the association between HPV infection and tumor stage should be verified by a larger

study population.

To explore whether the existence of HPV16 DNA could be involved in colorectal cancer development, the presence of E6 and p53 proteins in tumor tissues and

p21 and Mdm2 mRNA expression in tumors and adjacent normal tissues were evaluated in a subset of colorectal tumors (11 of 69, 16%). E6 oncoprotein expression was detected in 8 of the 11 HPV16 DNA-positive tumors.

Among these eight E6-positive tumors, p21 and Mdm2 mRNA expression levels were markedly decreased in four E6-positive tumors carrying the wild-type *p53* gene; however, no significant decrease in both gene mRNA expression levels was noted in the other four E6-positive tumors carrying the mutated *p53* gene. Therefore, these results clearly show that E6 oncoprotein may be involved in this small subset of colorectal cancer development *via* the inactivated p53 pathway (Table 3).

Sexual activity has been considered to be a major route of transmission for HPV resulting in genital cancers, such as cervical, anal, and oropharyngeal cancers^[1,2]. However, there is evidence of HPV infections in infants and female university students who are virgins, revealing that HPV transmission *via* other routes than sexual intercourse may exist^[3,13,14,20-25]. In addition, peripheral blood lymphocytes (PBLs) from healthy donors have been shown to be infected with HPV^[13]. Therefore, it has been suggested that HPV infection in internal organ tissues might occur through blood circulation. Our previous lung cancer studies have indicated that HPV16/18 DNA and E6 oncoprotein not only exist in lung tumors but are also expressed in adjacent normal tissues including lymphocytes, endothelial cells, macrophages, and bronchial epithelial cells^[26]. We therefore speculated that PBLs may first be infected by HPV to act as a mediator of HPV infection to lung tissues *via* blood circulation^[14,26]. In the present study, IHC analysis clearly indicates that E6 oncoprotein was expressed in tumor-infiltrating lymphocytes of HPV16 DNA-positive colorectal tumors. In addition, E6 oncoprotein expression was also detected in the endothelial cells of the HPV16 DNA-positive colorectal tumors. These results seem to support our previous hypothesis that HPV infection in lung tumor tissues may be mediated through blood circulation and not as a direct contact transmission in cervical and oropharyngeal tumor tissues^[14,19,26].

To our knowledge, this is the first report to indicate that HPV16 E6 oncoprotein may downregulate p21 and Mdm2 transcription *via* inactivation of p53 in the involvement of colorectal cancer development. Similar observations of E6 oncoprotein expression in adjacent normal lung and colorectal tissue cells seem to support the possibility that HPV infection in colorectal tumors might be mediated through blood circulation. Notably, even though our present study provides support for the association between HPV infection and colorectal cancer, the involvement of HPV infection in colorectal cancer development is limited to a small subset of the population.

COMMENTS

Background

Human papilloma virus (HPV) DNA integration into the host chromosome plays a crucial role in HPV-associated tumorigenesis. When HPV DNA was spliced at E2, E6 and E7 oncoproteins were expressed to inactivate p53 and Rb pathways. A high risk of HPV16/18 infection has been documented to be involved in the development of cervical and anal genital cancers. Among non-genital cancers, the association of oropharyngeal cancer with HPV16/18 infection was recently evidenced. However, other non-genital cancers, including lung, breast, and colorectal cancers have not yet been identified.

Research frontiers

The authors provide the evidence to indicate that HPV16 may be involved in a small subset of colorectal cancer development. Therefore, HPV vaccination not only prevents cervical cancer but also reduces HPV-associated colorectal cancer development.

Innovations and breakthroughs

The association of HPV infection with colorectal cancer has been extensively investigated; however, no strong evidence supports the involvement of HPV in colorectal cancer development. Herein, nested-polymerase chain reaction and *in situ* hybridization were used to detect the presence of HPV16 DNA in colorectal tumors. Immunohistochemical data further showed that E6 oncoprotein is expressed in HPV16 DNA-positive tumors and E6 expression was negatively correlated with p53 expression. These results suggest that HPV16 might contribute to a small subset of colorectal cancer development.

Applications

HPV infection is not only involved in cervical and oropharyngeal cancers but is also linked with internal organ cancers, such as lung and colorectal cancers. Therefore, blood transmission of HPV infection in internal organs might be noted in public.

Peer review

The authors present an interesting work on the expression of HPV16 E6 oncoprotein in colorectal cancer. The manuscript is generally well written. The topic is very interesting and to some extent provocative. The manuscript is well structured and the cited literature is comprehensive and up-to-date.

Abstract

AIM: To investigate the role of anal cushions in hemorrhoidectomy and its effect on anal continence of the patients.

METHODS: Seventy-six consecutive patients (33 men and 43 women) with a mean age of 44 years were included. They underwent Milligan-Morgan hemorrhoidectomy because of symptomatic third- and fourth-degree hemorrhoids and failure in conservative treatment for years. Wexner score was recorded and liquid continence test was performed for each patient before and two months after operation using the techniques described in our previous work. The speed-constant rectal lavage apparatus was prepared in our laboratory. The device could output a pulsed and speed-constant saline stream with a high pressure, which is capable of overcoming any rectal resistance change. The patients were divided into three groups, group A (< 900 mL), group B (900-1200 mL) and group C (> 1200 mL) according to the results of the preoperative liquid continence test.

RESULTS: All the patients completed the study. The average number of hemorrhoidal masses excised was 2.4. Most patients presented with hemorrhoidal symptoms for more than one year, including a mean duration of incontinence of 5.2 years. The most common symptoms before surgery were anal bleeding ($n = 55$), prolapsed lesion ($n = 34$), anal pain ($n = 12$) and constipation ($n = 17$). There were grade III hemorrhoids in 39 (51.3%) patients, and grade IV in 37 (48.7%) patients according to Goligher classification. Five patients had experienced hemorrhoid surgery at least once. Compared with postoperative results, the retained volume in the preoperative liquid continence test was higher in 40 patients, lower in 27 patients, and similar in the other 9 patients. The overall preoperative retained volume in the liquid continence test was 1130.61 ± 78.35 mL, and postoperative volume was slightly decreased (991.27 ± 42.77 mL), but there was no significant difference ($P = 0.057$). Difference was significant in the test value before and after hemorrhoidectomy in group A (858.24 ± 32.01 mL vs 574.18 ± 60.28 mL, $P = 0.011$), but no obvious difference was noted in group B or group C. There was no significant difference in Wexner score before and after operation (1.68 ± 0.13 vs 2.10 ± 0.17 , $P = 0.064$). By further stratified analysis, there was significant difference before and 2 months after operation in group A (2.71 ± 0.30 vs 3.58 ± 0.40 , $P = 0.003$). In contrast, there were no significant differences in group B or group C (1.89 ± 0.15 vs 2.11 ± 0.19 , $P = 0.179$; 0.98 ± 0.11 vs 1.34 ± 0.19 , $P = 0.123$).

CONCLUSION: There is no difference in the continence status of patients before and after Milligan-Morgan hemorrhoidectomy. However, patients with preoperative compromised continence may have further deterioration of their continence, hence Milligan-Morgan hemorrhoidectomy should be avoided in such patients.

INTRODUCTION

Hemorrhoids are very common and it occurs in men and women of all ages. It is estimated that 50% of the people older than 50 years have hemorrhoids symptoms at least for a period of time^[1]. The most common symptoms include rectal bleeding, pain, anal irritation and anal mass prolapse and a disrupted quality of life. There has been much speculation over the years as to the nature of “hemorrhoids”. It is now generally accepted that “hemorrhoids” are a disorder of the anal cushions^[2]. Thomson demonstrated that in patients suffering from hemorrhoids, the specialized “cushions” of submucosal tissue lining the anal canal slide downwards, together with the anal mucosa, due to the fragmentation of Parks’ ligament^[3-5]. This means that hemorrhoids result from distal enlargement of the anal cushions. The anal cushions are connective tissue complexes that contain smooth cells and vascular channels; they are thought to provide an effective tight seal to close the anal in concert with the internal anal sphincter^[6].

For patients with grades III and IV hemorrhoids, surgical excision remains the most common choice of treatment. Two main approaches have been used, one removes the cushions (e.g., Milligan-Morgan hemorrhoidectomy) and the other retains the cushion (e.g., stapled hemorrhoidopexy or procedure for prolapse and hemorrhoids). The expensive stapled hemorrhoidopexy has become a widely accepted alternative to excisional hemorrhoidectomy for treating the third- and fourth-degree hemorrhoids in China over the recent decade, it even has a trend to replace the traditional hemorrhoidectomy^[7]. According to Thomson’s theory, impairment of the anal cushions may lead to anal incontinence. Some previous studies^[8-13] indicate that hemorrhoidectomy might be complicated with fecal incontinence. Therefore, many non-excisional options have become available to overcome the disadvantages of traditional surgery, which have given rise to dispute around the world. However, to our knowledge, there has been no direct evidence supporting the function of the anal cushion. Our study aims to define the role of the anal cushions in hemorrhoidectomized patients by performing a liquid continence test simulating analorectal continence of liquid stool and using the Wexner score (the Cleveland clinic continence scoring system)^[14,15].

MATERIALS AND METHODS

Patients

Consecutive patients with hemorrhoids were included in the study. Inclusion criteria for the cohort were: the existence of symptomatic third- and fourth-degree hemorrhoids, and failure in conservative treatment for years and intention for Milligan-Morgan hemorrhoidectomy. Patients younger than 18 or older than 80 years, who had experienced concomitant anal diseases (fissure, abscess, fistula, inflammatory bowel disease, rectal cancer) were excluded. Eligible patients were asked for signed informed consent. The study was approved by the local ethics committee.

Eighty patients who referred to our hospital between April 2005 and September 2010 were recruited. Four patients, who lost to follow-up and did not complete the second Wexner scoring and liquid continence test, were excluded. Eventually, 76 patients were eligible and completed the study. The demographic and clinical data, and the results of liquid continence test were obtained. The anal continence was assessed using the Wexner scoring system.

Liquid continence test was performed and Wexner score was recorded for each patient before and two months after operation. The patients were divided into three groups: group A (< 900 mL), group B (900-1200 mL) and group C (> 1200 mL) according to the retained volume in the liquid continence test done before operation.

Each patient underwent the standard Milligan-Morgan hemorrhoidectomy using conventional instruments for dissection and a monopolar coagulator for hemostasis by experienced surgeons.

Liquid continence test

Liquid continence test was performed preoperatively in all the patients. At 2 mo follow-up after operation, wounds were healed in all the patients. The same tests were repeated two months after surgery (60 ± 3 d).

This test was performed using the techniques described in our previous work^[16]. The speed-constant rectal lavage apparatus was prepared in our laboratory^[16]. The device could output a pulsed and speed-constant saline stream with a high pressure, capable of overcoming any rectal resistance change.

The first liquid continence test was performed at the preoperative days 1 and 2. Patients were advised to empty their rectums before the examination. The patient sat on the device. After a F16 balloon urethral catheter was introduced into the rectum about 8-cm deep, the balloon was inflated with 5 mL air. The warm saline (37 °C) was infused at a rate of 60 mL/min. The patients were instructed to hold the liquid as long as possible. If the device was alarmed when a leakage amount reached 10 mL or the infusing liquid reached the maximum (1500 mL), the test stopped. The total volume retained was recorded. After the end-point was recorded, the balloon was deflated and the catheter was extracted.

Table 1 Demographic characteristics of hemorrhoid patients

Variables	Values
Age (yr) ¹	44 (22-72)
Gender (male/female)	33/43
Chief complaints, <i>n</i> (%)	
Prolapse	32 (42.1)
Anal bleeding	55 (72.3)
Anal pain	12 (15.8)
Constipation	17 (25.4)
Hemorrhoids stage, <i>n</i> (%)	
Third-degree	39 (51.3)
Fourth-degree	37 (48.7)
Resected piles (<i>n</i>) ²	2.4 ± 0.3
Disease duration (yr) ²	3.6 ± 1.1

¹Data are median (range); ²Data are means ± SD.

Wexner score

Anal incontinence was assessed using the Wexner grading system^[14]. Wexner score contains three items about the type and frequency of incontinence (scored from zero to four) and items on pad usage and lifestyle alteration (both scored from zero to four). Data were collected by physicians through a patient interview.

Statistical analysis

Statistical analysis was performed with SPSS 16.0 software. The data were expressed as mean ± SD or median (range). Continuous data were compared using paired Student's *t* test. Difference was considered to be significant when the *P* value was < 0.05.

RESULTS

The demographics and clinical details of the 76 patients are shown in Table 1. The mean age of patients was 44 years (range: 22-72 years) and the male to female ratio was 1:1.3. The number of hemorrhoidal masses excised varied from 2-4 (mean: 2.4 ± 0.3). The mean duration of incontinence was 5.2 years. Most patients had hemorrhoidal symptoms for more than one year, and some patients even for more than 20 years. The most common symptoms observed in the patients before surgery was anal bleeding (55 cases), prolapsed lesion (34 cases), anal pain (12 cases) and constipation (17 cases) (Table 1). Thirty-nine (51.3%) patients had grade III hemorrhoids, and 37 patients (48.7%) had grade IV hemorrhoids according to the Goligher classification. Five patients experienced hemorrhoid surgery at least once.

Compared with the postoperative results, the retained volume in the preoperative liquid continence test was higher in 40 patients, lower in 27 patients, and similar in the rest 9 patients. The overall preoperative volume in the liquid continence test was 1130.61 ± 78.35 mL, and postoperative values were slightly decreased (991.27 ± 42.77 mL), but there was no significant difference (*P* = 0.057).

According to the results of preoperative test, patients were divided into three groups: 17 patients in group A (<

900 mL), 26 in group B (900-1200 mL) and 32 in group C (> 1200 mL) (Table 2). Interestingly, significant difference was found in the test results before and after hemorrhoidectomy in group A (858.24 ± 32.01 mL *vs* 574.18 ± 60.28 mL, *P* = 0.011), but no obvious difference was noted in group B or group C (Table 2).

There was no significant difference in the Wexner score before and after operation (1.68 ± 0.13 *vs* 2.10 ± 0.17, *P* = 0.064; Table 2).

By further stratified analysis, there was significant difference in the Wexner score before and two months after operation in group A (2.71 ± 0.30 *vs* 3.58 ± 0.40, *P* = 0.003). In contrast, there were no significant differences in group B or group C (1.89 ± 0.15 *vs* 2.11 ± 0.19, *P* = 0.179; 0.98 ± 0.11 *vs* 1.34 ± 0.19, *P* = 0.123; Table 2).

DISCUSSION

To evaluate accurately the anal continence is still a clinical challenge. Parks^[17] pointed out that it is difficult to evaluate postoperative anal continence due to the flaws related to subjective and objective factors. We, therefore, used liquid continence test and Wexner scoring system in combination to better assess the anal continence status. The liquid continence test could simulate liquid stool; compared with anorectal manometry, it is more applicable, which can yield objective assessment with quantitative data^[16,18,19]. The Wexner Continence Grading Scale has been widely used for evaluating anal continence^[20-22]. It is convenient in practice and easily acceptable by the patients. Consequently, our assessments based on liquid continence test and questionnaire scoring system, are likely to be more reliable.

In our study, the mean Wexner Continence Grading Scale did not vary significantly after surgery in the overall patients. By further subgroup analysis, after hemorrhoidectomy, the Wexner score significantly increased in patients with preoperative continence defect or subclinical incontinence (group A), while no significant difference was observed in the group with normal anal continence (groups B and C). Similar results were obtained by means of the liquid continence test. While the liquid continence test and Wexner scoring system yielded the similar results, the former is more direct and objective. Baxter *et al*^[23] insisted that fecal incontinence is manifested as a symptom, so any evaluation of incontinence must be built on the perception of the patient. This is one of the reasons why we prefer the liquid continence test in the evaluation.

What is the role of anal cushion in hemorrhoidectomy? In spite of the high incidence of hemorrhoidal diseases worldwide, some aspects of its pathophysiology still remain unknown. According to Thomson's attractive theory, the anal cushions serve as a conformable plug to ensure complete closure of the anal canal and contribute to the anal continence mechanism^[5]. Hemorrhoidectomy is associated with the removal of the anal cushions, and may occasionally lead to anal incontinence^[7,11]. Jóhannsson *et al*^[12] concluded from his questionnaire that 29% of

Table 2 Results of liquid continence test before and after hemorrhoidectomy and Wexner score assessments (mean)

	Liquid continence test (pre-operation) (mL)	Liquid continence test (post-operation) (mL)	P value	Wexner score (pre-operation)	Wexner score (post-operation)	P value
Total patients	1130.61 ± 78.35	991.27 ± 42.77	0.057	1.68 ± 0.13	2.10 ± 0.17	0.064
Group A (n = 17)	858.24 ± 32.01	574.18 ± 60.28	0.011	2.71 ± 0.30	3.58 ± 0.40	0.003
Group B (n = 26)	977.96 ± 15.96	927.31 ± 53.23	0.061	1.89 ± 0.15	2.11 ± 0.19	0.179
Group C (n = 33)	1391.21 ± 16.95	1257.79 ± 51.53	0.124	0.98 ± 0.11	1.34 ± 0.19	0.123

the patients reported the incontinence after hemorrhoidectomy. Thekkinkattil *et al.*^[24] demonstrated that the cushion: canal ratio was reduced in patients with idiopathic fecal incontinence. However, the theory is controversial by the fact that submucosal hemorrhoidectomy does not yield better functional outcome than excisional hemorrhoidectomy^[25]. Our study revealed that hemorrhoidectomy (excised anal cushions) did not impair the function of anal continence. Our findings agree with a previous report^[26] that no incontinence occurred after conventional hemorrhoidectomy. However, there is still much uncertainty regarding the role of anal cushion in fecal incontinence. It is important to note, although no obvious change was observed in anal continence in the patients after excising the anal cushion, further subgroup analysis showed that the patients with a lower value of liquid continence test (< 900 mL) after surgery did impair the fecal continence. This may be partly attributed to the fact that this group of patients had been complicated with continence defect or subclinical incontinence.

Our data support that the traditional hemorrhoidectomy, which necessitates excision of anal cushions, is a safe procedure for patients with normal fecal continence. From the perspectives of cost-effectiveness, the traditional hemorrhoidectomy should be recommended, especially in the developing countries. Nevertheless, surgeons should keep in mind that this kind of surgery may increase the risk of complicated anal incontinence in the patients with anal function defect or subclinical incontinence. Best of all, this study enhances the awareness of surgeons that preoperative evaluation of hemorrhoid patients is important regarding the choice of surgical procedure.

Our study had several limitations, such as a small sample size, short follow-up, and saline continence test could not assess the solid stool, which might result in improper findings. Further studies are being conducted to work out an objective test for solid and flatus stool, and compare the anal cushion preserving and non-preserving procedures as well.

In conclusion, removing anal cushions does not obviously impair the fecal continence in patients with a proper indication for the operation, and therefore it is a safe procedure. It is not necessary to pay excessive attention to anal cushion in hemorrhoid patients. Thorough investigations should be carried out on anal continence so as to prevent the occurrence of postoperative complications.

COMMENTS

Background

Traditional hemorrhoidectomy is tended to be replaced by stapled hemorrhoidopexy with anal cushion retained, because the anal cushion theory considers that the removal of the anal cushions will damage the anal rectal control function. In this study, water retention test and Wexner scoring were used to observe the changes of the anus and rectum control function in the patients treated with traditional hemorrhoidectomy.

Research frontiers

The authors evaluated the anal continence in the patients with hemorrhoids before and after operation using liquid continence test and Wexner scoring system in combination so as to define the role of anal cushions in hemorrhoidectomy.

Innovations and breakthroughs

To evaluate accurately the anal continence is still a clinical challenge, and it is especially difficult to evaluate the postoperative anal continence due to flaws related to subjective and objective factors. The authors, therefore, used liquid continence test and Wexner scoring system in combination in an attempt to better assess the anal continence. The liquid continence test could simulate liquid stool, thus yielding objective assessment with quantitative data. The Wexner scoring system is convenient in practice and easily acceptable by the patients. Consequently, the assessments obtained by this study based on liquid continence test and questionnaire scoring system, are likely to be more reliable. The authors also found that removing anal cushions does not obviously impair the fecal continence in patients with a proper indication for the traditional hemorrhoidectomy, and therefore it is a safe procedure.

Applications

According to this study, that the traditional hemorrhoidectomy, which necessitates excision of anal cushions, is a safe procedure for patients with normal fecal continence. From the perspectives of cost-effectiveness, the traditional hemorrhoidectomy should be recommended, especially in the developing countries. Nevertheless, surgeons should keep in mind that this kind of surgery may increase the risk of complicated anal incontinence in the patients with anal function defect or subclinical incontinence.

Peer review

This study provides new evidences on the safety of Milligan-Morgan hemorrhoidectomy which is less expensive for patients. Some elements may substantiate the study, such as fecal continence test for not only liquid and but also for solid and flatus stools, and comparison between anal cushion preserving and non-preserving procedures.

Abstract

Carcinosarcomas are rare, malignant, biphasic tumors simultaneously comprising carcinoma and sarcoma in a single tumor. We present an extremely rare case of gastric carcinosarcoma with an osteoblastic component that drastically changed its shape within 2 mo. A 59-year-old male patient presented to the emergency outpatient unit with a complaint of black stool. Gastrointestinal endoscopy showed an ulcerated mass in the cardia of the lesser curvature of the stomach. Biopsy specimens revealed only adenocarcinoma. Two months later, the ulcerated lesion drastically changed its shape into an exophytic tumor. Total gastrectomy was performed. In the resected specimen, the gastric tumor contained both adenocarcinoma and sarcoma components with lace-like osteoid. The patient died 7 mo after the operation, and an autopsy was performed. In the autopsy, widespread metastases were present in the liver, lung, lymph nodes and peritoneum. In this report, we describe a case of gastric carcinosarcoma and presume its tumorigenesis based on the autopsy findings.

INTRODUCTION

Carcinosarcomas are rare, malignant, biphasic tumors simultaneously comprising carcinoma and sarcoma in a single tumor. Although carcinosarcomas of the esophagus are most frequently observed in the upper gastrointestinal tract^[1], they are very rarely found in the stomach. We performed a keyword search of the literature for gastric carcinosarcoma. Published articles, limited to English abstracts indexed primarily in the PubMed database, through to 2012, were reviewed. Until 2012, at least 46 cases of gastric carcinosarcoma have been reported^[2-20]; most of them in Japanese patients. **In this article, we present a rare case of gastric carcinosarcoma with an osteoblastic component that drastically changed its shape.**

CASE REPORT

Case history

A 59-year-old Japanese male patient presented to the emergency outpatient unit with a complaint of black stool. He was an office worker. He had no apparent past

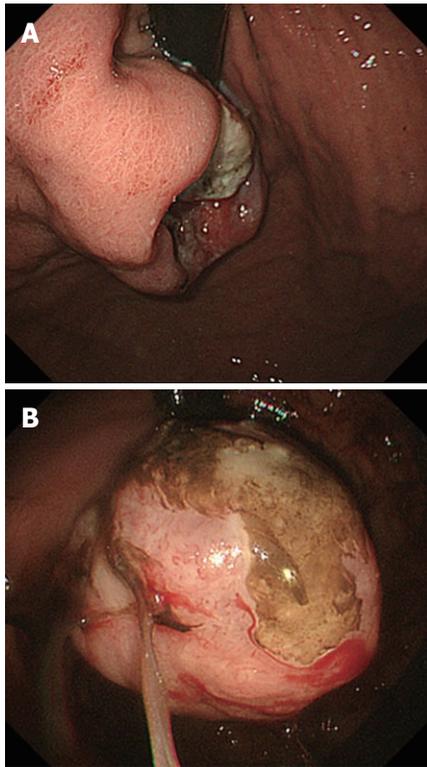

Figure 1 Retroflexed endoscopic view of the lesion in the gastric cardia. A: Ulcerated lesion; B: Two months later, the lesion changed its shape into an exophytic mass.

medical history and took no medications. There was no family history of malignant neoplasm. On physical examination, the abdomen was flat and not tender. Laboratory data were normal with the exception of a white blood cell count of $13\,100/\mu\text{L}$ and an elevated serum carcinoembryonic antigen (CEA) level of 12.5 ng/mL (normal, $< 5.0\text{ ng/mL}$).

Gastrointestinal endoscopy showed an ulcerated mass in the cardia of the lesser curvature of the stomach (Figure 1A). The esophagogastric junction was not involved with the tumor. Biopsy from the lesion showed tubular adenocarcinoma. Two months later, upper gastrointestinal endoscopy was performed again and showed that the ulcerated lesion had drastically changed its shape into an exophytic mass (Figure 1B). Although the patient had multiple liver metastases, palliative total gastrectomy was performed to control gastric bleeding and ameliorate anemia.

After the palliative operation, systemic chemotherapy with S-1 and cisplatin was performed. As a result of tumor progression, the patient received second-line chemotherapy of irinotecan (CPT-11) and mitomycin C. Although three cycles of second-line chemotherapy were performed, liver metastases continued to develop. His general condition gradually worsened, and he died 7 mo after the operation. An autopsy was performed.

Pathological findings

On macroscopic examination of a $27\text{ cm} \times 21\text{ cm}$ total gastrectomy specimen, an $11.5\text{ cm} \times 10.5\text{ cm} \times 5.0\text{ cm}$

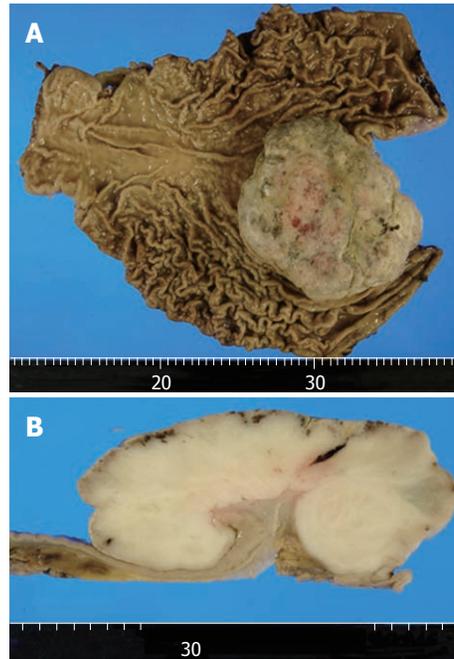

Figure 2 Macroscopic view of the resected specimen. A: An exophytic tumor located in the gastric cardia; B: Cross section of the tumor.

exophytic tumor was found in the cardia (Figure 2A). Erosion and necrosis were observed on the tumor surface. The cut surfaces of the tumor were tan-gray and fleshy (Figure 2B).

On light microscopy, the tumor contained both epithelial and spindle cell components. Spindle cell clusters and fascicles with the appearance of stromal sarcomas were observed in large regions. A small amount of lace-like osteoid was found in the sarcoma component (Figure 3A). Irregular fused glands with cuboidal and columnar cells appearing to overlap these regions were observed (Figure 3B). The spindle cells generally had coarse chromatin, elongated oval nuclei, small nucleoli, pale eosinophilic cytoplasm, and frequent mitotic activity. In adjacent regions of the tumor, dysplastic glands and goblet cell metaplasia were seen within the mucosa. No *Helicobacter pylori* (*H. pylori*) was observed. The tumor infiltrated the subserosal layer. Lymph node metastases with an adenocarcinoma component were detected in seven of 22 resected lymph nodes. Venous and lymphatic involvements with adenocarcinoma components were also observed. Immunohistochemically, cytokeratin AE1/AE3 positivity was observed in the tubular adenocarcinoma component (Figure 4A). There was no staining with cytokeratin AE1/AE3 in spindle cells. In spindle cells, positive staining with vimentin and negative staining with desmin, smooth muscle actin, c-kit, S-100, CD34, and HHF-35 was observed (Figure 4B). Widespread positive nuclear staining with p53 and more limitedly with Ki-67 was observed in both glandular and spindle tumor cells.

In the autopsy, widespread metastases were present in the liver, lungs, lymph nodes, and peritoneum. Although liver metastases showed both adenocarcinoma and spindle cell components, only the adenocarcinoma compo-

ment was present in lung metastases. Carcinosarcoma and pulmonary thromboembolism were the major causes of death in this case.

DISCUSSION

Gastric carcinosarcomas are rare tumors. They have also been referred to in the literature as sarcomatoid carcinomas. The first report of sarcomatoid carcinoma of the stomach was by Queckenstadt in 1904. Additional cases have been subsequently reported^[2-19]. In 2007, Ikeda *et al*^[20] reported one case and reviewed 43 cases from the literature. Until 2012, at least 46 cases of gastric carcinosarcoma have been reported; most of them in Japanese patients. We reported gastric carcinosarcoma containing an osteoblastic component, which is extremely rare. Based on our knowledge, there has been only one report of gastric carcinosarcoma with osteoblastic differentiation^[14]. No previous report has described gastric carcinosarcoma as a tumor that rapidly deformed within 2 mo.

The histogenesis of biphasic tumors remains unclear. Some researchers have argued that a primary carcinoma stimulates excessive stromal proliferation, resulting in a carcinosarcoma^[21]. Other researchers, however, are of the opinion that the spindle cell component reflects anaplasia within the carcinoma^[4,22-24].

There are findings supporting the idea that gastric biphasic tumors are epithelial in origin^[3,5,11]. In a number of studies, cells with an intermediate appearance between

that of epithelial and sarcomatous components have been seen, and these cells have been reported to stain positively with epithelial differentiation markers such as CEA. However, there have been cases in which spindle cells were differentiated as entirely smooth muscle or cartilage. In the literature, gastric carcinosarcomas differentiated as rhabdomyoblastic, neuroblastic, or osteoblastic have been reported^[14,25-27]. A combination of carcinosarcoma and carcinoid tumor with neuroendocrine malignancy was reported in two cases^[13,25]. Therefore, it may be that in their beginning, these tumors developed with diverse differentiation of a multipotent stem cell.

The histological findings observed in our case may support the theory that gastric biphasic tumors are epithelial in origin. All biopsy specimens obtained at the initial endoscopy showed only adenocarcinoma. However, in the surgically resected specimen, the spindle cell component occupied > 90% of the tumor, and a small number of adenocarcinoma cells were observed in the peripheral zone of the tumor. In the autopsy, the liver metastases that had been detected in the ante-mortem examination were composed of both spindle cell and adenocarcinoma components. In contrast, small metastases of the lung first diagnosed at autopsy showed only adenocarcinoma. Although these differences in tumor components at each metastatic site might have resulted from differences in affinities of each tumor component for lymphatics or veins, we believe that the development of the adenocarcinoma component might have preceded

that of the sarcoma component in our case. Rapid proliferation of the sarcoma component may have accounted for the drastic deformation of the tumor in our case. Although the tumorigenesis of this lesion is interesting from the perspective of epithelial-mesenchymal transition^[28,29], a more sophisticated approach will be required to elucidate this problem.

From a clinical standpoint, gastric carcinosarcomas share clinicopathological features with gastric adenocarcinomas. The age range of the 46 cases previously reported was 29 to 83 years with a mean of 56 years^[8,20,29]. There were 33 male and 13 female patients. Tumors that showed polypoid growth and ulcerated lesions were present in 22 and 19 cases, respectively. In our patient, the tumor exhibiting the ulcerative lesion rapidly changed its shape into an exophytic mass and was located in the cardia.

Gastric carcinosarcomas have a low incidence of metastasis, but mortality is high^[5,11,13,14,25,26,30]. Approximately 50% of previously reported patients with gastric carcinosarcoma died of the disease within 6 mo^[8,20,27]. In those cases that metastasize, the metastases may show pure carcinoma, pure sarcoma, or a mixture of both^[16]. In our case, both components were present.

Histologically, carcinosarcomas include epithelial and sarcomatous regions, and the two tumor components may be separate or overlapping^[3,5,13,14,25,26]. The tumor is often accompanied by atrophy, dysplasia, and intestinal metaplasia^[5,11]. Several types of differentiation of the sarcoma component have been reported, including smooth muscle, cartilage, striated muscle, and neuroendocrine cells. However, production of osteoid by the sarcoma component is extremely rare. We observed staining with cytokeratin AE1/AE3 only in the epithelial component in the case presented. Vimentin positivity and production of lace-like osteoid suggested that spindle cells had differentiated as osteosarcoma. In our patient, widespread p53 and Ki-67 positivity confirmed the high proliferation and malignant potential of this tumor. *H. pylori* may not be strongly associated with carcinosarcoma^[51,32].

In summary, we reported a case of gastric carcinosarcoma with an osteoblastic component that rapidly deformed within 2 mo. Carcinosarcoma of the stomach is a rare tumor and has a poor prognosis. It is impossible to establish standard therapy for this rare disease with a large-scale clinical trial, therefore, detailed descriptions and collections of individual cases should be continued.

Abstract

We report a case of cerebral lipiodol embolism (CLE) after transarterial chemoembolization (TACE) for unresectable hepatic carcinoma (HCC). A 54-year-old man with unresectable HCC underwent TACE *via* the right hepatic artery and right inferior phrenic artery using a mixture of 40 mg pirarubicin and 30 mL lipiodol. His level of consciousness deteriorated after TACE, and non-contrast computed tomography revealed a CLE. The cerebral conditions improved after supportive therapy. The complication might have been due to hepatic arterio-pulmonary vein shunt caused by direct invasion of the tumor. Even though CLE is an uncommon complication of TACE, we should be aware of these rare complications in patients with high risk factors.

Cerebral lipiodol embolism after transarterial chemoembolization for hepatic carcinoma: A case report. *World J Gastroenterol* 2012; 18(30): 4069-4070 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i30/4069.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i30.4069>

INTRODUCTION

Hepatic carcinoma (HCC) is one of the leading causes of cancer-related death. It has a tendency to invade the tissue around the tumor, such as diaphragm, portal and hepatic veins, which may result in formation of hepatic arteriopulmonary vein or hepatic arteriovenous shunts. Transarterial chemoembolization (TACE) is one of the most common treatment modalities as a palliative and preoperative method for patients with advanced HCC. Although various complications of TACE have been reported, cerebral lipiodol embolism (CLE) after TACE is rare. In this paper, we report a case of CLE after TACE for advanced HCC.

CASE REPORT

A 54-year-old man was admitted with right upper quadrant pain. He was a hepatitis B virus carrier for 30 years. The α -fetoprotein level was 1200 ng/mL. Enhance computed tomography (CT) revealed a 13-cm mass of the right liver lobe. These clinical signs indicated that the patient had unresectable HCC and Child-Pugh class A. As revealed by angiography, the huge hypervascular tumor located in the right liver was supplied by the right hepatic artery (RHA) and right inferior phrenic artery (RIPA) without arteriovenous shunt. TACE was performed *via* the RHA and RIPA using a mixture of 40 mg pirarubicin and 30 mL lipiodol. Toward the end of the procedure, the lipiodol was deposited in the tumor densely. The embolism process was monitored by fluoroscopy all the way and no abnormal flow of the lipiodol was found. Twenty

minutes after TACE, the patient complained of a serious headache and followed by confusion. Non-contrast enhanced CT scanning showed no hyper-intense lesions in the bilateral lungs, but multiple disseminated hyper-intense lesions in the brain, consistent with the deposition of lipiodol. His neurologic symptoms disappeared completely when discharged 9 d later.

DISCUSSION

TACE can result in various severe complications, including acute hepatic failure, intrahepatic biloma, pseudoaneurysm formation, and ectopic infarction, which occur in less than 1% of the patients. Although CLE is a rare complication of TACE, sporadic cases of CLE after TACE have been reported^[1,2]. We encountered a case of CLE after TACE, which was probably associated with hepatic or right inferior phrenic arteriopulmonary vein shunt. The patient had no specific respiratory symptoms such as cough, dyspnoea, but had neurological symptoms including headache and followed by confusion. CT scanning showed some positive findings, indicating deposition of lipiodol, and the diagnosis of CLE was confirmed clinically.

The underlying mechanisms of CLE after TACE are still obscure. Hepatic arterio-pulmonary vein shunt, which is associated with pulmonary vein invasion of HCC, may be the reasonable explanation for CLE. Vascular abnormalities, referred to as hepatic vein invasion, pulmonary arteriovenous shunt, can be found in patients with advanced HCC^[3]. An intracardiac right-to-left shunt *via* a patent foramen ovale or intrapulmonary arteriovenous shunt can lead to CLE. Patients with advanced HCC are likely to have a pulmonary arteriovenous shunt^[4], and a right-to-left shunt from the RIPA to the pulmonary vasculature is also a possible route^[5]. It has been shown that fat globules < 7 μm in diameter can pass directly through the pulmonary arteriolar network (i.e., transpulmonary shunt) and result in cerebral injury^[6]. Therefore, presence of intracardiac shunt may not be a requisite for CLE as has been demonstrated in mongrel dogs^[7]. But this kind of patients usually had specific respiratory symptoms such as cough, dyspnoea and so on. Wu *et al*^[1] thought that pulmonary and CLE might be correlated closely with the bypass between tumor feeding artery and pulmonary vessels due to the tumor invading the thoracic cavity. Matsumoto *et al*^[2] concluded that communication between tumor feeding artery and pulmonary vein might have occurred *via* adhesive pleural or tumor invasion into the diaphragm. Therefore, a small dose of lipiodol could enter into the systemic circulation quickly and caused CLE. Thus, we hypothesize that lipiodol passed through the hepatic or right inferior phrenic arteriopulmonary vein shunt or hepatic arteriovenous shunt, and then traveled to the cerebral artery through intrapulmonary arte-

riovenous shunt.

Although CLE is a rare complication of TACE in patients with HCC, we should keep alert when we observe complications of TACE. When angiogram shows any hepatic arteriovenous or hepatic arteriopulmonary vein shunts, we should decrease the dose of lipiodol during the procedure and pay attention to the respiratory and neurological symptoms after the procedure, which may be caused by ectopic embolism.

In addition to after-embolization syndrome, with its symptoms manifested as fever, pain, nausea and vomiting, there are also some severe complications of TACE, including acute hepatic failure, intrahepatic biloma, pseudoaneurysm formation, ectopic infarction, *etc.* Clinicians should keep in mind that a small number of patients after TACE will suffer from some severe and rare complications. Our patient developed a severe headache and followed by confusion 20 min after the procedure. If some symptoms such as cough, chest pain, chest distress, headache, nausea, and vomiting occur in patients after TACE, physical examinations should be done so as to exclude pulmonary and cerebral complications.

In conclusion, even though CLE is an uncommon complication of TACE, we should be aware of the rare complications in patients with high-risk factors such as a large-size tumor, hepatic vein or diaphragm invasion of tumor and congenital cardiovascular disease, and reduce the dose of lipiodol or stop the procedure accordingly. To reduce the risk of lipiodol embolism, a small lipiodol dose and detection of intracardiac shunt before TACE should be considered in the HCC patients with high risk factors.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the “priority” and “copyright” of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers’ names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homoge-

neous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/esps/>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically

for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

Instructions to authors

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of "To investigate/study/..."; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of *P* values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be la-

beled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as ν (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h; blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kho I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (<http://www.wjgnet.com/1007-9327/office/>). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

It has been established that cancer can be promoted and exacerbated by inflammation. Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide, and its long-term prognosis remains poor. Although HCC is a complex and heterogeneous tumor with several genomic mutations, it usually develops in the context of chronic liver damage and inflammation, suggesting that understanding the mechanism(s) of inflammation-mediated hepatocarcinogenesis is essential for the treatment and prevention of HCC. Chronic liver damage induces a persistent cycle of necroinflammation and hepatocyte regeneration, resulting in genetic mutations in hepatocytes and expansion of initiated cells, eventually leading to HCC development. Recently, several inflammation- and stress-related signaling pathways have been identified as key players in these processes, which include the nuclear factor- κ B, signal transducer and activator of transcription, and stress-activated mitogen-activated protein kinase pathways. Although these pathways may suggest potential therapeutic targets, they have a wide range of functions and complex crosstalk occurs among them.

This review focuses on recent advances in our understanding of the roles of these signaling pathways in hepatocarcinogenesis.

INTRODUCTION

Various types of cancer arise in the setting of chronic inflammation, suggesting a strong link between inflammation and carcinogenesis^[1,2]. Although Virchow first suggested this relationship in the 19th century, clear evidence for it has been obtained only during the last decade^[3]. The development of hepatocellular carcinoma (HCC) is one of the most extensively investigated inflammation-based carcinogenic processes because more than 90% of HCCs develop in the context of chronic liver damage and inflammation.

HCC is diagnosed in more than half a million people each year and is the third most common cause of cancer mortality worldwide^[4]. The short-term prognosis of patients with HCC has improved recently due to advances in early diagnosis and treatment, but long-term prognosis remains unsatisfactory, as indicated by the low overall survival of 22%-35% at 10 years after curative treatment^[5,6]. Thus, understanding the molecular carcinogenic mechanisms and the unique pathogenic biology of HCC has become an important issue worldwide.

HCC is a complex and heterogeneous tumor with several genomic mutations, but even the most frequent genetic mutations, such as those in p53 and β -catenin, are seen in 30%-50% of HCC cases at most^[7]. On the other hand, as mentioned above, more than 90% of HCC develops based on chronic inflammation, indicating that understanding the mechanism(s) of inflammation-mediated hepatocarcinogenesis is necessary for the treatment and prevention of HCC.

The main cause of HCC is viral hepatitis caused by the hepatitis B virus (HBV) or hepatitis C virus (HCV); other major etiologies include hemochromatosis, alcoholic hepatitis, and non-alcoholic steatohepatitis (NASH)^[7]. Most of these diseases are known to cause chronic inflammation in the liver, which plays a critical role in hepatocarcinogenesis. For example, in chronic viral hepatitis, the host immune responses to HBV or HCV are often insufficiently strong to completely clear the infection, resulting in chronic stimulation of an antigen-specific immune response^[8]. Virus-infected hepatocytes are killed by host immune cells as well as the intrinsic cytopathic effects of the hepatitis viruses, triggering the production of various cytokines and growth factors and subsequently inducing compensatory hepatocyte regeneration. This persistent cycle of necro-inflammation and hepatocyte regeneration is thought to increase the risk of genetic mutation in hepatocytes, and, furthermore, to promote survival and expansion of initiated cells^[9-11]. Additionally, reactive oxygen species (ROS) and nitrogen oxygen species, generated by both initiated cells and inflammatory cells, could accelerate hepatocarcinogenesis through several mechanisms, such as the induction of oxidative DNA damage, DNA methylation, and hepatocyte injury^[11].

Multiple signaling pathways are involved in these processes. Among them, recent *in vivo* studies have shown that several inflammation- and stress-related signaling pathways are key players in hepatocarcinogenesis, including the nuclear factor- κ B (NF- κ B), signal transducer and activator of transcription (STAT), and stress-activated mitogen-activated protein kinase (MAPK) pathways. Mutations in genes involved in these signaling pathways are currently thought to be rare. Nevertheless, constitutive activation of these pathways is frequently seen in the tumor and surrounding liver tissues, and may be due to the inflammatory microenvironment. Interestingly, these signaling pathways do not act independently, but are linked through extensive crosstalk. This review highlights

advances in the understanding of these interesting but complex signaling pathways in hepatocarcinogenesis.

INFLAMMATION-RELATED SIGNALING IN HEPATOCARCINOGENESIS

Role of the I κ B kinase/NF- κ B pathway in hepatocytes

The NF- κ B family of transcription factors consists of five members: p65/RelA, c-Rel, RelB, p50/NF- κ B1, and p52/NF- κ B2. Two of the five members dimerize and are held in the cytoplasm by the inhibitor of NF- κ B (I κ B) proteins^[12]. In response to many kinds of proinflammatory stimuli, the I κ B kinase (IKK) complex, which consists of two catalytic subunits, IKK α and IKK β , and a regulatory component, IKK γ /I κ B kinase (NEMO), phosphorylates I κ B and subsequently induces degradation of it. Once activated, NF- κ B dimers translocate into the nucleus and stimulate the transcription of various genes, such as those encoding cytokines and anti-apoptotic factors^[13]. Mice lacking RelA, IKK β , or NEMO reveal embryonic lethality with extensive liver apoptosis and degeneration^[14-16]. This liver apoptosis is induced by tumor necrosis factor (TNF)- α , and intercrossing with TNF receptor 1 knockout mice prevents liver damage and the lethal phenotype^[14,17,18]. Furthermore, hepatocyte-specific IKK β or NEMO knockout mice are not embryonic-lethal, but are more sensitive to TNF- α -mediated liver injury^[19,20]. Thus, NF- κ B plays a key role in liver homeostasis by preventing hepatocyte death.

The role of IKK β in hepatocarcinogenesis has been examined using the diethylnitrosamine (DEN)-induced mouse HCC model^[21]. DEN is the most commonly used genotoxic chemical carcinogen to investigate the mechanism of hepatocarcinogenesis, because it is easy to induce HCC and DEN-induced HCC shows histology and gene expression similar to human HCC, especially with a poor prognosis^[22,23]. A single dose of DEN given to 2-wk-old male mice is sufficient to induce HCC. However, when DEN is administered to mice older than 4 wk of age, it cannot induce HCC and requires assistance from tumor promoters, such as phenobarbital, because hepatocyte proliferation is rare in adult mice^[24]. Thus, some stimulation that induces hepatocyte proliferation is indispensable as a tumor promoter in this model.

Strikingly, DEN-induced HCC was markedly increased in hepatocyte-specific IKK β knockout mice^[21]. Hepatocyte-specific knockout of IKK β induced a greater extent of hepatocyte death with ROS accumulation after DEN administration, because NF- κ B activation is required for the up-regulation of antioxidative genes, such as ferritin heavy chain and manganese-dependent superoxide dismutase. Excess ROS accumulation promotes cell death through various mechanisms, including prolonged c-Jun NH₂ terminal kinase (JNK) activation^[25]. Cell death is accompanied by an inflammatory reaction, and the elevated hepatocyte death rate enhances compensatory proliferation. Thus, the hepatocyte-specific deletion of

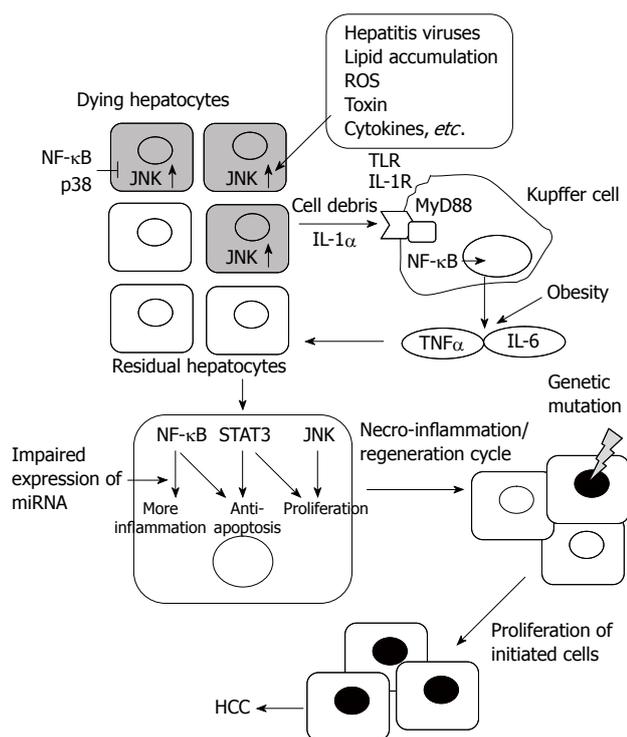

Figure 1 Role of inflammation- and stress-related signaling pathways in hepatocarcinogenesis. Chronic liver damage induces a persistent cycle of necro-inflammation and hepatocyte regeneration, resulting in genetic mutations in hepatocytes and expansion of initiated cells, eventually leading to hepatocellular carcinoma (HCC) development. As shown in the figure, nuclear factor- κ B, signal transducer and activator of transcription 3, and stress-activated mitogen-activated protein kinase pathways play critical roles in these processes. Furthermore, other factors, such as obesity and impaired expression of microRNA, can modify these inflammatory processes and accelerate HCC development. ROS: Reactive oxygen species; TLR: Toll-like receptor; NF- κ B: Nuclear factor- κ B; TNF: Tumor necrosis factor; IL: Interleukin; JNK: c-Jun NH₂ terminal kinase; STAT: Signal transducer and activator of transcription.

IKK β augments DEN-induced hepatocyte death and cytokine-driven compensatory proliferation, which acts as a tumor promoter and eventually leads to increased HCC development (Figure 1). Similar findings were obtained in mice lacking IKK γ /NEMO, the hepatocyte-specific deletion of which results in spontaneous liver damage, hepatosteatosis, fibrosis, and HCC development^[20].

Although the experiments described above demonstrate a tumor-suppressive role of NF- κ B in the hepatocyte, hepatocyte NF- κ B has been also identified to have tumor-promoting roles in other HCC models that depend on chronic inflammation rather than liver damage and death-driven compensatory proliferation. Experiments crossing transgenic mice expressing a non-degradable I κ B α mutant in hepatocytes with *MDR2* knockout mice, which show low-grade chronic inflammation in the portal area and subsequent cancer development, revealed that the inhibition of NF- κ B activation resulted in reduced HCC development^[26]. In this model, NF- κ B activation in the hepatocyte promoted a low degree of TNF- α production and paracrine TNF- α signaling maintained NF- κ B activation in the malignant cells, leading to

the expression of anti-apoptotic genes and the survival of malignant cells. Notably, NF- κ B activation is more important in the progression of hepatocarcinogenesis than in the initiation step in this model. A similar tumor-promoting role of NF- κ B in the hepatocyte has been reported in hepatocyte-specific lymphotoxin $\alpha\beta$ transgenic mice^[27]. Lymphotoxin $\alpha\beta$ transgenic hepatocytes produce chemokines, such as CCL2, CCL7, CXCL1, and CXCL10, in an IKK β -dependent manner, recruiting inflammatory cells into the liver and inducing spontaneous chronic inflammation and the subsequent development of HCC. These findings suggest that NF- κ B activation in the hepatocyte is involved in the production of cytokines and chemokines that maintain the inflammatory environment as a tumor promoter. Thus, the NF- κ B pathway in the hepatocyte plays dual roles in hepatocarcinogenesis, according to the disease model and the carcinogenesis stage.

Role of the IKK/NF- κ B pathway in myeloid cells

The role of the NF- κ B pathway in myeloid cells has also been investigated using a DEN-induced HCC model^[21]. In contrast to hepatocyte-specific IKK β knockout mice, deletion of IKK β in both hepatocytes and myeloid cells, including Kupffer cells, strongly inhibited DEN-induced HCC development. This phenotype was derived from the markedly reduced production of cytokines, such as TNF- α , interleukin-6 (IL-6), and hepatocyte growth factor, which are secreted by non-parenchymal cells in response to dying hepatocytes and induce compensatory proliferation of residual hepatocytes. Thus, IKK β /NF- κ B in myeloid cells is required for the production of liver growth factors and subsequent hepatocarcinogenesis. Furthermore, IKK β in myeloid cells, especially in Kupffer cells, has also been implicated in the development of metastatic liver tumors through IL-6 production^[28]. Thus, the IKK β /NF- κ B pathway orchestrates inflammatory crosstalk between hepatocytes and myeloid cells in liver cancer development (Figure 1).

Role of inflammatory cytokines in hepatocarcinogenesis

As mentioned above, NF- κ B activation-mediated production of inflammatory cytokines plays an important role in the inflammation-carcinogenesis axis of the liver. Various inflammatory cytokines, including TNF- α , IL-1 α , IL-1 β , IL-6, and IL-8, have been implicated in chronic liver inflammation, among which IL-6 is thought to be one of the most important^[8,29,30]. In chronic hepatitis, IL-6 is considered to be produced mainly by activated Kupffer cells and to intensify local inflammatory responses, and then induce compensatory hepatocyte proliferation, facilitating malignant transformation of hepatocytes^[30]. Hepatocytes express high amounts of the IL-6 receptor and a signal-transducing element (gp130) that, upon IL-6 binding, activates two signaling pathways, Janus activated kinase (JAK)-STAT and MAPK, which are important in the regulation of cell survival and proliferation^[31]. In fact, serum IL-6 levels are elevated in patients with chronic liv-

er diseases, including alcoholic hepatitis, HBV and HCV infections, and NASH^[32-34]. Additionally, a higher serum IL-6 level correlates with future HCC development in patients with chronic hepatitis B or C^[35,36]. These findings suggest that IL-6 plays a role linking chronic inflammation and hepatocarcinogenesis in humans.

In a mouse HCC model, IL-6 knockout mice showed a marked reduction in DEN-induced HCC development, indicating that IL-6 signaling is directly involved in hepatocarcinogenesis^[37]. This study also demonstrated the key role played by the toll-like receptor (TLR) adapter protein MyD88. Necrotic hepatocyte-induced IL-6 production was reduced significantly in MyD88-deficient Kupffer cells. Furthermore, deletion of MyD88 suppresses DEN-induced carcinogenesis, indicating that IL-6 production through the TLR/MyD88/NF- κ B pathway in Kupffer cells is essential for HCC development. Another study showed that the DEN-induced acute inflammatory response is triggered by IL-1 α release from necrotic hepatocytes, and IL-1 α subsequently induces IL-6 production by Kupffer cells^[38]. Indeed, IL-1 receptor knockout mice showed significantly reduced DEN-induced IL-6 production and subsequent HCC development^[38]. Of note, a clinical study revealed that higher serum IL-6 levels correlated with higher aspartate aminotransferase levels in chronic hepatitis C, suggesting that IL-6 may be produced in response to HCV-induced hepatocyte injury^[36].

HCC develops much more frequently in males than in females in almost all populations, with a male-to-female ratio of 2:1-4:1^[39]. Interestingly, although this sex disparity is also found in this DEN-induced HCC model, ablation of IL-6 abolished the sex differences in hepatocarcinogenesis^[37]. However, ovariectomized female mice revealed enhanced IL-6 production and aggravated HCC development. Furthermore, estrogen administration to Kupffer cells inhibits necrotic hepatocyte-induced IL-6 production. These results suggest that estrogen-mediated down-regulation of IL-6 may partly explain the sex disparity in HCC development. However, more recently, Li *et al*^[40] reported that transcription factors Foxa1 and Foxa2 in the hepatocyte played important roles in the sex disparity in hepatocarcinogenesis through an interaction with the estrogen and androgen receptors, independent of IL-6 signaling. Thus, the sex disparity in hepatocarcinogenesis may have several causes in addition to estrogen-mediated down-regulation of IL-6.

Several epidemiologic studies have shown that obesity and metabolic syndrome increase the risk of HCC^[41-43]. Although the mechanism by which obesity and metabolic syndrome promote hepatocarcinogenesis is not fully understood, it seems likely to be mediated, in part, by a state of chronic inflammation. A recent report by Park *et al*^[44] demonstrated that dietary- or genetically induced obesity promoted DEN-induced HCC along with low-grade inflammation, and ablation of IL-6 or the TNF receptor 1 abrogated their tumor-promoting effects, suggesting that IL-6 and TNF- α are required for the promotion of obesity-associated HCC. IL-6 and TNF- α produced by

adipose tissue or Kupffer cells activate hepatocyte STAT3 and NF- κ B, respectively, promoting cell proliferation and survival of initiated hepatocytes. In fact, recent clinical studies have suggested that visceral fat accumulation, insulin resistance, and dysregulation of adipokines, which induce the activation of the inflammatory response, play important roles in hepatocarcinogenesis^[45-47]. As the incidence rate of such obesity-associated hepatocarcinogenesis is likely to increase in the near future, inflammatory cytokines have also attracted considerable attention as a mediator of the association between obesity and hepatocarcinogenesis^[48].

Role of JAK-STAT signaling

JAK/STAT signaling pathways are important components of many cytokine receptor systems. Cytokines function by specifically recognizing their receptors, which, as a result of binding to their ligand, undergo conformational changes, resulting in the displacement of JAKs, and subsequently JAKs phosphorylate and activate STATs. The STAT protein family consists of seven members encoded by distinct genes. Among them, STAT3 is the most important IL-6 signaling pathway molecule and is recognized as a key player linking inflammation and cancer^[49,50]. In response to IL-6 signaling through gp130/JAK, STAT3 forms homodimers that translocate to the nucleus. STAT3 is constitutively active in many tumor cells, but not in normal cells, and regulates the expression of genes involved in tumor progression, such as cell survival, proliferation, invasion, and angiogenesis^[51].

Clinical and experimental evidence suggest the involvement of the STAT3 signaling pathway in hepatocarcinogenesis. Activated nuclear STAT3 is found in 60% of HCC and is more pronounced in aggressive tumors^[52]. In contrast, suppressors of this pathway, such as suppressor of cytokine signaling 3 (SOCS3), are down-regulated in HCC^[53]. In a mouse model, hepatocyte-specific STAT3 ablation prevented DEN-induced HCC development^[52], whereas hepatocyte-specific SOCS3 knockout mice were susceptible to HCC development through the enhanced activation of JAK/STAT and MAPK signaling^[53]. Hepatocyte-specific IL-6 and IL-6R transgenic mice spontaneously develop hepatocellular hyperplasia and adenomas, which are considered precancerous lesions in humans, accompanying STAT3 activation^[54]. Furthermore, in a human study, gain-of-function mutations in gp130 have been identified in 60% of benign hepatocellular adenomas with an inflammatory phenotype, and when combined with β -catenin-activating mutation, lead to HCC development^[55]. Thus, the IL-6-gp130-JAK-STAT3 signaling axis is an important contributor to HCC development, making it an attractive target for the treatment and/or prevention of hepatocarcinogenesis.

Interaction between STAT3 and NF- κ B has been reported at several levels in tumors. Some studies showed that STAT3 and NF- κ B co-regulate numerous oncogenic and inflammatory genes^[50]. Additionally, STAT3 directly interacts with RelA, trapping it in the nucleus, thereby

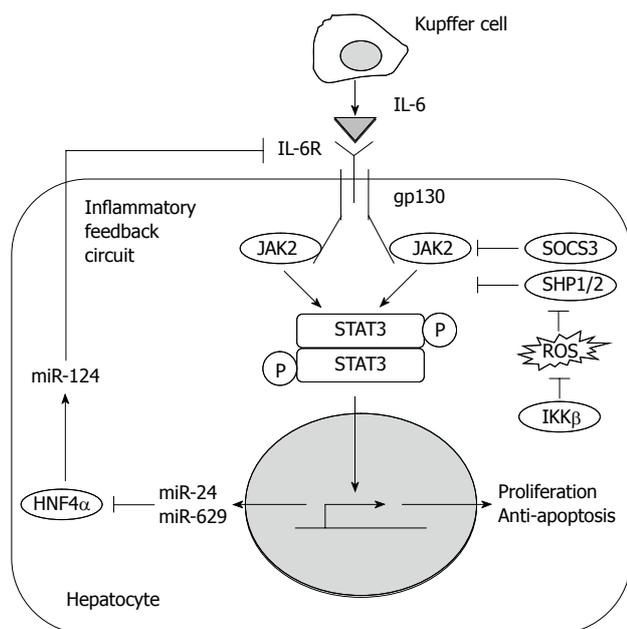

Figure 2 Implications and regulatory system of interleukin-6/gp130/janus activated kinase/signal transducer and activator of transcription 3 signaling in hepatocarcinogenesis. Interleukin (IL)-6 secreted by Kupffer cells activates signal transducer and activator of transcription (STAT) 3, which promotes the proliferation and survival of initiated hepatocytes. STAT3 activation is suppressed by I κ B kinase β through the prevention of reactive oxygen species. However, once STAT3 is activated, STAT3 activation becomes sustained through a microRNA feedback inflammatory loop. JAK: Janus activated kinase; SOCS3: Suppressor of cytokine signaling 3; IKK: I κ B kinase; HNF: Hepatocyte nuclear factor; ROS: Reactive oxygen species.

contributing to constitutive NF- κ B activation^[56]. On the other hand, a recent *in vivo* study revealed that IKK β /NF- κ B in the hepatocyte negatively regulated STAT3 activation in a DEN-induced HCC model^[52]. Inactivation of IKK β caused ROS accumulation and ROS were found to oxidize protein tyrosine phosphatases, including SHP1 and SHP2, which dephosphorylated JAK2 and STAT3. Oxidation of SHP1 and SHP2 results in the loss of their catalytic activity and the constitutive activation of STAT3. In fact, an inverse correlation between NF- κ B and STAT3 has been found in human HCC samples. This crosstalk may be a reason for the aggravation of DEN-induced HCC in hepatocyte-specific IKK β knockout mice. Furthermore, Bard-Chapeau *et al.*^[57] showed that hepatocyte-specific SHP2 knockout mice revealed spontaneous liver inflammation and tumorigenesis, accompanied by STAT3 activation. These mice also showed enhanced DEN-induced HCC, which was decreased significantly by intercrossing with hepatocyte-specific STAT3 knockout mice. These results suggest that the inhibition of STAT3 activation by SHP2 plays an important tumor-suppressing role in hepatocarcinogenesis (Figure 2).

Implications of microRNA in inflammatory signaling

MicroRNAs (miRNAs) are endogenous 20-23-nucleotide RNAs that play important gene-regulatory roles by pairing with the messenger RNAs of protein-coding genes to

direct their post-translational repression^[58]. Recently, miRNAs have been reported to be implicated in hepatocarcinogenesis through modulating inflammatory signaling pathways. Ji *et al.*^[59] found that miR-26 was significantly reduced in human HCC tissues, compared with surrounding non-tumor tissues, and a gene network analysis revealed that miR-26 expression was inversely correlated with the activation of NF- κ B and IL-6 signaling pathways. Although a causal relationship between miR-26 and hepatocarcinogenesis could not be evaluated in this study, Kota *et al.*^[60] showed that low miR-26 expression played a causal role in hepatocarcinogenesis using a myc-induced mouse HCC model, and induction of miR-26 by gene therapy suppressed HCC development.

More recently, hepatocyte nuclear factor 4 α (HNF4 α), a transcription factor that is essential for the development of hepatocytes, was reported to play a key role in hepatocarcinogenesis, linking miRNAs and inflammatory signaling pathways^[61]. Transient suppression of HNF4 α induces decreased miR-124 expression, leading to increased IL-6R expression and subsequent STAT3 activation. STAT3 activation not only plays the tumor-promoting roles described above, but also up-regulates HNF4 α -targeting miRNAs, miR-24 and miR-629, resulting in continued suppression of HNF4 α . Thus, transient suppression of HNF4 α initiates an IL-6/STAT3-mediated hepatocarcinogenesis process through a miRNA feedback loop circuit (Figure 2). The authors also showed that systemic administration of miR-124 prevented hepatocarcinogenesis by inhibiting the feedback loop and inducing tumor-specific apoptosis in mice. Thus, a therapeutic strategy targeting miRNA may be useful for the prevention and treatment of HCC.

STRESS-RELATED SIGNALING IN HEPATOCARCINOGENESIS

Stress-activated MAPK

MAPK cascades are signaling systems that transmit intracellular signals initiated by extracellular stimuli to the nucleus^[62,63]. The MAPK family consists of three major MAPK cascades, converging on extracellular signal-regulated kinases (ERKs), JNKs, and p38 MAPKs. Each MAPK signaling system comprises at least three components: MAPK, MAPK kinase (MAPKK), and MAPKK kinase (MAP3K). MAP3K phosphorylates, and thereby activates, MAPKK, and activated MAPKK, in turn, phosphorylates and activates MAPK. Among the three MAPKs, ERKs are activated predominantly by growth factors, whereas JNKs and p38 MAPKs, also called stress-activated MAPKs, are activated by stresses. We discuss the function and regulation of the stress-activated MAPKs in hepatocarcinogenesis in detail below.

Role of JNK signaling

JNK has three isoforms (JNK1, JNK2, JNK3) encoded by three loci. JNK1 and JNK2 are expressed ubiquitously, including in the liver, whereas JNK3 is expressed primar-

ily in the brain^[64]. JNK is phosphorylated and activated by two MAPKs, MKK4 and MKK7, and subsequently phosphorylates transcription factors, such as c-Jun and JunD, which compose the AP-1 complex^[65]. Additionally, JNK phosphorylates other proteins, such as Bcl-2 family members, and exerts various kinds of functions, depending on the cell type and stimuli^[66]. Furthermore, although JNK1 and JNK2 isoforms play redundant roles in many physiological processes, they also have distinct biological activities in some situations^[67,68].

The major functions of JNK in the liver are thought to be the induction of hepatocyte proliferation and cell death. JNK is involved in cell cycle progression, mostly through the activation of c-Jun. In this function, JNK1 is considered to be more important than JNK2, because proliferation of hepatocytes after partial hepatectomy is significantly impaired in JNK1 knockout mice, but not in JNK2 knockout mice^[69]. Additionally, hepatocyte death due to TNF- α , lipotoxicity, ER stress, ischemia-reperfusion, and drug toxicity, such as that from acetaminophen, are also considered to be JNK-dependent^[19,70-73]. JNK1 and JNK2 are, to some extent, redundant in this function. Although the downstream targets of JNK are not fully understood, most studies have demonstrated that JNK is required for the activation of the mitochondrial apoptotic pathway, through the activation of pro-apoptotic Bcl-2 family members^[74,75].

The role of JNK in hepatocarcinogenesis has been investigated using the DEN-induced HCC model^[76]. As mentioned above, hepatocyte-specific knockout of IKK β markedly promotes DEN-induced HCC, through enhanced hepatocyte death and compensatory proliferation^[21]. These phenomena can be partly explained by enhanced JNK activation in the setting of IKK β depletion. Because prolonged JNK activation is closely related to cell death, systems for the regulation of JNK activity are needed for tissue homeostasis. In this regard, NF- κ B plays an important role. Although several mechanisms have been proposed in the NF- κ B-mediated inhibition of JNK activation, ROS is one of the most important mediators^[25,77-79]. ROS accumulation, caused by the reduced expression of NF- κ B-dependent antioxidative enzymes, extends JNK activation by inactivating MAPK phosphatases that are essential for the dephosphorylation of activated JNK^[25]. In fact, the administration of antioxidants to hepatocyte-specific IKK β knockout mice decreased sustained JNK activation and hepatocyte death after DEN injection, and furthermore, intercrossing hepatocyte-specific IKK β knockout mice with JNK1 knockout mice significantly reduced DEN-induced hepatocyte death and compensatory proliferation, eventually suppressing HCC development^[21,76]. Additionally, JNK1 knockout mice showed a significant reduction of DEN-induced HCC, compared with wild-type controls. Thus, JNK1 is involved in hepatocarcinogenesis through hepatocyte death and proliferation, which are key components of necro-inflammatory cycles (Figure 1). Furthermore, in addition to the initial phase, JNK1 plays a tumor-

promoting role by enhancing cancer cell proliferation and neovascularization through the increased expression of cyclin D1 and vascular endothelial growth factor, respectively^[76]. Another study showed that JNK1 promoted HCC cell proliferation *in vivo* through the up-regulation of c-myc expression and the down-regulation of p21 expression^[69]. This study, however, also showed that JNK2 was not involved in hepatocarcinogenesis. In fact, JNK1, but not JNK2, is activated in approximately half of human HCC tissues, compared with adjacent non-tumor tissues^[69,80]. These results suggest that JNKs, especially JNK1, play an important role in the development of HCC. Notably, the pharmacological inhibition of JNK suppressed DEN-induced HCC and the growth of xenografted human HCC cells, suggesting that JNK may be a promising therapeutic target for HCC^[69].

On the other hand, a recent study using conditional JNK knockout mice showed that the ablation of both JNK isoforms, JNK1 and JNK2, in hepatocytes increased DEN-induced HCC, whereas the ablation of JNK1 and JNK2 in both hepatocytes and myeloid cells reduced hepatic inflammation and the development of HCC, indicating that JNK plays dual roles in hepatocarcinogenesis, depending on cell type and carcinogenesis stage^[81].

JNK plays a pivotal role in the development of metabolic syndrome-related disorders, including NASH^[41]. Inflammatory cytokines and ROS accumulation in the liver caused by obesity and fatty liver disease induce JNK activation, leading to insulin resistance by increasing inhibitory insulin receptor substrate 1 ser307 phosphorylation^[82]. As a clinical study showed that insulin resistance was a major contributor to obesity-mediated hepatocarcinogenesis, JNK may be a candidate therapeutic target in such situations^[83]. Furthermore, ROS-mediated JNK activation in the liver is linked not only to liver disease, but also to systemic disorders, such as atherosclerotic cerebrovascular diseases; thus, further elucidation of this process is important^[84,85].

Role of p38 signaling

The p38 MAPK family consists of four members: p38 α , p38 β , p38 γ , and p38 δ ^[86]. Among them, p38 α is abundant in most cell types, and its function has been investigated in most published studies of p38 MAPKs. p38 is activated through phosphorylation, primarily by MKK3 and MKK6, but phosphorylation by MKK4 and autophosphorylation are also involved in some stimuli^[87]. p38 can activate not only transcription factors, such as ATF2, p53, and Mitf, but also protein kinases, such as MAPKAP kinase 2 (MK2) and MK5^[88]. Although p38 was initially discovered as a regulator of inflammatory cytokine production, recent studies have revealed that it has tumor-suppressing properties. p38 inhibits tumorigenesis by the down-regulation of cyclins, up-regulation of cyclin-dependent kinase inhibitors, and modulation of the tumor suppressor p53, resulting in cell cycle arrest, oncogene-induced senescence, apoptosis induction, and contact inhibition^[86].

Although the roles of p38 in the liver have yet to be clarified, compared with JNK, major roles reported to date are the inhibition of hepatocyte death and proliferation. These effects of p38 are partially mediated by negative regulation of the JNK/c-Jun pathway. For example, hepatocyte-specific p38 α knockout mice showed much stronger lipopolysaccharide (LPS)-induced JNK activation in the liver, and intercrossing with hepatocyte specific IKK β knockout mice induced severe liver injury after LPS administration, suggesting that p38 α and IKK β act synergistically to protect the liver from TNF- α -induced hepatocyte death^[89].

The role of p38 in hepatocarcinogenesis has also been investigated using the DEN-induced HCC model^[38]. Similar to hepatocyte-specific IKK β knockout mice, hepatocyte-specific p38 α knockout mice showed enhancement of DEN-induced ROS accumulation, JNK activation, liver damage, and compensatory hepatocyte proliferation, eventually resulting in enhanced carcinogenesis. Another study showed the tumor-suppressing role of p38 through interaction with the JNK/c-Jun pathway by focusing on the antiproliferative effects in the advanced stage^[90]. However, in contrast to IKK β knockout mice, enhanced activation of the JNK pathway in p38 α knockout mice was accompanied by MAPKK activation, suggesting that the targets of p38 α may be upstream of JNK, such as MAPKKs and MAP3Ks^[38]. Consistent with these animal experiments, in human samples, the activity of the MKK6/p38 pathway is decreased in HCC tissues, compared with adjacent non-tumor tissues, and is significantly lower in larger HCC tissues^[91]. These findings suggest that the p38 pathway may play an anti-proliferative role in human HCC.

Regulatory system of stress-activated MAPK signaling by MAP3Ks

The evidence presented above suggests that JNK acts generally as a tumor promoter and p38 acts generally as a tumor suppressor in hepatocarcinogenesis, but some studies have shown opposite roles in HCC and other cancers. For example, JNK plays tumor-suppressing roles in mouse skin cancer and mammalian cancer models^[92,93]. Additionally, JNK has been reported to act as a tumor suppressor by inducing cancer cell apoptosis in HCC^[94]. As mentioned above, JNK was also reported to play dual roles in hepatocarcinogenesis, depending on cell type and carcinogenesis stage^[81]. p38 may also have oncogenic effects, facilitating cell invasion, inflammation, and angiogenesis^[95,96]. Furthermore, crosstalk among JNK, p38, and molecules involved in other signaling pathways, such as NF- κ B, further complicates their roles^[97]. Thus, understanding of the regulatory system of stress-activated MAPK signaling is necessary for the potential use of these molecules as therapeutic targets. Importantly, only two molecules, JNK and p38, are downstream in this pathway, whereas more than 10 molecules have been identified for upstream MAP3Ks^[98]. Each MAP3K is activated by several different kinds of stimuli, and integrated

into a unique pattern of MAPK activation and substrate phosphorylation, leading to a specific cellular response to the stimulus. Thus, the activities of JNK and p38 are tightly regulated by MAP3Ks. Several recent studies have uncovered roles of MAP3Ks in the regulation of stress-activated MAPK signaling in hepatocarcinogenesis.

Role of apoptosis signal-regulating kinase 1

Apoptosis signal-regulating kinase 1 (ASK1), one of the most important MAP3Ks, selectively activates JNK and p38 signaling in response to a variety of stimuli, including ROS and cytokines^[99]. In particular, ASK1 plays a key role in oxidative stress-induced cell death. In the absence of oxidative stress, thioredoxin (Trx), a reduction/oxidation regulatory protein, inhibits ASK1 kinase activity *via* direct binding to the N-terminal region of ASK1. However, once oxidative stress occurs in the cell, Trx is converted to its oxidized form and dissociates from ASK1, resulting in ASK1 kinase activation^[100]. ASK1 is considered to induce cell death through stress-activated MAPK-mediated activation of the mitochondrial cell death pathway^[101]. In fact, ASK1 is involved in acetaminophen-induced hepatocyte death, a typical ROS-mediated liver injury, through mechanisms involving Trx-ASK1 dissociation^[102]. Furthermore, ASK1 is involved in hepatocyte death mediated by death receptors, such as TNF-R and Fas^[75].

ASK1 knockout mice showed significantly increased DEN-induced HCC, suggesting that ASK1 plays tumor-suppressing roles in hepatocarcinogenesis in this model^[75]. Activation of JNK and the pro-apoptotic Bcl-2 family member Bim, which are required for death receptor-mediated apoptosis, are attenuated in ASK1 knockout HCC, resulting in decreased cancer cell apoptosis. On the other hand, ASK1 plays a minor role in the tumor-promoting effects of JNK, such as the DEN-induced acute phase reaction, cancer cell proliferation, and neovascularization. Thus, ASK1 is considered to play major roles in the tumor-suppressing part of JNK activity in hepatocarcinogenesis. Furthermore, DNA damage-induced p38 activation and subsequent p21 up-regulation is impaired in ASK1 knockout mice. Thus, ASK1 controls the tumor-suppressing function in stress-activated MAPK signaling through the induction of apoptosis and the DNA damage response.

Another study indicated that ASK1 and Bim are also required for sorafenib-induced apoptosis in HCC cells^[103]. Sorafenib is a small-molecule multikinase inhibitor that is currently the sole therapeutic drug effective for the treatment of HCC^[104]. Most recently, somatic mutations in the ASK1 gene, which reduce the kinase activity of ASK1, have been identified in melanoma^[105]. Thus, it may be important to clarify whether similar mutations are found in HCC, from the point of view of not only the carcinogenesis mechanism, but also possible therapeutic effects of anticancer drugs.

Role of transforming growth factor β -activated kinase 1

Another major MAP3K, activated kinase 1 (TAK1), is

activated through TNF receptor, TLR, IL-1 receptor, and transforming growth factor β receptor signaling, and then activates the JNK and NF- κ B pathways, which play opposing roles in cell death^[106]. Interestingly, hepatocyte-specific TAK1 knockout mice show spontaneous hepatocyte death, and this phenotype is partially rescued by crossing with TNF receptor 1 knockout mice, suggesting that TAK1 knockout hepatocytes are highly sensitive to endogenous TNF- α -induced apoptosis^[107]. This spontaneous cell death subsequently causes compensatory hepatocyte proliferation, inflammation, fibrosis, and the eventual development of HCC in aged mice^[107,108]. These phenomena resemble the phenotype observed in hepatocyte-specific NF- κ B knockout mice. Furthermore, JNK activation is rather enhanced in TAK1 knockout mice, indicating that TAK1 in the hepatocytes acts as a tumor suppressor, mainly by regulating the activation of the NF- κ B pathway. However, enhanced JNK activation in TAK1 knockout mice occurs partially through the activation of another MAP3K, TAO2, suggesting that TAK1 may interact with other MAP3Ks^[108]. Interestingly, crossing hepatocyte-specific TAK1 knockout mice with NEMO knockout mice attenuated JNK activation and prevented hepatocyte death and the development of HCC, suggesting that NEMO has a tumor-promoting function in the setting of TAK1 deletion^[108]. Additionally, this function of NEMO is considered to be independent of NF- κ B. Furthermore, a recent study showed that TAK1 inhibits ASK1-mediated apoptosis through a direct interaction between the C-terminal domain of TAK1 and the N-terminal or C-terminal domain of ASK1 in HEK 293 cells^[109]. Thus, in the setting of TAK1 deletion, ASK1 may play a tumor-promoting role by accelerating hepatocyte apoptosis and subsequent inflammation. Because crosstalk among MAP3Ks is less well understood, further studies are needed to clarify the whole picture of stress-activated MAPK signaling pathways.

CONCLUSION

One of the most important reasons for the poor prognosis of HCC is its frequent recurrence. Once HCC has developed, the recurrence rate does not decline with time, suggesting that most cases of late-phase recurrence are due to metachronous multicentric carcinogenesis caused by persistent chronic inflammation^[110]. Thus, determining the molecular mechanism(s) of inflammation-mediated hepatocarcinogenesis is important in preventing not only the occurrence, but also the recurrence, of HCC. As discussed in this review, recent studies have indicated that NF- κ B, STAT3, and stress-activated MAPK signaling pathways play key roles in inflammation-mediated hepatocarcinogenesis. These findings may prompt their introduction into the clinical setting as therapeutic targets. However, these pathways have a wide range of functions and exhibit complex crosstalk, and furthermore, may play opposing roles, depending on the cell type and carcinogenesis stage. Thus, alternative strategies, such as

targeting particular isoforms, including JNK1; upstream regulators, including MAP3K; and other modulators, including miRNA; may be more beneficial than targeting the entire pathway. In this regard, further studies clarifying the entire picture of the signaling network are needed to translate these signaling pathways into clinical practice.

Abstract

Acute pancreatitis is a common complication of endoscopic retrograde cholangiopancreatography (ERCP). Pancreatic duct stent insertion after ERCP has been widely accepted as the standard of care for the prevention of this complication in high-risk patients. Unfortunately, the placement of pancreatic stents requires higher level of endoscopic expertise and is not always feasible due to anatomic considerations. Therefore, effective non-invasive pharmacologic prophylaxis remains appealing, particularly if it is inexpensive, easily administered, has a low risk side effect profile and is widely available. There have been multiple studies evaluating potential pharmacologic candidates for post-ERCP pancreatitis (PEP) prophylaxis, most of them yielding disappointing results. A recently published large, multi-center, randomized controlled trial reported that in high risk patients a single dose of rectal indomethacin administered immediately after the ERCP significantly decreased the incidence of PEP compare to placebo.

INVITED COMMENTARY ON HOT ARTICLES

Acute pancreatitis is the most frequent complication of endoscopic retrograde cholangiopancreatography (ERCP). The incidence of post-ERCP pancreatitis (PEP) varies between 1%-10%, with incidence exceeding 25% being reported in certain high-risk patient populations^[1,2]. The wide range for this incidence is mostly due to the heterogeneous interplay of patient characteristics, procedure-related, and operator-related factors^[3,4].

Numerous agents and interventions have been studied so far in the prevention of PEP. These can be divided into sphincter relaxants, protease inhibitors, types of contrast, anti-inflammatory/anti-oxidant agents, anti-secretory agents, electrosurgical techniques, and placement of various types of pancreatic stents^[5]. The results have generally been disappointing and at present the only fea-

sible option to decrease the rate of PEP is the insertion of pancreatic stent in high risk patients. Unfortunately, the placement of pancreatic stents requires higher level of endoscopic expertise and is not always feasible due to anatomic considerations. Indeed, a recent survey reported that more than 20% of physicians performing ERCP never place pancreatic stents^[6]. Therefore, effective pharmacologic prophylaxis remains appealing, particularly if it is inexpensive, easily administered, has a low risk side effect profile and is widely available. Intravenous gabexate, a protease inhibitor, and somatostatin, an anti-secretory agent, have been shown to prevent PEP^[7]. However, both of these therapies are not readily available and require continuous intravenous infusion. As such, the search for effective, cheap and feasible pharmacologic prophylaxis for PEP has been continued.

Phospholipase A₂ is presumed to play a pivotal role in the inflammatory cascade associated with acute pancreatitis^[8]. This has been the basis for several prospective placebo-controlled randomized controlled trials (RCTs) evaluating non-steroidal anti-inflammatory drugs (NSAIDs), potent inhibitors of phospholipase A₂ activity, in the prevention of PEP. In 2003, Murray *et al*^[9] showed that rectal diclofenac given immediately after ERCP reduced the incidence of PEP in a high-risk patient population. These findings were corroborated by Khoshbaten *et al*^[10], who also demonstrated that immediate administration of rectal diclofenac after ERCP reduced the incidence of acute pancreatitis in patients undergoing pancreatogram. Studies evaluating rectal indomethacin have also suggested a protective effect against PEP in patients undergoing pancreatography or ERCP for biliary obstruction^[11,12]. In spite of these promising findings, the relatively small sample size of each of these studies and the heterogeneous study groups, have yielded overall inconclusive results.

A meta-analysis published in 2008 attempted to further validate the role of prophylactic rectal NSAIDs on PEP^[13]. Assuming a two-tailed $\alpha = 0.05$, a power of 0.9 and PEP incidences of 12.06% and 4.38% in the placebo and NSAID groups respectively, the authors concluded that a total of 586 patients would be required to demonstrate the intended decrease in the incidence of PEP. By compiling the results of four previous RCTs, an adequate pooled sample size was achieved to detect a statistically significant 64% (95% CI: 0.22-0.60) reduction in acute pancreatitis in patients who received NSAIDs immediately after ERCP when compared to placebo. The results of this meta-analysis further emphasized the apparent benefit of rectal administered NSAIDs for PEP prophylaxis and the need of large prospective multi-center trials to confirm these findings.

On the background of these promising results, Elmunzer *et al*^[14], report the results of a multi-center, randomized, placebo-controlled, double-blind clinical trial conducted to determine the effect of a single dose of rectal indomethacin administered immediately after ERCP in patients at elevated risk for PEP. Inclusion cri-

teria selected patients with an elevated baseline risk of PEP as defined by one or more of the following major criteria: clinical suspicion of sphincter of Oddi dysfunction (SOD), a history of PEP, pancreatic sphincterotomy, precut sphincterotomy, more than eight cannulation attempts, pneumatic dilatation of an intact biliary sphincter, or ampullectomy. Patients were also eligible if they met two or more of the following minor criteria: an age of less than 50 years and female sex, history of recurrent pancreatitis (≥ 2 episodes), three or more injections of contrast agent into the pancreatic duct with at least one injection to the tail of the pancreas, excessive injection of contrast agent into the pancreatic duct resulting in opacification of pancreatic acini, or the acquisition of a cytologic specimen from the pancreatic duct with the use of a brush. The study design consisted of patients randomly assigned to receive either two 50 mg indomethacin suppositories or two identical-appearing placebo suppositories immediately after ERCP. The randomization was concealed by using centralized location and stratified by study center. The primary and secondary outcomes of the study were the development of PEP^[15] and moderate or severe PEP, respectively. Patients with post-ERCP abdominal pain were hospitalized, followed clinically, and had their serum amylase and lipase measured at least once 24 h after the procedure. Patients discharged after uneventful ERCP were contacted within 5 d and again at 30 d to capture delayed occurrence of primary outcome and to assess for any delayed adverse events.

The study enrolled a total of 602 subjects from February 2009 through July 2011. An interim analysis recommended the study to be terminated early on the basis of the benefit of indomethacin compared with placebo. A total of 295 patients received indomethacin, and 307 patients received placebo. Baseline characteristics were similar in the two study groups. The majority of patients (82%) had a clinical suspicion of sphincter of Oddi dysfunction. The overall incidence of PEP was 13.1% (79 of 602 patients). The incidence of PEP was 9.2% (27 of 295 patients) in the indomethacin group compared to 16.9% (52 of 307) in the placebo group ($P = 0.005$), corresponding to an absolute risk reduction of 7.7 percentage points, relative risk reduction of 46%, with a number needed to treat to prevent one additional episode of PEP of 13. The secondary outcome of moderate or severe PEP occurred in 40 patients, 13 (4.4%) in the indomethacin group compared to 27 (8.8%) in the placebo group ($P = 0.03$). Among patients hospitalized for PEP, the median length of hospital stay was 0.5 d shorter in the indomethacin group (3.5 d) than in the placebo group (4 d) ($P < 0.001$). A persistent protective effect of indomethacin against PEP was noted in the post-hoc analysis of patients stratified based on their pre-treatment risk of PEP^[16], regardless of whether patients had undergone pancreatic stenting, clinical suspicion of SOD, and in all subtypes of SOD. The authors concluded that among patients at high risk for post-ERCP pancreatitis, rectal indomethacin significantly reduced the incidence of the

condition.

Acute pancreatitis remains the most common major complication of ERCP. NSAIDs represent an attractive pharmacological agent for PEP prophylaxis because they are inexpensive, can be easily administered and have a relatively low risk profile. Previous efforts to endorse NSAIDs for PEP prophylaxis have been limited by small single-center studies with conflicting results.

This study by Elmunzer *et al*^[14] is the first large multi-center, randomized, controlled trial that demonstrates the protective effects of a single dose rectal indomethacin against PEP in high-risk patients. The validity of the conclusions is supported by a number of the study methodological strengths including double blinded randomized design, adequate allocation concealment, strict clinically meaningful definition of PEP, thorough follow up with very low lost-to-follow-up rate and intention-to-treat analysis. The authors should also be commended for following the patients thirty days post-procedure to evaluate for any delayed pancreatitis or adverse events. A reduction in the incidence of PEP with rectal NSAIDs in the study group consisting primarily of patients with clinical suspicion of SOD (82%) confirms the benefit of this prophylactic agent in this challenging patient population. This finding is congruent with previous trials suggesting a maximal benefit from prophylactic NSAIDs in high-risk patients. Moreover, this study showed that the relative treatment effect of indomethacin remained across the spectrum of patient's risk of PEP. These results, in conjunction with a trend toward benefit with respect to rates of PEP in patients without clinical suspicion of SOD treated with indomethacin, suggest the need of additional studies to confirm a potential protective effect even in low-risk patients. The very high prevalence of patients with suspected SOD in this trial should be considered when interpreting the external validity of the results and applying them to other high risk PEP patients.

Prophylactic temporary pancreatic duct stenting has been widely accepted for PEP prophylaxis^[17]. One of the main limitations of previous prospective trials regarding the effects of NSAIDs for PEP prophylaxis is their failure to report the use of prophylactic pancreatic stents in their study population. A particular strength of this study is that the majority of patients (> 80%) underwent pancreatic stent placement in addition to the study intervention (indomethacin or placebo). Indomethacin reduced the risk of PEP to a similar degree irrespective to whether the patient received a pancreatic stent or not. These findings highlight the additive protective effect of NSAIDs for PEP prophylaxis in high-risk patients receiving temporary pancreatic duct stenting. Furthermore, it suggests that NSAIDs may be an alternate non-invasive prophylactic measure for PEP in those patients in whom pancreatic stenting may not be feasible or not recommended; however, this requires further investigation.

Elmunzer *et al*^[14] also reported that prophylactic indomethacin was associated with decreased severity of PEP, which is congruent with previous findings by

Sotoudehmanesh and colleagues. In the subgroup of patients that were hospitalized post-ERCP, the indomethacin group also had a shorter hospital stay when compared to placebo. These results suggest that the benefits of NSAIDs are not limited to reducing the incidence of PEP; but potentially also includes disease severity modulation presumably by regulating the inflammatory response and clinical manifestation of PEP. If further validated, these findings have both clinical as well as economic implications, given the substantial morbidity with increasing severity of PEP and associated health care expenditures.

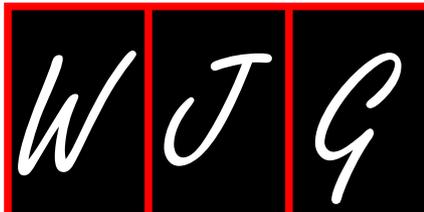

In summary, this multi-center double blinded randomized controlled trial further supports the use of prophylactic rectal NSAIDs in the prevention of PEP and addresses several limitations of previous studies that have been met with general skepticism. This study demonstrates that rectal indomethacin can reduce the incidence and severity of PEP in high-risk population consisting mostly of patients with suspected SOD and could potentially have a benefit even in low-risk patients. The low cost and risk profile associated with a single standard dose of rectal indomethacin makes this an attractive prophylactic pharmacological agent in those patients in whom this medication is not otherwise contraindicated. While clinical judgment in selecting patients with appropriate indications for ERCP remains the most important measure in preventing PEP, rectal indomethacin is a safe, easily administered, widely available pharmacological prophylactic measure that could change how we address this serious ERCP-associated complication.

Abstract

To date, limited research has been carried out in developing methods and materials that offer three-dimensional (3-D) representation of the digestive tract. In the field of capsule endoscopy (CE), hardware approaches have been developed that provide real time both 3-D information and texture using an infrared projector and a complementary metal oxide semiconductor camera. The major drawbacks of this system are its size, power consumption and packaging issues. A software approach to approximate a 3-D representation of digestive tract surface utilising current CE technology has been proposed. The algorithm utilizes the Shape from Shading technique and seem to provide promising results for polypoid structures and angioectasias. Further clinical evaluation is currently under way.

INVITED COMMENTARY ON HOT ARTICLES

I read with great interest the recent paper by Karargyris *et al*^[1] on the use of elastic video interpolation in the three-dimensional (3-D) reconstruction of the digestive wall in capsule endoscopy (CE) videos. The article presents promising 3-D approaches in CE; due to its technical nature though it may be slightly difficult for the general gastroenterologist. Therefore, I invited its first author to help me present the clinically relevant points. These authors believe that proper consideration should be given for its further clinical application in CE.

Wireless CE, a milestone in minimally invasive investigation of the gastrointestinal tract, was made possible by the advent of power efficient/low cost image sensors based on complementary metal oxide semiconductor (CMOS) technology^[2,3]. Upon the 1950's debut of the world's first gastro-camera, few could have envisaged that, just half a century later, imaging of the human digestive tract would become wireless^[4-6]. However, this spectacular advent in medical endoscopy is not without its limitations. Let us not forget that a complete capsule platform

Figure 1 Various sensors which are commercially available^[12]. A: Miniature magnetometers offer orientation and acceleration information, [Bertda Services (SEA) Pte. Ltd.]; B: Three-dimensional (3-D) range camera used in a widely commercial product; C: 3-D guidance system used in endoscopy devices (inition).

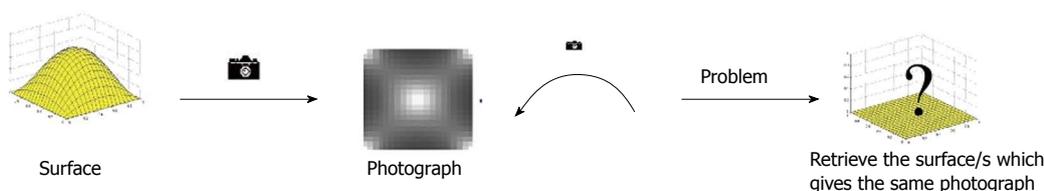

Figure 2 The Shape from Shading flow^[12,13]. Capturing a surface using a camera removes depth information. Shape from Shading techniques try to reproduce the missing depth information from a given image.

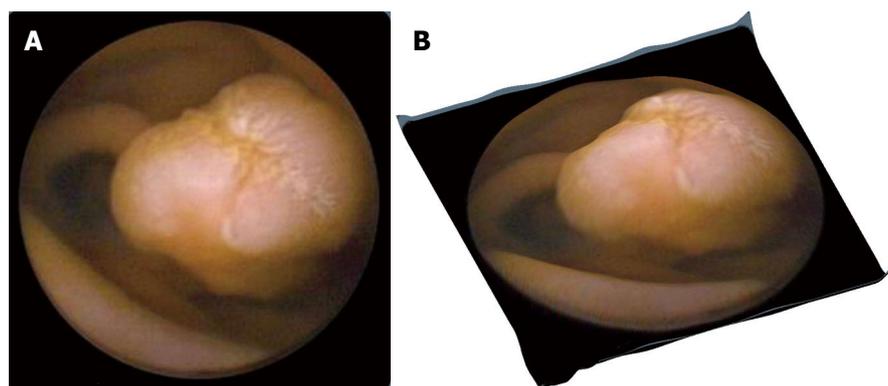

Figure 3 Original capsule endoscopy and 3-D represented image depicting a protrusion. A: Original capsule endoscopy image depicting a protrusion (polyp); B: Its 3-D represented image processed by the proposed Shape from Shading approach.

comprises six fundamental modules: locomotion, vision, telemetry, localisation, power and diagnostic/tissue manipulation tools^[7]. To present, due to space constraints, the majority of commercially available capsules include only a subset of the aforementioned modules^[7]. Furthermore, power limitation is a major hurdle which current CE technology has yet to overcome^[1,5,7].

Since the capsule needs 6-8 h to traverse through the small-bowel^[7,8], cameras within the currently marketed capsule endoscopes work at a capture rate of 2-3 frames per second (fps) in order to comply with power requirements^[7]. Nonetheless, this has an adverse effect on the smoothness of motion between consecutive frames and creates a visually unpleasant effect to the human eye^[1,7]. Furthermore, shape is an important element in human perception, yet CE suffers, unlike other diagnostic modalities i.e., Computed tomography, magnetic resonance imaging, from lack of 3-D information^[1]. Practically, this

can only be feasible with the use of new generation devices that have yet to be realised.

3-D technology is currently in use e.g., a magnetometer can provide not only acceleration values on the three axes but also the 3-D orientation of the device (Figure 1A)^[9]. Commercial time-of-flight range cameras (i.e., Microsoft's Kinect Project, Figure 1B)^[10] already exist in the market and in the near future this may be further improved and miniaturised for use inside a capsule endoscope. These cameras offer information on depth and colour. We should not forget that 3-D guidance systems are already used for endoscopic surgeries offering 3-D position information of the sensor (Figure 1C). Therefore, using the acquired information (orientation, acceleration, depth values, position *etc.*) from these miniature sensors in conjunction with sophisticated registration software algorithms, an accurate 3-D representation of the digestive tract could be created successfully.

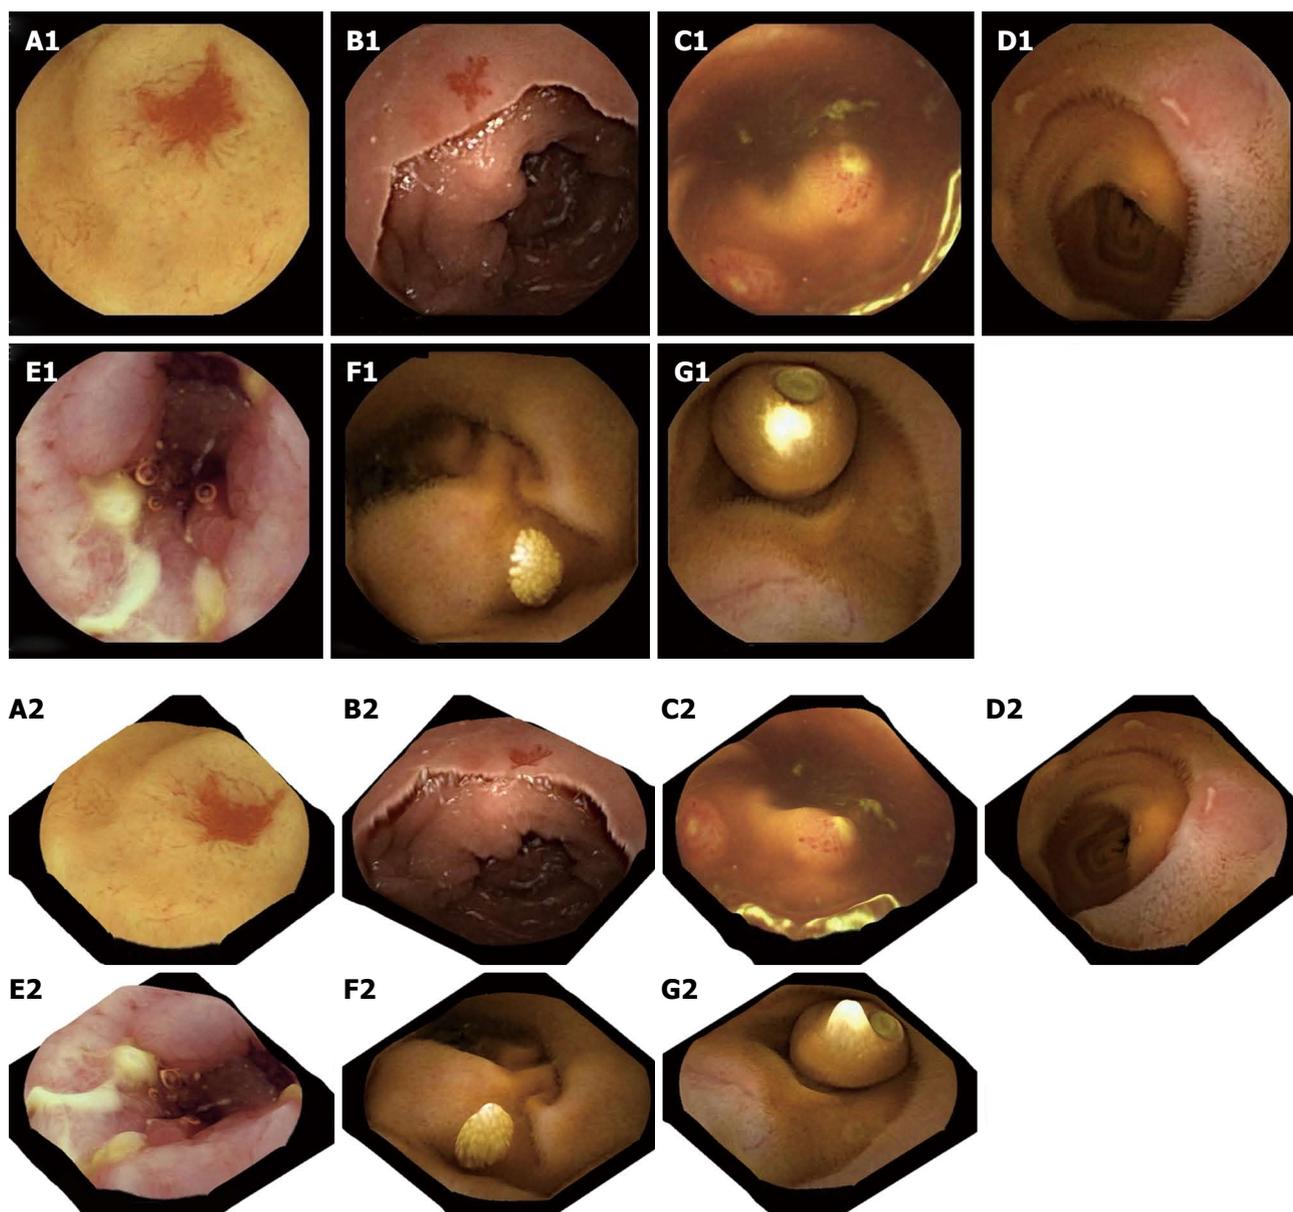

Figure 4 Two-dimensional capsule endoscopy images (upper panel) and three-dimensional representation of above structures is seen (lower panel). A1, A2: P2 angiectasia; B1, B2: P1 angiectasia; C1, C2: Lymphoid hyperplasia with superficial ulceration; D1, D2: Aphthous ulcers; E1, E2: Serpiginous ulcers; F1, F2: Nodular lymphangiectasia; G1, G2: Another capsule endoscope still inside the small-bowel.

Highlights removal

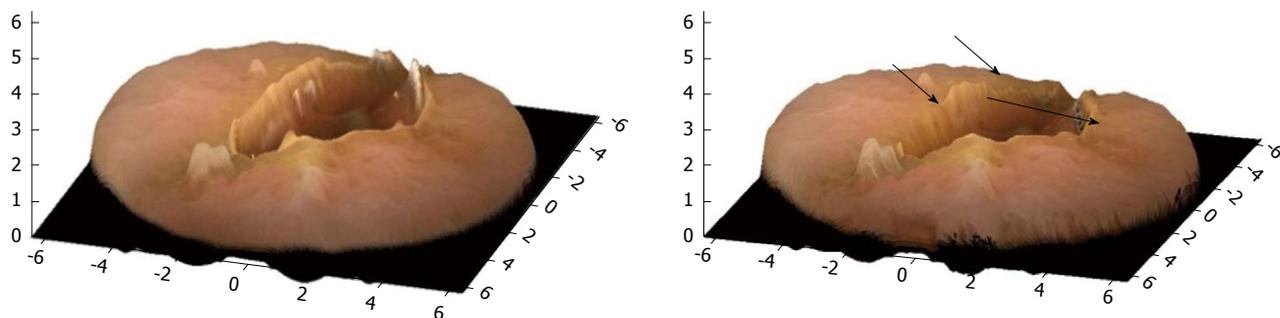

Figure 5 3-D representation of a single video capsule image with highlights removal (arrows).

3-D representation for endoscopy

To date, limited research has been carried out in developing methods and materials that offer 3-D representation of the digestive tract. For conventional endoscopy systems, stereo technology has been introduced to capture stereo images and to create depth information and therefore 3-D reconstruction of digestive structures. However, due to issues with size, such systems have not been widely accepted^[1,5]. Likewise, in CE there has been a hardware approach that provides in real time both 3-D information and texture using an infrared projector and a CMOS camera. The major drawbacks of this system are its size, power consumption and packaging issues^[11]. Therefore, in order to tackle the problem of the current hardware limitations, Karargyris *et al.*^[1,12] proposed the use of a software approach to approximate a 3-D representation of digestive tract surface utilising current CE technology.

Shape from shading

The Shape from Shading (SfS) technique is a member of a family of “shape recovery” algorithms called shape-from-X techniques^[1,13]. Essentially, SfS algorithms try to recover the shape of objects by using the gradual variation of shading (Figure 2)^[14]. SfS techniques can be divided into four groups or approaches: minimisation, propagation, local, and linear approaches^[13,14].

Karargyris *et al.*^[1] propose using a specific sub-category of SfS methods: the Tsai’s method (or linear approach)^[1,15] because (1) it produces good results for spherical surfaces, which in fact is the case with most shapes of digestive tract pathology e.g., polyps; (2) it is very fast; and (3) it “behaves” relatively well with specular surfaces (surfaces with mirror-like reflection of light). Of note, in CE the light source axis and the miniature camera are basically aligned. Tsai’s method works well on smooth objects and spherical structures^[15]. Additionally, Tsai’s method takes into consideration only the light direction, which in our case is 0° degrees (since the lighting direction and that of the camera are parallel).

A correction on the camera distortion is not performed because there is insufficient data on the capsule camera optics’ specifications. The result of applying Tsai’s method in a CE frame is given in Figure 3. Figure 3A shows a polyp in a conventional 2-D CE frame, whereas in Figure 3B the same polyp is presented using the 3-D software. The SfS approach gives promising outcomes, especially for visualizing polyps and vascular lesions, but less so for ulcers or lymphangiectasia (Figure 4). In the first 2 cases, the 3-D result is rather exciting, supporting the argument for further evaluation of this technique for use in clinical practice. Additionally, a 3-D representation may be helpful in the design of more accurate and robust computer-aided detection algorithms, incorporating other image enhancement tools e.g., virtual chromoendoscopy (FICE)^[16] or colour (blue) mode^[17] analysis of CE videos instead of still CE frames. However, prior to any software integration, further qualitative assessment and accuracy assessment should take place (work currently undertaken by

these authors).

Conversely, in cases of sudden large intensity change, Tsai’s method fails because it takes into consideration the preservation of intensity gradient. However, in non-artificial images such as CE frames, the brightness (image pixel values) transitions smoothly with no abrupt changes. Technically however, one can notice in Figure 5 the presence of highlights, hence false information about the shape. Highlights are essentially linear combinations of specular and diffuse reflection (light reflected at various angles) components of the surface.

Many objects in the real world are dielectric and homogeneous, hence displaying both types of reflections. Most digestive structures fall into this category^[18]. When the light beams fall on to such an object, some of them reflect back immediately creating the specular reflection, while the rest of the beams first penetrate the object and then reflect creating the diffuse reflection. Along with 3-D representation algorithm a highlight suppression scheme is applied to the original CE images to produce desired better results, whilst maintaining the shapes and structures of the digestive tract. Figure 5 shows the successful highlight removal without affecting the shapes of other objects. It has to be mentioned that highlights from light reflections on the surface of the digestive tract are still an open problem not only for a 3-D representation but also for traditional CE review.

In conclusion, the software by Karargyris *et al.*^[1] offers a new potential to reform and enhance the currently existing reading software in capsule endoscopy by improving lesion demarcation and highlighting the textural features of ulcers, angioectasias and polyps^[5,19]. Further work is needed to prove its clinical validity but the idea of a 3-D aid (with the present level of CE technology) seems, at least for this author, not only captivating but promising as well. However, it should not be forgotten that true 3-D capability requires dual video images, although the inclusion of two cameras within the shell of a capsule endoscopy might be unwieldy at present^[5].

Abstract

The inflammatory bowel diseases (IBD), Crohn's disease (CD) and ulcerative colitis (UC), may be complicated by colorectal cancer (CRC). In a recent population-based cohort study of 47 347 Danish patients with IBD by Tine Jess and colleagues 268 patients with UC and 70 patients with CD developed CRC during 30 years of observation. The overall risk of CRC among patients with UC and CD was comparable with that of the general population. However, patients diagnosed with UC during childhood or as adolescents, patients with long duration of disease and those with concomitant primary sclerosing cholangitis were at increased risk. In this commentary, we discuss the mechanisms underlying carcinogenesis in IBD and current investigations of genetic susceptibility in IBD patients. Further advances will depend on the cooperative work by epidemiologist and molecular geneticists in order to identify genetic polymorphisms involved in IBD-associated CRC. The ultimate goal is to incorporate genotypes and clinical

parameters into a predictive model that will refine the prediction of risk for CRC in colonic IBD. The challenge will be to translate these new findings into clinical practice and to determine appropriate preventive strategies in order to avoid CRC in IBD patients. The achieved knowledge may also be relevant for other inflammation-associated cancers.

INVITED COMMENTARY ON HOT ARTICLES

Incidence of colorectal cancer in inflammatory bowel diseases

The inflammatory bowel diseases (IBD), Crohn's disease (CD) and ulcerative colitis (UC), may be complicated by colorectal cancer (CRC). In a new population-based cohort study encompassing 47 347 Danish patients with IBD, 268 patients with UC and 70 patients with CD developed CRC during 30 years of observation^[1]. The authors concluded that the overall risk of CRC among patients with UC was comparable with that of the general

population [relative risk (RR), 1.07; 95% confidence interval (CI): 0.95-1.21]. The observed risk estimate persisted even after exclusion of patients with hemorrhagic proctitis (RR, 1.04; 95% CI: 0.91-1.18). When adjusted for age at diagnosis and duration of UC, a decreased risk of CRC among UC patients diagnosed in 1999-2008 was observed compared to UC patients diagnosed in 1989-1998 (RR, 0.59; 95% CI: 0.39-0.90). However, patients diagnosed with UC during childhood or adolescents (age 0-19 years; RR, 43.8; 95% CI: 27.2-70.7, age 20-39 years; RR, 2.65; 95% CI: 1.97-3.56) may be at increased risk as well as those with long duration of disease. Thirteen years after diagnosis, the CRC risk was significantly increased over background, and with longer follow-up the risk remained 50% above the risk in non-IBD individuals. The risk of CRC in patients with CD was similar to that of the non-IBD population. RR for CRC was 0.85 (95% CI: 0.67-1.07) among patients with CD and 0.80 (95% CI: 0.43-1.49) among patients with colonic CD.

Risk of CRC in IBD has been assessed previously in a Swedish population-based study^[2]. In agreement with the present study there was a trend towards lowered risk with shorter observation period^[2]. During 198 227 person-years follow-up for 7607 IBD cases, 188 cases of CRC were observed from 1954 to 2004^[2]. After adjusting for sex, age, duration of disease, type and extent of IBD, the authors found a decline in relative risk from a 5-fold increased risk in the 1960s to a doubled risk of CRC in the time-period 2000-2004 (*P* for trend 0.006). The overall risk of CRC among the patients with IBD, UC and CD colitis was found to be increased compared with the general population (standardized incidence ratio 2.3; 95% CI: 2.0-2.6, 2.7; 95% CI: 2.3-3.2, and 2.1; 95% CI: 1.2-3.4, respectively). The CRC risk among patients with colonic CD has also been estimated in hospital-based or community-based case-control studies^[3-5] and the overall relative risk estimate over the past 30 years was found to be 4.5 (range: 1.3-14.9) in a meta-analysis, with declining risk estimate over the past 30 years^[3]. On the other hand, a recent study by Herrington *et al*^[6] which was also published in *Gastroenterology* assessed time changes in risk of CRC within the Kaiser Permanente Medical Care Program, a community-based health care delivery system, from 1998 to 2010. The authors identified 29 and 53 CRC cases among CD and UC patients, respectively, corresponding to an incidence of CRC in patients with IBD which was 60% higher than in the general population. Furthermore, the incidence was found to be essentially constant over time. The study design may have some drawbacks such as missing detailed data on the study participants, selection bias, and too short observation period to detect the impact of optimizing IBD management on CRC risks which were discussed in the Editorials^[7].

There is general agreement that patients with UC diagnosed at a young age, with primary sclerosing cholangitis, and with long disease duration are at increased risk of CRC^[8-10]. Most cancers arise in extensive colitis and pancolitis and there is little or no increased risk associated

with proctitis while left sided colitis is associated with an intermediate cancer risk^[11,12]. The Danish study found no risk associated with having UC even after excluding cases with proctitis compared to the general population^[1].

According to the British Society of Gastroenterology (BSG) "It is now widely accepted that patients with ulcerative colitis have a similar risk to those with Crohn's colitis for a similar extent and duration of colonic involvement"^[13]. The Danish population-based study covered 30 years follow-up of all UC and CD patients and is by far the largest study to date on IBD and CRC risk^[1]. This study found no risk of CRC among patients with colonic CD compared to the general population which the authors speculated could be due to the medical treatment and follow-up leading to control of the intestinal inflammation^[1].

Surveillance colonoscopy is considered to be the gold standard in diagnosing early dysplastic alterations. The recent years new and emerging endoscopic imaging techniques have improved neoplasia detection rate^[14]. The existing recommendation is, however, based on evidence level IV: Evidence obtained from expert committee reports, opinions or clinical experiences of respected authorities^[13]. The study by Jess and colleagues constitutes a basis for future evidence-based guidelines.

Understanding the mechanism(s) of CRC in IBD

The relationship between inflammation and cancer has been well established in the gastro-intestinal system. Colitis-associated cancer has been investigated in mouse models^[15-17]. These studies have highlighted the role of toll-like receptors (TLR) and tumour necrosis factor- α (TNF- α) in the activation of nuclear factor κ B (NF κ B), which induces transcription of genes involved in tumorigenesis, including COX-2^[15-17]. Defect signalling via p53 may be an early event in the progression of colitis-induced dysplasia to cancer^[18]. Without p53-induced apoptosis, aberrant cells are not eliminated and cancer may ensue^[18]. Probiotic bacteria may prevent carcinogenesis in mouse models of cancer by producing conjugated linoleic acid which activates PPAR γ , inhibits COX-2 and induces apoptosis^[19,20].

Current strategies to identify genetic predictors of CRC in IBD

It is increasingly recognized that CRC consists of many entities having similar phenotypic appearance. This heterogeneity may at least in part be due to differences in genetic susceptibility which may act in combination with various environmental factors such as diet and intestinal microbes. Patients with IBD and CRC constitute 1%-2% of all cases of CRC^[21]. As a group, patients with IBD-associated CRC are characterized by intestinal inflammation and may thus represent a model with a relatively homogeneous mechanism for developing CRC. Indeed, distinct characteristics have been found for IBD-associated CRC. For example, a Norwegian study found that cancer was more often widespread than localized at diag-

nosis, age at diagnosis of CRC was lower, and prognosis poorer in IBD-associated CRC compared to CRC in the background population^[22]. Thus, "IBD-associated cancer serves as an excellent model of inflammation-associated cancer and might provide many important clues to understanding the pathogenesis of sporadic colorectal cancer"^[23]. On the other hand, a Swedish population-based study of more than 30 000 IBD cases identified 560 CRCs cases among first-degree relatives, giving no increased risk of CRC among first-degree relatives^[24]. The authors concluded that the study did not suggest a common cause of IBD and CRC in general and the risk of CRC in IBD seemed to be the result of the disease rather than genetic predisposition^[23].

The International IBD Genetics Consortium is a network of researchers working on the genetics of IBD^[25]. This group has initiated a case-control study to determine if genetic polymorphisms associated with IBD and other immune disorders related to IBD are more prevalent in patients with colonic IBD and CRC/dysplasia than in patients with colonic IBD alone. For each case with IBD-associated CRC/dysplasia, two IBD non-cancer cases from the same centre will be included. Analyses are carried out using the Immunochip, an Illumina Infinium genotyping chip containing 196 524 polymorphisms (718 small insertion deletions, 195 806 SNPs). The Immunochip was initiated by the Wellcome Trust Case-Control Consortium and designed to perform deep replication of major autoimmune and inflammatory pathways^[26]. Phenotypic information includes age at IBD and CRC/dysplasia diagnosis, gender, disease location, family history of CRC/dysplasia, medication, history of hospitalizations, and smoking habits.

Another approach may be based on utilizing existing pathological samples. For example, in Denmark, individual-based registration-systems have been developed along with the introduction of information technology and since 1978 nation-wide reporting of clinical diagnosis has been implemented^[27]. Due to the introduction of DNA changes (e.g., mutations and polyploidy) during carcinogenesis, pathological samples with signs of CRC should be avoided. Samples with signs of IBD which precede CRC development, may be used for DNA extraction and assessment of genetic polymorphisms^[28-31]. Furthermore, data may be linked to other registers such as Danish National Patient Register and The Danish Prescription Database for further investigations^[32]. The validity of the diagnoses of IBD and CRC, respectively, in the Danish National Patient Register are more than 90%^[33,34]. Thereby, candidate gene analyses of genetic polymorphisms in inflammatory pathways and associations found by genome-wide association studies may be performed and sought replicated.

Future research directions to predict the risk for CRC in IBD

A major challenge is now to identify the patients who would benefit from preventive strategies. Large and well-

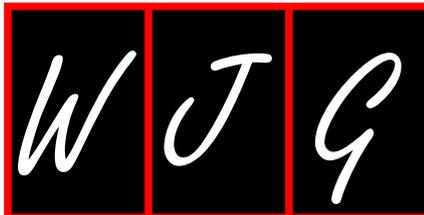

designed cohorts, such as population-based cohorts, with prospectively recorded data are required for the assessment of patients at risk. Provided that genetic susceptibility contributes to the risk of CRC in IBD, investigating genetic susceptibility in IBD patients may be particularly rewarding due to the expected relatively homogeneous biological mechanism(s) of action in this group. This may imply that associations may be identified in relatively small groups of well-characterized patients. The further advance will depend on the cooperative work of e.g., epidemiologists and molecular geneticists. The ultimate goal is to incorporate genotypes and clinical parameters into a predictive model that will refine the risk for CRC in colonic IBD. The challenge will be to translate these new findings into clinical practice and to determine appropriate preventive strategies in order to avoid CRC in IBD patients.

Abstract

Celiac disease (CD) is an autoimmune inflammatory disease of the small intestine as a result of reaction to wheat protein, gluten. Exclusion of dietary gluten is the mainstay of the treatment that necessitates a precise diagnosis of the disease. Serological screening may aid in identifying patients with suspected CD, which should be confirmed by intestinal biopsy. It has been shown that duodenal biopsies are good for detection of the disease in most patients. However, there is a group of patients with positive serology and inconclusive pathology. As a result of the widespread use of serology, many patients with equivocal findings grow quickly. Unfortunately current endoscopic methods can only diagnose villous atrophy, which can be present in the later grades of disease (i.e., Marsh III). To diagnose CD correctly, going deeper in the intestine may be necessary. Enteroscopy can reveal changes in CD in the intestinal mucosa in 10%-17% of cases that have negative histology at initial workup. Invasiveness of the method limits its use. Capsule endoscopy may be a good substitute for enteroscopy. However, both techniques should be reserved for patients with suspected diagnosis of complications. This paper reviews the current literature in terms of the value of enteroscopy for diagnosis of CD.

INTRODUCTION

Celiac disease (CD) is the most common inflammatory disease of the small bowel with a prevalence of 1%-2.1% in different countries^[1]. CD was previously thought to be a pediatric malabsorption syndrome, but it is now primarily recognized as an adult disease that resembles a multisystem disorder with a range of clinical manifestations that vary according to age of presentation. The clinical presentation among adults has clearly changed over time. Typical presentation should not be expected in the adult population; fewer patients present with diarrhea or a malabsorption syndrome. Instead, silent symptoms such as anemia, osteoporosis or dyspepsia are the most common manifestations, and interestingly, patients are frequently overweight or even obese at presentation. Patients may also present with vague dyspeptic symptoms or esophageal reflux, irritable bowel syndrome, iron deficiency, or neurological disorders. In fact, over time there has been a substantial increase in prevalence of the disease, and serological testing for CD has affected the rate of diagnosis^[1-4].

Widespread use and availability of serology and awareness of the disease have led to a surge in the diagnosis of CD from a very rare disease to a common one.

In fact, screening of asymptomatic and at-risk individuals has contributed to this high prevalence^[3]. The majority of CD patients detected by screening (> 80%) are clinically silent or so called “oligosymptomatic”^[4]. Mainstay vehicles for screening are autoantibodies to tissue transglutaminase and endomysial antibody (EMA), which are highly sensitive and specific^[4-7].

Despite these effective tools, small bowel biopsy should be performed in suspected patients, and histopathological examination of the small intestine must show any of the following: villous atrophy, crypt hyperplasia and elevated intraepithelial lymphocytes (IELs). Although small bowel mucosal changes are not specific for CD, abnormal biopsy findings can confirm the diagnosis in the context of the clinical setting that includes symptoms, serology and exclusion of other disorders. The only current and effective treatment is dietary restriction of the gluten in affected individuals, which necessitates the correct diagnosis.

CD AT A GLANCE

Characteristic pathological changes of the small bowel found in CD have been classified by Marsh and further modified by Oberhuber^[8,9]. It is believed that small-bowel mucosal damage has three phases. In phase 1, the infiltrative phase, there are increased numbers of IELs. In phase 2, the hyperplastic phase, there is crypt hypertrophy. The destructive phase 3 of the disease is associated with varying degrees of villous atrophy that can be assessed during endoscopy^[8,9]. The mucosal changes associated with CD can be patchy with parts of the mucosa appearing normal and nearby parts severely affected in children and adults. This patchy villous atrophy or disease poses a significant sampling error that leads to the possibility of missing the diagnosis, which can be detrimental for a young patient with long life expectancy, because the course of untreated CD is not always benign. Delay in diagnosis in patients with severe presentation is associated with increased mortality, primarily because of malignancy. A major question is the ultimate outcome of undiagnosed, presumed silent CD? It has been suggested that there is a significantly increased risk of mortality in patients with undiagnosed CD. However, the association with increased mortality is not universal nor is the association with increased malignancy^[10-12]. Early diagnosis and treatment of CD has the potential to decrease risks of lymphoma, gastrointestinal cancer, bone disease, endocrine abnormalities, infertility and other autoimmune diseases^[13].

As a consequence of an intensified screening policy, individuals with positive antibodies but without diagnostic small-bowel mucosal villous atrophy frequently are found. The condition often is considered false-positive, but there also is evidence to suggest that such a finding is indicative of early stage CD. Randomized clinical trials on the natural history and treatment of CD patients with mild mucosal changes and positive antibodies are lacking, and there is no consensus whether these patients should be treated at all with a gluten-free diet before villous atro-

phy has developed^[2,10,13-15].

Despite recent advances in endoscopic imaging and serological tests, the accurate diagnosis of CD remains challenging. The site and number of biopsies to diagnose CD correctly have been the focus of recent research. Newly introduced technologies may carry a high yield but availability may limit their widespread use.

The gold standard of diagnosis relies on duodenal biopsy^[16]; however, the reliability of duodenal biopsy is not straightforward. Patients come to biopsy because of the result of positive serological tests, a high index of suspicion for a mucosal disease process, or because of routine duodenal biopsy at endoscopy^[17]. Biopsies from different sites of the duodenum in patients with positive celiac serology undergoing biopsy showed that none of the biopsies were considered normal. Moreover, in only 50% of patients was the degree of villous atrophy present in all sites the same; consistent with the patchy nature of the degree of villous atrophy. An interesting observation is that total villous atrophy significantly increased in a distal direction. Although more severe degrees of villous atrophy have been found distally, the diagnosis has mostly been confirmed in any location in the duodenum or jejunum^[2,9,10,15].

INTESTINAL INVOLVEMENT

CD involves the proximal small intestine including duodenum and upper jejunum and extends distally for a variable length into the ileum. Damaged small bowel mucosa heals in a distal to proximal direction. Mucosal atrophy is continuous in most patients as a diffuse proximal enteropathy, which can be seen by any means of endoscopy. Autopsy studies on CD patients have also confirmed the involvement of the duodenum and jejunum in most cases and occasional extension into the ileum. However, distribution and extent of the CD are variable^[13,18].

Dickey *et al*^[19] have evaluated terminal ileal biopsies of 30 patients with CD and control patients and found that IEL counts were significantly higher in the CD group. They concluded that increased IELs in the terminal ileum correlated with duodenal atrophy, and that this finding should alert physicians to consider CD.

Although evaluation of the extent of the bowel involvement is not possible by conventional methods, capsule endoscopy (CE) can give an estimation about whether the whole of the small bowel is affected. It has been reported that 66.6% of patients with CD had an extension of the mucosal changes beyond the proximal small intestine and 11.1% had entire small bowel involvement^[20]. According to Murray *et al*^[21], in the majority of patients, the abnormal findings seen in the CE started in the proximal duodenum and extended into the jejunum. Findings of atrophy were seen in a continuous pattern in the duodenum, but features of atrophy were seen less obviously and were patchy in the jejunum. Extensive enteropathy was seen in 59% of the patients, denoting that CD affected the small bowel more than we think.

Mucosal specimens can be obtained using radiographically guided suction capsule (Crosby capsule) biopsy, which has disadvantages such as long procedure time, high failure rate, discomfort and radiation exposure during the procedure, although it is possible to take large biopsy specimens. Perforation, intramural hematoma of the small bowel and pancreatitis are reported complications^[22]. Nowadays, Crosby capsule biopsy is not performed due to comparable efficacy of the duodenal biopsy to detect villous atrophy. Another important fact to take into account is the patchy nature of CD, which necessitates multiple biopsy approach to minimize sampling errors^[23].

There are no clear-cut recommendations for the exact number of biopsy specimens to confirm or exclude diagnosis of CD, although the American Gastroenterological Association technical review recommends 4-6 biopsies^[24]. Unfortunately, there is a gap between evidence-based data and real-life practice. A survey has shown that 63% of patients had fewer than four duodenum biopsies, which may indicate the reluctance of the endoscopists to take an adequate number of biopsies^[25].

Site of the biopsy is another object of the debate. Pais *et al*^[26] have found that duodenal biopsy specimens show some variability in terms of histological changes, and a minority of patients may have a discrepancy of more than two Marsh grades between biopsy sites. Ravelli *et al*^[15] have found no cases of normal histology and coexisting villous atrophy in the same patient. This observation was supported by another study by Thijs *et al*^[22] in which no discrepancy between jejunal and duodenal biopsies was found. Biopsies from the duodenum have been demonstrated to be useful for the diagnosis of CD and almost replaced the need for the jejunal biopsy.

Unfortunately, biopsy specimens from the duodenum harbor some problems and may not be a good place for the diagnosis of CD, given the nature of the disease and necessity of a strict diet. Not only is there more natural irregularity of the proximal duodenal mucosa, but specifically, the influence of nutrients mixed with gastric acid from the stomach and digestive fluids released into the duodenum in reaction to a meal may induce a chronic mild inflammatory response^[27,28]. This may alter the appearance of mucosal inflammation and villous architectural changes, and therefore, disqualify duodenal biopsies for diagnostic use, especially when minor architectural changes and intraepithelial lymphocytosis must be considered^[29].

All of the current endoscopic imaging techniques rely on the morphological changes of the mucosa associated with CD, which may direct the endoscopist for sampling. The value of endoscopy in the diagnosis of CD is limited to villous atrophy (Marsh grade 3). Celiac patients with villous atrophy are easily diagnosed, and most of them have positive serology, thus making this group of patients non-challenging. Histological changes in this group are so characteristic that they cannot be mistaken for other diseases. In contrast, patients with milder enteropathy,

which is the most prevalent form of the disease at present, may show increased IELs that cannot be identified under white light or even with narrow band imaging or magnification endoscopy.

Diagnostic accuracy of biopsy specimens can be improved with advanced endoscopic technologies. Magnification endoscopy with narrow band imaging is a useful tool for obtaining biopsies at diseased sites^[30]. These white light or blue-green light endoscopies are not capable of detecting increased IELs, which in turn limits us to the advanced stage of the disease with apparent atrophy and changes, but the problem is to detect the patients with subtle changes (i.e., Marsh grades 1 and 2). Confocal endomicroscopy (CEM) may aid in diagnosis in theory. However, fact is a little different from theory; CEM is good at detecting atrophy, although it cannot differentiate subgrades, and increased IELs, but falls short at detecting crypt hyperplasia, topical acriflavine use is helpful for quantification of IELs but fluorescein is not helpful. Very limited availability and safety issues on acriflavine use are the major drawbacks of CEM, and some imaging improvements should be done before its prime time use in CD^[31].

ENDOSCOPIC FEATURES OF CD

The opportunity to make a correct diagnosis of CD might, therefore, also depend on the endoscopic appearance of the small bowel mucosa. Several endoscopic markers related but not specific to CD have been identified. These endoscopic markers are useful to determine whether duodenal biopsies are indicated and possibly to target from where biopsies should be taken. Endoscopic markers of CD are as follows: a reduction or absence of duodenal folds; scalloping, which is a notched appearance of the duodenal folds; visible submucosal vasculature; a mosaic pattern, which is the micronodular or cobblestone appearance of the mucosal surface; and mucosal fissures, crevices or grooves^[17] (Figure 1). These indirect signs of villous atrophy have been helpful for predicting the presence or absence of duodenal villi and for targeting duodenal biopsies during upper endoscopy for diagnosing CD. Nevertheless, the sensitivity of these signs has been demonstrated to be variable in the different studies, and therefore, multiple endoscopic biopsies from descending duodenum and bulbar mucosa are recommended to ameliorate the diagnostic accuracy and to avoid underdiagnosis of patchy forms of CD^[32,33].

Contradictory results concerning the value of these endoscopic markers of villous atrophy have been reported. Among several studies, the overall sensitivity and specificity of endoscopic markers of CD vary from 6% to 94% and from 83% to 100%, respectively. Several possible explanations exist for the absence of endoscopic markers in patients with CD. For example, such markers might actually be absent for degrees of enteropathy milder than subtotal or total villous atrophy (e.g., partial villous atrophy) and absent in cases in which the histo-

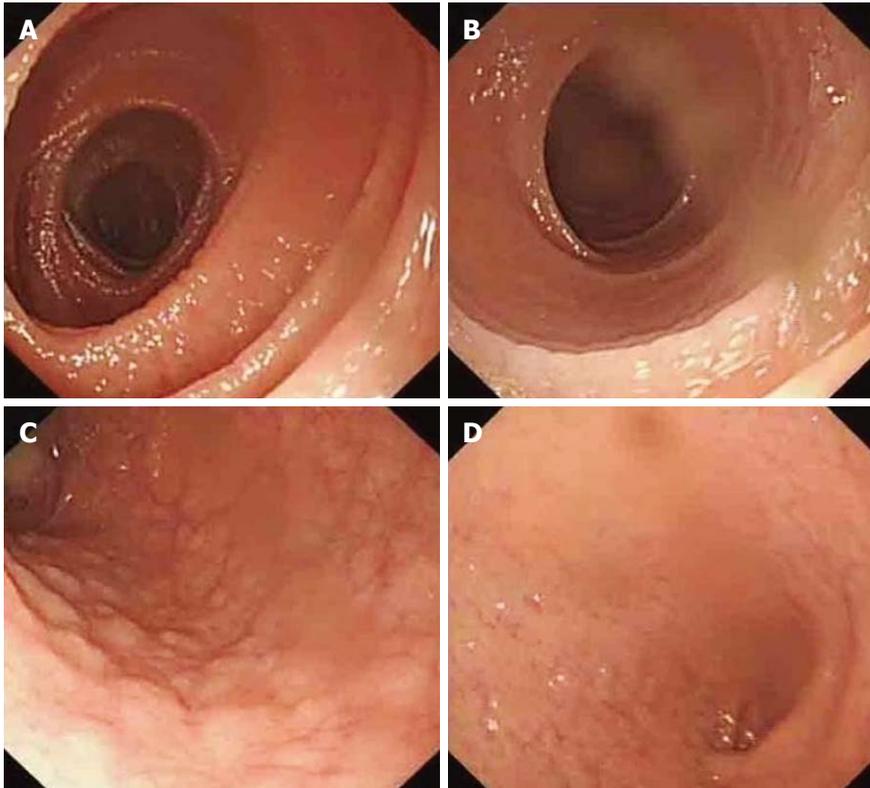

Figure 1 Proximal jejunum mucosa showing scalloping (A), reduced loss of mucosal folds (B), nodularity and mosaic appearance (C) and total mucosal atrophy (D), seen in patients with celiac disease during enteroscopy.

pathological involvement of the duodenum is patchy. In contrast, scalloping of duodenal folds has been reported in some patients who have moderate-to-severe enteropathy that is unrelated to CD; scalloping has a positive predictive value of 69% for CD and 96% for any duodenal mucosal pathology^[34]. Scalloping is not specific for CD but rather a predictor of mucosal disease as evidenced by villous atrophy, widening, and edema^[35].

It is possible to augment the villous changes by a simple procedure of underwater examination of the mucosa, which is called the water-immersion technique (WIT), which consists of the instillation of water into the duodenum after removal of air and adds only a few seconds to the examination time. WIT-assisted duodenoscopy has been demonstrated as reliable in distinguishing accurately the presence or absence of villi in the duodenal bulb and the descending duodenum^[32,33]. However, no study has specifically addressed the value of WIT during enteroscopy. We usually perform WIT to assess the villi structure in the jejunum during the enteroscopy examination of patients with diarrhea and malabsorption and find it useful for diagnosis of CD.

MAKING THE CASE FOR ENTEROSCOPY

CD is a gluten-dependent enteropathy characterized by chronic small intestinal inflammation and villous atrophy. However, CD is not the only cause of an inflammatory cell infiltrate with or without villous atrophy in duodenal

mucosa. Other causes include postviral enteritis, cow or soy milk enteritis, Crohn's disease, common variable immunodeficiency, autoimmune enteropathy, nonsteroidal anti-inflammatory drugs, giardiasis, tropical sprue, and tuberculosis. It is more likely that the normal state of the bulb mucosa is not as free of inflammation as is mucosa of the second or third part of the duodenum, nor does it have a villous/crypt ratio the same as these zones. It has been proposed that the anatomical location of the bulb makes it more vulnerable than the more distal duodenum to injury by gluten. However, similar reasoning applies also to potential injury of the bulbar mucosa by aforementioned causes and gastric acid. In addition, Brunner's glands and lymphoid nodules can give a common endoscopic finding of nodularity in the duodenal bulb, which can also distort the overlying architecture. On biopsy, lymphoid aggregates are also commonly found in the duodenal bulb of younger children. That is why some findings in the bulb may be a part of life rather than disease. Biopsy samples from the duodenal bulb may be difficult to interpret, in fact, the duodenal bulb is not considered a useful site for the diagnosis of CD, even though this site has rarely been reported to be the only one showing reliable histological changes in adults and children with CD. Taking biopsy samples more distally may decrease the likelihood of confusing histological findings^[34].

CD has many atypical manifestations, and endoscopic findings alone are not considered sensitive or specific for the diagnosis of CD. Pais *et al*^[20] examined 247 patients

to determine how many duodenal biopsy specimens were needed to diagnose CD. They concluded that only two specimens led to confirmation of CD in 90% of cases and that four descending duodenal biopsy specimens led to 100% confidence in the diagnosis. Comparison of biopsy specimens from the second, third, and fourth parts of the duodenum, the ligament of Treitz, and the proximal jejunum has shown that each site is suitable for diagnosing CD^[7]. Mucosal specimens taken from the distal duodenal or jejunal mucosa are strongly correlated, therefore, biopsy samples from the second or third part of the duodenum are considered adequate to obtain material for histological interpretation^[29]. Thus, biopsy of the other parts of the small intestine may be needed for precise diagnosis of CD, which is an indication for enteroscopy.

ENTEROSCOPY

We have long been aware that complete examination of the small bowel is crucial for evaluation of refractory disease or its complications. However, conventional endoscopy has limited value for evaluation of complications like ulcerative jejunoileitis and lymphoma that may be located deep in the small bowel, which necessitates deep enteroscopy techniques such as push enteroscopy (PE), balloon-assisted enteroscopy (BAE) and CE. Invasiveness of the enteroscopy technique limits its use. Two studies have explored the value of PE for the diagnosis of complicated CD.

Höroldt *et al*^[36] have searched the possible role of PE with jejunal biopsies. They prospectively recruited 31 patients who had symptoms suggestive of CD and positive serology, but non-diagnostic duodenal biopsies that were either normal or showed increased IELs. Enteroscopy with duodenal and additional jejunal biopsies was performed in all of the patients, who continued a normal gluten containing diet, 6-12 wk after index endoscopy. Repeat biopsies confirmed CD in five of the eight patients who were positive for EMA. Moreover, in 60% of cases, these changes were diagnostic in the jejunal biopsies only. De Vitis *et al*^[37] also studied a similar group of 23 patients, and in their group, only four patients were diagnosed with CD according to jejunal biopsies alone. According to these enteroscopy studies, CD can be further diagnosed in 10%-17% of patients with equivocal findings in the previous studies of patients who were presumed to have CD. A limitation of PE is that it evaluates a fraction of the small bowel, leaving the majority of the small bowel uninvestigated.

Cellier *et al*^[38] demonstrated that PE detected jejunal ulcerations in 62.5% of CD patients, in whom no duodenal lesions were observed. They found that PE with jejunal biopsies has diagnostic value only in patients with refractory CD but not in those with uncomplicated CD. However PE requires expertise and takes longer than standard esophagogastroduodenoscopy (EGD). Nowadays, it has mostly been replaced by BAE, which enables concise investigation of the small bowel. However, is it

worth digging deeper? BAE makes it possible to evaluate the entire small bowel with biopsy capability. After the introduction of BAE into clinical practice, it has been used to evaluate the small bowel in various diseases, with a high success rate for complete bowel examination^[39]. Unfortunately, there is no study specially addressing the value of BAE in the diagnosis of uncomplicated CD. According to a report by Hadithi *et al*^[40], who performed double balloon enteroscopy (DBE) in refractory CD, DBE had a significant diagnostic yield and revealed complications such as ulcerative jejunoileitis and lymphoma in 30% of patients. A further important result of the study was that DBE successfully ruled out T cell lymphoma in 25% of patients. Potential risks of BAE limit its use in every patient, which makes it difficult to recommend the procedure to every single CD patient, and it should be reserved for those patients with unequivocal findings or abnormal imaging results. Enteroscopy should be considered in patients with refractory CD and in those with a high clinical or serological suspicion of CD but inconclusive duodenal biopsies. Although this group of patients will always remain small, it is important to bear in mind that enteroscopy can sometimes be of value to diagnose CD^[41]. It should be emphasized that BAE is an effective way for the evaluation of the complications of CD and should be utilized early in the diagnostic algorithm.

Another way of examining the small intestine is CE, which may be a possible substitute for EGD because of its minimal invasiveness, however, its cost and limited availability make it insufficient to replace EGD. CE has an eightfold magnification capacity and therefore is able to assess the small bowel mucosa. For this reason, CE could offer an alternative in patients who are unable or unwilling to undergo endoscopic examination. CE is done without air inflation, with the round dome-shaped edge housing the optical system close to the mucosa. It allows examination of the entire small bowel and facilitates diagnosis of complications^[42]. CE studies have failed to demonstrate any correlation between clinical presentation and the length of involvement. Diagnostic yield of CE increases significantly when a CD patient is under the risk of having a complication or malignancy, such as patients with iron deficiency anemia or refractory disease. In these high probability patients, ulcerations or other positive findings can be revealed in up to half the patients^[43]. CE is not superior to the conventional EGD in the case of new diagnosis of CD patients^[44]. Another point to remember is that CE is a poor modality for examination of the duodenum due to rapid transfer of the capsule in this area. That is why, if there is limited proximal enteropathy, CE may miss the mucosal changes; even Marsh grade 3c changes can be missed. Addition of Fuji Intelligent Color Enhancement - capability or post-processing of the acquired images may aid discrimination of villous atrophy^[45]. When should we use CE for the diagnosis of uncomplicated CD? Patients who have less than four duodenal biopsies should be directed for repeat endoscopy with at least four biopsies and CE should be performed in those patients

who still have normal duodenal histology and are positive for celiac serology and HLA-DQ2 or HLA-DQ8^[46]. Similar reasoning may also apply to BAE with biopsy of the jejunum or deep intestine, and in this case, BAE with biopsy could be superior to CE in terms of biopsy and histological confirmation of the disease. Otherwise, both methods rely on white light visible morphological changes. Therefore, it should be stressed that CE is not a substitute for histological examination, however, CE can detect complications missed by routine EGD^[44]. That is why the use of both BAEs and CE to evaluate the entire small bowel at the time of initial diagnosis does not seem to be justified^[47].

CONCLUSION

Is enteroscopy needed for the diagnosis of the CD? We can answer “yes” to this question, with reserve. Based on these findings, enteroscopy examination for CD should be reserved for patients with positive serology and negative histopathology at initial EGD, and in the search for complications during follow-up. Enteroscopy cannot be recommended at the initial work-up of CD patients. CE may find a place for the diagnosis of complications of CD because of its noninvasiveness and ease of use. The main problem is to diagnose the early forms of the disease by simple examination, for which the current endoscopy methods have failed in terms of detection, because these methods successfully detect atrophy, which is the only visible sign of the disease. We believe that addition of water immersion, even during enteroscopy, is helpful, easy and incurs no cost, and should be performed in every suspected patient to minimize unnecessary biopsies.

Abstract

Diffusion-weighted magnetic resonance imaging (DWI)

is a well established method for the evaluation of intracranial diseases, such as acute stroke. DWI for extracranial application is more difficult due to physiological motion artifacts and the heterogeneous composition of the organs. However, thanks to the newer technical development of DWI, DWI has become increasingly used over the past few years in extracranial organs including the abdomen and pelvis. Most previous studies of DWI have been limited to the evaluation of diffuse parenchymal abnormalities and focal lesions in abdominal organs, whereas there are few studies about DWI for the evaluation of the biliopancreatic tract. Although further studies are needed to determine its performance in evaluating bile duct, gallbladder and pancreas diseases, DWI has potential in the assessment of the functional information on the biliopancreatic tract concerning the status of tissue cellularity, because increased cellularity is associated with impeded diffusion, as indicated by a reduction in the apparent diffusion coefficient. The detection of malignant lesions and their differentiation from benign tumor-like lesions in the biliopancreatic tract could be improved using DWI in conjunction with findings obtained with conventional magnetic resonance cholangiopancreatography. Additionally, DWI can be useful for the assessment of the biliopancreatic tract in patients with renal impairment because contrast-enhanced computed tomography or magnetic resonance scans should be avoided in these patients.

INTRODUCTION

Diffusion-weighted magnetic resonance imaging (DWI) provides information on the random (Brownian) motion of water molecules in the body. It is well established that DWI is a useful tool for the evaluation of intracranial diseases, such as acute stroke. The development of phased-array surface coils, high-gradient amplitudes, and rapid imaging techniques such as echo planar imaging (EPI) and parallel imaging have been instrumental in allowing the extracranial application of DWI^[1-3].

The degree of restriction to water diffusion in biological tissues is directly proportional to tissue cellularity and the integrity of cell membranes. In tissues with a high cell density and associated with many intact cell membranes, such as malignant tumors, the motion of water molecules is more restricted than in less cellular tissue. The degree of water motion is found to be proportional to the degree of signal attenuation in DWI. Thus, more cellular solid tumors show relatively higher signal intensities and exhibit lower apparent diffusion coefficient (ADC, expressed in mm^2/s) values on DWI using two or more b values than do less cellular tissues. Recently, this utility of DWI has been expanded to examination of abdominal organs; the ADC values of malignant masses are significantly lower than those of benign masses in the liver, pancreas, kidney, and prostate, although there is a small degree of overlap^[4-9]. Most previous studies on DWI have been limited to the evaluation of diffuse parenchymal abnormalities and focal lesions in abdominal organs, whereas there are few studies about DWI for the evaluation of the biliopancreatic tract^[10].

To date, contrast-enhanced magnetic resonance imaging (MRI) combined with magnetic resonance cholangiopancreatography (MRCP) has been found to be accurate for diagnosis of biliopancreatic diseases. The role of DWI for the evaluation of biliopancreatic diseases is not yet well established. However, because DWI yields qualitative and quantitative information reflecting cell membrane integrity and tissue cellularity, DWI can be used to differentiate normal and abnormal structures of tissues better, and thus may help in the characterization of various abnormalities in the biliopancreatic tract when added to conventional MRI.

In this article, we briefly review the basic concepts for the biological basis of DWI and its technical considerations. Additionally, we illustrate clinical applications of DWI for the following: evaluation of the biliopancreatic tract, including stone-related complications such as

acute cholangitis, hepatic abscesses, and acute gallstone pancreatitis; characterization and diagnosis of gallbladder lesions, including cholecystitis, gallbladder empyema, and gallbladder carcinoma; characterization of intrahepatic biliary lesions and diagnosis of malignant lesions in the intrahepatic bile ducts; and characterization of extrahepatic biliary lesions and diagnosis of malignant lesions in the extrahepatic bile ducts, including extrahepatic cholangiocarcinoma, pancreatic carcinoma, and focal pancreatitis. We also describe pitfalls of DWI misinterpretation.

BASIC CONCEPTS

In biological tissue, the diffusion of water molecules is impeded or restricted by natural barriers, such as cell membranes, large protein molecules, and tissue cellularity. Pathological conditions, such as tumors, cytotoxic edema, abscesses, and fibrosis, in which the physical nature of the intracellular and extracellular spaces changes, result in increased restriction of the diffusion of water molecules. In tissues of low cellularity or where the cellular membranes have been disrupted, the diffusion of water molecules is relatively free or less restricted (Figure 1)^[1-3,8,11].

DWI is typically obtained using an ultrafast T2-weighted single-shot spin-echo EPI sequence by applying a symmetric pair diffusion-sensitizing gradient, known as the Stejskal-Tanner sequence. It provides information on the random (Brownian) motion of water molecules in tissues between the first dephasing (diffusion-sensitizing) gradient and the second rephasing gradient on either side of the 180° refocusing pulse. Static molecules acquire phase information from the first diffusion-sensitizing gradient, but information will be cancelled out by the second gradient. As a result, signal intensity is preserved, with the exception of T2 decay. In contrast, less restricted water molecules move a considerable distance between the first dephasing (diffusion-sensitizing) and second rephasing gradients. The moving water molecules are not entirely rephased, resulting in reduction of the overall T2 signal intensity (Figure 2)^[1-3].

The sensitivity of a DWI sequence to water diffusion can be altered by changing the parameter known as the b value, which represents the diffusion factor (measured in s/mm^2) and the strength of the diffusion gradients. DWI is obtained with at least two different b values. DWI using lower b values ($50\text{-}100 \text{ s}/\text{mm}^2$) is sensitive only to fast motion of water molecules. On DWI using lower b values, water molecules in vessels are depicted as dark blood flow (black-blood images). DWI using higher b values ($> 500 \text{ s}/\text{mm}^2$) is sensitive to both fast and slow motion of water molecules. Water movements in highly cellular tissue are restricted and retain their signals even at higher b values. The images obtained at different b values allow the quantification of the ADC of tissues, which is usually displayed as a parametric (ADC) map. The mean or median ADC value can be measured by drawing regions of interest (ROIs) on the ADC map. Tissues with restricted

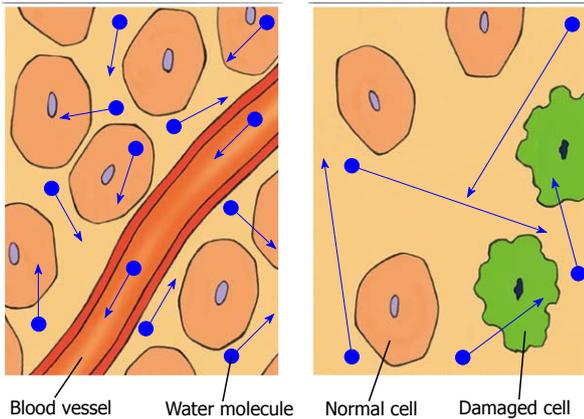

Figure 1 Diffusion of water molecules. Highly cellular tissues with intact cell membrane restrict the movement of water molecules within intravascular, intracellular, and extracellular space. In contrast, relatively less cellular tissues or damaged cells with defective cellular membrane increase extracellular space, which allow greater water molecule movement.

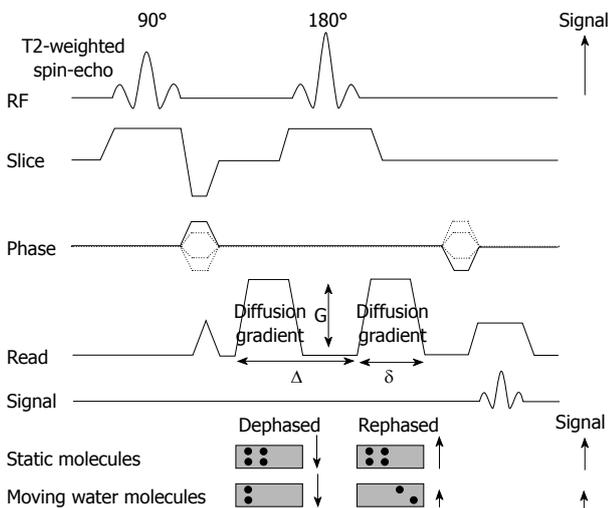

Figure 2 Diagram of diffusion-weighted sequence. DWI is based on T2-weighted spin-echo sequencing with application of two equal gradient pulses (a dephasing gradient and a rephasing gradient) on each side of the 180° radiofrequency pulse. Static molecules are dephased by the first diffusion gradient and rephased perfectly by the second diffusion gradient; therefore measured high signal intensity is preserved. In contrast, moving molecules undergo dephasing but are not entirely rephased by the second gradient because of their motion, thereby resulting in signal loss. DWI: Diffusion-weighted magnetic resonance imaging; RF: Radiofrequency.

diffusion and high cellular density show low ADC values, whereas tissues with less cellular density show higher ADC values^[1,2].

TECHNICAL CONSIDERATIONS

The signal intensity on DWI is dependent on diffusion of water molecules and T2 relaxation time. Thus, an area with a very long T2 relaxation time (e.g., bile in the biliary tract) maintains high signals on high-b-value DWI, and can be mistaken for restricted diffusion. This phenomenon is known as the “T2 shine-through” effect (Figure 3). The T2 shine-through effect inevitably

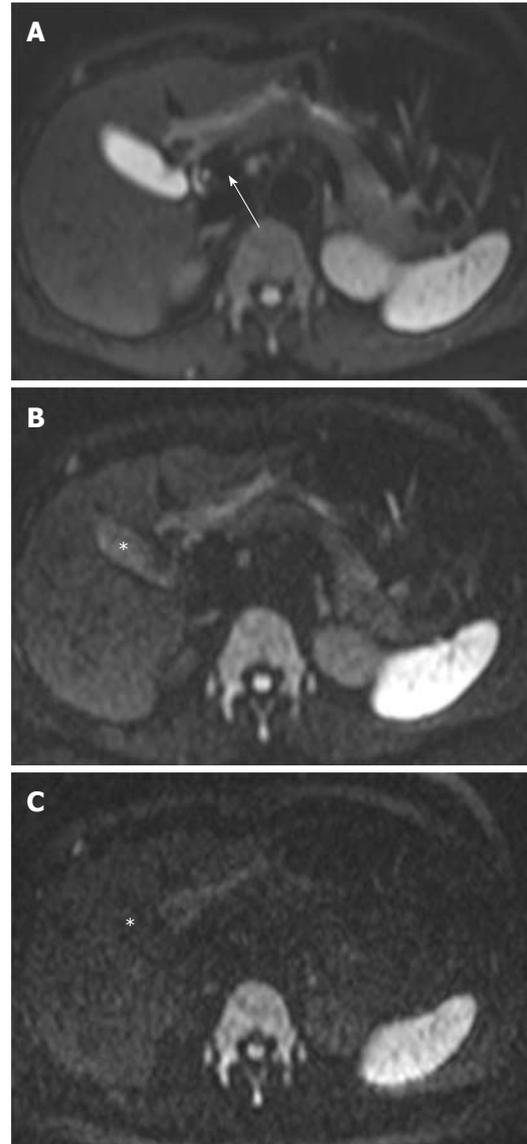

Figure 3 DWI of the normal liver, pancreas, and biliary tract. A: DWI at $b = 50 \text{ s/mm}^2$ shows that the liver is hypointense compared to the kidney and spleen, and isointense compared to the pancreas; there is a signal void within the portal vein (arrow). DWI using low b values results in decreasing signals of fast motion of water molecules, such as that occurring within vessels. Such images are referred to as black-blood images; B: DWI at $b = 500 \text{ s/mm}^2$ shows that the signal intensity of bile is decreased (asterisk) and the wall of the gallbladder is not identified. The liver is isointense compared to the pancreas; C: DWI at $b = 1000 \text{ s/mm}^2$ shows a significant reduction in the signal intensity of bile in the gallbladder (asterisk). DWI: Diffusion-weighted magnetic resonance imaging.

confounds DWI images, and the ADC map eliminates this effect. In clinical practice, higher-b-value DWI (usually $800\text{-}1000 \text{ s/mm}^2$) results in a reduction of the signal from moving protons in the bile ducts, cyst, vessels, and fluid in the bowel. This leads to a reduction in the T2 shine-through effect, resulting in increased contrast between lesions and visceral organs such as the liver or gallbladder. However, the tradeoffs of higher-b-value DWI are a lower signal-to-noise ratio, the possibility of ADC error, and increased image distortion due to the longer echo time required^[1,2,8,12].

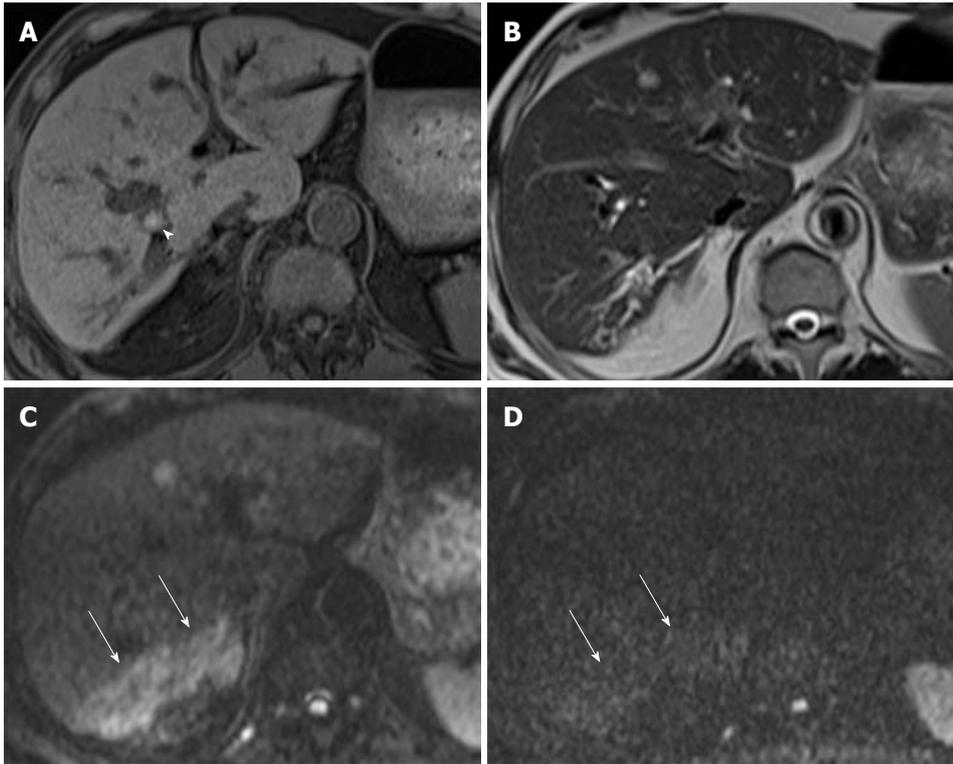

Figure 4 Parenchymal changes in acute cholangitis in a 76-year-old man. A: Axial fat-saturated T1-weighted image shows a hyperintense stone (arrowhead) with upstream bile duct dilation; B: Axial T2-weighted rapid acquisition relaxation enhancement image shows mild bile duct dilatation in the right lobe of the liver, but no definite area of increased parenchymal signal intensity; C: DWI at $b = 50 \text{ s/mm}^2$ shows wedge-shaped areas of increased parenchymal signal intensity in segment 6 (arrows). Parenchymal changes are more conspicuous on black-blood images than on routine T2-weighted images; D: DWI at $b = 800 \text{ s/mm}^2$ shows that most areas of increased parenchymal signal intensity usually return to isointensity (arrows). Such a finding can be a clue for differentiating parenchymal changes due to cholangitis from abscesses. DWI: Diffusion-weighted magnetic resonance imaging.

DWI performed during free breathing can lead to substantial signal loss. Thus, breath-hold or respiration-triggered DWI would be necessary to prevent signal loss as a result of respiratory movement. Breath-hold DWI is generally used because of its short acquisition time. However, only a limited number of image sections of relatively large section thicknesses can be acquired. Moreover, because this technique is usually performed using a single-shot EPI technique, the signal-to-noise ratio and lesion conspicuity is reduced. In contrast, respiration-triggered DWI provides higher signal-to-noise and contrast-to-noise ratios, although its acquisition time is longer than that of breath-hold DWI^[13,14].

Fat suppression is necessary to increase the dynamic range of DWI and reduce the chemical shift artifacts that are prevalent in EPI. Inversion recovery sequence is preferred when performing DWI over a large area of the body, because it is likely to produce more uniform fat suppression^[13].

Unlike brain imaging where b values are well established, b values in other parts of the body vary widely between investigators. Thus, b values for body imaging require optimization. Biexponential signal intensity in the abdominal organs has been shown in DWI with increasing b values; the initial rapid decrease in signal intensity is noted with a small increase in b value, and is followed by a more gradual decrease of signal intensity

beyond approximately $b = 100 \text{ s/mm}^2$. ADC measurement using at least three b values adequately reflects this biexponential behavior, compared with the use of only two b values. Low b values are sensitive to capillary perfusion, which can increase the amount of perfusion contamination in ADC measurement. In contrast, high b values enable less perfusion contamination in the ADC measurement and reflect tissue sensitivity^[13].

In our institution, MRI is performed with a superconductive 1.5-T imaging unit (Magnetom Avanto; Siemens Medical Solutions, Erlangen, Germany), and a 3.0-T imaging unit (Magnetom Trio; Siemens Medical Solutions) by using a phased-array multicoil. For DWI, respiration-triggered, fat-suppressed, single-shot EPI is performed in the transverse plane with a parallel imaging (generalized autocalibrating partially parallel acquisition) acceleration factor of two. DWI is performed prior to the intravenous injection of gadolinium chelates. Pre-contrast DWI is usually preferred because gadolinium chelates may affect the ADC values by decreasing the signal intensity on these T2-sequences due to shortening of the T1 and T2 relaxation time. However, it has been reported that DWI after administration of gadolinium chelates does not appear to affect ADC values significantly^[15]. The imaging parameters of DWI in the 1.5-T unit are as follows: 5000/103 (repetition time ms/echo time ms), 90° flip angle, 4-mm section thickness, 1-mm

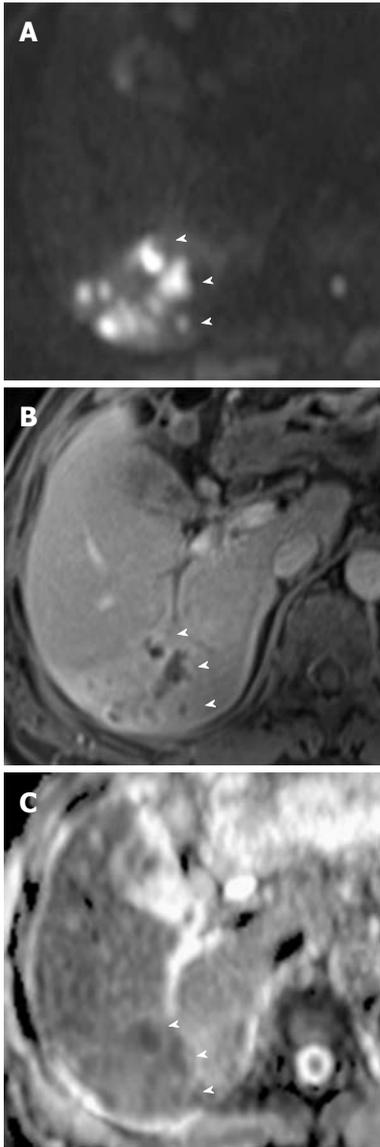

Figure 5 Liver abscesses complicating acute cholangitis in a 79-year-old man. A: DWI at $b = 1000 \text{ s/mm}^2$ shows multiple liver abscesses with high signal intensity (arrowheads); B: Multiple abscesses with peripheral rim enhancement (arrowheads) are less conspicuous on contrast-enhanced fat-saturated T1-weighted images (B) than on DWI (A); C: On an ADC map, multiple abscesses appear as low signal intensity (arrowheads) due to restriction of diffusion. DWI: Diffusion-weighted magnetic resonance imaging; ADC: Apparent diffusion coefficient.

intersection gap, 964-Hz/pixel bandwidth, 20 slices, 230-mm field of view, 192×192 matrix, and 85-s acquisition time. Imaging parameters in the 3.0-T unit are as follows: 3900/92 (repetition time ms/echo time ms), 90° flip angle, 5-mm section thickness, 0.5-mm intersection gap, 1184-Hz/pixel bandwidth, 24 slices, 230-mm field of view, 192×192 matrix, and 85-s acquisition time. Each acquisition is obtained using five different b values including low values (0 s/mm^2 and 50 s/mm^2) and high values (500 s/mm^2 , 800 s/mm^2 and 1000 s/mm^2)^[16,17]. The ADC map is generated automatically with the built-in software of the MRI unit.

The signal intensity of the normal liver on DWI is

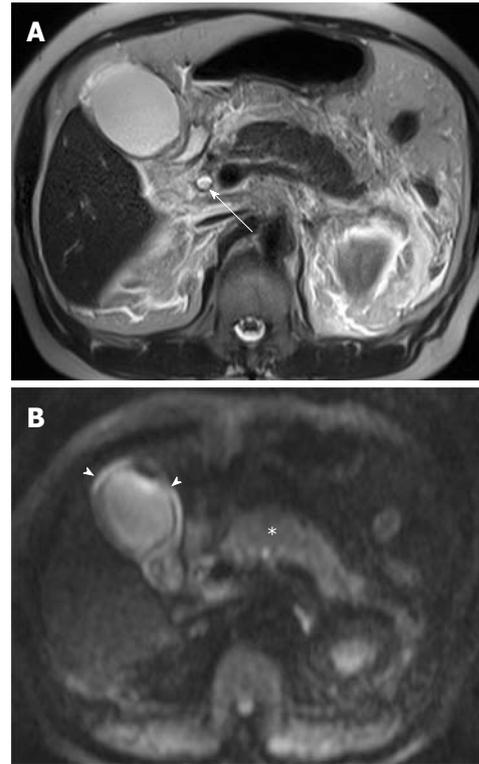

Figure 6 Acute pancreatitis and cholecystitis due to a bile duct stone in a 72-year-old woman. A: Axial T2-weighted rapid acquisition relaxation enhancement image demonstrates stones in the distal common bile duct (arrow), a distended gallbladder with pericholecystic fluid, and pancreatic edema with peripancreatic fluid, findings suggestive of cholecystitis and pancreatitis; B: DWI at $b = 800 \text{ s/mm}^2$ shows that the pancreas is slightly hyperintense (asterisk) compared to the liver, and the presence of a peripancreatic fluid collection; findings indicative of pancreatitis. A distended gallbladder with diffuse and symmetric high signal intensity in the wall (arrowheads), due to the restriction of water diffusion in the inflamed gallbladder wall, is also seen. DWI: Diffusion-weighted magnetic resonance imaging.

the same as on T2-weighted images. The liver is hypointense compared to the kidney and spleen, and isointense or hypointense compared to the pancreas (Figure 3). The reported ADC value of the normal liver ranges from $1.02 \times 10^{-3} \text{ mm}^2/\text{s}$ to $1.83 \times 10^{-3} \text{ mm}^2/\text{s}$ ^[4,18-20]. Yoshikawa *et al.*^[18] have reported that the mean ADC value of the pancreas ranges from $1.02 \times 10^{-3} \text{ mm}^2/\text{s}$ to $1.94 \times 10^{-3} \text{ mm}^2/\text{s}$ using DWI with two values (0 s/mm^2 and 600 s/mm^2). On higher DWI (usually $800\text{-}1000 \text{ s/mm}^2$), the walls of the bile duct and gallbladder are not identified (Figure 3).

CLINICAL APPLICATIONS OF DWI FOR EVALUATION OF THE BILIOPANCREATIC TRACT

DWI for evaluation of gallstone-related complications

Acute cholangitis is the most frequently encountered benign inflammatory lesion and is usually related to bile duct stones. Acute cholangitis usually manifests as a dilated bile duct, due to bile duct obstruction, mild and diffuse bile duct wall thickening, and hepatic paren-

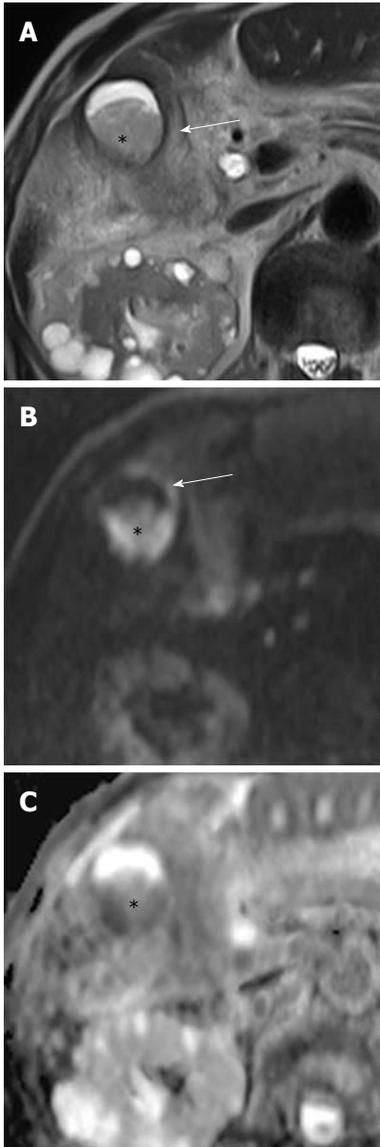

Figure 7 Gallbladder empyema in a 92-year-old man. A: Axial T2-weighted rapid acquisition relaxation enhancement image demonstrates a fluid-fluid level with low signal intensity in the dependent portion (asterisk) of an inflamed gallbladder (arrow); B: DWI at $b = 1000 \text{ s/mm}^2$ shows purulent bile with high signal intensity (asterisk), and diffuse, symmetric high signal intensity in the wall of the gallbladder (arrow); C: On an ADC map, pus in the dependent portion of the gallbladder appears with low signal intensity (asterisk) due to restriction of diffusion. Empyema was confirmed by aspiration of pus during percutaneous cholecystostomy. DWI: Diffusion-weighted magnetic resonance imaging; ADC: Apparent diffusion coefficient.

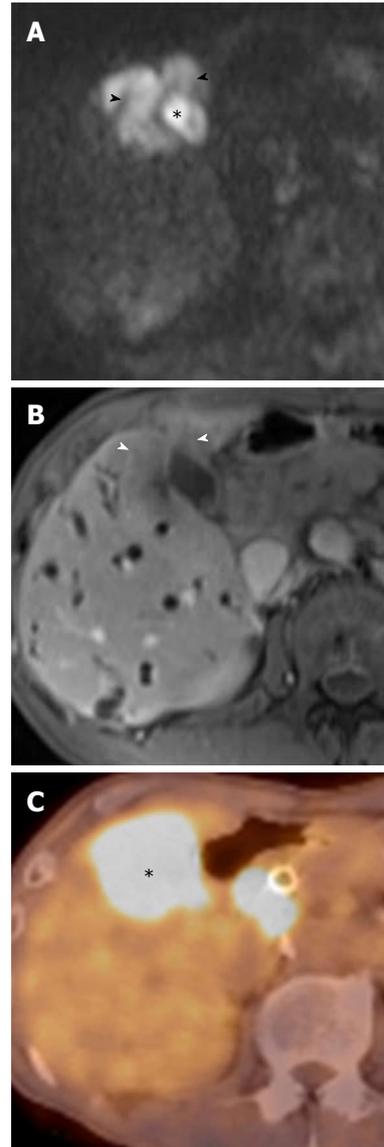

Figure 8 Gallbladder carcinoma in a 70-year-old man. A: DWI at $b = 1000 \text{ s/mm}^2$ shows high signal intensity in the mass occupying the entire gallbladder (asterisk), which invades the hepatic parenchyma adjacent to the gallbladder (arrowheads); B: Gallbladder carcinoma with direct liver invasion (arrowheads) is less conspicuous on contrast-enhanced, fat-saturated T1-weighted images than on DWI; C: Fused positron emission tomography-CT image confirms intense hypermetabolism (asterisk) in the gallbladder carcinoma with direct liver invasion adjacent to the gallbladder. DWI: Diffusion-weighted magnetic resonance imaging; CT: Computed tomography.

chymal changes on MRI. Hepatic parenchymal changes appear as patchy or wedge-shaped areas of increased parenchymal signal intensity on T2-weighted images and transient inhomogeneous parenchymal enhancement in arterial dominant phase imaging^[21,22].

In a recent study, DWI using low b values ($< 100 \text{ s/mm}^2$), giving black-blood images, detected focal hepatic lesions more clearly than routine turbo spin-echo T2-weighted images, and can potentially replace the routine turbo spin-echo T2-weighted images for lesion detection^[23]. In our experience, the increased parenchymal signal inten-

sity is more conspicuous on black-blood images than on routine T2-weighted images in patients with acute cholangitis. On DWI using high b values, areas of increased parenchymal signal intensity usually return to signal isointensity, and infrequently remain at high signal intensity (Figure 4). This may suggest the differentiation of parenchymal changes due to cholangitis from abscesses, which remain at very high signal intensity on DWI using high b values. The causes for signal changes on DWI in the setting of acute inflammation have not been studied extensively. On DWI using low b values, signal changes in cholangitis are influenced by both perfusion and dif-

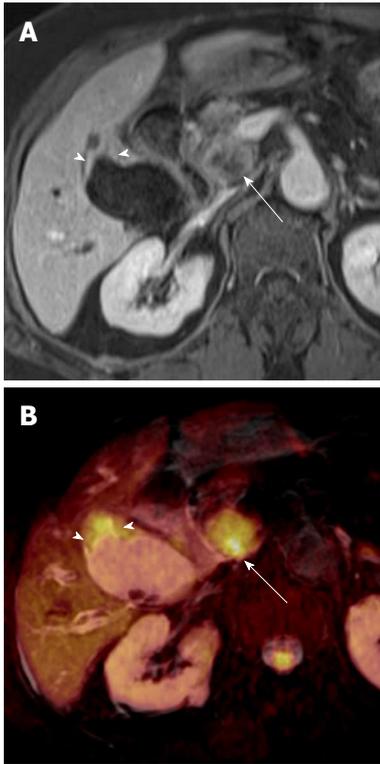

Figure 9 Gallbladder carcinoma (focal wall-thickening type) in a 77-year-old woman. A: Axial contrast-enhanced, fat-saturated, T1-weighted image shows focal wall thickening (arrowheads) in the gallbladder with a metastatic lymph node in the portocaval space (arrow); B: Fusion image of T2-weighted image and DWI at $b = 800 \text{ s/mm}^2$ shows focal, asymmetric high signal intensity in the fundal portion of the gallbladder (arrowheads) with a hyperintense metastatic lymph node in the portocaval space (arrow). DWI: Diffusion-weighted magnetic resonance imaging.

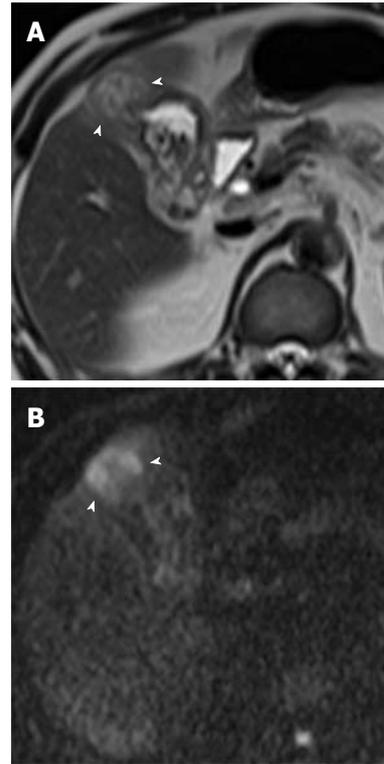

Figure 10 Xanthogranulomatous cholecystitis in a 55-year-old man. A: Axial T2-weighted rapid acquisition relaxation enhancement image shows focal wall thickening with a fundal mass (arrowheads). There is focal high signal intensity within the thickened wall of the gallbladder; a finding that is consistent with an intramural collection; B: DWI at $b = 800 \text{ s/mm}^2$ shows focal high signal intensity in the fundal portion of the gallbladder (arrowheads). Xanthogranulomatous cholecystitis was confirmed by laparoscopic cholecystectomy. DWI: Diffusion-weighted magnetic resonance imaging.

fusion; perfusion effects may be attributed to vasodilatation involving both arterioles and capillary beds, leading to increase blood flow, and diffusion effects may be explained by increases in the size and numbers of inflammatory cells, leading to restriction of water molecules. However, when going to higher b values, the perfusion effect is decreased, leading to decreased signal intensity on DWI. Increased parenchymal signal intensity on DWI may be reversible after treatment, although further studies are needed to confirm this.

Hepatic abscesses are defined as intrahepatic single or multiple collections of pus within the liver. They result from infectious cholangitis and are usually seen in patients with suppurative cholangitis. Pyogenic abscesses have variable signal intensities on T1- and T2-weighted images. However, most lesions appear hypointense on T1-weighted images and hyperintense on T2-weighted images. Peripheral rim enhancement and transient hepatic intensity differences associated with abscesses can be seen after administration of gadolinium. Abscesses can be a life-threatening emergency if not recognized and treated promptly^[24].

DWI is helpful in the early detection of abscesses and their differentiation from cystic or necrotic tumors. On DWI using high b values, abscesses appear hyperin-

tense with low ADC values (Figure 5). This appearance is explained by the dense viscous content of the abscess and the presence of cellular infiltrates within the abscess. In comparison, cystic or necrotic tumors have a greater degree of signal attenuation on higher-b-value DWI and return higher ADC values^[25].

In a recent study, there was no difference in the ability to detect acute pancreatitis between DWI and computed tomography (CT)^[26]. However, DWI can be useful to detect gallstone pancreatitis more clearly than can nonenhanced CT in the setting of contrast contraindications. Acute pancreatitis has restricted diffusion because of acute inflammation, and thus may appear as hyperintense on high-b-value DWI (Figure 6). Peripancreatic fluid usually has no restricted diffusion on high-b-value DWI, but infected fluid may have restricted diffusion. Signal changes in pancreatitis on DWI may be also reversible after treatment.

DWI for characterization and diagnosis of gallbladder lesions

Cholecystitis: Cholecystitis is defined as inflammation of the gallbladder and is usually related to the presence of gallstones. In patients clinically suspected to have acute cholecystitis, ultrasonography (US) is usually favored

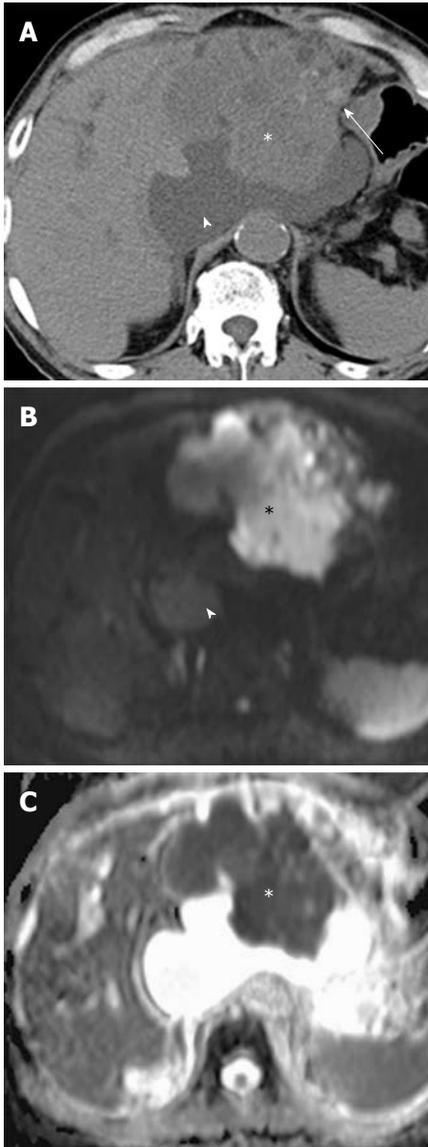

Figure 11 Intrahepatic cholangiocarcinoma (mass-forming type) in a 71-year-old man. A: Nonenhanced CT image shows intrahepatic cholangiocarcinoma in the left lobe of the liver (asterisk), stones in the dilated left bile ducts (arrow), and a fluid collection in the lesser sac (arrowhead); B: DWI at $b = 1000 \text{ s/mm}^2$ shows intrahepatic cholangiocarcinoma with high signal intensity (asterisk). Note a fluid collection (arrowhead) in the lesser sac, which appears as significant attenuation of the signal intensity reduction at a high b value; C: On the ADC map, cholangiocarcinoma appears as low signal intensity (asterisk) due to restriction of diffusion. DWI: Diffusion-weighted magnetic resonance imaging; CT: Computed tomography; ADC: Apparent diffusion coefficient.

as the initial imaging technique. CT and MRI usually provide morphological information similar to that provided by US, and can be performed initially if the clinical presentation is atypical. Increased wall enhancement of the gallbladder and increased pericholecystic hepatic parenchymal enhancement are frequent and specific CT and MRI findings of acute cholecystitis. In acute cholecystitis, the wall of the distended gallbladder is typically thickened due to inflammatory edema, inflammatory exudates, and hemorrhage^[21]. DWI can provide additional important information in cholecystitis when

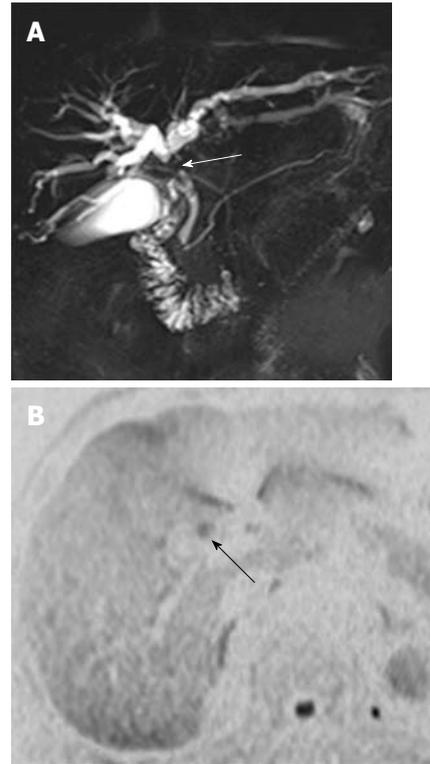

Figure 12 Cholangiocarcinoma (periductal-infiltrating type) in a 70-year-old man. A: Coronal image from thick-slab, single-shot MRCP shows marked dilatation of the intrahepatic ducts and abrupt narrowing at the confluence of the hepatic duct (arrow); B: DWI at $b = 800 \text{ s/mm}^2$ with inverted black-and-white image contrast clearly depicts the mass (arrow) at the confluence of the hepatic duct. DWI: Diffusion-weighted magnetic resonance imaging; MRCP: Magnetic resonance cholangiopancreatography.

added to conventional MRI or MRCP. On DWI using high b values, diffuse and symmetric hyperintensity in the wall of the gallbladder is seen in acute cholecystitis, because of restricted diffusion in the inflamed gallbladder wall (Figure 6). However, restricted diffusion in the gallbladder wall can be also seen in malignant lesions of the gallbladder.

Pus in the gallbladder (empyema) occurs in approximately 2%-3% of patients with acute cholecystitis. Empyema carries a high risk of sepsis and perforation. Thus, urgent drainage or surgical resection with systemic antibiotic coverage is required as soon as the diagnosis is suspected. A diagnosis of empyema may be suggested by the identification of pus as a fluid-fluid level in the dependent portion of the gallbladder on T2-weighted images. However, a fluid-fluid level of the bile in the gallbladder is not specific for empyema; this can be seen in other conditions, such as concentrated bile, sludge, or hemobilia^[21]. It has been reported that DWI is a reliable imaging technique for differentiating pyonephrosis from hydronephrosis. The pus in pyonephrosis has high viscosity and cellularity, thus leading to impeded diffusion and a low ADC value^[27]. DWI findings of gallbladder empyema on DWI may be similar to those of pyonephrosis (Figure 7). Thus, DWI may be helpful

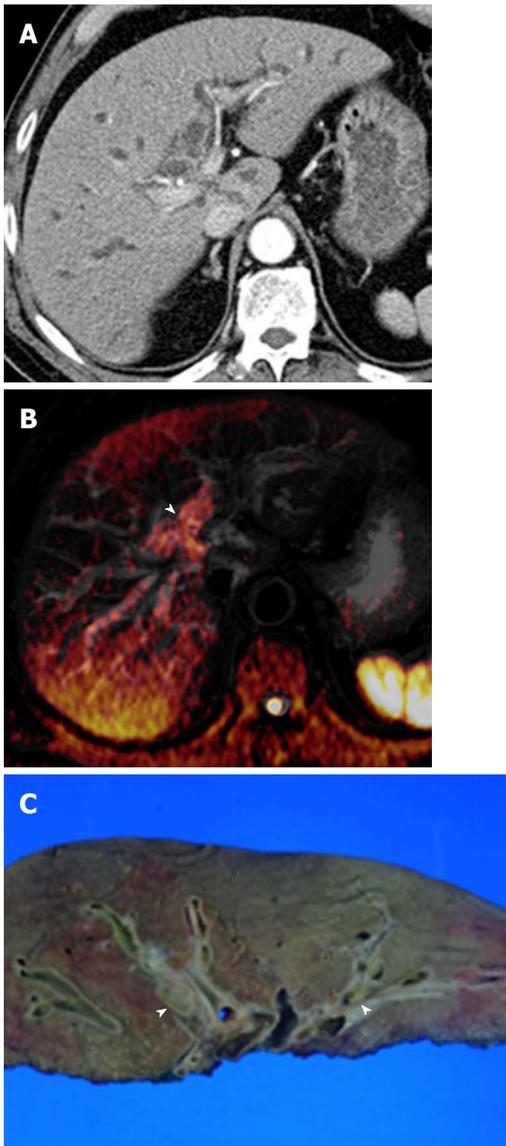

Figure 13 Hilar cholangiocarcinoma (intraductal-growing type) in a 67-year-old man. A: Contrast-enhanced CT shows mild intrahepatic duct dilatation. However, intraductal masses are not clearly depicted on CT; B: Fusion image of T2-weighted and diffusion-weighted images at $b = 800 \text{ s/mm}^2$ shows high signal intensity (arrowhead) at the first branch of the intrahepatic duct; C: Photograph of the gross specimen shows intraductal growing masses (arrowheads) in the bile duct. Histological analysis revealed biliary intraepithelial neoplasia with high grade dysplasia. CT: Computed tomography.

in differentiating pus from concentrated bile, sludge, or hemobilia in the gallbladder.

Gallbladder carcinoma: Imaging findings of focal or diffuse wall thickening or a mass replacing the gallbladder mimics the appearance of acute cholecystitis. DWI can be helpful in the diagnosis of gallbladder carcinoma, the detection of liver and lymph node metastasis, and differentiation from inflammatory conditions of the gallbladder. A hyperintense mass occupying the entire gallbladder lumen or focal and asymmetric high signal intensity in or around the gallbladder wall is more common in malignant lesions of the gallbladder (Figures 8 and 9)^[28]. In contrast, diffuse and smooth high signal intensity in

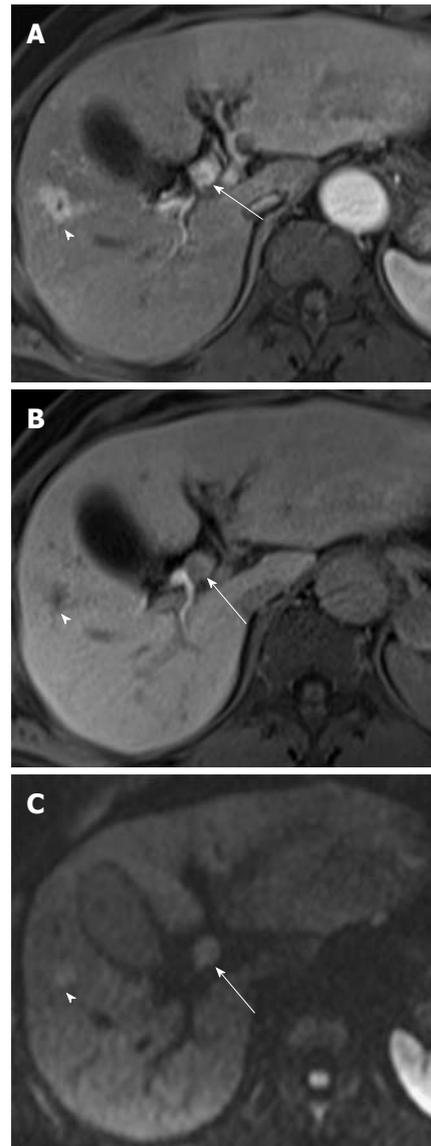

Figure 14 Hepatocellular carcinoma with tumor thrombus in bile duct in a 62-year-old man. A: Gadoteric acid-enhanced T1-weighted image obtained during the arterial phase shows a hypervascular HCC in the right lobe of the liver (arrowhead) and an intraluminal enhancing mass (arrow) in the common hepatic duct; B: On gadoteric acid-enhanced T1-weighted image obtained 20 min after injection, a small HCC (arrowhead) is hypointense relative to the surrounding liver. Contrast material filling the left intrahepatic duct is delayed owing to a partial bile duct obstruction caused by tumor thrombus in the bile duct (arrow); C: DWI at $b = 800 \text{ s/mm}^2$ shows a hyperintense small HCC (arrowhead) and tumor thrombus in the bile duct (arrow). HCC: Hepatocellular carcinoma.

the wall of the gallbladder due to acute inflammation is more common in cholecystitis on DWI using high b values. In our experience, however, focal and irregular high signal intensities in the gallbladder wall on DWI are also seen in xanthogranulomatous cholecystitis and papillary adenomatous polyps (Figure 10). Thus, differentiating gallbladder carcinoma from some adenomatous polyps or xanthogranulomatous cholecystitis may be difficult, even with DWI. Additionally, the presence of associated findings on DWI, such as direct invasion of the liver or adjacent structures, hematogenous liver metastasis, and nodal

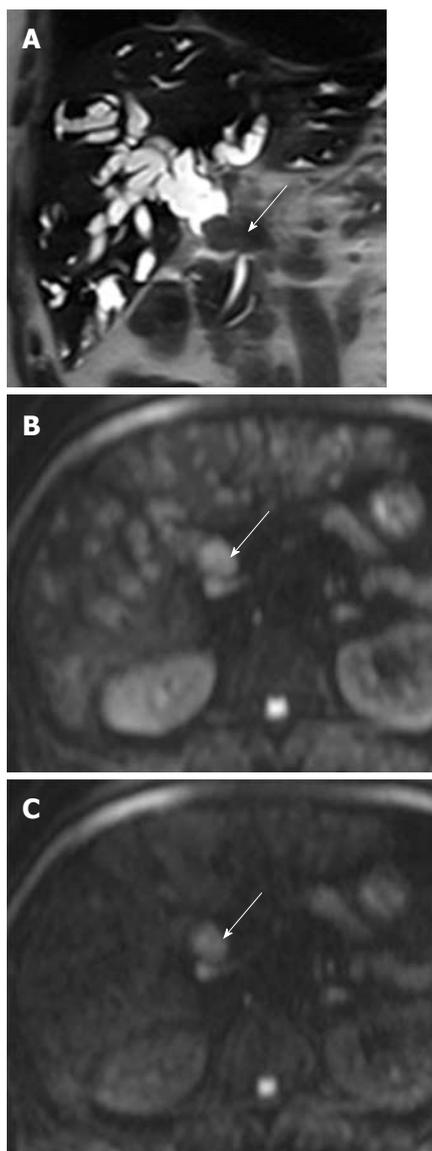

Figure 15 Extrahepatic cholangiocarcinoma in a 62-year-old man. A: Coronal T2-weighted rapid acquisition relaxation enhancement image shows a mass (arrow) in the distal common bile duct and marked upstream bile duct dilatation; B: DWI at $b = 800 \text{ s/mm}^2$ shows a mass with high signal intensity (arrow), but the signal intensity of bile is also increased; C: DWI at $b = 1000 \text{ s/mm}^2$ shows a mass with high signal intensity (arrow). Note that the signal intensity of bile in the bile duct is significantly reduced. DWI: Diffusion-weighted magnetic resonance imaging.

metastasis, favor the diagnosis of gallbladder carcinoma rather than benign gallbladder lesions (Figures 8 and 9).

DWI for characterization of intrahepatic biliary lesions and diagnosis of malignant lesions in the intrahepatic bile duct

Depending on their sites of origin, cholangiocarcinoma is classified as intrahepatic or extrahepatic. Based on its growth pattern, it is also classified as mass-forming, periductal-infiltrating, or intraductal-growing type. Intrahepatic cholangiocarcinoma originates from second-order or greater peripheral branches of the intrahepatic bile duct. The mass-forming cholangiocarcinoma is the

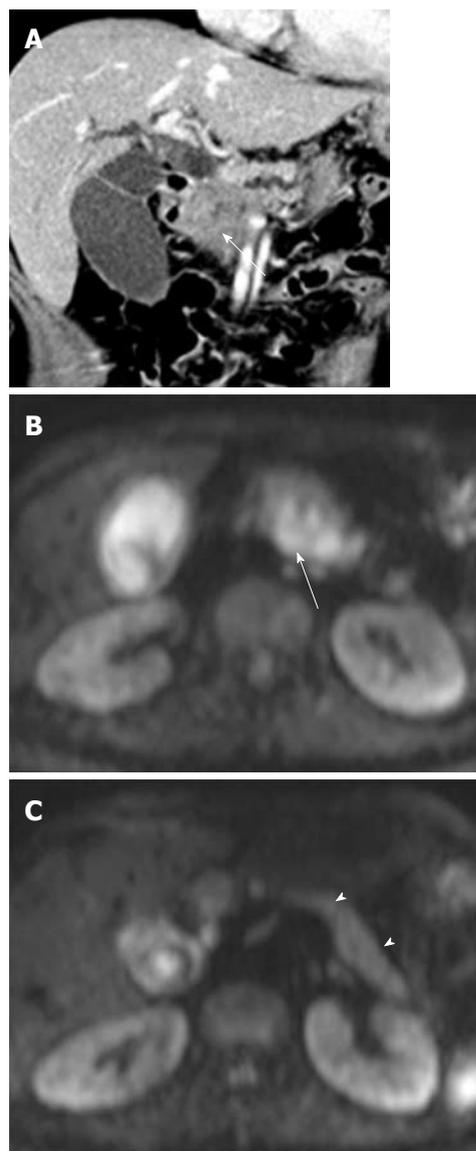

Figure 16 Pancreatic adenocarcinoma in a 50-year-old woman. A: Coronal reformatted contrast-enhanced CT image shows a double duct sign secondary to a pancreatic head cancer (arrow); B: On DWI at $b = 800 \text{ s/mm}^2$, pancreatic adenocarcinoma (arrow) shows hyperintensity; C: DWI at $b = 800 \text{ s/mm}^2$ superior to (B) shows high signal intensity of the remaining pancreas (arrowheads) due to obstructive pancreatitis. However, the remaining pancreas is less hyperintense relative to pancreatic adenocarcinoma. The ADC value of pancreatic cancer ($1.23 \pm 0.32 \text{ mm}^2/\text{s}$) is significantly lower than that of the remaining pancreas ($1.85 \pm 0.45 \text{ mm}^2/\text{s}$). DWI: Diffusion-weighted magnetic resonance imaging; CT: Computed tomography; ADC: Apparent diffusion coefficient.

most common type of intrahepatic cholangiocarcinoma, but periductal-infiltrating and intraductal-growing intrahepatic cholangiocarcinoma is also seen^[29,30].

Mass-forming intrahepatic cholangiocarcinoma appears as a single, predominantly homogeneous mass with well-circumscribed lobulated margins. Satellite nodules are frequent and vary in size. They usually appear as noncapsulated tumors, hypointense on T1-weighted images, and mild-to-moderately hyperintense on T2-weighted images, depending on the amount of fibrous tissue, necrosis, and mucin content. Dynamic-enhanced

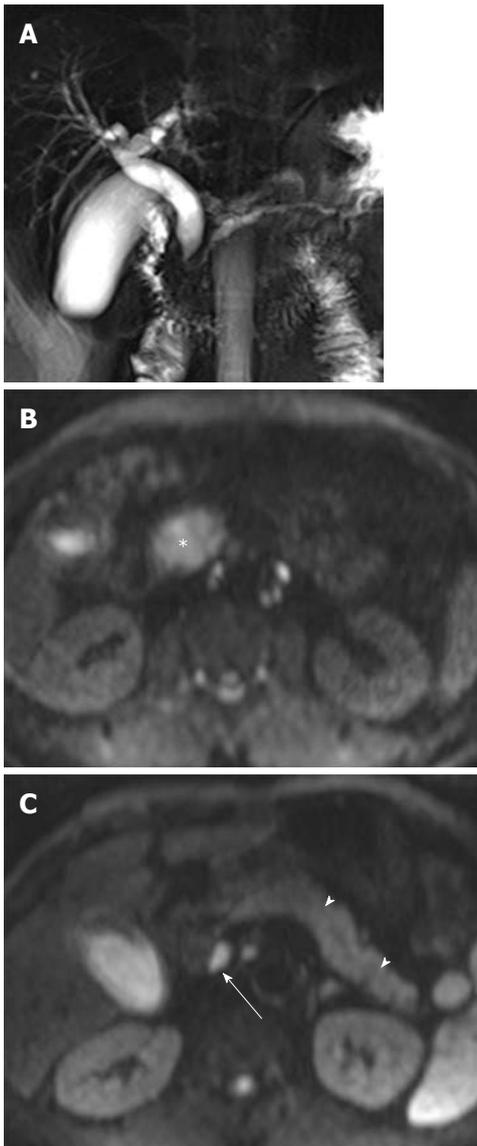

Figure 17 Focal pancreatitis in a 52-year-old man. A: Coronal image from thick-slab single-shot MRCP shows a double duct sign with tapered narrowing of pancreatic duct in the head of the pancreas; B: On DWI at $b = 800 \text{ s/mm}^2$ focal pancreatitis (asterisk) shows hyperintensity; C: DWI at $b = 800 \text{ s/mm}^2$ superior to (B) shows high signal intensity of the remaining pancreas due to obstructive pancreatitis. The remaining pancreas is slightly hypointense (arrowheads) relative to pancreatic adenocarcinoma. The ADC value of focal pancreatitis ($1.48 \pm 0.16 \text{ mm}^2/\text{s}$) is similar to that of the remaining pancreas ($1.54 \pm 0.28 \text{ mm}^2/\text{s}$). Note a hyperintense reactive lymph node (arrow). DWI: Diffusion-weighted magnetic resonance imaging; MRCP: Magnetic resonance cholangiopancreatography; ADC: Apparent diffusion coefficient.

MRI reveals minimal-to-moderate initial peripheral rim enhancement followed by progressive and concentric incomplete filling of the tumor with contrast material^[29].

In several studies, DWI is useful for detection of focal hepatic lesions, differentiation of cystic and solid hepatic lesions, and differentiation of benign and malignant focal hepatic lesions^[4,19,31]. In one investigation using two b values (0 and 500 s/mm^2), there were significant differences between the ADCs of benign and malignant focal hepatic lesions ($2.45 \pm 0.96 \times 10^{-3}$ and $1.08 \pm 0.50 \times 10^{-3} \text{ mm}^2/\text{s}$ for $b = 0$ and 500 s/mm^2 , respectively; $P < 0.001$),

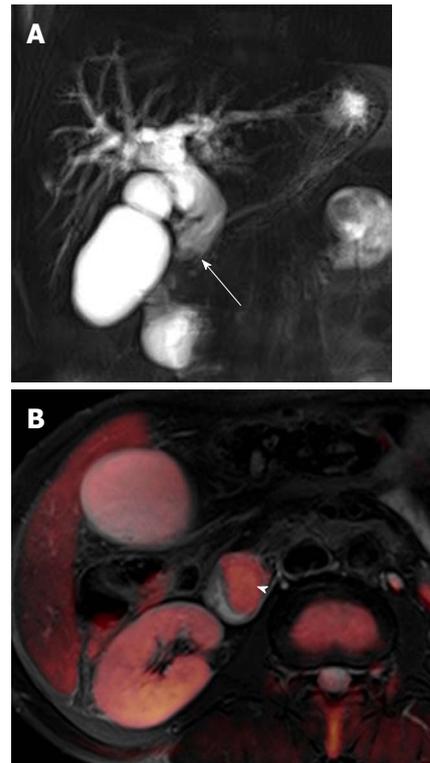

Figure 18 Ampullary carcinoma in a 63-year-old man. A: Coronal image from thick-slab single-shot MRCP shows marked bile duct dilatation with abrupt narrowing (arrow) at the distal common bile duct; B: Fusion image of T2-weighted and diffusion-weighted imaging at $b = 800 \text{ s/mm}^2$ shows an ampullary mass with hyperintensity (arrowhead). MRCP: Magnetic resonance cholangiopancreatography.

although there was some overlap^[4].

Mass-forming intrahepatic cholangiocarcinoma is usually large, achieving a diameter of up to 15 cm because early symptoms are rarely present. Thus, it is readily depicted on DWI and remains hyperintense on DWI using high b values with low ADC values; similar to values of other malignant focal hepatic lesions (Figure 11). Central hypointensity of the mass lesion may be seen on T2-weighted images and DWI using high b values, which may reflect fibrotic tissue in the central portion of the tumor. Peripheral hyperintensity can be demonstrated on DWI using high b values, corresponding to the more highly cellular region. As mentioned earlier, it is, however, difficult to distinguish mass-forming intrahepatic cholangiocarcinoma, hepatocellular carcinoma (HCC), and metastasis. Thus, DWI should be used along with conventional MRI sequences, such as dynamic-enhanced MRI, to differentiate mass-forming intrahepatic cholangiocarcinoma from other hepatic malignancies.

Cholangiocarcinoma tends to occur in atrophied or heavily stone-burdened segments. On cross-sectional images, it is difficult to diagnose cholangiocarcinoma associated with hepatolithiasis. A diagnosis of cholangiocarcinoma associated with hepatolithiasis should be considered when a mass involving or surrounding the bile duct is seen, or when focal nodular biliary wall thickening with increased enhancement is present in the

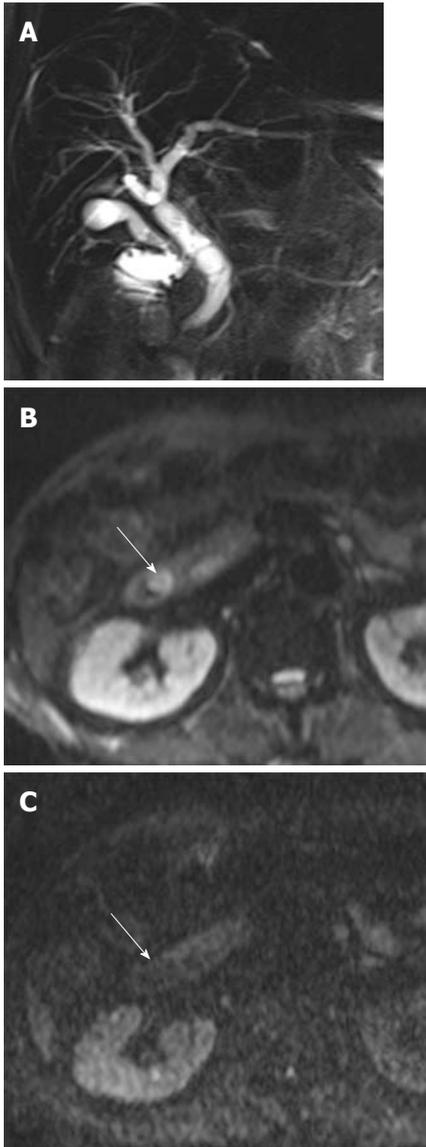

Figure 19 Papillitis due to a recently passed stone in a 75-year-old man. A: Coronal image from thick-slab single-shot MRCP shows mild bile duct dilatation; B: DWI at $b = 50 \text{ s/mm}^2$ shows a papilla with high signal intensity (arrow); C: On DWI at $b = 800 \text{ s/mm}^2$, the signal intensity of the papilla returns to the isosignal intensity (arrow). DWI: Diffusion-weighted magnetic resonance imaging; MRCP: Magnetic resonance cholangiopancreatography.

region of the stricture^[32]. DWI using high b values can be useful for the detection of cholangiocarcinoma associated with hepatolithiasis (Figure 11).

Diffuse periductal thickening along the bile duct in the periductal-infiltrating type, causing mild-to-marked bile duct dilatation, is seen in intrahepatic cholangiocarcinoma^[29]. DWI may be helpful for the detection of malignant bile duct lesions causing a variable degree of intrahepatic bile duct dilatation, as well as for differentiating between intrahepatic malignant and benign bile duct lesions (Figure 12).

Intraductal-growing cholangiocarcinoma appears as hyperintense intraluminal filling defects on DWI using high b values with low ADC values (Figure 13). However, detection of small malignant bile duct lesions is

limited on DWI because tumor detection with DWI is affected by variable causes, such as low spatial resolution of higher- b -value DWI, tumor cellularity, bowel peristalsis, and artifacts.

Invasion of the intrahepatic bile duct is infrequent in HCC, and seen in approximately 3.3%-9.0% of cases^[33]. Obstruction of the bile duct in patients with HCC is caused by invasion of the intrahepatic bile duct, blood clots from the tumor, and tumor fragments. HCC with bile duct tumor thrombi can be distinguished from hematomas in the bile duct based on the presence of mass enhancement on dynamic-enhanced CT or MRI^[34,35]. DWI can be useful for the differentiation of HCC and bile duct tumor thrombi from blood clots within the bile on the basis of identification of restricted diffusion of the mass lesion in the bile duct. They appear as hyperintense intraluminal filling defects on DWI using high b values with low ADC values (Figure 14). However, because imaging findings of HCC with bile duct thrombi are similar to those of intraductal-growing cholangiocarcinoma, conventional MRI findings of a mass outside the ductal system, hypervascularity on dynamic imaging, and underlying cirrhosis favor the diagnosis of HCC with bile duct tumor thrombi rather than intraductal cholangiocarcinoma.

DWI for characterization of extrahepatic biliary lesions and diagnosis of malignant lesions in the extrahepatic bile duct

Approximately two-thirds of extrahepatic bile duct cancer arises at the hepatic hilum (known as hilar cholangiocarcinoma or Klatskin tumor), and approximately one-third originates from the distal common bile duct. The most common pattern of tumor growth is focal infiltration of the ductal wall or the periductal-infiltrating type, resulting in focal strictures. Other tumor growth patterns include the mass-forming and intraductal-growing types^[29].

Extrahepatic bile duct carcinoma causes varying degrees of upstream bile duct dilatation. MRCP is highly accurate in identifying the presence and level of bile duct obstruction. Although differentiation between benign and malignant biliary lesions by MRCP is sometimes difficult, inspection of the bile duct lumen and wall on thin-section images helps to identify malignancies, which often cause an eccentric, abrupt change in the bile duct caliber, with irregular shouldering at the transition point from large obstructed to small-caliber decompressed ducts. Benign strictures tend to show short-segment involvement with smooth, gradual, and concentric narrowing^[36].

It has been reported that DWI is useful for the detection of extrahepatic cholangiocarcinoma and differentiation between malignant and benign biliary lesions. In a study using two b values (0 s/mm^2 and 500 s/mm^2), the sensitivity, specificity and accuracy of the detection of extrahepatic carcinoma were 94.3%, 100% and 96.4%, respectively^[10]. On DWI using high b values, a high signal intensity with a low ADC value at the transition point

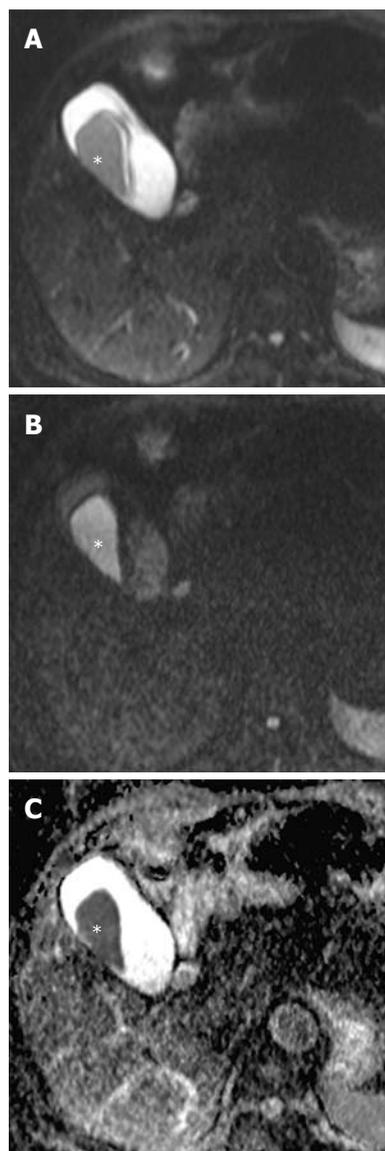

Figure 20 Hemobilia secondary to percutaneous liver biopsy in a 55-year-old man. A: DWI at $b = 50 \text{ s/mm}^2$ shows a hypointense hematoma in the gallbladder (asterisk); B: On DWI at $b = 800 \text{ s/mm}^2$, signal intensity of the hematoma changes to high signal (asterisk). C: On the ADC map, the hematoma in the gallbladder appears as low signal intensity (asterisk), which is associated with intact RBC membranes (i.e., hyperacute, acute, and early subacute hematomas). DWI: Diffusion-weighted magnetic resonance imaging; ADC: Apparent diffusion coefficient; RBC: Red blood cell.

from large obstructed to small-caliber decompressed ducts is a highly suggestive finding for malignant, rather than benign, biliary lesions because benign lesions usually show no hyper- or isointensity to the surrounding structures in the transitional area (Figure 15). Thus, this finding can be a clue for differentiating between malignant and benign biliary lesions. However, there is some degree of overlap; benign active inflammatory conditions rarely have hyperintensity, and some malignant lesions are not demonstrated on DWI using high b values^[10].

Pancreatic carcinoma, cholangiocarcinoma, or chronic pancreatitis should be considered when a bile duct stricture is limited to the distal (intrapancreatic) common

bile duct. Pancreatitis remains difficult to distinguish from pancreatic carcinoma on the basis of MRI findings, particularly in cases of acute or chronic mass-forming pancreatitis, because both appear as hypointense masses or mass-like lesions in the pancreas on T1-weighted images and are associated with ductal obstruction^[37].

In a study using b values (0 s/mm^2 and 600 s/mm^2), DWI is helpful in detecting focal pancreatic lesions and differentiating between pancreatic carcinoma and mass-forming pancreatitis. Mass-forming pancreatitis has either lower or higher ADC values than pancreatic carcinoma, but ultimately follows the ADC values of the remaining pancreatic parenchyma, whereas the focal lesion in pancreatic carcinoma is invariably lower than the remaining parenchyma (Figures 16 and 17)^[7]. In a study using a high b value (1000 s/mm^2), the sensitivity and specificity for the detection of pancreatic adenocarcinoma was 96.2% and 98.6%, respectively^[38]. ADC values in pancreatic carcinoma tend to be lower than in the normal pancreas in most studies, although there is some degree of overlap^[7,38]. Pancreatic carcinoma invokes a fibrotic response similar to desmoplastic reaction, therefore, ADC values are correlated with the degree of fibrosis; the ADC value of pancreatic carcinoma with loose fibrosis is higher than that of pancreatic carcinoma with dense fibrosis^[39]. In a recent study, ADC at lower b values ($< 500 \text{ s/mm}^2$) was higher in mass-forming pancreatitis than in pancreatic carcinoma, whereas ADC at high b values was not significantly different between mass-forming pancreatitis and pancreatic carcinoma^[17]. This was attributed to increasing perfusion effects at lower b values, which was correlated with high vascularity in chronic pancreatitis. Thus, DWI alone is suboptimal for the differentiation of pancreatic masses and mass-like lesions, and should be interpreted in conjunction with conventional MRI.

Periampullary lesions have one or more of the following MRI features: the presence of biliary dilatation at the level of the ampulla of Vater with or without a dilated pancreatic duct, bulging of the papilla, a mass lesion in or around the ampulla of Vater, and abnormal enhancement of the papilla. It is not always easy to distinguish between neoplastic and non-neoplastic conditions in or around the ampulla of Vater using conventional MRI, because of the confusing or overlapping findings^[40].

In our experience, ampullary or periampullary carcinoma displays mild-to-moderately high signal intensity on DWI using high b values with low ADC values, reflecting the high cellularity of tumors, whereas benign lesions, such as sphincter of Oddi dysfunction or papillary stenosis, show no high signal intensity in or around the ampulla of Vater (Figures 18 and 19). Thus, DWI can be helpful for detecting highly cellular malignant lesions and distinguishing between malignant and benign conditions in or around the ampulla of Vater. However, as mentioned earlier, some small malignant lesions in or around the ampulla of Vater are not identified on DWI using high b values.

Table 1 Characteristic diffusion-weighted magnetic resonance imaging features in the various biliopancreatic tract disorders

Categories	Diagnosis	Characteristic DWI features
DWI for the evaluation of gallstone-related complications	Acute cholangitis	Hyperintense parenchyma on low b values usually returns to isointense on high b values
	Hepatic abscess	Hyperintense on high b values with low ADC values
	Acute pancreatitis	Hyperintense on high b values
DWI for the characterization and diagnosis of gallbladder lesions	Cholecystitis	Diffuse and symmetric hyperintensity in the gallbladder wall on high b values Pus in the dependent portion: hyperintense on high b values with low ADC values
	Gallbladder carcinoma	Hyperintense mass occupying the entire gallbladder lumen or focal and asymmetric hyperintensity in or around the gallbladder wall on high b values
DWI for the characterization of intrahepatic biliary lesions and diagnosis of malignant lesions in the intrahepatic bile duct	Mass-forming cholangiocarcinoma	Hyperintense on high b values with low ADC values, similar to that of other malignant hepatic masses
	Periductal-infiltrative cholangiocarcinoma	Hyperintense periductal thickening along the bile duct on high b values with low ADC values
	Intraductal-growing cholangiocarcinoma	Hyperintense intraluminal filling defect on high b values with low ADC values
DWI for characterization of extrahepatic biliary lesions and diagnosis of malignant lesions in the extrahepatic bile duct	HCC with bile duct thrombi	Similar to that of intraductal-growing cholangiocarcinoma
	Extrahepatic cholangiocarcinoma	Hyperintense on high b values with low ADC values, at the transition point from large obstructed to small-caliber decompressed ducts
	Pancreatic carcinoma	Lower ADC values than those of the remaining pancreas
	Mass-forming pancreatitis	Similar ADC values to those of remaining pancreas
	Ampullary or periampullary carcinoma	Mild to moderate hyperintensity in or around ampulla of Vater on high b values with low ADC values
	Sphincter Oddi dysfunction or papillary stenosis	Isointensity in or around ampulla of vater on high b values

DWI: Diffusion-weighted magnetic resonance imaging; HCC: Hepatocellular carcinoma; ADC: Apparent diffusion coefficient.

PITFALLS

DWI is susceptible to a variety of artifacts that arise from motion, use of strong gradient pulses, and EPI technique. Physiological motion artifacts such as respiratory motion, cardiac pulsation, movement of the diaphragm, and motility of the bowel lead to ghosting images and blurring. The pulsatile motion of the heart and aorta obscure or diminish visualization of and increase ADC in the left lobe of the liver. These artifacts can be overcome using respiratory or electrocardiographic triggering. The EPI technique produces a low spatial resolution and signal-to-noise ratio. The rapid on-and-off switching of the high-intensity gradient field easily produce eddy currents, leading to geometrical distortion and image shearing artifacts that may become more pronounced with increased b values. DWI is also highly sensitive to magnetic field inhomogeneity. Susceptibility artifacts caused by field inhomogeneity are prevalent at air-tissue interfaces or around tissue-metal interfaces^[13,41].

Although restricted diffusion is generally considered to be associated with malignant lesions, some malignant lesions may not be detected on DWI. Some malignant tumors are too small for the DWI signal change to be obvious, or restriction to water diffusion is likely to be limited in malignant tumors with low cellularity, such as tumors with large cystic components. In contrast, some benign lesions sometimes exhibit restricted diffusion on imaging with high b values. The highly cellular tissue in reactive lymph nodes may show restricted diffusion (Figure 17). Thus, the role of DWI and ADC in distinguish-

ing between benign and malignant lymph nodes remains unclear^[42]. Additionally, diffusion of water in hematoma may be significantly restricted. Decreased ADC values in hemorrhage with intact red blood cell (RBC) membranes (i.e., hyperacute, acute, and early subacute hematoma) and increased ADCs after lysis of RBC membranes (i.e., "free" methemoglobin in subacute-to-chronic hematoma) have been reported (Figure 20). This may be mistaken for malignant lesions on DWI or the ADC map, causing erroneous detection or characterization of lesions^[43].

Thus, the radiologists have to be aware of potential pitfalls and limitation of the technique, and it should be kept in mind that DWI should be interpreted in conjunction with other conventional MRI.

CONCLUSION

DWI results for evaluating biliopancreatic diseases are still preliminary, and further studies are needed to determine its performance in the biliopancreatic tract. Additionally, correlation of DWI with pathological findings is required to define better the pathophysiology of various biliopancreatic diseases. Nevertheless, DWI can complement morphological information obtained by conventional MRCP by providing additional functional information concerning the alteration of tissue cellularity due to pathological processes. The detection of abnormal lesions and the differentiation of malignant from benign tumor-like lesions in the biliopancreatic tract can be improved by combined evaluation using both DWI and conventional MRI (Table 1). Moreover, DWI can

be a reasonable alternative technique for the assessment of the biliopancreatic tract in the setting of a contraindication to contrast agents such as renal insufficiency or contrast allergy.

Abstract

AIM: To investigate the hepatoprotective effect of MK615, a Japanese apricot extract, in an animal model, and its clinical therapeutic effect.

METHODS: Wistar rats were administered physiological saline (4 mL/kg) or MK615 solution (4 mL/kg) for 7 d. On the sixth d, acute hepatic injury was induced by

administering a single intraperitoneal injection (*ip*) of D-galactosamine hydrochloride (D-GalN) (600 mg/kg). Plasma levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) were determined, and liver tissues were used for histopathological analysis. Fifty-eight patients with liver disorders [hepatitis C ($n = 40$), non-alcoholic fatty liver disease ($n = 15$), and autoimmune liver disease ($n = 3$)] were orally administered commercially available Misatol ME-containing MK615 (13 g/d) daily for 12 wk. Blood and urine were sampled immediately before and 6 wk, 12 wk, and 16 wk after the start of intake to measure various biochemical parameters. The percentage change in ALT and AST levels after 12 wk from the pre-intake baseline served as a primary endpoint.

RESULTS: D-GalN effectively induced acute hepatic injury in the rats. At 48 h after the *ip* injection of D-GalN, the plasma levels of ALT (475.6 ± 191.5 IU/L *vs* 225.3 ± 194.2 IU/L, $P < 0.05$) and AST (1253.9 ± 223.4 IU/L *vs* 621.9 ± 478.2 IU/L, $P < 0.05$) in the MK615 group were significantly lower than the control group. Scattered single cell necrosis, loss of hepatocytes, and extensive inflammatory cell infiltration were observed in hepatic tissue samples collected from the control group. However, these findings were less pronounced in the group receiving MK615. At the end of the clinical study, serum ALT and AST levels were significantly decreased compared with pre-intake baseline levels from 103.5 ± 58.8 IU/L to 71.8 ± 39.3 IU/L ($P < 0.05$) and from 93.5 ± 55.6 IU/L to 65.5 ± 34.8 IU/L ($P < 0.05$), respectively. A reduction of $\geq 30\%$ from the pre-study baseline ALT level was observed in 26 (45%) of the 58 patients, while 25 (43%) patients exhibited similar AST level reductions. The chronic hepatitis C group exhibited significant ALT and AST level reductions from 93.4 ± 51.1 IU/L to 64.6 ± 35.1 IU/L ($P < 0.05$) and from 94.2 ± 55.5 IU/L to 67.2 ± 35.6 IU/L ($P < 0.05$), respectively. A reduction of $\geq 30\%$ from the pre-study baseline ALT level was observed in 20 (50%) of the 40 patients.

ALT levels in both the combined ursodeoxycholic acid (UDCA) treatment and the UDCA uncombined groups were significantly lower after Misatol ME administration. MK615 protected hepatocytes from D-GalN-induced cytotoxicity in rats. Misatol ME decreased elevated ALT and AST levels in patients with liver disorders.

CONCLUSION: These results suggest that MK615 and Misatol ME are promising hepatoprotective agents for patients with liver disorders.

INTRODUCTION

Japanese apricot (*Prunus mume* Sieb. et Zucc.), hereinafter referred to as *ume*, was brought to Japan from China around the eighth century. The flesh of this fruit has been used not only as food but also as medicine. *Ishinbo*, the oldest medical monograph in Japan, which was written in AD 984, indicates that both *umeboshi* (pickled *ume*) and *ubai* (smoke-dried *ume*) were used as medicines (e.g., as anti-diarrheal agents and for detoxification in food or drug poisoning). *Shokokukodenbiho*, published in 1817, also refers to the effectiveness of *ume* extracts. It is thus evident that *ume* was used extensively as a folk remedy in Japan. Syringaresinol, a lignan in *ume*, was recently shown to control infection by inhibiting the migration of *Helicobacter pylori*^[1]. MK615, an extract from Japanese apricot, contains triterpenoids such as ursolic acid (UA)^[2], oleanolic acid (OA)^[2,4], lupeol^[2,4], α -amyrin^[2], and β -sitosterol^[4]. These substances have been shown to exert various biological actions. Reports have described diverse effects, including anti-tumor activity (against tumor cell lines such as those of gastric cancer^[5], leukemia^[5], breast cancer^[4,6], hepatocellular carcinoma^[7,8], colon cancer^[9], pancreatic cancer^[10], and malignant melanoma^[11]) and immunopotentialiation in experimental animals exposed to X-rays^[4]. MK615 was previously reported to inhibit the release of high-mobility group box 1 (HMGB1) from lipopolysaccharide (LPS)-stimulated macrophage-like RAW264.7 cells and to activate the transcription factor nuclear factor erythroid 2-related factor 2 (Nrf2), resulting in the

induction of heme oxygenase-1 (HO-1). MK615 was also shown to suppress the formation of inflammation-inducing cytokines [tumor necrosis factor α (TNF- α) and interleukin-6 (IL-6)] by inactivating mitogen-activated protein kinases (MAPKs) and the transcription factor nuclear factor- κ B (NF- κ B)^[3,12]. It is thus evident that *ume* extracts exert anti-inflammatory and antioxidative actions. However, the significance of these actions in the liver has not been adequately clarified.

Given the anti-inflammatory and antioxidative actions of MK615, we investigated the hepatoprotective effects of MK615. In addition, the effects of Misatol ME, a beverage containing MK615 that is approved as a health food product in Japan, were clinically evaluated in patients with liver disorders that included hepatitis C, chronic inflammation of the liver, as well as fatty liver disease, which is closely involved in oxidative stress.

MATERIALS AND METHODS

Effect of MK615 on D-galactosamine hydrochloride-induced acute hepatic injury in rats

Preparation of MK615 solution: MK615 solution was prepared from a condensed extract of *ume*. In brief, *ume* were squeezed using a press, and the *ume* juice was then heated and concentrated 20-fold^[5]. The condensed extract was neutralized using NaOH and was then heat-sterilized. The MK615 solution contained the neutral, condensed *ume* extract.

D-galactosamine hydrochloride-induced hepatic injury in rats: Seven-week-old male Wistar rats (Crj:WI) weighing 200-240 g were purchased from Charles River Laboratories Japan (Yokohama, Japan). All rats were maintained under controlled temperature and lighting conditions (12/12-h dark/light cycle), and water and standard diet were provided ad libitum in accordance with the institute's guidelines for care and use of laboratory animals in research.

Acute hepatic injury was induced by administering a single intraperitoneal (*ip*) injection of D-galactosamine hydrochloride (D-GalN) (600 mg/kg; Wako Pure Chemical Industries, Osaka, Japan). In this study, rats were divided into 3 experimental groups. In group I (the vehicle control group), rats were administered physiological saline (4 mL/kg per day) *via* gavage for 7 d and injected with D-GalN (*ip*) 2 h after the sixth oral administration of saline (6 d from the first oral administration). In group II (the MK615 group), rats received MK615 solution (4 mL/kg per day) *via* gavage for 7 d and were injected with D-GalN (*ip*) 2 h after the sixth oral administration of MK615 solution. In group III, rats were administered the neutral MK615 solution (4 mL/kg per day) *via* gavage for 7 d and were injected with saline (*ip*) 2 h after the sixth oral administration of MK615 solution. group III served as a negative experimental control without D-GalN-induced hepatic injury (Figure 1). Treatments involving oral administration by gavage were conducted between

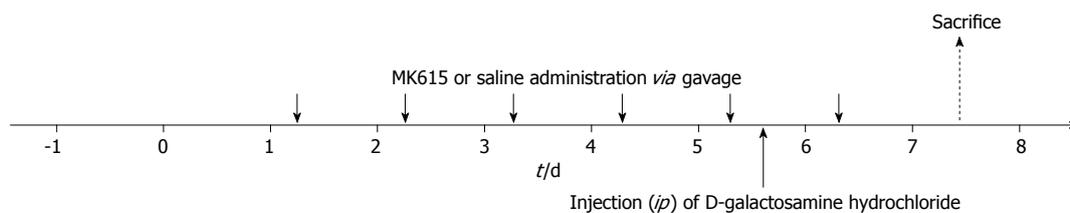

Figure 1 Experiment protocol of D-galactosamine hydrochloride-induced acute hepatic injury in rats.

9:00 and 10:00 AM and *ip* injections were administered between 11:00 AM and 12:00 noon. All rats were sacrificed by exsanguination under anesthesia 48 h after the *ip* injection of D-GalN or saline (8 d after the first oral administration). Blood samples from the abdominal aorta were immediately heparinized, and plasma samples were isolated by centrifugation. Plasma samples were frozen and stored at -80°C until used, and subsequently analyzed to determine the levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST). Liver tissue samples were also obtained from each rat and used for histopathological analysis. The plasma levels of ALT and AST were determined using a commercially available analytical kit (Transaminase CII-Test; Wako Pure Chemical Industries).

Evaluation of the effects of MK615 in patients with liver disorder

Subjects: This study involved patients who were definitively diagnosed with a liver disorder at the Jikei University School of Medicine Hospital, the St. Marianna University School of Medicine Hospital, or the Kurihara Clinic between December 2007 and December 2009 and who met the following requirements: (1) ALT level exceeding reference limits when tested within 3 mo before the start of this study, indicating the presence of hepatopathy; (2) serum hepatitis C virus (HCV)-RNA positivity (determined by real-time polymerase chain reaction) in patients with chronic hepatitis C; and (3) presence of fatty liver confirmed by diagnostic imaging in cases of non-alcoholic fatty liver disease (NAFLD). The following patients were excluded from the study: (1) those receiving treatment for liver cirrhosis, hepatocellular carcinoma, or other malignant tumors; (2) patients receiving treatment with Stronger Neo-Minophagen C; (3) those receiving treatment with interferon (IFN); and (4) habitual drinkers (alcohol consumption, > 30 g/d) or occasional heavy drinkers. Concomitant use of drugs or any treatment with antiviral, immunomodulating, or marrow-suppressive activity was prohibited during the study period, but continued use of drugs that had been initiated before the study was permitted. No patients were heavy drinkers. The ethics committee of each participating facility approved the study protocol. Informed consent to participate in the study was obtained in writing from all patients.

Methods: In Japan, MK615 solution is commercially available as Misatol ME (AdaBio Co. Ltd., Takasaki, Japan). For the clinical study, Misatol ME was used as the

MK615 solution and was ingested orally every d (2×6.5 g packs/d) for 12 wk. Blood and urine were sampled immediately before and 6 wk, 12 wk, and 16 wk after the start of MK615 intake to measure the following parameters: white blood cell (WBC) count, differential leukocyte count, red blood cell (RBC) count, hemoglobin, hematocrit, platelet count, ALT, AST, γ -glutamyl transpeptidase (γ -GTP), alkaline phosphatase (ALP), total protein, albumin, total cholesterol, cholinesterase, and total bilirubin, as well as urinalysis parameters. The percentage change in ALT and AST levels after 12 wk of intake from the pre-intake baseline served as primary and secondary endpoints, respectively. In the analysis of these endpoints, an improvement of $\geq 50\%$ from the pre-intake baseline was regarded “markedly effective”, $\geq 30\%$ was regarded “effective”, $\leq 30\%$ as “ineffective”, and an aggravation of $\geq 30\%$ as “worsened”. The response rate was defined as the percentage of “markedly effective” plus “effective” cases.

Statistical analysis

Data are expressed as mean \pm SD. Statistical analyses were performed using Stat View for Windows Version 5.0 (SAS Institute Inc., North Carolina, United States). Differences between 2 groups were analyzed using the Mann-Whitney *U* test. Comparisons between baseline and each time point were performed using Dunnett’s test. $P < 0.05$ was considered significant.

RESULTS

The effect of MK615 on D-galactosamine hydrochloride-induced acute hepatic injury in rats

ALT and AST plasma levels in control rats were elevated 48 h after D-GalN induction, with mean values of 475.6 ± 191.5 IU/L ($n = 8$) and 1253.9 ± 223.4 IU/L ($n = 8$), respectively. In the MK615 group, the ALT and AST levels were 225.3 ± 194.2 IU/L ($n = 9$) and 621.9 ± 478.2 IU/L ($n = 9$), respectively. The levels of ALT and AST in the MK615 group rats were significantly lower than in those of the control group ($P = 0.0433$ for ALT, $P = 0.0124$ for AST by Mann-Whitney *U* test) (Figure 2A and B).

Liver tissues were obtained from both control group rats and MK615 group rats at 48 h after D-GalN injection. Scattered single cell necrosis (swollen eosinophilic hepatocytes) and loss of hepatocytes was observed in hepatic tissue samples from the control group. Extensive inflammatory cell infiltration was also noted (Figure 2C). Figure 2D shows that these features of D-GalN-induced

hepatic injury were reduced in the treatment group re-

ceiving the MK615 solution.

The effects of MK615 in patients with liver disorders

We enrolled 58 patients in this clinical study (mean age, 61.4 ± 12.7 years; range: 29-82 years; 40 men and 18 women). The diagnosis was chronic hepatitis C in 40 patients, NAFLD in 15 patients, and autoimmune liver disease in 3 patients (2 with autoimmune hepatitis and 1 with primary sclerosing cholangitis). Table 1 lists the background variables in relation to the diseases diagnosed.

Analysis of the entire study population determined that ALT levels had decreased significantly from 103.5 ± 58.8 IU/L before the start of the study to 81.3 ± 45.7 IU/L ($P < 0.05$) at 6 wk, 71.8 ± 39.3 IU/L ($P < 0.05$) at 12 wk, and 72.3 ± 40.3 IU/L ($P < 0.05$) at 16 wk (Figure 3A). AST levels decreased significantly from 93.5 ± 55.6 IU/L before the start of the study to 77.6 ± 47.1 IU/L ($P < 0.05$) at 6 wk, 65.5 ± 34.8 IU/L ($P < 0.05$) at 12 wk, and 68.3 ± 37.8 IU/L ($P < 0.05$) at 16 wk (Figure 3B). A reduction of ≥ 30% from pre-study baseline ALT levels was observed in 26 (45%) of the 58 patients, whereas 25 (43%) patients exhibited a similar reduction in AST levels (Table 2).

When the effects of Misatol ME were analyzed in relation to the disease diagnosed, the chronic hepatitis C group exhibited significant ALT level reductions from the pre-study baseline of 93.4 ± 51.1 IU/L to 75.3 ± 46.6 IU/L ($P < 0.05$) at 6 wk, 64.6 ± 35.1 IU/L ($P < 0.05$) at 12 wk, and 64.6 ± 33.8 IU/L ($P < 0.05$) at 16 wk (Figure

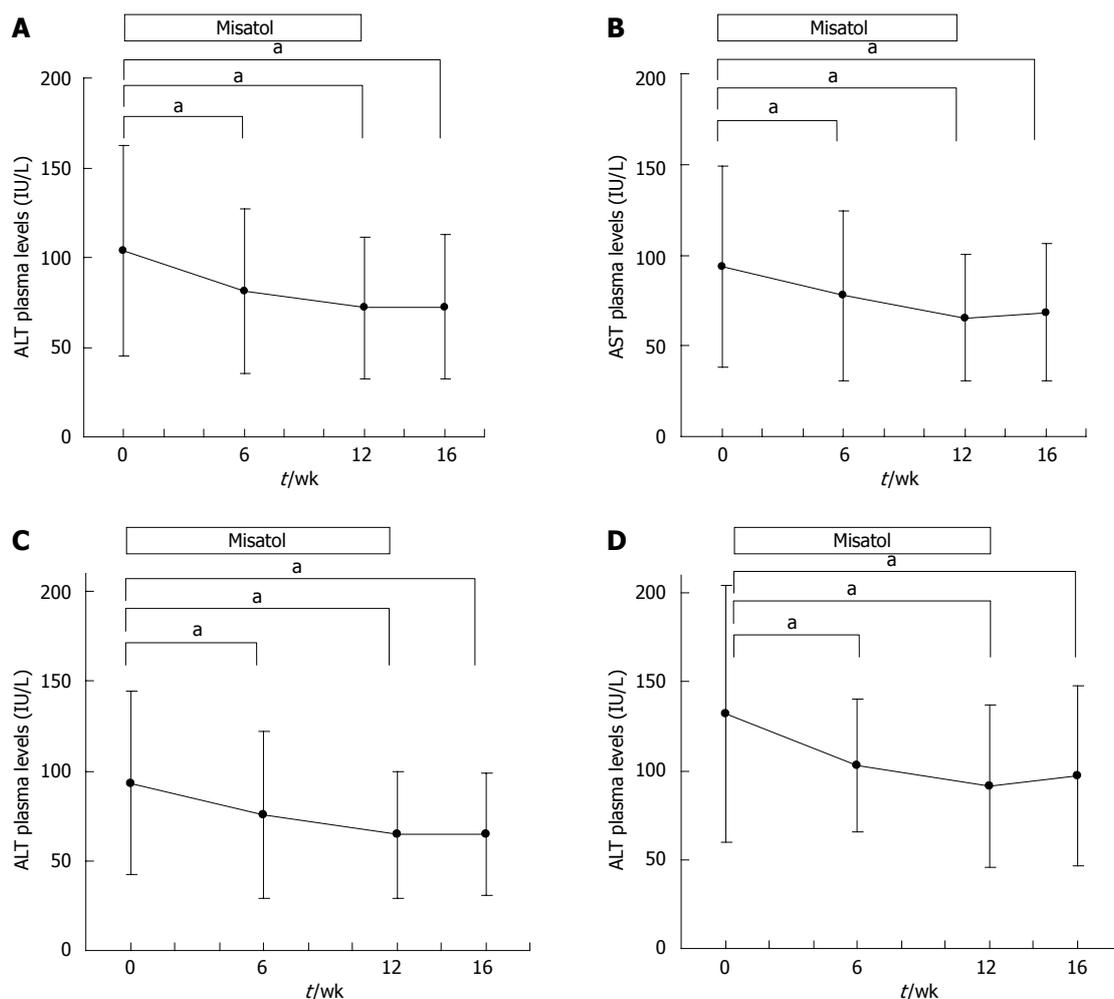

Figure 3 Effects of MK615 in patients with liver disorder, chronic hepatitis C and non-alcoholic fatty liver disease. A: Alanine aminotransferase (ALT); B: Aspartate aminotransferase (AST); C: Chronic hepatitis C group (ALT); D: Non-alcoholic fatty liver disease group (ALT). ^a*P* < 0.05 vs 0 wk group. Dunnett's test.

Table 2 Response rate of MK615 therapy in patients with liver disorder (%)		
	ALT	AST
Chronic hepatitis C	20/40 (50)	16/40 (40)
NAFLD	5/15 (33)	6/15 (40)
Autoimmune liver disease	1/3 (33)	3/3 (100)
Total	26/58 (45)	25/58 (43)

NAFLD: Non-alcoholic fatty liver disease; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase.

3C). This same group of patients exhibited significant AST level reductions from the pre-study baseline of 94.2 ± 55.5 IU/L to 78.8 ± 49.5 IU/L (*P* < 0.05) at 6 wk, 67.2 ± 35.6 IU/L (*P* < 0.05) at 12 wk, and 66.6 ± 33.7 IU/L (*P* < 0.05) at 16 wk. In the chronic hepatitis C group, a reduction of $\geq 30\%$ from the pre-study baseline ALT level was observed in 20 (50%) of the 40 patients, while 16 (40%) patients exhibited similar AST level reductions (Table 2). Among the patients with chronic hepatitis C, ALT data before the start of test beverage intake (24 wk before starting intake) were available for 32 patients. These patients were subdivided into combined ursode-

oxycholic acid (UDCA) treatment (*n* = 20) (Figure 4A) and UDCA uncombined (*n* = 12) groups (Figure 4B). In both the combined UDCA treatment and UDCA uncombined groups, ALT levels were significantly lower after the intake of Misatol ME compared with those before intake.

The NAFLD group exhibited significant ALT level reductions from 131.9 ± 72.5 IU/L before the start of the study to 102.8 ± 37.6 IU/L (*P* < 0.05) at 6 wk, 90.9 ± 45.6 IU/L (*P* < 0.05) at 12 wk, and 96.9 ± 50.8 IU/L (*P* < 0.05) at 16 wk (Figure 3D). This group also exhibited significant AST level reductions during the Misatol ME intake period compared with the pre-start baseline level; levels were 84.5 ± 50.0 IU/L before the start of the study, 66.7 ± 24.2 IU/L (*P* < 0.05) at 6 wk, 58.1 ± 26.0 IU/L (*P* < 0.05) at 12 wk, and 69.8 ± 41.9 IU/L (NS) at 16 wk. In the NAFLD group, a reduction of $\geq 30\%$ from the pre-study baseline ALT level was observed in 5 (33%) of the 15 patients, whereas similar AST level reductions were observed in 6 (40%) patients (Table 2).

The levels of γ -GTP in the entire study population also decreased significantly after Misatol ME intake compared with pre-intake baseline levels (data not shown).

Table 3 presents the hematological and biochemical

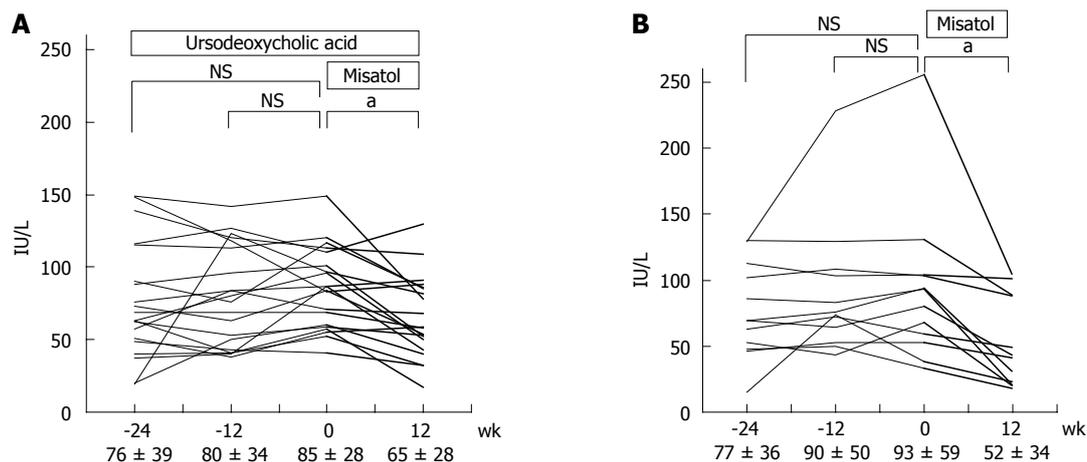

Figure 4 Effects of MK615 in patients with chronic hepatitis C (alanine aminotransferase). A: Misatol was added on ursodeoxycholic acid; B: Only Misatol was used. ^a $P < 0.05$ vs 0 wk group. Dunnett's test. NS: Not significant.

Table 3 Changes of serum level during MK615 therapy in patients with liver disorders

	Before therapy	During therapy 12 wk	P value ¹

Creatinine (mg/dL)	0.75 \pm 0.15	0.74 \pm 0.15	NS

Data are expressed as the mean \pm standard deviation. ¹Dunnett's test. NS: Not significant; WBC: White blood cell; RBC: Red blood cell; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; γ -GTP: γ -guanosine triphosphate; LDH: Lactate dehydrogenase; ALP: Alkaline phosphatase; BUN: Blood urea nitrogen; NS: Not significant.

data obtained for the clinical study. No change associated with Misatol ME intake was noted in any hematological or biochemical parameter other than in the indicators of liver function, which improved after MK615 intake. An unexplained eruption was observed in 1 patient with NAFLD, which was the only adverse event observed during this study, and was not found to have a causal relationship with the intake of Misatol ME.

DISCUSSION

This is the first study demonstrating that Misatol ME (a beverage containing MK615, an *ume* extract) lowers blood transaminase levels in patients with liver disorders such as chronic hepatitis C and NAFLD. *ume* has been used as traditional medicine and food in Japan since ancient

times^[5]. The clinical effects of *ume* have been attributed to the biological activity of MK615. MK615 contains triterpenoids such as OA, UA, lupeol, α -amyrin, and β -sitarosterol^[2-4], and has been shown to exert anti-tumor activity against various tumor cell lines, including those of gastric cancer^[5], leukemia^[5], breast cancer^[4,6], hepatocellular carcinoma^[7,8], colorectal cancer^[9], pancreatic cancer^[10], esophageal cancer^[2], and malignant melanoma^[11]. The possible mechanisms underlying the anti-tumor activity of MK615 include induction of apoptosis^[2,6,9,11], induction of autophagy^[9], cell cycle arrest^[2,6,7,10], reduced expression of receptors for advanced glycation end products (RAGE) on membrane surfaces of cancer cells^[8,11], and immunopotentialiation following exposure to X-rays^[4]. MK615 inhibits the release of HMGB1 from mouse macrophage-like RAW264.7 cells^[5]. This inhibitory activity is mediated by Nrf2 activation and HO-1 induction, suggesting that MK615 possesses antioxidative activity^[3]. The authors also previously demonstrated that MK615 suppressed the release of the inflammatory cytokines TNF- α and IL-6 in RAW264.7 cells^[12]. This suppression was mediated by the inactivation of MAPKs and NF- κ B, thus indicating an anti-inflammatory effect of MK615^[12].

The present study reveals that MK615 also exerts hepatoprotective activity in a rat model of D-GalN-induced hepatopathy, given that treatment with MK615 resulted in lower plasma ALT and AST levels accompanied by histological evidence of suppressed destruction of hepatic parenchymal cells when compared with untreated controls. Therefore, MK615 protected the rats from D-GalN-induced hepatopathy.

Previous studies using animal models of D-GalN-induced hepatopathy revealed the activation of MAPKs in the liver^[13], suggesting that liver protection might be achieved by the induction of HO-1^[14] or by the inhibition of NF- κ B in Kupffer cells^[15]. In the present study, the effects of MK615 in suppressing MAPK phosphorylation, inducing HO-1, and inhibiting NF- κ B activation may have protected the rats from D-GalN-induced hepatopathy.

Additionally, it was shown that the intake of Misatol

ME, which contains MK615, lowered the elevated levels of AST and ALT in patients with hepatic impairment. This effect was observed in patients with etiologically different hepatic diseases, i.e., those with hepatitis C and those with NAFLD. No adverse event was associated with the intake of Misatol ME during this study. Furthermore, add-on Misatol ME in combination with UDCA, which had been initiated before the start of Misatol ME intake, resulted in further AST and ALT level reductions in patients with hepatitis C. Moreover, the reduction in ALT levels was also noted in patients who were previously resistant to UDCA therapy.

A major approach to treating HCV infection is antiviral therapy using a combination of IFN and ribavirin^[16]. In cases in which the virus cannot be eradicated or IFN is not indicated, it is important to prevent the progression of HCV infection to liver cirrhosis or liver cancer^[17]. In practice, the progression of HCV infection to liver fibrosis is accelerated by higher levels of ALT^[18-21]. Therefore, when dealing with cases in which virus eradication is difficult, therapeutic interventions that result in lower ALT levels are important for delaying disease progression. In the present study, Misatol ME was shown to significantly reduce ALT levels in patients with chronic hepatitis C, and further reductions in ALT levels were also observed in patients refractory or poorly responsive to UDCA. Given the significance of these findings, Misatol ME warrants further evaluation as a potential treatment for liver disease, including an evaluation of its efficacy during prolonged use. Because Misatol ME is a functional food, conducting the same controlled study to investigate its potential as a medicine was difficult. Nevertheless, the usefulness of Misatol ME as a functional food was clarified. A future investigation is required in which a detailed analysis of the active principal component of Misatol ME should be conducted to elucidate the mechanism underlying its effectiveness as a functional food.

The mechanism underlying the hepatoprotective activity of Misatol ME in patients with chronic hepatitis C appears to involve the anti-inflammatory and antioxidative actions of the MK615 component of Misatol ME. Patients with chronic hepatitis C have high levels of inflammatory cytokines such as TNF- α and IL-6^[22-25]. MK615 inhibits the phosphorylation of MAPKs in LPS-stimulated macrophage-like RAW264.7 cells and suppresses the formation of TNF- α and IL-6 by inhibiting NF- κ B activation^[12]; these findings suggest that the effect of MK615 in suppressing cytokine formation contributes to the suppression of hepatocyte damage in patients with hepatic impairment. Given that Nrf2 activation^[26-29] and HO-1 induction^[14,30-32] are known to be hepatoprotective, the authors previously demonstrated that MK615 and its component OA activate the transcription factor Nrf2 in LPS-stimulated macrophage-like RAW264.7 cells and induce HO-1, one of the target genes^[3]. Whether MK615 also activates Nrf2 and induces HO-1 in clinical cases is unknown. However, it appears highly probable that the antioxidative action of MK615 protects the liver.

MK615 was also effective in patients with NAFLD,

reducing serum AST and ALT levels in these patients, as well as in those with hepatitis C. The involvement of factors such as oxidative stress, insulin resistance, and TNF- α in the progression of NAFLD into non-alcoholic steatohepatitis (NASH) has been suggested^[33-35]. Diet and exercise are the standard therapies for the treatment of such cases^[36,37]. However, the outcomes of these treatments are often unsatisfactory. The effects of MK615 on oxidative stress and insulin resistance in patients with NAFLD are most likely based on the antioxidative effect and the inflammatory cytokine-suppressive action of MK615. Therefore, MK615 therapy may be a promising new means of treating such cases clinically. Obesity is considered a major factor associated with NAFLD. The livers of obese individuals display disturbances in autophagy, with upregulation of autophagy reducing insulin resistance^[38]. Since MK615 has been demonstrated to induce autophagy in colorectal carcinoma cell lines^[9], this effect is also expected to be useful for treatment^[39]. More recently, it was reported that a rat model of NASH exhibited increased expression of RAGE in the liver, suggesting that inhibiting RAGE expression can protect the liver^[40]. MK615 reduces the expression of RAGE on the cell membranes of the high-RAGE expression hepatocellular carcinoma cell line HuH7^[8]. This RAGE suppression may also play a role in the hepatoprotective effects of Misatol ME.

In the present study, MK615 and Misatol ME, which contains MK615, were shown to potentially alleviate various types of hepatic impairment caused by different factors. MK615 contains multiple triterpenoids (OA, UA, lupeol, *etc.*); previous *in vitro* and *in vivo* studies have shown that these triterpenoids protect the liver from various hepatotoxic substances, such as D-galactosamine, acetaminophen, carbon tetrachloride, and ethanol^[27-29,41-47]. As a result of these diverse actions, Misatol ME may exert extensive hepatoprotective effects in patients with hepatic impairments of differing etiologies. Therefore, further studies are required to elucidate the diverse actions of Misatol ME and to assess the significance of its long-term use and its clinical efficacy in suppressing the onset and progression of cancer, as previously demonstrated at experimental level.

COMMENTS

Background

MK615, an extract from Japanese apricot, contains triterpenoids. These substances have been shown to exert various biological actions. In the present study, MK615 (a beverage containing MK615, an *ume* extract) was found to protect hepatocytes from D-galactosamine hydrochloride-induced cytotoxicity in rats. MK615 decreased the elevated alanine aminotransferase (ALT) and aspartate aminotransferase levels in the patients with liver disorder.

Research frontiers

The mechanism underlying the hepatoprotective activity of MK615 in patients with chronic hepatitis C appears to involve the anti-inflammatory and antioxidative actions of the MK615 component of MK615.

Innovations and breakthroughs

This is the first study to indicate that MK615 lowers blood transaminase levels in patients with liver disorders such as chronic hepatitis C and non-alcoholic

fatty liver disease.

Applications

In treating hepatitis C virus infection, therapeutic interventions that result in lower ALT levels are important for delaying disease progression. In the present study, MK615 was shown to significantly reduce the ALT levels in the patients with chronic hepatitis C, and further reductions in ALT levels were observed in the patients refractory or poorly responsive to ursodeoxycholic acid. Given the significance of these findings, MK615 warrants further evaluation as a potential treatment for liver disease, including an evaluation of its efficacy during prolonged use.

Terminology

MK615, an extract from Japanese apricot, contains triterpenoids such as ursolic acid, oleanolic acid, lupeol, α -amyrin, and -sitosterol. Ume extracts exert anti-inflammatory and antioxidative actions.

Peer review

The strongest point of this study should be the histological comparison of the rat livers with galactosamine-induced injury pretreated with MK615 and those not pretreated with MK615. The result is interesting and suggest that MK615 are promising hepatoprotective agents for patients with liver disorders.

We demonstrated the effect of TC21 downregulation of cell signaling in esophageal cancer cells by assessing the phosphorylation status of its downstream targets, phosphoinositide 3-kinase (PI3K), phosphatase and tensin homolog (PTEN), protein kinase B (pAkt), nuclear factor- κ B (NF- κ B) and cyclinD1 using specific antibodies. Cell survival analysis after cisplatin treatment was carried out by cell viability assay and cell cycle analysis using flow cytometry.

RESULTS: TC21 knockdown in human ESCC cell line TE13 cells, showed only a marginal increase (14.2%) in cell death compared with control cells. The expressions of the signaling proteins PI3K and pAkt, transcription factor NF- κ B, and cell cycle protein cyclin D1 were markedly decreased in response to TC21 downregulation, whereas the level of pPTEN, an antagonist of PI3K, was increased. In addition, we evaluated the potential of TC21 as a putative target for sensitizing ESCC cells to the chemotherapeutic agent cisplatin. Increased cell death (38.4%) was observed in cells treated with cisplatin after TC21 knockdown compared with cells which were treated with cisplatin alone (20% cell death).

CONCLUSION: Results suggest that TC21 mediates its effects *via* the PI3K-Akt pathway, NF- κ B and cyclin D1, and enhances chemoresistance in esophageal cancer cells.

Abstract

AIM: To determine the functional significance of TC21 in esophageal squamous cell carcinoma (ESCC).

METHODS: TC21 siRNA transfection was carried out using Hyperfectamine to knock down TC21, and transcripts were analyzed by reverse transcription-polymerase chain reaction and protein by Western blotting.

INTRODUCTION

Esophageal cancer is one of the most aggressive malignancies of the gastrointestinal tract, ranking as the sixth most common cancer among males and ninth most common cancer among females globally. Esophageal squamous cell carcinoma (ESCC) is the predominant histological subtype of esophageal cancer in India, characterized by a high mortality rate and strong association with dietary habits and lifestyle^[1,2]. It is the second most common cancer among males and fourth most common cancer among females in India^[3]. Despite advances in multimodality therapy, because of its insidious symptomatology, late stage of diagnosis and poor efficacy of treatment, the prognosis of patients with ESCC still remains poor, with an average 5-year survival of < 10% globally^[4,5] and 12% in India^[6,7].

TC21/R-Ras2 is the only member of the R-Ras subfamily for which overexpression or mutants were detected in human tumor cells, including cells derived from uterine sarcoma^[8], ovarian cancer^[9] and mammary tumors^[10]. Increased expression of TC21 was found in breast cancer cells^[11-13]. Our laboratory identified TC21 overexpression in human oral squamous cell carcinomas using differential display and verified its increased expressions independently in oral cancer^[14,15], as well as in esophageal carcinomas^[16]. These clinical studies suggested that deregulated TC21 activity might contribute to human oncogenesis, however like R-Ras, the functions of TC21 are not completely understood.

The R-Ras family of Ras-related proteins, including R-Ras, TC21 (R-Ras2), and M-Ras (R-Ras3), share 55% amino acid identity with H-Ras, including identical core effector regions^[17]. Besides H-, K-, and N-Ras, TC21 is the only Ras superfamily member known to transform epithelial and fibroblast cell lines^[18], and induce tumor formation *in vivo*^[9]. Despite their similarities, R-Ras and TC21/R-Ras2 exhibited differential transforming properties in a variety of cell lines. In NIH 3T3 fibroblasts, TC21/R-Ras2 induced foci formation and tumor growth more efficiently than R-Ras^[18]. TC21/R-Ras2 also potently transformed Rat-1 fibroblasts and various epithelial cell lines, including MCF-10A, RIE-1, and EpH4^[19,20]. In comparison, R-Ras was unable to transform Rat-1 fibroblasts, but promoted tumor growth in cervical epithelial cells^[21,22]. Phosphoinositide 3-kinase (PI3K) is the predominant effector of R-Ras and TC21/R-Ras2 transforming activity; however, these oncogenes also activate Raf1, Ral-GDS, extracellular signal-regulated kinase (ERK) 1/2, c-Jun NH2-terminal kinase, and p38 mitogen-activated protein kinase (MAPK) in a cell type-specific manner^[23-25]. Previous reports suggested that TC21 induces its effects in multiple ways in different cell types, for example TC21 has been shown to activate p38 MAPK in Cos7 cells^[18], and p38 MAPK activation is important for TC21-induced ureteric bud cell proliferation^[26], therefore, TC21-mediated signaling is tissue specific^[20-22,26,27]. We have earlier identified TC21 to be overexpressed in ESCC^[16], but its role in ESCC is not well understood. This study was designed to determine the

functional significance of TC21 protein in esophageal cancer. Further, we aimed to analyze the effect of TC21 downregulation on the sensitivity of ESCC cells to chemotherapeutic agents using cisplatin as a prototype.

MATERIALS AND METHODS

Reagents

Cisplatin, propidium iodide and protease inhibitor cocktail were procured from Sigma-Aldrich (St. Louis, MO, United States); protein assay reagent was obtained from Bio-Rad Laboratories (Hercules, CA, United States); lipofectamine, TC21 small interfering RNA (siRNA) and scrambled sequence siRNA from Qiagen, RPMI 1640 (Invitrogen); primary antibodies directed against protein kinase B [pAkt, (Ser 473)], pAkt (Thr 308), protein Glycogen synthase kinase 3β [pGSK3β (Ser9)], total Akt, phosphatase and tensin homolog [pPTEN, (Ser 380)], and protein Phosphoinositide-dependent kinase-1 [pPDK1 (Ser 241)] were procured from Cell Signaling Technology (Beverly, MA, United States); cyclin D1 and GSK3β were obtained from Santa Cruz Biotechnology Inc., (California, United States), β-actin (AC-15), GAPDH (Abcam Inc. Cambridge, MA, United States). Secondary antibodies, alkaline phosphatase conjugated goat anti-mouse IgG, goat anti rabbit IgG or rabbit anti-goat IgG, were from Cell Signaling Technology (Beverly, MA, United States). Enhanced chemiluminescence (ECL) Western blotting detection reagents were obtained from Santa Cruz Biotechnology Inc., CA, United States.

Cells and cell culture

A human ESCC line, TE13, were grown in RPMI-1640 supplemented with 10% heat inactivated fetal bovine serum, 100 units/mL penicillin and 100 μg/mL streptomycin. Cells were incubated at 37 °C in 5% humidified CO₂ enriched atmosphere and routinely sub-cultured every 2 d by trypsinization.

Cisplatin treatment and cell viability assay

Cells were seeded and grown to 60%-70% confluence in triplicates prior to addition of cisplatin. The cells were treated with varying doses of cisplatin (0-10 μg/mL) for 24 h. Thereafter, the cells were harvested and LD50 was determined by measuring the cell viability using 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) reagent according to the manufacturer's instructions. The conversion of MTT to formazan by mitochondrial dehydrogenases was measured at wavelength 570 nm in a microtiter plate reader. The percentage cell death was calculated individually for each dose as follows: $(A_{\text{control}} - A_{\text{treated}}) / A_{\text{control}} \times 100$, as described earlier^[28]. For further experiments, the cisplatin concentration required to inhibit cell growth by 50% (LD50) was determined by interpolation from dose-response curves.

RNA interference

TE13 cells were seeded and grown to 70% confluence

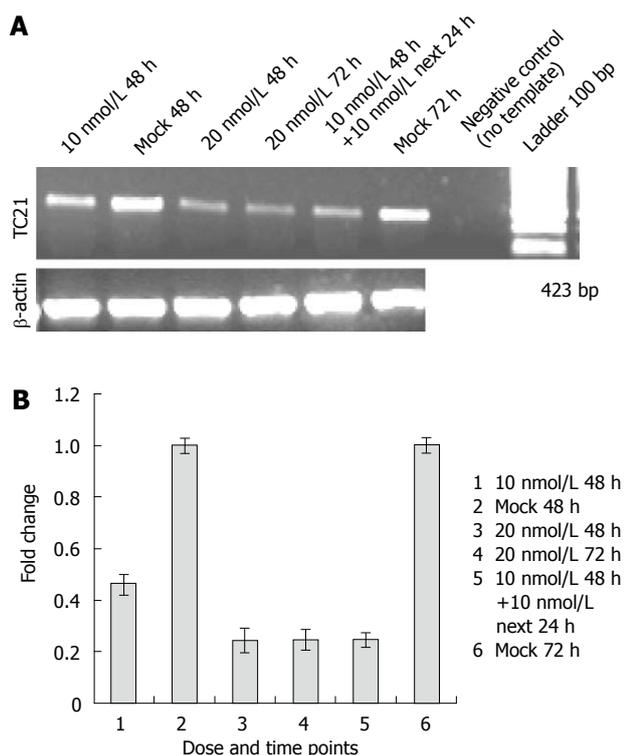

Figure 1 Small interfering RNA-targeting TC21/R-Ras2 was transfected in TE13 cells. A: Reverse transcriptase-polymerase chain reaction (RT-PCR) analysis: Small interfering RNA (siRNA)-targeting TC21/R-Ras2 was transfected in TE13 cells in a dose-dependent manner. After 48 h and 72 h, cells were lysed, RNA was isolated and the mRNA level was determined semiquantitatively by RT-PCR using TC21-specific primers; B: Bar diagram showing fold change in level of TC21 transcripts after TC21 knockdown.

in growth medium without antibiotics. Transfection was carried out using Hyperfectamine according to the manufacturer's instructions, using TC21 siRNA or scrambled sequence siRNA at final concentrations of 20 nmol/L and 10 nmol/L, respectively. After 24 h, 48 h and 72 h cells were harvested for reverse transcription-polymerase chain reaction (RT-PCR) and Western blotting analysis for detection of TC21. For cisplatin treatment the cells were transfected with TC21 siRNA for 48 h, followed by cisplatin treatment for 24 h and compared to untreated cells as controls, transfected with a scrambled sequence siRNA (negative control), or with the transfection reagent alone (mock). At least three independent experiments were performed with reproducible results. MAPK siRNA was used as a positive control and was detected by Western blotting for ERK.

RNA isolation

Total RNA was isolated from TE13 cells (untreated and TC21 siRNA transfected cells) using Qiagen kit following the manufacturer's instructions or the standard protocol. DNase I treatment of RNA was carried out using the Message Clean Kit (Gen Hunter Corp., Brookline, MASS, United States). RNA was quantified using formaldehyde agarose gel and by measuring spectrophotometrically the absorbance at 260 nm and 280 nm (ND-1000 UV-Vis Spectrophotometer from NanoDrop Technologies).

RT-PCR analysis

Briefly, cDNA was prepared using 1 μ g of total RNA and Moloney murine leukemia virus reverse transcriptase (Gibco BRL, Life Technologies Inc., Gaithersburg, MD, United States) with oligo dT as the primer. Primers used for amplification of TC21-specific sequences were forward 5'-CCTTAGACCAAGAAGCTGGC-3' and reverse 5'-CAGGCATTTGGTATTTTGGC-3'. The PCR cycling parameters were initial denaturation at 94 $^{\circ}$ C for 5 min; 30 cycles of 94 $^{\circ}$ C for 1 min, 54 $^{\circ}$ C for 1 min and 72 $^{\circ}$ C for 2 min and final extension at 72 $^{\circ}$ C for 10 min. PCR for β -actin was reverse transcribed for all the samples to check for the quality and quantity of the initial RNA used. The PCR-amplified products were electrophoresed on 1.2% agarose gels and bands were visualized by ethidium bromide staining.

Protein extraction and Western blotting

After the above described TC21 siRNA treatment with or without cisplatin, TE13 cells were harvested and protein extracts were made by lysing cells in buffer, containing 50 mmol Tris-HCl, pH 7.5, 150 mmol NaCl, 1% Triton X-100, 10% glycerol, 1 mmol DTT, 10 mmol NaF, supplemented with 1 mmol activated Na_3VO_4 and 1 \times protease inhibitor cocktail. Protein concentration was measured using Bradford reagent (Sigma) and bovine serum albumin as standard. Proteins were separated by Sodium Dodecyl Sulfate Polyacrylamide Gel Electrophoresis (SDS-PAGE) and transferred to polyvinylidene fluoride membranes by electroblotting. Membranes were blocked with phosphate-buffered saline containing 1% bovine serum albumin, followed by incubation with primary and secondary antibodies. Detection of antibody-protein complexes was done using an ECL Western blotting kit according to the manufacturer's instructions.

Flow cytometry

TE13 cells were transfected with TC21 siRNA, cisplatin alone, or a combination of siRNA and cisplatin for specific time intervals as described above, cells were harvested and resuspended in phosphate-buffered saline. For cell cycle analysis, cells were fixed in 70% ethanol overnight at -20 $^{\circ}$ C and stained with propidium iodide (20 μ g/mL) and RNaseA (10 μ g/mL). All flow cytometric analyses were done using a FACS Caliber flow cytometer (San Jose, CA, United States). The acquired data were analyzed using BD FACS Diva software. For each measurement 10 000 cells were analyzed.

Statistical analysis

The Western blotting data were subjected to statistical analyses using SPSS 10.0 software (Chicago). Densitometry analysis of Western blotting was carried out using ChemiImager 4400 software. The integrated density value was compared with the loading control. The protein expression of 4 different groups (mock, scrambled sequence, TC21siRNA 48 h treatment and TC21siRNA 72 h treatment) were compared using one-way analysis

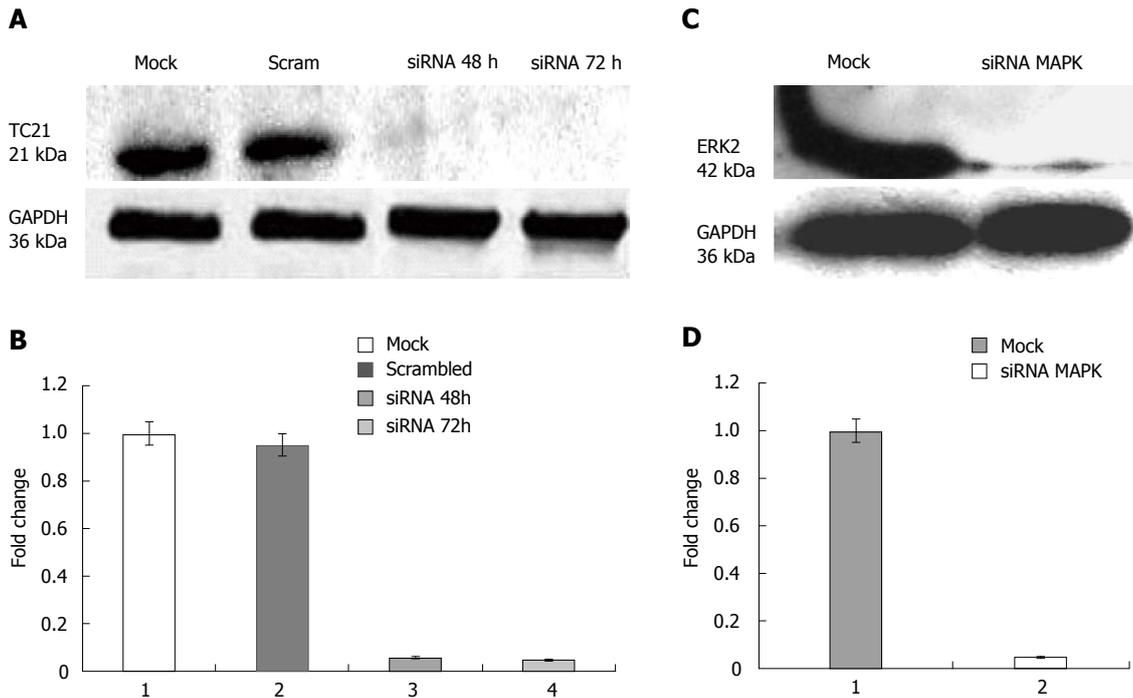

Figure 2 TC21 protein and extracellular signal-regulated kinase 2 level. A: Western blotting was carried out using specific antibody; the panel shows inhibition of TC21 protein compared with cells without transfection or transfection with a negative control siRNA (scrambled sequence); B: Bar diagram showing more than 95% decrease in TC21 protein level after TC21 knockdown compared with untreated mock and nonspecific scrambled sequence; C: Western blotting analyses show inhibition of ERK2 protein by targeted siRNA as positive control; D: Bar diagram showing more than 98% decrease in ERK2 level after MAPK knockdown compared with untreated mock and nonspecific scrambled siRNA sequence. ERK: Extracellular signal-regulated kinase; MAPK: Mitogen-activated protein kinase; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

of variance (ANOVA). ANOVA was applied for statistical analysis with the *post hoc* (Bonferroni) multiple range test. $P < 0.05$ was considered to be significant.

RESULTS

TC21/R-Ras2 gene silencing using siRNA

Evaluation of TC21 mRNA and protein levels 48 h and 72 h post-transfection of TC21 siRNA revealed an 80% reduction in mRNA levels and a 95% reduction in TC21 protein levels as compared with the respective controls transfected with scrambled siRNA (negative control) or with transfection reagent alone (mock) as shown in Figure 1A, B and Figure 2A, B. MAPK siRNA was used as a positive control and its detection was carried out by Western blotting for ERK (Figure 2C, D).

TC21 activates the Akt pathway in ESCC

Since TC21 has been shown to activate PI3K, we investigated the role of the PI3K pathway in TC21-mediated esophageal tumorigenesis. siRNA-mediated TC21 down-regulation resulted in a significant decrease in the expression of phosphorylated Akt/PKB with $P < 0.001$ (Ser 473, Thr 308 showed equal reduction) and phosphorylated glycogen synthase kinase-3 β , pGSK3 β (Ser 9), without any change in the levels of total Akt (Figure 3A, B). A significant increase in expression of PTEN was observed in TC21 siRNA-treated TE13 cells compared with con-

trols ($P < 0.001$). Since PTEN is a PI3K antagonist and inhibits downstream signaling through Akt, its upregulation in siRNA-treated cells suggests the involvement of PI3K in TC21-mediated esophageal tumorigenesis. Moreover, knockdown of TC21 resulted in a significant decrease in PDK1 expression which may be responsible for the decrease in the expression of pAkt/PKB, resulting in reduced levels of pGSK3 β (Figure 3A, B).

TC21 activates the anti-apoptotic factor nuclear factor- κ B and cyclin D1

Western blotting analysis of whole cell lysates from TC21-knockdown TE13 cells probed with antibodies specific for the p65 subunit of nuclear factor- κ B (NF- κ B) and cyclin D1 showed significant decrease in NF- κ B and cyclin D1 proteins compared with untransfected controls (Figure 3A, B). Our results suggest that NF- κ B targeting the growth promoting protein cyclin D1, may be the downstream targets of TC21 signaling through the PI3-K/Akt pathway, thereby increasing survival of esophageal cancer cells.

TC21 knockdown does not affect P-Raf protein

There was no significant change in phosphorylated Raf protein expression observed in TC21-knockdown esophageal cancer cells for 72 h of transfection in comparison with control cells, but there was a decreased P-Raf protein level observed in TC21 siRNA treated for 48 h (Figure 3A, B).

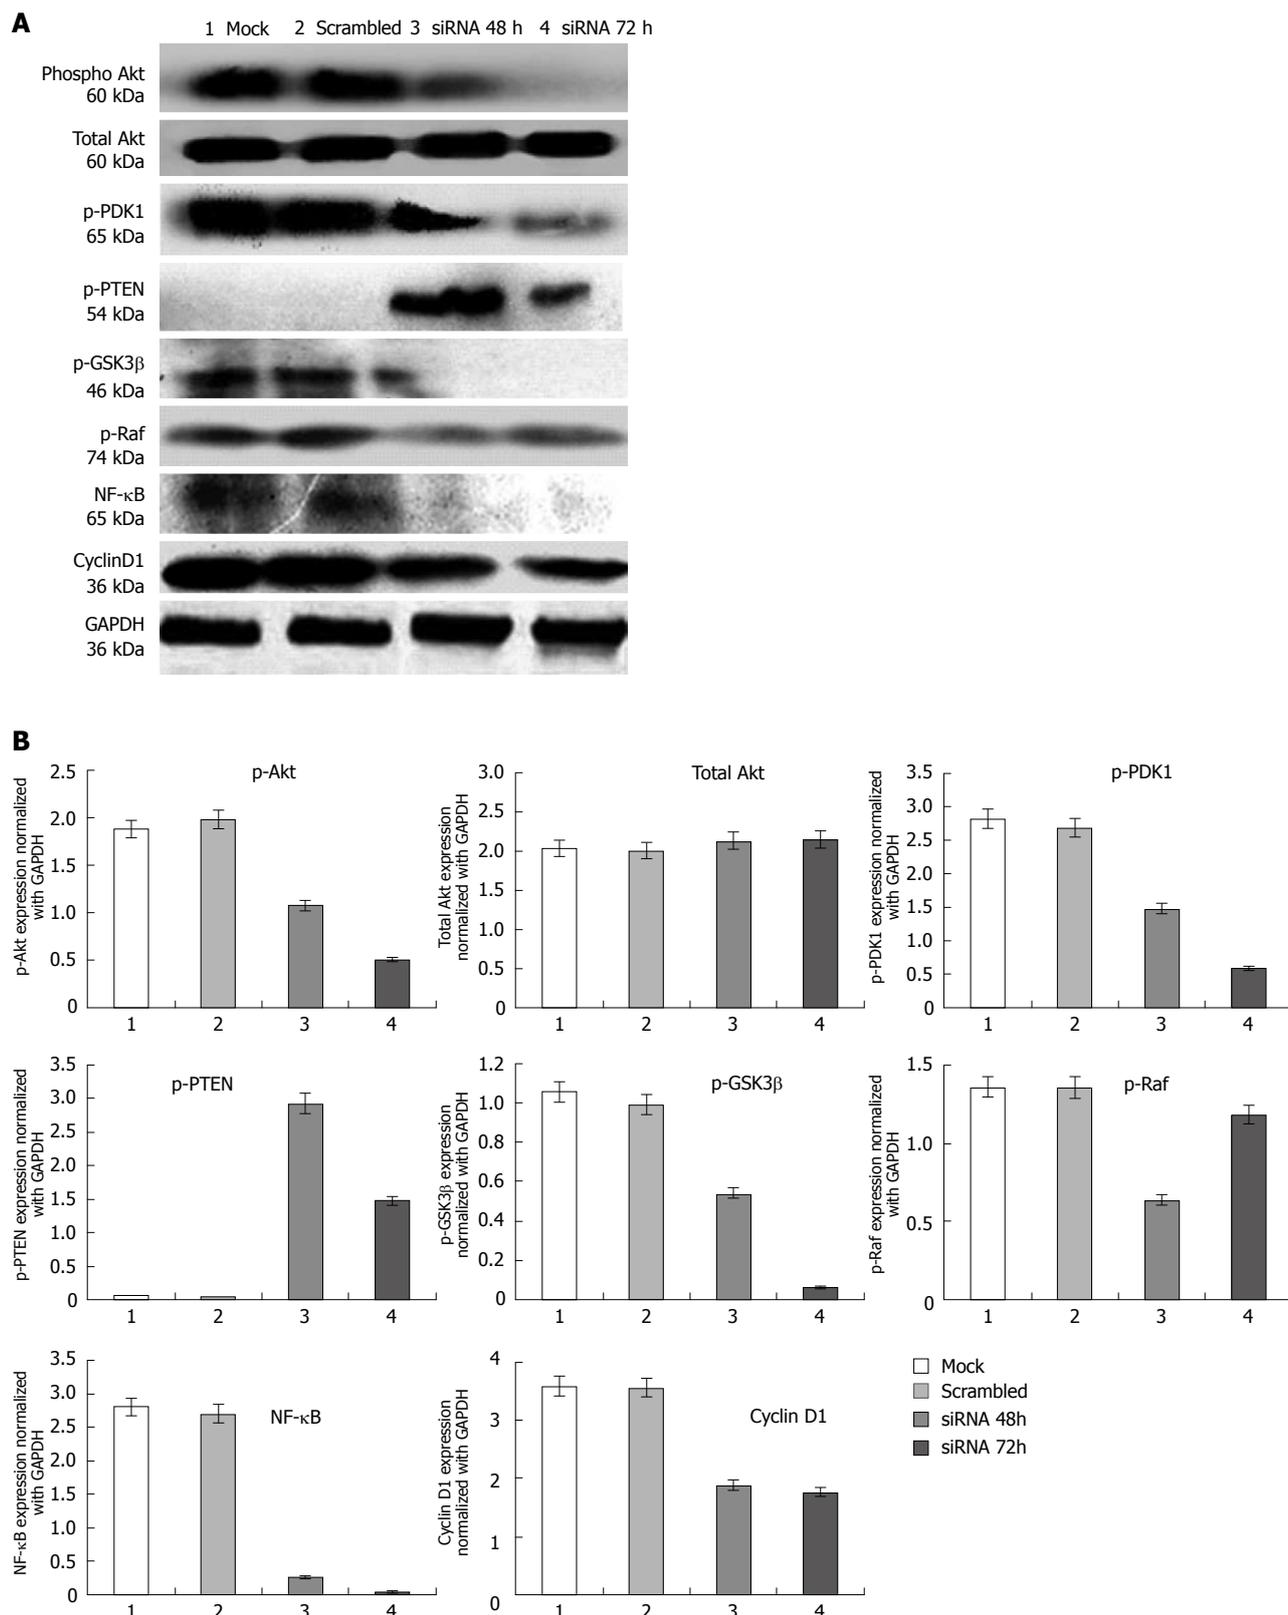

Figure 3 Expression of proteins in esophageal squamous cancer cells TE13 and compared with control. A: Expression analysis of protein kinase B (pAkt), total Akt, protein Glycogen synthase kinase 3β (pGSK3β), pRaf, protein Phosphoinositide-dependent kinase-1 (pPDK1), phosphatase and tensin homolog (pPTEN), nuclear factor-κB (NF-κB) and cyclin D1 proteins compared in esophageal squamous cancer cells TE13. Lane 1: Mock; Lane 2: Scrambled (non-target siRNA); Lane 3: TC21 siRNA transfected for 48 h; Lane 4: TC21 siRNA transfected for 72 h; B: Bar diagram showing relative levels of proteins in comparison with control protein GAPDH. GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

Table 1 Cell cycle analyses of siRNA-treated TE13 cells using flow cytometry

Experimental parameters	SubG0 (%)	G1 (%)	S (%)	G2/M (%)
Untreated TE13 ¹ cells for 24 h	5.7	37	21	34.8
Cisplatin treatment (8 µg/mL) for 24 h	17.8	30.6	11.8	38.2
Untreated TE13 cells for 48 h	7.9	34.7	10	41
TC21 siRNA ² (20 nmol) transfection for 48 h	14.2	22.8	12.2	42.3
Untreated TE13 cells for 72 h	10.3	36.7	27.7	25.8
TC21 siRNA transfection (20 nmol) for 48 h followed by cisplatin treatment for 24 h (total time of treatment is 72 h)	38.4	23.8	11.9	12.8

¹Esophageal squamous cell carcinoma cells; ²Small interfering RNA.

Knockdown of TC21 results in decreased G1/S population

TC21-knockdown TE13 cells resulted in a marginal increase (14.2%) in the subG0 population (cell death) compared with the mock control cells (7.9%), while the G1/S population decreased from 44% to 35% in the siRNA-treated cells (Figure 5A-2, B and Table 1).

Effect of cisplatin treatment on TE13 cells

The TE13 cells were treated with varying doses of cisplatin (0-10 µg/mL) for 24 h and LD50 was calculated by measuring the cell viability using MTT (Figure 4). LD50 was found to be 9 µg/mL. TE13 were treated with 8 µg/mL cisplatin for 24 h and flow cytometric analysis was performed to determine the cell cycle distribution. Cisplatin-treated TE13 cells showed a marginal increase in cell death (17.8%) compared with untreated cells (5.7%). There was a decrease in the S phase (11.8%) compared with 21% in the untreated control cells (Figure 5A-4, B and Table 1).

Knockdown of TC21 sensitizes TE13 cells to cisplatin treatment

The combined effect of TC21 siRNA and cisplatin treatment on TE13 cells was determined. In TC21 siRNA-transfected TE13 cells, 38.4% cell death was observed after exposure to 8 µg/mL cisplatin compared with 10.3% cell death in the untreated controls; 23.8% cells were found in the G₁ phase compared with 36.7% in the controls. Further, a decrease in S phase fraction (11.9%) was observed compared with the untreated control cells (27.7%) (Figure 5A-6, B and Table 1).

DISCUSSION

This study was focused on the effect of TC21 down-regulation on cell signaling in ESCC and its effect on the cisplatin response by downregulation of TC21 targets, both individually and in combination. In our study, TC21 protein expression correlated with cisplatin sensitivity. Earlier studies have shown that overexpression of TC21 resulted in cisplatin resistance to apoptosis^[29]. Therefore, we investigated whether TC21 downregulation would sensitize TE13 cells to cisplatin. Our results demonstrated that TC21 downregulation resulted in a

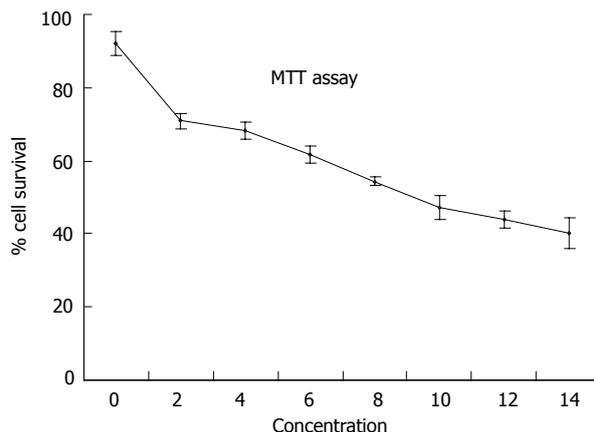

Figure 4 Cell viability assay. TE13 cells were treated with cisplatin in a dose-dependent manner for 24 h. Cell viability was determined using the MTT assay. LD50 was found to be 9 µg/mL. Further treatment with cisplatin was carried out at less than the LD50 dose.

significant reduction in the expression of the Akt pathway components, supporting that Akt pathway proteins serve as important downstream targets of TC21. Akt, an oncogenic protein implicated in human cancer development, is a key component of the PI3-K signaling pathway^[30,31]. Knockdown of TC21 decreased the expression of pAkt/PKB (antibodies specific for Ser 473 and Thr 308 showed similar effects), while the total Akt/PKB levels remained unaffected.

Furthermore, TC21 knockdown decreased the NF-κB levels. The TC21 oncogenic signals are mediated *via* the PI3K/Akt, NF-κB pathway, whereas the role of TC21 in activation of the extracellular signal-regulated kinase/MAPK pathway is less clear^[20].

Significant down-regulation of pGSK3β (Ser 9) in TC21-knockdown cells suggests a role of GSK3β downstream from Akt in TC21-mediated esophageal cancer. TC21 knockdown also suppressed the phosphorylation of the upstream kinase PDK1 (P-Serine 241). The phosphorylation of the p85 subunit of another upstream kinase, PI3K was also suppressed upon TC21 knockdown (data not shown). Suppression of Akt by TC21 siRNA led to the suppression of phosphorylation of GSK3β, the substrate for Akt. The serine/threonine kinase Akt, a key target of PIP3, is activated by TC21^[29], resulting in increased cell proliferation, transformation and survival

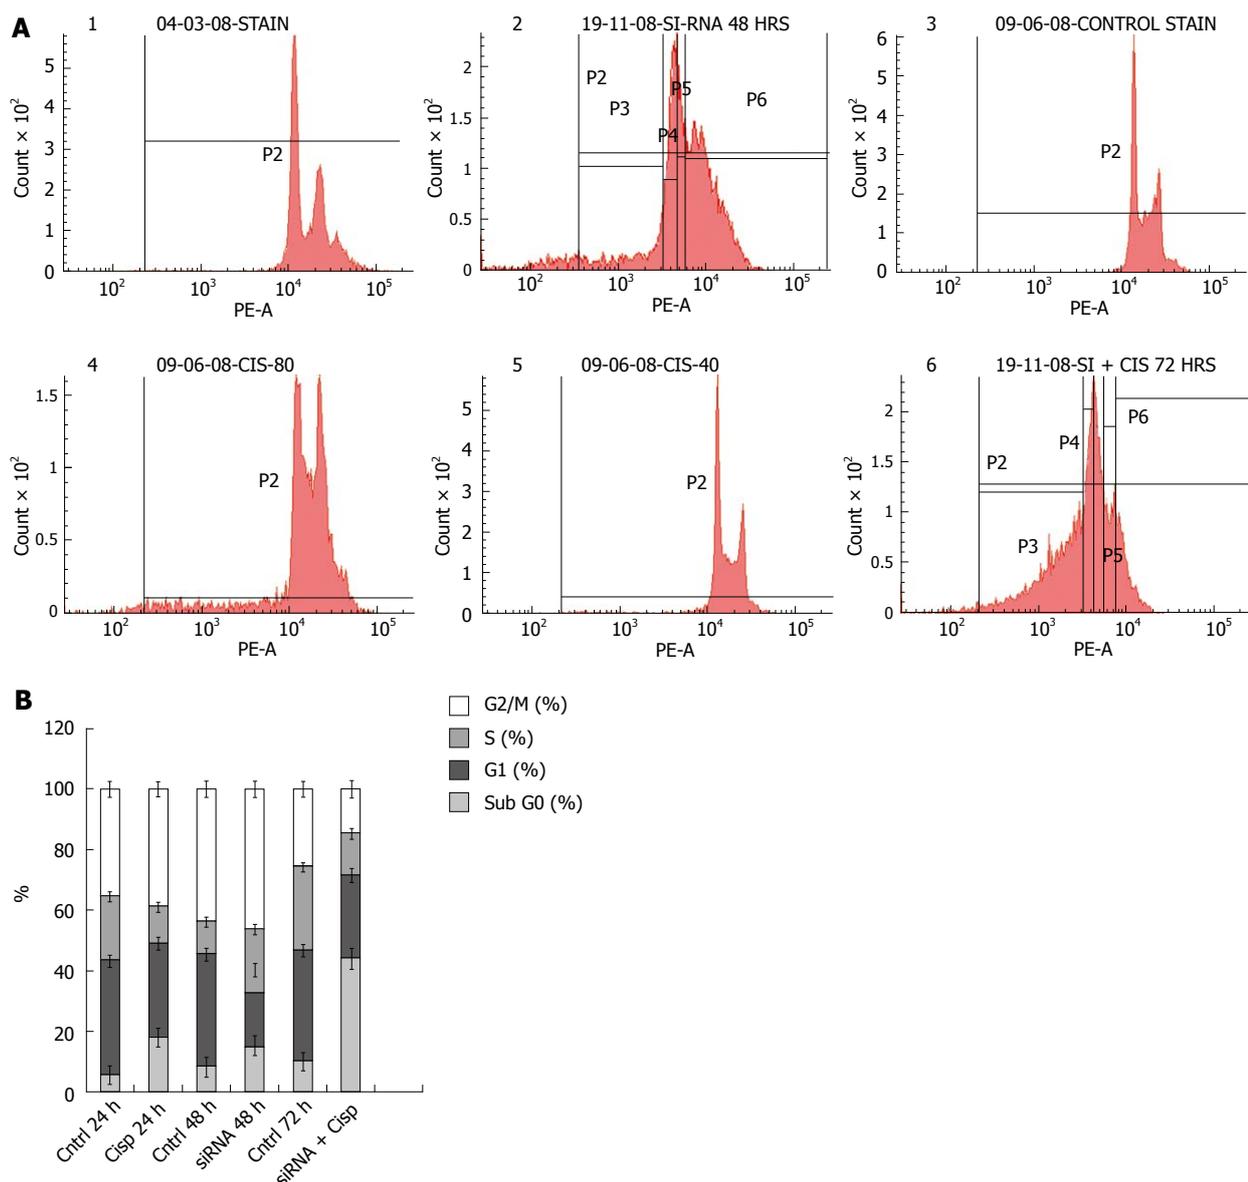

Figure 5 Cell cycle analyses. A: TC21-knockdown cells (20 nmol siRNA for 48 h) were treated with cisplatin (8 μg/mL) for 24 h and cell cycle analysis was performed by labeling cells with DNA binding dye propidium iodide. The panel shows 1: DNA histograms of mock-transfected TE13 cells for 48 h; 2: TE13 cells transfected with TC21 siRNA for 48 h showing increased cell death; 3: TE13 cells without transfection for 24 h; 4: TE13 cells were treated with cisplatin alone for 24 h; 5: TE13 cells without transfection for 72 h; 6: TE13 cells were transfected with TC21siRNA for 48 h for optimal knockdown followed by cisplatin at 8 μg/mL for 24 h; B: Stacked bar graph depicts the cell cycle distribution. Data presented here as mean of percentage events from 3 independent experiments.

through numerous effectors, including Bad, GSK-3β and mTOR^[32]. Notably, a significant increase in pPTEN expression was observed in TC21 siRNA-treated esophageal cancer cells compared with controls. Since pPTEN is a PI3K antagonist and inhibits downstream signaling through Akt, its upregulation in siRNA-treated cells suggests the involvement of PI3K in TC21-mediated esophageal tumorigenesis, suggesting that the PI3K/Akt is a downstream target of TC21.

TC21-knockdown esophageal cancer cells did not affect the level of P-Raf, suggesting that the TC21 pathway is independent of Raf. Our results support the previous report that TC21 is regulated similar to Ras except that it does not interact with full-length Raf 1, B raf, and A raf, suggesting that TC21 uses a Raf-independent

pathway to induce oncogenic transformation^[33]. It also interacts with Ral GDS *in vitro*, which may be responsible for the Raf-independent pathway^[34].

Cyclin D1 is a major regulator of the progression of cells into the proliferative stage of the cell cycle^[35]. Interestingly, TC21 knockdown resulted in reduced expression of cyclin D1, suggesting TC21 may increase cell survival of esophageal cancer by targeting cyclin D1. Thus cyclin D1 may be a target of TC21 signaling through the PI3K/Akt/NF-κB/cyclin D1 pathway. We observed that TC21 gene knockdown by RNAi alone induces an increase in the subG0 population of TE13 cells and a decrease in cyclin D1. Cell cycle progression from G0/G1 to the S phase requires cyclin/cyclin-dependent kinase (CDK) complexes and hyperphosphorylated reti-

noblastoma protein (Rb). In the early G1 phase, the cyclin D1/CDK 4 complex phosphorylates Rb, triggering a cascade of events, including the dissociation of E2F from hyperphosphorylated Rb, the activation of E2F transcription, and progression to the S phase^[36]. Keeping in view the above discussed facts it is possible that a TC21 knockdown-induced decrease in cyclin D1 expression may block transition from G1 to the S phase.

Overexpression of TC21 activated its downstream targets resulting in translocation of NF-κB to the nucleus and stimulated the transcription of anti-apoptotic genes including cyclin D1. Low cellular levels of cyclin D1 have been reported to potentially contribute to increased cisplatin sensitivity in human breast cancer cells CAL-148^[37]. Our results suggest that TC21 may enhance cell survival against cisplatin-induced cell death through activation of the PI3-K/Akt/NF-κB/cyclin D1 signaling pathway in esophageal cancer cells. Knockdown of TC21 sensitized TE-13 cells to cisplatin treatment and resulted in an increase in the subG0 population (cell death), a decrease in G1/S-phase and an increase in G2/M-phase populations. Further studies are needed to reveal new downstream targets of NF-κB responsible for TC21-mediated cell survival.

In summary, cyclin D1 is a downstream target for TC21 and TC21 may be a candidate marker for prediction of cisplatin treatment outcome in esophageal cancer patients. Our study draws attention to the relevance of TC21 in the context of cisplatin pharmacogenetics of esophageal cancer.

COMMENTS

Background

Esophageal cancer is one of the most aggressive malignancies of the gastrointestinal tract, ranking as the sixth most common cancer among males and ninth most common cancer among females globally. Esophageal squamous cell carcinoma (ESCC) is the predominant histological subtype of esophageal cancer in India, characterized by high mortality rate and strong association with dietary habits and lifestyle.

Research frontiers

TC21/R-Ras2 is the only member of the R-Ras subfamily for which overexpression or mutants were detected in human tumor cells, including cells derived from uterine sarcoma, ovarian cancer and mammary tumors. Increased expression of TC21 was found in breast cancer cells.

Innovations and breakthroughs

The effect of TC21 downregulation on cell signaling in esophageal cancer cells was determined by assessing the phosphorylation status of its downstream targets, phosphoinositide 3-kinase, phosphatase and tensin homolog, protein kinase B, nuclear factor-κB (NF-κB), and cyclin D1 using specific antibodies. Cell survival analysis after cisplatin treatment was carried out by a cell viability assay and cell cycle analysis using flow cytometry.

Applications

Cyclin D1 is a downstream target for TC21 and TC21 may be a candidate marker for prediction of cisplatin treatment outcome in esophageal cancer patients. The study draws attention to the relevance of TC21 in the context of cisplatin pharmacogenetics of esophageal cancer.

Peer review

This is a good descriptive study in which authors determine the functional significance of TC21 in ESCC. The results are interesting and suggest that TC21 mediates its effects via PI3K-Akt pathway, NF-κB and cyclin D1 and enhances chemoresistance in esophageal cancer cells.

Abstract

AIM: To investigate the value of two-dimensional (2D) and three-dimensional (3D) double contrast-enhanced ultrasonography (DCUS) imaging for evaluation of gastric lesions.

METHODS: 2D and 3D DCUS imaging with both oral and intravenous administrations of contrast agents was used to assess gastroscopically-confirmed gastric lesions in 46 patients with benign and malignant diseases. Initially, liquid-based ultrasound contrast agent (Xinzhang®) was given orally at dose of 500-600 mL for conventional ultrasound examination of the gastric lesions, and then a microbubble-based contrast agent (SonoVue) was injected intravenously at dose of 1.2-2.4 mL in bolus fashion to assess the perfusion pattern of the lesions

using contrast imaging modes. The parameters derived from time-intensity curves including the arrival time (AT), time to peak (TTP), peak intensity (PI) and enhanced intensity (EI) were measured on the 2D DCUS imaging. 3D DCUS of the lesions was acquired to demonstrate the value of this imaging mode.

RESULTS: There were 22 cases with benign lesions including chronic gastritis ($n = 5$), gastric ulcer ($n = 9$), gastric polyps ($n = 3$), gastric stromal tumors ($n = 5$), and 24 cases with malignant lesions including gastric cancer ($n = 20$), gastric cardia carcinoma ($n = 3$) and post-operative recurrent gastric cancer ($n = 1$) in the study. The oral contrast-enhanced ultrasonography (CEUS) imaging of the stomach clearly demonstrated the anatomy of the stomach and morphologic features of gastric lesions. With optimal scanning window and imaging display under oral CEUS, intravenous CEUS clearly showed the perfusion of gastric lesions with various characteristic manifestations. Both 2D and 3D DCUS images clearly demonstrated normal gastric wall as a three-layer structure, from the inside out, hyperechoic mucosa, hypoechoic muscularis and hyperechoic serosa, respectively. There were statistical significant differences of AT (8.68 ± 2.06 vs 10.43 ± 2.75 , $P = 0.017$), PI (34.64 ± 6.63 vs 29.58 ± 8.22 , $P = 0.023$) and EI (29.72 ± 6.69 vs 22.66 ± 7.01 , $P = 0.001$) between malignant lesions and normal gastric wall. However, no differences of AT, PI and EI between benign lesions and normal gastric wall tissue were found. 3D DCUS could intuitively display morphological features and vascularities of the lesions with multiplanar and volume views. 3D DCUS imaging provided comprehensive information complementary to 2D imaging. The crater or wellhead appearances and feeding vessels as well as distorted nourishing vasculature of gastric carcinoma were better seen with 3D imaging than 2D imaging.

CONCLUSION: DCUS imaging can simultaneously

display the anatomic and perfusion features of gastric lesions. 3D DCUS can provide additional information to 2D DCUS for evaluation of gastric lesions.

INTRODUCTION

The common methods for examination of the upper gastrointestinal (GI) tract are x-ray with oral barium-based contrast agent and endoscopy. Their shortcomings include the fact that they often cannot delineate submucosal mural structures of the GI tract. Limitations to the sonographic assessment of the upper GI tract and adjacent organs include patient body habitus and the presence of gas-filled bowel, which can produce shadowing artifacts^[1,2]. Although ingestion of degassed water has been used to improve sonographic assessments of the GI tract and retroperitoneal structures, water simply displaces gas within the GI tract and can produce inconsistent results. Imaging water-filled stomach usually results in an increase in the wall through transmission, which may cause tissues of otherwise normal echogenicity to appear more echogenic than expected, creating a potential source of diagnostic error. Over the years, researchers attempted to develop oral contrast agents to improve the assessment of the GI tract and adjacent structures by absorbing and displacing bowel gas and provide an acoustic window for sonographic visualization of upper GI tract. One of such oral contrast agent Xinzhang[®] (Huqingyutang Pharmaceuticals Co., Hangzhou, China) has been developed and commercially available in China for ultrasound imaging of upper GI tract in clinical settings^[3-5].

During the last two decades, contrast-enhanced ultrasound imaging (CEUS) with intravascular contrast agents has been investigated and has gradually emerged in clinical settings. The rapid development of contrast agents for sonography is precipitated by the performance limits of grayscale imaging and Doppler techniques. As US Imaging is used to study smaller and deeper structures in the abdomen, the spatial resolution of grayscale imaging and Doppler sensitivity becomes critical to the degree

that it impacts the clinical utility of sonography. Contrast agents promise to improve the sensitivity and specificity of current sonographic diagnoses and have the potential to expand the already broad range of its applications.

Recently, we have explored new technique which combines both oral and intravenous CEUS imaging methods, so called Double contrast-enhanced ultrasound (DCUS), for evaluation of gastric abnormalities. The purpose of this study was to investigate the value of DCUS imaging using both two-dimensional (2D) and three-dimensional (3D) modes for the evaluation of gastric lesions.

MATERIALS AND METHODS

Patients

The study protocol was approved by our hospital ethical committee, and all patients gave informed consent and agreed to participate in the study. During a period from 2007 to 2011, 2D and 3D DCUS imaging with both oral and intravenous administrations of contrast agents was used to assess gastroscopically-detected gastric lesions in 46 patients with 22 benign cases and 24 malignant cases. All final diagnoses are confirmed by endoscopic biopsy or surgical pathological findings. There were 31 males and 15 females, aged from 23 years to 80 years with a mean age of 54.93 ± 12.49 years.

Equipment and contrast agents

The DCUS was performed using full digital ultrasound scanners iU22 (Philips Medical Systems, Bothell, WA) with a C5-2 probe or Sequoia-512 (Siemens Medical Solutions, Mountain View, CA) with a 4C1 probe for 2D imaging. Philips C6-2 volume probe was used for acquiring 3D DCUS imaging. Conventional ultrasound imaging mode was used for oral contrast imaging while contrast imaging modes (Philips Pulse inversion harmonic imaging and Siemens contrast pulse sequencing techniques) were used for intravascular contrast imaging.

The commercially available oral contrast agent Xinzhang[®] (Huqingyutang Pharmaceuticals Co., Hangzhou, China) was supplied as powder which is derived from rice and soya. The 48 g per package was reconstituted by adding 500-600 mL of cooled boiling water and gently agitating by hand to form a homogeneous thin paste.

The intravenous contrast agent SonoVue[®] (Bracco SpA, Milan, Italy) was injected in bolus fashion at doses of 1.2-2.4 mL through brachial vein, followed by 5 mL normal saline flush.

Double oral and intravenous contrast imaging

DCUS examination was performed after patient's fasting for at least 8 h on the day of the study. The stomach of all patients was scanned using real time gray-scale imaging when the patients swallowed the oral agent to expand the cavity of the stomach. Using contrast agent-filled gastric cavity with homogenous moderate echogenicity as an acoustic window, the location, shape and size of any possible lesions and the wall thickness of the stomach were

carefully imaged and recorded under dynamic scanning with patients in the supine and both decubitus positions. The scanning parameters (e.g., the depth, focus, and gain) were adjusted to achieve optimal imaging display as conventional ultrasound examination.

After oral contrast imaging localization of the gastric lesion, vascular CEUS of was performed with a bolus injection of 1.2-2.4 mL of SonoVue *via* a 20-gauge peripheral intravenous catheter under contrast imaging mode with a low mechanical index (0.09-0.21). Initially, each subject underwent 2D imaging to observe the perfusion pattern and measure the time-intensity curve of the lesions and adjacent normal wall of stomach as control. The CEUS parameters of arrival time (AT), time to peak (TTP), infusion time (IT, $IT = TTP - AT$), baseline intensity (BI), peak intensity (PI) and enhanced intensity (EI, $EI = PI - BI$) was obtained and calculated from the time-intensity curve. Next, the regions of interest were selected based on the 2D contrast imaging and 3D images of the region of interest were acquired using a 3D probe with additional contrast agent injection during the arterial phase of enhancement. The 3D imaging volume files was stored digitally with both on-line and off-line imaging process and analysis.

Statistical analysis

SPSS 13.0 (SPSS Inc., Chicago, United States) was used for statistical analysis. The values of measurements were expressed as (mean \pm SD). Two sample *t*-test was used to compare each parameter (AT, TTP, PI, EI and IT) between benign or malignant lesions and normal gastric walls. For all analyses, a *P* value of less than 0.05 was considered statistically significant.

RESULTS

A total of 46 pathologically-proved cases were enrolled in the study. There were 22 cases with benign lesions including chronic gastritis ($n = 5$), gastric ulcer ($n = 9$), gastric polyps ($n = 3$), gastric stromal tumors ($n = 5$), and 24 cases with malignant lesions including gastric cancer ($n = 20$), gastric cardia carcinoma ($n = 3$) and post-operative recurrent gastric cancer ($n = 1$). The 2D DCUS with oral and intravenous contrast enhancement was successfully performed in all 46 patients. While 43 out of 46 patients underwent 3D contrast imaging studies. Both 2D and 3D DCUS images clearly demonstrated normal gastric wall as a three-layer structure, from the inside out, hyperechoic mucosa, hypoechoic muscularis and hyperechoic serosa, respectively (Figure 1). DCUS characteristic findings of gastric lesions were visualized as follows.

Benign lesions

Gastric ulceration lesion: Gastric ulceration lesion appeared as a contrast agent-filled defect on the stomach wall with a spot-like mural hyperechogenic area in 9 cases. There was a lack of localized partial or prominent gastric wall thickening. Intravenous contrast 2D imaging shown

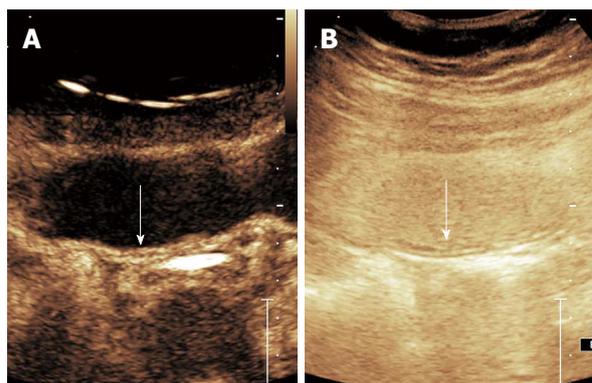

Figure 1 Two-dimensional double contrast-enhanced ultrasound imaging. A: The picture showing intravenous contrast harmonic imaging with the echo-free gastric cavity and three layers of normal gastric wall (arrow); B: The picture showing oral contrast imaging of normal gastric wall (arrow) and cavity filled with echogenic contrast agent.

uniformed enhancement of the gastric wall adjacent to the lesion and 3D DCUS imaging showed the gastric cavity and wall with a focal defect area consistent with an ulcer (Figure 2).

Gastric polyp: Gastric polyp appeared as a hyperechoic beansprout-shaped or a cone-shape mass projecting into the cavity of the stomach in 3 cases (Figure 3). Intravenous contrast 2D imaging shown simultaneous and equal enhancement of both lesions and normal gastric walls.

Gastric stromal tumor: Gastric stromal tumor shown as a hypoechoic or nearly anechoic mass within gastric wall under oral contrast imaging in 5 cases (Figure 4). These lesions had clear demarcation, regular around shape, and homogeneous echotexture. Larger ones protruded into the stomach cavity ($n = 3$) and have inhomogeneous echotexture ($n = 2$). Intravenous contrast 2D imaging demonstrated simultaneous or delayed enhancement of stromal tumors with homogeneous iso- or hypo-enhancement when compared with adjacent normal gastric wall. A ring enhancement appear in hypo-enhancement lesions ($n = 2$).

Gastric inflammatory lesion: Inflammatory thickening of the gastric wall was clearly seen under oral contrast displays in 5 chronic gastritis cases. The focal gastric inflammatory lesion appeared as homogeneous hypoechoic thickening associated with mild elevation of smooth surface of the wall. There was no remarkable change in the layers of the gastric wall. Intravenous contrast 2D imaging of the thickening wall shown uniform, simultaneous and iso- or hyper-enhancement compared to the normal gastric wall.

Malignant lesions

The characteristics of gastric carcinoma were demonstrated with oral contrast imaging in 24 cases. The features of malignant lesions included irregular shape, heterogeneous

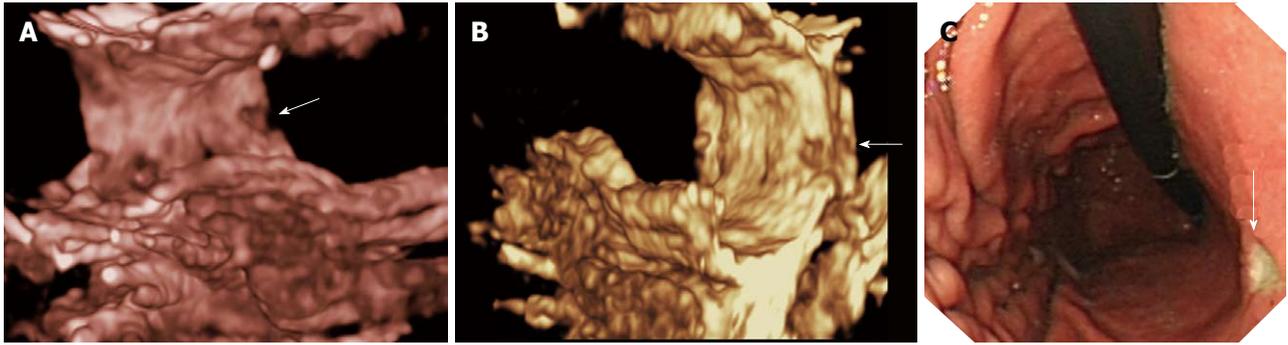

Figure 2 Double contrast-enhanced ultrasound imaging of gastric ulceration. A: Three-dimensional (3D) double contrast-enhanced ultrasound imaging showed the gastric cavity and wall with a focal defect area consistent with an ulcer (arrow); B: Another 3D imaging with different angle showed the ulcerative lesion (arrow) and the folds of gastric wall with pseudo-color which similar to gastroscopic imaging; C: The ulcerative lesion (arrow) is seen on gastroscopic imaging.

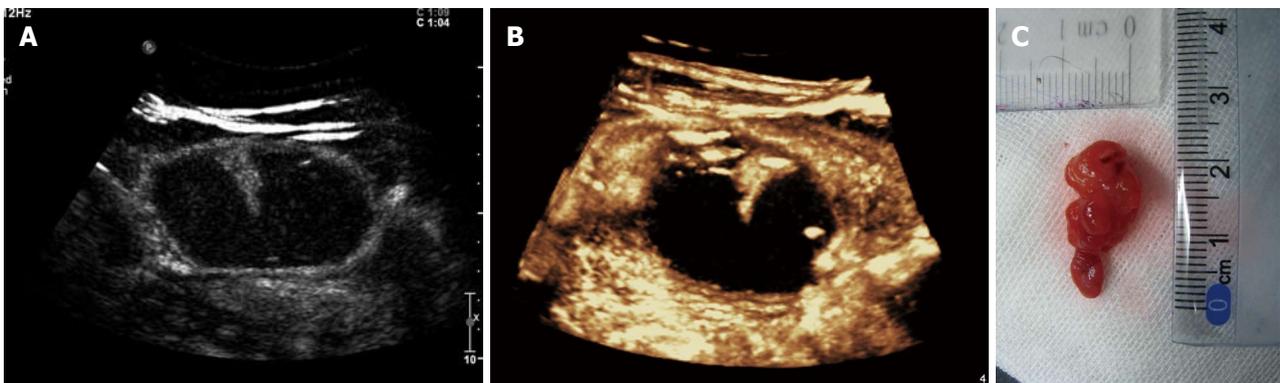

Figure 3 Double contrast-enhanced ultrasound imaging of gastric polyp. A: Two-dimensional double contrast-enhanced ultrasound (DCUS) imaging displayed a polyp with a wide base projecting into the gastric cavity. Contrast enhancement was seen on both polyp and gastric wall; B: Three-dimensional DCUS imaging of the polyp showed in figure A; C: The surgical specimen of the polyp confirmed the DCUS finding.

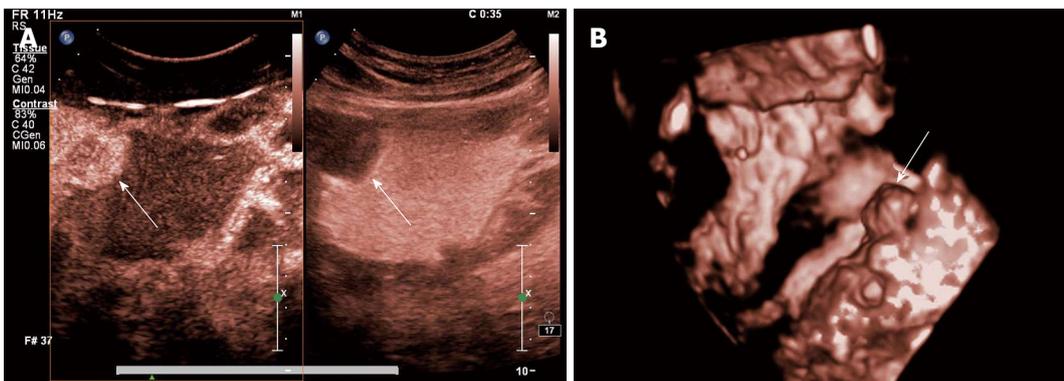

Figure 4 Double contrast-enhanced ultrasound imaging of gastric stromal tumor. A: Two-dimensional double contrast-enhanced ultrasound (DCUS) images displayed a anechoic mass into the gastric cavity in oral contrast ultrasonography (right figure), from which we hardly judged whether it was cystic or solid lesion; but the intravenous contrast imaging (left figure) showed there was contrast agent enhancement in the focus of infection (arrow); B: Three-dimensional DCUS imaging displayed the tumor elevated to the gastric cavity (arrow).

echotexture and disrupted layers of the gastric wall on the 2D oral contrast imaging. The mass-like lesion shown as a solid mass protruding into the cavity while the diffuse lesion appeared as a localized wall thickening and irregular surface of the lesions. The lesions with ulceration in 6 cases shown as filling defects within the lesions (Figure 5). Extensive infiltrative lesions in 9 cases shown diffuse het-

erogeneous thickening of the gastric wall which resulted in gastric cavity narrowing. The passage of oral contrast agent through the narrow gastric cavity can be seen with slow and stiff gastric peristalsis in real-time imaging. In 3 patients with carcinoma of gastric cardia, oral contrast imaging shown hypoechoic wall thickening of the distal esophageal and gastric cardia. Echogenic contrast agents

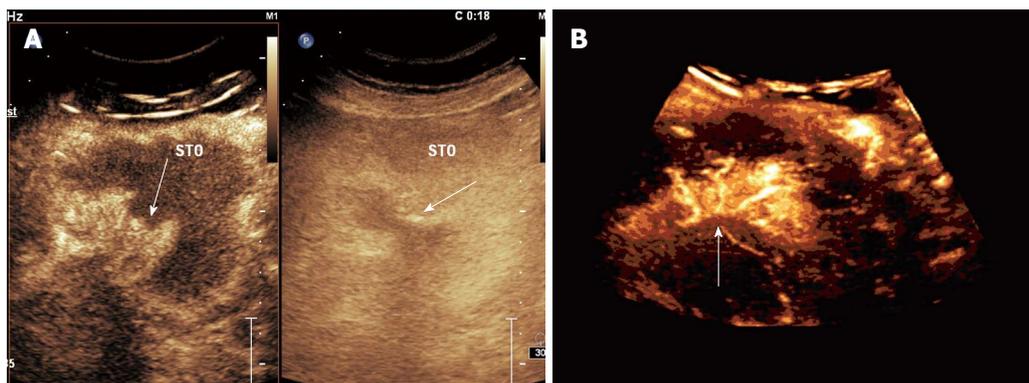

Figure 5 Double contrast-enhanced ultrasound imaging of ulcerative gastric cancer. A: Two-dimensional double contrast-enhanced ultrasound (DCUS) images (conventional imaging on the right and harmonic imaging on the left) showed a contrast-enhanced mass with crater-like ulcerative defect (arrow); B: Three-dimensional DCUS imaging showed distorted nourishing vasculature within the gastric cancer (arrow).

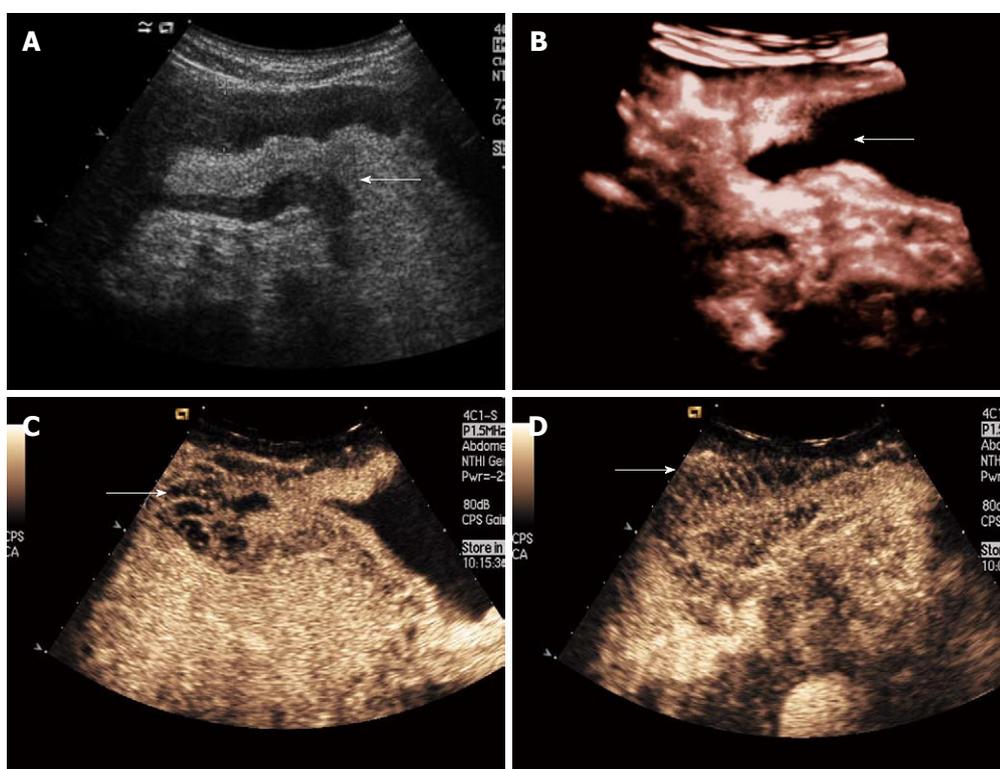

Figure 6 Double contrast-enhanced ultrasound imaging of infiltrative gastric cancer. A: An oral contrast image showed diffusely thickened gastric wall with narrowed gastric cavity (arrow) in a patient with gastric cancer; B: Three-dimensional double contrast-enhanced ultrasound (DCUS) imaging showed thickened gastric wall and narrowed echo-free gastric cavity (arrow); C, D: Two-dimensional DCUS images showed fence-like tumor vessels penetrating through thickened gastric wall in the arterial phase (arrows).

passing through the narrow lumen of gastroesophageal junction was seen during the swallowing of contrast agent. In 6 patients with gastric carcinoma, enlarged lymph nodes adjacent to gastric wall were identified with hypoechogenic and round-shape features.

Combining with oral contrast imaging, intravenous 2D contrast imaging demonstrated variable patterns of enhancement of the lesions. When compared to adjacent normal gastric wall, there were iso-enhancement in 2 lesions, hypo-enhancement in 1 lesions and hyper-enhancement in 21 lesions. The feeding vessels and dis-

torted tumor vasculature was clearly identified with 2D DCUS imaging (Figure 6). All lesions appeared as earlier enhancement in wash-in phase than the normal gastric wall. Under DCUS imaging condition, the enhancement parameters of time-intensity curves in both begin and malignant lesions shown in Table 1.

3D double contrast-enhanced ultrasonography imaging

Reconstructed 3D imaging demonstrated global rendering of DCUS imaging with different prospective of morphology for both normal structures and gastric le-

Table 1 Comparison between benign gastric lesions and normal gastric wall ($n = 22$), malignant gastric lesions and normal gastric wall ($n = 24$) from double contrast-enhanced ultrasound time-intensity curve

	Benign lesions	Normal gastric wall	<i>P</i> value	Malignant lesions	Normal gastric wall	<i>P</i> value
AT (s)	9.43 ± 2.25	9.22 ± 2.37	0.753	8.68 ± 2.06	10.43 ± 2.75	0.017
TTP (s)	16.24 ± 3.67	16.43 ± 3.32	0.862	15.86 ± 3.80	17.86 ± 4.19	0.089
IT (s)	6.85 ± 2.56	7.22 ± 2.57	0.643	7.17 ± 2.45	7.44 ± 3.03	0.344
BI (dB)	5.07 ± 3.49	5.29 ± 4.16	0.846	4.93 ± 3.25	6.92 ± 4.59	0.09
PI (dB)	31.36 ± 8.55	32.96 ± 8.58	0.538	34.64 ± 6.63	29.58 ± 8.22	0.023
EI (dB)	26.28 ± 9.90	27.64 ± 9.59	0.648	29.72 ± 6.69	22.66 ± 7.01	0.001

sions. 3D imaging displayed intuitive pictures of lesions and the gastric layers from multiple imaging angles and views, which corresponded well with surgical specimens (Figures 2, 3 and 7).

In cases with thickened wall bulging unevenly or a mass protruding into (or outward) the gastric cavity, 3D DCUS imaging provided comprehensive information to complementary to 2D imaging. The crater or wellhead appearances and feeding vessels as well as distorted nourishing vasculature of gastric carcinoma were better seen with 3D imaging than 2D imaging (Figures 5, 7).

DISCUSSION

Ultrasound imaging is a convenient and noninvasive diagnostic tool for evaluation of abdominal organs. However, its use in diagnosing gastric abnormalities is limited by the interference of the gas in the GI tract. In 1978, Warren first used hydrophilic methyl cellulose oral suspension in ultrasound examination to image retroperitoneal organs such as stomach, duodenum or pancreas^[6]. Since then, researchers have done many studies in oral contrast agent for gastric ultrasound imaging^[7-12]. Early-developed oral contrast agents have short emptying, large required quantity, and an unpalatable taste. The oral contrast agent Xinzhang[®] used in this study is vegetable-based with main components being beans and starch^[13], which is a uniform thin paste with pleasant taste and slow emptying feature without side effects, and thus is easily accepted by patients especially children and the elderly. The thin paste-based agent produces uniform moderate echogenic reflection within well-filled stomach, which clearly shows all normal layers of gastric wall, gastric lesions and surrounding structures under optimal contrast imaging. The gastric lesions revealed by oral contrast ultrasound in this study included mild thickening of the gastric wall, polypoid lesions and other stomach masses. Small lesions such as 0.5 cm diameter ulcer and 1.0 cm diameter stromal tumors can be identified. In addition, oral contrast gastric ultrasound imaging can be carried out using conventional ultrasound systems, which is easily applied in the clinical practice.

Although oral contrast imaging can show normal anatomy of the stomach and the location, shape and size of gastric lesions, its ability to determine internal structures and blood perfusion status of the lesion is limited. For example, gray-scale imaging cannot determine a very

hypoechoic mass (such as gastric stromal tumor) whether it is cystic or solid^[14-16]. Also, color Doppler ultrasound has a poor sensitivity in revealing small blood flow of the gastric wall or lesions. In previous study, intravenous contrast imaging has been used for the evaluation of gastric tumor in canine to determine the blood perfusion status of the tumors^[17-19]. However, without appropriated gray-scale imaging of the stomach, Intravenous contrast imaging cannot achieve useful information of blood perfusion for assessment of tumor vascularity and surrounding structures. Therefore, DCUS imaging is necessary for evaluation of gastric lesions in order to obtain comprehensive information.

Micro-bubble-based SonoVue is a second-generation intravenous ultrasound contrast agent. It has phospholipids as capsule, containing sulfur hexafluoride gas. Its diameter is similar to that of red blood cells, which enables it to reach microvessels of all peripheral organs through intravenous injection. This agent has an average half-life of 12 min *in vivo*. It is removed by lungs through respiration in 15 min and poses no obvious toxic effect to the liver and kidney. In term of the difference from CT contrast agents such as lipiodol, microbubble-based contrast agent does not penetrate vessel wall and leak into interstitial space. Its distribution in the lesion represents the distribution of the microvessels, and the intensity of the lesion enhancement represents the density of those vessels^[20-28]. Therefore, DCUS can be used to evaluate both the morphology and vascularity of gastric lesions.

In this study, we demonstrated that oral contrast imaging can provide excellent acoustic window for evaluation of a variety of gastric lesions by conventional gray-scale imaging. Furthermore, oral contrast imaging serves as important platform for assessment of blood perfusion of the lesions by intravascular contrast imaging. Thus, DCUS is able to demonstrate both morphologic appearances and perfusion status of both normal and abnormal structures, which improves the ability of differential diagnosis. For example, oral contrast imaging revealed 4 gastric stromal tumors as anechoic lesions which was difficult to decide whether they are cystic or solid lesions. However, the use of intravenous contrast imaging demonstrated internal blood perfusion of these tumor lesions, which confirmed they are solid lesions instead of cystic lesions. More important, DCUS can show the relationship of the lesion's vasculature and the gastric wall

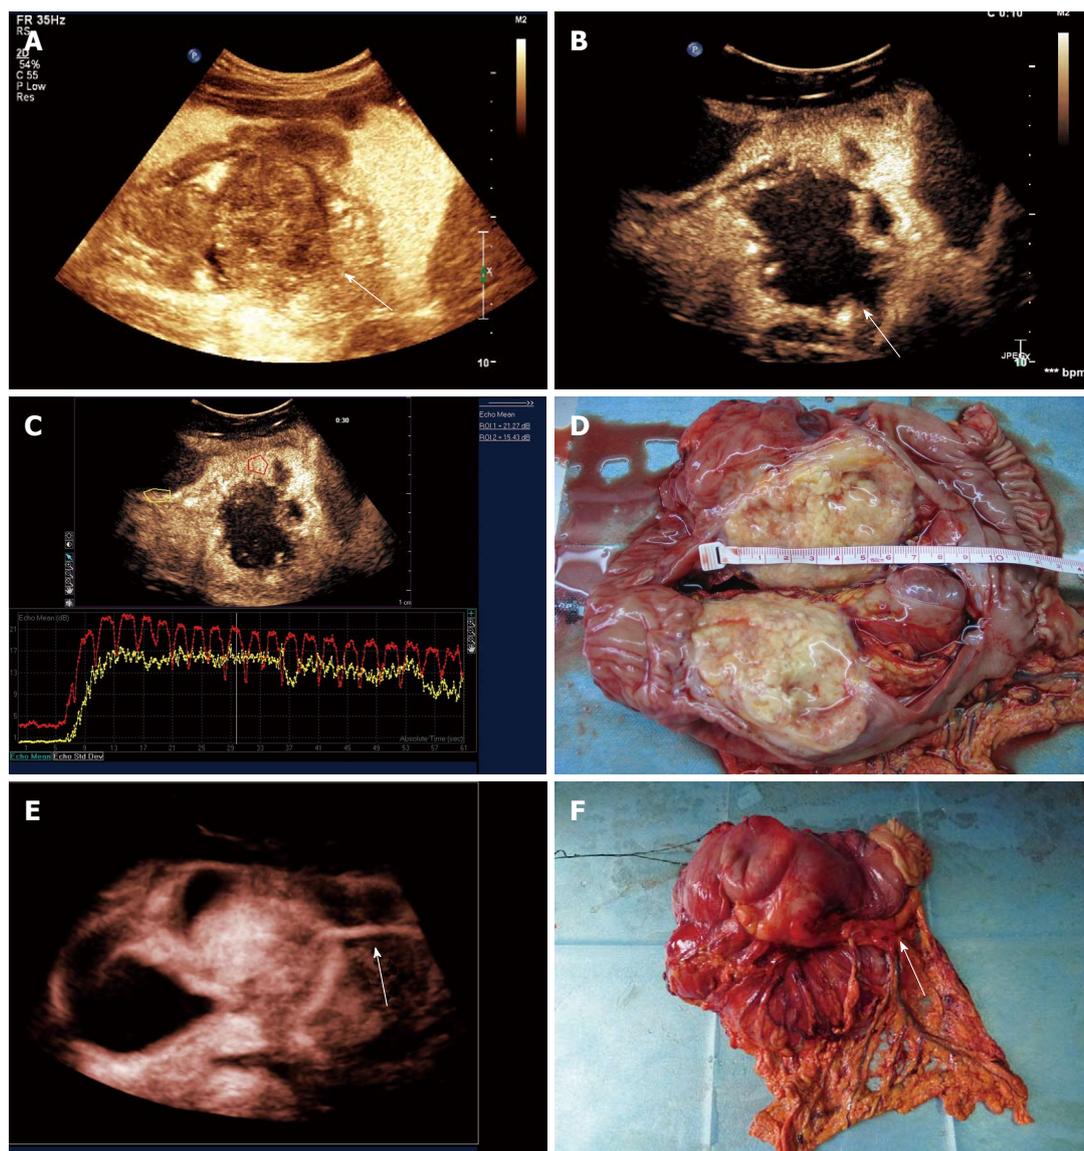

Figure 7 Double contrast-enhanced ultrasound imaging of mass-type gastric cancer. A: Oral contrast imaging revealed a tumor (arrow) extended into the back wall of stomach, which could not be seen by gastroscopy; B: Two-dimensional double contrast-enhanced ultrasound (DCUS) imaging showed the tumor attached to the posterior wall and enhanced in peripheral areas with the center of non-enhancement at early arterial phase; C: A contrast time-intensity curve of the lesion showed that the arrival time was shorter and the peak intensity was higher in the peripheral lesion (red curve) than those in normal gastric wall (yellow curve); D: The surgical specimen demonstrated the tumor with central necrosis which consistent to DCUS findings; E: Three-dimensional DCUS imaging showed the outer-growing lesion with a tumor feeding vessel (arrow); F: The feeding vessel on the gross specimen was seen and coincident with the DCUS imaging.

as well as their contours outlined by contrast imaging, which accentuates pathological features. Indeed, DCUS images can clearly show the pathological features of the lesions, which made sonographic diagnosis to fit with internationally wide adopted Borrmann's classification of advanced gastric cancer, i.e., polypoid lesion, ulcerated lesion, ulcerating infiltrative lesion, and infiltrative lesion.

Comparing malignant lesions with surrounding normal gastric tissue using contrast-enhanced time-intensity curve, values of AT, PI and EI parameters except TTP and IT were statistically significant ($P < 0.05$). Whereas comparing benign lesions with surrounding normal gastric tissue, all parameters including AT, TTP, IT, PI and EI are not statistically significant ($P > 0.05$). Thus, early AT and increased

PI, EI, can be used as potential indexes and indicators for evaluating gastric benign and malignant lesions^[29]. Since EI eliminated baseline intensity factor, it should reflect the actual intensity of the enhancement. Previous study have shown that, in gastric cancer, EI correlates well to the pathological microvessel density ($r = 0.921, P < 0.001$)^[30], which may reflect the density of microvessels with the lesion, and could be a new parameter for evaluating biological behavior and angiogenesis of gastric cancer.

3D DCUS imaging provides comprehensive and observational perspective for gastric wall and lesion morphology. It can show the intuitive appearance of the lesion relevant to the gastric wall which closely correlates to pathological specimen and increases the confidence

of clinical diagnosis. In malignant lesions, 3D imaging shown the dense, tortuous distorted and heavily cluttered vasculatures of the lesions, which is similar to the “tumor vascularity” seen in the liver and other organ malignancies^[31-35]. 3D DCUS imaging can supplement 2D imaging and provide more evidence for the diagnosis of benign and malignant gastric lesions.

It should be pointed out that this is preliminary observation of DCUS imaging applications. The limitations of this study include small number cases with various gastric abnormalities and no blinded comparison with endoscopic examinations. Prospective study design with larger clinical trial is needed for further investigations.

In conclusion, DCUS imaging is able to simultaneously display the sonographic features of various gastric lesions and its vasculatures as well as perfusion patterns. The parameters of AT, PI and EI could serve as potential indicators for differentiating benign and malignant gastric lesions. 3D DCUS could provide additional information to 2D DCUS for evaluation of gastric lesions.

COMMENTS

Background

The common methods for examination of the upper gastrointestinal (GI) tract are x-ray with oral barium-based contrast agent and endoscopy. Their shortcomings include the fact that they often cannot delineate submucosal mural structures of the GI tract. Over the years, oral contrast agents to improve the assessment of the GI tract and adjacent structures by absorbing and displacing bowel gas and provide an acoustic window for sonographic visualization of upper GI tract have been developed and commercially available in China, one of such oral contrast agent was Xinzhang®. Recently, the authors have explored new technique which combines both oral and intravenous contrast-enhanced ultrasonography (CEUS) imaging methods, called Double contrast-enhanced ultrasound, for evaluation both morphologic appearances and perfusion status of gastric abnormalities.

Research frontiers

Two-dimensional (2D) double contrast-enhanced ultrasound (DCUS) could clearly demonstrate normal gastric wall and differentiate normal gastric wall from benign and malignant lesions. Three-dimensional (3D) DCUS could intuitively display morphological features and vascularities of the lesions with multi-planar and volume views.

Innovations and breakthroughs

The oral contrast agent Xinzhang® used in this study is vegetable-based with main components being beans and starch, which is a uniform thin paste with pleasant taste and slow emptying feature without side effects, and thus is easily accepted by patients especially children and the elderly. DCUS is able to demonstrate both morphologic appearances and perfusion status of both normal and abnormal structures, which improves the ability of differential diagnosis. In the study, small lesions such as 0.5 cm diameter ulcer and 1.0 cm diameter stromal tumors can be identified.

Applications

The study results suggest that 2D and 3D double DCUS was safe, highly sensitive and specific and could be applied for evaluation of gastric lesions.

Peer review

This is an interesting and well written study aimed at assessing the role of contrast enhanced 2D and 3D US in the evaluation of gastric lesions. Even if it is a preliminary study and further prospective validation is needed, the manuscript is very clear and very well documented by images.

Abstract

AIM: To compare the clinical outcome and pathologic features of non-alcoholic steatohepatitis (NASH) patients with hepatocellular carcinoma (HCC) and hepatitis C virus (HCV) patients with HCC (another group in which HCC is commonly seen) undergoing liver transplantation.

METHODS: Patients transplanted for HCV and NASH at our institution from January 2000 to April 2011 were analyzed. All explanted liver histology and pre-transplant liver biopsies were examined by two specialist liver histopathologists. Patient demographics, disease free survival, explant liver characteristics and HCC features (tumour number, cumulative tumour size, vascular invasion and differentiation) were compared between HCV

and NASH liver transplant recipients.

RESULTS: A total of 102 patients with NASH and 283 patients with HCV were transplanted. The incidence of HCC in NASH transplant recipients was 16.7% (17/102). The incidence of HCC in HCV transplant recipients was 22.6% (64/283). Patients with NASH-HCC were statistically older than HCV-HCC patients ($P < 0.001$). A significantly higher proportion of HCV-HCC patients had vascular invasion (23.4% vs 6.4%, $P = 0.002$) and poorly differentiated HCC (4.7% vs 0%, $P < 0.001$) compared to the NASH-HCC group. A trend of poorer recurrence free survival at 5 years was seen in HCV-HCC patients compared to NASH-HCC who underwent a Liver transplantation ($P = 0.11$).

CONCLUSION: Patients transplanted for NASH-HCC appear to have less aggressive tumour features compared to those with HCV-HCC, which likely in part accounts for their improved recurrence free survival.

INTRODUCTION

The prevalence of obesity in North American Society continues to rise^[1]. With this increasing rate of obesity there has been a concomitant increase in the prevalence of non-alcoholic fatty liver disease (NAFLD)^[2]. The natural history of NAFLD is quite variable. It includes a spectrum ranging from reversible steatosis to steatohepatitis with hepatic fibrosis (NASH), and ultimately cirrhosis^[3-5]. Up to 30% of adults in North America and Western Europe are known to have excess fat accumulation in the liver^[6]. Of these, nearly 10% have NASH, which represents 2%-3% of all adults. There is speculation that NASH may soon become one of the main causes of End Stage Liver Disease (ESLD) requiring liver transplantation in North America^[7].

Hepatitis C virus (HCV) is one of the most common underlying liver diseases in hepatocellular carcinoma (HCC), accounting for about one-third of the cases of HCC in the United States^[8]. It is well established that patients with NASH can progress to develop HCC with previous reports suggesting that the 5 year prevalence may be as high as 7.6%^[9]. However as increasing numbers of HCC cases arising from NASH are being seen, it is important to clarify the outcomes and recurrence by comparing the clinical and pathological features of HCC due to NASH with those of HCC caused by one the more common underlying liver diseases in HCC, HCV infection, as a benchmark.

Previous studies have suggested that patients with NASH cirrhosis are less likely than those with HCV to get transplanted^[10]. This may be in large part to a higher likelihood of being denied listing for co-morbid conditions. Previous authors have shown that NASH patients with diabetes, hypertension, body mass index (BMI) > 30 years and age > 60 years undergoing liver transplantation have a poor (50%) 1 year mortality^[11]. However in appropriately selected NASH patients post liver transplant survival can fair at least as well as individuals who undergo transplant for other etiologies. The outcome of NASH patients with underlying HCC undergoing a liver transplantation compared to HCV patients with underlying HCC (another group in which HCC is commonly seen) has not been thoroughly investigated. Specifically the tumour characteristics in explanted livers and disease free survival between these groups have not been compared. The goal of the present study was to compare the clinical and pathological parameters as well as disease free survival in the two groups.

MATERIALS AND METHODS

We performed a retrospective review on all patients who underwent liver transplantation (LT) for HCV or NASH cirrhosis from January 2000 to April 2011 at our institution. Patients less than 18 years of age were excluded. Data on these patients were prospectively entered in our transplant database. In order to confirm or refute the

original histological diagnoses, all explanted liver histology and pre-transplant liver biopsies were re-examined by two specialist liver histopathologists who were blinded to the original diagnoses.

The etiology of the original liver disease was diagnosed by set criteria. NASH was determined to be the cause of chronic liver disease in patients with histological evidence of steatohepatitis in pre-transplant liver biopsies or in liver explants (steatosis, portal and/or lobular inflammation, hepatocyte ballooning, pericellular fibrosis and the presence of Mallory bodies)^[12,13], in conjunction with no history of alcohol consumption. HCV-related liver disease was confirmed by explants pathology and the presence of HCV RNA.

All patients with a pre and post-transplant diagnosis of HCC were identified in both the NASH and HCV groups. Listed patients with known HCC all fell within Milan Criteria^[14]. Patients who received pre-transplant radiofrequency ablation were excluded. HCC was confirmed histologically in the explanted liver. All Donation after Cardiac Death (DCD) organs were procured from controlled DCD donors using techniques previously published by our group^[15]. Primary outcomes were patient survival as well as pathologic features of HCC (tumour number, cumulative tumour size, vascular invasion and differentiation). Level of differentiation of HCC tumours was graded using the Modified Edmondson-Steiner grading system^[16]. Additional variables investigated included age at diagnosis, gender and α -feto-protein (AFP) levels. Recurrence free survival was taken at the time point of maximal follow-up.

Statistical analysis

All data are presented as means \pm SD. Differences between groups were analyzed using the unpaired *t* test for continuous variables and by the χ^2 test or continuity correction method for categorical variables. Survival curves for patient and graft survival were generated using the Kaplan-Meier method and compared by the log-rank test. All statistical tests were two-sided and differences were considered significant when $P < 0.05$.

RESULTS

A total of 832 liver transplants were performed at the London Health Sciences Centre during the study period. Of these, 283 (34.0%) recipients were positive for HCV based on the aforementioned criteria. NASH was the indication for liver transplantation in 96 (11.5%) recipients, and 42 (5.1%) recipients were diagnosed with 'cryptogenic' or 'idiopathic' cirrhosis. The remaining 411 (49.4%) recipients had liver failure due to other identifiable causes. Of the 42 cases originally diagnosed as cryptogenic cirrhosis, 6 were re-designated as NASH associated cirrhosis based on current histologic and clinical definitions. Thus the final analysis of HCV and NASH liver transplant recipients was: 283 (34.0%), 102 (12.3%) respectively (Figure 1).

Vascular invasion	23.40%	6.30%	0.002
Poorly differentiated	4.70%	0%	< 0.001

AFP: α -feto-protein; DBD: Donation after brain death; DCD: Donation after circulatory death; LD: Living donor; HCC: Hepatocellular carcinoma; HCV: Hepatitis C virus; NASH: Non-alcoholic steatohepatitis; NA: Not available.

The incidence of HCC in NASH recipients was 16.7% (17/102). Importantly, none of the re-categorized NASH patients who were originally designated cryptogenic were found to have HCC. The incidence of HCC in HCV liver transplant recipients at our centre was 22.6% (64/283).

Patients with NASH-HCC were statistically older than HCV-HCC patients (58.6 ± 4.2 years *vs* 52.6 ± 5.8 years, $P < 0.001$). There was no significant difference in gender or preoperative AFP level between the two groups. No patients with NASH-HCC received a DCD liver allograft (Table 1). The diagnosis of HCC was made before liver transplantation using multiple imaging techniques in 65% of NASH patients and 89% of HCV patients. HCC was more likely to be found incidentally in transplanted NASH patients (35%) than in transplanted HCV patients (11%) ($P = 0.015$).

Pathological characteristics of the NASH-HCC tumours were compared with those of HCV-HCC tumours (Table 1). A significantly higher proportion of HCV-HCC patients had vascular invasion (23.4% *vs* 6.4%, $P = 0.002$) as well as poorly differentiated tumours (4.7% *vs* 0%, $P < 0.001$) compared to the NASH-HCC. There was

no significant difference in the mean number of tumours or the mean cumulative size of the tumours between the two groups. In both groups, the tumours satisfied Milan criteria pre-transplantation.

Disease free survival at time of maximal follow-up was not statistically significant between the two groups however there was a clear trend towards lower disease free survival in the HCV-HCC group ($P = 0.11$, Figure 2).

DISCUSSION

The prevalence of NAFLD has continued to increase as the obesity epidemic continues. The rate of progression from NAFLD to the development of NASH or end stage liver disease is unknown. However, the frequency of NASH in patients listed for transplantation in North America has been previously determined to be 2.9%^[17]. This is likely an underestimate as this number was based on data collected from the 1990s, whereas in the last decade the rates of obesity and metabolic syndrome have increased dramatically. A more recent analysis of data from the Scientific Registry of Transplant Recipients (SRTR) reported that the rate had increased to 3.5%^[18]. In our series, 12.3% of patients have NASH as the diagnosis leading to liver failure requiring transplantation. NASH as a primary diagnosis in patients being listed or transplantation has continued to increase at our centre.

The natural history of NAFLD ranging from reversible steatosis to steatohepatitis with hepatic fibrosis (NASH), and ultimately the possibility of developing HCC has been previously described^[19]. In small previously published North American series of patients transplanted for NASH, HCC was found in 22% (2/9) of patients^[20]. In our series of 102 patients with NASH cirrhosis, 16.7% had HCC at the time of transplantation. This is a similar rate to the 22.6% of our HCV cirrhotic patients requiring transplantation, another well known high risk group for developing HCC. The high incidence of HCC in NASH patients undergoing liver transplantation suggests that these patients are at high risk of devel-

oping HCC and should undergo frequent ultrasound surveillance in a similar fashion to that performed in patients with HCV.

It has also been shown that patients with NASH are less likely to be listed for transplantation due to comorbidities, a justifiable practice given suboptimal results in NASH patients possessing these comorbidities^[10]. However in selected NASH patients receiving liver transplantation, others have shown that 5 year disease free survival after transplantation was significantly better than disease free survival in the C and B viral groups, 66%, 29% and 39% respectively^[21]. More recent studies have suggested there is no difference in 1 year and 3 year survival between patients transplanted for NASH and those transplanted for other indications^[22]. The outcome in patients with HCV is clearly affected by possible recurrence of HCV cirrhosis however NASH patients are also at risk for recurrence of NASH cirrhosis with some studies suggesting the incidence of recurrent NASH being as high as 25%^[23-25].

Patients with NASH and HCC post-transplant outcomes have not been previously investigated compared to patients with HCV and HCC (another group in which HCC is commonly seen). In previous studies looking at patients undergoing liver resection for HCC, cumulative survival after resection was comparable among HCV-HCC and NASH-HCC patient groups^[21].

In our study a significantly higher proportion of HCV-HCC patients had vascular invasion as well as poorly differentiated tumours compared to the NASH-HCC group. Vascular invasion is the strongest predictor of recurrence in patients with HCC^[26].

In the present study a trend of poorer recurrence free survival was seen in HCV-HCC patients compared to NASH-HCC who underwent a Liver transplantation. The higher proportion of patients with vascular invasion and poorly differentiated tumours may at least in part account for this difference in recurrence free survival. Based on our results it therefore appears that NASH associated HCC might be a less aggressive form of HCC compared with HCV associated HCC. It must also be entertained that some of the sickest NASH patients may not be listed for transplantation because of significant comorbidities or poor operative candidacy.

Limitations of the present study include its single centre nature as well as the lack of generalizability to non-transplant NASH and HCC populations due to the unique social and biologic factors of patients approved for transplantation.

In summary in those where NASH progresses to cirrhosis, there is a significant proportion that go on to develop HCC suggesting these individuals should undergo aggressive screening protocols directed toward the early detection of HCC, in a similar fashion to patients with HCV-cirrhosis. Patients with NASH-HCC undergoing liver transplantation also appear to be older than HCV-HCC patients undergoing liver transplantation. In appropriately selected patients with NASH and HCC post-transplant outcomes equal if not better than patients with

HCV-HCC (another group in which HCC is commonly seen). This may be related to less vascular invasion and less poorly differentiated pathology.

COMMENTS

Background

There is speculation that Non-alcoholic steatohepatitis (NASH) may soon become one of the main causes of end stage liver disease requiring liver transplantation in North America. The clinical outcome and pathologic features of NASH patients with hepatocellular carcinoma (HCC) undergoing liver transplantation compared with hepatitis c virus (HCV) patients with HCC (another group in which HCC is commonly seen) has not been thoroughly investigated.

Research frontiers

A significantly higher proportion of HCV-HCC patients had vascular invasion (23.4% vs 6.4%) and poorly differentiated HCC (4.7% vs 0%) compared to the NASH-HCC group. A trend of poorer recurrence free survival at 5 years was seen in HCV-HCC patients compared to NASH-HCC who underwent a Liver transplantation.

Innovations and breakthroughs

To knowledge, this represents the first study to compare the tumour characteristics in explanted livers and disease free survival between NASH-HCC and HCV-HCC patients undergoing liver transplantation.

Applications

In appropriately selected patients with NASH and HCC post-transplant outcomes equal if not better than patients with HCV HCC (another group in which HCC is commonly seen). This may be related to less vascular invasion and less poorly differentiated pathology.

Peer review

In this manuscript, the authors investigated the clinical outcome and pathologic features of NASH patients with HCC undergoing liver transplantation compared with HCV patients with HCC. This is a retrospective analysis. The originality of this study was not so high. Nonetheless, the data were properly presented and the manuscript was well prepared. The results of this study may provide useful information to the clinicians.

Abstract

AIM: To find a possible relationship between inflammation and CA19-9 tumor marker by analyzing data from patients with benign jaundice (BJ) and malignant jaundice (MJ).

METHODS: All patients admitted for obstructive jaundice, in the period 2005-2009, were prospectively enrolled in the study, obtaining a total of 102 patients. On admission, all patients underwent complete standard blood test examinations including C-reactive protein (CRP), bilirubin, CA19-9. Patients were considered eligible for the study when they presented obstructive jaundice confirmed by instrumental examinations and increased serum bilirubin levels (total bilirubin > 2.0 mg/dL). The standard cut-off level for CA19-9 was 32 U/mL, whereas for CRP this was 1.5 mg/L. The CA19-9 level was adjusted by dividing it by the value of serum bilirubin or by the CRP value. The patients were divided

into 2 groups, MJ and BJ, and after the adjustment a comparison between the 2 groups of patients was performed. Sensitivity, specificity and positive predictive values were calculated before and after the adjustment.

RESULTS: Of the 102 patients, 51 were affected by BJ and 51 by MJ. Pathologic CA19-9 levels were found in 71.7% of the patients. In the group of 51 BJ patients there were 29 (56.9%) males and 22 (43.1%) females with a median age of 66 years (range 24-96 years), whereas in the MJ group there were 24 (47%) males and 27 (53%) females, with a mean age of 70 years (range 30-92 years). Pathologic CA19-9 serum level was found in 82.3% of MJ. CRP levels were pathologic in 66.6% of the patients with BJ and in 49% with MJ. Bilirubin and CA19-9 average levels were significantly higher in MJ compared with BJ ($P = 0.000$ and $P = 0.02$), while the CRP level was significantly higher in BJ ($P = 0.000$). Considering a CA19-9 cut-off level of 32 U/mL, 82.3% in the MJ group and 54.9% in the BJ group were positive for CA19-9 ($P = 0.002$). A CA19-9 cut-off of 100 U/mL increases the difference between the two groups: 35.3% in BJ and 68.6% in MJ ($P = 0.0007$). Adjusting the CA19-9 value by dividing it by serum bilirubin level meant that 21.5% in the BJ and 49% in the MJ group remained with a positive CA19-9 value ($P = 0.003$), while adjusting the CA19-9 value by dividing it by serum CRP value meant that 31.4% in the BJ group and 76.5% in the MJ group still had a positive CA19-9 value ($P = 0.000004$). Sensitivity, specificity, positive predictive values of CA19-9 > 32 U/mL were 82.3%, 45% and 59.1%; when the cut-off was CA19-9 > 100 U/mL they were, respectively, 68.6%, 64.7% and 66%. When the CA19-9 value was adjusted by dividing it by the bilirubin or CRP values, these became 49%, 78.4%, 69.4% and 76.5%, 68.6%, 70.9%, respectively.

CONCLUSION: The present study proposes CRP as a new and useful correction factor to improve the diag-

nostic value of the CA19-9 tumor marker in patients with cholestatic jaundice.

INTRODUCTION

CA19-9 is a tumor marker that increases in pancreatic and biliary malignancy and it has been promoted as a reliable test for the detection of pancreato-biliary malignancy. In pancreatic cancer, CA19-9 has been reported to have 70%-80% sensitivity and 80%-90% specificity in tumor diagnosis, whereas in cholangiocarcinoma without history of sclerosing cholangitis the sensitivity and specificity are, respectively, 77.9% and 76.3%^[1-2]. CA19-9 is unfortunately increased not only in patients with pancreatic or biliary cancers but also in benign biliary diseases which often present with jaundice and is therefore often misleading, reducing significantly the diagnostic accuracy of this marker^[3-5]. The relationship between CA19-9 and jaundice has been analyzed and studied to find possible adjustments to increase the sensitivity, specificity and predictive value of the test in differential diagnosis of hepatobiliary diseases associated with jaundice. Therefore, some authors have suggested to adjust CA19-9 value by dividing it empirically by the serum bilirubin value^[6,7]. Other factors that could influence and alter the values of this tumor marker have not been studied yet. Inflammation contributes to elevating the CA19-9 value and it can be assessed by monitoring the acute-phase proteins: one of these is the C-reactive protein (CRP) which rises in response to infection, injury and neoplasm.

This research was stimulated by our own experience of patients presenting with jaundice of benign etiology who were found to have grossly elevated CA19-9 levels. The purpose of this study was to clarify the clinical interpretation and diagnostic value of an elevated serum CA19-9 level, with special reference to coexistent obstructive jaundice. The present study, first in the literature, analyzes a possible relationship between CA19-9, bilirubin and inflammation, expressed as CRP value, aiming to find a ratio or a better corrective factor to increase predictivity of CA19-9 and reduce the number of misleading false positive results.

MATERIALS AND METHODS

All the patients admitted for obstructive jaundice to the Department of Emergency Surgery, Cannizzaro Hospital, University of Catania, Italy, between September 2005 and September 2009, were considered for the present study. The patients were enrolled prospectively, 51 for each group of benign jaundice (BJ) and malignant jaundice (MJ) patients, obtaining a total of 102 patients. At admission, all patients underwent complete standard blood test examinations, including serum bilirubin levels. Patients were considered eligible for the study when they presented obstructive jaundice confirmed by instrumental examinations and increased bilirubin serum levels (total bilirubin > 2.0 mg/dL). Serum levels of CA19-9 and CRP were also measured at the time of admission. The standard cut-off level of CA19-9 was 32 U/mL, whereas for CRP this was 1.5 mg/L. The definitive diagnosis was obtained by instrumental examinations, surgical exploration and pathology. Instrumental examinations included ultrasonography, computed tomography scan, magnetic resonance imaging, endoscopic ultrasound scan and endoscopic retrograde cholangiopancreatography. The CA19-9 level was adjusted by dividing it by the value of serum bilirubin firstly, and then by the CRP value. The patients were divided into 2 groups: MJ and BJ. After the adjustment a comparison between the serum levels in the 2 groups of patients was obtained by Wilcoxon two sample test. Differences for categorical variables were assessed using the chi-square test or Fisher's exact test when adequate. Spearman correlation between the 3 parameters of CA19-9, bilirubin and CRP in each group of patients was computed. The receiver operating characteristic curve was used to establish the probability that a patient with MJ has a high value of CA19-9. A *P* value less than 0.05 was considered statistically significant.

RESULTS

The present longitudinal study analyzed a total of 102 patients: 53 (52%) men and 49 (48%) women with a median age of 69 years (range 24-96 years). In the group of 51 BJ patients there were 29 (56.9%) males and 22 (43.1%) females with a median age of 66 years (range 24-96 years), whereas in the MJ group there were 24 (47%) males and 27 (53%) females, with a median age of 70 years (range 30-92 years). Causes of BJ included: common bile duct (CBD) stones (66.6%), gallbladder stones with cholangitis (15.7%), biliary pancreatitis (15.7%), papillitis (1.9%). Causes of MJ included: pancreatic cancer (49%), bile duct cancer (19.6%), gallbladder cancer (13.7%), ampullary cancer (9.8%), intrahepatic cholangiocarcinoma (1.9%) and other malignancy (5.8%; 2 patients with metastatic nodes in porta hepatis and one patient with peritoneal carcinomatosis from ovarian cancer). Pathologic CA19-9 serum level was found in 82.3% of MJ, but in two patients the CA19-9 was 2.5 U/mL. CA19-9 did not correlate directly with the grade of biliary obstruction either expressed as bilirubin level in BJ and MJ (Figure 1). CRP

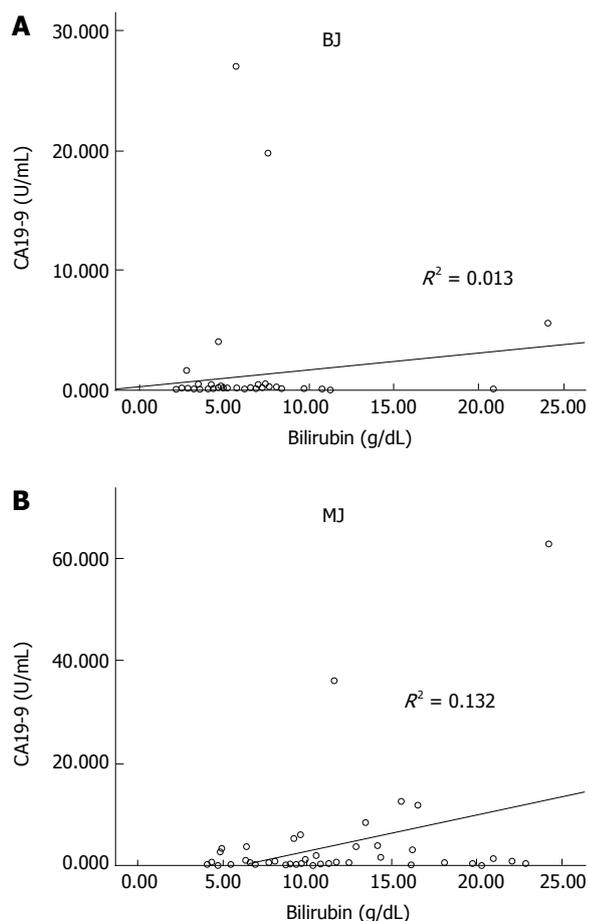

Figure 1 Correlation between total bilirubin and CA19-9 for benign jaundice (exponential line fit, $R^2 = 0.013$) (A) and malignant jaundice (exponential line fit, $R^2 = 0.132$) (B). BJ: Benign jaundice; MJ: Malignant jaundice.

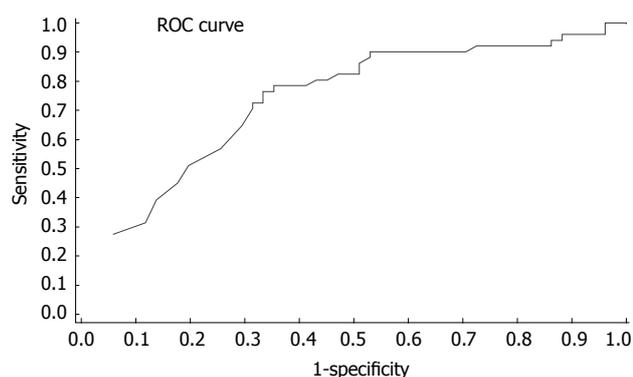

Figure 2 Receiver operating characteristic curve for biomarker CA19-9. ROC: Receiver operating characteristic.

levels were pathologic in 66.6% of the patients with BJ and in 49.0% with MJ. Mean bilirubin and CA19-9 levels were significantly higher in MJ compared to BJ, while the CRP level was significantly higher in BJ (Table 1). Table 2 reports the serum level of bilirubin, CA19-9 and CRP according to the cause of jaundice. There were no relevant differences in bilirubin according to the cause of jaundice. Comparing the CA19-9 value between patients with pancreatic cancer and patients with other causes of MJ and

	Benign	Malignant	P value
No. of patients	51	51	
Bilirubin serum level (median and range) (g/dL)	5.2 (2.12-24.03)	9.7 (4.07-24.25)	< 0.0001
95% CI = 5.0-7.2		95% CI = 9.6-12.5	
CA19-9 serum level (median and range) (U/mL)	36 (2-27019)	405 (2.5-62974)	0.02
95% CI = 0-2.508		95% CI = 699-6282	
> 32 (%)	28/51 (54.9)	42/51 (82.3)	0.003
> 100 (%)	18/51 (35.3)	35/51 (68.6)	0.0007
CRP (median and range) (U/mL)	6.91 (0.1-30)	2.97 (0.1-13.2)	0.0002
95% CI = 4.6-8.3		95% CI = 2.3-4.1	
> 1.5 (%)	34/51 (66.6)	25/51 (49.0)	0.005
> 5 (%)	21/51 (41.2)	7/51 (13.7)	0.004

CRP: C-reactive protein; CI: Confidence interval.

BJ, no difference was reported. CRP was significantly ($P = 0.04$) higher in patients with CBD stones than in pancreatic cancer, and patients with BJ and pancreatitis had the highest value of CRP. In MJ the average level of CRP was significantly higher in gallbladder cancer than in bile duct cancer, but not different from that in pancreatic cancer.

When considering the CA19-9 cut-off level of 32 U/mL, 42 of 51 patients (82.3%) in the malignant group and 28 of 51 (54.9%) in the benign group were positive for CA19-9 (Fisher's exact test: $P = 0.002$). Figure 2 shows that the area under the curve or probability that a patient diagnosed with MJ has a major value of CA19-9 compared to a patient diagnosed with BJ was 0.71. Increasing the cut-off level of CA19-9 to 100 U/mL, the difference between the two groups increases: 35.3% in BJ and 68.6% in MJ (Fisher's exact test: $P = 0.0007$). Changing the cut-off level alters the sensitivity and specificity as shown in Table 3, but by pushing up the cut-off level in spite of an increase of specificity we have obtained a reduction in the sensitivity of the test.

Adjusting the CA19-9 value by dividing it by serum bilirubin level, 11 of 51 patients (21.6%) in the BJ and 26 of 51 patients (51.0%) in the MJ group remained with a positive CA19-9 value (Fisher's exact test: $P = 0.003$), increasing the specificity to 78.4% but reducing the sensitivity to 49%.

The second mode of adjustment of the CA19-9 value was performed by dividing it by serum CRP value. Consequently, 16 of 51 patients (31.4%) in the BJ group and 39 of 51 patients (76.5%) in the MJ group remained with a positive CA19-9 value (Fisher's exact test: $P = 0.000004$). By this adjustment the sensitivity increases to 76.5%, the specificity to 68.6% and the positive predictive value (PPV) to 70.9%.

DISCUSSION

The diagnostic role of CA19-9 as a test for the detection of pancreato-biliary malignancy remains poorly defined, because, as in other diagnostic modalities, the utility of

Table 2 Bilirubin, CA19-9 and C-reactive protein levels according to jaundice cause at time of hospital admission *n* (%)

Table 3 Adjustments of the value of CA19-9: Differences in sensitivity, specificity and positive predictive value (%)

	Sensitivity	Specificity	PPV
CA19-9 > 32 U/mL	82.3	45.0	59.1
CA19-9 > 100 U/mL	68.6	64.7	66.0
CA19-9/BIL	49.0	78.4	69.4
CA19-9/CRP	76.5	68.6	70.9

PPV: Positive predictive value; BIL: Bilirubin; CRP: C-reactive protein.

CA19-9 has several confounding limitations. Firstly, false positive elevations in CA19-9 exist in benign conditions such as liver diseases (primary sclerosing cholangitis, primary biliary cirrhosis, chronic hepatitis, acute liver failure), obstructive jaundice, pancreatitis^[3,5,8-11]. Even diseases not related to the hepatobiliary tract such as interstitial pulmonary disease^[12], collagen vascular diseases and, reportedly, heavy tea consumption^[4,13], suggest that CA19-9 may be expressed as a marker of a systemic inflammatory response. Furthermore, CA19-9 has also been shown to be upregulated in other malignant tumors including gastric, ovarian, and colorectal carcinoma^[14]. However, the most common cause of false positive CA19-9 is obstructive jaundice^[10]. Physiologically, biliary epithelial cells secrete mucins carrying the epitope of CA19-9, hence the high level of CA19-9 in serum during the obstructive jaundice, reflecting both inflammatory hypersecretion and leakage of biliary mucins into serum. This process can be reversed by resolution of the jaundice, which is often associated with a fall in CA19-9 greater in benign disease than in malignant^[3], because in malignant disease the synthesis of CA19-9 by proliferating cells contributes to the total level in a manner independent from any associated condition^[5,5]. In this series patient with malignant jaundice had higher mean levels of bilirubin than those with benign jaundice; additionally, the level of CA19-9 was significantly higher in malignant than in benign, especially if we considered a cut off level > 100 U/mL. Unfortunately, in our study,

CA19-9 does not correlate directly with the grade of biliary obstruction either in benign or in malignant jaundice (Figure 1), even if we observed that in patients with benign disease levels of CA19-9 decreased after relief of biliary obstruction (data not shown).

Secondly, the concentration of this tumor marker in the serum may be influenced by the patient's secretor status, because patients who are genotypically negative for the Lewis blood group antigen (a-, b-), approximately 4%-15% of the general population, do not synthesize CA19-9^[15]. As above in the present series the rate of MJ with a CA19-9 value less than 2 U/mL is 3.9%.

Furthermore, not only hyperbilirubinemia can obscure the clinical value of CA19-9, but inflammation can contribute and have a role. CRP, synthesized in hepatocytes, is one of the acute-phase proteins which are components of the innate immune responses that increase after infections, trauma, burns, tissue infarction, inflammatory process and tumors. In general, increased CRP levels in malignant disease could also be caused by an inflammatory response to tumor invasion^[16]. Padillo *et al*^[17], analysing CRP in 24 jaundice patients, found CRP levels significantly higher in patients with cancer. Differently from that study, this series showed the CRP serum levels are higher in benign obstructive jaundice than in malignant. Indeed, Table 2 reports that CRP is significantly (*P* = 0.04) higher in patients with CBD stones than those with pancreatic cancer; in particular, patients with BJ and pancreatitis have the highest value of CRP. Malignancy such as gallbladder cancer and intrahepatic cholangiocarcinoma present values of CRP comparable to BJ, probably due to an intensive inflammatory response to the tumor.

In our series, 54.9% of patients with benign jaundice had positive CA19-9 levels (cut-off 32 U/mL), and 35.5% had CA19-9 value over 100 U/mL; therefore, although the overall increase of the tumor marker in benign jaundice was inferior compared to that observed in malignancies, there was an overlap of values between cancer and non-cancer causes. This resulted in a low

accuracy of CA19-9 to diagnose pancreatic-biliary malignancies in patients with jaundice, especially since this marker is not able to distinguish pancreatic carcinoma from other malignancy or other benign causes of jaundice, as reported in Table 2, differing from what has been shown in other studies^[14,18]. Even when considering a cut-off level of 100 U/mL, the specificity is still 64.7%. As a result of this diagnostic overlap, the American Society of Clinical Oncology does not currently advocate its use for screening, evaluation of resectability or disease follow-up^[19]. For this reason some authors suggested to push up the cut-off level to 300 U/mL in presence of cholangitis and cholestasis to increase CA19-9 specificity, but this was associated with a significant decrease of sensitivity^[20]. To achieve a specificity of 100%, cut-off levels greater than 1000 U/mL should be considered^[21]. We recorded ten BJ patients with CA19-9 level greater than 300 U/mL and five BJ patients with more than 1000 U/mL, and all of them had serum bilirubin level lower than 8 mg/dL. These data can explain why there is no difference in the mean CA19-9 value between each cause of BJ and pancreatic cancer jaundice (Table 2). Indeed, multiple reports of patients with extremely high CA19-9 values in patients with BJ can be found in the literature^[22-24]. Several studies have shown that the association of elevated levels of CA19-9 with the diagnosis of cancer is significantly obscured in the face of obstructive jaundice, and because the bilirubin level correlates with CA19-9, they suggest that this value should be adjusted for hyperbilirubinemia^[10,11]. In our study CA19-9 does not correlate directly with the grade of biliary obstruction, either in BJ or in MJ.

Hence, based on the knowledge that in benign jaundice high levels of CA19-9 are an expression of obstruction and inflammation and CRP levels are higher in this group of patients, the most appropriate adjusting factor could be the CRP and not the bilirubin value. Indeed, 54.9% of patients with BJ had a CA19-9 level greater than 32 U/mL, and using a CA19-9 cut-off of 100 U/mL, the specificity of the test to detect malignancy is increased, with little decrease in the sensitivity. But the majority of benign jaundice patients have a CA19-9 value < 100 U/mL, so by adjusting this value with the CRP it is possible to increase the reliability of the test. As shown in Table 3 using the bilirubin as adjusting factor, even if the specificity reaches 78.4%, the sensitivity falls down to 49%; instead the CRP value better reflects the inflammatory status, obtaining 76.5% sensitivity, 68.6% specificity and 70.9% PPV. Certainly, the CA19-9 value has to be considered as an adjunctive value to the patient's history in the diagnosis of patients with obstructive jaundice, and its value, even after adjustment, should be helpful in planning the type and priority of further investigations with regard to the liver, bile ducts and pancreas.

In conclusion, the present study proposes adjusting to the CA19-9/CRP ratio as a new diagnostic tool in patients with cholestatic jaundice, which has not been reported in similar studies in the literature. This simple

ratio can significantly increase the specificity and the positive predictive value of CA19-9 in the differential diagnosis between malignant and benign jaundice. Other complementary studies of these markers are essential for diagnosis of malignant tumors when jaundice is present.

COMMENTS

Background

CA19-9 is a tumor marker which is increased in both benign and malignant hepatobiliary diseases. Previous studies have shown that CA19-9 has high sensitivity and specificity in pancreatic cancer. However, this tumor marker has been found to be elevated in benign biliary diseases as well. Hence the accuracy of CA19-9 is unreliable. The authors have tried to analyze the relationship between CA19-9, bilirubin and CRP levels to predict the accuracy of CA19-9 in malignant obstructive jaundice.

Research frontiers

After experiencing patients presenting with jaundice of benign etiology and having grossly elevated CA19-9 levels, the authors aimed to clarify the clinical interpretation and diagnostic value of an elevated serum CA19-9 level, with special reference to coexistent obstructive jaundice. CA19-9 is demonstrated to be influenced by bilirubin level, but other factors such as inflammation could influence and alter the values of this tumor marker. The research hotspot is how the inflammation influences the level of CA19-9.

Innovations and breakthroughs

In the past, the accuracy of CA19-9 level was improved by dividing it by bilirubin level, but the high level of CA19-9 in serum during obstructive jaundice reflects also an inflammatory hypersecretion. The inflammation can be assessed by monitoring the acute-phase proteins: one of these is the C-reactive protein (CRP). In this regard, in the present study, the CA19-9 level was adjusted by dividing it by the value of serum bilirubin and by the CRP value to look for a ratio or a better corrective factor to increase predictivity of CA19-9 and reduce the amount of misleading false positives. In fact, this adjustment increases the sensitivity to 76.5%, the specificity to 68.6% and the positive predictive value to 70.9%.

Applications

The study results suggest that considering inflammation as a reliable factor which increases the CA19-9 level in benign disease, abnormal tumor marker values in these patients can be corrected using the CRP in order to reduce the false positive results. In this way, it is possible to concentrate efforts in planning the type and priority of further investigations in the liver, bile ducts and pancreas in patients affected by malignancy.

Terminology

CA19-9: Tumor marker that increases in pancreatic and biliary malignancy, as physiologically biliary epithelial cells secrete mucins carrying the epitope of CA19-9; CRP: Synthesized in hepatocytes, is one of the acute-phase proteins, which are components of the innate immune responses that increase after infections, trauma, burns, tissue infarction, inflammatory process and tumors.

Peer review

This is a good longitudinal study in which authors analyze the relationship between CA19-9, bilirubin and CRP levels to predict the accuracy of CA19-9 in malignant obstructive jaundice. The results are interesting and suggest that the inflammation influences the CA19-9 value and reducing this confounding factor can help to better identify patients with malignant obstructive jaundice.

Abstract

AIM: To screen for genes related to metabotropic receptors that might be involved in the development of chronic hepatitis.

METHODS: Assessment of 20 genes associated with metabotropic receptors was performed in liver specimens obtained by punch biopsy from 12 patients with autoimmune and chronic hepatitis type B and C. For this purpose, a microarray with low integrity grade and with oligonucleotide DNA probes complementary to target transcripts was used. Evaluation of gene ex-

pression was performed in relation to transcript level, correlation between samples and grouping of clinical parameters used in chronic hepatitis assessment. Clinical markers of chronic hepatitis included alanine and aspartate aminotransferase, γ -glutamyltranspeptidase, alkaline phosphatase and cholinesterase activity, levels of iron ions, total cholesterol, triglycerides, albumin, glucose, hemoglobin, platelets, histological analysis of inflammatory and necrotic status, fibrosis according to METAVIR score, steatosis, as well as anthropometric body mass index, waist/hip index, percentage of adipose tissue and liver size in ultrasound examination. Gender, age, concomitant diseases and drugs were also taken into account. Validation of oligonucleotide microarray gene expression results was done with the use of quantitative real-time polymerase chain reaction (qRT-PCR).

RESULTS: The highest ($0.002 < P < 0.046$) expression among genes encoding main components of metabotropic receptor pathways, such as the α subunit of G-coupled protein, phosphoinositol-dependent protein kinase or arrestin was comparable to that of angiotensinogen synthesized in the liver. Carcinogenesis suppressor genes, such as chemokine ligand 4, transcription factor early growth response protein 1 and lysophosphatidic acid receptor, were characterized by the lowest expression ($0.002 < P < 0.046$), while the factor potentially triggering hepatic cancer, transcription factor *JUN-B*, had a 20-fold higher expression. The correlation between expression of genes of protein kinases PDPK1, phosphoinositide 3-kinase and protein kinase A (Spearman's coefficient range: 0.762-0.769) confirmed a functional link between these enzymes. Gender ($P = 0.0046$) and inflammation severity, measured by alanine aminotransferase activity ($P = 0.035$), were characterized by diverse metabotropic receptor gene expression patterns. The Pearson's coefficient ranging from -0.35 to 0.99 from the results of qRT-PCR and microarray indicated that qRT-PCR had certain

limitations as a validation tool for oligonucleotide microarray studies.

CONCLUSION: A microarray-based analysis of hepatocyte metabotropic G-protein-related gene expression can reveal the molecular basis of chronic hepatitis.

INTRODUCTION

The natural course of chronic viral hepatitis is affected by progression of fibrosis and the risk of hepatocellular carcinoma development^[1]. Current data indicate that intracellular signaling disturbances have an impact on progression of inflammation and fibrosis, as well as carcinogenesis, in the course of chronic hepatitis.

G-protein-coupled receptors (GPCRs) are a family of cell surface receptors which receive, integrate and enhance the majority of extracellular signals. After stimulation with different signals, GPCRs activate amplifying enzymatic cascades, regulatory proteins and ion channels. This activation regulates cellular responses, including growth, proliferation, and cell survival.

In the present study, using microarray DNA analysis, we attempt to define genes related to metabotropic receptors associated with progression of chronic hepatitis.

DNA technology with genomic profiling and cluster analysis allows determination of the role of genes in the pathogenesis of liver injury^[2]. We assessed the activity of 20 genes encoding metabotropic receptors, some of which have been documented to have probable significance in the progression of chronic hepatitis.

The assessment of expression of genes of the main component of GPCR, such as the G-protein α subunit (*GNA5*), 3-phosphoinositide-dependent protein kinase-1 (*PDPK1*), phosphoinositide 3-kinase (*PIK3CG*), protein kinase A (*AKT1*) and arrestin β (*ARRB2*) was performed. We determined transcription factor *JUN-B*, ETS-domain protein (*ELK4*), early growth response protein 1 (*EGR1*) activated as the result of GPCR stimulation, angiotensinogen (*AGT*), which is a GPCR-ligand,

dual-specificity protein phosphatases 14 (*DUSP14*), which is responsible for dephosphorylation of kinase products, calcitonin receptor proteins (*CALCR*), thyrotropin receptor (*TSHR*), colony stimulating factor-3 (*CSF3*), sphingosine-1-phosphate receptor 1 (*EDG1*), and lysophosphatidic acid receptor (*EDG2*) associated with G-protein. The selection of *EDG2*, *EGR1*, *JUN-B*, chemokine (C-C motif) ligand 4 (*CCLA*), *ELK4* genes was based on their association with cellular proliferation, differentiation and apoptosis^[3-6]. Additionally, the selected group represented genes involved in regulation of inflammatory response and liver fibrosis, which included genes for interleukin 1 β (*IL-1 β*) and its receptors IL1 type I (*IL1R1*), IL1 type II (*IL1R2*), *CALCR*, *EDG1*, *CCLA*, *AGT* and adhesion molecules vascular cell adhesion molecule 1 (*VCAM1*)^[7-14].

MATERIALS AND METHODS

In the group of 12 patients (7 men, 5 women; age 36 ± 10.8 years) with chronic hepatitis type B (2 patients) and C (8 patients) and autoimmune hepatitis (2 patients), according to clinical indications, a liver biopsy was performed by the Menghini technique. From the obtained liver sections, a sample of 2-3 mm in length was frozen at -75°C until the analysis of mRNA of 20 selected genes was performed (gene list Figure 1). During the histopathological investigation of the biopsies, the degree of inflammation and fibrosis was assessed by the METAVIR score and steatosis by the steatosis scoring system.

On the day of liver biopsy, the activity of serum alanine aminotransferase (ALT/GPT Cobas, Roche Diagnostics, Mannheim, Germany), aspartate aminotransferase (ASPART/GOT Cobas), γ -glutamyltransferase (GGT Cobas), alkaline phosphatase (ALP Cobas), cholinesterase (CHE Cobas), the level of iron (Fe Cobas), total cholesterol (CHOD-PAP Cobas), triglycerides (TG Cobas), albumin (ALB plus Cobas), glucose (GLU Cobas), hemoglobin and platelet (Sysmex XE-2100, Sysmex Europe GMBH, Norderstedt, Germany) were assessed. Anthropometric measurements, including body mass index, waist/hip index and the percentage of fatty mass was assessed by skin fold thickness. The size of the liver was measured during ultrasound examination of the abdomen. Patient characteristics included the presence of concomitant illnesses, drug history, as well as the use of such substances as alcohol and cigarettes (Figure 2). In women, the menstrual cycle phase and menopause were taken into account. Biochemical, histological and anthropometric parameters are presented in Figure 2. The gene expression studies were performed using microarray (with low integration level), with DNA oligonucleotides complementary to the investigated transcripts. Total RNA was isolated from liver samples using the TRI Reagent (Sigma-Aldrich, St. Louis, United States), and then purified using the RNeasy MiniElute spin columns with a DNA eliminator (Qiagen, Hilden, Germany). The quantity of isolated RNA was assessed by a spectrophotometer (NanoDrop, Wilmington, United States), and subsequently its degradation level was

measured by a capillary electrophoresis system (Experion, Bio-Rad, Hercules, United States). For further analysis only samples without evidence of RNA degradation were qualified (RQI > 8.5 Rna Quality Index). Subsequently, based on the obtained RNA, probes were synthesized according to the manufacturer's instructions (SABiosciences, Frederick, United States), and then hybridized to a microarray. We used the Oligo GEArray Human GPCR Signaling Pathway Finder Microarray (OHS-071) supplied by SABiosciences. Detection of the array probes is achieved based on chemiluminescence, using the FujiLAS System (FujiFilm, Tokyo, Japan). The resulting images (the signal density) were quantified using the OligoAnalyser (SABiosciences). The obtained results describing the relative levels of gene expression (with respect to the reference gene) were further examined.

Diversification in gene expression was assessed by agglomerative hierarchical clustering methods. Using the Spearman's rank correlation coefficient for activity of the investigated genes, we searched for pairs of objects and then for clusters with the smallest distance (Figure 1). An analogous classification was carried out using biochemical, histological and anthropometric parameters (Figure 2). Determination of a direct correlation between gene expression and clinical features was done based on agglomerative hierarchical clustering of both the investigated indicators of chronic hepatitis. The genotype-phenotype distinction was analyzed using Fisher's exact test, to de-

termine the difference between clustering of patients achieved on the basis of a dendrogram of clinical signs and a dendrogram of gene expression (Figures 1 and 2). Differentiation of clinical parameters between groups of patients with the biggest difference in gene expression was performed by the Mann-Whitney *U* test and Fisher's exact test. In the present study, these were patients number 2, 10, 9, 7 *vs* the rest (Figure 1). The Wilcoxon signed-rank test was used to assess differential expression between the selected genes, to determine the three groups of genes with the highest, moderate, and lowest activity (Figure 3).

The results of the microarray experiment were verified by means of quantitative real-time polymerase chain reaction (qRT-PCR) for *IL1B*, *VCAM1*, *PIK3CG*, *AGT*, *PDPK1*, *GNAS*, *JUN-B*, *EDG2*, *CCL4*, *EGR1*, *IL1R1*, *IL1R2*, *CALCR*, *AKT1* and *ARRB2*. Total RNA acquired from the tissues of interest was reverse-transcribed using the High-Capacity cDNA Archive Kit (Applied Biosystems, Foster City, United States) for the 2-step qRT-PCR assays. The qRT-PCR was performed on a Chromo 4 (Bio-Rad), using the ABI SYBR Green master mix (Applied Biosystems). Primer sets against sequences of genes are indicated by microarray. They are commercially available at OriGene (Rockville, United States), but were additionally checked for specificity with National Center for Biotechnology Information (NCBI) The Basic Local Alignment Search Tool (BLAST). The optimum annealing temperature for each primer set was determined prior to the analysis of experimental samples. Following amplification, dissociation curves were

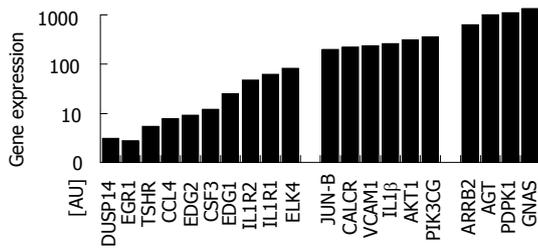

Figure 3 Arithmetic mean of gene activity. There was a statistically significant difference in the Wilcoxon signed-rank test between the genes with the highest expression, *GNAS*, *PDPK1*, *AGT*, and *ARRB2*, and moderate expression, *PIK3CG*, *AKT1*, *IL1 β* , *VCAM1*, *CALCR*, and *JUN-B*, and between the genes with moderate expression and the remaining genes with low expression.

analyzed for each reaction. A sample volume of 20 μ L was used for all assays which contained a 1X final concentration of SYBR green PCR master mix, 100 nmol gene specific primers, and 1 μ L of template. The assays were run using the following protocol: 95 $^{\circ}$ C for 10 min, 95 $^{\circ}$ C for 40 s, gene specific annealing temperature (58-62 $^{\circ}$ C) for 60 s for 40 cycles, followed by a gradual increase in temperature from 55 $^{\circ}$ C to 95 $^{\circ}$ C during the dissociation stage.

Following amplification, the instrument software was used to set the baseline and threshold for each reaction, as well as to determine the reaction efficiency. A cycle threshold (Ct) was assigned at the beginning of the logarithmic phase of PCR amplification and the difference in the Ct values [corrected for reaction efficiency: $Ct = Ct \times \log(\text{efficiency})/\log(2)$] of the housekeeping genes [mean Ct of glucuronidase (GUS) and beta-actin (BAKT)] and the gene of interest were used to determine the relative expression of the gene in each sample. Relative expression levels were then calculated as fold changes to the housekeeping genes, where each PCR cycle represented a 2-fold change.

The data of PCR and microarray experiments were then correlated using Pearson's coefficient.

The study was carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association.

RESULTS

Using the agglomerative hierarchical clustering methods we found statistically significant correlations between the *EDG1*, *DUSP14*, *EGR1* and *EDG2* genes and *PDPK1*, *PIK3CG*, *AKT1*, as well as clustering, though not statistically significant, for *GNAS* and *ARRB2* (Figure 1). Spearman's rank correlation coefficients were 0.762 for *PDPK1* and *AKT1*, 0.769 ($P < 0.05$) for *PDPK1* and *PIK3CG*, 0.769 ($P < 0.05$) for *AKT1* and *PIK3CG*, and 0.699 ($P < 0.05$) for *GNAS* and *ARRB2*. In case of *EDG1*, *DUSP14*, *EGR1* and *EDG2*, in 10 out of 12 patients there was no transcriptional activity. Except for the transcriptional factor *JUN-B* and the stage of fibrosis $r = 0.667$ ($P < 0.05$), we did not observe any correlation between the activity of the selected genes and the in-

vestigated clinical factors. Assessing patient distribution based on dendrograms of the investigated genotype and phenotype, a difference on the border of statistical significance was found in Fisher's exact test ($P = 0.08$). The patients with the highest diversity in gene expression (Figure 1) showed a statistically significant difference in gender and ALT activity ($P = 0.0046$ and $P = 0.035$, respectively). Based on expression activity, the genes were divided into a group with high activity, which included *GNAS*, *PDPK1*, *AGT* and *ARRB2* and statistically differed ($0.002 < P < 0.046$) from the genes with moderate and low expression. The group of genes with moderate activity of *AKT1*, *PIK3CG*, *IL1 β* , *VCAM1*, *JUN-B* and *CALCR* also showed a statistically significant difference ($0.002 < P < 0.041$) compared with genes which were classified as belonging to the group with low expression (Figure 3).

For the following genes: *JUN-B*, *EDG2*, *CCL4* and *EGR1*, estimated with the use of microarrays and qRT-PCR, there was a strong positive correlation, with Pearson's coefficient within the range of 0.61-0.99. For other genes, *IL1B*, *VCAM1*, *PIK3CG*, *AGT*, *PDPK1*, and *GNAS*, the correlation was weakly positive, with Pearson's coefficient ranging from 0.07 to 0.43; and for *IL1R1*, *IL1R2*, *CALCR*, *AKT1*, and *ARRB2* the correlation of expression estimated with the two methods was weakly negative (Pearson's coefficient ranging from -0.1 to -0.35).

DISCUSSION

With the exception of the correlation between *JUN-B* and fibrosis stage, we did not reveal any direct relationship between expression of genes related to metabotropic receptors in hepatocytes and anthropometric, histological and biochemical parameters that are commonly used for monitoring progression of chronic hepatitis. In assessing the connection between gene expression and the investigated clinical features, we found an impact of gender and concentration of ALT in the serum on changes in gene expression. The effect of these two factors was detected as the result of the analysis of not any single, but rather all the investigated genes. In the probability test, it was gender which better determined changes in gene activity rather than ALT. In chronic hepatitis C and B, gender is the factor which defines the course and prognosis of the disease^[1]. Changes in gene expression resulting from gender differences can influence the progression of liver disease.

In the present study, among different markers of inflammation and fibrosis in the liver parenchyma, only the ALT level differentiated the gene activity. Among the investigated genes, there were important mediators of inflammation, including IL-1 β , with their receptors, as well as chemokines and adhesion factors. Also protein products of such genes as *EDG1*, *EDG2*, *CALCR* are involved in the induction of the inflammatory response^[9,15]. In contrast to ALT, a small histological difference used to assess the inflammatory process in the

liver, classified in the majority of cases as score 1 or 2 according to METAVIR, were not useful in assessing gene expression.

The reported values of genes expression and their statistical diversity allow distinction between three groups of genes with high, moderate and low activity. Because there is no direct correlation between gene activity and clinical markers of chronic hepatitis, it is difficult to determine if the observed gene expression is induced or constitutional.

In the group of genes with the highest activity there were genes of the main metabotropic receptor proteins, *GNAS*, *PDPK1* and *ARRB2*. Their high transcriptional activity is related to their essential role in the metabotropic receptor system. *GNAS* expression, despite individual differences, showed the highest correlation with *ARRB2* among the investigated genes. Proportional to the level of stimulation of GPCR, *ARRB2* triggers the mechanism of receptor internalization, which is an adaptation to overstimulation^[16]. Also mRNA encoding AGT was characterized by high expression. This observation remains in accordance with current literature and is associated with the liver being the main site of AGT synthesis^[17]. Because AGT is incorporated only indirectly by the renin-angiotensin system in the progression of liver fibrosis^[18,19], its gene activity did not correlate with the histological assessment of this process.

In the group of genes with moderate activity, there were genes which encode products involved in the pathogenesis of liver injury. Disturbances of *PIK3CG* described in chronic hepatitis as caused by NS5 protein of hepatitis C virus and HBx protein of hepatitis B virus destabilize and damage hepatocytes^[20,21]. However, in the present study, expression of *PIK3CG* did not correlate with the markers of liver injury.

As there were no cases with advanced fibrosis among the investigated patients, we did not observe any increased expression of *VCAM1*, which is characteristic only for liver cirrhosis^[22].

The correlation of expression of phosphatidylinositol kinases observed in the study confirms the functional association of the investigated enzymes. A significantly higher expression of *PDPK1* compared with *PIK3CG* is due to the amplification of *PDPK1* during phosphorylation catalyzed by *PIK3CG*. *PDPK1* in turn activates *AKT1* correspondingly; therefore, the 3-fold higher activity of *PDPK1* is noteworthy.

Among the investigated phosphatases that dephosphorylate active kinases, *DUSP14* was measured. However, this phosphatase, which is not functionally associated with the presently studied kinases, showed low expression values and was not correlated with the expression of kinases. Interestingly, a statistically significant correlation was determined between the stage of fibrosis and expression of transcriptional factor *JUN-B*. This factor, in the malfunctioning of the liver, is responsible for reprogramming of hepatocyte genes to the phase of cell proliferation^[23,24]. Its increase is frequently observed

in liver injury and hepatic carcinogenesis^[25].

The higher expression of this factor linked to carcinogenesis correlated with a low activity of the genes *CCLA*, *EGR1*, *EDG2* involved in the induction of apoptosis and suppression of neoplasia^[26].

The results obtained in the present study indicate that qRT-PCR has certain limitations as a validation tool for oligonucleotide microarray studies. Only four genes have shown a similar expression pattern between results obtained with the use of both techniques. A weak positive and negative correlation observed for other genes might result from potential pitfalls inherent in both approaches, and might be a source of errors encountered while employing each method.

However, the range of differences in the correlation coefficient observed in the present study remains within the range described in the literature, from -0.48 to 0.94^[27,28]. The results obtained in this study reflect the debate over which methods produce the most accurate measurements of gene expression.

In conclusion, gender and inflammation activity, as determined by ALT level, were associated with a more diverse pattern of metabotropic receptor gene expression. The highest gene expression was observed for mRNA of the main components of the metabotropic receptor pathway, such as *GNAS*, *PDPK1*, *ARRB2*, and correlated with mRNA of angiotensinogen synthesized in the liver. The correlation of expression of protein kinases *PDPK1*, *PIK3CG* and *AKT1* points to a functional association of these enzymes. The genes suppressing carcinogenesis, *CCLA*, *EGR*, *EDG2*, were characterized by the lowest expression levels among the investigated genes. On the other hand, *JUN-B*, a factor potentially involved in the development of hepatocellular cancer, was characterized by a 20-fold higher level of expression.

COMMENTS

Background

Metabotropic G protein-coupled receptors activate various signaling pathways, which trigger multiple sub-cellular reactions. Microarray-based analysis of expression of hepatocyte genes related to metabotropic receptors can reveal the molecular basis of liver diseases.

Research frontiers

The natural course of chronic viral hepatitis is associated with progression of fibrosis and the risk of hepatocellular carcinoma development. Current data indicate that intracellular signaling disturbances have an impact on progression of inflammation and fibrosis as well as carcinogenesis in the course of chronic hepatitis.

Innovations and breakthroughs

The highest gene expression was in the mRNAs of the main components of the metabotropic receptor pathways, such as the α subunit of G-coupled protein, phosphoinositide-dependent protein kinase (*PDPK1*) and arrestin β and correlated with the mRNA for angiotensinogen synthesized in liver. Carcinogenesis suppressor genes such as chemokine *CCL4*, transcription factor *EGR1* and lysophosphatidic acid receptor were characterized by the lowest expression, while the factor potentially triggering hepatic cancer, *JUN-B*, had 20-fold higher expression. Comparable expression of genes encoding protein kinases *PDPK1*, phosphoinositide 3-kinase and protein kinase A confirms a functional link between these enzymes. Gender and inflammation severity, measured by alanine aminotransferase activity, were characterized by different expression patterns

of genes related to metabotropic receptors.

Applications

Results of the presented work enables better delineation of mechanisms governing the course of chronic hepatitis and form the basis for future investigations.

Terminology

G-protein-coupled receptors are a family of the cell surface receptors, which receive, integrate and enhance most of the extracellular signals implicated in cell growth, proliferation, and survival. Microarray DNA technology with genomic profiling and cluster analysis allows determination of the role of genes in the pathogenesis of liver injury.

Peer review

This is a good descriptive study in which authors screen for genes related to metabotropic receptors family that might be involved in the development of chronic hepatitis. The results are interesting and suggest that a microarray-based analysis of hepatocyte metabotropic G protein-related gene expression can reveal the molecular basis of chronic hepatitis.

Abstract

AIM: To investigate the cytotoxic effects of spray-dried extracts of *Phyllanthus niruri* in combination with cisplatin on two cancer cell lines.

METHODS: Colorectal carcinoma (HT29) and human hepatocellular carcinoma (HepG2) cells were treated with spray-dried extracts of *Phyllanthus niruri* (SDEPN) either alone or in combination with cisplatin at different concentrations (0.5 mg/mL and 1 mg/mL) for 4 h and 24 h. To verify and quantify cancer cells treated with these products as well as identify the cell cycle stage and cell viability, we stained the cells with propidium iodide and assessed them by flow cytometry. The percentage of cells in different cell cycle phases was quantified and data were expressed as histograms. Significant differences between groups were determined using analysis of variance and Bonferroni's test, as indicated. A value of $P < 0.05$ was considered to be statistically significant.

RESULTS: SDEPN had significantly different cytotoxic effects on HT29 (2.81 ± 0.11 vs 3.51 ± 1.13 , $P > 0.05$) and HepG2 (5.07 ± 0.3 vs 15.9 ± 1.04 , $P < 0.001$) cells when compared to control cells for 4 h. SDEPN also had significantly different cytotoxic effects on HT29 (1.91 ± 0.57 vs 4.53 ± 1.22 , $P > 0.05$) and HepG2 (14.56 ± 1.6 vs 35.67 ± 3.94 , $P < 0.001$) cells when compared to control cells for 24 h. Both cell lines were killed by cisplatin in a dose-dependent manner compared to control cells (HepG2 cells for 4 h: 10.78 ± 1.58 vs 53.89 ± 1.53 , $P < 0.001$; 24 h: 8.9 ± 1.43 vs 62.78 ± 1.87 , $P < 0.001$ and HT29 cells for 4 h: 9.52 ± 0.913 vs 49.86 ± 2.89 , $P < 0.001$; 24 h: 11.78 ± 1.05 vs 53.34 ± 2.65 , $P < 0.001$). In HT29 cells, pretreatment with SDEPN and subsequent treatment with cis-

platin resulted in a greater number of cells being killed (12.78 ± 1.01 vs 93.76 ± 1.6 , $P < 0.001$). HepG2 cells showed significant cell killing with treatment with SDEPN when combined with cisplatin (12.87 ± 2.78 vs 78.8 ± 3.02 , $P < 0.001$).

CONCLUSION: SDEPN is selectively toxic against two cancer cell lines. Moreover, SDEPN in combination with cisplatin induces a synergistic increase in the cell death of both HT29 and HepG2 cells.

INTRODUCTION

Phyllanthus niruri has many effective traditional uses for a wide variety of diseases. Some of the medicinal uses have been supported in experimental models, suggesting that the plant extracts possess various pharmacological properties. Due to its impressive preclinical therapeutic potential, extracts of species of the genus *Phyllanthus* have been evaluated to treat hypertension, jaundice, diabetes, hypercalciuria, and urolithiasis^[1]. Other studies revealed preclinical pharmacological activity and therapeutic potential of phytochemicals isolated from *Phyllanthus niruri*. The species has demonstrated an antimutagenic and anticarcinogenic action^[2], antitumor^[3], antioxidant^[4], hepatoprotective^[5,6] and antihyperuricemic properties^[7], as well as antihyperlipemic activity^[8,9].

Phytochemicals exhibit different structural characteristics with various pharmacological actions. For example, lignans have excellent hepatoprotective^[10,11] and anti-viral properties^[12], whereas terpenes exhibit anti-microbial activities^[13]. Flavonoids from *Phyllanthus niruri* have been shown to have antioxidant^[14], antileishmanial^[15], and anti-inflammatory properties^[16]. Phytochemical studies have shown that extracts of genus *Phyllanthus* contain a variety of components, including gallic acid^[1,17]. Furthermore, studies have demonstrated cytotoxic activity of gallic acid on the human promyelocytic leukemia HL-60 cell lines^[18,19]. Gallic acid has also been shown to induce apoptotic cell death in HSC-2 and HL-60 cells^[20].

More importantly, no side effects or toxicities have been reported for this herb after many years of research. Although extensive research has been conducted, there is still an abundance of unanswered questions regarding *Phyllanthus niruri*, particularly towards understanding the mechanism of biological activity of phytochemicals from the herb with emphasis on components that have anti-human immunodeficiency virus (HIV)^[21] and anti-hepatitis B^[22] properties. *Phyllanthus niruri* has been found to exhibit a marked inhibitory effect on the hepatitis B virus, as evidenced by its exhaustive utility in cases of chronic jaundice. However, to date, no research has focused on the identification and validation of active pharmacophores of *Phyllanthus niruri* that are responsible for the reported inhibitory effect of its aqueous extract on HIV^[21]. Investigations have examined anti-HIV effects of the alkaloidal extract from *Phyllanthus niruri* on human cell lines. An alkaloidal extract of *Phyllanthus niruri* showed suppressive activity on strains of HIV-1 cultured on the huT-4 cell line^[21].

Directed studies of botanical extracts may lead to the discovery of new agents with improved and intriguing pharmacological properties. This may be achieved by molecular modeling studies that assess the interactions of bioactive phytochemicals from *Phyllanthus niruri* with their respective molecular targets. Moreover, upon improvement of binding affinity to the specified target by virtual chemical modification of existing pharmacophores, new small molecules may be identified and synthesized in the laboratory^[23].

Other species of the genus *Phyllanthus*, such as *Phyllanthus polyphyllus* and *Phyllanthus emblica*, have demonstrated growth inhibitory activity with a certain degree of selectivity towards the two cancer cell lines tested. It has been previously shown that cisplatin can inhibit the growth of colorectal carcinoma (HT29) and human hepatocellular carcinoma (HepG2) cells in a dose-dependent manner^[20,24,25].

In this study, we investigated the antiproliferative or cell-killing activities of spray-dried extracts of *Phyllanthus niruri* on the human colorectal carcinoma HT29 and human hepatocellular HepG2 cell lines. In addition, we assessed the capacity of these extracts to potentiate the action of cis-diamminedichloroplatinum II (cisplatin).

MATERIALS AND METHODS

Preparation of *Phyllanthus niruri* spray dried extracts

A spray-dried extract of *Phyllanthus niruri* (SDEPN) containing 12.33 mg/g of gallic acid^[26] and 94.4 mg/g of total flavonoids^[27] was prepared following the manufacturer's instructions using a Spray Dryer Production Minor (GEA Niro, Denmark).

Cell culture

The human colorectal cancer cell line HT-29 and human hepatocellular carcinoma cell line HepG2 were

purchased from the Culture Collection of the Faculty of Medicine, University of São Paulo. The cells were maintained in Dulbecco's modified Eagle's medium (DMEM; Life Technologies, Inc., Grand Island, NY, United States) supplemented with 10% (v/v) heat-inactivated fetal bovine serum.

Flow cytometry

To verify and quantify cells treated with SDEPN extract and to identify the cell cycle stage and cell viability, we stained cells with propidium iodide (PI). PI emits different fluorescence intensities depending on the phase of the cell cycle, which in turn are captured by the photomultiplier detectors in a flow cytometer (BD Facs canto II). Cancer cells were plated in 6-well plates at a cell density of 5×10^5 cells/well in 2 mL of medium. Cells were treated with SDEPN alone, cisplatin alone, or SDEPN followed by cisplatin. After 24 h, the cells were treated with a series of SDEPN concentrations (0-75 mmol/L) for 4 h or 24 h. After this incubation, the medium containing SDEPN was replaced with medium containing 2.5 or 12 μ mol/L cisplatin. The cells were harvested by trypsinization when they reached approximately 80% confluence. The cells were placed in 70% ethanol and centrifuged for 5 min at 300 g. They were then resuspended in 200 μ L of a PI solution (20 mL PBS, 20 μ L 0.1% Triton X-100, 200 mg/mL RNase, and 20 μ g/mL PI), placed in FACS tubes, and incubated for 30 min at room temperature protected from light. The labeled cells were captured with a FACScalibur cytometer (BD Bioscience, Franklin Lakes, NJ, United States) and analyzed with the software CELLQuest™ (BD Biosciences). The percentage of cells in different cell cycle phases was quantified and data were expressed as histograms.

Statistical analysis

All experiments were performed at least in triplicate. The significance of differences between groups was calculated by applying analysis of variance and Bonferroni's test, as indicated. A value of $P < 0.05$ was considered to be statistically significant.

RESULTS

Cytotoxic effects of SDEPN on HT29 and HepG2 cells

The effects of SDEPN on cell killing in two cancer cell lines were determined by flow cytometry. All cell lines were killed in a dose-dependent manner after exposure to the plant extracts (Figure 1). SDEPN had significantly different cytotoxic effects on HT29 (2.81 ± 0.11 vs 3.51 ± 1.13 , $P > 0.05$) and HepG2 (5.07 ± 0.3 vs 15.9 ± 1.04 , $P < 0.001$) cells when compared to control cells for 4 h. SDEPN also had significantly different cytotoxic effects on HT29 (1.91 ± 0.57 vs 4.53 ± 1.22 , $P > 0.05$) and HepG2 (14.56 ± 1.6 vs 35.67 ± 3.94 , $P < 0.001$) cells when compared to control cells for 24 h. These results indicated that the plant extract was selectively toxic against the cancer cells tested. We therefore hypoth-

esized that the combination of these plant extracts with chemotherapeutic drugs may have a synergistic cytotoxic effect on these cells. Primary flow cytometry analyses are shown in Figure 2.

The effect of cisplatin on HT29 and HepG2 cells

Using flow cytometry, we assessed the effects of cisplatin on the proliferation of HepG2 and HT29 cells. Both cell lines were killed in a dose-dependent manner compared to control cells (HepG2 cells for 4 h: 10.78 ± 1.58 vs 53.89 ± 1.53 , $P < 0.001$; 24 h: 8.9 ± 1.43 vs 62.78 ± 1.87 , $P < 0.001$ and HT29 cells for 4 h: 9.52 ± 0.913 vs 49.86 ± 2.89 , $P < 0.001$; 24 h: 11.78 ± 1.05 vs 53.34 ± 2.65 , $P < 0.001$; Figure 1). Primary flow cytometry analyses are shown in Figure 2.

The combination of cisplatin and Phyllanthus niruri extracts has a synergistic cytotoxic effect on HT29 and HepG2 cells

HT29 cells did not undergo cell death when SDEPN was used alone ($P > 0.05$) but HepG2 cells ($P < 0.001$) showed significant cell killing with treatment with SDEPN alone (Figure 1), but also very significantly (12.87 ± 2.78 vs 78.8 ± 3.02 , $P < 0.001$) when combined with cisplatin (Figure 1). However, HT29 cells underwent cell death (12.78 ± 1.01 vs 93.76 ± 1.6 , $P < 0.001$) when treated with SDEPN for 24 h prior to cisplatin treatment (Figure 1). The primary images of flow cytometry analysis can be seen in Figure 2.

In HT29 cells, pretreatment with SDEPN and subsequent treatment with cisplatin resulted in a greater number of cells being killed compared to treatment with cisplatin or SDEPN alone (Figure 1A and B). This increase in the number of HepG2 cells killed in response to combination treatment was observed at the lower concentration of SDEPN (Figure 1C and D). Therefore, pretreatment with SDEPN allowed the cells (HT29) to be sensitized to killing induced by cisplatin. This suggests that this cell type is more able to adapt to stressful conditions.

DISCUSSION

In this study, the growth inhibitory activity of SDEPN extract alone and in combination with cisplatin was investigated in HT29 and HepG2 cells. Our results indicated that SDEPN extract significantly inhibited the growth of both cell lines in a dose-dependent manner when combined with cisplatin.

Cisplatin is a well-known cancer therapeutic agent that causes high toxicity to normal tissues during cancer therapy, inducing cell death through interaction of the platinum complex with DNA molecules which induces crosslinking in DNA^[28,29]. The platinum compound is used to treat various types of human solid tumors^[30]. The major limitation to clinical use of cisplatin is the adverse effects, mainly nephrotoxicity, caused by the compound^[31]. In addition to DNA interactions, cisplatin

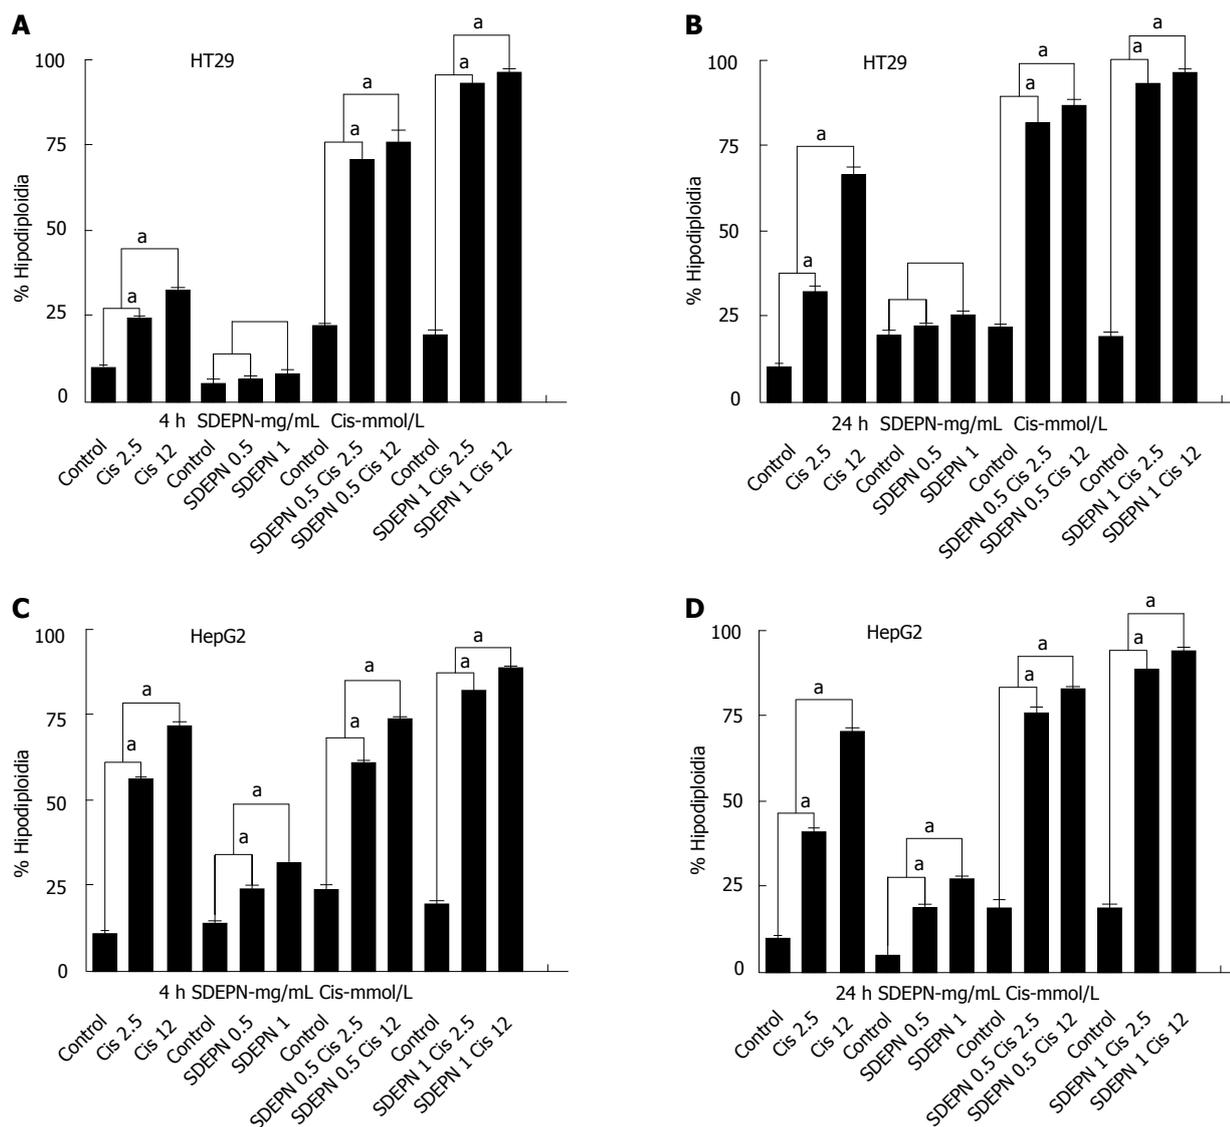

Figure 1 HT29 cells and HepG2 cells were treated for 4 h or 24 h with cisplatin alone, spray-dried extract of *Phyllanthus niruri* alone, or both. A, C: 4 h; B, D: 24 h. ^a $P < 0.05$ vs control group. SDEPN: Spray-dried extract of *Phyllanthus niruri*; Cis: Cisplatin; HT29: Colorectal carcinoma; HepG2: Human hepatocellular carcinoma.

is capable of generating oxidative stress through mitochondrial dysfunction, which results in the increased production of reactive oxygen species (ROS)^[32]. Therefore, our data show that HT29 cells are more resistant to SDEPN- or cisplatin-mediated cell death, and this resistance may be related to their ability to adapt to stressful conditions. In addition, HepG2 cells were more sensitive to both treatments, suggesting that these cells may be less adapted to stress. In this study we found that the combination of SDEPN with cisplatin induced growth inhibition and cell death at different dose levels in HT29 and HepG2 cell lines.

The mechanism of action of some plant extracts is still unclear, since they are not a single active ingredient but rather consist of multiple compounds that could potentially induce the observed effects^[1,23]. Plant-derived polyphenols, including gallic acid^[33,34] and tannins^[35], were reported to be the main components of *Phyllanthus*

niruri extracts^[1]. Therefore, the effects of SDEPN may induce apoptosis and cell death in the cell lines used in this study through multiple pathways due to the multiple components present in the extract. The active ingredients in *Phyllanthus niruri* that exert anticancer effects may include polyphenols, such as gallic acid, flavanoids or tannins, which are abundant in the herb. However, the detailed mechanism responsible for the anticancer effect of SDEPN extract and identification of the actual functional components require further elucidation.

It has been previously demonstrated that the effect of gallic acid on cancer cells, particularly lung cancer cells, involves caspase activation and oxidative processes^[33]. In addition, gallic acid has the capacity to induce apoptosis and increase the efficacy of cisplatin in LL-2 lung cancer cells^[34].

Our study provides corroborative evidence that SDEPN has selective cytotoxic effects against HT29 and HepG2

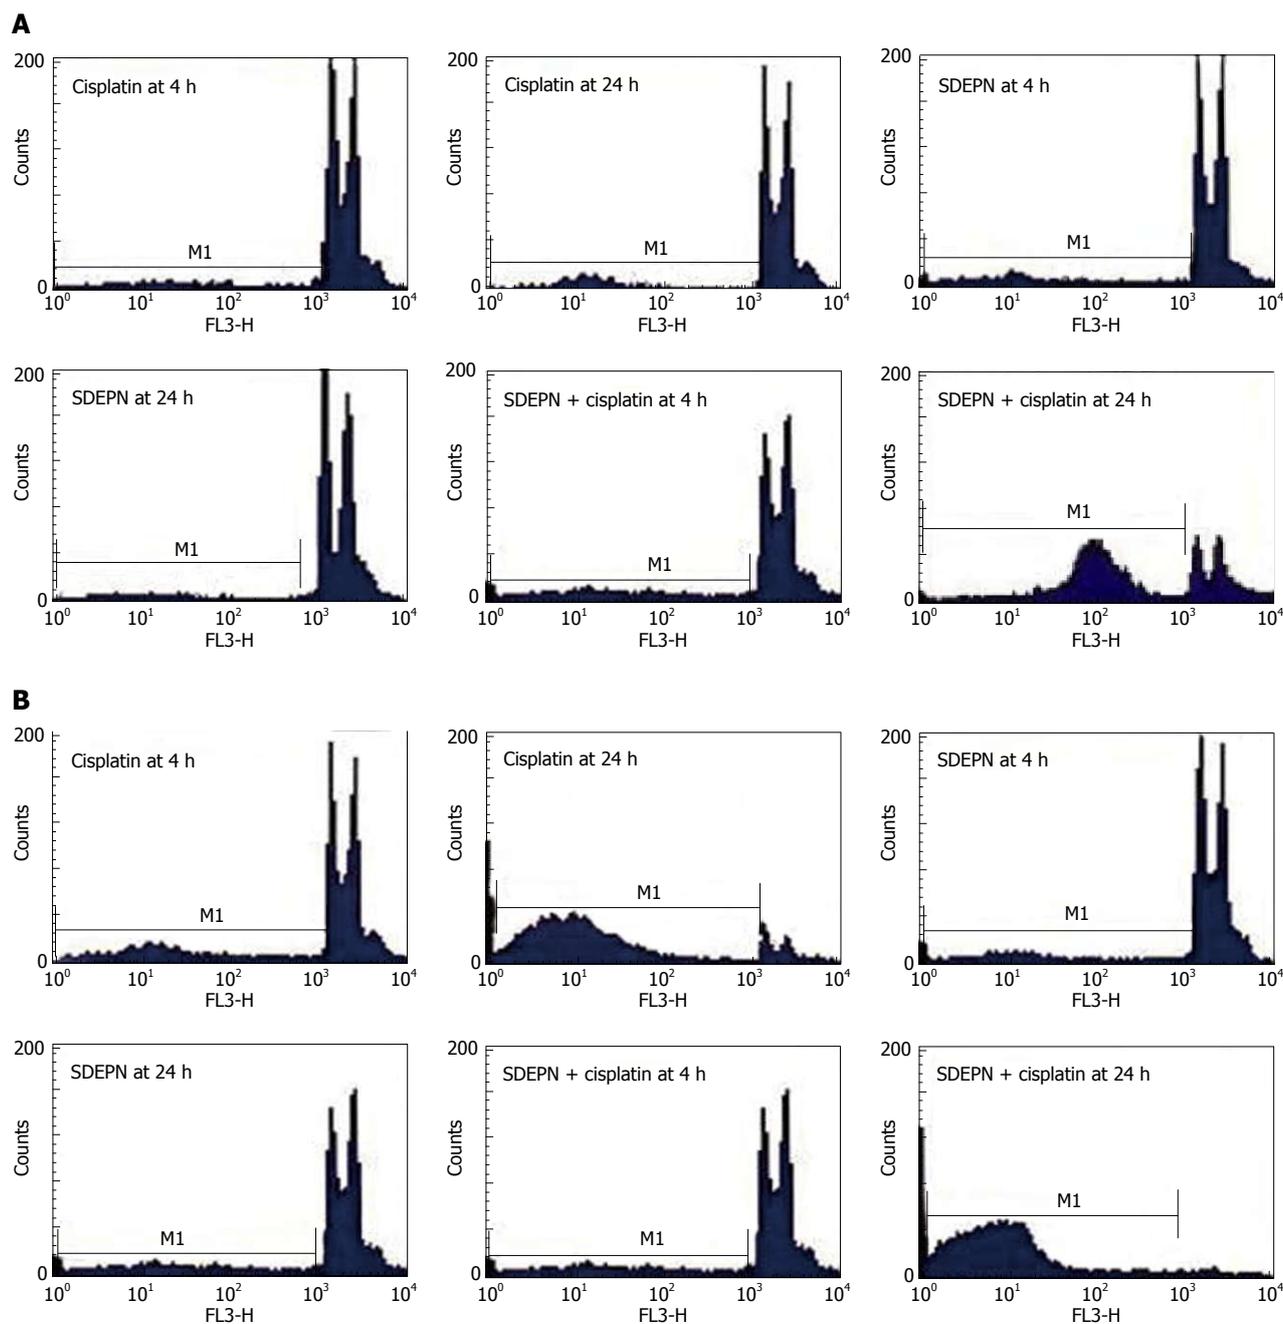

Figure 2 Effects of cisplatin, spray-dried extract of *Phyllanthus niruri*, or both on HT29 cells or HepG2 cells as assessed by flow cytometry. A: HT29 cells; B: HepG2 cells.

cells. Moreover, a synergistic effect was seen when the cells were treated with the extract in combination with cisplatin. This finding supports our hypothesis that combinations of plant extracts and chemotherapeutic agents may allow for a reduction in the dosage of the more toxic chemotherapeutic agent while retaining the therapeutic efficacy and minimizing toxicities. The induction of cell death by SDEPN may increase the sensitivity of HT29 cells to cisplatin-mediated cytotoxicity. Other species of the genus *Phyllanthus* have demonstrated growth inhibitory activity with a certain degree of selectivity towards the two cancer cell lines tested^[20].

The findings of this study support our hypothesis

that combinations of plant extracts and chemotherapeutic agents allow for a reduction in the dosage of the latter (i.e., cisplatin), while maintaining therapeutic efficacy. Moreover, the induction of cell death by SDEPN may be a strategy for increasing the sensitivity of HT29 cells to cisplatin-mediated cell death.

COMMENTS

Background

Phyllanthus niruri is a widespread tropical plant that is commonly found in coastal areas of Mexico, Argentina, and Brazil. In Brazil, some plant extracts have been distributed to patients by the Public Health Programme since 2010

as an adjunctive therapy for various diseases. The extract from aerial sections of *Phyllanthus niruri* was included in this list due to the long history of use in traditional medicine for the treatment of kidney and bladder diseases, intestinal infections, diabetes, and hepatitis B. Furthermore, this study has demonstrated an *in vitro* pro-death potential in cancer cells when *Phyllanthus niruri* is associated with cisplatin. *In vivo* studies are still needed to confirm our findings.

Research frontiers

Currently, a variety of effective phytochemicals have been tested in cancer treatment, which are used alone or in combination with chemotherapeutic agents for treatment. A spray-dried extract from *Phyllanthus niruri* (SDEPN) was found to be selectively toxic against two cancer cell lines and induced an increase in cell death of HT29 and HepG2 cells when used in combination with cisplatin. HT29 cells did not undergo cell death when SDEPN was used alone. The mechanism of this effect is currently unknown, but may involve apoptosis, since a major component of SDEPN extract is gallic acid, which has been shown to induce apoptotic pathways.

Innovations and breakthroughs

In this report, the authors have demonstrated that combinations of SDEPN with cisplatin in HT29 and HepG2 cell lines have a more potent effect than either agent alone.

Applications

Spray-dried extract of SDEPN appears to be cytotoxic against hepatocellular carcinoma and less toxic against colorectal carcinoma. A combination of SDEPN extract with a chemotherapeutic agent may therefore enhance the efficacy of each component against these cancers. Future *in vivo* studies will be performed by our group to study the anticancer activity of SDEPN alone and in combination with cisplatin as well as the toxicity against normal tissues.

Terminology

Dried herbal extracts are widely used as therapeutic products with improved pharmaceutical properties, such as stability and content uniformity. Additionally, dried extracts are successfully used to obtain solid dosage forms that contain a high dose of herbal extracts, such as capsules and tablets. Therefore, spray drying is the most commonly used procedure to obtain dried extracts (spray-dried extracts) in the herbal processing industry.

Peer review

The manuscript is well written and the findings are interesting to some extent. However, some concerns need to be addressed.

Abstract

AIM: To investigate whether suspected blood indicator (SBI) in capsule endoscopy (CE) is affected by background color and capsule passage velocity.

METHODS: Experimental models of the small intestine constructed from paper in a variety of colors were used to simulate the background colors observed in CE images. The background colors studied included very pale yellow, yellow, very pale magenta, light grayish pink, burnt sienna, and deep and dark brown, and red spots were attached inside them. An endoscopic capsule was manually passed through the models. The rate of detection of the red spots by the SBI was evaluated based on the colors of the models and the capsule passage velocities (0.5 cm/s, 1 cm/s, and 2 cm/s).

RESULTS: The rate of detection of the red spots by

the SBI differed significantly according to the background color of the model ($P < 0.001$). Detection rates were highest for backgrounds of very pale magenta, burnt sienna, and yellow, in that order. They were lowest for backgrounds of dark brown and very pale yellow. The rate of detection of red spots by the SBI tended to decrease at rapid capsule passage velocities (1-2 cm/s) compared to slow velocities (0.5 cm/s) for backgrounds of very pale yellow ($P = 0.042$), yellow ($P = 0.001$), very pale magenta ($P = 0.002$), and burnt sienna ($P = 0.001$). No significant differences in the rate of detection were observed according to velocity for light grayish pink ($P = 0.643$) or dark brown ($P = 0.396$).

CONCLUSION: SBI sensitivity was affected by background color and capsule passage velocity in the models. These findings may facilitate the rapid detection of bleeding lesions by CE.

INTRODUCTION

Capsule endoscopy (CE) is a useful method for the diagnosis of small bowel diseases, such as gastrointestinal bleeding of an unknown cause^[1-7]. However, it is relatively

time consuming to examine and interpret the results. To reduce the reading time of this procedure, the RAPID software (Given Imaging Ltd., Duluth, GA, United States) contains a suspected blood identification system, which identifies hemorrhages and suspicious vascular lesions by recognizing red-colored pixels against different colored backgrounds that may be encountered in the small intestine^[8].

Reports on the usefulness of the suspected blood indicator (SBI) generally show a low and variable overall sensitivity for lesions, ranging from 20% to 56.4%^[8-12]. Positive predictive values are also observed to be variable, from 24% to 90.3%. Therefore, SBI generates false-positive and false-negative results, and its clinical usefulness has not been verified.

Active bleeding is the most important factor affecting SBI sensitivity. The sensitivity increases to a range of 58.3% to 93% in cases of active bleeding. Additionally, the sensitivity of SBI may also be affected by other factors. However, not all of the factors that can affect SBI sensitivity have been fully assessed.

The RAPID software includes a tissue color bar function that represents the average color of the region of interest in the intestine and provides information to help determine the anatomical location of a lesion^[13]. When the small intestine is observed *via* CE, on-screen images are primarily composed of the intestinal mucosa and liquid present in the lumen. The background color behind a lesion may vary according to the color of the small intestinal mucosa, which is affected by patient factors, such as hemoglobin and bilirubin levels. Thus, very pale magenta, which is the normal mucous membrane color, can appear very pale yellow in patients with anemia or burnt sienna or deep brown in patients with jaundice. The background color can also be affected by the presence of intestinal fluid. The color and the degree of transparency of the fluid can vary depending on the presence of bile, debris, stool residue, and blood in the intestine. Therefore, a combination of these elements may produce many different colors that can be presented on screen during CE. The various background colors of lesions may influence the detection of SBI in CE images.

The velocity of the passage of a capsule through the small intestine can vary depending on the presence of underlying disease, such as diabetes and disorders of intestinal peristalsis^[14]. Furthermore, the passage velocity can vary in different sections of the small intestine. Capsule movement may be influenced regionally by the gastric emptying time, chronic intestinal motility disorders, small bowel obstruction, intestinal diverticulosis, and other factors^[15]. These differences in capsule passage velocity according to the clinical circumstances may also affect SBI sensitivity. It would be useful to examine the different factors that influence the sensitivity of the SBI for shortening the time required to interpret CE-generated video.

Therefore, we investigated the rate of detection of red spots using SBI according to the background colors of the screen image and the capsule passage velocity in experimental models of the small intestine to determine

the factors that affect SBI sensitivity in diverse clinical situations.

MATERIALS AND METHODS

Experimental small intestine model

To represent a variety of background colors that may be encountered in clinical situations, experimental small intestine models prepared with seven colors of paper were produced. The colors included very pale yellow, yellow, very pale magenta, light grayish pink, burnt sienna, deep brown, and dark brown (Figure 1). Very pale magenta corresponds to the color of a normal intestinal mucous membrane. Lighter colors can be observed in conditions such as anemia, and darker colors are visible in mucosae with concentrated bile. The Hue and Tone 120-color system that was developed by the Nippon Color and Design Institute was used to define the colors and hues used in this study, and all color saturation levels were uniform^[16]. Small bowel models that were 3 cm in diameter and 50 cm in length were constructed, and ten 6-mm red spots were attached inside the models at 5-cm intervals to simulate angiodysplasia.

Investigation of capsule passage

A CE device (M2A capsule; Given Imaging Ltd., Yoqneam, Israel) was fixed to a solid-line cardiac catheter and passed inside the cylinder of each small intestine model at a constant speed (0.5 cm/s). The screen image from the CE instrument as it passed through model was observed using a real-time viewer (Figure 2). To detect differences in the SBI sensitivity according to the background color, 150 red dots were required to achieve a power of 80% ($\alpha = 5\%$) according to a preliminary pilot study. Therefore, through repetition, the CE instrument was guided past 150 red spots on each of the background colors, and the number of red tags on the scroll bar was examined during the application of SBI.

Differences in the SBI sensitivity were examined when the CE was passed through the intestinal models at speeds of 0.5 cm/s, 1 cm/s, and 2 cm/s.

Statistical analysis

For all statistical analysis in this study, SPSS version 12.0 (SPSS Inc., Chicago, IL, United States) was used. Continuous variables were expressed as the mean \pm SD or as the median. For comparative analysis of continuous variables, the Student's *t*-test, the Mann-Whitney *U* test, or the Kruskal-Wallis test were used depending on the normality of the data. For the comparison of nominal variables, Fisher's exact test and a χ^2 test were used. A post-hoc Bonferroni's correction was applied for comparative analysis of the groups. All values with a *P* < 0.05 were considered statistically significant.

RESULTS

Detection according to background color

We compared the number of red tags recognized by the

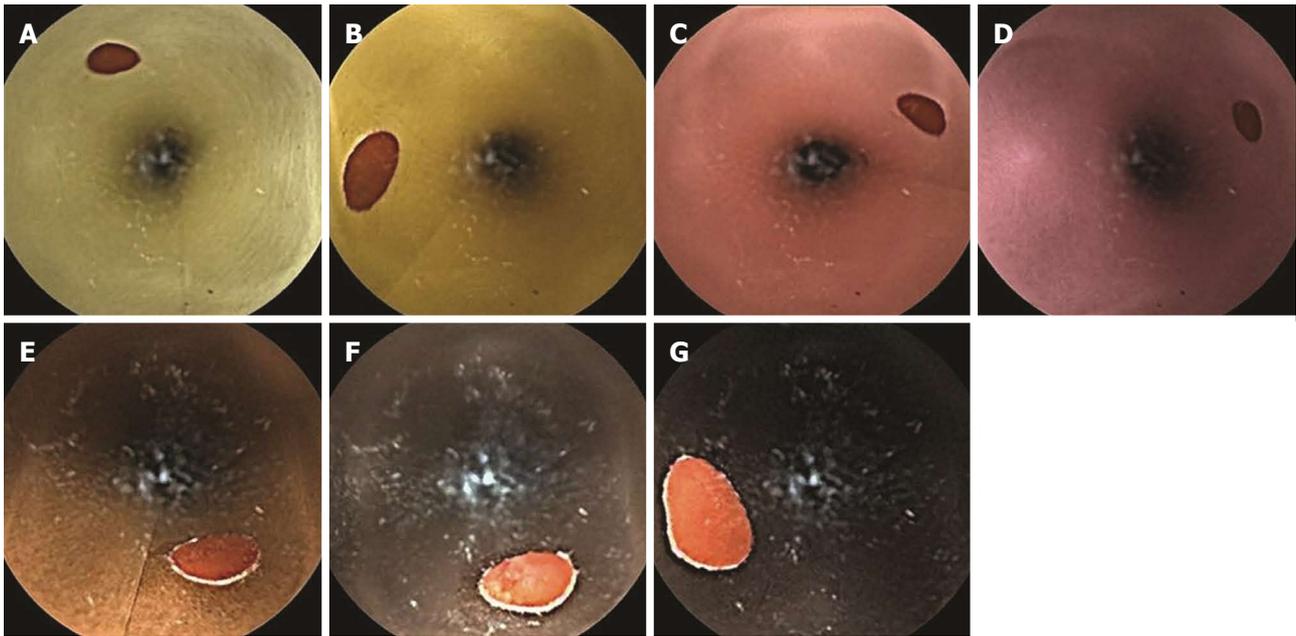

Figure 1 Endoscopic findings on backgrounds of different colors. A: Very pale yellow; B: Yellow; C: Very pale magenta; D: Light grayish pink; E: Burnt sienna; F: Deep brown; G: Dark brown.

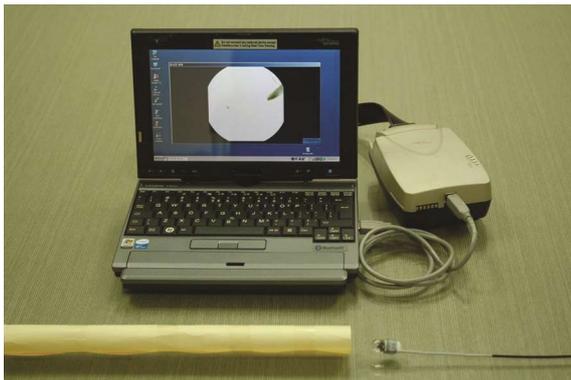

Figure 2 Experimental settings used for this study. A capsule endoscopy (CE) device was manually passed through models of the small bowel. The CE screen was observed using a real-time viewer.

SBI in the small intestine model for each background color. A significant difference was observed in the SBI detection rates on different background colors ($P < 0.001$, Table 1). The detection rates were highest for very pale magenta, burnt sienna, and yellow, in that order, and they were lowest for dark brown. Thus, the sensitivity of the SBI was the highest for a background of very pale magenta, which represented a normal mucosal color with good bowel cleansing, and the sensitivity was the lowest for dark brown, which represented concentrated bile. For a background of very pale yellow, which represented light bile, the detection rate of the red spots was low.

The sensitivity of the SBI for different background colors, analyzed with Bonferroni's correction, showed a significant difference for very pale magenta, for which the detection rate was the highest, compared to that of the other colors. The detection rate with a burnt sienna

Color	Detection rate (%)	Rank
Very pale yellow	16/150 (10.7)	6
Yellow	28/150 (18.7)	3
Very pale magenta	64/150 (42.7)	1
Light grayish pink	19/150 (12.7)	4
Burnt sienna	36/150 (24.0)	2
Deep brown	18/150 (12.0)	5
Dark brown	5/150 (3.3)	7
Total	186/1050 (17.7)	$P < 0.001$

background was different from that with a very pale yellow and dark brown background, and the detection rate with a yellow background was different from that when a dark brown background was used (Table 2).

Detection according to capsule passage velocity

Generally, statistically significant differences were observed in the SBI detection rates of the red spots according to the capsule passage velocity in the small intestine models of some colors (Figure 3). Detection of the red spots by SBI tended to decrease at rapid capsule passage velocities (1-2 cm/s) compared to slow velocities (0.5 cm/s) for very pale yellow ($P = 0.042$), yellow ($P = 0.001$), very pale magenta ($P = 0.002$), and burnt sienna ($P = 0.001$) backgrounds. No significant differences were observed according to velocity for light grayish pink ($P = 0.643$) or dark brown ($P = 0.396$). Thus, differences according to velocity were highly pronounced in models constructed from colors that showed high SBI detection rates, and differences in sensitivity were not present for models with colors that had lower detection rates.

Table 2 Differences in detection rate among background colors using Bonferroni's correction

Color	Detection rate (%)	Dark brown	Very pale yellow	Deep brown	Light grayish pink	Yellow	Burnt sienna	Very pale magenta
Dark brown	3.3	1	0.0130	0.0049	0.0029	0.0000	0.0000	0.0000
Very pale yellow	10.7		1	0.7161	0.5901	0.0506	0.0023	0.0000

DISCUSSION

CE was developed to diagnose lesions of the small intestine, and it is a useful method for diagnosing obscure gastrointestinal bleeding, Crohn's disease, polyposis syndrome, and small bowel tumors^[2-4,17-19]. CE has a higher diagnostic rate than radiological diagnosis methods and is less invasive and easier to perform than enteroscopy^[2-4,7,20]. However, CE has the disadvantage of requiring time to interpret multiple images^[21,22]. Usually, 45 min to two hours of viewing are required, although the reading time can be shortened using the multiview function, which allows the simultaneous observation of several images^[22]. To solve these problems, particularly in patients with suspected small intestine bleeding, SBI was developed^[10,23,24].

SBI can display frames that depict red zones during CE. The technique is activated in the first image frame of the duodenum and operates only in frames corresponding to the small intestine. The function is activated by an SBI view button within the software, resulting in the automatic identification of red pixels on the screen as

red hash marks on the scroll bar. Frame with suspected bleeding lesions can be selected in this way. Therefore, SBI helps physicians to review the video quickly, and bleeding lesions can be found easily. SBI provides supplementary information, but it does not replace the analysis of the video image. All frames recognized using the SBI feature should be later examined by a clinician in more detail.

In the first report on the accuracy of SBI in 24 patients by Liangpunsakul *et al.*^[8] in 2003, the sensitivity of the SBI was 25.7% (Table 3). However, when only active bleeding lesions were targeted, the sensitivity increased to 81.2%. In another study by Signorelli *et al.*^[12], the sensitivity was only 40.9% in 100 patients, although it increased to 60.9% in the presence of red blood or actively bleeding lesions. In another study, the overall sensitivity was 45%, with 83% for active bleeding^[10]. In a study by Buscaglia *et al.*^[9], the overall sensitivity was 56.4% and that in patients with active bleeding was 58.3%. According to a Korean report by Kim *et al.*^[11], SBI sensitivity of was as low as 20%; however, for actively bleeding lesions, such as angiodysplasia, a much higher sensitivity was observed (93%). SBI sensitivity showed large differences in these studies, ranging from 20% to 56.4%. The positive predictive value also varied from 24% to 90.3%. Even with active bleeding, sensitivity still differed from 58.3% to 93%. Therefore, SBI is thought to be useful as an adjunct method to screen for bleeding lesions using CE. Still, SBI cannot completely replace the reading of the CE-generated video.

Cases with no significant bleeding, but in which bleeding was still suspected, are problematic and clinically important^[25]. The cause of the variability in SBI sensitivity is likely to be due to the differences in CE images. The presence of bile, debris, stool residue, and blood in the small intestine can vary depending on the patient's condition and bowel preparation. The intestinal fluid may

be yellowish due to bile juices, light grayish pink due to blood, brownish due to stool residue, or dark brownish due to discolored stool. It can also vary according to the concentrations of bile and debris. That is, the intestinal fluid may be very pale yellow or yellow when clear of bile, or it may be burnt sienna or deep brown when thick bile is present. Therefore, the background colors may vary within the same patient depending on the area investigated. Additionally, the color of the intestinal mucosa may be different according to the underlying diseases of patients, such as anemia or jaundice.

The color contrast indicates that the presence of a combination of different colors can influence the detection of individual colors^[26]. The contrast is greatest when a color is combined with its complementary color in the color circle. The color contrast includes contrast related to lightness, hue, saturation, and square. In the color circle, the complementary color of red is blue-green, for which the contrast is greatest. Saturation contrast means that if other vivid colors are located close to the color of interest, the saturation of the color will be reduced. In this study, we investigated whether the ability of SBI to detect red pixels was affected by color contrast, especially in conditions of similar color saturation. We found that the detection rate of red spots was 42.7% for a very pale magenta color, significantly decreasing to 3.3% for dark brown and 10.7% for very pale yellow. A decreased detection rate of 12% was observed when a deep brown background was used. Therefore, significant differences in the SBI detection rates were observed for the different background colors. For colors commonly observed during CE, such as very pale magenta, yellow, and burnt sienna, the SBI sensitivity was similar to that of the clinical data. The sensitivity was decreased for background colors such as dark brown or very pale yellow, which may be infrequently observed in clinical settings. These results suggest that the SBI sensitivity may vary depending on the amount of concentrated bile, food or debris present in the small intestinal lumen and the underlying diseases of patients.

The average time of capsule passage through the intestine is 217 ± 90 min^[14]. However, this can vary from 48 min to more than eight hours depending on the underlying disease, such as diabetes, and on intestinal peristalsis. Significant differences in the sensitivity of SBI were observed at different capsule passage velocities in the experimental intestine models: the faster the capsule moved, the lower the sensitivity.

The results of our experiments suggest that SBI has low detection rates at sites that have colors that are significantly different from those of the normal intestine and in the areas where the capsule passed through relatively quickly. That is, even when the SBI technique fails to detect red pixels, a bleeding spot (i.e., angiodysplasia) may exist in those regions. Physicians must examine the images from these sites to detect false-negatives. The different background colors of the screen image can be easily located by using the tissue color bar in the software.

Therefore, the results of our study may assist physicians in the interpretation of SBI results and reduce the time required for detection of bleeding sites within the small intestine.

This study may be helpful for improving the diagnostic accuracy of SBI. To improve SBI sensitivity, technical improvements should be made. Additionally, the results of this study suggest clinically correctable factors for SBI. Bowel preparation before CE will improve the SBI sensitivity by minimizing the presence of bile and debris in the small intestine. To confirm this hypothesis, further studies investigating the factors that affect SBI sensitivity in different clinical situations are necessary.

The limitation of this study is that experimental models were used. Although the clinical situations of patients vary, if the capsule passes through an average of 6-7 m of small intestine in four hours, the actual average velocity is approximately 0.04 cm/s. The velocities used in this study of 0.5 cm/s, 1 cm/s, and 2 cm/s are not typically experienced in the clinic. Because it is technically difficult to artificially replicate an average capsule passage velocity, we randomly selected a velocity that was easy to replicate. Therefore, our results are difficult to apply directly to a clinical setting. However, it was shown that the sensitivity of SBI can differ depending on the velocity of the capsule.

In summary, the SBI sensitivity was significantly lower for some background colors on CE images, and the sensitivity decreased with faster capsule passage velocities in experimental models of the small intestine. Therefore, physicians should consider these factors when using SBI in the evaluation of CE images.

COMMENTS

Background

It is relatively time consuming to examine and interpret the results of capsule endoscopy (CE). The suspected blood indicator (SBI) is used for rapid screening of gastrointestinal bleeding, and it automatically recognizes frames that include red-colored pixels. However, reports on the usefulness of a SBI generally show low and variable overall sensitivity for lesions.

Research frontiers

SBI generates false-positive and false-negative results, and its clinical usefulness has not been verified. The color of the small intestinal mucosa and luminal fluid, which are the backgrounds on which lesions are detected, and the capsule passage velocity may vary according to bowel preparation and patient factors.

Innovations and breakthroughs

The detection by SBI differed significantly according to the background colors used ($P < 0.001$). The sensitivities on very pale magenta, burnt sienna and yellow backgrounds were significantly higher than on the other colors, such as very pale yellow or dark brown. The sensitivity tended to decrease at rapid capsule velocities in experimental models of the small intestine.

Applications

The results of this study may assist physicians in the interpretation of SBI results and reduce the time required for detecting bleeding sites in the small intestine. Physicians must examine the images that contain sites that could have false negative results more carefully than other sites. Bowel preparation before CE is useful for improving SBI sensitivity by minimizing bile or debris in the small intestine.

Peer review

The paper seeks to assess the automatic diagnostic yield using the suspected

blood identification system from GIVEN Imaging Ltd., designed to reduce the time spent reviewing CE images in patients with intermediate hemorrhage. The authors developed an experimental method to assess the sensitivity of SBI in different conditions.

Abstract

AIM: To evaluate the impact of surgical volume on nationwide hospital mortality after pancreaticoduodenectomy (PD) for periampullary tumors in South Korea.

METHODS: Periampullary cancer patients who underwent PD between 2005 and 2008 were analyzed from the database of the Health Insurance Review and Assessment Service of South Korea. A total of 126 hospitals were divided into 5 categories, each similar in terms of surgical volume for each category. We used hospital mortality as a quality indicator, which was defined as death during the hospital stay for PD, and calculated adjusted mortality through multivariate logistic models using several confounder variables.

RESULTS: A total of eligible 4975 patients were enrolled in this study. Average annual surgical volume of hospitals was markedly varied, ranging from 215 PDs in the very-high-volume hospital to < 10 PDs in the very-low-volume hospitals. Admission route, type of medical

security, and type of operation were significantly different by surgical volume. The overall hospital mortality was 2.1% and the observed hospital mortality by surgical volume showed statistical difference. Surgical volume, age, and type of operation were independent risk factors for hospital death, and adjusted hospital mortality showed a similar difference between hospitals with observed mortality. The result of the Hosmer-Lemeshow test was 5.76 ($P = 0.674$), indicating an acceptable appropriateness of our regression model.

CONCLUSION: The higher-volume hospitals showed lower hospital mortality than the lower-volume hospitals after PD in South Korea, which were clarified through the nationwide database.

INTRODUCTION

Nowadays pancreaticoduodenectomy (PD) is considered a common and feasibly-performed abdominal surgery for periampullary tumors, but it is still a high-risk surgical procedure with potential morbidity and mortality rates.

Reducing the morbidity and mortality of this formidable operation is therefore imperative. Although several acceptable results after PD in low-volume hospitals have been reported^[1-4], most studies on volume-outcome correlation in performing PD have purported better outcomes in high-volume hospitals, suggesting centralization or regionalization of PD^[5-13].

Centralization of PD can be affected by the national healthcare system, information on hospital quality, or patient hospital preference. The Korean healthcare system is based on compulsory insurance of the whole population and free selection of medical care and hospital under step-wise referral to tertiary hospital without regional restriction. Although we have no governmental guidelines for distribution of cancer treatment service or information on hospital quality officially provided by the government, PD tends to be centralized in the large and well-equipped hospitals in Seoul, the capital city of South Korea.

Analyzing the present state of centralization of PD and providing information on hospital quality can help facilitate the government to develop nationwide guidelines and help patients to select good-quality hospitals for themselves. Hospital quality can be representatively appraised through PD-related morbidity or mortality. However, perioperative morbidity may vary from institution to institution according to the criteria or definitions of particular complications, making it difficult to obtain reliable nationwide morbidity data. Therefore, more definitive and objective data, such as standardized or risk-adjusted mortality rates, are requisite as an indicator for hospital quality.

With the implication toward public reporting, we performed this study to evaluate the impact of surgical volume on nationwide hospital mortality after PD for periampullary tumors and to validate the utility of surgical volume as a quality indicator of hospitals in South Korea. To date, just a few nationwide studies have been carried out to assess the effect of surgical volume on outcomes after PD. We hope the present study can contribute to nationwide evidence for the volume-outcome correlation in performing PD.

MATERIALS AND METHODS

Data sources and subjects

Data were obtained from the Health Insurance Review and Assessment Service (HIRA), whose database was constructed through the process of medical fee claims. After providing medical treatment, the medical institutions submit treatment details and file medical fee claims through an electronic billing system in the form of diskettes, compact discs or electronic data interchange (EDI). The EDI system, which was developed to review medical fees electronically by converting claim information into an EDI file and automatically reviewing items such as medical and drug fees within the software, occupies 99.7% of all medical claims in South Korea. Each claim contains information on demographic data, diagnoses,

procedures, comorbidity, route of admission, length of stay, discharge status, source of payment, hospital charges, *etc.* Diagnostic data were coded using the International Classification of Diseases, 10th Revision (ICD-10), and procedural data were coded using the health insurance claims code developed by the Ministry of Health and Welfare. From the HIRA database, we obtained anonymous data on patients who underwent PD for periampullary cancers during the period from January 2005 to December 2008. Only the primary cancers were included, and cancers originating at the adjacent organs such as the colon, stomach, or gallbladder were excluded. Benign diseases, including trauma, were also excluded. Additionally, patients with other combined operations which could affect the surgical outcomes such as hepatectomy, gastrectomy, or colectomy were not analyzed.

Categorization of hospitals

A total of 126 hospitals performed at least one PD from 2005 to 2008 in South Korea. Four-year surgical volume of each hospital showed a large gap, ranging from 1 to 861. Therefore, we divided the hospitals into quintiles; very-low, low, medium, high, and very-high categories. For this fractionation, the hospitals were sorted in descending order by total surgical volume, and cut-off points were decided to categorize hospitals into five similarly-sized groups.

Assessment of outcome

For clarification of volume-outcome correlation of PD, we adopted hospital mortality as an outcome indicator, which was defined as death during the hospital stay for PD. Hospital mortality had to be calculated in the form of adjusted mortality, because the hospital and patient characteristics of each category were different. For this adjustment of hospital mortality, we selected several risk factors for death from the HIRA database and the literature; age, sex, admission route as a surrogate for patient's general condition [outpatient department *vs* emergency room (ER)], Charlson comorbidity score^[14] as an index for current comorbid status (≥ 3 *vs* < 3), type of medical security as a surrogate for socioeconomic status (medical aid for the destitute *vs* health insurance for the others), and operation type [classical pancreaticoduodenectomy (CPD) *vs* pylorus-preserving pancreaticoduodenectomy (PPPD)]. However, we were unable to obtain more detailed information on preoperative treatment, tumor node metastasis stage, PD-specific complications, or radicality of PD from the HIRA database, which was a major limitation of the nationwide data. Observed mortality was first obtained according to surgical volume and patient characteristics. Risk-adjusted mortality was then calculated through: (observed hospital deaths/predicted hospital deaths) \times overall mortality rate. The predicted mortality of each category could be produced by summing the probability of death of each patient in that category, and the probability of death was determined by adjustment with significant confounder variables validated through

multivariate logistic regression.

Statistical analysis

Statistical analysis was carried out using the SAS statistical package version 9.1 (SAS System for Windows, SAS Institute, Cary, NC, United States). Descriptive statistics were used to obtain patient characteristics and hospital mortality in each surgical volume category. Continuous variables were compared with Student's *t* test for two groups and with analysis of variance for multiple groups. Categorical variables were assessed with χ^2 tests. Multivariate logistic regression was used to assess the correlation between surgical volume and hospital mortality, with risk-adjusted mortality as the dependent variable and surgical volume and other risk factors for death as covariates. The result of the Hosmer-Lemeshow test was 5.76 ($P = 0.674$), indicating an acceptable appropriateness of our regression model. Statistical significance was set at P values < 0.05.

RESULTS

Hospital and patient characteristics by surgical volume

Of the patients who underwent PD for periampullary cancers during the period from 2005 to 2008 in South Korea, a total of 4975 patients were eligible for the inclusion criteria and enrolled in this study. Pancreatic cancer (1800, 36.2%) occupied the most common indication for PD and was followed by common bile duct cancer (1433, 28.8%), ampulla of Vater cancer (1280, 25.7%), duodenal cancer (238, 4.8%), and other periampullary cancers (227, 4.5%).

PD patients of each category were arranged to be similar in number; 1021 (20.5%) in the very-low-volume hospitals, 1005 (20.2%) in the low-volume hospitals, 1020 (20.5%) in the medium-volume hospitals, 1068 (21.5%) in the high-volume hospitals and 861 (17.3%) in the very-high-volume hospitals. Only one hospital corresponded

to the very-high-volume hospital, whereas as many as 92 (73.0%) hospitals belonged to the very-low-volume hospitals. Average annual surgical volume of the total 126 participating hospitals was markedly varied; 215 PDs in the very-high-volume hospital and fewer than 10 PDs in the very-low-volume hospitals (Table 1). Even worse, 33 of the very-low-volume hospitals performed less than 1 PD per year.

The mean age of the PD patients was 61.5 years and there were 1.5 times more males than females. Admission *via* ER was significantly more frequent and the percentage of payment by medical aid was significantly lower in the higher-volume hospitals (both $P < 0.001$). However, the Charlson comorbidity score didn't show any association with the surgical volume category. PPPD was performed in 59.6% (2964/4975) and this proportion increased with an increase in surgical volume, ranging from 40.8% in the very-low-volume hospitals to 69.6% in the high-volume hospitals ($P < 0.001$, Table 1).

Observed hospital mortality

The overall hospital mortality rate after PD was 2.1% during the study period. The observed hospital mortality rates were higher in lower-volume hospitals, the medical aid group, and CPD patients ($P < 0.001$, $P = 0.015$, $P < 0.001$, respectively). The mean age of both the mortality and survival group was also significantly different (66.0 *vs* 61.4, $P < 0.001$). Other risk factors didn't affect hospital mortality (Table 2).

Adjusted hospital mortality

All the risk factors with $P < 0.25$ in univariate logistic regression were included for multivariate analysis. These were: age, sex, type of medical security and operation type. Table 3 shows the results of multivariate logistic regression. Hospital mortality had a significant correlation with surgical volume ($P < 0.001$). Although there was no statistical difference in hospital mortality between the

Table 2 Observed hospital mortality by patient characteristics

Characteristics	No. of patients	Mortality (%)	P value
Age			< 0.001

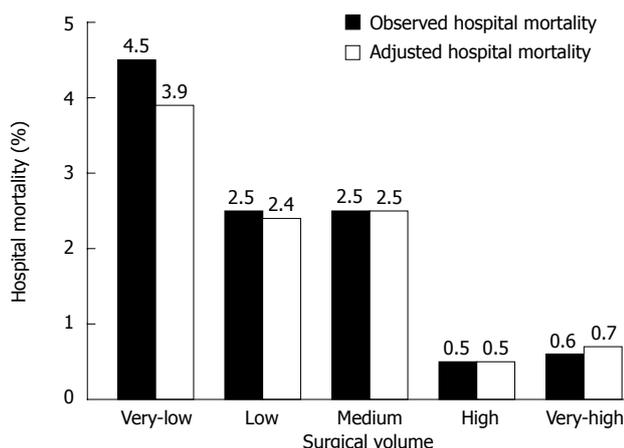

Figure 1 Observed and adjusted hospital mortality according to surgical volume. Observed hospital mortality rates showed a significant decreasing trend as surgical volume increased ($P < 0.001$). Adjusted hospital mortality rates were then calculated through multivariate logistic regression with hospital mortality rates as a dependent variable and age and operation type as significant confounder variables.

very-low-volume and medium-volume hospitals, or just a small statistical difference between the very-low-volume and low-volume hospitals, adjusted odds ratios (ORs) for hospital death of the high-volume and very-high-volume hospitals were significant lower than those of the very-low-volume hospitals (both $P < 0.001$). Age and operation type were the only significant confounder variables ($P < 0.001$ and $P = 0.025$, respectively) and were used for adjustment to produce the predicted mortality. Risk-adjusted hospital mortality rates according to surgical volume are depicted in Figure 1, ranging from 0.5% to 3.9%.

DISCUSSION

We used the nationwide database to validate the associa-

Table 3 Logistic regression for hospital mortality

Characteristics	Odds ratio (95% CI)	P value
Surgical volume

tion of surgical volume and hospital mortality. Nationwide data has the power to yield reliable and objective results by itself, mainly due to a large number of subjects and the least influence of selection bias. Of the nationwide reports, however, there have been just a few studies on only PD^[5,8,10,11,13,15,16], whereas the majority included all types of pancreatic resections, including PD^[17-21]. It is known that PD is different from left-sided pancreatectomy, at least in postoperative morbidity and mortality. Nationwide hospital mortality results on PD would be reliable evidence and a base to support governmental or administrative guidelines for the establishment of policy on medical service, to select high-quality hospitals for patients, and to compare quality of care providers within and beyond South Korea.

The inverse relationship between surgical volume and hospital mortality in performing PD has been clarified in South Korea through this study. The risk-adjusted hospital mortality rates of the high-volume and very-high-volume hospitals were very low (0.5% and 0.7%) compared to those of the very-low-volume, low-volume and medium-volume hospitals (3.9%, 2.4% and 2.5%, respectively). This difference in the adjusted hospital mortality rates was found to be similar to that in the observed hospital mortality rates (0.5% and 0.6% *vs* 4.5%, 2.5% and 2.5%). In other words, the ORs for hospital mortality in the low-volume and medium-volume hospitals *vs* the very-low-volume hospitals were around 0.6 (a 40% decrease in the probability of hospital mortality), whereas the ORs in the high-volume and very-high-volume hospitals *vs* the very-low-volume hospitals were as low as 0.13 and 0.16 (a decrease of more than 80%).

The overall hospital mortality rate after PD in South Korea between 2005 and 2008 was 2.1%. This value was much lower than mortality rates from other statewide^[12,22,23] or nationwide^[5,8,10,11,13,15] databases, but a slightly higher than those from high-volume single insti-

tutions^[7,24-27]. Hospital mortality after PD is affected by many independent variables. Significant risk factors for hospital mortality, other than surgical volume as mentioned above, were age and operation type in this study. Type of medical security showed statistical significance in univariate analysis but not in multivariate analysis. Significant confounder variables for hospital mortality in PD were similar within the literature. Age, gender, body mass index, and urgent admission were advocated in other studies^[8,11,28].

Regionalization and centralization in severe medical illnesses and high-risk surgical procedures are worldwide trends which may occur naturally by patients' free selection, or intentionally by governmental policy across the world. About 40% of PDs were undertaken in the high-volume and very-high-volume hospitals, or the big 4 hospitals in South Korea. Again, more than 50% of PDs were performed only in 14 (11.1%) out of 126 hospitals. With these data, South Korea can be said to show a typical example of centralization for PD. Despite trends toward regionalization of care^[5,9,12,13,29], not a few PDs were safely performed in community hospitals by surgeons with varying degrees of experience^[28], as evidenced by a comparably low mortality rate and a high one-year survival rate^[1-4]. About 20% of patients still received PD in as many as 92 very-low-volume hospitals (73.0%) performing fewer than 10 PDs per year in South Korea. There could be several community hospitals with comparably low mortality rates, because the overall mortality rate of the very-low-volume hospitals in South Korea was not so high.

Hospital quality can be assessed with diverse outcome indicators. These are divided into short-term and long-term outcomes, with short-term outcomes including mortality, morbidity, hospital cost, and postoperative hospital stay. Survival outcome represents the long-term outcome. Considering that PD is a very complicated surgical procedure, postoperative morbidity results are very useful in comparing short-term outcomes between hospitals. However, our nationwide study didn't include morbidity results due to difficulty in data collection through the medical fee claims system of the HIRA. Additional drawbacks of this study were as follows; no long-term outcome, total hospital stay not postoperative hospital stay, no pathology-related data, or no surgeon volume. Of these drawbacks, surgeon volume is worthy of note. Surgeon volume^[19,22,28,30-32] or experience^[30], could be a more exact and detailed indicator of hospital outcome after PD than total hospital surgical volume. The HIRA database does not yet have the surgeon identifier which was used in the study by Eppsteiner *et al.*^[33]; therefore we couldn't analyze the correlation of surgeon volume and hospital outcome. In one study^[30], an experienced surgeon was defined as one performing 50 or more PDs, and experienced surgeons had comparable outcomes irrespective of annual volume. Learning curves also projected that less experienced surgeons would achieve morbidity and mortality rates equivalent to those of experienced surgeons when they reached 20 and 60 PDs, respectively. In other studies,

a high-volume surgeon was defined as having an average of 10 or more PDs per year^[28], or 5 or more PDs per year^[33]. Like stratification of hospitals by surgical volume, defining experienced or high-volume surgeons is difficult and varies according to the medical situation or surgeon training system of each country.

Quality indicators other than surgical volume have been introduced. Some researchers focused on the importance of surgery residency training programs, reporting a greater impact on outcomes after PD than hospital volume or surgeon frequency^[34]. Similarly, Joseph *et al.*^[35] put emphasis on hospital clinical resources, such as the Leapfrog Safe Practice Score, HealthGrades 5-star rating, or interventional radiology services, as well as surgical volume for lower operative mortality after PD. A pathologic indicator was also proposed by reporting that patients undergoing PD at low-volume centers were more likely to have margin-positive resections^[36].

Categorization of hospitals was carried out by two methods in the previous reports; by cut-off points of hospital similar in size in each category like our study and by cut-off points of surgical volume that were arbitrarily determined. These cutoff points of surgical volume were varying according to the medical situation and total surgical volume of states or countries. For example, Birkmeyer *et al.*^[10] defined > 5/year for high-volume hospitals in United States between 1992 and 1995, and Topal *et al.*^[5] did > 10/year for high-volume and > 20/year for very-high-volume hospitals in Belgium between 2000 and 2004, while Balzano *et al.*^[11] used a cut-off point of 14-51/year for high-volume hospitals and 89-104/year for very-high-volume hospitals in Italy in 2003. For this stratification of hospitals by surgical volume, the size of each category was uneven according to the cut-off points. In our study, the high-volume hospitals corresponded to 54-111/year and the very-high-volume hospital did 215/year between 2005 and 2008, as a result of dividing hospitals into 5 similar-sized categories. In addition, quintile division^[5,17] was rarely used in the previous studies, with the majority being performed in three or four stratifications. Accordingly it is not easy to reach an international consent on established stratification of hospitals by surgical volume.

In conclusion, the nationwide database clarified the impact of surgical volume on hospital mortality after PD in South Korea. The higher-volume hospitals had a better mortality outcome than the lower-volume hospitals. PD performance showed centralization in South Korea and the overall hospital mortality rate was comparable among countries. Further nationwide studies with surgeon volume, morbidity data, and long-term survival results after PD are warranted for more detailed information, and for a domestic and international comparison.

COMMENTS

Background

Pancreaticoduodenectomy (PD), performed for various diseases around the

duodenal ampulla, is one of the high-risk surgical procedures which tend to be centralized in high-volume hospitals across the world. Previous studies have reported that high-volume hospitals show better surgical outcomes than low-volume hospitals. Up to now, however, there have been no reports on surgical outcomes after PD, or whether surgical volume is a good quality indicator of care providers in South Korea.

Research frontiers

The correlation of surgical volume and hospital outcome after PD is well known between individual institutions or in a limited area. For research into clarifying this relationship, comprehensive results from nationwide databases are important for patients and government, as well as medical personnel.

Innovations and breakthroughs

Although there have been many studies on the relationship between surgical volume and hospital outcome after all types of pancreatic surgery from nationwide databases or after only PD from databases of institutions or states, nationwide results on only PD, which is still an operation with high morbidity and mortality rates, are very rare. Moreover, this is the first study of its type performed in South Korea and having a recent study period of four years.

Applications

With the information on the relationship between surgical volume and nationwide hospital mortality after PD in South Korea, reference guidelines for establishing medical policy and selecting good-quality hospitals could be supported.

Peer review

This is a frontier study on the relationship between surgical volume and hospital outcome after one type of major surgery in South Korea. This is a well-analyzed and clear manuscript that describes the impact of hospital volume on mortality following pancreaticoduodenectomy.

Abstract

AIM: To evaluate whether diabetic patients had a higher risk of colon cancer mortality and its associated risk factors.

METHODS: The sex-specific crude and age-standardized (to the 2000 World Health Organization population) mortality rates of colon cancer in the Taiwanese general population were first calculated from 1995 to 2006. The trends were evaluated by linear regression. A total of 113 347 diabetic men and 131 573 diabetic women aged ≥ 25 years at recruitment from 1995 to 1998 were followed up until the end of 2006. Age/sex-specific colon cancer mortality rate ratios were calculated comparing the mortality rates of the diabetic patients with the average mortality rates of the general population within 12 years (1995-2006). A sub-cohort of diabetic patients (42 260 men and 49 405 women) was interviewed using a baseline questionnaire and Cox's regression was used to evaluate the risk factors for colon cancer mortality in these diabetic patients.

RESULTS: The crude and age-standardized trends of colon cancer mortality from 1995 to 2006 increased significantly for both sexes in the general population. A total of 641 diabetic men and 573 diabetic women died of colon cancer, with a mortality rate of 74.4 and 54.3 per 100 000 person-years, respectively. Mortality rate ratios [95% confidence intervals (CIs)] showed a significantly higher risk of mortality from colon cancer for the diabetic patients compared to the general population, with the magnitude increasing with decreasing age: 1.65 (1.40-1.95), 2.01 (1.78-2.27), 2.75 (2.36-3.21) and 5.69 (4.65-6.96) for ≥ 75 , 65-74, 55-64 and 25-54 years old, respectively, for men; and 1.46 (1.24-1.72), 2.09 (1.84-2.38), 2.67 (2.27-3.14) and 3.05 (2.29-4.06), respectively, for women. Among the sub-cohort of diabetic patients who had been interviewed with the baseline questionnaire, including information on age, sex, diabetes duration, diabetes type, body mass index, smoking, insulin use and area of residence, age and smoking were significantly predictive for colon cancer mortality, with respective adjusted hazard ratios (HRs) (95% CIs) of 1.077 (1.066-1.088) and 1.384 (1.068-1.792). Diabetes duration became a significant factor when those who died of colon cancer within 5 years of diabetes diagnosis were excluded to minimize the possible contamination of diabetes caused by incipient colon cancer, with an adjusted hazard ratio of 1.021 (1.007-1.034). Sex, diabetes type, insulin use, body mass index and area of residence were not significant predictors for colon cancer mortality in the diabetic patients. Although insulin use was categorized into subgroups of duration of use (non-users and users < 5 years, 5-9 years and ≥ 10 years), none of the HRs for colon cancer mortality was significant with regards to different durations of insulin use.

CONCLUSION: Colon cancer mortality is increasing in Taiwan. A higher risk is observed in diabetic patients. Smoking, but not insulin use, is a modifiable risk factor.

INTRODUCTION

Colorectal cancer is a major cause of death in developed countries^[1]. In Taiwan, it is the third most common cause of cancer-related death^[2], and the trend of its age-adjusted mortality showed an increase from 1971 to 1996^[3]. A meta-analysis concluded there was a 30% higher risk in diabetic patients^[4]. However, most studies were done in western countries, and the only one involving Asians in the meta-analysis was conducted in Korea, which showed a 28% higher risk of mortality in diabetic men, but not women^[5]. On the other hand, some studies showed an association in women^[6,7].

Most previous studies did not distinguish between type 1 and type 2 diabetes. A recent prospective study in the United States identified patients with type 2 diabetes and nondiabetic subjects aged 50-74 years in 1992-1993 and followed biannually by questionnaires from 1997 to 2007^[8]. Diabetes was significantly associated with colorectal cancer in men who were either insulin users or non-users; but diabetes and insulin use were not associated with a higher risk among women^[8].

Whether insulin use is associated with colon cancer mortality has rarely been studied. Furthermore, no previous studies have examined prospectively the confounding effects of diabetes duration and age; both being highly associated with insulin use. Therefore, this study evaluated: (1) the trends of colon cancer mortality in the Taiwanese general population; (2) the age/sex-specific mortality rate ratio between diabetic patients and the general population; and (3) the risk factors for colon cancer mortality in diabetic patients, including age, sex, diabetes duration, diabetes type, body mass index, smoking, insulin use/duration of insulin use and area of residence.

MATERIALS AND METHODS

Colon cancer mortality in the general population

The study was approved and supported by the Department of Health, Executive Yuan, Taiwan. In Taiwan, every resident has a unique identification number and events like birth, death, marriage or migration should be registered. If a person dies, a death certificate should be

reported to the household registration offices within 30 d as required by law. The death certificate database includes the identification number, date of birth, sex, and date and cause of death. The causes of death coded in the ninth revision of the International Classification of Diseases are used. Colon cancer has a code of 153.

The age/sex-specific population numbers are reported annually by the government. The sex-specific trends of crude and age-standardized (to the 2000 World Health Organization population) mortality rates for colon cancer in the general population were first calculated from 1995 to 2006 for all ages. Linear regression was used to evaluate whether the trends changed with regard to calendar years, where the mortality rate was the dependent variable and the calendar year the independent variable.

Colon cancer is rare in young individuals, therefore, we analyzed the data for those aged ≥ 25 years in the following groups: 25-54 years, 55-64 years, 65-74 years and ≥ 75 years old. Age/sex-specific average mortality rates during 1995-2006 were calculated by dividing the average numbers of colon cancer deaths by the average mid-year population of the specific age and sex within the period.

Colon cancer mortality in diabetic patients

Figure 1 shows a flow chart for the follow-up of diabetic patients. In March 1995, a compulsory and universal National Health Insurance (NHI) program was implemented and covered $> 96\%$ of the population. From 1995 to 1998 a cohort of 256 036 diabetic patients ("the original cohort") using the NHI was established (detailed elsewhere)^[9,10].

All patients were followed until 2006. The date and cause of death were obtained from the death certificate database. Mortality rates were computed using a person-years denominator: the duration from enrollment until the end of 2006 for those who were alive or to the date of death. The patients were categorized into age subgroups by their age at enrollment. Age/sex-specific mortality rates and mortality rate ratios were calculated. The mortality rate ratio was calculated using the average mortality rate of that subgroup within the 12 years in the general population as a reference. To reduce the aging effect on age subgroup categorization, analyses for the original cohort were also performed by splitting the follow-up duration into two periods: (1) from enrollment to the end of 2000: age categorized at enrollment and mortality followed from enrollment to 2000; and (2) from 2001 to the end of 2006: those who died before the end of 2000 were excluded, age calculated at 2001 and mortality followed from 2001-2006.

For sub-cohort analyses, we calculated the mortality rates and mortality rate ratios in the patients who had been interviewed with a baseline questionnaire (detailed elsewhere)^[11-13]. The number interviewed was 93 484 and among them 91 665 patients (42 260 men and 49 405 women) were aged ≥ 25 years ("sub-cohort diabetic patients"). To evaluate whether an association was found in

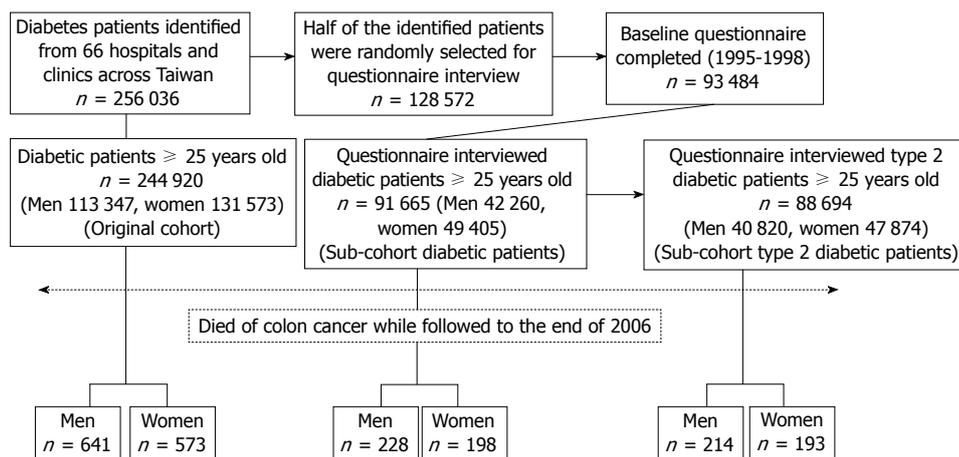

Figure 1 Flow chart showing the procedures in the calculation of colon cancer mortality in the diabetic cohorts.

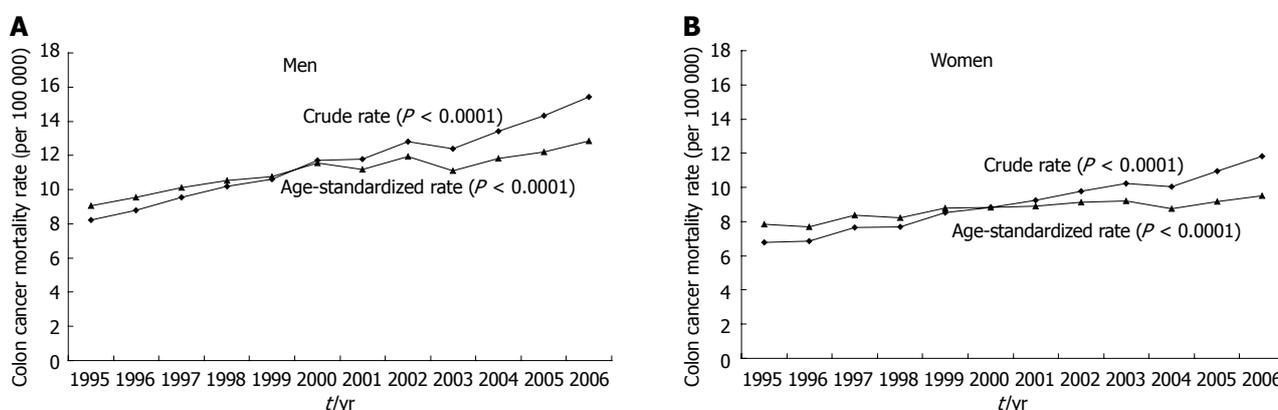

Figure 2 Secular trends of mortality from colon cancer from 1995 to 2006 in the general population of Taiwan in men (A) and women (B), respectively. The 2000 World Health Organization population was used as reference for age standardization.

patients with type 2 diabetes, mortality rates and mortality rate ratios were calculated after excluding patients with type 1 diabetes based on diabetic ketoacidosis at diabetes onset, or the need for insulin injection within 1 year after diabetes diagnosis. There were 40 820 diabetic men and 47 874 diabetic women after this exclusion (“sub-cohort type 2 diabetic patients”). Only 1440 men and 1531 women were excluded for type 1 diabetes, and among them only 14 men and five women died of colon cancer, therefore, we did not analyze the association with type 1 diabetes. To minimize the possibility that diabetes might be caused by incipient colon cancer, analyses were also done by dividing the patients into subgroups with a diabetes duration at enrollment < 10 years and ≥ 10 years.

Risk factors for colon cancer mortality in diabetic patients

The baseline characteristics of the sub-cohort diabetic patients who had been interviewed (Figure 1) were compared between men and women by either the *t* test for continuous variables or the χ^2 test for categorical variables. Cox proportional hazards models were then used to identify the risk factors for colon cancer mortality. Colon cancer mortality was the dependent variable in the models and the independent variables included age,

sex (men *vs* women), diabetes duration, diabetes type (type 2 *vs* type 1), body mass index, smoking (yes *vs* no), insulin use (yes *vs* no) and area of residence (urban *vs* rural). The area of residence was defined as urban for the Metropolitan Taipei area including Taipei City and Taipei County (New Taipei City) and other administratively named cities across Taiwan; and as rural for administratively named counties and offshore islands. To evaluate whether the duration of insulin use could be associated with colon cancer mortality, Cox models were also created by comparing insulin use at < 5 years, 5-9 years and ≥ 10 years to insulin non-users, before adjustment, at adjustment for age, sex, diabetes type, diabetes duration, body mass index, smoking and area of residence one at a time, and at adjustment for all these factors simultaneously (full model). The analyses were done before and after excluding patients who died of colon cancer within 5 years of diabetes onset, to minimize the possibility that diabetes might be caused by incipient colon cancer or might occur after the diagnosis of colon cancer.

RESULTS

The trends of crude and age-standardized colon cancer mortality showed a significant increase in both sexes in

^a*P* < 0.05 vs general population. PY: Person-years; MR: Mortality rate; MRR: Mortality rate ratio; CI: Confidence interval; *n*: Case number of colon cancer; *N*: Case number observed.

the general population during the period from 1995 to 2006 in Taiwan (Figure 2). The average mortality rates for colon cancer during the period in the general population aged 25-54 years, 55-64 years, 65-74 years and ≥ 75 years were 5.1, 24.75, 76.6 and 160.92 per 100 000 for men, respectively, and 4.51, 18.01, 46.08 and 130.90 for women.

A total of 113 347 diabetic men and 131 573 diabetic women in the original cohort were followed (Figure 1). Among them, 641 men and 573 women died of colon cancer, with mortality rates of 74.4 and 54.3 per 100 000

person-years, respectively. The age/sex-specific mortality rates in the diabetic patients and their mortality rate ratios compared to the general population are shown in Table 1. Except for those aged ≥ 75 years and with a diabetes duration of ≥ 10 years at enrollment in men, and with a diabetes duration of < 10 years at enrollment in women (Table 1), the mortality rate ratios were all significant, and especially remarkable in those aged 25-54 years. Diabetes was unlikely to be caused by colon cancer, because diabetes diagnosed ≥ 10 years before colon

Table 2 Baseline characteristics of the sub-cohort of diabetic men and women who had been interviewed with a baseline questionnaire

Variable	Men	Women	P value
n	42 260	49 405

Data are expressed as mean (SD) or n (%).

cancer mortality can hardly be a consequence of the carcinogenic process. The aging effect during follow-up on age subgroup categorization was also minimal because the results were similar when the long duration was split into two shorter periods in the original cohort analyses.

All baseline characteristics of the sub-cohort diabetic patients who had been interviewed with a baseline questionnaire differed significantly between the diabetic men and women (Table 2). The unadjusted and mutually-adjusted HRs for different age groups are shown in Table 3. In the adjusted models, age and smoking (especially in those aged < 65 years) were significant. When diabetic patients who died of colon cancer within 5 years of diabetes diagnosis were excluded, diabetes duration was significant (especially in those aged \geq 65 years). Sex, diabetes type, insulin use, body mass index and area of residence were not significant after adjustment.

Table 4 shows the HRs for different durations of insulin use compared to non-users in unadjusted and adjusted models. Before exclusion of patients with a duration of < 5 years between the onset of diabetes and colon cancer mortality, none of the HRs was significant. In models after exclusion, insulin use \geq 10 years might be associated with a higher risk. However, in the models after respective adjustment for age, diabetes type or diabetes duration, and in the full model, insulin use of any duration was not predictive, suggesting that the association with insulin use might be due to the effects of some confounders.

DISCUSSION

Contrary to the decreasing trend since the mid-1980s in the United States^[14], colon cancer mortality in Taiwan is increasing (Figure 2), and has been since 1971 if the observation of Chen *et al*^[3] is considered simultaneously. Although the etiology of the increasing trend remains to be explored, it may be due to the westernization of the Taiwanese lifestyle in recent decades, with increased fat intake, and the high prevalence of metabolic syndrome and diabetes. The higher risk among diabetic patients of both sexes (Table 1) was also contrary to Korean^[5] and

United States^[8] studies showing an association in men but not in women, and to others showing an association only in women^[7].

It is interesting that the increased mortality rate ratio was more remarkable at the youngest age of 25-54 years (Table 1). This has public health importance because the incidence of diabetes is increasing dramatically in the younger generation^[9]. One explanation is that age *per se* is a strong risk factor, and therefore, the impact of diabetes might not be as obvious in the elderly, resulting in a remarkably higher incidence rate ratio and a higher mortality rate ratio in the younger age group. Other explanations include that diabetes has a different impact on colon cancer mortality in different age groups, and that younger diabetic patients with colon cancer would have a poorer prognosis than non-diabetic patients. Mucin production in colorectal cancer has an inverse effect on survival among Taiwanese patients^[15]. Taiwanese patients with colon cancer and aged < 40 years also have significantly poorer 5-year survival^[16]; age is inversely associated with tumor stage at diagnosis, tumor differentiation and mucin production^[17]. In addition, the healthy survivor effect might also lead to a reduced mortality rate ratio in the elderly.

Metabolic syndrome is associated with a 35% higher risk of colon cancer in Taiwan^[18]. Similarly, a cluster of three components of the metabolic syndrome (hypertension, body mass index \geq 25 kg/m² and high-density lipoprotein cholesterol < 40 mg/dL) was associated with a 58% higher risk in a Finnish study^[19]. In Taiwan, metabolic syndrome is present in 76.2% of diabetic patients^[20], in contrast to 15% in the general population^[21]. Therefore, the higher prevalence rates of hypertension, obesity and dyslipidemia in diabetic patients might explain partly their higher risk of colon cancer.

Contrary to other studies showing an association between body mass index and distal colon adenoma^[22] or colorectal cancer^[19], body mass index was not predictive for colon cancer mortality in the present study (Table 3). One possibility is that the risk factors for incidence and mortality or for different ethnicities might be different. It is also possible that if diabetes *per se* incurred a markedly higher risk, the impact of other risk factors might be overshadowed. Therefore, risk factors in diabetic patients might not be the same as those observed in non-diabetic subjects.

The association between colorectal neoplasm and insulin use in patients with type 2 diabetes has been controversial^[8,23,24]. Although two retrospective studies suggested a positive link, a recent prospective study concluded a lack of association^[8]. A study conducted in Korea suggested a threefold higher risk of colorectal adenoma associated with insulin therapy^[23]. However, this study used a retrospective case-control design and evaluated adenoma rather than cancer. Another retrospective cohort study using the General Practice Research Database from the United Kingdom showed a significantly twofold higher risk of colorectal cancer associated with

insulin use^[24]. On the other hand, a prospective cohort study conducted in the United States did not suggest an association between colorectal cancer and insulin use in either men or women^[8]. The finding of the present study was in line with the United States study, suggesting a lack of association between insulin use and colon cancer mortality (Tables 3 and 4). Insulin use is essential in patients with type 1 diabetes and is always seen in older patients with type 2 diabetes who might have prolonged duration of diabetes. Therefore, it is worth mentioning that adjustments should be made simultaneously for age, diabetes duration and diabetes type in the analyses evaluating the risk of cancer associated with insulin use. The present study is probably the longest follow-up study showing that insulin use was not predictive for colon cancer mortality after adjustment for confounders, including all of these factors (Tables 3 and 4).

Consistent with some prior studies^[25,26], smoking was significantly predictive, especially in those aged < 65 years (Table 3). A recent Swedish retrospective cohort study evaluating the use of snuff and colorectal and anal cancer found no significant association^[27]. We were not able to evaluate the effect of snuff use because of a lack

of information. Although we could not evaluate the impact of socioeconomic status, this study did not show an association with area of residence (Table 3).

Incidence and mortality are two different entities, and probably linked to different factors. If diabetic patients with colon cancer had a poorer prognosis, the mortality rate ratio would not properly reflect the incidence rate ratio. A recently published prospective study (Cancer Prevention Study-II Nutrition Cohort) conducted among 2278 patients with colorectal cancer suggested that patients with type 2 diabetes had a higher risk of mortality than those without diabetes; especially a higher risk of death from cardiovascular disease^[28]. A study from Taiwan also showed that diabetic patients with colon cancer had an overall 21% higher mortality than nondiabetic patients^[29]. However, this was only observed in stage II cancer. It was believed that the 21% higher case-fatality rate could not explain the several-fold higher mortality rate ratios in the diabetic patients (Table 1).

The strengths of this study included a prospective follow-up of a large cohort of diabetic patients over a long duration; the completeness of the ascertainment of vital status by matching with the death certificate

Table 4 Cox proportional hazards models for mortality from colon cancer by duration of insulin use (reference group: diabetic patients not using insulin) before and after exclusion of patients with a duration of < 5 years between onset of diabetes and colon cancer mortality

database; and the consistency observed in both sexes, and in different age groups, enrollment periods and sub-cohorts of diabetic patients.

There were limitations to the study. First, diabetic patients might have visited their physicians more frequently, resulting in a higher probability of detecting cancer. However, this might only suggest a higher rate of detection of early colon cancer with a better prognosis, which might have attenuated the magnitude of the mortality rate ratios. Second, the use of cause of death on the death certificate as the only source of colon cancer diagnosis might have underestimated the mortality related to colon cancer, because some patients with colon cancer might have died without having colon cancer listed as the cause of death. Therefore the impact of this possible effect awaits further investigation. Third, multiple drug therapy in diabetic patients might have complicated the situation. For example, statin, aspirin and nonsteroidal anti-inflammatory drugs are possibly preventive for colorectal cancer^[30,31]. A higher proportion of diabetic patients might have been using these medications for the prevention of cardiovascular diseases. Different oral antidiabetic agents may have different effects on cancer development. For example, metformin has been shown to be preventive for cancer^[32], but the use of sulfonylureas may be associated with a higher risk of cancer^[33]. We could not evaluate the effects of these medications because such information was not collected. Fourth, this study did not consider confounders identified in Taiwan, including less exercise, less vegetable and fruit consumption, increased meat intake, and alcohol intake^[25]. Furthermore, we were not able to adjust for some other

confounders, as discussed below. For example, hyperhomocysteinemia has been shown to be a risk factor for type 2 diabetes and is also associated with abnormal DNA methylation, which has the potential to inactivate tumor suppressor genes leading to colorectal cancer^[31]. Family history and inflammatory bowel disease are also significant risk factors for colorectal cancer^[34-36]. None of these potential confounders were measured and could not be considered for adjustment.

In summary, we have demonstrated an increasing trend in colon cancer mortality in the Taiwanese general population from 1995 to 2006. The risk is increased in diabetic patients, with the magnitude of the mortality rate ratio becoming larger with decreasing age. Smoking is a risk factor, but insulin use is not. Given that the population is aging and the incidence of type 2 diabetes is increasing, the impact of the link between diabetes and colon cancer on the mortality of the population warrants public health attention.

COMMENTS

Background

Diabetic patients may have a higher risk of colon cancer, but whether insulin use in the diabetic patients can be a risk factor is controversial. Studies related to these issues are rarely conducted in Asian populations.

Research frontiers

A meta-analysis suggested a 30% higher risk of colorectal cancer in diabetic patients. However, most studies were done in western countries. In Korea, a 28% higher risk of mortality was observed in diabetic men, but not women. Whether insulin use is associated with colorectal cancer has rarely been studied. A recent prospective United States study showed that diabetes was significantly associated with colorectal cancer in men who were either insulin users or

non-users, but diabetes and insulin use were not associated with a higher risk among women.

Innovations and breakthroughs

The author demonstrated an increasing trend in colon cancer mortality in the Taiwanese general population from 1995 to 2006. The risk is increased in diabetic patients, with the magnitude of the mortality rate ratio becoming larger with decreasing age. In patients with diabetes, smoking is a risk factor for colon cancer mortality, but insulin use is not. The strengths of this study included a prospective follow-up of a large cohort of diabetic patients over a long duration of 12 years; the completeness of the ascertainment of vital status by matching with the national death certificate database; the consistency observed in both sexes, and in different age groups, enrollment periods and sub-cohorts of diabetic patients; and consideration of the confounding effects of diabetes duration and age - both being highly associated with insulin use.

Applications

Given that the population is aging and the incidence of diabetes is increasing, the impact of the link between diabetes and colon cancer on the mortality of the population warrants public health attention. Insulin is commonly used in diabetic patients, therefore, clarification of a lack of insulin effect on colon cancer development relieves concern about the use of insulin.

Terminology

Secular trend of mortality: a systematic change in mortality rates over a period of (calendar) time; Mortality rate ratio: ratio of two mortality rates.

Peer review

This was a well-performed study that may be published when some corrections have been done.

Abstract

AIM: To determine the effect of body mass index (BMI) on the characteristics and overall outcome of colon cancer in Taiwan.

METHODS: From January 1995 to July 2003, 2138 patients with colon cancer were enrolled in this study. BMI categories (in kg/m²) were established according to the classification of the Department of Health of Taiwan. Postoperative morbidities and mortality, and survival analysis including overall survival (OS), disease-free survival (DFS), and cancer-specific survival (CSS) were compared across the BMI categories.

RESULTS: There were 164 (7.7%) underweight (BMI < 18.5 kg/m²), 1109 (51.9%) normal-weight (BMI = 18.5-23.9 kg/m²), 550 (25.7%) overweight (BMI = 24.0-26.9 kg/m²), and 315 (14.7%) obese (BMI ≥

27 kg/m²) patients. Being female, apparently anemic, hypoalbuminemic, and having body weight loss was more likely among underweight patients than among the other patients ($P < 0.001$). Underweight patients had higher mortality rate ($P = 0.007$) and lower OS ($P < 0.001$) and DFS ($P = 0.002$) than the other patients. OS and DFS did not differ significantly between normal-weight, overweight, and obese patients, while CSS did not differ significantly with the BMI category.

CONCLUSION: In Taiwan, BMI does not significantly affect colon-CSS. Underweight patients had a higher rate of surgical mortality and a worse OS and DFS than the other patients. Obesity does not predict a worse survival.

INTRODUCTION

The prevalence of obesity and the incidence of colon cancer continue to increase in Taiwan as in other developed countries. The findings of many studies support the idea that obesity is a risk factor for the development of colon cancer^[1-3]. However, the few studies that have investigated the influence of body mass index (BMI) on the outcomes of colon cancer patients have produced

inconsistent findings^[4-7]. These previous reports were mostly from Western countries and based on clinical trial data. We investigated herein the role of BMI in general colon cancer patients in Taiwan; the population of this study may represent both Chinese people and Asians in general, in terms of the clinical characteristics, postoperative morbidities and mortalities, and long-term outcome defined by overall survival (OS), disease-free survival (DFS), and cancer-specific survival (CSS).

MATERIALS AND METHODS

Study population

From January 1995 to July 2003, 2138 patients from a total population of 2765 patients with histologically confirmed adenocarcinoma of the colon were enrolled in this study; 14 nonmetastatic patients without available BMI data and 613 patients with metastatic disease were excluded. The included patients had regular follow-up visits with a healthcare professional until December 2008 (i.e., a postoperative follow-up period of at least 5 years) or until death.

The demographic and clinicopathologic data evaluated for each patient included age, gender, body height and weight, tumor stage (as defined according to the American Joint Committee on Cancer TNM staging system, sixth edition, New York: Springer-Verlag, 2002), tumor location, degree of tumor differentiation, timing of surgery (i.e., elective or emergent), medical illness, and preoperative laboratory data.

BMI was calculated as the weight in kilograms divided by the height in meters squared. The following BMI categories were established according to the classification of the Department of Health (DOH) of Taiwan:^[8] underweight (BMI < 18.5 kg/m²), normal weight (BMI = 18.5-23.9 kg/m²), overweight (BMI = 24.0-26.9 kg/m²), and obese (BMI ≥ 27 kg/m²). For long-term outcome, BMI was also categorized according to the World Health Organization (WHO) classification^[9] as follows: underweight (BMI < 18.5 kg/m²), normal weight (BMI = 18.5-24.9 kg/m²), overweight (BMI = 25-29.9 kg/m²), and obese (BMI ≥ 30 kg/m²) to enable comparison with the Taiwanese classification, since The Expert Consultation on BMI in Asian populations recommended that the current WHO BMI cut-off points be retained as the international classification^[10].

Local recurrence or distant metastasis was confirmed histologically or radiographically, while postoperative mortality was defined as death within 30 d of the primary surgery. The patients were divided into three age groups: younger than 40 years (younger group), 40-75 years (middle age group), and older than 75 years (elderly group). The carcinoembryonic antigen (CEA) level was considered to be abnormal at > 5 ng/mL. Tumor location was categorized as right (from the cecum to the transverse colon) or left (from the splenic flexure to the sigmoid colon). Hypoalbuminemia was defined as a serum albumin level of < 35 g/L and apparent anemia was defined as a hemoglobin level of < 10 g/dL.

Except where stated otherwise, data are the percentage of the particular body mass index (BMI) category population. CEA: Carcinoembryonic antigen.

Statistical analysis

Survival curves were constructed using the Kaplan-Meier method and then compared using the log-rank test. OS was calculated as the number of years from primary surgery to the date of death. DFS was calculated as the number of years from primary surgery to either the first disease recurrence or death. CSS was calculated as the number of years from primary surgery to the first of disease recurrence. The two arms were compared by Pearson χ^2 test and independent-samples *t* tests to

detect any differences in proportions and means. A Cox regression model was used for multivariate analysis. All *P* values were two-tailed, and they were considered to be statistically significant at < 0.05 .

RESULTS

Disease and patient characteristics

The study population comprised 2138 patients with colon cancer, of whom 1109 were males and 1029 were females. BMI in this study ranged from 12.2 kg/m² to 49.0 kg/m², with a mean of 23.4 kg/m². Of the 2138 patients, 164 (7.7%) were underweight, 1109 (51.9%) were normal weight, 550 (25.7%) were overweight, and 315 (14.7%) were obese.

The characteristics of the patients and tumors are presented stratified according to BMI category in Table 1. The age of the entire study population was 61.4 ± 13.9 years (mean ± SD); those of the underweight, normal-weight, overweight, and obese patients were 63.5 ± 17.3 years, 61.8 ± 14.0 years, 61.9 ± 12.4 years, and 61.7 ± 12.3 years, respectively. The mean age did not differ significantly with the BMI category (*P* = 0.828). However, the distribution of age groups differed significantly with the BMI category, with the proportions of younger and elderly patients being higher in underweight-patients group than in the other groups (*P* < 0.001). The gender distribution also differed significantly between the underweight patients and the other groups, with underweight

patients being more likely to be female. The tumor location also differed significantly, with the proportion of right colon cancer decreasing as the BMI category increased (*P* < 0.001).

With respect to the distribution of tumor stage among the BMI categories, the number of stage I tumors was lower in the underweight and normal-weight patients than in the overweight and obese patients. The obese patients had the lowest number of stage III tumors.

The proportion of emergent operations did not differ significantly with the BMI category: 3.7% of underweight, 3.4% of normal-weight, 2.5% of overweight, and 2.2% of obese patients (*P* = 0.584).

Underweight patients were the most likely to exhibit apparent anemia (hemoglobin < 10 g/dL) and have hypoalbuminemia and body weight loss (*P* < 0.001). The proportion of patients with body weight loss, hypoalbuminemia, and apparent anemia decreased as the BMI category increased. The percentage of patients with an abnormal preoperative CEA level did not differ significantly with the BMI category.

Finally, with regard to associated medical illnesses, the percentage of patients with hypertension or diabetes mellitus increased with the BMI category. Obese patients were the most likely to have heart disease. The other associated comorbidities including previous stroke, asthma, peptic ulcer disease, chronic hepatitis, renal insufficiency, and others (e.g., gall stones and thyroid disease) did not differ significantly with the BMI category.

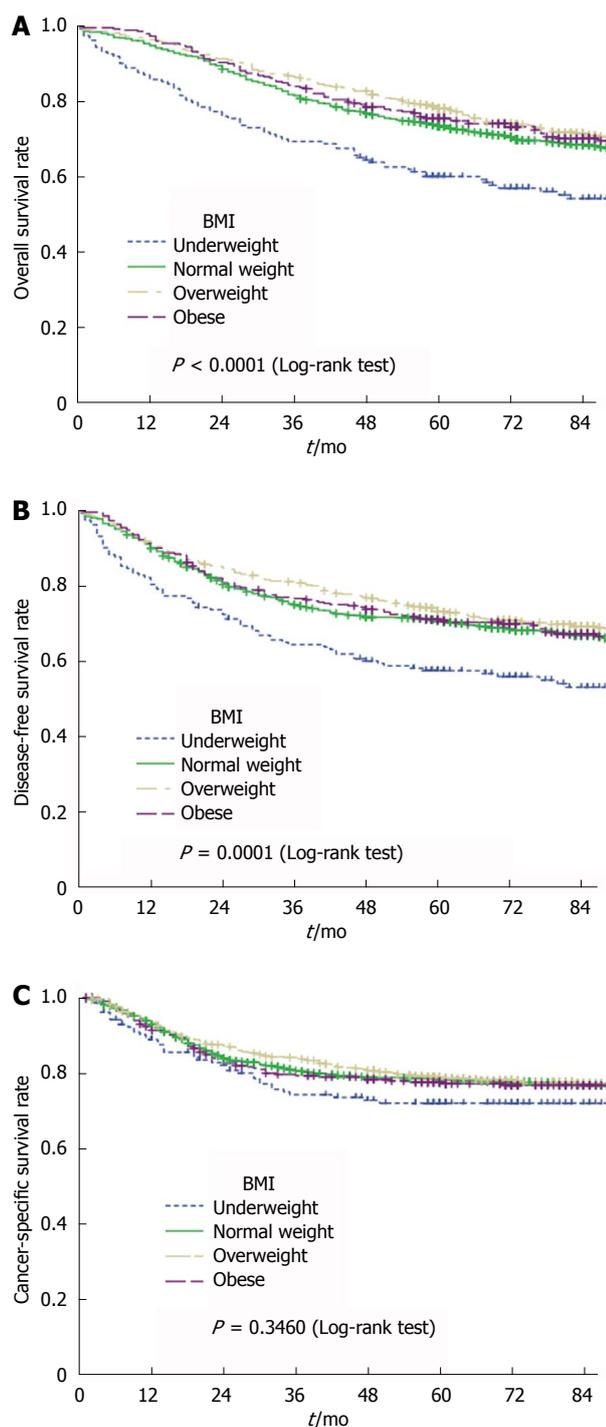

Figure 1 Overall survival curves (A), disease-free survival curves (B) and cancer-specific survival curves (C) relative to body mass index category using the Kaplan-Meier method, and comparison using the log-rank test. BMI: Body mass index.

Short-term outcome

The postoperative morbidity, anastomotic leakage, and mortality rates did not differ significantly between the underweight, normal-weight, overweight, and obese patients: 12.8%, 12.9%, 13.3% and 15.6%, respectively ($P = 0.667$); 1.2%, 1.4%, 1.6%, and 1.9%, respectively ($P = 0.880$); and 3.7%, 1.3%, 1.1%, and 0%, respectively ($P = 0.007$).

Long-term outcome

Data from all patients who received surgery were used to analyze the long-term outcome. Univariate analysis was performed using the Kaplan-Meier method, along with the log-rank test and Cox proportional-hazards model. The results of our statistical analysis are presented in Table 2, and the survival curves are shown in Figure 1A (OS), Figure 1B (DFS), and Figure 1C (CCS).

Univariate analysis revealed that OS ($P < 0.001$) and DFS ($P = 0.001$) were lowest in the underweight patients. The OS was marginally higher ($P = 0.046$) in overweight patients than in normal-weight patients, but the DFS ($P = 0.103$) did not differ significantly between the two groups. No significant difference in OS ($P = 0.500$) or DFS ($P = 0.807$) was observed between normal-weight and obese patients.

CSS did not differ significantly with the BMI category ($P = 0.346$). The results were similar when these patients were categorized according to the WHO BMI classifications.

Adjuvant chemotherapy was offered to 58.0%, 70.1%, 73.9%, and 70.8% of underweight, normal-weight, overweight, and obese patients with stage III tumors, respectively ($P = 0.096$). In total, 70.2% of patients with stage III tumors received adjuvant chemotherapy.

Since the compositions of patients and tumors differed with the BMI category, multivariate analysis was used to determine the effect of BMI along with other confounding factors on the long-term outcome. The variables of the Cox regression model included BMI, TNM stage, age group, gender, comorbidities (patients were divided into three groups: without, with one or two kinds, and with more than two kinds of comorbidity), CEA (normal *vs* abnormal), hemoglobin (< 10 g/L *vs* ≥ 10 g/L), albumin (normal *vs* hypoalbuminemia), timing of surgery (elective *vs* emergent), postoperative morbidity (with *vs* without), tumor location (right *vs* left), histologic type (adenocarcinoma *vs* mucinous *vs* signet-ring type), and histologic grade (high *vs* moderate *vs* low differentiation). The hazard ratio (HR) of each BMI category was compared with that of the normal-weight patients. The results of multivariate analysis for OS, DFS, and CSS are listed in Table 3.

As documented in Table 4, underweight patients had a significantly worse OS [HR, 1.58; 95% confidence interval (CI), 1.23-2.05; $P < 0.001$] and DFS (HR, 1.49; 95% CI, 1.16-1.93; $P = 0.002$), but their CSS did not differ significantly (HR, 1.33; 95% CI, 0.94-1.87; $P = 0.107$) when compared with the normal-weight patients. OS, DFS, or CSS did not differ significantly between the normal-weight, overweight, and obese patients.

To determine whether the prognostic effect of BMI was related to patient gender, a multivariate analysis was applied to separated data from male and female patients. The results of this statistical analysis yielded the same findings between the genders: CSS did not differ significantly with the BMI category for all patients or for male

or female patients.

DISCUSSION

BMI is a simple and easy-to-determine index used to classify individuals as being underweight, overweight, or obese. The classification of BMI was established to evaluate health risks such as type 2 diabetes and cardiovascular disease^[9,10]. The associations between BMI, percentage of body fat, and distribution of body fat differ across populations, which has resulted in different cut-off points for classifications being used in different countries. Furthermore, the cut-off points for certain risks vary between different Asian populations^[10]. The Expert Consultation on BMI in Asian populations recommended that the current WHO BMI cut-off points be retained as the international classification^[10]. In the present study, BMI classifications were based on the definition of the DOH, Taiwan. In addition, the WHO BMI classifications were used to evaluate the long-term outcome of colon cancer survivors and to compare with the Taiwan BMI classification system. In the present study, the prevalence rates of diabetes and hypertension increased significantly with the BMI category; this finding is highly consistent with the intended meaning of the BMI classification system. However, the risks of other comorbidities such as asthma, hepatitis, peptic ulcer disease, and renal insufficiency were not correlated with the BMI category.

Obesity is a growing problem in Taiwan and is known to increase the risk of developing colon cancer^[1-3]. It has also been reported that obese patients have a higher risk of surgical complications^[11-13]. Previous studies have produced controversial results regarding the relationship between obesity and anastomotic leakage^[14,15]. Sorensen *et al*^[14] reported that obesity is not a risk factor for anastomotic leakage in colonic resection, while Biondo *et al*^[15] reported that obesity is an independent risk factor, but is only associated with emergent procedures of the left colon. Miransky *et al*^[16] reported that obesity and a contaminated surgical procedure independently predicted surgical-site infection in colorectal procedures. Riou *et al*^[17] reported that obesity was a significant independent risk factor for wound dehiscence. Obesity has also been reported to be a risk factor for the postoperative occurrence of pulmonary complications^[18,19]. The postoperative morbidity rate and anastomotic leakage rate did not differ significantly with the BMI category in our study. However, one of the limitations of this study is that we did not examine whether the occurrence rate of the other type of complications differed with the BMI category.

In the present study, the risk of postoperative mortality was highest in underweight patients. This finding is similar to that of Hickman *et al*^[20]. Although obese patients have higher rates of comorbidities with cardiovascular disease and diabetes, the postoperative morbidity and mortality rates were comparable with the normal-weight patients. Conversely, the underweight patients had

¹HR was calculated using the Cox regression model; the variables in the multivariate analysis included TNM stage, age, gender (when analyzing all patients), comorbidities, CEA, hemoglobin, albumin, operative timing, postoperative morbidity, tumor location, histologic type, and histologic grade; ²Each category compared to normal-weight patients. HR: Hazard ratio; CI: Confidence interval; BMI: Body mass index; TNM: Tumor, nodes, metastasis; CEA: Carcinoembryonic antigen.

a lower rate of comorbidities but a higher rate of postoperative mortality than did the other patients. However, a higher proportion of underweight patients in this study were hypoalbuminemic and anemic. The observed higher postoperative mortality rate may be at least partially attributed to the associated disease conditions.

Whether obese colon cancer patients have a worse long-term outcome than other patients remains a matter of controversy. Sinicrope *et al*⁷¹ reported that underweight patients had a significantly worse OS ($P = 0.0258$), and that BMI ≥ 35 kg/m² patients exhibited a trend toward a worse DFS ($P = 0.0725$) and OS ($P = 0.0805$) compared with normal-weight patients, but there was no significant difference. When they analyzed the data according to patient gender, males with BMI ≥ 35 kg/m² exhibited a reduced OS, and females with obesity (BMI = 30-34 kg/m²) had a reduced OS when compared with their normal-weight counterparts. BMI category was significantly associated with both DFS and OS in multivariate analysis in their study. Meyerhardt *et al*⁶¹ reported that neither BMI nor weight change was significantly associated with colon cancer patient survival indicators,

including the OS, DFS, and recurrence-free survival, even for underweight patients. Dignam *et al*⁵¹ reported that OS and DFS were significantly worse for underweight patients (BMI < 18.5 kg/m²) and very obese patients (BMI ≥ 35 kg/m²) than for normal-weight patients. Very obese patients had a greater risk of cancer recurrence or secondary primary tumors. In the present study, we found that BMI by itself was not a significant factor of CSS in colon cancer, but OS and DFS did tend to be worse for underweight patients than for the other patients. We found no differential effect of gender on either BMI or obesity. Compared with other patients, underweight patients had a worse OS but a similar CSS. This implies that many underweight patients died from noncancer events. It would have been reasonable to conclude that underlying comorbidities caused the higher mortality risk among the underweight patients, but in the present study this group actually had the smallest number of comorbidities. Further research should be conducted to establish the mechanisms responsible for the observed higher mortality risk in underweight patients. Furthermore, previous studies have shown that highly

obese patients (BMI ≥ 35 kg/m²) or males may have a worse long-term outcome than normal-weight patients, but the obese cohort of the present study was not large enough to allow analysis of the difference.

In this study, tumor location was found to be correlated with BMI, such that the proportion of patients with right colon cancer increased as the BMI category decreased. Whether patients with a lower BMI tend to have right-side colon cancer is not well known or studied. However, since the lumen is larger for the right than the left colon, symptoms related to the tumor such as small-caliber or bloody stool need more time to be sensed by patients with right colon cancer, resulting in a longer period of nutrition depletion and body weight loss. Minoo *et al.*^[21] reported that proximally located tumors are significantly larger than those found in the distal colon. We have shown previously that the prevalence of malnutrition (hypoalbuminemia) is higher for right colon tumors than for left colon tumors^[22]. Moreover, body weight loss is more common in right colon cancer than in left colon cancer (48.8% and 33.5%, respectively; $P < 0.001$). BMI is reduced in patients with body weight loss, and more patients with right colon tumors have body weight loss resulting in a lower BMI, which may partly explain the greater number of left-side tumors in the groups with a higher BMI.

The findings of this study suggest that a low BMI is a marker of weight loss, blood loss, nutrition depletion, and more-advanced disease, all of which are associated with a worse DFS and OS^[22-24]. This could be the reason why the low-BMI group had a lower DFS and OS.

This study was subject to some limitations. It lacked data regarding changes in body weight before and after surgery, measurement of central obesity, physical activity, and diet changes after surgery, and involved a smaller sample than did previous studies. However, the study's cohort came from a single medical institution with a standard collection of patients' data, and so there was no selection bias as might be expected in a clinical trial. The results of this study pertain to patients from Taiwan and hence may not be generalizable to other populations.

For the population of Taiwan, which represents both Chinese people and Asians in general, BMI does not appear to be a significant factor of colon-CSS, but underweight patients appear to have a higher postoperative mortality and worse OS, and are less likely to experience DFS than those in the other BMI categories. The obese patients had a higher wound complication rate, but exhibited a similar survival rate when compared to the normal-weight patients.

COMMENTS

Background

The prevalence of obesity and the incidence of colon cancer continue to increase in Taiwan as in other developed countries. Studies that have investigated the influence of body mass index (BMI) on the outcomes of colon cancer patients have produced inconsistent findings. These previous reports were mostly from Western countries, and lacked data regarding Asian people. The authors

therefore investigated the role of BMI in general colon cancer patients of Taiwan, in terms of the clinical characteristics and short- and long-term outcomes.

Research frontiers

BMI is a simple index that is used to classify individuals as being underweight, overweight, or obese. The cut-off points of BMI for classifications vary in different countries. The World Health Organization BMI classifications were used to evaluate the long-term outcome of colon cancer survivors and were compared with those determined using the Taiwan BMI classification system.

Innovations and breakthroughs

The findings of the present study demonstrate that a low BMI could be a marker of weight loss, blood loss, nutrition depletion, and more-advanced disease. For the population of Taiwan, which represents both Chinese people and other Asians in general, BMI does not appear to significantly affect the colon-cancer-specific survival, although underweight patients do appear to have a higher postoperative mortality and worse overall survival, and are less likely to experience disease-free survival than patients in the other BMI categories.

Applications

BMI is a simple index that can be used to evaluate the likelihood of colon cancer patients developing weight loss, blood loss, nutrition depletion, and more-advanced disease.

Terminology

BMI was calculated as the weight in kilograms divided by the height in meters squared. The classification of BMI was established to evaluate health risks such as type 2 diabetes and cardiovascular disease.

Peer review

This study investigated the effect of body mass index on the characteristics and overall outcome of colon cancer in Taiwan. This manuscript addresses a highly relevant subject and could be important for the cancer field.

Abstract

AIM: To investigate the potential mechanism of Arg-Gly-Asp (RGD) peptide-labeled liposome loading oxymatrine (OM) therapy in CCl₄-induced hepatic fibrosis in rats.

METHODS: We constructed a rat model of CCl₄-induced hepatic fibrosis and treated the rats with different formulations of OM. To evaluate the antifibrotic effect of OM, we detected levels of alkaline phosphatase, hepatic histopathology (hematoxylin and eosin stain and Masson staining) and fibrosis-related gene expression of matrix metalloproteinase (MMP)-2, tissue inhibitor of metalloproteinase (TIMP)-1 as well as type I procollagen *via* quantitative real-time polymerase chain reaction. To detect cell viability and apoptosis of hepatic stellate cells (HSCs), we performed 3-(4,5)-dimethylthiazoliazolo(2-yl)-2,5-diphenyltetrazolium bromide assay and flow cytometry. To reinforce the

combination of oxymatrine with HSCs, we constructed fluorescein-isothiocyanate-conjugated Arg-Gly-Asp peptide-labeled liposomes loading OM, and its targeting of HSCs was examined by fluorescent microscopy.

RESULTS: OM attenuated CCl₄-induced hepatic fibrosis, as defined by reducing serum alkaline phosphatase (344.47 ± 27.52 U/L *vs* 550.69 ± 43.78 U/L, $P < 0.05$), attenuating liver injury and improving collagen deposits ($2.36\% \pm 0.09\%$ *vs* $7.70\% \pm 0.60\%$, $P < 0.05$) and downregulating fibrosis-related gene expression, that is, MMP-2, TIMP-1 and type I procollagen ($P < 0.05$). OM inhibited cell viability and induced apoptosis of HSCs *in vitro*. RGD promoted OM targeting of HSCs and enhanced the therapeutic effect of OM in terms of serum alkaline phosphatase (272.51 ± 19.55 U/L *vs* 344.47 ± 27.52 U/L, $P < 0.05$), liver injury, collagen deposits ($0.26\% \pm 0.09\%$ *vs* $2.36\% \pm 0.09\%$, $P < 0.05$) and downregulating fibrosis-related gene expression, that is, MMP-2, TIMP-1 and type I procollagen ($P < 0.05$). Moreover, *in vitro* assay demonstrated that RGD enhanced the effect of OM on HSC viability and apoptosis.

CONCLUSION: OM attenuated hepatic fibrosis by inhibiting viability and inducing apoptosis of HSCs. The RGD-labeled formulation enhanced the targeting efficiency for HSCs and the therapeutic effect.

INTRODUCTION

Hepatic fibrosis is characterized by excessive deposition of extracellular matrix (ECM) components in the interstitial space of the liver^[1,2]. The fibrogenesis is triggered by a variety of events that lead to chronic injury, including viral infection, drug or alcoholic toxicity, autoimmune disorders and metabolic diseases. As a consequence of liver damage, nonparenchymal cells are activated by a concert of mediators released from injured hepatocytes. A population of nonparenchymal cells, the hepatic stellate cells (HSCs), have been identified and recognized for their contributing role in the fibrotic process after transformation towards myofibroblasts^[3]. Thus, HSCs represent an attractive target for the development of antifibrotic strategies incorporating a selective targeting approach for hepatic fibrosis^[4]. Recently, several therapeutic strategies have been developed by means of targeting hepatic fibrosis, including inhibition of collagen synthesis^[5], interruption of matrix deposition^[6], stimulation of matrix degradation, modulation of HSC activation^[7], or induction of HSC death^[8]. Despite advance in understanding hepatic fibrogenesis, therapeutic repertoire for hepatic fibrosis treatment is still limited.

Oxymatrine (OM), an alkaloid extracted from the medicinal plant *Sophora alopecuroides* L, has received increasing attention for its multiple pharmacological functions. OM has been demonstrated to exert an inhibitory effect on the replication of hepatitis B^[9] and C^[10] viruses *in vitro*. Preclinical and clinical studies have shown that OM effectively inhibited infection with hepatitis B virus^[11]. In addition to antiviral effects, OM has been reported to have a beneficial effect on progression of CCl₄-induced hepatic fibrosis in rats. Recent studies have demonstrated that OM induces apoptosis in a variety of cells; mainly malignant cells^[12]. Apoptosis-inducing activity of OM makes it an attractive antifibrotic agent. However, there is limited evidence for the efficacy of OM in hepatic fibrosis and the underlying mechanism.

In the present study we aimed to investigate whether Arg-Gly-Asp (RGD)-mediated targeting delivery of OM exerted antifibrogenic action with improved efficiency of fibrogenic liver^[13]. *In vitro* experiments showed that uptake of OM in HSCs was enhanced and the apoptotic process was induced. In CCl₄-induced rats, delivery of OM to HSCs with this formulation strategy improved the efficacy of this medication in the treatment of hepatic fibrosis.

MATERIALS AND METHODS

Preparation of OM-RGD liposomes

The lipid phase consisting of a mixture of lecithin and cholesterol in a ratio of 2:1 was dissolved in CHCl₃-MeOH (1:1) followed by evaporation and addition of pleic acid and polysorbate. Lipids were mixed with the aqueous solution containing OM and polyvinylpyrrolidone in phosphate-buffered saline (PBS; pH 7.4).

The mixture was sonicated for 5 min at 50% amplifying strength resulting in a water-in-oil emulsion. After removal of the organic solvent with a rotary evaporator under vacuum, the dispersion of liposomes was formed.

RGD peptide was synthesized by the Chinese Peptide Company (Hangzhou, China). RGD peptide coupling was performed as described previously^[14]. In brief, 4 nmol cyclo-Arg-Gly-Asp (cRGD) peptide per mmol total lipid was added after deacetylation of the peptide in 0.5 mol hydroxylamine solution, and incubated for 1 h at room temperature. Unloaded liposomes and unbound RGD were separated by CL-4B column (Amersham, Piscataway, NJ, United States).

HSC preparation

HSCs were isolated by collagenase perfusion through the portal vein in Sprague-Dawley rats, followed by Nycomed gradient centrifugation. Cells were incubated in Dulbecco's Modified Eagle's Medium (DMEM) supplemented with 10% fetal bovine serum (v/v) and 100 U/mL penicillin and streptomycin, and maintained at 37 °C in a humidified incubator (90% humidity) containing 50 mL/L CO₂. HSCs seeded at a density of 10⁴ cells/cm² attained confluence in 6 d and formed a monolayer of closely apposed polygonal cells. The morphology and growth of HSCs were confirmed and evaluated by microscopy.

Cell viability assay

Cell viability was determined through 3-(4,5)-dimethyl thiaziazol(-z-y1)-3,5-diphenyltetrazolium bromide (MTT) assay. The MTT assay depends on the extent to which viable cells convert MTT bromide to an insoluble colored formazan product that can be determined spectrophotometrically. After treatment, cells were harvested and washed in PBS, and 200 mL DMEM without phenol red, containing 5 mg/mL MTT, was added to each cell. Three hours later, the medium was aspirated, and the converted dye was solubilized with isopropanol (0.1 mol/L HCl in isopropanol). The resulting absorbance from each cell was measured at a wavelength of 570 nm with background subtraction at 630 nm.

Flow cytometry

HSCs were treated with different concentration of OM-RGD liposomes for 48 h at a cell density of 2 × 10⁵ cells/mL, and then stained with annexin V-fluorescein isothiocyanate (FITC) and propidium iodide (PI) (Sigma, St Louis, MO, United States). Annexin V-FITC-positive and PI-negative cells were considered to be apoptotic cells.

Transmission electron microscopy

HSCs were cultured with different formulation of OM at 37 °C for 24 h and then harvested by trypsinization and centrifugation for 10 min at 3500 rpm at room temperature. Cells were fixed in 4% (v/v) glutaraldehyde for 4 h at 4 °C. The specimens were washed with sodium

cacodylate buffer (pH 7.4) followed by post-fixation in 1% osmium tetroxide at 4 °C. Cells were then washed with cacodylate buffer (pH 7.4) and dehydrated with a graded series of acetone. The cells were embedded with 100% resin in a beam capsule. A sample block was sectioned using an ultramicrotome. The sections were placed into a grid and stained with uranyl acetate for 10 min followed by 50% filtered acetone, and finally stained with lead. The stained samples were then viewed under a transmission electron microscope (Phillips, Eindhoven, The Netherlands).

Real-time PCR

Total RNA was extracted from cells using the TRIzol reagent. The amount of each RNA sample was determined by Qubit fluorometer. Reverse transcription was performed in a 20-μL reaction system with 200 ng total RNA using high capacity cDNA reverse transcription kits. Relative quantification of designated genes including *MMP-2*, *TIMP* and type I procollagen were assessed by real-time PCR through the ABI 7900HT system. A housekeeping gene glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) was used as an internal control. Primer sequences used are shown as follows: type I procollagen, 5'-CCTGGCAGAACGGAGATGAT-3', 5'-ACCA CAGCACCATCGTTACC-3'; *MMP-2*, 5'-CTATTCTGT CAGCACTT TGG-3', 5'-CAGACTTTGGTTCTC-CA ACTT-3'; *TIMP-1*, 5'-ACA GCTTT CTGCA ACTCG-3', 5'-CTATAGGTCTTT ACGAAGGCC-3'; *GADPH*, 5'-AC CCCC AATGTATCCGTGT-3', 5'-TA CTCCTTGGAGGCCATGTA-3'. The relative abundance of target mRNA was determined with the comparative cycle threshold method.

Animals and experimental design

Male Sprague-Dawley rats came from the Experimental Animal Center of Beijing Medical University (Beijing, China) and were caged in an environment with regulated temperature (21 ± 1.6 °C), humidity (45% ± 10%), and an alternating 12-h light and dark cycle. The animals had

free access to water and diet throughout the study.

For the chronic liver injury model, animals were injected intraperitoneally with 50% CCl₄ (CCl₄:vegetable oil = 1:1) at a dose of 0.15 mL/100 g body weight and were also divided into four groups: Group A (administered with OM-loaded liposome); Group B (administered with OM-RGD liposome); Group C (hepatic fibrosis); and Group D (blank vector). Injections were given three times weekly for 8 wk. After treatment, the rats received an intravenous injection according to their subgrouping. Groups A and B were given OM liposomes and OM-RGD liposomes, respectively. The rats in Group D were administered with 0.5 mL blank liposomes. The rats were sacrificed 8 wk after injection, and the livers and blood samples were collected for further assessments.

For HSC targeting, CCl₄-treated animals were injected with FITC-labeled OM liposomes and OM-RGD liposomes *via* the tail vein. Hepatocytes and HSCs were isolated from each individual rat 24 h post-injection, as described previously^[15].

Histological analysis

Animals were sacrificed 8 wk after treatment. Liver samples from each group were harvested, fixed with 10% formaldehyde, embedded in olefin, and stained with hematoxylin and eosin (HE) as well as Masson collagen staining.

Statistical analysis

The data are expressed as mean ± SD. Student's *t*-test or Dunnett's *t*-test was used to compare the differences between treated and control groups, and differences were considered significant at *P* < 0.05.

RESULTS

Antifibrogenic effect of OM-RGD liposomes in CCl₄-induced fibrotic liver

We evaluated the therapeutic effect of OM-RGD liposomes on CCl₄-induced liver injury in rats. As shown in Table 1, elevated levels of alkaline phosphatase were reduced by OM. Histopathological analysis revealed that CCl₄-induced hepatic fibrosis was ameliorated by OM (Figure 1A). Excessive collagen deposited in response to CCl₄-induced liver injury was ameliorated by OM (Table 1, Figure 1B). Moreover, the RGD-labeled liposomal formulation exerted a more aggressive therapeutic effect in hepatic fibrosis than did OM in terms of alkaline phosphatase (Table 1), histopathology (Figure 1A), and collagen deposits (Table 1, Figure 1B).

OM-RGD liposomes induced apoptosis in HSCs in vitro

The inhibitory effect of OM-RGD liposomes on the viability of primary HSCs was determined by MTT assay. As shown in Figure 2A, OM-RGD liposomes significantly inhibited the viability of HSCs, whereas OM liposomes exhibited low cytotoxicity in HSCs. The ultrastructure of HSCs treated with different formulation of OM was

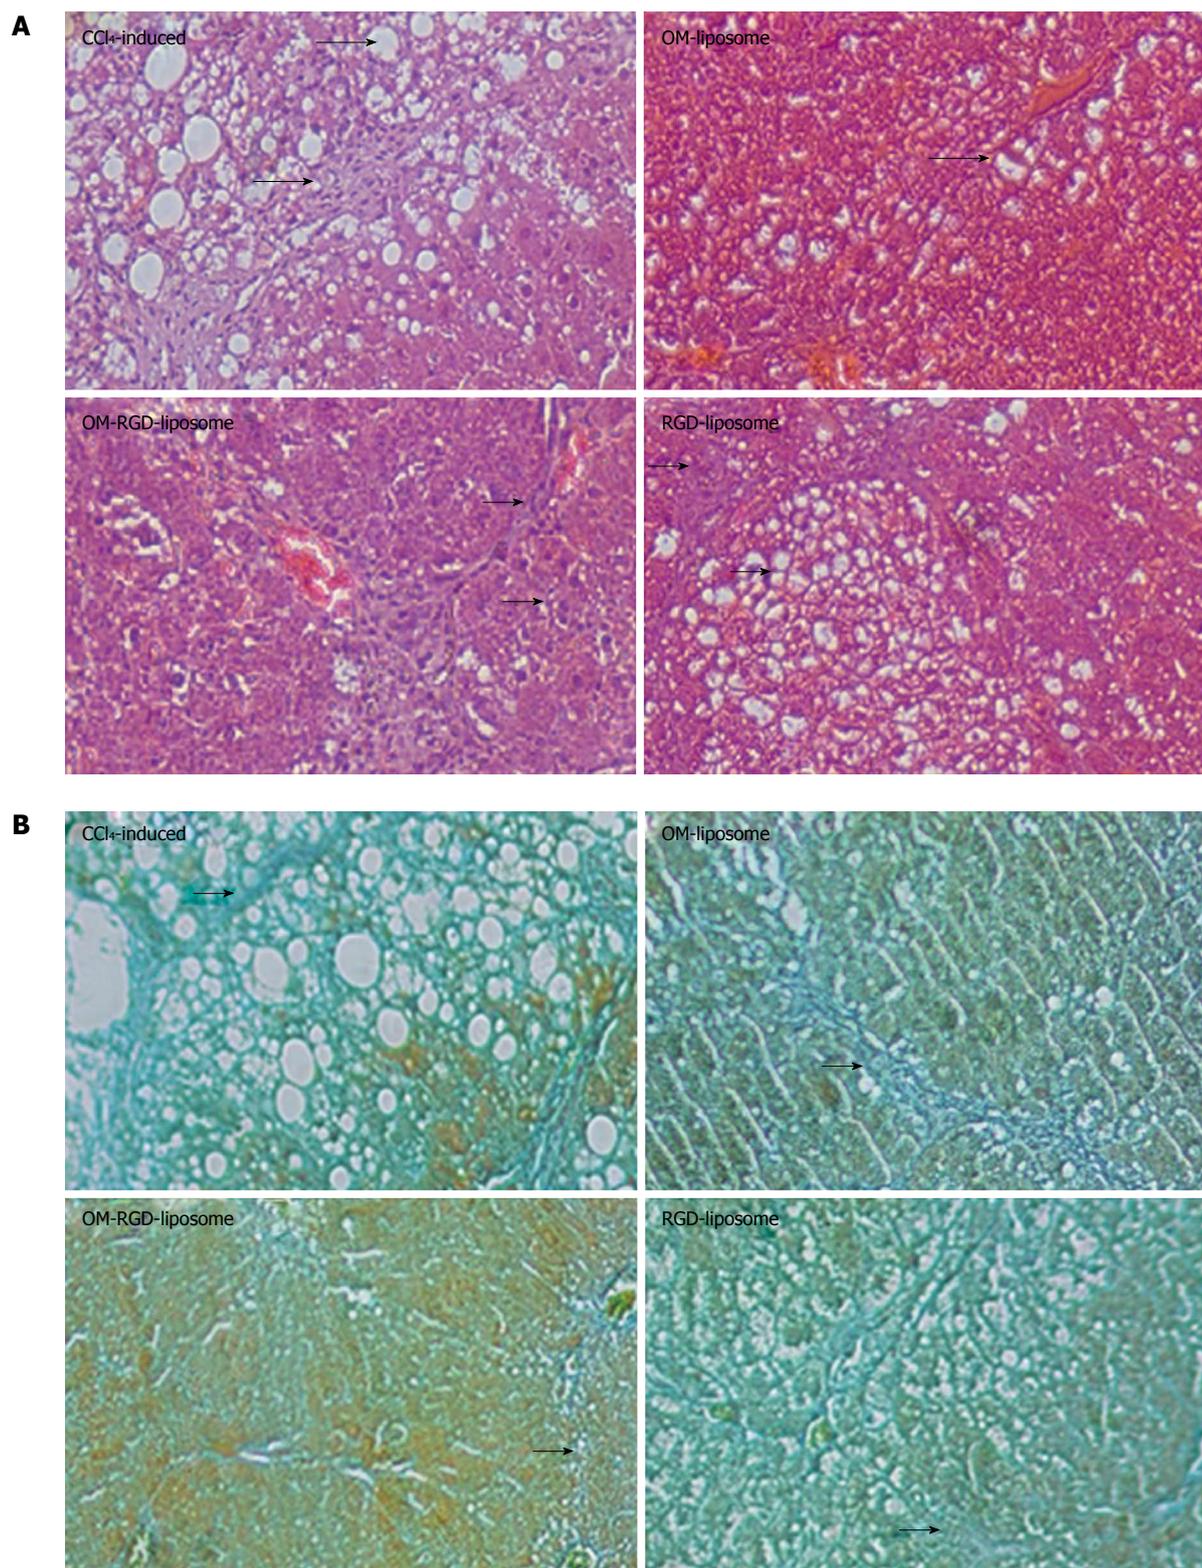

Figure 1 Oxymatrine liposomes attenuated hepatic fibrosis and improved collagen deposition. A: Representative images of liver treated with oxymatrine (OM) in different liposomal formulations in rats with CCl₄-induced hepatic fibrosis. Liver tissues were obtained at 4 wk after treatment and stained with HE; B: Representative histological images of liver treated with OM in different liposomal formulations in rats with CCl₄-induced hepatic fibrosis. Liver tissues were obtained at 4 wk after treatment and stained with Masson stain (original magnification × 100). HE: Hematoxylin and eosin.

examined by transmission electron microscopy (TEM). TEM revealed that treatment with OM-RGD liposomes resulted in typical morphological sign of apoptosis, including cell shrinkage, increased cellular granularity, and

formation of apoptotic bodies (Figure 2B). The apoptotic effect of different formulations of OM was determined by using flow cytometry. Cell cycle analysis revealed that incubation with OM-RGD liposomes resulted

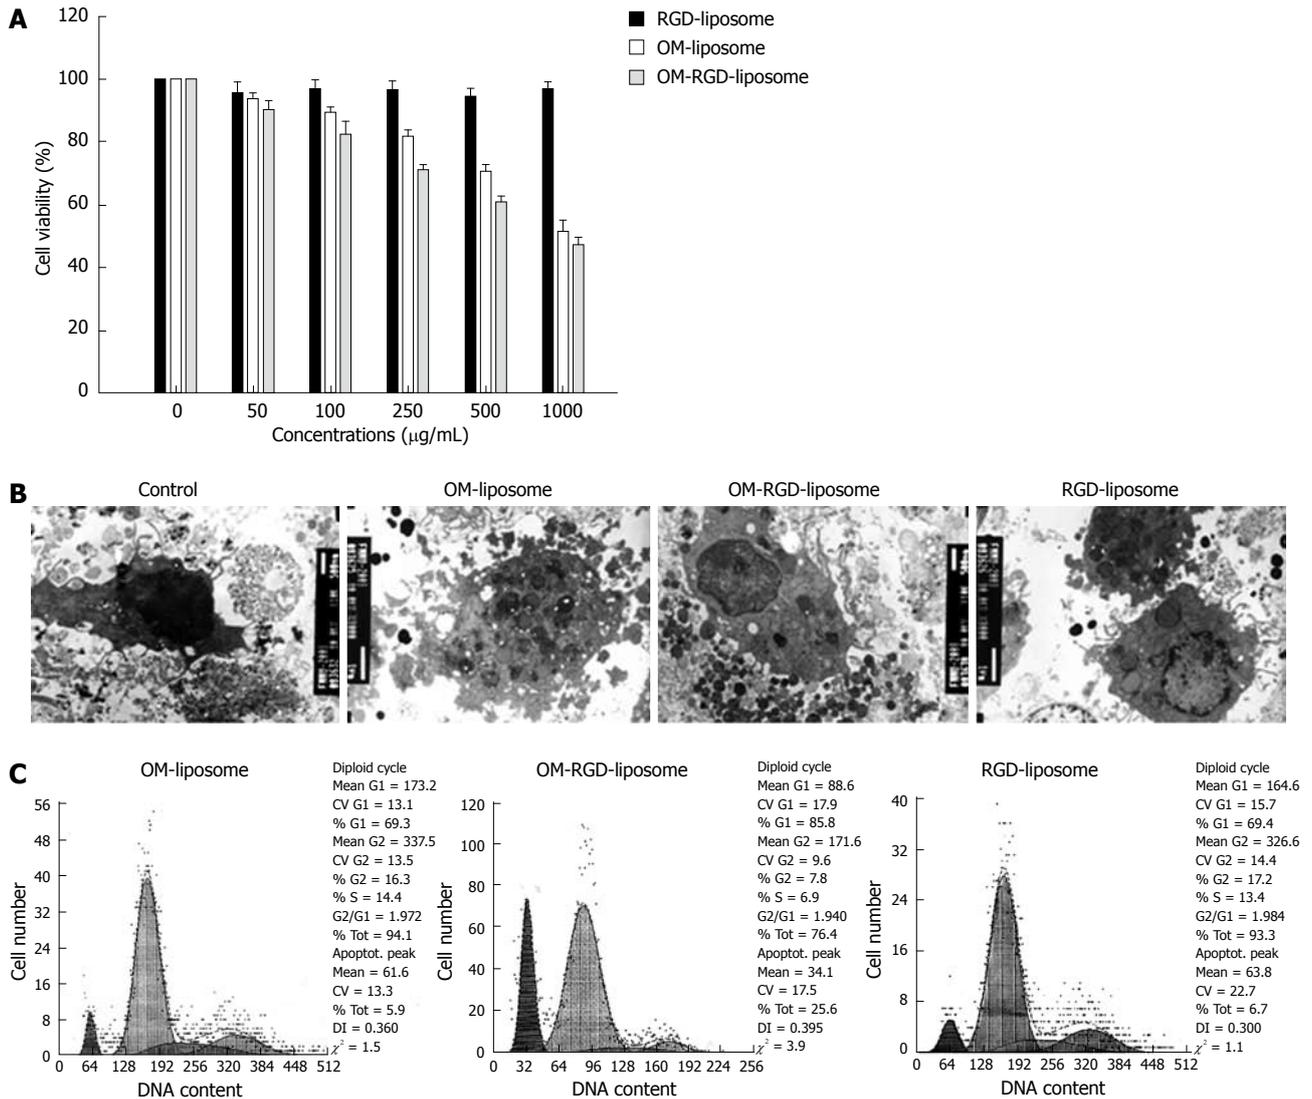

Figure 2 Oxymatrine liposomes induced apoptosis in hepatic stellate cells *in vitro*. **A:** Inhibitory effect of oxymatrine (OM) on hepatic stellate cell (HSC) viability *in vitro*. HSCs were isolated and treated with OM in different liposomal formulations. Cell viability was determined using MTT assay; **B:** Electron micrograph of untreated HSCs demonstrates the normal structure of HSCs. OM-liposome-treated (24 h) HSCs had morphological features of apoptosis: cell shrinkage and apoptotic body formation. OM-RGD-liposome-treated HSCs showed typical morphological features of apoptosis: cell shrinkage and apoptotic body formation. RGD-liposome-treated HSCs showed normal structure; **C:** Cell cycle analysis after induction of apoptosis in HSCs by OM *via* flow cytometry. The cells were incubated with different formulation of OM for 24 h, and stained with PI. MTT: 3-(4,5)-dimethylthiazolozol-2-yl-2,5-diphenyltetrazolium bromide; RGD: Arg-Gly-Asp; PI: Propidium iodide; DI: DNA grading index.

in a significant increase in sub-G₁ phase accumulation that was recognized as a biomarker of apoptosis (Figure 2C). Moreover, the RGD-labeled liposomal formulation had a more aggressive effect on HSCs than that of OM in terms of cell viability (Figure 2) and apoptosis (Figures 3 and 4)

OM-RGD liposomes inhibited fibrosis-related gene expression in CCl₄-induced fibrotic liver injury

We also examined the change in mRNA expression of fibrosis-related genes upon treatment with OM in different liposomal formulations. As shown in Figure 3, mRNA expression of MMP-2, TIMP-1 and type I procollagen was considerably elevated upon CCl₄ induction (*vs* normal, *P* < 0.05). Treatment with OM resulted in significant decreases in mRNA expression of these designated fibro-

sis-related genes and fibrosis-related gene expression (*vs* CCl₄-induced group, *P* < 0.05). Moreover, RGD-labeled liposomal formulation had a more aggressive downregulation of fibrosis-related gene expression than that of OM (*vs* CCl₄-induced hepatic fibrosis group, *P* < 0.05; as compared to OM liposomes, *P* < 0.05).

RGD enhanced OM targeting of HSCs in fibrotic rats

To evaluate the specificity of binding to HSCs in fibrotic liver, OM-RGD liposomes were conjugated with FITC and injected intravenously to rats with CCl₄-induced hepatic fibrosis. HSCs were isolated and examined by fluorescence microscopy. As shown in Figure 4, a significantly high number of FITC-positive HSCs was found in the OM-RGD liposome group compared with the OM liposome group.

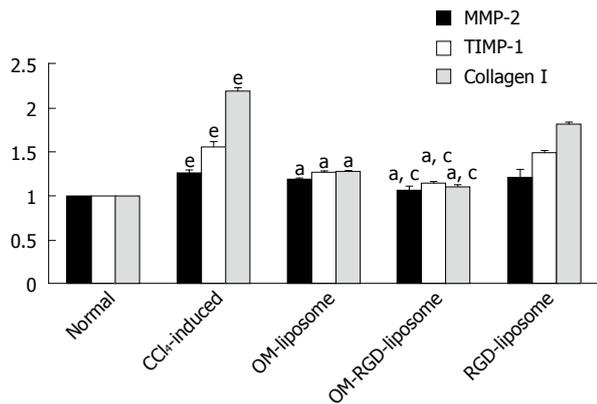

Figure 3 Oxymatrine liposomes inhibited fibrosis-related gene expression. The expression of fibrosis-related gene, such as MMP-2, TIMP-1 and collagen I was evaluated by real-time polymerase chain reaction. ^a*P* < 0.05 vs normal; ^c*P* < 0.05 vs CCl₄-induced hepatic fibrosis; ^{a, c}*P* < 0.05 vs oxymatrine liposomes. MMP: Matrix metalloproteinase; TIMP: Tissue inhibitor of metalloproteinase; OM: Oxymatrine; RGD: Arg-Gly-Asp.

DISCUSSION

Increased understanding of the pathogenesis of hepatic fibrosis has led to drug discovery for its treatment. Pre-clinical and clinical studies have reported that hepatic fibrosis is dynamic and possibly reversible^[16,17]. During recent decades, antifibrotic strategies have predominantly focused on eradication of causative factors, for example, clearance of virus^[18]. Since the pathogenesis of fibrosis was clarified recently^[19], researches have focused on agents that could prevent or reverse fibrosis. OM has been reported for its pharmacological potential to treat liver disorders, particularly inhibiting viral infection^[10,11,20,21]. It has been demonstrated to exert antifibrotic action^[22]. In our study, we confirmed that OM could attenuate CCl₄-induced hepatic fibrosis in a rat model, as defined by a significant decrease in the serum level of alkaline phosphatase and improvement of histopathological change.

OM was recently referred to as an antifibrosis agent in clinical and preclinical studies. However, its mechanisms of action were still puzzling. In preclinical studies, it was proved that OM showed prophylactic and therapeutic effects in D-galactosamine-induced rat hepatic fibrosis, partly by protecting hepatocytes and suppressing fibrosis accumulation through acting against lipid peroxidation^[23]. Another study also demonstrated that OM was effective in reducing the production and deposition of collagen in the liver tissue of experimental rats in ways that relate to modulating the fibrogenic signal transduction *via* the p38 mitogen-activated protein kinase signaling pathway^[24]. Moreover, OM could promote the expression of Smad 7 and inhibit the expression of Smad 3 and cAMP-response element binding protein-binding protein in CCl₄-induced hepatic fibrosis in rats, and modulate the fibrogenic signal transduction of the transforming growth factor (TGF)- β -Smad pathway^[25]. Clinical studies have proved that the effect of OM against hepatic fibrosis is

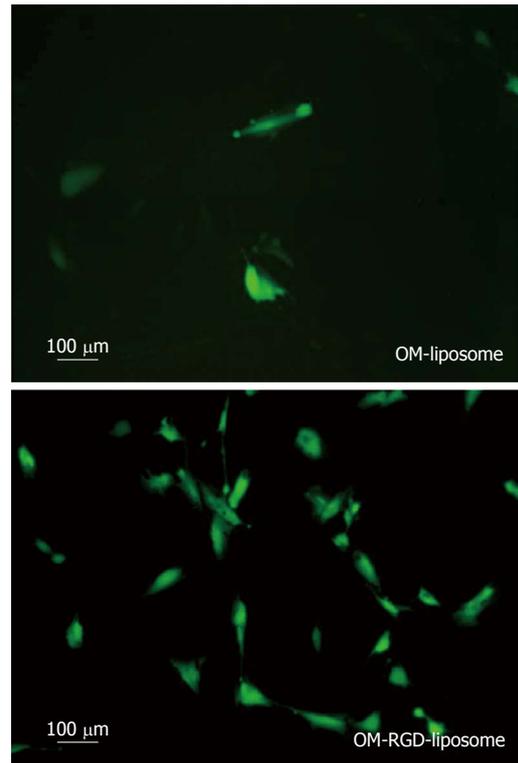

Figure 4 Representative fluorescein isothiocyanate hepatic stellate cells in rat hepatic tissue treated with oxymatrine liposomes and oxymatrine-Arg-Gly-Asp liposomes (original magnification \times 200). OM: Oxymatrine; RGD: Arg-Gly-Asp.

mediated by lowering the levels of TGF- β 1 and tumor necrosis factor- α and increasing the level of interleukin-10 in chronic hepatitis B patients^[26]. OM could also target directly fibrogenic effector cells, which has received much attention^[27]. Various cells are involved in the fibrogenic process. HSCs, the most important fibrogenic cells, are activated during injury and contribute to excessive synthesis of ECM, resulting in deposition of scar or fibrous tissue^[28-31]. OM has been demonstrated to prevent pig-serum-induced liver fibrosis in rats by inhibiting the activation of HSCs and synthesis of collagen^[32]. However, how OM inhibits HSC activation was not determined in that study^[32].

We explored the effect of OM on HSCs *in vitro*. OM inhibited viability and induced apoptosis of HSCs. This might be the underlying mechanism involved in OM therapy of hepatic fibrosis. Furthermore, we also detected fibrosis-related gene expression after OM administration. MMP-2, produced by HSCs, plays an important role in liver fibrogenesis^[33]. TIMPs, especially TIMP-1 and -2 expression and activity, were significantly increased at 8 wk in a rat porcine-serum-induced hepatic fibrosis model^[34]. Furthermore, inhibition of cell viability and type I procollagen expression in rat HSCs could improve recovery from CCl₄-induced liver fibrogenesis in rats^[35]. As shown in our study, mRNA expression of MMP-2, TIMP-1 and type I procollagen was considerably elevated upon CCl₄ induction. Treatment with OM resulted

in significant decreases in mRNA expression of these designated fibrosis-related genes. All the data indicated that OM could attenuate hepatic fibrosis *via* its effect on HSCs, such as inhibiting cell viability, inducing apoptosis and downregulation of fibrosis-related gene expression.

Since OM therapy was dependent on its interaction with HSCs, binding to HSCs became a key factor for its function. Due to a relatively small population of HSCs in the liver and lack of specific membrane receptors, HSC-specific targeting therapy has remained unavailable. Several studies have attempted to use different formulation approaches for targeting HSCs. Beljaars *et al.*^[36] have reported that human serum albumin (HSA) modified with mannose 6-phosphate (M6P) accumulated in HSCs by binding to the M6P-insulin-like growth factor II receptors found on activated HSCs. Modification of HSA with a cyclic peptide that recognizes the collagen type VI receptor has been demonstrated to enhance effectiveness and tissue specificity of antifibrogenic drugs^[37]. Moreover, the affinity of a cyclic peptide, cRGD, for collagen type VI receptor on HSCs was confirmed in both *in vitro* and *in vivo* experiments^[13]. In our study, in order to facilitate OM binding to HSCs, we conjugated liposomes targeted to HSCs in rats with CCl₄-induced hepatic fibrosis. Fluorescence microscopy showed more FITC-positive HSCs in the OM-RGD-liposome group compared with the OM-liposome group. We compared the difference in therapeutic effect of the alternative formulations of OM on liver fibrosis. We demonstrated better results in the OM-RGD-liposome group, as demonstrated by significant decreases in serum alkaline phosphatase and improvement of histopathological changes, compared with the OM-liposome group. Moreover, OM-RGD liposomes showed a more aggressive effect on viability, apoptosis and fibrosis-related gene expression of HSCs, compared with the OM liposomes. The results showed that specific binding of this liposomal formulation to HSCs enhanced the liver protective effect of OM.

In conclusion, we conjugated OM with RGD liposomes and confirmed that this formulation could enhance OM binding to HSCs and the therapeutic effect on hepatic fibrosis induced by CCl₄. We also demonstrated that the therapeutic effects of OM on hepatic fibrosis were partly dependent on inhibiting cell viability, inducing apoptosis, and downregulating fibrosis-related gene expression of HSCs, thus highlighting OM-RGD liposomes as an attractive novel therapy in liver fibrosis.

COMMENTS

Background

Oxymatrine (OM) has been reported to have a beneficial effect on progression of CCl₄-induced hepatic fibrosis in rats, however, its mechanism of action is still uncertain. Hepatic stellate cells (HSCs) have been identified as an important factor in the hepatic fibrotic process. Drugs that could induce HSC apoptosis or death might be the potential strategy for treatment of hepatic fibrosis. Recent studies have demonstrated that OM induces apoptosis in a variety of cells; mainly malignant cells. Thus, the authors performed an assay to demonstrate whether OM could attenuate hepatic fibrosis *via* inducing HSC apoptosis.

Research frontiers

OM was demonstrated to attenuate hepatic fibrosis but its mechanisms of action were still uncertain. Moreover, targeting of HSCs might facilitate the therapeutic effect of OM. The research hotspot is to clarify the mechanism of action of OM in attenuating hepatic fibrosis and how to enhance OM binding to HSCs.

Innovations and breakthroughs

Apoptosis-inducing activity of OM makes it an attractive antifibrotic agent. However, there is limited evidence for the efficacy of OM in hepatic fibrosis and the underlying mechanism of action. The authors demonstrated for the first time that OM could attenuate hepatic fibrosis *via* inhibiting viability and inducing apoptosis of HSCs. Moreover, Arg-Gly-Asp (RGD) could promote OM targeting to HSCs and enhance its effect on hepatic fibrosis.

Peer review

This study aimed to analyze the effects of RGD-peptide-labeled liposomes on CCl₄-induced hepatic fibrosis in rats. This is an interesting approach that clearly improves the efficacy of treatment. The research combined *in vitro* and *in vivo* studies, and data are clear and well presented.

Abstract

AIM: To perform a systematic meta-analysis to investigate the association between X-ray repair cross-complementing group 1 (*XRCC1*) polymorphisms and hepatocellular carcinoma (HCC) risk.

METHODS: Relevant studies extracted from PubMed, Embase, Wanfang, VIP and the Chinese National Knowledge Infrastructure databases up to March 2012 were included in the study. Stata software, version 11.0, was used for the statistical analysis. The odds ratios (ORs) and 95% confidence interval (CI) of the *XRCC1* polymorphisms in HCC patients were analyzed and compared with healthy controls. The meta-analysis was performed using fixed-effect or random-effect

methods, depending on the absence or presence of significant heterogeneity.

RESULTS: Eleven studies with 2075 HCC cases and 2604 controls met our eligibility criteria (four studies, 888 cases and 938 controls for Arg194Trp, four studies, 858 cases and 880 controls for Arg280His, and nine studies, 1845 cases and 2401 controls for Arg399Gln). The meta-analysis revealed no associations between the Arg194Trp and Arg399Gln polymorphisms of the *XRCC1* gene and HCC risk under all contrast models (codominant, dominant and recessive models) in the overall analysis and sensitivity analysis (the studies with controls not in the Hardy-Weinberg equilibrium were excluded). For *XRCC1* Arg280His polymorphism, the overall analysis revealed the significant association between the His/His genotype and the increased risk of HCC (His/His vs Arg/Arg model, OR: 1.96, 95% CI: 1.03-3.75, $P = 0.04$). However, sensitivity analysis showed an altered pattern of result and non-significant association (OR: 2.06, 95% CI: 0.67-6.25, $P = 0.20$). The heterogeneity hypothesis test did not reveal any heterogeneity, and Begg's and Egger's tests did not find any obvious publication bias.

CONCLUSION: The *XRCC1* Arg194Trp and Arg399Gln polymorphisms are not associated with HCC risk. More rigorous association studies are needed to verify the involvement of *XRCC1* Arg280His polymorphism in HCC susceptibility.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the fifth most common malignancy worldwide^[1]. It is accepted that the carcinogenesis of HCC is a multistep process, and multiple factors are involved in this complex process^[2]. Epidemiological studies have indicated that chronic hepatitis B virus (HBV), chronic hepatitis C virus (HCV), heavy cigarette smoking, and alcohol abuse are associated with the risk of HCC^[1]. The progression of HCC might result from a complex interaction of both environmental (including HBV or HCV infection) and genetic factors^[2]. Loss of genomic stability and the gene alterations resulting from endogenous and/or exogenous damage appear to be crucial molecular and pathogenic steps that occur early in the carcinogenesis process of HCC^[2]. Various enzymes and proteins involved in the DNA repair system play a pivotal role in maintaining the genome integrity in cells through the reversal of DNA damage^[3]. The mutations and single-nucleotide polymorphisms (SNPs) in corresponding DNA repair genes may impair their repair or reversal capacity and increase the risk of cancer^[4].

The X-ray repair cross-complementing group 1 (*XRCC1*) gene, located on chromosome 19 (19q13.2), encodes a crucial scaffold protein that is closely associated with the base excision repair (BER) pathway^[5]. The *XRCC1* protein is responsible for the repair of oxidative DNA damage and single-strand breaks through interacting with DNA ligase 3 and the complexes with DNA polymerase and poly (adenosine diphosphate-ribose) polymerase (PARP)^[6,7]. Although more than 300 validated SNPs have been identified and described in the *XRCC1* gene, only three common SNPs have been extensively studied: Arg194Trp (rs1799782, C/T substitution at position 26304 on exon 6), Arg280His (rs25489, G/A substitution at position 27466 on exon 9), and Arg399Gln (rs25487, G/A substitution at position 28152 on exon 10)^[8]. Numerous studies have focused on the association between these *XRCC1* polymorphisms and development of cancer in humans^[9-16]. *XRCC1* SNPs have been shown in the previous meta-analyses to be significantly associated with risk of gastric^[9], breast^[12] and lung^[16] cancer.

Over the past decade, a considerable number of epidemiological studies have focused on the association between *XRCC1* polymorphisms and HCC risk. However, the results remain either controversial or inconclusive. To address these issues, we carried out a systematic review and meta-analysis of all eligible case-control studies

to estimate the risk of HCC associated with the *XRCC1* polymorphisms.

MATERIALS AND METHODS

Literature search

To identify the studies eligible for inclusion in the systematic review and meta-analysis, the following electronic databases were searched: PubMed, Embase, Wanfang (Chinese), VIP (Chinese) and the Chinese National Knowledge Infrastructure (CNKI) (up to March 1, 2012). The following keywords were used: “X-ray repair cross-complementing group 1” or “XRCC1 and haplotype or polymorphism” and “liver cancer” or “hepatocellular carcinoma”. The search was performed without restriction on language and all studies on human subjects were included. Additional studies were identified by a manual search of the references of the original studies. Of the studies with overlapping data published by the same investigators, only the most recent or complete study was included in this meta-analysis.

Inclusion/exclusion criteria

The included studies had to meet all the following criteria: (1) evaluated *XRCC1* polymorphisms and HCC risk; (2) case-control or cohort studies; and (3) contained sufficient published data for estimating an odds ratio (OR) with a 95% confidence interval (CI). The polymorphisms, for which eligible data were reported in at least three published studies, were included into the meta-analysis.

Data extraction

Information was carefully extracted independently by two investigators according to the inclusion criteria. The following data were collected: the first author's surname, year of publication, country of origin, ethnicity, mean age and type of cases and controls, and the number of cases and controls for each genotype of *XRCC1* polymorphisms. Ethnic origins were categorized as Caucasian, Asian, and African. If a study did not present the ethnic origin, or if it was not possible to separate the participants into a mono-ethnic group according to the phenotypes, the group reported was termed “mixed”.

Statistical analysis

The Hardy-Weinberg equilibrium (HWE) in the control groups was calculated in our meta-analysis to determine selective bias in the control population. The χ^2 goodness-of-fit test was used to identify deviation from HWE ($P < 0.05$ was considered significant).

Associations between HCC risk and SNPs in Arg194-Trp, Arg280His, and Arg399Gln were estimated by ORs and 95% CI. The statistical significance of the summary OR was determined with the Z test according to Thakkinian's method^[17] ($P < 0.05$). For each polymorphism, the wild-type allele was set as A and the risk allele as B. The

Yu <i>et al.</i> ^[28]	China (Asian)	PCR-RFLP	577/389	Population	Age and sex matched, HBsAg (+), and without HCC	Arg399Gln

XRCC1: X-ray repair cross-complementing group 1; PCR-RFLP: Polymerase chain reaction-restriction fragment length polymorphism; SNP: Single nucleotide polymorphism; HBsAg: Hepatitis B surface antigen; HCV: Hepatitis C virus; HCC: Hepatocellular carcinoma.

A and B allele frequencies were first compared between the case and the control groups. Then, we evaluated the multiple comparisons including BB *vs* AA (codominant model), AB *vs* AA (codominant model), BB *vs* AB, (BB + AB) *vs* AA (dominant model), BB *vs* (AB + AA) (recessive model), and (BB + AA) *vs* AB (complete overdominant model).

The χ^2 -based Q statistic was used to test for the between-study heterogeneity^[18]. When $P < 0.1$ or $I^2 > 50\%$, the heterogeneity was considered statistically significant^[19]. The data were analyzed using a random-effects model if heterogeneity existed. In the absence of heterogeneity, a fixed-effects model was used. Sensitivity analysis was performed to examine the effect of excluded specific studies, such as studies with controls that were not in HWE. The statistical significance of the summary OR was determined with the Z test ($P < 0.05$).

The publication bias was assessed qualitatively by the Begg's rank correlation method and the Egger's weighted regression method ($P < 0.05$). All statistical analyses were performed with Stata software (version 11.0; Stata Corporation, College Station, TX) using two-sided P values.

RESULTS

With the retrieval strategy, 60 potentially relevant papers were extracted (12 from PubMed, 15 from Embase, 16 from Wanfang, 3 from VIP and 14 from CNKI). Forty-seven studies were subjected to a full-text review and excluded according to the selection criteria stated above. Eleven studies were identified that examined the association between the *XRCC1* polymorphisms and HCC risk^[20-30]. Table 1 summarizes the data from these studies,

which included 2075 HCC patients and 2604 control subjects. The HCC was defined according to the clinical pathological examinations. Those with no clinical evidence of HCC served as controls.

These studies focused on three identified polymorphisms of the *XRCC1* gene: Arg194Trp, Arg280His, and Arg399Gln. The genotypes and allelic frequencies of these three *XRCC1* polymorphisms in the eligible studies are listed in Table 2. Three studies which respectively analyzed the Arg194Trp^[30], the Arg280His^[22], and the Arg399Gln polymorphisms^[29] significantly deviated from the HWE ($P < 0.05$).

Arg194Trp

The Arg194Trp polymorphism is located on exon 6 of the *XRCC1* gene and has been investigated in association studies in patients with HCC. A positive association was initially noted by Kiran *et al.*^[22] who reported an excess frequency of the Arg/Trp genotype in an Indian sample of HCC patients *vs* controls. Furthermore, Bo *et al.*^[30] reported significant associations among a Chinese population between HCC and the Arg/Trp and Trp/Trp genotypes. However, another two studies of a Chinese population reported no association between the Arg194Trp polymorphism of the *XRCC1* gene and HCC^[26,31].

In this meta-analysis, four studies focused on the Arg194Trp polymorphism of *XRCC1* gene in an Asian population, including 888 HCC cases and 938 controls. An evaluation of the association between the Arg194Trp polymorphism and HCC risk is presented in Table 3. No significant association was detected between HCC and the Arg/Trp or Trp/Trp genotype (the Arg/Trp *vs* the Arg/Arg model, fixed-effects OR: 1.30, 95% CI:

HWE: Hardy-Weinberg equilibrium.

0.68-2.48, $P = 0.42$; the Trp/Trp *vs* the Arg/Arg model, fixed-effects OR: 1.03, 95% CI: 0.71-1.49, $P = 0.86$). Furthermore, no significant results were observed in any other genetic models. Sensitivity analysis was performed after excluding the study conducted by Bo *et al.*^[30], because the controls were not in HWE.

Arg280His

The Arg280His allele is located on exon 9 of the XRCC1 gene. A study by Kiran *et al.*^[22] in an Indian population showed that the Arg280His polymorphism of the XRCC1 gene was positively associated with HCC. The Arg/His genotype was associated with a significantly increased risk of HCC. However, three studies in Chinese populations reported no association between the Arg280His polymorphism of the XRCC1 gene and HCC^[28,29,31].

In this study, the four studies on the Arg280His polymorphism of the XRCC1 gene among Asian populations, included 858 HCC cases and 880 controls. Overall, significant association was found for the His/His *vs* Arg/Arg model (fixed-effects OR: 1.96, 95% CI: 1.03-3.75, $P = 0.04$) (Table 3). However, sensitivity analysis after exclusion of the study^[22] with controls not in HWE did not suggest the association (the His/His *vs* Arg/Arg model, fixed-effects OR: 2.06, 95% CI: 0.67-6.25, $P = 0.20$). No significant results were observed in any other genetic models in the overall analysis and sensitivity analysis.

Arg399Gln

The Arg399Gln allele is located on the exon 10 of the XRCC1 gene. Studies by Long *et al.*^[24] and Tang *et al.*^[26] reported an excess frequency of the Arg/Gln genotype of the XRCC1 gene in HCC patients *vs* controls in Chinese populations. However, this observation was not replicated in four other studies^[21,25,30,31] of the Chinese population. A positive association between the Arg/Gln

genotype and a significantly increased risk of HCC in the African population was reported by Kirk *et al.*^[23]. The study by Borentain *et al.*^[20] in a Caucasian population showed an increased frequency of the Arg/Arg genotype in HCC patients *vs* controls. Moreover, Kiran *et al.*^[22] reported significant associations among an Indian population between HCC and the Gln/Gln genotype acting as a protective genotype for HCC.

We retrieved nine studies involving 1845 HCC cases and 2401 controls of different populations (one Caucasian, one African, and seven Asian) reporting detailed allele frequencies^[20-26,28,29]. The overall meta-analysis did not suggest any association between the XRCC1 Arg399Gln polymorphism and HCC susceptibility in all genetic models (Table 3). For example, the ORs of the HCC risks associated with the Arg399Gln polymorphism were 1.07 (random-effects, 95% CI: 0.84-1.34, $P = 0.56$) for the comparison of Arg allele *vs* Gln allele, 1.05 (random-effects, 95% CI: 0.71-1.56, $P = 0.77$) for the comparison of Gln/Gln *vs* Arg/Arg genotype, and 1.13 (random-effects, 95% CI: 0.80-1.57, $P = 0.71$) for the comparison of Arg/Gln *vs* Arg/Arg. The results were consistent after we excluded one study^[29] with controls not in HWE.

By stratifying the meta-analysis by ethnicity, no significant association between XRCC1 Arg399Gln polymorphism and HCC risk was observed in the Asian subgroup, which included 1594 HCC cases and 1960 controls. Sensitivity analysis was performed after one study was excluded^[29]. This did not alter the pattern of the results.

Publication bias

The Begg's rank correlation method and Egger's weighted regression method were used to assess publication

bias. There was no evidence of publication bias for these polymorphisms.

DISCUSSION

The *XRCC1* protein is a key molecule of BER in the DNA repair process, which plays a key role in the integrity and stability of the genome and the pathogenesis and progression of human cancers^[31]. Polymorphisms that can alter *XRCC1* expression and function may contribute to the risk of cancers. Several studies have been conducted in recent years to evaluate the association between the *XRCC1* SNPs and HCC risk predisposition in different ethnic populations, but the results have been conflicting^[20-30].

In the present study, we performed a systematic review and meta-analysis to examine the association between three *XRCC1* gene polymorphisms and HCC risk. These three polymorphisms of the *XRCC1* gene result in nonconservative amino-acid changes at evolutionary conserved regions: a C to T substitution in codon 194 of exon 6 (Arg to Trp), a G to A substitution in codon 280 of exon 9 (Arg to His), and a G to A substitution in codon 399 of exon 10 (Arg to Gln)^[32]. Although the functional effects of these nonsynonymous polymorphisms in *XRCC1* are not well known, the nature of the amino acid substitutions may cause functional changes in the *XRCC1* protein and impair DNA repair efficiency or accuracy, which could be implicated in the risk of cancer. However, previous meta-analysis showed inconsistent results in the association between the polymorphisms of the *XRCC1* gene and the risk of cancers.

These previous meta-analysis found that the carriers of homozygous Trp/Trp variant genotype of the Arg-194Trp polymorphism had an increased risk of gastric cancer^[9] and other cancers, especially lung cancer and esophageal cancer, in the Chinese mainland population^[11]. However, no associations were observed between the Arg194Trp polymorphism with skin^[15], colorectal^[33], and prostate cancer^[34], and nasopharyngeal carcinoma^[10]. The Arg280His polymorphism was associated with an approximate 3.5-fold increase in skin cancer risk in homozygote codominant and recessive models^[15]. However, the Arg280His polymorphism was not found to be a statistically significant risk factor for gastric cancer^[9] and nasopharyngeal carcinoma^[10]. The Gln/Gln genotype of the Arg399Gln polymorphism was associated with an increased risk of prostate cancer^[34] and nasopharyngeal carcinoma^[10], but was not correlated with skin^[15], gastric^[9], and colorectal^[33] cancer susceptibility for all genetic models. For prostate cancer, Wei *et al.*^[34] concluded that the Gln allele of the Arg399Gln polymorphism might be a low-

penetrant risk factor for prostate cancer only in Asian men, but was not related to overall prostate cancer risk.

It is difficult to interpret the reasons for these inconsistent results; nonetheless, several factors may influence the function of these polymorphisms of the *XRCC1* gene in various ways, including variation in the exposure of different populations to carcinogens and variation in different types of DNA damage associated with the initiation of different cancers. Further research is needed to clarify this inconsistency.

There has been no previous meta-analysis of the effect of the Arg194Trp and Arg280His polymorphisms of the *XRCC1* gene on the risk of HCC. Our data suggested that the Arg194Trp polymorphism might not be a risk factor for HCC. For the *XRCC1* Arg280His polymorphism, our meta-analysis on the available studies showed that the His/His genotype was significantly associated with increased HCC risk. However, the sensitivity analysis after exclusion of the study with controls not in HWE did not suggest this association. Our meta-analysis does not strongly support the association between the His/His genotype of the *XRCC1* Arg280His polymorphism and the increased risk in HCC. Although there is some evidence of association between the *XRCC1* Arg280His polymorphism and HCC, the above finding deserves further and more rigorous association studies. A previous meta-analysis study found that the Arg399Gln polymorphism had no association with HCC^[13], which is similar to our current finding. Recently, another variant in the *XRCC1* gene located in the 5'-untranslated region, -77 T to C, was identified^[35] and indicated as a genetic determinant for developing breast cancer^[14]. However, there is a lack of association study between the -77 T/C polymorphism of the *XRCC1* gene and HCC risk.

Similar to other systematic reviews and meta-analyses, there were some limitations in this study. Firstly, the sample sizes in the overall and subgroup analyses were small. Secondly, only two published studies included in this meta-analysis focused on the Arg399Gln polymorphism and its relationship with HCC in Caucasian and African populations. Thirdly, the sources of heterogeneity that existed among the studies for most polymorphisms were not addressed. Finally, this meta-analysis was based on unadjusted data, whereas a more precise analysis could be performed if individual data were available. Additional well-designed, more-detailed studies with larger populations and different ethnicities are needed to further evaluate the associations.

In conclusion, The *XRCC1* Arg194Trp and Arg399Gln polymorphisms are not associated with HCC risk. More rigorous association studies are needed to clarify the involvement of *XRCC1* Arg280His polymorphism in

HCC susceptibility. No publication biases regarding these three evaluated polymorphisms were found in this meta-analysis.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is the fifth most common malignancy worldwide. The X-ray repair cross-complementing group 1 (XRCC1) gene encodes a crucial scaffold protein that is responsible for the repair of oxidative DNA damage and single-strand breaks. Many studies have explored the association between the XRCC1 polymorphisms and HCC risk, but the results remain either controversial or inconclusive. To address these issues, the authors carried out a systematic review and meta-analysis of all eligible case-control studies to estimate the association between the XRCC1 polymorphisms and the risk of HCC.

Research frontiers

To date, a number of studies have assessed the association between the XRCC1 polymorphisms and HCC risk among different populations; however, the results have been inconsistent and inconclusive.

Innovations and breakthroughs

This meta-analysis suggested that none of the Arg194Trp and Arg399Gln polymorphisms of XRCC1 were significantly associated with a risk of HCC. More rigorous association studies are needed to verify the involvement of XRCC1 Arg280His polymorphism in HCC susceptibility.

Applications

This meta-analysis showed that the Arg399Gln and Arg194Trp polymorphisms of the XRCC1 gene did not alter the susceptibility to HCC. The findings may provide valuable information about the etiology of HCC for both researchers and clinicians.

Peer review

This manuscript was a meta-analysis to analyze the association between X-ray repair cross-complementing group 1 polymorphisms and HCC. This is a scientifically interesting topic. Although the results show that this is a negative study, it is very important to systematically review these relevant reports.

Abstract

AIM: To investigate the association between metabolic syndrome (MetS) and the development of gallstone disease (GSD).

METHODS: A cross-sectional study was conducted in 7570 subjects (4978 men aged 45.0 ± 8.8 years, and 2592 women aged 45.3 ± 9.5 years) enrolled from the physical check-up center of the hospital. The subjects included 918 patients with gallstones (653 men and 265 women) and 6652 healthy controls (4325 men and 2327 women) without gallstones. Body mass index (BMI), waist circumference, blood pressure, fasting plasma glucose (FPG) and serum lipids and lipoproteins levels were measured. Colorimetric method was used to measure cholesterol, high-density lipoprotein cholesterol (HDL-C) and low-density lipoprotein cholesterol (LDL-C). Dextrose oxidizing enzyme method was used to measure FPG. Subjects were asked to complete a questionnaire that enquired about the information on

demographic data, age, gender, histories of diabetes mellitus, hypertension, and chronic liver disease and so on. Metabolic syndrome was diagnosed according to the Adult Treatment Panel III (ATP III) criteria. Gallstones were defined by the presence of strong intraluminal echoes that were gravity-dependent or attenuated ultrasound transmission.

RESULTS: Among the 7570 subjects, the prevalence of the gallstone disease was 12.1% (13.1% in men and 10.2% in women). BMI, waist circumference, systolic blood pressure, diastolic blood pressure, fasting blood glucose and serum triglyceride (TG) in cases group were higher than in controls, while serum high-density lipid was lower than in controls. There were significant differences in the waist circumference, blood pressure, FPG and TG between cases and controls. In an age-adjusted logistic regression model, metabolic syndrome was associated with gallstone disease. The age-adjusted odds ratio of MetS for GSD in men was 1.29 [95% confidence interval (CI), 1.09-1.52; $P = 0.0030$], and 1.68 (95% CI, 1.26-2.25; $P = 0.0004$) in women; the overall age-adjusted odds ratio of MetS for GSD was 1.42 (95% CI, 1.23-1.64; $P < 0.0001$). The men with more metabolic disorders had a higher prevalence of gallstone disease, the trend had statistical significance ($P < 0.0001$). The presence of 5 components of the MetS increased the risk of gallstone disease by 3.4 times ($P < 0.0001$). The prevalence of GSD in women who had 5 components of MetS was 5 times higher than in those without MetS. The more the components of MetS, the higher the prevalence of GSD ($P < 0.0001$). The presence of 5 components of the MetS increased the risk of gallstone disease by 4.0 times.

CONCLUSION: GSD appears to be strongly associated with MetS, and the more the components of MetS, the higher the prevalence of GSD.

INTRODUCTION

China is one of the fastest developing countries. Rapid economic development and industrialization have brought about changes in traditional diets and increasingly sedentary lifestyles. Metabolic syndrome (MetS) is defined as a cluster of multiple cardiovascular risk factors, including central obesity, elevated fasting plasma glucose, high blood pressure, lower high-density lipid (HDL), and higher serum triglyceride (TG) levels. The prevalence of MetS has been increasing gradually in China. In 1992, the overall prevalence of MetS in China was 13.3% (12.7% in men and 14.2% in women)^[1]. By 2000, the prevalence of MetS had elevated to 15.1%; 13.6% in men and 16.6% in women^[2]. In 2009, a population-based cross-sectional survey in China showed that the crude and age-standardized prevalence of MetS was 31.5% and 30.5%, respectively^[3]. Numerous studies have indicated that MetS is closely associated with some common diseases, such as diabetes, hypertension, cardiovascular diseases, cancer, and gallstone disease. Consequently, the increasing prevalence of MetS may potentially associate with the increased prevalence of these diseases. Studies about the association between gallstone disease and MetS suggested that MetS is a risk factor for gallstone disease (GSD)^[4], and some studies concluded that GSD might be a component of MetS^[4,5] although it needs to be validated by more evidences.

GSD represents a significant burden for health care worldwide^[6] and is one of the most common disorders among the patients admitted to the emergency rooms with abdominal discomfort, epigastric pain, nausea, vomiting, loss of appetite, *etc*^[7]. Ethnicity and family traits are recognized as contributing factors^[8]. GSD is known to affect 60%-70% of native Americans and a proportionately smaller number of individuals of mixed hispanic/native American origin^[9]. The incidence of GSD is at least 10% among white adults in Western countries^[10], but it is lower in African Americans and East Asians^[9]. GSD is also on the rise and becoming a major health problem in China^[11,12]; according to the reported estimates that the prevalence of GSD increased from 4.3% in 1989 to as high as 10.7% in 1995^[12]. Risk factors associated with

cholelithiasis include female gender, age, obesity, diabetes, hyperlipidemia, rapid appetite loss, hepatitis C, cirrhosis, and high caloric intake^[9,13,14]. The association between GSD and MetS has been a focus of some recent studies. To the best of our knowledge, the prevalence of the disease and the association between the development of GSD and MetS are not fully elucidated. Moreover, there is currently only minimal data regarding the relationship between GSD and MetS in apparently healthy Asian people. This study aimed to establish if there is an association between the presence of MetS and the development of GSD. MetS is known to be strongly associated with lifestyle, and if MetS is proved to be related to gallstone, we may reduce the prevalence of gallstones through lifestyle interventions.

MATERIALS AND METHODS

Data resource and data collection

We conducted a cross-sectional study in 7570 subjects enrolled from the Physical Check-Up Center of the Sir Run Run Shaw Hospital. Among them, there were 4978 men, aged 45.0 ± 8.8 years, and 2592 women, aged 45.3 ± 9.5 years. The study protocol was approved by the Ethics Committee of the hospital. All the subjects signed the informed consent. And 918 (653 men and 265 women) subjects were found to have gallstones. The gallstone cases and controls consisted of a series of consecutive asymptomatic subjects. Exclusion criteria included histories of cholecystectomy, pancreatitis, sequela of clonorchis sinensis infection, gallbladder polyps, silt, dimly disease or gallbladder wall thickening, chronic kidney disease, pregnancy, and major gastrointestinal surgeries. Blood samples were collected via venipuncture from the study participants after they had fasted overnight for laboratory tests. Fasting plasma glucose (FPG), TG, total cholesterol, high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C) concentrations were measured using the AEROSET analyze system (ADDO™, America). Colorimetric method was used to measure cholesterol, HDL-C and LDL-C. Dextrose oxidizing enzyme method was used to measure FPG. Ultrasonographic examinations were also done.

Questionnaire

Subjects were asked to complete a questionnaire that enquired for information on demographic data, age, gender, marital status, address, telephone, histories of diabetes mellitus, hypertension, chronic liver disease, hyperlipidemia, systemic diseases, gastrointestinal surgery (vagotomy gastrectomy for peptic ulcer, ileal resection for inflammatory bowel disease, or any other disease or cause), gravidity, and the use of oral contraceptives, any other medications, and family history.

Table 1 Demographic and clinical characteristics of the study subjects (mean \pm SD) *n* (%)

Variables	Cases (<i>n</i> = 918)	Controls (<i>n</i> = 6652)	<i>P</i> values
Age (yr)	48.5 \pm 9.1	44.7 \pm 9.0	< 0.0001
Height (cm)	165.6 \pm 7.9	165.6 \pm 7.7	0.2791
Weight (kg)	72.6 \pm 11.3	69.4 \pm 12.2	< 0.0001
Body mass index (kg/m ²)	26.3 \pm 3.0	25.2 \pm 3.4	< 0.0001
Waist circumference (cm)	91.6 \pm 9.4	87.8 \pm 10.7	< 0.0001
Systolic blood pressure (mmHg)	123.6 \pm 14.3	119.8 \pm 14.5	< 0.0001
Diastolic blood pressure (mmHg)	74.1 \pm 9.8	72.2 \pm 10.4	< 0.0001
Fasting blood glucose (mmol/L)	5.39 \pm 1.37	5.11 \pm 1.04	< 0.0001
High density lipid (mg/L)	44.6 \pm 10.9	46.0 \pm 0.58	0.0004
Triglyceride (mg/L)	201.1 \pm 183.3	183.7 \pm 182.7	0.0069
Male	653 (71.1)	4325 (65.0)	0.0003
Larger waist circumference	673 (73.3)	3918 (58.9)	< 0.0001
Higher blood pressure	401 (43.7)	2072 (31.2)	< 0.0001
Higher FPG	146 (15.9)	600 (9.0)	< 0.0001
Lower high-density lipid	407 (44.3)	2842 (42.8)	0.3551
Higher triglyceride	473 (51.5)	3044 (45.8)	0.0010

Student *t* test was applied to compare the differences between cases and controls for all continuous variables. Larger waist circumference denotes waist circumference \geq 80 cm for females or \geq 90 cm for males; higher blood pressure denotes systolic blood pressure \geq 130 or diastolic blood pressure \geq 85 mmHg or drug treatment; raised fasting plasma glucose (FPG) denotes FPG \geq 5.6 mmol/L or drug treatment; raised triglyceride denotes triglyceride \geq 1.70 mmol/L or drug treatment; lower HDL-C denotes HDL < 1.29 mmol/L for females or < 1.03 mmol/L for males or drug treatment. χ^2 test was used to compare the differences between cases and controls for all category variables. HDL: High blood pressure; HDL-C: High-density lipoprotein cholesterol.

and without shoes, was measured to the nearest 0.10 kg. Height was measured to the nearest 0.5 cm. Body mass index (BMI) was calculated as weight (kg) divided by height (m) squared (kg/m²). Waist circumference (at the nearest 0.1 cm) was measured at the midpoint between the lower border of the rib cage and the iliac crest. Three blood pressure readings were obtained at 1-min intervals, and the second and third systolic and diastolic pressure readings were averaged and used in the analyses.

Diagnostic criteria

MetS was diagnosed using the Adult Treatment Panel III (ATP III) criteria. According to the ATP III criteria, MetS was defined as the presence of any three of the following five traits: (1) Abdominal obesity, defined as a waist circumference in men \geq 90 cm and in women \geq 80 cm; (2) Serum triglycerides \geq 150 mg/dL (1.7 mmol/L) or medicinal treatment for elevated TG; (3) Serum HDL cholesterol < 40 mg/dL (1.03 mmol/L) in men and < 50 mg/dL (1.29 mmol/L) in women or medication for low HDL-C; (4) Blood pressure \geq 130/85 mmHg or medication for high blood pressure; and (5) Fasting plasma glucose (FPG) \geq 100 mg/dL (5.6 mmol/L) or

Age-adjusted logistic regression model was used to test the associations between metabolic syndrome (MetS) and human gallstone. OR: Odds ratio; CI: Confidence interval.

medication for elevated blood glucose^[15].

The diagnosis of GSD was established on the basis of the results of abdominal ultrasound (US) using a 3.5-MHz transducer. US was conducted by an experienced radiologist, who was unaware of the objectives of the study and blinded to laboratory values. Gallstones were defined by the presence of strong intraluminal echoes that were gravity-dependent or that attenuated ultrasound transmission (acoustic shadowing)^[16].

Statistical analysis

All statistical analyses were conducted using SPSS version 13.0 (SPSS Inc, Chicago, Ill). The results were expressed as the mean \pm SD. Binary variables were summarized by N and percentage. Student *t* test was applied to compare the differences between cases and controls for all continuous variables. χ^2 test was used to compare the differences between cases and controls for all category variables. Age-adjusted logistic regression model was used to test the association between MetS and human gallstones.

RESULTS

Of the 7570 examined subjects, the prevalence of the GSD was 12.1% (13.1% in men and 10.2% in women). The results of univariate analysis of various factors and its relationship with GSD are shown in Table 1. In comparison with subjects without GSD, those with GSD were significantly older and had a higher waist circumference (WC), BMI, systolic blood pressure, diastolic blood pressure, fasting blood glucose and TG. Moreover, subjects with GSD had a significantly lower HDL cholesterol level than those without GSD. The incidence of larger waist circumference, higher blood pressure, increased FPG and TG was obviously higher in cases group than in the controls.

In age-adjusted logistic regression analyses (Table 2), MetS was significantly associated with the risk of GSD irrespective of the sex of the subjects. The age-adjusted odds ratio of MetS for GSD was 1.29 [95% Confidence

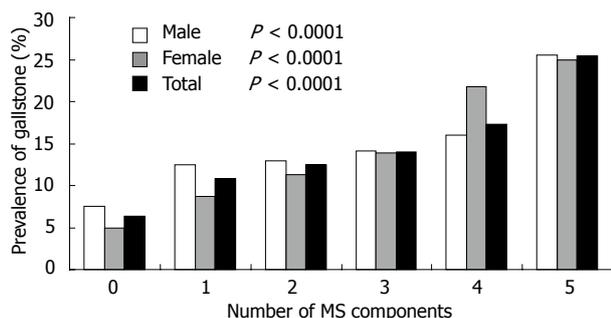

Figure 1 Trend test of the prevalence of gallstone disease and the number of metabolic syndrome components in males, females and total study subjects respectively. Trend test of the prevalence of gallstone disease and the number of metabolic syndrome components in males, in females and in total study subjects. MS: Metabolic syndrome.

interval (CI), 1.09-1.52; $P = 0.0030$] in men, and 1.68 (95% CI, 1.26-2.25; $P = 0.0004$) in women; and the overall age-adjusted odds ratio of MetS for GSD was 1.42 (95% CI, 1.23-1.64; $P < 0.0001$).

We also analyzed the association between the prevalence of GSD and the number of MetS components. Figure 1 shows that the more the components of MetS, the higher the prevalence of GSD in men, and the trend was significant ($P < 0.0001$). The presence of 5 components of the MetS increased the risk of gallstone disease by 3.4 times ($P < 0.0001$). We found the same trend in the women. The prevalence of GSD in women who had 5 components of MetS, was 5 times that of those without MetS component. The overall prevalence of GSD, and the trend was also significant ($P < 0.0001$).

DISCUSSION

In China, the study about the prevalence of GSD is rare, and the available studies are not sufficient in sample size or lack of appropriate statistical methods. We designed the cross-sectional study with a large sample of Chinese population. We found that the prevalence of the GSD was 12.1% (13.1% in men and 10.2% in women), which was slightly higher than the figure presented in a previous hospital-based study conducted at the West China Hospital, Sichuan University, which was reported to be 10.7% (9.9% in men and 11.6% in women)^[17]. A population-based screening study conducted in Taiwan in 2006 reported that the overall prevalence of GSD was 5.0% (4.6% in men, 5.4% in women), without significant gender differences^[18]. The apparently higher prevalence rate in our study may contribute to the Westernized lifestyle of our subjects who were of middle-to-high income class.

According to most of the previous epidemiologic studies, women have a higher prevalence of GSD than men in the Western world, and estrogen is considered to be an obvious factor for the gender difference^[19]. However, our findings showed that the prevalence of GSD was higher in men than in women. Actually, gender as a risk factor for cholelithiasis still remains controversial. While the majority of studies conducted in the West have

concluded that women are more likely to develop cholelithiasis^[20,21] than men, studies among Asian patients have failed to identify a gender-related difference^[22,23]. In fact, Liu *et al.*^[24] found a higher incidence of cholelithiasis in men than in women below 50 years of age, but a higher incidence in women than in men in age groups above 50 years. And Hung *et al.*^[25] indicated that menopause is a risk factor for cholelithiasis in women. Moreover, female predominance is less evident in Asia where the pigmented stone diseases are more common^[26]. So the male predominance with GSD in our study may be attributed to the fact that our subjects were of Asian ethnicity and most of them were aged below 50 years, meanwhile most of our female subjects were premenopausal women.

Older age is another significant risk factor for GSD^[27,28], so we used age-adjusted logistic regression model to test the associations between MetS and human gallstone. It has been reported that the presence of MetS as an insulin resistance phenotype was associated with an increased prevalence of gallstones^[29]. In our age-adjusted logistic regression analysis, MetS was associated with an increased risk of GSD.

Obesity is a major cornerstone of MetS, in our study, the presence of a high waist circumference was common in patients with GSD. A population-based follow-up study on GSD in Kinmen also showed that greater waist circumference was associated with the development of GSD among type 2 diabetics^[30]. Cojocar *et al.*^[29] found that waist circumference and BMI were significantly associated with a higher risk of cholesterol gallstone. Obesity is a major risk factor for developing GSD because it can increase hepatic secretion of cholesterol^[31].

Although dyslipidemia is very common in MetS, no conclusive evidence links dyslipidemia and GSD. A Korean study demonstrated that HDL cholesterol level was significantly lower in subjects with GSD; however, they did not find any component of dyslipidemia related to MetS that could be correlated with GSD formation^[19]. A cross-sectional study in a check-up unit in a university hospital in Mexico City described the influence of low HDL cholesterol on developing GSD (OR = 2.32)^[4]. In our study, subjects with GSD had lower HDL cholesterol and higher TG, but there was only difference in the incidence of higher TG between cases and controls. The relationship between HDL and GSD remains unclear. In most patients with higher TG, an association with overweight and insulin resistance is often observed based on the supersaturated (cholesterol) bile and diminished gallbladder motility, both contributing to gallstone formation^[14]. Phase separation of cholesterol crystals from supersaturated bile is considered the key event in cholesterol gallstone formation. It is a basal framework of the interactions between the sterol, bile salts and phospholipids in aqueous solutions. Biliary bile acid and phospholipids are important to solubilize cholesterol^[32]. Phospholipid transfer protein (PLTP) transfers lipids from low-density lipoproteins to high-density lipoproteins. It was found that an inhibitory effect of haptoglobin over PLTP activ-

ity in hyperlipidemic plasma may contribute to the regulation of reverse cholesterol transport^[33]. Huang *et al.*^[34] revealed a hitherto unrecognized role of protein kinase C β (PKC β) in the fine tuning diet-induced cholesterol and bile acid homeostasis, thus identifying PKC β as a major physiological regulator of both triglyceride and cholesterol homeostasis. Moreover, polymorphisms in the gene encoding are also found to increase the gallstone risk. Such as the cholesterol transporter ABCG5-G8 and phospholipid floppase ABCB4^[32].

Considering the obvious association between gallstone disease and MetS in this study, the fact that higher blood pressure was associated with MetS and GSD appears reasonable. Systolic blood pressure and diastolic blood pressure were higher in patients with GSD as compared with the controls. A study in Taiwan documented that cholelithiasis in Asian obese patients is significantly associated with increased diastolic blood pressure^[35]. Blood pressure $\geq 130/85$ mmHg was significantly associated with a higher risk of cholesterol gallstone^[36]. The mechanism why higher blood pressure increased the risk of GSD still remains unclear. Some scholars considered that this association could be explained by the action of insulin in hypertension. To validate the mechanism, we will further study the relationship between hypertension and GSD. We have designed a study to investigate the association between BP and GSD, as well as the impact of medication for hypertension on GSD.

Previous studies indicated that diabetes mellitus was a risk factor for GSD^[37-39]. GSD appeared strongly associated with fasting glycemia^[29]. We noted that there was a positive correlation between prevalence of gallstone with higher FPG. The possible mechanisms for this association may be as follows: hyperglycemia inhibits bile secretion from the liver and disturbs gallbladder contraction^[40]; hyperglycemia may affect gallbladder motility^[41]; or some factors modifying the crystal nucleation and mucous secretion in bile^[42].

Finally, GSD appears to be strongly associated with MetS. The result is consistent with the hypothesis that insulin resistance plays an important role in the pathogenesis of GSD. Animal experiments demonstrated that mice with isolated hepatic insulin resistance created by liver-specific disruption of the insulin receptor [Liver insulin receptor knockout (LIRKO) mice] are markedly predisposed towards cholesterol gallstone formation. After only one week on a lithogenic diet, 36% of LIRKO mice developed gallstones and 100% had gallstones by 12 wk^[43]. Chang *et al.*^[6], showed that insulin resistance was positively associated with gallstones in non-diabetic Korean men, and this occurred regardless of obesity. Taking into account this association, some authors raised the question whether administration of lipid-lowering drug is a therapeutic option for GSD? Ezetimibe was shown to have a beneficial effect against cholelithiasis in both animal and humans^[44], it is, therefore, possible to suggest that a clinical trial designed to investigate the potential efficiency of ezetimibe for reducing biliary cholesterol

saturation and insulin resistance in populations with a predisposition to cholelithiasis should be now warranted.

In conclusion, GSD is common in China, and the present study shows an obvious association between MetS and GSD, and the more the metabolic components of MetS, the higher the prevalence of the GSD. But the mechanism for the association remains unclear, further research is needed to clarify how BP influences the formation of GSD, whether medication for dyslipidemia benefits the GSD patients, and whether we can reduce the prevalence of GSD through lifestyle interventions.

COMMENTS

Background

China is one of the fastest developing countries. The rapid economic growth and industrialization has brought about changes in traditional diets and lifestyles. The prevalence of metabolic syndrome (MetS) is increasing. But there have been few studies about the prevalence of gallstone disease (GSD), and the association between the development of GSD and MetS is not fully elucidated.

Research frontiers

The authors designed a cross-sectional study with a large sample of Chinese subjects to evaluate the association between MetS and the development of GSD. They concluded that GSD is strongly associated with MetS.

Innovations and breakthroughs

This study demonstrated a strong association between GSD and MetS, but the prevalence of GSD was higher in men than in women. This finding is not consistent with the results from most previous epidemiologic studies. The reason for the discrepancy may be that the subjects in this study are of Asian ethnicity and most of the subjects are below 50 years of age, meanwhile most of the female subjects are premenopausal women.

Applications

There is only minimal data regarding the relationship between GSD and MetS in apparently healthy Asian population. The findings of this study will make it possible to reduce the prevalence of gallstones with appropriate administration of medication and/or lifestyle interventions.

Peer review

This article is well written. This study demonstrated a strong association between GSD and MetS. The presentation of results is logic and the discussion is comprehensive.

Abstract

Eosinophilic esophagitis (EE) is the most frequent condition found in a group of gastrointestinal disorders called eosinophilic gastrointestinal diseases. The hypothetical pathophysiological mechanism is related to a hypersensitivity reaction. Gastroesophageal reflux disease-like complaints not ameliorated by acid blockade or occasional symptoms of dysphagia or food impaction are likely presentations of EE. Due to its unclear pathogenesis and unspecific symptoms, it is difficult to diagnose EE without a strong suspicion. Although histological criteria are necessary to diagnosis EE, there are some characteristic endoscopic features. We present the case of a healthy 55-year-old woman with dysphagia and several episodes of esophageal food impaction over the last six months. This case report stresses the most distinguishing endoscopic findings-mucosa rings, white exudative plaques and linear furrows-that can help in the prompt recognition of this condition.

INTRODUCTION

Eosinophilic gastrointestinal diseases (EGD) are rare conditions of growing interest due to their increasing diagnostic frequency in well developed countries^[1]. Eosinophilic esophagitis (EE) is the most common EGD, and its clinical presentation varies extensively making the diagnosis difficult and clinical suspicion fundamental. Although not entirely clear, given that EE correlates with other atopic disorders and has a good response to corticoid treatment, it seems that its pathophysiological mechanism is related to a hypersensitivity reaction^[1].

In this case report, through several expressive images, we highlight the set of endoscopic features which helped in the early recognition of EE.

CASE REPORT

A 55-year-old woman with no previous medical history presented with dysphagia and several episodes of esophageal food impaction over the last six months. Upper gastrointestinal (GI) endoscopy revealed scattered white plaques in the proximal esophagus (Figure 1A), a whitish exudate coating the mucosa in the distal part of the esophagus (Figure 1B), and characteristic images of concentric transient rings and linear furrows (Figure 1C).

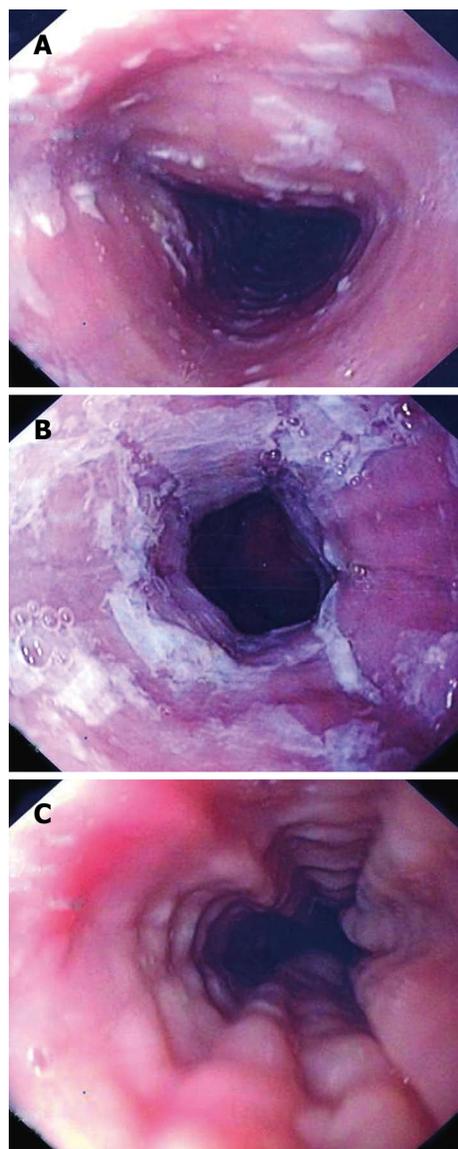

Figure 1 A 55-year-old woman presented with dysphagia and several episodes of esophageal food impaction over the last six months. A: Scattered white plaques in the proximal esophagus; B: Whitish exudate coating the mucosa in the distal part of the esophagus; C: Concentric transient rings and linear furrows on esophagoscopy.

Biopsy specimens showed dense eosinophilic infiltrates, > 20 eosinophils/high power field (HPF) and microabscesses (Figure 2A and B). Gastroesophageal reflux disease (GERD) was excluded when no improvement was observed following the administration of a proton pump inhibitor (PPI). The patient started treatment with a budesonide inhaler twice daily (instructions to swallow) and experienced symptom relief.

DISCUSSION

EE is part of a group of disease known as the eosinophilic gastrointestinal disorders. The pathogenesis of EE is not yet understood, although it appears to be related

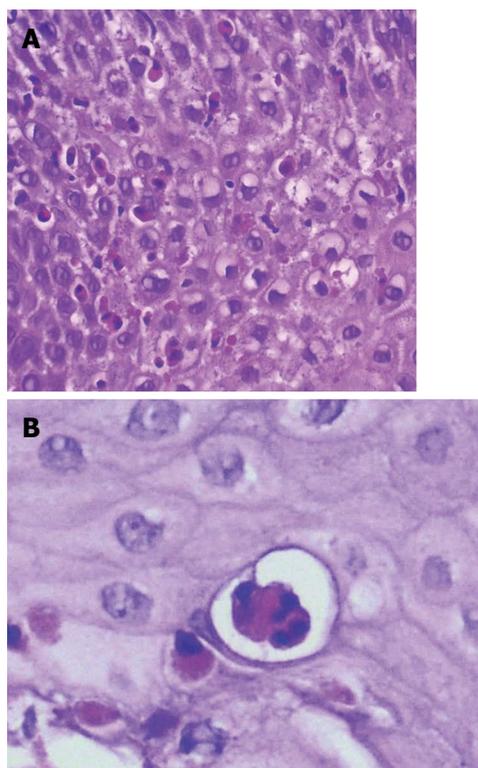

Figure 2 Histological findings in esophageal biopsy specimen. A: Dense eosinophilic infiltrates; B: Microabscesses on esophageal microscopy.

to a hypersensitivity reaction. Some studies suggest that increased mucosa permeability allows contact with potential allergenic digestion products leading to a consequent immunologic response^[2]. EE tends to be a chronic disorder with intermittent or persistent symptoms, usually GERD-like complaints which are not ameliorated by acid blockade with PPI. Additionally, patients may present with symptoms of dysphagia or food impaction. Due to its unspecific esophageal symptoms, clinical suspicion is critical in the diagnosis of EE. Although endoscopy may be normal in one third of cases, images of mucosal rings, white exudative plaques and esophageal strictures are characteristic findings of this pathology. Nevertheless, multiple biopsies should be performed in different esophageal locations, as well as in the stomach and duodenum as the diagnosis of EE relies on histological criteria-one HPF must contain, at least, 15 intraepithelial eosinophils. Additional histological features include eosinophilic microabscesses^[1,3].

To date, there are no large randomized controlled trials on EGD treatment. The majority of data are from smaller studies where corticosteroids play a role in the treatment of these disorders. Generally, oral or topical corticoid therapy is given to the patient for at least eight weeks followed by a gradual taper. The symptoms usually recur, suggesting the need for continuous therapy. Some case reports show evidence of better symptom control following maintenance treatment with mast cell inhibitors or leukotriene receptor antagonists, however,

larger trials are needed^[2,3].

Abstract

Gastric perforation is one of the most serious complications that can occur during endoscopic submucosal dissection (ESD). In terms of the treatment of such perforations, we previously reported that perforations immediately observed and successfully closed with endoclips during endoscopic resection could be managed conservatively. We now report the first case in our medical facility of a gastric perforation during ESD that was ineffectively treated conservatively even after successful endoscopic closure. In December 2006, we performed ESD on a recurrent early gastric cancer in an 81-year-old man with a medical history of laparotomy for cholelithiasis. A perforation occurred during ESD that was immediately observed and successfully closed with endoclips so that ESD could be continued resulting

INTRODUCTION

Endoscopic submucosal dissection (ESD) is now an accepted therapy for node-negative early gastric cancer (EGC). Compared to endoscopic mucosal resection (EMR), ESD is often preferred because this technique provides a higher rate of successful *en-bloc* resections^[1-7], however, the risk of complications, particularly perforations, is also higher with ESD. The incidence of perforations occurring during ESD has been reported to range from 3.5% to 6.1%^[2-8]. In terms of the treatment of gastric perforations during endoscopic resection, we previously reported that perforations immediately observed

and successfully closed with endoclips during endoscopic resection could be treated conservatively without the need for an emergency laparotomy^[8]. We now report the first case in our medical facility of a gastric perforation during ESD of EGC which was ineffectively treated conservatively, even though it was immediately detected and successfully closed with endoclips. Laparotomy was performed five days after ESD due to dehiscence following endoscopic closure.

CASE REPORT

An 81-year-old man with a medical history of laparotomy for cholelithiasis performed in 1987 was admitted to our hospital in December 2006 for the endoscopic treatment of a recurrent EGC. He had previously undergone an initial ESD for EGC at the lesser curvature of the lower gastric body in 1999. Pathological findings revealed a well-differentiated mucosal adenocarcinoma without lymphovascular involvement. The lateral margin could not be properly evaluated, however, because an incision had inadvertently been made in the lesion during ESD. After the initial ESD, endoscopic examinations were performed periodically and a recurrent tumor 20 mm in size was detected at the site of the ESD scar in October 2006 (Figure 1A).

In December 2006, ESD was performed on the recurrent tumor and an oval perforation 5 mm in length occurred during the procedure at the site of extensive fibrosis from the initial ESD scar (Figure 1B). The perforation was immediately observed and successfully closed with endoclips (HX-610-090; Olympus Medical Systems Corp., Tokyo, Japan) (Figure 1C) so that the ESD could then be continued resulting in an *en-bloc* resection. Pathological examination revealed a well to moderately differentiated mucosal adenocarcinoma with ulcer scar from the initial ESD without lymphovascular involvement (Figure 1D, E and F). The lateral and vertical margins were negative. Following ESD, the patient was intensively managed with nasogastric suction, fasting and intravenous antibiotic therapy. The patient's abdominal symptoms were unremarkable with no physical indications of diffuse peritonitis observed, although the patient had a fever and high C-reactive peptide level during the observation period. Despite intensive conservative management, the patient's fever persisted and his C-reactive peptide level remained elevated at 20 mg/dL, thus we performed an endoscopic examination five days after ESD which revealed that the perforation site previously closed with endoclips had split open (Figure 2A). Since the open perforation site could not be closed endoscopically, an emergent laparotomy was performed on the same day. Surgical findings indicated that the perforation of the gastric wall extending to the omental bursa was 30 mm × 10 mm in length and the perforation site was not covered with adipose tissue (Figure 2B). Pigmentation from bile and localized findings of inflammation were observed in the omental bursa probably caused by adhesions from the previous laparotomy for cholelithiasis performed in 1987. Distal gastrectomy was performed instead of omental implantation because

the gastric wall at the perforation site was fragile and the split-open perforation was relatively large in size. The patient recovered well postoperatively and was discharged 11 d after surgery with no recurrence detected as of December 2010.

DISCUSSION

We previously reported that gastric perforations which occurred during endoscopic resection could be managed conservatively with complete endoscopic closure based on the analysis of 117 patients with such perforations at our facility^[8]. In our analysis, endoscopic closure with endoclips was successful in 115 of the 117 patients (98.3%) and conservative management for those 115 patients was uneventful. That is, none of the patients with successful endoscopic closure required an emergency laparotomy. In the present case, however, conservative management proved to be ineffective despite the fact that successful endoscopic closure was performed during ESD. An endoscopic examination conducted five days after ESD revealed that the perforation site previously closed successfully with endoclips had split open necessitating an emergency laparotomy.

The gastric lesion in our patient was a recurrent tumor following an initial ESD, and the existence of fibrosis at the site of ESD scar was considered to be one of the factors associated with incomplete healing of the perforation. However, on referring to our previous analysis of 46 patients who received ESDs for locally recurrent EGCs after prior endoscopic resections, perforations occurred during ESD in four patients (8.7%) with all four patients fully recovering following successful endoscopic closure with endoclips^[9]. Therefore, based on those earlier reported results, we cannot conclude that the existence of fibrosis in connection with local recurrence was the only reason for failure of the healing process in the present perforation case. We speculate that there may have been another contributing cause, specifically the patient's medical history of laparotomy for cholelithiasis. It is thought that the reason the perforation site did not heal after successful endoscopic closure was related to the adhesions resulting from the previous laparotomy. Adipose tissue did not cover the perforation site after endoscopic closure due to these adhesions, thus the perforation site was unable to heal properly. We believe that the patient's unremarkable abdominal symptoms were also related to these adhesions as they created a closed space in the abdominal cavity thus localizing the peritonitis resulting from the gastric perforation.

Our experience in this case indicates that gastric perforations which occur during ESD cannot always be treated conservatively even after successful endoscopic closure using endoclips, particularly if the patient has a medical history of laparotomy. Consequently, we must keep this possibility in mind when performing ESD on an EGC patient with a medical history of laparotomy. In addition, we need to remember that perforation patients with a medical history of laparotomy do not always show

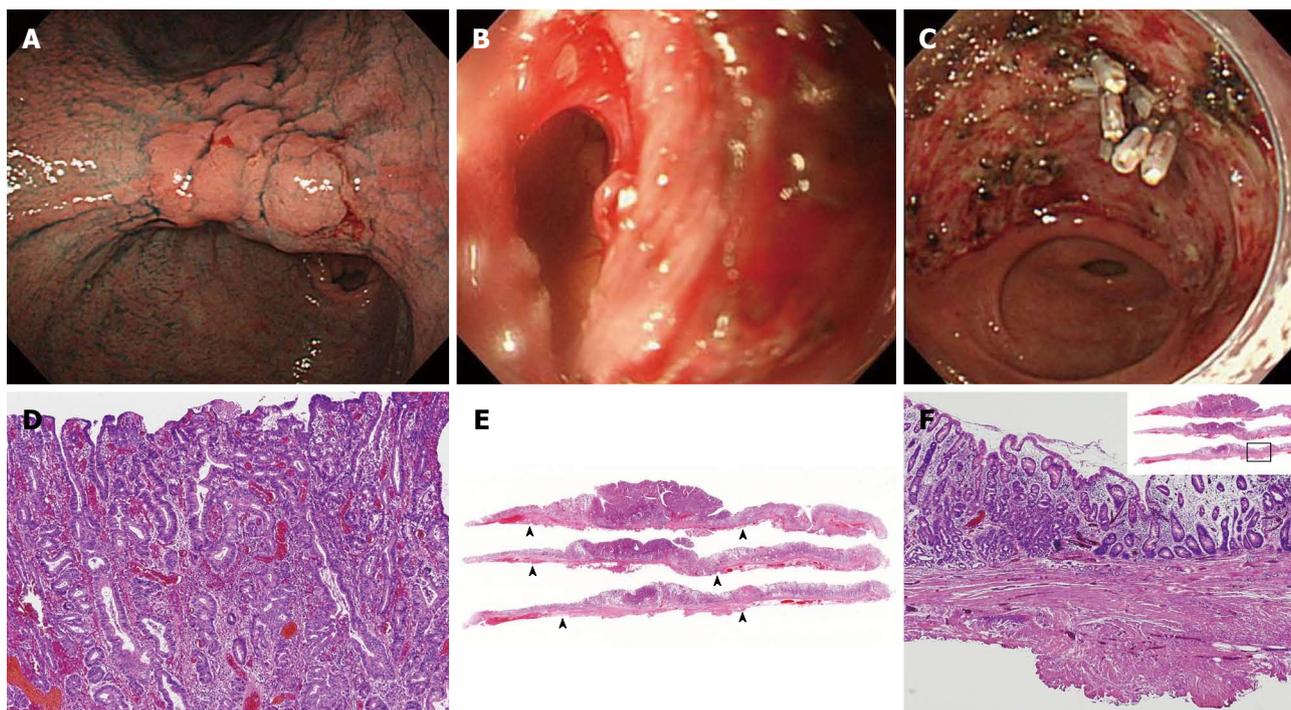

Figure 1 Endoscopic submucosal dissection of a recurrent tumor in December 2006. A: Pre-treatment endoscopy. A recurrent tumor 20 mm in size was detected at the site of the initial endoscopic submucosal dissection (ESD) scar by surveillance endoscopy; B: Endoscopic treatment. ESD was performed on the recurrent tumor, and an oval perforation 5 mm in length occurred at the site of extensive fibrosis during ESD; C: Endoscopic closure of the gastric perforation. The perforation was immediately observed and successfully closed with endoclips so that ESD could be continued resulting in *en-bloc* resection; D: Microscopic examination. A well to moderately differentiated mucosal adenocarcinoma without lymphovascular involvement was shown (hematoxylin and eosin stain, $\times 40$); E, F: Histopathologically, an ulcer scar from the initial ESD (UI-III)s was also shown [between arrowheads (E)] [hematoxylin and eosin stain, $\times 1$ (E), $\times 20$ (F)].

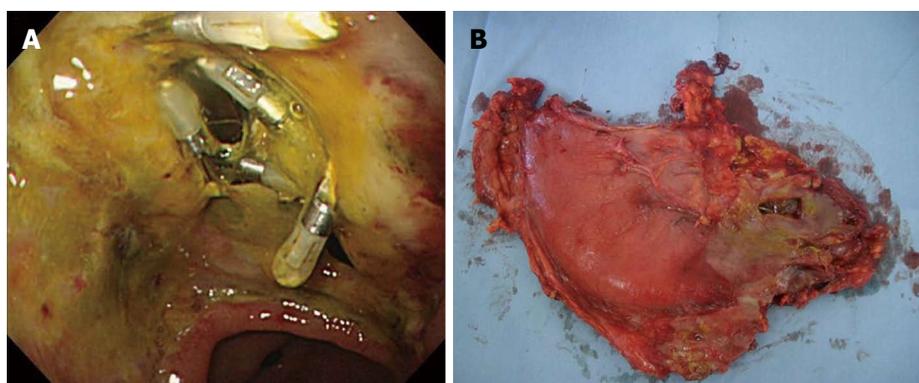

Figure 2 Dehiscence following successful endoscopic closure of the gastric perforation. A: Endoscopy five days after endoscopic submucosal dissection (ESD). The split-open perforation previously closed successfully with endoclips during ESD was revealed; B: Surgical findings. A perforation of the gastric wall extending to the omental bursa 30 mm \times 10 mm in length was seen. The perforation site was not covered with adipose tissue.

remarkable abdominal symptoms and physical findings of diffuse peritonitis.

Abstract

We present three cases of autoimmune pancreatitis (AIP) complicated by gastric varices. Case 1: A 57-year-old man was diagnosed with AIP complicated by gastric varices and splenic vein obstruction. Splenomegaly was not detected at the time of the diagnosis. The AIP improved using steroid therapy, the splenic vein was reperfused, and the gastric varices disappeared; case 2: A 55-year-old man was diagnosed with AIP complicated by gastric varices, splenic vein obstruction, and splenomegaly. Although the AIP improved using steroid therapy, the gastric varices and splenic vein obstruction did not resolve; case 3: A 68-year-old man was diagnosed with AIP complicated by gastric varices, splenic vein obstruction, and splenomegaly. The gastric varices, splenic vein obstruction, and AIP did not improve using steroid therapy. These three cases suggest that gastric varices or splenic vein obstruction without splenomegaly may be an indication for steroid therapy in patients with AIP because the complications will likely become irreversible over time.

INTRODUCTION

Autoimmune pancreatitis (AIP) is accepted worldwide as a distinctive type of pancreatitis, and the number of patients with AIP is increasing^[1-5]. However, there are few reports of AIP complicated by gastric varices, and the effect of steroid therapy on the gastric varices is unknown. We present three cases of autoimmune pancreatitis complicated by gastric varices.

CASE REPORT

Case 1

A 57-year-old man was admitted to the hospital due to back pain and jaundice. He had a history of diabetes mellitus and no history of habitual alcohol consumption. Laboratory studies revealed liver dysfunction (total bilirubin 3.1 mg/dL, aspartate aminotransferase 275 IU/L, alanine aminotransferase 557 IU/L, and alkaline phosphatase 2822 IU/L), hyperglycemia (236 mg/dL), elevated hemoglobin A1c (7.9%), and elevated IgG4 (176.4 mg/dL). Tumor markers, a complete blood count, electrolyte plasma levels, coagulation tests, amylase levels, lipase levels, and kidney function were all within the nor-

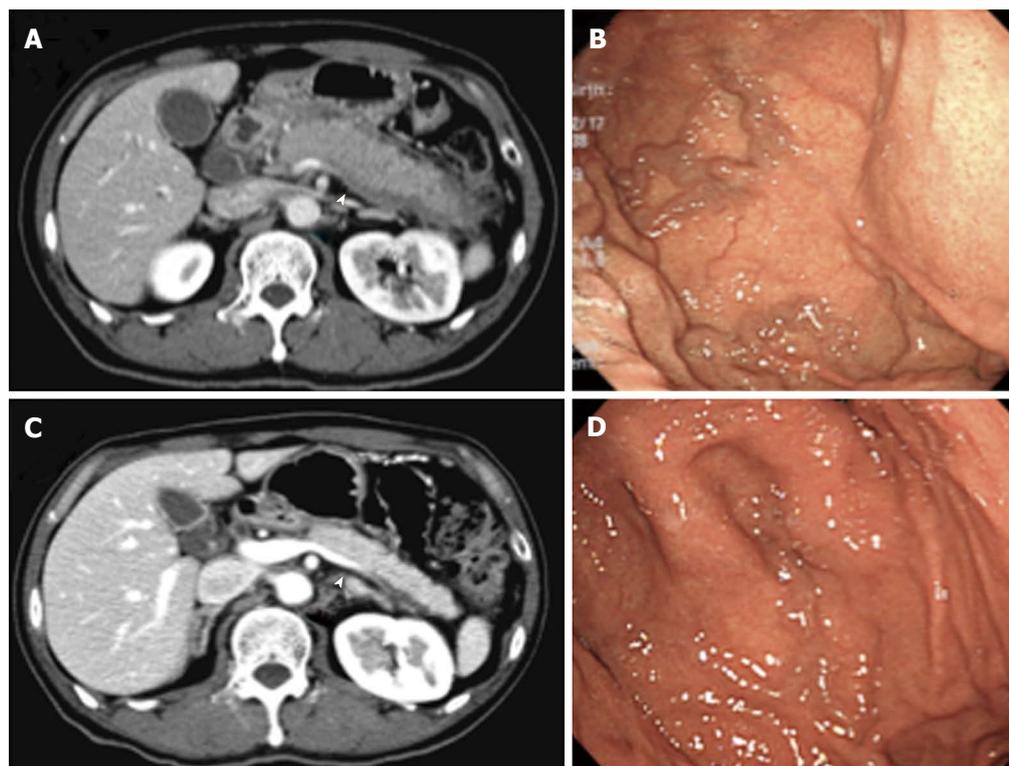

Figure 1 Disappearance of gastric varices following steroid therapy. A: Computed tomography showed a diffusely enlarged pancreas with a capsule-like rim, obstructed splenic vein (arrowhead), and dilated common bile duct; B: Esophagogastroduodenoscopy showed gastric varices in the fundus of the stomach; C: The splenic vein was reperused (arrowhead), and autoimmune pancreatitis improved following steroid therapy; D: Gastric varices disappeared following steroid therapy.

mal limits. Computed tomography (CT) of the abdomen revealed a diffusely enlarged pancreas with a capsule-like rim, an obstructed splenic vein, and a dilated common bile duct (Figure 1A). Endoscopic retrograde cholangiopancreatography (ERCP) revealed irregular narrowing of the main pancreatic duct and stricture of the lower common bile duct. Esophagogastroduodenoscopy (EGD) revealed gastric varices in the fundus of the stomach (Figure 1B).

According to the 2006 Clinical Diagnostic Criteria of The Japan Pancreas Society, the patient was diagnosed with AIP complicated by splenic vein obstruction and gastric varices. Endoscopic biliary drainage by stent placement was performed to alleviate the obstructive jaundice, followed by the oral administration of 30 mg/d prednisolone for 2 wk. The dose was tapered by 5 mg every 2 wk to a maintenance dose of 5 mg/d. Two weeks after the initial treatment, a CT scan showed that the enlarged pancreas had improved and that the splenic vein was reperused (Figure 1C). Six mo after the initial therapy, EGD showed that the gastric varices had disappeared (Figure 1D). Twenty-one mo after admission to the hospital, the patient was followed in the clinic with a maintenance dose of 5 mg/d prednisolone.

Case 2

A 55-year-old man was admitted to the hospital following the incidental detection of gastric fundal varices on EGD during a complete physical examination (Figure 2A). He

had no previous illnesses and no history of habitual alcohol consumption. The patient was asymptomatic, and nothing abnormal was detected on physical examination. A CT scan revealed a locally enlarged pancreatic tail with a capsule-like rim around the lesion, an obstructed splenic vein, and splenomegaly (Figure 2B). ERCP was performed, revealing irregular narrowing of the main pancreatic duct in the pancreatic tail (Figure 2C). Laboratory studies showed an elevated IgG4 (239.1 mg/dL). Tumor markers, a complete blood count, electrolyte plasma levels, coagulation tests, amylase levels, lipase levels, and kidney and liver functions were all within the normal limits.

According to the 2006 Clinical Diagnostic Criteria, the patient was diagnosed with AIP complicated by splenic vein obstruction, gastric varices, and splenomegaly. Oral administration of 30 mg/d prednisolone for 4 wk was used to induce remission, and the dose was tapered by 5 mg every 2 wk to a maintenance dose of 5 mg/d. Two weeks after the initial treatment, a CT scan showed that the enlarged pancreas tail had improved and that the capsule-like rim had disappeared (Figure 2D). However, the splenic vein was not reperused. Ten mo after the initial therapy, EGD showed no improvement of the gastric varices. One year after hospital admission, the patient was followed in the clinic with a maintenance dose of 5 mg/d prednisolone.

Case 3

A 68-year-old man was admitted to the hospital due

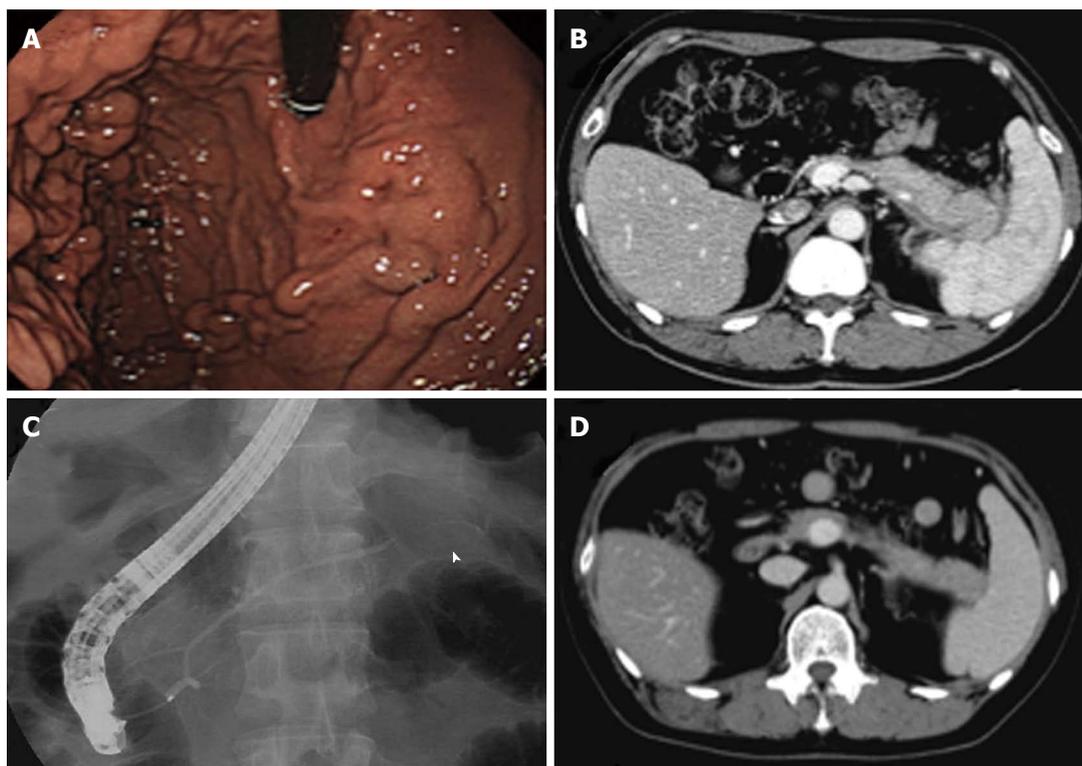

Figure 2 The splenic vein was not reperfused, although the autoimmune pancreatitis improved. A: Esophagogastroduodenoscopy showed gastric varices in the fundus of the stomach; B: Computed tomography showed a locally enlarged pancreatic tail with a capsule-like rim, an obstructed splenic vein, and splenomegaly; C: Endoscopic retrograde cholangiopancreatography showed irregular narrowing of the main pancreatic duct in the pancreatic tail (arrowhead); D: Autoimmune pancreatitis improved following steroid therapy, but the splenic vein was not reperfused.

to hematemesis. An emergency EGD was performed, revealing gastric ulcer bleeding at the gastric notch and incidentally detected gastric varices in the fundus of the stomach (Figure 3A). The gastric ulcer was successfully treated with endoscopic coagulation and administration of a proton pump inhibitor. Additional investigations were performed to ascertain the cause of the gastric varices. The patient had a past history of diabetes mellitus and no history of habitual alcohol consumption. A CT scan revealed a slightly enlarged pancreas with a capsule-like rim around the lesion, a pancreatic stone in the pancreatic tail, an obstructed splenic vein, and splenomegaly (Figure 3B and C). Magnetic resonance cholangiopancreatography (MRCP) revealed irregular narrowing of the main pancreatic duct in the pancreatic head and body, slight dilation of the main pancreatic duct in the pancreatic tail, stricture of the hilar bile duct and lower bile duct, and dilation of the right intra-hepatic bile duct (Figure 3D). ERCP showed the same findings as MRCP. Laboratory studies revealed elevated levels of IgG4 (186 mg/dL), hemoglobin A1c (8.0%), carcinoembryonic antigen (8.2 ng/mL), CA19-9 (38.7 U/mL), and alkaline phosphatase (345 IU/L). The complete blood count, electrolyte plasma levels, coagulation tests, amylase levels, lipase levels, and kidney function were all within the normal limits.

Although the slight dilation of the distal main pancreatic duct was atypical of AIP, the slightly enlarged pancreas, the irregular narrowing of the main pancreatic duct in

the pancreatic head and body, and the elevated levels of IgG4 met the 2006 Clinical Diagnostic Criteria. The patient was diagnosed with AIP complicated by splenic vein obstruction, gastric varices, splenomegaly, and sclerosing cholangitis. Oral administration of 30 mg/d prednisolone for 4 wk was used to induce remission, and the dose was tapered by 5 mg every 2 wk to a maintenance dose of 5 mg/d. However, a CT scan showed no improvement of the pancreatic lesion, and EGD showed no improvement of the gastric varices. Because steroid therapy was not effective, maintenance therapy was discontinued 5 mo after the initial treatment. One year after hospital admission, the patient was followed in the clinic without treatment.

DISCUSSION

There are few reports of autoimmune pancreatitis complicated by gastric varices. The effects of steroid therapy on the varices is unknown^[6]. However, the reported 8%^[7] frequency of splenic vein obstruction in patients with chronic pancreatitis indicates that it is not a rare complication. Splenic vein obstruction causes a localized form of portal hypertension, known as sinistral portal hypertension, which leads to the formation of gastric varices along the fundus and the greater curvature of the stomach due to increased blood flow through the short gastric veins or the gastroepiploic vein^[8]. From 1999 to 2011, our hospital treated 20 consecutive patients with AIP who fulfilled either the 2006 Clinical Diagnostic Criteria

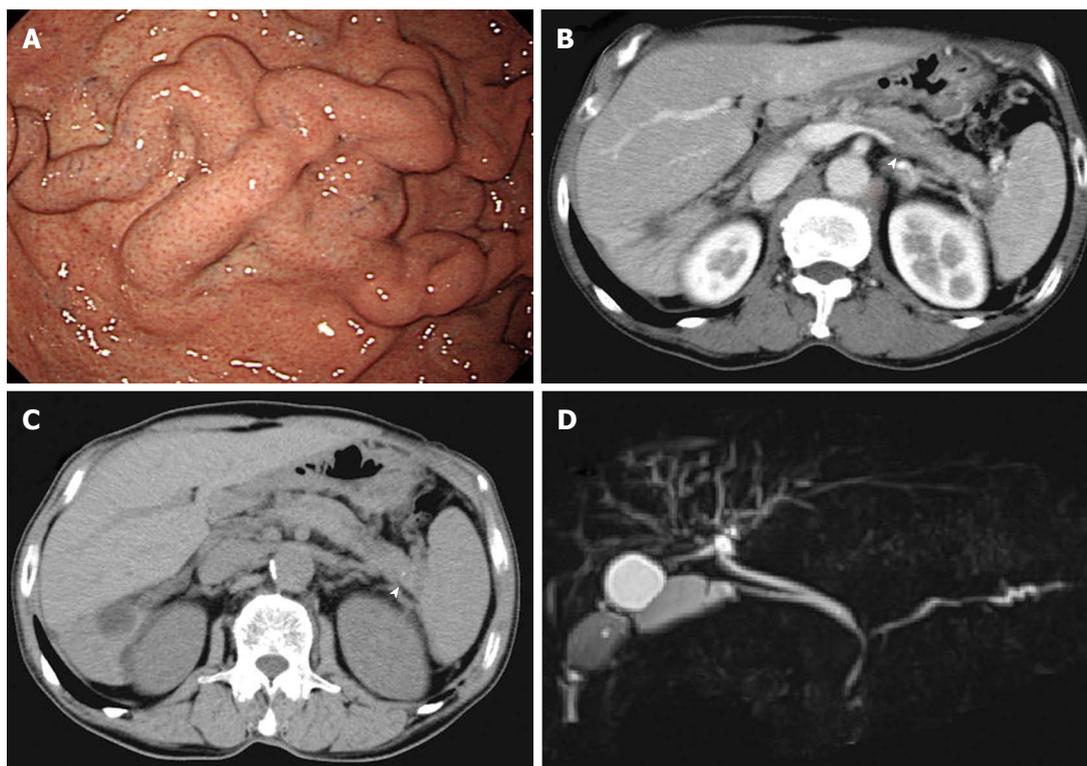

Figure 3 Autoimmune pancreatitis that did not improve with steroid therapy. A: Esophagogastroduodenoscopy showed gastric varices in the fundus of the stomach; B: Computed tomography (CT) showed a slightly enlarged pancreas with a capsule-like rim, an obstructed splenic vein (arrowhead), and splenomegaly; C: CT showed a pancreatic stone in the pancreatic tail (arrowhead); D: Magnetic resonance cholangiopancreatography showed irregular narrowing of the main pancreatic duct in the pancreatic head and body, slight dilation of the main pancreatic duct in the pancreatic tail, stricture of the hilar bile duct and lower bile duct, and dilation of the right intra-hepatic bile duct.

of The Japan Pancreas Society or the Asia diagnostic criteria. Splenic vein obstruction was confirmed in 4 of the patients (20%) using CT, and 3 of the 4 patients (15%) had gastric varices.

The clinical course of these three cases varied depending on the presence of splenomegaly. In case 1, splenomegaly was not detected at the time of diagnosis. Gastric varices disappeared as the AIP improved using steroid therapy; In case 2, splenomegaly was detected at the time of diagnosis. The gastric varices did not improve, although the AIP improved using steroid therapy; In case 3, splenomegaly was detected at the time of diagnosis. Neither the gastric varices nor the AIP improved with steroid therapy. These three cases suggest that gastric varices complicating AIP without splenomegaly may improve using steroid therapy.

The pathogenetic hypothesis of splenic vein obstruction has been related to many factors: compression by a pseudocyst or an enlarged pancreatic parenchyma and secondary involvement of the vein by surrounding edema, cellular infiltration, and the fibroinflammatory process^[9]. Whether the splenic vein obstruction is formed by mechanical force or inflammatory infiltration, the obstruction will become an irreversible thrombosis over time. Although the AIP improved in case 2, the splenic vein obstruction, which had likely progressed into a thrombosis, was irreversible. A gastrosplenic shunt or other collateral veins that drain into the systemic circulation

were not detected on CT scans in any of the three cases. Development of congestive splenomegaly may have been dependent on the length of time the patients had been affected with sinistral portal hypertension. These three cases indicate the need to reperfuse the obstructed splenic vein before the development of splenomegaly, otherwise the obstruction becomes irreversible. According to a nationwide survey by the Research Committee of Intractable Pancreatic Diseases conducted by the Ministry of Health, Labor and Welfare of Japan, the remission rate of steroid-treated AIP is 98%^[10]. However, rare cases of steroid-refractory AIP can occur. Kamisawa *et al*^[11] reported the development of pancreatic atrophy in 5 out of 23 patients with AIP. Takayama *et al*^[12] reported that AIP has the potential to be a progressive disease with pancreatic stones. These reports suggest that recurrent cases of AIP can turn into chronic pancreatitis-like lesions during long-term follow-up and become refractory to steroid therapy. In case 3, the AIP was refractory to steroid therapy. Because the enlargement of the pancreas was not prominent and a pancreatic stone was detected, the lesion was likely the result of recurrent inflammation of AIP.

The role of a prophylactic splenectomy in asymptomatic patients with splenic vein obstruction and gastric varices remains controversial. Badley concluded that the benefit of preventing possible bleeding of the varices outweighs the risk of postsplenectomy sepsis^[13], although

Bernades *et al*^[7] reported that the risk of variceal bleeding is lower than previously reported. In cases 2 and 3, we did not perform a prophylactic splenectomy or partial splenic embolization because the patients opted for a watchful waiting approach.

The indications for steroid therapy in patients with AIP are symptoms such as obstructive jaundice, abdominal pain, back pain and the presence of symptomatic extrapancreatic lesions^[1]. However, some patients with AIP improve spontaneously^[1,14]. The treatment of asymptomatic patients with AIP remains controversial. Based on the potential risk and benefits, these three cases suggest that patients with AIP and gastric varices or splenic vein obstruction without splenomegaly should be treated with steroids before pancreatic lesions or splenic vein obstructions become irreversible. Because this study only included three cases, it is necessary to collect data on more patients with AIP complicated by gastric varices to effectively evaluate this hypothesis.

In conclusion, we treated 3 cases of autoimmune pancreatitis complicated with gastric varices. Gastric varices or splenic vein obstruction without splenomegaly may be an indication for steroid therapy in patients with AIP.

Abstract

Ischemic colitis is a rare complication of interferon administration. Only 9 cases in 6 reports have been described to-date. This report describes a case of ischemic colitis during pegylated interferon and ribavirin treatment for chronic hepatitis C, and includes a review of the relevant literature. A 48-year-old woman was treated with pegylated interferon α -2a and ribavirin for chronic hepatitis C, genotype 1b. After 19 wk of treatment, the patient complained of severe afebrile abdominal pain with hematochezia. Vital signs were stable and serum white blood cell count was within the normal range. Abdominal computed tomography showed diffuse colonic wall thickening from the splenic flexure to the proximal sigmoid colon, which is the most vulnerable area for the development of ischemic

colitis. Colonoscopy revealed an acute mucosal hyperemic change, with edema and ulcerations extending from the proximal descending colon to the sigmoid colon. Colonic mucosal biopsy revealed acute exudative colitis. Polymerase chain reaction and culture for *Mycobacterium tuberculosis* were negative and the cultures for cytomegalovirus, *Salmonella* and *Shigella* species were negative. After discontinuation of interferon and ribavirin therapy, abdominal pain and hematochezia subsided and, following colonoscopy showed improvement of the mucosal ulcerations. Ischemic colitis cases during interferon therapy in patients with chronic hepatitis C reported so far have all involved the descending colon. Ischemic colitis is a rarely encountered complication of interferon administration in patients with chronic hepatitis C and should be considered when a patient complains of abdominal pain and hematochezia.

INTRODUCTION

Pegylated interferon (IFN) combined with ribavirin is currently the standard treatment for chronic hepatitis C (CHC) and can achieve sustained virological response

in approximately 55% of genotype-I hepatitis C virus (HCV) infections^[1]. The side effects of this combination treatment result in premature treatment termination in 10%-15% and dose adjustment in 32%-42% of patients^[1]. Therefore, physicians need to be well aware of both the common and uncommon side effects of treatment. Ischemic colitis is a rare complication of interferon administration^[2]. Only 9 cases in 6 reports (one in Japanese^[3] and 5 in English^[2,4-7]) have been described to date. This report describes a case of ischemic colitis during pegylated interferon and ribavirin treatment for CHC and includes a review of the relevant literatures.

CASE REPORT

A 48-year-old woman was admitted for the evaluation of acute abdominal pain and hematochezia. The patient had been treated with combination therapy of pegylated IFN- α 2a (180 μ g/wk) (Pegasys; Roche, Basel, Switzerland) and ribavirin (1000 mg/d) (LG Ribavirin; LG Life Sciences, Seoul, Korea) for CHC, genotype Ib. A qualitative HCV test was initially obtained using reverse transcription-polymerase chain reaction (RT-PCR) (Abbott Laboratories, Abbott Park, IL, United States), and the serum HCV viral load was 1.67×10^6 viral copies/mL. The serum HCV RNA level decreased to undetectable levels after 12 wk of treatment. The treatment process was uneventful until 16 wk of therapy. At week 16, the patient complained of mild epigastric discomfort and nausea, which resolved spontaneously a few days later. Three weeks later, at week 19 of therapy, the patient complained of severe abdominal pain with hematochezia, but she remained afebrile. Small amounts of bloody stool were passed 2-3 times per day. The patient denied recent travel or additional medications such as antibiotics or non-steroidal anti-inflammatory drugs. The patient had no history of diabetes mellitus, hypertension, inflammatory bowel disease, atrial fibrillation, valvular heart disease, coronary artery disease, or hypercoagulable conditions. She was a non-smoker, and her family history was unremarkable.

Physical examination revealed direct tenderness on the left lower quadrant of the abdomen. Blood pressure was 114/76 mmHg, pulse 80 beats/min, respiration rate 20/min, and body temperature 37.9 °C. Complete blood count revealed a hematocrit of 26.9%, hemoglobin 8.7 gm/dL, platelets 115 000/ μ L, and white blood cell count 4700/ μ L with differential counts within the normal range. C-reactive protein was slightly elevated at 0.7 mg/dL (normal < 0.4 mg/dL). Serum electrolytes, liver profile, renal function tests, amylase, and lipase were within normal limits. The coagulation profile was within the normal range, with a prothrombin time of 11.2 s and an activated partial thromboplastin time of 23.9 s. Upper endoscopy was performed 6 mo prior to admission, which documented a healing stage small gastric ulceration at the antrum. *Helicobacter pylori* infection was documented by histological examination and was successfully eradicated

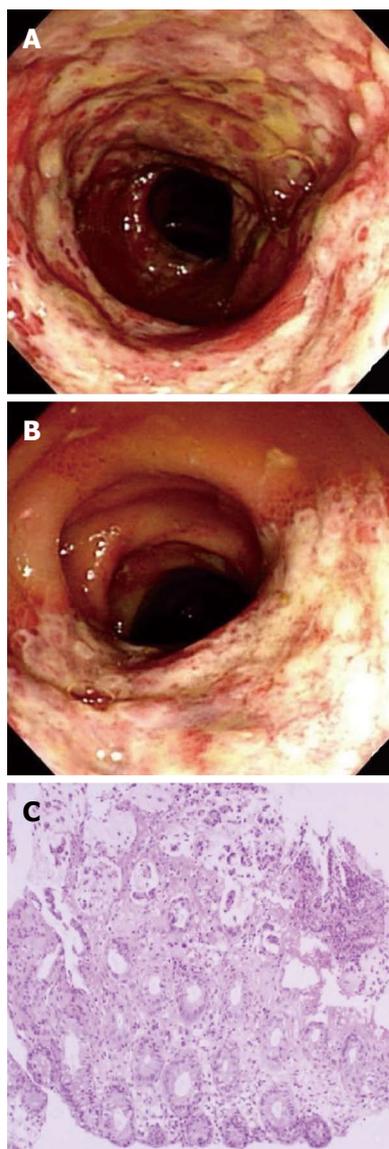

Figure 1 Colonoscopy images and pathology. A: Mucosal hyperemic change with edema, erosion, and ulcerations and hemorrhagic friable mucosa on the sigmoid colon; B: Segmental ulceration was seen on the proximal descending colon; C: Pathological examination of the descending colon showed acute exudative colitis. Epithelial detachment was observed (hematoxylin and eosin stain, $\times 40$).

with antibiotic therapy at that time. At admission, upper endoscopy was negative for an active bleeding source, and colonoscopic examination revealed acute hyperemic mucosal changes with edema, erosion, and ulcerations. Acute inflamed, friable mucosal changes extended from the sigmoid colon (Figure 1A) to the proximal descending colon (Figure 1B). The rectum showed relatively normal mucosa. Colonic mucosal biopsy revealed acute exudative colitis compatible with a diagnosis of ischemic colitis (Figure 1C). On the biopsy specimen, staining for cytomegalovirus showed no positive cells, and staining for acid-fast bacilli was negative. Tuberculous nucleic acid was undetectable by polymerase chain reaction. A serum anti-Streptolysin O test was negative. Bacteriologic culture studies of stool and colonic fluid were negative

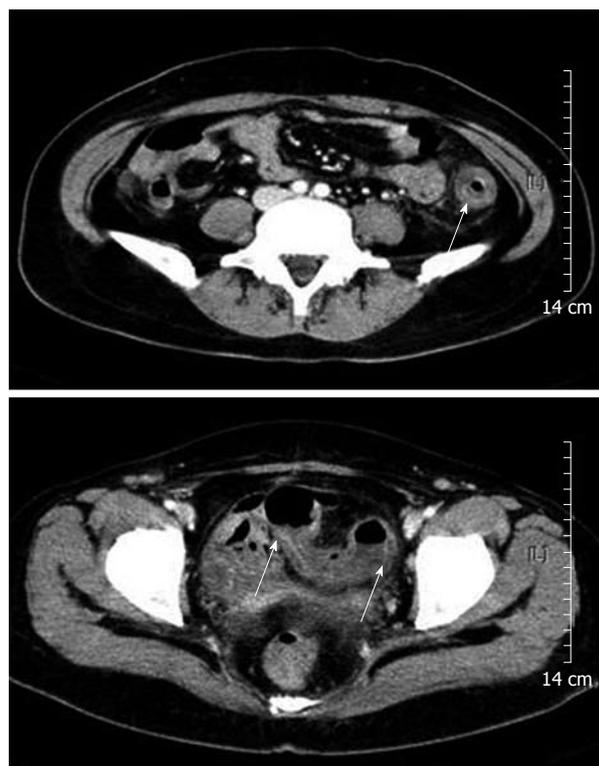

Figure 2 Abdominal computed tomography. A: Circumferentially layered wall thickening and pericolic fat infiltration at the descending colon (arrow); B: Circumferential wall thickening and pericolic fat infiltration at the proximal sigmoid colon (arrows).

for *Mycobacterium*, *Salmonella*, and *Shigella* species. Abdominal computed tomography showed circumferential wall thickening and pericolic fat infiltration from the descending colon to the proximal sigmoid colon, a well-known predisposing area for the development of ischemic colitis (Figure 2). The findings from colonoscopy, computed tomography, and pathology were all compatible with the diagnosis of ischemic colitis.

After IFN and ribavirin treatment were discontinued, the patient's abdominal pain decreased and hematochezia resolved. One week later, subsequent colonoscopy showed marked improvement in ulceration and mucosal edema. Serum HCV RNA remained undetectable for up to 3 mo after cessation of treatment, but reappeared 1 year later. The reappearance of serum HCV RNA suggests that the antiviral treatment for CHC was not successful.

DISCUSSION

In current standard combination therapy of pegylated IFN and ribavirin in CHC patients, more than 50% of sustained virological response is expected. However, a large proportion of the patients are not eligible for the treatment or drop out early during the treatment due to side effects.

The side effects of IFN and ribavirin combination therapy are mostly associated with IFN administration, while hemolytic anemia is attributable to ribavirin^[1]. Side

effects associated with IFN treatment have been described not only in CHC, but also in chronic hepatitis B^[8], chronic myeloid leukemia^[9], metastatic renal cell carcinoma^[10], and multiple myeloma^[11]. Flu-like symptoms such as general malaise, fever, arthralgia, headache, and hematologic abnormalities such as leukopenia and thrombocytopenia are frequently observed early adverse effects of IFN- α administration^[2]. Although the severity of these symptoms is directly related to the dose and frequency of IFN administration, remarkable individual variation has been observed^[2]. Among the various gastrointestinal side effects of IFN- α , ischemic colitis is rarely reported during treatment of CHC, occurring in less than 1% of patients^[12]. Other than ischemic colitis, microscopic colitis^[7] and ulcerative colitis^[13] have also been reported.

Nine cases of ischemic colitis related to IFN therapy in CHC have been reported in 6 studies, and the most common symptoms were abdominal pain and lower gastrointestinal bleeding such as melena and hematochezia^[2-7]. The descending colon was most frequently involved in all ischemic colitis cases associated with CHC (Table 1). In reported cases, hematochezia and melena appeared between week 4 and 34 of IFN treatment, and the mean duration of IFN treatment before the occurrence of ischemic colitis was 14 wk. The characteristics of this case correspond well with those of previously reported cases in terms of symptoms, location, and period of duration.

The etiology of ischemic colitis is not yet clearly elucidated. The mechanism of IFN-induced ischemic colitis is thought to be associated with immune modulation of cytokine networks. Sparano *et al*^[10] documented the role of interleukin-2 (IL-2) and IFN- α in the development of colonic ischemia. They suggested that a disordered coagulation cascade played a role in the pathogenesis of colonic ischemia, assuming that derangement of coagulation is

mediated by tumor necrosis factor or its interactions with other cytokines^[10]. IFN therapy also induces an increase in plasma-activated complement C5a, a potent intravascular aggregator of granulocytes, favoring the development of microthrombi in small vessels. IFN-induced vasculitic reactions, mediated by the deposition of immune complexes in the vasculature, may also play a pathogenic role in ischemia of various organs^[14,15]. Thrombogenic effects of activated cytokines and immune complex-mediated vasculitic reactions may play a role in the pathogenesis of IFN-induced ischemic colitis^[14]. The potential role of cytokines for the development of IFN induced ischemic colitis needs to be investigated further.

In conclusion, physicians should be vigilant of the various common and uncommon complications of both pegylated IFN and ribavirin. Ischemic colitis is a rarely encountered complication of pegylated IFN administration but it should be considered when a patient complains of abdominal pain and hematochezia.

Abstract

Spontaneous hemoperitoneum (SP) is defined as the presence of blood within the peritoneal cavity that is unrelated to trauma. Although there is a vast array of etiologies for SP, primary hepatocellular carcinoma and hepatic adenoma are considered to be the most common causes. Hepatic metastatic tumor associated with spontaneous rupture is rare. SP from hepatic metastatic trophoblastic tumor may initially present with a sudden onset of abdominal pain. Abdominal computed tomography (CT) plays an important role in establishing the diagnosis of SP, indicating its origin and etiology, and determining subsequent management. Herein, we report an uncommon case of hemoperitoneum from spontaneous rupture of a hepatic metastatic trophoblastic tumor in a young female patient. Interestingly, the contrast-enhanced CT findings demonstrated hypervascular hepatic masses with persistent enhancement at all phases, which were completely different from the

INTRODUCTION

Spontaneous hemoperitoneum (SP) is defined as the presence of blood within the peritoneal cavity that is unrelated to trauma. Primary hepatocellular carcinoma (HCC) and hepatic adenoma are considered to be the most common causes; however, hepatic metastatic tumors associated with SP are rare. Those metastatic tumors may include colon, lung, renal cell and testicular neoplasms, and Wilm's tumor, but few cases of metastatic trophoblastic tumor responsible for HP have been reported, especially in the absent evidence of primary malignant tumor. Computed tomography (CT) plays an important role in establishing the diagnosis of SP. Metastatic liver tumors display variant appearances in routine CT scan and are often classified as hypervascular, hypovascular and nonvascular metastases on dynamic contrast-enhanced CT scan. Most of the hepatic metastatic tumors present with hypovascular appearances, namely mild enhancement in both the portal

phase and delayed phase. But in our patient with hepatic trophoblastic tumor, there were typically unusual presentations, which showed almost identical enhancement patterns with abdominal aorta in all phases. To our knowledge, there are few reports of similar cases focusing on uncommon CT manifestations in hepatic metastatic trophoblastic tumor. We report an uncommon case of hemoperitoneum from spontaneous rupture of a hepatic metastatic trophoblastic tumor in a young female patient below.

CASE REPORT

A 24-year-old girl was admitted to our emergency department because of sudden onset of abdominal pain, and emergent non-enhanced CT scan showed intrahepatic multiple lesions associated with rupture and bleeding into the peritoneal cavity (Figure 1). Three months ago, she underwent splenic repair, and her family could not tell about the specific cause even after she was discharged from the hospital. She had a history of pregnancy and abortion two years ago. Physical examination on admission was unremarkable except for mild epigastric tenderness and longitudinal abdominal scar. At exploratory laparotomy, there was dark red blood in the abdominal cavity. After cleaning of the blood, multiple cystic masses bulging from the surface of the liver were found, one of which was ruptured and then removed for pathological analysis. Her serum beta human chorionic gonadotropin (β -HCG), alpha-fetoprotein (AFP) and cancer antigen-125 (CA-125) levels were 94 mIU/mL (reference range: 0-6 mIU/mL), 1.01 ng/mL (reference range: < 7.0 ng/mL) and 46.86 ng/mL (reference range: < 3.4 ng/mL), respectively. Post-operative contrast-enhanced CT of abdomen showed multiple hepatic hypervascular masses keeping the similar enhancement with abdominal aorta in all phases (the diameter of the masses ranged from 0.8 cm to 2.8 cm) and arteriportal shunts (Figures 2, 3A and B). CT scan of the chest and pelvis revealed no abnormalities. Histopathological examination confirmed the tumor to be predominantly composed of mononuclear epithelioid cells with pink cytoplasm and large, irregularly shaped nuclei with prominent nucleoid (Figure 4). Immunostaining was positive for placental alkaline phosphatase (Figure 5), while negative for HepPar-1, smooth muscle actin. Hepatic metastatic trophoblastic tumor was diagnosed by histopathological examination and immunohistochemical analyses. No abnormality was found in the all-round gynecological checkup, especially in the uterus. The patient refused to chemotherapy and died a month later despite of receiving supportive treatment. Her family refused the autopsy.

DISCUSSION

SP, an uncommon cause of acute abdominal pain, is defined as the presence of blood within the peritoneal cavity that is unrelated to trauma. Its occurrence may

Figure 1 Axial computed tomography showing multiple hypodense nodules in the liver and hemoperitoneum around the liver and spleen.

Figure 2 Contrast-enhanced computed tomography scan showing multiple hypervascular nodules similar to the enhancement of abdominal aorta in the arterial phase.

be catastrophic. There are various causes for SP, such as hepatic, splenic, gynecological and vascular involvement, and altered coagulation status^[1,2]. Therefore, underlying causes must be identified if the patient survives the initial events. As for hepatic causes, previously undetected liver lesion may be a relatively common cause of spontaneous rupture leading to hemoperitoneum, and unnoticeable

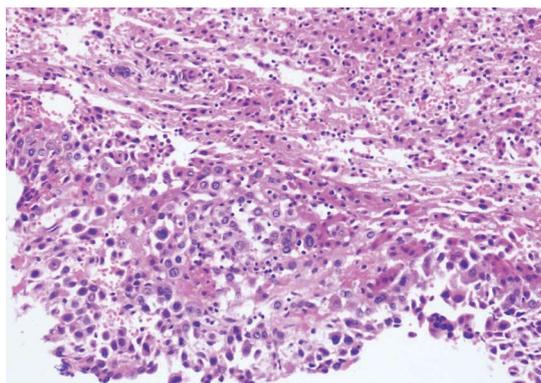

Figure 4 Histopathology showing the tumor composed of mononuclear epithelioid cells with large, irregularly shaped nuclei (hematoxylin and eosin stain × 200).

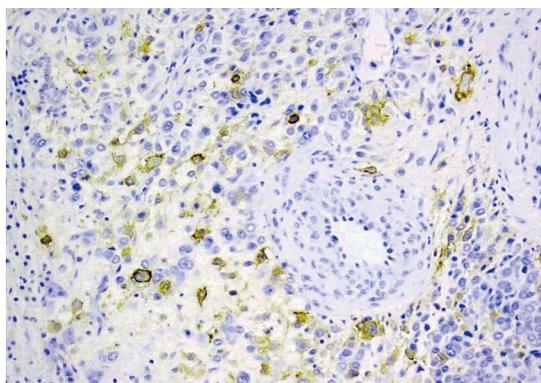

Figure 5 Immunohistochemical analysis was positive for placental alkaline phosphatase (× 200).

minor trauma may be the precipitating factor. Hepatic adenoma and HCC developed from cirrhosis are the most common causes for SP^[3,4], however, hepatic metastatic tumor associated with SP is rare, as most of them tend to be less invasive, and have less blood vessels and less propensities to penetrate the liver capsule as compared with HCC. In our case, hepatic metastatic tumor associated with SP was due to the rupture of hepatic metastasis of a trophoblastic tumor with hypervascularity, which was seldom found responsible for SP in clinical practice.

The mechanism for the rupture of hepatic metastasis remains unclear, but the large lesion adjacent to the liver capsule is at the greatest risk due to direct pressure against the capsular surface, especially in increased intra-abdominal pressure. Acute hemoperitoneum as a result of hemorrhage from liver metastasis is an uncommon but a terminal event. In a large report of 70 patients with SP, metastatic disease was only found responsible for one case^[5]. Those metastatic lesions may include colon, lung, renal cell, testicular tumors, and Wilm's tumor^[6-8]. So, a thorough search should be made for evidence of a primary tumor that may have metastasized to the liver. However, hepatic involvement from trophoblastic tumor accounts for only 10% of the patients and occurs in the late course of the disease. Regression of a primary tumor

after it has metastasized is not uncommon, and one-third of cases manifests as complications of metastatic diseases^[9].

The available imaging modalities used for the diagnosis of SP include sonography, CT and magnetic resonance imaging. Meticulous imaging technique and careful observation of key imaging features are important for accurate characterization of the organ origin of the spontaneous bleeding. Currently, CT scan is the most frequently used modality in evaluating the patients with suspected hemoperitoneum^[2,10,11]. Emphasis should be laid on detecting hemoperitoneum, then localizing the source of bleeding and finally detecting the primary cause. On CT imaging, the appearance of blood within the peritoneum varies depending on the site and the extent of bleeding, and the age of blood. If the time interval between bleeding and imaging is several hours, high attenuation clot may be seen. Over the next few days, the attenuation of the blood decreases, which becomes similar to simple fluid after 2-3 wk. High attenuation clots may appear at the site of the bleeding and suggest a clue as to the site of the bleeding origin. Once the presence of hemoperitoneum has been identified or active bleeding is controlled, a comprehensive search should be made further for an underlying cause. This may start with a careful evaluation of the liver and spleen, because they are the most common organs responsible for spontaneous bleeding. If the SP is derived from a hepatic or splenic cause, the peritoneal blood may be centered around the responsible lesion^[12,13], as described in our case. Although hepatic metastases can come from many locations of the body, SP secondary to metastases exhibit similar findings on non-enhanced CT scan.

Dramatic advance in multi-detector technology has significantly improved the accuracy of CT and dynamic contrast-enhanced CT scan which can identify imaging characteristics of intrahepatic lesions, especially the rare appearances from uncommon disease entity. Metastatic tumors of liver present with intra-liver occupied lesions on unenhanced CT scan, including multi-nodules similar to the "bull's eye" sign, homogenized low-density mononodule, equal- or high-density mass and cystic lesion. Appearances of dynamic contrast-enhanced CT scan for these disease entities may have variant enhancement patterns according to the vascularity of the primary tumor and are often classified as hypervascular, hypovascular and nonvascular metastases. Most of hepatic metastatic tumors show mild enhancement in the portal phase and delayed phase consistent with hypovascular lesions, while there were typically unusual presentations in our patient, which showed the synchronized enhancement with abdominal aorta in all phases. The similar case is extremely rare in the reported literature. Therefore, for a female patient in child-bearing age who presents with SP and unusual contrast-enhanced CT findings similar to our patient's, we should be alert to the possibility of the spontaneous rupture of metastatic trophoblastic disease in the liver, even though the primary lesion is not found on that

occasion.

Prognosis of patients with rupture hepatic metastasis of trophoblastic disease is extremely poor, and the choice of treatment depends on the tumor size, tumor location, severity of bleeding and the general condition of the patient. Surgery and embolisation with or without chemotherapy are the mandatory therapeutic choices^[14,15]. Because of the severe condition of our patient, transcatheter arterial chemotherapeutic embolization is abortive.

In conclusion, we described the CT findings of SP secondary to rupture of hepatic metastatic trophoblastic disease in a female patient. Unusual enhancement patterns on contrast-enhanced CT scan will further enhance our recognition of the SP from hepatic metastatic trophoblastic disease and help differentiate it from other hypervascular hepatic masses.

Abstract

Intestinal bacteria play a role in the development of non-steroidal anti-inflammatory drugs (NSAID)-induced small intestinal injury. Agents such as probiotics, able to modify the gut ecology, might theoretically be useful in preventing small intestinal damage induced by NSAIDs. The clinical studies available so far do suggest that some probiotic agents can be effective in this respect.

TO THE EDITOR

Park *et al*^[1,2] in their interesting editorial^[1] about small intestinal injury induced by non-steroidal anti-inflammatory drugs (NSAIDs), discussed the possible role of the intestinal flora in the pathogenesis of the enteric damage, but, oddly enough, when listing the pharmacological agents theoretically useful as protective or therapeutic medicines, they omitted to mention probiotics. Live micro-organisms could prevent NSAID-induced small intestinal damage by both modifying intestinal microbial ecology and modulating the local immune function.

Various studies have addressed the issue. While a pilot study in human volunteers failed to demonstrate any effect of *Lactobacillus GG* in preventing indomethacin-induced alterations of intestinal permeability^[3], a subsequent experimental study demonstrated that in rats pretreated with *Lactobacillus casei*, strain Shirota significantly prevents the development of indomethacin-induced enteropathy^[4], although the mechanism responsible for this phenomenon remains not completely clear.

In a recent trial, patients treated for three months with low-dose enteric-coated aspirin (100 mg daily) were randomized to receive either co-administration of *Lactobacillus casei* or no additional treatment^[5]. Capsule endoscopy, performed before and after treatment, showed a significant decrease ($P = 0.039$) in the number of mucosal breaks and in the endoscopic score in the probiotic group as compared with controls.

In a randomized, double-blind, cross-over placebo-controlled study in healthy volunteers, the probiotic mixture VSL # 3 was found to prevent the increase in faecal concentration of the inflammatory marker calprotectin during intake of indomethacin 50 mg daily^[6].

The role of bacteria in the development of small intestinal lesions during NSAID administration seems indirectly confirmed, but the recent experimental observations showed that proton pump inhibitors significantly worsen intestinal ulcerations and bleeding in naproxen- and celecoxib-treated rats and this is related to substantial

shifts in enteric microbial population (e.g., a marked reduction in *Actinobacteria* and *Bifidobacteria*)^[7].

All in all, it appears that probiotics can represent promising agents in the prevention of NSAID-induced small intestine injury, although additional studies are needed to better clarify this point. However, the efficacy of any single probiotic strain should be evaluated separately, due to the differences in the biological effects and mode of actions of the various agents currently available.

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the “priority” and “copy-right” of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers’ names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homoge-

neous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/esps/>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically

for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision for acceptance is made only when at least two experts recommend an article for publication. Reviewers for accepted manuscripts are acknowledged in each manuscript, and reviewers of articles which were not accepted will be acknowledged at the end of each issue. To ensure the quality of the articles published in *WJG*, reviewers of accepted manuscripts will be announced by publishing the name, title/position and institution of the reviewer in the footnote accompanying the printed article. For example, reviewers: Professor Jing-Yuan Fang, Shanghai Institute of Digestive Disease, Shanghai, Affiliated Renji Hospital, Medical Faculty, Shanghai Jiaotong University, Shanghai, China; Professor Xin-Wei Han, Department of Radiology, The First Affiliated Hospital, Zhengzhou University, Zhengzhou, Henan Province, China; and Professor Anren Kuang, Department of Nuclear Medicine, Huaxi Hospital, Sichuan University, Chengdu, Sichuan Province, China.

Abstract

There are unstructured abstracts (no less than 256 words) and structured abstracts (no less than 480). The specific requirements for structured abstracts are as follows:

An informative, structured abstracts of no less than 480 words should accompany each manuscript. Abstracts for original contributions should be structured into the following sections.

Instructions to authors

AIM (no more than 20 words): Only the purpose should be included. Please write the aim as the form of “To investigate/study/...”; MATERIALS AND METHODS (no less than 140 words); RESULTS (no less than 294 words): You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$; CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...etc. It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, etc., and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a $P < 0.05$, ^b $P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, ^c $P < 0.05$ and ^d $P < 0.01$ are used. A third series of *P* values can be expressed as ^e $P < 0.05$ and ^f $P < 0.01$. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be la-

beled with ●, ○, ■, □, ▲, △, etc., in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, “Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]”. If references are cited directly in the text, they should be put together within the text, for example, “From references^[19,22-24], we know that...”.

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 \pm 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantum numbers can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Please revise your article according to the revision policies of *WJG*. The revised version including manuscript and high-resolution image figures (if any) should be re-submitted online (<http://www.wjgnet.com/esps/>). The author should send the copyright transfer letter, responses to the reviewers, English language Grade B certificate (for non-native speakers of English) and final manuscript checklist to wjg@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For paper supported by a foundation, authors should provide a copy of the document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted manuscripts are suggested to write a science news item to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for news items should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news items should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

APPENDIX	I	Meetings
	I-VI	Instructions to authors

ABOUT COVER Dr. Lian-Sheng Ma, the Editor-in-Chief from Baishideng Publishing Group Co., Limited, attended the Digestive Disease Week (DDW2012) in San Diego from May 19 to 22, 2012, during which he browsed 4272 posters. On May 28, Dr. Ma emailed to the potential authors to invite them to submit high-quality papers to the *World Journal of Gastroenterology (WJG)*. Until June 30, we had received a total of 109 papers. After peer-review, 54 papers were accepted and the rest 55 papers were rejected. The 28 accepted papers were published on August 28, 2012 free of charge.

Abstract

Our aim was to record pancreaticobiliary endoscopic ultrasound (EUS) literature of the past 3 decades and evaluate its role based on a critical appraisal of published studies according to levels of evidence (LE). Original research articles (randomized controlled trials, prospective and retrospective studies), meta-analyses, reviews and surveys pertinent to gastrointestinal EUS were included. All articles published until September 2011 were retrieved from PubMed and classified according to specific disease entities, anatomical subdivisions and therapeutic applications of EUS. The North of England evidence-based guidelines were used to determine LE. A total of 1089 pertinent articles were reviewed. Published research focused primarily on solid pancreatic neoplasms, followed by disorders of the extrahepatic biliary tree, pancreatic cystic lesions, therapeutic-interventional EUS, chronic and acute pancreatitis. A uniform observation in all six categories of articles was the predominance of LE III studies followed by LE IV, II b, II a, I b and I a, in descending order. EUS remains the most accurate method for detecting small (< 3 cm) pancreatic tumors,

ampullary neoplasms and small (< 4 mm) bile duct stones, and the best test to define vascular invasion in pancreatic and peri-ampullary neoplasms. Detailed EUS imaging, along with biochemical and molecular cyst fluid analysis, improve the differentiation of pancreatic cysts and help predict their malignant potential. Early diagnosis of chronic pancreatitis appears feasible and reliable. Novel imaging techniques (contrast-enhanced EUS, elastography) seem promising for the evaluation of pancreatic cancer and autoimmune pancreatitis. Therapeutic applications currently involve pancreaticobiliary drainage and targeted fine needle injection-guided antitumor therapy. Despite the ongoing development of extra-corporeal imaging modalities, such as computed tomography, magnetic resonance imaging, and positron emission tomography, EUS still holds a leading role in the investigation of the pancreaticobiliary area. The major challenge of EUS evolution is its expanding therapeutic potential towards an effective and minimally invasive management of complex pancreaticobiliary disorders.

INTRODUCTION

A unique property of endoscopic ultrasonography (EUS) is the detailed imaging of organs in close proximity to the digestive tract. This has been long documented in the investigation of the pancreaticobiliary area. Since its early days, EUS proved an accurate imaging modality for the pancreas and the extrahepatic biliary tree^[1-3]. The introduction of curvilinear-array echoendoscopes and the potential of tissue sampling by EUS-guided fine needle aspiration (EUS-FNA) highly upgraded the diagnostic value of EUS and enabled its evolution to an advanced interventional technique with a wide range of applications.

A prolific trend of pancreaticobiliary EUS-related studies was recently reported, rendering pancreas and extrahepatic biliary tree the major fields of modern EUS research^[4]. This review aimed to record the entire body of literature accumulated over the past 3 decades and to present a comprehensive perspective of current EUS indications, applications and test performance in the pancreatic and extrahepatic biliary tree pathology. Our objectives were then to perform a critical appraisal of published articles, based on the classification of studies according to levels of evidence (LE), in order to assess the scientific progress made in this field and to further inform policy regarding areas that need further research and improvements.

LITERATURE SEARCH

Based on our previous research on EUS literature of the period 1980-2010^[4,5], all articles relevant to pancreaticobiliary diseases were extracted. The PubMed search was extended up to September 2011, to retrieve all additional publications. Moreover, the bibliographies of reviewed articles were scrutinized to obtain any other reference that eluded the primary search.

Original research articles [randomized controlled trials (RCTs), prospective and retrospective studies], meta-analyses, reviews and surveys pertinent to gastrointestinal EUS were included. Studies enrolling up to 15 patients were categorized as case series. Editorials, commentaries, letters, case reports, non-English language articles, abstracts, and articles in which EUS did not represent the principal study matter were not considered for review.

In regard to data collection, priority was assigned to the study subject, design and methods, the type and year of publication and the number of patients enrolled. All articles were classified in six major categories based on specific disease entities, anatomical subdivisions and therapeutic applications of EUS: (1) solid pancreatic tumors; (2) cystic pancreatic lesions; (3) chronic pancreatitis; (4) acute pancreatitis; (5) extrahepatic biliary tree; and (6) therapeutic EUS. The content of each study was further analyzed to identify relevant clinical issues such as the diagnostic and staging accuracy of the technique, technical properties of EUS procedures and the role of EUS-FNA.

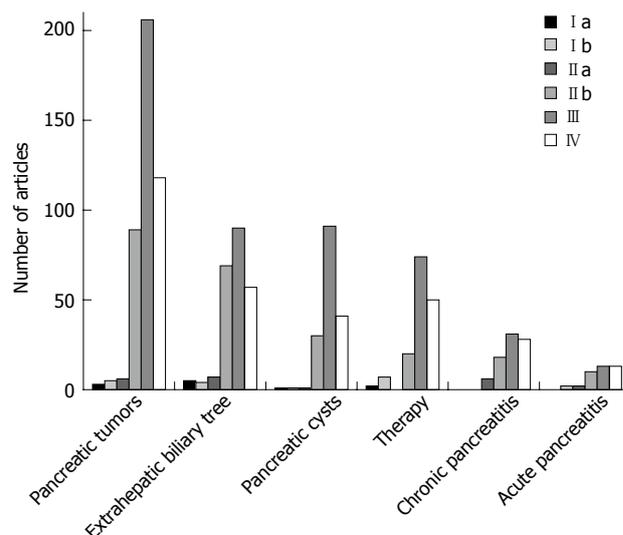

Figure 1 Distribution of papers in pancreaticobiliary endoscopic ultrasonography according to the levels of evidence.

Levels of evidence were stratified according to the North of England evidence-based guidelines^[6,7]. LE I a: Evidence obtained from meta-analysis of randomized controlled trials; LE I b: Evidence obtained from at least one RCT; LE II a: Evidence obtained from at least one well designed controlled study without randomization; LE II b: Evidence obtained from at least one other type of well-designed quasi-experimental study; LE III: Evidence obtained from well-designed non-experimental descriptive studies such as comparative studies, correlation studies, and case studies; LE IV: Evidence obtained from expert committee reports or opinions, or clinical experiences of respected authorities.

A total of 1089 pertinent articles were retrieved (Figure 1). A detailed classification of the studies, according to the main subject-matters and subclasses, and the corresponding LE, is presented in Table 1. Published research focused primarily on solid pancreatic neoplasms (418 studies overall), followed by disorders of the extrahepatic biliary tree (230 studies), pancreatic cystic lesions (165 studies), therapeutic-interventional EUS (153 studies), chronic and acute pancreatitis (83 and 40 studies respectively). A uniform observation in all six categories of articles was the predominance of LE III studies followed by LE IV, II b, II a, I b and I a, in descending order. Strong evidence trials (LE I b, II a) and meta-analyses (I a) were mainly recorded on pancreatic tumor diagnosis and staging, EUS-FNA of solid and cystic pancreatic lesions, common bile duct (CBD) stone detection and on the role of EUS-guided celiac plexus neurolysis (CPN). Novel therapeutic applications, like EUS-guided pancreaticobiliary drainage and pancreatic tumor therapy, are recently being increasingly addressed in well-designed studies (LE II b, III), but data are still limited reflecting lack of maturation of these techniques. Due to the abundance of existing data, a focused description of well-evidenced issues is highlighted below, in a point-by-point form.

Table 1 Levels of evidence per subject: Pancreatic disorders, extrahepatic biliary tree, endoscopic ultrasonography-guided therapy

EUS-FNA: Endoscopic ultrasound-fine needle aspiration; TCB: Trucut biopsy; CH-EUS: Contrast harmonic EUS; IPMN: Intraductal papillary mucinous neoplasm; CBD: Common bile duct; IDUS: Intraductal ultrasound; CPN: Celiac plexus neurolysis; CPB: Celiac plexus block.

SOLID PANCREATIC TUMORS

Diagnosis

The only meta-analysis available, comparing the test performance of different diagnostic modalities, reports a sensitivity of combined positron emission tomography/computerized tomography (PET/CT) (90.1%) higher than PET (88.4%) and EUS (81.2%) alone, but a specificity of EUS (93.2%) higher than PET (83.1%) and PET/CT (80.1%) in diagnosing primary pancreatic

carcinoma^[8] (I a).

In a systematic review of the period 1986-2004, EUS was found more sensitive (range: 93%-100%) than CT (50%-89%), especially for the detection of pancreatic tumors smaller than 3 cm^[9] (I a).

Early comparative studies indicate that the sensitivity and specificity of EUS (94%-99% and 100%, respectively) is higher than transabdominal ultrasound (US) (67% and 40%), CT (69%-77% and 53%-64%) and magnetic resonance imaging (MRI) (83% and 100%), for demonstrating the presence of a pancreatic neoplasm. This is even more obvious in small pancreatic tumors of 3 cm and less. The sensitivity of detecting tumors less than 3 cm was 93% for EUS, 53% for CT, and 67% for MRI imaging. However, as with other imaging procedures, EUS was not able to differentiate reliably malignant from inflammatory pancreatic masses (accuracy 76% for malignancy and 46% for focal inflammation)^[10,11] (II b).

The presence of a dilated pancreatic duct is related to a 65% prevalence of malignancy, compared to a prevalence of 17% in its absence^[12] (II a).

Data from retrospective studies demonstrates a negative predictive value (NPV) for EUS as high as 100%, suggesting that a normal EUS of the pancreas in the setting of subtle radiologic findings, serologic abnormalities, and/or nonspecific symptoms definitively rules out the presence of pancreatic cancer^[13,14] (III).

Molecular markers

Broad panel microsatellite loss and K-ras point mutation analysis can reliably be performed on EUS-FNA samples from pancreatic masses, improving the diagnostic accuracy and differentiation between malignant and benign pancreatic masses^[15] (II a). When K-ras mutation analysis is combined with cytopathology, sensitivity, specificity, positive predictive value (PPV), NPV and overall accuracy reach 88%, 100%, 100%, 63% and 90%, respectively^[16] (II b).

Mucin expression pattern of EUS-FNA aspirates could serve as a potential biological marker for malignant lesions^[17] (II b), and combination of routine cytology with positive fluorescence *in situ* hybridization and K-ras analyses may help the discrimination of atypical FNA samples to benign and malignant^[18] (III).

Mutation status of K-ras, p53 and allelic losses at 9p and 18q are not prognostic markers in patients with pancreatic cancer. None of these markers was identified as an independent factor of survival prognosis^[19] (II b).

Staging

Although EUS is the best test to define vascular invasion in pancreatic and peri-ampullary cancers, the specificity (90%) is high but the sensitivity (73%) is not as high as previously suggested^[20] (I a).

EUS is superior to angiography in the preoperative assessment of vascular involvement for patients with pancreatic carcinoma (sensitivity 86% *vs* 21%, respectively; specificity and accuracy 71% and 81% *vs* 71% and

38%, respectively)^[21] (II b).

No decisive comparative data between EUS and MRI exists. The most recent report shows that EUS and MRI have marginal correlation for staging, especially in the case of advanced tumors. Therefore, both tests should be performed for accurate staging^[22] (II b).

Comparison of EUS vs CT

Helical CT is more accurate in assessing the extent of primary tumor (73%), locoregional extension, vascular invasion, distant metastases, tumor node metastasis stage and tumor resectability, whereas EUS is more accurate in assessing tumor size and lymph node involvement^[23] (II b).

For portal vein and superior mesenteric vein invasion, multislice CT (MSCT) seems superior to EUS (sensitivity 88% *vs* 50%, respectively and specificity 92% *vs* 83%). For resectability, there is no significant difference and agreement is good among the two techniques. Therefore MSCT is the imaging method of choice and routine EUS should be reserved for tumors with borderline resectability on MSCT^[24] (II b).

Compared with MSCT, EUS is superior for tumor detection and staging but similar for nodal staging and resectability of preoperatively suspected non-metastatic pancreatic cancer^[25] (II b).

EUS-FNA

The sensitivity, specificity, PPV and NPV of EUS-FNA for solid pancreatic masses reach 95%, 100%, 100% and 85%, respectively. Patients with suspicious and atypical EUS-FNA aspirates deserve further clinical evaluation^[26,27] (III).

In patients with negative CT-guided biopsies, EUS-FNA yields 90% sensitivity for malignancy, 50% specificity and 84% accuracy. Corresponding values for EUS-FNA in patients with negative endoscopic retrograde cholangiopancreatography (ERCP) tissue sampling are as high as 94%, 67% and 92%, respectively^[28] (II b). A more recent RCT comparing CT/US-FNA and EUS-FNA concludes that EUS-FNA is numerically (though not quite statistically) superior to CT/US-FNA for the diagnosis of pancreatic malignancy^[29] (I b).

A lower sensitivity for EUS-FNA is observed in patients with chronic pancreatitis (CP) than in those without CP (73.9% *vs* 91.3%). While patients with CP had a higher NPV (88.9% *vs* 45.5%), no significant differences were observed for specificity (100% *vs* 93.8%), PPV (100% *vs* 99.5%), and accuracy (91.5% *vs* 91.4%) between those with and without CP^[30] (II b).

False positive EUS-FNA cytology was recently recorded in a large cohort trial, i.e., 1.1% when only “positive” cytology findings were interpreted as malignant and 3.8% when both suspicious and positive cytology findings were interpreted as malignant. False positive cases occurred primarily as a result of cytological misinterpretation in the setting of CP^[31].

No statistically significant differences exist in the diagnostic yield of EUS-FNA between 22G *vs* 25G and 22G

vs 19G needles, nor in the handling of different commercially available needle assemblies^[32,33] (I b).

EUS-FNA sampling with suction of solid masses increases the number of pathology slides, the sensitivity and negative predictive value, without increasing the overall bloodiness of samples^[34] (I b). Neither trained EUS performers nor cytotechnologists seem able to provide a reliable assessment of pancreatic FNA adequacy by using gross visual inspection of the specimen on a slide^[35]. On the other hand, rapid on-site cytopathology performed by an attending cytopathologist shows excellent agreement with the final cytological evaluation^[36] and may reduce the number of passes, ensure specimen adequacy and lower the number of inadequate samples^[37] (II b).

EUS-FNA of solid pancreatic masses is safe when performed by experienced endosonographers. The frequency of post EUS-FNA pancreatitis may be underestimated by retrospective analysis (0.64% when data was prospectively collected *vs* 0.26% in retrospective cohorts)^[38] (II b). A higher incidence of pancreatitis after pancreatic EUS-FNA (2%, with some more cases of silent hyperamylasemia) was recorded in a prospective controlled trial^[39] (II a).

Neuroendocrine tumors

EUS is reliable for the localization of pancreatic neuroendocrine tumors (NETs) (sensitivity, 82% and specificity, 95%) and highly accurate in estimating the actual size of these tumors (deviation within 2 mm between EUS and surgical pathology). Compared to angiography, EUS is significantly more sensitive for tumor localization (sensitivity, 82% *vs* 27%)^[40] (II b).

In patients with multiple endocrine neoplasia type 1 (MEN1) syndrome undergoing screening EUS, pancreatic NETs are identified in 17% of cases before the development of significant biochemical abnormalities^[41] (II b). The frequency of nonfunctioning pancreatic endocrine tumors is higher (55%) than previously thought and pancreatic EUS should be performed once MEN1 is diagnosed, to monitor disease progression^[42] (II b).

In patients with suspected pancreatic NETs undergoing EUS and MSCT, the sensitivity of EUS is greater than MSCT (92% *vs* 63%, respectively), particularly for insulinomas (84% *vs* 32%, respectively) and for lesions smaller than 2 cm. EUS may detect in up to 91% of cases missed by MSCT^[43] (II b).

Screening

A EUS-based strategy of screening for individuals at high risk for pancreatic cancer is feasible and safe. The incidence of clinically relevant findings at first screening is high, reaching 7%-10% for early asymptomatic cancer and 16% for premalignant intraductal papillary mucinous neoplasms (IPMN)-like lesions. Nevertheless, whether screening improves survival remains to be determined, as does the optimal screening interval with EUS. Moreover, without the ability to further quantify these patients' risk, the most effective strategy in clinical and economical

terms may be doing nothing^[44-46] (II a).

In familial pancreatic cancer a EUS/magnetic resonance cholangiopancreatography (MRCP) based screening program leads to the detection of potential precursor lesions of pancreatic cancer. However, the yield of an extensive screening program is low, especially since the tumorigenic value of low grade pancreatic intraepithelial neoplasia is not yet defined. Taking into account the enormous psychological stress for the tested individual and the high costs, a general pancreatic cancer screening in high-risk individuals is not justified^[47] (II b).

New imaging techniques

Detection of a hypoenhancing and inhomogeneous mass with contrast harmonic EUS (CH-EUS) accurately identifies patients with pancreatic adenocarcinoma. CH-EUS increases the detection of malignant lesions in difficult cases (patients with chronic pancreatitis or biliary stents) and helps to guide EUS-FNA. A hyper-enhancing pattern can be used to rule out adenocarcinoma^[48] (II b).

Hypoenhancement in CH-EUS yields higher sensitivity (89% *vs* 72%), lower specificity (88% *vs* 100%) and comparable accuracy (88.5% *vs* 86%) than EUS-FNA, for the diagnosis of pancreatic adenocarcinoma^[49] (II b).

Quantitative analysis of contrast-enhanced EUS seems to improve the efficacy of the technique. The diagnostic accuracy, based on contrast imaging pattern (84%) and time-intensity curves (TICs) (88%), was higher than that based on B-mode imaging (83%) and dynamic CT (81%). EUS in combination with TIC demonstrated increased sensitivity, specificity, and accuracy up to 96%, 93%, and 95%, respectively^[50] (III).

EUS elastography is useful for the differential diagnosis of solid pancreatic masses and allows an objective evaluation of tissue stiffness^[51] (II b). The operating characteristics of the technique for detecting malignancy are: sensitivity 93%, specificity 66%, PPV 92%, NPV 69% and overall accuracy 85%^[52,53] (II b).

The sensitivity, specificity, and accuracy of combined contrast-enhanced power Doppler and real-time sonoelastography in differentiating hypovascular hard masses suggestive of pancreatic carcinoma were 76%, 95% and 83%, respectively, with a PPV and NPV of 96% and 71%, respectively^[54] (II b).

PANCREATIC CYSTS

Diagnosis

Certain morphologic features have been used to discriminate specific types of pancreatic cysts. A cystic lesion with accompanying parenchymal changes, in the absence of intracystic septation or mural nodule, is compatible with a pseudocyst. Multiple microcysts (< 3 mm) within a cystic lesion and a honeycomb appearance are typical of serous cystadenomas, but macrocystic types can also be found. Mucinous cystadenomas usually present with septations of variable thickness, a visible wall, and peripheral calcifications in up to 15% of cases. A communication

between the cyst and the main pancreatic duct is strongly suggestive of IPMN^[55-57] (III).

There is no universally accepted morphologic parameter to reliably predict the malignancy of pancreatic cysts by EUS. The size of cysts is generally considered suspicious for malignancy above the diameter of 3 cm; moreover, a cyst growth rate of more than 2 mm/year has been proposed to indicate a higher risk of malignancy (5-year risk 45.5% *vs* 1.8% for cysts with lower growth rate). The presence and size of mural nodules within the cysts is also predictive of malignancy in IPMNs^[58-60] (III).

There is little more than chance interobserver agreement (IA) among experienced endosonographers for the diagnosis of neoplastic versus non-neoplastic (fair IA), specific type (moderately good IA for serous cystadenomas, but fair for other types of pancreatic cysts), and EUS features (IA ranged from slight to moderately good) of pancreatic cystic lesions. Accuracy rates of EUS for the diagnosis of neoplastic versus non-neoplastic lesions range from 40% to 93%^[61] (II b).

Interobserver agreement for the presence of mural nodules seems good among experts and fair in the semi-expert and novice groups. With respect to specific overall diagnosis, agreement is moderate in the expert group, poor among the semi-experts, and fair among novices^[62] (II b).

Preoperative assessment by intraductal ultrasound (IDUS) has an 85% diagnostic accuracy for tumor extension of IPMN compared with 50% for other imaging methods. Preoperative IDUS is useful in determining the type of surgery and the extent of resection, especially in main-duct IPMN^[63] (I b).

EUS-FNA

EUS-FNA based cytology has overall low sensitivity (63%) but good specificity (88%) in differentiating mucinous cystic lesions (MCLs) from non-mucinous lesions (NMCLs). Further research is required to improve the overall sensitivity of EUS-FNA-based cytology to diagnose MCLs^[64] (I a).

The decision to proceed with non-operative management should not be based on a negative or non-diagnostic FNA alone, as 67% of negative and 92% of non-diagnostic specimens may be associated with malignant or premalignant pathology at surgical pathology^[65] (II b).

Complications of EUS-FNA are encountered in 2.2% of patients overall, and comprise pancreatitis, abdominal pain, retroperitoneal bleed, infection and bradycardia. Type of cyst, size, presence of septations or mass, and same-day ERCP are not predictors of complications^[66] (III).

Two small studies suggest that cytology brushings are more likely to provide an adequate mucinous epithelium specimen than standard FNA and could aid the diagnosis of cystic pancreatic lesions in a selective group of patients^[67] (II a). EUS brushing increases cellular diagnosis of pancreatic cystic lesions compared to fluid analysis, mainly in mucinous lesions. However, its use is not rec-

ommended in patients under anticoagulation therapy even after withdrawal of anticoagulants, as a fatal complication has been reported^[68] (II b). Whether this approach is superior to cyst fluid analysis has not been substantiated by data. The cost of the combined needle and the brush should also be taken into consideration.

Molecular markers

The accuracy of carcinoembryonic antigen (CEA) (79%) is significantly higher compared to EUS morphology (51%) or cytology (59%). No combination of tests provides greater accuracy than CEA alone. Of tested markers, cyst fluid CEA is the most accurate test available for the diagnosis of mucinous cystic lesions of the pancreas^[69] (II b).

Malignant cysts may be differentiated from premalignant cysts on the basis of fluid CEA level, DNA quality, number of mutations and on the sequence of mutations acquired. Early k-ras mutation followed by allelic loss was the most predictive of a malignant cyst (sensitivity, 91%; specificity, 93%)^[70,71] (II b).

There is poor agreement between CEA and molecular analysis (DNA quantity, k-ras mutation, and 2 or more allelic imbalance mutations) for the classification of mucinous cysts. Based on the final pathologic diagnosis, CEA has a sensitivity of 82% compared with 77% for molecular analysis. When CEA and molecular analysis are combined, 100% sensitivity can be achieved^[72] (II b).

Follow-up, clinical outcome

Most branch duct-IPMN asymptomatic patients who have no mural nodules on EUS can be managed without surgery. However, careful attention should be paid to disease progression and the development of pancreatic cancer during follow-up^[73] (II b).

Ductal adenocarcinoma of the pancreas distinct from IPMN may develop in patients with branch duct IPMNs during follow-up. The 5-year rate of ductal carcinoma has been reported to reach 6.9%, with annual incidence of 1.1%. In the same series, cancer developed in IPMN in 3% of branch duct IPMNs during follow-up^[74] (II b).

There is considerable variation in size estimates of pancreatic cysts by different imaging modalities. Median size differences between studies are: between EUS and CT (i.e., absolute value of size determined by EUS minus size determined by CT): 4 mm (range: 0-25 mm), between EUS and MRI: 4 mm (range: 0-17 mm), between CT and MRI: 3 mm (range: 2-20 mm). Median size differences for surgical pathology specimens compared to imaging estimates were as follows: EUS and pathology: 9.5 mm (range: 0-20 mm), CT and pathology: 5 mm (range: 0-21 mm), MRI and pathology: 5.5 mm (range: 2-44 mm). Clinicians should take into account these variations when making management decisions and prefer a single modality during follow-up^[75] (II b).

CHRONIC PANCREATITIS

Diagnosis

Various EUS features have been found to predict changes

of chronic pancreatitis (CP). Parenchymal features comprise calcifications with shadowing, echogenic foci without shadowing, focal regions of reduced echogenicity (lobularity), hyperechoic strands and the presence of cysts within the gland. Ductal features include main pancreatic duct (MPD) calculi, dilation or irregular contour of the MPD, increased thickness/echogenicity of the MPD wall, and side branch dilation. EUS is highly sensitive and specific (> 85%) depending on the number of criteria present. CP is likely (PPV > 85%) when more than 2 criteria (for CP in general) and more than 6 criteria (for moderate to severe CP) are present. Moderate to severe CP is unlikely (NPV > 85%) when fewer than 3 criteria are present^[76,77] (II a).

An attempt to quantify the individual weight of widely accepted EUS features classifies them in major (hyperechoic foci with shadowing, MPD calculi and parenchymal lobularity with honeycombing) and minor criteria (cysts, dilated MPD or side branches, irregular MPD contour, hyperechoic MPD wall, strands, non-shadowing hyperechoic foci and non-contiguous lobularity). The diagnosis of CP is labeled as “most consistent with”, “suggestive of”, “indeterminate for” and “normal” depending on the number of major and minor criteria visualized^[78] (IV).

EUS is as sensitive and effective as ERCP in the detection of CP, particularly when only mild disease is present. However, EUS findings have limited specificity (60%), particularly in patients with mild disease^[79] (II b).

Reports on the concordance of EUS and endoscopic pancreatic function test are inconclusive for patients with suspected early CP, but the combination of the two techniques can add complimentary information and reach a sensitivity of 100%^[80,81] (II b).

EUS may be more sensitive but equally specific, compared with MRCP, in diagnosing CP. The combination of EUS and MRCP has a sensitivity of 98% for either EUS or MRCP and a specificity of 100% for both EUS and MRCP^[82] (II b).

There is good intra-observer agreement in the interpretation of EUS features of CP. The intra-observer agreement seems better than the published inter-observer agreement for EUS features of CP and better than the published intra-observer agreement for ERCP^[83] (II b).

EUS-FNA

EUS-FNA with cytology is safe and improves the negative predictive value (from 75% to 100%) of EUS. Negative EUS-FNA findings rule out CP, but cytology alone does not improve the specificity of EUS findings (from 60% to 67%). Further improvements in tissue sampling and analysis are necessary to support routine use of FNA in patients with CP^[78] (II b).

Transgastric EUS-trucut biopsy of suspected non-focal CP infrequently demonstrates histologic CP in clinically suspected disease. Because of potential complications (acute pancreatitis) and limited diagnostic yield, this technique is not currently recommended for evaluation of these patients^[84] (II b).

Autoimmune pancreatitis

A diffusely hypoechoic, enlarged pancreas, together with chronic inflammatory cells in aspirated cytological specimens, is supportive of the diagnosis of autoimmune pancreatitis (AIP)^[85]. The presence of stromal fragments of high cellularity with a lymphoid infiltrate, in conjunction with clinical and radiology findings, could potentially establish the diagnosis of AIP and exclude carcinoma, thus preventing pancreatic resection^[86] (II b).

Diffuse or focal hypoechoic areas, diffuse or focal enlargement of pancreas, bile duct wall thickening, lymphadenopathy, and peri-pancreatic hypoechoic margins are significantly more frequent in AIP than in pancreatic cancer. All these features may resolve after steroid treatment^[87] (III).

In AIP patients, CH-EUS demonstrates a unique vascularization pattern which enables discrimination between AIP and lesions caused by pancreatic cancer. Lesions caused by AIP and the surrounding pancreas typically demonstrate hyper-vascularization, whereas lesions caused by pancreatic cancer present hypo-vascularized^[88] (III).

EUS elastography shows a typical and unique finding of homogenous stiffness of the whole organ, and this distinguishes AIP from the circumscribed mass lesion in ductal adenocarcinoma^[89] (III).

ACUTE PANCREATITIS

In selected patients with acute pancreatitis (AP), EUS can safely replace diagnostic ERCP and select patients eligible for therapeutic ERCP with a higher success rate^[90]. EUS may prevent ERCP in 71% of patients with AP and offers a complication-free alternative, whereas sphincterotomy is associated with bleeding in up to 22% of cases^[91] (I b).

EUS seems superior to MRCP (51% *vs* 20%) in the evaluation of AP. Cholelithiasis and biliary sludge (24%) are the most frequent EUS diagnoses, and pancreas divisum (8%) is the most frequent MRCP diagnosis. Only in 6% of cases does MRCP identify additional features in patients etiologically undiagnosed using EUS. The EUS yield is lower in patients with a previous cholecystectomy (11% *vs* 60%)^[92] (II a).

In univariate analysis, the presence of peri-pancreatic edema, parenchymal inhomogeneity, CBD dilation and ascites is associated with severe pancreatitis. In multivariate analysis, only the presence of peri-pancreatic edema in EUS correlates with the severity of AP according to the Atlanta criteria. EUS may be a new useful imaging modality for the prediction of severity of AP with prognostic significance in the early phase of AP^[93] (III).

EXTRAHEPATIC BILIARY TREE

CBD stones

EUS has excellent overall sensitivity (94%) and specificity (95%) for the diagnosis of choledocholithiasis^[94]. EUS performance is superior in detecting CBD stones com-

pared to CBD malignancy (sensitivity 78%, specificity 84%)^[95] (I a).

By performing EUS first, ERCP may be safely avoided in two-thirds of patients with CBD stones. A EUS-based selection of patients for therapeutic ERCP significantly reduces the complication rate^[96] (I a).

For patients with intermediate probability of CBD stones, EUS is more sensitive than ERCP in detecting stones smaller than 4 mm (90% *vs* 23%). A management strategy based on EUS (with selective ERCP in patients with confirmed stones) is safer and not associated with an excess of endoscopic procedures (can spare ERCP in up to 75% of patients) compared with a strategy based on ERCP alone^[97-99] (I b).

With respect to sensitivity, specificity and accuracy, there is no statistically significant difference between EUS and MRCP for the detection of choledocholithiasis^[100,101] (I a). However, the sensitivity of MRCP seems to diminish in the setting of small (< 6 mm) CBD stones, while EUS remains highly sensitive even for small stones^[102] (I a).

The diagnostic accuracy of catheter-probe extra-ductal ultrasonography is comparable to that of conventional EUS for the detection of CBD stones^[103] (II a).

Approximately half (57%) of patients with echogenic CBD material visible on IDUS actually have biliary crystals on bile microscopy. The size of the echogenic material is the only significant factor associated with bile microscopy positivity with an optimal size value of 1.4 mm (sensitivity and specificity 71% and 75%, respectively)^[104] (II b).

CBD neoplasms

EUS is significantly more sensitive than US or CT (100% *vs* 80% and 83%, respectively) in making a positive diagnosis of obstruction. EUS is also significantly more accurate than US and CT (97% *vs* 49% and 66%) in diagnosing the cause of the obstruction and in the loco-regional staging of malignant obstructions (75% *vs* 38% and 62%)^[105] (II b).

A comparison between ERCP and EUS for tissue diagnosis of biliary strictures depicts higher sensitivity for ERCP-based techniques in the subgroup biliary tumors (ERCP 75% *vs* EUS 25%), whereas EUS-guided biopsy is superior for pancreatic masses (EUS 60% *vs* ERCP 38%)^[106] (II B).

EUS-FNA is valuable for tissue diagnosis of undetermined hilar strictures. It is technically feasible without significant risks, when other diagnostic tests are inconclusive and is able to change preplanned management in about half of the patients. Accuracy, sensitivity, and specificity are 91%, 89% and 100%, respectively^[107] (II b).

EUS and EUS-FNA are sensitive (overall 73%) for the diagnosis of cholangiocarcinoma and very specific (97%) in predicting unresectability. The sensitivity of EUS-FNA is significantly higher in distal (81%) than in proximal (59%) lesions^[108] (II b).

IDUS is a valuable adjunct to ERCP-guided tissue sampling that increases the ability to distinguish malig-

nant from benign strictures, but cannot assess the lymph node spread of malignant strictures^[109] (II b). When used in conjunction, IDUS increases the accuracy of ERCP for the characterization of biliary strictures from 58% to 90%^[110] (II b).

Ampullary lesions

Early observational studies reported high detection rates (96%-100%) and staging accuracy of EUS with respect to duodenal or CBD wall involvement, invasion of the pancreas and portal vein, and spread to regional lymph nodes. Accuracy rates for cancer extent was 78% for ampullary carcinoma and 81% for CBD carcinoma, when compared with surgical findings^[111,112] (III).

In patients with biliary symptoms, EUS can reliably visualize and characterize a malignant lesion as the first diagnostic tool (detection rate 82%, overall sensitivity of 92% and specificity of 75%) and may be considered the basis for subsequent diagnostic steps^[113] (III).

EUS is more accurate than CT and MRI in local tumor staging of ampullary neoplasms (EUS 78%, CT 24%, MRI 46%). No significant difference in nodal staging exists between the three imaging modalities (EUS 68%, CT 59%, MRI 77%). EUS T-staging accuracy decreases from 84% to 72% in the presence of a trans-papillary endo-biliary stent. This is most prominent in T2/T3 carcinomas and may result in underestimating the need for a Whipple resection because of tumor understaging^[114] (II b).

EUS is more sensitive and specific than CT for tumor and nodal staging of ampullary cancer, and the association of CT to EUS findings does not improve the final test performance characteristics of EUS^[115] (II b).

THERAPEUTIC EUS

EUS-guided celiac plexus neurolysis and block

Alcohol-based EUS-guided celiac plexus neurolysis (EUS-CPN) is a safe and effective technique for patients with pancreatic cancer and pain intractable to narcotic analgesics. The pooled proportion of patients that experience pain relief is 80%. On the other hand, in patients with pain due to CP the outcomes of EUS-CPN are inferior (59% clinical benefit) and better techniques or injected materials are needed to improve the response^[116] (I a).

Steroid-based EUS-guided celiac plexus block (EUS-CPB), although superior to the percutaneous fluoroscopy-guided approach^[117], proves moderately adequate in managing abdominal pain in patients with chronic pancreatitis, and warrants improvement in patient selection and refinement of the technique^[118] (I a).

Pancreatic collection drainage and necrosectomy

Technical success is significantly greater for EUS-guided pancreatic pseudocyst drainage compared to the “blind” endoscopic approach, even after adjusting for luminal compression-bulging. Short-term clinical outcomes seem to favor the EUS-guided technique, yet long-term results

are similar. EUS should be considered the first-line treatment modality for endoscopic drainage of non-bulging lesions^[119,120] (I b).

EUS-guided endoscopic trans-gastric necrosectomy of infected necrosis in acute pancreatitis appears to be a feasible and relatively safe treatment option in patients who are not critically ill. Emergency surgery as the initial treatment can be avoided in the majority of cases. Complications may include minor bleeding after balloon dilation and later development of recurrent pseudocysts because of the “disconnected-duct syndrome”^[121,122] (III).

Biliary and pancreatic duct drainage

The overall success rate of EUS-guided cholangiography *via* an intrahepatic (trans-papillary, trans-gastric) or extrahepatic (trans-papillary, trans-enteric) route approaches 85%-90%, with complication rates in the range of 10%-16%. Based on intention-to-treat analysis, similar success rates of over 70% can be achieved by both types of approach^[123,124] (III).

EUS-guided biliary drainage with one-step placement of a fully-covered self-expanding metal stent seems to be a feasible, safe, and effective alternative to percutaneous trans-hepatic biliary drainage in cases of malignant biliary obstruction when ERCP is unsuccessful^[125] (II b).

EUS-guided pancreaticogastrostomy or pancreaticobulbostomy appears to be an effective (technical success 90%, clinical success 70%) and relatively safe (major complications in 5.5%, including bleeding, severe AP and perigastric collection) procedure. It is indicated for the management of pain secondary to pancreatic ductal hypertension due to chronic pancreatitis or post-Whipple resection anastomotic strictures, in patients with inaccessible main pancreatic ducts by a trans-papillary route. Nevertheless, stent dysfunction may occur in up to 55% of patients after mid- to long-term follow-up, the procedure is technically demanding and careful pre-therapeutic evaluation is required^[126,127] (III).

Pancreatic cyst ablation

EUS-guided ethanol lavage results in a greater decrease in pancreatic cyst size (43%) compared with saline solution lavage (11%), with a similar safety profile. Overall CT-defined complete pancreatic cyst ablation reaches 33%^[128] (I b).

EUS-guided ethanol injection and lavage, followed by injection of paclitaxel, appears to be a safe method for treating pancreatic cysts; 62% of patients may have complete resolution. Small cyst volume predicts complete resolution^[129] (II b).

Pancreatic cancer therapy

High technical and clinical success rates (90%) have been reported for EUS-guided fiducial placement in patients with locally advanced and recurrent pancreatic cancer. The complication rate (mild pancreatitis in 2%), as well as the rate of migration from the initial injection site, seem low^[130,131] (II b).

EUS-guided brachytherapy by implantation of radioactive seeds into unresectable pancreatic tumors could yield a “partial” objective tumor response in 27% of patients, “minimal” response in 20% patients, and “stable disease” in 33% of patients, during a median follow-up period of 10.6 mo. Up to 30% of patients may experience clinical benefit, mostly due to reduction in pain, but this lasts for a limited time. Local complications (pancreatitis and pseudocyst formation) occur in 20% of patients^[132]. Worse clinical outcomes (partial remission in 13.6% and stable disease in 45.5%) were reported in more recent series^[133] (II b).

EUS-guided injection of the oncolytic virus ON-YX-015 into unresectable pancreatic carcinomas by the trans-gastric route with prophylactic antibiotics is feasible and generally well tolerated either alone or in combination with gemcitabine^[134] (II b).

A single administration of cytoimplant (allogeneic mixed lymphocyte culture) immunotherapy by EUS-guided fine needle injection appears to be feasible and not associated with substantial toxicity^[135] (III).

CONCLUSION

Despite the ongoing development of other cross-sectional imaging modalities, namely MSCT and MRI, EUS still holds a leading role in the investigation of pancreaticobiliary disorders. EUS remains the most accurate method for the detection of small (< 3 cm) pancreatic lesions, including NETs and ampullary neoplasms, and the best test to define vascular invasion in pancreatic and periampullary tumors. The ability of tissue acquisition by EUS-FNA is pivotal for clinical decision-making in patients with pancreatic cancer; it demonstrates excellent sensitivity and specificity and appears to be safe when performed by experienced endosonographers. The adjunct of molecular analysis of aspirates, particularly K-ras point mutation analysis, could guide the differential diagnosis of solid pancreatic lesions, once incorporated to routine clinical practice. Furthermore, early diagnosis of asymptomatic tumors in screening programs for familial pancreatic cancer and MEN1 syndrome seems feasible and reliable, but data regarding the management of these patients are still inconclusive. Novel imaging techniques such as CH-EUS and EUS-elastography are promising for the detection of pancreatic cancer, which exhibits a characteristic imaging pattern; quantitative analysis enables an objective evaluation of lesions and will potentially increase intra- and inter-observer agreement, but prospective comparative studies are still pending.

EUS provides detailed imaging of pancreatic cysts and helps their differentiation according to subtle structural features. Although no single criterion has been established to predict malignancy, the size of lesions, the presence and size of mural nodules and the cyst growth rate seem useful in estimating the risk of malignancy. This has been well documented in the case of branch-duct type IPMNs, where long term EUS follow-up has

provided a deep insight to their natural history. The malignant potential can be further evaluated on the basis of biochemical (amylase, CEA) and molecular cyst fluid analysis (K-ras mutation). These markers also seem to compensate for the generally low yield of EUS-FNA based cytology, but refinement of the technique and the adjunct of EUS-FNA brushing may increase the cellularity of aspirates.

Early diagnosis of CP is challenging. EUS is equally sensitive, yet much safer than ERCP, and more sensitive than MRCP in detecting the subtle changes of mild disease. EUS-FNA seems to increase the specificity of the technique, but further improvement in tissue sampling and analysis is necessary to support the routine use of FNA for patients with CP. EUS could also add valuable information in cases of suspected AIP, by demonstrating characteristic morphologic features and a typical pattern on elastography and CH-EUS, compatible with the disease.

EUS is the most sensitive and specific modality for the diagnosis of small CBD stones (< 4 mm). This fact has a critical impact on the management of patients with biliary symptoms or AP; a strategy based on performing EUS as the primary diagnostic modality can prevent futile diagnostic ERCPs in more than two thirds of patients and select those who will benefit from a therapeutic ERCP with higher success and lower complication rates.

Probably the greatest challenge of EUS evolution is its expanding therapeutic potential. EUS-CPN for patients with pancreatic cancer and EUS-guided pseudocyst drainage are now established alternatives to more invasive and risky surgical or radiologic interventions, which are routinely performed by experienced endosonographers. EUS-guided pancreaticobiliary drainage and targeted fine needle injection therapy for pancreatic cysts and solid tumors are novel therapeutic applications with encouraging preliminary outcomes that await to be confirmed by further studies.

Abstract

AIM: To analyze gene expression profiles in an experimental pancreatitis and provide functional reversal of hypersensitivity with candidate gene endothelin-1 antagonists.

METHODS: Dibutyltin dichloride (DBTC) is a chemical used as a polyvinyl carbonate stabilizer/catalyzer, biocide in agriculture, antifouling agent in paint and

fabric. DBTC induces an acute pancreatitis flare through generation of reactive oxygen species. Lewis-inbred rats received a single i.v. injection with either DBTC or vehicle. Spinal cord and dorsal root ganglia (DRG) were taken at the peak of inflammation and processed for transcriptional profiling with a cDNA microarray biased for rat brain-specific genes. In a second study, groups of animals with DBTC-induced pancreatitis were treated with endothelin (ET) receptor antagonists [ET-A (BQ123) and ET-B BQ788]. Spontaneous pain related mechanical and thermal hypersensitivity were measured. Immunohistochemical analysis was performed using anti-ET-A and ET-B antibodies on sections from pancreatic tissues and DRG of the T10-12 spinal segments.

RESULTS: Animals developed acute pancreatic inflammation persisting 7-10 d as confirmed by pathological studies (edema in parenchyma, loss of pancreatic architecture and islets, infiltration of inflammatory cells, neutrophil and mononuclear cells, degeneration, vacuolization and necrosis of acinar cells) and the pain-related behaviors (cutaneous secondary mechanical and thermal hypersensitivity). Gene expression profile was different in the spinal cord from animals with pancreatitis compared to the vehicle control group. Over 260 up-regulated and 60 down-regulated unique genes could be classified into 8 functional gene families: circulatory/acute phase/immunomodulatory; extracellular matrix; structural; channel/receptor/transporter; signaling transduction; transcription/translation-related; anti-oxidants/chaperones/heat shock; pancreatic and other enzymes. ET-1 was among the 52 candidate genes up-regulated greater than 2-fold in animals with pancreatic inflammation and visceral pain-related behavior. Treatments with the ET-A (BQ123) and ET-B (BQ-788) antagonists revealed significant protection against inflammatory pain related mechanical and thermal hypersensitivity behaviors in animals with pancreatitis ($P < 0.05$). Open field spontaneous behavioral activity (at baseline, day 6 and 30 min after drug treatments

(BQ123, BQ788) showed overall stable activity levels indicating that the drugs produced no undesirable effects on normal exploratory behaviors, except for a trend toward reduction of the active time and increase in resting time at the highest dose (300 $\mu\text{mol/L}$). Immunocytochemical localization revealed that expression of ET-A and ET-B receptors increased in DRG from animals with pancreatitis. Endothelin receptor localization was combined in dual staining with neuronal marker NeuN, and glia marker, glial fibrillary acidic protein. ET-A was expressed in the cell bodies and occasional nuclei of DRG neurons in naïve animals. However, phenotypic expression of ET-A receptor was greatly increased in neurons of all sizes in animals with pancreatitis. Similarly, ET-B receptor was localized in neurons and in the satellite glia, as well as in the Schwann cell glial myelin sheaths surrounding the axons passing through the DRG.

CONCLUSION: Endothelin-receptor antagonists protect against inflammatory pain responses without interfering with normal exploratory behaviors. Candidate genes can serve as future biomarkers for diagnosis and/or targeted gene therapy.

INTRODUCTION

Abdominal pain ranging from mild to severe pain is the chief symptom of patients with pancreatic disorders. Neural innervation of the pancreas is important in the initiation and maintenance of inflammation. Activation of pancreatic sensory neurons causes release of neurotransmitters in the spinal cord and neurogenic activation signals in the pancreas itself producing plasma extravasation and neutrophil infiltration. Abundant evidence has suggested that endothelins (ETs) may play a role in the transmission of nociceptive information in animals^[1-5] and in humans^[1,6,7]. ET1 has been shown to induce abdominal constrictions in mice, incapacitation in dogs, and intradermal injection into humans caused wheal and flare and itching responses^[1]. Additionally, duc-

tal fibrosis induced constriction is enhanced through endothelin autocrine loops caused by stellate cell activation. Therefore, endothelin cascade is implicated as a major contributing factor in pancreatic pain in both pancreatitis and pancreatic cancer^[8-11].

Multifunctional ETs^[1-3] comprise a family of peptides of 21 amino acids which interact with their specific receptor subtypes that are involved in regulation of blood flow, cell proliferation, muscle contraction or relaxation, secretion and ion transport^[12]. The ETs are expressed by a variety of cell types including endothelial cells, macrophages, astrocytes and neurons. Previous data also indicate that ETs can have direct effects on the peripheral sensory nervous system (including neurons and glial cells and may directly be involved in signaling nociceptive events in peripheral tissues)^[3]. In inflammatory states the levels of ETs are increased^[1]. In mammals, ETs produce their biological effects *via* activation of two receptor subtypes, the endothelin-A (ET-A) receptor and the endothelin-B (ET-B) receptor^[3]. ET-A and ET-B receptors are expressed in different cell types in peripheral nerve and sensory ganglia and are involved in pain transmission^[3]. ET receptor blockade in severe acute pancreatitis leads to systemic enhancement of microcirculation, stabilization of capillary permeability, and improved survival in rats^[13,14]. ET-A receptors are mainly localized in dorsal root ganglia (DRG), enteric motor neurons^[15], and brain blood vessels. In peripheral nerves, small unmyelinated fibers, are reported to express both ET-A and ET-B receptors. ET-B receptors are expressed primarily in the glia, epithelia, ependymal, in addition to neuronal cells. ET-A receptor action produces vasoconstriction and they are involved in hypoxia mediated neuropathic pain, while action of ET-B receptors results in vasodilatation that has been implicated in inflammatory pain and nociception^[16]. ET-1 is a potent vasoconstrictor peptide increased in inflammatory states and known to induce pain in animals through its actions on endothelin receptors^[3]. In addition, ET-1 increases capillary permeability changes and plays a role in aggravating the development of acute hemorrhagic pancreatitis through its action on the pancreatic microcirculation^[17]. ET-1 is recognized as the key player in the immune-mediated hypernociception and inflammatory diseases as depicted in autoimmune pancreatitis^[18]. Indeed, ET-1 is considered as the main cause of pancreas microcirculation disturbance during acute pancreatitis. ET-1 increases capillary permeability changes. Nitric oxide (NO) is the mediator of the cascade of inflammatory responses^[19]. Normally, ET-1 and NO together are in a dynamic balance regulating the elasticity of blood vessels, and maintaining the peripheral resistance of vessels and local vasomotor function. Once this balance is disrupted, it leads to vasomotor dysfunction and microcirculation disturbances^[20].

Objectives of the present study were to analyze the gene expression profile in the thoracic spinal cord and DRG to elucidate whether pancreatitis can induce gene regulation in these tissues. One of the genes upregulated

by dibutyltin dichloride (DBTC)-induced pancreatitis was endothelin-1. As a test of phenotypic expression and functional significance, the present study examined localization of endothelin-A and B receptors in the pancreas and the DRG, as well as determined the effects of pharmacological agents known to be ET-A or ET-B receptor antagonists. Thus, we used the chemically-induced pancreatitis model by a single *iv* injection of the polyvinyl carbonate stabilizer/catalyzer, biocide in agriculture, anti-fouling agent in paint and fabric of DBTC that results in acute pancreatitis through reactive oxygen species. Pancreatitis induced by DBTC persists through seven days allowing a more clinically relevant study of the ongoing processes evoked by activation of viscer-nociceptive pathways that are likely maintaining the central sensitization state characteristic of experimental and clinical pancreatitis^[21,22]. We hypothesized that the pancreatitis-induced hypersensitivity is mediated by the endothelin imbalance and its action on related receptors. Furthermore was tested the notion that pain related responses generated by endothelins could be pharmacologically reduced using specific endothelin receptor antagonists. To reduce the activation in viscer-nociceptive pathways, we assessed the ability of ET-A (BQ123) and ET-B (BQ788) receptor antagonists to reverse the behavioral syndrome induced by the experimental pancreatitis as described previously^[21,22]. This behavioral syndrome is a measurable end point indicative of the central sensitization state ongoing in the spinal cord and peripheral nerves.

MATERIALS AND METHODS

Animal study

All animal procedures were approved by the Institutional Animal Care and Use Committee. Male Lewis-inbred rats (125-150 g) were purchased from Harlan Laboratories (Indianapolis, IN). Rats were housed 2 per cages with a 12-h/12-h light/dark cycle and allowed access to food and water *ad libitum* except during behavioral testing. Rats were monitored daily for continued weight gain and general health. Health Status and Procedures were documented daily on the post-operative evaluation form. After one week acclimatization/quarantine, they were assigned to experimental groups. Baseline behavioral measures were assessed prior to induction of pancreatitis with DBTC and one week later, before and after treatment with ET-A antagonist BQ123 or ET-B antagonist BQ-788. A flowchart for the experimental design is provided in (Figure 1).

Animals were divided into groups: Naïve control, Vehicle/phosphate buffer (PBS) and DBTC/PBS. The study was repeated for each of the endothelin antagonists (Table 1).

Induction of persistent acute pancreatitis: Acute persistent pancreatitis was induced in Lewis rats by a single tail vein injection with DBTC (Sigma-Aldrich, St Louis, MO). DBTC was dissolved in 95% ethanol (two parts)

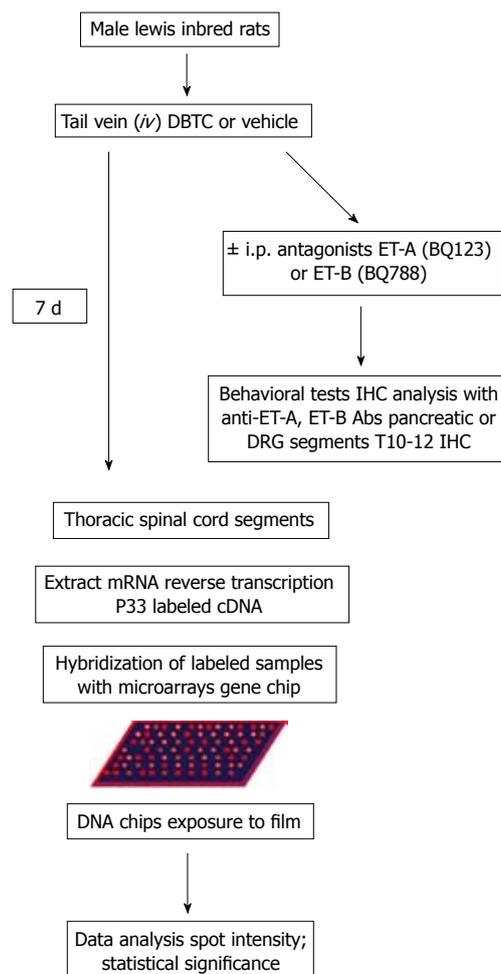

Figure 1 Schematic drawing of the study design. DBTC: Dibutyltin dichloride; DRG: Dorsal root ganglia. ET: Endothelin; IHC: Immunohistochemistry.

Table 1 Experimental design

No.	Groups (<i>n</i> = 5 per group)	<i>iv</i> injection	Drug administration (<i>ip</i>)
1	Naïve	Non	Non
2	Vehicle/PBS	Vehicle	0.1 mol/L PBS
3	Vehicle/BQ-123 or BQ-788	Vehicle	300 µmol/L
4	DBTC/PBS	DBTC	0.1 mol/L PBS
5	DBTC/BQ-123 or BQ-788	DBTC	33 µmol/L
6	DBTC/BQ-123 or BQ-788	DBTC	100 µmol/L
7	DBTC/BQ-123 or BQ-788	DBTC	300 µmol/L

Rats were injected with dibutyltin dichloride (DBTC) or vehicle (ethanol + glycerol) *via* tail vein to induce pancreatitis. On day 7 animals were treated with sham or endothelin receptor A (BQ-123) or endothelin receptor B (BQ-788) antagonists and tested for the behavioral hypersensitivity. Each group was constituted of at least *n* = 5. Experiment was repeated at least once. PBS: Phosphate buffer.

and then mixed with glycerol (three parts). In rats anesthetized with isoflurane inhalation, a maximum volume of 200 µL of DBTC (8 mg/kg body weight) was injected into the tail vein at a rate of 25 µL/min over 10 min using a syringe pump (Harvard Apparatus 22). Sham control rats received the vehicle (95% ethanol + glycerol, 2:3) also *via* tail vein. All animals (DBTC and sham controls)

were fed Teklad 8626 chow and given 10% alcohol + 5% apple juice in their drinking water as a maintenance diet to support persistence pancreatitis in the model.

Tissue acquisition, RNA extraction, and gene chip analysis: Rat DRGs and segments of T10-T12 spinal cord were taken 7 d after injection at the peak of pancreatic inflammation and processed for transcriptional profiling using the rat brain-biased cDNA nylon array generated by Millennium Pharmaceuticals Inc. (Cambridge, MA) for gene discovery (both normal and subtractive). The cDNA libraries, array construction, hybridization, sequencing, process technology, informatics, TRACE for library construction, expressed sequence tag sequencing, data acquisition, and software have been detailed previously^[23]. Therefore, rats were sacrificed and tissues were rapidly dissected from three animals per each group, frozen in dry ice, and stored at -80 °C before RNA isolation. Frozen tissues were homogenized in 1 mL of the TRIZOL reagent (Invitrogen, Carlsbad, CA) per 50-100 mg tissue and total RNA was extracted following the manufacturer's protocol. Briefly, total RNA from each sample was column purified, and oligonucleotide primers flanking the cloning site was used to amplify the cDNA insert by polymerase chain reaction. After purification over CHROMA SPIN TE+30 columns, the labeled cDNA was annealed at 65 °C for 1 h with 10 µg poly (dA) > 200 (Amersham Pharmacia). At 2×10^6 cpm/mL, the annealed cDNA mixture was added to array filters in preannealing solution containing 100 mg/mL sheared salmon sperm DNA in 7% sodium dodecyl sulphate, 0.25 mol/L sodium phosphate, 1 mmol/L ethylene diamine tetraacetic acid, and 10% formamide. Following overnight hybridization the radioactive signals captured by a Fuji BAS 2500 phosphorimager (Fuji Medical Systems, Stamford, CT) and were quantified by using ARRAY VISION software (Imaging Research, St. Catherine's, ON, Canada). Array hybridizations were performed in triplicate. Expression profiling data analysis and data clustering algorithm were done according to the published methodology^[23]. Regulated genes were selected based on the array spot intensity that was normalized to the average of housekeeping genes and normal controls across the array. Total 3 animals/each group was used for the microarray analysis and the study repeated at least $\times 2$. The average greater than or equal 2 fold changes in gene expressions were included in the study. Animal study design is shown in the Figure 1.

Pain-related behavioral assessments: Experimental procedures: Day 0: Baseline testing of abdominal nociceptive responses to mechanical and heat stimuli was applied to the upper left abdominal quadrant skin of rats as previously described^[21,22,24]. Pain-related behavior was assessed throughout the study by an observer blinded to group assignment. (1) Assessment of Secondary Mechanical Hyperalgesia/Allodynia by Testing Abdominal Withdrawal Threshold. Mechanical hypersensitivity in the abdominal area was quantified by measuring the number

of withdrawal events (either abdominal withdraw from the von Frey filament or consequent licking of the abdominal area, or whole body withdrawal) in response to normally innocuous or sub-threshold mechanical stimuli. The stimuli, applied to the upper left abdominal skin area, were von Frey filaments with bending forces of 3.52 mN, 10.78 mN and 47.24 mN (considered sub-threshold stimuli), and with bending forces of 215.6 mN (used as a supra-threshold stimulus). Reflex testing for "referred" secondary mechanical hyperalgesia/allodynia with von Frey fibers was developed by Max von Frey, who in 1896 identified "pain spots" on human skin, and has remained the standard in the field of pain assessment in humans and in animals. Mechanical nociceptive assay scores were expressed as an average percent response to ten applications of the von Frey filaments or the total number of withdrawal events to ten applications of three individual filaments as described previously^[21,22,24]. Before testing, all animals were shaved on the rostral abdominal area and placed into clear plastic enclosures (7 cm \times 4 cm \times 4 cm) on the metal meshed (3 cm \times 3 cm) platform (36 cm \times 29 cm \times 21.5 cm) and acclimated for 30 min. The von Frey filaments were applied from underneath through the mesh floor to the surface of the rostral abdominal area at different points. A single trial consisted of 10 applications of every von Frey filament. Each application was held for 1-2 s with a 5 s rest interval between applications to allow the animal to cease any response and return to a relatively inactive position. Totally, there were 3 trials through the graded series with a 10 min interval between trials. The withdrawal events for the three trials were averaged to get a single value per rat per time point. A percentage response was calculated (average of withdraw events/10 \times 100) for the study. A positive response was defined as an abrupt withdrawal (flick response) of the abdomen during stimulation or immediately after the removal of stimulus. The abdominal withdrawal tests were performed at baseline; before DBTC insult (day 6); and on day 7 after endothelin receptor antagonist' injection and von Frey filaments mechanic stimulation at 0 min, 20 min, 40 min, 75 min after BQ123 or BQ788 i.p. injection. Comparisons were made to baseline response; (2) Assessment of Secondary Thermal Hyperalgesia. In this assay, rats were placed on a regulated hotplate (52 °C) in a clear plastic enclosure (14 inches \times 14 inches). The latency to responses (foot flick, jumping, licking, *etc.*) was determined on day 7 after DBTC insult and before (0) and 20 min, 40 min and 75 min after injection of endothelin receptor antagonists; and (3) Open Field Box Spontaneous Exploratory Behavioral Measures. On day 6, spontaneous exploratory behavioral activities were collected using open field 16 \times 16 Photobeam Activity System (PAS) with FLEXFIELD software coupled to a PC (San Diego Instrument, Inc. CA). The PAS allows acquisition of movements in an x, y and z axis oriented grid system within an activity chamber (40 cm \times 40 cm \times 40 cm) by recording the number of times photobeams are obstructed. Data was collected

in 5 min intervals for 30 min. Six different behavioral measures of spontaneous activity were examined: rearing events, rearing time (s), active time (s), rest time (s), distance traveled (inch), and total counts (number of beams broken). Resting time was defined as a period when the animal remained in place for 1 s or longer. Active and rest time are important to determine effect of the treatment on the total amount of time spent for both exploratory and stationary movements. Changes in each parameter were evaluated individually.

Endothelin receptor antagonist administration: ET-A receptor antagonist (BQ-123) and ET-B receptor antagonist (BQ-788) from American Peptide, CA, were tested in this model to assess their effect on pain related behavioral modification. The drugs were dissolved in PBS with final concentration in 1 mL and administrated (i.p.). Rats were treated with ET-A and ET-B receptor antagonists (0 min, 20 min, 40 min and 75 min) day 7 after induction of pancreatitis. The concentrations used are based on the respective K_i for the drugs. The K_i for BQ-123 has been reported to be 10 nmol/L^[25]. The K_i for BQ-788 has been reported to be 100 nmol/L^[26]. The 33 μ mol/L, 100 μ mol/L and 300 μ mol/L treatments were used for generating the BQ-123 dose response curve by examining the effects of post-treatment on behavioral testing in animals with pancreatitis ($n = 5$ per each dose). Then, the maximal effective dose (300 μ mol/L) was selected for the rest of study including for the drug, ET-B receptor antagonist (BQ-788, American Peptide, CA). Control rats received PBS injections (i.p.).

Therefore, seven different experimental groups were designed: BQ-123 or BQ-788 treated rats with or without pancreatitis; PBS treated rats with or without pancreatitis as well as naïve rats. Five rats in each group were included in this study (Table 1).

Morphine administration: Morphine was injected in cumulative doses of 1, 5 and 10 mg/kg body weight or sham saline given i.p. to rats ($n = 6$ /group). Systemic administration of morphine is used as a gold standard analgesic in different pain related behavioral modification studies.

Necropsy and sample collection

Perfusion and tissue collection: At the end of the experiment, rats were given an overdose of pentobarbital (75 mg/kg). Fresh pancreatic tissues were collected. Dorsal root ganglia (DRG) and spinal cord from 10th-12th thoracic segments were dissected as they receive the sensory information from the neuronal fibers that innervate the pancreas. Samples were flash frozen in liquid nitrogen and kept at -80°C and processed for transcriptional profiling microarray analysis biased for rat brain-specific genes as mentioned above and for immunohistochemistry. The study design is shown in the Figure 1.

Immunohistochemical study

Spinal cord, DRG and pancreatic tissues collected

for immunohistochemical analysis: At the end of the experiment, rats were given an overdose of pentobarbital and transcardially perfused with 4% buffered paraformaldehyde. Spinal cord segments T7-T12 and DRGs were taken 7 d after injection at the end of the experiment. Tissue were removed and stored overnight at 4°C followed by immersing in 30% sucrose. The frozen sections were cut as 30 μ m thickness. The fresh pancreas was directly fixed in 4% paraformaldehyde for 24 h followed by storing in 70% alcohol. The tissue was processed for paraffin sections (4 μ m) which were mounted onto the chrome-gelatin pre-coated glass slides. After deparaffinization in xylene for 5 min ($\times 2$), the sections were hydrated gradually with 100%, 95%, 80% and 70% alcohol followed by washes with distilled water. Polyclonal rabbit anti- ET-A and ET-B receptor (Alomone Labs, Jerusalem, Israel) were used for staining frozen sections of the DRG. In addition, paraffin sections of pancreas were prepared from rats with different treatments. Then, immunohistochemical staining procedures for both frozen and paraffin section were performed. After rinsing in 0.1 mol/L PBS, the tissues were blocked with 5% normal goat serum in 0.1 mol/L PBS plus 0.05% Triton X-100 and 0.3% bovine serum (NGSTB) for 40 min. Then, the tissues were double stained with specific antibodies produced in two different species in the following combinations: (1) Endothelin receptor A and neuronal marker (NeuN); and (2) Endothelin receptor B and glial fibrillary acidic protein marker for all glia (GFAP) (satellite and Schwann cells). This was accomplished by incubating the cut tissue sections with rabbit anti-ET-AR (1:400) and mouse anti-NeuN (1:5000) or ET-BR (1:200) and mouse anti-GFAP (1:500) diluted in 1% NGSTB overnight at room temperature. After rinsing with 0.1 mol/L PBS, the tissues were incubated for 1 h in a fluorescent tagged secondary antibody, red Alexa fluor 568 goat anti-rabbit IgG (1:1000) and green Alexa fluor 488 goat anti-mouse IgG (1:1000) diluted in 1% NGSTB. Finally, the tissues were rinsed with 0.1 mol/L PBS, cover-slipped with mounting media hard set with hard set mounting media with blue 4',6-diamidino-2-phenylindole counterstain (Vector Labs, Burlingame, CA). Pictures were taken using the Act-1 program with a Nikon E1000 microscope.

Statistical analysis

All data are presented as mean \pm SD unless otherwise stated. Statistical analysis was performed by the ANOVA-test (two way analysis of variance). If significant differences were found Bonferroni post *hoc* and when appropriate student *t* test statistical analysis were performed to assess changes over time for each group separately to compare (1) baseline and 7 d after induction of pancreatitis; (2) before and after drug treatment; and (3) drug treated group compared to controls without drug treatment. Statistical significance was set at $P \leq 0.05$.

RESULTS

Animals that received sham vehicle significantly gained

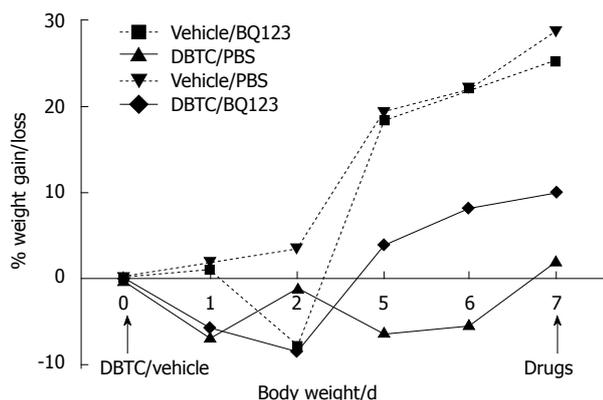

Figure 2 Timeline demonstrates % body weight gain/loss in rats during the study comparing naive rats and rats with pancreatitis (n = 5). DBTC: Dibutyltin dichloride; PBS: Phosphate buffered saline.

weight (27%) on the diet (vehicle: D1 *vs* D7, *P* < 0.01) compared the DBTC induced pancreatitis rats which differed (vehicle *vs* DBTC) by an average of 21% (Figure 2).
