the primary cilium of cholangiocytes^[44]. Many of these proteins interact with each other forming complexes that signal through common pathways. Mutations in genes encoding proteins located in the primary cilium of cholangiocytes result in physical and functional defects of this organelle, and outcome in the development of several forms of PCLD classified as ciliopathies. For this reason, and because the only cells in the liver that have cilia are cholangiocytes, the PCLDs affecting genes encoding proteins which are localized in the cilia are called cholangiociliopathies^[44]. It has been recently demonstrated that hepatic cystogenesis in PCLDs is the result of hyperproliferation^[45], hypersecretion^[46], and alteration in the pattern of miRNAs in the bile duct cells^[47], and that these alterations are intracellularly associated with an increase in the levels of cAMP and a decrease in calcium^[45,48,49]. In this regard, global changes in the expression pattern of miRNAs were observed between cultured cholangiocytes from normal and PCK rats (animal model of hepatorenal polycystic disease, i.e., autosomal recessive polycystic kidney disease)^[47,50]. In total, 121 and 148 miRNAs were detected in normal and PCK rat cholangiocytes, respectively. Twelve miRNAs were expressed in normal rat cholangiocytes and not in PCK rat cholangiocytes, and 39 were present only in PCK rat cholangiocytes. Moreover, there were changes in the expression of 109 common miRNAs between both cell lines. Interestingly, 97 of these common miRNAs (i.e., 87%) were found to be downregulated in PCK rat cholangiocytes compared to normal rat cholangiocytes, and 12 miRNAs (11%) were overexpressed in cystic cholangiocytes. Among those highly downregulated miRNAs in cultured PCK rat cholangiocytes, miRNA-15a is also downregulated *in vivo* in cholangiocytes from PCK rats and PCLD patients^[47]. This miRNA-15a downregulation

runs in parallel with the upregulation of its predicted target, the cell-cycle regulator cell division cycle 25A (Cdc25A). Experimental overexpression of miRNA-15a in PCK rat cholangiocytes results in decreased Cdc25A protein levels, inhibition of cell proliferation, and cyst growth reduction. Interestingly, experimental suppression of miRNA-15a in normal rat cholangiocytes accelerates cell proliferation, increases Cdc25A expression, and promotes cyst growth^[47]. All these data suggest that the miRNA-15a/Cdc25A interplay could be a potential target to inhibit hepatic cystogenesis (Figure 1). Importantly, inhibition of Cdc25A with its inhibitor vitamin K3 suppresses hepatorenal cystogenesis in rodent models of polycystic kidney and liver disease, being a valuable potential pharmacological approach to test in clinical trials^[51] (Figure 1). Moreover, it will be interesting to demonstrate in future studies the role of many other altered miRNAs in the pathogenesis of PCLDs.

PRIMARY BILIARY CIRRHOSIS

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease that mainly affects middle-aged women^[52]. It is a rare disease, with an estimated prevalence of 1:8000 in countries such as the United Kingdom. Four stages of this disorder have been characterized by progressive bile-duct loss that runs in parallel with an increase in cholestasis and fibrosis^[52]. The etiology of PBC remains unknown, and the pathogenesis is poorly understood. The serological hallmark of PBC is the development of high titers of antimitochondrial autoantibodies (AMAs) in serum associated with an immunological attack on the small intrahepatic bile ducts^[52]. Interestingly, PBC patients usually have a poor response to immunosuppressants and the only therapeutic option that improves the outcome of the disease in two thirds of PBC patients is daily administration of ursodeoxycholic acid (UDCA), a hypercholeretic bile acid^[52]. In addition, and importantly, PBC patients show alterations in the biliary secretion of bicarbonate. Thus, PBC patients show a failure in the secretin-stimulated biliary secretion of bicarbonate^[53], as well as a reduction in the hepatobiliary expression of anion exchanger 2 (AE2/SLC4A2)^[54,55]. AE2 is a Cl⁻/HCO₃⁻ exchanger located in the canalicular membrane of hepatocytes and in the apical membrane of cholangiocytes that controls the intracellular pH (pH_i) and promotes the alkalization and fluidization of bile^[1,2,56]. An interesting hypothesis suggests that, in PBC patients, long-term maintained alteration of pH_i by AE2 downregulation might modify cholangiocyte and lymphocyte function^[57]. To test the etiopathogenic role of AE2 downregulation in PBC, an Ae2^{a,b1,b2} mouse knockout was generated. Interestingly, these animals spontaneously reproduce over time many PBC features^[57], such as: (1) portal infiltration of T lymphocytes and bile duct damage; (2) increased oxidative stress in cholangiocytes; (3) elevated production of interferon-γ and IL-12; (4) periductular hepatic fibrosis; (5) increased levels of

Figure 2 Role of miRNA-506 in the etiopathogenesis of primary biliary cirrhosis. Different risk factors could induce genetic alterations leading to anion exchange 2 (AE2) downregulation in primary biliary cirrhosis (PBC) cholangiocytes. miRNA-506 is overexpressed in PBC cholangiocytes, thus resulting in the inhibition of both AE2 protein translation and subsequent $\text{Cl}^-/\text{HCO}_3^-$ activity, and impairing the biliary secretory functions.

IgM, IgG, and hepatic alkaline phosphatase; and (6) the presence of PBC-specific AMAs. Different agents such as hormones, metabolic influences, infectious agents, xenobiotics, cytokines/inflammatory mediators, and/or miRNAs could be involved in the AE2 downregulation present in PBC patients. Regarding miRNAs, a differentially expressed miRNA profile in livers from PBC patients compared with normal controls has been recently reported^[58]. The change consists of 35 differentially expressed miRNAs (11 upregulated and 24 downregulated), which were predicted to target genetic transcripts involved in cell proliferation, apoptosis, inflammation, oxidative stress and metabolism^[58]. Regarding those miRNAs that were overexpressed in the miRNA array, we observed by using bioinformatics approaches that miRNA-506 could be a potential direct AE2 regulator. Therefore, we tested if AE2 downregulation in PBC cholangiocytes is dependent on miRNAs, and specifically on miRNA-506. Our data showed that miR-506 is upregulated in cholangiocytes from PBC patients, binds to the 3'-UTR of AE2 mRNA, and prevents protein translation, leading to diminished AE2 activity and impaired biliary secretory functions^[59]. These data suggest the etiopathogenic role of miR-506 in the AE2 downregulation characteristic of PBC cholangiocytes (Figure 2). On the other hand, the reported AE2 downregulation in PBC lymphocytes was not associated with changes in the expression of miRNA-506^[59]. This disease preferentially affects women, therefore, it is interesting to remark that the gene encoding miRNA-506 is located in the X chromosome. Further investigations are needed to characterize fully the role of miRNA-506 in the regulation of other targets and cellular features, as well as the analysis of its expression in other tissues. Moreover, the role of

UDCA and estrogens on miRNA-506 expression will be valuable information to expand the etiopathogenic role of this miRNA in PBC.

CONCLUSION

In summary, the available information clearly indicates that miRNAs represent a new research area in the field of biliary pathophysiology. As stated in this review, they may modify different features in cholangiocytes, such as secretion, apoptosis, proliferation, and migration, and can be regulated by different mechanisms and conditions, such as epigenetics, hypoxia, or circadian rhythms. There is still limited information about the role of miRNAs in biliary diseases, but future investigations will provide more evidence regarding their role in the development and progression of cholangiopathies, as well as in their potential use for diagnosis and therapy. Finally, it is important to remark upon the increasing information about the role of stem cells in the pathophysiology of biliary diseases^[60]; in this regard, the potential role of miRNAs in the regulation of biliary stem cells during cholangiocyte injury, as well as the role of miRNAs in the development of cancer stem cells in CCA^[61] need to be elucidated.

Abstract

Biliary strictures are considered indeterminate when basic work-up, including transabdominal imaging and endoscopic retrograde cholangiopancreatography with routine cytologic brushing, are non-diagnostic. Indeterminate biliary strictures can easily be mischaracterized which may dramatically affect patient's outcome. Early and accurate diagnosis of malignancy impacts not only a patient's candidacy for surgery, but also potential timely targeted chemotherapies. A significant portion of patients with indeterminate biliary strictures have benign disease and accurate diagnosis is, thus, paramount to avoid unnecessary surgery. Current sampling strategies have suboptimal accuracy for the diagnosis of malignancy. Emerging data on other diagnostic modalities, such as ancillary cytology techniques, single operator cholangioscopy, and endoscopic ultrasonography-guided fine needle aspiration, revealed promising results with much improved sensitivity.

INTRODUCTION

Cholangiocarcinoma is usually diagnosed at an advanced stage, which is the main reason for the poor prognosis of this tumor. Patients with T1 stage tumor who undergo resection have an excellent prognosis with a cumulative 5-year survival rate of about 100%^[1]. T1 stage tumors are confined to the bile-duct wall and are limited to the mucosa or fibromuscular layer of the bile duct and do not usually present with lymph node metastases. Therefore, a diagnosis of bile duct carcinoma in T1 stage is crucial for long term survival. Serum alkaline phosphatase and gamma-glutamyltransferase are elevated in 40% of these patients and 40% are non-icteric^[1]. Cholangiocarcinoma typically presents as biliary strictures. These strictures remain a diagnostic dilemma since a

significant proportion of them remain indeterminate for malignancy despite radiologic, endoscopic, and laboratory testing. Early and accurate diagnosis impacts not only patients' outcome and patients' possible surgical candidacy, but also potential targeted chemotherapies. Since 13% to 24% of patients with presumed hilar cholangiocarcinoma are found to have benign disease^[2,3], accurate diagnosis is paramount to avoid unnecessary surgery for patients with benign strictures. The difficulty is amplified when attempting to discern malignant from non-malignant strictures in patients with primary sclerosing cholangitis (PSC) as this affects transplantation decision. This review explores strategies that can be employed by the endoscopist to improve the diagnostic yield of endoscopic work-up in patients with indeterminate strictures. Biliary strictures are considered indeterminate when basic work-up, including transabdominal imaging and endoscopic retrograde cholangiopancreatography (ERCP) with routine cytologic brushing, are non-diagnostic.

RADIOLOGIC WORK-UP

Transabdominal ultrasound (TUS) is usually the initial diagnostic modality used to investigate suspected biliary pathology. TUS is non-invasive, relatively cheap, widely available, and allows visualization of the biliary tree. However, TUS does not reliably examine the distal part of the common bile duct because of the interference of bowel gas^[4]. Abdominal computed tomography (CT) is useful for work-up of patients with suspected cholangiocarcinoma. However, it has suboptimal sensitivity for the detection of early tumors^[5]. Since its introduction in 1991^[6], magnetic resonance cholangiopancreatography (MRCP) has emerged as an accurate noninvasive modality for biliary imaging^[7]. MRCP has a high sensitivity for bile-duct stenosis and filling defects associated with bile duct carcinoma; however, its specificity and positive predictive values are suboptimal as it cannot reliably distinguish malignant strictures from other strictures due to benign etiologies^[8,9]. Still, some ductal features on MRCP and ERCP may suggest malignant or benign etiology of biliary strictures. Malignancy is suggested by long (> 10 mm), asymmetric, and irregular strictures. However, these criteria are not particularly sensitive or specific^[10]. Therefore, unless abdominal imaging detects biliary mass lesions, further endoscopic work-up is warranted to determine the etiology of biliary strictures.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Intraductal brushing during ERCP (Figure 1) remains the first-line approach for tissue sampling of biliary strictures because of its wide availability and technical ease in most cases. However, most studies report a poor sensitivity of 27% to 56%^[11-14]. Multiple strategies have been employed to improve the sensitivity without sacrificing the specificity. These have included novel brushes^[15], biliary stricture

Figure 1 Fluoroscopic image during endoscopic retrograde cholangiopancreatography showing a hilar stricture with left intrahepatic biliary dilation. Endoscopic brushing was performed and routine cytology confirmed hilar cholangiocarcinoma.

dilation with subsequent brushings^[16], repeated brushings, immunohistochemistry testing, mutational analysis, digital image analysis (DIA), and fluorescence *in situ* hybridization (FISH)^[17].

Fogel *et al.*^[15] studied the use of a longer biliary cytology brush with stiffer bristles. Despite improved cellularity, cancer detection rates were not improved by using the new brush design. The low sensitivity of biliary brushings is attributed to the submucosal pattern of tumor growth or extrinsic malignancy. Interrupting the mucosa with endoscopic dilation may theoretically improve the cytologic yield. de Bellis *et al.*^[16] studied this strategy by obtaining brushing cytology pre and post dilation. Sensitivity did not improve after dilation (35% and 31%, respectively); however, importantly, the combined sensitivity was improved at 44%. The authors concluded that stricture dilation was not helpful but that repeat biliary brushings increase the diagnostic yield. Inadequate biliary cytology specimens are the main reason for non-diagnostic samples. This may be overcome by the presence of an onsite cytopathologist or technician, which allows real time assessment of cytology samples and may decrease the likelihood of inadequate samples and improper sample preparation [same as widely practiced with endoscopic ultrasound-guided fine needle aspiration (EUS-FNA)]^[18]. If this is not possible, other practiced strategies include cutting the entire brush and submitting it to pathology in a fixative solution or creation of slides by the endoscopy team and placing them in a fixative solution prior to submission to pathology^[18].

Ancillary cytology techniques

Chromosomal abnormalities are typically seen in biliary tract malignancies. Flow cytometric analysis for DNA content has been used with moderate gains in sensitivity at 42%, but at the expense of a lower specificity of 77%^[19]. This technique is also limited by its requirement of a relatively large amount of tissue for examination. New ancillary cytologic techniques, such as FISH and DIA, have recently been used to improve the sensitivity of routine cytology for the diagnosis of malignancy in

pancreatobiliary strictures. FISH analysis detects chromosomal polysomy using fluorescent probes, whereas DIA technique quantifies nuclear DNA *via* special stains to assess for the presence of aneuploidy^[17,20,21]. Only 80% of pancreaticobiliary malignancies manifest these cellular alterations. Therefore, the sensitivity of these advanced techniques is still not optimal. Levy *et al*^[20] found that FISH improves sensitivity 14% to 24% when routine cytology is negative. Fritcher *et al*^[17] found that patients with abnormal FISH results were 77 times more likely to have carcinoma than those with normal FISH. They also found that DIA had a higher sensitivity (44.8%) than cytology. However, specificity was significantly lower at 89.1%. In addition, DIA was not found to be a significant independent predictor of malignancy^[17]. Therefore, FISH seems to be a more valuable ancillary cytologic technique for the evaluation of indeterminate biliary strictures. It is particularly useful in biliary malignancy as it requires fewer cells for analysis than routine cytology or flow cytometry. A recent report studied the additional value of including deletion of 9p21 (p16) in the diagnostic criteria of FISH for malignant biliary strictures^[22]. This significantly improved the sensitivity of FISH from 47% to 84%.

It is crucial to realize that benign strictures in patients with PSC may manifest chromosomal abnormalities and, thus, the specificity of FISH in this setting (67%-88%) is lower than routine cytology^[23]. However, the sensitivity of FISH for malignancy in this setting is still higher than that of routine cytology at 72%^[23]. In short, FISH increases the sensitivity of brush cytology of indeterminate biliary strictures at the expense of a lower specificity. Therefore, FISH should be reserved for patients with high pre-test probability for malignant strictures (e.g., PSC patients with dominant stricture, patients with persistent elevation of carbohydrate antigen 19-9 after biliary decompression, *etc.*).

Endobiliary forceps biopsy

Endobiliary forceps biopsy of biliary strictures during ERCP is another endoscopic technique used in routine clinical practice for sampling biliary strictures. In general, forceps biopsies have had the highest yield when compared to brush cytology and fluoroscopically-guided FNA. Cancer detection rates using endobiliary forceps range from 44% to 89 % for cholangiocarcinoma and 33% to 71 % for pancreatic cancer^[24-27]. Wright *et al*^[28] studied the “smash protocol” for handling biopsies of biliary strictures obtained using endobiliary forceps. Biopsies were smashed between two glass slides, stained by rapid Papanicolaou, and immediately read by on-site pathologists in the ERCP suite. The authors found that immediate cytopathologic diagnosis at ERCP was established in 72 % of cases and concluded that this approach permits immediate diagnosis and avoids the need for subsequent procedures, adds little cost and time, and is safe to perform. External validation of these results is warranted. Jailwala *et al*^[29] showed that endobiliary

Figure 2 Intraductal ultrasound showing bile duct mass and surrounding lymph nodes.

forceps biopsy of biliary strictures had an incremental diagnostic yield for diagnosis of bile duct malignancy as compared to cytology alone. Triple sampling with brushing, transpapillary biopsy and endoluminal FNA had the highest sensitivity. The authors recommended the use of at least two sampling methods. However, endobiliary biopsy remains technically challenging (especially for proximal biliary strictures) and complications, including bleeding and biliary perforation, have been infrequently described. Jailwala *et al*^[29] remark that biopsy sampling added 10 to 15 min to the procedure time. Currently most biopsies are done using standard biopsy forceps alongside a guidewire which makes positioning the forceps more difficult^[30]. While adapted biopsy forceps^[31,32] are used they are not widely available or utilized. Widely available dedicated biliary forceps are needed to improve the yield and safety of biliary biopsies.

Intraductal ultrasound

ERCP with intraductal ultrasound (IDUS) has also been utilized to improve the diagnostic yield of biliary strictures^[33-35]. IDUS is accomplished by over-the-wire insertion of a small and high-frequency ultrasound probe into the biliary system through a standard duodenoscope under fluoroscopic guidance^[36]. Advantages of these probes include ease of biliary cannulation obviating the need for sphincterotomy in most cases, and the provision of high resolution, detailed images of ductal and periductal tissues without significantly lengthening the ERCP procedure. Moreover, although distant metastases and lymph node involvement may fall outside the imaging field of the device, IDUS can provide local staging required to select patients who would benefit from surgical resection when a malignancy is identified^[37]. IDUS has consequently emerged as an adjunct to ERCP in the evaluation of biliary strictures (Figure 2). Sonographic features seen during IDUS that are suggestive of malignancy include eccentric wall thickening with an irregular surface, a hypoechoic mass, heterogeneity of the internal echo pattern, a papillary surface, disruption of the normal three-layer sonographic structure of the bile duct, presence of lymph nodes, and vascular invasion^[38]. Find-

ings suggestive of benign lesions include preservation of the normal three-layered sonographic appearance of the bile duct wall, homogeneous echo-rich masses with smooth margins, and the absence of a mass lesion^[38]. The accuracy of these criteria in patients with biliary strictures ranges from 83% to 90%^[36,39,40]. IDUS has been shown to improve the diagnostic accuracy of ERCP (with routine cytology) to 58% to 90%^[35,39,41]. The benefit of IDUS, however, is limited in the repeated evaluation of strictures, as the presence of a previously placed biliary stent affects its diagnostic yield^[42]. Lee *et al*^[42] favored EUS to IDUS given that their patients typically had prior stents placed for the treatment of indeterminate strictures. However, IDUS may have a role in concert with EUS, especially in patients without prior stent or in those with proximal biliary (e.g., hilar strictures) lesions, where EUS has shown suboptimal accuracy (see below)^[35,43].

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS) has become a valuable tool in the evaluation of lesions in the gastrointestinal tract as well as pancreaticobiliary system. It has the advantage of being able to both provide real time imaging of the GI tract and adjacent organs as well as obtain tissue through FNA. EUS-FNA has a sensitivity of about 85% and a specificity approaching 100% for the diagnosis of pancreatic tumors^[44,45]. The role of EUS in indeterminate biliary strictures is still not well defined. EUS has a sensitivity and specificity comparable to MRCP in the diagnosis of pancreaticobiliary disease^[46]. Sai *et al*^[9] studied 123 non-icteric patients with elevated alkaline phosphatase and common bile duct dilation on TUS. MRCP followed by EUS had a sensitivity of 90% and specificity of 98% for the diagnosis of cholangiocarcinoma. The positive predictive value was also dramatically increased from 35% to 70% when EUS was added to MRCP^[9].

The advantages of EUS-FNA in the diagnostic work-up of patients with indeterminate biliary strictures are multiple. EUS may visualize a biliary mass missed by other imaging modalities in a significant proportion of patients (Figure 3). Eloubeidi *et al*^[47] reported visualizing a mass in 33% of patients following previously non-diagnostic imaging. Similarly, a more recent study reported a mass visualized on EUS in 94% of patients (Figure 4), while CT and magnetic resonance imaging (MRI) revealed a mass in only 30% and 42% of these patients, respectively^[43]. EUS allows performance of FNA of visualized masses with reported sensitivity for malignancy of 43% to 86%^[42,47-49]. It is noteworthy mentioning that the sensitivity of EUS-FNA is significantly higher in distal than in proximal cholangiocarcinoma. Mohamadnejad *et al*^[43] studied 81 patients with cholangiocarcinoma who underwent EUS. Sensitivity of EUS-FNA was significantly higher in distal compared with proximal cholangiocarcinoma (81% *vs* 59%, respectively; *P* = 0.04). Another advantage of EUS is ability to define

unresectable tumors in some patients where CT and/or MRI failed to detect unresectability^[43]. In addition, EUS-FNA permits identification of extraductal tumors and allows triage of patients to potential non-operative management (e.g., lymphoma, metastatic lesions)^[50,51]. Therefore, EUS-FNA is an important diagnostic modality in patients with a distal indeterminate biliary stricture. ERCP remains the preferred initial approach in patients with proximal (defined as < 2 cm from the hilum) strictures. In symptomatic (i.e. icteric) patients, ERCP should still be the first-line approach because drainage can be accomplished concomitantly with tissue sampling. EUS-FNA can be performed subsequently if tissue samples obtained during ERCP are non-diagnostic.

CHOLANGIOSCOPY

Direct visualization of biliary strictures through cholangioscopy (percutaneous or endoscopic) may improve the diagnostic yield of cholangiography and routine cytology^[52]. Percutaneous cholangioscopy is effective in visualizing the biliary tree; however, it requires a percutaneous biliary access and repeated dilations to accept the cholangioscope. The use of “mother-baby” scopes have fallen out of favor due to requirement of two operators, fragility, suboptimal irrigation systems, and lack of 4 way tip deflection (Figure 5)^[53]. The Spyglass direct visualization system (Boston Scientific, Natick, MA, United States)^[54-56] allows for single operator cholangioscopy (SOC)^[54-56]. The components of the SOC system include the disposable SpyScope (Boston Scientific), a 10Fr access and delivery catheter with a 1.2 mm diameter working channel and 2 dedicated irrigation channels (Figure 6). It is introduced through a duodenoscope with a minimum working channel diameter of 4.2 mm. The catheter is capable of tip deflection of at least 30 degrees in 4 directions^[54,56]. The reusable SpyGlass Fiber Optic Probe (Boston Scientific) provides 6000 pixel images. The disposable SpyBite Biopsy Forceps (Boston Scientific) incorporates jaws at the tip designed to excise and retrieve visually targeted tissue.

An initial prospective observational feasibility study at 2 tertiary medical centers demonstrated that the SOC system can provide adequate samples for histologic diagnosis and to successfully guide stone therapy^[54]. Subsequently, Chen *et al*^[57] conducted a larger scale multicenter prospective observational study of SOC procedures in 297 patients with biliary strictures and/or stones and aimed to provide confirmatory evidence that direct visualization using the SOC system can aid in the diagnosis of biliary disease and facilitate stone therapy. The overall procedure success rate was 89%. SOC visual impression had a sensitivity, specificity, positive predictive value and negative predictive value for diagnosing malignancy of 78%, 82%, 80% and 80%, respectively (Figure 7). For SOC-directed biopsy, the respective results were 49%, 98%, 100% and 72%. Sensitivity was higher (84% and 66%, respectively) for intrinsic bile duct malignancies

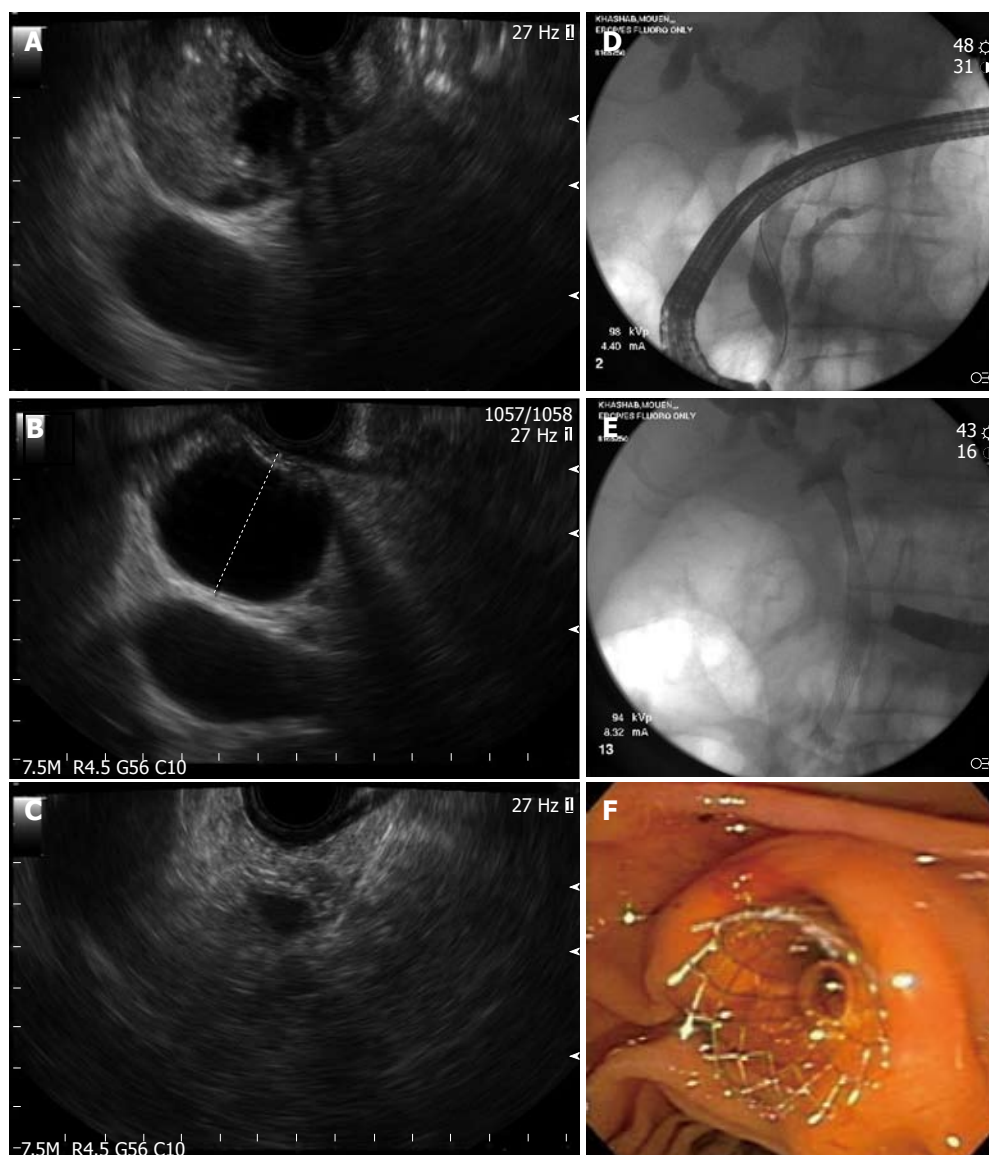

Figure 3 Endoscopic diagnosis and therapy for a bile duct mass missed on transabdominal imaging. A: Endoscopic ultrasound showing a bile duct mass that was missed by computed tomography and magnetic resonance imaging; B: Biliary dilation was present proximal to the stenosis; C: Endoscopic ultrasound-guided fine needle aspiration was performed and was diagnostic of cholangiocarcinoma; D: Endoscopic retrograde cholangioscopy was performed during the same session and cholangiography revealed distal biliary stricture; E, F: A fully-covered metal biliary stent was placed.

as compared to non-intrinsic malignancies. Diagnostic SOC procedures altered clinical management in 64% of patients. The incidence of serious procedure-related adverse events was 7.5% for diagnostic SOC. Ramchandani *et al*^[58] recently described a sensitivity of 95% and specificity of 79% for visual impression during Spyglass cholangioscopy in 36 patients with indeterminate biliary strictures. Both sensitivity and specificity were 82% after utilizing Spybite cholangioscopic biopsies^[58]. Draganov *et al*^[59] reported that the SOC guided biopsies had significantly higher accuracy of 84.6% as compared to standard transpapillary biopsies and cytology with accuracies of 53.9% and 35.5%, respectively. The authors were careful to point out that SOC guided biopsies had suboptimal negative predictive value of 69.2% over the mean 22 mo follow up^[59]. These results suggest a benefit of SOC in patients with indeterminate biliary strictures.

Visual impression of malignancy is an integral part of cholangioscopy, especially that the yield of SpyBite biopsies is suboptimal. Presence of “tumor vessels” within biliary strictures during cholangioscopy is indicative of biliary malignancy^[60]. These irregular, dilated vessels are due to neovascularization at the site of the stricture due to tumor growth. Their presence has sensitivity up to 100% for malignancy^[61]. Intraductal nodules and masses (Figure 8) can be visualized during cholangioscopy and are indicative of malignancy^[60]. However, these ductal findings are only visualized in a fraction of patients with cholangiocarcinoma. Biliary mucosal changes can be further delineated using methylene blue-aided cholangioscopy. In a feasibility study, Hoffman *et al*^[62] showed that normal and non-dysplastic mucosa was characterized by a homogenous light blue staining pattern, where as inflamed and dysplastic mucosa was characterized by in-

Figure 4 Endoscopic ultrasound evaluation of bile duct mass not seen on transabdominal imaging. A: Endoscopic ultrasound demonstrating the presence of bile duct mass; B: Endoscopic ultrasound-guided fine needle aspiration was diagnostic of cholangiocarcinoma

tense and inhomogeneous dark blue staining. More studies are needed to depict the utility of chromoendoscopy during cholangioscopy.

SOC is a technically feasible but is currently not a first line modality for evaluation of biliary strictures. It has some limitations. The 10 French catheter size typically requires sphincterotomy to advance the cholangioscope into the bile duct. At times due to the location and diameter of the stricture, the system cannot be advanced to the desired location. Complications for ERCP with cholangioscopy are reported by Chen *et al*^[57] as 7.5% for

Figure 6 Spyglass single operator cholangioscopy system. A: SpyScope 10Fr access and delivery catheter; B: SpyGlass fiber optic probe; C: SpyBite biopsy forceps.

the diagnostic SOC. Sethi *et al*^[63] report that ERCP with cholangioscopy had complication rate of 7.0% as compared to the ERCP only rate of 2.9%. Subgroup analysis revealed a high proportion of cholangitis in the cholangioscopy group. They postulate that this may be due to the saline infusion used in cholangioscopy^[63]. Draganov *et al*^[59] did not report any episodes of cholangitis in 26 patients who underwent SOC for indeterminate stricture. A recent editorial from Gaidhane *et al*^[64] suggests that this lack of cholangitis may be due to aggressive biliary drainage in these patients.

Probe-based confocal laser endomicroscopy

Confocal laser endomicroscopy permits real time histologic evaluation during endoscopy. Probe-based confocal laser endomicroscopy (p-CLE) can be used to generate microscopic information during ERCP^[65]. The Cholan-

Figure 7 Single operator cholangioscopy used to obtain a diagnosis in a stricture with nondiagnostic cytology. A: Magnetic resonance cholangiopancreatography showing a long distal biliary stricture with proximal biliary dilation. Endoscopic retrograde cholangiopancreatography with brushing was non-diagnostic; B: SpyGlass cholangioscopy revealed a malignant-appearing ulcerated biliary stricture. Spybite biopsies confirmed cholangiocarcinoma.

Figure 8 SpyGlass cholangioscopy revealing a bile duct mass. This is indicative of cholangiocarcinoma.

gioFlex probe (Maunakea Tech, Paris, France) is specially designed for p-CLE during ERCP procedures and has been miniaturized to have an external diameter of 0.94 mm. The probe fits in the 1.2 mm diameter working channel of a cholangioscope. The probe can be inserted as a standard ERCP accessory device. The radio opacity of the probe tip allows for fluoroscopic guidance and probe positioning, and the optical penetration of the confocal plane provides subsurface information with no interference from bile or solid residues. In a feasibility prospective study on 14 patients with indeterminate biliary strictures, the investigators predicted neoplasia with a sensitivity of 83%, specificity of 88%, and accuracy of 86%^[66]. In a larger study of 102 patients with indeterminate pancreaticobiliary strictures, the overall diagnostic accuracy of pCLE was 81%^[67]. p-CLE resulted in a significant increase in overall diagnostic accuracy of ERCP with tissue acquisition (90% *vs* 73%, $P = 0.001$). Biliary p-CLE is still in its infancy and requires further study before its routine use in the work-up of indeterminate biliary strictures is recommended.

Direct peroral video cholangioscopy

Direct peroral video cholangioscopy (D-PVCS) involves direct insertion of an ultra slim endoscope into the bile duct. This is advantageous as it requires one operator, provides high quality digital images (including narrow band imaging), provides separate water and air channels, and allows a larger working channel for diagnosis and therapeutics^[68,69]. D-PVCS has been accomplished using a variety of methods including direct insertion, wire-guided insertion, overtube-balloon assisted insertion, occlusion balloon-assisted insertion, and anchoring balloon-assisted insertion^[70]. D-PVCS requires an adequate biliary sphincterotomy to facilitate insertion of the ultra slim scope. Insertion rates have improved with intraductal anchoring balloons. Moon *et al*^[71] reported insertion success of 95.2% using an intraductal balloon catheter. A dedicated anchoring balloon system was sub-

sequently developed by Cook Medical (Winston-Salem, NC) to facilitate D-PVCS^[62]. However, few episodes of cardiac and cerebral air embolisms have been reported with this system and were thought to be due to bilio-venous fistula^[64]. Carbon dioxide insufflation during D-PVCS may decrease or eliminate embolization risk. However, this has to be further studied in animal models before embarking on further human studies.

In conclusion, indeterminate biliary strictures remain elusive. ERCP with routine cytology and transpapillary biopsy is the first diagnostic test of choice, especially in that these strictures often require treatment with dilation and/or stenting. Advances in endoscopic and cytopathologic techniques and accessories have improved the diagnostic yield of endoscopic work-up. These advances include EUS +/-FNA, IDUS, cholangioscopy, ancillary cytology techniques, among others. If initial ERCP with routine cytology and biopsy is non-diagnostic, one or a combination of these diagnostic techniques is warranted. The choice of what next diagnostic modality should be used should be individualized and depends on local expertise, patients' anatomy, comorbidities (e.g., PSC), and preferences.

lium. A number of pathogenetic theories have been proposed over the years, involving the role of luminal agents, autoimmunity, eosinophils, genetics (human leukocyte antigen), biliary acids, infections, alterations of pericryptal fibroblasts, and drug intake; drugs like ticlopidine, carbamazepine or ranitidine are especially associated with the development of LC, while CC is more frequently linked to cimetidine, non-steroidal antiinflammatory drugs and lansoprazole. Microscopic colitis typically presents as chronic or intermittent watery diarrhea, that may be accompanied by symptoms such as abdominal pain, weight loss and incontinence. Recent evidence has added new pharmacological options for the treatment of microscopic colitis: the role of steroidal therapy, especially oral budesonide, has gained relevance, as well as immunosuppressive agents such as azathioprine and 6-mercaptopurine. The use of anti-tumor necrosis factor- α agents, infliximab and adalimumab, constitutes a new, interesting tool for the treatment of microscopic colitis, but larger, adequately designed studies are needed to confirm existing data.

Abstract

Microscopic colitis may be defined as a clinical syndrome, of unknown etiology, consisting of chronic watery diarrhea, with no alterations in the large bowel at the endoscopic and radiologic evaluation. Therefore, a definitive diagnosis is only possible by histological analysis. The epidemiological impact of this disease has become increasingly clear in the last years, with most data coming from Western countries. Microscopic colitis includes two histological subtypes [collagenous colitis (CC) and lymphocytic colitis (LC)] with no differences in clinical presentation and management. Collagenous colitis is characterized by a thickening of the subepithelial collagen layer that is absent in LC. The main feature of LC is an increase of the density of intra-epithelial lymphocytes in the surface epithe-

INTRODUCTION

Microscopic colitis is a clinical syndrome of unknown etiology, characterized by chronic watery diarrhea in the absence of macroscopic changes in the large bowel. Once a rare diagnosis, its prevalence is now increasing, also because of the reduction of misdiagnoses, as it is included more and more often in the differential diagnosis of watery diarrhea.

As a consequence, knowledge about microscopic colitis has significantly improved in the last decade, with breakthroughs such as the recent reports of endoscopic findings or the use of anti-tumor necrosis factor (TNF)- α agents (infliximab and adalimumab) for refractory forms of the disease.

This paper will review the state of the art of epidemiology, theories on pathogenesis, diagnostic opportunities and, in particular, therapeutic improvements for microscopic colitis.

EPIDEMIOLOGY

Epidemiological data on microscopic colitis (MC)^[1] mainly originate from the Western world. MC accounts for 4%-13% of cases of chronic diarrhea. In Europe, collagenous colitis (CC)^[2] has an incidence of 0.6-2.3/100 000 per year, and a prevalence of 10-15.7/100 000. Lymphocytic colitis (LC)^[3], on the other hand, has an incidence of 3.1/100 000 per year, and a prevalence of 14.4/100 000. In particular, three European epidemiological studies have shown data on the incidence of MC in, respectively, France (0.6/100 000 per year), Sweden (1.8/100 000 per year) and Spain (1.1/100 000 per year). Recent data from North America report an incidence of 3.1-4.6/100 000 per year for CC and 5.4/100 000 per year for LC^[4-7]. A Spanish study has devoted particular attention to the epidemiological differences between CC and LC: patients with CC seem to be younger than patients with LC in a statistically significant way; moreover, in these patients diagnosis occurs later than in those with LC^[5]. Both pathologies are more frequent among females, but more markedly so in CC^[8], though this finding is not statistically significant^[9].

Actually, it may be difficult to determine the real epidemiological impact of MC for at least two reasons. First, the low specificity of signs and symptoms may cause the diagnosis to be missed or at least delayed, so that the incidence of the condition is underestimated. Secondly, until recently there were no epidemiological population studies, the scientific literature on MC mainly consisting of sporadic case reports. It is therefore unclear whether the increased incidence of MC is real or a simple consequence of the increased attention drawn to the disease^[10].

PATHOGENESIS

The aetiology of MC is still unknown: a number of

pathogenetic theories have been however proposed over the years, often in small or conflicting reports.

Abnormal response of luminal antigens

This group of theories is supported by multiple pieces of evidence. It has been shown that an ileostomy with a diversion of the faecal flow determines the clinical and histological resolution of the disease^[11-13]; in a case in which a Hartmann's intervention had been performed, the disease was still present in the intact proximal colon, whereas it had disappeared in the distal colon, that had undergone diversion^[14].

Moreover, the benefits of drugs such as colestyramine in affected patients could be partly related to the removal of luminal toxins^[15]. However, most of the patients with CC do not improve with cholestyramine; if toxins do play a role, it could therefore be less important in CC than in LC^[16].

Chronic inflammation/autoimmunity

One of the most plausible pathogenetic hypotheses identifies the cause of MC in autoimmunity: a chronic inflammatory process against self antigens unleashed by an initial stimulation (infectious, chemical, or of other nature) in a predisposed individual.

This theory rests on diverse, solid items of evidence: (1), MC is more common among females, like most other autoimmune diseases; (2), in MC various markers of autoimmunity have been found, such as the antinuclear antibodies (ANAs) and antiwall antibodies^[17], and, in one case, antineutrophilic cytoplasmic antibodies^[18]; moreover, a recent controlled study by Holstein and colleagues has found a statistically significant association of IgG ANA, antigliadin IgA, anti-Saccharomyces cerevisiae antibodies IgA and IgG with CC, but not with LC^[19]; and (3), there is association between MC and various autoimmune diseases, such as thyroid diseases, rheumatoid arthritis, diabetes mellitus 1, disorders of the connective tissue, and coeliac disease^[17]; this latter association has a particular importance: in about 30% of untreated celiac patients, colon biopsies show lesions identical to those of LC, and these lesions are even more evident in the cases of refractory coeliac disease^[20-22]. Conversely, another study has evaluated the frequency of coeliac disease in the patients with LC: of 46 patients with MC who had undergone the screening for coeliac disease, 19 had CC and 27 had LC; of these, 4 were coeliac, and all had LC, an incidence much higher than in the general population^[23]. Moreover, another study shows that the CC can be a way of presentation of the coeliac disease^[24]. The possibility that the autoimmune process could be mediated by an abnormal response to luminal antigens (a notion included in the above described theory) would strengthen both theories and pave the way to linking them to each other or even merging them.

Malabsorption of biliary acids

There is conflicting evidence on the role of biliary acids.

The colic infusion of biliary acids in animal models may determine a colitis^[25,26], and patients with ileal resection causing malabsorption of biliary acids may have diarrhea. An association between atrophy of ileal villi and MC has also been described^[27,28].

However, small studies conducted with the bile acid breath test have shown little or no evidence of malabsorption of biliary acids in patients with MC^[29,31]. Other studies investigating the retention of selenium homocholyltaurine have found variable degrees of malabsorption^[27,28,32], but this method is still considered uncertain and of dubious validity.

Brainerd diarrhea and other forms of infection

The term “brainerd diarrhea” indicates a watery diarrhea related to the exposure of an unknown etiologic agent (the agent that initially gave its name to the syndrome is raw milk)^[33].

Brainerd diarrhea is indistinguishable from MC both clinically^[34] and histologically, as it displays the same mucosal lymphocytosis, epithelial damage and collagen deposits^[33,34]. Moreover, a subpopulation of patients with MC responds to antibiotic therapy^[32,34-36], in particular to metronidazole. Finally, a study on an animal model has shown that human leukocyte antigen (HLA) B27/β 2 microglobulin transgenic mice, exposed to colon bacteria, develop a damage similar to that of LC^[37].

A role has also been suggested of infectious agents such as *Yersinia*^[38] and *Clostridium difficile* (*C. difficile*)^[39,40]. However, this body of evidence has not yet led to identifying a specific etiologic agent.

Correlation with HLA

In general, studies on HLA haplotypes provide insubstantial information: LC has been found to be positively associated with haplotypes A1 and DRW53, DQ2 e DQ1.3, and negatively associated with A3; CC has been found to be both positively and negatively associated with DQ2^[17,41,42]; other studies have found no statistically significant association between HLA haplotypes and MC^[43].

Role of eosinophils

It has been shown that histamine may cause a chloride hypersecretion in the colon, and this mechanism might contribute to cause the secretory diarrhea associated with CC, through increased blood flow and a reduced sphincter activity. Moreover, a case has been reported of a patient with LC and a significant intraepithelial eosinophil infiltrate that improved with antihistaminic therapy^[44]. Also, mast cells could mediate the abnormal deposition of collagen^[45], as patients with systemic mastocytosis often display fibrosis^[46].

Abnormalities of pericryptal fibroblasts

Physiologic production of collagen at the level of the lamina propria is ensured by a sheath of fibroblasts that surrounds lieberkuhn crypts (pericryptal fibroblasts): the

collagen they produce deposits around the crypts in the basal lamina^[47-50]. These fibroblasts have a myofibroblast-like behaviour: they form in the deepest part of the crypts and later climb them. During this migration they mature into collagen producing fibrocytes^[50]. It has been hypothesized that abnormalities of this process could contribute to the excess deposition of collagen in CC, where collagen deposits below the basal lamina in a subepithelial position^[47]. Studies have been conducted with the purpose characterize the subepithelial collagen, but findings are heterogeneous: some reports show that the subepithelial band mostly consists of collagen type VI^[51,52], which finding would have pointed to a primary alteration of collagen synthesis^[44]; other studies have demonstrated the presence of collagen I and III - the latter probably representing an attempt to repair after a chronic inflammatory damage^[53] - and the absence of collagen type IV^[44]; Günther *et al*^[54] have shown the presence of collagen VI along with I and III.

Ischemic processes are an insufficient explanation for the differences between LC and CC: while ischemia does not result in alterations of collagen deposition, it also does not account for the inflammatory infiltrate, and no sign of ischemia has been found in LC. Moreover, abnormalities of pericryptal fibroblast similar to those of CC have been also observed in the fibrotic form of ulcerative colitis^[49]. Therefore, no clear relationship has been defined so far between MC and dysfunctions of pericryptal fibroblasts.

Drug intake

Use of several drugs has been associated with the development of MC. LC has been suggested to be associated with ticlopidine^[55], carbamazepine^[56], ranitidine^[57], vinbazine^[58], tardyferon^[59], acarbose^[60] and Cyclo 3 Fort^[61]. In particular, Berrebi *et al*^[55] have shown that ticlopidine-induced LC is accompanied by increased epithelial apoptosis - which could be either a second effect of the drug-associated damage or a consequence of the colitis itself.

The list of drugs suggested as causes of CC includes cimetidine^[62], non-steroid anti-inflammatory drugs^[63,64], and, more recently, lansoprazole^[65].

Recently, Beaugerie *et al*^[66] have proposed a scoring system specific for drug-induced MC, based on chronological and causality criteria. Chronological criteria are based on the time between exposure to a drug and an adverse event, the evolution of the event if the therapy is interrupted, and the evolution if the therapy is restored; causality criteria are based on the exclusion of other causes of diarrhea and on specific histological findings. By combining the two sets of criteria, a score is obtained that defines the probability that a drug has caused MC: 0, not related; 1, doubtful; 2, possible; 3, likely; 4, almost definite.

HISTOPATHOLOGY

Definitive diagnosis of MC rests on histological exami-

nation, which is necessary both to rule out other possible causes of chronic diarrhea and to distinguish between LC and CC.

The diagnosis of LC is based on the following features. First, an increase of the density of intra-epithelial lymphocytes (IEL) in the surface epithelium. Physiologically, IEL of the colonic mucosa are less than 5 per 100 epithelial cells, while in LC they are at least 25 per 100 surface epithelial cells^[3,15,67], typically CD8⁺, carrying the $\alpha\beta$ T-cell receptor^[68-70] and expressing the human mucosal lymphocyte antigen, specific for intestinal lymphocytes^[68,71,72]; lymphocytosis in the crypt epithelium is also seen, but is less constant^[3].

Rarely, an infiltrate of eosinophils in the epithelium can also be found, and in a few reports neutrophils have been described, considered as a sign of acute stage of colitis^[73].

Second, an inflammatory infiltrate in the lamina propria, with prevalence of mononuclear cells such as lymphocytes and plasma cells, but with the sporadic presence of eosinophils, mast cells, macrophages and neutrophils (very rare); unlike those in the surface epithelium, lymphocytes of the lamina propria are mostly CD4⁺^[68,69]. It has been argued that lymphocytosis in the epithelium and in the lamina propria could be a histological response to a *primum movens* inflammatory process, rather than a primitive immunological dysfunction^[16].

Third, surface epithelial damage, manifested with flattening and degeneration of the epithelial cells (with features such as vacuolization of cytoplasm, nuclear irregularity, karyorrhexis and pyknosis) and focal loss and detachment of the epithelium - these features being more common in CC^[3,74,75]. There is also a minimal distortion of the structure of the crypts, but no crypt abscesses and granulomas^[76]. Moreover, active cryptitis has been reported by Gledhill *et al*^[49] in 41% of subjects with LC and in 29% with CC.

CC is characterized by a thickening of the subepithelial collagen layer that is absent in LC. The collagen band appears extremely eosinophilic in routine hematoxylin-eosin staining, but is better recognizable with Masson's trichrome staining; tenascin immunohistochemical stain appears to further improve sensitivity^[77,78].

In the healthy colon, the subepithelial collagen band is thinner than 3 μm ^[48]. The diagnostic criterion for CC has been proposed to be a thickness of at least 10 μm by some authors^[15,32,74], at least 7 μm by others^[29,49,76]. However, it is plausible that in most cases the collagen band reaches even 100 μm ^[15]. According to Lazenby *et al*^[3], the thickness of the collagen band alone is neither sufficient nor necessary for the diagnosis of CC: there are also some qualitative abnormalities, such as entrapment of red blood cells and cells of inflammation in the collagen band, and an irregular appearance of the inferior edge of the basement membrane, because of collagen bundles extending into the lamina propria. Some studies report a decreasing gradient of presence of intraepithelial lymphocytes and thickness of collagen band from the

cecum to the rectum^[69,76], others suggest that biopsies of the transverse colon give the best chance of diagnosis^[79], but as a general rule left-sided colonic biopsies, easily carried out with a flexible rectosigmoidoscope, are considered sufficient for the diagnosis of MC; if descending colon biopsies are not diagnostic and clinical suspicion is strong, a colonoscopy with random biopsies can be performed.

Studies of immunohistochemistry have shown that the collagen band consists basically of type III collagen - the subtype produced with repair functions - pointing to a reactive origin (the normal basement membrane mainly consists of fibronectin, laminin and type IV collagen)^[80].

The histological features of MC are not specific: CC-like findings have been reported in colon cancer, carcinoid lesions, hyperplastic polyps, *C. difficile* infection, Crohn's colitis, constipation and healthy people^[48,76,80-87], while features resembling LC have been described in human immunodeficiency virus, Crohn's disease, healthy people^[67,81,88,89].

CLINICAL MANIFESTATIONS

MC typically presents as chronic or intermittent watery diarrhea. The colon is normal both on endoscopic investigations and on imaging, so that a conclusive diagnosis can only be reached through biopsy and histological examination^[90]. Lately, however, endoscopic findings have been described in patients with MC (as carefully reviewed by Koulaouzidis *et al*^[91]), especially CC, such as colonic mucosal defects (mucosal tears or fractures)^[92-94] and alterations of vascular patterns, e.g. crowding of vessels, with dilated, circling or winding blood capillaries^[95]. Endomicroscopy^[96] and indigo carmine chromoendoscopy^[97] for the endoscopic diagnosis of MC have also been tested.

The severity of symptoms is variable: up to 22% of patients have > 10 bowel movements per day and up to 27% having nocturnal diarrhea^[32].

Diarrhea may be accompanied by symptoms such as abdominal pain, weight loss, incontinence^[88,98-103]. MC has been associated with a significant impairment of the overall quality of life, comparable to if not worse than that of other severe gastroenterological conditions such as anal fissures, severe chronic constipation, faecal incontinence^[104].

MC may be associated with an increased risk of lymphoma^[105,106], and, in women, lung cancer, even though the overall risk of malignancy and mortality is not different from the general population^[107]. Cases of MC as paraneoplastic manifestation have been described, e.g. in colon cancer^[108].

The natural course of the disease is extremely variable. The rate of spontaneous symptomatic remission after many years was reported as varying between 60% and 93% in LC^[88,109] and as much as from 2% to 92% in CC^[32,110-112]. More informative data come from studies that have analysed the smaller timeframe of 6/8

wk, highlighting a general tendency to lower response rates to placebo for CC (12%-20%)^[109-111] than for LC (48%)^[112]. These findings suggest that LC might have an intrinsically higher tendency to spontaneous remission than CC.

TREATMENT

More evidence is available on the treatment of CC than LC, but there is general agreement that there is no reason why the approach to their treatment should differ^[113]; available studies also confirm that therapies that proved effective in one tend to be confirmed as effective for the other as well^[112]. Another accepted guideline for medical therapy, based on the finding that MC has a high rate of spontaneous remission and remission after therapy, is that intermittent therapy should be favoured and that long-term therapy should only be considered when relapses or refractory symptoms leave no other choice^[114]. Therapeutic algorithms that combine available therapies in a meaningful way were proposed in 2003^[110], 2008^[113] and 2011^[90].

Proved association of MC with a range of drugs and with coeliac sprue suggests that both these etiologies are excluded before any medical therapy is initiated. Since patient with coeliac sprue presenting as MC tend to be negative for the typical immune markers of coeliac sprue, a small intestine biopsy remains the most reliable way of ruling it out^[115,116]; however, the invasive nature of the test makes it advisable to use it only for patients with a clinical situation strongly suggesting coeliac disease or with a previously diagnosed MC that has already proved refractory to therapy^[90].

A number of medical treatments have been attempted in patients with MC. A general consensus persists as to the use of traditional antidiarrhoic agents (loperamide, diphenoxylate) as first-line medical therapy, especially for patients with mild symptoms. The main options to be used as second line therapy are represented by bismuth subsalicylate^[117-119] and mesalazine, with or without colestyramine^[120]. Despite the efficacy of both is proved by trials, bismuth subsalicylate presents the drawback that it is not suitable for long-term therapy because of its unfavourable side effects profile. The association mesalazine-colestyramine, on the other end, is made physiologically reasonable by previous evidence on the association between MC and bile acids malabsorption^[121,122], and probably deserved to be further investigated.

There is now overwhelming evidence proving the efficacy of short-term therapy with oral budesonide in MC, a corticosteroid that is quickly metabolized by the liver and has therefore limited side effects compared to other steroids^[109-112]. Still, the overall adverse effects profile and the high risk of steroid dependency impose that this option be kept for second line or third line after the above mentioned agents, or at the very least that it only be considered as first line in cases with severe symptoms. The efficacy of prednisone has also been assessed^[114,123],

but because of its intrinsically severe adverse effects profile it should only be used in patients refractory to budesonide, if at all.

Studies on immunosuppressive therapy for refractory MC have made their appearance since budesonide was first proposed as a treatment, mainly because of the similarity between MC and inflammatory bowel diseases. The first ones to be studied were azathioprine and 6-mercaptopurine^[124-126], so that were recognized as a valid choice for steroid refractory MC early on^[127]. Later on, methotrexate was also proved to be effective^[128].

In patients refractory to all medical therapy, the surgical option should be considered^[125]. A number of interventions, which substantially overlap with the surgical approaches to the inflammatory bowel disease, have shown to have a potential of leading to a complete resolution of the symptoms^[13,14,129].

Boswellia serrata extract and probiotics have been found ineffective by one radionuclide computed tomography each^[130,131] so that they have since not been proposed in any therapeutic algorithm or reconsidered for subsequent trials.

The most recent developments appear to be focused on two lines of research. The first is the use of low-dosage budesonide as maintenance therapy; this approach appears to be more clinically viable than expected^[132,133] and has been deemed as promising^[134]. The second is the use of a new category of immunosuppressive agents, anti-TNF- α agents, already used with great results for the treatment of inflammatory bowel diseases: good results in therapies with both infliximab and adalimumab have been recently reported in experiences of limited size^[135-137], providing a valid rationale for a future larger controlled study.

Based on the accepted body of evidence on MC in combination with the most recent developments, we suggest a systematic treatment algorithm for MC (Figure 1).

CONCLUSION

Microscopic colitis is a quite common cause of chronic watery diarrhea, whose epidemiological impact has grown in the last years. Colon biopsies are required for the definitive diagnosis, and for the histological characterisation of the two subtypes of the disease (CC and LC), whose clinical features and management do not present however differences.

Over the last years, a series of new pharmacological agents for the treatment of MC has been proposed. The role of steroidal therapy, especially regarding the use of oral budesonide, has gained relevance, as well as immunosuppressive agents as azathioprine and 6-mercaptopurine. Few and very recent evidences has introduced anti-TNF- α agents (infliximab and adalimumab) as the possible cutting-edge for the treatment of MC, but larger and adequately designed studies are required to confirm these data.

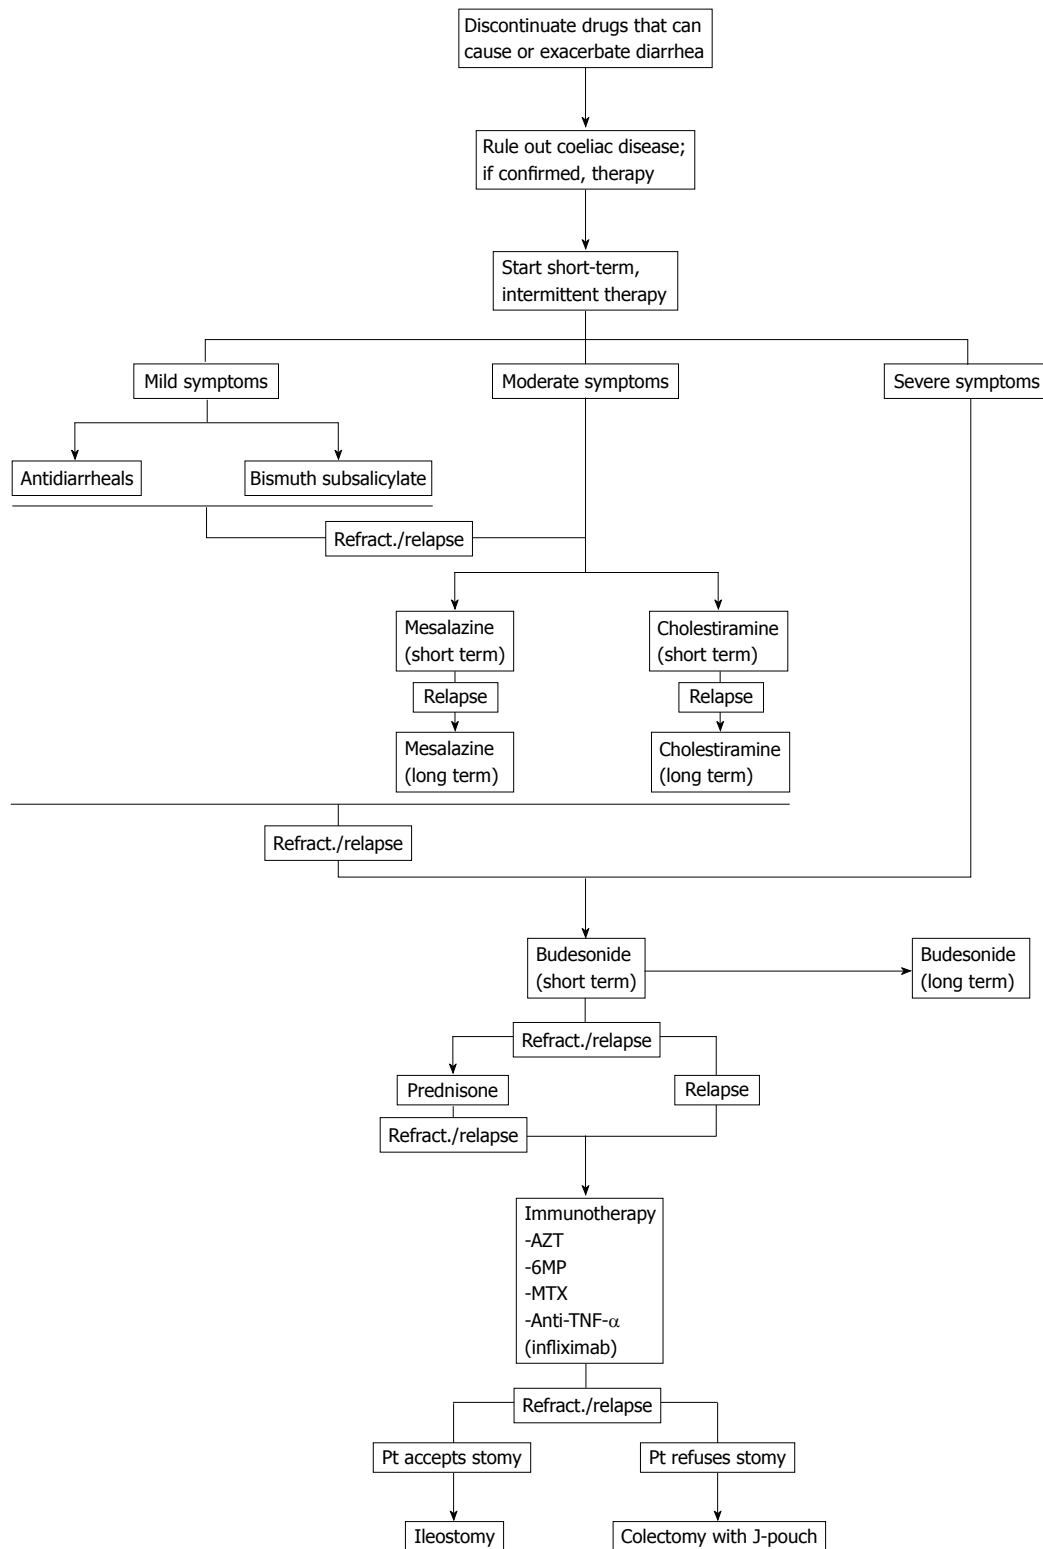

Figure 1 A proposed algorithm for the systemic treatment of microscopic colitis. TNF- α : Tumor necrosis factor- α ; Refract.: Refractory; AZT: Azathioprine; MP: Mercaptopurine; MTX: Methotrexate; Pt: Patient.

Abstract

Barrett's esophagus is a condition resulting from chronic gastro-esophageal reflux disease with a documented risk of esophageal adenocarcinoma. Current strategies for improved survival in patients with Barrett's adenocarcinoma focus on detection of dysplasia. This can be obtained by screening programs in high-risk cohorts of patients and/or endoscopic biopsy surveillance of patients with known Barrett's esophagus (BE). Several therapies have been developed in attempts to reverse BE and reduce cancer risk. Aggressive medical management of acid reflux, lifestyle modifications, antireflux surgery, and endoscopic treatments have been recommended for many patients with BE. Whether these interventions are cost-effective or reduce mortality from esophageal cancer remains controversial. Current treatment requires combinations of endoscopic mucosal resection techniques to eliminate visible lesions followed by ablation of residual metaplastic tissue. Esophagectomy is currently indicated in multifocal high-grade neoplasia or mucosal Barrett's carcinoma which cannot be managed by endoscopic approach.

Key words: Barrett's esophagus; Diagnosis; Manage-

INTRODUCTION

Barrett's esophagus (BE) is a condition resulting from chronic gastro-esophageal reflux disease (GERD). The clinical importance of the definition of BE is that it should identify a lesion documented to be at risk of esophageal adenocarcinoma.

Presently, the diagnosis of BE is based on a combination of endoscopic and histologic criteria^[1,2]. The diagnosis of BE is established when intestinal metaplasia (IM) is found in biopsy specimens obtained from salmon-colored mucosa in the distal esophagus proximal to the gastro-esophageal junction (Figure 1).

DIAGNOSIS

The diagnosis of BE requires systematic biopsy of the abnormal-appearing esophageal mucosa to document IM and to detect dysplasia^[1]. The "Seattle" protocol with random four-quadrant biopsies taken at 1-2-cm intervals along the endoscopically visible BE is the current recommended procedure in guidelines for the detection of dysplasia in patients with established BE^[3-6].

BE is currently graded with use of the Prague circumference and maximum criteria, which is a standardized, validated system based on the circumferential and

Figure 1 Endoscopic and histologic images of Barrett's esophagus. A: Endoscopic view of salmon-colored mucosa above the gastro-esophageal junction; B: Intestinal metaplasia with goblet cells (arrows) was found in biopsy specimens at histology.

maximal extent of the columnar-lined esophagus^[7-9].

THE PROBLEM: WHY, WHO, WHEN AND HOW TO TREAT FOR BE

BE develops in approximately 5% to 15% of patients with gastro-esophageal reflux undergoing endoscopic evaluation and in 1% to 2% of unselected population undergoing endoscopy^[10-14]. Evidence from one case series suggests that at least 60% of patients with BE develop the disease as a result of chronic reflux; other condition of mucosal inflammation of the lower esophagus, such as mucosal damage by chemotherapy, non-steroidal anti-inflammatory drugs, and viral infections are associated with the development of BE in about 1% of cases respectively^[15-19].

BE is associated with an increased risk of adenocarcinoma of the esophagus. Patients with BE are about 40 times more likely to have esophageal adenocarcinoma (EAC) than those without IM. The risk for an individual patient with BE has been estimated to range from 1 in 50 to 1 in 200 patient-years, or roughly 0.5% per year. Recent large cohort studies suggest the rate of progression is 0.1%-0.3% per year^[20-23].

Barrett's adenocarcinoma is considered a multistep process evolving from normal squamous mucosa to metaplasia to dysplasia to carcinoma. Why such a progression occurs, who is at risk, and what promotes these

changes remain unclear. Clinical and demographic factors, such as, age, male gender, longer duration and increased frequency of GERD symptoms, length of BE segment are associated with modestly increased odds of progression to EAC in some studies^[24-29]. Biomarkers^[30-33] such as aneuploidy and p53 loss have been recently associated with increased risk of progression to high-grade dysplasia (HGD) and/or EAC^[34-37].

At present, the strongest known predictor of cancer risk in the setting of BE is the degree of dysplasia. Subjects with no dysplasia have extremely low cancer rates for the five years following the index endoscopy. Conversely, subjects with HGD have rates reported as high as 10% per year^[38-40].

It is of paramount importance that the correct diagnosis is established. In many instances, especially in the presence of severe inflammation, there is an inter-observer disagreement on the diagnosis and grading of dysplasia. All biopsies with suspected dysplasia should be reviewed by a second "expert" pathologist^[41-43].

Several therapies have been developed in attempts to reverse BE and reduce cancer risk. Aggressive medical management of acid reflux, lifestyle modifications, anti-reflux surgery^[44-49], and endoscopic treatments^[50-52] have been recommended for many patients with BE. Whether these interventions are cost-effective or reduce mortality from esophageal cancer remains controversial.

MANAGEMENT STRATEGIES

Screening and surveillance for BE

Current strategies for improved survival in patients with Barrett's adenocarcinoma focus on detection of dysplasia. This can be obtained by screening programs in high-risk cohorts of patients and/or endoscopic biopsy surveillance of patients with known BE.

There is inadequate evidence of benefit to recommend endoscopic screening for BE in the general population of patients with GERD who do not have risk factors^[53-58]. Well-established risk factors for BE include age older than 50 years, male sex, white race, chronic GERD^[1-5], hiatal hernia^[59], elevated body mass index, and intra-abdominal distribution of body fat^[60,61]. The risk factors can be used to determine the threshold for endoscopy in patients with GERD to screen for the presence of BE^[2].

Endoscopic surveillance for patients with BE is recommended to identify curable neoplasia. Survey data indicate that although surveillance is widely practiced, there is marked variability in the technique and interval of surveillance because practice guidelines are not widely followed (Table 1)^[62].

Endoscopic imaging for the detection of dysplasia and early cancer: Endoscopy with multiple systematic biopsies (the "Seattle" protocol) is needed for the detection of dysplasia or adenocarcinoma for the surveillance of BE. This approach, requiring a large number of

Table 1 Guidelines for evaluation and management of Barrett's esophagus

	ACG	ASGE	AGA	BSG
No-dysplasia	Two esophageal examination with biopsy within 1 yr and follow up with endoscopy every 3 yr	Two consecutive esophageal examination with biopsy within 1 yr and follow up with endoscopy every 3 yr	Assess within 1 yr and if no dysplasia, defer for 5 yr or until cancer therapy is not possible of life expectancy is limited	Surveillance every 2 yr, if appropriate
Indefinite -	-	Repeat biopsy after 8 wk of acid suppression, if evidence of acute inflammation due to gastro-esophageal acid reflux	-	Assess with extensive biopsies after course of proton pump inhibitors and return to routine surveillance, if no definite dysplasia at 6 mo
LGD	Treat based on highest grade of dysplasia seen on two esophageal examinations within 6 mo, with pathologist's confirmation, and follow up with endoscopy every year until dysplasia is absent on two subsequent examinations	Follow up after 6 mo with concentrated biopsies in area of dysplasia; follow up every 12 mo if dysplasia persists	Assess in 1 yr and re-examine every year if dysplasia is confirmed by two pathologists (if there is disagreement about the presence of dysplasia then re-examine in 2 yr)	Extensive biopsy after intensive acid suppression for 8-12 wk; surveillance every 6 mo if dysplasia persists; surveillance intervals of 2-3 yr if regression occurs on two sequential examinations
HGD	Document any mucosal irregularities, repeat esophageal examination with biopsy within 3 mo, with pathologist's confirmation, to eliminate the possibility of cancer; follow up with endoscopic mucosal resection in the case of any mucosal irregularity; then intensive endoscopic surveillance every 3 mo or an intervention, such as esophagectomy or ablation, in the case of flat mucosa	Diagnosis should be confirmed by a pathologist; surgical candidates can choose to have a surgery or endoscopic therapy; follow up patients who choose surveillance every 3 mo for 1 yr with several large biopsies every 1 cm along esophagus; after 1 yr without cancer detection, surveillance duration can be lengthened, provided dysplastic changes are absent on two subsequent examinations	Diagnosis should be confirmed by two pathologists; patients should be treated with surgical resection or endoscopic therapy; surveillance can be offered provided follow up with endoscopy is every 3 mo with a minimum of eight biopsies every 2 cm along esophagus	Esophagectomy recommended if changes persist after intensive acid suppression, if confirmed by two pathologists, and if patient considered fit for surgery; if unfit for surgery, use endoscopic ablation or mucosal resection

ACG: American College of Gastroenterology; ASGE: American Society for Gastrointestinal Endoscopy; AGA: American Gastroenterological Association; BSG: British Society of Gastroenterology; LGD: Low-grade dysplasia; HGD: High-grade dysplasia.

biopsies, is time consuming and has several limitations, including sampling error and inconsistent histological interpretation^[2-6].

Several endoscopic imaging techniques to improve the accuracy of endoscopic diagnosis, have been developed and tested recently, with variable results^[63-67]. Enhanced optical imaging techniques may improve the efficiency and accuracy of endoscopic surveillance^[68-72]. Enhanced techniques can generally be categorized as broad-field (red-flag) techniques, such as high-definition/high-resolution white-light endoscopy (HD-WLE) and narrow-band imaging (NBI)^[73-75], and focal techniques, such as confocal laser endomicroscopy (CLE)^[76-80]. The broad-field techniques are good for providing an overview of the entire BE segment, and point out an area of interest, whereas focal techniques can provide greater detail of the area of interest (Figures 2 and 3)^[81-85].

Recent reports demonstrated that, in BE patients undergoing surveillance endoscopy, CLE imaging with targeted biopsies significantly improved the yield of biopsies for dysplasia compared with standard endoscopy with random biopsies when CLE imaging is conducted on suspect areas evidenced with both HD-WLE and NBI. Similarly, CLE was useful as a tool to identify non-dysplastic BE, and hence potentially to reduce the number of biopsies needed^[86-89].

DRUG THERAPY

Acid suppressive therapy, specifically proton pump inhibitors (PPIs), has been shown to improve symptoms and to heal and prevent relapse of erosive esophagitis in patients with BE^[4,90,91]. Evidence to support use of PPIs, in patients with BE solely to reduce risk of progression to dysplasia or cancer is indirect and has not been proven in a long-term controlled trial^[92-96]. Epidemiologic data suggest a lower risk of progression in PPI users. There is also some evidence to suggest that long-term therapy may induce regression of IM and promote the development of squamous islands^[97-99].

There is epidemiologic and experimental evidence to suggest that chemoprevention using non-steroidal anti-inflammatory drugs, aspirin^[100-104], and selective cyclooxygenase-2 inhibitors^[105-107] may reduce the risk of cancer in BE patients. However, human trials to date has not proved that these treatments are associated with a lower risk for neoplastic progression^[108].

The A phase III, randomised study of aspirin and esoprazole chemoprevention in Barrett's metaplasia trial currently underway is seeking to determine the effects of high- and low-dose proton pump inhibitor therapy with and without low-dose aspirin as BE chemoprevention^[109,110].

Figure 2 White-light and enhanced endoscopic images of non-dysplastic Barrett's esophagus. A: White-light of Barrett's esophagus; B: Narrow-band imaging endoscopic of Barrett's esophagus; C: Probe-based confocal laser endomicroscopy (pCLE) images of Barrett's esophagus. p-CLE image shows uniform villiform architecture, columnar cells (solid arrow) and dark goblet cells (dash arrow) predictive of non-dysplastic Barrett's esophagus.

ENDOSCOPIC THERAPY

Endoscopic treatment is focused on destruction of the existing metaplastic-dysplastic tissue using different modalities that eliminate the mucosa. The theory behind endoscopic treatment is that the injury of the metaplastic-dysplastic BE combined with vigorous acid suppression or with antireflux surgery would lead to reversion of the BE to squamous epithelium and reduce the risk of progression to cancer^[111-115].

Endoscopic treatment modalities include endoscopic resection techniques such as endoscopic mucosal resection and endoscopic submucosal dissection^[114] and endoscopic ablation therapy^[116,117], such as argon plasma coagulation (APC)^[118,119], laser ablation, photodynamic

Figure 3 Enhanced narrow-band imaging and probe-based confocal laser endomicroscopy images of dysplastic Barrett's esophagus. A: Narrow-band imaging images shows distorted pits with irregular microvasculature (white circle); B: The corresponding probe-based confocal laser endomicroscopy image shows disorganized, distorted villiform structure and crypts, dark columnar cells (dash arrow) and dilated irregular vessels (solid arrow); C: High-grade dysplasia was found at histology in biopsy specimens performed at this level.

therapy (PDT)^[120], radiofrequency ablation (RFA)^[121,122], and cryotherapy^[123-127].

Current treatment requires combinations of mucosal resection techniques to eliminate visible lesions followed by ablation of residual metaplastic tissue. Endoscopic resection of focal lesions is currently the only method to accurately and reliably determine the depth of invasion of a superficial lesion since it is the only endoscopic technique that provides histology.

Several studies have reported on a variety of ablation methods and have demonstrated difficulty in achieving complete eradication of BE. Thermal ablative modalities, such as APC, and laser therapy suffer from several pitfalls including a not homogeneous ablation of the

mucosa and inconsistent depth of tissue penetration causing that some glands can persist under the neosquamous epithelium^[128,129].

At present, after the areas of mucosal abnormality are removed, ablation of the residual Barrett's mucosa is most commonly performed with PDT or RFA. Photodynamic therapy has been proved to be effective for dysplasia, with a success rate of > 90%. However, following this treatment, there is a high rate of complication and side effects, mainly characterized by strictures and photosensitivity^[12,120,130-132]. Radiofrequency ablation is associated with fewer complications since it has a limited depth of injury, although stricture formation is approximately 6% in some prospective series^[133-137]. After RFA, complete eradication of dysplasia was reported in > 90% of patients with LGD and > 80% of patients with HGD, 1 year after the initial treatment. After 3 years, complete eradication of dysplasia and complete eradication of IM was reported in 98% and 91% of patients, respectively. At 5 years follow up, complete eradication of IM was demonstrated in 92% of the patients^[138-142].

Buried metaplasia is reported less frequently after RFA (< 1%) than after other different ablative endoscopic therapies, including PDT. However RFA is a relatively new procedure and, therefore, available studies on RFA describe only brief follow-up intervals^[143,144].

Because of the esophagus remains after endoscopic therapy, surveillance endoscopy at regular intervals, is necessary, even after complete ablation of BE has been accomplished.

SURGICAL THERAPY

As development of BE is based on gastro-esophageal reflux, a potential concept would be to stop reflux by anti-reflux surgery and thereby interrupt the mechanisms of malignant degeneration. Patients who are appropriate surgical candidates may elect anti-reflux surgery^[145-148]. Fundoplication effectively controls reflux symptoms in most patients^[149,150]. Surgical control of reflux disease, however, has not been found to be associated with a decrease in the incidence of esophageal cancer^[151-154].

Before the advent of endoscopic therapies, esophagectomy was the primary treatment option for patients with HGD.

Esophagectomy offers the most definite treatment in patients with BE with HGD (in particular in patients with multifocal HGD) since it eliminates all of the Barrett's epithelium preventing the risk of progression. In patients with HGD, a benefit of esophagectomy includes the treatment of an occult carcinoma (surgical series summarizing the incidence of occult adenocarcinoma, in patients with the preoperative diagnosis of HGD in resected series show an incidence ranging from 0% to 73%)^[155-159].

The standard surgical resection in most patients includes a total esophagectomy with a transhiatal or trans-thoracic approach, and reconstruction with gastric pull-

up or tubularized gastric conduit and the anastomosis performed in the neck or the high chest. In some cases esophageal resection could be performed minimally invasively. Limited vagal-sparing surgery like esophageal stripping or Merendino's operation is currently indicated in multifocal high-grade neoplasia or mucosal Barrett's carcinoma which cannot be managed by endoscopic approach. Strong consideration should be given for the performance of surgery in a high-volume hospital, by a specialty-trained surgeon with a large-volume esophageal practice^[160-162].

CONCLUSION

BE is a premalignant condition, with dysplasia usually preceding the development of adenocarcinoma. Patients with chronic reflux, especially white males, have the highest risk. Reducing reflux either medically or surgically may diminish the occurrence and/or progression of disease. Management of BE may vary from essentially a surveillance strategy to highly invasive esophagectomy.

Several therapies have been developed in attempts to reverse BE and reduce cancer risk, such as medical management of acid reflux, antireflux surgery, and endoscopic treatments. Whether these interventions are cost-effective or reduce mortality from esophageal cancer remains controversial. Endoscopic mucosal ablation techniques show promise as emerging therapeutic options. Current treatment requires combinations of endoscopic mucosal resection techniques to eliminate visible lesions followed by ablation of residual metaplastic tissue.

Esophagectomy is currently indicated in multifocal high-grade neoplasia or mucosal Barrett's carcinoma which cannot be managed by endoscopic approach.

Abstract

AIM: To gain insights into the molecular action of erlotinib in pancreatic cancer (PC) cells.

METHODS: Two PC cell lines, BxPC-3 and Capan-1, were treated with various concentrations of erlotinib, the specific mitogen-activated protein kinase kinase (MEK) inhibitor U0126, and protein kinase B (AKT) inhibitor XIV. DNA synthesis was measured by 5-bromo-2'-deoxyuridine (BrdU) assays. Expression and phosphorylation of the epidermal growth factor receptor (EGFR) and downstream signaling molecules were

quantified by Western blot analysis. The data were processed to calibrate a mathematical model, based on ordinary differential equations, describing the EGFR-mediated signal transduction.

RESULTS: Erlotinib significantly inhibited BrdU incorporation in BxPC-3 cells at a concentration of 1 $\mu\text{mol/L}$, whereas Capan-1 cells were much more resistant. In both cell lines, MEK inhibitor U0126 and erlotinib attenuated DNA synthesis in a cumulative manner, whereas the AKT pathway-specific inhibitor did not enhance the effects of erlotinib. While basal phosphorylation of EGFR and extracellular signal-regulated kinase (ERK) did not differ much between the two cell lines, BxPC-3 cells displayed a more than five-times higher basal phospho-AKT level than Capan-1 cells. Epidermal growth factor (EGF) at 10 ng/mL induced the phosphorylation of EGFR, AKT and ERK in both cell lines with similar kinetics. In BxPC-3 cells, higher levels of phospho-AKT and phospho-ERK (normalized to the total protein levels) were observed. Independent of the cell line, erlotinib efficiently inhibited phosphorylation of EGFR, AKT and ERK. The mathematical model successfully simulated the experimental findings and provided predictions regarding phosphoprotein levels that could be verified experimentally.

CONCLUSION: Our data suggest basal AKT phosphorylation and the degree of EGF-induced activation of AKT and ERK as molecular determinants of erlotinib efficiency in PC cells.

INTRODUCTION

Pancreatic cancer (PC) is the fourth leading cause of cancer death in the western hemisphere, with an overall five-year survival rate less than 6%^[1]. The most common kind of PC is pancreatic ductal adenocarcinoma, which accounts for more than 90% of all cases. **Major reasons** for this poor outcome are a late diagnosis and the lack of appropriate therapy approaches. Aside from genetic alterations in oncogenes like *KRAS*, or tumor suppressor genes such as *TP53*, *p16/CDKN2A*, and *SMAD4/DPC4*^[2], an increased expression of protein kinase B 2 (AKT2) and epidermal growth factor receptor (EGFR) can be found in a broad range of patient samples^[3-8]. Overexpression of EGFR was accompanied by a worse overall survival^[9]. Most carcinomas are diagnosed in an advanced non-resectable state, with palliative care remaining as the only treatment option.

Erlotinib, a small molecule inhibitor of the EGFR, is approved for the treatment of advanced PC. Combination treatment with gemcitabine has a moderate, but significant, survival benefit over standard treatment with gemcitabine alone^[10]. Rash is a prominent side effect of EGFR-targeted therapies with monoclonal antibodies and small molecule inhibitors. In various studies, a correlation of the efficacy of a targeted therapy with erlotinib and rash was observed^[10,11].

In non-small-cell lung cancer (NSCLC), activating EGFR mutations were identified as an indicator of a good response to small molecule inhibitors targeting this receptor^[12]. However, EGFR activating mutations are uncommon in PC^[13-15]. **Unlike in NSCLC, no predictive marker** (besides rash) for a response to erlotinib has been established to date in PC. It is believed that the identification of such markers holds promise for the classification of patient subgroups that would benefit most from targeted therapy in PC.

Erlotinib binds to the adenosine-5'-triphosphate (ATP) binding site of the EGFR and prevents ligand-induced receptor activation. Hence, no transphosphorylation of receptor complexes takes place, and executive downstream signaling pathways, like Ras-Raf-mitogen-activated protein kinase kinase (MEK)-extracellular signal-regulated kinase (ERK) and phosphatidylinositol 3-kinase (PI3K)-AKT, are not activated. To this day, erlotinib-attenuated signal transduction in PC is poorly understood.

Computational approaches for analyzing biochemical reactions are increasingly recognized as useful tools for the study of signaling networks and gaining deeper insights into dynamic processes^[16,17]. We, along with others, have previously shown that a combination of experimental and mathematical approaches can also be successfully applied to the analysis of pathophysiological mechanisms in PC and pancreatic fibrosis^[18-20].

In this study, we have addressed the question of how erlotinib modulates signal transduction *via* the EGFR, in order to determine molecular predictors of erlotinib sensitivity and resistance. To this end, two commonly-used and well-characterized human PC cell lines that differ in their biological sensitivity to erlotinib were chosen for a comparison of the molecular effects of the small molecule inhibitor. Experimental findings were used to establish a mathematical model that simulated major signaling pathways downstream of the EGFR. Together, our data suggest basal AKT phosphorylation and the degree of EGF-induced activation of downstream signaling pathways as molecular determinants of erlotinib efficiency.

MATERIALS AND METHODS

Materials

Iscove's modified Dulbecco's medium (IMDM) was from Biochrom (Berlin, Germany), and RPMI 1640 and fetal calf serum (FCS) was from PAA Laboratories (Pasching, Austria). Erlotinib was supplied by Biaffin (Kassel, Germany), and AKT inhibitor XIV and U0126 by Merck (Darmstadt, Germany). Recombinant human EGF and bovine serum albumin (BSA) were delivered by Sigma-Aldrich (St Louis, MO, United States).

Phospho-EGFR (pEGFR) (Tyr1068) rabbit mAb, phospho-AKT (pAKT) (Ser473) rabbit mAb, phospho-p44/42 mitogen-activated protein kinase (phospho-extracellular signal-regulated kinase 1/2, pERK1/2) (Thr202/Tyr204) rabbit pAb, AKT rabbit mAb, and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) rabbit mAb, were purchased from New England Biolabs (Frankfurt, Germany). EGFR rabbit mAb was from Epitomics (Burlingame, CA, United States) and MAP Kinase 1/2 (ERK1/2) rabbit pAb from Millipore (Billerica, MA, United States). **Fluorescently-labeled secondary antibodies** for immunoblot analysis were delivered by LI-COR (Lincoln, NE, United States). **Polyvinylidene fluoride (PVDF)** membrane was obtained from Millipore. Standard laboratory chemicals were from Sigma-Aldrich.

Cell culture

The human PC cell lines BxPC-3 and Capan-1 were obtained from the American Type Culture Collection. BxPC-3 was cultured in RPMI 1640 medium supplemented with 10% FCS, 10⁵ U/L penicillin, and 100 mg/L streptomycin. Capan-1 was cultured in IMDM medium supplemented with 17% FCS, 10 mL/L non-essential amino acids (dilution of a 100 × stock solution), 10⁵ U/L penicillin, and 100 mg/L streptomycin. **The cells were grown** at 37 °C in a 5% CO₂ humidified atmosphere.

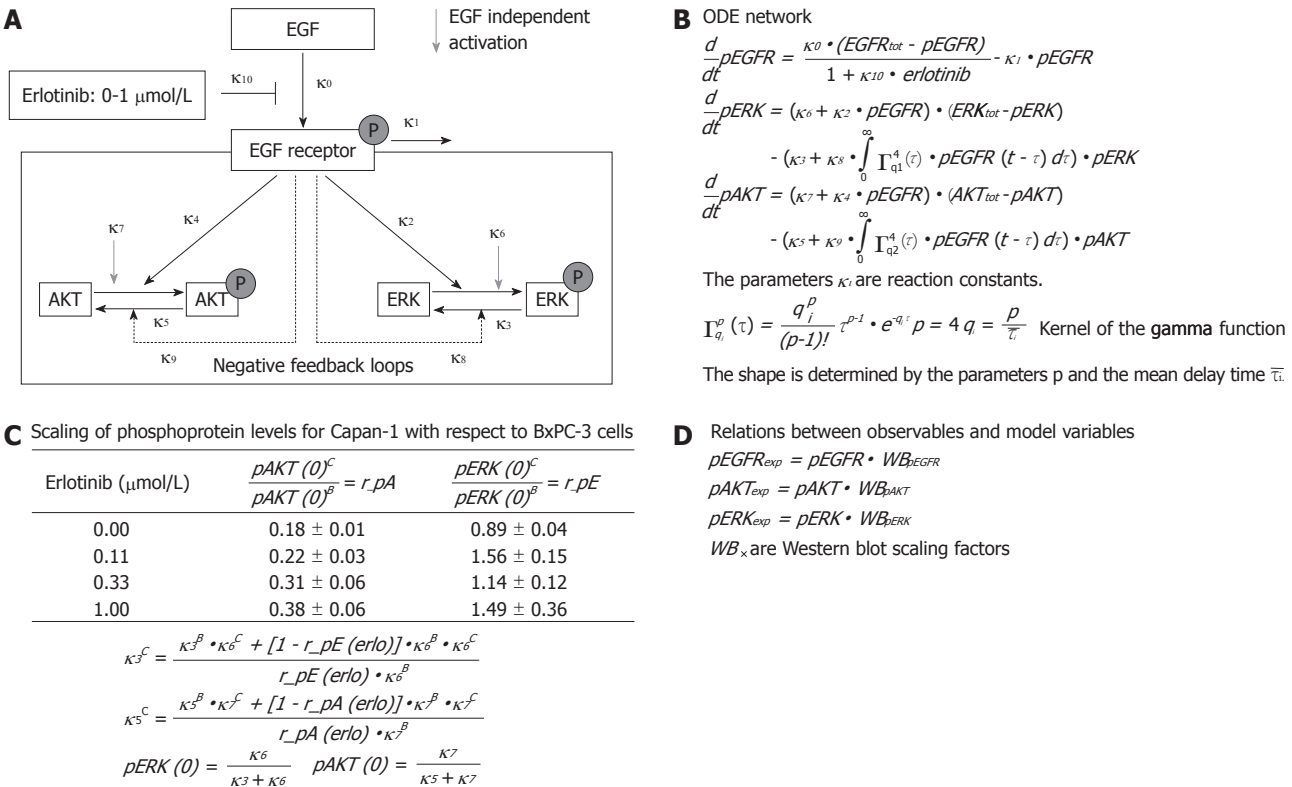

Figure 1 Flow chart of epidermal growth factor signal transduction and the ordinary differential equation network. A: Simplified reaction network. Solid black arrows show epidermal growth factor-dependent processes, whereas grey arrows represent basal phosphorylation. Two epidermal growth factor receptor (EGFR)-dependent negative feedback loops are shown by black dotted lines; B: Translation of the reaction network into an ordinary differential equation (ODE) model describing EGFR-mediated signal transduction; C: Ratio of basal levels of phosphorylated protein kinase B (AKT) (r_{pA}) and extracellular signal-regulated kinase (ERK) (r_{pE}) in BxPC-3 (superscript B) and Capan-1 (superscript C) cells. These calculations are implemented in the mathematical model; D: Equations describe relations between observables (fitted to experimental data) and model variables. For further description see “mathematical model” in the “materials and methods” section. EGF: Epidermal growth factor; pAKT: Phospho-AKT; ERK: Extracellular signal-regulated kinase; pERK: Phospho-ERK; WB: Western blot.

Cell proliferation assay

To analyze the inhibitory effects of erlotinib, AKT inhibitor XIV, U0126, and combinations thereof on cell proliferation, DNA synthesis was measured using a 5-bromo-2'-deoxy-uridine (BrdU) incorporation assay (Roche Applied Science, Mannheim, Germany). Therefore, the cells were seeded in 96 half-area plates. The following day, the cells were serum-starved and the inhibitors alone or in combination were applied as indicated. After 24 h, BrdU labeling solution was added for an additional 8 h and DNA synthesis was measured following the instructions of the manufacturer.

Immunoblotting analysis

Serum-starved BxPC-3 and Capan-1 cells were preincubated with different doses of erlotinib, AKT inhibitor XIV, or U0126, for 4 h before they were stimulated with 10 ng/mL human recombinant EGF. The cells were harvested by medium aspiration and boiled in lysis buffer [2% sodium dodecyl sulphate (SDS), 10% glycerol, 5 mmol/L ethylenediaminetetraacetic acid (pH 8.0), 62.5 mmol/L Tris-HCl (pH 6.8), 0.01% 3,3',5,5'-tetrabromophenol-sulfonphthalein, 5% β -mercaptoethanol]. The cellular proteins were separated by SDS-polyacrylamide gel electrophoresis (PAGE) and blotted onto PVDF membrane.

Afterwards, the blots were blocked with 1% BSA dissolved in tris-buffered saline [TBS; 20 mmol/L Tris-HCl (pH 7.6), 140 mmol/L NaCl] for 1 h, followed by incubation with primary antibody in TBST (TBS + 0.1% Tween 20) overnight at 4 °C. After washing with TBST, the blots were incubated in secondary antibody solution for 30 min. Immunofluorescence was detected using an Odyssey Infrared Imaging system. Signals for pERK, pAKT, pEGFR, the corresponding total proteins, and GAPDH were quantified using Odyssey® Application Software 3.16.

Phosphoprotein and total protein fluorescence intensities were adjusted to GAPDH and the potential effects of gel inhomogeneities were minimized by normalizing the individually-adjusted signal intensities to the mean of all samples of the gel. At least six independent experiments were performed to calculate mean and SE.

Potential inhibitory effects of erlotinib on the basal phosphorylation of the proteins (prior to the application of EGF) were considered as follows: the time curves of EGF stimulation were adjusted with experimentally-measured basal pERK/ERK and pAKT/AKT ratios for different erlotinib concentrations in both cell lines. Results for Capan-1 cells were related to the corresponding data for BxPC-3 cells (Figure 1). However, no meaning-

Figure 2 Effects of erlotinib on the proliferation of pancreatic cancer cell lines. BxPC-3 and Capan-1 cells growing in 96 half-area well plates were starved from serum and treated with different doses of erlotinib for a total of 32 h. DNA synthesis was measured by 5-bromo-2'-deoxyuridine (BrdU) incorporation over the last 8 h. Data represent mean \pm SE ($n = 6$). ^a $P < 0.05$ between control cultures without erlotinib.

ful scaling of pEGFR for different erlotinib concentrations without EGF stimulation could be performed, as basal phosphorylation of the EGFR was too weak.

Mathematical model

To examine the signal transduction dynamics downstream of the EGFR, we combined experimental data and mathematical modeling in a systems biological approach. A simplified network of EGFR signaling (Figure 1A) was chosen to describe the different steps in Figure 1A with the help of ordinary differential equations (ODE), whose terms are interpreted using mass action kinetics (Figure 1B). In the ODE model, EGF binds to the EGFR and triggers the phosphorylation of the receptor. Experimentally, only a low level of phosphorylated receptor was found in the absence of EGF. Therefore, no EGF-independent receptor phosphorylation was assumed. The receptor activation can be attenuated directly by erlotinib in a dose-dependent manner and by dephosphorylation. In turn, the phosphorylated receptor triggers the activation of downstream signaling pathways, where AKT and ERK were chosen as representative components. For simplicity, only two individual EGFR-induced feedback loops enhancing the dephosphorylation of AKT and ERK were assumed, although both kinases are targets of multiple inhibitory pathways^[21,22].

It was shown that PC cells may secrete EGF in an autocrine loop^[23]. Taking this into account, and to simulate an oncogenic *KRAS*-driven activation of the Ras-Raf-MEK-ERK pathway in Capan-1 cells, a phosphorylation of AKT and ERK independent of exocrine EGF was considered in the model.

We also included the experimentally measured ratios of basal phosphorylated AKT and ERK in Capan-1 versus BxPC-3 cells for all erlotinib concentrations. This information led to algebraic relations between the model

parameters, and between the initial conditions and the model parameters (Figure 1C).

The relationship between the observables which are fitted to the experimental time series and the variables of the mathematical model include scaling parameters, since the levels of the phosphorylated proteins could not be quantified in an absolute manner (Figure 1D).

To optimize the parameter values, the mathematical model was trained against quantitative immunoblot data. The optimization was done with a hybrid algorithm combining a global and a local search implemented in pWFitBoost of the MATLAB Toolbox PottersWheel^[24].

Statistical analysis

All experimental results represent mean \pm SE for the indicated number of experiments. The Wilcoxon rank-sum test was used to test differences for statistical significance. $P < 0.05$ was considered statistically significant.

RESULTS

Erlotinib and pathway-specific inhibitors reduce DNA synthesis of PC cells

In initial experiments, two PC cell lines with different *KRAS* status, BxPC-3 (wild-type) and Capan-1 (harboring mutant *KRAS*), were tested for their sensitivity to erlotinib. Therefore, the effects of clinically achievable concentrations of erlotinib^[25,26] on DNA synthesis were measured using a BrdU assay (Figure 2). Erlotinib significantly inhibited the incorporation of BrdU into newly synthesized DNA in BxPC-3 cells in a dose-dependent manner. Capan-1 cells were much more resistant to erlotinib treatment, and only the highest concentration of 10 μ mol/L significantly reduced the DNA synthesis of the cells. Neither of the two cell lines carried genetic alterations in exons 19 and 21 of EGFR, the sites of hotspot mutations sensitizing the receptor to erlotinib in NSCLC^[27] (data not shown).

Next, the question was addressed if one of the two major pathways downstream of the EGFR, Ras-Raf-MEK-ERK and PI3K-AKT, is more sensitive against a perturbation at the EGFR level than the other. Therefore, two pathway-specific inhibitors were used. As shown in Figure 3, AKT inhibitor XIV at a concentration of 10 μ mol/L diminished DNA synthesis in both cell lines. When AKT inhibitor XIV and erlotinib treatment were combined, no additional growth reduction over erlotinib alone was observed.

At a concentration of 10 μ mol/L, the MEK inhibitor U0126 inhibited the DNA synthesis of both cell types. Unlike in the case of AKT inhibitor XIV, an additional treatment with erlotinib further increased the inhibition of DNA synthesis of the cells. Comparing both cell lines, BxPC-3 cells were much more sensitive to U0126 than Capan-1.

Erlotinib inhibits EGFR, ERK and AKT phosphorylation

The differences in the biological response of BxPC-3

Figure 3 Effects of U0126, protein kinase B inhibitor XIV and erlotinib on proliferation of BxPC-3 and Capan-1 cells. The cells were seeded in 96 half-area well plates, starved from serum and treated with protein kinase B (AKT) inhibitor XIV or mitogen-activated protein kinase inhibitor U0126 in the presence or absence of erlotinib for a total of 32 h. DNA synthesis was measured by 5-bromo-2'-deoxyuridine (BrdU) incorporation over the last 8 h. Data represent mean \pm SE ($n = 6$). ^a $P < 0.05$ vs cultures with erlotinib only. $P < 0.05$ between all samples vs untreated cells (not indicated in the figure).

and Capan-1 cells to erlotinib and the two pathway-specific inhibitors raised the question of the underlying molecular mechanism. In our approach, we focused on the EGFR and the major downstream signaling cascades, where AKT and ERK were chosen as representative components.

The basal (EGF-independent) phosphorylation level of the EGFR and ERK did not differ much between both cell lines; while pEGFR was barely detectable, pERK1/2 was present at a low level. In contrast, BxPC-3 cells displayed a more than five-times higher basal pAKT/AKT ratio than Capan-1 cells (Figures 4 and 5).

To activate the EGFR and its related pathways, cells were stimulated with 10 ng/mL human EGF. As shown in Figure 4, in response to EGF, a phosphorylation of EGFR, AKT and ERK was observed in both cell lines. The pEGFR level increased over the first 60 min of stimulation (Figure 4) and only slightly attenuated afterwards (data not shown). AKT had its maximum phosphorylation at 5 min and ERK at 10-15 min, respectively. Subsequently, pAKT decreased to the initial phosphoprotein level, while ERK phosphorylation remained above the basal level until the end of treatment (Figures 4 and 5). As shown in Figure 5, BxPC-3 cells displayed, at all time points, higher levels of pAKT and pERK than Capan-1 cells.

The phosphorylation of all three signaling components was efficiently inhibited by preincubation of the cells with 1 μ mol/L erlotinib (Figures 4 and 5).

The mathematical model describes the experimental data and predicts phosphoprotein levels of AKT and ERK

To further characterize the signal transduction dynamics downstream of the EGFR, a mathematical model was established. Towards this goal, the experimental data set presented in Figure 4 was extended with phosphopro-

Figure 4 Effects of erlotinib on epidermal growth factor receptor signal transduction in BxPC-3 and Capan-1 cells. Serum-starved pancreatic cancer cells were preincubated with erlotinib at 1 μ mol/L for 4 h, as indicated, before they were stimulated with 10 ng/mL epidermal growth factor (EGF) for the indicated times. Protein extracts from equal amounts of cells were subjected to Western blot analysis. Phospho-epidermal growth factor receptor (pEGFR), phospho-protein kinase B (pAKT), phospho-extracellular signal-regulated kinase 1/2 (pERK1/2), their respective total proteins and glyceraldehyde-3-phosphate dehydrogenase (GAPDH) were detected using fluorescein (IRDye®)-labeled secondary antibodies. One representative Western blot is shown. For mean values of independent experiments, please refer to Figure 5. AKT: Protein kinase B; ERK: Extracellular signal-regulated kinase; EGFR: Epidermal growth factor receptor.

tein data obtained by using additional erlotinib concentrations and time points of EGF stimulation. Figure 5 shows for pAKT and pERK the comparison of the experimental data and model simulations, using optimized parameter values for all erlotinib concentrations and both cell lines. Parameter values and initial conditions of fixed parameters are summarized in Table 1.

As shown by experimental data and model simulation (Figure 5), erlotinib attenuated the activation of AKT and ERK in a dose-dependent manner in both cell types. Phosphoprotein levels in the two cell lines were diminished to a similar degree, except for ERK phosphorylation being more sensitive to erlotinib treatment in BxPC-3 than in Capan-1 cells.

To perform a validation of our mathematical model, we experimentally verified the peaks of the phosphoprotein levels of AKT and ERK for different doses of erlotinib that were previously predicted by computational simulation. Therefore, pAKT and pERK levels were quantified for the indicated times and compared with the model calculations (Figure 6). As shown, the model was able to provide suitable predictions of phosphoprotein peaks of both signaling components in BxPC-3 and Capan-1 cells.

DISCUSSION

In this study, a combined experimental and mathematical approach was chosen to gain deeper insights into the mechanisms of EGFR signaling and erlotinib action in PC cells. In agreement with previous studies, we observed a high biological erlotinib sensitivity of BxPC-3

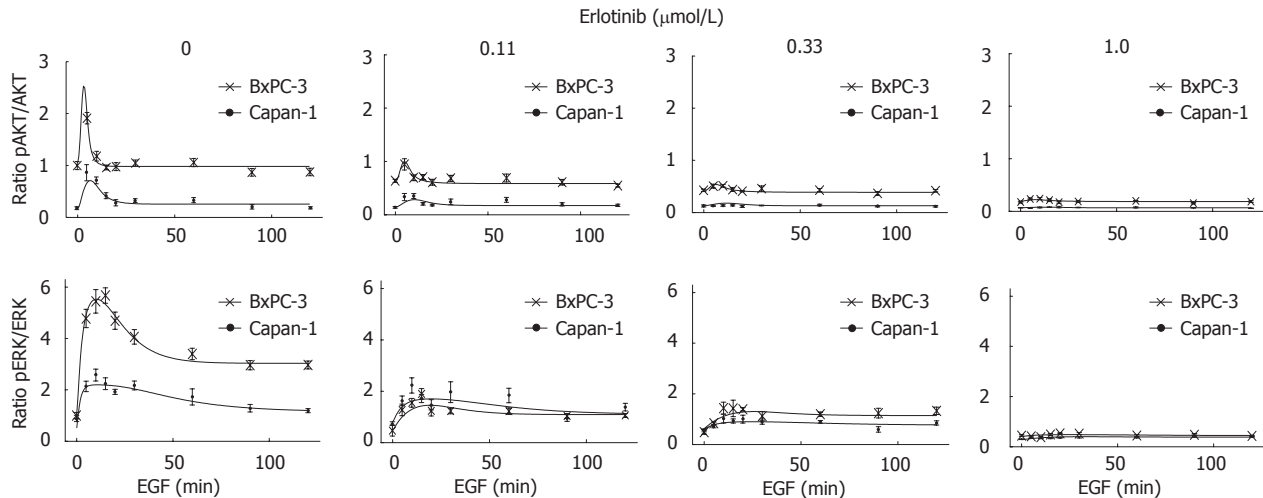

Figure 5 Simulations of the mathematical model reflect the experimental time series. Serum-starved BxPC-3 and Capan-1 cells were preincubated with different doses of erlotinib for 4 h and stimulated with 10 ng/mL epidermal growth factor (EGF) for the indicated times. Cellular lysates were analyzed by quantitative immunoblotting, and phospho-protein kinase B (pAKT), protein kinase B (AKT), phospho-extracellular signal-regulated kinase (pERK), extracellular signal-regulated kinase (ERK) and glyceraldehyde-3-phosphate dehydrogenase levels were determined. Plotted are experimental results (BxPC-3 and Capan-1); mean \pm SE of at least six independent experiments and model simulation (lines) for BxPC-3 and Capan-1 cells for different times of EGF stimulation. All data were scaled to the untreated BxPC-3 cells (absence of EGF and erlotinib), where the ratio was set as 1.

Figure 6 Mathematical prediction of phospho-extracellular signal-regulated kinase and phospho-protein kinase B levels after erlotinib treatment. Serum-starved BxPC-3 and Capan-1 cells were preincubated with different doses of erlotinib for 4 h and stimulated with 10 ng/mL human epidermal growth factor for the indicated times afterwards. Protein kinase B (AKT) and extracellular regulated protein kinases (ERK) phosphorylation were detected by immunoblot analysis. Experimental data (black dots) are expressed as arbitrary units (a.u.) of four independent experiments (mean \pm SE). Model predictions are indicated by cross symbols. EGF: Epidermal growth factor; pAKT: Phospho-AKT; pERK: Phosphomito-gen-extracellular signal-regulated kinase.

cells and a lesser sensitivity for Capan-1 cells^[28-31].

In the two cell lines, EGF induced the phosphorylation of EGFR, AKT, and ERK with similar kinetics, but different amplitudes (higher ratios of pAKT/AKT and pERK/ERK in BxPC-3 than in Capan-1 cells). Furthermore, BxPC-3 cells displayed a more than five-times higher basal pAKT level than Capan-1 cells. Factors that may contribute to the increased AKT phosphorylation are the amplification of *AKT2*, and the existence of an autocrine EGF loop in BxPC-3 but not Capan-1 cells^[32,33]. Despite the presence of an oncogenic *KRAS* allele in Capan-1 cells, basal pERK levels were similarly low in both cell lines. This seemingly surprising finding is in agreement with previous studies^[34], where low levels of pERK in *KRAS* mutant PC cells were linked to the activity of MKP-2, a member of the dual-specificity phosphatase family that acts in a negative feedback loop^[35].

In both cell lines, erlotinib efficiently inhibited phosphorylation of EGFR, ERK and AKT.

Next, we analyzed if both the PI3K-AKT and the Ras-Raf-MEK-ERK pathway were involved in mediating the anti-proliferative effects of erlotinib. We therefore challenged the cells with erlotinib or additional MEK and AKT-specific inhibitors to compare the effects on cell proliferation. In both cell types, erlotinib enhanced inhibition of cell proliferation by the pathway-specific inhibitors. U0126, but not AKT inhibitor XIV, was able to increase the growth-inhibitory effect of erlotinib. Together, these data are compatible with the hypothesis that both the AKT and ERK pathway are involved in the mediation of the antiproliferative effects of erlotinib in BxPC-3 and Capan-1 cells. The additional growth inhibitory effect of U0126 plus erlotinib versus erlotinib alone might possibly be explained by off-target effects of the MEK inhibitor, which have previously been described^[36].

Table 1 Optimized parameter values for the BxPC-3 and Capan-1 model

Model parameter	Value	
	BxPC-3	Capan-1

a: Calculated according to Figure 1C; EGFR: Epidermal growth factor receptor; AKT: Protein kinase B; ERK: Extracellular signal-regulated kinase; EGF: Epidermal growth factor; pAKT: Phospho-AKT; pERK: Phosphomito-gen-ERK; a.u.: Arbitrary units.

Our observations of BxPC-3 cells are in agreement with a previous study by Diep *et al*^[37], who showed that in *KR4S* wild-type PC cells, erlotinib-attenuated cell proliferation could be further diminished with MEK inhibitors. The results of the two studies, however, differ in that we observed a similar effect of the drug combination in *KR4S* mutant cells, while Diep *et al*^[37] did not. These contradictory findings are possibly due to the fact that different *KR4S* mutant cell lines and non-identical MEK inhibitors were used.

The antiproliferative effect of erlotinib in PC cells has previously already been linked to the expression of HER3 (ErbB3)^[28,38,39]. Interestingly, HER3 has also been shown to act upstream of AKT in a pathway that is activated by EGF-induced formation of EGFR/HER3 heterodimers^[39]. Thus, by blocking EGFR-mediated transphosphorylation of HER3, erlotinib may effectively

interfere with AKT activation in EGF-treated PC cells. Furthermore, using a systems biology approach, Schoeberl *et al*^[40] found that, in ovarian cancer cells, HER3 and AKT are particularly sensitive components of the HER receptor signaling network.

In conclusion, our data are in agreement with recent publications suggesting inhibition of EGF-induced ERK and AKT signaling as key components of erlotinib action in PC cells. A new finding of this study is that cells with high and low erlotinib sensitivity differed in their basal pAKT level. Furthermore, erlotinib displayed a stronger growth-inhibitory effect in the cells with a more pronounced activation of AKT and ERK in response to EGF (BxPC-3). Although we found a correlation between *KR4S* status and the growth-inhibitory effect of erlotinib, our data did not reveal a causal relationship, since the drug blocked ERK phosphorylation in *KR4S* wild-type and mutant cells with equal efficiency.

The ODE model of EGFR signaling in PC cells, established in the course of this study, accurately reflected the experimental findings. This observation suggested that the model, despite its simplifications, still contained all the components crucial to reproducing EGFR-triggered activation of AKT and ERK *in silico*. In support of this conclusion, the model also provided predictions regarding erlotinib-dependent changes of the phosphoprotein levels that could be verified experimentally. We consider the introduction of a mathematical model of EGFR signaling in PC cells as a first step on a path towards the identification of promising drug targets by means of computational modeling. Potential applications also include the *in silico*-testing of novel therapeutics targeting the EGFR pathway, and the further analysis of mechanisms of drug sensitivity and resistance.

Taken together, the results of this study may facilitate the search for molecular markers of erlotinib efficiency in PC patients. Mathematical models, like the one established here, are helping to gain further insights into signaling processes in cancer cells. In the long run, they may also become useful for predicting drug efficiencies in a clinical setting. In this regard, the particular advantages of mathematical models are that they can be based on a relatively small number of measurable parameters, and provide information about dynamic processes.

ACKNOWLEDGEMENTS

We thank Katja Bergmann for expert technical support and Andreas Frost for helping us to analyze the experimental data.

COMMENTS

Background

Of all common malignancies, pancreatic cancer (PC) has the lowest survival rate. The epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor erlotinib is the only new drug for the treatment of locally advanced, unresectable, or metastatic PC that has been successfully introduced into the clinics in recent years, but its positive effect on survival time is small.

Research frontiers

To date, only rash, a common side effect of EGFR targeted therapies, is an indicator of a possible response to an erlotinib treatment. Identification of molecular markers holds promise for classifying subgroups of patients who would benefit most from erlotinib therapy.

Innovations and breakthroughs

This is the first study combining experimental data and mathematical modeling to elucidate epidermal growth factor and erlotinib action in PC cells. The authors observed that PC cells with a high biological sensitivity to erlotinib displayed a higher basal phospho-protein kinase B level and increased activation of EGFR-induced downstream signaling pathways than less sensitive cells. The mathematical model not only reflected the experimental findings, but also provided predictions regarding phosphoprotein levels that could be verified experimentally.

Applications

The results of this study may facilitate the search for molecular markers of erlotinib efficiency in PC patients. Mathematical models, like the one established here, are currently applicable in order to gain molecular insights into signaling processes in cancer cells. In the long run, they may also become useful for predicting drug efficiencies in a clinical setting.

Peer review

The authors present a manuscript with important data which may be helpful for patient stratification for the treatment of pancreatic carcinoma using erlotinib. Of course, the model as established in this study should be confirmed through further *in vivo* tests, including clinical trials, and a group of biomarkers may be developed in the future and applied for a selection of potentially sensitive patients.

Abstract

AIM: To define which segments of the gastrointestinal tract are most likely to yield angioectasias for ablative therapy.

METHODS: A retrospective chart review was performed for patients treated in the Louisiana State University Health Sciences Center Gastroenterology clinics between the dates of July 1, 2007 and October 1, 2010. The selection of cases for review was initiated by use of our electronic medical record to identify all patients with a diagnosis of angioectasia, angiodysplasia, or arteriovenous malformation. Of these cases, chart reviews identified patients who had a complete evaluation of their gastrointestinal tract as defined by at least one upper endoscopy, colonoscopy and small bowel capsule endoscopy within the past three years. Patients without evidence of overt gastrointestinal bleeding or iron deficiency anemia associated with intestinal angioectasias were classified as asymptomatic and excluded from this analysis. Thirty-five patients with confirmed, bleeding intestinal angioectasias who had undergone complete endoscopic evaluation of the gas-

trointestinal tract were included in the final analysis.

RESULTS: A total of 127 cases were reviewed. Sixty-six were excluded during subsequent screening due to lack of complete small bowel evaluation and/or lack of documentation of overt bleeding or iron deficiency anemia. The 61 remaining cases were carefully examined with independent review of endoscopic images as well as complete capsule endoscopy videos. This analysis excluded 26 additional cases due to insufficient records/images for review, incomplete capsule examination, poor capsule visualization or lack of confirmation of typical angioectasias by the principal investigator on independent review. Thirty-five cases met criteria for final analysis. All study patients were age 50 years or older and 13 patients (37.1%) had chronic kidney disease stage 3 or higher. Twenty of 35 patients were taking aspirin (81 mg or 325 mg), clopidogrel, and/or warfarin, with 8/20 on combination therapy. The number and location of angioectasis was documented for each case. Lesions were then classified into the following segments of the gastrointestinal tract: esophagus, stomach, duodenum, jejunum, ileum, right colon and left colon. The location of lesions within the small bowel observed by capsule endoscopy was generally defined by percentage of total small bowel transit time with times of 0%-9%, 10%-39%, and 40%-100% corresponding to the duodenum, jejunum and ileum, respectively. Independent review of complete capsule studies allowed for deviation from this guideline if capsule passage was delayed in one or more segments. In addition, the location and number of angioectasias observed in the small bowel was further modified or confirmed by subsequent device-assisted enteroscopy (DAE) performed in the 83% of cases. In our study population, angioectasias were most commonly found in the jejunum (80%) followed by the duodenum (51%), stomach (22.8%), and right colon (11.4%). Only two patients were found to have angioectasias in the ileum (5.7%). Twenty-one patients (60%) had angioectasias in more than one location.

CONCLUSION: Patients being considered for endoscopic ablation of symptomatic angioectasias should undergo push enteroscopy or antegrade DAE and re-inspection of the right colon.

INTRODUCTION

Intestinal angioectasias are culprit lesions in up to 5%-6% of gastrointestinal bleeding cases and are the most common source of bleeding from the small intestine in patients older than 50-60 years^[1]. In patients who experience symptomatic blood loss due to these lesions, approximately 40%-50% will experience recurrent bleeding^[2]. Endoscopic ablation of these lesions using bipolar cautery or argon plasma coagulation is a standard therapy to prevent bleeding recurrence^[1,3]. However, localization of these lesions can be challenging as they are commonly small, evanescent and/or located deep in the small intestine. These lesions are also multiple in many cases^[4]. Understanding the natural distribution of these lesions in the gastrointestinal tract is useful to guide endoscopic evaluation and therapy.

Endoscopic visualization of the entire gastrointestinal tract has not been readily available until the advent of wireless capsule endoscopy and double balloon enteroscopy in 2001^[5,6]. Prior to the introduction of these technologies, complete examinations of the intestinal lumen were limited to cases in which intraoperative enteroscopy was performed. Recent studies of the distribution of angioectasias using capsule endoscopy and balloon enteroscopy demonstrate that these lesions are common causes of bleeding from the small intestine. However, the most frequent location of lesions within the small intestine has varied between populations. In Eastern populations, angioectasias have been found to be distributed almost equally between the proximal and distal small intestine (44%-69% and 31%-56%, respectively)^[7-9]. These findings are in contrast to a recent study in the United States which found that the vast majority

of lesions occur in the jejunum (93%) rather than the ileum (7%)^[10]. Anecdotal reports from our center or other centers performing balloon enteroscopy in the United States are similar to the findings of Gerson *et al*^[10].

In order to better define the distribution of angioectasias in the gastrointestinal tract, we studied the location of specific lesions in patients with overt or occult gastrointestinal blood loss attributed to symptomatic angioectasias.

MATERIALS AND METHODS

This study was designed as a single-center retrospective chart review. Institutional review board approval was obtained during final protocol development. Prior to study initiation, the terminology regarding intestinal vascular lesions was delineated. Angioectasias were defined pathologically as dilated submucosal veins with overlying ectasia of mucosal venules and capillaries. The term angiodysplasia was used interchangeably with angioectasia although the equivalence of these terms has been debated. Due to the presence of arteriovenous communications in some angioectasias, lesions identified as arteriovenous malformations were also included in this study provided that the observed lesion was not protruding or obviously deep to the submucosa. Using these pathologic definitions as a reference, all superficial lesions 1mm or greater in size which are cherry-red in color with a fern-like pattern were included for analysis (Figure 1). Lesions characterized by pulsatile bleeding but no mucosal defect were generally classified as Dieulafoy lesions and were excluded^[11].

Selection of cases for review was initiated by use of our electronic medical record to identify cases in which a diagnosis of angioectasia, angiodysplasia, or arteriovenous malformation was made between the dates of July 1, 2007 and October 1, 2010. Of these cases, chart reviews identified patients who had a complete evaluation of their gastrointestinal tract as defined by at least one upper endoscopy, colonoscopy and small bowel capsule endoscopy within the past three years. Patients without evidence of overt gastrointestinal bleeding or iron deficiency anemia associated with intestinal angioectasias were classified as asymptomatic and excluded from this analysis. Patients with a diagnosis of hereditary hemorrhagic telangiectasia or gastric antral vascular ectasia were also excluded.

RESULTS

A total 127 cases were initially reviewed. A large number (66) of these were excluded during subsequent screening due to lack of complete small bowel evaluation (primarily lack of capsule endoscopy) and/or lack of documentation of overt bleeding or iron deficiency anemia. The 61 remaining cases were carefully examined with independent review of endoscopic images as well as complete capsule endoscopy videos. This analysis excluded 26

Figure 1 A typical angioectasia (arrow) observed in the small intestine by capsule endoscopy.

additional cases due to insufficient records/images for review, incomplete capsule examination, poor capsule visualization or lack of confirmation of typical angioectasias by the principal investigator on independent review. A total of 35 cases met criteria for final analysis. The number and location of angioectasias were documented for each case. Lesions were then classified into the following segments of the gastrointestinal tract: esophagus, stomach, duodenum, jejunum, ileum, right colon and left colon. The location of lesions within the small bowel observed by capsule endoscopy was generally defined by percentage of total small bowel transit time with times of 0%-9%, 10%-39%, and 40%-100% corresponding to the duodenum, jejunum and ileum, respectively. Independent review of complete capsule studies allowed for deviation from this guideline in cases in which capsule passage was delayed in one or more segments. In addition, the location and number of angioectasias observed in the small bowel was further modified or confirmed by subsequent device-assisted enteroscopy (DAE) performed in the 83% of cases.

In the final analysis, all study patients were age 50 years or older (age range 50-91 years) and 13 patients (37.1%) had chronic kidney disease stage 3 or higher (defined by Kidney disease outcomes quality initiative staging: stage 3 = glomerular filtration rate (GFR) 30-59, stage 4 = GFR 15-29, stage 5 = GFR < 15 or on dialysis). Twenty of 35 patients were taking aspirin (81 mg or 325 mg), clopidogrel, and/or warfarin. Of these 20 patients, 8 were on a combination of these medical therapies.

In our study population, the jejunum was the most common location of symptomatic angioectasias in the gastrointestinal tract. Out of 150 total angioectasias observed in 35 patients, 78 were localized to the jejunum (52%), 34 to the duodenum (23%), 22 to the stomach (15%), 9 to the ileum (6%), and 7 to the right colon (4.7%). Twenty-eight patients had lesions in the jejunum (80%), 18 had lesions in the duodenum (51%), 8 had lesions in the stomach (22.8%), 4 had lesions in the right colon (11.4%) and 2 had lesions in the ileum (5.7%). There were no angioectasias localized to the esophagus or left colon. Twenty-five patients had more than one

lesion (71.4%). Twenty-one patients had lesions in more than one location (60%).

Spatial clustering of lesions was also observed. In patients with lesions in multiple segments, the most common sites were the duodenum and jejunum (14 patients or 40%). Other clustering occurred in the stomach and jejunum (6 patients or 17%), stomach and duodenum (5 patients or 14.3%), jejunum and right colon (5 patients or 14.3%), duodenum and right colon (3 patients or 8.6%), stomach and right colon (1 patient or 2.9%), and duodenum and ileum (1 patient or 2.9%).

Eight patients had angioectasias isolated to the jejunum (22.8%), while two patients had angioectasias isolated to the duodenum (5.7%). Other angioectasias isolated to a single segment were found in the stomach and ileum in one patient each (2.9%). None of our patients had angioectasias located in the esophagus or left colon and no patients had isolated angioectasias in the right colon.

DISCUSSION

Recent studies of obscure bleeding in Eastern populations indicate that angioectasias are not the most common cause of small bowel hemorrhage and that these lesions are distributed fairly equally throughout the small intestine^[7-9,12-14]. However, studies of Western populations report that angioectasias account for 60%-70% of bleeding sources in the small bowel and are generally found in the proximal small bowel^[10,15,16]. One study by May *et al*^[17] described a high incidence of symptomatic small bowel angioectasias in a United States population, with lesions seen in 17 of 52 push enteroscopies, 21 of 52 oral push-and-pull enteroscopies, and 2 of 52 anal push-and-pull enteroscopies. In our study population, angioectasias were most commonly found in the proximal small bowel, namely the jejunum and duodenum. Spatial clustering of these lesions also occurred most frequently in these segments.

Treatment of bleeding angioectasias is difficult. Data regarding the use of hormones, thalidomide or octreotide is limited with pharmacologic therapy reported as effective in some studies but not others. Treatment with estrogen and progesterone is the most common pharmacologic therapy, although recent studies have shown failed to confirm the efficacy observed in smaller, earlier trials^[1,18-20]. Somatostatin and octreotide have reportedly shown some reduction of blood loss from angioectasias, although only in case reports and one small study. It is theorized that somatostatin may prevent recurrent bleeding from angioectasias by reduction in mesenteric blood flow and inhibition of vasodilator peptides^[19]. Although this rationale seems plausible, there are currently no randomized, double-blinded studies supporting these hypotheses^[1]. Endoscopic ablation is a commonly utilized therapy in patients with overt bleeding or iron deficiency anemia attributed to intestinal angioectasias. Although the effectiveness of this therapy has not been proven in a randomized, controlled trial, the practice of endoscop-

ic ablation is supported by the lack of compelling data for medical therapy. Small studies of rebleeding rates after ablative therapy support this practice. In one study conducted in the United Kingdom, heater probe ablation of angioectasias was performed in 23 patients during push enteroscopy. The authors found this therapy to be effective although repeated ablation was required in 30% of cases^[21]. Another early study of endoscopic therapy in London found that argon lasers, although seemingly promising, did not completely ablate the angioectasia. The first of their 18 studied cases ultimately required an emergency gastrectomy, so the investigators observed the argon laser's effects on the resected specimen. Despite the laser's small ulcer created during endoscopy, the arteriovenous malformation remained intact under normal mucosa, increasing the likelihood of rebleeding. In a separate case, investigators had better results with the neodymium Yag (Nd YAG) laser, which created fibrotic zones three to four times thicker than the argon laser^[22]. This finding was validated by two separate studies which showed a reduction in blood transfusion requirements after treating patients with angioectasias with endoscopic Nd YAG laser. However, the investigators of these studies performed only upper gastrointestinal endoscopy, and admitted that the Nd YAG laser would need to be used with caution in the thinner bowel walls of the lower gastrointestinal tract^[23,24]. In Japan, Ohmiya *et al.*^[25] used a combination of double balloon endoscopy with enteroscopic electrocoagulation to locate and treat 19 patients with small bowel angioectasias. Of the 19 patients, 7 rebled after treatment. Nakase *et al.*^[26] also DBE to localize bleeding angioectasias in the small bowel of 8 patients, and reported successful hemostasis in all cases using combination therapy of local injection of hypertonic-saline epinephrine and heat coagulation. However, since bleeding from angioectasias often occurs intermittently, it is difficult to evaluate the effects of any therapy on rebleeding rates. For this reason, both endoscopic therapy and medical therapy are still used in clinical practice with medical therapy often reserved for patients with comorbidities preventing endoscopic ablation, patients with multiple lesions or in cases in which bleeding recurs despite ablation^[1].

Weaknesses of our study include retrospective design and relatively small number of patients included in the final analysis. Also, patients with angioectasias located within reach of standard endoscopy may not have been included if additional evaluation by capsule endoscopy was not pursued thus leading to overstatement of the percentage of patients with small bowel lesions. The lack of angioectasias found in the ileum is still a compelling finding despite these considerations. When applying this finding towards clinical practice, examination of the ileum by retrograde DAE or attempted total enteroscopy by antrograde DAE is unlikely to yield angioectasias candidate for ablation unless lesions are observed in this segment by capsule study. Close inspection of the duodenum and jejunum using push enteroscopy or

anterograde DAE combined with re-inspection of the right colon and terminal ileum may be the most effective approach in these patients.

COMMENTS

Background

Intestinal angioectasias are the most common source of bleeding from the small intestine in patients older than 50-60 years. Nearly half of patients who experience symptomatic blood loss due to these lesions will experience recurrent bleeding. Additionally, many patients have multiple angioectasias that may bleed. Localization and endoscopic treatment of these lesions can be challenging as they are commonly small, evanescent and/or located deep in the small intestine. In order to better define the distribution of angioectasias in the gastrointestinal tract, we studied the location of specific lesions in patients with overt or occult gastrointestinal blood loss attributed to symptomatic angioectasias.

Research frontiers

Endoscopic visualization of the entire gastrointestinal tract has not been readily available until the advent of wireless capsule endoscopy and double balloon enteroscopy in 2001. Since that time, localization and endoscopic treatment of angioectasias have become areas of interest for clinicians and researchers alike.

Innovations and breakthroughs

Recent studies of the distribution of angioectasias using capsule endoscopy and balloon enteroscopy demonstrate that these lesions are common causes of bleeding from the small intestine. However, the most frequent location of lesions within the small intestine has varied between populations. In Eastern populations, angioectasias are almost equally distributed between the proximal and distal small intestine. In Western populations, however, the vast majority of lesions occur in the proximal small bowel.

Applications

The majority of small bowel angioectasias in the study were located in the proximal small bowel. When applying this finding towards clinical practice, examination of the ileum by retrograde device-assisted enteroscopy (DAE) or attempted total enteroscopy by antrograde DAE is unlikely to yield angioectasias candidate for ablation unless lesions are observed in this segment by capsule study. Close inspection of the duodenum and jejunum using push enteroscopy or antrograde DAE combined with re-inspection of the right colon and terminal ileum may be the most effective approach in these patients.

Peer review

It is a retrospective study of 35 patients with bleeding intestinal angioectasias who had undergone complete endoscopic evaluation of the gastrointestinal tract. They showed that angioectasias were most commonly found in the jejunum (80%) followed by the duodenum (51%), stomach (22.8%), and right colon (11.4%). It has an interesting report but the main limitation its small sample size.

Abstract

AIM: To undertake a metasynthesis of qualitative studies to understand the health and social needs of people living with inflammatory bowel disease (IBD).

METHODS: A systematic search strategy identified qualitative studies exploring the phenomenon of living with inflammatory bowel disease. Databases included MEDLINE, PsychInfo, EMBASE, CINAHL and the British Nursing Index *via* the OVID platform. Qualitative search filters were adapted from Hedges database (http://www.urmc.rochester.edu/hsit/miner/digital_library/tip_sheets/Cinahl_eb_filters.pdf). Qualitative empirical studies exploring the health and social needs of people living with inflammatory bowel disease were selected. Study eligibility and data extraction were independently completed using the Critical

Appraisal Skills Programme for qualitative studies. The studies were analysed and synthesised using meta-synthesis methodology. The themes from the studies allowed for common translations into a new interpretation of the impact of living with inflammatory bowel disease.

RESULTS: Of 1395 studies, six published studies and one unpublished thesis fulfilled the inclusion criteria. First iteration of synthesis identified 16 themes, 2nd iteration synthesised these into three main 2nd order constructs: "detained by the disease"; "living in a world of disease" and "wrestling with life". "Detained by the disease" is the fear of incontinence, the behaviour the patients display due to the fear, and the impact this has on the individual, such as social isolation and missing out on life events. All of these serve to "pull" the patient back from normal living. "Living in a world of disease" is the long term effects of living with a long term condition and the fear of these effects. "Wrestling with life" is the continued fight to thrive, the "push" to continue normal living.

CONCLUSION: The metasynthesis provides a comprehensive representation of living with IBD. The un-mistakeable burden of incontinence is exposed and its ongoing effects are demonstrated. The combined overall impact of living with IBD is the tension these patients live with: "Pushed and pulled: a compromised life", people living with IBD experience a constant conflict throughout their lives, they push to be normal but IBD pulls them back. The impact of the fear of incontinence and behaviour of the individual as a result, requires further qualitative enquiry.

INTRODUCTION

Inflammatory bowel disease (IBD) is a chronic inflammatory disease of the gastrointestinal tract that is divided into two subgroups: Crohn's disease (CD) and ulcerative colitis (UC). Characterised by periods of remission and relapse, bowel movements may be up to 20 times per day with associated faecal urgency and incontinence. IBD is also associated with extra intestinal manifestations, affecting joints, eyes, skin, bones and organs as a consequence of the disease process^[1].

The disease often has a negative effect on the patient's emotional and social life, which are not always visually apparent^[2]. Loss of bowel control, feeling dirty and smelly, producing offensive body odours, unfulfilled potential in the workforce and issues with sexual relationships, were concerns ranked highly in a patient survey of people with IBD^[3]. One of the most prevalent concerns is fatigue^[3,4]. Fatigue in people with IBD was found to be comparable to those suffering from cancer^[5]. Fatigue affects the ability to work and socialise, confirming the disability associated with IBD^[6]. Unemployment and sick leave is more common in IBD patients compared to the general population^[7,8], with ability to work regarded as a global marker of the total impact of IBD^[3].

People with IBD have a poorer quality of life than the general population^[9-13] and are more likely to report increased levels of anxiety and depression with increased disease activity^[14]. Evidence reveals that the disease continues to impact on the individuals psychological status even when in remission^[9,15]. Overall, evidence suggests that the subjective experience of ill health associated with IBD does not always correlate with clinical disease activity.

The health-related quality of life (HRQoL) of people with IBD has been extensively evaluated with the development of two key disease specific tools: the Inflammatory Bowel Disease Questionnaire (IBDQ)^[16] and the Rating Form for Inflammatory Bowel Disease Patient Concerns (RFIPC)^[4]. The IBDQ was developed using survey methodology and measures subjective emotional and social functioning. The RFIPC was developed to measure neglected but important IBD concerns including disease related, body related, and inter/intrapersonal and sex related.

Whilst useful measures, the IBDQ and RFIPC fail to capture the essence of living with IBD from the patient's

perspective^[4,16]. For example, the RFIPC includes loss of bowel control as a concern but fails to encapsulate the real impact this has on the individual^[17]. A study exploring concerns and worries of patients with CD identified other concerns and worries that were not captured within the RFIPC^[18]. Objective indices within the tools do not fully summarize the patient's clinical symptoms, nor reflect the individual's experience of IBD^[19-21]. Failure to capture the lived experience of IBD has been confirmed by the European Federation of Crohn's and Colitis Associations (EFCCA) patient survey^[22] which reported that quality of life (QoL) and patient concerns were not taken into account when caring for patients with IBD, despite the plethora of studies highlighting this fundamental principle^[23-25]. The EFCCA study identified that half of the patients surveyed were not questioned by their doctor about the impact of their symptoms on their QoL.

In contrast to quantitative measures, qualitative methods are more able to capture the essence of living with IBD from the patients perspective^[26,27]. They can provide insight into the meanings, behaviours, experiences and beliefs of the participants with the aim of "drawing out understandings and perceptions and understand the linkages between process and outcomes"^[28].

In order to understand IBD, tailor treatment and provide personalised care, capturing the patient experience is imperative. There are a number of small scale qualitative studies exploring the experience of living with IBD from the patient's perspective but there is a need to synthesis this evidence to further understand this before undertaking larger in-depth qualitative studies. The studies relating to IBD are small and often are not published in journals normally accessed by healthcare professionals responsible for managing these patients. Meta synthesis meets this need by the systematic selection, comparison and analysis of these qualitative combined studies and translating them to create new interpretations^[28].

The qualitative meta synthesis is a set of techniques for the interpretive integration of qualitative research findings^[29], it overcomes the limitations of small studies^[30] and has the ability to promote a greater understanding in a particular area^[31]. In this study, the purpose was to integrate and interpret the qualitative studies of the experience of living with IBD. Systematic reviews are accepted as the cornerstone of evidence based practice^[32] and are based on reviews of effectiveness and of "what works". However there is now a move toward addressing the wider questions, such as why there is a problem in the first place and how it has come about. These questions need to be answered in order to develop patient centred interventions^[33,34], implement studies of effectiveness and provide answers for the policy makers^[31,33].

MATERIALS AND METHODS

Inclusion criteria

Qualitative studies which explored the phenomena of

Figure 1 Flow chart summarising search strategy.

living with IBD from the patient's perspective were included in the synthesis. Additional inclusion criteria were studies restricted to English language only, published and unpublished studies and sample population adults > 16 years.

Exclusion criteria

The study focused on only one aspect e.g. living with a colostomy or diet, and mixed studies of irritable bowel syndrome and IBD.

Systematic search

Electronic literature searches were conducted in MEDLINE (1966-2010), PsychInfo (1967-2010), EMBASE (1980-2010) and CINAHL databases (1982-2010) and the British Nursing Index (1994-2010) via the OVID platform. Search filters developed by the Hedges database from McMaster University Health Information Research Unit and Kathryn Nesbit, Edward G Milner Library, University of Rochester Medical Centre, were adapted to aid the search (http://www.urmc.rochester.edu/hslt/miner/digital_library/tip_sheets/Cinahl_eb_filters.pdf). The search was conducted from the inception of the databases to August 2010. Web of Knowledge and CINAHL were used for citation searches, foot note chasing and journal runs. Author searches were also incorporated into the search of the literature from journals including Qualitative Health Research, Gastroenterology Nurse, and Inflammatory Bowel Diseases^[35].

Of the 1395 papers generated by the preliminary search of all the databases combined, 1282 were excluded as they were irrelevant to the study question. 113 abstracts were selected for further review, of which 92 were excluded based on duplication, quantitative methodology, and wrong subject matter. Four unpublished dissertations were identified within this and obtained,

two excluded due to the quantitative methodological approach used^[36,37], the remaining two were included for initial screening^[38,39]. Full text papers were obtained for the remaining 17 papers. These 17 papers and two dissertations were then screened for initial inclusion using three screening questions: Does this paper report on findings taken from qualitative work? Did the work involve both qualitative methods of data collection and analysis? Is this research relevant to the topic area?^[40].

Of the 17 papers and two dissertations screened, 11 papers and one dissertation were excluded from the synthesis. The dissertation was excluded as no qualitative methodological analysis was undertaken^[39]. The remaining papers were excluded based on: methodological approach used an online survey method^[19]; paediatric age group^[41]; subject matter focused on living with an ostomy^[42]; narrative journey with no qualitative methodology^[43]; participant responses used to validate commonly used indices^[21] and six papers excluded as the subject group was a mixture of patients with IBD and irritable bowel disease and unable to distinguish between responses from each group^[44-49].

The final selection of six papers^[17,50-54] and one unpublished dissertation^[38] were reviewed by all three authors. Data extraction forms were developed and data extraction, including study eligibility, study demographics, study characteristics, and themes, and data extraction were independently completed by three reviewers (Kemp K, Griffiths J, Lovell K).

The CASP^[55] tool was used to quality appraise the papers and also to aid the interpretation and exploration process of the synthesis^[56]. Further synthesis of the themes from the studies was agreed collectively at synthesis meetings to develop the new translations. The search summary is found in Figure 1 and full details of the search strategy are available from the authors.

RESULTS

Seven studies met the inclusion criteria. Summaries of the included studies are given in Table 1 and their corresponding demographics in Table 2. A list of excluded studies is available from the authors.

Characteristics of included studies

The seven selected studies were published from 1996-2010. Two were conducted in the United Kingdom^[50,54], one in Sweden^[52], one in Canada^[51], one in New Zealand^[53], and two in America^[17,38]. All of the studies used in depth interviews^[17,38,51-54] and one study combined interviews with focus groups^[50].

A total of 86 patients with an age range was 16-83 years were included and only one reported one patient from an ethnic background^[52]. Two studies focused on CD only^[52,53], and one study UC patients only^[17]. The remaining studies included people with both UC and CD. Patients were recruited from relevant national IBD charities^[38,53], directly from outpatients clinics^[17,52,54], media advertisements^[51], and from a previous community

Table 1 Characteristics of synthesised studies

Ref.	Theoretical perspective	Sampling strategy	Recruitment setting	Data collection method	Analytical approach
Dudley-Brown ^[17]	Phenomenological	Convenience sample (n = 3)	Patients sampled from IBD outpatient clinic when attending for their scheduled appointment	In depth semi structured interviews	Coding and memo system used, grouped and transformed into an interpretive understanding of the phenomenology of living with UC, with the extraction of emergent themes
Daniel <i>et al</i> ^[51]	Phenomenological	Purposive sample (n = 5)	Patients recruited by an advertisement in national newspaper	In depth semi structured interviews	Kings Goal Attainment Framework used as theoretical framework; thematic content analysis of interviews to develop themes in line with this framework
Hall <i>et al</i> ^[50]	Grounded theory	Purposive sample (n = 31)	Recruited from a previous unconnected study, sampled by lowest quintile of UK-IBDQ, established low quality of life	In depth interviews and focus groups	Concurrent data collection and analysis to identify emerging themes; selective coding was used to enabled theoretical framework
Burger <i>et al</i> ^[38]	Interpretive phenomenological design	Convenience sample (n = 8)	Participants from mailing list of Indiana Chapter of Crohn's and Colitis Foundation of America, answered advert and recruited according to inclusion/exclusion criteria	In depth interviews, each participant interviewed 3 times	Thematic analysis, identification analysis and identification of paradigm cases used
Lynch <i>et al</i> ^[53]	Phenomenological	Purposive sample (n = 4)	Participants recruited from Crohn's and Colitis New Zealand	Semi structured in depth interviews	Thematic analysis from transcribed data, ongoing process of interpretation used to refine themes to describe nature of the experience
Pihl-Lesnovska <i>et al</i> ^[52]	Grounded theory	Theoretical sample (n = 11)	Patients recruited from the gastroenterology outpatient clinic	Unstructured in depth interviews	Constant comparative analysis used, saturation determined sample size; core category and related categories identified; two authors analysed all interview transcripts
Cooper <i>et al</i> ^[54]	Framework	Purposive sampling (n = 24)	Patients sampled from IBD outpatient clinic when attending for their scheduled appointment	Semi structured in depth interviews	Thematic content analysis using framework

IBD: Inflammatory bowel disease; UK-IBDQ: United Kingdom version of the McMaster Inflammatory Bowel Disease Questionnaire; UC: Ulcerative colitis.

IBD: Inflammatory bowel disease.

based study^[50]. The theoretical perspectives were mainly phenomenology^[17,38,51,53] and grounded theory^[50,52] with one study using framework^[54].

Synthesis of the evidence

The three authors independently reviewed all of the studies. The emergent themes were subject to constant examination until an argument to explain the data of the combined studies was developed. The themes and

findings of each study were compared with one another repeatedly to identify the 1st order constructs. This revealed the similarities and differences in the data, which led to 2nd order constructs and the interpretation of all of the synthesised studies. For example, study 1 may have had findings AB and C, study 2 may have findings AC and D, a new finding. The synthesis from studies 1 and 2 was compared to study 3 and so forth, until all of the papers were synthesised^[29,57]. Early on in the synthe-

IBD: Inflammatory bowel disease.

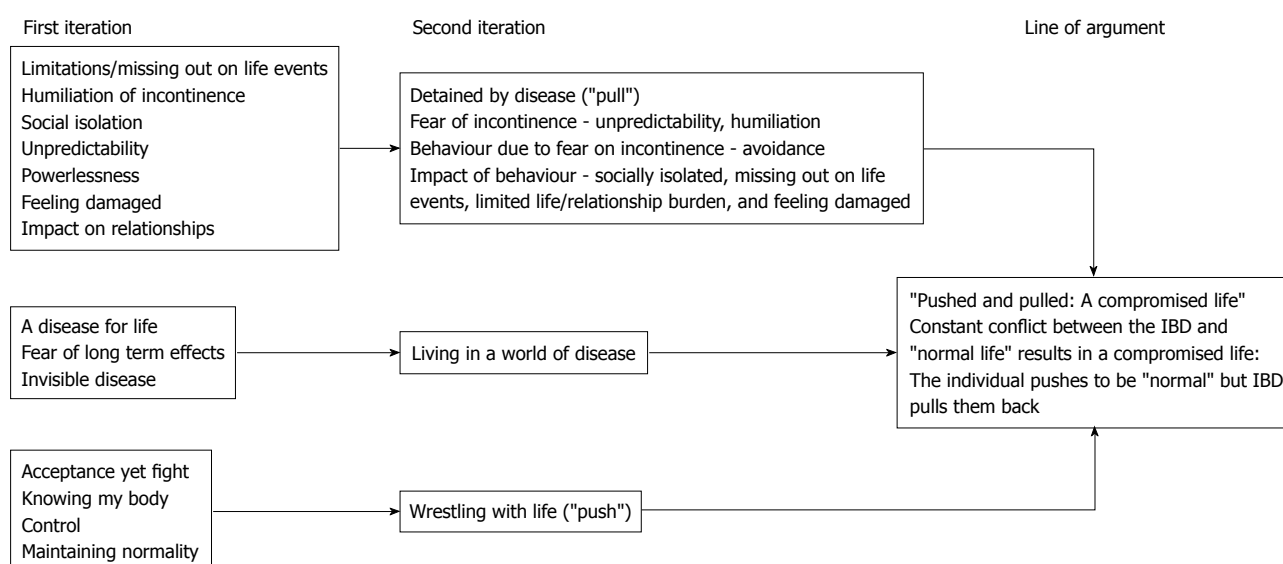

Figure 2 Relationship between synthesised studies. IBD: Inflammatory bowel disease.

sis it was clear that the relationship between the studies was mutual, all sharing common themes^[58]. As the studies had a "reciprocal" arrangement, a new argument was developed. This process was followed systematically, starting with the oldest study first^[17] in keeping with the model of "line of argument" synthesis^[58]. The themes and concepts are illustrated in Table 3 and the relationship between them identified in Figure 2.

Results - synthesis of the evidence

The synthesis of the seven studies identified that people with IBD endure many daily challenges, stress, pain, fatigue, and fighting for control. The combined impact of living with IBD is the tension they live with. The meta-synthesis has provided an in-depth exploration of living

with IBD: "pushed and pulled: a compromised life", people living with IBD experience a constant conflict throughout their lives, they push to be normal but IBD pulls them back.

Living in a world of disease

A disease for life: Participants were acutely aware that they had been diagnosed with a long term condition with no cure. Facing and accepting the incurable illness was met with a variety of responses yet the need to get back to normal, but inability to do so, was a theme running through all of the studies.

Fear of long term effects: The fear of long term effects, of death and dying left people feeling powerless^[52].

The risks of cancer development and passing on the illness to children added to the burden of living with the physiological aspects of the illness^[38,52].

Invisible disease: A difficult aspect of living with IBD is its invisibility^[17,38,52,53]. The studies detail how this concept affected the individuals. The lack of understanding from others doubting that they were actually sick as it was not visible, added to their feelings of anger and frustration, in particular with family members^[51]. “My sister says I’m blowing this up...it’s an act...I’m trying to get attention”^[51].

Wrestling with life: Striving to thrive (“push”)

Acceptance yet fight: A common theme throughout all of the studies was the individual’s willingness and need to wrestle with their illness. Three of the studies discussed the acceptance of living with the illness yet continuing to fight it^[38,52-54]. This can be interpreted as neither a submission to the illness nor as out and out combat but more where individuals made peace with their illness. “This is how I am...to me it’s no different than saying I have a dog”^[38].

Control: The concept of control is visible in all seven studies, whether this was trying to control the illness^[50], controlling bowel urgency^[38] or losing control^[51]. Individuals fought to gain and maintain control and find a balance between what they could control and what they needed to control, for life to be acceptable^[54]. Gaining “control” had a positive impact on the individuals, recognising “performance accomplishments”^[54] and allowing them to feel “normal”^[50]. However the cost of achieving this was a large trade off which was capable of wearing the individual down and losing its ability to continue to fight, fatigue becoming a significant problem^[50]. Attempting to control their illness was their attempt to try to maintain “normality” for many people within the studies^[38,50,52,53].

Knowing my body: Participants voiced the theme of “knowing my body”, with accounts of knowing when their illness flared up better than their doctor. An increased awareness of their body led the individuals to try to identify triggers or patterns and recognise when their illness flared up. By learning about their own body the individual tried to gain some scale of control but often this concluded in them feeling helpless and misunderstood^[53]. “He stated that he knew it was not his CD even though it was the physician’s first inclination”^[38]. Wrestling with life culminates with the individual pushing to be normal, accepting their illness yet striving to thrive and survive.

Detained by the disease (“pull”)

Fear of incontinence (unpredictability, humiliation): All of the studies report the patient’s fear of incontinence and how they try to live with this^[17,38,50-54]. The fear appeared to be associated with past experiences of

actual episodes of incontinence and remembering the humiliation this produced. Actual episodes were rare but the fear remained constant. Patients felt ashamed, not only of the actual incontinence but also of their ongoing fear. Some people reported the overwhelming shame of incontinence. Shame and humiliation was even experienced within the family unit, one grandmother describing the embarrassment should her grandchildren know that she cannot make it to the bathroom^[38,51,54]. This fear of incontinence was all consuming for some patients and became a focus of living with IBD, over and above the physical symptoms. “It’s terrible, but that’s the biggest fear”^[38].

Behaviour due to fear of incontinence (avoidance):

The fear of incontinence and its unpredictability had a profound effect on the individual’s behaviour. For many this fear led to an avoidance or curtailing of daily activities and impaired individuals work, social and leisure and private functioning^[17,38,51].

Individuals used a range of coping strategies to either manage or avoid incontinence and included carrying pot-ties and spare clothes, wearing nappies and identifying bathrooms prior to any travel^[17,38]. Travelling anywhere required extra time and was dictated by the individual’s bowel frequency and control. “Planning an escape route provided a sense of security even if it was not needed”^[38].

The impact of this behaviour led to avoiding places and people. Studies describe patients only attending safe places^[50] with a dependency on toilets^[51] or avoiding public places all together^[17].

Impact of behaviour (missing out on life events, socially isolated):

The fear of incontinence, coupled with avoidance behaviour, was immensely detrimental to the individual’s QoL. They became socially isolated very easily: had limited activity with family and friends^[38]; became reclusive^[50]; and missed out on life events^[51]. The self enforced social isolation led to feelings of social inadequacy, lacking the necessary societal skills for everyday living^[51]. “I’ve just missed a whole part of my life”^[51].

Individuals expressed feeling damaged, a failure, weak and feeble with overwhelming feelings of anger, frustration and depression^[50,53]. Unable to identify a pattern or trigger for their disease reinforced all of these negative emotions^[17,38,53].

Stress was overtly discussed in five studies^[38,51-54]. Triggers for stress ranged from the illness itself to outside factors such as the ability to work and financial concerns and manifested itself in the form of fatigue and exacerbations of their disease. Lack of understanding from family members and feeling redundant in the family home^[50] left people feeling alienated from partners and family^[51], and people reported complex emotions of “letting people down”^[53].

Fatigue, tiredness and exhaustion contributed to people’s feelings of frustration, stress and powerlessness^[52]. Some people felt that fatigue was a sign of weakness^[53] and was generally misunderstood by others^[50] as it was

not evidently visible, reinforcing the invisibility of the disease.

Detained by the disease became evident as the analysis of the studies revealed that the fear of incontinence, the behaviour associated with it and the resultant enforced social isolation, resulted in “pulling” the individual back from “normal” living.

Line of argument

A line of argument was derived from the synthesis of the seven studies^[58]. The common translations from the studies were taken a step further and constructed into a new interpretation.

Line of argument synthesis: the ongoing factors identified by the qualitative studies impact on the individual's whole life with IBD leading to a compromised life: the individual pushes to be normal yet IBD pulls them back. The individual is in constant conflict, fighting to be normal with the impact of this resulting in constant tension within.

The synthesised studies revealed the fear and humiliation surrounding incontinence which resulted in severely reduced social interactions. Descriptions how the illness “intruded” into the participant's life and the constant “fight” for normality was evidenced throughout all of the studies. Phrases, including the “see-sawing of fears and hopes”, illustrate the uncertainties and contradictions of living with IBD. Importantly, the individuals describe the courage required to break the social isolation resulting from bowel symptoms. All of these aspects of living with IBD are directly related to everyday life.

DISCUSSION

The aim of this metasynthesis was to provide an interpretation of the health and social needs of patients living with IBD by synthesising qualitative studies and key issues emerged. People with IBD endure many daily challenges including stress, pain, and fatigue and fighting to maintain normality. The combined overall impact of living with IBD is the tension these patients live with. The value of metasynthesis is the interpretation of all of the synthesised studies to provide an inclusive representation of living with IBD: “Pushed and pulled: a compromised life”, people living with IBD experience a constant conflict throughout their lives, they push to be normal but IBD pulls them back.

Considering the plethora of evidence pertaining to the patient's QoL, symptom burden, and psychosocial factors related to IBD^[3,10,12,25,59,60], there are few qualitative studies directly exploring the patient's beliefs and behaviours from the patient's perspective. Only seven studies were identified, six published and one unpublished thesis, the earliest undertaken in 1996 and the latest in 2010, during a 14 year time span. The studies amount to only 86 patient accounts of living with IBD.

People diagnosed with a chronic disease must adjust to the demands of the disease as well as to the treatments for their condition^[61]. The disease may affect how

the individual perceives him or herself and their relationship with others. The shifting perspectives model of chronic illness determined that life with a chronic illness does not follow a predictable trajectory but people experience a “complex dialectic between themselves and their world”^[62]. This process of debate and argument, trying to cope with the disease is all encompassing; the individual with IBD lives in a world of disease, even when in remission.

Studies have identified the long term complications of IBD, such as bone problems and colorectal cancer^[63]. These potential long term complications heighten the individual's fear of the disease. The uncertain nature of the illness and developing cancer were concerns ranked highly for people with IBD^[4,23]. The fear of long term complications and dying are difficult discuss with others when outwardly the individual appears fine^[38,51].

The issue of control is important within all of the studies. The ability to take control and the relationship with psychological functioning has been established in the literature. Personal control may be informed by self efficacy^[64] or the Common Sense Model whereby the extent to which the individual believes that their illness is manageable and possible to control, becomes focal to their behaviour^[65]. Individuals with IBD have been found to have significantly poorer psychological health than those without IBD^[66] and the metasynthesis has illustrated that control and coping are important factors and assist the psychological well being in these individuals. Controllability and coping strategies were closely linked to knowing how their body reacted to their illness and identification of flare ups^[38], maintaining normality and acceptance of IBD within the individual's life^[50,52-54].

The unmistakeable burden of the fear of incontinence, the behaviour related to this fear and the impact of this behaviour on the individual, is exposed and its ongoing effects are demonstrated much more clearly by the metasynthesis. An early study identified urgency of defecation and the fear of incontinence as factors affecting the QoL in individuals with CD^[54]. Behaviour due to fear and coping strategies, such as avoidance of public places, carrying potties when leaving the house^[38], changing working schedules^[21], have been identified in other studies, but the collective impact of this fear and behaviour reveals the true impact IBD has on the individual. The humiliation of incontinence and unpredictable nature of the disease leave the individual socially isolated and missing out on important life events. The reality that this fear and behaviour continues into disease remission compounds the stress, fatigue and debilitating nature of it.

All of the synthesised studies identified the issue of incontinence but the unmistakeable burden of this is exposed and its ongoing effects are demonstrated much more clearly by the metasynthesis, supporting the value of the metasynthesis and its ability to interpret studies into new translations.

There are limitations to the metasynthesis: the low number of people with IBD included in the synthesis;

the subjective nature of the synthesis; and grouping studies from various countries with different and changing health care systems over a period of 14 years and combining them and the advent of biologic drugs. The countries have similar socio-economic systems with developed healthcare resources but differ in terms of the financial aids required to access healthcare. Over the past decade the profile of chronic disease management has increased due to the aging population and the role of health care in the management of this area has changed dramatically with greater emphasis placed on self management. Early studies may be deemed outdated. However the methodology of the metasynthesis and the accounts of living with IBD in the studies remain important to capture the phenomenon of living with IBD.

Based on our analysis, we conclude that the fear of incontinence, the behaviour related to this fear and the impact of this behaviour on the individual, are perhaps the most significant issues to emerge from the metasynthesis. The findings highlight the daily challenges and tensions that individuals with IBD face, whether their disease is in remission or not. Evidence has found the incidence and prevalence of IBD to be increasing, indicating its emergence as a global disease^[67]. Perhaps with the emergence of biologic therapies and gene identification, emphasis has been placed upon the acute aspect of IBD and the chronicity of the disease is forgotten.

The physical symptoms alone do not validate the subjective impact of living with IBD^[3]. The psychological burden of living with IBD, QoL and specific psychological co morbidities are described as “un-promoted issues”: issues that are not always addressed in the medical literature^[68]. Identification and clarity of these “un-promoted issues” can only be met by undertaking qualitative studies and health care professionals need to be aware of the influences these have on the individual when developing treatment strategies. More focused attention on the patient’s perspective of living with IBD is needed to provide patient centred care and structure health care services. The emergence of the immense impact of incontinence, fear and behaviour on the individual from this metasynthesis requires further qualitative enquiry.

COMMENTS

Background

The incidence and prevalence of inflammatory bowel disease (IBD) is increasing and it is being recognised as a global long term condition, with significant morbidity and cost. In order to provide patient centred care, an understanding of the impact of living with IBD, from the patient’s perception, is important. The Rating Form for IBD Patient Concerns and Inflammatory Bowel Disease Questionnaire are widely used measures to describe what it is like to live with IBD but these fail to capture the essence of this. There are few qualitative studies which fully demonstrate the impact of living with this condition. By using metasynthesis methodology, this study adds significant understanding of IBD and the impact of living with IBD, from the patient’s perspective.

Research frontiers

There is growing emphasis that the needs and preferences of patients must be addressed when developing and evaluating new models of care delivery. Incorporating patient preference, choice and experience is acquired through qualitative studies. Synthesising qualitative studies of IBD gives a profound insight into

the disease. Capturing this evidence can lead to a greater understating of the condition and help to tailor treatments and provide personalised care.

Innovations and breakthroughs

Recent audits from the European Federation of Crohn’s and Colitis Association has demonstrated, on a large scale, the impact IBD has on the individual’s personal, work and social life. This audit highlighted some important considerations of IBD care in Europe, however, a more immersed understanding is required. This is the first metasynthesis of IBD and provides a comprehensive insight of what it is like to live with.

Applications

The findings from this study emphasises the impact incontinence has on the individual, even in remission. The fear of incontinence, the behaviour related to this fear and the impact of this behaviour on the individual, are the most significant issues to emerge from the metasynthesis, and requires further qualitative enquiry.

Terminology

IBD is a collective term for Crohn’s disease and ulcerative colitis. Qualitative studies typically use focus groups and/or interviews to gather data. Qualitative studies, from the patient’s perspective, are used to highlight the lived experience of a phenomenon. Metasynthesis is a method of identifying and bringing together (synthesising) relevant research evidence from a variety of qualitative studies. Metasynthesis methodology seeks to expand the understanding of patient experience.

Peer review

The enclosed metasynthesis analyses the data from the literature regarding understanding the health and social care needs of patients with IBD. The paper is very well written. The authors observed that the most significant issues were fear of incontinence, the behaviour related to this fear and the impact of this behaviour on the individual. This paper adds a lot of important information on health quality of life in IBD patients and help readers to understand the IBD more.

Abstract

AIM: To evaluate the role of sequential therapy and *Lactobacillus reuteri* (*L. reuteri*) supplementation, in the eradication treatment of *Helicobacter pylori* (*H. pylori*).

METHODS: *H. pylori* infection was diagnosed in 90 adult dyspeptic patients. Patients were excluded if previously treated for *H. pylori* infection or if they were taking a proton pump inhibitor (PPI), H₂-receptor antagonist or antibiotics. Patients were assigned to receive one of the following therapies: (1) 7-d triple therapy (PPI plus clarithromycin and amoxicillin or metronidazole) plus *L. reuteri* supplementation during antibiotic treatment; (2) 7-d triple therapy plus *L. reuteri* supplementation after antibiotic treatment; (3) sequential regimen (5-d PPI plus amoxicillin therapy followed by a 5-d PPI, clarithromycin and tinidazole) plus *L. reuteri* supplementation during antibiotic treatment; and (4) sequential regimen plus *L. reuteri* supplementation after antibiotic treatment. Success-

ful eradication therapy was defined as a negative urea breath test at least 4 wk following treatment.

RESULTS: Ninety adult dyspeptic patients were enrolled, and 83 (30 male, 53 female; mean age 57 ± 13 years) completed the study. Nineteen patients were administered a 7-d triple treatment: 11 with *L. reuteri* supplementation during and 8 after therapy. Sixty-four patients were administered a sequential regimen: 32 with *L. reuteri* supplementation during and 32 after therapy. The eradication rate was significantly higher in the sequential group compared with the 7-d triple regimen (88% vs 63%, $P = 0.01$). No difference was found between two types of PPI. No difference in eradication rates was observed between patients submitted to *L. reuteri* supplementation during or after antibiotic treatment. Compliance with therapy was excellent in all patients. No difference in adverse effects was observed between the different antibiotic treatments and between patients submitted to *L. reuteri* supplementation during and after antibiotic treatment. There was a low incidence of adverse effects in all groups of patients with sequential therapy, probably due to the presence of the *L. reuteri* supplementation.

CONCLUSION: The sequential treatment regimen achieved a significantly higher eradication rate of *H. pylori* compared with standard 7-d regimen. *L. reuteri* supplementation could reduce the frequency and the intensity of antibiotic-associated side-effects.

Helicobacter pylori eradication: Sequential therapy and *Lactobacillus reuteri* supplementation. *World J Gastroenterol* 2012; 18(43): 6250-6254 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i43/6250.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i43.6250>

INTRODUCTION

Helicobacter pylori (*H. pylori*) infection is a worldwide disease causing significant morbidity. At present, the role of this infection is well known, particularly in peptic ulcer disease, gastric neoplasia (mucosa-associated lymphoid tissue-lymphoma and carcinoma), non-ulcer dyspepsia (chronic gastritis) and the possible interaction with non-steroidal anti-inflammatory drugs to damage the gastric mucosa^[1-3].

There are numerous treatment options for curing *H. pylori* infection and many are still under investigation. The eradication rate of *H. pylori* following 7-d triple treatment [proton pump inhibitor (PPI) plus clarithromycin and amoxicillin or metronidazole] is decreasing due to an increasing prevalence of bacterial resistance, poor patient compliance and the occurrence of antibiotic adverse effects^[4]. Therefore, further approaches aimed to improve standard triple therapy efficacy should be attempted. In some large studies^[5-7], a sequential regimen, i.e., simple 5-d dual (PPI plus amoxicillin) therapy followed by a 5-d triple therapy (PPI, clarithromycin and tinidazole) was more effective than 7-d triple treatment (PPI plus clarithromycin and amoxicillin or metronidazole), with few adverse effects in children, adults and elderly patients. Moreover, the Italian Working Group of the Cervia II meeting advised the use of sequential therapy as an alternative to 7-14 d triple therapy as first-line treatment^[8].

As reported by the Maastricht III Consensus Report, probiotics could also play a relevant role in the management of *H. pylori* infection by improving treatment tolerability and increasing eradication rates^[4]. Indeed, some *Lactobacilli* have been shown to possess antagonistic activity against *H. pylori*, both *in vitro* and *in vivo*^[9,10]. *L. reuteri* ATCC 55730, a probiotic of human origin, has been demonstrated to reduce adverse effects during antibiotic therapy and to increase eradication of the *H. pylori* infection^[11-13]. Further studies support that *L. reuteri* colonizes the human gastric mucosa, inhibits the binding of *H. pylori* to gastric epithelial cell lines and suppresses *H. pylori* urease activity^[14-16].

The primary end-point of our prospective study was to compare the eradication rate of 7-d triple treatment with a sequential regimen. The secondary end-point was to evaluate the role of *L. reuteri* supplementation in *H. pylori* infection.

MATERIALS AND METHODS

Patients

Between January 2008 to December 2009, 90 adult dys-

peptic outpatients aged > 18 years were consecutively referred to our Division of Gastroenterology. One hundred and five outpatients were screened for enrolment and only 15 of these were excluded. The exclusion criteria were the following: (1) the presence, at endoscopy evaluation, of an active gastro-duodenal ulcer; (2) previous treatment for *H. pylori* infection; (3) PPI, H2-receptor antagonist or antibiotic treatment in the 4 wk before the study; and (4) a known allergy to the antibiotics used in the present study. No subjects had gastric malignancy at endoscopy.

H. pylori assessment

Patients were enrolled if *H. pylori* infection was detected. *H. pylori* infection was diagnosed based on an upper endoscopy with gastric biopsy (2 samples from the antrum and 2 samples from the corpus) or by means of the *H. pylori* stool antigen-test (SAT) or the ¹³C urea breath test (UBT). The gold standard for *H. pylori* diagnosis was an upper endoscopy with multiple gastric biopsies. All but 5 patients underwent endoscopy and, in 3 of these, *H. pylori* status was assessed by UBT and by SAT in the remaining 2 patients.

Urea breath test: Citric acid (1.5 g) as test meal and 75 mg of ¹³C-urea as water solution were given to the patients after collection of a baseline sample, obtained by blowing through a disposable plastic straw into a 20 mL container, and a further breath sample was collected 30 min later. The breath samples were considered positive if there was a greater than 5 per 1000 of ¹³CO₂ difference over baseline, according to the manufacturer's recommendations.

***H. pylori* stool antigen-test:** *H. pylori* in stool specimens was investigated by a commercial enzymatic immunoassay test (Bioscience). The enzyme immunoassay utilized for the detection of *H. pylori* antigens in human stool was the Premier Platinum HpSA Plus. The test utilizes monoclonal anti-*H. pylori* capture antibody adsorbed to microwells. Diluted patient samples and a peroxidase-conjugated polyclonal antibody were added to the wells and incubated for 1 h at room temperature. A wash was performed to remove unbound material. Substrate was added and incubated for 10 min at room temperature. Color developed in the presence of bound enzyme. Stop solution was added and the results were interpreted visually or spectrophotometrically.

Treatments

The 7-d triple therapy included a PPI 20 mg *bid* plus clarithromycin 500 mg *bid* and amoxicillin 1 g *bid* for 7 d, while the sequential regimen consisted of 5-d dual (PPI 20 mg *bid* plus amoxicillin 1 g *bid*) therapy followed by a 5-d triple therapy (PPI 20 mg *bid*, clarithromycin 500 mg *bid* and tinidazole 500 mg *bid*). The PPI (lansoprazole or pantoprazole) was continued for 30 d at a dose of 20 mg daily. A Reuflor tablet (kindly provided by Italchimici, Rome) containing *L. reuteri* (ATCC 55730; 10⁸ CFU)

Figure 1 *Helicobacter pylori* eradication rate in the following groups of patients. 1: 10-d sequential therapy plus *Lactobacillus reuteri* (*L. reuteri*) post therapy; 2: 10-d sequential therapy plus *L. reuteri* during therapy; 3: 10-d sequential therapy; 4: 7-d standard triple therapy plus *L. reuteri* post therapy; 5: 7-d standard triple therapy plus *L. reuteri* during therapy; 6: 7-d standard triple therapy. The eradication rate was significantly higher in the sequential group compared with the 7-d triple therapy group (88% vs 63%, $P = 0.01$). No difference was found between patients submitted to *L. reuteri* supplementation during or after antibiotic treatment.

was taken once a day. Some patients received *L. reuteri* supplementation after the 7th or 10th day of antibiotic therapy, 12 h after administration of the last tablet of antibiotic. The other patients received the *L. reuteri* on the first day of antibiotic treatment.

For each therapy regimen, the PPI was prescribed 30 min before breakfast and dinner, whereas all antibiotics were given immediately after these meals.

Study groups

Consecutive patients were assigned to receive one of the following therapies: (1) 7-d triple therapy plus *L. reuteri* supplementation during the antibiotic treatment; (2) 7-d triple therapy plus *L. reuteri* supplementation after the antibiotic treatment; (3) 10-d sequential regimen plus *L. reuteri* supplementation during the antibiotic treatment; and (4) 10-d sequential regimen plus *L. reuteri* supplementation after the antibiotic treatment.

In detail, the patients enrolled between 1 January 2008 and 30 November 2008 were treated with 7-d triple therapy, while those enrolled between 1 December 2008 and 31 December 2009 were treated with sequential therapy.

Informed consent was obtained from all patients enrolled in the study. The local Ethical Committee approved the study protocol.

Follow-up

Patients were asked to return at the end of treatment to assess the compliance with therapy and to determine possible adverse effects. Compliance was defined as consumption of > 90% of the prescribed drugs. Adverse effects were evaluated using a structured questionnaire by personal interview. Bacterial eradication was checked in all patients at least 4 wk following the eradication treatment by using UBT.

Table 1 Demographic characteristics of the patient groups

Therapy	Patients	Mean age (yr)	Male/female
7-d standard triple therapy plus <i>L. reuteri</i> during therapy	11	54 ± 8	6/5
7-d standard triple therapy plus <i>L. reuteri</i> post therapy	8	59 ± 5	2/6
10-d sequential therapy plus <i>L. reuteri</i> during therapy	32	57 ± 2	7/25
10-d sequential therapy plus <i>L. reuteri</i> post therapy	32	60 ± 2	11/21

L. reuteri: *Lactobacillus reuteri*.

Statistical analysis

The data are expressed as mean ± SE. The statistical analysis was conducted by χ^2 test. $P < 0.05$ was considered statistically significant.

RESULTS

Overall, ninety adult dyspeptic patients were enrolled in the study. All but 7 patients completed the study, with one lost to follow-up and 6 noncompliant. Therefore, 83 patients (30 male, 53 female; mean age 57 ± 13 years) completed the study. Nineteen patients were administered a 7-d triple treatment: 11 with *L. reuteri* supplementation during and 8 after therapy. Sixty-four patients were administered the sequential regimen: 32 with *L. reuteri* supplementation during and 32 after therapy (Table 1).

The eradication rate was significantly higher in the sequential group compared with the 7-d triple therapy; 88% vs 63%, $P = 0.01$ (Figure 1). No difference in eradication rates was observed between patients submitted to *L. reuteri* supplementation during or after antibiotic treatment. No difference was found between the two different types of PPI (lansoprazole or pantoprazole).

Compliance and adverse effects

The reported compliance with therapy was excellent in all patients. All adverse effects, mainly mild diarrhea and abdominal pain, were self-limiting after the end of therapy. No difference in the number and type of adverse effects was observed between the different antibiotic regimens and between patients submitted to *L. reuteri* supplementation during or after antibiotic treatment.

DISCUSSION

In the last few years, with an increasing prevalence of antimicrobial resistance, the *H. pylori* cure rate with standard triple therapy has declined to unacceptable levels (i.e., 80% or less) in most countries. Two very large meta-analyses showed that standard 7-14 d triple therapies fail to eradicate *H. pylori* infection in up to 25% of patients^[17,18]. More recent data have demonstrated that triple therapy with amoxicillin, clarithromycin and a PPI has an eradication rate of only 74%-76%^[19]. Therefore, several treatment regimens have emerged for cure of

H. pylori infection. In Italy, since the prevalence of primary clarithromycin resistance is higher than 15%^[20,21], the Cervia II Working Group advised the use of 7-14 d triple therapies or a sequential therapy, as first-line treatment. To date, the efficacy of sequential therapy has been investigated in 22 trials including more than 2000 patients. The success rate of the sequential regimen was distinctly higher than that achieved by standard triple therapies^[22,23]. Zullo *et al.*^[18] found that the sequential regimen was significantly superior to either 7-d and 10-d standard triple therapies with an overall eradication rate of 93.7%, 75.9% and 79.6%, respectively. These results were confirmed in 2 other recent meta-analyses^[24,25]. It was known that a dual therapy (PPI plus amoxicillin) administered for less than 7 d was able to achieve a cure rate of up to 50%, and that the efficacy of a triple therapy (PPI, clarithromycin and tinidazole) was inversely related to the bacterial load, with higher eradication rates being achieved in those with a low bacterial density in the stomach. Because amoxicillin acts on the bacterial cell wall and damages it, the initial phase of treatment may prevent the development of efflux channels by weakening the cell wall of the bacterium. An important limitation is that data regarding the efficacy of the sequential regimen mainly came from Italian studies, and the use of metronidazole instead of tinidazole in different studies performed in other geographic areas could reduce the eradication rate^[26,27].

The primary aim of this study was to evaluate the efficacy of sequential therapy compared with standard triple therapy. We found that the eradication rate was significantly higher in the sequential group as compared with the 7-d triple therapy group (88% *vs* 63%; *P* = 0.01). These results confirm that 10-d sequential therapy is superior to standard regimens (range: 91%-96% *vs* 71%-83%), as reported by systematic reviews and meta-analyses of randomized, controlled trials comparing these 2 treatments and published until October 2008^[24,25,28]. Some prospective randomized Italian studies also more recently^[16,29,30], confirmed these results, constantly achieving very high (range: 92%-95%) eradication rates in children, adults, and elderly patients treated with sequential therapy compared with 7-d or 10-d triple treatment (range: 74%-77%).

The secondary end-point was the assessment the role of *L. reuteri* on the outcome of *H. pylori* infection. Among probiotics, it was demonstrated that *L. reuteri* colonizes the human gastric mucosa, inhibits the binding of *H. pylori* to gastric epithelial cell lines and suppresses *H. pylori* urease activity^[14-16]. Interestingly, in some studies^[12,31], monotherapy with *L. reuteri* showed a reduction in the *H. pylori* bacterial load.

In our population, all patients were assigned to receive *L. reuteri* supplementation. In the sequential therapy group, the eradication rate of *H. pylori* with this probiotic was 88%, similar to that reported in literature. In a double-blind placebo-controlled study^[16], *H. pylori*-positive adult subjects were given *L. reuteri* for 4 wk before antibiotic therapy or placebo. As with our results after the

10-d sequential regimen, the rate of *H. pylori* eradication in those who had received the probiotic was 88%.

In our study, in the 7-d therapy group, the eradication rate of *H. pylori* was 63%, greater than 53% reported by a prospective, pilot study^[32] in a subgroup of patients assigned to receive the same therapy with *L. reuteri* supplementation.

In our population, it a low incidence of adverse effects was observed in all groups of patients with sequential therapy, probably due to the presence of *L. reuteri*.

In conclusion, sequential therapy appears to be more effective than standard 7-d triple therapy, and *L. reuteri* supplementation could play a role in the eradication of *H. pylori*, but a large, double-blind, controlled study is needed to confirm these results and to explain the exact function of *L. reuteri*. Indeed, it may improve the tolerability to antibiotic therapy by decreasing adverse effects or play a primary role in the eradication of *H. pylori* infection.

ACKNOWLEDGMENTS

Reuflor was kindly provided by Italtchimici (Rome).

COMMENTS

Background

The *Helicobacter pylori* (*H. pylori*) cure rate following standard triple therapies is decreasing worldwide. The need for alternative treatment strategies for *H. pylori* infections has created an interest in control of this pathogen with further antibiotic protocols and probiotics.

Research frontiers

In some large studies, the sequential regimen, i.e., simple 5-d dual [proton pump inhibitor (PPI) plus amoxicillin] therapy followed by a 5-d triple therapy (PPI, clarithromycin and tinidazole), is more effective than 7-d triple treatment (PPI plus clarithromycin and amoxicillin or metronidazole). *Lactobacillus reuteri* (*L. reuteri*) ATCC 55730, a probiotic of human origin, has been demonstrated to reduce adverse effects during antibiotic therapy and to increase eradication of the *H. pylori* infection. Further studies support that *L. reuteri* colonizes the human gastric mucosa, inhibits the binding of *H. pylori* to gastric epithelial cell lines and suppresses *H. pylori* urease activity.

Innovations and breakthroughs

The *H. pylori* eradication rate was significantly higher in the sequential group compared with 7-d triple therapy. These results confirmed that 10-d sequential therapy is superior to standard regimens, as reported by systematic reviews and meta-analyses of randomized trials. Moreover, *L. reuteri* supplementation could play a role in the eradication of *H. pylori* and improve the tolerability to antibiotic therapy, despite conflicting results in previous studies.

Applications

Sequential therapy appears to be more effective than standard 7-d therapy and is a well-tolerated, promising therapy and should be recommended as first-line treatment. *L. reuteri* supplementation could play a role in the eradication of *H. pylori*, but a large, double-blind, controlled study is needed to confirm these results and to explain its exact function. It may improve the tolerability to the antibiotic therapy or play a primary role in reducing *H. pylori* infection.

Peer review

The authors investigated standard triple drug therapy treatment of *H. pylori* infection of human patients versus sequential therapy, with all therapies also including *L. reuteri* probiotic. In 83 patients, they found that eradication rates were higher in the sequential therapy group over that of the standard triple therapy group.

METHODS: Large-scale screening of serum antibodies against tissue transglutaminase (tTG), and deamidated gliadin using enzyme-linked immunosorbent assay and serum antibodies against endomysium using immunohistochemistry, in patients with various liver diseases ($n = 962$) and patients who underwent liver transplantation (OLTx, $n = 523$) was performed. The expression of tTG in liver tissue samples of patients simultaneously suffering from celiac disease and from various liver diseases using immunohistochemistry was carried out. The final diagnosis of celiac disease was confirmed by histological analysis of small-intestinal biopsy.

RESULTS: We found that 29 of 962 patients (3%) with liver diseases and 5 of 523 patients (0.8%) who underwent OLTx were seropositive for IgA and IgG anti-tTG antibodies. However, celiac disease was biopsy-diagnosed in 16 patients: 4 with autoimmune hepatitis type I, 3 with Wilson's disease, 3 with celiac hepatitis, 2 with primary sclerosing cholangitis, 1 with primary biliary cirrhosis, 1 with Budd-Chiari syndrome, 1 with toxic hepatitis, and 1 with non-alcoholic steatohepatitis. Unexpectedly, the highest prevalence of celiac disease was found in patients with Wilson's disease (9.7%), with which it is only rarely associated. On the other hand, no OLTx patients were diagnosed with celiac disease in our study. A pilot study of the expression of tTG in liver tissue using immunohistochemistry documented the overexpression of this molecule in endothelial cells and periportal hepatocytes of patients simultaneously suffering from celiac disease and toxic hepatitis, primary sclerosing cholangitis or autoimmune hepatitis type I.

CONCLUSION: We suggest that screening for celiac disease may be beneficial not only in patients with associated liver diseases, but also in patients with Wilson's disease.

Abstract

AIM: To study the coincidence of celiac disease, we tested its serological markers in patients with various liver diseases.

INTRODUCTION

Celiac disease (CLD) is a frequent, lifelong, primarily small intestinal enteropathy with an incidence of more than 1:250 which is induced in genetically susceptible individuals after ingestion of wheat gluten. The duodenal and jejunal mucosa of patients with active CLD is infiltrated by leukocytes and structurally remodeled. Villous flattening and crypt hyperplasia develop in the mucosa of these patients and cause malabsorption syndrome, diarrhea, abdominal pain, and weight loss. However, these symptoms predominate in pediatric patients (accompanied by growth retardation), whereas latent and silent forms of CLD occur more often in adult patients^[1-3].

Interestingly, a growing proportion of new cases of CLD are being diagnosed in adults and in patients with extraintestinal manifestations. CLD may affect several organs including kidney, skin, heart, and the nervous, endocrine and reproductive systems, however, liver injury is one of the most frequent extraintestinal manifestations of the disease. Although the spectrum of liver manifestations associated with CLD is particularly wide, two main forms of liver damage, namely cryptogenic and autoimmune, appear to be strictly related to this disease. The most frequent finding documenting liver damage in CLD is a cryptogenic hypertransaminasemia, observed in approximately 15%-55% of untreated patients, as an expression of mild liver dysfunction with a histological picture of nonspecific reactive hepatitis ("celiac hepatitis"). However, in a few cases a more severe liver injury, characterized by a cryptogenic chronic hepatitis or liver cirrhosis requiring liver transplantation, is present. A close association is known to exist between CLD and autoimmune liver diseases such as primary biliary cirrhosis with a prevalence of 3%-7%, autoimmune hepatitis (3%-6%), and primary sclerosing cholangitis (2%-3%). This is probably related to an association between CLD and the human leukocyte antigen (HLA)-DQ heterodi-

mer DQA1/0501/DQB1/0201 on antigen-presenting cells. In CLD, the number of gliadin-specific HLA-DQ2- or HLA-DR4-restricted T-lymphocytes expands and high titers of antibodies against gliadin and various autologous antigens are generated, which can affect the functions of many organs^[3-7].

The therapy of CLD is still based on the withdrawal of gluten and its related proteins from the diet of patients [gluten-free diet (GFD)]. After 6-12 mo on a GFD, most CLD patients experience a clinical improvement accompanied by restoration of the intestinal mucosa and a reduction in the number of gliadin and autoantigen-restricted lymphocytes. The serum concentrations of anti-gliadin antibodies and antibodies against autologous antigens are also reduced. Interestingly, mild liver dysfunction with a histological picture of nonspecific reactive hepatitis (celiac hepatitis) may improve after institution of a GFD^[8-11]. Although the withdrawal of gluten from the patients' diet improves celiac hepatitis, its influence on autoimmune hepatitis is controversial and in childhood, in which the diagnosis and the introduction of GFD are not usually delayed, it seems ineffective. However, the diet may reduce the risk of CLD complications and development of the most severe refractory CLD^[12-15].

The diagnosis of CLD is based on the histological analysis of a duodenal/jejunal biopsy and the testing of serum antibodies against gliadin and autoantibodies against endomysium or tissue transglutaminase (tTG).

This study focused on serological screening for CLD in patients with liver diseases and those who underwent liver transplantation, i.e., patients with a known higher risk of developing CLD. Moreover, we also analyzed the tissue expression and distribution of tTG in the liver of patients with various liver diseases, especially those simultaneously suffering from CLD and compared these to morphologically unaltered liver tissue.

MATERIALS AND METHODS

Patients and controls

The study enrolled patients treated in the Department of Hepatogastroenterology, Institute for Clinical and Experimental Medicine, Prague, in 2009-2010. Sera from a total of 1485 patients were tested. The tested cohorts included 962 patients with diagnosed liver diseases (mean age 55 years, range: 21-76 years) and 523 patients (mean age 49 years, range: 18-66 years) who underwent liver transplantation during 1994-2010 as a consequence of end stage of liver disease. Table 1 summarizes the baseline clinical characteristics of the patients and healthy controls included in our study. The cohort of healthy controls ($n = 300$, mean age 23 years, range: 18-45 years) was selected from the Institute of Hematology and Blood Transfusion (Prague, Czech Republic).

The diagnostic criteria for primary biliary cirrhosis included clinical symptoms, clinical chemistry, exclusion of infection with hepatitis viruses and evidence of anti-

mitochondrial antibodies type M2. The diagnosis of autoimmune hepatitis was based on the scoring system devised by the International Autoimmune Hepatitis Group and International Association for the Study of the Liver^[16]. The main diagnostic criteria for alcoholic liver cirrhosis were the patient's medical history, liver histology, and exclusion of other causes of liver cirrhosis. Diagnosis of Wilson's disease was based on the recommendation of Kodama *et al.*^[17], and Budd-Chiari syndrome in accordance with the concept of Fox *et al.*^[18]. Patients who underwent liver transplantation were treated with standard immunosuppressive therapy following appropriate guidelines. The study was approved by the local Ethics Committee.

Serology

Diagnostics and markers for screening of CLD: All serum samples were tested for immunoglobulin (Ig) A and IgG antibodies against tTG. Individuals seropositive for IgA or IgG anti-tTG antibodies were tested for IgA or IgG (in the case of patients with IgA immunodeficiency) isotypes of antibodies against deamidated gliadin (IgA and IgG) and anti-endomysium (IgA or IgG). The final diagnosis of CLD, in individuals seropositive for these IgA or IgG antibodies, was performed by duodenal/jejunal biopsy.

Serological assays used for CLD screening: All tests were performed in the immunological laboratory of

the Institute for Clinical and Experimental Medicine according to the manufacturer's instructions. The BINDAZYME™ Anti-Tissue Transglutaminase EIA kit (the Binding Site, Birmingham, United Kingdom) and ORG 540A and ORG 540G Anti-Tissue-Transglutaminase ELISA kit (ORGENTEC Diagnostika GmbH, Mainz, Germany) were simultaneously used to test for IgA or IgG anti-tTG antibodies, IgA or IgG anti-gliadin antibodies were tested using QUANTA Lite Gliadin IgA or QUANTA Lite Gliadin IgG (INOVA Diagnostic Inc., San Diego, CA, United States), and by ELISA kits ANTI GLIADIN MGP IgA and ANTI GLIADIN MGP IgG (Binding Site). The results of the serological testing were expressed as a percentage of antibody-positive patients within individual groups. To exclude immunoglobulin deficiency, total IgA and IgG blood levels were analyzed using a routine method in all tested patients.

Detection of anti-endomysial antibodies

Anti-endomysial antibodies were routinely tested by an indirect immunofluorescence method using human umbilical cord tissue cryostat sections. The test serum samples were diluted 1:20 and 1:50. Slides were examined using a Nikon Eclipse E600 immunofluorescence microscope (Nikon, Japan). A positive result was recorded if the connective tissue surrounding the muscle cells was brightly fluorescent, forming a honeycomb pattern.

Immunohistochemistry

Analysis of tTG expression in liver tissue: The expression and distribution of tTG in the liver biopsy samples from 25 patients were analyzed and compared. Eight patients suffered from CLD simultaneously with liver diseases (2 patients with primary sclerosing cholangitis, 1 with autoimmune hepatitis type I, 1 with toxic hepatitis, 1 with Budd-Chiari syndrome, 3 with celiac hepatitis), 8 patients with liver diseases (3 with primary sclerosing cholangitis, 2 with autoimmune hepatitis type I, 1 patient with steatosis, 1 with Budd-Chiari syndrome and 1 patient with primary biliary cirrhosis), and 9 patients with liver metastasis from colorectal carcinoma where tTG expression was analyzed on histologically confirmed unaltered liver tissue at least 3 cm away from the metastasis. The patients with liver disease simultaneously suffering from CLD were seropositive for IgA antibodies against tTG, endomysium and gliadin. MARSH IIIb-c stage of jejunal mucosa was present in these patients. On the other hand, the patients suffering from liver diseases, but not from CLD, included in the analysis of tTG expression in liver were seronegative for all of the mentioned antibodies. Therefore, there was no reason to perform a small intestinal biopsy in these patients.

The tTG detection in liver tissue was performed using the immunoperoxidase staining technique, N-Histofine® Simple Stain MAX PO (MULTI, Nichirei, Japan). Detection was performed on 4 µm thick paraffin sections. Tissue sections were deparaffinated, rehydrated, and antigen retrieval was performed using heat-induced

epitope restoration in an EDTA buffer of pH 8.0. Endogenous peroxidase was inactivated with 0.3% H₂O₂ in 70% methanol for 30 min at room temperature. The sections were then incubated for 2 h with anti-tTG antibody CUB 7402 (Acris, Germany), diluted at 1:1200 in antibody diluent, Dako Real (Dako, Glostrup, Denmark). After a washing step, Histofine Simple Stain Max PO was added for 30 min. Tissue staining was visualized with a 3,3'-diaminobenzidine substrate chromogen solution (Dako). Slides were counterstained with hematoxylin, dehydrated, and mounted. A negative control was included by omitting the anti-tTG antibody. An isotype control was included using a nonspecific mouse IgG1 instead of specific anti-tTG antibody.

RESULTS

CLD seropositivity and final diagnosis in patients with severe liver disease

In our study, 29 of 962 adult patients with various liver diseases (3%) were seropositive for IgA anti-tTG antibodies. A summary of the data on seropositive patients is given in Table 2. Seropositivity for anti-tTG antibodies-detected by employing two different diagnostic kits-was found in five patients with autoimmune hepatitis type I, four patients with liver steatosis, four with Wilson's disease, two with primary sclerosing cholangitis, two with non-alcoholic steatohepatitis, and one each with polycystic liver disease, Budd-Chiari syndrome, primary biliary cirrhosis, toxic hepatitis, and hepatitis B. Seven patients with mild liver test abnormalities were also seropositive for anti-tTG.

Sixteen of 29 patients, i.e., those who were positive for IgA anti-tTG antibodies, were also seropositive for IgA anti-gliadin and anti-endomysial antibodies. This cohort included patients with autoimmune hepatitis type I (4), Wilson's disease (3), celiac hepatitis (3, re-

cruited from the group of anti-tTG seropositive patients with mild liver test abnormalities), primary sclerosing cholangitis (2), primary biliary cirrhosis (1), Budd-Chiari syndrome (1), toxic hepatitis (1), and non-alcoholic steatohepatitis (1). Histological analysis of duodenal or jejunal specimens confirmed the diagnosis of CLD in these 16 patients according to European Society for Paediatric Gastroenterology, Hepatology, and Nutrition criteria. MARSH IIIa-c stages of gut mucosa were observed in all 16 patients. The clinical data of these newly diagnosed patients are summarized in Table 3. After 6 mo of adherence to the GFD, all tested antibodies decreased to values occurring in healthy individuals and staging of mucosal lesions improved substantially (MARSH 0- I) in these patients. Four of these 16 patients (three with celiac hepatitis, one with non-alcoholic steatohepatitis) showed normalization of liver tests. However, no substantial clinical and laboratory improvements were observed in the other patients adequately treated for liver disease and adhering to a GFD.

Ten of the 16 newly diagnosed patients showed some non-specific symptoms of CLD (weight loss, diarrhea, abdominal pain), while 6 patients were asymptomatic for CLD.

Serum samples from the blood donors were negative for IgA anti-tTG antibodies.

CLD seropositivity in patients who underwent liver transplantation

Of the 523 patients who underwent liver transplantation, five (0.8%) were positive for IgA anti-tTG antibodies. A summary of the data on seropositive patients is given in Table 2. Anti-tTG antibody seropositivity occurred in 2 patients transplanted for autoimmune hepatitis type I, two for Wilson's disease and one transplanted for alcoholic liver cirrhosis. However, none of these patients was seropositive for IgA anti-endomysial antibodies or for IgA and IgG anti-gliadin antibodies. CLD symptoms were not observed in five patients who were seropositive for IgA anti-tTG. For that reason, small intestinal biopsy was not performed in these patients.

TTG expression in liver tissue

In liver diseases, tTG is closely related with tissue repair, fibrogenesis and inflammation^[19]. For this reason, we analyzed tTG expression in the liver tissue of twenty five patients simultaneously suffering from active CLD and liver disease, patients suffering from liver disease, but not from CLD, and patients with metastatic colorectal carcinoma.

In this pilot study, we found overexpression of tTG in the liver tissue of patients suffering from liver diseases in contrast to morphologically unaltered tissues. However, individual variability in tTG expression in the liver tissue of these patients was detected. Despite this, the overexpression of tTG was predominantly localized in endothelial cells and periportal hepatocytes and was more pronounced in the liver tissue of all patients suf-

Table 3 Patients with liver disease newly diagnosed with celiac disease

No.	Age	Gender	Diagnosis	Liver histology
1	34	F	PSC	Portal tracts with ductular reaction and minimal inflammation, features of chronic cholestasis

fering simultaneously from both liver diseases and active CLD in contrast to patients suffering only from liver disease. Figure 1 shows more pronounced tTG staining in the liver specimens of patients simultaneously suffering from active CLD and primary sclerosing cholangitis, toxic hepatitis, and autoimmune hepatitis type I compared to patients suffering only from primary sclerosing cholangitis and steatosis.

DISCUSSION

CLD is frequently associated with various autoimmune liver diseases such as autoimmune hepatitis, primary biliary cirrhosis and primary sclerosing cholangitis, all of which may be indications for liver transplantation. On the other hand, a controversial association exists between hepatitis B and C virus and CLD. Chronic untreated CLD of long duration may also lead to liver damage severe enough to require liver transplantation^[4,6,20-24]. Consistent with the above, reversal of hepatic failure has been described in CLD patients simultaneously suffering from liver disorders who followed a GFD^[25]. On the other hand, GFD did not always lead to complete resolution of liver damage in all patients with CLD associated with liver disease^[26-28].

This study on the occurrence of CLD and its serological markers in patients with various hepatic disorders and in those who underwent liver transplantation in the Czech Republic complements the serological screening for CLD in the general population (blood donors) and high-risk patients groups e.g., patients with osteoporosis, female infertility and some autoimmune diseases including systemic lupus erythematosus, Sjögren's syndrome and patients with connective tissue disorders in the Czech population performed by Vanciková *et al.*^[29]. In the present study, we estimated, for the first time,

the coincidence of CLD and liver diseases and the relationship between CLD and liver transplantation in the Czech population. Surprisingly, our results documented the highest incidence of CLD in patients with Wilson's disease (9.7%), followed by autoimmune hepatitis (3.9%), primary biliary cirrhosis (3.0%), and primary sclerosing cholangitis (3.4%). While a higher incidence of CLD with primary biliary cirrhosis, primary sclerosing cholangitis and autoimmune hepatitis has been well described^[26,28], the association between CLD and Wilson's disease is rare^[30-32]. The coincidence of Wilson's disease and CLD was high compared with the coincidence of CLD and osteoporosis (0.98%), female infertility (1.13%) and systemic lupus erythematosus (approximately 2.7%) in the Czech population^[29]. Our findings of a higher incidence of CLD in adult patients could be associated with the underestimation of CLD diagnosis described in the elderly^[33].

Despite the fact that Wilson's disease, which is characterized by accumulation of copper in tissue, is rarely associated with CLD^[30-32], it has been reported that copper metabolism is also impaired in CLD. In CLD patients, copper uptake from the gut is significantly reduced and levels of copper in urine are higher than in healthy individuals^[31,32].

In our study, anti-tTG seropositivity in patients who underwent liver transplantation was lower than that described in previous studies^[6]. A possible explanation for this is the exclusion from screening of 5 patients who underwent liver transplantation for primary sclerosing cholangitis (2 men, 39 years and 40 years), autoimmune hepatitis type I (woman, 25 years), viral hepatitis B (woman, 51 years) and viral hepatitis C (woman, 56 years), in whom CLD was diagnosed before the beginning of this study. All five patients who underwent liver transplantation and were seropositive for IgA anti-tTG

Figure 1 Tissue transglutaminase expression in liver tissue specimens from patients. A: Specimens from patients simultaneously suffering from active celiac disease and primary sclerosing cholangitis; B: Toxic hepatitis; C: Autoimmune hepatitis type I; D: Patient with primary sclerosing cholangitis without celiac disease (CLD); E: Steatosis without CLD; F, G: The basal tissue transglutaminase (tTG) expression in morphologically unaltered liver tissue surrounding colorectal adenocarcinoma metastasis; H: Negative control (no anti-tTG antibody); I: Isotype control (nonspecific mouse Immunoglobulin G1 antibody).

antibodies were also seropositive for the IgG isotype of the antibodies, but seronegative for the remaining CLD markers - antibodies against deamidated gliadin and endomysium. The antibody levels, as well as histological changes in small intestine mucosa characteristic of CLD,

could have been affected by immunosuppressive treatment complicating the diagnosis of CLD in those patients who underwent liver transplantation^[34]. This could also be the reason for the difference in seropositivity between cohorts of patients suffering from liver dis-

ease and patients who underwent liver transplantation. The putative reason for the development of anti-tTG antibodies in patients who underwent liver transplantation could be overexpression of tTG in the graft during repair and healing processes. However, our findings concerning the expression of tTG in liver and induction of anti-tTG antibodies need further investigation. Nevertheless, the testing of CLD serological markers seems to be useful in patients considered for liver transplantation.

In conclusion, we suggest that screening for CLD may be beneficial not only in groups of patients with well-known associated diseases (autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis), but also in patients with Wilson's disease, where the relationship to CLD has not been fully analyzed.

COMMENTS

Background

Celiac disease (CLD) is a frequent, lifelong, primarily small intestinal enteropathy with an incidence of more than 1:250 which is induced in genetically susceptible individuals after ingestion of wheat gluten. A growing proportion of new cases of CLD are being diagnosed in adults and in patients with extraintestinal manifestations. CLD may affect several organs including kidney, skin, heart, and the nervous, endocrine and reproductive systems, however, liver injury is one of the most frequent extraintestinal manifestations of the disease.

Research frontiers

This study on the occurrence of CLD and its serological markers in patients with various hepatic disorders and in those who underwent liver transplantation in the Czech Republic complements the serological screening for CLD in the general population (blood donors) and high-risk patients groups.

Innovations and breakthroughs

The authors suggest that screening for CLD may be beneficial not only in groups of patients with well-known associated diseases (autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis), but also in patients with Wilson's disease, where the relationship to CLD has not been fully analyzed.

Applications

Their findings on the expression of tissue transglutaminase (tTG) in liver and induction of anti-tTG antibodies need further investigation. Nevertheless, the testing of CLD serological markers seems to be useful in patients considered for liver transplantation.

Peer review

The study is a large scale serological investigation on CLD in patients with liver disease. This study first time revealed a relation between Wilson's disease and CLD, and overexpression of tTG in liver tissue.

Abstract

AIM: To compare the clinicopathological characteristics of human epidermal growth factor receptor 2 (HER2)-positive and HER2-negative Barrett's adenocarcinoma in Japan.

METHODS: We performed immunohistochemical analysis of HER2 in 30 samples taken from patients with Barrett's adenocarcinoma and dual color *in situ* hybridization in cases showing 2+ reactions. We compared the clinicopathological characteristics of HER2-positive and HER2-negative patients.

RESULTS: HER2 positivity was identified in 8 (27%) carcinoma samples. We found that HER2 expression was associated with p53 overexpression (100% vs 52.6% in pT1 tumor; 100% vs 54.5% in all stage tumor, $P < 0.05$) and protruding lesions at the early disease stage. There was no association between the mucin phenotype of the carcinomas and prognosis. HER2 expression and low clinical stage were unexpectedly different between Barrett's adenocarcinoma patients and gastric cancer patients, but the macroscopic features may be associated with earlier diagnosis in these patients.

CONCLUSION: Our results suggest that HER2-positive Barrett's adenocarcinomas are associated with p53 overexpression and lesion protrusion at the early disease stage.

INTRODUCTION

Recent studies have shown that the incidence of Barrett's

adenocarcinoma has been increasing in Japan. Although human epidermal growth factor receptor 2 (HER2) was reported to be amplified and overexpressed in some Barrett's adenocarcinomas, the relationship between HER2 expression and patient clinicopathological characteristics has not yet been clarified.

The *HER2* gene, a proto-oncogene, is located on chromosome 17q11.2-12 and encodes the transmembrane glycoprotein receptor p185^{HER2} (or HER2), which is targeted by the humanized monoclonal antibody trastuzumab (Herceptin®)^[1]. HER2 is amplified and overexpressed in approximately 25% of breast cancer patients, and is associated with an aggressive clinical course and poor prognosis^[2]. Recently, HER2 overexpression and amplification was detected in approximately 22% of advanced gastric cancers, and targeting of the extracellular domain of HER2 in these patients was associated with improved clinical benefits compared with chemotherapy alone in a phase III trial^[3]. Several recent studies have reported HER2 status in Barrett's adenocarcinoma; they observed a prevalence of HER2 protein overexpression or gene amplification in Barrett's adenocarcinomas ranging from 11% to 72%^[4-8]. Lack of agreement among these studies may be related to the differing sensitivities of the assay methods used to assess HER2^[9-13].

HER2 has been recognized as an important prognostic factor in breast cancer^[2]. However, the clinicopathological characteristics of HER-positive Barrett's adenocarcinoma are controversial. In this study, we used the criteria of the trastuzumab for gastric cancer (ToGA) trial to evaluate the HER2 status of Barrett's adenocarcinomas in Japan by clarifying the clinicopathological characteristics of HER2-positive Barrett's esophageal adenocarcinomas and examining their morphological immunohistochemical characteristics.

MATERIALS AND METHODS

Patients included in the study

Samples were collected from 30 patients who visited the Okayama University Hospital between May 1998 and March 2011. Histological sections and immunohistochemical results were reviewed to confirm the diagnosis. The definition of Barrett's esophagus and Barrett's adenocarcinoma is controversial^[14,15]. In this study, the criterion for the clinical diagnosis of Barrett's adenocarcinoma was that the tumor foci were located in Barrett's mucosa, which is also referred to as the columnar-lined esophagus. The histological criterion was carcinoma that presented or was in contact with Barrett's mucosa, defined as columnar-lined mucosa with or without intestinal-type epithelium. Clinical information was obtained from the medical records of patients at Okayama University Hospital. The patients underwent a standardized informed consent procedure.

Immunohistochemistry

An automated immunostainer (Ventana Medical Systems, Tucson, AZ, United States) was used to perform all im-

munochemical analyses. The following monoclonal antibodies were used: p53 (DO-7; Dako, Glostrup, Denmark), MUC2 (Ccp58; Novocastra Laboratories, Newcastle upon Tyne, United Kingdom), MUC5AC (CLH2, Novocastra Laboratories, Newcastle upon Tyne, United Kingdom), MUC6 (CLH5; Novocastra Laboratories), and CD10 (56C6; Dako). For the evaluation of p53 staining, only cells with nuclear immunostaining significantly more pronounced than that of the control cells of the normal esophageal mucosa were considered positive. MUC5AC and MUC6 are markers of gastric epithelial cells, and MUC2 and CD10 are typical of the intestinal epithelial cell phenotype^[16]. Barrett's adenocarcinoma, in which more than 10% of the section area consisted of at least 1 gastric or intestinal epithelial cell phenotype, were classified as gastric (G type) or intestinal (I type) phenotypic cancers. Those which showed both gastric and intestinal phenotypes were classified as gastric and intestinal mixed phenotypic (GI type) cancers, whereas those showing neither gastric nor intestinal phenotypic expression were grouped as unclassified (N type).

HER2 testing methods and criteria

HER2 protein expression was assessed in carcinoma cells by immunohistochemistry (IHC) in paraffin-embedded 5-μm tissue sections according to the manufacturer's instructions (Ventana I-VIEW pathway HER2/neu kit; Ventana Medical Systems). Only cell membrane staining was considered positive. Each case was analyzed by a pathologist blinded to the clinical outcome who used criteria specific to upper gastrointestinal cancer that included 2 parameters: (1) the intensity of complete, basolateral, or lateral membrane staining (0, none; 1, faint; 2, weak to moderate; and 3, strong); and (2) the percentage of cancer cells with a given staining intensity. These parameters were used to determine the IHC score according to the ToGA criteria: high (IHC 3+), strong intensity in 10% or more of the cancer cells; medium (IHC 2+), weak to moderate intensity in 10% or more; low (IHC 1+), faint intensity in 10% or more; absent (IHC 0). Dual *in situ* hybridization (DISH) using a Ventana INFORM HER2 ISH kit (Ventana Medical Systems) was used to assess *HER2* gene amplification in all IHC 2+ cases by preparing the carcinoma cells in 5 μm tissue sections. Briefly, for each case, a parallel hematoxylin and eosin-stained slide was examined for regions of carcinoma by a pathologist. The complete tissue section was scanned by the pathologist to detect any subpopulation of amplified cells. A total of 20 representative nuclei from the invasive tumor were scored. A specimen with a HER2/centromeric enumeration probe 17 (CEP17) ratio of 2.0 or more in tumor cells was classified as HER2 amplified according to the ToGA guidelines^[17].

Definition of HER2-positive status

A case was considered HER2 positive if it was (1) IHC 3+ or (2) IHC 2+ plus after gene amplification. The remaining cases (i.e., non-amplified IHC 2+ or IHC 0-1+) were considered HER2 negative.

G: Gastric phenotype; GI: Gastrointestinal phenotype; I: Intestinal phenotype; N: Null type.

Statistical analysis

A χ^2 test or Fisher's exact test, depending on the sample size, was used to examine categorical variables to compare the clinical characteristics of the different groups of patients. The *t*-test was used to compare mean values. SPSS Version 14.0 (SPSS, Chicago, IL, United States) was used to analyze the data.

RESULTS

Characteristics of the studied population

The studied population consisted of 20 men and 10 women (male to female ratio = 2:1). Their ages ranged from 42 to 87 years old. Sixteen lesions were identified as protruded or superficial elevated types (type 0- I or type 0- II a), 1 lesion was identified as flat type (type 0- II b), and 11 lesions were identified as superficial depressed type (type 0- II c). Three lesions were identified as Borrmann type 3. In accordance with the World Health Organization's classification standards, 21 patients (70%) had well-differentiated tumors and 9 had moderately differentiated tumors (30%). According to the tumor-node-metastasis classification, 13 patients were pT1a, 13 were pT1b, 1 was pT2, 2 were pT3, and 1 was pT4a. All stage pT3 and pT4 patients died from the disease, but the other patients remained alive without suffering from the disease. Taking into account the combination of expression of 4 markers, the 30 cancers were divided phenotypically into 7 G, 12 GI, 8 I, and 3 N types, independent of the histological classification. Expression of p53 was demonstrated in 20 (67%) of 30 cancers. The available data for each patient are summarized in Table 1.

Expression of HER2

Of the 30 patients diagnosed with Barrett's adenocarcinoma, stained sections in 4 cases (13%) were classified as IHC 3+ (Figure 1A), 6 cases (20%) were IHC 2+ (Figure 1B), 4 cases (13%) were IHC 1+, and 16 cases (53%) were IHC 0 (Figure 1C). Criteria developed for the evaluation of upper gastrointestinal tract carcinoma were used to score the HER2-stained samples. DISH was used to assess *HER2* gene amplification in 6 IHC 2+ cases. A specimen with a *HER2*/CEP17 ratio of 2.0

Figure 1 Immunohistochemical pattern of Barrett's adenocarcinoma. A: Immunohistochemistry (IHC) 3+ reaction in a well-differentiated tumor with papillary growth pattern; B: IHC 2+ reaction in a well-differentiated tumor with tubular pattern. Human epidermal growth factor receptor 2 (*HER2*) dual-color *in situ* hybridization amplification *HER2*/centromeric enumeration probe ratio = 3.18; C: IHC 0 reaction in a well-differentiated tumor.

or more in cancer cells was classified as *HER2* amplified (Figure 1B), consistent with the eligibility criteria for the ToGA study. *HER2* amplification was detected in 4 of IHC 2+ cases.

We defined *HER2* positivity as IHC 3+ or IHC 2+ with gene amplification, which were the characteristics of the group that derived the greatest benefit from trastuzumab in the ToGA study. The positive rate of *HER2* was 27% (Table 2).

Association of *HER2* with clinicopathological features

HER2-positive adenocarcinomas were present in 4 men and 4 women. The patients ranged in age from 52 to 80 years. Six cases were the protruded or superficially elevated types (0- I or 0- II a). Three tumors were located in

Mucin phenotype: G/GI/I/N	4/2/1/0	3/9/6/1	4/2/2/0	3/10/6/3
p53: positive/negative	7/0	10/9	8/0	12/10

The human epidermal growth factor receptor 2 (HER2)-positive cases were significantly associated with protruding lesions compared with the HER2-negative cases ($P < 0.05$), and the p53-positivity rate was more common in the HER2-positive tumors ($P < 0.05$). G: Gastric phenotype; GI: Gastrointestinal phenotype; I: Intestinal phenotype; N: Null type.

the Siewert I region and 5 in the Siewert II region. The mean tumor size was 23.6 mm (11-60 mm). Of the pT1 cases, HER2-positive cases were significantly more associated with protruding lesions compared with HER2-negative cases ($P < 0.05$) (Table 2). Seven cases had well-differentiated tumors, and 1 case had a moderately-differentiated tumor. In the mucin phenotypical analysis, 4 cases were G type, 2 cases GI type, and 2 cases were I type; there were no significant differences in mucin phenotypes between the HER2-positive and HER2-negative cases. The p53 positivity rate was higher in the HER2-positive tumors than in the HER2-negative tumors ($P < 0.05$) (Table 2). There were no prognostic differences between the HER2-positive and HER2-negative cases.

DISCUSSION

In this study, we confirmed that 27% Barrett's adenocarcinomas in Japanese patients were HER2 positive. We also found that early-stage HER2-positive Barrett's adenocarcinomas were significantly associated with protruding lesions and had a high rate of p53 positivity.

Previous studies that have examined HER2 status in Barrett's adenocarcinoma observed a prevalence of HER2 protein overexpression or gene amplification ranging from 11% to 72%^[4-8]. Except for 1 study, the lack of agreement among these studies may have been related to the differing sensitivities of the assay methods used to assess HER2. Various antibodies and probes for *in situ* hybridization were used, and the test conditions also were not standardized. In this study, the HER2 tests were performed according to the criteria of the ToGA trial, which is the standard test for HER2 status of gastric cancer. Brien *et al*^[18] used fluorescence *in situ* hybridization to evaluate HER2 amplification and reported a significant association between amplification and poorer survival. However, in the present study, a low threshold of 4 or more signals per nucleus was used to determine HER2 amplification. On the other hand, according to the ToGA criteria, HER2-positive esophageal adenocarcinomas with Barrett's esophagus had favorable prog-

noses^[19]. The influence and criteria of HER2 expression may still be controversial. In this study, there were no prognostic differences between the HER2-positive and HER2-negative cases. Except for the pT3 and pT4 patients, most patients were early stage and remained alive without disease. Thus, the prognostic significance of HER2 expression was not clarified in this study.

Barrett's adenocarcinoma is thought to develop as a result of gastroesophageal reflux that initiates a metaplastic change in the lower esophageal epithelium. Barrett's esophagus is significant because the condition has a risk for neoplastic transformation through a metaplasia-dysplasia-carcinoma sequence. In Western populations, there has been an increase in the incidence of adenocarcinoma of the esophagus and esophagogastric junction region. In Japan, esophageal Barrett's adenocarcinomas are less common than in Western countries. However, in recent years there has been a gradual increase in the detection of both Barrett's esophagus and Barrett's adenocarcinoma^[12]. Traditionally, Barrett's adenocarcinoma has been believed to be preceded by the development of dysplasia with intestinal characteristics. Recently, Brown *et al*^[13] and Park *et al*^[20] validated the existence of 2 main types of dysplasia (i.e., foveolar and adenomatous) which were significantly associated with gastric and intestinal immunophenotypic markers. Khor *et al*^[21] suggested that non-intestinal columnar metaplasia may be an unstable intermediate state at risk for neoplastic progression. In this study, we evaluated the mucin phenotype of Barrett's adenocarcinoma and found that more than half of the cases were grouped as gastric and mixed phenotypes. This result suggests the presence of a gastric pathway of carcinogenesis in Barrett's esophagus. Heterogeneity of HER2 status was seen in approximately 80% of samples with moderate or strong HER2 IHC reactivity, which was higher than that observed in breast cancer. There were only 2 diffusely strong positive cases. In our study, heterogeneity of HER2 overexpression and gene amplification appeared to represent clusters, and the intensity of IHC staining within clusters was relatively uniform. The IHC staining patterns and gene amplification ap-

peared correlated.

Seven (23%) of the 30 studied cases were the pure gastric mucin phenotype, and 12 cases were the mixed phenotype. In these cases, the background Barrett's mucosa also showed the foveolar type with or without specialized columnar epithelium (intestinal type mucosa). Carcinogenesis of complete gastric type adenocarcinomas is derived from foveolar type dysplasia with aneuploidy^[22], and intestinal type carcinomas were regarded as progressing through the metaplasia-dysplasia-carcinoma sequence, with p53 alteration^[23]. In this study, HER2-positive carcinomas showed both gastric and intestinal phenotypes. It is believed that p53 has an important role in intestinal-type Barrett's adenocarcinoma; however, p53 overexpression was observed in all HER2-positive cases regardless of mucin phenotype. These results suggest a third pathway involving abnormalities of both HER2 and p53. Gastric adenocarcinoma is also significantly correlated with HER2 positivity^[24-26]. These data suggest a possible role of p53 abnormality in the development of HER2-positive adenocarcinoma of the upper gastro-intestinal tract.

The macroscopic appearance of HER2-positive Barrett's adenocarcinomas was different from that of the HER2-negative cases in early-stage disease (pT1). The frequency of protruding lesions was significantly higher in the HER2-positive cases than in HER2-negative cases. Ten cases of HER2-negative adenocarcinomas were the protruded type, 9 cases were mixed or intestinal mucin phenotypes, and only 1 case was the gastric phenotype. Thus, protruded-type lesions of the complete gastric phenotype can indicate HER2-positive status.

COMMENTS

Background

In Japan, the incidence of esophageal adenocarcinoma has been increasing, but is still very low compared with squamous cell carcinoma. The incidence of Barrett's adenocarcinoma is much higher in Western countries than in Japan. The relationship between human epidermal growth factor receptor 2 (HER2) expression and patient clinicopathological characteristics has not yet been clarified.

Research frontiers

HER2 was reported to be amplified and overexpressed in some Barrett's adenocarcinomas. The reported expression rates have varied widely due to various different methods and criteria being applied to determine HER2 expression. A practical method for determining HER2 expression has been established on the basis of the results of the trastuzumab for gastric cancer trial.

Innovations and breakthroughs

This was a retrospective study that assessed the incidence of HER2 positivity according to newly-established methods and criteria, and investigated the clinicopathological characteristics according to the new diagnostic criteria.

Applications

Since the sample size of the study was not sufficiently large, the evidence may not be robust. Even so, the authors believe that this study provides valuable data from the evaluation of HER2-positive Barrett's adenocarcinoma.

Terminology

HER2 is an important member of the epidermal growth factor receptor family that has been shown to act as an oncogene in many types of cancers.

Peer review

This is a good descriptive study in which authors analyzed the clinicopathological characteristics of HER-2 positive Barrett's adenocarcinoma. The results

suggest that HER2-positive Barrett's adenocarcinomas are associated with p53 overexpression and lesion protrusion at the early disease stage.

Abstract

AIM: To clarify features of hepatic hemangiomas on gadolinium-ethoxybenzyl-diethylenetriaminopentaacetic acid (Gd-EOB-DTPA)-enhanced magnetic resonance imaging (MRI) compared with enhanced computed tomography (CT).

METHODS: Twenty-six patients with 61 hepatic hemangiomas who underwent both Gd-EOB-DTPA-enhanced MRI and enhanced CT were retrospectively reviewed. Hemangioma appearances (presence of peripheral nodular enhancement, central nodular enhancement, diffuse homogenous enhancement, and arterioportal shunt during the arterial phase, fill-in enhancement during the portal venous phase, and prolonged enhancement during the equilibrium phase) on Gd-EOB-DTPA-enhanced MRI and enhanced CT were evaluated.

The degree of contrast enhancement at the enhancing portion within the hemangioma was visually assessed using a five-point scale during each phase. For quantitative analysis, the tumor-muscle signal intensity ratio (SIR), the liver-muscle SIR, and the attenuation value of the tumor and liver parenchyma were calculated. The McNemar test and the Wilcoxon's signed rank test were used to assess the significance of differences in the appearances of hemangiomas and in the visual grade of tumor contrast enhancement between Gd-EOB-DTPA-enhanced MRI and enhanced CT.

RESULTS: There was no significant difference between Gd-EOB-DTPA-enhanced MRI and enhanced CT in the presence of peripheral nodular enhancement (85% vs 82%), central nodular enhancement (3% vs 3%), diffuse enhancement (11% vs 16%), or arterioportal shunt (23% vs 34%) during arterial phase, or fill-in enhancement (79% vs 80%) during portal venous phase. Prolonged enhancement during equilibrium phase was observed less frequently on Gd-EOB-DTPA-enhanced MRI than on enhanced CT (52% vs 100%, $P < 0.001$). On visual inspection, there was significantly less contrast enhancement of the enhancing portion on Gd-EOB-DTPA-enhanced MRI than on enhanced CT during the arterial (3.94 ± 0.98 vs 4.57 ± 0.64 , respectively, $P < 0.001$), portal venous (3.72 ± 0.82 vs 4.36 ± 0.53 , respectively, $P < 0.001$), and equilibrium phases (2.01 ± 0.95 vs 4.04 ± 0.51 , respectively, $P < 0.001$). In the quantitative analysis, the tumor-muscle SIR and the liver-muscle SIR observed with Gd-EOB-DTPA-enhanced MRI were 0.80 ± 0.24 and 1.28 ± 0.33 precontrast, 1.92 ± 0.58 and 1.57 ± 0.55 during the arterial phase, 1.87 ± 0.44 and 1.73 ± 0.39 during the portal venous phase, 1.63 ± 0.41 and 1.78 ± 0.39 during the equilibrium phase, and 1.10 ± 0.43 and 1.92 ± 0.50 during the hepatobiliary phase, respectively. The attenuation values in the tumor and liver parenchyma observed

with enhanced CT were 40.60 ± 8.78 and 53.78 ± 7.37 precontrast, 172.66 ± 73.89 and 92.76 ± 17.92 during the arterial phase, 152.76 ± 35.73 and 120.12 ± 18.02 during the portal venous phase, and 108.74 ± 18.70 and 89.04 ± 7.25 during the equilibrium phase, respectively. Hemangiomas demonstrated peak enhancement during the arterial phase, and both the SIR with Gd-EOB-DTPA-enhanced MRI and the attenuation value with enhanced CT decreased with time. The SIR of hemangiomas was lower than that of liver parenchyma during the equilibrium and hepatobiliary phases on Gd-EOB-DTPA-enhanced MRI. However, the attenuation of hemangiomas after contrast injection was higher than that of liver parenchyma during all phases of enhanced CT.

CONCLUSION: Prolonged enhancement during the equilibrium phase was observed less frequently on Gd-EOB-DTPA-enhanced MRI than enhanced CT, which may exacerbate differentiating between hemangiomas and malignant tumors.

INTRODUCTION

Hepatic hemangioma is the most common benign hepatic neoplasm; it occurs with a reported incidence of 0.4%-7.3% in an autopsy series^[1]. Differentiation from malignant liver tumors is very important because hemangiomas usually do not require treatment^[2]. Enhanced computed tomography (CT) and gadolinium-diethylenetriaminepentaacetic acid (Gd-DTPA)-enhanced magnetic resonance imaging (MRI) are useful modalities for the diagnosis of hepatic hemangiomas and their differentiation from malignant liver tumors^[3-7].

Gadolinium-ethoxybenzyl-diethylenetriaminopentaacetic acid (Gd-EOB-DTPA) is a new hepatobiliary contrast agent that improves the detection and characterization of focal liver lesions in clinical studies^[8-12]. This contrast agent exhibits high T1 relaxivity in the liver and shows enhancement on both early perfusion phase

images and delayed hepatobiliary phase images. Immediately after injection, Gd-EOB-DTPA is distributed into the extracellular fluid space and yields additional diagnostic information for the characterization of liver lesions, similar to performing MRI with extracellular contrast agents, such as Gd-DTPA^[13]. Hepatocellular uptake of Gd-EOB-DTPA starts approximately 90 s after injection, and Gd-EOB-DTPA is excreted equally *via* the biliary route and renal clearance^[11,12]. The enhanced liver signal intensity plateaus approximately 20 min after injection, and delayed hepatobiliary phase images have high diagnostic quality for the detection of focal liver lesions^[11].

Some studies have shown that Gd-EOB-DTPA-enhanced MRI is more useful than enhanced CT and Gd-DTPA-enhanced MRI for the detection and characterization of focal liver lesions^[8,10-12,14]. The dynamic images obtained after injection of Gd-EOB-DTPA are similar in some aspects but not the same as those images obtained using extracellular contrast agents^[11,12,14,15]. Recently, the differences in the appearances of Gd-EOB-DTPA-enhanced MRI between hemangiomas and metastases have been reported^[16,17]. To our knowledge, however, published reports regarding the findings of hemangiomas observed with Gd-EOB-DTPA-enhanced MRI have been limited^[9,16-19]. Moreover, the appearance and the degree of contrast enhancement of hepatic hemangiomas observed with Gd-EOB-DTPA-enhanced MRI compared with enhanced CT have not been elucidated. Therefore, the purpose of the present study was to clarify the features of hepatic hemangiomas observed with Gd-EOB-DTPA-enhanced MRI compared with enhanced CT.

MATERIALS AND METHODS

Patients

Institutional ethics review board approval was obtained, and informed consent was waived for this retrospective study. From February 2008 to February 2010, 432 consecutive patients underwent Gd-EOB-DTPA-enhanced MRI for the evaluation of suspected liver tumors. Among these patients, 27 were included in this study because they were suspected of having hepatic hemangiomas on three-phase enhanced CT with at least three of the following four well-documented CT characteristic findings of hepatic hemangiomas^[4-7]: relative hypoattenuation compared to normal liver on precontrast images, peripheral nodular enhancement during the arterial phase, fill-in enhancement (progressive opacification from the periphery to the center) during the portal venous phase, and prolonged enhancement (showing iso- or hyperattenuation relative to the liver) during the equilibrium phase. One patient was excluded from the study because the hemangioma did not have the typical appearance of bright signal intensity on T2-weighted MRI^[20]. Therefore, the final study group comprised 26 patients (8 men, 18 women; age range: 31-77 years;

mean age: 53.5 years) with 61 hepatic hemangiomas (size: mean, 26 mm; range 5–120 mm). Four hemangiomas in two patients were diagnosed by histological examination following surgical resections because of the risk of spontaneous rupture.

MRI technique

MRI was performed with a 3-T system (Magnetom Trio; Siemens AG, Erlangen, Germany) with a maximum gradient amplitude of 45 mT/m and a slew rate of 200 T/m·s⁻¹. The coil had four linear elements in a left-to-right direction for both the anterior and posterior components. The standard sequences performed prior to Gd-EOB-DTPA administration included T1-weighted gradient-echo, T2-weighted turbo spin-echo, and respiratory-triggered with navigator-echo technique fat-suppressed T2-weighted turbo spin-echo. Dynamic images using a three-dimensional (3D) fat-suppressed T1-weighted gradient-echo volumetric interpolated breath-hold examination (VIBE) axial series were obtained before and after intravenous contrast injection. The image parameters were as follows: repetition time/echo time, 3.06/1.12; flip angle, 10°; slice thickness, 2 mm; field of view, 350 mm × 280 mm; matrix, 256 × 224; acceleration factor, 2; number of partitions, 80; and acquisition time, 20 s. Before dynamic MRI, a test dose of 1 mL of Gd-EOB-DTPA was injected at a rate of 1 mL/s through a cubital intravenous line, and the bolus was flushed with 40 mL saline using a power injector. During the test injection, the image at the level of the celiac axis in which the aorta was enhanced the most was chosen, and its acquisition time was adopted as the peak aortic enhancement time. For dynamic MRI, 0.025 mmol/kg body weight of Gd-EOB-DTPA was intravenously administered at a flow rate of 1 mL/s, followed by a 40-mL saline solution flush. Breath-hold 3D fat-suppressed T1-weighted VIBE dynamic MRI was repeated at 10 s (arterial phase), 50 s (portal venous phase), 160 s (equilibrium phase), and 20 min (hepatobiliary phase) after the peak aortic enhancement time, which was determined by the test injection. In this study, only precontrast, arterial, portal venous, equilibrium, and hepatobiliary phase T1-weighted VIBE images were evaluated.

CT technique

Three-phase enhanced CT was performed with a 16-slice multidetector-row CT scanner (Aquilion, Toshiba Medical Systems, Tokyo, Japan). All scans were conducted from the top to the bottom of the liver with a tube voltage of 120 kVp and gantry rotation speed of 0.5 s. Unenhanced images were acquired using the following parameters: tube current, 350 mA; detector row configuration, 16 mm × 2 mm; and table increment, 30 mm/rotation. The imaging parameters for three-phase enhanced images were as follows: tube current, 440 mA; detector row configuration, 16 mm × 1 mm; and table increment, 15 mm/rotation in the cephalocaudal direction. In all patients, 2 mL/kg body weight of nonionic contrast ma-

terial with an iodine concentration of 300 mg I/mL was injected over a fixed duration of 30 s, followed by 20 mL of saline was injected at the same rate through a 20-gauge plastic intravenous catheter in an upper extremity vein. Automatic bolus tracking was employed using Sure Start software (Toshiba, Tokyo, Japan) to determine individual scan delays from the injection of the contrast material to commencement of the first pass. For bolus tracking, a series of nonhelical sequential images were obtained 8 s after contrast material administration. These images were acquired with a gantry rotation speed of 0.5 s and a low-dose radiation technique (120 kVp, 50 mA). A circular region of interest with an area of 50 pixels was placed in the aorta at the level of the celiac axis. The arterial phase scan was initiated automatically 20 s after the bolus-tracking program detected the threshold enhancement of 50 Hounsfield units in the aorta. The portal venous and equilibrium phases were obtained 70 s and 300 s, respectively, after the beginning of contrast material injection.

Image analysis

Gd-EOB-DTPA-enhanced MRI and enhanced CT images were qualitatively and quantitatively assessed. Three radiologists (Takumi K, Shindo T and Kumagae Y, with 10, 10 and 9 years of experience, respectively) with knowledge of the diagnosis of hepatic hemangioma assessed the following MRI and CT features in random order on two occasions with an interval of ≥ 2 wk: presence of peripheral nodular enhancement, central nodular enhancement, diffuse homogenous enhancement, and arteriportal shunt during the arterial phase, fill-in enhancement during the portal venous phase, and prolonged enhancement during the equilibrium phase. In the case of discrepancies between the three readers, the discrepancies were discussed during an additional reading session until a consensus was reached.

To assess the visual grades of tumor contrast enhancement relative to the surrounding liver parenchyma, the above three radiologists independently determined the degree of contrast enhancement in the enhancing portion of the hemangioma during each phase using the following five-grade scale: grade 5, a prominently greater enhancement than in the liver parenchyma; grade 4, a mildly greater enhancement than in the liver parenchyma; grade 3, an equal enhancement to the liver parenchyma; grade 2, a slightly decreased enhancement compared with the liver parenchyma; and grade 1, a prominently decreased enhancement compared with the liver parenchyma (Figure 1).

For quantitative analysis, one radiologist (Tateyama A, with 8 years of experience) who did not attend each reading session to minimize the bias of the measurements measured signal intensities of the enhancing portion of the hemangioma, liver parenchyma, and paravertebral muscle on Gd-EOB-DTPA-enhanced MRI and attenuation of the enhancing portions of the hemangioma and liver parenchyma on enhanced CT using operator-defined circular region of interests (ROIs). Figure 1 A 49-year-old man with hepatic hemangioma. The arterial, portal venous, and equilibrium phases on enhanced computed tomography and gadolinium-ethoxybenzyl-diethylenetriaminopentaacetic acid-enhanced magnetic resonance imaging. A: The hemangioma (arrow) shows peripheral nodular enhancement, and the enhancement degree was classified as visual grade 5 (prominently greater enhancement than in the liver parenchyma); B: The hemangioma (arrow) shows fill-in enhancement, and the enhancement degree was classified as visual grade 5 (prominently greater enhancement than in the liver parenchyma); C: The hemangioma (arrow) shows prolonged enhancement, and the enhancement degree was classified as visual grade 4 (mildly greater enhancement than in the liver parenchyma); D: The hemangioma (arrow) shows peripheral nodular enhancement, and the enhancement degree was classified as visual grade 4 (mildly greater enhancement than in the liver parenchyma); E: The hemangioma (arrow) shows fill-in enhancement, and the enhancement degree was classified as visual grade 4 (mildly greater enhancement than in the liver parenchyma); F: The hemangioma (arrow) did not show prolonged enhancement, and the enhancement degree was classified as visual grade 1 (prominently decreased enhancement compared with the liver parenchyma).

the enhancing portion of the hemangioma during each phase, the largest possible ROIs were selected to measure signal intensity and attenuation. The ROIs of the liver parenchyma at the level of the hilum of the liver were 100–200 mm² in size and were drawn in the lateral, anterior, and posterior segments, avoiding blood vessels and artifacts; the intensity and attenuation measurements were averaged. The ROIs of paravertebral muscle were 100 mm² in size. The tumor-muscle and liver-muscle signal intensity ratios (SIRs) were calculated respectively by dividing the signal intensity of the enhancing portion of the hemangioma and the liver by the signal intensity of the paravertebral muscle. The tumor-liver contrast (TLC) on Gd-EOB-DTPA-enhanced MRI was calculated with the following equation: $TLC = (\text{signal intensity of the enhancing portion} - \text{signal intensity of the liver parenchyma}) / \text{signal intensity of the paravertebral muscle}$. The TLC on enhanced CT was calculated as the difference in attenuation between the enhancing portion of the hemangioma and the liver parenchyma.

Statistical analysis

Statistical analyses were performed using SPSS 14.0 software for Windows (SPSS Version 14.0, Chicago, IL). The McNemar test was used to assess the significance

of differences in the appearances of hemangiomas between Gd-EOB-DTPA-enhanced MRI and enhanced CT. The Wilcoxon's signed rank test was used to assess the significance of differences in the visual grade of tumor contrast enhancement between Gd-EOB-DTPA-enhanced MRI and enhanced CT. To assess interobserver variability in the visual analysis of tumor contrast enhancement, the weighted κ test of concordance was applied to measure the degree of agreement between the three radiologists. Agreement was graded as poor (κ value < 0.20), moderate (≥ 0.20 and < 0.40), fair (≥ 0.40 and < 0.60), good (≥ 0.60 and < 0.80), or very good (≥ 0.80 –1). The relationship between the visual grades of tumor contrast enhancement and TLC was analyzed using the Spearman rank correlation coefficient (R_s). For all statistical analyses, $P < 0.05$ was considered significant.

RESULTS

There were no significant differences between GdEOB-DTPA-enhanced MRI and enhanced CT in the presence of peripheral nodular enhancement (85% *vs* 82%), central nodular enhancement (3% *vs* 3%), diffuse enhancement (11% *vs* 16%), or arteriportal shunt (23% *vs* 34%) during the arterial phase. There was also no difference

Table 1 Appearances and visual grades of tumor contrast enhancement of hemangiomas on gadolinium-ethoxybenzyl-diethylenetriaminopentaacetic acid-enhanced magnetic resonance imaging and enhanced computed tomography

Appearance	Tumors		<i>P</i> value
	Gd-EOB-DTPA-enhanced MRI	Enhanced CT	
Peripheral nodular enhancement	52 (85)	50 (82)	0.754 ¹
Central nodular enhancement	2 (3)	2 (3)	1.000 ¹
Diffuse homogenous enhancement	7 (11)	10 (16)	0.508 ¹
Arteriportal shunt	14 (23)	21 (34)	0.065 ¹
Fill-in enhancement	48 (79)	49 (80)	1.000 ¹
Prolonged enhancement	32 (52)	61 (100)	< 0.001 ¹
Visual grade			
Arterial phase	3.94 ± 0.98	4.57 ± 0.64	< 0.001 ²
Portal venous phase	3.72 ± 0.82	4.36 ± 0.53	< 0.001 ²
Equilibrium phase	2.01 ± 0.95	4.04 ± 0.51	< 0.001 ²

Data are presented as mean ± SD or *n* (%). ¹*P* value between gadolinium-ethoxybenzyl-diethylenetriaminopentaacetic acid (Gd-EOB-DTPA)-enhanced magnetic resonance imaging (MRI) and enhanced computed tomography (CT) by a McNemar test; ²*P* value between Gd-EOB-DTPA-enhanced MRI and enhanced CT by a Wilcoxon's signed rank test.

in fill-in enhancement (79% *vs* 80%, respectively) during the portal venous phase. Prolonged enhancement during the equilibrium phase was observed significantly less frequently on Gd-EOB-DTPA-enhanced MRI than on enhanced CT (52% *vs* 100%, respectively, *P* < 0.001) (Table 1).

The visual grade of tumor contrast enhancement was significantly less on Gd-EOB-DTPA-enhanced MRI than enhanced CT during the arterial phase (3.94 ± 0.98 *vs* 4.57 ± 0.64, respectively, *P* < 0.001), the portal venous phase (3.72 ± 0.82 *vs* 4.36 ± 0.53, respectively, *P* < 0.001), and the equilibrium phase (2.01 ± 0.95 *vs* 4.04 ± 0.51, respectively, *P* < 0.001) (Table 1). There was good interobserver agreement for the visual grade of tumor contrast enhancement, with weighted κ values ranging from 0.59 to 0.92.

In the quantitative analysis, the tumor-muscle SIR and the liver muscle SIR observed with Gd-EOB-DTPA-enhanced MRI were, respectively, 0.80 ± 0.24 and 1.28 ± 0.33 precontrast, 1.92 ± 0.58 and 1.57 ± 0.55 during the arterial phase, 1.87 ± 0.44 and 1.73 ± 0.39 during the portal venous phase, 1.63 ± 0.41 and 1.78 ± 0.39 during the equilibrium phase, and 1.10 ± 0.43 and 1.92 ± 0.50 during the hepatobiliary phase (Figure 2A). The attenuation values in the tumor and liver parenchyma observed with enhanced CT were, respectively, 40.60 ± 8.78 and 53.78 ± 7.37 precontrast, 172.66 ± 73.89 and 92.76 ± 17.92 during the arterial phase, 152.76 ± 35.73 and 120.12 ± 18.02 during the portal venous phase, and 108.74 ± 18.70 and 89.04 ± 7.25 during the equilibrium phase (Figure 2B). Hemangiomas demonstrated peak enhancement during the arterial phase, and both the SIR observed with Gd-EOB-DTPA-enhanced MRI and the attenuation value observed with enhanced CT decreased with time. The SIR of hemangiomas was lower than

Figure 2 Temporal profiles of the signal intensity ratios on gadolinium-ethoxybenzyl-diethylenetriaminopentaacetic acid-enhanced magnetic resonance imaging and the attenuation values on enhanced computed tomography. A: Tumor-muscle and liver-muscle signal intensity ratios (SIRs) before and after gadolinium-ethoxybenzyl-diethylenetriaminopentaacetic acid (Gd-EOB-DTPA) injection; B: The attenuation values in the tumor and liver parenchyma before and after nonionic contrast material injection. Tumor-muscle SIR = signal intensity of the hemangiomas/signal intensity of the paravertebral muscle; Liver-muscle SIR = signal intensity of the liver parenchyma/signal intensity of the paravertebral muscle. PRE: Precontrast scan; AR: Arterial phase; PV: Portal venous phase; EQ: Equilibrium phase; HB: Hepatobiliary phase; HU: Hounsfield unit.

the SIR of liver parenchyma during the equilibrium and hepatobiliary phases observed with Gd-EOB-DTPA-enhanced MRI (Figure 2). The TLC observed with Gd-EOB-DTPA-enhanced MRI were -0.48 ± 0.20 precontrast, 0.35 ± 0.53 during the arterial phase, 0.15 ± 0.43 during the portal venous phase, and -0.15 ± 0.28 during the equilibrium phase. In comparison, the TLC observed with enhanced CT were -13.18 ± 7.79 precontrast, 79.9 ± 35.9 during the arterial phase, 32.6 ± 17.4 during the portal venous phase, and 19.7 ± 13.5 during the equilibrium phase. The visual assessment of tumor contrast enhancement correlated well with the TLC in the quantitative analysis of both Gd-EOB-DTPA-enhanced MRI and enhanced CT, with *R*_s values ranging from 0.45 to 0.71 (all *P* < 0.001).

DISCUSSION

Enhanced CT and Gd-DTPA-enhanced MRI findings of hepatic hemangiomas have been well documented in

many reports, and the dynamic characteristics observed using both modalities are similar^[3-7]. The typical findings of hepatic hemangioma on enhanced CT are hypodensities similar to the attenuation of vessels on pre-contrast images, peripheral nodular enhancement during the arterial phase, fill-in enhancement during the portal venous phase, and prolonged enhancement during the equilibrium phase^[4-7].

In previous reports, peripheral nodular enhancement during the arterial phase was identified in 55%-87% of hemangiomas^[4,5,7,21], and fill-in enhancement during the portal venous phase was observed in 59%-96% of hemangiomas observed with enhanced CT^[4,5,7,22,23]. In the present study, peripheral nodular enhancement during the arterial phase and fill-in enhancement during the portal venous phase on enhanced CT were observed in 50 (82%) and 49 (80%) of 61 hemangiomas, respectively. Goshima *et al.*^[16] reported that peripheral nodular enhancement with fill-in enhancement was observed in 28% who underwent Gd-EOB-DTPA-enhanced MRI. To our knowledge, no reports have compared the Gd-EOB-DTPA-enhanced MRI findings of hemangiomas with enhanced CT. In the present study, peripheral nodular enhancement was identified in 52 (85%) and fill-in enhancement was shown in 48 (79%) of 61 hemangiomas visualized with Gd-EOB-DTPA-enhanced MRI. No significant differences were observed in the presence of peripheral nodular and fill-in enhancement between Gd-EOB-DTPA-enhanced MRI and enhanced CT. In the quantitative analysis, enhanced portions of the hemangiomas demonstrated peak contrast enhancement during the arterial phase, and the contrast enhancement decreased with time on both Gd-EOB-DTPA-enhanced MRI and enhanced CT. However, tumor contrast enhancement during the arterial and portal venous phases was significantly reduced on Gd-EOB-DTPA-enhanced MRI compared with enhanced CT by both visual assessment and quantitative analysis. This result may be influenced by the lower gadolinium dose used with Gd-EOB-DTPA^[12,14].

Hemangiomas showing diffuse homogenous enhancement during the arterial phase can mimic hypervascular malignant tumors such as hepatocellular carcinomas or hypervascular metastases^[21,22,24,25]. In previous reports, diffuse homogenous enhancement during the arterial phase was observed in 8%-35% of hemangiomas on enhanced CT^[22,24] and 34% on Gd-EOB-DTPA-enhanced MRI^[16]. In the present study, diffuse homogenous enhancement during the arterial phase was observed in 10 (16%) and 7 (11%) of 61 hemangiomas on enhanced CT and Gd-EOB-DTPA-enhanced MRI, respectively. There were no significant differences between Gd-EOB-DTPA-enhanced MRI and enhanced CT in this respect.

Prolonged enhancement during the equilibrium phase is present in approximately 59%-96% of hemangiomas observed with enhanced CT^[22-24] and 37%-72% of hemangiomas observed with Gd-EOB-DTPA-enhanced

MRI^[16,17]. This difference in the presence of prolonged enhancement on Gd-EOB-DTPA-enhanced MRI may be explained by differences in case selection. In addition, on enhanced CT, once the regions in the hemangioma enhance during the arterial phase, they also show prolonged enhancement^[25]. In the present study, prolonged enhancement was observed on enhanced CT in all 61 hemangiomas, whereas Gd-EOB-DTPA-enhanced MRI showed prolonged enhancement only in 52% of the hemangiomas. The contrast enhancement was significantly reduced when using Gd-EOB-DTPA-enhanced MRI instead of enhanced CT. Ringe *et al.*^[18] reported that hemangiomas appear iso- or hypointense compared to the liver parenchyma during the equilibrium and hepatobiliary phases on Gd-EOB-DTPA-enhanced MRI. They suggest that this reduction is because of Gd-EOB-DTPA uptake in the surrounding normal liver parenchyma, the lower gadolinium dose, and the shorter plasma half-life of Gd-EOB-DTPA. Hemangiomas showing diffuse homogenous enhancement during the arterial phase can be differentiated from hypervascular malignant tumors on enhanced CT and Gd-DTPA-enhanced MRI because hemangiomas show isoattenuation or hyperattenuation relative to the liver parenchyma during the equilibrium phase^[3,22,25]. In the present study, however, none of the hemangiomas with diffuse homogenous enhancement during the arterial phase showed prolonged enhancement during the equilibrium phase of Gd-EOB-DTPA-enhanced MRI. Moreover, 22 (40%) of 54 hemangiomas without diffuse enhancement during the arterial phase did not show prolonged enhancement during the equilibrium phase of Gd-EOB-DTPA-enhanced MRI. Hypovascular metastatic tumors show relatively low signal intensity during the equilibrium phase of Gd-EOB-DTPA-enhanced MRI^[9,11,16]. Therefore, the present results suggest that it may be difficult to differentiate hemangiomas from malignant tumors such as hepatocellular carcinomas and metastatic tumors on Gd-EOB-DTPA-enhanced MRI because approximately half the hemangiomas exhibited relatively low signal intensity during the equilibrium phase. Enhanced MRI with extracellular contrast agents, such as Gd-DTPA, may be more useful for the diagnosis of hepatic hemangiomas. However, Gd-EOB-DTPA-enhanced MRI is widely used for evaluating the presence of hepatocellular carcinoma or metastasis in patients with liver cirrhosis or an extrahepatic malignancy because of its higher detectability compared with Gd-DTPA-enhanced MRI^[11,12]. The differentiation of hemangioma from HCC or metastases on Gd-EOB-DTPA-enhanced MRI is frequently required in a clinical practice.

The present study has several potential limitations. First, pathological proof was obtained only for four hemangiomas and was not obtained for the majority of the lesions. Tissue biopsies were not obtained because hemangiomas are benign lesions and usually do not require invasive procedures. Therefore, case selection depended solely on imaging findings, but the typical

findings on enhanced CT and bright signal intensity on T2-weighted MRI are accepted as diagnostic for hepatic hemangioma. Second, the present study may have a potential selection bias because atypical hemangiomas that did not meet the present selection criteria were not included. Therefore, further investigation will be necessary to elucidate the appearance of atypical hemangiomas on Gd-EOB-DTPA-enhanced MRI. Third, all the lesions were hemangiomas; other liver tumors were not included in the present study. Therefore, this selection may bias the interpretation of the Gd-EOB-DTPA-enhanced MRI and enhanced CT findings. However, the purpose of the present study was to compare the features of hepatic hemangiomas on Gd-EOB-DTPA-enhanced with enhanced CT. Fourth, the imaging parameters, injection rate, duration of the contrast material, and scanning timing were not identical for Gd-EOB-DTPA-enhanced MRI and enhanced CT. However, it is impractical to make them uniform because they have been optimized for each imaging modality.

In conclusion, the typical findings of hemangiomas, such as peripheral nodular enhancement, central nodular enhancement, diffuse enhancement, or arterioportal shunt during the arterial phase, or fill-in enhancement during the portal venous phase, are useful for the diagnosis of hemangiomas using Gd-EOB-DTPA-enhanced MRI and enhanced CT. However, prolonged enhancement during the equilibrium phase was observed significantly less frequently on Gd-EOB-DTPA-enhanced MRI. Some hemangiomas show relatively low signal intensity during the equilibrium phase, which may mimic malignant tumors. Knowledge of Gd-EOB-DTPA-enhanced MRI findings is important for arriving at the correct diagnosis of hepatic hemangioma.

COMMENTS

Background

Hepatic hemangioma is the most common benign hepatic neoplasm, and its differentiation from malignant liver tumors is very important. The most common enhanced computed tomography (CT) and gadolinium-diethylenetriaminepentaacetic acid (Gd-DTPA)-enhanced magnetic resonance imaging (MRI) features of hepatic hemangiomas are peripheral nodular enhancement during the arterial phase, fill-in enhancement during the portal venous phase, and prolonged enhancement during the equilibrium phase. Recently, gadolinium-ethoxybenzyl-diethylenetriaminepentaacetic acid (Gd-EOB-DTPA)-enhanced MRI has been used to evaluate liver lesions.

Research frontiers

It is important to clarify the features of hepatic hemangiomas observed with Gd-EOB-DTPA-enhanced MRI. However, limited reports describe the findings of hemangiomas observed with Gd-EOB-DTPA-enhanced MRI. Moreover, the appearance and the degree of contrast enhancement of hepatic hemangiomas observed with Gd-EOB-DTPA-enhanced MRI compared with enhanced CT have not been elucidated.

Innovations and breakthroughs

The tumor-to-liver contrast enhancement during each phase was significantly lower on Gd-EOB-DTPA-enhanced MRI than enhanced CT. Prolonged enhancement during the equilibrium phase, which is an important finding for diagnosing hepatic hemangiomas, was observed less frequently on Gd-EOB-DTPA-enhanced MRI than enhanced CT.

Applications

Some hemangiomas show relatively low signal intensity during the equilibrium

phase and may mimic malignant tumors. Knowledge of Gd-EOB-DTPA-enhanced MRI findings is important for arriving at the correct diagnosis of hepatic hemangioma.

Terminology

Gd-EOB-DTPA is a new hepatobiliary contrast agent that exhibits high T1 relaxivity in the liver and shows enhancement on both early perfusion phase images and delayed hepatobiliary phase images. Gd-EOB-DTPA-enhanced MRI is more useful for the detection and characterization of focal liver lesions than enhanced CT and Gd-DTPA-enhanced MRI.

Peer review

The authors compare the liver-tumor contrasts obtained for hepatic hemangioma with hepatobiliary contrast in MRI with extracellular contrast in CT, which is of clinical interest.

Abstract

AIM: To evaluate the durability in hepatitis B e antigen (HBeAg) positive chronic hepatitis B patients who discontinued antiviral treatment.

METHODS: A total of 48 HBeAg positive chronic hepatitis B patients who were administered nucleoside analogues and maintained virological response for ≥ 6 mo [hepatitis B virus (HBV) DNA < 300 copies/mL and HBeAg seroconversion] before cessation of treatment were enrolled between February 2007 and January 2010. The criteria for the cessation of the antiviral treatment were defined as follows: (1) achievement of virological response; and (2) duration of consolida-

tion therapy (≥ 6 mo). After treatment cessation, the patients were followed up at 3-6 mo intervals. The primary endpoint was serologic and virologic recurrence rates after withdrawal of antiviral treatment. Serologic recurrence was defined as reappearance of HBeAg positivity after HBeAg seroconversion. Virologic recurrence was defined as an increase in HBV-DNA level > 10^4 copies/mL after HBeAg seroconversion with previously undetectable HBV-DNA level.

RESULTS: During the median follow-up period of 18.2 mo (range: 5.1-47.5 mo) after cessation of antiviral treatment, the cumulative serological recurrence rate was 15 % at 12 mo. The median duration between the cessation of antiviral treatment and serologic recurrence was 7.2 mo (range: 1.2-10.9 mo). Of the 48 patients with HBeAg positive chronic hepatitis, 20 (41.6%) showed virological recurrence. The cumulative virologic recurrence rates at 12 mo after discontinuing the antiviral agent were 41%. The median duration between off-treatment and virologic recurrence was 7.6 mo (range: 4.3-27.1 mo). The mean age of the virological recurrence group was older than that of the non-recurrence group (46.7 ± 12.1 years vs 38.8 ± 12.7 years, respectively; $P = 0.022$). Age (> 40 years) and the duration of consolidation treatment (≥ 15 mo) were significant predictive factors for off-treatment durability in the multivariate analysis [$P = 0.049$, relative risk (RR) 0.31, 95% CI (0.096-0.998) and $P = 0.005$, RR 11.29, 95% CI (2.054-65.12), respectively]. Patients with age (≤ 40 years) who received consolidation treatment (≥ 15 mo) significantly showed durability in HBeAg positive chronic hepatitis B patients ($P = 0.014$). These results suggest that additional treatment for more than 15 mo after HBeAg seroconversion in patients who are ≤ 40 years old may be beneficial in providing a sustained virological response.

CONCLUSION: Our data suggest that HBeAg seroconversion is an imperfect end point in antiviral treat-

ment. Long-term consolidation treatment (≥ 15 mo) in younger patients is important for producing better prognosis in HBeAg positive chronic hepatitis B.

Durability of viral response after off-treatment in HBeAg positive chronic hepatitis B. *World J Gastroenterol* 2012; 18(43): 6277-6283 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i43/6277.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i43.6277>

INTRODUCTION

Chronic hepatitis B virus (HBV) infection is a major problem in medical health care with approximately 400 million people infected worldwide^[1,2]. Since lamivudine was introduced as an effective antiviral agent for chronic hepatitis B in the late 1990s, many types of nucleos(t)ide analogues (NUCs) have been developed to prevent the progression of cirrhosis and hepatocellular carcinoma^[3-6]. To assess these effects of antiviral therapy, surrogate markers such as hepatitis B e antigen (HBeAg) seroconversion or HBsAg loss have been reported^[7-12].

The current end-points of therapy are durable HBeAg seroconversion in HBeAg-positive patients^[13]. International guidelines on HBV therapy suggest that finite duration of treatment with a NUC is a reasonable option, and recommend that treatment may be stopped after HBeAg seroconversion and an additional 6-12 mo of consolidation therapy in HBeAg-positive hepatitis^[13,14]. However, it may be necessary to maintain long-term treatment for the ideal end-points such as HBsAg clearance or sustained virologic response in HBeAg-positive chronic hepatitis B due to a higher relapse rate^[15,16].

The optimum treatment durations of NUCs also remain ill defined. Several studies on the durability of HBeAg seroconversion induced by lamivudine have produced contradictory results^[16-19]. Reijnders *et al*^[20] have reported that HBeAg seroconversion is an imperfect end point in antiviral treatment. Studies investigating the durability of the response to newer agents such as entecavir and clevudine are still lacking.

The durability of virological response (HBeAg seroconversion and undetectable HBV DNA) is important

for developing a treatment strategy for chronic hepatitis B patients. In this study, we evaluated the off-treatment durability of response and the predictive factors for virologic recurrence in HBeAg positive chronic hepatitis B patients who achieved successful end point of therapy with nucleoside analogues such as entecavir and clevudine. Furthermore, we compared the durability of response between entecavir and clevudine.

MATERIALS AND METHODS

Study population

This study included 48 Korean patients with chronic hepatitis B infection (HBsAg and HBeAg positivity for at least 6 mo) who were hospitalized at the Seoul St. Mary's Hospital, Gangnam Severance Hospital, Inje University Ilsan Paik Hospital and Chung-Ang University Hospital between February 2007 and January 2010. All patients were treated with nucleoside analogue therapy such as clevudine and entecavir. When the therapy was initiated, the serum HBV DNA levels were at least 105 copies/mL and alanine aminotransferase (ALT) or aspartate aminotransferase (AST) levels were more than two times the upper limit of normal (ULN, 40 IU/L). There were no signs of either co-infection with hepatitis C virus or human immunodeficiency virus or hepatic decompensation such as ascites, variceal bleeding or hepatic encephalopathy, and treatment with (pegylated) interferon was discontinued at least 6 mo before the start of the NUC treatment.

The cessation criteria of the NUC treatment were defined as follows: (1) the achievement of a virological response; and (2) duration of consolidation therapy (≥ 6 mo). Virological response was defined as HBeAg seroconversion, HBV DNA < 300 copies/mL and normal ALT levels. The study was approved by the institutional Ethics Review Board and complied with the Declaration of Helsinki.

Follow-up evaluation

All patients were monitored at least every 3-6 mo during the antiviral treatment period. Biochemical (serum AST, ALT) and virological parameters (HBeAg, HBeAb status and quantitative HBV DNA) were assessed at every visit. Nucleoside analogue-treated patients who achieved virological response were evaluated every 3 mo. Consolidation therapy was continued for more than 6 mo after achieving virological response. In cases in which NUC treatment was discontinued, the patients were followed up at 3-6 mo intervals for a median period of 18.2 mo (range: 5.1-47.5 mo).

End points

The primary endpoint was serologic and virologic recurrence rates after withdrawal of antiviral treatment. Serologic recurrence was defined as reappearance of HBeAg positivity after HBeAg seroconversion. Virologic recurrence was defined as an increase in HBV-DNA

Table 1 Baseline characteristics of the study population

Baseline characteristics	Total (<i>n</i> = 48)
Age, yr (mean \pm SD)	42.1 \pm 12.9
Sex (male/female)	29/19
Pretreatment ALT level (IU/L)	198 (11-374)
Pretreatment HBV DNA level (log ₁₀ copies/mL)	8.5 (5.0-10)
Time to undetectable HBV (mo)	7.7 (1.3-39.4)
Time to HBeAg seroconversion (mo)	13.4 (0.8-39.4)
Consolidation treatment duration (mo)	10.3 (6-37.9)
Total treatment duration (mo)	26.1 (9.4-47.4)
Antiviral agent (entecavir/clevudine)	31/17
Previous NUC treatment (naïve/lamivudine)	41/7

ALT: Alanine aminotransferase; HBV: Hepatitis B virus; HBeAg: Hepatitis B e antigen; NUC: Nucleos(t)ide analogues.

level $> 10^4$ copies/mL after HBeAg seroconversion with previously undetectable HBV-DNA level because a viral load of more than 10 000 copies/mL is associated with progression of liver disease^[4,21].

The secondary endpoint was to evaluate the difference in the durability between entecavir and clevudine.

Laboratory testing

Serum HBeAg and HBeAb were measured with a radioimmunoassay according to the manufacturer's protocol (Abbott Laboratories, Chicago, IL, United States). Serum HBV-DNA levels were measured with real-time PCR using Abott Realtime HBV Quantification Kit (Abott Molecular Inc., IL, United States).

Ethics approval

Ethics approval was provided by the institutional Ethics Review Board, The Catholic University of Korea (KC11RIMI0560).

Statistical analysis

The continuous variables are expressed as the mean \pm SE or median (range) where appropriate. Durability was calculated from the date of the antiviral treatment cessation to the date of virologic recurrence or censorship. The cumulative rates of virologic recurrence, HBeAg seroreversion were estimated with the Kaplan-Meier method. The Cox's proportional hazard model was adopted to determine the predictive factors for relapse, among various variables including age, pretreatment ALT, AST level, pretreatment HBV DNA levels, consolidation treatment duration and total treatment duration. $P < 0.05$ was considered to be significant (SPSS 17, Chicago, IL).

RESULTS

Clinical characteristics of the patients

The baseline characteristics of all patients are shown in Table 1. A total of 48 patients with chronic hepatitis B who were treated with a nucleoside analogue in multi-center were included in the analysis. Of the 48 patients, 29 (60.4%) were men and the mean age was 42.1 ± 12.9

years. The pretreatment ALT level and serum HBV DNA level were 198 IU/L (11-374 IU/L) and 8.8 log₁₀ copies/mL (range: 5-10 log₁₀ copies/mL), respectively. Overall, 31 of the 48 patients with HBeAg positive hepatitis were treated with entecavir, and 17 were treated with clevudine. A total of 41 (85.4%) patients were nucleoside analog treatment naïve, whereas 7 (14.6%) patients had received prior treatment with lamivudine. All patients who were treated with lamivudine did not have any evidence of lamivudine-resistance at the initiation of entecavir or clevudine treatment. The median duration of therapy was 26.1 mo (range: 9.4-47.4 mo). Patients were followed up for a median of 45.6 mo (range: 23.6-60.2 mo); 82 % (43/48) were followed up for more than 3 years.

Serologic recurrence after HBeAg seroconversion

The median follow-up time after HBeAg seroconversion for 48 patients was 32.1 mo (range: 10.3-55.8 mo). Serologic recurrence occurred in 6 of 48 (12.5%) patients. The cumulative serologic recurrence rates at 6 mo, 12 mo and 18 mo after NUC induced HBeAg seroconversion were 0%, 7% and 15%, respectively. The median duration between the cessation of antiviral treatment and serologic recurrence was 7.2 mo (range: 1.2-10.9 mo). In 1 case, serologic recurrence occurred less than 6 mo after the cessation of NUC treatment, and in 5/6 (83%) cases, serologic recurrence occurred within 12 mo after off-treatment (Figure 1A).

Virologic recurrence after HBeAg seroconversion and undetectable HBV DNA in HBeAg positive hepatitis

Virologic recurrence occurred in 20 of 48 patients (41.6%) after HBeAg seroconversion. The cumulative virologic recurrence rates at 6 mo, 12 mo and 24 mo after discontinuing the antiviral agent were 38%, 41% and 60%, respectively (Figure 1B). Of these 20 patients, 6 reverted to chronic HBeAg-positive chronic hepatitis B, and 14 progressed to HBeAg negative chronic hepatitis B. One of 6 patients with HBeAg reversion (16.6%) showed HBV DNA levels of 10-100 copies/L. Six of 14 patients with HBeAg seronegativity (42.8%) showed HBV DNA levels of more than 100 copies/L (Table 2). The median duration between off-treatment and virologic recurrence was 7.6 mo (range: 4.3-27.1 mo) in HBeAg positive hepatitis. Seventeen cases (85%) of virologic recurrence occurred within 12 mo after off-treatment.

Durable response

In HBeAg positive chronic hepatitis, only 28 (58.3%) had a durable response, as defined by the continued absence of HBeAg and HBV DNA levels less than 10 copies/L, during a median follow-up period of 18.2 mo (range: 5.1-47.5 mo). In all patients, NUC therapy was discontinued after HBeAg seroconversion occurred and at least 6 mo of consolidation therapy. The clinical features and laboratory data including age, sex, pretreatment ALT, HBV DNA titer, duration of consolidation

Figure 1 Serologic recurrence and virologic recurrence after off-treatment in patients with hepatitis B e antigen positive hepatitis. A: Serologic recurrence after off-treatment in patients with hepatitis B e antigen (HBeAg) positive hepatitis who achieved the successful end point of virologic response; B: Virologic recurrence after off-treatment in HBeAg positive hepatitis.

treatment, total treatment duration, and duration of treatment before the HBV DNA levels were undetectable were compared between the virologic recurrence and the non-recurrence group (Table 3). The mean age of the recurrence group was older than that of the non-recurrence group (46.7 ± 12.1 years *vs* 38.8 ± 12.7 years, respectively; $P = 0.022$).

Univariate analysis was performed to determine the predictive factors of durability. The variables including age, sex, pretreatment ALT, level, pretreatment HBV DNA levels, time to undetectable HBV DNA, time to HBeAg seroconversion, consolidation treatment duration and total treatment duration. Age (≤ 40 years) and the duration of consolidation treatment (≥ 15 mo) were significant predictive factors for off-treatment durability ($P = 0.017$, $P = 0.046$, respectively). In the multivariate analysis using the Cox's proportional hazard model, the factors of age (≤ 40 years) and prolonged-consolidation treatment ≥ 15 mo were also significant predictive factors of virological recurrence in HBeAg positive chronic hepatitis B patients [$P = 0.049$, 95% CI (0.096-0.998); $P = 0.005$, 95% CI (2.054-65.12)]. Serologic or virologic recurrence did not show a significant difference between clevudine and entecavir treatment (Table 4).

Using the two predictive factors including age (≤ 40 years) and prolonged-consolidation treatment ≥ 15 mo

Figure 2 Using the two predictive factors for virological recurrence (age > 40 yr *vs* ≤ 40 yr and consolidation treatment duration < 15 mo *vs* ≥ 15 mo). Patients were categorized into 3 groups. Group A: Patients with aged ≤ 40 yr and consolidation treatment duration ≥ 15 mo; Group B: Patients with either aged ≤ 40 yr or consolidation treatment duration ≥ 15 mo; Group C: Patients with aged > 40 yr and consolidation treatment for < 15 mo. P values were derived from the log-rank test (group A *vs* group B, $P = 0.291$; group A *vs* group C, $P = 0.014$, respectively).

Table 2 Summary of patients who showed serologic and virological recurrence

Patient No.	Age (yr)	Sex	Serologic recurrence (HBeAg reversion)	Virological recurrence (copies/L)	ALT level at relapse (U/L)
1	28	Female	Yes	97 600	139
2	24	Female	Yes	645 000 000	236
3	42	Male	Yes	120 759	71
4	46	Male	Yes	980 000	45
5	47	Male	Yes	254 251 078	89
6	48	Female	Yes	320 630	287
7	46	Male	No	42 900	42
8	32	Female	No	20 916	32
9	67	Male	No	10 083	38
10	42	Male	No	41 982	65
11	46	Male	No	86 000	40

14	67	Female	No	10 032	31
15	62	Female	No	637 898	28
16	50	Male	No	43 719	98
17	51	Female	No	32 033	101
18	42	Male	No	86 6197	243
19	53	Male	No	6 158 288	54
20	37	Female	No	116 000 000	436

ALT: Alanine aminotransferase; HBeAg: Hepatitis B e antigen.

patients could be classified into 3 groups: patients who had both of the good predictors (age ≤ 40 years and consolidation treatment ≥ 15 mo, group A); patients with either ≥ 40 years old or underwent consolidation treatment ≥ 15 mo (group B), and patients with neither of the two good predictors (group C). Among these 3 groups, group C showed a significantly higher recurrence rate (Figure 2). These results suggest that additional treatment for more than 15 mo after HBeAg seroconversion in patients who are ≤ 40 years old may be beneficial in providing a sustained virological response.

Table 3 Clinical characteristics in virological recurrence and non-recurrence

	Virological recurrence (<i>n</i> = 20)	Virological non-recurrence (<i>n</i> = 28)	<i>P</i> value
Age, yr (mean ± SD)	46.7 ± 12.1	38.8 ± 12.7	0.022
Sex (male/female)	11/9	29/19	0.561
Pretreatment ALT level (IU/L)	199 (40-374)	189 (11-364)	0.491
Pretreatment HBV DNA level (log ₁₀ copies/mL)	7.7 (5.1-10)	7 (5.0-9.1)	0.125
Time to undetectable HBV (mo)	6.7 (2.3-39.4)	9.1 (1.3-25.0)	0.490

HBV: Hepatitis B virus; HBeAg: Hepatitis B e antigen; ULN: Upper limit of normal; ALT: Alanine aminotransferase; RR: Relative risk.

DISCUSSION

The end points of chronic hepatitis B treatment, independent of HBeAg status, are the sustained suppression of HBV replication, the remission of liver disease and the prevention of hepatocellular carcinoma^[22,23]. Clinical studies have reported that rapid and sustained suppression of viral load is an important factor in the prediction of the virological response. It was reported that entecavir had the potential for a very rapid and effective antiviral response and clevudine-induced viral response was durable after discontinuation of treatment^[24]. It was hypothesized that entecavir would induce a more durable suppression of viral load compared with that of clevudine after discontinuation of treatment.

We studied the durability of off treatment for chronic HBV infection among entecavir-treated and clevudine-treated patients who achieved “virological response”. Current international guidelines suggest that treatment with NUC can be discontinued after 6-12 mo of consolidation therapy after HBeAg seroconversion^[14].

Consistent with these recommendations, NUC treatment was discontinued in all patients after 6 mo of consolidation treatment. During follow-up after the discontinuation of NUC therapy, only 20 (41.6%) of the 48 patients showed a durable response, which was defined as HBeAg seroconversion and HBV DNA levels less than 10 copies/L. Moreover, a sustained response was achieved in patients who discontinued therapy after a

consolidation therapy period of at least 15 mo regardless of the type of antiviral drug.

In our study, both serologic and virological recurrence after HBeAg seroconversion and undetectable HBV DNA were considered. Serologic recurrence showed 5 of 6 patients (83%) and virological recurrence occurred 17 of 20 patients (85%) within 12 mo after discontinuing the antiviral agent. This recurrence rate was consistent with a previous study^[20]. These results showed longer treatment durations of nucleoside analogs may contribute to the suppression of viral replication and the clearance of infected hepatocytes, but HBV cannot be completely eradicated. Therefore, HBeAg seroconversion and consolidation therapy for more than 6 mo might be an imperfect end point in antiviral treatment.

Patients who were ≤ 40 years old also showed independently significant associations with a sustained response based on the multivariate analysis. Younger patients had a more sustained durability. This result was similar to that reported by Chien *et al*^[25] who demonstrated that Taiwanese patients who were < 36 years of age had a more sustained response. This difference in durability based on age may be related to immune system activity^[26]. It is assumed that younger patients were more likely to be sufficiently immunocompetent to maintain viral suppression, which contributed to a higher rate of off-treatment durability. While age appears to be directly related to durability in this study, further research is necessary to more clearly define the cutoff age.

This study has some limitations in a retrospective study. First, a limited number of patients were treated with either entecavir or clevudine monotherapy; Second, HBsAg loss in a more stable remission of chronic hepatitis B compared with HBeAg seroconversion was not analyzed because the follow-up period was relatively short. However, we intended to analyze the predictive factors of sustained virologic response in HBeAg positive chronic hepatitis B patients who discontinued successful antiviral therapy that was considered as high potency antiviral agent more than lamivudine. Our results might suggest that the high recurrence rates after achieving sustained virologic response (HBeAg seroconversion and undetectable HBV DNA) showed no difference of durability regardless of the type of oral high potency antiviral agent.

In conclusion, this study shows that HBeAg seroconversion and consolidation therapy for more than 6 mo are an imperfect end point in antiviral treatment. Long-term consolidation treatment (≥ 15 mo) in younger patients is important to produce better prognosis in HBeAg positive chronic hepatitis B.

COMMENTS

Background

The durability of the virologic response is important to plan the strategy of treatment in chronic hepatitis B. The present study evaluated the off-treatment durability of response and the predictive factors for virologic recurrence in hepatitis B e antigen (HBeAg) positive chronic hepatitis B patients who achieved the successful end point of nucleotide analogue therapy.

Research frontiers

This study showed that HBeAg seroconversion is an imperfect end point in antiviral treatment. Long-term consolidation treatment (≥ 15 mo) in younger patients is important for producing better prognosis in HBeAg positive chronic hepatitis B.

Innovations and breakthroughs

The high recurrence rates after achieving sustained virologic response (HBeAg seroconversion and undetectable hepatitis B virus DNA) showed no difference of durability regardless of the type of oral high potency antiviral agent.

Applications

The study results suggest that long-term consolidation treatment (≥ 15 mo) after achieving virological response is important for maintaining better sustained virological response in HBeAg positive chronic hepatitis B.

Terminology

The criteria for the cessation of treatment were defined as follows: (1) achievement of virological response; and (2) duration of consolidation therapy (≥ 6 mo). Virological response defined HBeAg seroconversion, HBV DNA < 300 copies/mL and normal alanine aminotransferase levels. Virologic recurrence was defined as an increase of HBV-DNA level > 10 copies/L after HBeAg seroconversion with previously undetectable HBV-DNA level because a viral load of more than 10 copies/L is associated with progression of liver disease.

Peer review

This study can be considered as a preliminary report of the comparison between entecavir and clevudine therapy in chronic HBV in relation to the behaviour of HBeAg positive and viral load. It was well designed and conducted but a continuation of this study must be done with a greatest number of patients under a longest time of therapy before discontinuation.

Abstract

AIM: To determine whether bispectral index (BIS) monitoring is useful for propofol administration for deep sedation during endoscopic retrograde cholangiopancreatography (ERCP).

METHODS: Fifty-nine consecutive patients with a variety of reasons for ERCP who underwent the procedure at least twice between 1 July 2010 and 30 November 2010. This was a randomized cross-over study, in which each patient underwent ERCP twice, once with BIS monitoring and once with control monitoring. Whether BIS monitoring was done during the first or second ERCP procedure was random. Patients were intermittently administered a mixed regimen including

midazolam, pethidine, and propofol by trained nurses. The nurse used a routine practice to monitor sedation using the Modified Observer's Assessment of Alertness/Sedation (MOAA/S) scale or the BIS monitoring. The total amount of midazolam and propofol used and serious side effects were compared between the BIS and control groups.

RESULTS: The mean total propofol dose administered was 53.1 ± 32.2 mg in the BIS group and 54.9 ± 30.8 mg in the control group ($P = 0.673$). The individual propofol dose received per minute during the ERCP procedure was 2.90 ± 1.83 mg/min in the BIS group and 3.44 ± 2.04 mg in the control group ($P = 0.103$). The median value of the MOAA/S score during the maintenance phase of sedation was comparable for the two groups. The mean BIS values throughout the procedure (from insertion to removal of the endoscope) were 76.5 ± 8.7 for all 59 patients in using the BIS monitor. No significant differences in the frequency of $< 80\%$ oxygen saturation, hypotension (< 80 mmHg), or bradycardia (< 50 beats/min) were observed between the two study groups. Four cases of poor cooperation occurred, in which the procedure should be stopped to add the propofol dose. After adding the propofol, the procedure could be conducted successfully (one case in the BIS group, three cases in the control group). The endoscopist rated patient sedation as excellent for all patients in both groups. All patients in both groups rated their level of satisfaction as high (no discomfort). During the post-procedural follow-up in the recovery area, no cases of clinically significant hypoxic episodes were recorded in either group. No other postoperative side effects related to sedation were observed in either group.

CONCLUSION: BIS monitoring trend to slightly reduce the mean propofol dose. Nurse-administered propofol

sedation under the supervision of a gastroenterologist may be considered an alternative under anesthesiologist.

INTRODUCTION

Electroencephalography (EEG)-guided sedation has been used by anesthesiologists to achieve optimal titration of sedatives^[1]. Bispectral index (BIS) monitoring is an EEG-based method that quantifies the depth of anesthesia by analyzing the EEG and uses a complex algorithm to generate an index score, providing an objective measurement of the level of consciousness in sedated patients^[1]. The value of BIS monitoring as an adjunct to endoscopic sedation has been tested in a limited number of endoscopic studies^[2-6]. The EEG-guided method was originally evaluated for facilitation of sedation in endoscopic retrograde cholangiopancreatography (ERCP)^[7-10].

Propofol can rapidly and easily induce deep sedation, and the depth of sedation can be adjusted^[11]. The Division of Drug Risk Evaluation in the United States has stated that “doses of propofol should be kept as low as effectively possible and patients who are sedated with propofol should be monitored properly”^[12]. A combination of propofol and midazolam significantly reduces the total propofol amount required and consequently reduces the risk of apnea; however, recovery time is prolonged as compared with propofol alone^[8]. According to Athens international statements^[12] and the American Society of Anesthesiologists Physical Status Classification (ASA grade), patients of classes I, II and often III can be safely sedated to the level of conscious sedation by nurses qualified in cardiopulmonary resuscitation for esophagogastroduodenoscopy and colonoscopy, but there are no data for sedation by nurses during ERCP.

In this study, we hypothesized that if we employed BIS monitoring to achieve the desired level of deep sedation using the minimal doses of propofol, then the risk of respiratory depression would be reduced. In

particular, a combination of propofol and midazolam, administered by trained nurses with BIS monitoring, was used to evaluate the usefulness of this sedation method during ERCP.

We determined whether BIS monitoring is a useful adjunct technique for the administration of propofol titrated for deep sedation, as measured by differences in the dose of propofol administered during ERCP.

MATERIALS AND METHODS

This study was approved by the hospital ethics committee, and informed consent was obtained from participating patients. Fifty-nine consecutive patients with a variety of reasons for ERCP and who underwent the procedure at least twice between 1 July 2010 and 30 Nov 2010 were prospectively included in this study. Associated medical illnesses were graded according to ASA grade^[13]. Exclusion criteria were age < 20 years, critical illness (ASA grade IV or V), pregnancy, chronic use of benzodiazepines or opiates, and history of allergy to eggs. No patient was excluded after randomization.

All procedures were therapeutic and were performed by one gastroenterologist (Jung MK, who has performed > 500 ERCP procedures per annum for 5 years). Trained three nurses administered the sedative agents and carried out the anesthetic protocol, which was generated by an anesthesiologist (Jeon YH, who has performed > 1000 general anesthesia procedures per annum for 15 years). This was a randomized cross-over study, in which each patient underwent ERCP twice, once with BIS monitoring and once with control monitoring. Whether BIS monitoring was done during the first or second ERCP procedure was random (Figure 1). The endoscopist, trained nurse, radiologist, and assistant nurse had access to the randomization scheme when the patient was admitted to the endoscopy suite. The independent research fellow (Park HG) who performed all pre- and post-procedural assessments was blinded to the randomization scheme.

The sedation end point was conscious sedation^[14]. Patient received the fixed dose midazolam, propofol and pethidine before the procedure. Trained nurse reassessed the sedation grade using BIS monitor or the modified Observer's Assessment of Alertness/Sedation (MOAA/S) scale every minute^[3]. Patients were intermittently administered a mixed regimen including midazolam, pethidine, and propofol by trained nurse. The end point of sedation was a MOAA/S score of 1. For the BIS monitoring group, the nurse was instructed to use BIS as the primary end point for titration of propofol and to target the BIS value to between 65 and 80. Patients were moved to the recovery area immediately after the procedure if their vital signs were stable. All patients were routinely kept in the hospital for at least 24 h after the ERCP procedure. If patients awoke or were hyperactive during sedation, this was considered a significant adverse event. And the procedure should be stopped to add the propofol dose. After adding the propofol, patient could be controlled. the procedure could be conducted successfully.

BIS monitoring

All patients were continuously monitored for heart rate, oxygen saturation (pulse oximetry), and blood pressure (automated blood pressure cuff, serial measurements every 3 min).

Baseline vital signs were recorded immediately before the procedure. All patients were given supplemental intranasal oxygen (5 L/min). Respiratory depression was considered significant when oxygen saturation was < 80% for > 15 s with oxygen supplementation. A drop in systolic arterial blood pressure below 80 mmHg or a heart rate below 50 beats/min was considered a significant adverse event. All patients were monitored in the recovery area by electrocardiography, pulse oximetry, and blood pressure recording. All patients were monitored for BIS scores using the BIS VIEW device (BIS Monitoring System) and a specific BIS Quatro Sensor (Aspect Medical System, Newton, MA, United States). During the procedure, BIS scores were monitored every 3 min.

Statistical analysis

The total amount of midazolam, propofol used and serious side effects between the BIS and control groups were compared. Continuous data were compared using the paired Student's *t*-test. Categorical variables were tested using the χ^2 test. The criterion for statistical significance was $P < 0.05$. SPSS Version 15 (SPSS, Chicago, IL, United States) was used for analyses. Data are presented as the mean \pm SD.

RESULTS

Baseline characteristics of the 59 patients are presented in Table 1. The mean total propofol dose administered was 53.1 ± 32.2 mg in the BIS group and 54.9 ± 30.8 mg in the control group ($P = 0.673$; Table 2). The individual propofol dose administered per minute during the ERCP procedure was 2.90 ± 1.83 mg/min in the BIS group and 3.44 ± 2.04 mg/min in the control group ($P = 0.103$). The median value of the MOAA/S score during the maintenance phase of sedation was comparable between the two groups. The mean BIS values throughout the procedure (from insertion to removal of the endoscope) were 76.5 ± 8.7 .

No significant differences in the frequency of < 80% oxygen saturation, hypotension (< 80 mmHg), or bradycardia (< 50 beats/min) were observed between the two study groups. Four cases of poor cooperation occurred, in which the procedure should be stopped to add the propofol dose. After adding the propofol, the procedure could be conducted successfully (one case in the BIS group, three cases in the control group).

The endoscopist rated the patient sedation as excellent for all the patients in both groups. All patients in both groups rated their level of satisfaction as high (no discomfort). During the post-procedural follow-up in the recovery area, no cases of clinically significant hypoxic episodes were recorded in either group. No other

postoperative side effects related to sedation were observed in either group.

DISCUSSION

Sedation and analgesia reduce pain, discomfort, and stress in patients undergoing unpleasant and prolonged procedures such as ERCP and contribute to better patient tolerance and compliance^[15]. Moreover, sedation and analgesia reduce the danger of injuries during ERCP due to a lack of cooperation by the patient and facilitate the endoscopist's task^[16]. Since the first report of endoscopic cannulation of major papilla in 1968^[17], ERCP has evolved from being a simple diagnostic procedure to becoming a therapeutic procedure with increased duration and complexity, requiring a high degree of patient cooperation. Reports have indicated that complications such as duodenal perforation and pancreatitis result as a consequence of poor patient cooperation manifested by restlessness and anxiety during the procedure^[18]. Successful ERCP procedures have been performed with the patient either moderately or deeply sedated or under general anesthesia. Patel *et al*^[19] reported that even when the target level of sedation was moderate, deep sedation episodes of all sedation occurred in 35% of ERCP patients. ERCP is thus recognized as an independent risk factor of deep sedation.

Propofol is a lipophilic anesthetic agent with rapid distribution and elimination times, and it does not have a cumulative effect after infusion. Its therapeutic spectrum is much narrower than that of midazolam, so careful

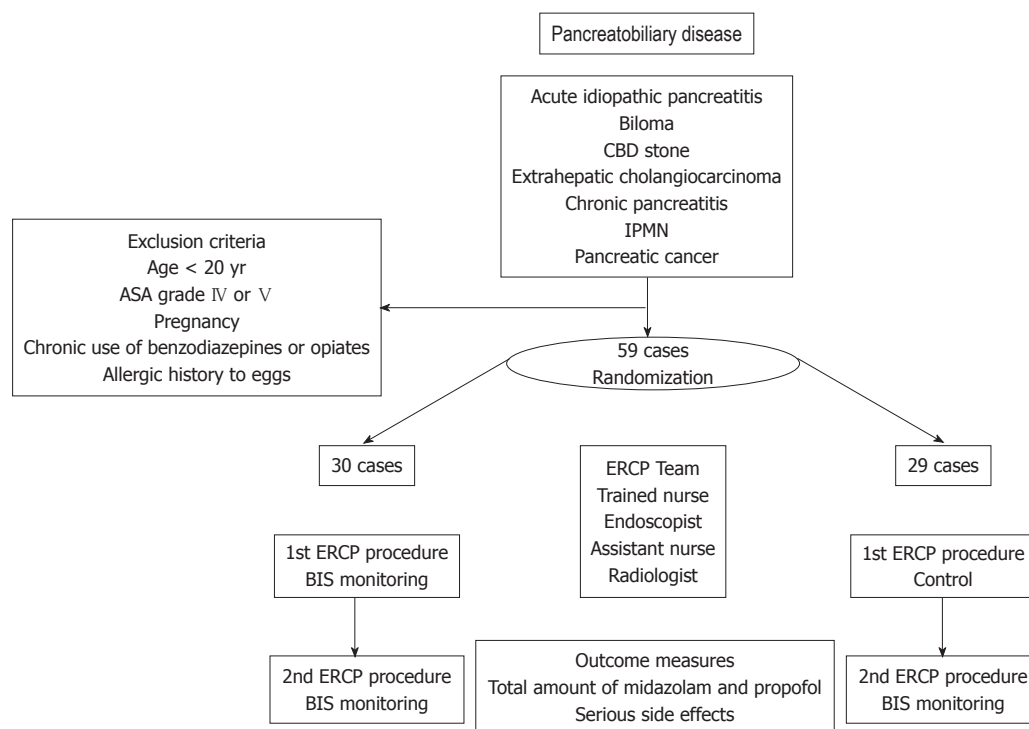

Figure 1 Flow chart of the enrolled patients. ASA grade: American Society of Anesthesiologists Physical Status Classification; BIS: Bispectral index; CBD: Common bile duct; ERCP: Endoscopic retrograde cholangiopancreatography; IPMN: Intraductal papillary mucinous neoplasm.

monitoring is much more demanding to differentiate between moderate and deep sedation and general anesthesia. Propofol has been evaluated in a variety of regimens in ERCP and has been shown to provide the same or superior sedation quality as midazolam with the advantage of better patient cooperation and shorter recovery time^[20-24]. One large multicenter study from North America demonstrated that the leading cause of death from ERCP was cardiopulmonary complications^[25]. In a large audit of upper endoscopy procedures from the United Kingdom, cardiopulmonary complications resulted in mortality in one in 2000 procedures^[26]. Sedation-related complications were attributed to high doses of sedatives and inadequate monitoring. In a retrospective analysis, Sharma *et al*^[27] showed that the incidence of cardiopulmonary complications in ERCP (2.1%) was almost double that during colonoscopy (1.1%) and more than triple that during upper endoscopy (0.6%).

The computer-generated BIS ranges from 0 (coma) to 100 (fully awake) and reflects the level of sedation regardless of a patient's clinical characteristics and the type of sedative drug used. The main aim of this study was to determine whether BIS monitoring could be a useful adjunct technique to the administration of propofol that was titrated to achieve conscious sedation, as measured by a difference in the propofol dose administered during ERCP. The primary outcome observed was a slightly lower mean dose of propofol in the group of patients who were deeply sedated with the use of BIS monitoring.

As the primary end point, we chose the amount of propofol given, because we believe that this will be of significant interest for endoscopists. More specifically,

our guiding hypothesis was that if we achieved the desired level of sedation using a minimal dose of propofol with BIS monitoring, then the risk of respiratory depression would be reduced.

The method of sedation during ERCP procedures involves a formulation of benzodiazepines in combination with opioids and propofol. The level of sedation is a continuum, and deep sedation is logically associated with an increased frequency of inadequate ventilation or airway obstruction^[28].

The Practice Committee of the American Society for Gastrointestinal Endoscopy has stated that "the use of EEG monitoring may have a role in the future for the delivery of sedation during selected endoscopic procedures"^[29]. EEG monitoring, which is a more complex technique than BIS monitoring with respect to interpretation, enables more effective titration of the propofol dose for sedation during ERCP^[10]. More specifically, Wehrmann *et al*^[10] found that the mean propofol dose was significantly lower in the group of patients sedated with EEG-guided monitoring as compared with that of the control group. The results from a previous colonoscopy study suggested that BIS monitoring may be useful in preventing over-sedation as well as in reducing the propofol dose during the maintenance phase of the sedation^[2]. A randomized controlled trial published 2 years later by the same group did not confirm these suggestions^[3]. This may be explained by the notably shorter time required for a colonoscopy and, in particular, the especially shorter maintenance phase during a colonoscopy, during which over-sedation is less likely to occur. BIS monitoring may be valuable during ERCP

during which patients are sedated with the conventional regimen of benzodiazepines plus opioids^[7]. More specifically, in that study the total dose of midazolam was significantly lower in the BIS group as compared with the control group^[7]. In a recent study, BIS monitoring during propofol sedation during endoscopic submucosal dissection did not lead to a reduction in the dose of propofol required but did lead to higher satisfaction scores from the patients and endoscopists^[30]. In this study, BIS monitoring during midazolam and propofol sedation during ERCP was safe and effective when sedatives were intermittently infused by well-trained nurses.

The role of BIS monitoring for conscious sedation targeted to the moderate level has not been established^[4]. BIS monitoring is less accurate for detecting deep sedation episodes during endoscopy where a particular level of conscious sedation is desired^[4,19]. In contrast, a meta-analysis of ambulatory surgery studies showed that the use of BIS monitoring significantly reduces the amount of anesthetic administered by 19%^[31]. Furthermore, titrating propofol with BIS monitoring during balanced anesthesia can decrease the amount of propofol required^[32]. Moreover, BIS monitoring may prevent awareness during general anesthesia^[33], although conflicting data have been reported^[34].

There are some limitations to our study. First, the nurse was not blinded to the absence or presence of BIS monitoring during ERCP. It was impossible for this study to be scheduled in a blinded fashion. Second, it is well established that BIS values lag behind actual sedation scores during induction of sedation as well as during recovery^[2]. However, it is noteworthy that all patients in the BIS group were deeply sedated during the maintenance phase (BIS score of 65-80).

In conclusion, BIS monitoring trend to slightly reduce the mean propofol dose, when the BIS index is used as the primary target for sedation during ERCP procedures. Approaches such as nurse-administered propofol sedation under the supervision of a gastroenterologist may be considered an alternative under the anesthesiologist.

COMMENTS

Background

Electroencephalography (EEG)-guided sedation has been used by anesthesiologists to achieve optimal titration of sedatives. Bispectral index (BIS) monitoring is an EEG-based method that quantifies the depth of anesthesia by analyzing the EEG and uses a complex algorithm to generate an index score, providing an objective measurement of the level of consciousness in sedated patients.

Research frontiers

Successful endoscopic retrograde cholangiopancreatography (ERCP) procedures have been performed with the patient either moderately or deeply sedated or under general anesthesia. Even when the target level of sedation was moderate, deep sedation episodes of all sedation occurred in 35% of ERCP patients. ERCP is thus recognized as an independent risk factor of deep sedation.

Innovations and breakthroughs

BIS monitoring trend to slightly reduce the mean propofol dose. Nurse-administered propofol sedation under the supervision of a gastroenterologist may be considered an alternative under anesthesiologist.

Peer review

The authors studied the usefulness of BIS monitor in the sedation of ERCP. The findings reported are of clinical importance.

Abstract

AIM: To compare the effects of telbivudine (LDT) and entecavir (ETV) in treatment of hepatitis B e antigen (HBeAg)-positive chronic hepatitis B by meta-analysis.

METHODS: We conducted a literature search using PubMed, MEDLINE, EMBASE, the China National Knowledge Infrastructure, the VIP database, the Wanfang database and the Cochrane Controlled Trial Register for all relevant articles published before April 1, 2012. Randomized controlled trials (RCTs) comparing LDT with ETV for treatment of HBeAg-positive chronic hepatitis B were included. The data was analyzed with Review Manager Software 5.0. We used relative risk (RR) as an effect measure, and reported its 95% CI. Meta-analysis was performed using either a fixed-effect or random-effect model, based on the absence or presence of significant heterogeneity. Two reviewers assessed the risk of bias and extracted data independently and in duplicate. The analysis was executed using the main outcome parameters including hepatitis

B virus (HBV) DNA undetectability, alanine aminotransferase (ALT) normalization, HBeAg loss, HBeAg seroconversion, drug-resistance, and adverse reactions. Meta-analysis of the included trials and subgroup analyses were conducted to examine the association between pre-specified characteristics with the therapeutic effects of the two agents.

RESULTS: Thirteen eligible trials (3925 patients in total) were included and evaluated for methodological quality and heterogeneity. In various treatment durations of 4 wk, 8 wk, 12 wk, 24 wk, 36 wk, 48 wk, 52 wk, 60 wk and 72 wk, the rates of HBV DNA undetectability and ALT normalization in the two groups were similar, without statistical significance. At 4 wk and 8 wk of the treatment, no statistical differences were found in the rate of HBeAg loss between the two groups, while the rate in the LDT group was higher than in the ETV group at 12 wk, 24 wk, 48 wk and 52 wk, respectively (RR 2.28, 95% CI 1.16, 7.03, $P = 0.02$; RR 1.45, 95% CI 1.16, 1.82, $P = 0.001$; RR 1.45, 95% CI 1.11, 1.89, $P = 0.006$; and RR 1.86, 95% CI 1.04, 3.32, $P = 0.04$). At 4 wk, 8 wk, 60 wk and 72 wk of the treatment, there were no significant differences in the rate of HBeAg seroconversion between the two groups, while at 12 wk, 24 wk, 48 wk and 52 wk, the rate in the LDT group was higher than in the ETV group (RR 2.10, 95% CI 1.36, 3.24, $P = 0.0008$; RR 1.71, 95% CI 1.29, 2.28, $P = 0.0002$; RR 1.86, 95% CI 1.36, 2.54, $P < 0.0001$; and RR 1.87, 95% CI 1.21, 2.90, $P = 0.005$). The rate of drug-resistance was higher in the LDT group than in the ETV group (RR 3.76, 95% CI 1.28, 11.01, $P = 0.02$). In addition, no severe adverse drug reactions were observed in the two groups. And the rate of increased creatine kinase in the LDT group was higher than in the ETV group (RR 5.58, 95% CI 2.22, 13.98, $P = 0.0002$).

CONCLUSION: LDT and ETV have similar virological and biomedical responses, and both are safe and well tolerated. However, LDT has better serological response and higher drug-resistance.

INTRODUCTION

Chronic hepatitis B (CHB) infection is a major health problem affecting over 350 million people worldwide^[1,2]. CHB can lead to various life-threatening conditions, such as liver failure, liver cirrhosis (LC) and hepatocellular carcinoma (HCC)^[3]. Hepatitis B virus (HBV) covalent closed circular DNA (cccDNA) is the main cause of the sustainability of the hepatitis virus, and it is difficult to completely eliminate it^[4]. So the primary therapeutic goal is to sustain viral suppression. Current anti-viral medication includes interferon [interferon-alpha (IFN- α), and pegylated (PEG) IFN- α] and nucleosides or nucleoside analogues [entecavir (ETV), adefovir dipivoxil, telbivudine (LDT), and lamivudine]^[5]. Recent studies have shown that LDT and ETV are the strongest nucleoside analogues. LDT (β -L-2'-deoxythymidine) is an orally bioavailable L-nucleoside. It can effectively suppress HBV DNA replication, and has a higher rate of hepatitis B e antigen (HBeAg) seroconversion than other current oral antiviral agents^[6]. However, its drug-resistance remains high^[7]. ETV is a new generation nucleoside analogues. It has the advantage of higher rate of HBV DNA suppression, low drug-resistance and high safety, especially in lamivudine-resistant CHB patients^[8]. But the rates of HBeAg loss and seroconversion are very low in ETV group, which is difficult to meet the withdrawal standards. There are few systematic reviews about the comparison of LDT and ETV. Therefore, we conducted a meta-analysis of the randomized controlled trials (RCTs) using the Cochrane methodology to explore the efficacy of LDT and ETV for clinical treatment of HBeAg-positive chronic hepatitis B.

MATERIALS AND METHODS

Literature search

We searched PubMed, MEDLINE, EMBASE, China

National Knowledge Infrastructure, the VIP database, the Wanfang database and the Cochrane Controlled Trial Register for articles published up to April 1, 2012, using the following keywords: "HBeAg-positive chronic hepatitis B", "telbivudine", "entecavir", and "RCTs". The reference lists of eligible studies were also searched.

Inclusion criteria

The following inclusion criteria were used: (1) RCTs; (2) Articles studying HBeAg-positive chronic hepatitis B patients, according to diagnostic standards in "China guidelines for HBV management (2010)"^[9]; (3) Studies comparing LDT (600 mg/d) with ETV (0.5 mg/d); and (4) The main outcome parameters included virological, biochemical, and serological responses [HBV DNA undetectability, alanine aminotransferase (ALT) normalization, HBeAg loss, HBeAg seroconversion, drug-resistance, and adverse reactions]. Virological response was defined as attainment of undetectable levels of HBV DNA. Determined by quantitative polymerase chain reaction, the threshold of detection was 1000 copies/mL or less in each corresponding study (Table 1). Biochemical response was defined as normalization of ALT levels to below the upper limit of normal (< 40 IU/mL). HBeAg loss was defined as HBeAg levels < 1.0 S/CO, HBeAg seroconversion was defined as HBeAg loss and the presence of anti-HBeAg, determined by microparticle enzyme immunoassay or enzyme-linked immunosorbent assay.

Exclusion criteria

The following exclusion criteria were used: (1) Nonrandomized controlled trials (NRCTs); (2) Insufficient analytical information regarding treatment schedule, follow-up, and outcomes; (3) Patients receiving interferon, nucleosides or nucleotides for CHB within 6 mo; (4) Patients coinfecting with hepatitis A, C, D and E virus, cytomegalovirus, or human immunodeficiency virus; (5) Patients with liver failure, HCC, and liver-related complications caused by alcoholism, autoimmune disease, and cholestasis; and (6) Pregnant and breastfeeding patients.

Data extraction

Data extraction was assessed independently by two reviewers (Song LY and Zhang SR). Discrepancies were solved through discussions between the reviewers or by a third person. Systematic Reviews of Interventions Version 5.0.2 (Cochrane Collaboration, Oxford, United Kingdom) was used to assess risk of bias (adequate sequence generation, allocation concealment, blinding, incomplete outcome data addressed, free of selective reporting and free of other bias)^[10]. Basic information obtained from each eligible trial included study design, patient characteristics, number of two groups, treatment duration and related study results. Data were reviewed to eliminate duplicate reports of the same trial.

Statistical analysis

We used Review Manager Software 5.0 (Cochrane Collab-

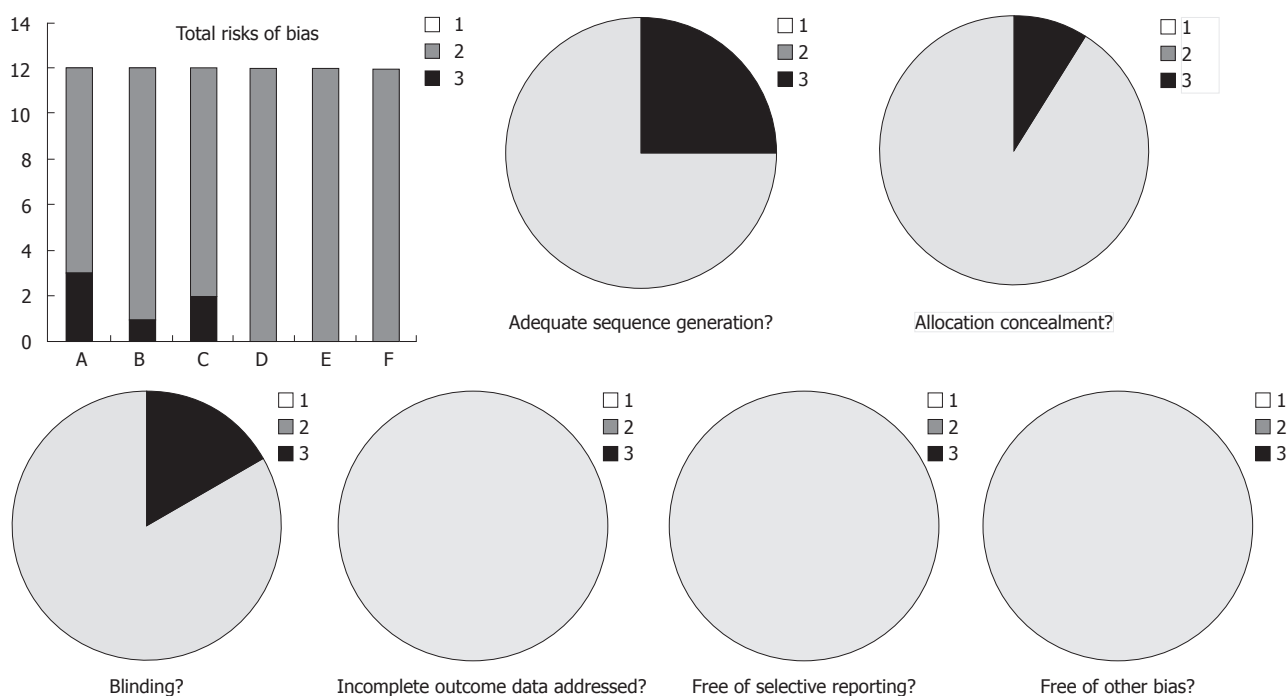

Figure 1 Risk of bias in included trials. A: Adequate sequence generation; B: Allocation concealment; C: Blinding; D: Incomplete outcome data addressed; E: Free of selective reporting; F: Free of other bias. 1: No (high risk of bias); 2: Unclear; 3: Yes (low risk of bias).

oration, Oxford, United Kingdom) for the data analysis. For dichotomous data, we used relative risk (RR) as an effect measure, and reported its 95% CI. Meta-analysis was performed using either a fixed-effect or random-effect model, based on the absence or presence of significant heterogeneity.

Statistical heterogeneity between trials was evaluated by χ^2 and I^2 analysis. The fixed-effect method was used in the absence of statistically significant heterogeneity ($P \geq 0.1$), and the random-effect method was used when the heterogeneity test was statistically significant ($P < 0.1$). $P < 0.05$ was regarded as statistically significant. Subgroup analysis was performed to examine the association between pre-specified characteristics (treatment duration) and the therapeutic effect, sensitivity analysis was made to estimate result stability, and funnel plots were used to assess publication bias if more than five trials were included^[11].

RESULTS

Characteristics and quality of studies

We initially identified 1165 abstracts, and after evaluating the full texts, we included 13 trials (12 in Chinese and one in English)^[12-24] based on the pre-specified criteria. A total of 3925 patients were included: 1987 treated with LDT and 1938 treated with ETV. Table 1 shows the characteristics of the 13 trials. All these studies showed baseline comparability, 9 of them reported the baseline of two groups in detail^[13-15,17,19,20,22-24], the other 4 presented no significant differences in gender, age and duration of treatment between the two groups^[12,16,18,21]. Three described the methods of randomization in detail^[13,14,24],

nine reported randomization, but did not describe the method of randomization in detail^[12,15,17-23], one reported allocation concealment^[24] and two presented blinding method^[22,24]. None of the trials referred to incomplete outcome data addressed, free of selective reporting, and free of other bias. Various risks of bias in the 13 trials. In addition, none of the trials reported mortality, life quality and liver cancer incidence are shown in Figure 1.

HBV DNA undetectability

All the trials reported the rate of HBV DNA undetectability. χ^2 and I^2 analyses showed no heterogeneity ($\chi^2 = 35.37$, $P = 0.74$, $I^2 = 0\%$); therefore, we used the fixed-effect method to analyze the data. The results showed that in various treatment durations of 4 wk, 8 wk, 12 wk, 24 wk, 36 wk, 48 wk, 52 wk, 60 wk and 72 wk, there were no statistical differences in the rate of HBV DNA undetectability between the two groups (RR 1.04, 95% CI 0.72, 1.49, $P = 0.85$; RR 0.98, 95% CI 0.74, 1.28, $P = 0.86$; RR 1.01, 95% CI 0.89, 1.15, $P = 0.83$; RR 1.06, 95% CI 0.99, 1.14, $P = 0.12$; RR 1.03, 95% CI 0.86, 1.37, $P = 1.24$; RR 1.02, 95% CI 0.95, 1.09, $P = 0.63$; RR 0.95, 95% CI 0.86, 1.05, $P = 0.29$; RR 1.02, 95% CI 0.83, 1.24, $P = 0.88$; and RR 0.95, 95% CI 0.80, 1.12, $P = 0.54$) (Figure 2A).

ALT normalization

Eleven trials reported the rate of ALT normalization^[12,13,15-20,22-24]. χ^2 and I^2 analysis showed no heterogeneity ($\chi^2 = 32.22$, $P = 0.51$, $I^2 = 0\%$). At various treatment durations of 4 wk, 8 wk, 12 wk, 24 wk, 36 wk, 48 wk, 52 wk, 60 wk and 72 wk, there were no statistical differences in the rate of ALT normalization between the two groups (RR 1.08, 95% CI 0.81, 1.43, $P = 0.59$; RR 1.05, 95% CI 0.77, 1.43, $P = 0.77$;

RR 1.05, 95% CI 0.94, 1.16, $P = 0.40$; RR 1.00, 95% CI 0.93, 1.08, $P = 0.91$; RR 0.95, 95% CI 0.67, 1.34, $P = 0.78$; RR 1.01, 95% CI 0.92, 1.11, $P = 1.08$; RR 0.94, 95% CI 0.86, 1.02, $P = 0.14$; RR 0.96, 95% CI 0.77, 1.19, $P = 0.69$; and RR 0.98, 95% CI 0.84, 1.13, $P = 0.76$) (Figure 2B).

HBeAg loss

Ten trials reported the rate of HBeAg loss^[13-16,18,20-24]. χ^2 and I^2 analyses found no heterogeneity ($\chi^2 = 38.84$, $P = 0.04$, $I^2 = 36\%$). At 4 wk and 8 wk of the treatment, no statistical differences in the rate of HBeAg loss were observed between the two groups (RR 2.89, 95% CI 0.31, 27.23, $P = 0.35$; and RR 1.50, 95% CI 0.50, 4.46, $P = 0.47$). At 12 wk, 24 wk, 48 wk and 52 wk, the rate of HBeAg loss was higher in the LDT group than in the ETV group, and the difference between two groups was statistically significant (RR 2.28, 95% CI 1.16, 7.03, $P = 0.02$; RR 1.45, 95% CI 1.16, 1.82, $P = 0.001$; RR 1.45, 95% CI 1.11, 1.89, $P = 0.006$; RR 1.86, 95% CI 1.04, 3.32, $P = 0.04$) (Figure 2C).

HBeAg seroconversion

All the trials reported the rate of HBeAg seroconversion. χ^2 and I^2 analyses showed no heterogeneity ($\chi^2 = 22.15$, $P = 0.85$, $I^2 = 0\%$). At 4 wk, 8 wk, 60 wk and 72 wk of the treatment, the rate of HBeAg seroconversion in the two groups was similar, and no statistical significances were observed (RR 2.34, 95% CI 0.55, 9.92, $P = 0.25$; RR 1.55, 95% CI 0.77, 3.12, $P = 0.22$; RR 1.56, 95% CI 0.91, 2.67, $P = 0.1$). However, at 12 wk, 24 wk, 48 wk and 52 wk, the rate of HBeAg loss was higher in the LDT group than in the ETV group, with statistically significant difference between two groups (RR 2.1, 95% CI 1.36, 3.24, $P = 0.0008$; RR 1.71, 95% CI 1.29, 2.28, $P = 0.0002$; RR 1.86, 95% CI 1.36, 2.54, $P < 0.0001$; RR 1.87, 95% CI 1.21, 2.90, $P = 0.005$) (Figure 2D).

Drug-resistance

Six trials reported drug-resistance^[12,13,16,17,22,23]. χ^2 and I^2 analyses showed no heterogeneity ($\chi^2 = 0.63$, $P = 0.96$,

$I^2 = 0\%$). The rate of drug-resistance was higher in the LDT group than in the ETV group, and the difference between two groups was statistically significant (RR = 3.76, 95% CI 1.28, 11.01, $P = 0.02$) (Figure 2E).

Adverse reactions

Ten trials reported on the adverse reactions^[12-18,20,23,24]. No severe adverse reactions were observed in both groups. Common adverse reactions in the two groups included influenza-like symptoms such as fever, headache, fatigue, muscular stiffness, gastrointestinal upset such as nausea and diarrhea, alopecia and rash. Five of the trials reported the rate of increased creatine kinase (CK)^[15,17,18,23,24]. χ^2 and I^2 analyses showed no heterogeneity ($\chi^2 = 1.06$, $P = 0.94$, $I^2 = 0\%$). The rate of increased CK was higher in the LDT group than in the ETV group, the difference being statistically significant (RR 5.58, 95% CI 2.22, 13.98, $P = 0.0002$). But the increased CK recovered without any intervention, and did not influence the anti-HBV treatment (Figure 2F).

Statistical analysis

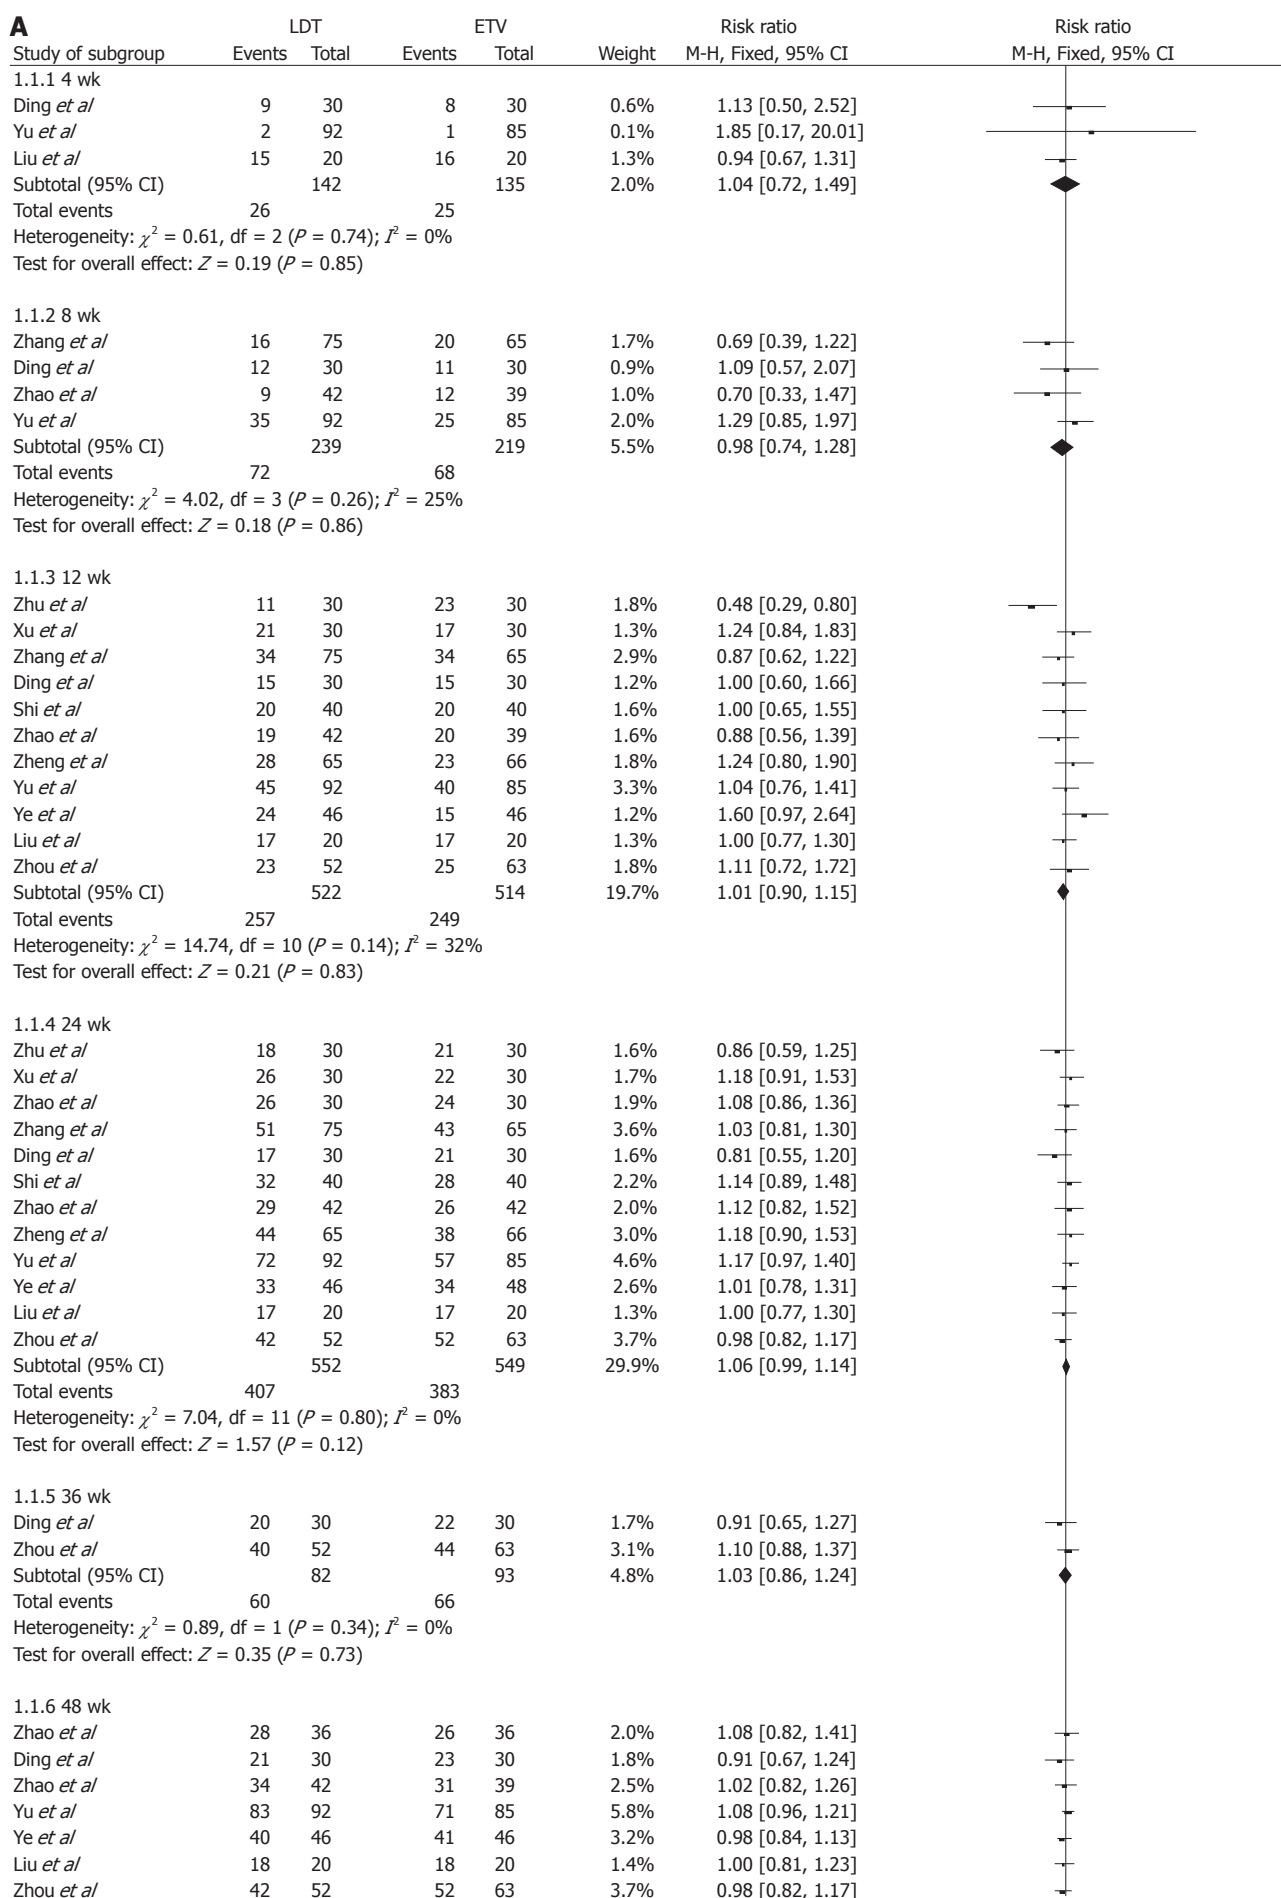

Meta-analysis was performed based on the rate of HBeAg seroconversion, using the fixed-effect model, and the minimum sample size trials were excluded^[18]. Odds ratio (OR) of all sensitivity analyses was higher than 1 and statistically significant ($P < 0.05$) (Table 2).

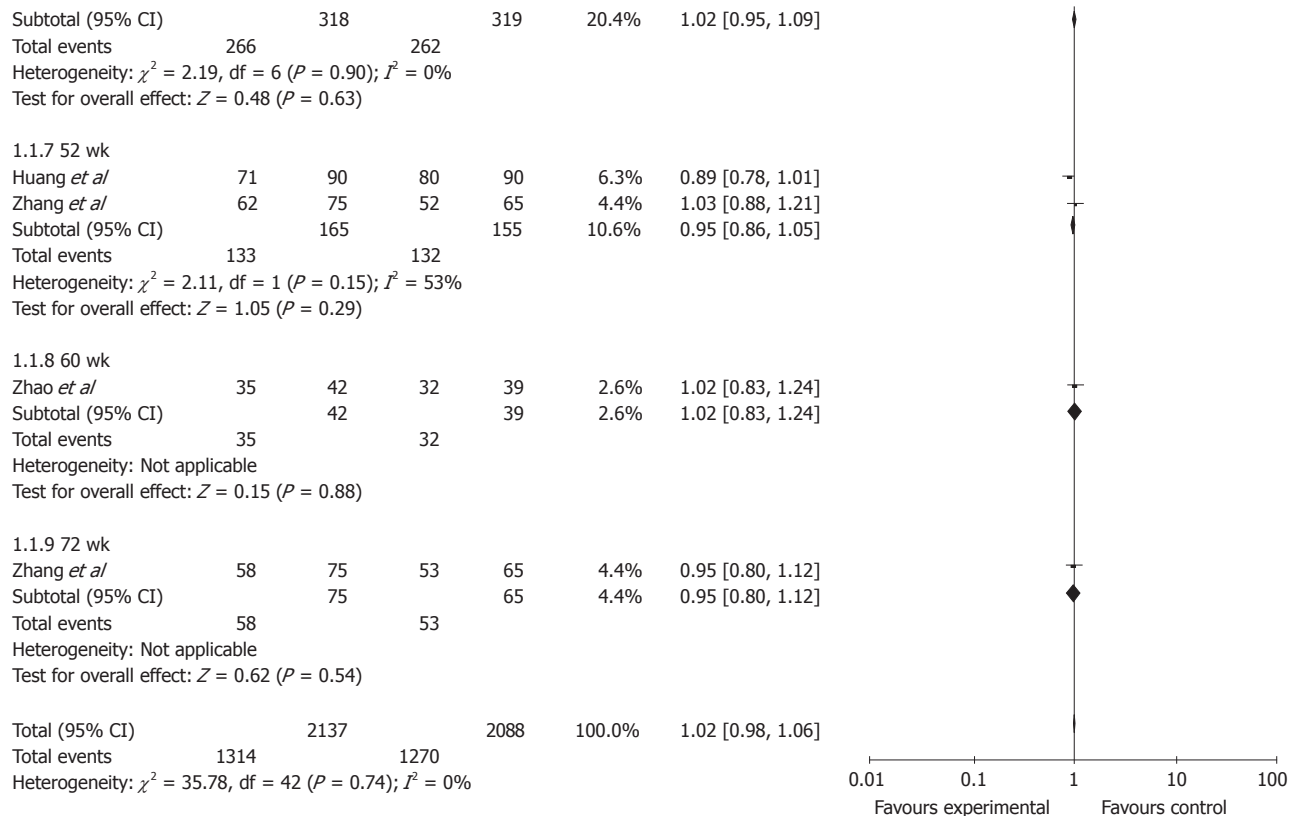

Funnel plots

Funnel plots were performed based on the rate of HBV DNA undetectability. The results showed that funnel plots were symmetric and suggested that there was no publication bias (Figure 3).

DISCUSSION

The RCTs comparing LDT with ETV for patients with HBeAg-positive chronic hepatitis B were included, and meta-analyses on virology, serology, biochemical respons-

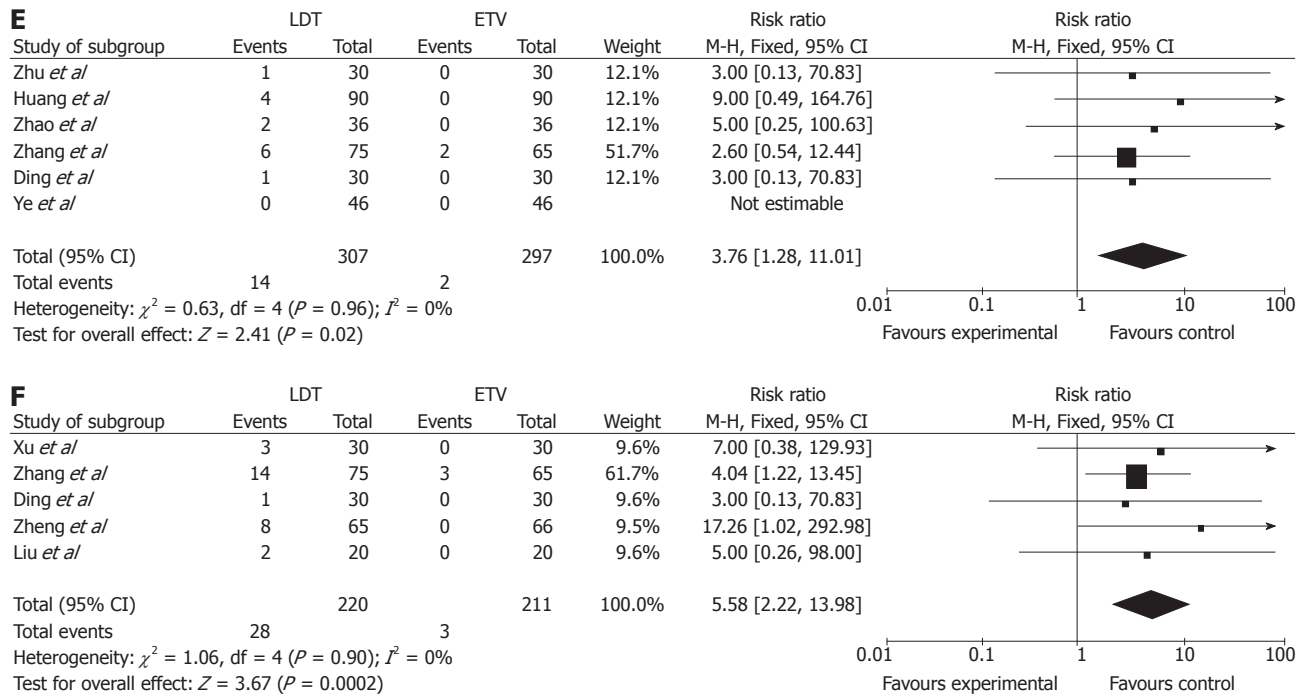

Figure 2 Meta-analysis of the two groups. A: Hepatitis B virus DNA undetectability; B: Alanine aminotransferase normalization; C: Hepatitis B e antigen (HBeAg) loss; D: HBeAg seroconversion; E: Drug-resistance; F: Increased creatine kinase (CK). ETV: Entecavir; LDT: Telbivudine.

Figure 3 Funnel plots of the two groups in hepatitis B virus DNA undetectability. RR: Relative risk;

es, drug-resistance and adverse reactions were performed to examine the association between pre-specified characteristics (treatment duration) and the therapeutic effect of the two drugs.

HBV DNA level is a primary prognostic marker for the treatment of patients with CHB^[25,26]. The early and sustained suppression of HBV DNA replication is associated with improved long-term rates of virological, serological and biochemical responses. Rapidly and effectively suppressing HBV DNA replication can decrease the incidence of liver cirrhosis (LC), HCC and drug-resistance^[27,28]. The results of the meta-analysis showed that in various treatment durations (4 wk, 8 wk, 12 wk, 24 wk, 36 wk, 48 wk, 52 wk, 60 wk and 72 wk), there were no statistical differences in the rate of HBV DNA undetect-

Table 2 Sensitivity analysis

Index	Total HBeAg loss	
	OR (95% CI)	P value
Excluding the minimum sample size trials ^[18]	1.64 (1.31, 2.05)	< 0.00 010
Using random-effect model	1.68 (1.35, 2.09)	< 0.00 001
Using fixed-effect model	1.69 (1.46, 1.97)	< 0.00 001

OR: Odds ratio; HBeAg: Hepatitis B e antigen.

ability between the two groups. This suggested that both LDT and ETV have rapid and effective anti-viral activity and the result is similar with a large sample size study^[29]. In addition, there was also no significant difference in the rate of ALT normalization between the two drugs.

HBeAg is a protein expressed by *pre-C* gene. HBeAg loss occurs with the rise of immunomodulatory effect which can suppress HBV DNA replication. HBeAg seroconversion has been established as a key marker of treatment response and is associated with improved clinical outcomes. It is one of the significant withdrawal standards for HBeAg-positive patients and suggests that patients can obtain sustained immune response^[30]. The results of the meta-analysis showed that at 4 wk and 8 wk of the treatment, the rates of HBeAg loss and HBeAg seroconversion were similar, with no statistical difference between the two groups, while at 12 wk, 24 wk, 48 wk and 52 wk, the rate was higher in the LDT group than in the ETV group, the difference being statistically significant. At 60 wk and 72 wk, there was no significant difference in the rate of HBeAg seroconversion between the two groups. These results suggested that the rates of HBeAg loss and HBeAg seroconversion in the short-term and medium-

term treatment were higher in the LDT group than in the ETV group. So LDT can be used as a primary drug for HBeAg-positive patients. However, its long-term efficacy needs to be further explored.

The higher rate of HBeAg seroconversion during LDT treatment might be associated with the potential immunomodulatory effect of LDT. CHB is a viral as well as an immunological disease. Specific immune function is impaired in the patients with CHB. Many studies suggested that LDT promoted T-helper 1 cytokine and CD4+/CD8+ cell production, but only downregulated programmed death ligand 1, regulatory T cell and T-helper 2 cytokine production^[31-33]. These immunomodulatory effects increase the rate of HBeAg seroconversion.

ETV has a high genetic barrier to resistance^[34-36]. The meta-analysis (Figure 2E) showed that the rate of drug-resistance was higher in the LDT group (4.69%) than in the ETV group (0.75%), the difference being statistically significant between the two groups. ETV has a lower drug-resistance than LDT and it is preferred for long-term anti-HBV activity.

The meta-analysis (Figure 2F) showed no severe adverse reactions in the two groups. Although the rate of increased CK in the LDT group was higher than in the ETV group, CK can recover without any intervention, and does not influence the anti-HBV treatment. These results suggest that both LDT and ETV are safe and well tolerated.

COMMENTS

Background

Chronic hepatitis B (CHB) infection is a major health problem affecting over 350 million people worldwide. CHB can lead to a number of life-threatening conditions such as liver failure, liver cirrhosis and hepatocellular carcinoma. Recent studies have shown that telbivudine (LDT) and entecavir (ETV) are the strongest nucleoside analogues in the treatment of CHB. But there are few systematic reviews about the comparison of LDT and ETV.

Research frontiers

LDT is an orally bioavailable L-nucleoside. It can rapidly and effectively suppress HBV DNA replication, but it has a higher drug-resistance. ETV is a new generation nucleoside analogues. It has the advantage of a higher rate of HBV DNA suppression, low drug-resistance and high safety, especially in lamivudine-resistant CHB patients. But the rate of hepatitis B e antigen (HBeAg) loss and HBeAg seroconversion was very low, which is difficult to meet the withdrawal standards.

Innovations and breakthroughs

There are few systematic reviews about the efficacy of LDT and ETV in the CHB treatment. The authors conducted a meta-analysis of the included randomized controlled trials using the Cochrane methodology and explored the efficacy of LDT and ETV for clinical treatment of HBeAg-positive chronic hepatitis B.

Applications

The results of this meta-analysis suggest that LDT and ETV have similar virological and biomedical response, and both are safe and well tolerated. However, LDT has better serological response and higher rate of drug-resistance.

Peer review

This study reviewed 13 trials comparing the effects of telbivudine and entecavir for patients with chronic HBeAg-positive chronic hepatitis B infection. Based on their analyses, the authors conclude that LDT and ETV exert an effective antiviral effect on HBV. Regarding the undetectability and ALT normalization, there was no big difference between the two drugs. The analysis was carefully performed, and the results were clearly presented and summarized, which provided valuable advice for clinical treatment of CHB.

Abstract

AIM: To investigate whether the addition of probiotics can improve the eradication effect of triple therapy for *Helicobacter pylori* (*H. pylori*) infection.

METHODS: This open randomized trial recruited 234 *H. pylori* positive gastritis patients from seven local centers. The patients were randomized to one-week standard triple therapy (omeprazole 20 mg *bid*, clarithro-

mycin 500 mg *bid*, and amoxicillin 1000 mg *bid*; OCA group, $n = 79$); two weeks of pre-treatment with probiotics, containing 3×10^7 *Lactobacillus acidophilus* per day, prior to one week of triple therapy (POCA group, $n = 78$); or one week of triple therapy followed by two weeks of the same probiotics (OCAP group, $n = 77$). Successful eradication was defined as a negative C13 or C14 urease breath test four weeks after triple therapy. Patients were asked to report associated symptoms at baseline and during follow-up, and side effects related to therapy were recorded. Data were analyzed by both intention-to-treat (ITT) and per-protocol (PP) methods.

RESULTS: PP analysis involved 228 patients, 78 in the OCA, 76 in the POCA and 74 in the OCAP group. Successful eradication was observed in 171 patients; by PP analysis, the eradication rates were significantly higher ($P = 0.007$ each) in the POCA (62/76; 81.6%, 95% CI 72.8%-90.4%) and OCAP (61/74; 82.4%, 95% CI 73.6%-91.2%) groups than in the OCA group (48/78; 61.5%, 95% CI 50.6%-72.4%). ITT analysis also showed that eradication rates were significantly higher in the POCA (62/78; 79.5%, 95% CI 70.4%-88.6%) and OCAP (61/77; 79.2%, 95% CI 70%-88.4%) groups than in the OCA group (48/79; 60.8%, 95% CI 49.9%-71.7%), ($P = 0.014$ and $P = 0.015$). The symptom relieving rates in the POCA, OCAP and OCA groups were 85.5%, 89.2% and 87.2%, respectively. Only one of the 228 patients experienced an adverse reaction.

CONCLUSION: Administration of probiotics before or after standard triple therapy may improve *H. pylori* eradication rates.

INTRODUCTION

Eradication therapy has been widely used since *Helicobacter pylori* (*H. pylori*) was recognized as a major cause of peptic ulcers, gastric atrophy and stomach neoplasms^[1]. However, the classic one-week triple therapy, consisting of a proton pump inhibitor (PPI), clarithromycin and amoxicillin, has become less effective, with eradication rates as low as 50%-70%^[2,3], especially in areas with a high prevalence of clarithromycin resistance^[4]. For example, in Shanghai from 2000 to 2009, the resistance rates of *H. pylori* to clarithromycin and levofloxacin increased from 8.6% to 20.7% and from 10.3% to 32.5%, respectively, whereas the resistance rates to metronidazole remained stable at 40%-50%^[5]. In addition, the high rates of antibiotic-associated side-effects may result in poor patient compliance^[6]. Administration of probiotics to adults^[7,8] and children^[9,10] has been reported to improve *H. pylori* eradication rates and to reduce the side-effects of PPI-based eradicating therapies. However, the timing of probiotic administration relative to the triple therapy has not been well characterized. In most studies, probiotics were started immediately after the start of triple therapy and were administered for one^[11] to four^[12] weeks. Bacteria of the *Lactobacillus* family were shown to inhibit *H. pylori* colonization of the stomach^[13,14] and the binding of *H. pylori* to its glycolipid receptors^[15]. To better investigate the effects of probiotics, in the present work we examined whether probiotics administered before or after eradication therapy to *H. pylori*-infected individuals could better enhance the eradication rate.

Lactobacillus acidophilus (*L. acidophilus*) is a common bacterium that resides in the human gastrointestinal tract and is added to food and milk. Compared with other *Lactobacillus* species, *L. acidophilus* has shown promising effects in the treatment of *H. pylori*^[16,17]. We therefore used a compound probiotic, with *L. acidophilus* as the predominant bacterium. In this multicenter, open and randomized trial, we assessed whether probiotics, administered before or after *H. pylori* eradication therapy, could enhance eradication rates. We found that both approaches improved eradication rates, although the rate was somewhat higher in patients administered probiotics after than before triple therapy.

MATERIALS AND METHODS

Patients

The patient population consisted of individuals, aged

Data are presented as mean ± SD or *n* (%). ¹Student's *t* test; ²Fisher's exact test. *H. pylori*: *Helicobacter pylori*; UBT: Urea breath test; RUT: Rapid urease test; HE: Hematoxylin and eosin stain; POCA: Probiotic pre-treated group; OCAP: Probiotic post-treated group; OCA: Standard therapy group.

18-65 years, newly diagnosed with gastritis or dyspepsia and infected with *H. pylori*. *H. pylori* infection was determined by rapid urease tests (RUT) during endoscopy; by pathologic examination of antrum specimens; or by C13 or C14 urea breath tests (UBT)^[18]. The method used by each participating center is shown in Table 1. Candidates for inclusion were screened from November 2008 to July 2009. Exclusion criteria were: (1) neoplasm or peptic ulcer with or without complications, or gastroesophageal reflux disease; (2) previous failure of *H. pylori* eradication or a history of gastric surgery; (3) consumption of acid-inhibitors, bismuth compounds, antibiotics, or probiotics during the previous 4 wk; and (4) known allergy to antibiotics or probiotics.

Study design

The enrolled patients were randomized 1:1:1 into three groups (Figure 1). One group received standard triple therapy, consisting of omeprazole 20 mg *bid*, clarithromycin 500 mg *bid*, and amoxicillin 1000 mg *bid* for 7 d (OCA group). The second group received two weeks of pre-treatment with probiotics, containing 3×10^7 *L. acidophilus* per day, prior to one week of triple therapy (POCA group), and the third group received one week of triple therapy followed by two weeks of the same probiotics (OCAP group).

Due to uncertainties about the effects of the addition of probiotics, we estimated sample size by the non-inferiority method. Assuming eradication rates of 90% and 85% in probiotic-combined and OCA groups ($\alpha = 0.05$ and $\beta = 0.2$), respectively, at least 70 individuals per group would be required. We calculated a final sample size of 240, including 30 patients at each center and 60 at the leading institute. The randomization number was produced by SPSS 18.0 software with a block of three and assigned to each center.

Each probiotic tablet (Yi Jun Kang®, He Li Pharm. Co. Ltd. China), weighing 0.5 g, contained 5×10^6

H. pylori: *Helicobacter pylori*; UBT: Urea breath test; POCA: Probiotic pre-treated group; OCAP: Probiotic post-treated group; OCA: Standard therapy group.

L. acidophilus, 2.5 × 10⁶ *Streptococcus faecalis* (*S. faecalis*) and 5 × 10³ *Bacillus subtilis* (*B. subtilis*). Patients were instructed to take two of these tablets 30 min after meal, three times a day. Boxes containing a sufficient number of these tablets for the study period were provided to each patient by the probiotics producer.

Patient compliance was evaluated by counting the number of tablets returned, with an error rate lower than 5% considered acceptable. Four weeks after the completion of *H. pylori* eradication therapy, *H. pylori* status was assessed using a C13 or C14 based UBT (Table 2), with complete eradication defined as < 4.0 dpm and < 100 dpm, respectively.

The study was performed in accordance with good clinical practice and the guidelines of the Declaration of Helsinki. All patients provided a written informed consent and the study protocol was approved by the Ethics Committee of Changhai Hospital (CHEC2008-041).

Symptoms and safety evaluation

All patients were asked to report associated symptoms at baseline and during follow-up, including abdominal pain, acid regurgitation, heartburn, nausea, vomiting, abdominal distension and diarrhea. Any side effect related to therapy was recorded and analyzed.

Statistical analysis

Data were computerized and analyzed with SPSS 18.0 software (IBM Corporation, NY, United States). The intention-to-treat (ITT) population consisted of all randomized patients, whereas the per-protocol (PP) population consisted of subjects who completed the entire study without any major protocol violations. The baseline demographic and clinical characteristics of the ITT and PP populations, and of the three groups of randomized patients in each population, were compared using Student's *t* tests and Fisher's exact tests, as warranted. Eradication rates in the three groups were compared by Fisher's exact tests. The eradication rate and 95% confidence intervals in each group were calculated for both the PP and ITT populations. All statistical tests were two-sided, with a 5% level of significance.

RESULTS

We enrolled 234 *H. pylori* positive subjects. Of them, 228 were included in the PP population, with 76, 74 and 78 subjects in the POCA, OCAP and OCA groups, respectively (Figure 2). Two patients were randomized in error, including one patient aged 81 years randomized to OCAP and one patient with a bleeding duodenal ulcer randomized to POCA. One subject in the OCAP group was reassessed by RUT. Two patients showed a

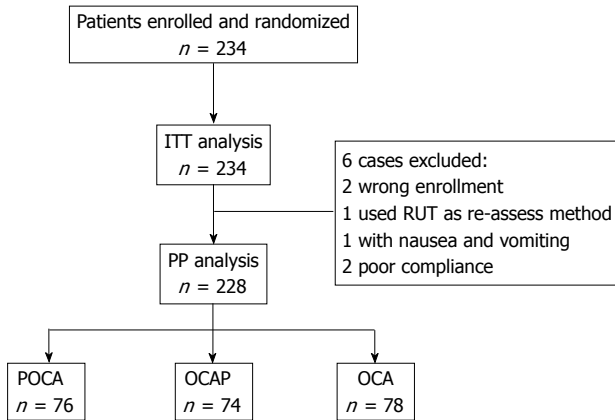

Figure 2 Flow diagram showing numbers of patients enrolled and missed for per protocol and intention-to-treat analyses. ITT: Intention-to-treat; PP: Per-protocol; RUT: Rapid urease test; POCA: Probiotic pre-treated group; OCAP: Probiotic post-treated group; OCA: Standard therapy group.

poor compliance with treatment, one each in the OCAP and OCA groups. One patient in the POCA group complained of nausea and vomiting on the fourth day of triple therapy and discontinued the study. The baseline demographic and clinical characteristics of the 228 enrolled patients are shown in Table 1. There were no significant differences in mean age, sex distribution, and distribution of *H. pylori* detecting methods. *H. pylori* was initially assessed by RUT in 102 (44.7%) patients, by UBT in 105 (46.1%) and by pathology in 21 (9.2%). C13 UBT was used for the second assessment of *H. pylori* in about 50% of patients, and C14 UBT in the other 50%. The mean follow-up time was significantly longer in the POCA (58.2 d) than in the OCAP and OCA (44 d) groups, due to the study design and treatment protocol (Figure 1).

Helicobacter pylori eradication

Four weeks after the completion of triple therapy, *H. pylori* test on C13 or C14 UBT was negative in 171 (75%) of the 228 patients. There were significant differences among the groups, however. PP analysis showed that the eradication rates were significantly higher in the POCA (81.6%, 95% CI: 72.8%-90.4%) and OCAP (82.4%, 95% CI: 73.6%-91.2%) groups than in the OCA (61.5%, 95% CI: 50.6%-72.4%) group ($P = 0.007$ each, Figure 3). ITT analysis showed that, compared with the OCA group (48/79; 60.8%, 95% CI: 49.9%-71.7%), success rates were significantly higher in the POCA (62/78; 79.5%, 95% CI: 70.4%-88.6%, $P = 0.014$) and OCAP (61/77; 79.2%, 95% CI: 70%-88.4%, $P = 0.015$) groups. Further analysis showed that probiotic supplementation was associated with a higher eradication rate in all centers except for Centers 2 and 7 (Table 2).

Symptoms and safety assessment

The symptom relieving rates in the POCA, OCAP and OCA groups were 85.5% (65/76), 89.2% (66/74) and 87.2% (68/78), respectively. Only one of the 228 (0.4%)

Figure 3 *Helicobacter pylori* eradication rates in groups treated with triple therapy, with or without probiotics. ^a $P < 0.05$, ^b $P < 0.01$ vs the standard therapy group (OCA group) by Fisher's exact test. *H. pylori*: *Helicobacter pylori*; POCA: Probiotic pre-treated group; OCAP: Probiotic post-treated group; PP: Per protocol; ITT: Intention-to-treat.

patients experienced an adverse effect. This patient, randomized to the POCA group, experienced severe vomiting on the fourth day of antibiotic treatment. Side-effect rates did not differ significantly among the three groups.

DISCUSSION

To our knowledge, this study is the first to show that administration of probiotics, either before or after traditional triple therapy, enhances *H. pylori* eradication rates. We found, in particular, that probiotic treatment after triple therapy significantly increased the eradication rate. Other than the studies, in which probiotics were started at the same time as PPI-based therapy, only one study has found that four weeks of pre-treatment with *Lactobacillus*- and *Bifidobacterium*-containing yogurt resulted in a higher *H. pylori* eradication rate than quadruple therapy alone (85% vs 71%, $P < 0.05$)^[19]. That study, however, assessed second-line therapy for *H. pylori*, whereas we evaluated first-line treatment. We found that pre-treatment with *L. acidophilus*, *S. faecalis* and *B. subtilis* for two weeks prior to triple therapy improved the eradication rate, from 60.8% to 79.5%. Pretreatment with probiotics may decrease *H. pylori* load despite antimicrobial resistance, thus improving the efficacy of eradication therapy^[19].

Pretreatment with probiotics has been found to significantly reduce the *H. pylori* colonization rate in mice, from 100% to 50% ($P = 0.02$)^[20] and to reduce inflammation in the gastric antrum. In humans, four weeks of treatment with *Lactobacillus reuteri* ATCC 55730 reduced *H. pylori* load and decreased the occurrence of dyspeptic symptoms^[21]. Although our results confirm previous findings^[22], that pretreatment with suitable probiotics could benefit *H. pylori* infected patients, the optimal treatment period (two or four weeks) and optimal dose of probiotics have not been determined.

It is not clear whether simultaneously administered probiotics will be destroyed by anti-*H. pylori* drugs. Although pre-treatment with probiotics may constitute a solution, it results in a prolonged course of therapy, two

weeks longer than the routine method. It is also unclear whether pre-treatment with probiotics could reduce the rates of antibiotic-related side effects to those observed with combined therapy^[23-26]. Large clinical trials are required to compare the side-effect reduction rates of patients administered probiotics before and during eradication therapy.

Another possible regimen is to treat patients with probiotics after the completion of eradication therapy. Interestingly, we found that this regimen significantly increased the *H. pylori* eradication rate compared with eradication therapy alone, from 60.8% to 79.2%. To compare the outcome, we performed repeat UBT in our OCAP group four weeks after triple therapy (two weeks after probiotic therapy). Probiotics may inhibit residual *H. pylori* and mask UBT tests as 'false negatives', similar to the effects of PPIs. Further long-term studies are needed to determine if *H. pylori* eradication is true and permanent.

The recommended species and number of bacteria in probiotics have not been determined^[27,28]. An 833-fold higher dose of *L. acidophilus* (2.5×10^{10} /d) than ours, when added to triple therapy containing esomeprazole, amoxicillin, and clarithromycin, failed to increase the eradication rate observed with triple therapy alone (an eradication rate, 83.9% *vs* 80.6%, $P = 0.74$)^[29]. This may have been due to the relatively small number of subjects, the short duration of probiotic administration (8 d) and the use of a single species of bacteria. Probiotic mixtures appear to be effective against a wide range of end points, including treatment of *H. pylori* infection, with multi-strain probiotics showing greater efficacy than single strains, including strains that are components of the mixtures themselves^[30]. *H. pylori* may be less sensitive to single than to multiple probiotics, similar to resistance to antibiotics.

The probiotic mixture we tested is easily acquired in China and has been used widely to treat diarrhea and inflammatory bowel disease. If our findings are confirmed, Chinese *H. pylori* infected patients may benefit from probiotic treatment.

Due to the low incidence of side effects we observed, we could not evaluate whether probiotics reduce the adverse effects of antibiotics. However, safety evaluation was not a primary end point of this study. Other limitations include the lack of blinding; the absence of a placebo group; the lack of standardization of the *H. pylori* assay method; the short follow-up period; and the lack of confirmation of *H. pylori* load by biopsy or culture. Nevertheless, this study is the first to provide information on the timing of probiotics relative to routine eradication therapy in *H. pylori* infected patients. We found that both pre- and post-treatment with probiotics increased the eradication rates of triple therapy, with post-treatment being more effective than pre-treatment.

In conclusion, our results suggest that either pre- or post-administration of probiotics may improve the *H. pylori* eradication effect of standard triple therapy.

COMMENTS

Background

Eradication therapy has been widely used since *Helicobacter pylori* (*H. pylori*) was first recognized as a major cause of gastric diseases. Classic triple therapy, including a proton pump inhibitor (PPI) and the antibiotics clarithromycin and amoxicillin, has become less effective over time. Addition of probiotics may improve the eradication rates of triple therapy, but the optimal timing of probiotics remains unclear.

Research frontiers

Pretreatment with probiotics has been shown to reduce *H. pylori* colonization in animals and humans.

Innovations and breakthroughs

This is the first study to show that both pre- and, particularly, post-treatment with probiotics increased the eradication rates of triple therapy. These results suggest that mixed probiotics may improve the *H. pylori* eradication effect of standard triple therapy with fewer adverse effects.

Applications

These results provide a guide for better use of probiotics, in combination with triple therapy, for the clinical treatment of *H. pylori*-infected patients. This new regimen may be particularly applicable to *H. pylori* eradication in areas of high resistance to antibiotics.

Peer review

This study was designed to determine whether the administration of probiotics, before or after standard triple therapy, could improve *H. pylori* eradication rates. Interestingly, both regimens were effective in improving the efficacy of standard triple therapy. The study is well designed and the results are interesting.

Abstract

AIM: To investigate the effect of different secondary warm ischemia time (SWIT) on bile duct injury in liver-transplanted rats.

METHODS: Forty-eight male inbred Sprague-Dawley rats were randomly assigned into four groups: a sham-operation group and three groups with secondary biliary warm ischemia time of 0 min, 10 min and 20 min. A rat model of autologous liver transplantation under ether anesthesia was established, and six rats were killed in each group and blood samples and the median lobe of the liver were collected for assay at 6 h and 24 h after hepatic arterial reperfusion.

RESULTS: With prolongation of biliary warm ischemia time, the level of vascular endothelial growth factor-A was significantly decreased, and the value at 24 h was

higher than that at 6 h after hepatic arterial reperfusion, but with no significant difference. The extended biliary SWIT led to a significant increase in bile duct epithelial cell apoptosis, and a decrease in the number of blood vessels, the bile duct surrounding the blood vessels and bile duct epithelial cell proliferation in the early postoperative portal area. Pathologic examinations showed that inflammation of the rat portal area was aggravated, and biliary epithelial cell injury was significantly worsened.

CONCLUSION: A prolonged biliary warm ischemia time results in aggravated injury of the bile duct and the surrounding vascular plexus in rat autologous orthotopic liver transplantation.

INTRODUCTION

Orthotopic liver transplantation (OLT) has proven to be a successful treatment choice for patients with end-stage chronic or acute liver failure. However, biliary complications remain a significant source of morbidity and have

been associated with a mortality rate ranging from 8% to 15%^[1,2]. With improvement in surgical techniques, the incidence of anastomotic biliary strictures was markedly reduced, whereas non-anastomotic biliary strictures (NAS) have become a predominant biliary complication of liver allografts^[3]. Diffuse NAS after OLT have been termed as ischemic-type biliary complications, ischemic cholangitis and ischemic cholangiopathy. NAS remains the most challenging type of biliary complication as it is frequently therapy-resistant and often associated with long-term consequences^[4,5].

The cause of NAS is multifactorial, and ischemia/reperfusion injury of the biliary epithelium is considered as one of the major causes^[6]. Warm ischemic time in donors after cardiac death (DCD), in addition to subsequent cold ischemia-reperfusion injury, is believed to result in increased damage to biliary epithelial cells^[7,8]. The most commonly used procedure for revascularization of the liver graft in clinical practice is initial portal reperfusion and subsequent reconstruction of the hepatic artery. Compared with liver cells, the bile duct epithelial cells experience an extra ischemic process from portal venous recanalization to hepatic arterial recanalization, which is defined as the “secondary warm ischemia time (SWIT) in the biliary tract” or “relative warm ischemia time in the biliary tract”. This is a special phase of biliary warm ischemia in the graft. Because warm ischemia time in the harvesting of donor livers after cardiac death is inevitable, more and more studies have shifted their focus to the effect of SWIT on bile duct injury^[9].

The terminal branches of the hepatic artery are represented by either the extra- or intra-hepatic peribiliary arterial plexus (PBP). The function of the intrahepatic biliary tree is linked to its vascular supply sustained by PBP^[10]. Alterations of intrahepatic bile duct mass are associated with the architectural changes in the PBP. In this study, we investigated the impact of different SWITs on the bile duct and PBP in a rat autologous liver transplantation model.

MATERIALS AND METHODS

Animals and experimental groups

Forty-eight male inbred SD rats weighing 220–250 g were purchased from the Animal Center of Yangzhou University (Yangzhou, China). The rats were housed and fed at the Animal Center of Drum Tower Hospital for at least 7 d before transplantation for acclimatization to the environment. All rats were provided with standard laboratory chow and water and housed in accordance with institutional animal care policies. The rats were fasted for 8 h, but allowed free access to water before being used in the study.

The following experimental protocol was approved by the Animal Care and Use Committee of the Drum Tower Hospital and conformed to Guide for the Care and Use of Laboratory Animals from National Institutes of Health.

A rat model of autologous liver transplantation was

established using the technique of Wang *et al.*^[11] under ether anesthesia. Rats were randomly assigned into four groups according to the SWIT: a sham-operation group and three groups with the biliary SWIT of 0 min, 10 min and 20 min. In the sham-operation group (group I), the liver was mobilized without cold or warm ischemia-reperfusion injury to exclude the influence of surgery. In group II with no SWIT, simultaneous reperfusion was performed through the portal vein and hepatic artery after cold perfusion. In groups III and IV with SWIT of 10 min and 20 min, hepatic arterial perfusion was performed for 10 min and 20 min, respectively, after portal venous reperfusion.

Sample collection

At 6 h and 24 h after hepatic arterial reperfusion, 6 rats were killed in each group, and blood samples were collected via the infrahepatic vena cava, and the median lobe of liver was obtained for assay. The serum was separated and stored at -70 °C until analysis. After washing with cold saline solution, the liver samples were stored immediately in liquid nitrogen until analysis.

Assessment of vascular endothelial growth factor-A level

Vascular endothelial growth factor-A (VEGF-A) plasma levels of the samples collected at 6 h and 24 h after hepatic arterial reperfusion were determined with enzyme-linked immunosorbent assay kits (Ruiqi Biotechnology Co. Ltd, Shanghai, China) according to the manufacturer's instruction.

Bile ducts and blood vessels in portal area

The liver specimens were fixed with 10% formalin and embedded in paraffin. The liver tissues were cut into sequential slices of 2.5 mm. The bile ducts were immunolocalized by CK19 polyclonal antibody (Boside Biotechnology Co. Ltd, Wuhan, China), and the blood vessels were tagged with rabbit factor VIII-related antigen (Boaoseng Biotechnology Co. Ltd, Beijing, China). In the portal area, the number of bile ducts, blood vessels, and bile ducts with and without blood vessels were counted.

Assessment of cholangiocyte proliferation with proliferating-cell nuclear antigen immunolabeling

The number of proliferating-cell nuclear antigen (PCNA)-positive cells was used to evaluate cholangiocyte proliferation with immunohistochemistry. After rehydration, the silane-coated slides were treated with 0.3% H₂O₂ in methyl alcohol for 15 min and then briefly washed in phosphate buffer saline. They were then incubated overnight at 4 °C, with a 1:100 dilution of anti-PCNA monoclonal antibody, and subsequently incubated with Envision Plus Sunpoly-H III HRP rabbit/mouse kit (Boshide Biotech Co. Ltd., Wuhan, China) for 30 min at 37 °C. Finally, the sections were counterstained with hematoxylin and coverslipped. After staining, sections were analyzed in a coded fashion under a light microscope.

Table 1 Effect of different secondary warm ischemia times on vascular endothelial growth factor-A level (mean \pm SD)

Group	6 h	24 h
I	183.44 \pm 11.65	185.04 \pm 10.11
II	185.32 \pm 12.06	154.55 \pm 11.77 ^a
III	181.42 \pm 9.97	142.32 \pm 10.30 ^{a,c}
IV	177.93 \pm 10.40	126.44 \pm 16.03 ^{b,c,e}

^a*P* < 0.05 *vs* group I; ^b*P* < 0.01 *vs* group I; ^c*P* < 0.05 *vs* group II; ^e*P* < 0.05 *vs* group III.

PCNA protein expression appeared brown in the cell nucleus. The cholangiocyte proliferation index was measured as the number of PCNA-positive cholangiocytes per 100 cells under high magnification (\times 400).

Apoptosis of bile duct epithelial cells

Apoptosis of bile duct epithelial cells was identified by detecting DNA fragmentation *in situ* in serial sections at 6 h and 24 h after hepatic arterial reperfusion. DNA fragmentation was detected by terminal -deoxynucleotidyl transferase mediated nick end labeling (TUNEL) staining, which was performed on deparaffinized and dehydrated sections using the In Situ Cell Death Detection kit (Zhongshan Biomedical Technology Co., Beijing, China) according to the manufacturer's instructions. TUNEL-positive cholangiocytes displayed a characteristic morphology of apoptosis, including chromatin condensation, cell fragmentation and apoptotic bodies. Apoptotic cells were examined at original magnification \times 400 in 10 randomly selected fields per section. The apoptotic index was calculated as the percentage of apoptotic cells in the total number of cholangiocytes.

Histological evaluation of bile duct injury

Six liver specimens were collected at 24 h after hepatic arterial reperfusion in each group. The liver specimens for light microscopy were fixed with 10% formalin and embedded in paraffin. The sections were stained with hematoxylin and eosin for histological examination. Bile duct injury in the specimens was semiquantified by calculating a bile duct injury severity score (BDISS)^[12] based on the following three components: bile duct damage (graded as 0, absent; 1, mild; 2, moderate; 3, severe; modified from the Banff criteria for acute rejection); ductular proliferation (graded 0-3, using a similar scale as stated earlier); and cholestasis (graded 0-3, using a similar scale as stated earlier). This resulted in a minimal BDISS of zero and a maximum score of 9 points. All examinations were conducted by an experienced pathologist who was unaware of the other study data.

Statistical analysis

The results were expressed as mean \pm SD. Data were analyzed using the Statistical Analysis System (SAS Institute, Cary, NC, United States). One-way analysis of variance was used for multiple comparisons with Student-Newman-Keulstest. *P* < 0.05 was considered statistically significant.

RESULTS

Assessment of VEGF-A level

There was no significant difference in VEGF-A at 6 h postoperatively between group I and the other three groups, but there was a significant decrease in VEGF-A at 24 h in groups II-IV. The VEGF-A was lower in group IV than in groups II and III, and there were significant differences among these three groups (*P* < 0.05) (Table 1).

Bile ducts and blood vessels in the portal area

The number of bile ducts in each portal area in group I was 6.10 \pm 0.74, and the bile ducts were always accompanied by blood vessels. Compared with group I, there was a significant decrease in the number of bile ducts, blood vessels and bile ducts with blood vessels in the portal area, and a significant increase in bile ducts without blood vessels in the other three groups. No significant difference in the number of bile ducts and blood vessels was found at 6 h postoperatively among groups II, III and IV. The number of bile ducts, blood vessels and bile ducts with blood vessels in portal area at 24 h was significantly lower in group IV than in groups II and III (*P* < 0.05) (Table 2).

Assessment of cholangiocyte proliferation with PCNA immunolabeling

Compared with group I, the number of PCNA-positive cholangiocytes was significantly reduced at 6 h and 24 h postoperatively in groups II and III (*P* < 0.05), and a very significant decrease in cholangiocyte proliferation was observed in group IV (*P* < 0.01). The number of PCNA-positive cholangiocytes in group IV was lower than in groups II and III, and there were significant differences among these three groups at 6 h and 24 h postoperatively (*P* < 0.05). The number of PCNA-positive cholangiocytes at 24 h after hepatic arterial reperfusion was reduced in all groups compared with the result at 6 h, but no significant differences were noted (Table 3, Figure 1).

Apoptosis of bile duct epithelial cells

There were a few apoptotic bodies in the liver sections of group I. Compared with group II, a significant increase in apoptosis index was found at 6 h and 24 h postoperatively in groups III and IV (*P* < 0.05). The apoptosis index in group IV was significantly higher than in group III at 6 h postoperatively (*P* < 0.05). In groups II, III and IV, the apoptosis index at 24 h after hepatic arterial reperfusion was higher than that at 6 h, but no significant differences were noted (Table 3, Figure 2).

Histological evaluation of bile duct injury

The histological findings indicated that the degree of bile duct injury was mild in group I. The main bile duct injuries in group II included cholangiocytes lining in disarray with diversified morphous, edematous, inflammatory cell infiltration, migrated chromatin, and necrotic

Table 2 Effect of different secondary warm ischemia time on the number of bile ducts and blood vessels in portal area (mean \pm SD)

	Time (h)	Group I	Group II	Group III	Group IV

cell debris in the lumen. The bile duct showed more histological changes in groups III and IV, and more marked injuries in group IV. Microthrombi were found in the microangium around the biliary tract in some sections from groups III and IV.

Compared with group II, a significant increase in BDISS was observed at 6 h and 24 h postoperatively in groups III and IV (*P* < 0.05). The BDISS in group IV was higher than that in group III, and there was significant difference between the two groups (*P* < 0.05). BDISS at 24 h after hepatic arterial reperfusion increased in all groups compared with BDISS at 6 h, but no significant differences were noted (Table 3, Figure 3).

DISCUSSION

Warm ischemia time in DCD is associated with a higher risk of biliary strictures^[13], and the incidence of NAS in DCD ranges from 10% to 30% compared with an incidence of 1%-10% in donation after brain death^[14,15]. We used a model of rat autologous orthotopic liver transplantation to simulate ischemia-reperfusion injury of the biliary tract, which mimics the whole process of clinical liver transplantation. This model decreases the possibility of blood vessel or vascular anastomosis damage compared with the allogeneic orthotopic liver transplantation, and it minimizes the effects of immunologic rejection. It is a simple model used with a high success rate, which better reflects the pathophysiologic process of bile ducts, and affords a useful tool for the investigation of intrahepatic bile duct damage in liver transplantation caused directly by ischemia-reperfusion injury^[16].

Hepatocytes are supplied by both the hepatic artery and the portal vein, but bile ducts entirely rely on arterial blood supply for oxygenation. The terminal branches of the hepatic artery end in the PBP, which is the direct source of blood supply to the intrahepatic bile ducts. Therefore, the changes of PBP often result in alterations of intrahepatic bile duct structure^[17]. Post-transplantational hepatic arterial ischemia induces ischemia and occlusion of PBP, thus aggravating ischemia of intrahepatic bile ducts^[18,19]. The pathomorphologic changes of bile ducts indicated that there was a time-dependent relationship between secondary ischemia time and pathological injury, and in this study, group IV had the most severe bile duct injury among the four groups. Microthrombi were found in the microangium around the biliary tract in some sections from groups III and IV.

The etiopathogenesis of nonanastomotic stenosis of bile ducts after liver transplantation is complicated, and the factors that cause damage to the bile ducts are mediated by either direct or indirect effects of the PBP. Cholangiocytes can express VEGF and its receptors to regulate the adaptive proliferation of the PBP^[20]. In this study, VEGF-A in groups III and IV decreased significantly, and the number of blood vessels and bile ducts with blood vessels in the portal area also decreased significantly.

Cholangiocyte proliferation is regulated by a number of factors including cAMP, gastrointestinal hormones (e.g., gastrin and somatostatin), bile salts, cholinergic, adrenergic and serotonergic neurotransmitters, and vascular growth factors^[21-23]. The number of PCNA-positive cholangiocytes was reduced compared with that

Figure 1 With prolongation of secondary biliary warm ischemia time, the number of proliferating-cell nuclear antigen-positive cholangiocytes was significantly reduced. A: Proliferating-cell nuclear antigen (PCNA)-positive cholangiocytes in group II at 24 h after hepatic artery (HA) reperfusion; B: PCNA-positive cholangiocytes in group IV at 24 h after HA reperfusion. A and B, original magnification $\times 400$.

Figure 2 With prolongation of secondary biliary warm ischemia time, more biliary epithelial cells became apoptotic. A: Biliary epithelial cell apoptosis in group II at 24 h after hepatic artery (HA) reperfusion; B: Biliary epithelial cell apoptosis in group IV at 24 h after HA reperfusion. A and B, original magnification $\times 400$.

Figure 3 Histological examination of the liver at 24 h after hepatic arterial reperfusion. A: Cholangiocyte injury can be found in group I; B: More marked injury occurs in group IV. A and B: Hematoxylin-eosin, original magnification $\times 400$.

in normal rats, most obviously in group IV. And the numbers of bile ducts and bile ducts with blood vessels decreased significantly in group IV.

Bile duct epithelia are highly susceptible to reoxygenation after anoxia^[24]. The increased susceptibility to reoxygenation injury by cholangiocytes is associated with increased production of toxic reactive oxygen species by cholangiocytes during reoxygenation, with concomitant low basal levels of the antioxidant glutathione in these

epithelial cells^[25,26]. There are two mechanisms by which cell death occurs: one is apoptosis and the other is the pathological process of necrosis. Accumulating evidence suggests that apoptosis plays an important role in ischemia-reperfusion injury in organ transplantation^[11], and it is widely taken as a reference index to evaluate bile duct epithelial injury. With the prolongation of biliary warm ischemia time, the biliary epithelial cell apoptosis index was significantly elevated.

In conclusion, a prolonged biliary warm ischemia time would result in aggravated injury of the bile duct and the surrounding vascular plexus in autologous orthotopic liver transplantation. The secondary biliary warm ischemia time in liver transplantation should be minimized to reduce the injury of the bile duct and its surrounding blood vascular plexus.

ACKNOWLEDGMENTS

We want to thank Dr. Chen Jun for his work in pathological analysis.

COMMENTS

Background

With the improvement in surgical techniques, the incidence of anastomotic biliary strictures after liver transplantation decreased markedly, whereas non-anastomotic biliary strictures (NAS) became the major type of biliary complications of liver allografting. Diffuse NAS remain the most challenging type of biliary complication as they are frequently therapy-resistant and are often associated with long-term consequences.

Research frontiers

Warm ischemia time in donors after cardiac death, in addition to subsequent cold ischemia-reperfusion injury, is believed to result in increased damage to biliary epithelial cells. Compared with liver cells, the bile duct epithelial cells experience an extra ischemic process from portal venous recanalization to hepatic arterial recanalization, which is defined as the "secondary warm ischemia time (SWIT) in the biliary tract" or "relative warm ischemia time in the biliary tract". This is a special phase of biliary warm ischemia in the graft; and more and more studies have shifted their focus to the effect of SWIT on bile duct injury in organ transplantation.

Innovations and breakthroughs

The function of the intrahepatic biliary tree is linked with its vascular supply sustained by the intrahepatic peribiliary arterial plexus (PBP). Alterations of intrahepatic bile duct mass are associated with changes in the PBP architecture. In this study, the authors investigated the impact of different SWITs on the bile duct and PBP in a rat autologous liver transplantation model.

Applications

The authors concluded that the prolonged biliary warm ischemia time would result in aggravated injury of the bile duct and the surrounding vascular plexus in autologous orthotopic liver transplantation. Therefore, secondary biliary warm ischemia time in liver transplantation should be minimized to reduce injury to the bile duct and its surrounding blood vascular plexus.

Peer review

This is a concise manuscript, addressing the important problem of non-anastomotic biliary injuries in liver transplantation. The experimental design is clear, methods are valid and the results support the idea that with increasing secondary biliary warm ischemia time, an increase of bile duct injury, mediated by adverse effects of ischemia on the bile duct surrounding blood vascular plexus, could be observed.

Abstract

AIM: To evaluate whether antecolic reconstruction for duodenojejunostomy (DJ) can decrease delayed gastric emptying (DGE) rate after pylorus-preserving pancreaticoduodenectomy (PPPD) through literature review and meta-analysis.

METHODS: Articles published between January 1991 and April 2012 comparing antecolic and retrocolic reconstruction for DJ after PPPD were retrieved from the databases of MEDLINE (PubMed), EMBASE, OVID and Cochrane Library Central. The primary outcome of interest was DGE. Either fixed effects model or random effects model was used to assess the pooled effect based on the heterogeneity.

RESULTS: Five articles were identified for inclusion: two randomized controlled trials and three non-randomized controlled trials. The meta-analysis revealed

that antecolic reconstruction for DJ after PPPD was associated with a statistically significant decrease in the incidence of DGE [odds ratio (OR), 0.06; 95% CI, 0.02-0.17; $P < 0.0001$] and intra-operative blood loss [mean difference (MD), -317.68; 95% CI, -416.67 to -218.70; $P < 0.0001$]. There was no significant difference between the groups of antecolic and retrocolic reconstruction in operative time (MD, 25.23; 95% CI, -14.37 to 64.83; $P = 0.21$), postoperative mortality, overall morbidity (OR, 0.54; 95% CI, 0.20-1.46; $P = 0.22$) and length of postoperative hospital stay (MD, -9.08; 95% CI, -21.28 to 3.11; $P = 0.14$).

CONCLUSION: Antecolic reconstruction for DJ can decrease the DGE rate after PPPD.

INTRODUCTION

Pylorus-preserving pancreaticoduodenectomy (PPPD), which preserves the whole stomach and 2.5 cm of duodenum^[1], is generally accepted as a standard modality for periampullary malignancies. Compared with the classical pancreaticoduodenectomy (PD), PPPD was reported to have many advantages: (1) easier to perform; (2) less operative time and blood loss; and (3) better improvement of quality of life, nutritional status and weight gain^[2-5]. However, despite the improvements in surgical techniques and postoperative management, PPPD has been associated with a higher delayed gastric emptying (DGE) rate than classical PD^[6,7], although controversies still exist^[8,9]. DGE, with an incidence ranging from 33% to 44%, is reported to be the major complication after PPPD^[10-12]. Although not a lethal complication, DGE is often responsible for prolonged hospital stay and increased associated morbidity and hospital costs. Several studies revealed that DGE was closely related to the reconstruction technique^[13,14]. Therefore, various modifications of reconstruction technique have been advocated to decrease the incidence of DGE.

A recently reported modification in the PPPD procedure is the performance of antecolic duodenojejunostomy (DJ) instead of retrocolic one. It has been found that antecolic reconstruction for DJ could significantly decrease the DGE rate after PPPD^[15-19]. The reported DGE rate was > 30% for retrocolic reconstruction whereas it was < 15% for the antecolic reconstruction^[19]. Nevertheless, two randomized controlled trials (RCTs) demonstrated that antecolic reconstruction was not superior to retrocolic reconstruction for DJ with respect to DGE after PPPD^[20,21]. Up to date, the use of antecolic reconstruction for DJ to decrease the incidence of DGE after PPPD remains a topic of debate.

The primary objective of this study is to analyze the existing evidence regarding the antecolic and retrocolic reconstruction for DJ after PPPD in a systematic review and to perform a meta-analysis of operative outcomes, postoperative mortality, morbidity and length of postoperative hospital stay. The primary outcome of interest was DGE.

MATERIALS AND METHODS

Selection of studies

Multiple databases, including MEDLINE (PubMed), EMBASE, OVID, and Cochrane Library Central, were searched for RCTs or non-RCTs (N-RCTs) that evaluated antecolic *vs* retrocolic reconstruction for DJ after PPPD from January 1991 to April 2012. The following Mesh search headings were used: pylorus-preserving pancreaticoduodenectomy, duodenojejunostomy, delayed gastric emptying, gastroparesis, antecolic reconstruction and retrocolic reconstruction. Citations were limited to those published on humans and in English language. A search was also performed for reference lists of the retrieved relevant articles for additional trials.

Inclusion and exclusion criteria

All included studies should fulfill the following criteria: (1) reporting the indication of PPPD; (2) comparing the results of antecolic and retrocolic reconstruction for DJ after PPPD; (3) reporting the incidence of DGE and other complications; and (4) when two or multiple studies were published by the same institution and/or authors, either one of the higher quality or the most recent article was included in the meta-analysis. Abstracts, case reports, letters, commentary, reviews without original data, studies lacking control groups or appropriate data for extraction and the number of patients less than 35 were excluded.

Study eligibility assessment

Two authors (Cao SS and Zhang Y) independently screened the title and abstract of each publication for potentially eligible studies. Then full articles of eligible trials were obtained for detailed evaluation. Any disagreement in the selection process was resolved through discussion by the two authors. If the two authors could not reach an agreement, a third person (Tian BL) would make a final decision on the eligibility of the study.

Data extraction

Two authors (Cao SS and Zhang Y) independently extracted data from all eligible studies, and then cross-checked the data. Data extracted from each study included: first author, study period, study design, inclusion and exclusion criteria, participant characteristics, interventions used, technique of reconstruction, morbidity and mortality rates, definition of DGE, DGE rate, and length of postoperative hospital stay. Any disagreements were resolved using the same method as mentioned above.

Quality assessment

Jadad scoring system, which evaluates studies based on appropriate randomization, proper blinding, and an adequate description of withdrawals and dropouts, was used to assess the quality of RCTs^[22]. The N-RCTs were scored on the following basis: prospective *vs* retrospective data collection; assignment to antecolic route or retrocolic route by means other than surgeon preference; and an explicit definition of DGE (studies were given a score of 1 for each of these areas; score 1-4)^[23]. The study was considered to be of high quality if the quality score is ≥ 3 .

Statistical analysis

Meta-analysis was performed in accordance with the recommendations of the Cochrane Collaboration. The effect outcomes estimated were odds ratio (OR) for dichotomous variables and mean difference (MD) for continuous variables, both reported with 95% CI. OR was defined as the odds of an adverse event occurring in the antecolic group (AG) *vs* the retrocolic group (RG) and it was considered statistically significant at $P < 0.05$.

Figure 1 Flow chart showing the search strategy used to identify studies. CPD: Classic pancreaticoduodenectomy; PPPD: Pylorus-preserving pancreaticoduodenectomy.

if the 95% CI did not cross the value 1. MD represented the difference between the two groups in the continuous variables and it was considered statistically significant at $P < 0.05$ if the 95% CI did not cross the value 0. Heterogeneity between studies was measured using χ^2 and I^2 , and $I^2 > 50\%$ was considered statistically significant. Either fixed effects model or random effects model was applied to calculate the pooled effect based on the heterogeneity. But random effects model was used first to assess the heterogeneity. Subgroups were used for sensitivity analysis and a funnel plot was used to identify publication bias.

RESULTS

Eligible studies

The literature searching strategy identified five articles^[16-20] that met the inclusion criteria: two RCTs and three N-RCTs (Figure 1). The five studies involved a total of 451 patients: 240 in the AG and 211 in the RG. The details of the included studies are summarized in Table 1. The sample size ranged from 35 to 200 patients. The mean age of the patients varied between 61 and 70 years. The mean proportion of males varied between 41% and 67% and the proportion of malignancy varied between 63% and 100%. There were no significant differences between the two groups in age (MD, 1.50; 95% CI, -1.67 to 4.66; $P = 0.35$), sex (OR, 0.91; 95% CI, 0.62-1.32; $P = 0.61$) and the proportion of malignancy (OR, 0.75; 95% CI, 0.49-1.16; $P = 0.20$). Of the five studies, only one reported the length of follow-up^[19]. Surgical reconstruction and the definition of DGE are

described in Table 2. In three studies^[18-20], the description of reconstruction method revealed adequate consistency. There was some variation in the postoperative management, including the indication for nasogastric tube (NGT) removal, and administration of somatostatin analogues (SSA), antacid and prokinetic agents (PA).

Meta-analysis of operative outcomes

Operation time (min): Four studies^[16,17,19,20] provided information regarding operation time. The random effects model was used because of significant heterogeneity ($I^2 = 83\%$) between studies, and the result of pooled analysis showed no statistically significant difference between the two groups (MD, 25.23; 95% CI, -14.37 to 64.83; $P = 0.21$) (Figure 2A).

Intra-operative blood loss (mL): Four studies^[16,17,19,20] reported on intra-operative blood loss. It was significantly lower in the AG than in the RG (MD, -317.68; 95% CI, -416.67 to -218.70; $P < 0.0001$) (Figure 2B).

Meta-analysis of postoperative outcomes

Mortality: All the five studies reported on hospital mortality. Among the 451 patients involved, only one patient reported by Tani *et al.*^[19] died from acute hemorrhagic shock because of a Dieulafoy's type ulcer in the RG. Therefore, there was no difference in mortality between the two groups.

Morbidity: Three studies^[17,18,20], including 367 patients, were analyzed for the overall postoperative morbidity. No statistically significant difference was found between the two groups: 17.9% (AG) *vs* 32.0% (RG) (OR, 0.54; 95% CI, 0.20-1.46; $P = 0.22$). But there was statistically significant heterogeneity between the groups in the three studies ($I^2 = 71\%$) (Figure 2C). All studies provided data on DGE rate and pancreatic fistula (PF) rate. The summarized effect of DGE with random effects model ($I^2 = 52\%$) revealed a statistically significant result favoring AG with a DGE incidence of 7.1% (17/240) compared with a DGE rate of 45.5% (96/211) in the RG (OR, 0.06; 95% CI, 0.02-0.17; $P < 0.0001$) (Figure 2D). However, the difference of the occurrence of PF between the two groups was not statistically significant. Concerning other postoperative complications, there was no significant difference between AG and RG in hemorrhage, intra-abdominal abscesses, bile leakage, the anastomotic leakage, wound infection and reoperation (Table 3).

Postoperative time to remove NGT (d): Time for postoperative removal of NGT was reported in four studies^[16,17,19,20], and three^[17,19,20] studies reported the data using mean \pm SD. No SD was reported by Kurosaki *et al.*^[16] (3 *vs* 14, $P < 0.0001$). The random effects model was used due to significant heterogeneity ($I^2 = 98\%$) between studies, and the overall effect indicated no difference between the AG and RG (MD, -7.38; 95% CI, -17.39 to 2.63; $P = 0.15$) (Figure 2E).

mation (14 *vs* 28, $P < 0.0001$)^[16]. The summarized effect with random effects model ($I^2 = 95\%$) revealed no difference between the two groups (MD, -8.32; 95% CI, -17.89 to 1.26; $P = 0.09$) (Figure 2G).

Length of postoperative hospital stay (d): Data of length of postoperative hospital stay was available in four studies^[17-20], but Hartel *et al*^[18] did not report the SD (11.5 *vs* 17.5, $P < 0.001$). The other three studies showed no statistically significant difference between the two groups (MD, -9.08; 95% CI, -21.28 to 3.11; $P = 0.14$), which was associated with significant heterogeneity between the groups in all available studies for pooled analysis ($I^2 = 77\%$) (Figure 2H).

Sensitivity analysis

The following four subgroups were used for the sensitivity analysis: RCTs, N-RCTs, reconstruction with Billroth II in the AG and RG and reconstruction with Billroth II in AG and Billroth I in RG. The results of the analysis (Table 4), were the same as those when all studies were selected.

Publication bias

A funnel plot of all the studies reporting on DGE used in this meta-analysis is shown in Figure 3. There was no strong evidence of publication bias because all the studies were equally distributed around the vertical axis.

DISCUSSION

This meta-analysis found that antecolic reconstruction for DJ during PPPD was associated with a statistically significant decrease in the incidence of DGE and intra-operative blood loss. But antecolic reconstruction was not superior to retrocolic reconstruction with respect to operation time, postoperative mortality, overall morbidity, postoperative time to remove NGT and start liquid

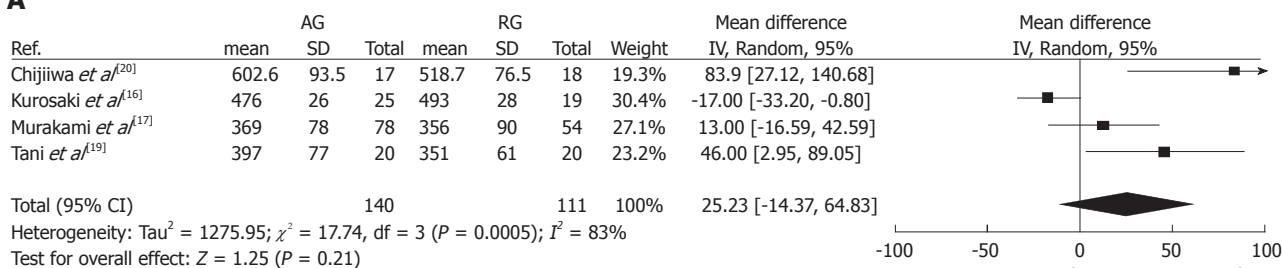

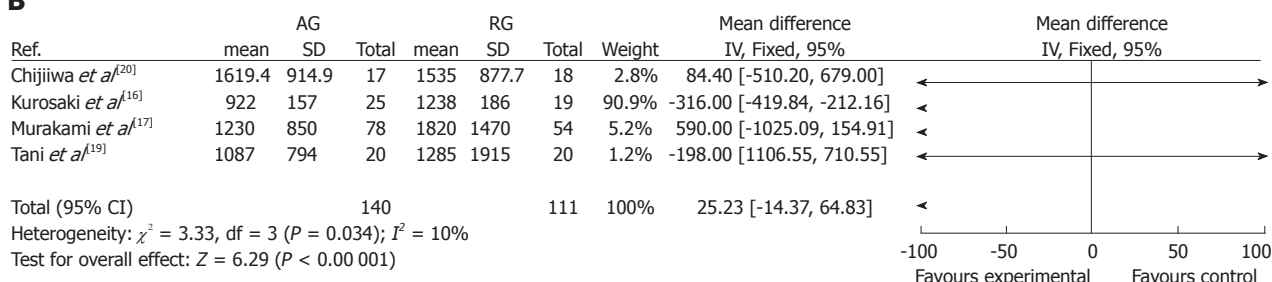

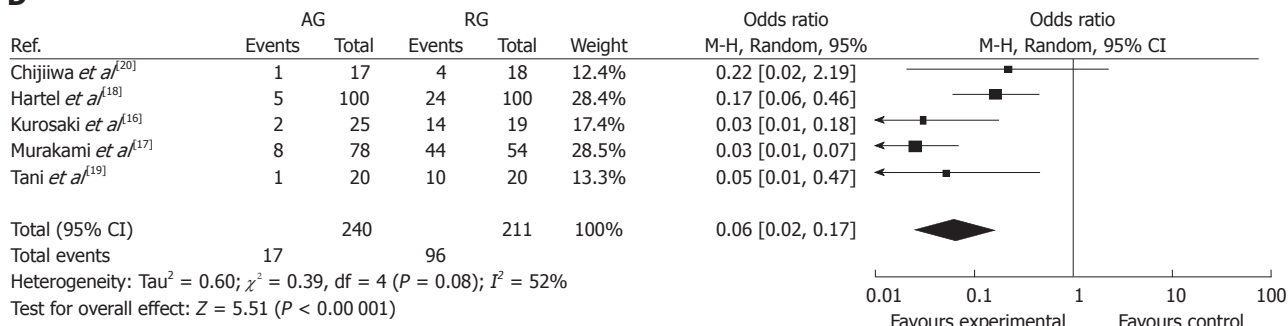

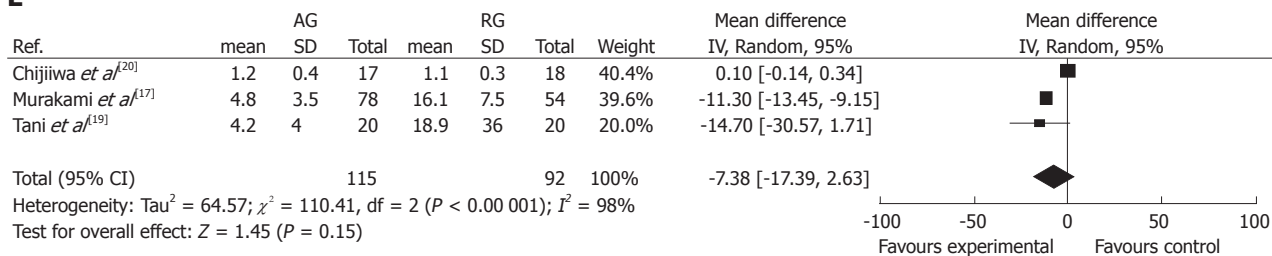

meal and solid food, and length of postoperative hospital stay.

Although DGE is the most frequent postoperative complication after PPPD, the true mechanism has not been fully clarified. A number of theories, including local ischemia of the antrum, low plasma motilin concentrations, gastric atony, transient pancreatitis, and gastric dysrhythmias, have been postulated to explain the occurrence of DGE after PPPD^[29]. Moreover, DGE is always associated with angulation or torsion of the DJ in the early postoperative period^[30].

Compared with retrocolic reconstruction, antecolic reconstruction may have several theoretical advantages. Antecolic reconstruction is believed to be less prone to torsion or angulation, causing DGE by mechanical obstruction^[18,31]. In the antecolic reconstruction, the DJ anastomosis is located further away from pancreaticojejunostomy compared with the retrocolic reconstruction, which reduces the negative effect on antroduodenal motility by a small pancreatic anastomotic leak or a transient mild postoperative pancreatitis^[18]. Furthermore, the descending jejunal loop is more mobile after antecolic reconstruction than after retrocolic reconstruction because of a minor degree of venous congestion and bowel edema^[28].

DGE due to postoperative complications has been an accepted concept in the literature^[31,32]. However, in the current study, the postoperative complications, including PF, hemorrhage, intra-abdominal abscesses, bile leakage, the anastomotic leakage, wound infection and reoperation, were similar in both groups. The lack of generally accepted definitions of postoperative complications may influence the results. Perhaps the significant higher intro-abdominal blood loss during surgery in the retrocolic reconstruction group may contribute to a risk for DGE.

DGE not only leads to repeated episodes of nausea and vomiting which prolongs NGT intubation and delays

food intake, but also has an impact on duration of hospitalization^[33]. Nevertheless, this meta-analysis demonstrated that antecolic reconstruction did not seem to offer an advantage with respect to postoperative time to remove NGT and start liquid meal and solid food, and length of postoperative hospital stay. This may result from a small number of studies providing insufficient information for analysis. Kurosaki *et al*^[16] reported that postoperative time to remove NGT and start liquid meal and solid food were significantly shortened in antecolic reconstruction group. Hartel *et al*^[18] also found that the median postoperative stay was significantly shorter in the antecolic reconstruction group than in the retrocolic reconstruction group. But neither of the studies reported the SD, which would greatly influence these pooled results.

The three types of reconstructions, including Billroth I, Billroth II and Roux-en Y, are frequently performed for digestive tract reconstruction after PPPD.

Of the five studies included in the current meta-analysis, three studies applied Billroth II reconstruction for both groups^[18-20] and pooled analysis showed a significantly decreased DGE rate in the antecolic reconstruction group. One study showed that Billroth II reconstruction with antecolic DJ achieved a significantly lower incidence of DGE than Billroth I reconstruction with retrocolic DJ^[16]. Another research showed that DGE rate was significantly lowered with antecolic Roux-en Y reconstruction. However, according to the description and schematic illustration of the reconstruction method, the reconstruction method used should be the antecolic Billroth II reconstruction, but not the Roux-en Y reconstruction^[17]. These data suggest that antecolic Billroth II reconstruction for DJ could be a useful method after PPPD to decrease the occurrence of DGE.

The present study has some limitations and the results should be interpreted with caution. First, this meta-analysis included a small number of studies and patients. Second, some low-quality studies were incorporated, and 60% of the data came from N-RCTs. Third, a test for heterogeneity was significant for most outcomes analyzed. The differences between the studies have led to heterogeneity, including differences in the type of digestive tract reconstruction, definition of DGE and postoperative management. In order to reduce the heterogeneity, subgroup analysis was performed and the results were the same as those when all studies were selected, which further confirmed the conclusion drawn above.

In conclusion, the current study suggests that antecolic reconstruction for DJ can decrease DGE rate after PPPD. However, further standardized RCTs with general type of digestive tract reconstruction and definition of DGE are urgently needed to draw a definitive conclusion.

COMMENTS

Background

Various modifications of reconstruction technique have been advocated to decrease delayed gastric emptying (DGE) rate after pylorus-preserving pancreaticoduodenectomy (PPPD). A recently reported modification is the performance of antecolic duodenojejunostomy (DJ) instead of retrocolic approach. Up to now, however, the selection of antecolic or retrocolic reconstruction for DJ remains an issue of debate. In this paper, therefore, a systematic review and meta-analysis were performed to evaluate whether antecolic reconstruction for DJ can decrease DGE rate after PPPD.

Research frontiers

DGE is reported to be the leading complication after PPPD. Although not a lethal complication, DGE is often responsible for prolonged hospital stay and increased associated morbidity and hospital costs. In the area of decreasing DGE rate with different reconstructions for DJ, the research hotspot is to evaluate the effect of antecolic and retrocolic reconstruction for DJ on the incidence of DGE after PPPD.

Innovations and breakthroughs

This review suggests that antecolic reconstruction for DJ can decrease DGE rate after PPPD. According to the authors, this is the first systematic review using the meta-analysis to study the benefit of antecolic reconstruction for DJ in decreasing the DGE rate after PPPD.

Applications

The study result that antecolic reconstruction for DJ can decrease DGE rate after PPPD could guide the selection of the reconstruction route for DJ.

Peer review

This is a technically good study of antecolic vs retrocolic reconstruction for DJ after PPPD. The results are interesting and suggest that antecolic reconstruction for DJ can decrease DGE rate after PPPD.

Abstract

Granular cell tumor (GCT) of the biliary system is rare. It is reported that it occurs more commonly in young black women. We report here our seldom experience of a Japanese case in whom icterus was found as a first symptom just after a caesarean operation. A 36-year-old Japanese woman developed icterus after delivery by the Caesarean operation. A surgical operation was performed without can deny that there was a tumor-related change in a bile duct as a result of examination for various images. As a result of pathological evaluation, GCT was diagnosed. By the preoperative organization biomicroscopy result, it was not able to be attached a right diagnosis. It was thought that this tumor, although rare, should be considered as one of the causes of biliary stenosis in the younger population.

INTRODUCTION

Granular cell tumor was initially described by Abrikossoff in 1926; it was found in the skeletal muscle of the tongue^[1], and first reported in the biliary system in 1952 by Coggins^[2]. A lot of researchers favor the theory that such tumors are generated from Schwann cells. The theory of Schwann cell origin is based on histological, electron microscopic, and immunohistochemical findings^[3,4]. The tumors generally arise in the oral cavity, skin, and subcutaneous tissues, and less than 1% of granular cell tumor (GCT) occurs in the biliary tract^[5,6]. To date, there have been no reports on malignant GCT in bile duct. Most patients suffering from GCT in the bile duct are young, female, and black. Benign tumors in bile duct are rare (4%) and GCT in bile duct is very rare^[5].

This is a Japanese case report of bile duct GCT. This case was first suspected of being adenocarcinoma by the result of tumor biopsy on endoscopic retrograde cholangiopancreatography (ERCP) before the operation, as this was the result in other previous cases.

CASE REPORT

A 36-year-old Japanese woman was hospitalized for toxemia during pregnancy. She had hypertension and renal disorder at gestational age 30 wk and 2 d. Her blood pressure was 160-170/100 mmHg with albuminuria. Because her condition was resistant to treatment, she gave birth to twins by preparative Caesarean section at gestational age 32 wk and 2 d. During surgical procedures, her and her babies' general conditions were good. The Caesarean section was completed without noticeable complications.

After delivery, her systolic arterial pressure decreased to 120 mmHg and the proteinuria disappeared in several weeks. Three days after the delivery, liver enzymes and bile tract enzymes suddenly increased. In addition, six days after the delivery, icterus was recognized (Table 1). Serum bilirubin increased to 5.0 mg/dL (direct bilirubin 4.0 mg/dL) in 3 d. At first, the liver damage was regarded as a side effect of the various medicines. For example, Cephalosporin antibiotic was administered on the day and the day after the Caesarean operation and Ca blocker was prescribed for the purpose of lowering the blood pressure. Abdominal ultrasonography showed a swollen gallbladder, as well as debris associated with it. However, for the common bile duct (CBD), no expansion was observed given its diameter of 0.7 cm in the measurement (Figure 1). Tumor shadows or stenosis of CBD were also recognized. Contrast-enhanced abdominal computed tomography and magnetic resonance cholangiopancreatography also showed about 10 mm long stenosis and wall thickening in the middle part of the bile duct. Tumor marker Carcinoembryonic antigen was 2.0 ng/mL (normal 0-5 ng/dL) and carbohydrate antigen 19-9 was 32.0 U/mL (0-37 U/mL).

ERCP suggested there was a 6.1 mm-long stenosis at the middle part of the bile duct. The shape of the tumor was nodular (Figure 2). Mucosal layer (m) and fibromucosal layer (fm) thickening was identified by intraductal ultrasonography. Endoscopic brush cytology of the bile duct resulted in a status of "quantity not sufficient" and findings of forceps biopsy were atypical but inconclusive. In spite of these investigations, bile duct carcinoma could not be ruled out, so pancreaticoduodenectomy was performed 37 d after the Caesarean section.

At the operation, the tumor felt hard to touch in liver-duodenum ligament. Lymph nodes around the aorta and the lymph node on the posterior surface of the pancreatic head were slightly swollen, but they were free of malignancy on frozen section. The tumor was a poorly circumscribed nodule, measuring 9.0 mm × 5.5 mm, located at the lower portion of the CBD at the level of the upper margin of the pancreas and involved all layers of the bile duct wall (Figure 3A). **Microscopically**, tumors were rounded or polygonal with eosinophilic granular cytoplasm, arranged in nests and cords separated by fibrous tissue septa (Figure 3B). The GCT cells partly infiltrated a peripheral nerve fibrous tissue bunch in the bile duct wall. In addition, they infiltrated the vein

Figure 1 Upon abdominal ultrasound, the gallbladder was swollen. Dilatation of the bile duct was not apparent upon measurement, however, a segment of the common bile duct seemed to be obstructed, warranting further investigation.

Figure 2 Endoscopic retrograde cholangiopancreatography shows stricture at the middle part of the bile duct.

Table 1 Laboratory data on the day of first appearance of icterus

Complete blood count	Blood chemistry

lymph nodes were free of tumor. Five years have passed since the surgery and the patient is well.

DISCUSSION

Almost all bile duct tumors or stenosis are suspected as being malignant because benign tumors are comparatively rare in the bile duct. In 2003, Principe *et al*^[5] reviewed 179 (90 men and 89 women) patients who were diagnosed with malignant stricture of bile duct and judged to be operable from 1982 to 2001. In 153 cases, an operation was carried out. Of these 147 (96.1%) cases were found to have a malignant cause as gall bladder carcinoma or cholangiocarcinoma. Cases in which radical operation was possible constituted only 24.8% of these. It was judged not to be possible to remove the tumor surgically in the other cases, and only an operation for reducing jaundice was carried out. The remaining 6 cases (4%) were benign strictures and only one of them was GCT (0.7% of the total). Benign tumor in bile duct is rare so almost all cases of stenosis in it tend to be considered as malignant stricture. We searched for “granular cell tumor” and “bile duct” in the Pub-Med database and obtained reports on 47 previous cases of GCT of the bile duct. We verified 48 cases including our case.

Most of the patients were young. The average age at diagnosis was 33.9 years old (range 11 years to 56 years). Almost all of the patients (81.0%) were female and many were black. In terms of ethnic origin, 60.5% of them were black (including Jamaican and Ethiopian), 31.6%

Figure 4 The granular cell tumor cells partially infiltrated a peripheral nerve fibrous tissue bunch in the bile duct wall. In addition, they infiltrated the vein in the bile duct wall and occluded some of the vein lumina. A: Granular cell tumor involving a small nerve (Elastica-Masson stain, $\times 4$); B: A vein is replaced by a neoplastic cell (Elastica-Masson stain, $\times 4$).

were Caucasoid (including Algerian), and 7.9% of them were Mongoloid (including Japanese and Thai). The chief complaints were jaundice, pain, and a pruritus feeling, which are symptoms caused by obstructive jaundice. There is no specific symptom of this tumor, as forecast. The range of tumor size was 0.5 cm^[7] to 4.0 cm^[8] and the average was 1.6 cm. As for the site of the tumors, 58.1% were in CBD, 23.3% in common hepatic duct (CHD), 14.0% in cystic duct (CD), and 2.3% in gallbladder and ampulla of Vater. They might tend to be located at confluences with 41.9% of them near the confluence of CBD (CHD and CD and CBD), and 11.6% of them near the confluence of CHD (right and left hepatic ducts). However, the divergence position of the CD was not mentioned in all reports, and some contained vague descriptions, for example, “CBD” or “CD”.

It is generally difficult to make diagnoses as GCT histologically before an operation. A correct diagnosis might be made from several repeated biopsies, as in our case. Because almost all tumors of bile duct are malignant, the diagnosis of “suggested adenocarcinoma” is difficult to the default setting doubt.

Histologically, GCT involves large granular-like eosinophilic cells. It generally occurs in skin and the oral cavity, and two-thirds of cases occur in cutis and sub-mucosa^[9]. It is rare in infants, and occurs in adults of 30-40 years old. As for the sex ratio, its prevalence is four times higher in women than in men. Many cases of

GCT occurring in bile duct in women, the young, and in black people have been reported. In the literature, GCT is described as being not often diagnosed with histology before an operation. Even if it is diagnosed as benign tumor, surgical operation may be chosen for various reasons. One is that it is not easy to rule out malignant tumor completely because of the frequency of malignant tumor in bile duct. Another reason is that some symptoms like jaundice or pain can be caused, no matter how small it is. The average size was 1.6 cm, which is small. The smallest size was 0.5 cm. Generally, it is difficult to discover small tumors without symptoms. These tumors tend to cause small symptoms, at an early stage.

It occurs at a rate under 2%, but there is malignant GCT^[9-11]. There are some cases that relapsed after surgical excision and spread, finally resulting in death. These malignant GCTs are usually larger than 5 cm^[12]. However, no one has reported malignant GCT in bile duct, for example, a case of it spreading to other organs, recurring several years later, or invading surrounding tissue. Although only one case resulted in mortality^[13], this was not due to primary disease but to postoperative severe adult respiratory distress syndrome and disseminated intravascular coagulopathy with fulminant sepsis, 3 wk after Roux-en-Y hepaticojejunostomy.

Benign tumors in the biliary system are so rare that it is difficult to rule out malignant tumor. If intraoperative frozen section could establish an exact diagnosis, we would be able to select reduction operation depending on the location of GCT in bile duct.

GCT is a rare disease among Asian population. According to past case reports, it is a tumor that tends to occur in the bile duct in young black women. A benign tumor developing in the bile duct is very rare and it is unusual in Asians.

In conclusion, we experienced a case of GCT that occurred in a young Japanese woman. It was thought that this tumor, although rare, should be considered as one of the causes of biliary stenosis in the younger population.

Abstract

Lymphangioma is a rare benign condition characterized by proliferation of lymphatic spaces. It is usually found in the head and neck of affected children. Lymphangioma of the small-bowel mesentery is rare, having been reported for less than 1% of all lymphangiomas. Importantly, it can cause fatal complications such as volvulus or involvement of the main branch of the mesenteric arteries, requiring emergency surgery. Moreover, the gross and histopathologic findings may resemble benign multicystic mesothelioma and lymphangiomyoma. Immunohistochemical study for factor VIII-related antigen, D2-40, calretinin and human melanoma black-45 (HMB-45) are essential for diagnosis. Factor VIII-related antigen and D2-40 are positive in lymphangioma but negative in benign multicystic mesothelioma. HMB-45 shows positive study in

the smooth-muscle cells around the lymphatic spaces of the lymphangiomyoma. We report a case of small-bowel volvulus induced by mesenteric lymphangioma in a 2-year-and-9-mo-old boy who presented with rapid abdominal distension and vomiting. The abdominal computed tomography scan showed a multiseptated mass at the right lower quadrant with a whirl-like small-bowel dilatation, suggestive of a mesenteric cyst with midgut volvulus. The intraoperative findings revealed a huge, lobulated, yellowish pink, cystic mass measuring 20 cm × 20 cm × 10 cm, that was originated from the small bowel mesentery with small-bowel volvulus and small-bowel dilatation. Cut surface of the mass revealed multicystic spaces containing a milky white fluid. The patient underwent tumor removal with small-bowel resection and end-to-end anastomosis. Microscopic examination revealed that the cystic walls were lined with flat endothelial cells and comprised of smooth muscle in the walls. The flat endothelial cells were positive for factor VIII-related antigen and D2-40 but negative for calretinin. HMB-45 showed negative study in the smooth-muscle cells around the lymphatic spaces. Thus, the diagnosis was lymphangioma of the small bowel mesentery with associated small bowel volvulus.

INTRODUCTION

Lymphangioma is a benign condition characterized by proliferation of the thin-walled lymphatic spaces^[1]. It is believed to result from congenital lymphatic malformation rather than a true lymphatic neoplasm^[2,3]. It is usually found in the head and neck regions during the first few years of life^[1]. Lymphangioma of the small-bowel mesentery is rare, representing less than 1% of all lymphangiomas^[2]. Volvulus is the most common manifestation of mesenteric lymphangioma^[3].

CASE REPORT

We report a case of a 2-year-and-9-mo-old boy who suffered from unexplained intermittent abdominal pain with vomiting since he was 6 mo old. These symptoms were temporarily relieved by treatment with anti-flatulence and anti-vomiting agents. However, the frequency and severity seemed to gradually increased. Fifteen days prior to admission to the hospital, he developed mucous bloody diarrhea with low-grade fever. He was treated by oral and intramuscular antibacterial agents and oral rehydration. Three days later, the diarrhea had diminished, but the low-grade fever persisted. When he was first brought to the emergency room, his vital signs were not remarkable except the pulse rate, 130 beats/min. Physical examination revealed abdominal distension. Other features were unremarkable. Stool exam was not performed. The initial diagnosis was acute infectious diarrhea. Intravenous fluid was administered, but the patient was not hospitalized. He was treated by oral antibacterial agents and oral rehydration. Five days later, the child was brought to the hospital for the second visit with a 1-d history of intermittent abdominal pain, rapid abdominal distension, and vomiting. However, there was no mucous bloody diarrhea or fever. The vomited content was food material admixed with greenish watery fluid. The patient's vital signs were unremarkable except for the pulse rate, 110 beats/min. Physical examination revealed abdominal distension with diffuse tenderness and hyperactive bowel sounds but no abdominal rigidity. Rectal digital examination revealed yellow feces. Other features were unremarkable. Plain abdominal radiography revealed dilatation of the small-bowel loops at the upper and mid abdomen with multiple air-fluid levels, suggestive of small-bowel obstruction (Figure 1A and B). Abdominal CT scan revealed a thin-walled, fluid-filled, multiseptated mass, about 7.8 cm × 7 cm × 6.9 cm, at the right lower quadrant with compression of the adjacent bowel and generalized dilatation of the small-bowel loops in a whirl-like pattern, suggestive of a chylous mesenteric cyst associated with midgut volvulus (Figure 1C and D). Laparotomy was performed. During the operation, small-bowel volvulus with small-bowel dilatation and a mesenteric mass were found (Figure 2A and B). The mesenteric mass was lobulated, yellowish pink, cystic, and huge, measuring approximately 20 cm × 20 cm × 10 cm. The mass content was milky white, approximately 100 mL. The mesenteric mass with adjacent

small-bowel segment were resected. Small-bowel anastomosis and decompression were performed. After formalin fixation, the mesenteric mass collapsed and shrank to 5.5 cm × 4.5 cm × 2.4 cm (Figure 2C). It was lobulated, cystic, semitranslucent, and pale tan with an adjacent small-bowel segment 5 cm long and 2 cm across. Cut surfaces of the mass revealed multicystic spaces of varying size (Figure 2D). The cystic walls were generally thin, but some walls were relatively thick. There was no fluid in the mass because it had been previously drained. However, there was residual milky white fluid in the specimen container representing the drained lymphatic fluid (inset of Figure 2D). The small-bowel mucosa was grossly unremarkable without invagination into the mass. Microscopic examination revealed that the cystic walls comprised of smooth muscle were lined with flat endothelial cells (Figure 3A and B). The stroma showed various sizes of small lymphatic spaces lined by a flat endothelium and containing small lymphoid cells (Figure 3C). The stroma also contained smooth-muscle bands and scattered lymphoid infiltrates (Figure 3C). Few subendothelial lymphoid follicles were observed, supporting the diagnosis of cystic lymphangioma (Figure 3D). The cell lining of the cystic walls was immunoreactive for factor VIII-related antigen (Figure 3E) and D2-40 (focal) (Figure 3F) but not for calretinin (Figure 3G) and human melanoma black-45 (HMB-45) (Figure 3H).

In conclusion, the diagnosis was cystic lymphangioma as indicated by proliferation of cystically dilated lymphatic spaces, immunoreactivity with factor VIII-related antigen and D2-40, and milky white content. Negative study of calretinin and HMB-45 excluded benign multicystic mesothelioma and lymphangiomatoma, respectively.

DISCUSSION

Lymphangioma is a mass-forming lesion characterized by numerous thin-walled lymphatic spaces and usually manifests in the first few years of life^[1]. The common sites are the head, neck, and axillary regions. Other locations such as the abdominal or mediastinal cavity are rare, accounting for approximately 5% of lymphangiomas^[2]. Among these, lymphangioma of the small-bowel mesentery has been described in less than 1% of lymphangiomas^[1]. Lymphangioma appears to result from congenital malformation of lymphatic vessels rather than a true lymphatic tumor^[2,3]. The former causes sequestration of lymphatic vessels during the embryonic period^[1]. However, some data suggest that inflammation, abdominal trauma, abdominal surgery, radiation, or lymphatic obstruction may play a role in the genesis as a tumor^[4,5]. Of note, the patient described in this case study had a history of intermittent abdominal pain without an identifiable cause from the time he was 6 mo old. This supports the theory of lymphangioma resulting from congenital malformation of lymphatic vessels rather than a tumor. Lymphangiomas are traditionally classified into three histologic types: capillary (simple), cavernous, and cystic^[1]. The capillary (simple) type usually originates in the skin and con-

Figure 1 Radiologic study. A, B: Plain abdominal radiography in supine (A) and upright (B) positions showed small-bowel dilatation with multiple air-fluid levels in the upright position (B); C: Coronal view of the abdominal computed tomography (CT) scan revealed twist of the mesentery and its vessels (arrows) with a fluid-filled multiloculated mass in the right lower quadrant (between arrowheads); D: Axial view of the abdominal CT scan showed a twist of the mesenteric fat and its vessels (arrow) with small-bowel dilatation.

Figure 2 Gross pathology. A, B: Intraoperative photographs show a lobulated cystic yellowish pink mass that originated from the small-bowel mesentery (arrow in A) with small bowel dilatation. The mass shows vascular streaks (B); C, D: The formalin-fixed specimen reveals a partially collapsed, cystic, lobulated, pale tan mesenteric mass with vascular streaks (C). The cut surface reveals thin-wall multicystic spaces with thickened white appearance in some cystic walls (D). The inset shows milky white fluid. The small-bowel mucosa is not remarkable.

sists of uniform small thin-walled lymphatic spaces. The cavernous type is composed of various sizes of dilated lymphatic spaces associated with lymphoid stroma and shows a connection with the adjacent normal lymphatic spaces. The cystic type consists of dilated lymphatic spaces of various sizes associated with collagen and smooth-muscle bundles in the stroma but lacks connection to the adjacent normal lymphatic spaces. Cystic lymphangioma findings are similar to cavernous lymphangioma findings in that dilated lymphatic spaces of variable size are seen for both^[6].

In this case study, the mass was composed of cysti-

cally dilated lymphatic spaces of varying size associated with smooth-muscle cells, characteristic of cystic lymphangioma. An immunohistochemical study for D2-40, a lymphatic endothelial marker, showed focal positivity in the cystic wall endothelium, supporting the diagnosis^[7]. Lymphoid follicles and lymphoid infiltrates in the stroma supported the diagnosis^[8]. The milky white fluid content supported lymphangioma, in which the white color results from accumulated lymphoid cells. The differential diagnoses were lymphangiomyoma and benign multicystic mesothelioma. The former shows smooth-muscle cell proliferation around the lymphatic spaces with pericytic

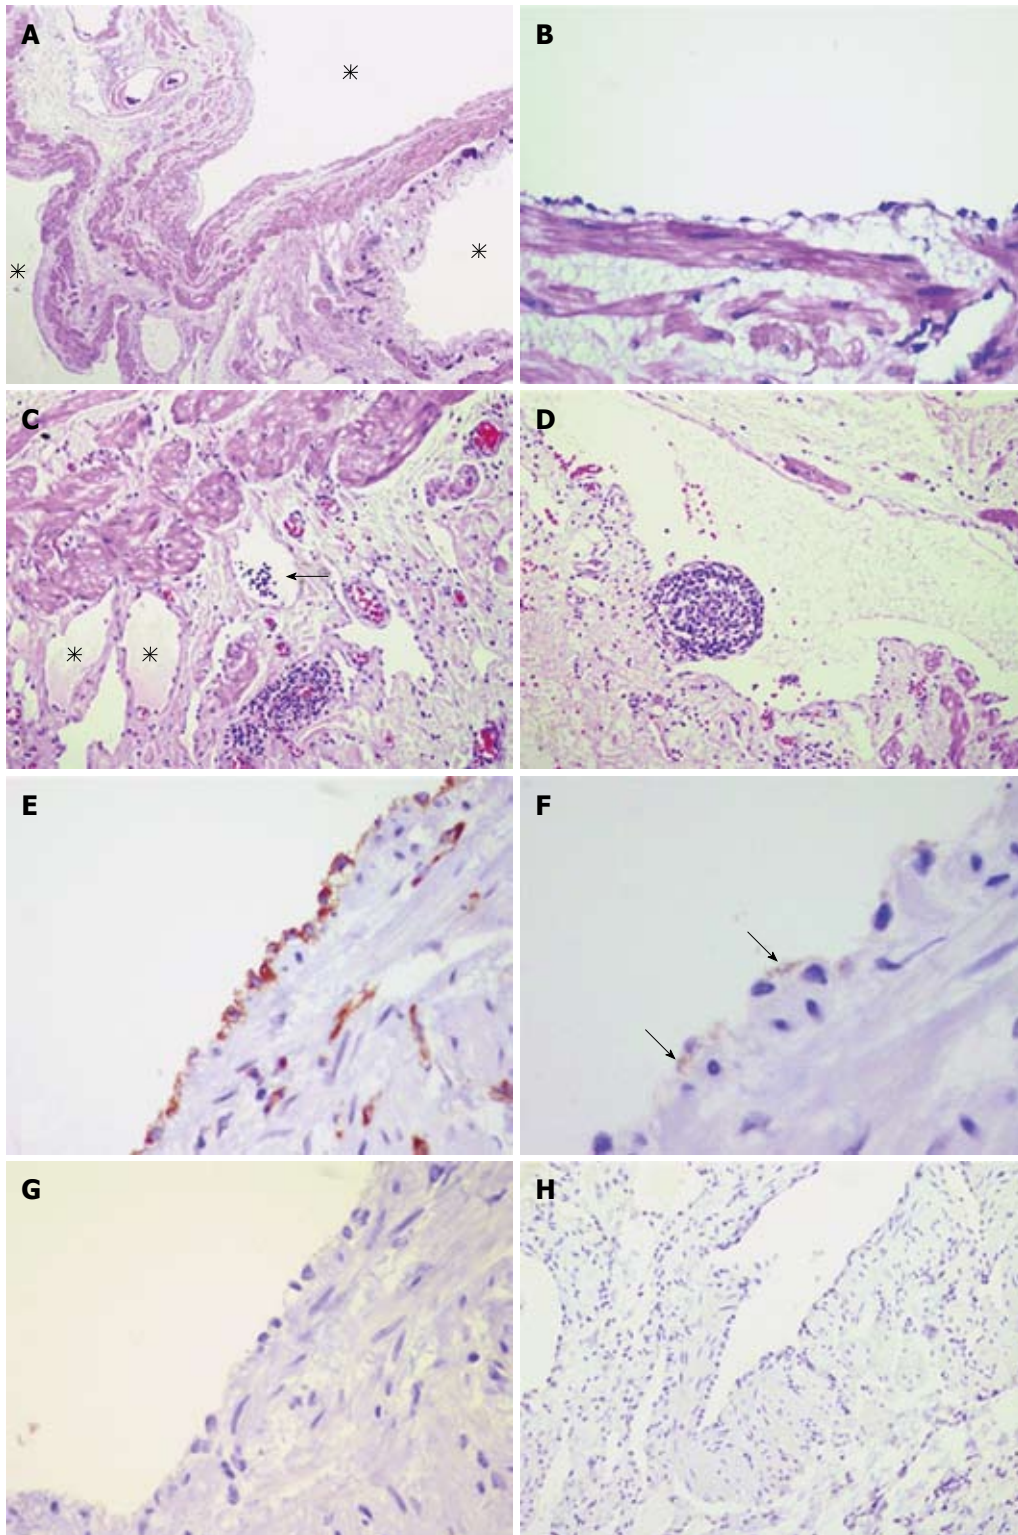

Figure 3 Histopathology. A: Cystic spaces (asterisks) with smooth muscle in their walls (hematoxylin and eosin, 40 ×); B: Flat lining cells of the cystic spaces with smooth muscle below them (hematoxylin and eosin, 400 ×); C: Lymphatic spaces in the stroma containing lymphoid cells (arrow) and pale eosinophilic fluid, suggestive of lymph (asterisks) (hematoxylin and eosin, 200 ×); D: Subendothelial lymphoid follicle (hematoxylin and eosin, 200 ×); E-G: Immunohistochemical study of the lining cells of the cystic wall shows strong cytoplasmic immunoreactivity for factor VIII-related antigen (E, 600 ×) and focal reactivity with D2-40 (F, 1000 ×, arrows) but not for calretinin (G, 600 ×); H: Immunohistochemical study for human melanoma black-45 shows negative result in the smooth muscle of the lymphatic wall (100 ×).

differentiation, demonstrated by HMB-45 immunoreactivity^[8]. Benign multicystic mesothelioma consists of variably sized spaces lined by cuboidal or flattened mesothelial cells, with positive staining for mesothelial marker such

as calretinin^[9]. In this case study, the smooth-muscle cells around the lymphatic spaces were non-immunoreactive for HMB-45, and the lining cells of the cystic walls were non-immunoreactive for calretinin. Therefore, lymph-

angiomyoma and benign multicystic mesothelioma were excluded.

Intra-abdominal lymphangioma usually presents as abdominal distension, a palpable abdominal mass, or acute intestinal obstruction^[2]. The latter is the most common presentation of mesenteric lymphangioma in the form of small-bowel volvulus^[3]. Small-bowel volvulus is the rotation of the small bowel and its mesentery, usually complicated by acute intestinal obstruction. The precipitating factors to volvulus include postoperative adhesion bands, congenital bands, colostomy, ileostomy, fistula, tumors, omental defect, and Meckel's diverticulum^[10]. Mesenteric lymphangioma induces rotation of the small bowel, resulting in small-bowel volvulus with subsequent closed-loop small-bowel obstruction. Partial small-bowel obstruction induced by volvulus was responsible for the patient's first visit, as manifested by abdominal distension. The patient's fever and mucous bloody diarrhea might have resulted from secondary bowel inflammation related to volvulus, particularly hemorrhagic infarction, or from unrelated infectious diarrhea. Small-bowel volvulus with closed-loop obstruction resulted in the patient's second visit and required emergency surgery. One month after the operation, the patient was brought for follow-up and did not manifest postoperative complications.

In conclusion, lymphangioma of the small-bowel mesentery is rare but can cause fatal complications such as volvulus or involvement of the main branch of the mesenteric arteries that requires emergency surgery^[1]. The gross and microscopic findings may mimic benign multicystic mesothelioma in case of an overwhelming

flattened mesothelium, and these conditions can be distinguished by immunohistochemical study.

Abstract

A number of disorders have been described to cause protein losing enteropathy (PLE) in children. Primary intestinal lymphangiectasia (PIL) is one mechanism leading to PLE. Few syndromes are associated with PIL; Hennekam syndrome (HS) is one of them. The principal treatment for PIL is a high protein, low fat diet with medium chain triglycerides supplementation. Supportive therapy includes albumin infusion. Few publications have supported the use of octreotide to diminish protein loss and minimize hypoalbuminemia seen in PIL. There are no publications on the treatment of PIL with octreotide in patients with HS. We report two children with HS and PLE in which we used octreotide to decrease intestinal protein loss. In one patient, octreotide increased serum albumin to an acceptable level without further need for albumin infusions. The other patient responded more dramatically with near normal serum albumin levels and cessation of albumin infusions. In achieving a good response to octreotide in both patients, we add to the publications supporting the use of octreotide in PIL and suggest that octreotide should be tried in patients with PIL

secondary to HS. To the best of our knowledge, this is the first case report on the use of octreotide in HS-associated PIL.

INTRODUCTION

Protein losing enteropathy (PLE) occurs in a variety of intestinal disorders leading to excessive loss of proteins into the gastrointestinal (GI) tract^[1]. There are two different mechanisms through which intestinal protein loss can occur: lymphatic system abnormalities and mucosal injury. Primary intestinal lymphangiectasia (PIL) is a congenital disorder of the lymphatic system resulting in impaired lymphatic drainage. In the intestines, impaired lymphatic drainage leads to excessive protein-rich chyle loss, hypoalbuminemia and peripheral edema. Mucosal edema leads to malabsorption and steatorrhea. The diagnosis of PIL is based on typical endoscopic and/or histological findings plus exclusion of a secondary cause of intestinal lymphangiectasia such as cardiac disease, malignancy or post-abdominal surgical complications^[2,3]. A

number of disorders have been described to cause PLE in children. Few syndromes are associated with PIL; Hennekam syndrome (HS) is one of them^[4]. HS (OMIM 235510) is an autosomal recessive disorder comprising intestinal lymphangiectasia, severe lymphedema of the limbs, genitalia and face, facial dysmorphism and mental retardation^[4]. Several authors have reported additional symptoms of HS. The frequency of HS is uncertain with widespread occurrence of the gene. There is inter-familial variability in the phenotype. HS is characterized by generalized maldevelopment of the lymphatic system. PIL and PLE are reported in most patients^[4-6]. Phenotypic abnormalities are due to impaired lymphatic flow resulting from insufficient *CCBE1* gene function during lymphangiogenesis. The *CCBE1* protein plays a direct role in the formation of lymphatic vessels and venous sprouting^[7]. Mutations in the *CCBE1* gene have been identified as a cause of HS^[5,7,8]. The principal treatment for PIL is a high protein, low fat diet associated with medium chain triglycerides (MCT) supplementation. Supportive therapy includes albumin infusion and paracentesis, when required. In patients not responding to such therapy, other options, such as octreotide, antiplasmin, tranexemic acid and surgical resection of segmental or localized disease may be a therapeutic option^[9,10]. Somatostatin and its synthetic analogue, octreotide, have been used to treat secretory diarrhea and other GI and pancreatic disorders^[11]. The mechanism of action of octreotide in diminishing protein loss through the GI tract is still unclear. Both somatostatin and octreotide decrease splanchnic blood flow *via* splanchnic vasoconstriction. They also decrease intestinal motility, gastric emptying, gallbladder contraction and pancreatic secretion. Octreotide inhibits GI hormone secretion and results in decreased chloride secretion, increased chloride and sodium absorption and decreased water loss. Therefore, octreotide has been used in the treatment of secretory diarrhea associated with Zollinger-Ellison syndrome, acquired immunodeficiency syndrome, graft versus host disease, carcinoid syndrome, and multiple endocrine neoplasia-2A^[11]. Octreotide inhibits triglycerides absorption^[12]. Little is known about its action on chyle production and pressure regulation in the lymphatic system. Somatostatin inhibits thoracic lymph flow in dogs^[13]. Reports of somatostatin and its analogues on reducing lymphatic fluid outflow in both pediatric and adult patients were described in surgically created thoracic duct injuries^[14,15]. The most commonly reported adverse reactions in clinical trials following octreotide administration were diarrhea, abdominal pain, nausea, flatulence, headache, cholelithiasis, hyperglycemia and constipation. Other commonly reported adverse reactions were pruritus, rash, alopecia, dizziness, localized pain, biliary sludge, thyroid dysfunction, loose stools, vomiting, asthenia, and hypoglycemia. In very rare instances, acute pancreatitis has been reported within the first hours or days of sandostatin treatment. Cardiac adverse effects include bradycardia and less commonly tachycardia^[16].

CASE REPORT

Case 1

A male baby was born at term with a normal birth weight. There were no antenatal or postnatal complications. The infant was born with generalized anasarca and was found to have low serum total protein and serum albumin. There was a history of consanguinity and a family history of a 15-year-old maternal cousin with generalized edema diagnosed to have HS and managed at a different center. The infant was referred to our hospital at the age of 1 mo for evaluation of generalized edema. He had a history of diarrhea, occasional vomiting, abdominal distension and poor feeding. He was not thriving well. There were no symptoms of heart failure. He had normal urine output. Physical examination revealed generalized pitting edema of the lower limbs and non-pitting edema of the hands. There were dysmorphic features manifested as down slanting palpebral fissure, broad nasal bridge, flat stubby nose with midface hypoplasia, long philtrum and hypoplastic low set ears. Chest and cardiovascular examinations were unremarkable. The abdomen was distended and non-tender with ascites and no hepatosplenomegaly. He had scrotal edema. Investigations revealed normal full blood count (FBC), renal function, liver enzymes and liver function. He had low serum total protein (23 g/L), low serum albumin (16 g/L), and low serum immunoglobulin levels (immunoglobulin A of 0.09 g/L, IgG of 0.9 g/L and immunoglobulin M of 0.26 g/L). Urine analysis was negative for protein and 24-h urine protein was low (0.2 g/24 h). Human serum albumin scintigraphy revealed loss of protein into the intestinal tract. An upper GI endoscopy study revealed widespread whitish patches with snowflake appearance seen in the second and third parts of the duodenum. The stomach showed slight gastric wall edema. Histological examination of a biopsy specimen from the duodenum showed marked edema in the lamina propria. There were no dilated lymphatics observed on the examined specimens. Gastric biopsy revealed congestion and edema of the lamina propria. The lack of dilated lymphatics on histological examination of the intestinal biopsies was due to the patchy distribution of lymphangiectasia in the intestinal mucosa. The child was diagnosed with PLE due to PIL. Given the family history of HS, clinical features and dysmorphism, and a biochemical diagnosis of PLE, we suspected a diagnosis of HS. We performed a genetic test for mutation in the *CCBE1* gene. He was found to have homozygous mutation c.305G>C (p.Cys102Ser) in the *CCBE1* gene which confirmed the diagnosis of HS. He was started on MCT-based formula, a low fat, high protein diet, fat soluble vitamin supplements and intravenous infusion of albumin every few days due to the occurrence of severe pericardial effusion and recurrent ascites. However, his serum albumin continued to be on the low side. Given the severity of hypoalbuminemia and his requirement for frequent albumin infusions, he was started on octreotide subcutaneous (s/c) injections,

Table 1 Cases of intestinal lymphangiectasia treated with octreotide in the literature

Number of patients	Age of patients	Etiology of PLE	Dose of octreotide	Pre octreotide serum albumin	Post octreotide serum albumin	Ref.
6	0-24 mo	PIL	15-20 µg/kg twice daily	14-25 g/L	Normal in 3/6	[2]
1	38 yr	IL	100 µg twice daily	12 g/L	Above 40 g/L	[17]
1	21 yr	PIL	150 µg twice daily	22 g/L	39 g/L	[18]
1	25 yr	IL	Slow release octreotide 20 mg every 4 wk	20 g/L	35 g/L	[19]
1	27 yr	Type I IL	200 µg twice daily then SR octreotide 30 mg every 4 wk	19 g/L	NA (graph indicates 30-40 g/L)	[20]
1	47 yr	Cirrhosis induced IL	0.1 mg three times daily	22 g/L	28 g/L	[21]
1	17 yr	PIL	200 µg twice daily	15 g/L	22-26 g/L	[24]
2	2-12 mo	HS associated IL	100 µg twice daily	16 g/L	28-36 g/L	Current report

IL: Intestinal lymphangiectasia; PLE: Protein losing enteropathy; PIL: Primary intestinal lymphangiectasia; SR: Slow release; NA: Not available; HS: Hennekam syndrome.

which gradually reached 100 mg twice daily. A few weeks later, the patient was discharged home on s/c octreotide injections. Albumin infusion requirement was reduced to once monthly 2 mo after starting octreotide therapy, and subsequently stopped. Total serum protein increased to 49 g/L and serum albumin to 28 g/L. He is now 3 years old, tolerating octreotide with no complications.

Case 2

A term male baby was born to a primi mother with a normal birth weight. There were no antenatal or post-natal complications. The infant was noted to have generalized edema from day 1 of life with low serum total protein and serum albumin. There was a history of consanguinity and 2 maternal cousins were diagnosed with HS (patient in case 1 and his older cousin). He was referred to our hospital at the age of 6 wk. There was no weight gain. There was no history of diarrhea, vomiting or jaundice. He was passing urine normally. There were no signs of heart failure or ascites. Physical examination revealed dysmorphic features in the form of hypertelorism, broad flat nasal bridge and a long hypoplastic philtrum. There was generalized edema, periorbital edema, bilateral non-pitting edema of the upper limbs and bilateral pitting edema of the lower limbs with scrotal edema. The remainder of the systemic examination was unremarkable.

Investigations revealed normal FBC, renal function, liver enzymes and liver function. He had low serum total protein (26 g/L) and low serum albumin (16 g/L). Urine analysis was negative for proteinuria. Twenty-four hour urine protein was normal. His bone profile revealed rickets with low 1, 25 hydroxyvitamin D and 25 hydroxyvitamin D. Stool alpha 1 antitrypsin was high at 2.34 g/L. Given the family history of HS, clinical features and dysmorphism, and a biochemical diagnosis of PLE, we suspected a diagnosis of HS and performed a genetic test for familial mutation in the *CCBE1* gene. He was found to have homozygous mutation c.305G>C (p.Cys102Ser) in the *CCBE1* gene using sequence analysis. This confirmed the clinical diagnosis of HS. The patient was managed conservatively with MCT-based formula, fat soluble vitamins, and rickets treatment with frequent

albumin infusions and diuretics. Following albumin infusions, his generalized edema improved. The infant was left with genital, periorbital and lower limb non-pitting edema. Serum albumin decreased to very low levels of 12-16 g/L within a few days of albumin infusions. At the age of 8 wk, we started him on octreotide subcutaneous injections of 80 mg twice daily and increased this to 100 mg twice daily at the age of four months. His serum albumin levels increased to 36 g/L a few months later with no further albumin infusions required. He is now 11 mo old with a good response to octreotide in terms of reducing hypoalbuminemia and cessation of albumin infusions with no noted complications to octreotide.

DISCUSSION

To date, no publications have supported the use of octreotide to diminish protein loss and minimize hypoalbuminemia seen in PIL. These publications are summarized in Table 1. Most clinical research on the use of octreotide in humans has been limited to adults. One of the first experiences of using octreotide in PIL was by Bac *et al*^[17] in 1995. They reported a patient with PLE due to intestinal lymphangiectasia. The patient was treated with and responded to octreotide with normalization of serum albumin and a decrease in fecal protein loss. Few subsequent case reports have supported this experience^[18-21]. The suggested dose of octreotide ranges from 100 µg two or three times a day to 200 µg two times a day or the slow release formulation which can lead to clinical, biochemical and histological improvement^[10,18,20]. The first use of somatostatin in pediatric patients was for non-GI conditions such as excessive growth hormone release, hyperinsulinism and others^[22,23]. Almost all the experience in pediatric patients with PIL is in the form of case reports^[11]. In 1998, Ballinger *et al*^[24] reported the use of octreotide in an adolescent with PIL. Enteric protein loss was decreased and serum albumin levels were stabilized with resolution of peripheral edema and cessation of re-accumulation of recurrent pleural effusions. A recent study of a series of 6 pediatric patients^[2] suggested that octreotide might be useful in controlling findings and maintaining serum albumin

at normal levels. Serum albumin level was maintained at normal levels in 3 patients. The requirement for albumin infusions decreased in all 6 patients. This study concluded that octreotide should be considered in the long-term treatment of PIL when other options are ineffective. They also suggested weighing the benefits of octreotide against the risk of adverse effects. Pediatric case reports have shown that octreotide decreases stool output in a variety of cases^[25-27]. In these case reports, there was no standardization of dose or duration of octreotide use to achieve the required effect. The specific use of octreotide in diarrhea secondary to chemotherapy^[28-30], GVHD^[31,32] and immunodeficiency^[33] has been reported in adults. Despite this, there are reports on the failure of octreotide to diminish stool output in a variety of cases^[34,35]. In one case report, octreotide failed to induce a clinical response and a study performed on an established guinea pig showed that octreotide did not alter lymphatic function^[36].

We report 2 children who were genetically diagnosed as having HS and associated PIL with PLE, who suffered from generalized mixed edema secondary to hypoalbuminemia and lymphangiectasia. By using octreotide in both patients, we eliminated the need for albumin infusions with resolution of pericardial effusion and ascites in one patient. The other younger patient's serum albumin increased dramatically to a normal level with resolution of pitting edema. In both patients, scrotal edema and non-pitting edema were still present. This is likely to be related to generalized maldevelopment of the lymphatic system seen in HS and the possibility that lymphatic function is not altered by octreotide.

In conclusion, our 2 children with genetically proven HS and PIL leading to PLE responded well to octreotide. In both patients, non-pitting edema was still present. This was attributed to lymphangiectasia and a probable reduced effect on the lymphatics in HS compared with other reports in the literature. Octreotide has been used in various GI disorders associated with PIL and PLE. To the best of our knowledge, this is the first case report on the use of octreotide to diminish PLE in HS-associated PIL. The lack of clinical data based on randomized trials in the pediatric population makes it difficult to confirm a positive effect of octreotide on PIL and PLE from the literature. There is a need for multicenter pediatric trials in this regard.

Abstract

Colonic intussusception and gastrointestinal duplication are diseases that arise in young children. The clinical presentation of adult cases of intussusception and enteric duplication is non-specific and thus poses a diagnostic challenge. A computed tomography (CT) scan is recommended in adult cases as the most sensitive diagnostic tool and the pathognomonic finding of outer intussuscepti and central intussusceptum is diagnostic. A septum of a duplicated colon in a non-intussuscepted segment has been rarely reported in the literature. With advancements in radiological imaging technology and the increased availability of CT scanners, the capacity for a correct pre-operative diagnosis has been significantly enhanced. Our current case report illustrates the importance of considering an uncommon etiology for enteric intussusception and duplication as a differential diagnosis of acute abdomen in an adult patient. Our analyses of this patient also highlight the successful use of CT scanning to make this diagnosis.

INTRODUCTION

Colonic intussusception and gastrointestinal duplication are diseases of young children. Symptomatic colonic duplication is very rare in adults. We report a case of a young adult patient with a duplication of the terminal ileum, appendix, colon and rectum who presented in our hospital with symptoms of acute intestinal obstruction and intussusception.

CASE REPORT

A 25-year-old man was admitted to our hospital for central abdominal pain for three days. He had a history of situs inversus and a watery bowel opening with blood streaks was noted on the day of admission. A physical examination revealed a distended abdomen, and tenderness and rebound over the lower abdomen.

Abdominal radiographs further revealed some dilated bowel loops at the right abdomen, which was a relatively non-specific finding (Figure 1). Fresh blood was found in the rectum during a sigmoidoscopic examination. Advancement beyond 30 cm could not be achieved during this examination due to an acute kink. A computed tomography (CT) scan was then performed for further assessment and an intestinal obstruction was confirmed. Intussusception at the region of the sigmoid and descending colon was detected at the right lower abdomen (since the patient had situs inversus) (Figure 2A). The duplicate appearance of the large bowel at the right lower quadrant of abdomen was also noted (Figure 2B).

Emergency surgery was performed and revealed a

Figure 1 Abdominal radiographs taken as an initial evaluation of the abdominal pain in the patient. A: Supine radiograph showing non-specific dilated bowel loops at the right abdomen; B: Erect radiograph revealing a right-sided stomach bubble in this patient with situs inversus.

Figure 3 Gastrografin enema. A: Enema performed via an enterostomy showing a duplicated terminal ileum; B: Enema performed via the anus showing a duplicated rectum.

grossly dilated sigmoid and descending colon. Intussusception into the distal sigmoid colon with a large gangrenous diverticulum formed by the septum of a duplicated colon was also observed. A partial small bowel resection, decompression and a colostomy were subsequently performed.

A post-operative gastrografin enema *via* the enterostomy and anus further confirmed a duplication of large bowel and terminal ileum in this patient (Figure 3).

DISCUSSION

Colonic intussusception and gastrointestinal duplication are diseases of young children that usually manifest before two years of age (male:female ratio, 3:1)^[1]. Intestinal intussusception in adults is very rare however. In a previously reported surgical series of 20 adults with intussusception, no single diagnosis of gastrointestinal duplication was identified as the underlying pathology^[2]. Colonic duplication represents 4%-18% of gastrointestinal duplication cases^[3]. Duplications are classified according to location or shape; cystic (more than 80%) or tubular^[4]. The classification of this disorder in accordance with the vascular pattern had also been proposed^[5].

The clinical presentation of an adult case with intussusception and enteric duplication is typically non-

Figure 2 Axial computed tomographic scans of the lower abdomen. A: Intussusception in the region of the sigmoid and descending colon at right lower quadrant of the abdomen (arrow); B: Scan at a more cranial level revealing a distended descending colon with a thin enhancing rim of a septum (arrow).

specific, i.e., abdominal pain, nausea and constipation. The mode of presentation can also be acute, subacute or chronic^[1].

CT scans are recommended as the most sensitive diagnostic tool in adult cases of intestinal intussusception^[1]. The pathognomonic finding of outer intussusceptans and central intussusceptum confirms the diagnosis of these cases. The complex mass is "sausage-shaped" or "target" like when the CT beam is oriented parallel or perpendicular to its axis, respectively^[6]. It can in rare cases present as a cystic mass at the left upper abdomen, thus causing diagnostic confusion as a pancreatic tumor^[7]. The diagnosis of enteric duplication in the absence of intussusception or intestinal obstruction is challenging and it is often difficult to do before surgery^[1,3]. CT scanning can reveal a cystic mass attached to the colon^[3]. The demonstration of a septum of a duplicated colon in a non-intussuscepted segment is a rarity in the current literature.

In summary, our present case illustrates the importance of considering an uncommon etiology involving enteric intussusception and duplication as a potential differential diagnosis for acute abdominal pain in an adult patient. Furthermore, our present findings demonstrate the applicability of a CT scan in making such a challenging diagnosis.

Abstract

An isolated parenchymal gastric metastasis from ovarian carcinoma without any other sites of recurrence is extremely rare. Only two cases have been reported, both of which were symptomatic. We herein report such a case without any symptoms. A 61-year-old woman presented with a high cancer antigen-125 level without any other clinical manifestation. A subsequent ¹⁸F-fluorodeoxyglucose (¹⁸F-FDG) positron emission tomography/computed tomography scan revealed a submucosal mass with hypermetabolism of ¹⁸F-FDG (standardized uptake value: 5.36) in the gastric antrum. The final pathology after gastric antrectomy showed a metastatic gastric tumor from a primary ovarian carcinoma. We also performed an extensive literature review about gastric metastasis from ovarian carcinoma published until recently, and this is the first case of an isolated parenchymal gastric metastasis from ovarian carcinoma without any symptoms.

INTRODUCTION

Ovarian carcinoma usually metastasizes along the peritoneum throughout the pelvic and abdominal cavity, such as pelvic wall, omentum and mesentery. Gastrointestinal involvement is not common. Even it happens, gastrointestinal tract metastasis of ovarian carcinoma is merely limited to serosa. Solitary parenchymal gastric metastasis from ovarian carcinoma is extremely rare, and only two cases have been reported in English up till now^[1,2]. We herein present a case of gastric metastasis from ovarian carcinoma without any symptoms and other sites of recurrence.

CASE REPORT

In December 2011, a 61-year-old woman was admitted to our hospital because of a high cancer antigen (CA)-125 level of up to 116.5 U/mL (normal, < 35U/mL), and she had no epigastric pain and fullness, hematemesis, melena, weight loss and any other clinical manifestations. In 1999, she underwent optimal debulking cytoreductive surgery in our hospital for ovarian adenocarcinoma, followed by ten cycles of adjuvant chemotherapy with cisplatin and cyclophosphamide. In May 2006, when her CA-125 level increased to 57.9 U/mL, she received

Figure 1 ^{18}F -fluorodeoxyglucose positron emission tomography/computed tomography shows a hypermetabolic lesion (standardized uptake value: 5.36) in the gastric antrum (arrows).

another ten cycles of adjuvant chemotherapy with taxol, cyclophosphamide, carboplatin and bleomycin. CA-125 level was tested every two months and it exceeded the normal range again in December 2011.

^{18}F -fluorodeoxyglucose positron emission tomography/computed tomography (^{18}F -FDG PET/CT) scanning for ruling out the recurrent ovarian carcinoma that was suspected due to the CA-125 level. ^{18}F -FDG PET/CT revealed a mass located in gastric antrum with high ^{18}F -FDG uptake (standardized uptake value: 5.36) (Figure 1), and there were no any other lesions with high ^{18}F -FDG uptake in the abdominopelvic region. A subsequent non-contrast-enhanced CT displayed a 2.4 cm \times 3.0 cm submucosal mass in the gastric antrum (Figure 2), which had not been found in the CT scanning done on April 4, 2010. The patient could not tolerate and refuse to take endoscopic examination, so we performed gastroenterography instead. Upper gastroenterography also showed clearly a lesion with a tiny ulceration on the surface of gastric mucosa (Figure 3).

The patient then underwent local gastrectomy. During the operation, we found that both mucosa and serosa were involved, but there was no intumescent lymph node around the gastric antrum. The incision of gastric antrum was fixed with a double-layer hand-sewn suture transversely.

On cut section, a gray-white tumor of 3.2 cm \times 2.8 cm \times 3.5 cm was situated in the muscularis propria and bulged into the serosa. Microscopically (Figure 4A), serous papillary adenocarcinoma cells infiltrated into normal gastric tissues with cancer embolus in the vessels. There was a deep ulceration on the overlying mucosa. A non-metastatic lymph node was found in the specimen. Values of the immunohistochemical detection of the tumor cells (Figure 4B) were: CA-125 (+++), Wilms' tumor-1 (+++), estrogen receptor (++), cytokeratin 7(+), cytokeratin 20(-), progesterone receptor (-) and CDX-2 (-). The immunohistochemical staining result supported the final diagnosis of gastric metastasis from ovarian serous adenocarcinoma.

CA-125 level was decreased to 53.1 U/mL on the

Figure 2 An abdominal computed tomography shows a low density, 2.4 cm \times 3.0 cm intramural mass of gastric antrum with tiny ulceration (arrows), which is suggestive of a gastric submucosal tumor, such as gastrointestinal stromal tumor. A: Cross section; B: Coronal section.

7th postoperative day. Her postoperative course was unremarkable and she was discharged on the 9th day after operation. When this manuscript was submitted, she had no experience of recurrent disease.

DISCUSSION

Metastatic disease involving stomach is unusual. A study found 17 metastases to the stomach among 1010 patients with malignant tumors, giving a frequency of 1.7%^[3]. Another series of autopsies discovered 92 gastric metastases among 7165 cases, with a rate of 1.28%^[4]. Most gastric metastases arise from primary breast cancer, followed by melanoma and lung cancer. The incidence of gastric metastases was 3.6% (25/694) in patients with breast cancer and 1.3% (10/747) in patients with lung cancer. No study had analyzed the incidence of gastric metastasis from ovarian carcinoma due to the extremely rare occurrence. According to our review of the literature, there has been no report of gastric metastases from ovarian carcinoma in Chinese.

We performed a very comprehensive review of all case reports of gastric metastasis from ovarian carcinoma. Until this April, ten other reports (Table 1) in English could be searched in PubMed. Patient age ranged from 42 years to 70 years. Two cases^[10,12] were diagnosed with primary ovarian carcinoma simultaneously, the longest time from diagnosis of primary tumor to discovery

Figure 3 Upper gastroenterography shows a lesion in the gastric antrum (arrows). The antrum was partially obstructed by the mass.

of gastric metastasis being 18 years^[2]. Clinical manifestations were diversified and nonspecific, and three cases were asymptomatic (3/11, 27.27%).

Due to the extremely low incidence, it is hard to make a correct diagnosis of gastric metastasis from ovarian carcinoma. According to our literature review, some cases^[2,9] only presented with CA-125 levels beyond normal range but without any symptoms. Since CT scanning, gastroenterography and gastroscopy all showed a submucosal tumor of stomach, a wrong diagnosis of gastrointestinal stromal tumor^[12] would be easily made^[12]. So, when a patient has a history of ovarian carcinoma, especially when her CA-125 level is high, metastasis from ovarian carcinoma should be considered. ¹⁸F-FDG PET/CT can be useful. In our case, ¹⁸F-FDG PET/CT scanning revealed a high metabolic uptake lesion of gastric antrum, which is similar to the findings as described by other authors^[2,12].

Ovarian carcinoma is more likely to metastasize along the peritoneal surface, but the mechanism of gastric metastasis remains unclear, it may be because of the rich

Figure 4 Pathological manifestation of the neoplasm. A: Microscopically, the tumor is composed of irregular sheets of cells with a high-grade nuclear atypia (HE stain, × 100); B: Immunohistochemically, the tumor cells are immunoreactive for cancer antigen 125 (× 100).

blood supply of stomach. Local excision without radical lymphadenectomy following adjuvant chemotherapy is effective and recommended for metastases of ovarian carcinoma. The prognosis of gastric metastases of ovarian carcinoma remains unknown, according to our literature review, a one-year survival rate can be expected optimistically (5/6, 83.33%).

Abstract

The expression of phosphatase and tensin homolog (*PTEN*), a tumor suppressor gene, is frequently down-regulated in gastric carcinomas due to mutation, loss of heterozygosity, and promoter hypermethylation. However, it is unknown if additional mechanisms may account for the down-regulation of *PTEN* expression. While neuronal precursor cell-expressed developmentally down-regulated 4-1 (NEDD4-1) is believed to be a potential dual regulator of *PTEN*, there are conflicting reports regarding their interaction. To gain further insight into the role of NEDD4-1 and its association with *PTEN* in gastric carcinoma development, we measured the protein expression of NEDD4-1 and *PTEN* in gastric mucosae with various pathological lesions and found that NEDD4-1 increased from normal gastric mucosa to intestinal metaplasia and decreased from dysplasia to gastric carcinoma. These changes did not correlate with *PTEN* expression changes during gastric carcinogenesis. Moreover, we found similar results in protein levels in the primary tumors and adjacent non-tumor-

TO THE EDITOR

One of the aims of cancer research is to identify mechanisms controlling the loss of tumor suppressors that promote cancer development. Expression of phosphatase and tensin homolog (*PTEN*), a tumor suppressor gene^[1-3], is frequently down-regulated in gastric carcinomas (GC) due to mutation, loss of heterozygosity, and promoter hypermethylation^[4-8]. In an effort to determine if neuronal precursor cell-expressed developmentally down-regulated 4-1 (NEDD4-1), a potential dual regulator of *PTEN*^[9,10], plays a role in the development of gastric carcinoma, Kim *et al*^[11] investigated NEDD4-1 protein expression in 60 specimens of gastric carcinoma tissues using immunohistochemistry. They found that 75% of GC were immunopositive for NEDD4-1, whereas the normal gastric mucosal cells displayed a weak or

NEDD4-1: Neuronal precursor cell-expressed developmentally down-regulated 4-1; PTEN: Phosphatase and tensin homolog.

no immunoreactivity. NEDD4-1, an E3 ubiquitin-protein ligase, is believed to play two opposite roles in regulation of PTEN^[9,10]. On one hand, it exercises an oncogenic function by catalyzing PTEN polyubiquitination, resulting in degradation of PTEN protein^[9]. On the other hand, it exerts a tumor suppressive function by catalyzing PTEN monoubiquitination and regulating PTEN nuclear transport^[10]. Together, these data suggest that NEDD4-1 may play a role in gastric carcinoma development and that it may function as a negative regulator of PTEN.

To gain further insight into the role of NEDD4-1, and more importantly, its association with PTEN in gastric carcinoma development, we measured expression of NEDD4-1 and PTEN by immunohistochemistry in biopsies or surgical specimens of 181 patients with various developmental stages of gastric carcinoma collected from January 2007 to September 2009 at the First Affiliated Hospital of Nanchang University. The specimens included 21 cases of normal gastric mucosa (NGM), 21 cases of chronic gastritis (CG), 41 cases of intestinal metaplasia (IM), 48 cases of dysplasia (Dys), and 50 cases of GC (Table 1). There were no significant differences in the age or gender distributions among these groups. These tissue specimens were sectioned and immunostained using the PV-9000 Polymer Detection System (Zhongshan Goldenbridge, Beijing, China), then reviewed and scored semi-quantitatively, as described previously^[12]. An additional 15 pairs of primary tumors and adjacent non-tumorous tissues were subjected to total cellular protein isolation and Western blot analysis of NEDD4-1 and PTEN expression. This work was approved by the Ethics Committee of the First Affiliated Hospital of Nanchang University. Primary antibodies used in this study were: rabbit polyclonal anti-human NEDD4-1 (Millipore, Billerica, MA, United States), PTEN (Abcam, Cambridge, United Kingdom), and β -actin (Santa Cruz Biotechnology, Santa Cruz, CA, United States).

The expression of NEDD4-1 was found to increase from NGM to IM, but to decrease from Dys to GC ($P < 0.05$). NEDD4-1 expression level was significantly decreased in GC compared with IM or Dys (Figure 1

and Table 1, $P < 0.05$). There were no significant differences in NEDD4-1 expression between GC and NGM or CG (Figure 1 and Table 1). The expression of PTEN was found to increase from NGM to CG, but to decrease from IM to GC ($P < 0.05$). The PTEN expression level was significantly decreased in GC compared with NGM, CG, IM and Dys (Figure 1 and Table 1, $P < 0.05$). Analysis of the data from cases of GC did not show an obvious association between NEDD4-1 or PTEN expression levels and clinicopathological grades. In addition, we did not find any correlations between NEDD4-1 expression and PTEN expression in different stages. In primary GC, 13 (86.7%) of 15 cases showed a reduction in PTEN expression in tumor tissues compared with the corresponding non-tumorous mucosa. The mean level of PTEN expression was significantly lower in tumor samples than in the non-cancerous counterparts (Figure 2, $P < 0.05$). However, there was no significant difference in the expression of NEDD4-1 between tumor samples and the non-cancerous counterparts (Figure 2, $P < 0.05$).

Since Kim *et al.*^[11] showed an increased expression of NEDD4-1 in GC, we expected to detect increased NEDD4-1 expression in GC. However, we found that NEDD4-1 was increased in the early stages of gastric carcinogenesis, but was then decreased in GC. In addition, we did not find increased NEDD4-1 expression in tumor tissues compared with the corresponding non-tumorous mucosa. More importantly, there was no correlation between NEDD4-1 expression and PTEN expression.

There are several factors that may explain the inconsistencies between the results from our study and those from others. First, although NEDD4-1 is believed to be a potential dual regulator of PTEN, there are discrepancies regarding the nature of the relationship between NEDD4-1 and PTEN. Fouladkou *et al.* reported that NEDD4-1 is not the E3 ligase regulating PTEN stability and subcellular localization^[9,10,13]. We did not see any correlation between NEDD4-1 and PTEN expressions, suggesting that NEDD4-1 may not be a regulator of PTEN in gastric carcinogenesis. Second, there was dif-

Figure 1 Immunohistochemical staining of neuronal precursor cell-expressed developmentally down-regulated 4-1 and phosphatase and tensin homolog protein in different histological samples of gastric tissues. Figure 2 Relative neuronal precursor cell-expressed developmentally down-regulated 4-1 and phosphatase and tensin homolog protein expression level in gastric carcinoma compared to adjacent non-tumorous mucosa. Immunoblots of neuronal precursor cell-expressed developmentally down-regulated 4-1 (NEDD4-1), phosphatase and tensin homolog (PTEN) were scanned and the relative protein expression level of tumor samples vs their non-cancerous counterparts is expressed as % of β -actin. ^a $P < 0.05$.

ference in the genetic background of the cohort from our study and a previous study. In our study, patients were from southern China, whereas in the study by Kim *et al*^[11], patients were from South Korea. In addition, the scoring systems of the two studies were different. In conclusion, we show in the present study that NEDD4-1 and PTEN are distinctly expressed in the various stages of gastric carcinogenesis. In addition, PTEN expression was significantly lower in primary tumors than in adjacent non-tumorous tissues, while there was no difference in NEDD4-1 expression between primary tumors and adjacent non-tumorous tissues. Therefore, NEDD4-1 may not be a regulator of PTEN in gastric carcinogenesis. To elucidate the roles of NEDD4-1 in gastric carcinogenesis, especially the role in regulation of PTEN function, further studies with larger samples in the various stages of gastric carcinoma are needed.

ACKNOWLEDGMENTS

We want to thank Professor Zhou XD from the First Affiliated Hospital of Nanchang University for providing the specimens of the primary tumors and adjacent non-tumorous tissues.

ACKNOWLEDGMENTS

Acknowledgments to reviewers of World Journal of Gastroenterology

We acknowledge our sincere thanks to our reviewers. Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of our World Series Journals. Both the editors of the journals and authors of the manuscripts submitted to the journals are grateful to the following reviewers for reviewing the articles (either published or rejected) over the past period of time.

INSTRUCTIONS TO AUTHORS

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the “priority” and “copy-right” of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers’ names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

Baishideng Publishing Group Co., Limited

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homoge-

neous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/esps/>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval

of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision on acceptance is made only when at least two experts recommend publication of an article. All peer-reviewers are acknowledged on Express Submission and Peer-review System website.

Abstract

There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of "To investigate/study/..."), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$), and CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:....; B:....; C:....; D:....; E:....; F:....; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P* < 0.05, ^b*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, ^c*P* < 0.05 and ^d*P* < 0.01 are used. A third series of *P* values can be expressed as ^e*P* < 0.05 and ^f*P* < 0.01. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals ac-

cording to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Please provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *ν* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindII*, *BamHI*, *Kho I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Authors must revise their manuscript carefully according to the revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade B certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to esps@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For papers supported by a foundation, authors should provide a copy of the approval document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted original articles are suggested to write science news to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for science news should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Oncological treatment is currently directed toward a tailored therapy concept. Squamous cell carcinoma of the anal canal could be considered a suitable platform to test new therapeutic strategies to minimize treatment morbidity. Standard of care for patients with anal canal cancer consists of a combination of radiotherapy and chemotherapy. This treatment has led to a high rate of local control and a 60% cure rate with preservation of the anal sphincter, thus replacing surgical abdominoperineal resection. Lymph node metastases represent a critical independent prognostic factor for local recurrence and survival. Mesorectal and iliac lymph nodes are usually included in the radiation field, whereas the inclusion of inguinal regions still remains controversial because of the subsequent adverse side effects. Sentinel lymph node biopsies could clearly identify inguinal node-positive patients eligible for therapeutic groin irradiation. A sentinel lymph node navigation procedure is reported here to be a feasible and effective method for establishing the true inguinal node status in patients suffering from anal canal cancer. Based on the results of sentinel node biopsies, a selective approach could be proposed where node-positive patients could be selected for inguinal node irradiation while node-negative patients could take advantage of inguinal sparing irra-

diation, thus avoiding toxic side effects.

INTRODUCTION

In the past two decades, tangible efforts have been made to understand the natural course and behavior of anal canal carcinoma, and, especially, to improve the efficacy of multimodality chemo-radiation treatment. Currently, the main issues in the treatment of this neoplasm are the recognition of a reliable staging system and strategies to obtain long-term survival while reducing radiation related side effects.

Anal canal squamous cell carcinoma represents 1% to 2% of all gastrointestinal malignancies^[1-3] and is associated with human papilloma virus infection^[4]. Diagnostic procedures include clinical and rectal examination, endorectal ultrasound, magnetic resonance imaging (MRI), computed tomography (CT) scan, and positron emission tomography (PET) scan^[1]. Clinical and pathological classification is based on tumor-node-metastasis

staging developed by the American Joint Committee on Cancer^[5].

The two most significant prognostic factors are tumor size and nodal status^[6,7]. Inguinal lymph node involvement is considered a major independent prognostic factor for local recurrence and overall survival^[2] with survival rates dropping from 70% in node-negative to 40% in node-positive patients. Synchronous inguinal metastases are strictly related to the tumor size and occur in 10% to 25% of patients^[8,9]. Metachronous metastases are found, usually during follow-up, in 5% to 25% of patients who were groin lymph node-negative at the time of diagnosis^[9].

Identification of the anal canal lymphatic drainage pattern is essential to predict secondary nodal involvement. Lymphatic drainage of anal canal cancer mostly depends on the tumor location. Based on anatomic and physiopathological studies, tumors located under the dentate line are more likely to drain to groin chains while tumors located above the dentate line are prone to drain to the internal iliac lymph node system, although the two drain systems are not separated from each other (Figure 1)^[10-12]. A tumor located laterally in the anal canal is more likely to drain to the homolateral side. Moreover, tumors located in the midline have the tendency to drain bilaterally in the inguinal regions^[12].

Figure 1 Anal canal lymphatic drainage pattern.

Figure 2 Radiation field of anal carcinoma with exclusion (green field) or inclusion of inguinal regions. A: Lateral view; B: Anterior view.

TREATMENT OPTIONS AND PROGNOSIS

Local excision with neoplasm-free margins is recommended for T1 well-differentiated tumors^[13]. Abdominoperineal resection and permanent colostomy has been traditionally performed for anal canal cancer achieving 40% to 70% survival rate at five years^[2,14]. Chemo-radiation treatment has replaced surgical resection since Nigro *et al*^[15] introduced his protocol in 1974 and has raised survival and eradication of tumors from 70% to 90% in selected patients^[16-19]. Predictably, prognosis is worsened by 50% with nodal involvement and tumor size larger than 5 cm^[2]. Local recurrence shown by pathology or incomplete pathological response after multimodality chemo-radiotherapy treatment is an indication of subsequent abdominoperineal resection^[13,20,21]. However, dose-related radiation side effects, such as anal ulcers, stenosis, and necrosis, can necessitate a subsequent colostomy in 6% to 12% of patients^[18,22-25]. Irradiation fields involving the groin lymph nodes chain can cause inguinal fibrosis, external genitalia edema, epidermolysis with superinfection of skin, necrosis of the femoral head, femoral head fracture, and stenosis of iliac artery^[18,22,24,26-30]. Death from radiation toxicity is reported in 2.0% to 2.7% of patients^[9]. Moreover, risk of radiation side effects do not decrease over time and might pose a lifelong risk of developing late complications^[24,29]. For these reasons, strategies to reduce the radiation field are advisable.

Metastatic involvement of inguinal nodes is a crucial point in the correct assessment of these patients.

In fact, involvement of mesorectal nodes does not affect the therapeutic approach because they are generally included in the radiation fields, while routine inclusion of groin lymph node stations remains controversial. Inguinal lymph node involvement is difficult to establish. The diagnostic accuracy of clinical evaluation and imaging tools remains low. In the case of clinically palpable nodes, a biopsy could be performed. However, as in the majority of cases, a clinically negative groin does not imply absence of metastatic disease. A “wait and see” position is recommended by some institutions^[31], while prophylactic groin irradiation is ordinarily practiced by other groups^[32]. Less frequently, the decision to irradiate the inguinal region is based on primary anal tumor size^[33].

(Figure 2).

Prophylactic groin irradiation has been proposed by several authors with a reduction of inguinal metastatic recurrence as low as 2.5% to 3%^[22,34-40]. Otherwise, Papillon *et al*^[41] and Gerard *et al*^[9] examined a large series of clinically node-negative patients after groin sparing irradiation and observed inguinal metachronous recurrence in 7.4% and 7.8% of patients, respectively.

Given this premise, it is clear that the majority of patients are over treated because effective nodal staging is not achieved. On the other hand, early T stage neoplasms with underrated nodal status may not receive the proper treatment by inguinal sparing.

RATIONALE AND IMPLICATIONS OF SENTINEL LYMPH NODE MAPPING

Because the standard treatment does not provide any specimens for pathological evaluation, the effective node status of these patients is not determined. Moreover, the wide lymphatic drainage pattern that characterizes the inguinal and the pelvic lymph node basin makes it difficult to predict synchronous and metachronous metastatic involvement^[42]. Furthermore, it has been observed that the size of the nodes is not a predictable parameter for nodal involvement because 44% of positive inguinal lymph nodes at pathological examination are smaller than 5 mm^[27]. Conversely, 50% of larger nodes appear to be inflammatory^[14]. Of note, in our previous case series, smaller lymph nodes (4-7 mm) were more likely to harbor metastases than larger ones^[43].

For these reasons, even more advanced imaging techniques, such as MRI, are not accurate in the detection of metastatic lymph nodes^[44]. PET has been used as an aid to achieve better staging and it has been demonstrated to detect up to 20% of metastases not diagnosed by clinical or radiological examination^[44]. Bannas *et al*^[45] has demonstrated that PET/CT is superior to PET or CT alone for staging anal cancer, particularly in identifying local regional lymph node metastases. Recently, Mistrangelo *et al*^[46] demonstrated that sentinel lymph node biopsy (SLNB) was superior to PET-CT for the staging of inguinal lymph nodes. In our experience, PET has a sensitivity of 33% and a specificity of 84%. Even though sensitivity of SLNB of the anal canal has not been yet addressed, the sensitivity of sentinel node biopsy detection in melanoma is reported to be up to 99%^[47-49].

These findings advocate the need to find a more reliable technique to identify positive nodes. Currently, histological evaluation is the gold standard to assess the presence of metastases in lymph nodes. Standard surgical node dissection for suspicious inguinal nodes has been proposed^[50,51]. However, this approach is also fraught with side effects^[52,53]. In addition, elective inguinal dissection for clinically suspicious nodal involvement revealed metastasis only in 50% of cases at histology^[14].

In this scenario, SLNB could help to accurately iden-

tify patients with inguinal metastatic spread and to avoid irradiation morbidity in node-negative subjects or, conversely, to enroll node-positive patients for inguinal irradiation. SLNB should not be performed in patients with clear evidence of clinically positive or suspicious inguinal nodes. Some reports have also suggested the exclusion of patients with locally advanced T4 cancer. Metastatic or even reactive nodes may alter the lymphatic drainage pattern, thus making the SLNB unreliable. For the same reason, patients who underwent prior surgical manipulation in the anal region should be excluded from the procedure^[12,54,55].

PATIENT SELECTION AND FEATURES

Patients with histologically confirmed squamous cell carcinoma of the anal canal were eligible for the SLNB procedure. Previous reports have also included tumors of the anal margin, which should be considered separately due to different clinical behavior. For the reasons explained above, patients with clear or suspicious inguinal nodes were generally not enrolled^[54].

From 2007 to 2012, 23 patients with proven squamous cell carcinoma of the anal canal and clinically negative inguinal nodes were enrolled in the prospective study. Pre-operative work-up included endoscopy and biopsy, pelvic RMI, endoanal ultrasound, and abdominal and lung CT scans. Tumor stage was classified as follows: T1, 3 pts; T2, 9 pts; T3, 7 pts; and T4, 4 pts.

In 2009, an inguinal sparing irradiation protocol was started. Fifteen patients were observed and three patients were excluded from the SLNB study for positive inguinal lymph nodes confirmed by cytology. Twelve patients with clinically negative inguinal regions were enrolled. After the SLNB procedure, patients with histologically positive inguinal nodes were treated with combined chemotherapy using 5-fluorouracil/mitomycin-C, and the standard radiotherapy field, including inguinal basins. Patients with tumor-free nodes did not undergo inguinal irradiation. Patients were then regularly followed-up every three months.

DESCRIPTION OF TECHNIQUES

Many authors have reported a standardized technique to isolate and retrieve sentinel lymph nodes for metastatic assessment^[12,28,54-64]. The first procedural step was a lymphoscintigraphy to evaluate the main lymphatic drainage and the first node in which the tracer is captured. The radiotracer (0.2 mL 99mTc nanocolloid) injection was performed submucosally, directly around the anal lesion in the four cardinal points with the aid of an anoscope. As the injection can be painful, a needle-free injection system^[56] could also be utilized to minimize patient discomfort. After injection, planar anterior and posterior images were taken with a Philips gamma camera, as previously described^[43], to localize the sentinel lymph

Figure 3 Lymphoscintigraphy of a sentinel lymph node in anal carcinoma. Anterior view showing injection site (blue arrow) and sentinel lymph node (red arrow).

node. Typical drainage patterns displayed radiotracer accumulation in the inguinal area or in the iliac internal lymph node system (Figure 3). If the accumulation was observed in the perirectal or external iliac lymph nodes, then patients did not undergo the sentinel lymph node procedure. Only patients showing radio accumulation in the inguinal area were enrolled for sentinel node surgical retrieval, and the overlying skin was marked by a waterproof pen. Marking the skin assisted in the intraoperative identification of the nodes and minimized surgical incision.

There was no consensus about the time gap between injection, lymphoscintigraphy acquisition, and surgery. Clearance of radioactive colloids by lymphatic drainage is related to the particle size; small particles are cleared first and large particles later^[65]. Moreover, tracers with small particle size are washed out from true sentinel nodes and move to other nodes^[66]. Therefore, a shorter period between injection and surgery is recommended with smaller particles. In our experience, 99mTc-nanocolloid with particles between 80 and 150 nm were employed. By virtue of their delayed wash-out, surgery could be performed even the day after injection. A delay of 12 to 16 h between injection and surgery allowed good intraoperative radio-localization with minimal interference by primary tumor radioactivity.

During surgery a second vital tracer, blue patent, was injected around the site of the anal tumor. In other reports, nearly all groups have used blue dye as a second vital tracer. The addition of intraoperative dye aids in the intraoperative search^[67] and tends to result in higher rates of lymph node detection. There are no data regarding the usefulness of dye with SLNB in anal cancer; however, the importance of dual mapping to reduce false negative results has recently been demonstrated in breast cancer^[68]. When accumulation was shown at lymphoscintigraphy on both groin regions, inguinal dissection was made bilaterally.

Local anesthesia was routinely employed in our institute, although the procedure can be performed under

general or local regional anesthesia. During surgery, a hand-held gamma detection probe was used to identify the radioactive lymph node (NEOPROBE Neo2000 Gamma Detection System). A small incision was made under radio probe guidance and over the marked skin. The sentinel lymph node was retrieved by visualization through the blue dye and radio detection by the hand-held gamma probe. During radio-navigation the gamma probe was directed away from the anus to avoid signal detection from the primary site of injection^[28]. Significant radio-colloid capture, compared to lymphatic basin, should be in a ratio of 5:1. After nodal excision, the surgical site was explored by the gamma probe to identify accessory nodes.

The isolated lymph node was sent for pathological examination and metastatic assessment. Hematoxylin and eosin (HE) staining was used to assess the presence of malignancy. Other reports have suggested using immunohistochemistry with pan-cytokeratin antibody markers for cases of negative HE^[28,54,56]. In our study, the specimen was examined using a particularly accurate technique. Briefly, sentinel lymph nodes were step-sectioned into 50-micron slices and serial sections of three microns thick were cut at each level. This number of sections provided good accuracy without having to resort to the more costly immunohistochemical analysis. Among the other related reports, only Gretschel *et al*^[54] have found micro-metastases or isolated tumor cells in lymph nodes examined after a negative HE.

Common complications related to lymph node mapping include wound infection, hematoma, and lymphorrhea from lymphatic fistula with subsequent seroma in the surgical site. Post-procedural side effects are easily managed and rarely require reintervention.

RESULTS OF SENTINEL LYMPH NODE ASSESSMENT

Since the first report published by Keshtgar *et al*^[56] in 2000, several reports have demonstrated the feasibility and effectiveness of the SLNB procedure in anal cancer^[43,54,57-63,69,70]. The technical aspects and results of the published studies are shown in Table 1. In these studies, patients with T1-T4 anal tumors with clinical or imaging negative inguinal nodes were enrolled. Lymphoscintigraphy accuracy was generally high, rating 90% to 100% in examined reports, and inguinal capture, as explained above, depended on the localization of the primary tumor. Surgical gamma probe detection was nearly 100%^[43,54,57-63,65,69,70]. Almost all groups suggested the double tracer technique to better visualize the sentinel lymph node intraoperatively. Metastatic node rate, among the sentinel nodes, varied between 0% and 33%; however, the case series were very heterogeneous and included advanced tumors (T stage ranging from T1 to T4) even though the majority of patients were clinically node-negative.

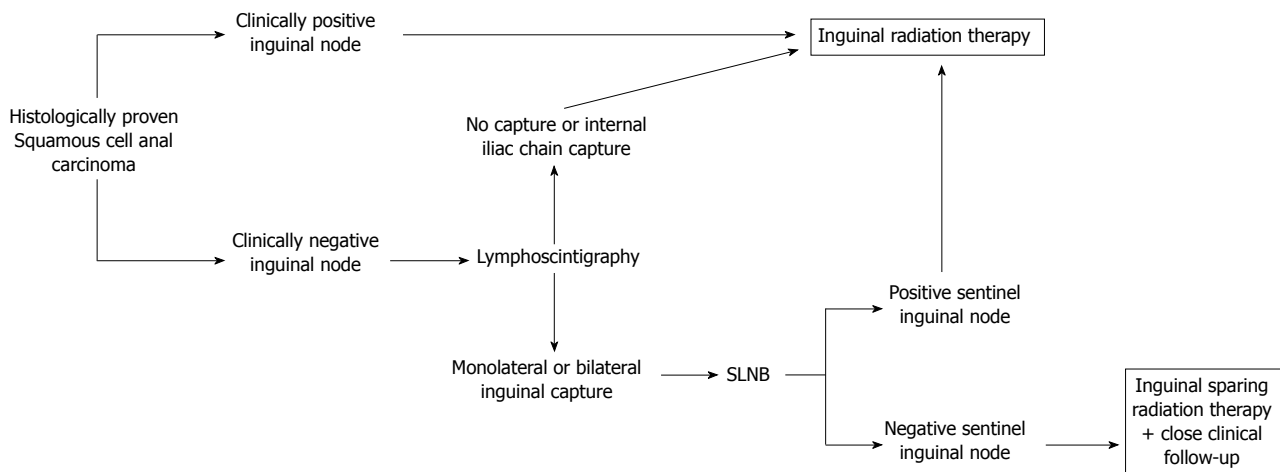

Figure 4 Diagnostic-therapeutic algorithm for squamous cell anal carcinoma. SLNB: Sentinel lymph node biopsy.

Among 23 patients, 19 with inguinal capture at lymphoscintigraphy underwent the SLNB procedure. Inguinal dissection was made bilaterally in two patients where accumulation was shown at lymphoscintigraphy on both groin regions. Sentinel lymph node retrieval by gamma probe was possible in all patients. Histological examination of nodes showed the presence of metastases in five patients (26%).

Among the 12 patients enrolled in the inguinal sparing radiation protocol with a clinically negative inguinal region, 10 patients had negative pathological SLN and received an inguinal sparing irradiation. At a median follow-up of 20 mo, none of these patients had developed inguinal metastases.

Gretschel *et al*^[54] reported that inguinal lymph node assessment was able to change the treatment plan recommended by national guidelines in 50% of patients. In the group of patients with inguinal sparing irradiation, inguinal recurrence was found in two out of 20 patients: one patient suffering from a T4 tumor, associated with

disseminated disease, and one patient with T1 tumor that was previously treated by local excision. Mistrangelo *et al*^[28] did not observe isolated inguinal recurrence in 28 node-negative patients at a median follow-up of 22 mo.

De Jong *et al*^[70] reported that SNLB provided alteration of treatment in at least 11 of 21 patients. However, inguinal recurrence within 12 to 24 mo was observed in two out of 14 node-negative patients undergoing node-sparing irradiation. Figure 4 demonstrates a simple diagnostic-therapeutic algorithm to identify patients eligible for the SLNB procedure to individualize irradiation treatment based on inguinal node status.

CONCLUSION

In spite of the low incidence of anal canal carcinoma, noticeable advances have been achieved in the past 30 years in understanding its etiology, biological behavior and therapy, with the current therapeutic approach be-

ing primary radio-chemotherapy. The identification of lymph nodes metastases, especially in the inguinal area, is still the main issue that needs to be addressed.

The low incidence of metachronous metastases and the considerable side effects after inguinal node dissection and radiotherapy do not justify a prophylactic treatment^[71]. A refined staging system with precise identification of disease extent could allow individualized therapy, ensuring the accurate coverage of disease while sparing disease-free organs.

In this context, SLNB, as a minimally invasive procedure, may improve disease staging and may be useful to select patients for inguinal radiation. Feasibility and efficacy of SLNB has been addressed by several reports and the clinical utility of this procedure in changing the therapeutic plan has also been outlined. However, further larger prospective studies are needed to confirm the clinical impact of this procedure. Continuous and stringent long-term follow-up is necessary to estimate the outcome in node-negative patients who did not undergo groin irradiation.

Abstract

Mucosal adaptation is an essential process in gut homeostasis. The intestinal mucosa adapts to a range of pathological conditions including starvation, short-gut syndrome, obesity, and bariatric surgery. Broadly, these adaptive functions can be grouped into proliferation and differentiation. These are influenced by diverse interactions with hormonal, immune, dietary, nervous, and mechanical stimuli. It seems likely that clinical outcomes can be improved by manipulating the physiology of adaptation. This review will summarize current understanding of the basic science surrounding adaptation, delineate the wide range of potential targets for therapeutic intervention, and discuss how these might be incorporated into an overall treatment plan. Deeper insight into the physiologic basis of adaptation will identify further targets for intervention to improve clinical outcomes.

INTRODUCTION

The small intestinal mucosa is adaptable but essential for survival. It has diverse biological roles including nutrient absorption, barrier function, injury response, and immunologic reservoir (Figure 1). Congenital or acquired diseases or medical and surgical interventions can alter intestinal mucosal mass and/or function with profound consequences to which the gut must adapt. The clinical challenges to gut adaptation include massive bowel resection, intestinal atresia, fasting, prolonged ileus, bariatric surgery, and total parenteral nutrition (TPN). The biology that regulates such adaptation represents a critical new frontier for gastroenterology and gastrointestinal (GI) surgery if outcomes are to be improved. This review discusses intestinal mucosal atrophy, hypertrophy, and barrier function, and how they may be influenced. We will begin this review by considering what is known about intestinal mucosal development, as this offers useful parallels to the intestinal mucosal response to pathology. Next, we will explore the biologic phenomena of mucosal atrophy and hypertrophy in more depth. Third, we will discuss the clinical syndrome of intestinal failure in more depth, and consider how our understanding of the biology of intestinal adaptation may guide therapeutic interventions. Finally we will discuss new frontiers in mucosal adaptation, focusing particularly on intersections with GI surgery, including both pro-absorptive procedures like intestinal lengthening procedures and anti-

absorptive procedures like bariatric surgery, and on some lessons that may be learned in the future from recent scientific advances. Many potential approaches are available for facilitating absorption and mucosal homeostasis, but their optimal application may require a better understanding of the biology that regulates these processes.

NATURAL MUCOSAL DEVELOPMENT AND GROWTH

Morphogenesis and cell proliferation

Enterocytes are columnar cells with microvilli at their apices that form the intestinal brush border. The microvilli are covered by a glycocalyx coat that acts as a physical barrier and contains brush border enzymes. Enterocytes are joined by tight junctions to form a relatively impermeable membrane^[1,2].

The small intestinal mucosa is folded to increase its surface area^[1,2]. Submucosal folding forms plicae circularis that each include many crypt-villus units. Villi are mucosal surface modifications, finger-like extensions of lining epithelium formed by projections of lamina propria covered with epithelium. Each villus extends into lamina propria as an intestinal gland or crypt of Lieberkuhn^[1,2]. Crypts have stem cells, paneth cells and enteroendocrine cells. Stem cells proliferate at the crypt base.

Mucosal growth and development are regulated by hormonal, nervous, immune, dietary and mechanical signals^[3]. The small bowel mucosa ultimately develops in stereotypic crypt-villus units containing absorptive, secretory, progenitor and stem cells^[4]. Intestinal stem cells maintained throughout life in the crypts give rise to progenitor cells that undergo a few cell divisions as they move out of the crypts toward the villi before final differentiation^[5,6]. Small bowel ontogeny proceeds in three successive phases: morphogenesis and proliferation, cell differentiation, and functional maturation^[7].

The field is beginning to identify molecular mechanisms that influence intestinal development^[8]. For instance, homeobox (*hox*) genes are early regulators of proximal to distal organ-specific patterning^[9]. Mucosal remodeling and villus formation precedes in a cranial-caudal direction^[10]. A primitive endodermal gut tube surrounded by mesenchyme forms early in gestation^[3]. Later, the endoderm transitions to stratified epithelium which ultimately matures to columnar epithelium starting at the apices of the developing villi. The intervillus epithelium differentiates last, and mitotic activity is restricted to intervillus regions and developing crypts by 16 wk^[8,11]. This correlates with Wnt/ β -catenin pathway activity that appears necessary for stem cell maintenance in fetuses and adults^[12]. Fibroblast growth factor receptor (FGFR)-3 signaling regulates crypt epithelial stem cell expansion and crypt morphogenesis *via* β -catenin/Tcf-4 pathways^[6].

Intestinal villus formation begins at embryonic week 8 in humans^[8]. Influenced by Hedgehog and platelet-derived growth factor (PDGF) signals, mesenchymal cells condense under the epithelium and then grow toward

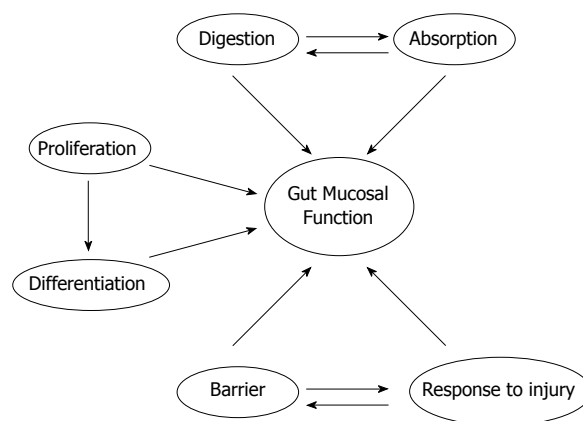

Figure 1 Diversity of gut mucosal function.

the central lumen to form characteristic fingerlike inward projections—the villi^[4,8,13,14]. With increasing age, villus epithelial turn-over, crypt depth, and villus height each increase^[8,15].

Differentiation

Proliferation occurs in the crypts but differentiation occurs as cells migrate up the villus. Thus, differentiated cells populate the villi^[6]. Each villus contains epithelium from the adjacent crypts^[16]. Crypt formation occurs by differential growth of mesenchyme and the crypt-villus junction moves upwards towards lumen^[17]. Crypt-base columnar cells are multipotent cells that differentiate into absorptive enterocytes and secretory mucous secreting goblet cells, entero-endocrine cells and paneth cells^[18]. Notch pathways decide differentiation into absorptive *vs* secretory cells^[19-21]. Crypt stem cells become monoclonal during development^[22]. Critical functional differentiation into distinct apical, lateral and basal cells occurs. Apical cells express digestive enzymes and transporters, while lateral cells chiefly express transporters, and basal cells carry receptors for interaction with basement membrane^[8]. The brush border complex formed by villin and myosin I appears at the apical surface of mature enterocytes^[23,24].

Intestinal growth and differentiation are regulated by an intrinsic program; extrinsic mediators play secondary roles^[25,26]. N-myc is an important regulator of proliferation^[27]. Growth factors like epidermal growth factor (EGF), transforming growth factor (TGF)- α , and TGF- β , insulin-like growth factor (IGF)-2, hepatocyte growth factor (HGF), glucagon like peptide (GLP)-2 and their receptors have been detected in fetal human intestine and likely influence intestinal development^[28]. Luminal and circulating factors are not necessary for fetal intestinal differentiation but may affect growth and maturation^[26,29-31]. Three known triggers are weaning, thyroxine and glucocorticoids^[3]. Regarding intrinsic regulation, it is thought that endoderm has an intrinsic program of regionalization of small intestine and it recruits other cells to complete the formation^[32,33]. Hepatic nuclear fac-

tor (HNF)-3 β , Cdx-1, Cdx-2, GATA transcription factor family and transcription factor CCAAT/enhancer-binding protein α are suggested to have important roles in intestinal development^[8]. Specific regulatory regions of the fatty acid-binding protein (*FABP*) genes are responsible for appropriate temporal, crypt/villus and proximal/distal expression of genes^[34]. Reciprocal permissive and instructive epithelial-mesenchymal interactions and signals direct organ-specific differentiation^[35]. Endoderm can recruit mesenchymal elements^[33]. Sonic hedgehog, bmp, Fkh6, H1x homeobox gene, tyrosine kinase receptors and fibroblast growth factors mediate intestinal growth by epithelial-mesenchymal interaction and direct regional patterning of the gut^[35-40]. The extracellular matrix influences epithelial differentiation by receptor-mediated signaling^[41] and by acting as reservoir for growth factors^[42]. The matrix also drives the enterocyte response to growth factors and physical forces^[43,44]. Matrix has a permissive effect on epithelial cells and is required for maximal differentiation^[45].

Functional development

Brush border membrane enzymes and brush border transport proteins represent the most important functional differentiation of small intestine. These enzymes provide digestive and absorptive functionality for carbohydrates, proteins, fats, minerals and vitamins. Brush border enzymes appear by week eight. Different disaccharidases, alkaline phosphatases, peptidases, and enterokinases mature at different rates in development^[46-48]. Lactase-phlorizin hydrolase (LPH) cleaves lactose into glucose and galactose. Studies of LPH development suggest a proximal to distal gradient in functional maturation of the intestinal epithelium^[46]. Although the human fetus expresses some enzymes and peptidases at levels similar to adults, many of these enzymes have different forms in the fetus^[49-52]. Various transporters for sugar and amino acids appear during gestation in parallel with crypt and villus development^[53,54]. Fetal intestine also starts developing the capacity to secrete lipoprotein fractions, chylomicrons, very-low-density lipoproteins and high-density lipoproteins^[55,56]. Absorptive function is partially detectable at 26 wk^[57].

The intestinal barrier exhibits immune and non-immune protective mechanisms. Although various mucosal defense systems appear early in gestation, immune function remains immature at birth^[58-64]. Tight junctions between enterocytes and goblet cell mucins form a physical barrier by 12 wk^[65].

In summary, the basal differentiation program is encoded in fetal endoderm and mediates spatial and cranio-caudal differentiation of intestinal epithelium *via* a complex intercellular communication network. Epithelial-mesenchymal interaction yields a specialized regional environment that influences gene expression and regulates the growth and differentiation of the intestinal mucosa into crypt-villus units.

MUCOSAL ATROPHY

Mucosal atrophy is characterized by diminished intestinal function as well as morphological changes including decreased villous height, crypt depth, surface area, and epithelial cell numbers^[66]. Atrophy is most common in the absence of enteral nutrition, and is a known long-term consequence of starvation, an effect likely reduced with age^[67]. Animal studies suggest incremental relief of atrophy with progressively greater intake, and that morphologic atrophy is most evident at the villous tip^[68].

Atrophy occurs even if adequate parenteral nutrition is provided. Animal studies first demonstrated the physiology of atrophy during TPN^[69], with atrophy of the proximal small intestinal mucosa with decreased intestinal weight and nitrogen content^[69]. Absence of luminal contents due to either starvation or TPN similarly causes mucosal hypoplasia in rodents, mediated at least in part by an altered tumor necrosis factor (TNF)- α /EGF signaling pathway^[70]. Additionally, rats receiving TPN have fewer Peyer's patches and less total T cells than rats fed enterally, demonstrating an attenuating effect on the gut-associated lymphoid tissue^[71]. Animal studies also demonstrate that TPN evokes enterocyte apoptosis *via* intraepithelial lymphocyte derived interferon- γ , resulting in a loss of the overall barrier function^[72]. Barrier function is further altered by TPN stimulation of ion secretion, an effect upon intestinal permeability further altered by interferon- γ ^[72]. The effect of TPN on immunologic function (including that in the gut) may have profound clinical consequences. For instance, infectious complications were doubled in pancreaticoduodenectomy patients receiving TPN rather than jejunal feeding^[73].

That the effects of fasting and TPN on the gut mucosa are not just from the TPN has been shown in animals. For instance, when a segment of rat jejunum is defunctionalized by a blind end Roux-en-y anastomosis and the rat is allowed to eat freely, the defunctionalized mucosa undergoes morphologic and biochemical atrophy, while the remainder of the gut mucosa remains intact^[74]. This suggests that direct interaction with luminal chyme is required to sustain the mucosa. Indeed, the effects of the absence of enteral feeding may reflect not only the loss of luminal nutrients themselves, but also aberrations in the physical forces to which the mucosa is subjected during gut interactions with luminal chyme, either directly by peristaltic compression against the non-compressible liquid contents of the bowel or indirectly by villus motility^[75-77]. It has long been known that luminal contents and distension influence postprandial intestinal motor activity^[78] that leads to deformation of the bowel mucosa. In addition, villus motility is markedly stimulated by luminal amino acids and fatty acids (but not glucose)^[79].

At the cellular level, atrophic loss of mucosal mass may reflect both decreased proliferation and increased apoptosis. EGF family cytokines are potent mitogens, but there are others, including GLP-2, while TNF- α and others mediate apoptosis. We found mostly decreased

proliferation in defunctionalized rat intestine, perhaps because the incidence of apoptosis is too low to be readily measurable^[74], except in chemotherapy-induced mucosal injury^[80]. Fasting leads to jejunal mucosal atrophy with enhanced apoptosis in a mechanism related to increased nitric oxide^[81]. Feng *et al*^[70] recently explored the interaction between growth factor-stimulated proliferation and cytokine-driven apoptosis in a murine TPN model. BCL-2 expression acts on mitochondria to prevent cytochrome C release, and caspase 3 directed cell death. Bax in contrast, acts on mitochondria to cause caspase 3 release, leading to programmed cell death. The ratio between these determines overall cell survival^[82,83]. Enterocytic differentiation is also impaired in mucosal atrophy, with decreased expression of brush border enzymes and other differentiation markers^[74,84,85], but the mechanism by which this occurs is much less well understood. While translational science strives to find better mitogens to promote enterocytic proliferation, how to promote enterocytic differentiation in patients or animals with mucosal atrophy may represent an important question for basic science in the future.

MUCOSAL ADAPTATION

Mucosal adaptation in many ways opposes atrophy, although that there may be subtle but important differences in the stimuli that prevent atrophy and maintain normal mucosal mass and those that induce adaptation. Teleologically, adaptation may be the attempt of the intestine to compensate for intestinal inadequacy. It has been best described after massive small bowel resection^[86,87]. However, exogenously induced adaptation may reverse chemotherapeutically induced atrophy. For example, profound intestinal injury by methotrexate may be mitigated by supplementation with L-arginine or n-3 fatty acids^[88,89].

Acute absence of nutrition alone cannot trigger full adaptation or fasting would cause intestinal hypertrophy rather than atrophy. The stimuli contributing to adaptation are diverse. Many cytokines facilitate adaptation, including PDGF- α , HGF, and interleukin (IL)-11^[86,90,91]. As detailed later, hormones such as IGF-1 and growth hormone (GH) appear to exert strong adaptive influ-

ences^[92,93]. Within enterocytes, intestinal resection invokes novel signals such as proline-rich protein 2 during wound healing^[94], glutathione reductase during intestinal apoptosis^[95], and basic Kruppel-like factor to activate the IGF-1 promoter^[96].

The anatomic location of the bowel mucosa has an important relationship with adaptive biology. The small and large intestinal mucosa demonstrate many differences in histology, cell phenotype, and transport proteins that reflect their differences in normal function. In addition, the small and large intestinal mucosa respond differently to stimuli of malignant transformation. For example, the APC (Min) mouse is a dominant mutation that leads to multiple intestinal neoplasia^[97]. Crypt cells express a balance of proliferation and differentiation, a process with aberrant regulation in these mutants. In mouse models with this mutation, small bowel neoplasms are much more common than colonic neoplasms, in contrast to the human condition in which colonic neoplasms are more common^[98]. The reason for this regional difference is as yet unknown but further investigation may offer important clues into differentiated intestinal epithelial biology.

Finally, the role of nutrition in adaptation is not yet fully explained. Glutamine has been most studied^[99] (Table 1). There may also be differences between the signals that stimulate the increase in mucosal mass and the signals that augment mucosal functionality during adaptation. Adaptation includes proliferation, augmentation of function and changes in intestinal epithelial phenotype (Figure 2).

Proliferation

Proliferation is one mechanism of adaptation. Proliferation increases villus height, crypt depth, surface area, and intestinal wet weight^[100]. The length of intestine resected correlates with the subsequent change in villus height in humans^[101]. The site of resection also influences adaptation^[102], with a notable increase in jejunal hyperplasia, and to some degree ileal hypertrophy. Animal studies also suggest increased intestinal stem cells after resection; these may contribute to increased crypt formation^[103]. Growth factors and nutritional supplementation stimulate intestinal epithelial proliferation and turnover.

The intestine also adapts from a functional standpoint. Proliferation increases overall function just by

Figure 2 Initial enterocytic stem cell proliferation is supplemented by differentiation to produce the four main intestinal epithelial phenotypes: absorptive enterocytes (A), enteroendocrine cells (B), mucin-secreting cells (C), and Paneth cells (D).

creating more cells that can contribute to amino acid, glucose, and electrolyte uptake. Increased absorption *via* the H⁺/peptide co-transporter 1 after intestinal resection occurs because of hyperplasia and not upregulation of transporters^[104]. Improved glucose uptake after massive small bowel resection is similarly driven by cellular proliferation rather than massive transporter upregulation^[105]. In addition, we can see increase in Na⁺/glucose transporter (Sgt1), Na⁺/H⁺ exchangers (NHE2/3), and some brush border membrane enzymes^[106].

Augmentation of intestinal mucosal function

Although most work has focused on enterocytes, adaptation also increases non-enterocytic mucosal epithelial cells. Goblet and paneth cells exhibit an early and sustained increase after bowel resection; these secretory cells may contribute to juxtacrine signaling that further stimulates intestinal adaptation^[107]. Finally, the role of angiogenesis has been relatively understudied in mucosal adaptation. Bowel resection in rats induces angiogenesis within the adapting intestinal villi^[108]. This may facilitate absorption, protect mucosal integrity and barrier function, and increase nutrients and oxygen delivery to the more rapidly proliferating mucosa.

Cellular differentiation

To maintain and control epithelial cell homeostasis, proliferation and differentiation are transcriptionally regulated in a sequential and spatially defined manner^[109]. The signals that control intestinal development also influence intestinal homeostasis. These include the canonical Wnt/ β -catenin pathway^[110], Notch^[111], Hedgehog^[112], the TGF- β family including bone morphometric proteins (BMP)^[113], PI-3K^[114] and Forkhead Box (FOX) and homeobox (*HOX*) genes^[115]. These pathways use various transcription factors including HNF1 α/β , HNF4 α ,

GATA factors, ETS, and Cdx1/2, alone or in combination^[116-120]. For instance, the combination of HNF1 α , GATA4-6 and Cdx2 regulates sucrase isomaltase transcription^[116] but in differentiated mouse epithelium; HNF4 α regulates expression of genes upregulated during differentiation such as alkaline phosphatase^[121]. GATA transcription factors are required for crypt cell proliferation and absorptive enterocyte gene expression^[119]. HNF3 β is expressed in small intestine and has critical role in foregut and midgut formation^[122-124]. Finally, Cdx2, which is restricted to adult small intestine and colon^[125], is necessary for maintenance of intestinal identity and differentiation of the small intestine epithelium (Table 2)^[126].

A recent landmark study demonstrated the guidance of human pluripotent stem cells into intestinal tissue^[127]. This study demonstrated that the activity of Wnt3a and FGF4 was adequate for hindgut patterning, specification and morphogenesis, with NEUROG3 transcription factor required for enteroendocrine cell development *in vitro*. Similarly, embryonic stem cells have been committed to intestine lineage in medium treated with Wnt3A, in a process that interestingly enough simulated the genes associated with distal gut-associated mesoderm (Foxf2, *hlx*, *Hoxd8*)^[128]. This process was successful in that it allowed engraftment of these cells into murine colonic mucosa.

CLINICAL SETTINGS IN WHICH MUCOSAL ADAPTATION IS IMPORTANT

Atrophy in starvation, fasting or TPN

Intestinal failure occurs when the absorptive surface area falls below a critical level, either because of loss of bowel length or mucosal atrophy with severely flattened epithelium. Intestinal failure presents with diarrhea, dehydration, malabsorption, progressive malnutrition, and electrolyte disturbance^[129].

TPN administration in starving animals or humans does not abrogate the atrophy observed in starvation alone. In addition, TPN may itself impair mucosal barrier function^[130] beyond the effects of starvation on the

epithelium. In adult trauma patients, this loss of barrier function may significantly increase sepsis^[131]. Trauma patients receiving enteral nutrition have fewer pneumonias, intra-abdominal abscesses, and line sepsis and less infections overall compared to patients on TPN^[131]. TPN-associated loss of epithelial barrier function may be related to altered mucosal lymphoid populations with increased interferon gamma and interleukin-10 expression, as well as loss of tight junctions and adherens junction proteins^[72]. Prolonged starvation, as in chronic TPN, pancreatitis, or other medical conditions, can lead to intestinal failure *via* mucosal atrophy. Indeed, poor enteral intake can cause pancreatitis and intestinal mucosal atrophy^[132] which in turn increases enterocyte apoptosis and alters glutamine and arginine transport^[133,134]. Atrophy in turn creates a propensity for bacterial translocation and sepsis^[135].

Short bowel syndrome

Massive small bowel resection can severely test the capacity of the remaining small bowel mucosa to adapt, resulting in short bowel syndrome, a devastating nutritional problem. The most common causes of short bowel syndrome in children include necrotizing enterocolitis, intestinal atresia, and midgut volvulus^[136,137]. In adults, common causes include inflammatory bowel disease, mesenteric ischemia, small bowel obstruction, and radiation enteritis. The loss of mucosal area associated with short bowel syndrome causes substantial malabsorption, with attendant diarrhea, abdominal pain, and weight loss, electrolyte imbalance, and chronic malnutrition. Mucosal adaptation in such patients is a slow and gradual process that may require up to 1-2 years to reach maximum. The simplest and earliest phases of adaptation involve enterocytic proliferation and villous hyperplasia, which may manifest as a reduction in diarrhea and attendant fluid and electrolyte loss. Nutritional adaptation that addresses nutrient absorption and digestion sufficiently to permit weaning from TPN is slower and requires greater complexity.

Current medical management of intestinal failure:

Intestinal failure is initially managed similarly whether due to atrophy or short gut. TPN supplies nutritional requirements while ways to transition to enteral feeding are sought. This is usually successful in mucosal atrophy, although it may be prolonged and difficult in some patients. Such transitions are less frequently successful in the short gut patient. The primary predictor of survival in adults with short gut is small bowel length. Eighty-three percent of adults with less than 50 cm of intestine require lifelong TPN; Twenty-five percent will die within 5 years^[138]. In pediatric short gut patients, cholestasis and age-adjusted small bowel length less than 10% of expected length predict mortality; small bowel length and an intact ileocecal valve predict successful weaning from TPN^[139]. The ileocecal valve slows transit through the small bowel, facilitating absorption and digestion. In

addition, the colon may both absorb water and salvage energy in such patients, perhaps mitigating the need for parenteral nutrition if the small bowel is marginally adequate^[140].

Whether as a bridge to enteral nutrition or as permanent maintenance, TPN is lifesaving in patients who cannot be nourished enterally. However, TPN has significant complications. TPN itself results in mucosal atrophy, impaired mucosal immunity with a proclivity towards intestinal infections, and dysfunction of the gut-associated lymphoid tissue^[141]. It is unclear to what extent these phenomena reflect the lack of enteral feeding and to what extent they are consequences of the infusion of large quantities of hyperosmotic or hyperlipidemic nutrients into the circulation. TPN is also associated with chronic systemic problems including mechanical complications related to the catheter, recurrent infections, liver failure, and death. Randomized, controlled trials have demonstrated the benefits of enteral feeding over parenteral feeding for diverse conditions^[142] with reductions in infection, intraabdominal abscess, anastomotic leak, hospital stay, and all other complications. Many enteral nutrients are essential for intestinal adaptation in both adult and pediatric populations^[143,144]. In both acutely ill hospitalized patients and chronic short gut patients at home, some enteral nutrition is therefore desirable even if parenteral supplementation is required. Such enteral intake both maintains the mucosal barrier and supports the patient psychologically. The central theme of modern management is to provide the gut with at least some nutrients and consequent hormonal stimuli even if parenteral supplementation is required.

“Intestinal rehabilitation” for short bowel syndrome uses chronic home TPN as a bridge to maintain patients while seeking to adapt them to eventual enteral nutrition. Intestinal rehabilitation is a multidisciplinary approach aimed at achieving enteral autonomy, and keeping patients alive while still requiring TPN. Teams of GI and transplant surgeons, gastroenterologists, dieticians, pharmacists, nurses, and social workers collaborate to offer improved nutritional care and dietary manipulation, facilitated discussion about needs for surgical interventions, and formal monitoring and manipulation of essential medications including mucosal mitogens. This approach may improve survival compared to historical controls, although this could also reflect improved treatments over time^[145].

NUTRITION AND INTESTINAL ADAPTATION

In rats with short bowel syndrome, early enteral feeding affects not only cellular proliferation, but also overall gut weight and length^[146]. Even marginal nutrition at the apical or luminal surfaces may improve human intestinal epithelial cell growth, motility, and absorption capacity^[147]. Overall, enteral feeding induces significant intestinal adaptation. Further interest lies in trying to modify the

nature of the diet.

Dietary fats

Dietary lipids encourage intestinal adaptation through several mechanisms. At the simplest level, early feeding of a fatty diet increases lipid absorption in the remnant intestine^[148]. Specific nutrients may be important. For instance, arachidonic acid stimulates intestinal adaptation more than linoleic acid^[149]. Rats on high-fat diet demonstrate increased fat absorptive capacity compared to rats eating standard chow^[150]. However there is some controversy about the role of enteral fatty acids. Other evidence does not demonstrate improved adaptation with enteral omega-3 fatty acids, but only with parenteral supplementation among rats^[151]. Dietary fish oil appears to increase fat absorption without a concurrent increase in bile acid synthesis in rats following ileocecal resection^[152].

Dietary fat intake might also modify gene expression and transport by altering the transcription and activation of signal proteins related to protein synthesis of nutrient transporters, including activation of peroxisome proliferator-activated receptors, HNF-4, and nuclear factor κ -B^[153]. Dietary fat may activate intracellular signals to alter mRNA expression.

Diet also affects gut membrane permeability. Membrane fluidity is altered dramatically by the intrinsic fatty acid saturation and also by cholesterol and ganglioside/glycosphingolipid content, and can inhibit degradation of gut occluding tight junctions in rats^[154]. Specialized parts of the membrane such as lipid rafts and caveolae affect signaling and protein intake in a manner altered by fatty acid intake^[155].

Intestinal lipid transfer is relatively quickly influenced by diet. Rats fed a high-fat diet for only seven days undergo intestinal adaptation, reflected in dramatic increases in the expression of sterol regulatory element-binding protein (SREBP)-1c. The activation of SREBP-1 increases its synthesis and translocation to the nucleus in intestinal cells, altering lipid metabolism^[156]. Further work is needed to identify the signals that influence short term and long term adaptation. This may have even morphological implications. Palmitic acid feeding increases rat bowel and mucosal weight after massive small bowel resection after only 14 d^[157].

Short-chain fatty acids

Interestingly, the colon also contributes to intestinal adaptation in malabsorption. In carbohydrate salvage, short-chain fatty acids (SCFA) produced by fermentation by anaerobic colonic bacteria are absorbed by the colonic mucosa, resulting in net energy absorption. These SCFA consist primarily of acetate, propionate, and butyrate. Luminal butyrate is the primary energy source of the colonocyte, and SCFA are trophic for the colonic mucosa. Adding SCFA to TPN prevents small bowel mucosal atrophy in fasting animals^[158,159]. Adding butyrate to TPN also improves lymphocyte numbers, small intestinal IgA levels, and small intestinal surface area^[159]. This demon-

strates that intravenous nutrition can interact with luminal enterocytes, facilitating their function and altering their structure to promote digestion. Indeed, parenteral butyrate alone increases plasma GLP-2 and directly promotes GLUT2 activity^[160,161]. Parenteral butyrate facilitates small bowel adaptation in piglets after massive resection, improving small intestinal morphology and reducing apoptosis^[161]. Butyrate also must act independently of GLUT2 since it promotes enterocytic differentiation in isolated cells in culture^[162]. Prebiotic supplementation with short-chain fructooligosaccharides may replace butyrate and also promote jejunal adaptation^[163].

Dietary carbohydrates

Traditionally attention has been placed on optimizing carbohydrate/fat/protein ratios to maximize nutrient delivery in short gut syndrome. However, enteral nutrients also influence intestinal adaptation. For example, dietary carbohydrate induces adaptation for monosaccharide absorption by increasing the quantity of carbohydrate transporters^[164]. Dietary fiber may also be helpful in modulating nutrient uptake. In TPN-nourished rats with 85% small bowel resection, supplementation with dietary fiber along with GH synergistically enhanced intestinal adaptation^[165].

Dietary proteins

Increased enteral protein content leads to adaptive amino acid uptake in the small bowel^[166]. Glutamine is a conditionally essential amino acid is also the enterocyte's primary energy source^[141]. Providing parenterally fed rats with glutamine reduces mucosal atrophy^[167], but this effect is less robust in enterally fed animals^[165]. Glutamine supplementation also enhances mucosal immunity in rats with gut-derived sepsis^[168]. However, animal results have been mixed^[169]. Some studies showed glutamine to be effective only when combined with GH as discussed below^[165]. One small uncontrolled study did report that glutamine promoted weaning from TPN, with increased growth and improved nutritional factors^[170]. Human studies for the most part have not demonstrated much efficacy^[171,172]. A recent prospective, randomized human study suggests that human GH may aid adaptation with or without glutamine, but only the patients who received GH along with glutamine maintained the reduction in parenteral nutrition at 3 mo^[173]. This points to the need for multimodality therapy, and suggests caution with regard to glutamine supplementation alone.

Retinoic acid

Adaptation may be facilitated by retinoic acid. Retinoic acid administered intravenously has significant trophic effects in rats undergoing small bowel resection, apparently by inhibiting apoptosis and stimulating crypt cell proliferation^[174]. Retinoic acid may act *via* changes in extracellular matrix^[175], by acting on hedgehog signaling, by increasing Reg1 and Pap1 activity, and by acting on retinoid and peroxisome proliferators-activated receptor pathways. Convincing human data are lacking.

Polyamines

Polyamines can be either synthesized from ornithine or ingested. Diet supplementation with ornithine α -ketoglutarate increases intestinal adaptation after intestinal resection^[176,177]. In one recent study, piglets with 80% small bowel resection were randomized to either parenteral nutrition alone or parenteral nutrition plus enteral feedings beginning on postoperative day 3^[146]. The piglets with additional enteral feedings exhibited greater weight per length of intestine, as well as increased cellular proliferation index and ornithine decarboxylase activity. Response to enteral plus parenteral feedings was greater than the group with sham operation as well. In summary, with only a few days of enteral feeding piglets could undergo exceptional adaptation to extensive surgical resection as marked by polyamine synthesis and crypt cell proliferation. However, it remains unclear to what extent the polyamine synthesis was the critical mechanism for the trophic effects of enteral feedings in this study, and, as for retinoic acid, data suggesting that polyamine supplementation alone will be effective in humans are lacking at this time.

CURRENT AND EMERGING PHARMACOTHERAPIES

Antibiotics

Enteral antibiotics are certainly effective in a very select group of short bowel patients in whom small bowel bacterial overgrowth potentiates malabsorption^[178,179]. The inflammatory response to small bowel resection may also be a potential target for intervention. In massively bowel-resected rats with bowel segment reversal, oral antibiotics were associated with increased IGF-1 and blunted increases in white blood cell count, IL-6, and serum nitric oxide. This demonstrated that antibiotics may attenuate the inflammatory response^[180]. However, more clinical outcomes associated intervention with this have yet to be assessed. This represents an important frontier for future work, but should not justify indiscriminate antibiotic use in patients without demonstrable bacterial overgrowth.

Stimulating cellular proliferation to enhance adaptation

Promoting enterocyte proliferation is an attractive strategy to treat short gut. Many agents have been promising *in vitro* and in animals. We will review several below. As of this writing, only GH and Teduglutide (outside the United States) are in clinical use. It remains unclear how substantial their effects are. In addition, the long term risks of treating the gut mucosa with mitogens over decades are unknown.

GH

GH is an anabolic protein that initiates mitosis. It is released by the anterior pituitary and may act through IGF-1^[181]. GH is perhaps the best studied short bowel

mitogen. Experimental studies suggest that GH might have several beneficial effects on adaptation^[182], including increases in mucosal hyperplasia and absorptive capacity^[165,183], bowel growth, villus height, and crypt depth^[184,185], and even increased length within the remaining intestine after extensive small bowel resection^[92]. In humans, GH alone, or combined with high carbohydrate diets and glutamine supplementation, may increase nutrient absorption^[186]. In children dependent on TPN for more than 50% of their nutritional needs, 12 wk of GH decreased TPN requirements. However, only two children (25%) were definitively weaned from TPN^[187]. This suggests the need for multimodal interventions to achieve clinically meaningful endpoints. Combining GH with dietary modification and glutamine supplementation may permit weaning from TPN in some patients^[183], and another prospective, double-blind randomized placebo-controlled trial demonstrated that a reduction in TPN use can persist for three months if GH is combined with glutamine^[173]. Four randomized, double-blind, placebo-controlled studies have asked whether GH supplementation increases body weight in this setting^[172,188-190]. These have yielded mixed results, although a recent Cochrane review found that glutamine overall increases weight, lean body mass, energy absorption, and nitrogen absorption^[191]. Reported side effects^[172] include myalgia, gynecomastia, insomnia, joint pain, and hyperglycemia. As of this writing, GH is the only FDA-approved agent to treat short bowel syndrome in the United States, but it is certainly not a panacea. To the extent to which GH is effective, it is most likely to benefit patients with 70-100 cm of small bowel remaining and without an intact colon. Side effects are significant.

Glucagon-like peptide-2: Glucagon-like peptide-1 physiologically is a humoral mediator of intestinal adaptation, normally secreted in response to enteral stimulus, especially by foods containing carbohydrates, fatty acids, and fibers^[192,193]. It is a 33 amino acid peptide derived from proteolytic cleavage and modification of proglucagon in the pancreatic α -cells and intestinal L-cells^[194].

GLP-2 production is most robust in the distal small bowel and large intestine^[195]. Effects of GLP-2 are specific to different regions of the bowel and appear to stimulate morphologic adaptation with increase in microvillus height and overall surface area. This was demonstrated in an animal model with 80% small bowel resection, using animals given TPN with or without GLP-2. After only one week intestines were examined for morphology, crypt cell proliferation, apoptosis, SGLT-1 expression and GLUT-5 transport proteins. In addition to the expected finding of morphologic adaptation, GLP-2 increased the jejunal crypt apoptotic index without increasing transport protein expression^[196].

Teduglutide (ALX-0600), a dipeptidyl peptidase IV (dpp-IV) resistant GLP-2 analog, has been reported to promote intestinal growth in short bowel patients, increas-

Table 3 Potential pharmacotherapy targets for intestinal failure

	Dose mg/kg per d	Side effects	Structure	Approval
Growth hormone	0.1	Fluid retention, joint pain, hyperglycemia	191-amino acid protein	FDA
EGF	NA ¹	NA	53-amino acid peptide	Not available commercially
GLP-2	0.1	Abdominal pain/obstructive symptoms	dpp-IV resistant 33-amino acid peptide	Phase III clinical trials available in Europe

¹Dose not specified for human use. FDA: Food and Drug Administration; GLP-2: Glucagon-like peptide-2; EGF: Epidermal growth factor; dpp-IV: Dipeptidyl peptidase IV; NA: Not available.

ing small intestinal villus height, crypt depth, and mitotic index and improving absorption over three weeks^[197]. 11 short bowel syndrome patients with Crohn's disease taking Teguglutide over 2 years demonstrated excellent compliance (93%), safety, and improved quality of life. The major reported side effects appear to be abdominal pain and obstructive symptoms, but it is difficult to determine the extent to which these side effects should be ascribed to Teguglutide or to the patients' underlying Crohn's disease. Whether other short gut patients will report less of these symptoms awaits study^[198]. Teguglutide may also aid weaning from TPN. In a randomized placebo-controlled trial, low-dose Teguglutide promoted weaning from TPN, although puzzlingly high-dose Teguglutide did not have this effect^[199] although secondary endpoints of villus height and body mass were increased by high-dose Teguglutide as well. This puzzling result was attributed to possible baseline differences between groups, although alternative explanations include difference in oral intake and side effects. In addition, a suprapharmacologic effect may limit efficacy. Teguglutide is in clinical use in some countries already, and will likely achieve broader distribution in the near future. Further studies with regard to the ideal dose, time course, and potential for synergy with other interventions would improve our understanding of how Teguglutide should be used (Table 3).

IGF: IGF may also enhance enterocyte proliferation after small bowel resection is^[200,201]. IGF-1 is produced primarily in the liver but it is also synthesized to a lesser extent within the intestine by subepithelial myofibroblasts^[202]. IGF-1 may upregulate digestive enzymes including sucrase, maltase, and leucine aminopeptidases after small bowel resection in animals^[203]. In addition, targeted overexpression of IGF-1 in transgenic mice leads to increased small bowel weight, length, and crypt cell proliferation^[204]. In short bowel syndrome rats on parenteral nutrition, IGF-1 treatment induced jejunal hyperplasia^[205]. In small bowel syndrome rats, IGF-1 increased jejunal mucosal mass by 20% and DNA content by 33%, reflecting increased enterocyte hyperplasia^[206].

EGF: EGF is a 53-amino acid peptide in saliva and pancreaticobiliary secretions. EGF stimulates crypt cell proliferation and suppresses apoptosis^[207]. EGF administration at the time of small bowel resection may facilitate intestinal adaptation, ameliorating weight loss and apoptosis^[208,209]. EGF functions intraluminally as small bowel resection in animals increases salivary EGF without increasing plasma EGF, and either removal of salivary glands^[209,210] or selective oral inhibition of the EGF receptor^[106] attenuates adaptation after small bowel resection. The EGF receptor is regulated at the level of ligand expression during intestinal epithelial differentiation^[211].

Other hormones of potential interest

Leptin has been studied most regarding appetite and the obesity physiology. It is also a potential target to manipulate adaptation. Parenteral leptin may stimulate structural adaptation in short bowel rats by increasing cell proliferation and decreasing apoptosis. Leptin also increases GLUT-5 levels^[212,213].

Bombesin is also being explored as a therapeutic target of interest. In rats, subcutaneous exposure to bombesin for 2 wk after massive small bowel resection enhanced enterocyte turnover with increased ileal transmural and mucosal weight, DNA and protein, villus height, crypt depth, and proliferation index. These rats also demonstrated increased ileal Bax and Bcl-2 and decreased apoptosis^[214].

Ghrelin is secreted in the stomach and other tissues and influences food intake and nutrition. Plasma ghrelin is decreased in short bowel syndrome^[215]. These changes are unrelated to hyperphagia. It is not yet known whether this decreased ghrelin is only reactive or has an adaptive function^[216].

Glucocorticoids: The stress response may play a critical role in intestinal adaptation. In rats undergoing either 80% small bowel resection or sham operation, dexamethasone infusion reduced weight, DNA content, and mucosal protein content regardless of surgical status. IGF-1 was markedly decreased in the steroid-treated rats, demonstrating a potentially deleterious effect on adaptation^[217]. In contrast, glucocorticoids may impact uptake of sugars by modulating uptake receptors with variable effects among the glucocorticoids^[218]. How to modulate these effects without adversely affecting other physiologic parameters remains unknown.

MULTIMODALITY THERAPY

Integrated multimodality treatment may prove the best strategy. For instance, just as GH may be more effective when combined with glutamine. GH and EGF in combination synergistically increased microvillus height and enhanced nutrient transport in a rabbit short bowel model^[219].

OTHER NEW FRONTIERS IN MUCOSAL ADAPTATION

Surgical interventions for short bowel syndrome

Surgery is more acutely risky than medical intervention but also offers hope to patients who otherwise would be condemned to permanent TPN. Potential interventions include intestinal lengthening procedures such as the Bianchi procedure or the serial transverse enteroplasty (STEP) procedure and small bowel transplantation^[141,220]. Intestinal lengthening procedures are more conservative.

The Bianchi procedure involves splitting a dilated bowel segment longitudinally and reanastomosing it. This could potentially double intestinal length. One institution recently reported a 40% TPN wean rate with Bianchi alone^[221]. There is significant potential, however, for bowel loss in the event of technical misadventure. The STEP is an alternative that involves plicating the small bowel with staple lines alternating on the mesenteric and antimesenteric edges. One series reported a 60% TPN wean rate among adult and pediatric patients with short bowel syndrome using the STEP procedure^[222]. On the horizon is the concept of using slow chronic intestinal distraction to stimulate intestinal mucosal and muscular proliferation and thus lengthen the small bowel slowly over time. This has been successfully performed in animal models with additional benefits including increased mucosal weight, and potentially improved function as given by increased disaccharidase activity^[223]. This makes conceptual sense since pressure^[224] and deformation^[225] stimulate intestinal epithelial proliferation.

Small intestinal transplantation is more aggressive and risky but offers even more potential for weaning from TPN. The indications for small-bowel transplantation according to the American Society of Transplantation include the high risk of death related to the underlying disease as well as intestinal failure with increased morbidity or poor acceptance of parenteral nutrition. The United States Center for Medicare and Medicaid lists home TPN complications including impending liver failure, central venous access thrombosis of 2 or more central veins, recurrent line sepsis, and repeated episodes of dehydration^[226]. We highlight the critical nature of these options to demonstrate the need for less morbid options. Risks specific to small intestine transplant include graft thrombosis, ischemia, infection related to immunosuppression, and graft rejection. Outcomes appear to be improving with time. Graft and patient survival in carefully selected patients have recently been reported as high as 75% and 80%, respectively^[226,227]. Although such surgical interventions are yielding increasingly impressive results, improved medical and nutritional therapy might obviate the need for such risky procedures.

Obesity surgery

Although we generally think about the intersection between mucosal function and surgery with regard to procedures to increase mucosal mass and digestive func-

tion, the biology of intestinal adaptation may also be relevant to morbid obesity surgery. Morbid obesity is a rising epidemic with profound cardiovascular, endocrine, and pulmonary systemic consequences^[228]. Such patients typically do not respond well to conventional instructions to eat less and exercise more. The induction of artificial malabsorption using steatorrheic agents can cause mild weight loss but is associated with poor compliance^[229]. Bariatric surgery has evolved as the most effective treatment for morbid obesity. Although many procedures have been described to induce weight loss, they can generally be categorized as to whether they have restrictive and/or malabsorptive components. Procedures including malabsorptive components, in which some of the small bowel is bypassed, generally achieve superior weight loss to purely restrictive procedures because malabsorption procedures create a functional short gut syndrome.

Such bariatric procedures generate initial weight loss, but many patients gain back weight later. Some failures are attributed to behavioral changes as patients learn to “out-eat” the surgical procedure. However, it seems likely that postoperative intestinal adaptation to the functional short gut also ameliorates weight loss by increasing the absorptive capacity of the intestine that remains in continuity.

Intestinal adaptation does occur after malabsorptive obesity surgery. Humans undergoing classical jejunoileal bypass develop increased small bowel villus height and improved nutritional intake without increases in individual cell height or width, identifying epithelial hyperplasia as part of the adaptive mechanism^[230]. However, the un-bypassed functional segment of small intestine demonstrates not only an adapted morphologic appearance with increased villus height but also increased activity of brush border enzymes^[231]. This suggests that individual intestinal epithelial cells, while not larger, are likely to be more functional, better able to absorb and digest nutrients, consistent with a bimodal model of adaptation in which the adapted intestine has not only more enterocytes but better enterocytes that more fully express characteristics needed for their function. It remains unclear whether similar changes occur in response to decreased nutrient consumption in the bowel of patients who undergo purely restrictive procedures such as laparoscopic gastric banding and gastric sleeve procedures. Human biopsies 11–22 mo after jejuno-ileal bypass reveal marked mucosal villus hypertrophy in the continuous segment of bowel, and atrophy within the bypassed segment^[232]. Obesity surgery also alters gut hormone levels. For instance, 6 mo after Roux-en-Y gastric bypass, fasting leptin and insulin decrease while peptide YY, enteroglucagon, and GLP-1 increase^[233]. This coincides with sustained postprandial satiety that may also be related to intestinal adaptation. These effects may persist for years after surgery^[234].

Mucosal atrophy and adaptation can also be reproduced in rat models for research. Adaptation in the remaining intestinal segment is well described in rats after massive small bowel resection. Conversely, we recently described a novel defunctionalizing Roux-en-Y anasto-

mosis rat model in which the defunctionalized segment (not actually anastomosed proximally but just ligated at its proximal end) displays morphological and biochemical evidence of mucosal atrophy reminiscent of that seen in TPN-nourished animals despite enteral nutrition passing through the remaining gut^[74]. Decreased mucosal mitogenic extracellular signal-regulated kinase (ERK) signaling correlates with decreased proliferation in this bypassed segment. This confirms that mucosal atrophy in the setting of TPN reflects loss of enteral nutrients in direct contact with the gut mucosa rather than loss of indirect neurohumoral effects associated with enteric food consumption.

Interestingly, more classical Roux-en-Y bypass rat models, in which the bypass limb receives continuous biliopancreatic secretions, result in increased villus height and crypt depth in the common limb as compared to the biliopancreatic limb, but decreased glucose transport overall, suggesting the importance of both overall mucosal mass and anatomic rearrangement in determining intestinal function^[235]. Importantly, the biliary limb of this anastomosis exhibits partial adaptation with increased width and increased crypt cell proliferation without further mucosal adaptation. The alimentary and common channel exhibits full adaptation in bowel width, villus height, crypt depth and proliferation. This demonstrates the importance of direct contact and local factors required for full adaptation^[236].

Some endocrine changes after obesity surgery probably contribute to the success of these procedures, beyond their anatomic restrictive and malabsorptive effects. However, some of the neurohumoral consequences of obesity surgery may act synergistically with the decrease in delivery of nutrients to the intestinal mucosa to promote intestinal adaptation which in turn undesirably enhances nutrient absorption and contributes to delayed weight gain. Altering this natural adaptation after obesity surgery could sustain weight loss with less frequent failure. If sufficiently severe mucosal atrophy could be pharmacologically induced, one might even create sufficient malabsorption to obviate the need for any surgical procedure.

Influence of physical forces

The gut mucosa may not only be influenced by chemical interactions with growth factors, cytokines, and nutrients but also by exposure to physical forces such as repetitive deformation and pressure. These forces can originate from peristaltic contractions, villous motility, and physical interactions between the intestinal villi and the relatively non-compressible luminal chyme. *In vitro*, the proliferation of human intestinal epithelial cells is stimulated by rhythmic deformation, and this mitogenic effect is synergistic with the mitogenic effect of L-glutamine supplementation^[237]. The mitogenic effects of strain are amplitude-dependent^[75] as well as frequency-dependent^[237], and occur not only in established cell lines but also in primary

intestinal epithelial cells derived from human surgical specimens^[44].

The pathway governing this mitogenic effect is complex. *In vitro* work suggests it includes a complex web of kinases^[238] (while *in vivo* such signals are activated by repetitive deformation of the intestine in anesthetized animals^[76]). Extracellular pressure may also be mitogenic for intestinal epithelial cells^[224]. Pressure stimulates colon cancer cell proliferation *via* protein kinase C and tyrosine kinase signals. Supraphysiologic extracellular pressure inhibits intestinal epithelial wound healing independently of luminal nutrient flow^[239]. Enterocytic differentiation is influenced by some of these same stimuli^[240,241].

Interestingly, the intestinal epithelial response to repetitive deformation seems regulated by a matrix-dependent switch. Under basal circumstances, repetitive deformation induces proliferation and differentiation consistent with the ideal enterocytic phenotype. However, when fibronectin is added to the matrix substrate or medium *in vitro*^[44] or deposited into the extracellular matrix *in vivo* during inflammation or injury^[239], then deformation promotes a shift to a migratory phenotype and more rapid cell motility to close the resultant mucosal defect and maintain the mucosal barrier. The signal pathways that regulate this mitogenic effect are similar to those by which deformation is mitogenic in the absence of fibronectin, but exhibit subtle but important differences that may permit selective targeting of each effect^[242]. For instance, repetitive deformation promotes epithelial motility across fibronectin *via* a FAK-Tyr 925-phosphorylation that occurs independently of Src, while the FAK-Tyr 925-phosphorylation that occurs in response to strain in the absence of fibronectin requires Src^[225]. We recently demonstrated that integrin-linked kinase, in association with focal adhesion kinase and Src, modifies the downstream response to strain, perhaps implicating ILK as a useful molecular target for intervention^[243].

Animal studies are beginning to validate these *in vitro* observations. The defunctionalized gut, deprived of chemical and physical interactions with luminal nutrients, displays mucosal atrophy throughout its length^[74] and slower mucosal wound healing in wounded areas into which fibronectin has been deposited^[239]. Targeting otherwise deformation-activated signals such as ILK^[243] or small GTP-binding proteins like RhoA, rho-associated kinases and the formin homology protein mDia^[244] may someday maintain the gut mucosa despite fasting or ileus.

TARGETS FOR CELLULAR DIFFERENTIATION IN ADAPTATION

While most therapeutic efforts have emphasized modulating intestinal epithelial proliferation, it may also be useful and important to modulate intestinal epithelial differentiation to achieve a fully and optimally functional intestinal mucosa. Schlafen-3 and Math-1 are potentially interesting targets.

Table 4 Questions for future study

What is the ideal timing for influence of proliferative and differentiation phases in small bowel adaptation with targeted therapy?
What are useful combination regimens of multimodality therapy?
What dietary supplementation is essential for optimization of adaptation?
What is an appropriate algorithm for advanced medical compared to surgical treatment of small bowel syndrome ?
What is the precise role for glutamine supplementation in facilitating adaptation?
What is the ideal dose of Teduglutide?
Can other agents such as polyamines or retinoic acid be useful?
How can surgical procedures best be combined with multimodal therapy?
How can the role of physical force in adaptation be replaced pharmacologically?
Why is neoplasm more common in the large intestine than in the small intestine?
Why do APC (Min) mice have more common neoplasms in the small bowel?

Schlafen-3

Schlafen-3 is a member of the Schlafen superfamily, a poorly understood heterogenous group of proteins first described in 1998 as a family of growth regulatory genes that modulate thymocyte development^[243]. Schlafen-3 is not expressed in humans, but could have a functional human ortholog. We recently demonstrated that the Schlafens could play an important role in modulating intestinal adaptation. Schlafen-3 levels increase in parallel with expression of differentiation markers like dipeptidyl dipeptidase activity and villin expression when non-transformed rat intestinal epithelial IEC-6 cells are induced to differentiate in response to repetitive deformation, TGF- β , or sodium butyrate. More importantly, reducing Schlafen-3 by specific siRNA prevents the differentiating effect of each of these stimuli^[240]. This suggests that Schlafen-3 may represent an important common or convergent node in the differentiating signal pathways invoked by these three very different stimuli. Schlafen-3 is also downregulated in the intestinal mucosa of aging rats^[246], but conversely substantially increases in expression between the fetal state over the first few days after birth when the rat intestine is maturing^[247].

Although Patel *et al*^[246] reported that Schlafen-3 slows proliferation, we observed no effect on basal or EGF-stimulated proliferation when modulating Schlafen-3^[240]. This discrepancy awaits exploration *in vivo*. Tracing and triggering the Schlafen-3-dependent pathway may offer a way to selectively promote intestinal epithelial differentiation, either without affecting proliferation or perhaps even synergistically with agents such as GH or Teduglutide to promote both proliferation and differentiation.

Targeting differentiation is clinically important because altering the function of naive cells may promote intestinal function. A recent piglet study replicated multiple previous findings of increased total villus cell numbers over 6 wk of adaptation to massive small bowel resection. However, this study demonstrated a disconnect between

early proliferation and the absence of increased early weight gain. This suggests that the early proliferation of immature enterocytes alone may not suffice for nutrition, and highlights the need to encourage earlier differentiation to optimize clinical gains^[248].

Math1

Although the Schlafen superfamily may promote differentiation toward an enterocytic phenotype, intestinal stem cells also differentiate into goblet cells, enteroendocrine cells, and paneth cells in addition to enterocytes. Although less abundant in the mucosa, these intestinal epithelial cells are also important for optimal mucosal function. Murine knockout studies have identified Math1 as a transcription factor that influences the differentiation of these secretory cell types^[249]. In fact, deletion of Math1 does not disturb the capacity for self-renewal in intestinal epithelium at the crypt base^[250].

Further terminal differentiation is still under intensive investigation. A series of downstream targets influence differentiation toward the endocrine lineage, including NGN3, BETA2, Pax4, and Pax6^[251]. Manipulating these targets may also be important in the future to promote a fully functional mucosa.

CONCLUSION

Intestinal adaptation is an extraordinary phenomenon, induced by diverse pathological and surgical conditions, but not always successful in recreating adequate mucosal function. The long term consequences of such deficits in intestinal function highlight the need for more effective therapy for short gut syndrome directed by investigation into the physiological basis of adaptation. Despite recent progress, current targets are limited. We propose not only continued efforts to stimulate small bowel mucosal proliferation, but also increased investigation into the role of differentiation in adaptation (Table 4). Addressing both proliferation and differentiation multimodally could greatly improve patient outcomes.

Abstract

Gastric cancer and cancer of the gastro-oesophageal junction (GOJ) are the 4th most common cancer diagnoses worldwide with regional differences in incidence rates. The treatment of gastric and GOJ cancers is complex and requires multimodality treatment including chemotherapy treatment, surgery, and radiotherapy. During the past decade considerable improvements were achieved by advanced surgical techniques, tailored chemotherapies/radiotherapy and technical innovations in clinical diagnostics. In patients with advanced or metastatic gastric/GOJ cancer systemic chemotherapy with fluoropyrimidine/platinum-based regimens (+/-human epidermal growth factor receptor-2 antibody) is the mainstay of treatment. Despite these improvements, the clinical outcome for patients with advanced or metastatic disease is generally poor with 5-year survival rates ranging between 5%-15%. These poor survival rates may to some extent be related that standard therapies beyond first-line therapies have never been defined. Considering that this patient population is often not fit enough to receive further treatments there is an increasing body of evidence from phase-2 studies that in fact second-line therapies may have a positive impact in terms of overall survival.

Moreover two recently published phase-3 studies support the use of second-line chemotherapy. A South Korean study compared either, irinotecan or docetaxel with best supportive care and a German study compared irinotecan with best supportive care-both studies met their primary endpoint overall survival. In this "Field of Vision" article, we review these recently published phase-3 studies and put them into the context of clinical prognostic factors helping to guide treatment decisions in patients who most likely benefit.

INVITED COMMENTARY ON HOT ARTICLES

Background

Gastric cancer and cancer of the gastro-esophageal junction are one of the most common cancers in the world with significant impact on health resources^[1]. Extensive

surgery is the therapy of choice in early disease stages and often accompanied by neo-adjuvant and/or adjuvant chemotherapy^[2]. However, a significant number of patients relapse after initial surgery and a large proportion of patients (30%) present with advanced disease. In this setting systemic 5-fluoropyrimidine/platinum based chemotherapy [+/-human epidermal growth factor receptor 2 (HER-2) antibody] has shown to be an effective first-line therapy^[3]. Although first-line therapy is effective in the majority of patients a large proportion has no or limited benefit and may merit further treatment. Over the last decade second-line therapy has been controversially debated as clinical evidence, mostly generated from small, single centre or retrospective studies, was sparse. In this "Field of Vision", we review the results of two recently published trials reporting the benefit of second-line therapy for patients with advanced gastric cancer and put this into the context of current treatment algorithms.

"Field of Vision" commentary

We followed with great interest two recently published papers addressing the use of second-line therapy in patients with advanced gastric cancer.

Briefly, the Arbeitsgemeinschaft Internistische Onkologie (AIO) trial was a prospective, randomised, multicentre, open-label phase-3 study of 40 patients which compared irinotecan ($n = 21$; 250 mg/m² first cycle and 350 mg/m² subsequent cycles, *qw* 3) *vs* best supportive care (BSC; $n = 19$) where crossover into the irinotecan arm was not allowed^[4]. Restaging was performed every 6 wk and toxicity assessed based on the common toxicity criteria version 2.0 (CTCv2.0). Patients were well balanced for performance status (0–≤ 2), pretreatment, primary tumour type, number of metastatic sites, age, however, there was an imbalance in the male:female-ratio in both arms. In total a median number of two cycles was administered (range: 0–9) and 37% of patients in the chemotherapy treatment arm were dose-escalated to 350 mg/m² irinotecan. Irinotecan was generally well tolerated and the main grade 3/4 toxicity was diarrhea (26% of patients)-no treatment related deaths were observed. There was no objective tumour response, however disease stabilisation > 6 wk was documented in 53% of patients and a significant proportion of patients reported improvement of symptoms while on treatment ($n = 9$, 50%). The progression free survival for patients on treatment was 2.5 mo (95%CI 1.6–3.9 mo) with a median overall survival (OS) of 4.0 mo compared to a 2.4 mo OS in the BSC arm [hazard ratio (HR) 0.48, 95%CI 0.25–0.92, $P = 0.012$; one-sided log-rank test]. As a result and supported by evidence from phase-2 studies the German Gastric Cancer national guideline committee approved the use of second-line chemotherapy in patients with advanced gastric cancer.

The second study was recently reported from a group in South Korea where second-line therapy was historically more widely used despite level 3 evidence.

In this prospective phase-3 study, 202 patients with

advanced gastric cancer who received at least one prior therapy were randomised in a 2:1 fashion and received either chemotherapy (irinotecan 150 mg/m², *qw* 2 or docetaxel 60 mg/m², *qw* 3) or best supportive care^[5]. Restaging was performed every 6 wk and toxicity assessed based on the CTCv3.0. Patients were well balanced for performance status (0–1), pretreatment, primary tumour type, number of metastatic sites, age, however, there was an imbalance in the male:female-ratio in both arms. The treatment was generally well tolerated (66 patients, docetaxel; 60 patients, irinotecan; 62 patients BSC). Grade 3/4 toxicities included anemia (30 and 32%), neutropenia (15% and 18%) and fatigue (26% and 10%) in the docetaxel and irinotecan arm, respectively. Anemia, fatigue and anorexia were the most common grade 3/4 toxicities in the BSC arm. After a median follow-up of 20 mo the intention to treat analysis showed an increase in OS from 3.8 mo in the BSC arm (95%CI 3.1–4.5 mo) to 5.3 mo (95%CI 4.1–6.5 mo) with a HR of 0.657 (95%CI 0.485–0.891, $P = 0.007$; one-sided log rank test). There was no difference in the treatment effect of docetaxel and irinotecan; $P = 0.116$. Further exploratory analysis showed that PS (0 *vs* 1), prior chemotherapy (1 *vs* ≥ 2) and chemotherapy-free interval (< 3 mo *vs* > 3 mo) were prognostic factors in the uni- and multivariate analyses.

Both phase-3 studies have shed light into a field which has been discussed controversially for the last few years (Table 1). Despite several limitations in design and recruitment there are several factors which we feel are important to highlight.

First, the two trials showed comparable clinical benefit in two different patient populations^[6]-both, the Western World and Asian population, tolerated treatments generally well and had had similar outcomes in terms of survival.

Second, the different choice of chemotherapy, e.g., weekly docetaxel or irinotecan as seen in the South Korean study, did not impact on outcome and therefore offers treatment choices in this setting. These results were recently supported in abstract format by a Japanese phase-3 study (WJOG4007) including 223 patients with advanced gastric cancer. Patients received either weekly docetaxel (80 mg/m²) or irinotecan (150 mg/m², *qw* 2) and were followed up until progression^[7]. In terms of toxicity both treatment regimens were comparable with grade 3/4 toxicities being: neutropenia (39% *vs* 29%), anemia (17% *vs* 7%) and fatigue (13% *vs* 7%), respectively.

Third, the multivariate analysis in the South Korean study identified clinical important prognosticators (performance status, number of prior chemotherapies and chemotherapy-free interval) which could serve physicians to make adequate treatment decisions. In this context, a recent retrospective study by Hasegawa *et al*^[8] identified additional clinical factors which could support treatment decision, namely PS (0–1 *vs* 2), albumin (> 35 mg/dL *vs* < 35 mg/dL) and time to progression on first-line therapy (> 170 d *vs* < 170 d). According to a prognostic model patients with two or more of these factors would not

Table 1 Clinical decision tool for second-line therapy

Prognostic marker	Treatment action	
	Support treatment	Caution-poor outcome
Albumin (mg/dL)	> 35	< 35
Performance status	0-1	2
Chemotherapy free interval (mo)	> 3	< 3
Time to progression on 1st-line therapy (mo)	> 6	< 6

benefit from second-line therapy.

Fourth, improved understanding of gastric/GOJ tumour biology have opened new avenues in combining chemotherapy with novel molecular targeted agents. For example, expression of the HER-2 has been associated with poor prognosis. Targeting this receptor *via* the monoclonal antibody trastuzumab (Herceptin) has shown improved outcome in the first-line setting in terms of response rates, progression free and overall survival^[9]. Other approaches in targeting the human epidermal growth factor family are *via* tyrosine kinase inhibitors such as lapatinib. Although lapatinib in the second-line setting had limited benefits as single agent the combination with taxanes is thought to have synergistic effects and several phase-2 and a randomised phase-3 trial (TYTAN-Study) are ongoing to test this hypothesis^[10]. Other molecular target drugs currently in the clinical arena are directed against the epidermal growth factor receptor (EGFR)-although results of early trials were ambiguous in unselected patient populations there are signs that selected patients with EGFR over-expression may have better outcome. For example, in pretreated patients the combination of irinotecan with cetuximab or nimotuzumab have resulted in trends towards better outcomes in those patients where EGFR was over-expressed^[11]. Other targets of interest are the oncogene c-Met which encodes the hepatic growth factor receptor and the insulin growth factor receptor-1-both receptors are often over-expressed in gastric/GOJ cancer and are thought to play a critical role in chemotherapy resistance^[12]. An increasing field of interest is the study of biomarker and molecular signatures predicting clinical outcome. For example, an increasing body of evidence suggests that downstream mutations in the Kirsten rat sarcoma viral oncogene or loss of the phosphatase and tensin homolog tumour suppressor gene are associated with poor prognosis and moreover predict inferior outcome in patients who are treated EGFR/HER2 targeted therapies^[13]. Other studies suggest that expression of the pro-apoptotic protein Bcl-2-associated protein X is associated with improved clinical outcome for a variety of chemotherapies including irinotecan and others^[14].

In summary, there is now increasing high-level evidence to support the use of second-line therapy in advanced gastric cancer. In addition easily derived clinical prognostic factors in combination with molecular sig-

natures should guide us in our attempt to rationalise the decision-making process to improve patient outcome.

Abstract

The present study aims to clarify the protective effect of supplementation with some antioxidants, such as idebenone (200 mg/kg, *ip*), melatonin (10 mg/kg, *ip*) and arginine (200 mg/kg, *ip*) and their combination, on liver function (T. protein, albumin, alanine aminotransferase, aspartate aminotransferase and alkaline phosphatase), energetic parameters (adenosine triphosphate, adenosine diphosphate, adenosine monophosphate, inorganic phosphate, total adenylate, adenylate energy charge and potential phosphate). The effect on glycolytic and glycogenolytic enzymes (glucose, glycogen, glycogen phosphorylase, pyruvate kinase and phosphofructokinase against hypoxia) was also studied. The drugs were administered 24 and 1 h prior sodium nitrite intoxication. All biochemical parameters were estimated 1 h after sodium nitrite injection. Injection of sodium nitrite (75 mg/kg, *sc*) produced a significant disturbance in

all biochemical parameters of liver function, energetic parameters and glycolytic and glycogenolytic enzymes. Hepatic damage was confirmed by histopathological examination of the liver as compared to controls. The marked changes in hepatic cells induced by sodium nitrite were completely abolished by pretreatment with the drug combination, suggesting potential protection against sodium nitrite-induced hypoxia. It could be concluded that a combination of both idebenone and melatonin or idebenone and arginine provides potential protection against sodium nitrite-induced hypoxia by improving biochemical parameters and preserving liver histology.

INTRODUCTION

Hypoxia, or hypoxiation, is a pathological condition in which the body as a whole (generalized hypoxia) or a region of the body (tissue hypoxia) is deprived of adequate oxygen supply. Variations in arterial oxygen concentrations can be part of the normal physiology, hypoxia in which there is complete deprivation of oxygen supply is referred to as anoxia. Hepatic tissue is quite vulnerable to

hypoxic injury. The morphological expression of hypoxic injury seems mediated by changes in the cortical cytoskeleton^[1]. Lemasters *et al.*^[2] produced hypoxia in isolated, hemoglobin-free, perfused rat liver by reducing the flow rate of oxygen-carrying fluid entering the organ. This caused anoxia in centrilobular regions. In these anoxic areas, structural derangements developed rapidly, characterized by bleb-like protrusions of hepatocyte plasma membrane through fenestrations in the sinusoidal endothelium. Periportal tissue remained normoxic and was completely spared.

Idebenone (hydroxydecyl benzoquinone), a short chain synthetic analogue of coenzyme-Q10 (CoQ-10), is a vital cell membrane antioxidant and essential constituent of the adenosine triphosphate (ATP) producing mitochondrial electron transport chain. It is a potent antioxidant agent and unlike CoQ-10 has the ability to operate under low oxygen tension situations^[3].

The pineal gland is the main source of melatonin (N-acetyl-5-methoxytryptamine) in the circulation. It is also produced in small amounts in the retina, gastrointestinal system and by leukocytes^[4]. Melatonin (MEL) is tiny^[5] and highly lipophilic, and for this reason, it is found abundantly in all parts of the cell. MEL protects the DNA, lipids and proteins against oxidative damage^[6,7]. The free radical scavenging and antioxidant effects of MEL have been shown in many studies^[8-11].

2-Amino-5-guanidinopentanoic acid (arginine) is an important, versatile and a conditionally essential amino acid. Besides serving as a building block for tissue proteins, arginine plays a critical role in ammonia detoxification, and nitric oxide and creatine production. Arginine supplementation is an essential component for the treatment of urea cycle defects but recently some reservations have been raised with regards to the doses used in the treatment regimens of these disorders^[12].

In the present study, we aimed to compare the protective effects of idebenone, melatonin, arginine, idebenone + melatonin and idebenone + arginine against liver injury through histological (hematoxylin and eosin) and biochemical [T. protein, albumin, alanine aminotransferase (ALT), aspartate aminotransferase (AST) and alkaline phosphatase (ALP), ATP, adenosine diphosphate (ADP), adenosine monophosphate (AMP), inorganic phosphate (Pi), total adenylate (TA), adenylate energy charge (AEC), *potential phosphate* (PO), glucose, glycogen, glycogen phosphorylase, pyruvate kinase (PK) and phosphofructokinase (PFK) parameters] against hypoxia in ameliorating sodium nitrite induced hypoxia in rat livers.

PRINCIPLES AND TECHNIQUE

Drugs and chemicals

Idebenone, melatonin, arginine and sodium nitrite used in this study were analytically pure products of Sigma-Aldrich Chemical Co., St. Louis, MO, United States. All other chemicals were of the highest analytical grade. Sodium nitrite and melatonin were dissolved in normal

Figure 1 Liver section (hematoxylin and eosin × 100 with lateral magnification × 200) showed the normal structure of liver control.

saline, while, idebenone and arginine were suspended in 1% gum acacia in normal saline.

Animals

Adult male albino rats, weighing 180-200 g obtained from the animal house of King Saud University, were used in this study. They were fed with a standard laboratory diet and tap water ad libitum and housed in cages (ten rats per cage). All animals were kept at standardized laboratory conditions ($25 \pm 5^\circ\text{C}$, $55\% \pm 5\%$ humidity, and a 12 h light/dark cycle). One week after acclimatization in the laboratory where experiments were performed, the animals were fasted for 3 h prior to drugs administration. All experiments were carried out according to recommendations of King Saud University of Experimental Animals Ethics Committee which is matched with international ethics for handling of experimental animals. The doses of sodium nitrite, idebenone, melatonin and arginine used in the current study were chosen according to preliminary studies in our laboratory and were matched with those in the literature^[13-16] respectively.

Experimental design

Animals were divided into seven groups ($n = 10$ rats) and were treated as follows: Group I normal group (Figure 1) treated with saline; group II treated with sodium nitrite only^[13] (75 mg/kg, *sc*); group III was administered idebenone^[14] (200 mg/kg, *ip*); group IV was injected with melatonin^[15] (10 mg/kg, *ip*); group V was treated with idebenone (200 mg/kg, *ip*) followed by melatonin (10 mg/kg, *ip*) one hour later; group VI was treated with arginine^[16] (200 mg/kg, *ip*); group VII was treated with idebenone (200 mg/kg, *ip*) followed by arginine. These drugs were injected 24 h and 1 h before sodium nitrite injection.

Liver tissues homogenate

Liver tissue was homogenized in 0.9 mol/L NaCl (1:10 w/v) for the estimation of glucose, total protein, albumin, ALT, AST and ALP. Liver tissue (0.25 g) was homogenized using 7% trichloroacetic acid for the extraction of adenosine nucleotides according to the method of Wijsman^[17]. For estimation of PFK, 0.25 g liver was

Data are expressed as means ± SD of ten rats in each group; a, b, c, d, e, f, g means within columns with no common superscripts differ significantly. Unshared superscript letters between groups are the significance values at $P < 0.05$. Statistical analysis is carried out using one way analysis of variance (ANOVA) using CoStat computer program. AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; ATP: Adenosine triphosphate; ADP: adenosine diphosphate; AMP: Adenosine monophosphate; AEC: Adenylate energy charge; PO: Potential phosphate; PK: Pyruvate kinase; PFK: Phosphofructokinase; Pi: Inorganic phosphate; TA: Total adenylate.

homogenized in 50 mmol Tris HCL, 1 mmol disodium ethylenediaminetetraacetate dehydrate (EDTA) and 5 mmol MgSO₄ at pH 8.2 and then centrifuged for 10 min at 0 °C. The supernatant was used for enzyme assays while 0.25 g tissue was homogenized in 5 mL Tris-HCL buffer pH 7.6 for detection of PK. On the other hand, 0.25 g tissue was homogenized in 100 mmol maleate-NaOH-buffer (pH 6.6) containing 20 mmol NaF, 1 mmol EDTA, 0.5 mg/mL bovine serum albumin and 10 mmol DL-dithiothreitol for estimation of glycogen phosphorylase.

Biochemical studies

Glucose was determined colorimetrically at 505 nm by the method described by Trinder^[18]. Total protein reacts with Bradford reagent to give a blue complex, which is measured calorimetrically at a wavelength of 595 nm (Bradford^[19]). The albumin level was measured according to the method of Doumas *et al.*^[20] using Randox Diagnostic kits. In a buffered solution, bromocresol green forms with albumin; a green colored complex, its intensity is proportional to the amount of albumin present in the sample. ALT was determined according to the method of Reitman and Frankel^[21]. AST was determined according to the method of Reitman *et al.*^[21]. ALP activity was measured photometrically^[22].

Energetic parameter evaluation

ATP was assayed following the procedure of Lamprecht

et al.^[23]. ADP and AMP were assayed in a single assay system according to the method of Jaworek *et al.*^[24].

Calculation of phosphate potential: PO is an alternative index used to indicate the free energy status of the tissues and can be calculated from the concentration of ATP, ADP and Pi according to Van Waarde *et al.*^[25] $PO = [ATP]/[ADP] [Pi]$.

Calculation of total adenylates: $TA = ATP + ADP + AMP$.

Calculation of adenylates energy charge: $AEC = 1/2 [ADP + ATP]/[AMP + ADP + ATP]$. Glycogen content was estimated by the method of Carroll *et al.*^[26] as the green color formed was read at 610 nm against blank. PK was measured according to the method of King^[27]. PFK was estimated according to the method of Zammit *et al.*^[28]. Glycogen phosphorylase was determined according to the method of Hedrick *et al.*^[29].

Histological study

Liver samples were removed and placed overnight in fixative containing 10% formalin, liver were paraffin-embedded for hematoxylin and eosin (HE) staining and cut at 5 μm in the longitudinal plane; liver samples from different groups were named as control (I), hypoxia (II), idebenone (III), melatonin (IV), idebenone + melatonin (V), arginine (VI), idebenone + arginine (VII). Sections

Figure 2 Liver section (hematoxylin and eosin $\times 200$) centrilobular region and periportal region. A: Liver section [hematoxylin and eosin (HE) $\times 200$] centrilobular region; B: Periportal region showed severe morphological changes as a result of giving sodium nitrite; C: Liver section (HE $\times 200$) centrilobular region; D: Periportal region of rats treated with melatonin against sodium nitrite.

were examined under the microscope for the extent of any damage and compared with the control group.

Statistical analysis

The results of biochemical analysis were analyzed using one-way analysis of variance followed by Co-stat computer program. Values of less than 0.05 were regarded as statistically significant.

RESULTS

Biochemical observation

There was a significant reduction in total protein, albumin, AST and ALT of 31%, 18.5%, 52.6% and 39% in the hypoxia group while ALP activity increased in this group (Table 1). All treated groups revealed enhancement of total protein activity of 7.9%, 10.6%, 15.5%, 13.6% and 17% in groups III, IV, V, VI and VII respectively. Albumin was enhanced by 17.6%, 41.6%, 18.6%, 15.8% and 23.5% in groups III, IV, V, VI and VII respectively. AST and ALT activities showed changes of 43%, 40.9%, 24%, 41%, 51% and 46.7%, 35%, 15%, 5%, 50.7% in treated groups III, IV, V, VI and VII respectively. Elevated ALP activity was inhibited by a different amount with different antioxidants.

There was a significant decrease in ATP level in hypoxic rats 59% (Table 1). Treatment of the hypoxic group produced significant amelioration of ATP level by 25.6%, 29%, 45%, 18% and 38% in groups III, IV, V, VI and VII respectively. When we studied hypoxic rats, significant increases of ADP (143%) and AMP (135%) levels were observed. Upon hypoxia, treated rats showed an improvement in ADP and AMP levels by 85.53%, 111.8%, 125%, 72% and 105% respectively for ADP and by 72.5%, 85%, 100%, 47.5% and 85% for AMP and for the same previous treatments respectively. In addition, there was significant reduction in Pi of 58.34% in the hypoxic group. Treated rats showed a significant amelioration of the effects of hypoxia, by 21.7%, 24%, 35.8%, 19.5% and 32% respectively for idebenone, melatonin, idebenone + melatonin, arginine and arginine +

idebenone respectively. At the same time, AEC showed a significant reduction of 24.44%. Significant enhancements of 15.6%, 16.7%, 21%, 11% and 18.9% were observed in treated groups, respectively. Measurements of ATP/ADP, ATP/AMP, PO and TA showed significant reductions in the hypoxic rats of 82.9%, 82%, 59.7% and -31.76%, respectively. Hypoxic groups that received treatment showed significant enhancements in ATP/ADP, ATP/AMP, PO and TA of 24.9%, 35%, 57.6%, 18% and 41%, respectively, for ATP/ADP and of 25.5%, 30%, 47%, 14% and 34%, respectively, for ATP/AMP. Changes in TA detected were 11.18%, 11.76%, 23.53%, 25.29% and 19.41%, respectively, while changes in PO recorded were 24.68%, 37.66%, 54.55%, 16.88% and 36.36% for the same previous mentioned treatments respectively. Glucose and glycogen content showed a marked decrease in the hypoxia group (21% and 61.8% respectively). Treatment with antioxidants changed these decreases to 11.7%, 6.1%, 8.7%, 9.8% and 12.6% respectively, for glucose (Table 1), and 59.9%, 61.7%, 60.7%, 60.9%, and 73.9% respectively for glycogen; while glycogen phosphorylase, PK and PFK enzyme activities showed significant increases in hypoxic rats of 95%, 203% and 292.5% respectively, but these increases were significantly ameliorated after treatment of hypoxic rats with idebenone, melatonin, idebenone + melatonin, arginine and idebenone + arginine. Changes in glycogen phosphorylase were 109%, 126%, 163.6%, 83.8% and 147.5% respectively for each treatment listed above while enhanced levels of PK of 57.5%, 61.8%, 73%, 48.5% and 67.5% were achieved, respectively. Changes in PFK were 138.85%, 166.67%, 268.38%, 143.5% and 207% respectively.

Histological observation

Severe morphological changes were seen in Figure 2A and B particularly in the peri-portal area, compared with Figure 1 control group with normal hepatocyte cells. The hepatocytes were shrunk and vacuolated. The radiating cordlike arrangement of the hepatocytes was disturbed, except in the region around the central veins. Figure 2C and D also showed morphological changes both in the

Figure 3 Liver section (hematoxylin and eosin $\times 200$) of rats. A: Liver section [hematoxylin and eosin (HE) $\times 200$] of rats treated with idebenone against hypoxia; B: Liver section (HE $\times 100$ with lateral magnification $\times 200$) of rats treated with idebenone + melatonin against sodium nitrite showing repairing of liver cells; C: Liver section (HE $\times 100$ with lateral magnification $\times 200$) of rats treated with arginine against sodium nitrite revealing normal hepatocyte; D: Liver section (HE $\times 100$ with lateral magnification $\times 200$) of rats treated with idebenone + arginine against sodium nitrite, showing hepatocytes with normal histological.

Figure 4 Chemical structures of idebenone, melatonin and arginine.

peri-portal and centrilobular regions. The liver cells were swollen and vacuolated and sinusoidal spaces appeared to be obliterated. Figure 3 did not show any marked difference as compared to the control group.

DISCUSSION

Liver injury causes vascular disorganization and local tissue hypoxia starting early in disease course. In this context, hypoxia acts not only as an aggravating factor of cell damage and inflammation, but also as an inhibitor of liver regeneration, a major stimulus of angiogenesis and fibrogenesis, and a promoter of liver carcinogenesis^[30]. Lack of oxygen causes metabolic cell death; increased

oxygen concentrations carry a risk for oxidative damage to proteins, lipids and nucleic acids, possibly initializing apoptosis or carcinogenesis^[31]. The present results demonstrate a reduction in ATP level in the liver of hypoxic rats, accompanied by an increase in ADP and AMP concentrations. This could easily be correlated with the aerobic-anaerobic transition induced by the hypoxia^[32]. The significant reduction in the Pi concentration in hypoxic rats despite the reduced level of ATP could be explained by the fact that, when liver is subjected to metabolic stress, a large amount of phosphate is trapped due to the presence of an abnormally high level of phosphoryl acceptor^[25]. The ATP/ADP ratio revealed that the energy utilization reaction was higher than the energy-generating reaction in the low oxygen state and, in turn, this could confirm the impairment of oxidative phosphorylation in the liver and reduced metabolism^[33]. The significant decrease in PO during the period of hypoxia confirmed the inhibition of Krebs cycle enzymes and the impairment of the electron transport chain^[34]. Liu *et al.*^[35] reported that hypoxia reduced the level of adenylate energy charge, ATP/ADP and ATP/AMP in collaboration with decreased levels of ATP, ADP and AMP due to an increase in the activity of adenylate kinase enzyme. The significant decrease of TA in hypoxic rats may be explained by the finding of a decrease in the ATP level which is considered to be the main contributing part of TA. In concurrence with the current result, Emerling *et al.*^[36] found that cells exposed to anoxia (0 mL/L O₂) show a decrease

in ATP levels. The intracellular ATP level might indeed direct AMP catabolism either towards IMP or adenosine. Jyoti *et al*^[37] demonstrated that hypoxia activates AMP-activated protein kinase (AMPK) signalling independent of a decrease in both ratios.

AEC is a linear measure of the ratio of ATP concentration to total adenylate concentration, which ranges in value from 1 in the fully charged state to 0. Paradoxically, high values of AEC are often associated with high toxicant exposures, and low AEC values with low exposure. These discrepancies may be caused by the inability of AEC measurements to adequately evaluate cytosolic adenylate concentrations, which are the critical parameters in enzymatic regulation^[38].

The present results also demonstrated a significant increase in PK, PFK and glycogen phosphorylase in the liver of hypoxic rats. In parallel results Solaini *et al*^[39] found that the AMPK pathway, which causes increases glycolysis, is driven by enhanced catalytic efficiency of some enzymes, including phosphofructokinase-1 and pyruvate kinase. The marked reduction in glucose and glycogen, while a significant increase in glycolytic enzymes PK, PFK was detected in liver tissue of hypoxic rats, may be due to an increase in metabolic activity in liver of hypoxic rats to compensate the inhibition of Krebs cycle caused by hypoxia. The increase in anaerobic glycolysis might be attributed to the activation of PFK due to decreased citrate formation provision of energy due to inhibition of the Krebs cycle and decreased nicotinamide adenine dinucleotide, oxidised form (NAD)/nicotinamide adenine dinucleotide, reduced form (NADH) (NAD/NADH) ratio due to inhibition of mitochondrial oxidation which favours the conversion of pyruvate to lactate^[40] with respect to glycogen phosphorylase, as glycogenolytic enzyme, it showed an enhanced activity in hypoxic rats which was attributed to degradation of stored glycogen inhibition of translocase, the glucose-6-phosphate transport protein^[41].

Milusheva *et al*^[42] reported that ATP, ATP/ADP and AEC were significantly decreased in the absence of glucose (glucose deprivation) and ascertained that hypoxia is combined with glucose and glycogen deprivation and inhibition of the glycolysis and glycogenolytic pathways. The lack of glucose is a common factor contributing to the reduction in ATP level and AEC. This agrees with the well-known fact that during anoxia oxidative phosphorylation is impaired while ATP production proceeds *via* anaerobic glycolysis. During metabolic stress, AMPK, a highly sensitive indicator of cellular energy status, leads to an increase in ATP synthesis and inhibition of anabolic pathways to limit ATP consumption during periods of exercise or hypoxia^[43]. AMPK downregulates ATP-consuming pathways, such as glycogen, cholesterol, and fatty acid synthesis^[44]. However, Ou *et al*^[45] declared that the evidence for increased glucose utilization under hypoxic conditions is equivocal. For example, rats acclimated to chronic hypoxia do not alter the capacity for anaerobic glycolysis in skeletal muscle, but rather increase

the capacity for fatty acid metabolism, possibly sparing carbohydrate metabolism for severe hypoxic conditions. Significant amelioration was detected upon treatment of hypoxic rats with idebenone, melatonin, idebenone + melatonin, arginine and arginine + idebenone with a fluctuating percent of amelioration, where the hypoxic rats receiving combined treatment of idebenone + melatonin showed the best result followed by idebenone + arginine. In agreement with the present findings, idebenone has been reported to preserve non-protein thiols, and inhibit lipid peroxidation in rat brain during post-cardiac arrest reperfusion^[46]. Idebenone also may indirectly reduce oxidative brain stress by elevating nerve growth factor^[47] which acutely blocks reactive oxygen species (ROS) formation in the brain^[48]. On the other hand, idebenone treatment suppressed leukocyte-enhanced cold ischemia/reperfusion injury of liver endothelium through almost complete suppression of the endothelial constitutive nitric oxide synthase mRNA expression after reperfusion^[49]. Moreover, idebenone treatment reduced nitric oxide (NO) generation and apoptosis in hepatocytes treated with toxic bile salt glycochenodeoxycholate. Acute reduction in cerebral oxygen delivery is known to lead to the breakdown of neuronal energy metabolism^[50]. Additionally, high concentrations of ROS, resulting from impaired oxidative phosphorylation or electron leakage, eventually leads to ATP depletion^[51]; this is in contradiction with this study in which the ATP level was markedly reduced in hypoxic liver tissue.

On the basis of these data, we can hypothesise that the induction of melatonin during or post hypoxia could be a defensive mechanism by which hepatic cells contrast these alterations. To support this hypothesis, Nagaoka *et al*^[38] reported that, melatonin, a lipophilic compound, acts directly or indirectly on ROS production; in fact, melatonin can directly scavenge free radicals or it can induce antioxidant enzymes *via* a specific melatonin receptor. These results could be attained in support of the presenting results that idebenone, melatonin or idebenone + melatonin produced obvious improvement in all the measured parameters in the liver of hypoxic rats, with a greater effect being seen with combined treatment. Glycogen synthesis, which is located in cytosol, depends on the uridine triphosphate supply and hence on ATP supplies resulting from both mitochondrial oxidative phosphorylation and cytosolic glycolysis^[3]. L-arginine has a protective role against ROS attack due to its direct chemical interaction with superoxide anions^[52]. Data from the L-arginine treated group suggests that a pharmacologic increase in NO levels did not exacerbate the increase in free radical formation. In fact, a high level of NO/or L-arginine itself in the L-arginine treated group may be protective, probably due to their ability to scavenge free radicals as well as inhibit xanthenes oxidase (XO) enzyme^[53]. Idebenone and/or L-arginine treatment ameliorated the depleting effect of nitrite-induced hypoxia on brain ATP content, suggesting that their protective effect may be mediated through improving the cerebral energy metabolism^[54]. In

addition, its role in scavenging ROS and inhibiting lipid peroxidation could be an important factor in improving the mitochondrial respiratory chain. Studies have shown that under cellular low oxygen conditions idebenone prevents the free radical damaging effect and maintains relatively normal cell ATP levels^[55]. The present data support these facts as the decrease in brain ATP content in hypoxic rats was accompanied by a significant increase in brain malondialdehyde (MDA) content and serum uric acid concentrations. L-arginine supplementation has been proven to significantly reduced the increased in cardiac XO activity, MDA levels, and serum uric acid caused by exhaustive exercise in rats^[56].

Hepatocytes in normal rats had a normal chromatin structure with round nuclei. The quantity and the structure of the mitochondria in the cytoplasm was normal. Liver pathophysiology consists of many mechanisms that have an impact on liver damage at different levels. The morphological alterations of liver histology detected in hypoxic rats induced severe alterations in the liver, such as congestion, sinusoidal and lymphatic expansion, regional hepatocellular vacuolization and hepatocyte swelling. These results are in agreement with those of previous studies^[10]. Liver injury was repaired when idebenone, melatonin, arginine, idebenone + melatonin and idebenone + arginine were administered.

In accordance with previous results^[57] which revealed that melatonin exerts a beneficial role in restoring tissue alterations after subjection to hypoxia (Figure 4).

In conclusion, a combination of idebenone + melatonin and idebenone + arginine yields significantly better results than idebenone, melatonin or arginine alone. They are likely responsible for liver tissue protection in hypoxic rats through their action on NO generation, reduction as well as scavenging of ROS, maintenance of normal enzymatic and non-enzymatic antioxidant systems, and improvement of energy production.

Therefore, the current findings may have important implications in the development of therapeutic strategies aimed at manipulating either idebenone + melatonin and l-arginine + idebenone supplementation for amelioration of hypoxic liver injury.

Abstract

Obstructive jaundice occurs in patients suffering from cholelithiasis and from neoplasms affecting the pancreas and the common bile duct. The absorption, distribution and elimination of drugs are impaired during this pathology. Prolonged cholestasis may alter both liver and kidney function. Lactam antibiotics, diuretics, non-steroidal anti-inflammatory drugs, several antiviral drugs as well as endogenous compounds are classified as organic anions. The hepatic and renal organic anion transport pathways play a key role in the pharmacokinetics of these compounds. It has been demonstrated that acute extrahepatic cholestasis is associated with increased renal elimination of organic anions. The present work describes the molecular mechanisms involved in the regulation of the expression and function of the renal and hepatic organic anion transporters in extrahepatic cholestasis, such as multidrug resistance-

associated protein 2, organic anion transporting polypeptide 1, organic anion transporter 3, bilitranslocase, bromosulphophthalein/bilirubin binding protein, organic anion transporter 1 and sodium dependent bile salt transporter. The modulation in the expression of renal organic anion transporters constitutes a compensatory mechanism to overcome the hepatic dysfunction in the elimination of organic anions.

INTRODUCTION

The kidney and the liver play the major role in the elimination of drugs. No common rules exist for the preference of kidney or liver in the elimination of drugs. While for some compounds one of these two routes is the dominant excretory pathway, for certain other substances both the kidneys and the liver play an important and

overlapping role as excretory organs^[1,2].

The relationship between renal and hepatic excretion of xenobiotics depends on the integrity of the elimination mechanisms. Impairment of liver or kidney function can be followed by compensation *via* the alternative elimination route, changing the relationship between renal and hepatic excretion of drugs^[1-3].

Since 1990, several membrane transport proteins have been cloned and characterized^[4-6]. Organic anion transporters (OATs) are located in the barrier epithelia of diverse organs, where they mediate the absorption and excretion of a wide range of metabolites, signaling molecules, and xenobiotics. The presence of overlapping substrate specificities among the different OAT isoforms suggests a possible role in remote signaling. Substrates excreted through one OAT isoform in one organ are taken up by another OAT isoform located in a different organ, thereby mediating communication between different organ systems. Ahn *et al.*^[7,8] have developed a “remote sensing and signaling hypothesis”. They suggested how the regulation of solute carrier 22 subfamily members (including those of the organic cation, organic carnitine, and unknown substrate transporter subfamilies) can be better understood by considering the organism’s broader need to communicate between epithelia and other tissues by simultaneous regulation of transport of metabolites, signaling molecules, drugs and toxins.

On a mechanistic basis, cholestasis usually is divided into “extrahepatic” and “intrahepatic” forms^[9-11]. The first refers to obstruction of large bile ducts outside the liver, for instance due to gallstones, while the causes of intrahepatic cholestasis lie within the liver. The main clinical manifestations and characteristics of “intrahepatic” and “extrahepatic” cholestasis are similar^[11,12]. It is possible to separate the two kinds of cholestasis by means of a careful evaluation of clinical, serologic, and histologic features. The mechanisms underlying the development of cholestasis in patients can be extremely varied. Intrahepatic cholestasis has multiple causes. Among these, familial cholestasis, drug-induced cholestasis, and many processes that affect bile formation/excretion and finally produce cholestasis, could be cited. Obstruction of the biliary tree due to gallstones or hepatic or biliary tumours causes stagnation of bile flow. Actually, patients with gallstones or tumours in the common biliary tract generally suffer from extrahepatic cholestasis. A well-established model of cholestasis in rodents is obtained by performing double ligation and division of the common bile duct (BDL). In animal models, a decrease in bile flow is associated in general with elevated cholestatic serum markers, altered liver histology and changes in liver functions related to sinusoidal and canalicular transport. Indeed, prolonged cholestasis alters the liver function due to an impaired uptake, changed biotransformation and secretion of compounds^[12]. In fact, cholestasis has been shown to alter the transport of the bile salts and of other organic anions^[9,11,13]. Moreover, altered absorption, distribution and elimination of drugs have been described in

this pathology^[4].

In obstructive jaundice, adaptive mechanisms may permit urinary excretion of those potentially toxic compounds that could not be eliminated by the liver because biliary transport is impaired^[4,10,11]. The modulation in the expression of renal OATs constitutes a compensative mechanism to overcome the hepatic dysfunction in the elimination of organic anions.

The expression and function of several transporters in kidneys and livers from rats with obstructive cholestasis will be reviewed. These transport proteins are as follows: (1) multidrug resistance-associated protein 2 (MRP2); (2) organic anion transporting polypeptide 1 (OATP1); (3) OAT3; (4) bilitranslocase (BTL); (5) bromosulphophthalein (BSP)/bilirubin binding protein (BBBP); (6) OAT1; and (7) sodium dependent bile salt transporter (ASBT).

MRP2, OATP1, OAT3, BTL and BBBP are expressed in kidney and liver, while OAT1 and ASBT are not expressed in liver. Their membrane localization is shown in Figure 1.

MRP2

Several members of MRP are expressed in liver and kidney tissues^[10,14]. They are known to function as ATP-dependent pumps for a broad range of organic anionic substrates. MRP2 is an efflux transporter that mediates the transfer or translocation of a wide variety of potentially toxic endogenous and exogenous compounds, including bilirubin, drugs, and carcinogens, in the form of amphiphilic anionic conjugates by an ATP-dependent mechanism^[10,14]. This efflux pump is also involved in BSP-conjugated derivatives and p-aminohippurate (PAH) transport^[15-18]. It has been localized on the apical membranes of hepatocytes, renal proximal tubular cells and jejunal cells, and is implicated in the excretion of different organic anions^[19].

During cholestasis, the canalicular conjugate export pump MRP2 exhibits a reduced expression that may contribute to impaired hepatic excretion of bile acids and other biliary constituents such as conjugated bilirubin^[20,21]. Thereafter, in obstructive jaundice, adaptive mechanisms may permit the liver to adapt to the higher burden of biliary constituents in part by altering the expression of hepatobiliary transporters. In fact, in order to limit hepatocellular accumulation of toxic compounds, upregulation of hepatocellular basolateral efflux pumps have been described^[10,13,22,23]. Afterwards, alternative elimination routes, such as *via* urine, might provide the only pathway to excrete these compounds from the body.

Under conditions of deficient hepatobiliary secretory function, an induction of renal proximal tubular MRP2 expression has been reported. Lee *et al.*^[13] demonstrated an upregulation in MRP2 protein expression in kidneys as early as one day after BDL. Moreover, renal MRP2 function has been studied by PAH clearance in a rat model of obstructive jaundice by Tanaka *et al.*^[24]. They described a significant increase in PAH clearance 24 h after BDL that

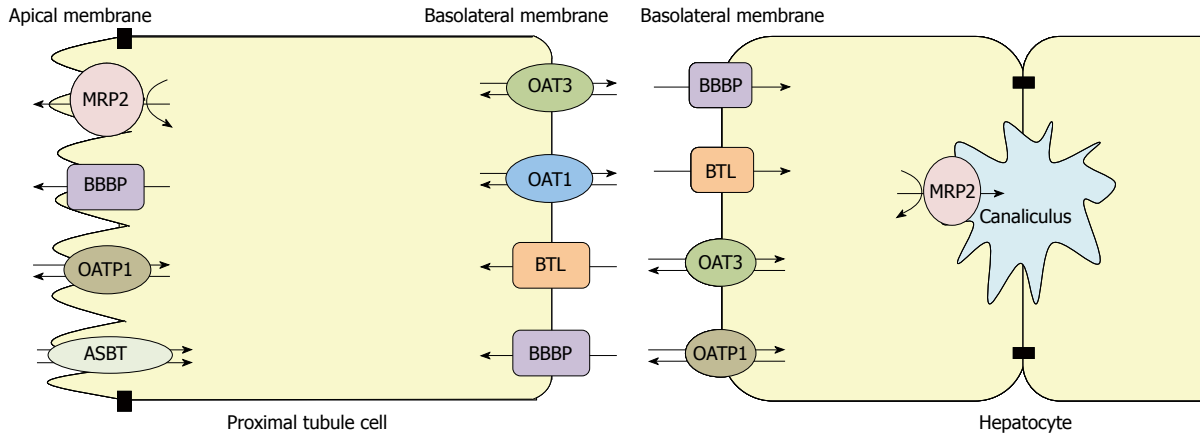

Figure 1 Membrane localization of organic anion transporters in hepatocytes and proximal renal tubule cells from rat. MRP2: Multidrug resistance-associated protein 2; OATP1: Organic anion transporting polypeptide 1; OAT: Organic anion transporter; BTL: Bilitranslocase; BBBP: Bilirubin binding protein; ASBT: Sodium dependent bile salt transporter.

was associated with high levels of renal MRP2 expression. In this study, in contrast to the liver where MRP2 protein and mRNA expression were downregulated after BDL, the protein and mRNA expression of MRP2 were significantly increased in the kidneys 24 h after BDL. They proposed that the increased renal MRP2 expression might be an alternative pathway for accelerating excretion of bilirubin conjugates during obstructive cholestasis. In order to gain insight into the mechanism by which BDL affects renal and hepatic MRP2 expression they also evaluated the effects of synthetic conjugated bilirubin, sulfate-conjugated bile acid, human bile, and unconjugated bilirubin on human MRP2 expression in an *in vitro* system using different cell lines. They described that mRNA expression of MRP2 increased in human renal proximal tubular epithelial cells after treatment with conjugated bilirubin, sulfate-conjugated bile acid or human bile. On the other hand, mRNA expression of MRP2 did not change in a human hepatoma cell line (HepG2 cells) compared with controls after the same treatments. These findings suggest that these substrates might regulate renal MRP2 expression by a cell-specific mechanism.

Downregulation of MRP2 in both liver and intestine from rats undergoing extrahepatic cholestasis might be explained by the increased levels of the inflammatory cytokine interleukin-1 β (IL-1 β) observed in these animals^[20,21]. These increased levels of IL-1 β would lead to decreased binding of RAR α :RXR α nuclear receptor dimer to the promoter region of MRP2 in BDL rats, which in turn downregulates MRP2 expression in the liver. In contrast, BDL rats exhibited upregulation of expression and function of MRP2 in the kidney, which likely results from preserved levels of RAR α :RXR α dimer in this tissue.

Villanueva *et al.*^[25] have reported an increased renal tubular conversion of 1-chloro-2,4-dinitrobenzene to its glutathione conjugate dinitrophenyl-S-glutathione (DNP-SG), followed by subsequent MRP2-mediated secretion into urine that partially compensates for altered liver function in experimental obstructive cholestasis.

At this point, it is noteworthy to mention that we have found increased BSP and PAH renal excretion in our experimental model of BDL in rats^[26-28], which in turn might be also explained by the upregulation of renal MRP2 expression^[29].

Finally, obstructive cholestasis leads to an upregulation of the apical transporter MRP2 in the kidneys that would be involved in the increased secretion into urine of organic anions, including BSP, PAH and DNP-SG. The current data demonstrate the relevance of renal elimination as an alternative pathway, particularly under conditions of impaired hepatobiliary secretory function, as occurs in obstructive cholestasis, for excreting those toxic compounds that the liver could not eliminate by itself from the body. Together, all these findings provide further evidence that transporters are regulated in cholestatic liver disease in a manner that facilitates extrahepatic mechanisms for organic anions excretion.

OATP1

OATP are members of a group of multispecific transporters with a wide spectrum of amphipathic substrates, including endogenous compounds and clinically important drugs^[30]. OATP1, the first member of this group of transporters identified, was isolated from rat liver and shown to mediate Na⁺-independent saturable transport of BSP^[31,32]. Nowadays, the sequences of almost 160 different members of OATP superfamily in over 25 animal species can be found in GenBank^[4].

Several members of this family of polypeptides are expressed in liver and kidneys, among others organs. In hepatic tissue, OATP1 is found at the basolateral membrane of hepatocytes where it plays an important role in the Na⁺-independent uptake of a wide variety of compounds, including bilirubin, BSP and conjugated and unconjugated bile acids^[33]. In contrast, in the kidneys, OATP1 is located at the apical membrane of the proximal tubules, specifically in the S3 segment, and has been

suggested to play a role in the secretion/reabsorption of selected anionic substrates, although its renal physiological function remains unclear^[4,30,32,34]. It could participate in the reabsorption of organic compounds that are filtered, like estradiol-17 β -glucuronide, or in the secretion process of some organic compounds that were taken up into tubular cells across the basolateral membrane^[34,35]. It is interesting to emphasize that renal secretion of BSP, a characteristic substrate for OATP1 transport, is negligible in non-pathological conditions.

Regulation of OATP1 expression and function occurs at both transcriptional and post-transcriptional levels, being tissue specific. Higher OATP1 renal expression in males than in females has been demonstrated in rodents probably as a result of testosterone stimulation and estrogen inhibition. On the other hand, hepatic OATP1 expression is not influenced by sex hormones^[10,34,36,37]. Phosphorylation of this transporter, in serine residues, by extracellular ATP produces its functional down regulation^[38,39]. In addition, protein kinase C (PKC) activation leads to a decreased transport of estrone-3-sulfate in OATP1 expressing *X. laevis* oocytes^[33,40].

The consequences of cholestasis, produced by BDL, are hepatic and systemic accumulation of potentially toxic biliary compounds, which are associated with progressive liver damage and jaundice^[41]. OATP1 hepatic mRNA and protein expression are downregulated in this pathology, with a less pronounced decrease in mRNA expression. This could be due to OATP1 protein having a longer half-life than its mRNA, but the occurrence of a post-transcriptional mechanism cannot be dismissed^[33,42]. It has been proposed that the observed OATP1 down-regulation could be due, at least in part, to a toxic effect of bile constituents retained in the hepatocyte. It was also proposed that this phenomenon might be explained as a protective feedback mechanism to prevent uptake of possible hepatotoxic bile constituents^[42]. In this model, the hepatic mRNA expression levels of cytochrome P450, transporters and conjugation enzymes were found altered. It has been suggested that increased bilirubin and fatty acid levels produced in cholestasis could modify the mRNA and protein levels of the constitutive androstane receptor and peroxisome proliferator-activated receptor α in the nucleus, altering the mRNA expression of several transporters, like OATP1^[43].

In obstructive cholestasis, several proinflammatory cytokines are released in the organism, such as tumor necrosis factor α (TNF- α) and IL-1 β . Cytokine-inactivation studies have demonstrated the existence of a TNF- α -dependent signaling pathway that mediates the down-regulation of the OATP1 gene, at mRNA and protein levels^[33].

Geier *et al.*^[33] also found unaltered kinetic parameters in Na⁺-independent bile salts (cholate and taurocholate) uptake in the presence of decreased OATP1 expression in extrahepatic cholestasis. In addition, they found that other sinusoidal OATPs, OATP2 and OATP4, have preserved expression in cholestatic hepatocytes, suggesting

that, in this pathology, Na⁺-independent bile salts uptake is mediated by OATP2 and OATP4 rather than OATP1, to compensate for its downregulation. This may be related to continuous elimination of other organic anions which also play an important role in determining cholestatic liver injury.

We have shown that BDL rats have a higher OATP1 protein renal expression at apical membranes despite no change in OATP1 abundance in kidney homogenates^[27]. These results could suggest altered OATP1 trafficking, as a result of an increased recruitment of preformed transporters into the membranes where they are functional, or impairment in the internalization of membrane transporters. These results indicate that the kidneys are able to adapt rapidly to obstructive cholestasis, since BSP renal elimination has been shown to increase almost 30-fold during the first day after induction of BDL. Renal adaptation to cholestasis could be due to an upregulation of the transport capacity of OATP1 in the proximal tubules. This increase in OATP1 protein expression at the apical membrane of renal cells may be a compensatory mechanism for reducing injury to hepatocytes or renal epithelia from cytotoxic substances that may accumulate in rats with obstructive cholestasis.

It is also important to emphasize that differential processing and trafficking of the OATP1 transporter in liver and kidney may have important functional and regulatory consequences. A complex series of hormonal changes in kidneys are induced in extrahepatic cholestasis^[44], which could affect OATP1 regulation. Several systemic and local factors are produced at the same time during cholestasis, and the role of such factors in the regulation of channels and transporters in renal cells is still unknown. Most likely, the accumulation of bilirubin, bile acids and other potential toxics existing in this cholestatic model may affect transcriptional regulation (e.g., fetal transcription factor, pregnane X receptor) and post-transcriptional regulatory mechanisms^[45].

In conclusion, the presented data shows that extrahepatic cholestasis induced by BDL in the rat produces renal OATP1 protein units redistribution into apical membranes from renal cells^[27] and a diminished OATP1 expression in the liver^[33,42]. Moreover, this probable adaptation to hepatic injury, particularly in elimination of biliary components, could possibly explain, at least to some extent, the huge increase in BSP renal excretion observed in this experimental model.

OAT3

Human and rat OAT3 is expressed primarily in the kidneys and to a lesser extent in the brain. In rats, OAT3 is also found in the liver^[46]. In the kidneys, immunohistochemistry studies showed that OAT3 protein is localized at the basolateral membrane of proximal tubule cells^[47,48]. Rat OAT3 was also observed in cortical and medullary thick ascending limb of Henle's loop, connecting tubules, and cortical and medullary collecting ducts^[49]. OAT3 was

characterized as an organic anion/dicarboxylate exchanger^[50,51]. This protein has the ability to transport PAH, estrone sulfate (ES), ochratoxin A, estradiol glucuronide, benzylpenicillin, cimetidine, glutarate and taurocholate. Although the selectivity of OAT3 overlaps that of OAT1, the affinity for the different substrates could permit discrimination between both transporters. Several studies demonstrated that ES is a specific substrate for mammalian OAT3 with moderately high affinity, whereas OAT1 interacts little with ES^[52-55]. Accordingly, ES is frequently used as a test substrate for OAT3 activity. Sweet *et al.*^[56] reported reduced uptake of PAH, ES, and taurocholate in renal cortical slices and nearly complete inhibition of transport of the fluorescent organic anion fluorescein in intact choroid plexus in OAT3 knockout mice.

The effects of obstructive cholestasis on the cortical renal expression of OAT3 and the consequences of these effects on the pharmacokinetics and renal excretion of PAH and furosemide (FS) were described by Brandoni *et al.*^[26,57] employing male Wistar rats. Results showed that rats at 21 h after BDL exhibit an enhanced systemic and renal clearance of both PAH and FS. At variance with OAT1 expression (as described below), Western blotting studies showed that OAT3 protein expression was increased significantly only in homogenates and not in basolateral membranes from renal cortex in BDL rats. These results were confirmed by immunohistochemical techniques. The upregulation observed for both OAT1 and OAT3 in this model of acute jaundice, could explain, at least in part, the increased systemic and renal elimination of PAH and FS. In addition, the production of various cytokines and growth factors that may affect gene transcription is associated with extrahepatic cholestasis^[58].

The function and expression of OAT1 and OAT3 were also studied by Brandoni *et al.*^[59] after 3 d of biliary obstruction. It was well documented that serum bile acids and bilirubin levels reach a peak after 3 d of BDL^[13,24,60]. A significantly lower renal clearance of PAH was observed after this period of time in rats with obstructive jaundice. In contrast to OAT1, OAT3 was increased both in homogenates and basolateral membranes from renal tissue after 3 d of BDL. As well as OAT1, both human and rat OAT3 transport PAH with relatively high affinity (87 $\mu\text{mol/L}$ and 65 $\mu\text{mol/L}$ respectively)^[6,47,61,62]. On the other hand, it was described, using *in vivo* and *in vitro* techniques, that OAT3 but not OAT1 has as substrates ES, cholate, and taurocholate^[6,47,56,61-63]. Furthermore, whereas OAT1 is limited to proximal tubules, OAT3 is expressed in different parts of the nephron^[48]. In extrahepatic cholestasis, the high plasma levels of bile acids compete with PAH for OAT3 transport, therefore, upregulation of OAT3 does not compensate for the downregulation of OAT1 in PAH transport^[59,64]. The expression of a number of genes implicated in the transport of bile salts is regulated by bile acids^[65,66]. In this sense, and as another example of substrate-specific regulation, it is possible that OAT3 overexpression would be regulated by high

bile acid levels, while OAT1 expression would be down-regulated.

Urinary excretion is the principal route of excretion of bile acids in obstructive jaundice. It was found that OAT3 mediated the renal secretion of bile acids such as cholic acid, glycocholic acid and taurocholic acid, which are mainly increased during cholestasis^[55,67]. The pharmacokinetic profile of its substrates could also be affected by cholestasis^[67]. Eisai hyperbilirubinemic rats (EHBR) are mutant rats lacking MRP2. Serum and urinary concentrations of total bile acids in EHBR rats are higher than those in wild-type Sprague-Dawley rats. It was described that OAT3 protein in renal plasma membranes was overexpressed in EHBR rats whereas OAT1 expression was unchanged. In addition, rat and human OAT3 transport activities are notably inhibited by diverse bile acids such as chenodeoxycholic acid and cholic acid but OAT1 is not. Cefotiam is also a specific substrate for OAT3. Some authors found that cefotiam clearance was reduced in EHBR despite upregulation of OAT3. This may be due to the inhibition of cefotiam transport *via* OAT3 by elevated serum bile acids. In summary, these results suggested that renal OAT3, but not OAT1, plays a critical role in the adaptative responses to the renal handling of bile acids in cholestasis.

Northern blot analyses demonstrated that OAT3 mRNA is expressed in rat liver, although such expression is not detected in mouse liver^[56,68]. Nevertheless, Buist *et al.*^[69], using branched DNA analysis, reported hepatic OAT3 mRNA expression in mice. In addition, gender differences in OAT3 mRNA expression in liver tissue were shown in both mice and rats^[56,69,70]. It was described also that the hepatic isoform of OAT3 may be the major contributor OAT in the basolateral uptake of organic anions in rats^[71]. Human OAT3 messenger is not expressed in liver.

We have observed in liver plasma membranes from rats with acute obstructive jaundice of 21 h, no differences in OAT3 protein expression when compared with sham rats^[72].

All these results might suggest the involvement of different regulatory mechanisms for OATs in obstructive cholestasis. To minimize liver injury, adaptive or protective responses to damage in the hepatobiliary transport of organic anions would appear, or reduced uptake into hepatocytes or enhanced efflux into the circulation. The observed changes could respond to increased intracellular levels of compounds that are normally excreted in the bile duct or to alterations in the levels of cytokines and other mediators in the liver, as previously described^[13,73,74].

To summarize, OAT3 could play a considerable pathophysiological role in protecting tissues from cholestatic damage by stimulating the renal secretion of bile acids. Indeed, ursodeoxycholic acid (UDCA) has been introduced as cholestatic liver disease therapy^[75]. It is possible that increased serum bile acids and/or administration of UDCA could influence the tubular secretion of

anionic drugs *via* OAT3 as was evidenced for cefotiam. Therefore, more attention should be paid to prevent the occurrence of drug interactions or drug-induced toxicity.

BTL

BTL is a bile pigment transporter that was originally isolated from rat livers^[18,76]. It is also expressed in kidney and stomach. BTL mediates the electrogenic hepatic uptake of cholephilic organic anions, such as BSP and thymol blue, the tetrapyrrole bilirubin, and flavonoids (the anthocyanin malvidin 3-glucoside and the flavonol quercetin)^[18]. BTL has been demonstrated to be involved in the renal transport of BSP, bilirubin and anthocyanins^[77,78]. In this way, BTL contributes to the hepatic and renal excretion of exogenous organic anions (such as BSP), endogenous metabolites (such as bilirubin) and anthocyanins (flavonoid-based pigments present in fruits and vegetables used in the human diet, which have been reported to be positively implicated in human health^[18,78]).

The protein expression and the functional activity of BTL was evaluated in rats with an early phase of acute extrahepatic cholestasis (21 h post BDL), by Western blotting and by measuring BSP electrogenic uptake, respectively, in liver plasma membrane and in renal basolateral membrane vesicles^[28]. No modifications were detected in BTL protein expression and in its activity in liver plasma membrane vesicles from BDL rats. In contrast, extrahepatic cholestasis caused a marked increase in renal BSP uptake, which was due to an increase in V_{max} (capacity). The difference in V_{max} suggests that a higher number of functional carrier units exists in renal basolateral membrane vesicles from BDL rats, which is in agreement with the higher expression of BTL detected in renal basolateral membranes. BDL rats have a higher renal expression of BTL at the basolateral membranes despite no change in kidney homogenates. This suggests an impairment in BTL trafficking.

These results suggest that the complex series of hormonal changes induced in kidneys by extrahepatic cholestasis^[44] might influence the regulation of BTL. The characteristic accumulation of bile acids, bilirubin, and other potential toxins in cholestasis may affect transcriptional and posttranscriptional regulatory mechanisms^[33,79] of BTL in kidneys. In this connection, as has been mentioned earlier, bilirubin, sulfate-conjugated bile acid and human bile upregulate the expression of MRP2 in renal tubular cells but not in liver cells^[24].

In summary, the higher expression and function of BTL observed in renal basolateral membranes from rats with obstructive cholestasis may also contribute to the marked increase in BSP renal excretion described in this experimental model. This would be another compensatory mechanism to overcome the hepatic impairment in the excretion of organic anions.

BSP/BBBP

The transporter protein BBBP has been isolated from

rat liver and described as an organic anion carrier protein involved in the well-known sodium-independent hepatic uptake of BSP and bilirubin^[80-83]. BBBP exhibits electroneutral transport as indicated by experiments in liver plasma membrane vesicles. In kidneys, BBBP has been localized in both apical and basolateral membrane domains, being implicated in PAH tubular transport^[84].

In rats with obstructive cholestasis, we have found an increased expression of BBBP in homogenates and in basolateral membranes from kidney cortex with no change in its apical membrane expression^[29,85,86]. These results might suggest an increase in the synthesis or a decrease in the degradation of this membrane transporter, while the trafficked protein would be preferably directed to the basolateral domain as no changes have been observed in the protein expression of BBBP in the apical membrane. As a consequence of hepatic function impairment, alterations in the renal elimination of organic anions were observed. Connected to this, we have also demonstrated a significant increase in renal excretion of two different organic anions in rats with extrahepatic cholestasis, BSP, an organic anion mainly excreted by the liver and PAH, an organic anion mainly excreted by the kidney. These observations could be explained, at least in part, by the higher basolateral membrane expression of BBBP described in this experimental model of acute cholestasis^[29,85,86].

As has already been mentioned, BBBP is a protein isolated from the sinusoidal membranes of rat liver. In liver plasma membranes from rats with extrahepatic cholestasis of 21 h, we have demonstrated no difference in BBBP abundance compared to sham animals^[85,86]. Modifications in hepatic excretion of organic anions have been demonstrated in rats with extrahepatic cholestasis^[9,10,13]. However, BBBP might not be involved in this observation since no change in its abundance was found in this experimental model in rats.

To this extent, it is noteworthy to remark on the relevant role of this kind of transporter, such as BBBP, in renal elimination of those organic anions excreted mainly by the liver, in the presence of obstructive cholestasis. In fact the increased renal abundance of the organic anion carrier BBBP, observed in rats with obstructive jaundice, might improve renal capacity to eliminate distinct negatively charged compounds, especially those that could not be removed by the liver.

OAT1

OAT1 is a key organic anion/ α -ketoglutarate exchanger^[48,87]. OAT1 is expressed predominantly in the kidneys, and weakly in the brain, and no expression has been described in the liver^[52,53,55,64]. This protein has been immunolocalized at the basolateral surface of the proximal tubule. OAT1 mediates the transport of many compounds (dicarboxylates, nucleotides, prostaglandins, antivirals, loop and thiazide diuretics, β -lactam antibiotics, non-steroidal anti-inflammatory drugs, including the prototypical substrate of the classical pathway, PAH)^[53,55]. Eraly *et al.*^[63] have

generated a colony of OAT1-knockout mice, permitting the elucidation of the role of OAT1 in the context of other potentially functional transporters. They found that the knockout mice manifested a profound loss of organic anion transport (e.g., PAH) both *ex vivo* (in isolated renal slices) as well as *in vivo* (as indicated by loss of renal secretion). The loss of renal secretion in knockout animals resulted in impaired diuretic responsiveness to furosemide^[63]. These results indicate an important role for the OAT1 transporter in the handling of organic anions by the classical pathway.

It has been reported that upregulation of OAT1 protein expression in rats at an early phase of acute obstructive cholestasis might explain the increased renal elimination of PAH and FS^[57]. We have also reported an increase in the systemic clearance of PAH associated with an increase in the abundance of OAT1 in renal cortex homogenates in rats during the early phase of acute extrahepatic cholestasis^[26,88].

FS is a loop diuretic secreted through the organic anion transport system. The capacity of the organic anion transport system to secrete a diuretic determines its intraluminal concentration, which is decisive of the diuretic activity. OAT1 and OAT3 are responsible for FS delivery to its site of action, since these proteins are involved in the renal tubular secretion of this diuretic^[55,89]. The protein expression of OAT1 was significantly increased both in cortical homogenates and in basolateral membranes from kidneys after 21 h of BDL^[26,57]. In fact, clearance and urinary excretion of PAH were both higher in BDL rats. Connected to this, PAH uptake rate^[57] was increased in basolateral membrane vesicles from BDL rats. OAT1 upregulation was also associated with a concomitant increase of systemic and renal FS clearance.

Similar studies were performed by Brandoni *et al.*^[59] after 3 d of obstructive cholestasis (the peak of elevation of serum bile acids and bilirubin). After this time, BDL rats displayed a decrease in the renal elimination of PAH. OAT1 protein expression in kidney homogenates was not modified, but was decreased in basolateral membranes. This study demonstrated, once more, the key role of OAT1 expression in the impaired elimination of PAH after 3 d of BDL. So, the evolution time of obstructive cholestasis has an important impact in the regulation of OAT1.

It has been described that bile acids and high bilirubin levels can activate PKC^[55,90]. We therefore postulate that the peak of elevation of bile acids and bilirubin (demonstrated after 3 d of BDL) can also trigger PKC activation. It has been described that PKC induces OAT1 downregulation through carrier retrieval from the cell membrane. This PKC activation may cause the phosphorylation of caveolin-2, which may induce the internalization of caveolae with OAT1 protein anchored with caveolin, as has been described by Kwak *et al.*^[91].

In summary, in this experimental model during an early phase of acute extrahepatic cholestasis where no evident renal cell injury exists yet, OAT1 upregulation as-

sociated with an increase in renal organic anion elimination was demonstrated. The protein expression of OAT1 was significantly increased both in cortical homogenates and in basolateral membranes from kidneys after 21 h of BDL, which might suggest an increase in the synthesis or a decrease in the degradation of this membrane transporter. In this experimental model, OAT1 upregulation may occur in order to enhance renal secretion of toxic compounds that are not eliminated by the liver in a pathological state. Connected to this, Tanaka *et al.*^[24] found that bilirubin ditaurate, sulfate conjugated bile acids, and some components of human bile upregulate the expression of MRP2 in human renal tubular cells. Moreover, we found an increased ³H-PAH uptake by S2 cells expressing OAT1 incubated with bilirubin ditaurate^[92].

Contrary to what has been described in an early phase of acute extrahepatic cholestasis, OAT1 expression significantly decreased in the basolateral membranes from kidneys after 3 d of BDL^[59]. It has been suggested that there is an increase in the internalization of membrane transporters or an inhibition in the recruitment of preformed transporters into the membranes. This study stressed, once more, the critical role of OAT1 renal expression in the excretion of organic anions, such as PAH, in a model of extrahepatic cholestasis in rats.

ASBT

ASBT is expressed in the ileum, in the cholangiocytes and in the kidneys^[93-96]. Bile acids, after secretion with bile into the small intestine, are nearly completely reabsorbed in the terminal ileum. They return with the portal venous blood to the liver where they are taken up and re-secreted into the bile. About 10%-50% of the reabsorbed bile acids avoid hepatic uptake and enter in the peripheral circulation. Around 10%-30% of the bile acids, present in the blood plasma, are subject to glomerular filtration. Urinary excretion of bile acids is much smaller than the amount filtered due to the tubular reabsorption of the filtered bile acids^[10,97]. Thus, the kidneys also take part in the recirculation process and aid conservation of bile acids. Tubular reabsorption of bile acids is accomplished by ASBT, which is expressed in the apical membrane of proximal tubule cells^[95,96].

Lee *et al.*^[13] have described decreased taurocholate transport in brush border membrane vesicles derived from rat kidneys after 14 d of BDL. The reduced taurocholate uptake was associated with a reduction of renal ASBT protein expression.

After one day of obstructive cholestasis, Schlattjan *et al.*^[98] demonstrated reduced taurocholate transport in proximal tubular cells without changes in the amount of the transport protein in these cells. The diminished taurocholate transport in this early phase of cholestasis may be mediated by a change in the phosphorylation status and hence the activity of ASBT and/or by a redistribution of the transporter between the plasma membrane

Figure 2 Protein expression of organic anion transporters in hepatocytes and proximal renal tubule cells from a rat with extrahepatic cholestasis of 21 h. PM: Plasma membranes; MRP2: Multidrug resistance-associated protein 2; OATP1: Organic anion transporting polypeptide 1; OAT: Organic anion transporter; BTL: Bilitranslocase; BBBP: Bilirubin binding protein; ASBT: Sodium dependent bile salt transporter.

and intracellular compartments of the proximal tubular cells. These studies have demonstrated that there is a functional adaptive downregulation of renal ASBT leading to enhance renal clearance of bile acids during the early phase of obstructive cholestasis.

Figure 2 shows a summary of the protein expression of the above mentioned transporters in liver and kidney from rats with extrahepatic cholestasis of 21 h.

CONCLUSION

Altered expression of different transporter proteins of organic anions have been described in liver and kidney from rats with extrahepatic cholestasis. MRP2 and OATP1 abundances were decreased while no changes were detected for BBBP, BTL and OAT3 protein expressions in hepatocytes from BDL rats. On the other hand, in proximal tubule renal cells, increased protein expressions were observed for OAT1, BTL, BBBP; MRP2 and OATP1. In contrast, a diminished abundance of renal ASBT was found in this experimental model to prevent reabsorption of excess bile acids that were eliminated in the urine. This pattern in renal cells may be a compensatory mechanism to increase the elimination of compounds that could not be excreted by the liver in this pathological state.

ACKNOWLEDGMENTS

The authors thank Professor Endou H and Anzai N (Department of Pharmacology and Toxicology, Kyorin University School of Medicine, Tokyo, Japan) for kindly providing OAT1 and OAT3 specific antibodies, to Professor Passamonti S (Department of Life Science, Trieste University, Italy) for kindly providing BTL specific antibodies and to Professor Stremmel W (Medizinische Universitätsklinik, Heidelberg University, Germany) for kindly providing BBBP specific antibodies.

hepatic resection in relationship with tumor burden were compared with those of available competing strategies, namely, radiofrequency ablation for early stages, and trans-arterial chemoembolization for intermediate and advanced stages. Finally, the choice for anatomical versus non-anatomical, as well as the role of laparoscopic approach, was overviewed. The literature review suggests that partial hepatectomy for HCC should be considered in the context of multi-disciplinary evaluation of cirrhotic patients. Scientific research on HCC has moved, in recent years, from surgical therapy toward non-surgical approaches and most of the literature regarding topics debated in the present review is represented by observational studies, whereas very few well-designed randomized controlled trials are currently available; thus, no robust recommendations can be derived.

Abstract

Hepatocellular carcinoma (HCC) is one of the most frequent neoplasms worldwide and in most cases it is associated with liver cirrhosis. Liver resection is considered the most potentially curative therapy for HCC patients when liver transplantation is not an option or is not immediately accessible. This review is aimed at investigating the current concepts that drive the surgical choice in the treatment of HCC in cirrhotic patients; Eastern and Western perspectives are highlighted. An extensive literature review of the last two decades was performed, on topics covering various aspects of hepatic resection. Early post-operative and long-term outcome measures adopted were firstly analyzed in an attempt to define an optimal standardization useful for research comparison. The need to avoid the development of post-hepatectomy liver failure represents the "conditio sine qua non" of surgical choice and the role of the current tools available for the assessment of liver function reserve were investigated. Results of he-

INTRODUCTION

Hepatocellular carcinoma (HCC), the most common primary malignancy of the liver, represents the fifth most common cancer in men and the seventh in women^[1].

The incidence of HCC varies widely in the different geographic areas according to the regional variations in exposure to risk factors for this tumor^[1-14]. Overall, 75%-80% of HCCs are attributable to chronic hepatitis B virus (50%-55%) or hepatitis C virus (25%-30%) infections^[3-7]. Chronic alcohol abuse, obesity, and diabetes have also been recognized as important risk factors, as well as hereditary hemochromatosis, primary biliary cirrhosis and several hereditary metabolic conditions^[8-14]. In all etiologies there is a male gender predominance^[1,8-14]. Most HCCs ensue in a cirrhotic liver, although the association rate between cirrhosis and HCC may range from 60% up to 90% in relation to the relative prevalences of the risk factors, that greatly differ worldwide^[5].

Risk stratification has been proposed to identify patients who benefit from surveillance for HCC occurrence^[5,13]. Indeed, surveillance can detect the tumor at early stages, amenable to curative treatments. The increasing use of surveillance in clinical practice and the advancements in diagnostic ability achieved in the last decades have greatly improved HCC management and patient survival^[15,16]. Liver resection still remains a mainstay of HCC treatment, being a potentially curative approach not only for early stage HCCs but also for some lesions not amenable to liver transplantation. Thanks to the considerable improvements in surgical techniques and perioperative care, the rates of death and complications after liver resection have remarkably decreased over time, giving added value to this procedure^[17,18]. In addition, the long-term survival after liver resection has been improved by the increased accuracy in detecting recurrences at early stages and the availability of potentially curative approaches even for patients no longer amenable to surgical re-treatment^[19]. The present review examines concepts driving the therapeutic choice for HCC toward hepatic resection in cirrhotic patients, and its results in both the Western and Eastern world.

SELECTING ADEQUATE OUTCOME MEASURES

Early outcome measures

The most feared complication of hepatic resection is the development of post-hepatectomy liver failure (PHLF) which is the main cause of perioperative mortality. Currently, there is no standardized definition of PHLF that allows an unequivocal comparison of results from different studies^[20]. This can explain, at least in part, the great variability of PHLF incidence, ranging from 1.2% to 32%, although differences in populations and surgical procedures may have contributed to this disparity^[21-28]. The analysis of the postoperative course of liver tests demonstrates that serum bilirubin and INR ordinarily return within the normal range on postoperative day 5, including patients who have undergone major resections and those with cirrhosis^[29,30]. A first attempt to standardize the definition of PHLF was made by Balzan *et al.*^[31]. In

an unselected population including patients with primary and secondary liver tumors undergoing elective surgery (12% only with cirrhosis), the authors observed that the association of prothrombin time < 50% and serum total bilirubin > 50 µmol/L (2.9 mg/dL) on post-operative day 5 was a strong predictor of mortality ("50-50 criteria"). Namely, patients who met this criterion had a 59% early postoperative mortality rate, compared with 1.2% found in their counterparts. The usefulness of such a definition is boosted by the selection of simple and objective criteria, while its drawbacks are: (1) the lack of a grading system able to segregate several strata at increasing death risk; and (2) the late identification (only on post-operative day 5) of a category with a huge mortality rate. Thus, PHLF definition needs to be better graded and detected earlier to be of clinical utility.

In 2010, the International Study Group of Liver Surgery performed an extensive literature search and proposed to define post-hepatectomy liver failure as "the impaired ability of the liver to maintain its synthetic, excretory, and detoxifying functions, which are characterized by an increased international normalized ratio and concomitant hyperbilirubinemia (according to the normal limits of the local laboratory) on or after post-operative day 5"^[20]. On the basis of this definition, the severity of PHLF should be graded based on its impact on clinical management (as the Dindo-Clavien classification^[32]): grade A requires no change of the patient's clinical management; grade B needs the clinical management of patients to deviate from the regular course but not to require invasive therapy; grade C claims invasive treatment, for example liver transplantation^[20]. Such a grading system overcomes the 50-50 criteria limits and well depicts the post-surgical course of patients; however, it is not liver specific, also being influenced by non-hepatic complications.

Long-term outcome measures

When selecting endpoints for studies, it should be considered that cirrhotic patients with HCC represent a peculiar oncologic category as their prognosis relies not only on the tumor burden but also on the severity of underlying liver disease. According to the guidelines released by the Panel of Experts in HCC-Design Clinical Trials, overall survival should be considered as the primary end-point for phase III trials^[33]. The document discourages the use of cancer-related mortality since it is a more subjective endpoint, particularly in HCC patients, in whom it can be difficult to ascertain the role played on mortality by the concurrent cirrhosis. Since the high rate of HCC recurrence is the main factor affecting survival after partial hepatectomy, many studies report composite endpoints including this adverse event, such as disease-free survival. However, such a composite endpoint can make the results unreliable because imbalance between groups in deaths, resulting from the natural history of cirrhosis, can mask the real benefit

provided by surgery (type II error). Therefore, disease-free survival should be considered as a tertiary endpoint (indirect surrogate), and its use as main endpoint necessarily implies a restrictive selection of patients with well-preserved liver function to minimize the impact of death unrelated to tumor progression^[33]. As mentioned above, tumor recurrence represents the main obstacle in achieving better results from hepatic surgery and recent efforts were directed toward adjuvant therapies aimed at reducing such an event^[34-36]. In these scenarios, *time-to-recurrence* or *recurrence-rate* can be used as primary and/or secondary end-points for phase II and III HCC studies assessing the outcome of hepatic resection and the utility of such therapies, such as sorafenib, capecitabine or interferon-based therapies^[34-36]. Even if there is currently no high level evidence for efficacy of any adjuvant protocols proposed until now, the correct choice of clinical endpoints is essential to detect an actual treatment advantage^[37].

ASSESSMENT OF LIVER FUNCTION RESERVE

HCC ensued in a cirrhotic liver represents an extremely heterogeneous clinical condition in which several treatments may potentially be considered, according to the tumor stage and liver function^[38]. The assessment of the latter is therefore essential in selecting the optimal strategy to adopt. The estimation of hepatic functional reserve before liver surgery is aimed at achieving proper patient selection and predicting, on an individual basis, the safety limit of the parenchymal resection. This may be performed with different tools.

Child-Turcotte-Pugh classification

The Child-Turcotte-Pugh (CTP) score is a simple system for grading liver function based on five easily measurable variables and has been considered a gold standard for more than four decades for selecting candidates for surgical resection. Indeed, there is general agreement that, in cirrhotic patients belonging to CTP class A, surgical resection can be safely performed. However, even Child-Pugh class A patients may develop hepatic decompensation following surgery due to limited functional hepatic reserve^[21,23,26]. Thus, the CTP score is not able to identify, among class A patients, those with an elevated risk of post-surgical liver failure, a drawback that can be defined as a “floor effect”. Other tools for assessing the underlying liver disease of candidates for surgery are therefore proposed.

Model for end-stage liver disease score

The model for end-stage liver disease (MELD) score was developed for survival prediction of patients undergoing the transjugular intrahepatic portosystemic shunt procedure^[39] and has been principally adopted for selecting patients for liver transplantation^[40]. The use of MELD for

predicting surgical risk in the non-transplant setting has provided good results, and it may thus ultimately supplant the CTP classification as the method for determining surgical risk. Evidence has been provided that good candidates for partial hepatectomy should have a MELD score ≤ 10 ^[23,41-43]. These patients will not experience mortality or post-hepatectomy liver failure and will have very low morbidity. Above this threshold, the morbidity rate is very high (up to 50%), with an unacceptable probability of developing irreversible hepatic failure (up to 15%) and dying (up to 29%)^[23,41-43]. Thus, patients with a MELD score > 10 should be considered for hepatic resection only in the setting of salvage transplantation^[23]. The pros of adopting the MELD score are represented by the fact that it does not require any extra-routine evaluation; the cons are represented by the fact that this score, being developed on a population quite different from surgical series^[39], requires further validation before being universally adopted in this setting.

Indocyanine green clearance test

The indocyanine green (ICG) clearance test is a popular liver function test in Asia. The cut-off of ICG retention rate at 15 min (ICGR-15) after intravenous injection of the dye that allows safe major hepatectomy is 14%^[44]. Indeed, the safe cut-off value for major hepatectomy can be pushed to 17% and to 22% for minor hepatectomy; limited resection may be allowed for ICGR-15 values up to 40%^[45-47]. However, these suggested thresholds derive from populations including cirrhotic and non-cirrhotic patients^[45-47] and to what extent these cut-offs are applicable to cirrhotic patients remains unsettled. The ICG test may overcome the above mentioned drawbacks of the CTP score system. Indeed, about 65% of CTP class B patients have been shown to have an ICGR-15 $< 22\%$ ^[48]; thus, the evaluation on the basis of the Child-Pugh classification only would lead to the exclusion of a large proportion of CTP B patients from surgery^[47]. The ICG R15 was recommended (grade B strength) for assessing liver function before surgery in the recent Japanese evidence-based clinical guidelines for the treatment of hepatocellular carcinoma^[49]. Indeed, ICGR-15 is easily applicable to all patients, and represents a routine exam in Eastern countries. Nevertheless, this test is unpopular in Western countries, and this drawback limits the reliability of its results in a clinical scenario where higher proportions of hepatitis C infected and cirrhotic patients can be expected as compared with Eastern countries.

In the setting of hepatic resection, there is no study that compared the utility of MELD score and ICGR-15, or challenged their combination against each single test. A recent report, comparing MELD score and ICGR-15 in the prognosis of a cohort of 395 cirrhotic patients not undergoing surgery, suggested that ICG half-life was the most accurate in predicting survival^[48]. This result was at variance with a smaller study conducted on 90

patients with decompensated cirrhosis reporting a better prognostic accuracy of the MELD score^[50]. Comparative data on MELD and ICGR-15 in the field of hepatic resection are warranted.

Hepatic vein portal gradient

The presence of clinical signs of portal hypertension implies a more advanced liver disease and, consequently, a poorer long-term outcome after hepatic resection. The Barcelona Clinic Liver Cancer (BCLC) group recommends hepatic resection only in patients without clinically significant portal hypertension, i.e. with a hepatic vein portal gradient (HVPG) < 10 mmHg^[13]. This is supported by data obtained in a small cohort (77 patients) studied in the 1990s^[51] and without external validation until recently^[52]. Data from 39 patients, 46% of whom with cirrhosis, undergoing hepatic resection after HVPG measurement showed a higher incidence of post-operative liver dysfunction and ascites in patients with HVPG > 5 mmHg^[52]. However, the small sample size and the proposed HVPG cut-off, that is roughly equivalent to the lowest value observed in cirrhotic patients of 6 mmHg^[53], do not help in clarifying the true usefulness of HVPG in the selection of candidates for hepatic resection. It can be said that the HVPG measurement can probably select surgical candidates, belonging to CTP class A, with a very low probability of post-operative hepatic decompensation; however, the drawback is represented by the exclusion of patients that can still benefit from surgery. In fact, there is growing evidence, coming from large Western^[54,55] and Eastern series^[56], that the presence of clinical signs of portal hypertension does not affect early postoperative and long-term survival in selected patients.

The BCLC group defines clinical signs of portal hypertension as the presence of esophageal varices at endoscopy or splenomegaly (major diameter > 12 cm) with a platelet count < 100 000/mm³ and, for these authors, the detection of these signs should contraindicate hepatic resection^[57]. In keeping with modern Western and Eastern perspectives, the presence of portal hypertension should not be considered an absolute contraindication for hepatic resection in patients with well compensated cirrhosis, belonging to Child-Pugh A or with a MELD score < 10^[54,55]. In fact, complications associated with portal hypertension, such as bleeding from variceal rupture and hemostatic disorders caused by thrombocytopenia, can be safely managed by applying appropriate pre- and peri-operative treatments^[28,58].

Future remnant liver volume and extension of hepatectomy

There is general agreement that, for patients without chronic liver disease, the minimal residual liver volume able to prevent severe postoperative hepatic dysfunction ranges from 20% to 30%^[59]. Conversely, the safe limit for liver resection in chronic liver disease and cirrhosis is

not well established. Very few studies, all published in the 1990s, investigated the prognostic role of future remnant liver (FRL) volume in cirrhotic patients. Shirabe *et al.*^[60] analyzed 80 patients with chronic liver disease (50% cirrhotics) who underwent major liver resection and showed that all liver failure-related deaths occurred in patients with a FRL volume < 250 mL/m². The authors therefore concluded that this FRL volume may be considered the safe limit for major liver resections.

More recently, most studies and treatment algorithms have been focused on the extension of hepatectomy as a surrogate of the FRL volume. A decision tree for hepatectomy procedure, very popular in Japan, has been proposed by Makuuchi *et al.*^[61]. This surgical algorithm has indeed improved the operative mortality and morbidity in HCC patients. The decision tree is based on 3 variables: absence/presence of ascites, serum bilirubin level and ICGR-15. Patients with ascites or high bilirubin level are considered not candidates for hepatic resection. In the remaining cases, the maximal extent of hepatectomy is calculated according to the ICGR-15 value as previously reported. Using this decision tree, a post-operative mortality close to zero has been reported^[61-63]. Thus, the ICGR-15 test might be useful for discriminating good and poor risk CTP A patients. There is also some evidence that the MELD score could be used to guide the extent of hepatectomy^[43]. In particular, data from a Western dual-center study suggest that patients with MELD score < 9 could be safely submitted to major hepatectomy with a risk of PHLF below 1%, and that serum sodium can add some information for cases with borderline MELD values (9 and 10): in the presence of a value < 140 mmol/L, resection should be limited to segmentectomy or wedge resection^[43].

Other liver function tests

Several other quantitative estimations of liver function, based on the hepatic clearance of substrates, have been proposed to predict the outcome of resection. Substrates include lidocaine, galactose, aminopyrine, amino acid and methacetin. Such tests have not been shown to be superior to the ICG clearance test in predicting liver failure or complications after surgery, and have never been compared to HVPG or MELD score^[47].

There is an interesting seminal experience, conducted on 72 patients, regarding the predictive role of transient elastography^[64]. The stiffness cut-off selected by receiver operating characteristics (ROC) curve analysis was 25.6 kPa, which gave the best statistical accuracy (sensitivity 71.4%; specificity 88.6%; positive predictive value 55.6%; negative predictive value 93.9%). It should be noted that the positive predictive value was quite low, whereas the negative predictive value was very high. Thus, liver stiffness would adequately identify patients who will not develop post-operative hepatic insufficiency while it has a suboptimal ability in identifying patients that should be excluded from surgical option because of a high risk of

post-hepatectomy failure. In this series, the area under the ROC curve of liver stiffness measurement was not statistically higher than that of ICGR-15, probably as a consequence of large confidence intervals. Given the increasing interest in elastography in relationship with different outcomes of cirrhotic patients, a possible role in pre-operative evaluation of surgical candidates seems reasonable^[65].

TUMOR STAGE

Cancer staging should serve to estimate the prognosis, select the most appropriate primary and adjuvant therapy for each stage, and assist in comparing results of different treatments or coming from different patient series. Ultimately, an accurate cancer stage can help physicians in managing oncologic patients and scientists in exchanging unambiguous information. According to the European Association for Study of the Liver (EASL) recommendations, a staging system for HCC should take into account four issues: tumour burden, degree of liver function impairment, general condition, and treatment efficacy^[13,15]. Indeed, staging of HCC is complex and, currently, there is no universally accepted staging system^[66]. The consensus conference of the American Hepato-Pancreato-Biliary Association (updated in 2010) re-proposed the use in clinical practice of different systems for different patients^[67]: as survival of early stage patients is greatly modified by treatment, prognostic prediction must include treatment-related variables; conversely, as treatment may not be a key predictor in advanced stages, it may not be a crucial variable of a prognostic index for patients with these tumors. Nowadays, clinicians can choose among several staging systems, although it should be underlined that only the BCLC staging system provides a treatment algorithm linked to the HCC stage.

Early stage tumors

According to the BCLC definition, a very early HCC is represented by single nodule < 2 cm, and an early HCC is a tumor fulfilling the Milan criteria at imaging techniques (one nodule \leq 5 cm or 3 nodules each \leq 3 cm, without vascular or lymph nodal invasion)^[57]. In CTP class A patients, survival after hepatic resection for early HCC reaches 70% at 5 years, and up to 90% for very early HCC^[68]; however, whether to prefer, in these patients, hepatic resection over liver transplantation, or percutaneous treatments such as radiofrequency ablation (RFA), still remains a matter of debate^[69,70]. Thus, the actual role of hepatic resection should be viewed in the light of such competing strategies.

The literature comparing the results of hepatic resection versus RFA for early HCC encompasses a number of retrospective studies, some case-control studies and only two randomized controlled trials (RCT), both coming from the Eastern world^[71,72]. The first one, conducted on 161 CTP class A patients with a solitary tumor \leq 5 cm, reports similar survival rates after surgery (90 pa-

tients) and percutaneous treatments (71 patients), with 4-year survival rates of 68% and 64%, respectively (5-year survival rates were not reported)^[71]. Also, DFS was not affected by the treatment adopted either in the whole population or in the subgroups of patients with tumors < 3 cm and between 3.1 cm and 5 cm^[71]. The second RCT was conducted on 230 patients with HCC meeting the Milan criteria, 6.1% of whom belonging to CTP class B^[72]. The authors found that resection (115 patients) was significantly superior to RFA (115 patients) in terms of both 5-year survival (75.7% *vs* 54.8%, respectively) and 5-year recurrence-free survival (51.3% *vs* 28.7%), and this was confirmed in post-hoc analyzes focused on individuals with solitary HCCs \leq 3 cm, those between 3.1 and 5 cm, as well as with multifocal tumors^[72]. Thus, the two RCTs provide conflicting results making it impossible to propose robust recommendations. Nevertheless, when observational studies are also considered, a trend seems to emerge toward better overall and disease-free survivals after resection. In fact, the 5-year survival rate of surgical patients with early HCC can be estimated to be around 70% while the rate of those submitted to RFA is around 60%; the difference is much more striking for the 5-year DFS, the figures being around 60% and 20%, respectively^[69,70]. However, the considerable heterogeneity among studies regarding both patient selection and results does not make it possible to reach definite conclusions on this topic. Pertinently, it should be noted that a recent multicenter prospective cohort study, in patients with a single tumor \leq 2 cm and potentially amenable to hepatic resection, reported a complete response (without local recurrence) in 97% of cases after RFA, and a 5-year survival rate up to 75%^[73]. In another study considering 104 of these patients, the 5-year survival rate achieved with resection and RFA was excellent (> 80%) and equivalent after correction to the one-to-one propensity analysis model for the confounding factors^[74].

Therefore, it can be said that in patients with early HCC, RFA provides a worse DFS as compared with hepatic resection, so that the need for retreatment is greater. Instead, hepatic resection and RFA would achieve similar results in very early HCCs. However, the drawback of RFA in terms of radicality is somehow counterbalanced by lower mortality, morbidity and costs (shorter hospital stay) and the easy repeatability of ablation. On the other hand, Markov models indicate that in HCC early stages, hepatic resection should be considered in the case of RFA local failure^[75] and that surgery provides better quality of life-adjusted survival, due to the lower risk of local recurrent disease requiring retreatment^[76]. Taken together, these observations suggest that hepatic resection and RFA should be considered as complementary rather than competitive treatments. In cases of deep tumor location, that require a removal of a large volume of parenchyma if resected (i.e., major hepatectomy), it is reasonable to consider RFA as the preferred strategy to adopt; conversely, superficial tumor location or tumors adjacent to main vessels or biliary structures, are

much better managed with hepatic resection. Nonetheless, for many experts, recommending RFA as first-line therapy for resectable small HCCs still requires a higher level of evidence^[77]. Such uncertainty is highlighted by the conclusions of the conference of the Japan Society of Hepatology held in 2009^[78]: to the question “Which treatment would you perform for 2-cm sized HCC nodules in patients with Child-Pugh A liver function?” 80% of surgeons responded “resection”, while 68% of non-surgeons responded “RFA”^[78]. Greater agreement was observed when asking about the optimal treatment of 3-cm sized nodules in patients with Child-Pugh A: 95% of surgeons and 79% of non-surgeons responded “resection”^[78].

As already stated, the role of hepatic resection in early stage HCC should be viewed in the light of competing strategies, and liver transplantation (LT) represents the most attractive alternative option because it removes both detectable and undetectable tumor nodules together with the pre-neoplastic cirrhotic background. However, LT use should be viewed in the context of shortage of available grafts, and decisions must consider, together with the benefit for the individual patient, the collective benefit of all potential liver recipients^[79]. Liver transplantation achieves excellent results in patients with limited tumor burden. Patients with HCC fulfilling Milan criteria have a 5-year survival of about 70%, with recurrence in less than 10%. This survival well matches post-transplant survival of most other indications for LT^[80,81]. This is a critical point, recalled by Recommendation No. 7 of the International Consensus Conference on Liver Transplantation for HCC, held in Zurich in 2010, which states that LT should be reserved for HCC patients who have a predicted 5-year survival comparable to non-HCC patients^[79]. When compared to LT, partial hepatectomy would seem to be inferior in terms of long-term survival, but most surgical series rely on patients who underwent resection of a wide spectrum of tumor extent, frequently beyond the Milan criteria. Notably, factors precluding LT, such as large or multifocal tumors and vascular invasion, are often included in series analyzing resection results, and are associated with early recurrence and shorter survival^[82]. There is evidence that hepatic resection and LT can indeed achieve similar post-operative and intention-to-treat survivals in patients respecting Milan criteria^[82]. Thus, when patients with more limited disease are selected, the results of hepatic resection are much more favorable, approaching the 5-year survival rate of 70% reported after LT^[19,83-85]. It should be considered that this figure is the end-result currently achievable thanks to both improved diagnostic imaging and therapies for recurrences, including salvage LT, that have been shown to significantly prolong survival after partial hepatectomy^[19]. Thus, the combination of resection and salvage LT seems to be a reasonable strategy to adopt for resectable HCC within Milan criteria^[86]. This strategy could also increase the proportion of grafts offered to

non-HCC candidates on the waiting list^[87].

Beyond the early stages of the tumor

Beyond the early stages, there is debate on the ability of the current staging systems in segregating patients into homogeneous prognostic strata able to assist clinicians in selecting the optimal treatment strategy. The BCLC intermediate stage (BCLC-B) includes patients in Child-Pugh class A or B, with multi-nodular or large HCC, and preserved performance status^[57]. This definition includes a very heterogeneous patient population, according to either tumor extent (from bifocal HCC to subtotal tumor replacement of liver parenchyma) or liver function (from perfectly compensated to decompensated cases with ascites and hyperbilirubinemia). The recommended treatment modality for this HCC stage by both EASL and American Association for the Study of Liver Diseases guidelines is trans-catheter arterial chemoembolization (TACE). Instead, due to the heterogeneity of this stage, patients are best served when the treatment decision is individualized and taken within a multidisciplinary team^[88,89]. Indeed, retrospective analyses have shown that, in BCLC stage B patients, hepatic resection yielded better survival rates than TACE^[90-92]. Stage B, but even stage C, patients can tolerate hepatic resection showing low mortality, acceptable morbidity, and survival benefits^[90]. The reported 3-year survival rate ranges from 56% to 74% for stage B and from 28.6% to 67% for stage C patients^[90-92]. Especially in stage B, resection is superior to the TACE in terms of survival^[57,91]. A very recent case-control study, conducted on a population of 603 patients (1:2 ratio), has shown that in patients with a portal vein tumor thrombus (PVTT) within segmental branches (type I) or the right or left portal vein (type II), resection provides a significant survival benefit in comparison to TACE^[93]. In particular, in the presence of type I PVTT, the 5-year survival rate was 37.9% after resection and only 3.6% after TACE; in the presence of type II PVTT, the corresponding figures were 17.2% and 0%, respectively. These results suggest a revision of the BCLC recommendations^[89]. Although the BCLC staging classification has been claimed as standard HCC classification in Western regions, its validation across Eastern and Western regions is required and some refinements are probably needed before it can be accepted for universal application. Indeed, most Asian experts state that the BCLC staging system does not satisfy the needs of surgeons and physicians in real clinical practice^[94]: when participants of the Japan Society of Hepatology were asked if they usually follow the BCLC treatment algorithm, 70% responded “no”^[78]. It should also be noted that resection is not excluded as an option for HCCs beyond the early stages in the Asian treatment algorithms^[94] and in real clinical practice about half the physicians include resection as a treatment choice, albeit in cases of advanced HCC^[79,95].

TYPE OF SURGICAL RESECTION

Anatomical vs non-anatomical resection

It remains unclear whether hepatectomy for HCC should be performed as anatomical resection (AR) or non-anatomical resection (NAR). The great majority of recurrences occur in the liver as a result of subclinical metastases, originating from the primary tumor through microscopic vascular invasion and peripheral spread along their intra-segmental branches, which are the most important factors associated with poor prognosis^[19,96,97]. On this basis, the systematic removal of the hepatic segment fed by tumor-bearing portal tributaries, namely the entire functional unit through an AR, was suggested as theoretically more effective for tumor and metastases eradication^[98]. Conversely, most surgeons prefer, in cirrhotic patients, to leave a portion of parenchyma greater than the functional unit, using the NAR, to reduce the risk of postoperative liver failure. Clear evidence of the superiority of one technique over the other is not available, since some studies report a survival benefit of AR^[99-101] that was not manifest in others^[102-104]. Two recent meta-analyses, conducted on observational studies, also reported conflicting results^[105,106]. Importantly, underlying cirrhosis was significantly more common in the NAR patients who also showed more advanced hepatic dysfunction compared with those in the AR group: these features were recently shown by a meta-regression approach to significantly affect results from meta-analyses, that is, patient survival and DFS after AR seem to be superior to NAR because the worse liver function reserve in the NAR group significantly affects prognosis^[107]. Thus, large randomized controlled trials are needed to define the best resective approach to patients with an HCC ensuing in a cirrhotic liver^[107].

Laparoscopic resection

In contrast to other fields of surgery where laparoscopic procedures are routinely performed, laparoscopic hepatectomy is only being performed in a few institutions worldwide; nonetheless, since the first laparoscopic liver resection was described in 1992, there has been an exponential growth of reported laparoscopic liver resections, with almost 3000 cases reported in the English literature so far^[108]. About 50% of them were performed for malignant tumors and, in this group, about half were HCCs. Since 2000, about 500 cases of laparoscopic resection for HCC can be collected from the literature^[109]. Most patients were cirrhotics, but a considerable proportion (about 40%) had pre-cirrhotic chronic hepatitis. Laparoscopic surgery consisted of minor resections (< 3 segments removed) in 90% of cases^[109]. Complications were more frequent after resection for HCC (50%) than for colorectal metastasis (11%), likely due to underlying liver disease^[108]. The 5-year overall survival ranges from 50% to 60%^[108]. These results are comparable to those achieved with open hepatic resection for HCC but the large proportion of patients without cirrhosis suggests

that studies enrolling only cirrhotic patients are still required to adequately compare outcomes in this specific cohort of patients^[109]. Advantages of laparoscopic liver resections are the less aggressive approach, less peritoneal dissection, less bleeding, minimal ascites and decreased post-hepatectomy liver failure^[110,111], extending the indication to liver resection to selected Child B patients^[110]. Moreover, fewer postoperative adhesions after laparoscopic liver resection compared to open liver resection facilitate subsequent salvage LT with decreased morbidity^[112]. On the other hand, the longer learning curve, the greater difficulty in achieving wide resection margins and performing anatomical resections, the difficulties in mobilization and parenchymal transaction, with risk of massive bleeding, are the major obstacles to the widespread diffusion of laparoscopic liver resection. Lastly, lesions located in posterior segments are not good indications for pure laparoscopic approach but suitable for hand-assisted laparoscopic resection^[113,114].

CONCLUSION

Despite improving results of non-surgical approaches, partial hepatectomy still represents a cornerstone for potentially curative treatment of HCC, able to offer long-term survival rates. However, like all the available treatments for HCC, hepatic resection should be considered in the context of multi-disciplinary evaluation of these patients, which increases the chances to cure the tumor and its recurrences, resulting in higher overall survival rates. As tumor recurrence remains the main obstacle in achieving better results in long-term survival after hepatic resection, clinical trials aimed at identifying effective adjuvant therapies are warranted. Regarding types of surgical approaches to HCC, the literature is rich in observational studies but very few well-designed RCTs are currently available; thus, no definitive suggestions can be derived regarding superiority of anatomic versus non-anatomic resection or laparoscopic approach.

Abstract

AIM: To study the association between inflammatory bowel disease (IBD) and genetic variations in eosinophil protein X (EPX) and eosinophil cationic protein (ECP).

METHODS: DNA was extracted from ethylene diamine tetraacetic acid blood of 587 patients with Crohn's disease (CD), 592 with ulcerative colitis (UC) and 300 healthy subjects. The EPX405 (G > C, rs2013109), ECP434 (G > C, rs2073342) and ECP562 (G > C, rs2233860) gene polymorphisms were analysed, by the 5'-nuclease allelic discrimination assay. For determination of intracellular content of EPX and ECP in granulocytes, 39 blood samples was collected and extracted with a buffer containing cetyltrimethylammonium bromide. The intracellular content of EPX was analysed using an enzyme-linked immunosorbent assay. The intracellular content of ECP was analysed with the UniCAP® system as described by the manufacturer. Statistical tests for calculations of results were χ^2 test, Fisher's exact test, ANOVA, Student-Newman-Keuls test, and Kaplan-Meier survival curve with Log-rank test for trend, the probability values of $P < 0.05$ were considered statistically significant.

RESULTS: The genotype frequency for males with UC and with an age of disease onset of ≥ 45 years ($n = 57$) was for ECP434 and ECP562, GG = 37%, GC = 60%, CC = 4% and GG = 51%, GC = 49%, CC = 0% respectively. This was significantly different from the healthy subject's genotype frequencies of ECP434 (GG = 57%, GC = 38%, CC = 5%; $P = 0.010$) and ECP562 (GG = 68%, GC = 29%, CC = 3%; $P = 0.009$). The genotype frequencies for females, with an age of disease onset of ≥ 45 years with CD ($n = 62$), was for the ECP434 and ECP562 genotypes GG = 37%, GC =

52%, CC = 11% and GG = 48%, GC = 47% and CC = 5% respectively. This was also statistically different from healthy controls for both ECP434 ($P = 0.010$) and ECP562 ($P = 0.013$). The intracellular protein concentration of EPX and ECP was calculated in $\mu\text{g}/10^6$ eosinophils and then correlated to the EPX 405 genotypes. The protein content of EPX was highest in the patients with the CC genotype of EPX405 (GG = 4.65, GC = 5.93, and CC = 6.57) and for ECP in the patients with the GG genotype of EPX405 (GG = 2.70, GC = 2.47 and CC = 1.90). ANOVA test demonstrated a difference in intracellular protein content for EPX ($P = 0.009$) and ECP ($P = 0.022$). The age of disease onset was linked to haplotypes of the *EPX405*, *ECP434* and *ECP562* genotypes. Kaplan Maier curve showed a difference between haplotype distributions for the females with CD ($P = 0.003$). The highest age of disease onset was seen in females with the *EPX405CC*, *ECP434GC*, *ECP562CC* haplotype (34 years) and the lowest in females with the *EPX405GC*, *ECP434GC*, *ECP562GG* haplotype (21 years). For males with UC there was also a difference between the highest and lowest age of the disease onset (*EPX405CC*, *ECP434CC*, *ECP562CC*, mean 24 years *vs* *EPX405GC*, *ECP434GC*, *ECP562GG*, mean 34 years, $P = 0.0009$). The relative risk for UC patients with *ECP434* or *ECP562-GC/CC* genotypes to develop dysplasia/cancer was 2.5 (95%CI: 1.2-5.4, $P = 0.01$) and 2.5 (95%CI: 1.1-5.4, $P = 0.02$) respectively, compared to patients carrying the GG-genotypes.

CONCLUSION: Polymorphisms of EPX and ECP are associated to IBD in an age and gender dependent manner, suggesting an essential role of eosinophils in the pathophysiology of IBD.

INTRODUCTION

The concept of inflammatory bowel disease (IBD) comprises the disorders Crohn's disease (CD) and ulcerative colitis (UC). The aetiology of the diseases is unknown, but IBD is currently believed to develop in individuals

with a hereditary predisposition. This is related to the reaction of the immune system to the bacterial challenge of the gut and/or defects in the gut wall, in addition to external environmental factors. IBD usually has an intermittent course of aggravations with common symptoms such as frequent diarrhoea, blood in stool, abdominal pain, and weight loss. The incidence of IBD has increased in the Western world in recent years, and new cases occur primarily in the group between 20 and 40 years of age^[1,2]. CD seems to affect women more than men, while UC appears to be more prevalent among men, but some studies showed no gender differences^[1,3,4]. A bimodal age distribution of disease onset has been reported and debated in population studies of CD and UC^[2,5-8]. Patients with CD and UC have an increased risk of developing colorectal cancer. This risk is more pronounced in patients with UC with an overall 2.7-fold increased risk as compared with the general population^[9].

Under normal conditions, the intestinal mucosa is in a state of "controlled inflammation". Different subsets of T-cells are present in the healthy intestine, as are eosinophils and antigen-presenting cells with a predominance of anti-inflammatory and regulatory cytokine responses that keep the mucosal homeostasis intact^[10]. However, in IBD the balance between mucosal responsiveness and tolerance towards antigens is disturbed, resulting in an exaggerated immune response to the commensal flora. It is well established that neutrophil granulocytes accumulate and infiltrate in the local processes in IBD. In recent years attention has been paid to the involvement of eosinophil granulocytes, since increased numbers of these cells are found in the intestinal mucosa of IBD^[11,12]. Studies now emphasise a key role of the eosinophil granulocyte in the pathophysiology of IBD^[13,14].

The eosinophil participate in a number of biological processes such as wound healing, defence against parasites and allergic inflammation^[15]. The eosinophils granulocyte are characterised by specific cytoplasmic granules containing four major proteins; eosinophil cationic protein (ECP)^[16], eosinophil peroxidase (EPO)^[17], eosinophil protein X (EPX)/eosinophil derived neurotoxin^[18], and major basic protein (MBP)^[15]. Increased intraluminal release of EPX, ECP and EPO has been shown in patients with UC^[19]. The cytotoxic activities of ECP and EPX as well as their potent RNase activities have been well documented^[20] and are generally conceived as part of the host defence against viruses, parasites and helminths^[21,22]. Furthermore both EPX and ECP have been associated with different types of cancer^[23-25]. The presence of eosinophils in the intestinal mucosa of healthy subjects may reflect these host defence activities of the cell. In addition EPX has been identified as a member of the Alarmin family with the capacity to affect various aspects of the dendritic cells^[26], and in aged asthma patients, relative to young, the degranulation of EPX was decreased^[27]. Larger numbers of activated eosinophils, identified as an increased expression of the cell surface receptor CD44, have been reported both in CD and UC, but even more

pronounced in quiescent than in active UC. Findings that might suggest a role of eosinophils in tissue remodelling and repair in IBD^[28,29].

By linkage analysis and genome-wide association studies many genetic variations, linked to IBD, have been found^[30]. The nucleotide sequences of EPX and ECP have a homology of 90%, and both genes have been located to chromosome 14q11.2^[31,32] within the IBD4 locus, located at the 14q11-12 region^[33]. Several single nucleotide polymorphisms (SNPs) were reported in the genes for EPX and ECP^[34]. An intron SNP in the EPX gene, EPX405 G > C (rs2013109) was together with a SNP from the 3' untranslated region in the ECP gene, ECP562 G > C (rs2233860)^[35], shown to be closely linked to the eosinophil content of EPX and ECP (Jönsson *et al*^[35], to be published). The C-allele of the nonsynonymous missense ECP434 G > C (rs2073342) polymorphism, gives rise to an arginine to threonine shift at amino acid position 97 in the mature protein^[34,36]. As shown with recombinant ECP proteins this amino acid shift resulted in an alteration of the protein and its cytotoxic activity^[37], but with no effect on its RNase activity^[38]. The loss of cytotoxicity of ECP containing threonine at position 97 was confirmed using purified native proteins from genotyped blood donors^[37]. The ECP434(G > C) polymorphism was shown to be associated with the expression of allergic symptoms^[39], and with disease severity in Hodgkin lymphoma^[39] in population based studies as well as to the prevalence and severity of *Schistosoma mansoni* infection in a Ugandan population^[40].

The aim of this study was to investigate the impact of SNPs in the EPX and ECP genes in a cohort of patients with IBD. The hypothesis was that alterations in the cytotoxic activities of ECP and/or the altered expression of EPX might affect the propensity to acquire IBD and also might affect different features of IBD. The influence of polymorphisms in the EPX and ECP genes was first analysed in a pilot cohort of patients with IBD from Uppsala University Hospital and then in a second step in a bigger Swedish cohort. The possible altered expression of EPX was in addition analysed by measuring the intracellular eosinophil content of EPX in a subset of the patients.

MATERIALS AND METHODS

Study population

The patient group consisted of 1179 individuals recruited from Uppsala University Hospital, Sweden (95 CD and 100 UC), and an established Swedish cohort recruited at Karolinska University Hospital and Örebro University Hospital (492 CD and 492 UC). Diagnoses of CD and UC was based on clinical, histological and endoscopic findings, according to standardized criteria^[41]. Bimodal patterns as to age of disease diagnosis were observed for both CD and UC irrespective of gender (Figure 1). The major peak of age at diagnosis of both diseases was seen at 20-25 years, with a second peak around 40-50 years.

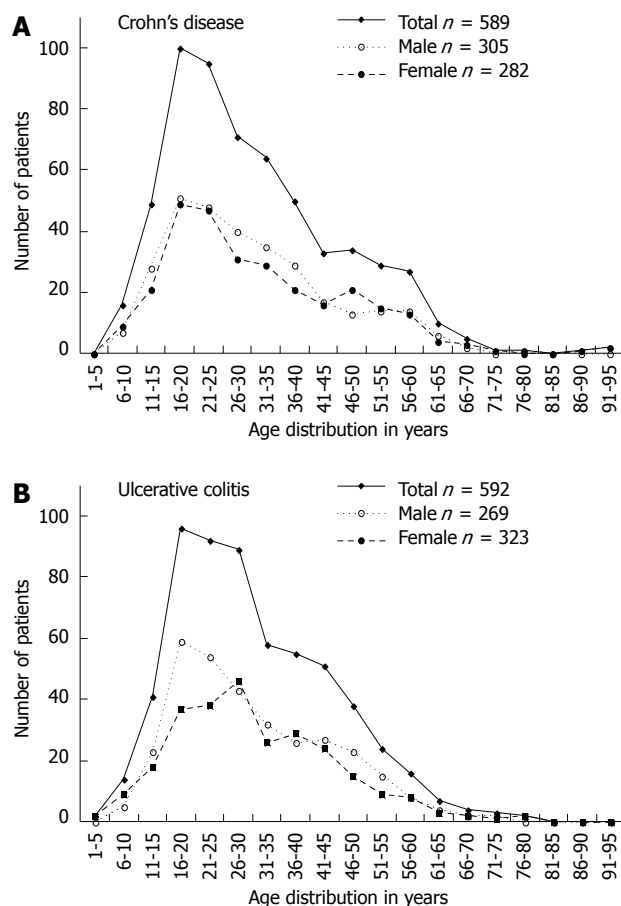

Figure 1 Incidence curves, given as a mean of 5 consecutive years, are shown for the inflammatory bowel disease study cohort. Curves separated by gender and displaying the total inflammatory bowel disease cohort are included.

A group of 300 healthy Swedish blood donors from the Uppsala blood bank served as reference population.

The study was approved by the local Ethics Committees of the Medical Faculties, of Uppsala University and Karolinska University Hospital, Stockholm, and all patients gave their informed consent to participate in the study (Table 1).

DNA extraction

Genomic DNA from all IBD patients and the reference group were extracted from whole ethylene diamine tetraacetic acid (EDTA) blood, by the use of the QIAamp DNA Blood Mini Kit from QIAGEN (QIAGEN Inc, Valencia, CA, United States), according to the manufactures description.

Genotyping

All IBD samples and controls were genotyped for the EPX405 (G > C), ECP434 (G > C) and the ECP562 (G > C) polymorphisms by use of the 5'-nuclease allelic discrimination assay. The assay has previously been described in detail^[42]. Oligonucleotide primers were designed by the use of Primer Express[®] (Applied Biosystems, Foster City, CA, United States) based on the se-

quence of the *EPX* (X16546) and *ECP* (X16545) genes available in GenBank. Sequences for primers and probes are displayed in Table 2.

Polymerase chain reaction (PCR) cycling was carried out in an ABI PRISM 7000 (Applied Biosystems) with the recommended thermal profile of: 50 °C for 2 min, 95 °C for 10 min followed by a total of 40 cycles of 95 °C for 15 s and 60 °C for 1 min. After the PCR cycling the genotypes were determined according to the application Allelic Discrimination of the ABI Prism 7000 SDS software (Applied Biosystems).

Blood cell count

Blood eosinophil count (B-Eos) (reference interval $0.0 \times 10^9/L$ – $0.5 \times 10^9/L$) and total white blood cell count (reference interval $3.5 \times 10^9/L$ – $9.0 \times 10^9/L$) were determined by an automated haematology analyser (Celdyn Sapphire; Abbott Laboratories, CA, United States) at the Department of Clinical Chemistry, Uppsala University Hospital, Uppsala, Sweden.

Whole blood extraction

The EPX and ECP polymorphisms were first only analysed in the Uppsala cohort. There was a difference in the EPX content between CD and UC patients, which lead to an interest in measuring the intracellular content of EPX and ECP in eosinophils. For the determination of intracellular content of EPX and ECP in granulocytes, EDTA blood was collected from 39 patient samples with

Table 3 Genotype and allelic frequency distribution among 300 healthy individuals and the total cohorts of Crohn's disease and ulcerative colitis

	GG- genotype (%)	GC- genotype (%)	CC- genotype (%)	G-allele (%)	C-allele (%)
Healthy					
ECP562	68	29	3	83	17
ECP434	57	38	5	76	24
EPX405 M ¹	64	32	4	80	20

ECP434	55	38	7	74	26
EPX405 M	62	31	7	78	22
EPX405 F	57	38	5	76	24

For ECP434 and ECP562 there was no difference between males and females. ¹In EPX405 there was a difference between the sexes according their genotype ($P = 0.049$) and allelic distribution ($P = 0.021$). UC: Ulcerative colitis; CD: Crohn's disease; EPX: Eosinophil protein X; ECP: Eosinophil cationic protein; F: Female; M: Male.

CD. The subjects were selected based on their *EPX405* (G > C) genotypes (GG = 15, GC = 16, and CC = 8). The method for whole blood extraction using cetyltrimethylammonium bromide has previously been described in detail (Jönsson *et al.*³⁵, to be published). The supernatants were stored at -20 °C until assayed for EPX and ECP concentrations.

Protein assays

EPX whole cell extract was analysed using an enzyme-linked immunosorbent assay (Diagnostics Development, Uppsala, Sweden), according to the recommendations of the manufacturer with minor modifications. The concentration of ECP was analysed with the UniCAP[®] system, (Phadia AB, Uppsala, Sweden) as described by the manufacturer.

Statistical analysis

All the statistical analyses were performed with the Statistica 9.0 software for Windows (StatSoft, Tulsa, United States), and MedCalc software (V.10, Mariakerke, Belgium). The statistical tests in use for the calculations of results were χ^2 and Fisher's exact test, ANOVA, Student-Newman-Keuls test, and Kaplan-Meier survival curve with the Log-rank test for trend. $P < 0.05$ were considered statistically significant.

RESULTS

Genotype distributions in healthy population vs patients with IBD

The distribution of the *EPX405*, *ECP434* and *ECP562* genotypes was investigated in the population of 1179

Difference (χ^2 , *P*-values displayed) between the genotype distributions and allelic frequencies, related to age at diagnosis, in individuals with CD or UC compared with the healthy population. UC: Ulcerative colitis; CD: Crohn's disease; NS: Not significant; EPX: Eosinophil protein X; ECP: Eosinophil cationic protein.

subjects with CD (*n* = 587) or UC (*n* = 592) (Table 1).

For comparison the distributions of the same genotypes were investigated in a group of apparently healthy blood donors (*n* = 300). In the healthy reference population males had a higher prevalence of the *EPX405* GG-genotype (*P* = 0.049) and the G-allele (*P* = 0.021) compared to females (Table 3). All continuing data has been calculated gender stratified for the *EPX405* genotype. No difference was seen between genders for the *ECP434* and *ECP 562* genotype in the control cohort (Table 3). No genotype differences were seen between younger (*n* = 150; median age: 31 years; range: 19-43 years) and older (*n* = 150; median age: 54 years; range: 44-73 years) healthy references. At first only the Uppsala cohort with CD (*n* = 95) and UC (*n* = 100) was examined. Here there was a difference between patients with CD and UC (*P* = 0.048) with more *EPX405* GC and CC in CD. These results could not be verified in the whole cohort where no general differences were found between the healthy and the patient cohorts, or between the CD and the UC cohorts, for any of the genotypes. When dividing the patient cohorts by their median (28 years) age at disease diagnosis (ADD) and comparing them, no difference was seen in any of the genotypes for younger *vs* older patients with CD (median ADD: 20 years; range: 6-28 years *vs* median ADD: 40 years; range: 28-93 years) or UC (median ADD: 20 years; range: 4-28 years *vs* median ADD: 40 years; range: 28-78 years). In the total cohort, no difference was seen in the genotype frequencies related to gender in patients with CD or UC. When the patient populations were separated by age at disease diagnosis, according to the Montreal classification^[43] (< 16 years, 17-40 years and > 40 years) and gender, a pattern with significant differences was observed. Since the incidence curve (Figure 1) of women with CD indicated a second peak of disease onset around 45 years the age range > 45 years was also included in the study. Thus, a lower prevalence of the *ECP434* and *ECP562*-GG genotypes and higher prevalence of the *ECP434* and *ECP562*-GC genotypes were found in female patients with CD, compared to the healthy reference population (Table 4). In males similar differences in the prevalence of the *ECP434* and *ECP562* genotypes were observed, but only in patients with UC (Table 4).

For both genders the genotype differences were observed in the older cohort of the population with an age at diagnosis above 40 years (Table 4). In the cohort of males with UC a higher prevalence of the *EPX405* GC-genotype, compared to healthy controls, was observed in patients with an ADD of > 40 years (*P* = 0.048).

Genotype distribution within different cohorts

Among females with CD and ADD of > 45 years, the GC-genotype of the *ECP434* (*P* = 0.020) and *ECP562* (*P* = 0.014) gene polymorphisms were more common than in females with ADD < 45 years. In females with UC, no such differences were observed. In males with UC there was a difference between those with an ADD over and under 40 and 45 years, concerning all three genotypes (40 years; *EPX405* *P* = 0.003, *ECP434* *P* = 0.003 and *ECP562* *P* = 0.004). The differences were, in all genotypes, due to a higher amount of the GC-genotypes among males > 40 years and > 45 years.

In Figure 2, a comparison of the *ECP434* genotype distributions between patients with CD and UC and an age of disease diagnosis of > 45 years is shown. In the comparison the population is separated by gender. Among female patients with CD there was a significantly lower prevalence of the *ECP434*GG genotype and a prevalence of the heterozygote genotype almost twice as high as in those women having UC (*P* = 0.010). This was contrasted by the findings in males, since those patients having CD had a predominance of the *ECP434* GG-genotype, as compared to patients with UC, who had a predominance of the GC-genotype (*P* = 0.004). Highly significant differences were found in *ECP434* genotype distributions between females and males (> 45 years) with CD (*P* = 0.001) and with UC (*P* = 0.001). Similar patterns were found for the *ECP562* genotypes, but not for the *EPX405* genotypes (not shown).

Relationships of age at disease diagnosis to genotypes and haplotypes

The relationships of the *EPX405*, *ECP435* and *ECP562* genotypes and haplotypes (Table 5) to ADD (females with CD and males with UC) are illustrated in Figure 3. The haplotypes analysed were chosen to include the wild type (WT) (haplotype 1; GG in all three genotypes) and

Figure 2 Prevalence of *ECP434* genotypes in Crohn's disease (black bars) and ulcerative colitis (grey bars). A: In females, age at disease diagnosis (ADD) > 45 years, a significant difference between Crohn's disease (CD) and ulcerative colitis (UC) concerning *ECP434* ($P = 0.01$, χ^2) was observed; B: In men, ADD > 45 years a significant difference between CD and UC concerning *ECP434* ($P = 0.004$) was observed. ECP: Eosinophil cationic protein.

the opposite extreme with CC in all genotypes (haplotype 27). The criterion for other haplotypes to be included was to differ from the WT and to contain at least 10 individuals in the group. We found significant associations between the respective genotypes and ADD for men with UC; *EPX405* ($P = 0.007$), *ECP434* ($P = 0.002$) and *ECP562* ($P = 0.010$) with the lowest ADD seen in those carrying the CC-genotypes and the highest ADD in those carrying the heterozygous genotypes (Figure 3C-E). To attain a better understanding of the significance of the genetic diversity of the polymorphisms in the *EPX* and *ECP* genes, four haplotypes were related to ADD. The haplotypes analysed in men with UC were haplotype 1, haplotype 13, haplotype 14 and haplotype 27 (Table 5). For females with CD the haplotypes analysed were haplotype 1, haplotype 4, haplotype 13 and haplotype 27 (Table 5).

As shown in Figure 3A, ADD differed significantly depending on haplotype ($P = 0.0009$) in men with UC and in females with CD ($P = 0.003$) (Figure 3B). In the female cohort extreme outliers (ADD > 80 years) were excluded from the analysis. The ADD was markedly

Table 5 Haplotype compositions and their frequencies in the studied population with inflammatory bowel disease

Gender	Haplotype	EPX405	ECP434	ECP562	Frequency %
Males with UC	1	GG	GG	GG	48
	13	GC	GC	GG	5
	14	GC	GC	GC	20
	27	CC	CC	CC	3
Females with CD	1	GG	GG	GG	46
	4	GG	GC	GG	6
	13	GC	GC	GG	5
	27	CC	CC	CC	5

UC: Ulcerative colitis; CD: Crohn's disease; EPX: Eosinophil protein X; ECP: Eosinophil cationic protein.

lower in males with UC who carried the haplotype 27 as compared to those who carried the haplotype 13. Almost reverse results were obtained in females with CD since ADD in those carrying haplotype 13 was the lowest and haplotype 4 the highest.

Intracellular protein content

As noted in the introduction the eosinophil content of the alarmin *EPX* is associated to the *EPX405* genotypes in healthy and allergic subjects. We therefore investigated the association of the cellular content in a selected subset of patients with CD from the Uppsala cohort. The eosinophil content of *EPX* was closely linked to the *EPX405* genotype with the highest content in the subjects carrying the *EPX405CC* genotype (ANOVA $P = 0.009$) (Figure 4). The eosinophil content of *ECP* was also linked to the *EPX405* genotype (ANOVA $P = 0.022$), but in a reverse mode (Figure 4).

Relationship to dysplasia/cancer

In the study UC cohort there were several patients ($n = 27$; females: 8; males: 19) that through continuous endoscopic examination were shown to have developed dysplasia and/or cancer (D/C) (median age at cancer diagnosis: 49 years; range: 27-67 years). The D/C cohort was compared to all UC patients, females and males who had not developed D/C, since no difference was shown between older and younger UC patients in the mixed cohort. The distributions of the *ECP434* and *ECP562* alleles in patients with UC, with and without findings of D/C of the intestine are shown in Figure 5. The C-allele of both genotypes was more prevalent among patients with D/C (*ECP434* $P = 0.034$ and *ECP562* $P = 0.019$). The D/C patients also differed from the healthy controls (*ECP434* $P = 0.027$ and *ECP562* $P = 0.007$) (Figure 5). The relative risk (RR), for UC patients with the *ECP434* GC or CC genotypes, to develop D/C was 2.5 (95%CI, 1.2-5.4) compared to other patients with UC. In patients with the *ECP562* GC or CC genotypes the RR was 2.5 (95%CI, 1.2-5.8) as compared to UC patients. Considering the whole cohort, no associations to the *EPX405* (G > C) genotypes were detected.

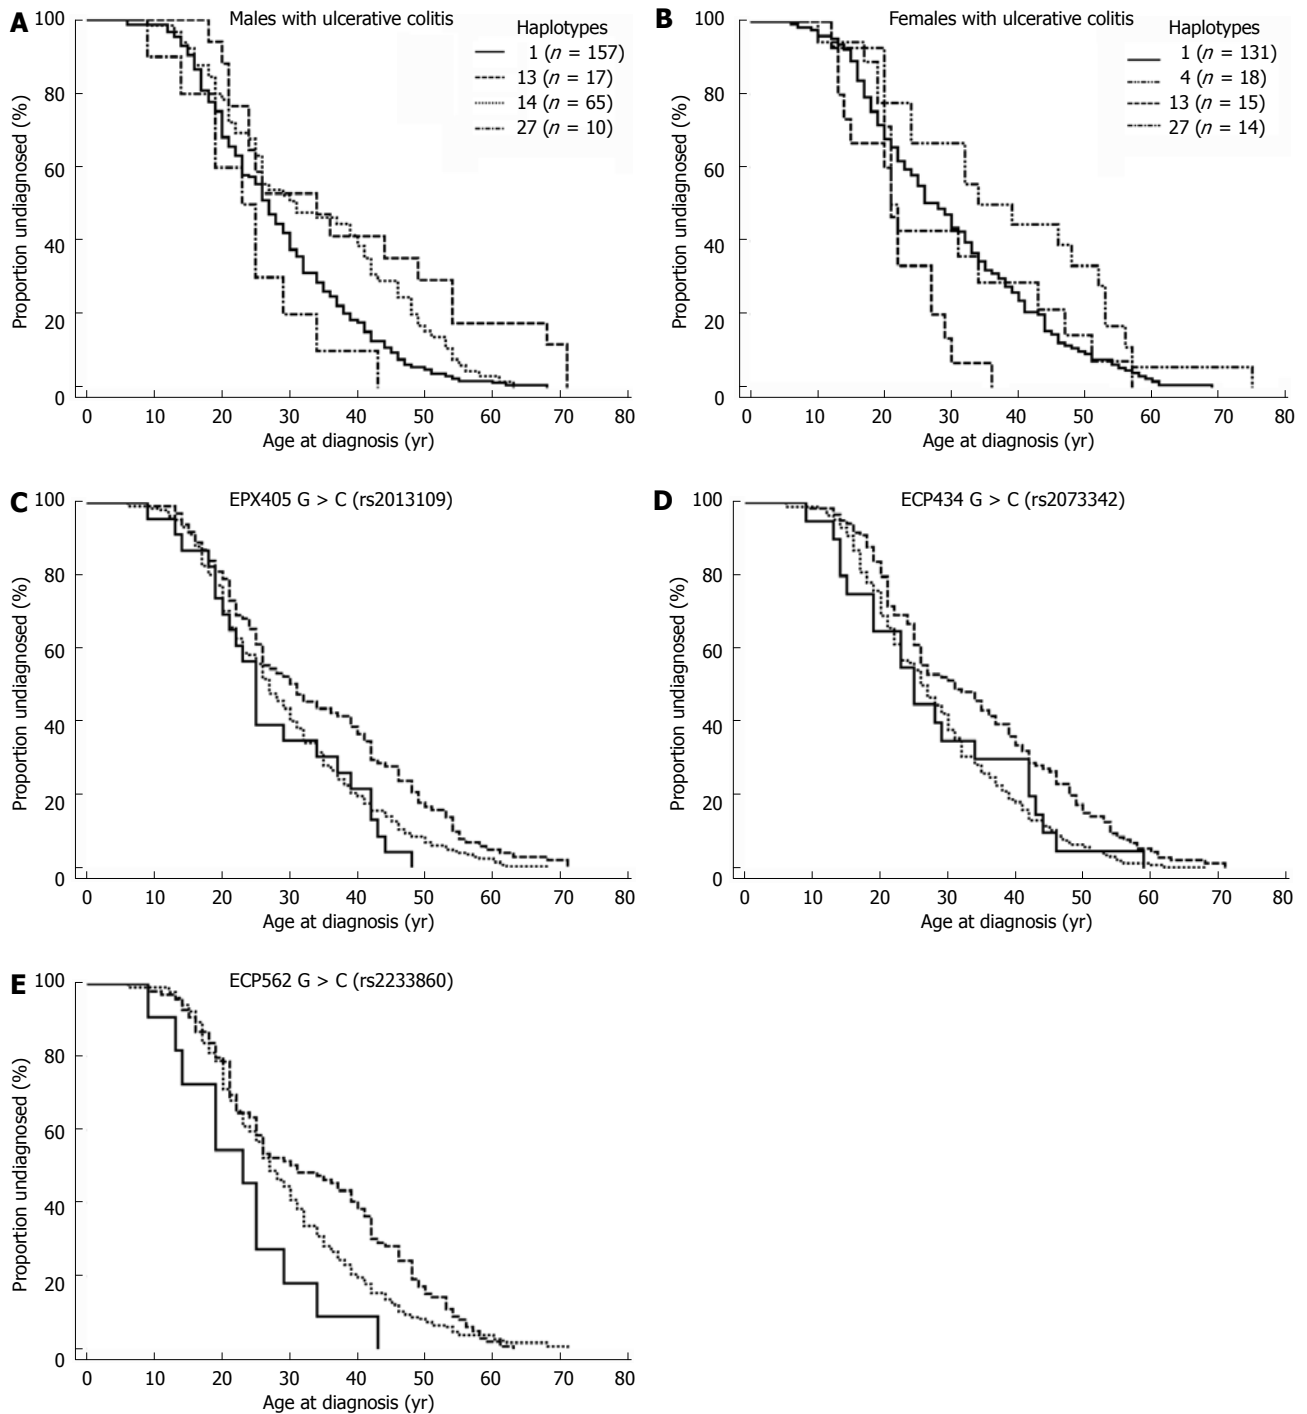

Figure 3 Kaplan-Meier Curve of four groups haplotypes and *EPX405*, *ECP562* genotypes. A: Kaplan-Meier Curve of four groups of haplotypes in male patients with ulcerative colitis (UC) ($P = 0.0009$); B: Kaplan-Meier Curve of four groups of haplotypes in female patients with Crohn's disease ($P = 0.003$); C: Kaplan-Meier curve of the *EPX405* genotype in men with UC ($P = 0.007$); D: Curve of the *ECP434* genotype in men with UC ($P = 0.002$); E: Curve of the *ECP562* genotype in males with UC ($P = 0.01$). Dotted line: GG genotype; Dashed line: GC genotype; Continuous line: CC genotype. ECP: Eosinophil cationic protein; EPX: Eosinophil protein X.

DISCUSSION

Inflammatory bowel disease, including CD and UC, are idiopathic diseases with chronic inflammation of the gut. A key role of the eosinophil in the pathophysiology of IBD has been suggested. Our findings in this report, of intriguing associations between gene polymorphisms of the two major eosinophil granule proteins ECP and EPX,

emphasize this notion. The primary results gained from the Uppsala cohort gave a hint that there was some association between the EPX and ECP polymorphisms and IBD. The associations, however, were in the larger cohort mainly found when the patients were separated into gender, age groups and diagnosis, since the associations were most apparent in older women with CD and in older men with UC. Another interesting observation was the higher

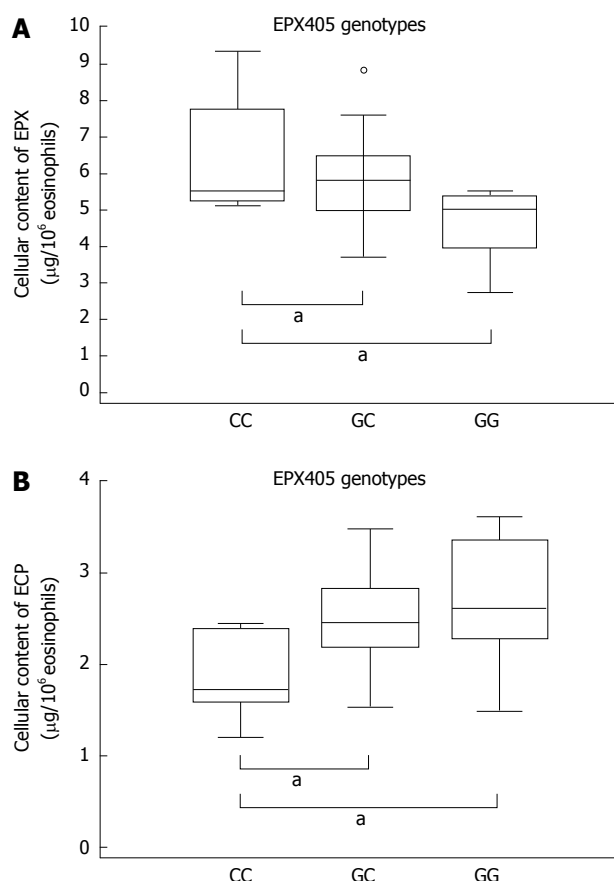

Figure 4 The box plots displays the association between the *EPX405* genotypes and the intracellular content of eosinophil protein X and eosinophil cationic protein in eosinophils. The box plots display the distribution of the protein content within each class of genotype. A: Intracellular content of eosinophil protein X (EPX) (ANOVA $P = 0.009$). $^aP < 0.05$ vs *EPX405* GG genotype (Student-Newman-Keuls test); B: Intracellular content of eosinophil cationic protein (ANOVA $P = 0.022$). $^aP < 0.05$ vs the *EPX405* CC genotype (Student-Newman-Keuls test).

prevalence of the *ECP434*C-allele in those patients with dysplasia/cancer, since this allele codes for the non-cytotoxic variant of ECP. We also confirmed the relationship between the *EPX405* (G > C) polymorphism and the eosinophil content of EPX, since an increased content of EPX was found in subjects carrying the C-allele. The C-allele was also related to the age of disease diagnosis suggesting an impact of the alarmin EPX on the course of the disease in IBD.

In our study, we show that older females with CD had a relatively higher amount of the *ECP434* GC and *ECP562* GC genotypes as compared to healthy individuals, and younger females with CD. Our novel findings show that in healthy individuals and females diagnosed with CD at a young age the GG genotype of *ECP434* and *ECP562* was more dominating than in older women with CD, implying a more cytotoxic ECP and a higher content of ECP. This interesting finding could have a bearing on granuloma formation in CD. Granuloma formation is one of the pathological hallmarks of CD and is detected in the gut wall in 37%-60% of the patients^[44]. Patients with granulomas, and particularly females, are

Figure 5 Distribution of allele frequencies, displaying the difference in patients with ulcerative colitis and dysplasia/cancer. Bars represent the allele frequency (%) of *ECP434* (A) and *ECP562* (B) single nucleotide polymorphism in patients with dysplasia/cancer (black bar), all patients with ulcerative colitis (grey bar), and healthy individuals (white bar). ECP: Eosinophil cationic protein.

diagnosed early in their course of disease^[45]. In CD, the production of tumor growth factor (TGF)- β appears critical in CD-associated fibrosis and in the formation of granulomas^[46,47]. ECP is known to promote TGF- β production and migration of fibroblasts^[48,49] and the *ECP434* GG genotype has been linked to increased fibrosis^[40]. All together this suggests a role of ECP in the production of granulomas in younger females with CD. Furthermore high numbers of bacteria, and mainly gram negative bacteria as *Escherichia coli* (*E. coli*), can induce secretion of ECP^[50]. By the use of laser capture microscopy and PCR it was shown that DNA from *E. coli* was present in 80% of granulomas from patients with CD^[51].

There are few studies associating genetic risk factors and gender to falling ill with IBD. For patients with UC, there is a gender-specific risk associated with the interleukin-10 promoter. Females with a particular genotype and haplotype have an increased risk of contracting the disease earlier in life^[52]. In patients with CD the DLG5 R30Q variant was shown to be associated with an increased risk for male patients to develop CD. This risk has been described both in the paediatric^[53] and the adult age group^[54]. We showed that age at diagnosis in females with CD is linked to the *EPX405* genotype. Females

with haplotype 13, including EPX405 GC, are diagnosed earlier in life. The longest span of years before onset of disease was observed in females carrying haplotype 4, including EPX405 GG. The C-allele of EPX405 is linked to a higher content of EPX in the eosinophils. The increased availability of EPX (in combination with unchanged amount of ECP) may result in an earlier disease onset in life. EPX was previously shown to present characteristics of an endogenous alarmin, which strengthens the immune systems Th2 immune response^[26]. CD has often been regarded as a disease with a dominant Th1 immune response, but a Th2 response in the early stages of the disease with active ileitis has been shown^[55,56]. EPX uses the toll-like receptor 2 (TLR2)-MyD88 signal transduction pathway to induce dendritic cell maturation and activation of NF- κ B^[26] and also acts as a chemotactic activator of dendritic cells^[57]. Few of the intestinal dendritic cells in healthy controls express TLR2, whereas in patients with IBD the TLR2 receptor density is increased^[58]. NOD2 also induces nuclear factor κ B (NF- κ B) activation through the MyD88 pathway^[59]. The potentiated activation of NF- κ B through the co-operation of EPX and NOD2 in CD, therefore, is an interesting possibility and may explain the differences found between CD and UC, since the 405C-allele was more common in CD in patients with shorter onset of disease.

In the cohort of older men with UC, the *ECP434* and *ECP562* GC genotypes were more common than in men with CD, females with UC, younger men with UC and the healthy population. Compared to younger men and the healthy reference population the *EPX405* genotype was also significantly different, with more GC genotype in the older cohort. Thus, older men had a lower content of less cytotoxic ECP and a higher content of EPX. These results are similar to the cohort of older females with CD. Thus, from a genetic point of view, females with CD show similar distributions of the ECP and EPX SNPs as men with UC. These are interesting findings and suggest major gender differences in the pathogenesis of the two diseases.

In men with UC the Kaplan Meier analysis showed the lowest ADD in subjects carrying haplotype 27, (*EPX405* CC, *ECP434* CC and *ECP562* CC) which codes for elevated production of EPX, less cytotoxic ECP and reduced production of ECP protein. The highest ADD was seen in those carrying haplotype 13 (*EPX405* GC, *ECP434* GC and *ECP562* GG), which codes for increased production of EPX and cytotoxic ECP. These findings suggest a protective role of ECP, putatively against the microbial challenge, in the development of UC, whereas the role of the increased availability of EPX may be involved in the initiation of the disease. In contrast to the findings in men with UC, haplotype 13 was associated with the lowest ADD in women with CD, which should result in the increased production of cytotoxic ECP. As noted above this finding may relate to early granuloma formation. Our findings emphasize major differences in the pathophysiology and role of eosinophils

in CD and UC. A notion supported by previous studies showing differences in the morphology and function of eosinophils in CD and UC^[12,27].

Our findings of an association between the *ECP434* and 562 SNPs and UC with complication of dysplasia/cancer suggest a role of ECP in the defence against malignant cell transformation, since the results indicate a lower production of ECP and that the produced protein is non-cytotoxic and unable to kill malignant cells^[37]. The relative risk for a patient with UC and a C-allele in *ECP434* or 562 to develop D/C is 2.5. When separating the cohort due to gender the *EPX405* genotype was also significantly associated to D/C in males (data not shown). It is noticed that the number of patients with D/C was limited in our cohort, but recent studies have pointed out the association of ECP and EPX and cancer^[23-25].

It is important to remember that the polymorphisms *EPX405*, *ECP434* and *ECP562* are in linkage disequilibrium (Jönsson *et al* to be published). Because of the profound linkage disequilibrium between the alleles, it is difficult to determine which allele that is the determining allele.

In conclusion, the present study has identified a gender and age related difference between polymorphisms in the *EPX* and *ECP* genes in CD and UC, and showed that the haplotype distributions are associated to the age of disease diagnosis. We also confirmed a link between the eosinophil content of *EPX* and the *EPX405* gene polymorphism. Finally our results suggested a link between polymorphisms in the *ECP* gene and the risk in patients with UC of developing dysplasia/cancer. The role of neutrophils in IBD is a hallmark of the disease, and the results presented in this study suggest a key role of eosinophil granulocytes and their major granule proteins in the pathophysiology of inflammatory bowel disease.

COMMENTS

Background

A role of eosinophils is implicated in inflammatory bowel disease. The intraluminal release of eosinophil derived cytotoxic proteins is increased in patients with ulcerative colitis (UC). Larger numbers of activated eosinophils, identified as CD44-high, are seen in quiescent as opposed to active UC. Gene polymorphisms in eosinophil protein X (EPX)/eosinophil derived neurotoxin and eosinophil cationic protein (ECP) affect the eosinophil content of EPX and ECP.

Research frontiers

The cytotoxic activities of ECP and EPX as well as their potent RNase activities have been well documented and are generally conceived as part of the host defence against viruses, parasites and helminths exerted by eosinophils. Polymorphisms in the genes of EPX and ECP are known to be linked to changes of cytotoxic affect and protein content. Increased release of EPX and ECP has been shown in patients with UC.

Innovations and breakthroughs

There are no previous studies focusing on the genetics of the eosinophil cationic proteins and inflammatory bowel disease (IBD). Studies of IBD and genetics in a gender and age dependent manner are few. With the present study, the

authors have combined the two, enhancing the relation between the eosinophils and IBD, and revealing the possible risk for cancer.

Applications

The study results have helped to attain an increased knowledge of the eosinophils role in IBD with focus on age and gender related differences. The results also suggest that the determination of the *EPX* and *ECP* genotypes may contribute in patients risk stratification for cancer development.

Terminology

Eosinophil granulocyte: the eosinophil granulocyte is a pro inflammatory cell. The cell participates in wound healing and host defence against parasites and helminths. The cell is also present in the process of the allergic inflammation. **Eosinophil cationic proteins:** the cationic proteins are granula proteins secreted by activated eosinophils. The proteins are eosinophil specific and are therefore often used as markers for the eosinophil activities. **Single nucleotide polymorphism (SNP):** this is a variation in the DNA sequence, occurring when a single nucleotide (A, C, G or T) in the genome, differs between paired chromosomes in an individual or in between individuals. If a SNP is present in the coding region of a gene this may result in an amino acid change, influencing the phenotype of a specific gene.

Peer review

The authors of this paper report that polymorphisms in the *EPX* and *ECP* genes are associated with IBD and contribute to the risk for the disease development in a gender-specific manner. Furthermore, these polymorphisms seem to be specifically related to the late-onset disease and to increased risk for colorectal cancer in UC patients. The results of this large study are certainly interesting, especially with the attention paid to gender-and age-stratified analysis which is a typical shortcoming of most of the genetic studies in IBD.

Abstract

AIM: To investigate the effect of insulin gene therapy using a glucose-responsive synthetic promoter in type 2 diabetic obese mice.

METHODS: We employed a recently developed novel insulin gene therapy strategy using a synthetic promoter that regulates insulin gene expression in the liver in response to blood glucose level changes. We intravenously administered a recombinant adenovirus expressing furin-cleavable rat insulin under the control of the synthetic promoter (rAd-SP-rINSfur) into diabetic *Lepr^{db/db}* mice. A recombinant adenovirus expressing β -galactosidase under the cytomegalovirus promoter was used as a control (rAd-CMV- β gal). Blood glucose

levels and body weights were monitored for 50 d. Glucose and insulin tolerance tests were performed. Immunohistochemical staining was performed to investigate islet morphology and insulin content.

RESULTS: Administration of rAd-SP-rINSfur lowered blood glucose levels and normoglycemia was maintained for 50 d, whereas the rAd-CMV- β gal control virus-injected mice remained hyperglycemic. Glucose tolerance tests showed that rAd-SP-rINSfur-treated mice cleared exogenous glucose from the blood more efficiently than control virus-injected mice at 4 wk [area under the curve (AUC): $21\,508.80 \pm 2248.18$ vs $62\,640.00 \pm 5014.28$, $P < 0.01$] and at 6 wk (AUC: $29\,956.60 \pm 1757.33$ vs $60\,016.60 \pm 3794.47$, $P < 0.01$). In addition, insulin sensitivity was also significantly improved in mice treated with rAd-SP-rINSfur compared with rAd-CMV- β gal-treated mice (AUC: 9150.17 ± 1007.78 vs $11\,994.20 \pm 474.40$, $P < 0.05$). The islets from rAd-SP-rINSfur-injected mice appeared to be smaller and to contain a higher concentration of insulin than those from rAd-CMV- β gal-injected mice.

CONCLUSION: Based on these results, we suggest that insulin gene therapy might be one therapeutic option for remission of type 2 diabetes.

INTRODUCTION

Type 2 diabetes is characterized by high blood glucose levels in the context of insulin resistance^[1]. Insulin resistance indicates that the body does not respond appropriately to serum insulin to regulate blood glucose levels^[2]. This phenomenon is mainly caused by metabolic disorders such as obesity, hypertension, non-alcoholic fatty liver disease and elevated serum lipid levels^[3-7]. Several peripheral organs contribute to an inappropriate insulin response in the body, which include the liver, muscle, hypothalamus and adipose tissues^[8]. For example, the liver regulates blood glucose levels by storing glucose as glycogen and releasing glucose in response to serum insulin changes; this regulation is lost in the insulin-resistant state^[9]. In adipocytes, insulin acts to inhibit lipolysis and the release of fatty acids from adipose tissue by decreasing the activity of hormone-sensitive lipase and adipose triglyceride lipase, which is attenuated in the insulin-resistant state^[10]. Muscle is another big player in regulating blood glucose levels by taking up serum glucose through GLUT4, a glucose transporter, in response to insulin^[11]. Due to insulin resistance in the peripheral organs, more insulin is required to maintain blood glucose levels in physiological range, which is evidenced by hyperinsulinemia and impaired glucose tolerance prior to overt type 2 diabetes^[12].

When type 2 diabetes is clinically diagnosed, only 50% of normal beta cell function remains^[13]. The United Kingdom Prospective Diabetes Study demonstrated that beta cell function continues to deteriorate over time despite treatment with diet, exercise, metformin, sulfonylurea, or insulin^[14]. Normal beta cells respond to blood glucose level very efficiently; however, they lose this responsiveness when they are exposed to high glucose levels or high lipid levels for prolonged periods^[15]. This loss of responsiveness is easily reversed in the early stages, so it is very important to keep blood glucose levels low to sustain beta cell function during the pathogenesis of type 2 diabetes^[16]. Another consideration for gradual loss of beta cell function is hyperinsulinemia, which is a common characteristic of early stage type 2 diabetes^[12]. Hyper-secretion of insulin from beta cells is beneficial to control blood glucose levels, but it is paradoxically detrimental to the beta cell itself. The increased demand for insulin drives beta cells to synthesize insulin beyond their capacity for protein folding and secretion, resulting in endoplasmic reticulum stress^[17-19]. Therefore, it is very important to relieve the burden on beta cells to preserve cell function during the pathogenesis of diabetes. In this

context, intensive insulin therapy is the most effective approach to achieve this goal^[16]. For example, it has been shown that patients injected once a day with long lasting insulin analogues showed significant improvement in glucose control, lower HbA1c levels and fewer complications related to diabetes^[20]. All of these results suggest that earlier insulin treatment might be important to maintain blood glucose levels in type 2 diabetic patients.

Insulin gene therapy is a novel approach to deliver the insulin gene into a target organ to express insulin under the control of an insulin responsive promoter, thus augmenting or replacing pancreatic insulin production. There have been several attempts to control blood glucose level using insulin gene therapy^[21-27]. However, most studies were unsuccessful because of lack of an effective promoter to control insulin gene expression. Recently, we developed a novel synthetic promoter that regulates insulin gene expression in the liver in response to blood glucose level changes^[28]. When diabetic mice were infected with an adenoviral vector expressing the insulin gene under this synthetic promoter, blood glucose levels were controlled in the normal physiological range for up to 1 mo^[28]. In the present study, we employed the same adenoviral vector system to investigate how insulin supplementation through insulin gene therapy might preserve beta cell function and help control blood glucose levels in a type 2 diabetic animal model.

MATERIALS AND METHODS

Animals

Eight-week-old *Lepr^{db/db}* mice were obtained from The Jackson Laboratory (Bar Harbor, ME) or from the South Korea Research Institute of Bioscience and Biotechnology (Daejeon, South Korea). Animals were maintained under specific pathogen-free conditions and provided with sterile food and water *ad libitum* at the Animal Resource Center, Faculty of Medicine, University of Calgary, Canada and at the facility at the Lee Gil Ya Cancer and Diabetes Institute, Gachon University of Medicine and Science. The use and care of the animals used in this study were approved by the Animal Care Committee, Faculty of Medicine, University of Calgary and Lee Gil Ya Cancer and Diabetes Institute, Gachon University of Medicine and Science.

Generation of recombinant adenovirus

Recombinant adenovirus expressing furin-cleavable rat insulin cDNA under the control of the synthetic promoter (rAd-SP-rINS_{fur}, Figure 1A) was produced as described previously^[28] using Transpose-AdTM Adenoviral vector system (Qbiogene, Carlsbad, CA). For generation of adenoviruses expressing β -galactosidase under the control of the cytomegalovirus (CMV) promoter (rAd-CMV- β gal), the lacZ coding region from pSV- β -galactosidase vector (Promega, Madison, WI) was cloned into the PCR259 transfer vector (Qbiogene), which has the CMV promoter to drive transgene expression. Recombinant viruses were generated and amplified on a

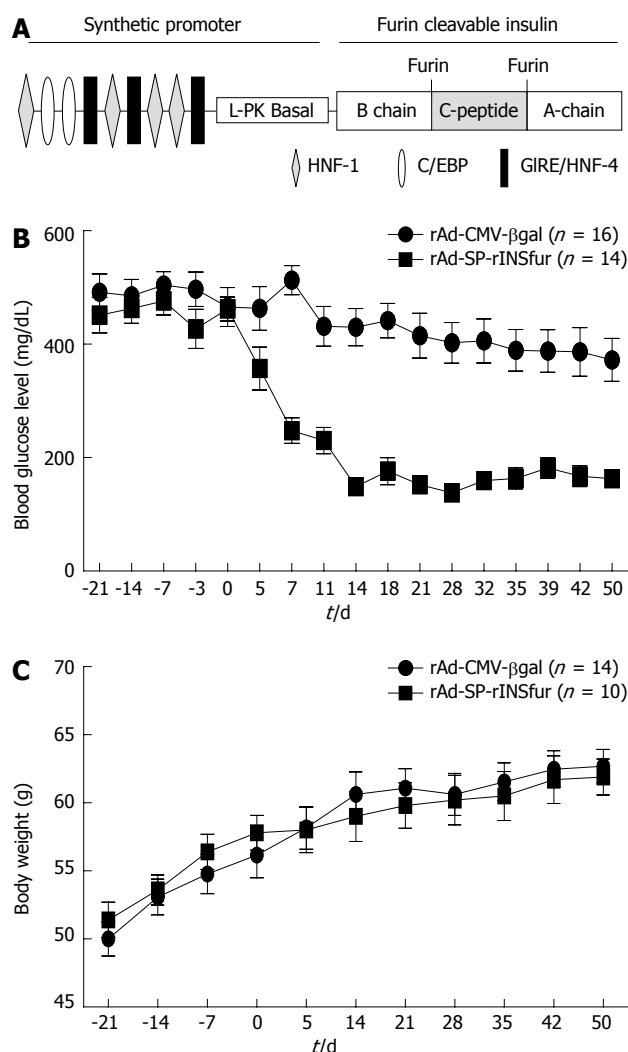

Figure 1 rAd-SP-rINSfur administration reduces high blood glucose levels to normal physiological range in *Lepr^{db/db}* mice. A: Schematic diagram of adenoviral construct expressing furin cleavable insulin gene under the control of synthetic promoter. The synthetic promoter is composed of nine transcription factor binding elements upstream of pyruvate kinase basal promoter (L-PK). A furin-cleavable site was introduced at the junction of the B-chain and C-peptide; B: Blood glucose levels; C: Body weights of *Lepr^{db/db}* mice treated with rAd-CMV-βgal or rAd-SP-rINSfur. Viruses were injected into experimental animals at 12 wk of age with a dose of 3×10^{10} viral particles, and blood glucose levels and body weights were monitored. Blood glucose levels and body weights were measured between 2-4 pm during the day, and food and water were given *ad libitum* during the experiments. All values are mean \pm SE. Day 0 indicates the day of viral injection. HNF-1: Hepatocyte nuclear factor-1; C/EBP: CCAAT enhancer binding protein; GIRE: Glucose responsive elements; HNF-4: Hepatocyte nuclear factor-4.

large scale in HEK293 cells and purified as previously described^[28]. Viral titer was determined by measurement of optical density at 260 nm.

Blood glucose monitoring and glucose tolerance tests

All mice were given *ad libitum* access to food and water during the experiments. Recombinant adenoviruses were administered intravenously into *Lepr^{db/db}* mice at 12 wk of age *via* the tail vein, and blood glucose levels were measured using a One-Touch Profile portable blood glu-

cose monitor (Lifescan, Milpitas, CA, United States). For glucose tolerance tests, animals were fasted for 6 h and then a 1 mol/L glucose solution was administered *via* an intraperitoneal injection at a dose of 2 g/kg body weight. Blood samples were collected from a small cut at the tip of the tail at 0, 15, 30, 60, 90 and 120 min after the glucose load.

Insulin tolerance tests

Animals were fasted for 6 h before injection of insulin (NPH, Lilly, Indianapolis, IN, United States) at a dose of 1.5 U/kg body weight. Blood samples were collected from a small cut at the tip of the tail at 0, 15, 30, 45, 60, 90 and 120 min after the insulin challenge.

Immunohistochemistry

Pancreatic tissues were removed from virus-treated *Lepr^{db/db}* mice on day 50 after virus treatment. The samples were fixed with 10% buffered formalin, embedded in paraffin, sectioned at 4.5 μ m, and mounted on glass slides. Hematoxylin and eosin staining was performed as previously described^[29]. For immunostaining with anti-insulin antibody, slides were treated with xylene, dehydrated in ethanol, and washed with tap water. Slides were incubated with guinea pig anti-rat insulin antibody for 1 h (1/200 in blocking buffer; DAKO, Carpinteria, CA, United States), washed, and incubated in biotinylated anti-guinea pig antibody (1/300) for 1 h. After washing, horseradish peroxidase-conjugated streptavidin was diluted in blocking buffer (1/300) and added to cells for 1 h, followed by color development using Vector VIP (Vector Laboratories, Burlingame, CA, United States) according to the manufacturer's instructions. After washing with tap water, samples were counterstained with Meyer's hematoxylin solution.

Statistical analysis

All data are presented as mean \pm SE. Differences between groups were evaluated using the Student *t* test, with significance at $P < 0.05$.

RESULTS

Administration of rAd-SP-rINSfur reduces blood glucose levels to normal range in *Lepr^{db/db}* mice

The *Lepr^{db/db}* mouse is a well-known type 2 diabetic animal model that is homozygous for a point mutation in the gene for the leptin receptor. The leptin hormone plays a key role in regulating energy intake and energy expenditure through its action on the leptin receptor^[30]. Since the *Lepr^{db/db}* mouse does not have a functional leptin receptor, it loses its control over food intake, leading to over-nutrition and obesity. To investigate the effect of augmented insulin gene expression on type 2 diabetes, we injected a recombinant adenovirus expressing rat insulin under the control of a synthetic promoter (rAd-SP-rINSfur, 3×10^{10} VP, Figure 1A) into diabetic

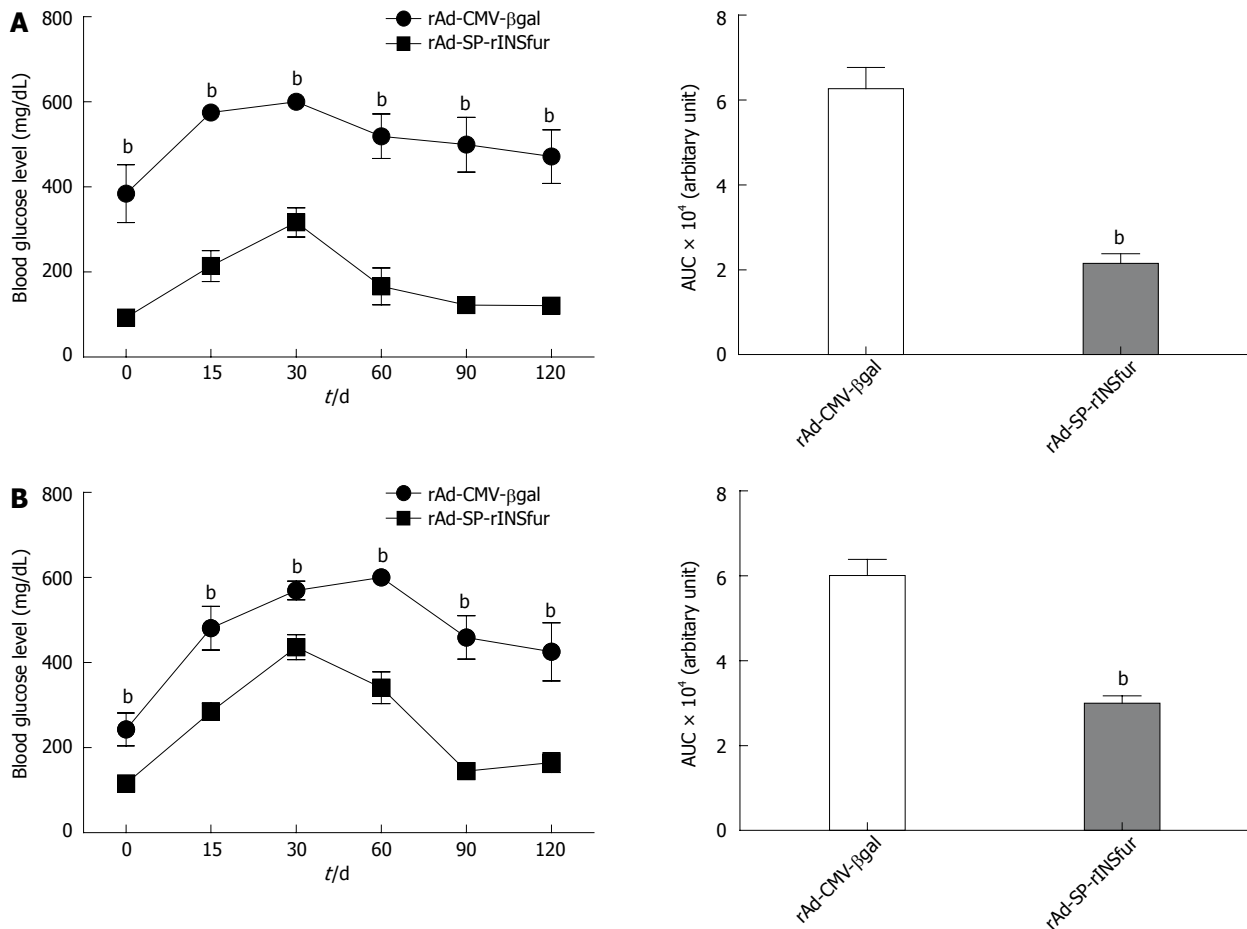

Figure 2 rAd-SP-rINSfur administration improves glucose tolerance in *Lep^{db/db}* mice. Glucose (2 g/kg body weight) was administered by intraperitoneal injection, and blood glucose levels were measured at (A) 4 wk and (B) 6 wk ($n = 4-6$) after virus injection. The area under the curve (AUC) for each glucose tolerance test was quantified. All values are mean \pm SE. ^b $P < 0.01$ vs rAd-CMV-βgal group.

Lep^{db/db} mice ($n = 14$). As a viral control, we injected adenovirus expressing β-galactosidase under the control of the CMV promoter (rAd-CMV-βgal) at same dosage into diabetic *Lep^{db/db}* mice ($n = 16$). Blood glucose levels started to decrease as early as day 5 after rAd-SP-rINSfur infection, whereas there was no significant change in the blood glucose levels of rAd-CMV-βgal-infected mice. Blood glucose levels reached the normal range on day 14 after virus infection, and were maintained up to 50 d after rAd-SP-rINSfur treatment, when animals were sacrificed (Figure 1B). We also checked the body weights during the experimental period. We found that there was no significant difference between the experimental groups (Figure 1C). These results indicate that augmented insulin gene expression maintained blood glucose levels in the normal physiological range but did not affect body weight gain.

rAd-SP-rINSfur administration improves glucose and insulin tolerance in *Lep^{db/db}* mice

Next, we investigated the ability of rAd-SP-rINSfur-treated mice to clear serum glucose during a glucose tolerance test. At 4 and 6 wk after virus injection, there was a significant difference between the groups in the ability

to remove challenged glucose. Mice injected with the control virus showed glucose intolerance, whereas mice treated with rAd-SP-rINSfur showed improved glucose clearance in response to glucose challenge (Figure 2A and B). Since this result indicated improved glucose responsiveness, we also checked insulin sensitivity. In addition to an enhanced ability to clear loaded glucose, the rAd-SP-rINSfur-treated *Lep^{db/db}* mice showed significantly improved insulin sensitivity compared with the *Lep^{db/db}* mice treated with control virus, which showed relative insulin resistance (Figure 3).

rAd-SP-rINSfur administration preserves endogenous islets in *Lep^{db/db}* mice

Since it is likely that the additional insulin expression from the liver in rAd-SP-rINSfur treated *Lep^{db/db}* mice might relieve the burden that was imposed on the beta cells in diabetic insulin-resistant *Lep^{db/db}* mice, we expected that beta cells would be protected in rAd-SP-rINSfur treated mice. In *Lep^{db/db}* mice, it is known that the increased demand for insulin causes beta cell hypertrophy to generate more insulin^[31], which is a typical characteristic of this type 2 diabetic animal model. Consistently, the islets in *Lep^{db/db}* mice injected with rAd-CMV-βgal virus

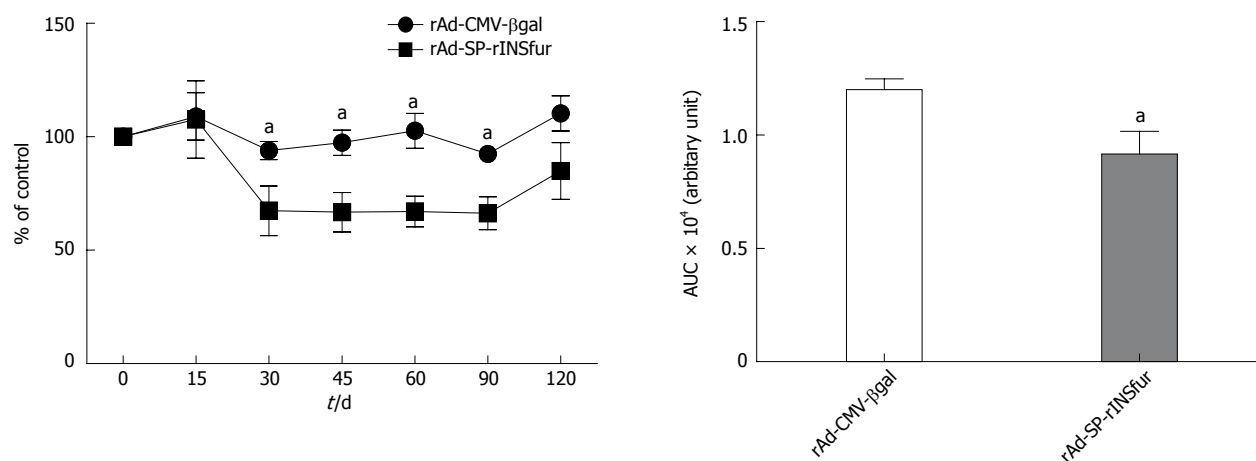

Figure 3 rAd-SP-rINSfur administration improves insulin tolerance in *Lep^{db/db}* mice. Insulin (1.5 U/kg body weight, *ip*) was administered to mice injected with rAd-CMV-βgal or rAd-SP-rINSfur at 5 wk after virus injection (*n* = 4-6), and blood glucose levels were measured. The area under the curve (AUC) for each insulin tolerance test was quantified. All values are mean ± SE. ^a*P* < 0.05 vs rAd-CMV-βgal group.

Figure 4 rAd-SP-rINSfur administration preserves endogenous islets in *Lep^{db/db}* mice. Pancreatic samples were obtained from rAd-CMV-βgal and rAd-SP-rINSfur virus-treated animals on day 50 after virus injection. Tissue sections were prepared and stained with hematoxylin and eosin (HE) or stained with anti-insulin antibody. (A) is 20 × and (B) is 40 × magnification.

were larger than those in rAd-SP-rINSfur-treated mice (Figure 4A). This result suggests that there is less demand for insulin, which will relieve the beta cells from overproduction of insulin. In addition to the size, there seemed to be greater insulin content in the islets from rAd-SP-rINSfur-treated mice (Figure 4B), as shown by darker immunocytochemical staining for insulin, indicating that beta cell function is also preserved by augmented insulin gene expression by insulin gene therapy.

DISCUSSION

The prevalence of type 2 diabetes is increasing in developed and especially in developing countries including South Korea^[32]. In the early period of diagnosis, blood glucose levels can be managed by exercise and oral medication such as rosiglitazone^[13]. However, during progression of disease, these approaches do not control blood glucose levels, and eventually diabetic patients need insulin treatment, as in type 1 diabetes, because the beta cells do not respond to glucose change or the beta cell mass is significantly reduced^[13]. This phenomenon is likely due to prolonged high blood glucose levels (glucotoxicity) and/or high blood lipid levels (lipotoxicity) under insulin resistance status. In addition, beta cells over-produce insulin to compensate for insulin resistance, resulting in endoplasmic reticulum stress, which is known to be one of the main causes of beta cell death in type 2 diabetes. In this context, it is important to find an approach to preserve beta cell function and mass during the early stage of type 2 diabetes. In fact, it was reported that in newly diagnosed type 2 diabetic patients with elevated fasting glucose levels, a short period of intensive insulin therapy helped patients control blood glucose levels in an acceptable range for a long time^[33].

In this study, we demonstrated that additional insulin production by insulin gene therapy improved serum glucose management and glucose tolerance in a type 2 diabetic animal model. In addition to these beneficial effects, there was improved insulin tolerance, indicating that insulin gene therapy is also beneficial for insulin sensitivity. Better glucose management can be explained by increased insulin sensitivity in the liver because of the autocrine action of insulin produced by liver *per se*. In addition, relieving the burden of insulin production would enable beta cells to store more insulin in the vesicles for later needs. We showed that islets from mice injected with rAd-SP-rINSfur appear smaller and appear to contain more insulin compared with control mice, which suggests that glucose tolerance is improved due to enough insulin reservoirs. In addition, lower blood glucose levels are beneficial to preserve beta cell function to secrete insulin in response to serum glucose level changes^[34].

Although there was improved glucose tolerance and insulin sensitivity, these effects were attenuated in the later period of treatment. It is most likely that insulin gene expression gradually decreases due to clearance by

the host's immune system^[28]. Our previous study clearly showed that an insulin gene delivered by gene therapy was cleared by immune surveillance and thus the effect of the gene was transient^[28]. This transient effect can be overcome by using the new generation of adenoviral vectors that lack most of the viral components, enabling them to escape the host's immune system^[35]. Using lentivirus is another option for prolonging the expression period. This viral vector enables the transgene to integrate into the host chromosome for long-term expression of the transgene^[35].

In this study, we successfully improved glucose management in a type 2 diabetic animal model through preservation of beta cells; however, there are several considerations to improve the current study. First, we need to extend the insulin gene expression for a longer time. Second, we need to consider safety. Even though expression of an insulin gene is beneficial to manage the blood glucose level, there is potential risk of hypoglycemia^[36,37]. Therefore, precautions must be taken to avoid any risk that can be encountered in a future clinical study.

COMMENTS

Background

The prevalence of type 2 diabetes is increasing quickly across the world, and it is widely recognized as one of the leading causes of death in the United States. It is closely related to insulin resistance and subsequent loss of beta cell function and mass.

Research frontiers

When type 2 diabetes is clinically diagnosed, there is still a portion of beta cells with normal function. However, this function continues to deteriorate over time despite treatment with diet, exercise or therapeutic drugs. However, studies have found that intensive insulin therapy improves glucose control and preserves beta cell function in the pathogenesis of diabetes. In this study, the authors demonstrate that early insulin treatment using gene therapy improves glucose levels and insulin resistance in obese diabetic mice.

Innovations and breakthroughs

Recent reports have suggested the importance of intensive insulin therapy in the early stages of type 2 diabetes to improve outcomes by preserving beta cell mass and function. In this study, the authors employed insulin gene therapy to provide extra insulin to the body. The therapy induced the liver to produce insulin, driven by a newly developed synthetic promoter which is glucose responsive. The authors successfully improved glucose management in a type 2 diabetic animal model through preservation of beta cells.

Applications

By showing the efficacy of insulin gene therapy, this study may provide a future strategy for therapeutic intervention in the treatment of type 2 diabetic patients.

Terminology

Insulin gene therapy: Delivering an insulin gene into a target organ in the body to express insulin under the control of a glucose-responsive promoter. The insulin required to maintain blood glucose is then provided by insulin gene expression by the target organ, replacing the need for exogenous insulin injections.

Peer review

The authors demonstrated that administration of adenovirus expressing insulin under the control of synthetic promoter that is responsive to glucose change improved serum glucose management and tolerance as well as insulin

tolerance in a genetically obese animal model.

Abstract

AIM: To investigate the capacity for 18F-fluorodeoxyglucose (18F-FDG) positron emission tomography (PET) to evaluate patients with gastrointestinal lesions of follicular lymphoma.

METHODS: This retrospective case series consisted of 41 patients with follicular lymphoma and gastrointestinal involvement who underwent 18F-FDG-PET and endoscopic evaluations at ten different institutions between November 1996 and October 2011. Data for endoscopic, radiological, and biological examinations performed were retrospectively reviewed from clinical records. A semi-quantitative analysis of 18F-FDG uptake was performed for each involved area by calculating the maximum standardized uptake value (SUV-max). Based on the positivity of 18F-FDG uptake in the gastrointestinal lesions analyzed, patients were subdivided into two groups. To identify potential predictive factors for 18F-FDG positivity, these two groups were compared with respect to gender, age at diagnosis of lymphoma, histopathological grade, pattern of follicular dendritic cells, mitotic rate, clinical stage, soluble interleukin-2 receptor levels detected by 18F-FDG-PET, lactate dehydrogenase (LDH) levels, hemoglobin levels,

bone marrow involvement, detectability of gastrointestinal lesions by computed tomography (CT) scanning, and follicular lymphoma international prognostic index (FLIPI) risk.

RESULTS: Involvement of follicular lymphoma in the stomach, duodenum, jejunum, ileum, cecum, colon, and rectum was identified in 1, 34, 6, 3, 2, 3, and 6 patients, respectively. No patient had esophageal involvement. In total, 19/41 (46.3%) patients exhibited true-positive 18F-FDG uptake in the lesions present in their gastrointestinal tract. In contrast, false-negative 18F-FDG uptake was detected in 24 patients (58.5%), while false-positive 18F-FDG uptake was detected in 5 patients (12.2%). In the former case, 2/19 patients had both 18F-FDG-positive lesions and 18F-FDG-negative lesions in the gastrointestinal tract. In patients with 18F-FDG avidity, the SUVmax value of the involved gastrointestinal tract ranged from 2.6 to 17.4 (median: 4.7). For the 18F-FDG-negative ($n = 22$) and -positive ($n = 19$) groups, there were no differences in the male to female ratios (10/12 *vs* 4/15, $P = 0.186$), patient age (63.6 ± 2.4 years *vs* 60.1 ± 2.6 years, $P = 0.323$), presence of histopathological grade 1 *vs* 2 (20/2 and 17/2, $P = 1.000$), follicular dendritic cell pattern (duodenal/nodal: 13/5 *vs* 10/3, $P = 1.000$), mitotic rate (low/partly high, 14/1 *vs* 10/3, $P = 0.311$), clinical stage according to the Ann Arbor system (stages I E and II E/other, 15/7 *vs* 15/4, $P = 0.499$), clinical stage according to the Lugano system (stages I and II-1/other, 14/8 *vs* 14/5, $P = 0.489$), soluble interleukin-2 receptor levels (495 ± 78 *vs* 402 ± 83 , $P = 0.884$), LDH levels (188 ± 7 *vs* 183 ± 8 , $P = 0.749$), hemoglobin levels (13.5 ± 0.3 *vs* 12.8 ± 0.4 , $P = 0.197$), bone marrow involvement (positive/negative, 1/8 *vs* 1/10, $P = 1.000$), detectability by CT scanning (positive/negative, 1/16 *vs* 4/13, $P = 0.335$), and FLIPI risk (low risk/other, 16/6 *vs* 13/6, $P = 0.763$), respectively in each case.

CONCLUSION: These findings indicate that it is not feasible to predict 18F-FDG-avidity. Therefore, 18F-FDG-PET scans represent a complementary modality for the detection of gastrointestinal involvements in follicular lymphoma patients, and surveillance of the entire gastrointestinal tract by endoscopic examinations is required.

INTRODUCTION

To date, 18F-fluorodeoxyglucose (18F-FDG) positron emission tomography (PET) has been widely used for the initial staging of various malignant diseases, as well as for the evaluation of therapeutic responses^[1-5]. Similar to other types of lymphomas^[6-10], follicular lymphoma exhibits a high avidity for 18F-FDG^[11-15]. Correspondingly, the percentage of patients with 18F-FDG-avid follicular lymphoma has been reported to range from 91% to 100%^[16-20]. Furthermore, nodal and extranodal lesions not detected by other modalities have been identified using 18F-FDG-PET, thereby resulting in a significant advance in lesion management^[18-22]. The usefulness of post-treatment 18F-FDG-PET during the follow-up period in cases of follicular lymphoma has also been noted, with positive 18F-FDG accumulation suggesting an adverse outcome^[23-25]. Consequently, 18F-FDG-PET is considered a valuable tool for the management of nodal follicular lymphoma.

Despite these advantages, few studies have addressed the use of 18F-FDG-PET for gastrointestinal involvement of follicular lymphoma. In 2004, Hoffmann *et al*^[26] reported eight cases of follicular lymphoma localized in the duodenum, and 18F-FDG did not accumulate in any of those patients. Subsequently, several authors described follicular lymphoma patients with positive 18F-FDG uptake in the gastrointestinal tract, including the stomach, duodenum, jejunum, ileum, cecum, and colon^[27-30]. However, a limited number of these cases have been reported. Therefore, the sensitivity of 18F-FDG-PET for gastrointestinal lesions of follicular lymphoma has not been sufficiently evaluated.

In this study, 18F-FDG-PET results and clinical characteristics of 41 follicular lymphoma patients with gastrointestinal involvement were retrospectively examined. Based on these results, the role of 18F-FDG-PET in the management of these cases was evaluated.

MATERIALS AND METHODS

A database search performed at the Department of Pathology of Okayama University Graduate School of Medicine, Dentistry, and Pharmaceutical Sciences identified follicular lymphoma patients with gastrointestinal involvement ($n = 80$) treated at ten collaborating institutions between November 1996 and October 2011. The diagnosis of follicular lymphoma was made according to World Health Organization (WHO) classifications^[31,32].

Figure 1 Typical histological features of follicular lymphoma. A, B: Small cleaved cells that infiltrated the duodenal mucosa and formed lymphoid follicles are present (hematoxylin and eosin staining); C: Representative immunohistochemical staining of lymphoma cells negative for CD3; D: Lymphoma cells positive for CD10; E: Lymphoma cells positive for BCL-2. All of the images shown are at 40 × magnification, except for panel B which is at 400 × magnification.

A histological diagnosis was based on morphologic and immunophenotypic analyses of endoscopically biopsied specimens or surgically resected specimens (Figure 1). Histopathological grading was also determined according to WHO criteria^[31]. Patients with grade 3 follicular lymphoma were excluded from this study since these cases are typically managed as diffuse large B cell lymphoma^[31]. A subset of the 80 patients examined were also subjects of our previous studies^[33-36].

Of the 80 patients identified, 30 were excluded since they did not undergo 18F-FDG-PET. Nine patients were further excluded from this study, and these included: four patients that received systemic chemotherapy and remained in complete remission during their 18F-FDG-PET examination, four patients that underwent surgical resection of gastrointestinal lesions and 18F-FDG-PET scans were postoperatively performed, and one patient that underwent 18F-FDG-PET during their initial staging, and later was diagnosed with follicular lymphoma by laparotomy. In the latter case, the patient was not endoscopically evaluated preoperatively. Therefore, a total of 41 patients were enrolled in this study, and data regarding endoscopic, radiological, and biological examinations performed were retrospectively reviewed from their clinical records. Gastrointestinal involvement was defined by gross findings of endoscopic examinations which included esophagogastroduodenoscopy, colonoscopy, double-balloon enteroscopy, and/or video capsule endoscopy. Typically, small, whitish polypoid nodules up to 2 mm in diameter were observed^[37,38]. In cases involving an atypical endoscopic appearance, a histopathological assessment of biopsy specimens was performed to confirm a diagnosis of gastrointestinal involvement.

For all patients, 18F-FDG-PET was performed after patients had fasted for at least 4 h, and it was confirmed that their serum glucose levels were below 150 mg/dL. Moreover, 18F-FDG-PET was preceded by a low-dose computed tomography (CT) scanning, and these scans were used to correct attenuation and to localize anatomical variations visualized in 18F-FDG-PET. The time to initiation of 18F-FDG-PET following the intravenous administration of 18F-FDG also varied according to institution (i.e., 60, 90, or 120 min). A semi-quantitative analysis of 18F-FDG uptake was then performed for each involved area by calculating the maximum standardized uptake value (SUVmax).

Based on the positivity of 18F-FDG uptake in the gastrointestinal lesions analyzed, patients were divided into two groups. To identify potential predictive factors for 18F-FDG positivity, patient gender, age at diagnosis of lymphoma, clinical stage, bone marrow involvement, histopathological grade, soluble interleukin-2 receptor (sIL-2R) levels, lactate dehydrogenase (LDH) levels, and hemoglobin levels were evaluated. CD21 and CD23 staining were also performed to characterize duodenal patterns and nodal patterns of follicular dendritic cells present, as previously described^[35]. To estimate the mitotic rate, Ki-67 staining was performed. Positive staining of 0%-5% of cells was classified as a low mitotic rate, while > 5% positivity was classified as high mitotic activity. The Lugano staging system for classification of gastrointestinal lymphoma^[39,40], and the classical Ann Arbor staging system for nodal lymphoma^[41], were used to determine patients' clinical stages. The follicular lymphoma international prognostic index (FLIPI) was used as well^[42]. Despite FLIPI-2 recently being introduced as an updated

Figure 2 Endoscopic images of follicular lymphoma. A: A gastric lesion with thickened rugae exhibiting a slight redness; B: Typical features of the whitish polypoid granules observed in the duodenum; C: Whitish polypoid lesions in the jejunum; D: Indigo carmine contrast was used to emphasize the slightly elevated small polyps present in the colon; E: An elevated lesion with a flat surface and a 20 mm diameter was observed in the rectum; F: In another patient, polypoid lesions exhibiting hypervascularity on the surface were detected in the rectum.

prognostic index^[43], it was not employed in this study since beta-2-microglobulin levels were not available for all of the patients. In some patients, CT scanning was separately performed from 18F-FDG-PET, and the detectability of gastrointestinal lesions by CT scanning was also analyzed.

For comparisons of the two groups, statistical analyses were performed by JMP 8.0.1 software (SAS Institute, Cary, NC, United States), which included *t*-tests, χ^2 tests, and *F*-tests. A *P*-value less than 0.05 was considered statistically significant.

RESULTS

For detection of gastrointestinal lesions, an esophago-gastroduodenoscopy was performed for all 41 patients included in this study. However, for one patient with colonic follicular lymphoma, the results of the esophago-gastroduodenoscopy performed at another referral center were not available. Colonoscopies were also performed for 29/41 patients. For these patients, the small intestines were evaluated by double-balloon enteroscopy (*n* = 7), video capsule endoscopy (*n* = 6), or both methods (*n* = 3). None of the patients had esophageal involvement. Furthermore, one patient had involvement of the stomach which manifested with thickened rugae observed to have a slight redness to its surface (Figure 2A). Involvement of the duodenum was identified in 34 patients, with the duodenal lesions present in 32 of these patients exhibiting an

accumulation of small, whitish polypoid nodules (Figure 2B). For the other two patients, one presented with erosions having peripheral whitish mucosa in the duodenum, while the other had confluent whitish granules in the duodenum. These atypical macroscopic features were previously described^[44,45]. Jejunal involvement was identified in six patients. Ileal lesions were found in three patients. In the jejunum and ileum, small whitish polypoid nodules, or ulcerative tumors, were observed (Figure 2C). The cecum was found to be involved in two cases, the colon in three patients, and the rectum in six patients. For cases involving the cecum and the colon, multiple polypoid lesions of various sizes were identified (Figure 2D). Moreover, rectal involvement varied in morphology, with nodules, polyps, submucosal tumors, and laterally spreading tumors observed (Figures 2E, F).

Representative images of 18F-FDG-PET performed are shown in Figures 3-6. In addition, the results of 18F-FDG accumulation in the gastrointestinal tract are summarized in Table 1. The sensitivity of 18F-FDG-PET for the detection of gastrointestinal lesions ranged from 33.3% to 100%. It is noteworthy that sensitivity for duodenal involvement was only identified in 35.3% of cases, while the duodenum was the most frequently affected site^[41]. In total, 19 of the 41 patients (46.3%) exhibited true-positive 18F-FDG uptake in the involved gastrointestinal tract. Furthermore, two of these cases had both 18F-FDG-positive lesions and 18F-FDG-negative lesions present in the same gastrointestinal tract. In one patient,

Figure 3 A 60-year-old male patient with duodenal follicular lymphoma without nodal lesions (Lugano system stage I, grade 1). A: An esophagogastroduodenoscopy detected features typical of primary duodenal follicular lymphoma, including small whitish nodules; B, C: 18F-fluorodeoxyglucose positron emission tomography detected tracer uptake in the duodenal second portion (indicated with arrows).

Figure 4 A 65-year-old female patient with duodenal and jejunal follicular lymphoma and intra-abdominal lymph node involvement (Lugano system stage II-1, grade 1). A: An esophagogastroduodenoscopy revealed small whitish nodules present in the duodenum; B: Video capsule endoscopy also identified small nodules present in the jejunum; C, D: 18F-fluorodeoxyglucose positron emission tomography detected tracer uptake in the duodenum (C) and the jejunum (D).

Table 1 Accumulation of 18F-fluorodeoxyglucose detected in the gastrointestinal tract

	Positive involvement (defined by endoscopy)	True-positive 18F-FDG uptake	False-positive 18F-FDG uptake	Sensitivity (%)
Esophagus	0	0	0	NA
Stomach	1	1	1	100.0
Duodenum	34	12	0	35.3
Jejunum	6	5	0	83.3
Ileum	3	1	1	33.3
Cecum	2	2	0	100.0
Colon	3	1	1	33.3
Rectum	6	3	2	50.0

18F-FDG: 18F-fluorodeoxyglucose; NA: Not available.

the duodenum, ileum, cecum, colon, and rectum were endoscopically involved, yet 18F-FDG only accumulated in the ileum, cecum, and colon (Figure 5). Another patient had involvement of the duodenum and ileum, yet only the ileal lesion accumulated 18F-FDG. On the other hand, false-positive 18F-FDG uptake was identified in five patients (12.2%), and false-negative 18F-FDG uptake was found in 24 patients (58.5%).

Thirty-four patients underwent CT scanning separate from 18F-FDG-PET. Gastrointestinal lesions de-

tected by CT involved the duodenum in two cases, the jejunum in one case, and the ileum in two cases. In all cases, gastrointestinal involvement was accompanied by a thickness of the intestinal wall. In 13 cases, gastrointestinal lesions that were not detected by CT scanning were identified by 18F-FDG-PET. Moreover, 18F-FDG-PET detected affected extra-gastrointestinal organs that were not diagnosed by CT scanning. These included the pleura, diaphragm, and adrenal gland in one patient, the pharynx in another, and diffuse splenic invasion in a third patient. Furthermore, regarding the latter patient, the results of 18F-FDG-PET resulted in an upgrade of the Ann Arbor clinical staging from II E to III ES, and in the Lugano system from stage II-2 to stage IV (Figure 6). In regard to 18F-FDG-avid patients, the SUVmax value of the involved gastrointestinal tract region ranged from 2.6 to 17.4 (median: 4.7). Moreover, while one patient had a relatively high SUVmax value of 17.4, the other patients had the SUVmax values less than 10.

A comparison of patients with positive 18F-FDG uptake by their gastrointestinal lesions *vs* those with negative 18F-FDG uptake had no difference in their clinical backgrounds (Table 2). No differences in patient gender, age at the time of diagnosis of lymphoma, clinical stage according to the Ann Arbor and Lugano systems, bone

Figure 5 A 37-year-old female patient with systemic follicular lymphoma and extended gastrointestinal involvement from the duodenum to the rectum (stage IV, grade 1). A: An esophagogastroduodenoscopy detected small whitish nodules present in the duodenum; B, C: A colonoscopy revealed multiple polyps present in the ileum (B), cecum, colon (C), and rectum. Jejunal involvement was confirmed by video capsule endoscopy; D: During 18F-fluorodeoxyglucose positron emission tomography, tracer uptake was only noted in the ileum and colon.

Figure 6 A 61-year-old female patient with follicular lymphoma and duodenal involvement (Lugano system stage IV, grade 1). A: In the duodenum, small whitish nodules were observed; B: 18F-fluorodeoxyglucose positron emission tomography (18F-FDG-PET) detected tracer uptake in the duodenum (indicated with an arrow); C: 18F-FDG-PET identified diffuse lymphoma infiltration into the spleen (indicated with an arrow), which was not detected by computed tomography scanning. In this case, these results upgraded the clinical stage.

marrow involvement, histopathological grade, pattern of follicular dendritic cells, mitotic rate, sIL-2R, LDH, hemoglobin levels, FLIPI, and detectability of gastrointestinal lesions by CT scanning were found between the two patient groups.

DISCUSSION

To the best of our knowledge, this is the largest study on the sensitivity of 18F-FDG-PET for gastrointestinal involvement of follicular lymphoma. Nineteen of our 41 patients showed true 18F-FDG uptake in the involved gastrointestinal tract, resulting in a sensitivity of 46.3%.

In contrast, false-negative 18F-FDG uptake was detected in 24 patients (58.5%), 22 patients (53.7%) exhibited false negative 18F-FDG uptake, and 2 patients (4.9%) showed both true positive and false negative 18F-FDG uptake in gastrointestinal lesions. These results indicate that 18F-FDG-PET is not a reliable imaging tool for evaluating the involvement of the gastrointestinal tract, since greater than half of the patients showed false-negative lesions. It is well-known that follicular lymphoma often affects multiple gastrointestinal tracts. For example, in our previous report, 46 of 54 duodenal follicular lymphoma patients (85.2%) who underwent whole gastrointestinal tract surveillance had extensive involvement within the

Table 2 Clinical backgrounds of the study subjects (mean \pm SD)

small intestine, predominantly in the jejunum (i.e., 40 of 54 patients, 74.1%)^[44]. These data are consistent with those reported in other studies where the percentage of patients with multiple lymphoma lesions in the small intestine ranged from 66.7% to 100%^[29,46-49]. Therefore, in combination, these results suggest that 18F-FDG-PET represents a complementary method for assessing gastrointestinal involvement of follicular lymphoma.

Regarding the false-negative 18F-FDG-PET results obtained in this study, there are many conditions to consider. First, some of the lymphoma lesions may have been too small to be detected by 18F-FDG-PET^[28]. For example, nodes less than 1 to 1.2 cm in diameter have previously been shown to exhibit a false-negative 18F-FDG uptake^[17,50]. In addition, the representative endoscopic features of gastrointestinal follicular lymphoma, especially in small intestinal cases, include the presence of small, whitish polypoid nodules up to 2 mm in diam-

eter^[37,38]. Generally, these lesions remain small and rarely form bulky tumors. In the present report, gastrointestinal lesions could not be detected by CT scanning in 29 of 34 cases (85.3%). In contrast, CT scanning was able to detect gastrointestinal lesions in five cases, four of which showed 18F-FDG uptake. Therefore, although the sensitivity of CT scanning did not statistically correlate with 18F-FDG avidity, small tumor volume appears to have contributed to the false-negative 18F-FDG uptake results obtained. Second, the intensity of 18F-FDG uptake in follicular lymphoma is relatively low compared with aggressive lymphomas^[50,51]. A SUVmax value is a relative quantification of local radiotracer accumulation. Schöder *et al.*^[50] reported SUVmax values for nodal lesions in indolent and aggressive lymphomas to be 7.0 \pm 3.1 and 19.6 \pm 9.3, respectively ($P < 0.01$). They also noted that a SUVmax value > 10 excluded indolent lymphoma with a specificity of 81%. In the present study, all but one patient had a SUVmax value < 10 , and the results of the present findings are in concordance with data reported in an earlier study^[50]. Consequently, small tumor volume and low tracer uptake intensity represent factors that can contribute to false-negative findings.

False-positive FDG uptake by the gastrointestinal tract is another disadvantage associated with 18F-FDG-PET. In this study, five patients had a false-positive 18F-FDG uptake detected in the gastrointestinal tract. Previously it was proposed that physiological peristaltic activity, normal gastrointestinal lymphoid tissue, and granulomatous or inflammatory conditions such as enterocolitis, Crohn's disease, tuberculosis, hemorrhoids, or diverticulitis can cause false-positive 18F-FDG uptake in the gastrointestinal tract^[52]. However, physiologic uptake in the gastrointestinal tract is usually diffuse and its intensity generally moderate. In contrast, intense 18F-FDG uptake can be detected under granulomatous or inflammatory conditions, and even in constipated patients^[53-55]. Therefore, both false-positive, and false-negative, 18F-FDG-uptake represent potential pitfalls in evaluating possible lymphoma involvement of the gastrointestinal tract.

Despite these disadvantages, there are several benefits to the application of 18F-FDG-PET to follicular lymphoma patients with gastrointestinal involvement. First, as demonstrated in the present study, 18F-FDG-PET was able to detect a greater number of involved gastrointestinal sites than CT scanning. For example, 34 patients underwent both CT scanning and 18F-FDG-PET. Of these, 13 (38.2%) had gastrointestinal lesions that were not detected by CT scanning. Second, 18F-FDG-PET was able to detect extra-gastrointestinal sites of involvement. For example, extra-gastrointestinal sites were detected in three patients, and this resulted in an upgrade of clinical stage for one of these patients (Figure 6). Similarly, previous studies of nodal cases found that the clinical staging of follicular lymphoma patients needed to be modified in 18% to 31% of cases based on 18F-FDG-PET results^[17,19,22]. This aspect is particularly

vital for stage I or stage II patients under consideration for radiotherapy as a curative treatment, since most treatment failures occur outside the involved field of radiotherapy^[56]. Thirdly, 18F-FDG-PET can be used to evaluate treatment response if a patient has 18F-FDG-avid gastrointestinal lesions. In nodal follicular lymphoma, disappearance of 18F-FDG accumulation after completion of treatment has been associated with a favorable outcome^[23-25]. Although the cost and benefit (e.g., sensitivity, specificity, and patient acceptability) of 18F-FDG-PET *vs* other modalities, including the combination of CT scanning and endoscopic examinations, remains to be investigated, 18F-FDG-PET represents an option for assessing the therapeutic effect in cases of gastrointestinal involvement of follicular lymphoma.

There were also several limitations associated with this study. First, not all of the patients underwent endoscopic surveillance for the entire gastrointestinal tract. In particular, the small intestine was not evaluated in 25 patients, although multiple sites, including the jejunum and ileum, were frequently involved^[34]. As a result, an overestimation of 18F-FDG-PET sensitivity may have occurred. Second, 18F-FDG-PET was performed under different conditions since the patients included had been treated at various institutions. For example, the period of time between the intravenous administration of 18F-FDG and the initiation of 18F-FDG-PET varied between 60 and 120 min. It is possible that other differences in methodology among the participating institutions may have affected the positivity of 18F-FDG uptake and SUVmax values as well^[57,58].

In conclusion, 19 of 41 follicular lymphoma patients (46.3%) exhibited true-positive 18F-FDG uptake in the involved gastrointestinal tract. In contrast, false-negative 18F-FDG uptake was detected in 24 patients (58.5%). There were also no differences found between the 18F-FDG-PET-positive group and the 18F-FDG-PET-negative group based on the clinical backgrounds of the patients examined, suggesting that it is not feasible to predict 18F-FDG-avidity. However, 18F-FDG-PET may facilitate the detection of gastrointestinal and extra-gastrointestinal sites of involvement. Therefore, we propose that 18F-FDG-PET represents a complementary method for the detection of gastrointestinal lesions of follicular lymphoma. However, endoscopic examinations should be performed to monitor the entire gastrointestinal tract.

COMMENTS

Background

18F-fluorodeoxyglucose (18F-FDG) positron emission tomography (PET) has been widely used for the initial staging of various malignant diseases. Similar to other types of lymphomas, follicular lymphoma exhibits a high avidity for 18F-FDG. The percentage of patients with 18F-FDG-avid follicular lymphoma has been reported to range from 91% to 100%. On the other hand, few studies have addressed the use of 18F-FDG-PET for gastrointestinal involvement of follicular lymphoma.

Research frontiers

Follicular lymphoma is the second most common form of non-Hodgkin's lymphoma in Western countries. Moreover, the number of patients newly diag-

nosed with gastrointestinal follicular lymphoma has been increasing. In the area of management of gastrointestinal follicular lymphoma, the research hotspot is what role does 18F-FDG-PET play in the initial staging.

Innovations and breakthroughs

In 2004, Hoffmann *et al* reported eight cases of follicular lymphoma localized in the duodenum, and they noted that 18F-FDG did not accumulate in any of those patients. Subsequently, several authors described follicular lymphoma patients with positive 18F-FDG uptake in the gastrointestinal tract including the stomach, duodenum, jejunum, ileum, cecum, and colon, but the number of reported cases is limited. Taken together, these inconsistent results indicate that the sensitivity of 18F-FDG-PET for gastrointestinal lesions of follicular lymphoma has not been sufficiently evaluated. Here, the authors provide the first report of the sensitivity of 18F-FDG-PET for the detection of gastrointestinal involvement in follicular lymphoma patients, 46.3%.

Applications

This study results indicates that 18F-FDG-PET may represent a complementary modality for the management of patients with gastrointestinal follicular lymphoma.

Peer review

The authors assessed 41 patients with follicular lymphoma and gastrointestinal involvement, who underwent 18F-FDG-PET and endoscopic evaluations. They demonstrated 46.3% true-positive of 18F-FDG PET in the lesions of the involved gastrointestinal tract. False-negative 18F-FDG uptake was 58.5%, and false-positive was 12.2%. They emphasized on the complementary role of 18F-FDG-PET scan in the diagnosis of gastrointestinal involvements in follicular lymphoma patients. This is a good descriptive study in this query which there is just limited available data.

Abstract

AIM: To identify hepatitis B virus polymerase gene mutations during antiviral therapy using lamivudine-adeфовir sequential monotherapy followed by lamivudine-adeфовir combination therapy.

METHODS: The patient cohort included four adult chronic hepatitis B patients who had undergone sequential monotherapy, first with lamivudine (LMV) and then, after developing viral breakthrough, with adefovir (ADV) therapy. All of the patients had non-response or viral breakthrough after LMV-ADV sequential monotherapy, which resulted in the switching of their antiviral regimen to LMV-ADV combination therapy. Eleven serum samples from the four patients who

showed non-response to rescue LMV-ADV combination therapy were collected sequentially at a time before the antiviral treatment and then during the LMV monotherapy, ADV monotherapy, and LMV-ADV combination therapy. For the genotypic analysis, the whole 1310-bp polymerase gene region was amplified, cloned and sequenced.

RESULTS: All patients had been previously treated with 100 mg of LMV once daily for a 15- to 26-mo period. The emergence of resistance mutations to LMV, such as rtM204V/I and/or rtL180M, were found in all patients. Their antiviral regimens were switched to ADV monotherapy as the second line treatment. All patients had viral breakthrough or non-response after the LMV-ADV sequential monotherapy. ADV-resistant mutations were detected after 13 to 19 mo of LMV-ADV sequential monotherapy. The rtA181V/T mutations were predominantly identified during the ADV treatment in the LMV-resistant patients. Twenty-seven of 38 clones were combined with an amino acid change at rt181; three clones had mutations in rt236 and one clone had a combined mutation. The rtA181V/T mutations were not suppressed by the LMV-ADV combination therapy. Thirty-nine of 64 clones showed an rtA181V/T mutation and six clones showed combined mutations in rt181 and rt236. Mutations in rt204 re-emerged during the combination treatment. The rt181 and rt204 mutations did not co-exist in one clone.

CONCLUSION: Add-on lamivudine therapy with adefovir for adefovir resistance may not suppress the pre-existing adefovir-resistant mutation that develops during lamivudine-adeфовir sequential monotherapy.

INTRODUCTION

Chronic infection with hepatitis B virus (HBV) can result in cirrhosis and hepatocellular carcinoma. The ultimate goal of antiviral therapy for chronic hepatitis is to prevent its devastating complications of decompensated liver cirrhosis and hepatocellular carcinoma. In recent years, the treatment of chronic hepatitis B (CHB) has been improved by introducing nucleos(t)ide analogs (NAs) such as lamivudine (LMV), adefovir (ADV), entecavir (ETV), telbivudine (LDT), and tenofovir (TDF)^[1-5]. However, drug-resistant HBV mutants frequently arise during treatment with NAs, leading to treatment failure and progression to liver disease^[6]. ADV, a phosphate acyclic nucleotide analog of adenosine monophosphate, is a potent inhibitor of HBV reverse transcriptase in the wild-type HBV, and in lamivudine-, telbivudine-, and entecavir-resistant mutants^[7,8]. Switching to ADV has become the most widely-used option since the emergence of LMV-resistant mutations, especially in Asian countries^[8]. The 5-year cumulative probability of genotypic resistance and viral breakthrough was 65.6% and 61.8%, respectively, in LMV-resistant CHB patients^[3]. Unfortunately, ADV resistance occurs more frequently in the second-line treatment of lamivudine-resistant patients than in treatment-naïve patients^[4]. According to large-scale clinical studies of ADV, the rtA181V and rtN236T mutations associated with resistance to ADV were identified in the HBV DNA polymerase gene^[5]. *In vitro* studies demonstrated that those two mutations decreased susceptibility to ADV by 4.3- to 23-fold^[8,9]. Other minor mutations resistant to ADV, such as rtS85A, rtT184S, rtQ215S, rtP237H, rtN238D, and rtM250L, have been reported, but the significance of these mutations is unclear^[4,10,11]. In 2006, it was reported that a novel ADV-resistant HBV variant rtI233V (substitution of isoleucine by valine) was reported to be a cause of primary resistance to ADV^[12,13]. Studies also showed that rtI233V was sensitive to TDF *in vitro*. However, this result was not confirmed in recent studies. To our knowledge, little is known about clonal analysis in patients who successively received LMV monotherapy, ADV monotherapy, and LMV-ADV combination therapy. We investigated the clonal evolution of genetic mutations in the HBV polymerase gene in non-responders to LMV-ADV sequential monotherapy followed by LMV-ADV combination therapy.

MATERIALS AND METHODS

Patients

From January 2003 to July 2007, four adult chronic hepatitis B patients who showed non-response during LMV-ADV combination therapy were identified at Konkuk University Medical Center in Seoul, South Korea. All patients had undergone sequential monotherapy, first with LMV and then, after developing viral breakthrough, with ADV therapy. All of the patients had non-response or viral breakthrough after the LMV-ADV sequential monotherapy which resulted in the switching of their antiviral regimen to LMV-ADV combination therapy. The patients were then followed from when they were switched to an antiviral regimen. These patients gave written informed consent for the treatment of CHB and testing for antiviral resistance. Approval for this study was obtained from the Institutional Review Board at the Konkuk University Medical Center.

Before ADV plus LMV, the clinical and laboratory data of each patient were analyzed, including the quantification of serum HBV DNA levels. After the initiation of LMV-ADV combination therapy, clinical, biochemical, and virological parameters, such as aspartate aminotransferase, alanine aminotransferase (ALT), and serum HBV DNA levels, were monitored every month up to three months. A clinical diagnosis of liver cirrhosis was based on imaging findings, using methods such as abdominal computed tomography or magnetic resonance imaging, together with compatible clinical features such as esophageal varices or thrombocytopenia. The severity of liver cirrhosis was classified according to the Child-Pugh score.

Definitions

Viral breakthrough was defined as a ≥ 1 log₁₀ IU/mL increase in HBV DNA from the nadir on two consecutive occasions after an initial virologic response or an initial decline in HBV DNA by ≥ 1 log₁₀ IU/mL. Non-response was defined as a decrease in serum HBV DNA ≤ 2 log₁₀ IU/mL after at least 24 wk of therapy.

HBV DNA quantification

Serial samples were collected from each patient at the time of initiation of each antiviral agent, every three months during treatment and at the time of viral breakthrough and stored frozen at -80 °C. The serum HBV DNA levels were quantified by real-time polymerase chain reaction, with a lower limit of detection of 2.6 log₁₀ copies/mL (approximately 400 copies/mL). The HBV DNA quantification was also performed before cloning and sequencing using the COBAS TaqMan HBV test (Roche Molecular Systems Inc, Pleasanton, CA, United States).

Detection of antiviral-resistant mutations

Using the stored serum samples, HBV DNA polymerase mutations were analyzed using a matrix-assisted laser desorption/ionization time of flight mass spectrometry

(MALDI-TOF MS)-based genotyping assay, termed a restriction fragment mass polymorphism (RFMP; GeneMatrix, Yongin, South Korea)^[14]. LMV-resistant mutations at rt180 or rt204, and ADV-resistant mutations at rt181 or rt236, were detected using this method.

Cloning of hepatitis B viral polymerase gene

For the genotypic analysis, the entire 1310-bp polymerase gene region was amplified, cloned, and sequenced. To analyze the complete sequence of HBV reverse transcriptase (RT) from four patients with resistant mutations during LMV-ADV combination therapy, we isolated HBV DNA from the patients' sera at the time of viral breakthrough during the antiviral therapy. DNA was extracted using a QIAamp MinElute virus spin kit (Valencia, CA, United States) according to the manufacturer's protocol. To generate HBV1.2mers harboring patient-derived RT mutations, we amplified the RT region of the HBV genome using the following primers: forward, 5'-AAT CTT CTC GAG GAC TGG GGA CCC TGC ACC-3' (the *Xho* I site is underlined) and reverse, 5'-GAG CAG CCA TGG GAA GGA GGT GTA TTT CCG-3' (the *Nco* I site is underlined)^[15]. The purified products were digested with *Xho* I and *Nco* I, after which the wild-type RT sequence of the HBV1.2mer was swapped for the patient-derived sequence. All clones were confirmed by sequencing.

RESULTS

Characteristics of the patients enrolled in this study

Four patients were included in this study. The age of the patients was between 39 and 58 years; all were men who had cirrhosis. All patients had been previously treated with

100 mg of LMV once daily for a 15- to 26-mo period. The emergence of resistant mutations to LMV, such as rtM204V/I and/or rtL180M, was found in all patients. Their antiviral regimens were switched to ADV monotherapy (10 mg/d) as the second line treatment and no patient required a dose reduction. All patients had viral breakthrough or non-response after the LMV-ADV sequential monotherapy (Table 1). ADV-resistant mutations, including rtA181V/T or rtN236T, were detected after 13 to 19 mo of LMV-ADV sequential monotherapy. LMV was added to the ongoing ADV treatment as a salvage therapy.

Virologic response during lamivudine-adefovir combination therapy

The outcome of the LMV-ADV combination therapy in the patients with ADV resistance is demonstrated in Table 1. The duration of the combination therapy was 9 to 15 mo. Patient 1 had viral breakthrough after 26 mo of LMV monotherapy. LMV was stopped and the patient was switched to ADV. Non-response occurred after 18 mo of ADV monotherapy. Patient 2 experienced non-response after 16 mo of second-line ADV monotherapy. Patient 3 had viral breakthrough after 15 mo of LMV monotherapy. Non-response occurred after 19 mo of second-line ADV monotherapy. Patient 4 experienced non-response after 13 mo of second-line ADV monotherapy. One patient continued to receive LMV-ADV combination therapy and three patients were switched to TDF-LMV combination therapy as a salvage therapy.

Evolution of HBV polymerase mutations during antiviral treatment

Clonal analyses were performed in four patients harbor-

ing antiviral resistant mutants at the time of viral breakthrough during the antiviral therapy. From eleven serum samples, we obtained and analyzed a total of 38 clones of the HBV polymerase gene during the ADV monotherapy and a total 64 of clones during the LMV-ADV combination therapy. The sequences were compared against the sequence from genotype C HBV (NCBI GenBank accession no. GQ872210), a wild type HBV genome isolated from the serum of a 25-year-old HBeAg-positive asymptomatic HBV carrier in our hospital.

During the ADV monotherapy, 27 of 38 clones were combined with an amino acid change at rt181. Four clones had a single mutation at rt236, one of which showed an rtA181T + N236T double mutation. During the treatment period with LMV-ADV combination therapy, 39 of 64 clones showed an rtA181V/T mutation. The viral quasispecies evolved with the extension of the combination therapy, followed by LMV-ADV sequential monotherapy (Figure 1). In all patients, clonal analyses during the LMV-ADV combination therapy revealed the maintenance of the rtA181V/T mutant that emerged during the ADV monotherapy (Figure 2). The combined mutation of rtA181V/T + N236T was detected in seven clones. The LMV-resistant mutation rtM204I reemerged in two clones. The combined LMV-resistant mutation rtM204I/V + L1801M was also detected in seven clones. However, the rt181 and rt204 mutations did not co-exist in the same clone.

The clinical course of four patients in whom the clonal analyses were performed during the antiviral treatment is illustrated in Figure 2. In patient 1, the previously noted resistant mutations to LMV, rtM204I, and rtL180M were suppressed, but a resistant mutation to ADV, rtA181V, was detected after the second-line ADV monotherapy. That ADV-resistant mutation remained detectable after 4 mo of combination therapy and a resistant mutation to LMV, rtM204I, was also detected. In patient 2, a resistant mutation to LMV, rtM204V, was suppressed, but a resistant mutation to ADV, rtA181V/T, was detected after the LMV-ADV sequential monotherapy. After 3 mo of LMV-ADV combination therapy, a resistant mutation to ADV remained detectable. In patient 3, the previously noted resistant mutations to LMV, rtM204I and rtL180M were suppressed, but a resistant mutation to ADV, rtA181V/T, was detected after 18 mo of second-line ADV monotherapy. After 10 mo of LMV-ADV combination therapy, a resistant mutation to ADV, rtA181V, remained detectable. In patient 4, resistant mutations to LMV, rtM204V and rtL180M, were suppressed, but a resistant mutation to ADV, rtA181V, was detected after the LMV-ADV sequential monotherapy. After 13 mo of LMV-ADV combination therapy, a resistant mutation to ADV remained detectable, and a resistant mutation to LMV, rtM204I, was also detected.

DISCUSSION

Sequential NA monotherapy can promote the selection for multidrug-resistant HBV mutants, but little is known

about the multidrug-resistant HBV based on clonal analysis. We analyzed the full-length genomic sequence of HBV polymerase in patients who successively received LMV monotherapy, ADV monotherapy, and LMV-ADV combination therapy. This study demonstrated that an ADV mutant, rtA181V/T, was not suppressed by LMV-ADV combination therapy.

Seven drugs are approved by the Food and Drug Administration in the United States for the treatment of HBV infection: interferon alpha, pegylated interferon α -2a, LMV, ADV, ETV, LDT, and TDF^[1]. The treatment of chronic hepatitis B has been improved by the introduction of these NAs. However, drug-resistant HBV mutants frequently arise after the extended use of NAs, leading to treatment failure and progression to liver disease^[16]. The drug resistant mutations selected with one agent may affect the efficacy of the other NAs^[17]. Several major HBV-evolutionary NA-resistance pathways have been characterized^[17]. The rtM204V/I pathway is responsible for the resistance to the L-nucleosides, such as LMV, LDT, and ETV^[17]. The rtN236T pathway is responsible for ADV and TDF resistance^[17]. The rtA181T/V pathway is associated with resistance to LMV and ADV, and is a potential multidrug resistance pathway^[17].

LMV resistance increases progressively over the course of treatment; 14%-32% of patients become resistant to the drug each year after the treatment is initiated, and more than 80% are resistant after 48 mo of treatment^[6,18]. The resistance to LMV was mediated primarily by mutations rtM204I/V \pm rtL180M and rtA181T/V^[6,19]. Viral replication levels may be increased by compensatory mutations, such as rtL80V/I, rtI169T, rtV173L, rtT184S/G, rtS202I, and rtQ215S^[6,20-23].

In treatment-naïve patients, the cumulative percentage of patients who showed ADV resistance has been reported to be 0% in year 1, 3% in year 2, 11% in year 3, 18% in year 4, and 28% in year 5^[4]. The cumulative percentage of patients who showed ADV resistance after ADV monotherapy in the LMV-resistant patients has been reported to be 18% in year 1 and 25% in year 2^[4,14]. The resistance to ADV was initially associated with the rtA181T/V and rtN236T substitutions^[6,24-26]. The rtN236T mutation does not significantly affect the sensitivity to LMV, LDT, or ETV, but does decrease the efficacy of TDF *in vitro*^[6,27]. The rtA181T mutation has been observed in patients who developed viral resistance to LMV or to ADV following LMV breakthrough^[19,28]. The other mutation, rtA181V, has been observed in patients who developed ADV resistance^[4,14,29-31]. Villet *et al.*^[24] suggested that a single amino acid change at position rt181 induced cross-resistance to LMV and ADV. They also reported that the rtA181V/T substitution induced a decreased susceptibility not only to the L-nucleoside LMV, but also to the alkyl phosphonates ADV and TDF^[6,24].

According to a recently reported meta-analysis, the therapeutic potential of the combination of ADV with LMV is beneficial for treating LMV-resistant CHB patients with ADV-associated mutations^[32]. Switching to ADV monotherapy has been widely used in CHB patients

with an LMV-resistant mutation in South Korea and has been reported to be cost-effective so far^[3,33]. However, LMV-ADV sequential monotherapy has led to the frequent development of ADV resistance^[4,5,14]. Combination therapy has been a practical treatment modality for patients who had an ADV-resistant mutation after LMV-ADV sequential monotherapy because TDF was not available. However, to date, the best treatment option for those with ADV resistance has not been identified.

In the present study, we observed the emergence of mutants harboring the rtA181V/T mutation in patients who were treated with LMV during ADV monotherapy^[4].

The emergence of the rtA181V/T mutant was associated with non-response or viral breakthrough during LMV-ADV sequential monotherapy and LMV-ADV combination therapy. We performed the RFMP assay to detect mutations resistant to antiviral agents. This assay enables better quantitative detection of mixed populations, but the result revealed the possibility of the presence of substitutions at other sites in the HBV reverse transcriptase. To analyze the complete sequence, we sequenced all of the clones.

In the present study, clonal analyses during LMV-ADV combination therapy revealed the maintenance of an rtA181V/T mutant that emerged during ADV

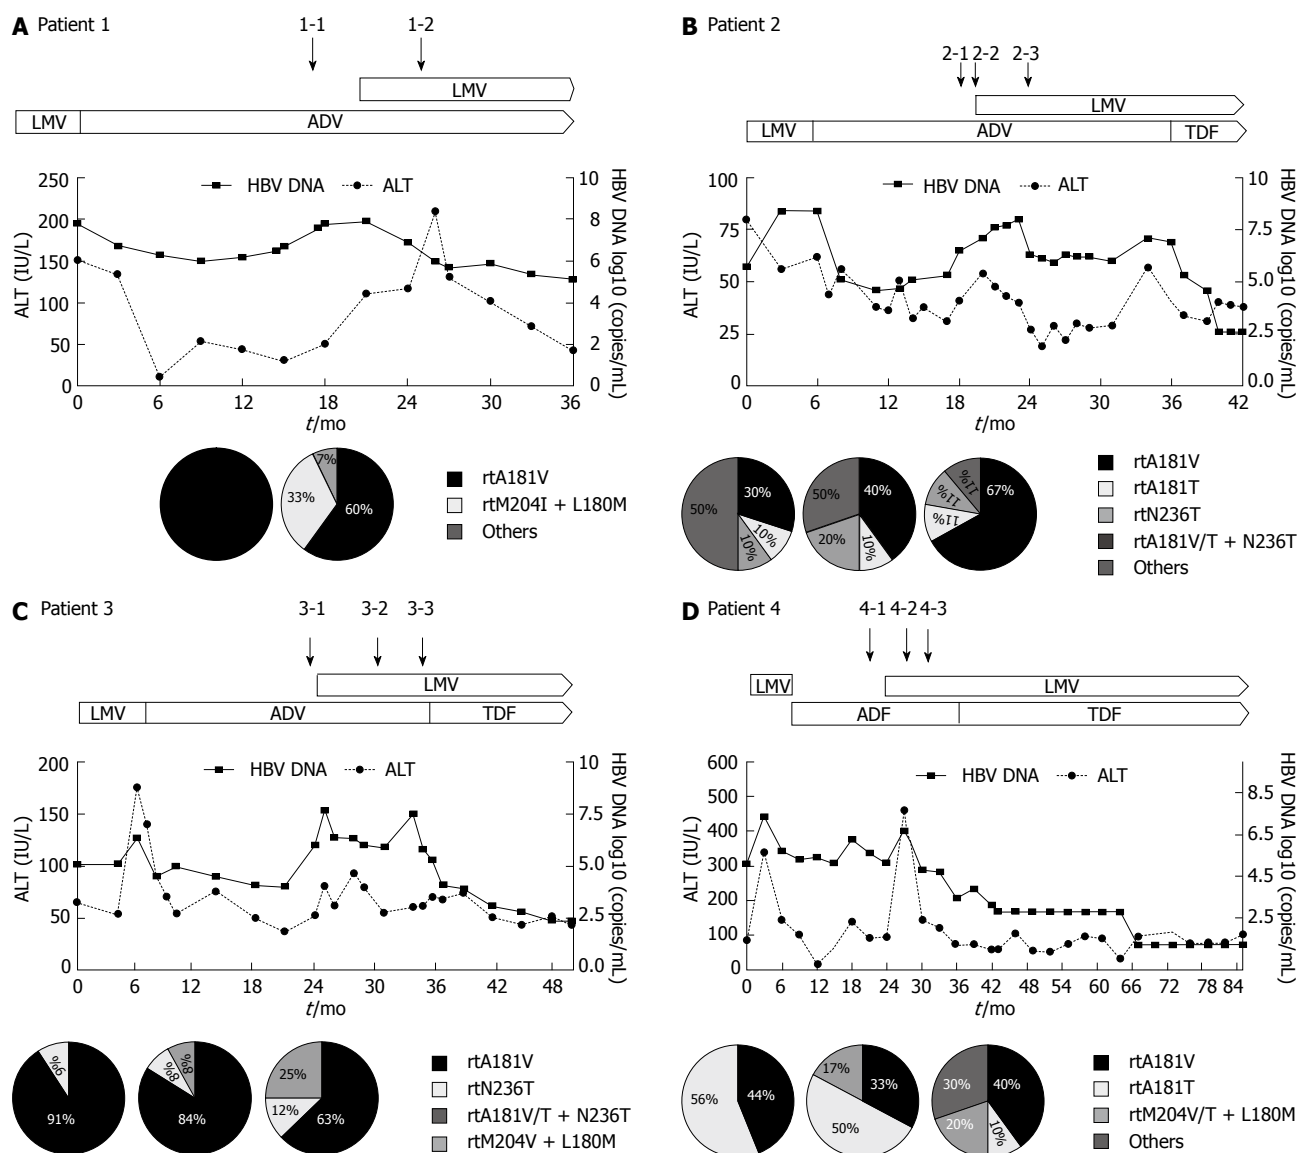

Figure 2 Clinical course and evolution of antiviral mutations in four patients. The arrows and numbers denote the time of the sampling of the serum and the sample number. ADV: Adefovir; ALT: Alanine aminotransferase; LMV: Lamivudine; TDF: Tenofovir; HBV: Hepatitis B virus.

monotherapy. The LMV-resistant mutations rtM204I/V and/or rtL180M reemerged during the LMV-ADV combination therapy. These results showed that LMV-ADV sequential monotherapy may induce the risk of the emergence of ADV-resistant strains in patients who were treated with LMV. Our observation also showed that add-on LMV therapy for ADV resistance might not suppress the pre-existing ADV-resistant mutation that emerged during the sequential treatment with ADV monotherapy for LMV resistance. This result was consistent with the study reported by Villet *et al.*^[24], who showed that a single amino acid change at position rt181 might induce cross-resistance to LMV and ADV.

This study demonstrated that a poor response to LMV-ADV combination therapy did not always occur due to the co-localization of each drug resistance mutation in the same genome. Antiviral agents with a low or modest antiviral potency and low genetic barrier of resistance, such as LMV or ADV, may strengthen viral fitness while not

being strong enough to suppress the drug mutation, and the combination of stronger drugs, such as ETV and TDF, with a high antiviral potency and high genetic barrier of resistance, would be more effective in the treatment of non-responders to LMV-ADV sequential monotherapy. Viral fitness, defined as the ability to produce infectious progeny in a defined environment, was proposed to be one of the most important factors in the process of selecting resistant mutants^[34-36]. We recently reported that TDF plus LMV is a useful therapeutic option for patients with resistance or non-response to ADV, particularly in patients with cirrhosis or who had previously received sequential LMV-ADV monotherapy. TDF-containing therapy was shown to result in a rapid viral load reduction, with HBV becoming undetectable in ADV-resistant patients. At three months, a viral load reduced to a level of 4 log₁₀ copies/mL was achieved in all six patients (100%), and fell to below the limit of detection in three patients (50%)^[37].

Our study has some limitations: the small number

of patients and the variations in the initial HBV DNA levels. These limitations may make establishing this combination as an optimal rescue therapy for patients with ADV-resistant HBV difficult. To verify the efficacy and safety of this regimen, further large cohort studies are warranted.

In conclusion, sequential LMV and ADV monotherapy may favor the emergence of HBV variants with cross-resistance to analogs of different chemical classes. The emergence of rtA181V/T with or without rtM204V/I resulted in viral breakthrough during ADV monotherapy and LMV-ADV combination treatment, as well as a poor response to ADV. Therefore, LMV-ADV combination therapy is not effective in patients with ADV-resistant mutations after LMV-ADV sequential monotherapy. This result may be attributed to an ADV mutation, rtA181V/T, which is responsible for cross-resistance to LMV and ADV. Therefore, careful monitoring and more effective antiviral agents should be considered in chronic hepatitis B patients with multiple resistance mutations.

COMMENTS

Background

The treatment of chronic hepatitis B has been improved by introducing nucleos(t)ide analogs such as lamivudine, adefovir, entecavir, telbivudine, and tenofovir. However, drug-resistant hepatitis B virus (HBV) mutants frequently arise during treatment with nucleos(t)ide analogs. Adefovir resistance occurs more frequently in the second-line treatment of lamivudine-resistant patients than in treatment-naïve patients.

Research frontiers

Little is known about clonal analysis in patients who successively received lamivudine monotherapy, adefovir monotherapy, and lamivudine-adefovir combination therapy. This research hotspot is to demonstrate HBV polymerase gene mutations during antiviral therapy using lamivudine-adefovir sequential monotherapy followed by lamivudine-adefovir combination therapy.

Innovations and breakthroughs

According to a recently reported meta-analysis, the therapeutic potential of the combination of adefovir with lamivudine is beneficial for treating lamivudine-resistant chronic hepatitis B patients with adefovir-associated mutations. However, lamivudine-adefovir sequential monotherapy has led to the frequent development of adefovir resistance. In the present study, clonal analyses during lamivudine-adefovir combination therapy revealed the maintenance of an rtA181V/T mutant that emerged during adefovir monotherapy. The lamivudine-resistant mutations rtM204I/V and/or rtL180M reemerged during lamivudine-adefovir combination therapy.

Applications

The study results suggest that add-on lamivudine therapy with adefovir for adefovir resistance may not suppress the pre-existing adefovir-resistant mutation that develops during the lamivudine-adefovir sequential monotherapy.

Peer review

Combination therapy of lamivudine and adefovir has been widely used in lamivudine-resistant chronic hepatitis B. However, a molecular mechanism is not clearly known by which non-response to combination therapy occurs. This is an interesting study to demonstrate the clonal evolution of HBV drug-resistant mutations during sequential and combination therapy in lamivudine-resistant chronic hepatitis B.

Abstract

AIM: To determine the incidence of human epidermal growth factor receptor 2 (HER2) over expression in oesophageal cancers.

METHODS: A retrospective study, of one hundred consecutive cases of endoscopic histological samples of oesophageal cancers from a single British cancer network were included. Cancer cases were diagnosed between April 2007 and June 2010. HER2 over expression was assessed using immunohistochemistry, those that scored "0" and "+1" were considered "negative" for HER2; those that scored "+3" were considered "Positive". Cases that were scored "+2" on immunohistochemistry further went on to have *HER2* gene analysis using the Ventana HER brightfield dual-colour *in situ* hybridisations (HER B DISH) assay and either came back to be positive or negative for HER2 over expression. Overall survival was measured from date of histological diagnosis until date of death. 93% of the cases were followed up till five years or death, and all were followed up till two years. Cases of gastro-oesophageal junctional tumours were excluded.

RESULTS: The median age of our sample was 66 years (range: 38-91 years). Eighty one were male and 19 female. Ninety-one of the cases were adenocarcinoma of the oesophagus and the rest were cases of squamous cell carcinoma. The anatomical distribution of the tumours was; upper oesophagus 2, middle oesophagus 11, and 87 were in the lower oesophagus. Operative resection was completed in 15 cases; seven cases had attempted surgical resections, i.e., open and close, 33 patients received definitive chemo-radiation and 52 had palliative treatment. Twenty-five of the cancers showed evidence of HER2 over expression, all were adenocarcinomas. Of the 25 cases that showed evidence of HER2 over expression, 21 (84%) were located in the lower third of the oesophagus. On staging, 24 out of the 25 HER2 positive cases were at stage 3 or more (13 at stage 3 and 11 at stage 4), For HER2 negative cases 37 were at stage 3 and 32 were staged as stage 4. Seventeen out of twenty five cases (68%) with HER2 over expression received palliative therapy, in comparison to thirty five out of seventy five (46.7%) in tumours not expressing HER2. No significant difference in overall survival was demonstrated between patients whose cancers showed evidence of HER2 over expression and those who did not; median overall survival for HER2 positive tumours was 15 mo (95%CI, 11-19 mo) compared to 13 mo (95%CI, 9-17 mo) for HER2 negative ones. Two years cumulative survival for cases with HER2 over expression was 33.7% compared to 31.6% in cases without HER2 over expression ($P = 0.576$). Only cancer's stage significantly affected overall survival on both univariate and multivariable analysis ($P = 0.034$ and $P = 0.009$ respectively). None of the patients included in this study received Trastuzumab.

CONCLUSION: Twenty-seven point five percent of oesophageal adenocarcinomas showed evidence of HER2 over expression. Routine testing for human HER2 in oesophageal adenocarcinomas can have significant implication on treatments offered to patients that may

potentially affect their prognosis.

INTRODUCTION

Gastro-oesophageal (GO) cancer is the fifth most common malignancy (and fourth most common cause of cancer death) in the United Kingdom, affecting around 13 500 people each year^[1]. Despite all recent advances in the diagnosis and management of these tumours their prognosis remains poor. Worldwide, gastric cancer is the second most common cause of cancer death^[2]; Oesophageal cancer has an overall five year survival of only 8%, and in view of the relatively high rate of chemotherapy resistance in oesophageal adenocarcinomas^[3,4], additional treatment options are desperately needed.

Human epidermal growth factor receptor 2 (HER2) is the second member of the cell membrane surface bound receptor tyrosine kinase family; this family is made up of four glycoproteins^[5]. Trastuzumab (Herceptin[®]) is a humanized monoclonal antibody targeting HER2^[6]; more evidence is mounting to support its use in upper gastrointestinal tract malignancies.

The ToGA trial studied the benefits of adding Trastuzumab to chemotherapy in patients with inoperable locally advanced, recurrent or metastatic adenocarcinoma of the stomach or GO junction^[7]. Addition of Trastuzumab to chemotherapy significantly improved overall survival. Previous studies to the ToGA trial demonstrated over expression of HER2 in gastric cancers^[8,9]. However, compared to gastric cancer, comprehensive data about HER2 expression in oesophageal adenocarcinomas are relatively scarce^[10].

In view of these facts, the HER2 status for oesophageal tumours was studied in a consecutive series of one hundred oesophageal cancer biopsy specimens obtained at endoscopy between April 2007 and June 2010 aiming to determine the incidence of HER2 in oesophageal cancer. Secondary end points were to assess how HER2 over expression reflects on patients' overall survival, tumours' location and what treatments patients received.

MATERIALS AND METHODS

HER2 assays were performed by an independent, validated and audited laboratory. A Ventana pathway HER2/neu 4B5 assay was utilised. Immunohistochemistry (IHC) scoring criteria were those described by Hofmann *et al*^[11]. Samples were scored as 0, +1, +2 and +3. 0 and +1 are considered negative +3 is positive. Patients with +2 results underwent HER2 gene analysis using the Ventana HER [brightfield dual-colour *in situ* hybridisations (HER B DISH)] assay and either shown to be positive or negative for HER2 over expression.

One hundred consecutive cases of oesophageal cancer were identified between April 2007 and June 2010 from a prospectively maintained British regional upper gastrointestinal tract cancer network database. Biopsies obtained at index endoscopy were analysed for HER2 status. All patients were followed up for two years or until death, 93% were followed up till five years or death. Death certification was obtained from the Office for National Statistics. Cases of GO junctional tumours were excluded.

Statistical analysis

Overall survival was measured from date of histological diagnosis until date of death. Methods appropriate for parametric data were used. Cumulative survival was calculated according to the life-table method of Kaplan and Meier, and differences in survival between groups of patients were analyzed with the log rank test. Correlation was assessed using the Pearson χ^2 test; $P < 0.05$ was considered a statistically significance value. Data analysis was performed using SPSS version 18.0 (Chicago, United States).

RESULTS

The median age of our sample was 66 ± 10.51 years (range: 38-91 years). Eighty-one were male and 19 female. The anatomical distribution of the tumours was; upper oesophagus 2, middle oesophagus 11, and 87 were in the lower oesophagus. Ninety-one of the cases were adenocarcinoma of the oesophagus and the rest were cases of squamous cell carcinoma. Operative resection was completed in 15 cases; eleven cases had an Ivor-Lewis oesophagectomy, three cases had Transhiatal oesophagectomy and one case underwent a three stage oesophagectomy. Seven cases had attempted surgical resections, i.e., open and close. In cases not suitable for surgery, 33 patients received definitive chemo-radiation and 52 had palliative treatment.

In this group of one hundred patients, 25 cases showed evidence of HER2 over expression. On IHC, 28 cases were scored as "0", 38 cases were scored as "+1" and 18 cases were scored as "+3". Of the 16 cases that were scored as "+2" and further underwent analysis using bright field DISH, seven were found positive. All tumours expressing HER2 were adenocarcinomas.

Figure 1 Kaplan-Meier survival curves for human epidermal growth factor receptor 2 positive vs negative groups. HER2: Human epidermal growth factor receptor 2.

None of the oesophageal squamous cell carcinoma cases showed evidence of HER2 over expression.

Of the 25 cases that showed evidence of HER2 over expression, 21 (84%) were located in the lower third of the oesophagus, four (16%) were in the middle third and none were in the upper third.

On staging, 24 out of the 25 HER2 positive cases were at stage 3 or more (13 at stage 3 and 11 at stage 4); one case was a stage 2 and none were a stage 1. For HER2 negative cases 37 and 32 were at stage 3 or 4 respectively, four cases were a stage 2 and two were a stage 1.

No significant difference in overall survival was demonstrated between patients whose cancers showed evidence of HER2 over expression and those who did not: Median overall survival for HER2 positive tumours was 15 mo (95%CI, 11-19 mo) compared to 13 mo (95%CI, 9-17 mo) for HER2 negative ones. This difference was not significant, both on univariate analysis ($P = 0.576$) and multivariable analysis ($P = 0.419$) that included patient's age, cancer stage, cancer location and HER2 status. On the other hand, cancers' stage significantly affected overall survival on both univariate and multivariable analysis ($P = 0.034$ and $P = 0.009$ respectively). Two years cumulative survival for cases with HER2 over expression was 33.7% compared to 31.6% in cases without HER2 over expression ($P = 0.576$). Figure 1 demonstrates Kaplan-Meier survival curves for the two groups.

Only two of the fifteen cases who had disease amenable to surgical resection showed HER2 over expression ($P = 0.208$). Both cases underwent Ivor-Lewis oesophagectomy. Definitive chemo-radiation was given to 33 patients, only six (18.2%) of them expressed HER2. Seventeen out of twenty five cases (68%) with HER2 over expression received palliative therapy, in comparison to thirty five out of seventy five (46.7%) in tumours not expressing HER2 ($P = 0.064$). None of the patients included in this study received Trastuzumab.

DISCUSSION

In our study population, 27.5% of oesophageal adeno-

carcinomas cases in a British regional cancer network demonstrated evidence of HER2 over expression, this rate is in line with previously published series from other countries^[12-14], and is as high, if not higher, than that found in other types of cancer.

In this study, HER2 positive oesophageal adenocarcinomas accounted for a small portion of cases which were suitable to have surgery or definitive chemo-radiation, 13.3% and 18.2% respectively; on the other hand, nearly two thirds of tumours expressing HER2 received palliative treatment (68%). These results may indicate a more aggressive behaviour for oesophageal adenocarcinomas expressing HER2, an observation expressed by other authors^[15].

In this series, HER2 overexpression did not affect overall survival; a recent series by Langer *et al*^[10] suggested otherwise, with tumours overexpressing HER2 having a shorter survival. Similar discrepancy has been described before and the literature holds conflicting data about the prognostic significance of HER2 overexpression^[16-19]. In our sample overall survival was measured from the time of histological diagnosis until time of death. This is inherently inaccurate in that it takes no account of the patient's onset and duration of symptoms nor the biological behaviour of the individual tumour. In Langer *et al*^[20] series, unlike ours, they used two different tissue microarrays for the assessment of HER2 status; with cores from different regions in the microarrays being assessed false-negative results due to intratumoral heterogeneity^[21,22] may have been eliminated. Moreover, for the determination of HER2 status, they used different *in situ* hybridisation methods, i.e., fluorescence *in situ* hybridisation, 3D fluorescence *in situ* hybridisation or bright field double *in situ* hybridisation, which eliminates false-negative results even further.

In this series none of the nine cases of oesophageal squamous cell carcinoma expressed HER2, there is, however, a growing body of evidence showing HER2 to be abnormally expressed in oesophageal squamous cell carcinomas and is associated with poor prognosis. Reported rates of HER2 overexpression in oesophageal squamous cell carcinoma can be as high as that found in oesophageal adenocarcinomas; researchers had described 26%-64% of oesophageal squamous cell carcinomas to test positive to HER2^[23,24]. HER2 over expression has been reported to be associated with extra mucosal tumour invasion and poor response to chemo radiation in oesophageal squamous cell carcinomas^[25,26].

Traditional phase III studies to ascertain the potential role of Trastuzumab in the treatment of oesophageal adenocarcinomas has proven difficult. A power calculation based on our results ($\alpha = 0.05$; 80% power) suggests a retrospective study of 180 patients would be required to clarify the situation. Having said that, a recent Phase I / II study by Safran *et al*^[27] exploring the use of Trastuzumab alongside chemo-radiotherapy in the treatment of oesophageal adenocarcinoma had initially aimed to recruit 25 patients; however, and after 42 mo, they only managed to enrol 19. Safran *et al*^[27] work had concluded

that adding Trastuzumab to chemo-radiotherapy regimens is safe and not associated with increased toxicity.

In the United Kingdom, The standard of care for patients with HER2 positive breast cancer is treatment with Trastuzumab^[28,29]. Also, the National Institute of Clinical Excellence guideline recommends Trastuzumab in combination with cisplatin and capecitabine or 5-fluorouracil in patients with metastatic adenocarcinoma of the stomach or GO junction expressing HER2. There is, however, no British guideline about the use Trastuzumab with HER2 positive oesophageal adenocarcinoma.

So, to summarise, this study demonstrates that in this British population of patients with oesophageal adenocarcinoma, 27.5% of them are HER2 positive. This is at least as high as that found in breast^[30] and probably higher than that found in gastric or GO junctional tumours. HER2 status in patients with oesophageal adenocarcinoma should be routinely assayed and patients should be offered treatment with Trastuzumab if their tumours showed evidence of HER2 over expression. New guidelines should be implemented in the United Kingdom in line with those issued in other countries to offer patients with oesophageal cancers a treatment that can potentially prolong their survival. More work is needed to look at HER2 status in patients with squamous carcinoma of the oesophagus.

ACKNOWLEDGMENTS

The authors would like to thank Dr. Howell S and Mr. Gable C for their help in preparing the histological specimens used in this study. We also would like to thank Ms. Winston K for her hard work liaising with the laboratory throughout the study period.

COMMENTS

Background

Over the last 20 years there has been a steady increase in the annual incidence of gastro-oesophageal (GO) cancers in the Western hemisphere. With that came a lot of research that brought developments to various aspects to these cancers diagnosis and treatment; never the less, these cancers continue to have a poor prognosis and new treatment modalities are desperately needed.

Research frontiers

Molecular targeted therapy offers a new frontier and hope to patients with GO cancers, especially since these cancers had shown resistance to conventional treatment modalities; i.e., chemotherapy and radiotherapy.

Innovations and breakthroughs

Molecular targeted therapy is becoming the standard of care for patients with suitable cancers of the oesophagus in many countries. In the United Kingdom, however, there are still no guidelines to recommend such therapy to British patients. This study demonstrates that the incidence of the target molecule for these new drugs in cases of oesophageal cancer in the United Kingdom is as high as that reported in other countries. British patients whose cancers express this molecule should be offered these new drugs.

Applications

Adding molecular targeted therapy to conventional treatments in patients with cancers of the oesophagus can potentially prolong their survival and improve their prognosis.

Peer review

The authors describe the results of human epidermal growth factor receptor 2

(HER2) assessment in esophageal cancers. They report that 27% of esophageal adenocarcinomas overexpressed HER2. The study is relatively straightforward and confirms existing knowledge on the subject.

Abstract

AIM: To investigate the effects of *Saccharomyces boulardii* (*S. boulardii*) in an experimental rat model of trinitrobenzene sulfonic acid (TNBS)-induced colitis.

METHODS: Thirty-two Wistar albino female rats were categorized into five groups. On the first day of the study, 50 mg TNBS was administered *via* a rectal catheter in order to induce colitis in all rats, except those in the control group. For 14 d, the rats were fed a standard diet, without the administration of any additional

supplements to either the control or TNBS groups, in addition to 1 mg/kg per day *S. boulardii* to the *S. boulardii* group, 1 mg/kg per day methyl prednisolone (MP) to the MP group. The animals in the *S. boulardii* + MP group were coadministered these doses of *S. boulardii* and MP. During the study, weight loss, stool consistency, and the presence of obvious blood in the stool were evaluated, and the disease activity index (DAI) for colitis was recorded. The intestines were examined and colitis was macro- and microscopically scored. The serum and tissue levels of tumor necrosis factor- α (TNF- α) and nitric oxide (NO) were determined, and fungemia was evaluated in the blood samples.

RESULTS: The mean DAI scores for the MP and *S. boulardii* + MP groups was significantly lower than the TNBS group (3.69 ± 0.61 vs 4.46 ± 0.34 , $P = 0.018$ and 3.77 ± 0.73 vs 4.46 ± 0.34 , $P = 0.025$, respectively). While no significant differences between the TNBS and the *S. boulardii* or MP groups could be determined in terms of serum NO levels, the level of serum NO in the *S. boulardii* + MP group was significantly higher than in the TNBS and *S. boulardii* groups (8.12 ± 4.25 $\mu\text{mol/L}$ vs 3.18 ± 1.19 $\mu\text{mol/L}$, $P = 0.013$; 8.12 ± 4.25 $\mu\text{mol/L}$ vs 3.47 ± 1.66 $\mu\text{mol/L}$, $P = 0.012$, respectively). The tissue NO levels in the *S. boulardii*, MP and *S. boulardii* + MP groups were significantly lower than the TNBS group (16.62 ± 2.27 $\mu\text{mol/L}$ vs 29.72 ± 6.10 $\mu\text{mol/L}$, $P = 0.002$; 14.66 ± 5.18 $\mu\text{mol/L}$ vs 29.72 ± 6.10 $\mu\text{mol/L}$, $P = 0.003$; 11.95 ± 2.34 $\mu\text{mol/L}$ vs 29.72 ± 6.10 $\mu\text{mol/L}$, $P = 0.002$, respectively). The tissue NO levels in the *S. boulardii*, MP and *S. boulardii* + MP groups were similar. The mean serum and tissue TNF- α levels were determined to be 12.97 ± 18.90 pg/mL and 21.75 ± 15.04 pg/mL in the control group, 18.25 ± 15.44 pg/mL and 25.27 ± 11.95 pg/mL in the TNBS group, 20.59 ± 16.15 pg/mL and 24.39 ± 13.06 pg/mL in the *S. boulardii* group, 9.05 ± 5.13 pg/mL and 24.46 ± 10.85 pg/mL in the MP group, and 13.95 ± 10.17 pg/mL and 24.26 ± 10.37 pg/mL in the *S. boulardii* + MP group.

Significant differences in terms of the levels of serum and tissue TNF- α and the macroscopic and microscopic scores were not found between the groups. *S. boulardii* fungemia was not observed in any of the rats. However, *Candida* fungemia was detected in one rat (14%) in the TNBS group, two rats (28%) in the *S. boulardii* group, three rats (50%) in the MP group, and three rats (42%) in *S. boulardii* + MP group.

CONCLUSION: *S. boulardii* does not demonstrate considerable effects on the DAI, pathological scores, or cytokine levels but does decrease the tissue NO levels.

INTRODUCTION

It is currently speculated that inflammatory bowel disease (IBD) develops in genetically prone individuals as a result of defective immune responses against enteric bacterial flora antigens. Antibiotics and immunomodulatory therapies are believed to play an important role in the treatment of this disease^[1].

Probiotics are live microorganisms that positively affect health when ingested. *Saccharomyces boulardii* (*S. boulardii*) is a thermophilic nonpathogenic yeast that is selectively used to treat antibiotic-associated and traveler's diarrhea^[2]. The main mechanisms of action of *S. boulardii* include antimicrobial activities, trophic effects upon the intestinal mucosa, and the modification of the host-signaling pathways that are involved in inflammatory and noninflammatory intestinal diseases. It has been shown that *S. boulardii* inhibits the production of proinflammatory cytokines by inhibiting the main regulators of inflammation, such as nuclear factor κ B and mitogen-activated protein kinases, which play crucial roles in the pathogenesis of IBD^[3,4]. *S. boulardii* is believed to effectively treat IBD because of its antimicrobial activities and its regulatory effects on enteric flora and the immune system^[5]. In a recent study^[6], it was shown that treating human colon epithelial cells with *S. boulardii* increases the

expression of peroxisome proliferator-activated receptor- γ and the secretion of inhibits interleukin-8 (IL-8). In the same study, it was demonstrated that *S. boulardii* decreases intestinal inflammation by reducing the mucosal expression of proinflammatory cytokines in rats with trinitrobenzene sulfonic acid (TNBS)-induced colitis. This earlier study demonstrates that colonic inflammation can be reduced by *S. boulardii* through the regulation of inflammatory gene expression.

Nitric oxide (NO) is an important messenger that is involved in vein permeability and tissue damage. It is possible that in patients with active ulcerative colitis (UC) and Crohn's disease (CD), the inducible activity of NO synthase is elevated in inflamed mucosal epithelial cells. Increased NO levels indicate inflammation and, in turn, the intensity of the disease. Variations in tissue NO levels are important indicators of progression and recovery from IBD. There is also evidence that *S. boulardii* inhibits inducible nitric oxide synthase^[7].

In the current literature, there are studies suggesting that *S. boulardii* causes fungemia, particularly in immunosuppressed and intensive care patients^[8]. However, controlled studies cannot be used to investigate the effectiveness of *S. boulardii* against IBD, although promising results have been reported in a few studies^[9,10].

The primary aim of our present study was to investigate the effects of *S. boulardii* on colonic inflammation and the disease activity index (DAI) in a rat model of TNBS-induced colitis. The secondary purpose of our current analyses was to investigate the risk of fungemia resulting from treatment with *S. boulardii* alone or in combination with corticosteroids.

MATERIALS AND METHODS

Animals

Approval was obtained from the animal ethics council of Dokuz Eylul University Medical Faculty (DEUTF). The DEUTF Hospital Experimental Research Laboratory provided 32 female Wistar albino rats weighing 200-250 g for use in this study which were divided into five groups. The control group included only four rats that were not treated with TNBS. All other groups consisted of seven rats (Table 1).

The rats were maintained in a room at a temperature of 23 ± 2 °C under a 12-h light/dark cycle at the DEUTF Experimental Animal Laboratory. Prior to and during the study, the rats were fed a standard diet (Yemta; Taris Ltd. Şti., Izmir, Turkey), and their weights were monitored daily. The rats were allowed water *ad libitum*.

Induction of colitis

After 24 h of fasting, 0.5 mL physiological serum was intracolonic administered to the rats in the control group *via* a cannula that was placed 8 cm proximal to the anus using a rectally inserted flexible polypropylene catheter. To induce colitis in the other groups, the rats were intracolonic treated with 0.5 mL of 100 mg/mL

Table 1 Study groups

Group	n	Application (day 1)	Application (days 1-14)
Control	4	Physiological serum	Physiological serum
TNBS	7	TNBS	No treatment
<i>S. boulardii</i>	7	TNBS	<i>S. boulardii</i>
MP	7	TNBS	MP
<i>S. boulardii</i> + MP	7	TNBS	<i>S. boulardii</i> + MP

TNBS: Trinitrobenzene sulfonic acid; *S. boulardii*: *Saccharomyces boulardii*; MP: Methyl prednisolone.

TNBS that was dissolved in 50% ethanol and administered *via* a cannula. Prior to catheter insertion, short-term sedation was provided *via* ether anesthesia. After TNBS administration, no rats developed perforation or exitus due to the formation of ulcerations in the colon.

Experimental design

As shown in the Table 1, 32 Wistar albino female rats were divided into five groups. The rats in the control group ($n = 4$) were not treated with TNBS after the intracolonic administration of physiological serum (*via* a cannula placed 8 cm proximal to the anus using a rectally inserted polypropylene catheter, similar to the administration of TNBS). After the administration of TNBS, the rats in the TNBS group ($n = 7$) were not treated. *S. boulardii* (Reflor; Biocodex laboratories, Gentilly, France) was prepared in its lyophilized form (282.5 mg/sachet with a biological activity of 5×10^9 viable cells) by the manufacturer. *S. boulardii* (1 mg/kg per day) was suspended in distilled water and added to the water supply of the rats in the *S. boulardii* group ($n = 7$) in the morning and evening starting on day 0. The rats in methyl prednisolone (MP) group ($n = 7$) were treated with MP (Prednol; Mustafa Nevzat, Istanbul, Turkey) at a dosage of 1 mg/kg per day, while the rats in the *S. boulardii* + MP group ($n = 7$) were treated with both *S. boulardii* and MP at the previously defined dosages using the previously discussed techniques.

Disease activity index

TNBS-induced colitis was scored according to the DAI proposed by Murthy *et al*^[11] (Table 2). Scoring was calculated according to body weight loss (as a percentage), differences in stool consistency, and the occurrence of rectal bleeding. Fecal occult blood testing (FOBT) of stool samples (Hemoccult II; Beckman Coulter Inc., Fullerton, CA, United States) was used to detect obscure bleeding.

Pathological examination

After 14 d, blood was drawn from the abdominal aorta under ether anesthesia following 24 h of fasting, and then the rats were sacrificed due to hypovolemia. Decapitation was performed after tissue samples were collected for pathological examination. The abdominal cavity was opened *via* a midline incision, and the whole small and large intestines were harvested from the pylorus to the rectum. The intestinal lumen was washed with physi-

Table 2 Disease activity index analysis¹

Score	Weight loss (%)	Stool consistency	Rectal bleeding
0	-	Normal	-
1	1-5	Loose stool	Occult blood in stool
2	5-10	Loose stool	Occult blood in stool
3	10-20	Loose stool	Occult blood in stool
4	> 20	Watery stool	Obvious blood in stool

¹Data are reported by Murthy *et al*^[11].

ological serum containing phosphate buffer (PBS), and the intestinal materials collected from the opened lumen was fixed in formaldehyde. A pathologist who was blind to the groups conducted the pathological examinations of the intestinal samples.

The scoring method defined by Wallace *et al*^[12] was used to evaluate damage due to colonic inflammation. Fixed intestinal tissue samples were microscopically examined ($5 \times$ magnification) and scored from 0-10 according to various inflammation markers, such as the diameters of any developing ulcers, thickening of the intestinal wall, and hyperemia. While intestinal tissues without any evidence of lesions were scored as 0, intestinal tissues with serious ulcerations were scored as 10. Subsequently, histological sections, including the peripheral normal mucosa, were prepared from gross ulcerative lesions. Approximately 1-cm sections were obtained from the intestines and transported on ice to the Department of Clinical Microbiology (DEUTF, Izmir, Turkey) for homogenization before fixation in formaldehyde. The tissues were fixed in formaldehyde, embedded in paraffin, and stained with hematoxylin and eosin. For the microscopic evaluation, we employed the defined scoring system described by Ameho *et al*^[13].

Tissue homogenization

Prior to sacrifice, blood samples were drawn from the vena cava under ether anesthesia, and the serum was separated by centrifugation and stored at -70°C until use. Homogenization of the intestinal tissues was performed in accordance with current methods^[14]. The intestinal tissues were first homogenized in an ice-cold buffer [0.1 mol/L potassium phosphate (pH 7.5) and 20 mmol/L ethylene diamine tetra acetic acid (EDTA), 1:10 w/v] using a mechanical homogenizer (Potter B. Braun; Gemini, Apeldoorn, The Netherlands) and then in an ultrasonic homogenizer on ice. The resulting lysates were centrifuged at 14 000 rpm for 10 min followed by an additional spin at 14 000 rpm for 20 min. The proteins were purified using zinc sulfate (300 g/L) at a 1:20 ratio, and the final sample concentration of 15 g/L was obtained *via* centrifugation. The final products were centrifuged at 4°C for 20 min at 2000 rpm, and 100- μL samples were subsequently prepared for evaluation of cytokine and NO levels.

NO analysis

The 100- μL intestinal tissue lysates and serum samples

were mixed with an equal volume of 100 μ L of Griess reagent (Ingredient A: 0.1% naphthalene diamine dihydrochloride at a final concentration of 5 mmol/L; Ingredient B: 1% sulfanilamide at a final concentration of 5 mmol/L in orthophosphoric acid) in a 96-well microtiter plate (Maxisorb Immunoplate; NUNC, Roskilde Denmark). After incubation for 10 min at room temperature, the absorbance at 540 nm was measured using a microplate reader (Reader Model 230S; Organon Teknika, Boxtel, The Netherlands). For each measurement, 2-fold increases in sodium nitrite in PBS, from 0–128 mmol/L, were used to generate a standard curve^[15].

Tumor necrosis factor- α analysis

Serum and tissue tumor necrosis factor (TNF)- α levels were measured using a commercially available rat-specific enzyme-linked immunosorbent assay kit according to the manufacturer's instructions (Invitrogen; Life Technologies, Camarillo, CA, United States).

Fungal isolation and identification

Blood samples were cultured in Petri dishes containing the following culture media: Sabouraud dextrose agar (BD Difco; Becton, Dickinson, NJ, United States) supplemented with 100 mg/L chloramphenicol and selective CHROMagar Candida (CHROMagar Candida; CHROMagar, Paris, France). Following incubation at 30 °C for 72 h, the yeast colonies were visually quantified, if they existed. A specimen from each colony variant was placed in a tube containing Sabouraud dextrose agar for storage and identification. Identification was based on the results of filament production tests; the production of the germinative tube, ascospores, urease, and phenoloxidase; and zymogram, auxanogram, and growth rates at different incubation temperatures, as recommended by Boekhout *et al.*^[16,17].

Statistical analysis

Statistical analyses were conducted using SPSS software for windows 11.0 (SPSS, Chicago, IL). Data are expressed as the mean \pm SD. Quantitative data, such as the macroscopic and microscopic scores and NO and TNF- α levels, were compared between groups using the Kruskal-Wallis and Mann-Whitney *U* tests. Differences between the mean were considered statistically significant when *P* < 0.05.

RESULTS

Clinical evaluation

We did not observe diarrhea or bloody stool in the four rats in the control group during the course of this study but these effects were observed in 27 rats starting on day 1, plus one rat on day 2, following the administration of TNBS. In the TNBS and *S. boulardii* groups, a loose stool was noted on day 7 and never returned to normal and diarrhea persisted for a total of 14 d over the course of this study. In the MP group, a loose stool was observed

on day 3 and had returned to normal by day 9. However, in the *S. boulardii* + MP group, the stool returned to normal by day 10 after becoming loose on day 2. The MP and *S. boulardii* + MP groups demonstrated 9 and 10 d of diarrhea, respectively (Figure 1A).

While defecation in the TNBS and *S. boulardii* groups macroscopically continued for an average of 9 and 7 d, respectively, in the following days the FOBT results were positive until day 14. In the MP group, bloody defecation was observed for an average of three days, while for the following six days the FOBT results were positive even without clearly noting bloody defecation. In addition, the blood in the stool was, on average, not observed until day 9. In the *S. boulardii* + MP group, bloody stool was observed for an average of two days, and the FOBT results were positive for seven days; however, there was no traceable blood in the stool samples after day 9 (Figure 1B).

The rats in the control group gained an average of 4.3 g in weight, those in the TNBS and *S. boulardii* groups gained an average of 11.9 and 2.4 g, respectively, and the rats in the MP and *S. boulardii* + MP groups lost 3 and 5.9 g, respectively. No significant differences in body weight changes could be determined between the *S. boulardii*, MP, and *S. boulardii* + MP groups. There were significant differences in body weight changes for the MP and *S. boulardii* + MP groups compared with the TNBS group (*P* = 0.01 and 0.02, respectively) (Table 3).

Based on the scoring system that was previously suggested by Murthy *et al.*^[11], DAI scores were 1 ± 0 for the control group, 4.46 ± 0.34 for the TNBS group, 4.07 ± 0.77 for the *S. boulardii* group, 3.69 ± 0.61 for the MP group, and 3.77 ± 0.73 for the *S. boulardii* + MP group. The DAI scores of the MP and *S. boulardii* + MP groups were significantly lower compared with the TNBS group (*P* = 0.018 and 0.025, respectively). Regarding the other groups, no significant differences in DAI could be determined (Figure 1C).

Pathological evaluation

Macroscopic ulceration was not observed in the control group, although inflammation was observed at the microscopic level. Upon macroscopic examination, a 14-mm ulcer in the intestinal tissue was observed in one rat in the TNBS group, while 3, 2, and 3 larger ulcers (> 2 cm) were observed in the *S. boulardii*, MP, and *S. boulardii* + MP groups, respectively. After macroscopic and microscopic scoring, of all the groups that were induced to form colitis, the lowest score was observed in the TNBS group. When the treated groups were examined, the *S. boulardii* group demonstrated the lowest scores, although significant differences were not found between the MP and *S. boulardii* + MP groups (Figure 1D).

Serum and tissue NO levels

The mean serum NO levels in the control, TNBS, *S. boulardii*, MP, and *S. boulardii* + MP groups were determined to be 5.92 ± 3.65 μ mol/L, 3.18 ± 1.19 μ mol/L, 3.47 ± 1.66 μ mol/L, 8.22 ± 6.28 μ mol/L, and 8.12 ± 4.25

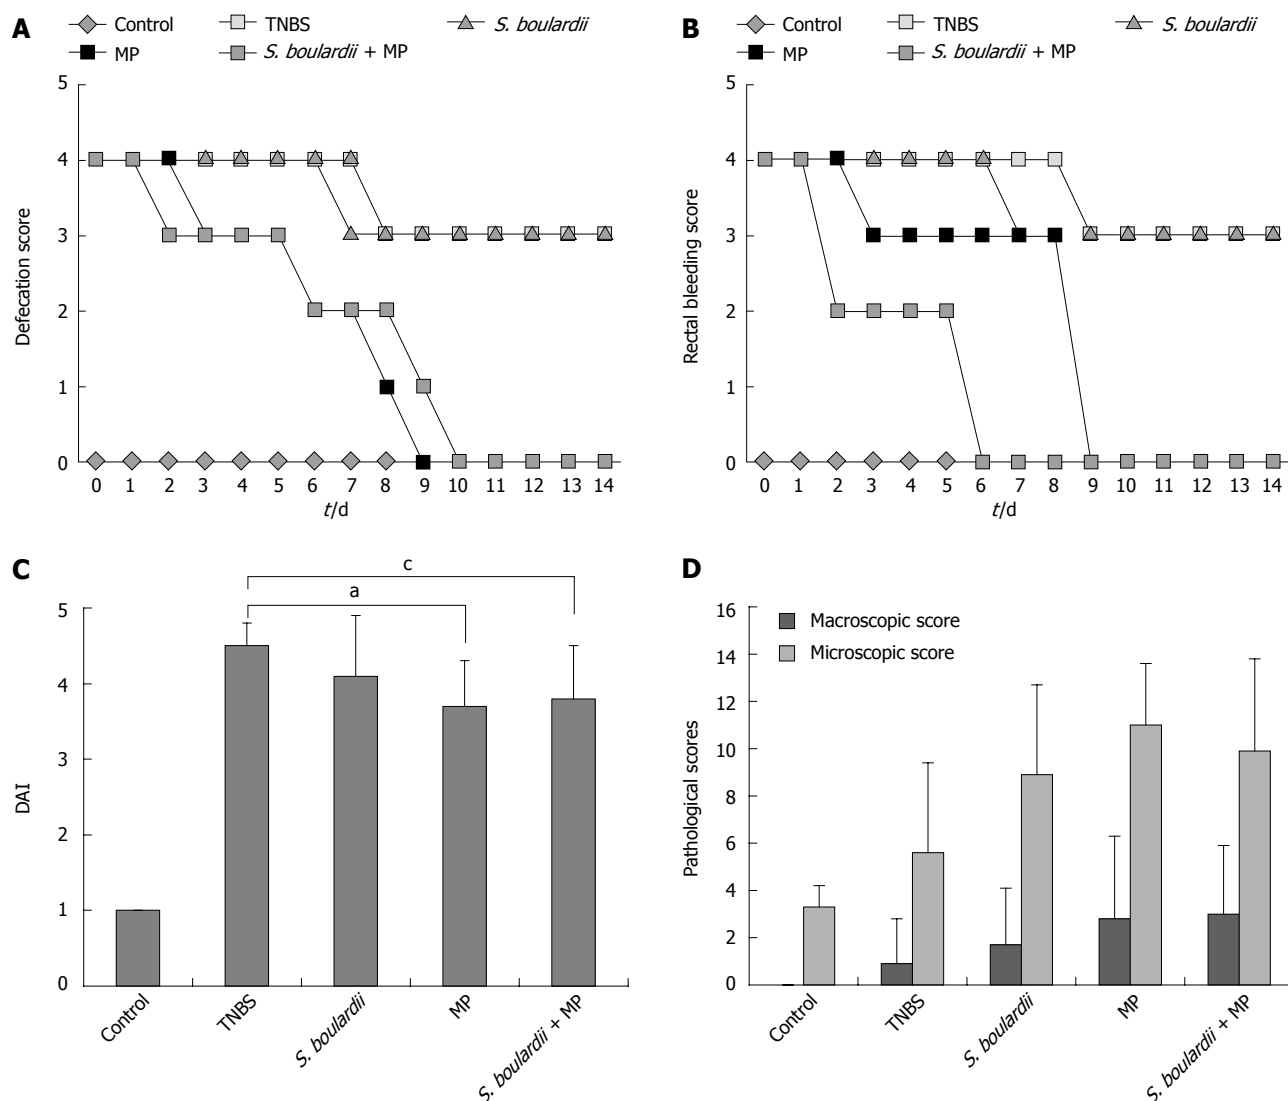

Figure 1 Daily defecation trends, rectal bleeding scores, disease activity index analyses, macro- and microscopic pathological scores of the experimental groups. A: Daily defecation trends; B: Rectal bleeding scores; C: Disease activity index analyses; The results are shown as the mean \pm SD. ^a $P = 0.018$ between trinitrobenzene sulfonic acid (TNBS) and methyl prednisolone (MP) group; ^b $P = 0.025$ between TNBS and *Saccharomyces boulardii* (*S. boulardii*) and TNBS group; D: Macro- and microscopic pathological scores. The results are shown as the mean \pm SD. DAI: Disease activity index.

$\mu\text{mol/L}$, respectively. The lowest serum NO levels were observed in the TNBS and *S. boulardii* groups. The serum NO levels in *S. boulardii* + MP group were higher than those in the TNBS and *S. boulardii* groups ($P = 0.013$ and 0.012 , respectively).

The mean tissue NO levels in the control, TNBS, *S. boulardii*, MP, and *S. boulardii* + MP groups were determined to be $7.95 \pm 0.50 \mu\text{mol/L}$, $29.72 \pm 6.10 \mu\text{mol/L}$, $16.62 \pm 2.27 \mu\text{mol/L}$, $14.66 \pm 5.18 \mu\text{mol/L}$, and $11.95 \pm 2.34 \mu\text{mol/L}$, respectively. The highest tissue NO level was observed in the TNBS group. The tissue NO levels in the *S. boulardii*, MP, and *S. boulardii* + MP groups were significantly lower in comparison with the TNBS group ($P = 0.002$, 0.003 and 0.002 , respectively). However, the tissue NO levels in the *S. boulardii*, MP, and *S. boulardii* + MP groups were similar (Figure 2A).

Serum and tissue TNF- α levels

The mean serum TNF- α levels were determined to be

$12.97 \pm 18.90 \text{ pg/mL}$ in the control group, $18.25 \pm 15.44 \text{ pg/mL}$ in TNBS group, $20.59 \pm 16.15 \text{ pg/mL}$ in *S. boulardii* group, $9.05 \pm 5.13 \text{ pg/mL}$ in MP group, and $13.95 \pm 10.17 \text{ pg/mL}$ in *S. boulardii* + MP group. The mean tissue TNF- α levels were determined to be $21.75 \pm 15.04 \text{ pg/mL}$ in the control group, $25.27 \pm 11.95 \text{ pg/mL}$ in TNBS group, $24.39 \pm 13.06 \text{ pg/mL}$ in *S. boulardii* group, $24.46 \pm 10.85 \text{ pg/mL}$ in MP group, and $24.26 \pm 10.37 \text{ pg/mL}$ in *S. boulardii* + MP group. The serum and tissue TNF- α levels were comparable between groups (Figure 2B).

Detection and identification of fungal pathogens

Fungemia was not observed in the control group but was detected in 1 of 7 rats (14%) in the TNBS group, 2 of 7 rats (28%) in the *S. boulardii* group, 3 of 6 rats (50%) in the MP group (1 rat in the MP group was excluded because sufficient blood samples could not be obtained), and 3 of 7 rats (42%) in the *S. boulardii* + MP group. The

Figure 2 Serum and tissue nitric oxide and tumor necrosis factor- α levels of the experimental groups. A: Serum and tissue nitric oxide levels; B: Serum and tissue tumor necrosis factor (TNF)- α levels. The results are shown as the mean \pm SD. ^a $P < 0.05$ vs *Saccharomyces boulardii* (*S. boulardii*) + methyl prednisolone (MP); ^b $P < 0.05$ vs trinitrobenzene sulfonic acid (TNBS). NO: Nitric oxide.

Table 3 Changes in body weight in the experimental groups

Groups	Baseline weight	Final weight	Difference in body weight
Control	214.0 \pm 18.4	218.25 \pm 19.6	4.3
TNBS	218.1 \pm 18.6	230.0 \pm 17.9	+ 11.9 ^{a,b}
<i>S. boulardii</i>	195.6 \pm 9.1	198.0 \pm 20.2	+ 2.4
MP	199.3 \pm 9.1	196.33 \pm 9.1	- 3.0
<i>S. boulardii</i> + MP	197.3 \pm 10.7	191.43 \pm 9.1	- 5.9

The results are shown as the mean \pm SD. ^a $P = 0.02$ vs *Saccharomyces boulardii* (*S. boulardii*) + methyl prednisolone (MP); ^b $P = 0.01$ vs MP. TNBS: Trinitrobenzene sulfonic acid.

fungemia was determined to be *Candida* fungi other than *C. albicans* using an identification process as explained in materials and methods section. *S. boulardii* fungemia was not identified in any of the rats.

DISCUSSION

It is thought that IBD develops in genetically prone individuals as a result of defective immune responses against the antigens of enteric bacterial flora. Antibiotics and immunomodulatory therapies are believed to be important for the treatment of these diseases^[1]. *S. boulardii* is a probiotic yeast, and it is known that probiotics inhibit pathogenic invasion and also demonstrate regulatory effects on the enteric flora and immune system^[2-5]. Although there are several published studies on probiotic bacterial therapies in experimental animals with induced IBD, there are only a few studies on *S. boulardii*. In this study, the effectiveness of *S. boulardii*, DAI, macro- and microscopic pathological ulcer scores, proinflammatory cytokine levels (i.e., serum and tissue levels of TNF- α), and the serum and tissue levels of lipid peroxidation products (i.e., NO) were evaluated.

In our study, the DAI in the groups that were admin-

istered individual MP or MP with *S. boulardii* were evaluated at significantly lower levels compared with the TNBS group. Meaningful differences in the DAI scores of the *S. boulardii* group were not determined, although the DAI score of the *S. boulardii* group was lower than that of the TNBS group. As expected, these results show that the treatment of colitis using MP effectively improves the symptoms that are observed in rat models of induced colitis. However, the DAI scores were comparable between the MP and *S. boulardii* + MP groups, suggesting that the application of MP in combination with *S. boulardii* might not be more effective than the individual application of MP. In a recent study^[18], *Lactobacillus* and *Bifidobacterium* were used to prevent colitis in rats using dextran sodium sulfate, and DAI scores in the probiotic-treated group were lower than the control group. However there are no other reported studies that have investigated the effects of *S. boulardii* on DAI in an experimental model of colitis.

There are a few clinical studies on the application of *S. boulardii* for the treatment of UC and CD patients. Guslandi *et al*^[9] conducted a study using 32 CD patients who were medically treated and had been in remission for 3 mo. For 6 mo, a group was administered only mesalamine (3 g/d) and another group was administered mesalamine (2 g/d) and *S. boulardii* (1 g/d). After 6 mo, 10 patients in the mesalamine-treated group and 15 patients from the mesalamine + *S. boulardii*-treated group were still in remission ($P < 0.04$). The same researchers conducted another pilot study^[10] on 25 patients with UC of mild/moderate intensity who could not be treated with corticosteroids. After 3 mo of mesalamine (3 g/d) treatment, the patients were additionally supplemented with *S. boulardii* (250 mg administered 3 \times per day) for 4 wk. At the end of treatment, 17 patients (68%) were in remission and had demonstrated an obvious reduction in their clinical activity scores ($P < 0.05$). However, in both studies, *S.*

boulardii was not used alone and a control group was not evaluated.

In our study, macroscopic and microscopic pathological scoring was performed to evaluate the effectiveness of *S. boulardii* against colonic inflammation. Statistically significant differences were not observed between the treated and untreated groups that were induced to form colitis. In addition, no improvement was noted in the colon mucosa following the administration of individual applications of MP and *S. boulardii* or the dual application of MP and *S. boulardii*. However, the use of probiotics, such as *Lactobacillus* and VSL#3 (contains one strain of *streptococcus thermophilus*, three strains of *bifidobacterium* and four strains of *lactobacillus*), for the treatment TNBS-induced colitis in rat models have demonstrated significant improvements in macroscopic and microscopic scores^[19,20]. Surprisingly, in our study, the macroscopic scores in the *S. boulardii*, MP, and *S. boulardii* + MP groups were higher, although they were not significantly different when compared with the TNBS group. In the MP and *S. boulardii* + MP groups, the macroscopic and microscopic pathology scores were higher than in the TNBS group, although these groups also demonstrated significantly lower DAI scores. Thus, these results suggest that the clinical responses are not consistent with the histopathological results. The higher macroscopic and microscopic pathology scores in the treatment groups compared with the TNBS group can be explained by delayed effects in ulcer improvement due to fungal colonization in the gastrointestinal (GI) tract. In our study, non-*Candida albicans* fungemia was detected at considerable frequencies in the treated groups. In a study^[21] on inhibiting *Candida* translocation in the GI tract using probiotics, a group of patients with UC and rats with acetic acid-induced stomach ulcers were included. It was shown that *Candida* colonies formed in these groups, which was accompanied by the delayed recovery of stomach ulcers and the persistence of both of gastric ulcers and UC symptoms. An increase in cytokine expression, especially TNF- α and IL-1 levels, was detected in the rats that were inoculated with *Candida*.

IBD is an immunosuppressive disease caused by a defective intestinal mucosal barrier that can be brought on by applied treatments. Thus, during the course of the disease, insidious infections, such as cytomegalovirus and *C. albicans*, can develop. There are reported cases of the development of fungemia caused by *Candida* species, such as *C. parapsilosis*, *C. albicans*, and *Saccharomyces cerevisiae*, in UC patients. *S. boulardii* fungemia was reported in a 33-year-old male patient who was diagnosed with IBD, underwent intestinal surgery, and was in the intensive care unit^[22]. In our study, fungemia due to *S. boulardii* did not develop in any of the groups. Accordingly, in the colitis rat model, an increase in the risk of developing *S. boulardii* fungemia was not determined upon the application of *S. boulardii* alone or in conjunction with MP. In this study, while fungemia was not observed in the control group, non-*C. albicans* was observed in the TNBS, *S.*

boulardii, MP, *S. boulardii* + MP groups with frequencies of 14%, 28%, 50%, and 48%, respectively. This result is not consistent with previously published reports on the inhibition of *Candida* translocation in the gastrointestinal tract due to the use of probiotics in immunosuppressed rats^[21,23].

In this study, the serum NO level in the group treated with *S. boulardii* + MP was high compared with the TNBS and *S. boulardii* groups. In addition, serum NO levels were comparable between the other groups. However, tissue NO levels in all 3 treatment groups were statistically and significantly lower in comparison with the TNBS group. As observed, the serum and tissue NO levels were inconsistent. However, it is known that the serum NO level is affected by systemic events, and tissue NO levels are more reliable. As a result, based on the results of the TNBS group, tissue NO levels are found to be low in all treatment groups. These results suggest that use of *S. boulardii* and MP alone or in combination can reduce the intensity of inflammation and damage to the colitis mucosa. It was also revealed that the addition of *S. boulardii* to MP treatment does not yield a synergistic effect because the tissue NO levels of the MP and *S. boulardii* + MP groups were similar. In another study^[7], *S. boulardii* treatment reportedly affected NO levels in a rat diarrhea model that was induced by castor oil. In that study, *S. boulardii* was a successful diarrhea treatment that inhibited inducible NO synthase activity. In addition, other probiotics, especially *Lactobacillus* that has been used in induced colitis models, have been reported to reduce the tissue NO level by inhibiting inducible NO synthase activities^[24].

TNF- α is produced by CD4 + T lymphocytes that are assembled around inflamed mucosa. TNF- α is a strong chemokine that functions in pathological inflammatory signal transduction by directing the migration of neutrophils to inflamed mucosa. Therefore, serum and tissue TNF- α levels are mainly used to evaluate the intensity of inflammation. In many studies conducted using *Lactobacillus* in TNBS-induced colitis models, the tissue TNF- α levels in the groups that were administered *Lactobacillus* were significantly reduced compared with the control group^[25,26]. It has been demonstrated that the *Lactobacillus* species used in those studies reduces the number of CD4 + T cells in inflamed mucosa, thus reducing TNF- α production. In addition to these effects, *Lactobacillus* increases the production of anti-inflammatory IL-10 by shifting the T helper₁ (Th₁) cellular immune response towards Th₂ and Th₃. By changing the TNF- α /IL-10 ratio, the intensity of inflammation can be reduced^[26]. In a recent study^[6], it was demonstrated that *S. boulardii* decreases intestinal inflammation by reducing the mucosal expression of proinflammatory cytokines in rats with TNBS-induced colitis. In our study, the serum and tissue TNF- α levels were similar in all groups. These results can be explained by non-*Candida albicans* fungemia, which can cause an increase in cytokine expression^[21]. While there are an insufficient number of studies conducted on *S. boulardii*, *S.*

boulardii is believed to be involved in anti-inflammatory effects by affecting various inflammatory mechanisms^[5-7].

In conclusion, this study establishes that *S. boulardii* does not improve DAI or colonic inflammation in rats with TNBS-induced colitis and does not reduce serum or tissue TNF- α levels. The only significant effect of *S. boulardii* is reducing tissue NO levels. *S. boulardii*-based fungemia was not detected in any of the rats included in this study.

COMMENTS

Background

It is thought that inflammatory bowel disease (IBD) develops in genetically prone individuals as a result of a defective immune response against the antigens of enteric bacterial flora. Antibiotics and immunomodulatory therapies play an important role in the treatment of these diseases. *Saccharomyces boulardii* (*S. boulardii*) is a probiotic yeast, and it is known that probiotics inhibit pathogenic invasion and demonstrate regulatory effects on the enteric flora and immune system. Although there are several published studies on the use of probiotic bacterial therapy in experimental animals with induced IBD, there are a few studies on the involvement of *S. boulardii*.

Research frontiers

The present study shows that *S. boulardii* is a probiotic agent that demonstrates no effects on the disease activity index (DAI), serum and tissue tumor necrosis factor- α (TNF- α) levels, or pathologic findings in a rat model of trinitrobenzene sulfonic acid (TNBS)-induced colitis. However *S. boulardii* may reduce tissue nitric oxide (NO) levels, which is an important messenger involved in vein permeability and tissue damage. *S. boulardii*-based fungemia was not detected.

Innovations and breakthroughs

There are a few clinical studies on the efficacy of *S. boulardii* for treating IBD. Based on the findings of these published studies, *S. boulardii* appears to be promising. In a recent study, it was shown that treating human colon epithelial cells with *S. boulardii* increases the expression of peroxisome proliferator-activated receptor- γ and inhibits the secretion of IL-8. In the same study, it was demonstrated that *S. boulardii* decreases intestinal inflammation by reducing the mucosal expression of proinflammatory cytokines in rats with TNBS-induced colitis. However the effects of *S. boulardii* on DAI and NO were not evaluated. The present study was conducted to investigate the effects of *S. boulardii* on DAI, pathological scores, TNF- α , and NO. Additionally, the risk of fungemia, which could result from treatment with *S. boulardii* alone or in combination with corticosteroids, was also evaluated.

Applications

The present study shows that *S. boulardii* does not improve DAI or colonic inflammation in rats with TNBS-induced colitis or reduce TNF- α levels. These results suggest that *S. boulardii* may not be an effective treatment for patients with IBD. In contrast, the limited number of studies conducted on this issue have reported some promising results. Therefore, further studies are needed in order to draw a firm conclusion.

Terminology

Crohn's disease and ulcerative colitis, both of which are referred to as IBD, are chronic inflammatory disorders of the gastrointestinal tract that have characteristic clinical, pathological, endoscopic, and radiological features. TNBS-induced colitis is well-established in various animal models of mucosal inflammation that have been used for over 2 decades for the study of IBD pathogenesis and in preclinical studies. Probiotics are live microorganisms that positively affect health when ingested. *S. boulardii* is a live yeast that is extensively used as a probiotic.

Peer review

This study examines the impact of *S. boulardii* on TNBS colitis. This is an excellent experimental study that evaluated the effects of *S. boulardii* on clinical activity scores, TNF- α levels, serum and tissue NO levels, and macroscopic and microscopic pathological scores in a rat model of TNBS-induced colitis.

Abstract

AIM: To examine factors influencing percutaneous endoscopic gastrostomy (PEG) uptake and outcomes in motor neuron disease (MND) in a tertiary care centre.

METHODS: Case notes from all patients with a confirmed diagnosis of MND who had attended the clinic at the Repatriation General Hospital between January 2007 and January 2011 and who had since died, were audited. Data were extracted for demographics (age and gender), disease characteristics (date of onset, bulbar or peripheral predominance, complications), date and nature of discussion of gastrostomy insertion, nutritional status [weight measurements, body mass index (BMI)], date of gastrostomy insertion and subsequent progress (duration of survival) and quality of life (QoL) [Amyotrophic Lateral Sclerosis Functional Rating Scale-Revised (ALSF-R)]. In addition, the type of clinician initiating

the discussion regarding gastrostomy was recorded as Nutritional Support Team (involved in providing nutrition input viz Gastroenterologist, Speech Pathologist, Dietitian) and other (involved in non-nutritional aspects of patient care). Factors affecting placement and outcomes including length of survival, change in weight and QoL were determined.

RESULTS: Case records were available for all 86 patients (49 men, mean age at diagnosis 66.4 years). Thirty-eight patients had bulbar symptoms and 48 had peripheral disease as their presenting feature. Sixty-six patients reported dysphagia. Thirty-one patients had undergone gastrostomy insertion. The major indications for PEG placement were dysphagia and weight loss. Nine patients required immediate full feeding, whereas 17 patients initially used the gastrostomy to supplement oral intake, 4 for medication administration and 1 for hydration. Initially the PEG regime met $73\% \pm 31\%$ of the estimated total energy requirements, increasing to $87\% \pm 32\%$ prior to death. There was stabilization of weight in patients undergoing gastrostomy [BMI at 3 mo ($22.6 \pm 2.2 \text{ kg/m}^2$) and 6 mo ($22.5 \pm 2.0 \text{ kg/m}^2$) after PEG placement compared to weight at the time of the procedure ($22.5 \pm 3.0 \text{ kg/m}^2$)]. However, weight loss recurred in the terminal stages of the illness. There was a strong trend for longer survival from diagnosis among MND in PEG recipients with limb onset presentation compared to similar patients who did not undergo the procedure ($P = 0.063$). Initial discussions regarding PEG insertion occurred earlier after diagnosis when seen by nutrition support team (NST) clinicians compared to other clinicians. ($5.4 \pm 7.0 \text{ mo}$ vs $11.9 \pm 13.4 \text{ mo}$, $P = 0.028$). There was a significant increase in PEG uptake (56% vs 24% , $P = 0.011$) if PEG discussions were initiated by the NST staff compared to other clinicians. There was no change in the ALSFRS-R score in patients who underwent PEG (pre 34.1 ± 8.6 vs post 34.8 ± 7.4), although in non-PEG recipients there was a non-significant fall in this score (33.7 ± 7.9 vs 31.6 ± 8.8). Four patients died within one month of the procedure,

4 developed bacterial site infection requiring antibiotics and 1 required endoscopic therapy for gastric bleeding. Less serious complications attributed to the procedure included persistent gastrostomy site discomfort, poor appetite, altered bowel function and bloating.

CONCLUSION: Initial discussion with NST clinicians increases PEG uptake in MND. Gastrostomy stabilizes patient weight but weight loss recurs with advancing disease.

Nutritional support teams increase percutaneous endoscopic gastrostomy uptake in motor neuron disease. *World J Gastroenterol* 2012; 18(44): 6461-6467 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i44/6461.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i44.6461>

INTRODUCTION

In patients with motor neuron disease (MND), the management of dysphagia either at diagnosis or developing during disease progression remains a major clinical issue^[1-3]. Provision of adequate nutrition is important in these patients as malnutrition and dehydration can increase the rate of disease progression and adversely upset quality of life (QoL)^[1]. Although percutaneous endoscopic gastrostomy (PEG) insertion is an important strategy in optimizing nutritional management, the effect of this intervention on survival remains controversial with studies reporting both benefit^[2] and lack of effectiveness^[3,4]. The reasons for these discrepancies are unclear and may relate, in part, to the timing of PEG insertion in different patient subgroups^[4,5]. Weight gain or weight maintenance has been reported as another positive outcome of PEG, but the duration of the effect is also uncertain^[2,6]. Although a number of indications, including weight loss and choking have been proposed for PEG insertion in MND^[6-8], published data indicate that the procedure is performed in less than 50% of patients, who fulfill these criteria^[1]. In part, this may reflect delays in PEG insertion until there is a major clinical deterioration in swallowing^[7], although limited data show subclinical abnormalities in pharyngeal function often occur earlier^[9]. Thus, it is possible that some patients who might benefit from supplemental nutrition may not receive this at the appropriate time^[7].

A number of strategies have been proposed to in-

crease the use of PEG including nutrition education and early discussion of alternative feeding routes^[10,11]. It has also been suggested that involvement of multidisciplinary teams may have a role and potentially improve the length of survival^[11-13].

The aim of the current study was to examine the factors associated with the uptake and the outcomes of PEG placement in patients with MND being managed in a tertiary referral centre.

MATERIALS AND METHODS

A retrospective case note audit was conducted at the Repatriation General Hospital (RGH), a 270-bed university affiliated teaching metropolitan hospital. The study was approved by the Southern Adelaide Clinical Human Research Ethics Committee. To preserve patient anonymity, a unique study ID was assigned to each patient, and personal details were kept separate from the research data.

Patients were included in this study if they had attended RGH for management of MND, and had died between January 2007 and January 2011. All diagnoses of MND were confirmed by one or two neurologists based on El Escorial criteria after appropriate clinical examinations and investigations. Patient characteristics including gender, age, dates of MND onset and diagnosis, presentation features of MND, and complications (the presence of respiratory insufficiency, dysphagia and dementia) were recorded.

The type of MND was classified as either bulbar or limb disease according to symptoms at presentation. Patients with both bulbar and limb symptoms were classified as having bulbar disease.

To assess nutrition status, weights at four times were determined: usual (prior to diagnosis of MND), at diagnosis, at assessment (when the dietetic service was involved), and at death. In patients undergoing gastrostomy, the weight at PEG insertion, and 3 and 6 mo post-procedure were also recorded. Body mass index (BMI) and percentage weight loss (PWL) were also calculated over time.

To assess the role of different clinical groups in PEG management in MND, the type of clinician initiating the discussion of PEG, dates of initial PEG discussion and PEG insertion, and reasons for accepting or declining the procedure, together with the rationale for PEG were recorded. Clinicians with expertise in PEG insertion and management (dietitian, gastroenterologist or speech pathologist) were considered as a nutritional support team (NST). Other clinicians involved in MND management were recorded individually (e.g, palliative care physicians, neurologists, specialist nurses, sleep registered nurses, rheumatologists and general physicians) and grouped as other.

To evaluate the effect of PEG placement on QoL, the results from the Amyotrophic Lateral Sclerosis Functional Rating Scale-Revised (ALSF-R)^[14] were obtained from the Palliative Care MND clinic at the RGH. Scores were extracted from the records at the closest time prior

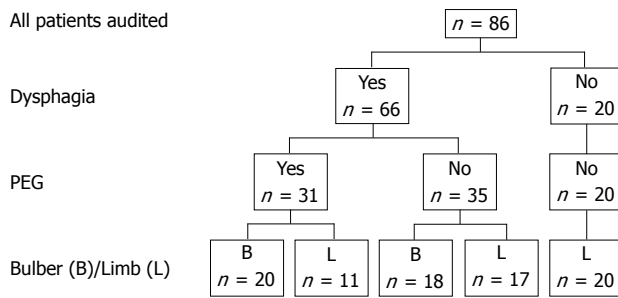

Figure 1 Patient numbers according to dysphagia, percutaneous endoscopic gastrostomy insertion and type of motor neuron disease. PEG: Percutaneous endoscopic gastrostomy.

to (≤ 1 to 5 mo) (Q1) and after (≤ 1 to 5 mo) (Q2) PEG insertion in these patients. For non-PEG patients, ALSFRS-R assessments at “correlated” time points Q1’ and Q2’, corresponding to the mean interval before and after PEG insertion were used for comparison.

The outcomes in terms of formula delivery and level of nutrition support as well as any complications of PEG placement were also recorded.

Extracted data were entered into a spreadsheet and analysed using Predictive Analytics Software Statistics Version 18.0.3 for Windows (PASW, formerly SPSS, SPSS Inc., 2010, Chicago, IL, United States). Patient characteristics were recorded as mean \pm SD and counts (percentages). Categorical data were compared by χ^2 tests. Continuous data between groups and within groups were compared by independent-sample *T* tests and paired-samples *T* tests, respectively. $P \leq 0.05$ was considered statistically significant in all analyses.

RESULTS

Case records were available for all 86 patients with MND who attended the hospital and met the selection criteria. Demographic and disease characteristics are shown in Table 1. The breakdown of the number of patients according to the type of MND, presence of dysphagia and PEG insertion are shown in Figure 1.

In total, 31 subjects underwent PEG placement using a pull technique with either a 20 Fr ($n = 28$) or an 18 Fr device. All of these patients had dysphagia. Patients with bulbar presentation (20/38, 53%), were more likely to have PEG inserted than those presenting with limb symptoms (11/48, 23%, $P = 0.004$).

PEG placement was discussed with 75.6% (65/86) patients, 92.1%, with bulbar (35/38) and 62.5% with limb onset (30/48). The NST initiated these discussions in 36 patients and other clinicians in 29 patients. There was a significant increase in the percentage of patients undergoing PEG when the initial discussions were held with the NST (56% *vs* 24%, $P < 0.02$, Table 2). In addition, these patients had longer time from symptom onset to diagnosis, and a shorter time from diagnosis to PEG. There was no difference in the time from the initial discussion to the

Diagnosis to PEG placement (mo)	10.8 \pm 8.3

MND: Motor neuron disease; PEG: Percutaneous endoscopic gastrostomy.

procedure between the groups.

The major reason for having a PEG inserted was dysphagia ($n = 26$), with severe weight loss ($n = 4$) and prophyllaxis ($n = 1$) also recorded. The reasons for PEG insertion not proceeding after discussion ($n = 38$) were patient preference ($n = 17$), death before PEG placement [$n = 9$, (4 discussed with NST, 5 with other)] and lack of medical fitness for procedure ($n = 1$). In 11 patients no reason for refusal was recorded. In patients who died before the PEG could be undertaken, 4 instances were due to advanced disease and respiratory failure preventing the safe performance of the procedure. Two of these were initially discussed with NST and 2 with other clinicians. Of the other 5 patients (2 NST, 3 other) the patients initially agreed to the gastrostomy but then failed to proceed with the procedure.

Regardless of the presentation (i.e., bulbar or limb), there was a trend towards longer survival in MND patients with dysphagia after PEG insertion (21.6 \pm 15.6 mo), compared to patients who had dysphagia, but did not undergo the procedure (16.8 \pm 11.0 mo, $P = 0.089$). This increased length of survival reflected the effect in patients with limb onset MND who developed dysphagia (PEG: 26.4 \pm 20.4 mo *vs* non-PEG: 14.4 \pm 10.8 mo, $P = 0.063$) (Figure 2) as in bulbar MND patients there was no difference in survival with or without PEG (19.2 \pm 12.0 mo *vs* 18.0 \pm 10.8 mo, $P = 0.656$).

PEG insertion was accompanied by stabilization of patient weight 3 and 6 mo after placement. In contrast, patients who did not undergo PEG placement had ongoing weight loss. However, further weight loss occurred in all patients as MND progressed (Table 3). Thus, the mean BMI for PEG patients decreased significantly from usual weight to diagnosis ($P = 0.003$), diagnosis to assessment for PEG ($P = 0.001$) and from this assessment to death ($P = 0.023$). There was a trend for PEG to be offered to patients who

¹Some data unavailable due to patients being unable to be weighed. Usual-pre-MND diagnosis; Diagnosis-at diagnosis of MND; Assessment-when dietetic service was involved pre-PEG insertion; ²Percentage of weight gain. MND: Motor neuron disease; PEG: Percutaneous endoscopic gastrostomy.

had greater weight loss from diagnosis to assessment (PWL of PEG patients: 5.9% ± 7.0% *vs* PWL of non-PEG patients with dysphagia: 2.3% ± 6.5%, *P* = 0.076).

Initially, 17 patients used PEG to supplement oral intake; nine required immediate full feeding; four used PEG for medication administration and one for hydration. Eight patients were nil by mouth. Initially the feeding regime met 73% ± 31% of the estimated total energy requirements and this increased to 87% ± 32% prior to death.

Fifty-nine patients (68.6%) had at least one assessment with the ALSFRS-R performed during their illness. There was no change in the ALSFRS-R score in patients who underwent PEG (34.1 ± 8.6, *n* = 19 at Q1 and 34.8 ± 7.4, *n* = 17 at Q2). Interestingly, in patients who did not undergo PEG placement, there was a non-significant fall in the ALSFRS-R score from 33.7 ± 7.9 (*n* = 31) at Q1¹ to 31.6 ± 8.8 (*n* = 18) at Q2². There was no significant difference between Q1 and Q1¹ (*P* = 0.886), or Q2 and Q2² (*P* = 0.252).

Possible adverse effects related to the procedure were

**Figure 2** Kaplan-Meier plots of survival probabilities after percutaneous endoscopic gastrostomy placement among patients with limb onset motor neuron disease who developed dysphagia. MND: Motor neuron disease; PEG: Percutaneous endoscopic gastrostomy.

recorded in 19 patients after PEG insertion. These included pain at the site of the gastrostomy at follow up (*n* = 9), poor appetite (*n* = 4), bacterial site infection requiring antibiotics (*n* = 4), death within 30 d (*n* = 4, respiratory failure), nausea (*n* = 3), constipation (*n* = 2), diarrhea (*n* = 2), vomiting (*n* = 2), bloating (*n* = 1) and gastric hemorrhage (*n* = 1).

DISCUSSION

The new findings from this study are that initial discussions of PEG insertion by a NST significantly increases the uptake of PEG by patients with MND, compared to when discussions were initiated by other clinicians. There was also a trend for increased survival for patients with limb onset disease who had a PEG, but not for patients with bulbar onset disease. Consistent with previous studies, PEG placement initially arrested weight loss, although with disease progression patients again lost weight prior to death. Data on the QoL were incomplete but no decrease was seen in the ratings in patients undergoing PEG placement.

Previous reports suggest that the uptake of PEG is approximately 20%^[1], although up to 80% of MND patients developed dysphagia at some point in their illness.

The reasons for this are unclear, but may reflect lack of enthusiasm by both patient and clinicians about a procedure whose value remains uncertain. Also, patients may lack sufficient information about the procedure and its implications. Additionally in some patients, respiratory dysfunction may present a contraindication to gastrostomy by preventing safe performance of the procedure^[9].

The current report extends previous data showing that involvement of multidisciplinary teams in the care of patients with MND enhances the uptake of interventions, including gastrostomy^[10,12,15,16]. In this study, possible PEG placement was discussed with the majority of patients regardless of the presence of dysphagia or the type of presentation of MND. However, the initiation of discussion by clinicians with a background in nutrition significantly increased the patients' uptake of PEG insertion. It is possible that clinicians familiar with MND are more aware of the importance of nutrition adequacy in MND management and clinicians who are closely involved in management of PEG insertions are able to better allay patients' concerns. Furthermore, the NST raised the topic significantly earlier than other clinicians after diagnosis, which potentially allowed more time for the patients to adjust to the concept and undergo PEG insertion before their overall condition deteriorated. The time from PEG discussion to PEG insertion was similar between these two clinician groups suggesting that patients were not simply referred to the NST when nutrition was inadequate. Overall survival of patients undergoing PEG placement was similar irrespective of their referring clinician, suggesting that there was no difference in the patients with whom the procedure was discussed to explain the difference in uptake.

The effect of PEG feeding on survival in patients with MND has been controversial. It is possible that differences in reported outcomes may reflect the different subtypes of MND undergoing the procedure as well as the timing of the procedure^[2,6,9]. In the current study, there was a strong trend for prolonged survival after PEG, but only in those patients with limb onset disease. The reasons for this are unclear. An early study^[2] suggested that PEG prolonged survival significantly in MND patients with bulbar symptoms, including those in whom dysphagia developed at any stage. However, in this study the symptoms at presentation (i.e., bulbar or limb) were not defined^[2]. Another case control study^[5] found no significant survival benefit of the use of PEG, but PEG was associated with prolonged survival in their whole study cohort and among those with bulbar onset; the reasons for this discrepancy are unclear but may reflect an older patient profile in the current study. Forbes *et al.*^[3] found no survival difference, and in their study limb onset patients fared worse than bulbar onset patients, although the survival in this study was shorter than in the present study. Strong *et al.*^[4] found that gastrojejunostomy was associated with shorter survival in either bulbar onset

or limb onset patients; however, the control group in this study contained patients who did not require PEG placement and therefore might have had better nutrition status initially.

Maintaining a patient's weight is a possible advantage of PEG in nutrition management in MND, but the duration of this effect is unclear. In the present study, the patients' weight stabilized for six months after PEG placement, but with disease progression, patients again lost weight. Weight gain at three months post-PEG has been previously described^[5,6], but only one report^[2] has described ongoing weight gain over 12 mo post-gastrostomy. In that study, the patients' baseline BMI prior to PEG insertion was lower (19.7 kg/m²) than in the present study (22.5 kg/m²) and this may explain the discrepancy.

The benefits of PEG in prolonging survival and maintaining weight did not reach statistical significance in this study, and may have reflected a bias in patient selection, since patients who underwent PEG placement had more severe weight loss. Several studies have concluded that lower PWL prior to PEG placement is associated with longer survival^[5]. This suggests that early recognition of weight loss may be important to optimize timing of the procedure^[7]. Consequently PWL has been recommended as the best indicator of malnutrition and for the referral for PEG, rather than BMI^[5,12,16]. In the United Kingdom, using $\geq 10\%$ PWL from baseline has been preferred as an indicator for PEG insertion instead of BMI in MND patients^[17]. An Irish review suggested that PEG was warranted when 5%-10% of weight loss was observed in MND patients^[18], and Chiò *et al.*^[5] found that patients with PWL $\geq 10\%$ fared worse after PEG placement. Thus, the optimal timing remains uncertain^[1,9]. In the current study, an additional interesting finding was that, consistent with other reports^[18], patients experienced rapid weight loss prior to death even with PEG nutrition. The reasons for this are unclear. Although overall PEG feeding did not achieve 100% of the feeding goals (reflecting the desire to provide supplemental feeding/hydration in some patients, and voluntary restriction in others in the terminal phase of their illness) overall nutrition intake appeared adequate. It is possible that loss of muscle mass with disease progression^[19] and increased energy requirement due to respiratory insufficiency^[18] may be important contributory factors.

A further potential benefit from PEG insertion in MND patients has been the potential to improve QoL^[6], but this has not been systematically assessed^[1,2,3,17]. In the current study, ALSFRS-R scores were maintained after the gastrostomy PEG. However, interpretation of the data is limited, in part because of difficulties in obtaining comparable data between PEG and non-PEG patients. In addition, the comparison of QoL is likely to be affected by the severity of dysphagia before PEG placement which in itself contributes to the probability

of the procedure^[8]. Also, adverse effects associated with gastrostomy placement are likely to reduce any positive effects^[1]. Although weight loss, pain and poor appetite have been identified as indicators of decreased QoL^[1,6], their relationship to PEG placement is difficult to assess.

The retrospective nature of the current study means that some caution is required in the interpretation of the data. Thus, although data from all patients with MND seen at the hospital were included in the study, it is impossible to exclude biases due to patient referral. However, the demographics of the patient group are similar to those reported previously. Moreover, as the hospital provides state-wide palliative care for the majority of patients with MND, data are likely to be representative of Australian patients with the condition. Although nutritional advice provided by services external to the hospital was not obtained, it seems unlikely that this impacted significantly on patient care.

In conclusion, initial discussion about PEG placement with a nutrition support team increased the uptake of PEG in patients with MND. Gastrostomy insertion was associated with a strong trend towards longer survival of patients with dysphagia who had limb onset but not bulbar disease. In patients undergoing PEG placement there was initial stabilization of weight, but with disease progression patient weight again decreased.

COMMENTS

Background

Although the importance of percutaneous endoscopic gastrostomy (PEG) feeding to facilitate nutrition support and reduce sarcopenia (potentially decreasing the rate of disease progression) is well recognised in patients with motor neuron disease (MND), only a minority of suitable patients undergo the procedure. The reasons for this are likely to be multifactorial, but may include the availability of information about the intervention. Multidisciplinary management of MND is associated with better uptake, but the reasons for this are uncertain.

Research frontiers

Currently only supportive therapy such as enteral nutrition is available for MND, but who should receive this and when is unclear. Increased knowledge on which sub-groups of patients are assisted by PEG feeding and the timing of the gastrostomy insertion allows patients and clinicians to make more informed decisions to optimize the benefits.

Innovations and breakthroughs

Patients who received counseling from a Nutrition Support Professional were more likely to undergo the procedure. Interestingly the patients with peripheral onset of disease had a trend to longer survival consistent with the concept that muscle mass is preserved by adequate nutrition.

Applications

The findings support the use of multidisciplinary teams in this disease and also provide a possible rationale for the findings of better survival in units where this is undertaken.

Terminology

MND is a progressive neurological condition of unknown aetiology characterized by relentless progression to respiratory failure.

Peer review

Well written manuscript (retrospective study) regarding PEG tube utilization in patients with MND. It provides some new insight to early PEG placement in patients with malnutrition and MND.

Abstract

AIM: To evaluate the utility of magnified narrow-band imaging (NBI) endoscopy for diagnosing and treating minute pharyngeal neoplasia.

METHODS: Magnified NBI gastrointestinal examinations were performed by the first author. A magnification hood was attached to the tip of the endoscope for quick focusing. Most of the examinations were performed under sedation. Magnified NBI examinations were performed for all of the pharyngeal lesions that had noticeable brownish areas under unmagnified NBI observation, and an intrapapillary capillary loop (IPCL) classification was made. A total of 93 consecutive pharyngeal lesions were diagnosed as IPCL type IV and were suspected to represent dysplasia. Sixty-two lesions of approximately 1 mm in diameter were biopsied in the clinic, and 17 lesions with larger diameters were resected by endoscopic submucosal dissection (ESD) at the Hiroshima University Hospital. In addition to the histological diagnoses, the lesion diameters were microscopically measured in 45 of the 62 biopsies. Thirty-

four of the 62 biopsied patients received endoscopic follow up.

RESULTS: Minute pharyngeal lesions were diagnosed in 93 of approximately 3000 patients receiving magnified NBI examinations at the clinic. Of the 93 patients with IPCL type IV lesions, 80 were men, and 13 were women. Fifty-six were drinkers, and 57 were smokers. Two had esophageal cancer. Twenty-one lesions were located on the posterior hypopharyngeal wall, and 72 lesions were located on the posterior oropharyngeal wall. All 93 lesions were flat and showed similar findings in the magnified and unmagnified NBI examinations. Although almost all of the IPCL type IV lesions showed faint redness when examined under white light, it was difficult to diagnose the lesions using only this technique because the contrast was weaker than that achieved in the NBI examinations. Of the 93 lesions, only 3 had diameters greater than 2.1 mm. Sixty-two lesions of approximately 1 mm were biopsied in the clinic, whereas 17 larger lesions were treated by ESD at the Hiroshima University Hospital. Of the 79 pharyngeal lesions that were biopsied or resected by ESD, 5 were histologically diagnosed as high-grade dysplasia, 39 were diagnosed as low-grade dysplasia, and 39 were determined to be non-dysplastic lesions. There were no cancerous lesions. Histologically, abnormal cell size variations and increased nuclear size were observed in all of the high-grade dysplasia lesions, while the incidence of these findings in the low-grade dysplasia lesions was low. Of the 62 biopsied lesions, 45 were microscopically measurable. The measured diameters ranged from 0.1 to 2.0 mm. The dysplasia ratios increased with the diameters. A follow-up endoscopic examination of the 34 biopsied patients found the rate of complete resection by biopsy to be 79%. The largest lesion in which complete resection was expected was a low-grade dysplasia of 1.9 mm in diameter.

CONCLUSION: Minute pharyngeal lesions suspected to be dysplasia that are identified by NBI magnifying

endoscopy should be biopsied to determine the diagnosis and further treatment.

Clinicopathological features of minute pharyngeal lesions diagnosed by narrow-band imaging endoscopy and biopsy. *World J Gastroenterol* 2012; 18(44): 6468-6474 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v18/i44/6468.htm> DOI: <http://dx.doi.org/10.3748/wjg.v18.i44.6468>

INTRODUCTION

Magnified narrow-band imaging (NBI) endoscopy is reportedly useful for early pharyngeal^[1-5] and esophageal cancer diagnosis^[6-10]. Magnified NBI is useful both for detecting suspicious changes and for further diagnostic purposes, such as determining whether a lesion is suspected of being dysplasia or cancer^[11,12]. We routinely examined upper gastrointestinal tracts using magnified NBI for one and a half years. When the unmagnified NBI detected a brownish area in the pharynx, a magnified NBI examination was used to aid the intrapapillary capillary loop (IPCL) classification^[12-14]. If IPCL type IV or V was observed, dysplasia or cancer was suspected, and treatment was considered. Although endoscopic submucosal dissection (ESD) leads to complete resection, ESD is an inpatient procedure that requires intubation anesthesia. For smaller (approximately 1 mm) lesions, therefore, our first choice is to biopsy the lesion for histological diagnosis while performing a complete resection. There have been no previous reports on the utility of biopsying minute pharyngeal lesions. This article reports our histological diagnosis, treatment, and follow-up findings from minute pharyngeal dysplasia biopsies.

MATERIALS AND METHODS

Patients

Most patients over 30 years old who require gastrointestinal endoscopy at the clinic are examined by magnified NBI. From August 2008 to March 2010, a total of 93 consecutive patients with IPCL type IV pharyngeal lesions, as determined by magnified NBI, were enrolled in this study (Table 1). The patients included 80 men aged 39-87 years (mean age, 66.9 years) and 13 women aged

43-84 years (mean age, 67.1 years). Drinking and smoking habits were assessed for 86 patients. Lesions of approximately 1 mm in diameter were found in 62 patients and were biopsied at the clinic, and the 17 patients with larger lesions were endoscopically resected by ESD at the Hiroshima University Hospital. Detailed histological assessments were performed for 62 of the biopsies. Thirty-four of the 62 biopsied patients received follow up endoscopy.

Instruments

The following instruments were used in this study: a magnifying endoscope that was capable of $\times 80$ magnification (GIF H260Z; Olympus Optical Co. Ltd, Tokyo, Japan), a standard videoendoscopy system (EVIS LUCERA; Olympus), and an NBI system (Olympus).

Endoscopic examination

All of the endoscopic examinations were performed by the first author (Kumamoto T). A magnification hood (MB-46, Olympus) was attached to the tip of the endoscope. Intravenous access and pulse oximetry monitoring were established prior to the examination. Most of the examinations were performed under intravenous pethidine hydrochloride (17.5-70 mg) and midazolam (0.5-4 mg) sedation. The pharynx was mainly observed by NBI from the beginning of the examination. The pharynx was examined in the following order: uvula, posterior oropharyngeal wall, epiglottis, posterior hypopharyngeal wall, and pyriform sinus. The pharynx observation time was approximately 1 min. Magnified NBI was used for all pharynx lesions with noticeable brownish areas in the NBI examination, and an IPCL classification was performed. The IPCL classification followed the criteria of Dr. Inoue H^[12,13]. According to these criteria, a lesion must meet three of the following four characteristics to be classified as IPCL type IV: dilatation, tortuous running, caliber changes, and different shapes in each IPCL^[12-14]. In the 93 IPCL type IV lesions, smaller lesions of approximately 1 mm in diameter were biopsied with disposable biopsy forceps (FB-210K, Olympus). To avoid post-biopsy bleeding, all anticoagulants were discontinued from 3 d before to 3 d after the biopsy. The biopsy patients remained in the clinic for 2-3 h, including a 1 h post-sedation recovery time. Annual magnified NBI examinations were recommended to all of the biopsy patients, and 34 of 62 biopsy patients received follow up. To reduce inter-observer variation, the results of the NBI and magnified NBI examinations were independently evaluated by 2 endoscopy examiners (Kumamoto T and Oka S). When the evaluations differed, a consensus decision was achieved by reviewing the magnified NBI images.

Histological methods and criteria for pathological diagnosis

The biopsy specimens were extended and fixed to a styrene foam plate by fine acupuncture needles. All of the specimens were fixed in 10% formalin and embedded in

paraffin wax. The tissue specimens were cut into 3- μ m thick sections, and all of the sections received routine pathological diagnoses. The pathological parameters of each lesion were independently evaluated by two pathologists (Sentani K, Yasui W) and used for further analyses. The dysplasia diagnoses followed the criteria proposed by the World Health Organization^[15]. In this study, dysplasia was classified as low-grade (mild or moderate dysplasia) or high-grade (severe dysplasia). These criteria were based on the architectural and cytological abnormalities. In addition to these abnormalities, IPCL changes were considered^[16]. As shown in Table 2, the histological diagnoses were based on the IPCL changes and on architectural and cytological atypia. The IPCL changes were defined as upward extension, dilatation and branching, and diameter expansion. Architectural atypia was determined by a proliferative cell distribution and the tumor front, and cytological atypia was assessed by cell size, nuclear arrangement and nuclear size. The lesion diameters were measured under light microscopy using the built-in measurement system of the light microscope, which measured to an accuracy of 0.1 mm.

RESULTS

Minute pharyngeal lesions were diagnosed in 93 of approximately 3000 patients who were examined by magnified NBI. The clinicopathological characteristics of the patients are shown in Table 1. Of the 93 patients, 80 were men, and 13 were women. Fifty-six patients were drinkers, 57 were smokers, and 2 had esophageal cancer. Other

cancers included gastric cancer in 8 patients and colon cancer in 1 patient. Twenty-one lesions were located on the posterior hypopharyngeal wall, and 72 lesions were found on the posterior oropharyngeal wall.

All 93 lesions were flat and showed similar findings in the magnified and unmagnified NBI examinations (Figures 1B, C; 2A, B). Most of the IPCL type IV lesions were identifiable immediately after the magnified NBI diagnosis by a faint redness under white light (Figure 1A). However, it was difficult to diagnose IPCL type IV lesions by this characteristic before an NBI examination because the contrast is weaker than that of NBI (Figure 1A, B). Of the 93 lesions, only 3 were greater than 2.1 mm in diameter, and the remaining lesions were less than 2.0 mm in diameter. Sixty-two lesions of approximately 1 mm in diameter were biopsied for histological diagnoses at the clinic, and 17 larger lesions were treated by ESD at the Hiroshima University Hospital. There were no complications, such as bleeding or pharyngeal pain, during or after the ESD.

The histological diagnoses of the 79 lesions resected by biopsy or ESD included 5 cases of high-grade dysplasia, 39 cases of low-grade dysplasia, and 35 non-dysplastic lesions. The 35 non-dysplastic cases consisted of 19 inflamed (pharyngitis) and 16 normal lesions. A lesion diagnosed as high-grade dysplasia is shown in Figure 1, and an example of low-grade dysplasia is shown in Figure 2. There were no cancerous lesions. The histological features of each type of dysplasia are shown in Table 2. In high-grade dysplasia, the polarity of the nucleus was lost, and the nuclear density was markedly increased throughout the intraepithelial layer, although the superficial portion of the epithelium was mature (Figure 1E). The microvascular irregularities were more severe than those seen in low-grade dysplasia. Basal cell palisading was observed in the low-grade dysplasia lesions; however, proliferative cells with enlarged nuclei that proliferated

Non-D: Non-dysplasia; LGD: Low-grade dysplasia; HGD: High-grade dysplasia.

in a lamellar pattern were limited to the lower two-thirds of the epithelial layer (Figure 2D). IPCL abnormalities such as upward extension, dilatation, and diameter expansion were clearly recognized. In the high-grade dysplasia lesions, abnormal variations in cell size and increased nuclear size were observed in all of the lesions, whereas the incidence of these findings in the low-grade dysplasia lesions was low (Figures 1E, 2D). In the non-dysplastic lesions, such as inflamed squamous epithelium, intercellular edema and intraepithelial inflammatory cells were recognizable.

Of the 62 biopsied lesions, 45 were measurable (Table 3). The measured diameters were 0.1-2.0 mm (average, 1.12 mm); 30 lesions were 0.1-1.0 mm in diameter, and 15 lesions were 1.1-2.0 mm in diameter. The distribution of the lesion diameters and the neoplasia ratios are shown in Table 3. The dysplasia ratios (low-grade or high-grade) were 0% less than 0.2 mm, 20%-40% from 0.3 to 0.8 mm, 71% from 0.9 to 1.0 mm, 89% from 1.1 to 1.2 mm, and 100% from 1.3 to 2.0 mm. The ratio increased as the diameter increased. The diameters of the 3 high-grade lesions were 1.0, 1.1, and 1.3 mm.

Twenty-seven of the 34 biopsy patients who received endoscopic follow up (79%) had no lesions at the biopsy site in their NBI examinations, and complete resection from the biopsy was expected in these patients. The interval from the first diagnosis to the follow-up ranged from 4-22 mo (mean, 12.5 mo). The diameters of the lesions in the 3 incomplete resection cases were 0.7 mm, 1.1 mm, and 1.1 mm. Sixteen of the 34 cases were of high- or low-grade dysplasia, and 13 of these 16 cases (81%) had no lesions at the biopsy site. Complete resection from the biopsy was expected in these cases. The largest lesion for which complete resection was expected was 1.9 mm in diameter and was classified as low-grade dysplasia.

DISCUSSION

Magnified NBI endoscopy is preferable for diagnosing minute pharyngeal lesions^[17-21]. The current practice at our clinic is to observe the pharynx and esophagus by NBI from the beginning of the examination. A distal magnification attachment on the endoscope tip is effective

for quick focusing. The typical time for a magnified NBI examination from the pharynx to the duodenum was 10-15 min. The routine pharynx examination time was approximately 1 min.

During the period from September 2008 to March 2010, 93 patients with minute pharyngeal IPCL type IV lesions of approximately 1 mm in diameter were diagnosed at our clinic by magnified NBI endoscopy. During this period, we performed approximately 3000 routine examinations of the upper gastrointestinal tract using magnified NBI endoscopy. Thus, the frequency of such lesions was approximately 3%. Although it is well known that male drinkers and smokers aged over 50 are at high risk for pharyngeal carcinoma^[22], we also observed several cases of low-grade dysplasia in women, and the youngest case was a 39-year-old man. Therefore, we routinely examine almost all men and women over 30 with magnified NBI endoscopy. In the present study, 2 patients had esophageal cancer^[23-26], 8 had gastric cancer, and one had colon cancer. A history of other cancers may also be considered a risk factor.

All 93 lesions were intraepithelial flat lesions. Because the magnified NBI endoscopy findings were similar and showed no clear differences among high-grade dysplasia, low-grade dysplasia and non-dysplastic lesions, the 93 lesions appeared to have similar characteristics. If the lesions had been followed for a longer period, transitions from low-grade to high-grade dysplasia might have occurred. There is controversy over whether such lesions should be followed, biopsied, or treated. Because the histological diagnosis for 3 biopsied cases and 2 ESD cases was high-grade dysplasia, at least 5 lesions (all of which were in men) were considered to be precancerous. Although there were no cancerous lesions in this series^[18], routinely using magnified NBI endoscopy seemed effective for diagnosing pharyngeal precancerous lesions early and showed that IPCL type IV lesions should be biopsied or resected by ESD. Because esophageal IPCL type IV lesions are thought to represent high-grade dysplasia, treatment is recommended^[13]. However, treating smaller esophageal or pharyngeal IPCL type IV lesions (approximately 1 mm in diameter) is still controversial. Whether they should be treated or followed remains to be determined. Because the smaller pharyngeal IPCL type IV lesions in our study contained some precancerous lesions, we recommend biopsy and treatment over follow up.

A survey of the diameters of the biopsied lesions indicated an increase in the dysplasia ratio as the diameter increased, and all lesions over 1.3 mm were found to be dysplastic. Our clinic sees typical outpatients with varied gastrointestinal symptoms or abnormal gastric X-ray findings, and the diameter distribution we observed appears to be close to the natural distribution of such lesions. The diameter of the 3 high-grade lesions ranged from 1.0 to 1.3 mm; therefore, it would appear that lesions greater than 1.0 mm in diameter should be resected by biopsy or ESD. Furthermore, because low-grade lesions as small as 0.3 mm in diameter were observed, it would be better to

resect all lesions less than 1.0 mm in diameter. The diameter distribution appears to show the natural progression from low-grade to high-grade dysplasia.

A follow-up study of the biopsied cases revealed that the resection rate by biopsy alone was 79%. The diameter of the largest resected lesion was 1.9 mm. Although annual endoscopic follow-up must be continued, biopsy may lead to complete resection in some cases and can be performed as a first-line therapy. Single-use disposable biopsy forceps were used to obtain a biopsy specimen as large and as deep as possible for complete resection. For the biopsy, the plane of the opened biopsy forceps should be horizontal, which can be achieved by rotating the handle. Precise, lesion-centered biopsies of 1 mm lesions are difficult^[13] and require high levels of concentration and cooperation between the examiner and the assisting medical staff. Recently, we have biopsied these lesions prior to inserting the endoscope into the esophagus because if we try to biopsy during the final withdrawal stage, the observations may be disturbed by secreted mucus and minute bleeding. Biopsying the pharynx appeared to be safe providing all anticoagulant drugs were discontinued from 3 d before to 3 d after biopsy. We experienced no complications (such as bleeding) after the biopsies.

Compared to the esophagus, the pharynx is sensitive to being touched by an endoscope. Therefore, almost all of the magnified NBI magnifying examinations were performed under sedation. The hypopharynx is particularly sensitive. Without sedation, the pharyngeal reflex causes responsive artificial bleeding, particularly when touched by the distal attachment during examination, and NBI observation becomes difficult due to the brownish color change in the entire endoscopic field. In our experience, magnified NBI endoscopy can be routinely performed with the patient under sedation. However, because deep sedation may cause respiratory depression, sedation should be used cautiously with an intravenous drip, and with oxygen and the counteracting effect of flumazenil readily available. In high-risk patients, such as those with respiratory or heart disease, for safety, we removed the distal attachment on the scope tip or changed the scope to a smaller diameter non-magnifying scope (GIF H260, Olympus).

In conclusion, magnified NBI endoscopy appears to be preferable for diagnosing pharyngeal neoplasia. Biopsy was useful for the diagnosis and treatment of minute pharyngeal neoplasia.

COMMENTS

Background

It has been difficult to diagnose an early-stage pharyngeal carcinoma. Narrow-band imaging (NBI) has enabled more accurate diagnosis and increased the detection rate of superficial pharyngeal carcinomas. Magnified NBI endoscopy is quite effective for diagnosing early-stage pharyngeal and esophageal carcinoma, that is, carcinomas in the squamous cell regions. The intrapapillary capillary loop (IPCL) classification for magnified NBI endoscopy is applicable only to the squamous cell regions, that is, the pharynx and the esophagus. Magnified NBI endoscopy for the stomach and the colon is evaluated by different diagnos-

tic classifications.

Research frontiers

Magnified NBI endoscopy made it possible to diagnose minute pharyngeal lesions with diameters of approximately 1 mm. It includes two steps. First, using NBI endoscopy without magnification, the authors detected suspicious changes as brownish areas. Second, using NBI magnifying of the brownish areas, the authors were able to diagnose whether the changes were suspicious of dysplasia or cancer or not according to the IPCL classification. IPCL type IV or V shows the possibility of dysplasia or cancer, whereas IPCL type I neglects the possibility.

Innovations and breakthroughs

For larger pharyngeal IPCL type IV lesions over 10 mm diameter, endoscopic submucosal dissection (ESD) is recommended. However, for smaller lesions of approximately 1 mm diameter, it remains to be determined whether they should be resected by ESD or followed up. Studies on the biopsy of such lesions are few. The authors concluded that biopsy can be the first-line procedure for such lesions not only for diagnosis but also for treatment.

Applications

The NBI system and magnifying endoscope are necessary to begin magnified NBI endoscopy. As the pharynx is sensitive, magnified NBI endoscopy of the pharynx should be performed under sedation. For safety, sedation should be carried out cautiously. As several biopsied minute pharyngeal lesions were high grade dysplasia, minute pharyngeal lesions should be biopsied for diagnosis. Furthermore, follow-up study of the biopsied lesions showed that even complete resection was expected by biopsy.

Terminology

NBI: NBI is a new image-enhanced optical technology that uses narrow band NBI filters; IPCL: IPCL is the microvascular tumor vessel classification system used for NBI magnifying endoscopy.

Peer review

Recently it has been reported that NBI can be useful in the early detection of superficial pharyngeal cancer. To determine the criteria of endoscopic treatment in patients with pharyngeal cancer and dysplasia, the resected specimen and follow up data are required. It is a good idea to investigate the usefulness of NBI magnifying endoscopy in the pharynx because biopsy in the pharynx is difficult.

Abstract

AIM: To survey irritable bowel syndrome (IBS) using Rome III criteria among Malays from the north-eastern region of Peninsular Malaysia.

METHODS: A previously validated Malay language Rome III IBS diagnostic questionnaire was used in the current study. A prospective sample of 232 Malay subjects (80% power) was initially screened. Using a stratified random sampling strategy, a total of 221 Malay subjects (112 subjects in a "full time job" and 109 subjects in "no full time job") were recruited. Subjects were visitors (friends and relatives) within the hospital compound and were representative of the local com-

munity. Red flags and psychosocial alarm symptoms were also assessed in the current study using previously translated and validated questionnaires. Subjects with IBS were sub-typed into constipation-predominant, diarrhea-predominant, mixed type and un-subtyped. Univariable and multivariable analyses were used to test for association between socioeconomic factors and presence of red flags and psychosocial alarm features among the Malays with IBS.

RESULTS: IBS was present in 10.9% (24/221), red flags in 22.2% (49/221) and psychosocial alarm features in 9.0% (20/221). Red flags were more commonly reported in subjects with IBS (83.3%) than psychosocial alarm features (20.8%, $P < 0.001$). Subjects with IBS were older (mean age 41.4 years vs 36.9 years, $P = 0.08$), but no difference in gender was noted ($P = 0.4$). Using univariable analysis, IBS was significantly associated with a tertiary education, high individual income above RM1000, married status, ex-smoker and the presence of red flags (all $P < 0.05$). In multiple logistic regression analysis, only the presence of red flags was significantly associated with IBS (odds ratio: 0.02, 95%CI: 0.004-0.1, $P < 0.001$). The commonest IBS sub-type was mixed type (58.3%), followed by constipation-predominant (20.8%), diarrhea-predominant (16.7%) and un-subtyped (4.2%). Four of 13 Malay females (30.8%) with IBS also had menstrual pain. Most subjects with IBS had at least one red flag (70.8%), 12.5% had two red flags and 16.7% with no red flags. The commonest red flag was a bowel habit change in subjects > 50 years old and this was reported by 16.7% of subjects with IBS.

CONCLUSION: Using the Rome III criteria, IBS was common among ethnic Malays from the north-eastern region of Peninsular Malaysia.

INTRODUCTION

In the West, irritable bowel syndrome (IBS) is a major gastroenterological condition seen in daily clinical practice, with a prevalence of 10%-20%^[1-5]. The prevalence of IBS in the East is reportedly lower. Previous studies from Thailand and Singapore reported a prevalence of less than 5%^[6,7]. Recent studies from Hong Kong, Beijing and India also reported a similar low prevalence, although the rate may differ depending on the criteria used^[8-11].

One of the earlier studies from Malaysia reported a prevalence of 15.8% among a group of young multi-ethnic medical students using Rome I criteria in central Peninsular Malaysia^[12]. A later study by Rajendra *et al.*^[13] reported a rate of 15.5% using Rome II criteria in a mixed urban and rural multi-ethnic population in the north-western region of Peninsular Malaysia. The prevalence rates of IBS reported among the ethnic Malays (12.4%-15.8%) from both studies were higher than that reported by a recent study from Singapore (6.8%-10.3%)^[14].

The north-eastern region of Peninsular Malaysia is more economically deprived and less developed compared with western and central parts of Peninsular Malaysia, and most of its population consists of ethnic Malays. We aimed to assess the prevalence of IBS among the Malay population in this region recruited within a hospital setting using a validated Malay language Rome III IBS Diagnostic Questionnaire. In addition, we also aimed to assess and compare the rates of red flags (alarm symptoms which may suggest the presence of organic diseases), psychosocial alarm features and other socioeconomic markers in IBS *vs* non-IBS in this population.

MATERIALS AND METHODS

Subjects

This was a prospective cross-sectional survey involving a native Malay population in the state of Kelantan situated in the north-eastern region of Peninsular Malaysia. The city of Kota Bharu is the state capital of Kelantan

with an estimated population of 570 000, and 90% of its population consists of ethnic Malays^[15]. The university hospital of Universiti Sains Malaysia (USM), located in the heart of Kota Bharu, is the largest tertiary hospital serving the whole state of Kelantan. As the region is less developed compared to the west coast of Peninsular Malaysia, private practice is scarce and all layers of the Malay community (from the poor to the rich) tend to seek healthcare at the hospital.

Volunteers consisting of visitors (friends and relatives of patients) within the hospital compound were identified with the assistance of an independent research assistant who was blinded to the study but was trained to assess for inclusion of volunteers based on a set of predefined criteria. A random sampling strategy (stratified according to occupational status; volunteers with no full time job *vs* volunteers with a full time job) was then employed by the investigator. All subjects were recruited from different families in order to avoid ambiguity. Subjects of different ethnic backgrounds, past medical, surgical or psychiatric backgrounds, pregnancy and physical disabilities which did not allow them to complete the questionnaire or attend the interview were excluded from the study.

A total of 232 subjects were screened with a response rate of 95.2%. The sample size was calculated for the Malay population only and was based on a prevalence rate of 15%^[12], an alpha level of 0.05 and a power of 80%. There were 221 Malay subjects (109 with “no full time job” and 112 with a “full time job”) included in the study to answer the printed questionnaire booklet and/or face-to-face interview with a trained interviewer after giving informed consent. There were two subjects with no full time job whose responses were not complete or inadequate for analysis and were therefore excluded from the final analysis.

Malay language Rome III IBS diagnostic questionnaire

The Rome III IBS diagnostic questionnaire was translated into the Malay language and validated according to guidelines set by the Rome foundation. The Rome III IBS diagnostic questionnaire contains 10 items with answers on an ordinal scale and individual frequency thresholds for each question. The 10 items include questions on symptom criteria (items 4 to 8), a question to exclude pain of gynecological origin (item 2), questions on time between transient and chronic gut symptoms (items 1 and 3), and questions to sub-type IBS according to stool form (items 9 and 10). Briefly, the Rome III symptom criteria for IBS included the following: (1) recurrent abdominal pain or discomfort at least 3 d a month in the last 3 mo with two or more of the following: improvement with defecation; onset associated with a change in frequency of defecation; onset associated with a change in form (appearance) of stool; and (2) the above criterion fulfilled for the last 3 mo with symptom onset at least 6 mo before diagnosis. The Malay language Rome III IBS diagnostic questionnaire has been reported to have an intra-class correlation coefficient (ICC) of 0.996 and a good discriminant valid-

ity (*P* < 0.001)^[16].

We have included red flags and psychosocial alarm questionnaires in the current study since red flags and psychological symptoms have been commonly reported from previous studies but their association with IBS is unknown^[12,17]. Briefly, the red flag questionnaire included a history in the past 3 mo of fever, weight loss, cancer in family members, blood mixed with stool, anemia and change in bowel habit after age 50. The psychosocial alarm questionnaire had seven items designed to identify those patients with psychological “problems” which can be “serious” or “non-serious”. The ICCs for the Malay language Red Flags and Psychosocial Alarm Questionnaires has been reported to be 0.962 and 0.994, respectively^[16].

Only one trained interviewer was involved to maintain consistency, and the interviewer was experienced with the Rome III questionnaires and Rome III diagnostic criteria for IBS. In addition, we incorporated additional questions in the survey including age, gender, educational level, individual income, marital status, number of children in the family, smoking status and presence of menstrual pain in females. Subjects with IBS were sub-typed based on Rome III supportive symptoms into the following categories: IBS-C, constipation-predominant; IBS-D, diarrhea-predominant; IBS-M, mixed type and IBS-U, unsubtyped.

The study was approved by the Human Ethics Committee of USM.

Statistical analysis

All data are presented as frequency and percentage unless otherwise stated. Univariable logistic regression was used to test the association of independent variables (including age, sex, education level, occupational status, individual's income level, marital status, number of children in the family, smoking status, red flags and psychosocial alarm features) with presence or absence of IBS, and reported as crude odds ratios (ORs) and 95% CIs. The same variables listed above were adjusted using multivariable logistic regression analysis and reported as adjusted ORs, 95%CI and *P* value. All analyses were carried out using SPSS version 18.0 (SPSS Inc, Chicago, IL, United States).

RESULTS

Among the 221 surveyed Malay subjects, 10.9% (24/221) had features of IBS according to the Rome III criteria. The mean age of recruited subjects was 37.7 years (15.7 years) and although subjects with IBS were slightly older (mean age 41.4 years) this was not statistically significant (*P* = 0.08). There was no difference in the prevalence rate of IBS between genders among Malay subjects (*P* =

Table 2 Comparison of prevalence of irritable bowel syndrome across populations in Malaysia and Singapore

IBS: Irritable bowel syndrome.

0.4) (Table 1). Red flag symptoms were present in 83.3% (20/24) of subjects with IBS and 22.2% (49/221) of the total subjects recruited ($P < 0.001$) (Table 1). Psychosocial alarm features were present in 20.8 (5/24) of subjects with IBS and 9.0% (20/221) of the total subjects recruited ($P = 0.4$) (Table 1).

With univariable analysis, tertiary education, high individual income ($> \text{RM}1000$), married status, ex-smoker and presence of red flag symptoms were significantly associated with IBS among Malays (Table 1). With multiple logistic regression analysis, only the presence of red flags remained significantly associated with IBS (OR: 0.02, 95%CI: 0.004-0.1, $P < 0.001$).

The commonest IBS sub-type was of mixed type, IBS-M (58.3%), followed by IBS-C (20.8%), IBS-D (16.7%), and IBS-U (4.2%). Four of 13 (30.8%) female subjects with IBS also complained of menstrual pain. Most subjects with IBS had at least one red flag (70.8%), 12.5% had 2 red flags and 16.7% had no red flags. A bowel habit change for those above 50 years old was reported in 16.7% of subjects with IBS.

DISCUSSION

In the current study, the reported IBS rate of 10.9% among ethnic Malays was very similar to the study from Singapore (prevalence of 10.3% using Rome I criteria)^[14] (Table 2). The reported IBS rate among ethnic Malays in the current study was relatively low compared with that in the study by Rajendra *et al*^[13] (rate of 12.4% using Rome II criteria) and Tan *et al*^[12] (rate of 15.8% using Rome I criteria) (Table 2).

These differences in prevalence rates between studies may be explained by differences in population demographic and socioeconomic backgrounds between different regions of Peninsular Malaysia. In the study by Tan *et al*^[12], the studied population consisted of highly educated and healthy young Malaysians (mean age 22 ± 1.8 years) in the Klang Valley, a well-developed economic region in the central belt of the Peninsula. It is known

that IBS is more common in a younger and more educated population^[9,18]. In the study by Rajendra *et al*^[13], the population from the north-western region of Peninsular Malaysia was a mix of urban and rural communities, was older (mean age 33.6 ± 13 years) and was recruited based on race-stratified disproportionate random sampling to ensure sufficient representation of all ethnic minorities. The economy in this region of Malaysia is less developed than the Klang Valley but is more developed than the north-eastern region of Peninsular Malaysia. The older population and the mixture of a rural community might explain the lower prevalence of IBS reported in the study by Rajendra *et al*^[13] as compared with the study by Tan *et al*^[12]. Our current study recruited only ethnic Malays (mean age 37.7 ± 15.7 years) who were visitors (friends and relatives) within a hospital setting. To ensure a homogenous representation of the general population, a random stratified sampling strategy based on occupation was used. An older population, a lower socioeconomic background compared with the other regions of the Peninsula and less education may have explained the prevalence seen in our current study. The similarity in prevalence rates between the Malays in our study and the study from Singapore somewhat validates our findings.

The diagnostic Rome criteria used was different across different studies from Malaysia and this can partially influence the reported prevalence rates^[19]. The current study did not compare different Rome diagnostic criteria which is a limitation. The total sampling size was also different between studies but if the sample calculation on just the ethnic Malays was taken into account then it was not much different (221 subjects in the current study, 278 subjects in Tan *et al*^[12], 314 subjects in Rajendra *et al*^[13] and 263 subjects in Gwee *et al*^[14]).

There was no gender difference among the Malays with or without IBS in the current study. This was in contrast with the studies of Rajendra *et al*^[13] and Tan *et al*^[12] which reported a female preponderance in subjects with IBS. While the cause is unknown, it is possible that

in their studies, the women are more educated and have greater health-seeking behavior in the more developed west coast of Peninsular Malaysia. Alternatively, it could be an ethnic-specific phenomenon with more Chinese or Indian women reporting more IBS symptoms than the Malay women. Another possibility is that more women in their study may have misconstrued menstrual cramp as an IBS symptom. We have noticed that a third of the Malay women with IBS in the current study also complained of menstruation-related pain. It is also possible that males in our study seek more medical attention than the females, similar to what has been reported by hospital-based studies from India and Sri Lanka^[11,20,21].

The current study also included assessment for red flags and psychosocial alarm symptoms since they were commonly reported from previous studies but their association with IBS is unknown^[12,17]. Of all surveyed subjects, 9% (20/221) with red flag signs might have gastrointestinal symptoms from various diseases. While the question on the change in bowel habit is present in both the red flag questionnaire and the Rome III IBS diagnostic questionnaire, the question on age is not included in the IBS diagnostic questionnaire. We have noticed a significant percentage of subjects over 50 years old with symptoms of IBS who also reported a change in their bowel habit. This is important since elderly subjects above 50 years old have a higher risk for other organic diseases especially colorectal cancer.

Psychosocial alarm features were not commonly reported in the Malay population, either in the IBS or non-IBS sub-group, and if they were present, they were often dismissed as not being serious. This is in contrast with the Western populations where psychological disturbances were fairly common in those subjects with IBS especially in females^[22]. One of the reasons for this discrepancy is the questionnaire itself, which may not have identified the idioms of psychological distress in this population^[23]. Secondly, the socio-cultural stigmata attached to psychological and mental disturbance in this largely traditional Malay population may have resulted in the under-reporting of symptoms. Finally, high levels of family support, religious beliefs and other unknown cultural factors may have protected them against psychological distress^[24].

The commonest sub-type of IBS reported in the current study was of mixed type followed by the constipation type which was similar to the study from Singapore^[14]. This distribution was however different from the study by Rajendra *et al.*^[13] where constipation-predominant was the commonest subtype followed by the mixed type and diarrheal type. Many subjects with mixed type IBS often have features of constipation rather than diarrhea, and therefore the distinction of mixed or constipation type needs further clarification on their symptoms. This is important since treatment targeted against serotonin receptors can have contrasting effects on constipation or diarrhea.

There were limitations worth noting in the current study. It could be argued that recruiting subjects within

the hospital compound might have led to sampling bias but this was unlikely. The recruited subjects involved all layers of the Malay community (from the poor to the rich) within a region of stable population dynamics and similar socio-cultural backgrounds. Furthermore, only native Malays were included in the current study and a proper stratified random sampling strategy was carried out. The sample size in the current study might have been relatively small but the study only involved ethnic Malays, and it was calculated with a good power. The current study did not report on results of investigations performed to rule out organic diseases in those subjects with red flags as this was not our research objective. However previous studies have shown that investigating these subjects very often has a low yield^[25,26]. The current study did not compare the prevalence using different types of diagnostic criteria (Rome I, II and Manning criteria) for IBS. However this is the first study on IBS among ethnic Malays using a locally translated and validated Rome III IBS diagnostic questionnaire.

In conclusion, using the Rome III criteria, IBS was found to be prevalent among ethnic Malays from the north-eastern region of Peninsular Malaysia.

ACKNOWLEDGMENTS

We thank the volunteers who agreed to participate in the study. A special thanks to the research assistant who has helped us in recruiting the volunteers.

COMMENTS

Background

There is variability in prevalence rates of irritable bowel syndrome (IBS) among the ethnic Malays (6.8%-15.8%) across South-East Asia. Previous reported studies from Malaysia and Singapore involved heterogeneous populations and different diagnostic criteria.

Research frontiers

Using a validated Malay language Rome III diagnostic questionnaire, this study surveyed for IBS among ethnic Malays from the North-Eastern region of Peninsular Malaysia.

Innovations and breakthroughs

Using Rome III criteria, IBS was found to be common among ethnic Malays from a poorly developed region of Peninsular Malaysia. They were generally older (mean age 41.4 years) with no difference between genders. Red flags were common in this population and this was similar to other reported studies.

Applications

Exact reasons for higher prevalence rates of IBS among Malays are unknown and await further studies. Within the primary care setting, the validated questionnaire may be useful to identify this group of Malay subjects who often present with vague symptoms.

Terminology

The new Rome III criteria for IBS are symptom-based (abdominal pain or discomfort and onset associated with a change in frequency and appearance of stools) and time-based (symptoms for the last 3 mo with onset at least 6 mo previously). Red flags and psychosocial alarm questionnaires are independent from Rome III diagnostic questionnaires and are helpful to identify subjects "at risk" for organic and psychological disorders.

Peer review

Surveying IBS amongst ethnic Malays offers a somewhat different perspective showing firstly, a higher frequency compared to other South-East Asian studies, confirming other Malaysian reports and secondly, gender equivalence like stud-

ies from India.

Abstract

AIM: To evaluate a novel biosensor-based microarray (BBM) assay for detecting rs12979860 and rs8099917 genotypes.

METHODS: Four probes specific for rs8099917C/T or rs12979860G/T detection and three sets of quality control probes were designed, constructed and arrayed on an optical biosensor to develop a microarray assay. Two sets of primers were used in a one tube polymerase chain reaction (PCR) system to amplify two target fragments simultaneously. The biosensor microarray contained probes that had been sequenced to confirm that they included the rs8099917C/T or rs12979860G/T alleles of interest and could serve as the specific assay standards. In addition to rehybridization of four probes of known sequence, a total of 40 clinical samples collected from hepatitis C seropositive patients were also tested. The target fragments of all

40 samples were amplified in a 50 μ L PCR system. Ten μ L of each amplicon was tested by BBM assay, and another 40 μ L was used for sequencing. The agreement of the results obtained by the two methods was tested statistically using the kappa coefficient. The sensitivity of the BBM assay was evaluated using serial dilutions of ten clinical blood samples containing 10^3 - 10^4 white cells/ μ L.

RESULTS: As shown by polyacrylamide gel electrophoresis, two target segments of the interleukin 28B-associated polymorphisms (SNPs) were successfully amplified in the one-tube PCR system. The lengths of the two amplified fragments were consistent with the known length of the target sequences, 137 and 159 bps. After hybridization of the PCR amplicons with the probes located on the BBM array, the signals of each allele of both the rs8099917 SNPs and rs12979860 SNPs were observed simultaneously and were clearly visible by the unaided eye. The signals were distinct from each other, could be interpreted visually, and accurately recorded using an ordinary digital camera. To evaluate the specificity of the assay, both the plasmids and clinical samples were applied to the microarray. First, 30 PCR amplicons of the various SNP alleles were hybridized on the BBM microarray. Full agreement between plasmids and the BBM assay was observed, with 30/30 correct matches (100%). The kappa value for the BBM assay with plasmids was 1.00 ($P < 0.05$). For the 40 clinical blood samples, the BBM assay hybridization and direct sequencing results were compared for each amplicon. For patient blood samples, agreement was 28/28 for rs8099917T/T, 9/11 for rs8099917T/G, 1/1 for rs8099917G/G, 24/24 for rs12979860C/C, 11/14 for rs12979860C/T, and 2/2 for rs12979860T/T. Only five clinical samples of amplicon assay and direct sequencing results were discordant and heterozygotes: 2/11 rs8099917T/G and 3/14 rs12979860C/T. The agreement of outcomes between BBM assay and direct sequencing for the detection of rs8099917 and rs12979860 was

95% and 92.5%, respectively; and the corresponding kappa values were 0.88 and 0.85 (A kappa value > 0.75 was defined as substantial agreement). The BBM assay and sequencing had similar specificities for detection and identification of the two SNPs and their alleles. The sensitivity evaluation showed that the BBM assay could detect and identify SNP sequences present in blood samples containing as few as 10^2 white blood cells/ μ L.

CONCLUSION: This biosensor microarray assay was highly specific, sensitive, rapid and easy to perform. It is compatible with clinical practice for detection of rs8099917 and rs12979860.

INTRODUCTION

Hepatitis C virus (HCV) infection is a worldwide health problem. It is estimated that about 3% of the world population are infected with HCV, including more than 170 million with chronic infection, who are at risk of developing liver cirrhosis and/or liver cancer. Approximately 3 to 4 million become infected with HCV, and more than 350 000 people die from HCV-related liver diseases each year^[1]. Only about 30% patients with acute hepatitis C experience spontaneous clearance^[2,3], while the remaining 70% develop persistent chronic infection and gradually progress to liver cirrhosis and/or hepatocellular carcinoma^[4,5]. Chronic HCV infection that progresses to end-stage liver disease often requires a liver transplant, with high cost and extensive use of medical resources. Hepatocellular carcinoma is the seventh most common cancer worldwide and the third leading cause of cancer-related deaths. HCV thus has a very high morbidity and mortality, which result in a substantial burden on society^[5].

Since the discovery of HCV in 1989, some improvement in treatment have been gained with the application of routine weekly injections of pegylated interferon (IFN) plus daily administration of oral ribavirin (Rb)^[6]. Although triple therapy with IFN + Rb and boceprevir or telaprevir has produced a sustained virologic response

(SVR) of approximately 70%, this regimen still requires co-administration of IFN + Rb and has a high cost in most countries^[7]. At present, only 50% of patients infected with HCV genotype 1 achieved an SVR, defined as absence of HCV RNA six months after the cessation of therapy^[8,9]. Even in non-genotype 1 patients, who are reported to have better responses to the combination treatment, the SVR rate was about 75%^[10,11]. A number of viral and host factors may reduce adherence to the treatment. In addition to a limited treatment response to current combined therapy by some patients, treatment is often poorly tolerated due to various adverse reactions, including flu-like symptoms, severe fatigue, and neutropenia^[12]. Moreover, the inconvenience of a prolonged course of weekly injections of pegylated interferon and the high costs of the antiviral drugs make some patients give up the combined therapy. Additional research to advance HCV treatment regimens is needed to increase the patient adherence and response to therapy, thereby increasing SVR rates.

It is also puzzling why approximately 30% of patients with acute HCV infection experience spontaneous viral clearance, whereas the rest become chronically infected^[2,3]. Meanwhile, the global epidemiology of HCV infection shows that the different HCV genotypes clearly show geographic variation in their relative frequencies. Genotype 1, consisting of subtypes 1a and 1b, is the most prevalent genotype worldwide, with a higher prevalence of 1b in Europe and 1a in the United States^[11-13]. The estimated prevalence of people with detectable anti-HCV antibodies is highest in Africa, with an overall seroprevalence of 5.3%, and most common in genotype 4. In contrast, the infection rate of HCV is lower, and genotype 2 or 3 are more frequent in Asia^[11-13]. Furthermore, previous studies have revealed that the effectiveness of the combination treatment with peg-interferon and ribavirin differs among various ethnic populations^[14]. In the US, chronic HCV patients of European ancestry have a higher probability of being cured than patients of African ancestry^[15]. It is well documented that patients originating from East Asia are more likely to achieve SVR than patients from Europe^[16]. These observations suggest that host genetic variations play a critical role in patients infected with HCV.

Four recent genome-wide association studies (GWAS) independently identified several single nucleotide polymorphisms (SNPs) in the interleukin 28B (IL28B) locus. Variability at that locus is known to be associated with the successful treatment of HCV infection^[15,17-19]. Ge *et al*^[15] identified an rs12979860 SNP residing approximately 3 kilo-bases upstream of the *IL28B* gene as the variant most strikingly associated with SVR, and demonstrated that patients with the CC genotype had a higher SVR rate than those with the TT genotype. Suppiah *et al*^[17], Tanaka *et al*^[18], and Rauch *et al*^[19] found a strong association between another SNP, rs8099917 located 8 kilo-bases upstream of the *IL28B* gene, and SVR, which is in linkage disequilibrium with rs12979860. Tanaka *et al*^[18] also found

that the rs8099917 GG allele was the most significant host factor for predicting nonvirological response after adjusting for confounding factors. Their results suggest that Japanese patients with a minor GG allele may require new antiviral therapies to achieve SVRs.

These exciting discoveries show promise that detecting the IL28B genotype will help predict treatment response, thus guiding clinical decisions in the choice of treatment regimens for chronic HCV infection^[7]. Such discoveries may ultimately usher in the era of personalized treatment for HCV infection^[18,20].

An easily performed and specific method for the detection of IL28B genotypes is urgently needed to improve the currently available methods. Currently there are several assays for the detection of IL28B genotypes. However, due to technological limitations, these assays focus on either rs8099917 or rs12979860. Until now, there has been no assay for the simultaneous detection of rs8099917 or rs12979860. Furthermore, none of the available assays can be routinely applied in clinical practice. For example, direct sequencing, widely used in current research, is not suitable for clinical practice because of its complex technology, high cost, and time consumption.

The primary aim of this study was to develop a novel biosensor-based clinical microarray (BBM) assay stemming from our previous research to detect the IL28B genotypes containing rs12979860 and rs8099917 SNPs, and to evaluate the specificity and sensitivity of the test^[21,22].

MATERIALS AND METHODS

Plasmids and clinical samples

Plasmids (Invitrogen, Shanghai, China) confirmed by direct sequencing to contain both rs8099917 and rs12979860 SNPs, were used to construct the probes that were arrayed on the BBM; and plasmids diluted to 10⁴ copies/mL were used to determine the assay specificity. The two alleles of each SNP were tested separately. Blood samples obtained from HCV seropositive patients at the 5th Affiliated Hospital of Sun Yat-Sen University (Zhuhai, China) were used to evaluate the clinical sensitivity and specificity of the BBM assay. The study protocol was approved by the Ethics Committee of our hospital and all patients enrolled in this study provided written informed consent.

BBM preparation

Several probes (Invitrogen, California, United States), highly specific for rs8099917 or rs12979860 polymorphisms, plus positive and negative quality control probes, were designed and synthesized. All the probe sequences included in this study were from a public database (<http://www.ncbi.nlm.nih.gov/>) and were based on the known human genome in the region of the IL28B gene. After optimization, the probes specific for the SNPs as well as positive and negative control probes were arrayed on the BBM as shown in Figure 1. The positive control probes were used to monitor the assay process. The negative probes served to monitor contamination. The probe se-

quences are summarized in Table 1.

DNA extraction and polymerase chain reaction amplification

Human genomic DNA was extracted from 200 µL of patient blood samples using 200 µL commercially available DNA extraction buffer (Qiagen, Dusseldorf, Germany) according to the manufacturer's instructions. To determine the SNP genotypes, two sets of special primers were designed to amplify the rs8099917 and rs12979860 SNP fragments within the IL28B gene region (Table 1). The extracted DNA was amplified by polymerase chain reaction (PCR). The reaction mixture (25 µL) contained 5 µL DNA, 2.5 µL of 10 µmol/L buffer (Juntan, Shanghai, China), 0.5 µL deoxynucleoside triphosphates (Roche, Basel, Switzerland), 1.5 µL primers (Invitrogen, California, United States), 1.25 U hot Taq polymerase (Juntan, Shanghai, China), and 14.25 µL high-performance liquid chromatography-grade water. Simultaneous amplification of two SNPs was carried out under the following conditions: an initial denaturation at 95 °C for 10 min, 40 cycles at a denaturation temperature of 94 °C for 30 s, annealing at 56 °C for 30 s, and extension at 72 °C for 30 s, with a final prolonged extension at 72 °C for 5 min. All PCR products were visualized on a 2% agarose gel or by polyacrylamide gel electrophoresis (PAGE) electrophoresis.

Detection of SNP genotype

All SNP amplicons were subjected to reverse hybridization and direct sequencing. A 10 µL volume of PCR amplified product was heated at 99 °C for 5 min and denatured, with subsequent cooling for 5 min on ice. Then the amplified product was placed on the surface of the BBM and incubated at 50 °C for 60 min with a prepared hybridization reaction mixture. The BBM was eluted three times at 45 °C, incubated with anti-biotin horseradish peroxidase reagent at room temperature (10-35 °C) for 10 min, rinsed three times with a buffer wash, and incubated with tetramethylbenzidine for 2 min in the dark. Finally, the residues on the BBM were washed in 0.1 × standard saline citrate and distilled water at room temperature so as to obtain a clear signal. The remaining amplified PCR product was sent for direct sequencing.

Assay specificity

Four synthetic plasmids, each including an SNP allele (rs12979860CC, rs12979860TT, rs8099917GG, and rs8099917TT) and 40 HCV-seropositive blood samples were used to validate the specificity of the assay to detect the two SNPs. Each successfully amplified product obtained from these plasmids was evaluated by the BBM assay, and the results thus obtained were compared with the their known genotypes. For the clinical evaluation, amplicons obtained from patient blood samples were tested under the same conditions as the amplified plasmid products. The percent agreement of the BBM assay results with the results of direct sequencing was determined for

Figure 2 Polymerase chain reaction products visualized on polyacrylamide gel electrophoresis. Lanes 1 and 8: Marker; Lanes 2, 5, 6: A single fragment amplified rs12979860 or rs8099917 primers; Lanes 3 and 4: Two fragments amplified by one tube polymerase chain reaction system of rs12979860 and rs8099917; Lane 7: Negative control.

both the synthetic probes and the clinical samples.

Assay sensitivity and detection limit

To estimate the sensitivity and detection limit of the SNP genotype assay in clinical practice, ten blood samples were used. The sensitivity calculation was based the white blood cell (WBC) count in the original sample and the amount of DNA extracted from the WBC remaining in serial dilutions of each sample. The WBC counts were determined in each sample and then diluted to 10^1 - 10^3

cells/ μ L. The DNA was extracted from 1 μ L of each sample and was amplified. All samples with successful PCR amplification were evaluated for SNP genotype by the BBM assay.

Statistical analysis

The kappa coefficient was used to measure the agreement between direct sequencing and the BBM assay for the detection of SNP genotype. A kappa value > 0.75 was defined as substantial agreement, and a kappa > 0.95 as perfect agreement. A $P < 0.05$ was considered statistically significant.

RESULTS

Amplification of rs8099917 and rs12979860 fragments

Both fragments were amplified simultaneously in the one-tube system, and the amplicons were analyzed on PAGE electrophoresis (Figure 2). The length of the two amplified fragments was about 137 and 159 bp, being consistent with the length of the target fragments. The results indicated that these two target fragments could be amplified in a single tube PCR system.

Simultaneous detection of two SNPs

As shown in Figures 1 and 3, the signals on the chip appeared sufficiently distinct seen with the unaided eye and photographed with a normal digital camera. It was thus confirmed that no special equipment was needed to read

Figure 3 Patterns detected by biosensor microarray assay for rs8099917 and 12979860 genotypes.

Table 2 Concordance of biosensor-based microarray assay with given plasmids for rs12979860 and rs8099917

the BBM assay results. Moreover, each allele of both rs8099917 rs12979860 was successfully detected at the same time. The BBM assay was able to simultaneously genotype the two SNPs.

Assay specificity

As shown in Figure 3, the positive signals were displayed clearly, and there were no signals from the sites containing the negative probes. There were no ambiguous signals on the chip background, which could have interfered with precise interpretation of the results. This suggested that the assay was specific for the detection of rs8099917 and rs12979860 polymorphisms.

To confirm the BBM assay specificity for detection of each allele, we tested all the possible genotypes using the available synthetic plasmids. As shown in Figure 3, the BBM assay clearly differentiated all the genotypes and haplotypes of the two SNPs. The signals of the alleles of each SNP were clearly differentiated from each other, with no visible evidence of cross-reaction at any SNP binding site. Data obtained using 30 plasmid amplicons

showed the same results for all the known genotypes of rs12979860 or rs8099917 (Tables 2 and 3), and its agreement rate with the plasmids was up to 100% in our tests. The results showed that the BBM was an accurate assay for genotype determination of these two SNPs.

To validate the BBM assay for clinical application, the amplicons derived from the 40 blood samples taken from HCV-infected patients were examined by both direct sequencing and BBM. As shown in Tables 2 and 3, the percent of agreement of the BBM assay results and direct sequencing of rs8099917 and rs12979860 were 95% and 92.5%, respectively. The corresponding kappa values were 0.88 and 0.85, respectively, with a *P* value < 0.05. The BBM assay accurately detected the two SNPs in clinical samples. Discordance of the BBM assay and direct sequencing of PCR amplicons most often occurred with heterozygous clinical samples.

Assay sensitivity and detection limit

Ten clinical blood samples and a series of sequential dilu-

tions were used to validate the sensitivity and detection limit of BBM. Blood samples with WBC counts ranging from 10^1 to 10^3 cells/ μ L were amplified with BBM primers, and visualized by PAGE electrophoresis. Amplicons with detectable human genomic DNA were assayed by reverse hybridization with the BBM. The hybridization signal was visualized clearly in the BBM assay in a total of 20 dilutions with WBC counts in the patient blood samples ranging from 10^2 to 10^3 cells/ μ L.

DISCUSSION

The combined therapy of pegylated interferon plus ribavirin is currently the standard of care for chronic HCV infection around the world^[6]. Its administration in clinical practice has resulted in substantial progress in the treatment of chronic hepatitis C over the past decades. However, several persistent shortcomings of the combined therapy prevent some patients from completing the entire 48-wk course of treatment. Patient adherence is frequently compromised by an inability to tolerate adverse reactions or the many weeks of routine subcutaneous injections, and the high cost of the drugs^[8,9,12]. The limited efficacy of pegylated interferon/ribavirin therapy to produce SVR, which varies unpredictably from patient to patient, makes it difficult for health care providers to make an informed choice of treatment regimens^[18-20]. There is an urgent need of personalized therapy for chronic hepatitis C.

The fact that about 30% of patients achieve natural clearance following acute hepatitis C virus infection and ethnic differences in response to treatment suggests that host genetic variation plays a critical role in the drug response^[2,11,17,19,20]. Four recent studies have found that two SNPs, rs8099917 and rs12979860, located near the *IL28B* gene were highly associated with treatment response and spontaneous clearance following acute hepatitis C infection^[15,17-19]. Subsequent studies found that the two SNPs had an impact on the occurrence of various side effects of the combined therapy, treatment response and the HCV RNA genotype distribution of the infecting virus^[23,24]. Other studies have shown that *IL28B* polymorphisms were a significant, independent predictive factor regardless of HCV genotype or HCV RNA load. The determination of *IL28B* polymorphisms may assist in evaluating the likelihood of response to treatment with peg-interferon and ribavirin therapy in patients chronically infected with HCV, especially for genotype 1 patients^[25-28]. The recent significant findings regarding *IL28B* SNPs and the genotyping of HCV showed how personalizing treatment for HCV infection may be possible^[24-27]. The development of an accurate assay for the detection of rs8099917 and rs12979860 polymorphisms, and progress in HCV genotyping will help both clinicians and patients choose the treatment regimen and its anticipated duration^[22] and this may be an early step in the era of personalized therapy for chronic hepatitis C^[20,29,30].

Host genetic diversity is of great significance in mak-

ing an informed decision regarding the risk-benefit treatment and the likelihood of success for any individual treatment, so developing a simple, rapid and clinically available assay is an urgent demand. An assay that could accurately and rapidly detect the *IL28B* SNPs is a priority for clinical practitioners. Developing a novel and efficient assay for the detection of *IL28B* polymorphisms has been the focus of numerous researches.

Direct sequencing of PCR amplicons, restriction fragment length polymorphism (RFLP) and traditional microarrays are valuable research techniques. However, the technical demands of these assays make them unsuitable for routine diagnostic use in clinical practice. For example, direct sequencing is technologically complicated, time-consuming and needs special expertise^[28,29]. The RFLP is almost impossible to be used for the detection of all significant SNPs since it requires a specific cutting site and restriction enzyme for the particular site^[31]. Microarray assays widely used in the previous research, apart from being provided by specialized and high-cost facilities, can only detect either of the two SNPs separately^[19,21-23]. No microarray assay was available currently that can detect the two SNPs simultaneously. There is a real need for a highly sensitive and specific rapid assay for the detection of *IL28B* polymorphisms that is easy to perform and compatible with clinical practice. The BBM described in our report may be an ideal clinical assay.

As depicted in Figure 3, the positive signals on the chip were sufficiently distinct to be completely discriminated from negative results. The results with plasmid amplicons showed that all the SNP alleles could be detected successfully and that heterozygous and homozygous alleles could be distinguished. Of 40 plasmid amplicons employed to validate the specificity of the BBM assay, a complete agreement between the results of the BBM assay and known plasmid sequences was observed, confirming the high specificity of the BBM assay in determining the rs8099917 and rs12979860 genotypes.

The clinical blood samples successfully amplified by the BBM assay primers were sent for both direct sequencing and reverse hybridization with BBM. The BBM assay showed a high agreement with direct sequencing in detecting the rs8099917 and rs12979860 polymorphisms. The agreement rates were 95% and 92.5%, and the kappa values were 0.88 and 0.85 for rs8099917 polymorphisms and rs12979860, respectively. These data indicated that the BBM assay showed a good agreement with direct sequencing and that it would be a satisfactory novel assay when used for determination of the two SNPs. The main difference between the BBM results and direct sequencing was the detection of allele heterozygotes. The BBM assay was more sensitive in detecting heterozygous alleles, which was consistent with other reverse hybridization procedures such as line probe assay^[32,33]. In brief, we demonstrated that the novel BBM assay could successfully detect all genotypes of the two SNPs simultaneously, not only in the synthetic plasmids but also in the clinical samples used in this study.

To evaluate the sensitivity and detection limit of the BBM assay, serial dilutions of 10 clinical blood samples were tested. The amount of human DNA from white blood cells in 1 μL peripheral blood containing 10^2 WBC/ μL was sufficient for SNP detection by the BBM assay. The DNA extracted from all samples was successfully amplified, and the blood samples with a starting white blood cell count $> 10^2$ WBC/ μL hybridized with the probes arrayed on the BBM. As the white blood cell count of human peripheral blood is generally greater than 10^3 WBC/ μL , the detection limit of the BBM assay ensures that clinical blood samples would be tested accurately. This novel method thus met the sensitivity criteria for clinical diagnosis, i.e., determination of IL28B polymorphisms of HCV-infected patients.

The results indicated that the BBM assay has the advantages of simple and convenient operation as well as rapid detection. After a successful PCR amplification, it took only one hour to detect the IL28B polymorphisms and less than four hours before getting the final result. More important, the signal on the chip was clear enough to be interpreted even by the naked eye, which meant that only an ordinary digital camera was needed to record the results. The results also suggest that the BBM assay might also be used in developing countries having limited access to the latest laboratory facilities. The assay is also suitable for clinical diagnostic and research laboratories where large numbers of samples are tested on a daily basis. In short, the BBM assay is more likely to be accepted for the clinical detection of IL28B polymorphisms than the other existing methods^[21,22].

The BBM assay has some disadvantages to overcome in its future development. The patient population benefiting from the BBM assay is small, being limited to patients with chronic HCV infection, meanwhile, the assay is only capable of detecting the presence of known SNPs. With the identification of more SNPs associated with drug response, novel probes have to be designed and the BBM assay has to be constantly upgraded.

In conclusion, we have demonstrated that the BBM assay is simple, rapid, accurate, and suitable for clinical application. The assay is highly sensitive and specific, and can simultaneously perform the detection of rs8099917 and rs12979860 genotypes, thereby enabling further progress in the diagnosis and treatment of chronic HCV infection.

COMMENTS

Background

Antivirals are essential to the therapeutic management of hepatitis C virus (HCV)-infected patients. However, sustained virological response is not achieved in all patients who receive the standard combination therapy of once-weekly injections of pegylated interferon plus daily oral ribavirin or even in those treated with the triple therapy regimen. Recent research has characterized single nucleotide polymorphisms (SNPs) in the interleukin 28B (*IL28B*) gene as the most important host factor influencing the efficacy of HCV therapy. Many scientists believe that identifying each of the IL28B SNPs related to HCV treatment response will usher in a new era of HCV personalized therapy.

Research frontiers

Four recent genome-wide association studies (GWAS) independently identified several SNPs in the *IL28B* gene locus that are associated with an individual's ability to respond to therapy for HCV infection. Ge *et al.*^[15] characterized rs12979860 as the variant most strongly associated with SVR, and demonstrated that patients with the CC genotype have a higher SVR rate than those with the TT genotype. In contrast, studies demonstrated that rs8099917 has the strongest association with SVR. However, GWAS are capable of only testing SNPs in isolation and could not determine if interaction between these two SNPs, or more, can affect a patient's response to HCV therapy. Thus, it is urgent to develop an accurate and easy clinical assay to test the panel of IL28B SNPs in a patient and assess the effect of multiple SNPs on SVR.

Innovations and breakthroughs

This is the first report of an assay that is capable of defining the rs8099917 and rs12979860 SNPs using clinical samples. This innovative biosensor-based microarray (BBM) assay can identify the two SNPs in less than four hours. In addition, evidence is provided to show that the new assay can accurately identify all of the SNPs and gene alleles with plasmids. There was a good concordance between BBM-detected SNPs in clinical samples and direct sequencing results of PCR amplicons and plasmids. Finally, the excellent sensitivity and reproducibility of the BBM assay supports the clinical applicability of this new detection approach.

Applications

This study aimed to develop a clinically applicable assay to accurately and rapidly detect IL28B SNPs in patient samples. The results indicate that the BBM assay is simple, rapid, accurate, and highly sensitive and specific in detecting the rs8099917 and rs12979860 genotypes. Thus, this novel assay has promise for clinical application and may facilitate accurate and timely prognosis of HCV-infected patients so that the appropriate therapies may be initiated earlier.

Terminology

BBM is a novel SNP detection assay based on biosensor technology, its most obvious advantage is *in situ* amplification that facilitates easy interpretation of results; rs8099917 and rs12979860 are SNPs in the *IL28B* gene locus; SNP is a single nucleotide polymorphism.

Peer review

In this work, the authors describe a new BBM assay to rapidly detect two SNPs in the *IL28B* gene. The interest of the paper is its description of this rapid and inexpensive technique to detect IL28B SNPs in clinical samples. The results suggest that the BBM assay is a simple, rapid, sensitive, and highly specific method that may be applied clinically to detect rs8099917 and rs12979860 without any large-scale instrumentation.

Abstract

AIM: To investigate the predictive factors of lymph node metastasis (LNM) in poorly differentiated early gastric cancer (EGC), and enlarge the possibility of using laparoscopic wedge resection (LWR).

METHODS: We retrospectively analyzed 85 patients with poorly differentiated EGC who underwent surgical resection between January 1992 and December 2010. The association between the clinicopathological factors and the presence of LNM was retrospectively analyzed by univariate and multivariate logistic regression analyses. Odds ratios (OR) with 95%CI were calculated. We further examined the relationship between the positive number of the three significant predictive factors and

the LNM rate.

RESULTS: In the univariate analysis, tumor size ($P = 0.011$), depth of invasion ($P = 0.007$) and lymphatic vessel involvement ($P < 0.001$) were significantly associated with a higher rate of LNM. In the multivariate model, tumor size (OR = 7.125, 95%CI: 1.251-38.218, $P = 0.041$), depth of invasion (OR = 16.624, 95%CI: 1.571-82.134, $P = 0.036$) and lymphatic vessel involvement (OR = 39.112, 95%CI: 1.745-123.671, $P = 0.011$) were found to be independently risk clinicopathological factors for LNM. Of the 85 patients diagnosed with poorly differentiated EGC, 12 (14.1%) had LNM. The LNM rates were 5.7%, 42.9% and 57.1%, respectively in cases with one, two and three of the risk factors respectively in poorly differentiated EGC. There was no LNM in 29 patients without the three risk clinicopathological factors.

CONCLUSION: LWR alone may be sufficient treatment for intramucosal poorly differentiated EGC if the tumor is less than or equal to 2.0 cm in size, and when lymphatic vessel involvement is absent at postoperative histological examination.

INTRODUCTION

Local resection for early gastric cancer (EGC) was first reported by Kitaoka *et al.*^[1] in 1984. Laparoscopic wedge resection (LWR) is a procedure based on local resection. This minimally invasive technique can be applied for the management of EGC without the risk of lymph node metastases (LNM)^[2-7]. The application of LWR has been limited to differentiated EGC because of the higher risk of lymph node metastases in undifferentiated EGC, compared to differentiated EGC^[8,9]. Therefore, gastrectomy with lymphadenectomy has been considered to be an essential treatment for patients with undifferentiated EGC. Undifferentiated carcinoma of gastric cancer includes poorly differentiated adenocarcinoma, signet ring cell carcinoma, and mucinous adenocarcinoma^[10]. However, almost all (96.6%) surgical cases of poorly differentiated EGC confined to the mucosa, have been found not to have LNM^[11], suggesting that gastrectomy with lymphadenectomy may be over-treatment for these cases.

Therefore, we carried out this retrospectively study to determine the clinicopathological factors that are predictive of LNM in poorly differentiated EGC. Furthermore, we established a simple criterion to expand the possibility of using LWR for the treatment of poorly differentiated EGC.

MATERIALS AND METHODS

Patients

Patients underwent a radical operation due to EGC in the Department of Oncology, Affiliated Xing Tai People's Hospital of Hebei Medical University, Xingtai, China between January 1992 and December 2010 were included in the screening for identification of cases with EGC in this retrospective study.

The inclusion criteria were: (1) lymph node dissection beyond limited (D1) dissection was performed; (2) the resected specimens and lymph nodes were pathologically analyzed, and poorly differentiated EGC was diagnosed, according to the Japanese Classification of Gastric Carcinoma (JCGC)^[10]; and (3) patient's medical records were available in the database.

During the 18 years, 85 patients (60 male, 25 female; mean age 52 years, range: 29-82 years) with histopathologically poorly differentiated tumor were identified to meet the inclusion criteria for further analysis in this study.

The study protocol was approved by the Ethics Com-

mittee of Hebei Medical University.

Dissection and classification of lymph nodes

Lymph nodes of each case were meticulously dissected from the enbloc specimens, and the classification of the dissected lymph nodes was determined by a surgeon after he/she who carefully reviewed the excised specimens based on the JCGC^[10]. Briefly, lymph nodes were classified into group 1 (perigastric lymph nodes) and groups 2 (lymph nodes along the left gastric artery, the common hepatic artery, and the splenic artery and around the celiac axis)^[10].

Assessment and classification of lymph node metastasis

Then, the resected lymph nodes were sectioned and stained with hematoxylin and eosin and examined by pathologists for metastasis and lymphatic vessel involvement (LVI).

Association between clinicopathological parameters and lymph node metastasis

Clinicopathological parameters that are covered in the JCGC^[10] were included in this study. They were the gender (male and female), age (< 60 years, ≥ 60 years), family medical history of gastric cancer, number of tumors (single or multitude), the location of the tumor (upper, middle, or lower of the stomach), tumor size (maximum dimension ≤ 2 cm, or > 2 cm), macroscopic type [protruded (type I), superficial elevated (type II a), flat (type II b), superficial depressed (type II c), or excavated (type III)], depth of invasion (mucosa, submucosa), lymphatic vessel involvement.

The associations between various clinicopathological factors and LNM were examined as described below.

Statistical analysis

All data were analyzed using SPSS 15.0 statistical software (Chicago, IL, United States). The differences in the clinicopathological parameters between patients with and without LNM were determined by the χ^2 test. A multivariate stepwise logistic regression analysis was performed subsequently in order to identify independent risk factors for LNM. Hazard ratio and 95%CI were calculated. A *P* value of less than 0.05 was considered statistically significant.

RESULTS

Of the 85 patients diagnosed with poorly differentiated EGC, 12 (14.1%) had LNM. As shown in Table 1, 8 (70.6%) were male and 13.3% of them had LNM.

Association between clinicopathological factors and lymph node metastasis

The association between various clinicopathological factors and LNM was first analyzed by the χ^2 test (Table 1). A tumor larger than 2.0 cm, submucosal invasion, and

Positive (<i>n</i> = 14)	8 (57.1)	< 0.001
Negative (<i>n</i> = 71)	4 (5.6)	

the presence of LVI were significantly associated with a higher rate of LNM (all $P < 0.05$). However, gender, age, family medical history of gastric cancer, number, location, and macroscopic type were found not to be associated with LNM.

Multivariate analysis of potential independent risk clinicopathological factors for lymph node metastasis

The three characteristics that were significantly associated with LNM by univariate analysis were found to be significant and independent risk factors for LNM by multivariate analysis (both $P < 0.05$, Table 2).

Lymph node metastasis in poorly differentiated EGC

The LNM rates were 5.7%, 42.9% and 57.1%, respectively in cases with one, two and three of the risk factors respectively in poorly differentiated EGC. There was no LNM in 29 patients without the three risk clinicopathological factors.

DISCUSSION

Because an increased rate of accurate diagnosis of EGC, which in turn leads to an improved prognosis, an increased interest has been focused on the improvement of the quality of life and minimization of invasive procedures^[12-14]. LWR has been associated with less pain, quicker return of gastrointestinal function, better pulmo-

Table 2 Multivariate analysis of potential risk factors for lymph node metastasis

nary function, decreased stress response, a shorter hospital stay and better postoperative quality of life than open gastrectomy^[15-19]. If the feasibility and safety of LWR in the treatment of EGC has been proven, it is also true that several reports have shown the efficacy of LWR in the cure of EGC with results comparable to those of an open gastrectomy^[20].

One of the critical factors in choosing LWR for EGC would be the precise prediction of whether the patient has LNM or not. To achieve this goal, several studies have attempted to identify risk factors predictive of LNM in EGC. Few reports, however, have focused on the applicability of laparoscopic treatment for poorly differentiated EGC.

The present multivariate analysis revealed that a tumor larger than 2.0 cm, submucosal invasion, and the presence of LVI were significant predictive factors for LNM in patients with poorly differentiated EGC. Our results together with the previous reports on undifferentiated EGC^[21-24] demonstrated a significant correlation between the high incidence of LNM and a tumor larger than 2.0 cm submucosal invasion, or presence of LVI^[25-27].

We then attempted to identify a subgroup among poorly differentiated EGC patients in whom the risk of LNM can be largely ruled out, i.e., candidates who can be curably treated by LWR. As a result, we found no LNM in patients with intramucosal cancer if the tumor is less than or equal to 2.0 cm in size without LVI. This may indicate that LWR could be sufficient to treat these cases, and that additional surgery is unnecessary.

We further examined the relationship between the positive number of the three significant predictive factors and the LNM rate in order to establish a simple criterion for an optimal strategy for treatment of poorly differentiated EGC. In the present study, the LNM rates were 5.7%, 42.9% and 57.1%, respectively in cases with one, two and three of the risk factors respectively in poorly differentiated EGC. Therefore, gastrectomy with lymphadenectomy is probably better for these patients with the risk factors.

However, there are some limitations in this study. First, this is a retrospective analysis. Second, the sample size is relatively small. Thus, the outcomes of the study may not be good enough to expose the truth.

According to our study, we would propose a treat-

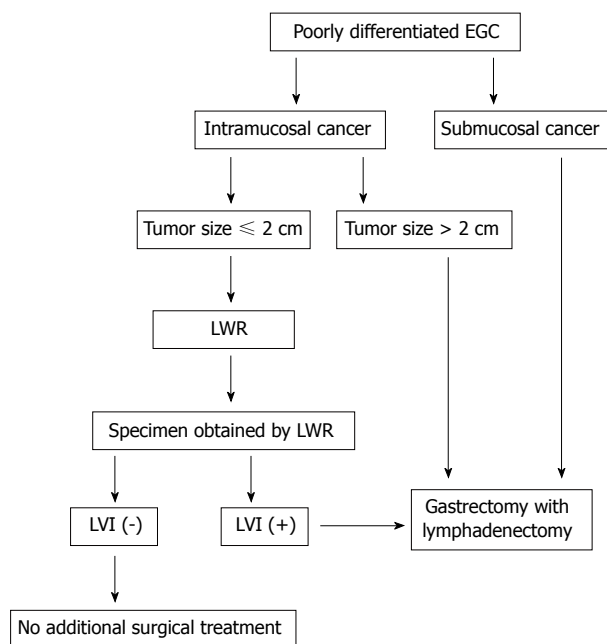

Figure 1 Flow chart of the therapeutic strategy for cases with poorly differentiated early gastric cancer. EGC: Early gastric cancer; LWR: Laparoscopic wedge resection; LVI: Lymphatic vessel involvement.

ment strategy for patients with poorly differentiated EGC (Figure 1). These predictive factors (tumor size and depth of invasion) were diagnosed by endoscopy and endoscopic ultrasound. The particular presence of LVI becomes first evident after the histological assessment of the entire specimen obtained by LWR. LWR alone may be a sufficient treatment for intramucosal poorly differentiated EGC if the tumor is less than or equal to 2.0 cm in size, and when LVI is absent at postoperative histological examination. When specimens show with LVI, an additional gastrectomy with lymphadenectomy should be recommended.

COMMENTS

Background

Gastrectomy with lymphadenectomy is the standard therapy for poorly differentiated early gastric cancer (EGC) with lymph node metastasis (LNM). However, because approximately 96.6% of in poorly differentiated intramucosal EGC have no LNM, gastrectomy with lymphadenectomy may be an over-treatment for such patients. The authors attempted to identify a subgroup of poorly differentiated EGC patients in whom the risk of LNM can be ruled out and treated them with laparoscopic wedge resection (LWR), which may serve as a breakthrough treatment of poorly differentiated EGC.

Research frontiers

Several studies have attempted to identify risk factors predictive of LNM in EGC. Few reports, however, have focused on the applicability of laparoscopic treatment for poorly differentiated EGC.

Innovations and breakthroughs

Tumor size, depth of invasion and lymphatic vessel involvement were found to be independently risk clinicopathological factors for LNM in poorly differentiated EGC. Furthermore, the authors established a simple criterion to expand the possibility of using LWR for the treatment of poorly differentiated EGC.

Applications

Based on the predictive factors for LNM, LWR is the treatment of choice for poorly differentiated EGC.

Terminology

LWR is a procedure based on local resection and a method of minimally invasive technique.

Peer review

This study analyzed the data from 85 patients with poorly differentiated EGC. They concluded that tumor size, depth of invasion and lymphatic vessel involvement are the significant risk factors for LNM. This is a well-designed retrospective study.

infiltrated part of the jejunum was successfully resected in a subsequent operation, and adjuvant chemotherapy with paclitaxel was planned. Angiosarcoma of the small intestine is an extremely rare malignant neoplasm that presents with bleeding and high mortality. Early diagnosis and treatment are essential to improve outcome. A small intestinal angiosarcoma is a challenging diagnosis to make because of its rarity, nonspecific symptoms of altered intestinal function, nonspecific abdominal pain, severe melena, and acute abdominal signs. Therefore, a quick clinical and histological diagnosis and decisive measures including surgery and adjuvant chemotherapy should be the aim.

Abstract

We report a case of an 84-year-old male patient with primary small intestinal angiosarcoma. The patient initially presented with anemia and melena. Consecutive endoscopy revealed no signs of upper or lower active gastrointestinal bleeding. The patient had been diagnosed 3 years previously with an aortic dilation, which was treated with a stent. Computed tomography suggested an aorto-intestinal fistula as the cause of the intestinal bleeding, leading to operative stent explantation and aortic replacement. However, an aorto-intestinal fistula was not found, and the intestinal bleeding did not arrest postoperatively. The constant need for blood transfusions made an exploratory laparotomy imperative, which showed multiple bleeding sites, predominately in the jejunal wall. A distal loop jejunostomy was conducted to contain the small intestinal bleeding and a segmental resection for histological evaluation was performed. The histological analysis revealed a less-differentiated tumor with characteristic CD31, cytokeratin, and vimentin expression, which led to the diagnosis of small intestinal angiosarcoma. Consequently, the

INTRODUCTION

Primary malignant tumors of the small intestine are rare neoplasms, which comprise < 2% of all gastrointestinal tumors^[1], including adenocarcinoma, carcinoid, sarcoma, gastrointestinal stromal tumors, and lymphoma. The reason for the poor prognosis of small bowel malignant tumors is partly due to a late diagnosis. The difficulty diagnosing this type of tumor is associated with the nonspecific symptoms, including nausea, vomiting, abdominal pain, constipation, generalized weakness, fatigue,

malaise, weight loss, anemia, diarrhea, ileus, intestinal perforation, or hemorrhage^[2], as well as limited diagnostic methods for the small intestine.

Angiosarcoma is a rare mesenchymal tumor that most often arises from skin and subcutaneous tissues^[3-7] but can ultimately arise anywhere in the body. Angiosarcomas have been described in the liver^[8-11], spleen^[12,13], adrenal glands^[14-16], ovaries^[17-19], heart^[20-22], lung^[23,24], breast^[25-27] and, very rarely, in the gastrointestinal tract^[28-32]. Consequently, an intestinal angiosarcoma that is located in the small bowel rather than the upper or lower gastrointestinal tract is a very rare medical condition. Angiosarcomas are aggressive tumors with a high rate of lymph node and peripheral metastases. This tumor arises as a *de novo* primary tumor or secondary to irradiation or chemical exposure. Angiosarcoma of the small intestine presents unique diagnostic challenges and is often discovered late, leading to a very poor prognosis.

Additionally, the histological diagnosis is difficult and can be confused with other neoplasms such as poorly differentiated carcinoma^[4,33,34]. Diagnosis is facilitated by immunohistochemical expression analysis of the endothelial markers CD31 and CD34, as well as factor VIII-associated antigens.

Herein, we describe the case of an 84-year-old man with the first episode of gastrointestinal bleeding due to angiosarcoma of the small intestine.

CASE REPORT

The patient was transferred to the Department of Internal Medicine of a peripheral hospital with gastrointestinal bleeding, which required a blood transfusion. Three lesions with coagulum and vessels necessitating application of two clips were found by endoscopy of the distal duodenum and upper segment of the jejunum. A colonoscopy revealed old blood, so bleeding in the small intestine was suspected. The patient had been diagnosed with an aortic aneurysm 3 years previously, which was treated with juxtarenal stent-graft prosthesis. A prosthetic-enteric fistula was suspected on the emergency abdominal aortic computed tomography (CT) scan. With this suspected diagnosis, the patient was transferred to the University Hospital Düsseldorf, and emergency vascular surgery was performed. The stent-graft prosthesis was removed and desobliteration of the saccular aortic aneurysm and the renal arteries was implemented, followed by implantation of an aorto-biiliacal silver-graft prosthesis. However, a prosthetic-enteric fistula was not revealed intraoperatively. The gastrointestinal bleeding did not arrest postoperatively, and Forrest IIB bleeding in the proximal jejunum was endoscopically diagnosed and treated. The local bleeding was stopped with hemoclips.

An exploratory laparotomy was performed due to persistent gastrointestinal hemorrhage, which showed multiple intra-abdominal hemorrhagic lesions in the intestinal wall of the jejunum (Figure 1). Three segmental

Figure 1 Multiple intra-abdominal hemorrhagic lesions in the intestinal wall of the jejunum. A: Intraoperative presentation of the jejunum with multiple subserous hemorrhages; B: Longitudinally lanced jejunum specimen with disseminated mucosal tumor manifestation.

resections and a distal loop jejunostomy were performed for a histological evaluation but achieved only temporal arrest of bleeding, which again became visible postoperatively after a loop jejunostomy. As no transanal bleeding was observed, and the histological analysis suggested a malignant angiosarcoma, a small bowel resection proximal to the loop jejunostomy with an end-to-end duodenoileostomy was subsequently performed.

Only approximately 1 m of small intestine could be preserved to achieve bleeding control. Adjuvant therapy was intended with paclitaxel, due to histological evidence of angiosarcoma. Unfortunately, a spontaneous intracranial hemorrhage with ventricular bleeding led to death of the patient, and the cause could not be determined. During hospitalization, the patient had received 75 erythrocyte concentrates, 49 units of fresh frozen plasma, 12 thrombocyte concentrates, and coagulation factors.

Histopathological findings

The small bowel showed an epithelium partly ulcerated with hemorrhage and infiltration of a mesenchymal fusiform tumor with parts of high-grade cells and nuclear polymorphism, including several mitoses and apoptosis formation (Figure 2). The tumor cells formed slit-shaped hollows, and they were predominantly grouped together with a solid appearance. The neoplastic cells were multifocal with macronucleoli. Eight mitoses were

Figure 2 Histopathological findings. A: Ileum section stained with hematoxylin and eosin (HE) shows extensive tumor infiltration ($\times 100$); B: HE-stained detailed section of an angiosarcoma with typical vascular proliferation ($\times 400$).

identified per 10 high-power fields. The tumor cells stained positive for CD31, cytokeratin, and vimentin and slightly weaker for CD34. The tumor cells were also focally positive for factor VIII. The MIB-1 marker of proliferation was expressed in approximately 40% of nuclei. The Berlin blue reaction indicated siderin deposits and Elastica-van-Gieson staining revealed collagen fibers. In summary, the tumor showed a less differentiated, multifocally growing epithelioid angiosarcoma (degree of malignancy III Coindre) in the submucosa with infiltration of the subserosal fat tissue and extensive lymphatic spread.

DISCUSSION

A gastrointestinal hemorrhage is a potentially dangerous condition that warrants a quick diagnosis and decisive treatment. The vast majority of these bleeding events are due to either upper or lower gastrointestinal bleeding, and only 5% cannot be localized endoscopically^[35]. These bleeding events typically occur from the small intestine. The most common cause of small intestinal bleeding is a vascular abnormality such as angioectasia, followed by tumors and, more infrequently, small bowel ulcers and aortoenteric fistulas^[36]. Angiosarcoma of the small intestine is an extremely rare but potentially life-threatening cause of such bleeding.

Angiosarcomas typically occur in skin and superficial

soft tissue, rather than in the gastrointestinal tract, and compromise $< 2\%$ of all sarcomas^[37,38]. Consequently, only 33 cases of small intestinal angiosarcoma have been reported in the English literature over the past 42 years (Table 1).

The precise predisposing factors remain unknown. Exposure to vinyl chloride, thorotrast, arsene, and radiation have been associated with the pathogenesis^[9,31,39-41]. Of the 33 cases reported, 14 describe patients developing an angiosarcoma after being treated with radiation for a malignant tumor, including ovarian carcinoma^[39,42], ovarian dysgerminoma^[40], squamous cell carcinoma of the uterine cervix^[43-46], endometrial adenocarcinoma of the uterus^[41,47], and Hodgkin's disease^[48]. The first report of an angiosarcoma of the small intestine after postoperative irradiation was published in 1979^[39]. That patient developed an angiosarcoma in the terminal ileum 8 years after irradiation for an ovarian carcinoma. Since then, 13 more angiosarcoma cases following radiation have been published (Table 1). In one case, an angiosarcoma occurred after exposure to irradiation and polyvinyl chloride^[31], but predisposing factors could not be identified in the remaining 19 cases. The patient presented in this report also did not have any known malignancy or exposure to irradiation, vinyl chloride, or other chemicals known to induce angiosarcomas such as thorotrast or arsene.

Categorization by sex and age does not reveal any clear-cut distribution. The average age of patients with this type of angiosarcoma was 62 years (range, 25-87 years), and 18 patients were male and 15 were female (Table 1).

The clinical manifestations of patients with angiosarcomas of the small intestine include lethargy, weakness, altered intestinal function, nonspecific abdominal pain, severe melena, anemia, acute abdominal signs and/or ileus symptoms, and even nonspecific chest pain (Table 1). In 15 of the 33 cases, the patient had signs of gastrointestinal bleeding^[30,31,37,49,50], similar to the patient described in this report. This variability in clinical manifestations makes it even more difficult to reach a quick and correct diagnosis. Furthermore, currently available diagnostic modalities, including CT, capsule endoscopy, double-balloon enteroscopy, magnetic resonance imaging, and positron emission tomography-CT all fail to detect the bleeding site, let alone lead to a diagnosis.

Angiosarcomas are classified as well-differentiated, poorly differentiated, and epithelioid tumors. A histological diagnosis can be challenging because angiosarcoma of the small intestine shows high architectural and cytological variability. The epithelioid morphology is typical but can be easily confused with other entities such as a poorly differentiated carcinoma^[4,47]. Immunohistochemical expression analysis for the endothelial markers CD31, CD34, and factor VIII-associated antigen is crucial. The majority of cases listed in Table 1 were positive for these antigens. Other antigens show limited relevance and can

cause confusion with other carcinomas. There is some controversy about the relevance of cytokeratin, which has been reported positive by some authors^[32,37,49,51]. However, most authors have reported no such expression by intestinal angiosarcomas^[29-31,48,52].

The current therapy for angiosarcoma includes bleeding control and symptomatic therapy to stabilize the patient, followed by radical tumor resection.

Six patients in the literature received adjuvant chemotherapy^[39,41,48,49,52], and three patients were treated with combination chemotherapy and radiation^[40,49,53]. Adjuvant therapy with paclitaxel was intended in the present case; however, the patient died before starting chemotherapy. All adjuvant therapy protocols are generally empiric and based on studies of cutaneous angiosarcoma, as randomized clinical studies on gastrointestinal angiosarcomas are lacking due to their rarity. The first case published received combination chemotherapy consisting of doxorubicin, vincristine, dacarbazine, and cyclophosphamide, after operative resection of the terminal ileum. That patient survived 14 mo^[39]. Another combination therapy that has been used is doxorubicin and dacarbazine, which led to 5 mo survival after diagnosis^[48]. Monotherapy with doxorubicin showed survival of 21 mo, at which time the tumor was widely disseminated^[41]. Furthermore, thalidomide therapy was initiated as an experimental measure after operative resection in one case^[52]. That patient was still alive 1 year after the initial diagnosis. No recommendation can usually be made, but paclitaxel and/or thalidomide are currently commonly considered^[52,54,55]. The newest studies suggest administering doxorubicin and paclitaxel weekly for cutaneous angiosarcoma, which seem to provide longer progression-free survival^[56-58].

Despite all efforts, survival of patients with small bowel angiosarcoma is generally poor. Survival usually ranges from several days after surgical intervention to

2 years. The majority of patients die within 6 mo to 1 year after being diagnosed (Table 1). Only two reported patients survived > 2 years after resection and adjuvant (radio-) chemotherapy^[2,53].

One major cause of this poor outcome seems to be that the diagnosis is difficult, and many tumors are diagnosed only in the late stages of the disease. Therefore, a quick diagnosis using endoscopy and imaging procedures, as well as fast and decisive surgical intervention and adjuvant chemotherapy are necessary.

Abstract

An extrahepatic arterioportal fistula (APF) involving the gastroduodenal artery and superior mesenteric vein is rare and mostly results from iatrogenic injuries. The clinical symptoms associated with APFs may include abdominal pain, gastrointestinal bleeding, ascites, nausea, vomiting, diarrhea, or even congestive heart failure. We present the case of a 70-year-old man who presented with chronic abdominal pain and gastrointestinal bleeding secondary to APF and portal vein thrombosis. The endovascular embolization of APF was accomplished successfully, and symptoms of portal hypertension resolved immediately after intervention. Unfortunately, the patient did not respond well to anticoagulation therapy with warfarin. Therefore, the patient underwent implantation of a transjugular intrahepatic portosystemic shunt, and the complications of portal hypertension resolved. In conclusion, the embolization of APF is technically feasible and effective and can be considered the first-choice therapy in selected patients.

INTRODUCTION

Upper gastrointestinal bleeding in patients with cirrhosis is usually due to portal hypertension, which is common in this population. Nevertheless, bleeding resulting from extrahepatic arterioportal fistulas (APFs) is extremely rare^[1-3]. Extrahepatic APF may cause severe portal hypertension, which leads to upper and lower gastrointestinal bleeding, refractory ascites, diarrhea, and hepatic encephalopathy. We present an unusual case of a 70-year-old man who presented with chronic abdominal pain and gastrointestinal bleeding secondary to APF and portal vein thrombosis.

CASE REPORT

A 70-year-old man with a history of cirrhosis resulting from hepatitis B virus infection was admitted to our hospital with complaints of chronic abdominal pain and melena. At the time of admission, his pulse rate was 63 beats/min, and his arterial blood pressure was 117/61

Figure 1 Contrast-enhanced computed tomography scan of the upper abdomen. A: Computerized tomography (CT) scan revealed a large aneurysm (white arrow) with dilated feeding gastroduodenal artery (GDA) (white arrowhead). Draining superior mesenteric vein (SMV) was observed at a lower level; B: Three-dimensional CT reconstruction demonstrated an arteriportal fistula (white arrow) arising from the GDA; C: CT scan showed a high-density mass in the right portal vein (black arrow), the patent main portal vein and SMV.

Figure 2 Selective angiography of the gastroduodenal artery. A: Angiography demonstrated an arteriportal fistula fistulating into the superior mesenteric vein; B: The varices were opacified.

Figure 3 After the placement of several metal coils, the arteriportal fistula was utterly abrogated.

mmHg. Laboratory tests disclosed the following values: red blood cells, $2.65 \times 10^{12}/L$; white blood cells, $5.65 \times 10^9/L$; PC, $207 \times 10^9/L$; prothrombin time, 15.9 s; total bilirubin, 1.1 mg/dL; albumin, 3.2 g/dL; aspartate aminotransferase, 47 IU/L; alanine aminotransferase, 43 IU/L; and alkaline phosphatase, 450 IU/L. The patient underwent cholecystectomy at the age of 67 because of acute cholecystitis.

Upper gastrointestinal endoscopy showed multiple severe esophageal and duodenal descendent varices and portal hypertensive gastropathy. Computerized tomography (CT) of the abdomen demonstrated the presence of a large aneurysm next to the head of the pancreas filled by the dilated gastroduodenal artery (GDA), draining into the superior mesenteric vein (SMV) (Figure 1). Other CT findings were cirrhotic liver, the presence of esophageal varices, portal thrombosis, moderate ascites and splenomegaly (Figure 1).

Under local anesthesia, a 5-F Cobra catheter (Teramo Co., Fijinomiya, Japan) was advanced into the GDA *via* the common femoral artery. Selective digital subtraction angiography showed an APF between the GDA and SMV, and the blood flow from the SMV did not go into the portal vein but into the collateral veins (Figure 2).

Embolization of the extrahepatic APF was performed to occlude the fistula and reduce portal pressure using stainless metal coils (Cook Incorporated, Bloomington, United States). A further angiography of the GDA confirmed immediate cessation of the fistula and the abrogation of the hyperkinetic portal flow (Figure 3). After the procedure, the gastrointestinal bleeding stopped, and the patient reported symptomatic improvement, with resolution of the chronic abdominal pain. Four days later, the patient was discharged in good condition. He was also started on anticoagulation therapy with warfarin, and the dose was adjusted to achieve an International Normalized Ratio of 2 to 3.

Three years after intervention, the patient presented to the emergency room with acute upper gastrointestinal bleeding. CT scan demonstrated multiple thromboses in the right and main portal vein and massive ascites, without any sign of APF (Figure 4). Because anticoagulation therapy was not successful, the patient underwent implantation of a transjugular intrahepatic portosystemic shunt (TIPS). Currently, two years after TIPS, despite several episodes of mild hepatic encephalopathy requiring conventional medical treatment, the patient remains clinically well.

Figure 4 Computerized tomography scan revealed massive intrahepatic portal vein thrombosis and main portal vein thrombosis.

DISCUSSION

Extrahepatic APF involving the GDA and SMV is an uncommon disorder of the mesenteric vasculature characterized by abnormal communication between the arterial and portal circulation. The most common causes of APFs are reported to be congenital vascular malformations, blunt or penetrating traumas and iatrogenic injuries^[1,4-6]. Our patient had no history of abdominal traumas or other vascular malformations, suggesting that the APF most likely arose as a result of iatrogenic vascular injury during the previous biliary surgery.

Both CT and magnetic resonance imaging with intravenous contrast material can provide useful information for the diagnosis of APFs, specifically, the exact anatomic location and extent of mesenteric vessel involvement. Doppler ultrasonography is another useful imaging modality for diagnosis, which can not only detect the position of an APF but also evaluate the flow direction. Arteriography should be performed as soon as possible for diagnostic purposes and evaluating APF hemodynamics, delineating the fistula site, and determining the size of the feeding artery. In the present case, CT of the abdomen clearly revealed a large aneurysm, which was supplied by the GDA and had fistulated into the SMV, with radiological evidence of portal hypertension.

APF is an uncommon but treatable cause of portal hypertension. The clinical symptoms associated with APFs may include abdominal pain, gastrointestinal bleeding, ascites, nausea, vomiting, diarrhea, or even congestive heart failure^[4,7]. In this case, extrahepatic APF led to secondary portal hypertension, resulting in upper gastrointestinal bleeding and moderate ascites. Portal hypertension disappeared immediately after cessation of the APF.

Generally, the early treatment of APF is mandated, even in asymptomatic patients with a high-flow fistula, to prevent complications. Both open and endovascular management of APFs has been well described^[5,8,9]. However, there is an increased use of endovascular techniques as first-choice therapy, including embolization or stent insertion^[8,10]. Endovascular techniques provide a less invasive alternative to surgical procedures, can be performed un-

der local anesthesia, and do not impede planned surgery. In our case, a 5-F Cobra catheter was used to extend the peripheral fistula position, and it allowed for the exact placement of the coils in the feeding GDA.

The endovascular embolization of APF was accomplished successfully, and symptoms of portal hypertension resolved immediately after intervention. Unfortunately, the patient did not respond well to anticoagulation therapy with warfarin. We elected to treat the patient with TIPS rather than endoscopic treatment for two reasons. The first reason is that because the patient did not respond well to warfarin, endoscopic therapy plus anticoagulation therapy seemed impossible to recanalize the portal vein. The second reason was that TIPS could not only reduce the portal pressure but also recanalize the portal vein and avoid rethrombosis by restoring portal flow through a low-resistance shunt.

In conclusion, extrahepatic APF is a rare cause of portal hypertension and may cause gastrointestinal bleeding and ascites. The embolization of APF is technically feasible and effective and can be considered the first-choice therapy in selected patients. Moreover, by embolizing the APF, chronic abdominal pain was also controlled.

Abstract

Progressive familial intrahepatic cholestasis type 1 is a rare disease that is characterized by low serum γ -glutamyltransferase levels due to mutation in *ATP8B1*. We present a 23-year-old male who experienced persistent marked pruritus for eighteen years and recurrent jaundice for thirteen years, in addition to cholestasis that eventually became fatal. Genetic sequencing studies of the entire coding (exon) sequences of *ATP8B1* and *ABCB11* uncovered a novel heterozygous missense 3035G>T mutation (S1012I) and a synonymous 696T>C mutation in *ATP8B1*. The patient's progression was associated with not only impaired familial intrahepatic cholestasis 1 (FIC1) function but also impaired

INTRODUCTION

Progressive familial intrahepatic cholestasis (PFIC) is a heterogeneous group of severe autosomal recessive liver disorders of childhood that result in cholestasis that can progress to end-stage in the first or second decade of life^[1,2]. PFIC-1 and PFIC-2 are characterized by low serum γ -glutamyltransferase (GGT) levels. Patients with PFIC-1 have mutations in *ATP8B1* (encoding FIC1), which maps to chromosome 18q21-22, and patients with PFIC-2 have mutations in *ABCB11* (encoding bile salt export pump, BSEP), which maps to chromosome 2q24. PFIC-3 is characterized by high serum GGT levels and is caused by genetic mutations in *ABCB4* (encoding multidrug resistant protein 3)^[3].

We report an unusual patient who presented with childhood-onset progressive intrahepatic cholestasis with low serum GGT levels and died in his third decade of life. Genetic sequencing analysis revealed a novel heterozygous 3035G>T mutation (S1012I) and a synonymous 696T>C mutation in *ATP8B1*.

CASE REPORT

A 23-year-old male presenting with an 18-year history of persistent pruritus and a 13-year history of recurrent jaundice was admitted to the department of infectious disease. He had gradually developed severe pruritus with pale yellow stools and dark urine 2 mo before admission. He had been admitted to hospital 13 years previously for pruritus, hyperbilirubinemia and mildly elevated alanine aminotransferase levels (Table 1). Skin pathology conducted at that time showed hyperkeratosis of epidermal cells, papilloma hyperplasia, acanthosis, and a slight increase of basal pigmentation (results not shown). The liver biopsy revealed intrahepatic cholestasis with ballooning degeneration of hepatocytes, no significant fibrosis, and multinucleated giant cells (Figure 1). Jaundice recurred four times during the subsequent 13 years. Serum biochemistry was returned to normal levels by treatment with a liver protectant. There was no family history of liver disease. On physical examination, the patient was 150 cm tall and 55 kg in weight. The skin and sclera were markedly icteric. The skin was rough and thickened (Figure 2). Palmar erythema and mild splenomegaly were noted. The rest of the examination was unremarkable.

Liver function tests showed conjugated hyperbilirubinemia, elevated serum aminotransferase levels, low serum GGT values, increased bile acids levels and hypoalbuminemia (Table 1). The patient was negative for markers of hepatitis virus. Antibodies to cytomegalovirus and Epstein-Barr virus were negative. Ceruloplasmin and serum copper were normal, and no Kayser-Fleischer ring was observed upon examination by an experienced ophthalmologist. A qualitative urinary porphyrin test was negative. Autoimmune antibodies including antimitochondrial antibody, antinuclear antibodies, antineutrophil cytoplasmic antibody were all negative, and serum α -1-antitrypsin concentration, thyroid function and other laboratory investigation results were normal.

A lesion in segment 4 of the liver, gallbladder stones, splenomegaly and an oval-shaped signal intensity in the spleen were observed upon magnetic resonance imaging (MRI) (Figure 3). No dilatation of the bile duct was observed by magnetic resonance cholangiopancreatography. A repeat biopsy was performed.

The liver biopsy revealed cholestasis, inflammation and fibrosis at the portal area. The mass consisted of normal liver tissue with normal liver architecture and mild fibrosis (data not shown). The fibrosis stained with hematoxylin and eosin and Masson's trichrome at portal area in the 23-year-old liver tissue was more severe than

that in the liver tissue sample taken from the same patient at 10 years of age. Atypical hyperplasia was not observed in the mass, and CD10, CD34 and α fetoprotein (AFP) immunochemistry staining were unremarkable (data not shown). BSEP expression was present only focally and was assessed as both faint and patchy in the liver biopsy tissue (Figure 4).

Ursodeoxycholic acid (UDCA) and vitamin supplements were prescribed. Serum total bilirubin was persistently elevated, and liver transplantation and partial external biliary diversion were advised. The patient declined surgery to resolve the cholestasis and was discharged. The patient was followed up but died of liver failure and hepatic encephalopathy two months later.

Mutation analysis

Genetic studies were performed with the informed consent of the patient, and the study was approved by the Ethics Committee of China Medical University. Genomic DNA was extracted from peripheral blood leucocytes. *ABCB11* and *ATP8B1* were analyzed by direct sequencing of polymerase chain reaction (PCR) products. PCR primers were designed to amplify the 27 exons of the entire coding sequence of the *ATP8B1* gene and the 28 exons of the *ABCB11* gene, followed by direct sequencing using a Genetic Analyzer 3730 instrument (Applied Biosystems). A synonymous 696T>C mutation and a novel heterozygous missense 3035G>T mutation (S1012I) were discovered in exons 7 and 24 of the *ATP8B1* gene. We obtained blood samples from the patient's parents and sisters, all of which were negative for the *ATP8B1* and *ABCB11* mutations. The mutations were absent in 100 control chromosomes (evaluated by direct sequencing). This missense mutation has not been reported in any other benign recurrent intrahepatic cholestasis (BRIC)-1 or PFIC-1 patient.

DISCUSSION

In this study, we present a patient with a novel mutation in *ATP8B1*, who experienced the onset of persistent severe pruritus at 5 years old and the onset of progressive intrahepatic cholestasis at 10 years old, eventually dying of liver failure at age 23. Common chronic cholestatic diseases such as primary biliary cirrhosis, sclerosing cholangitis and idiopathic ductopenia were excluded by laboratory, radiographic and histological examinations. Based on the absence of the missense mutation (S1012I) in 100 control chromosomes, the novel mutation S1012I is believed to be the disease-causing mutation. *ATP8B1* is also associated with BRIC1 and intrahepatic cholestasis of pregnancy, which are characterized by intermittent cholestasis without liver scarring^[4]. These clinical and histopathological features are generally considered diagnostic for PFIC-1 rather than BRIC type 1. The differences in clinical outcome and disease duration may be dictated by the variations of the structure and/or

function of the FIC1 protein due to the mutation in *ATP8B1*^[5]. Although the novel mutation 3035G>T is predicted to impair FIC1 function, the effects of the

Figure 2 Skin. The skin was rough and thickened.

missense 3035G>T mutation and the synonymous 696T>C mutation on the FIC1 protein are unknown.

Though the function of FIC1 protein is not yet known, it is thought to mediate the inward translocation of phosphatidylserine from the exoplasmic to the cytoplasmic leaflet of the plasma membrane^[5]. Immunohistochemistry for FIC1 protein was not performed due to the current lack of a commercially available specific antibody to detect the absence/alteration of the FIC1 protein. Impaired FIC1 function may lead to a loss of lipid asymmetry in the canalicular membranes of hepatocytes,

Figure 3 Liver magnetic resonance imaging. A: A 2.3 cm × 2.56 cm lesion was observed in segment 4 of the liver (T1-weighted). No obvious dilation of the intra or extrahepatic bile duct was observed; B: Following contrast magnetic resonance imaging (MRI), the capsule shows linear enhancement without enhancement of the lesion itself. Splenomegaly is observed, and several oval-shaped nodules in the spleen show slight enhancement; C: The oval-shaped nodules appear as low-intensity signals on a T1-weighted MRI image; D: The oval-shaped nodules in the spleen appear as a lower-intensity signal on T2-weighted MRI images than on T1-weighted images.

Figure 4 Expression pattern of the canalicular transporter bile salt export pump (rabbit anti-bile salt export pump polyclonal antibody, all images, × 400). A: Normal bile salt export pump (BSEP) staining in a control liver without cholestasis. Anti-BSEP antibody stains an orderly canalicular network; B: BSEP staining in liver tissue collected from the patient 13 years ago. BSEP is present only focally (arrows) and is both faint and patchy; C: BSEP staining in the recent sample of liver tissue BSEP expression is again faint and patchy; D: Canalliculi in negative control liver stained with phosphate-buffered saline.

resulting in BSEP dysfunction; decreased expression of BSEP (encoded by *ABCB11*) has been observed in livers from PFIC-1 patients, and this decrease is associated with the accumulation of bile salts in hepatocytes^[6,7]. It is also reported that a marked decrease in the activity of farnesoid X receptor, which can positively regulate the expression of BSEP and affects canalicular membrane composition to impair *ABCB11* activity, can be induced by a loss of FIC1 expression^[8,9]. Immunohistochemistry for BSEP in this patient revealed that BSEP expression was present only focally and was assessed as both faint and patchy in the liver biopsy sample. Thus, the chronic cholestasis in this patient was associated with not only impaired FIC1 protein function but also impaired BSEP expression. No mutation in *ABCB11* was detected, which suggested that impaired expression of BSEP in the patient was most likely induced by impaired FIC1 protein function.

PFIC-1 patients may exhibit extrahepatic features such as persistent short stature, diarrhea, pancreatitis and sensorineural hearing loss^[10], which were not present in this patient. Here, we show that a patient with intermittent cholestasis can develop progressive liver disease even after several decades. However, this does not imply that all patients with BRIC will progress to PFIC. Although van Ooteghem *et al.*^[11] reported that 4 of 63 patients with intermittent cholestasis developed progressive liver disease after several decades, only 2 of the 4 patients were diagnosed genetically, in assays that revealed the same splice site mutation resulting in skipping of exon 24. Here, we have uncovered a novel missense mutation in *ATP8B1* associated with progressive liver disease in a patient with intermittent cholestasis. A possible phenotypic continuum between BRIC-2 and PFIC-2 in a patient with mild disease, who experienced a complete remission of liver fibrosis following treatment with UDCA, was reported^[12]. The patient we presented did not respond to treatment with UDCA and died of liver failure, in contrast to the previously described patient with phenotypic continuum.

PFIC may induce hepatic malignancies, which can be coincident with hepatoblastoma^[13]. CD10, CD34 and AFP immunochemistry staining was performed to distinguish a well-differentiated hepatocellular carcinoma from normal and cirrhotic liver tissue or benign liver nodules were performed; the results were negative^[14,15]. The liver mass in this patient was found to be a benign lesion with normal liver architecture.

The current medical therapy for PFIC-1 is either non-existent or useful for only a limited duration, and some agents, including ursodeoxycholic acid, provide mainly symptomatic relief. Mutation-specific drugs may become a new tool for PFIC-1 therapy in the near future. Most patients with progressive cholestasis eventually require surgical intervention^[10]. Liver transplantation should be considered in patients who develop cirrhosis or progressive liver disease despite treatment.

In conclusion, we report a rare case that presented with onset persistent severe pruritus progressing to PFIC-1 due to a novel heterozygous *ATP8B1* mutation. Both impaired FIC1 function and impaired BSEP expression induced by the impaired FIC1 function were associated with this progression. This case shows that patients with intermittent cholestasis can develop progressive liver disease, even after several decades, and should be followed up regularly. Further studies are necessary to investigate the impact of the 3035G>T mutation on functional defects in FIC1 and BSEP.

Abstract

We describe herein a 68-year-old woman who was diagnosed with a quite rare entity of intraductal papillary mucinous neoplasms (IPMNs) occurring simultaneously in the left lateral lobe of liver and the tail of pancreas. Abdominal computed tomography and magnetic resonance cholangiopancreatography showed a cystic dilatation of the pancreatic duct in the pancreatic tail, which suggested an IPMN, and multiple intrahepatic duct stones in the left lateral lobe. The patient underwent a laparoscopic left lateral hepatectomy and spleen-preserving distal pancreatectomy. Intra-operative finding of massive mucin in the dilated bile duct implied an intraductal mucinous tumor in the liver. The diagnosis of synchronous IPMNs in the liver and pancreas was confirmed by pathological examination. The patient was followed up for 6 mo without signs of recurrence. Although several cases of IPMN of liver without any pancreatic association have been reported, the simultaneous occurrence of IPMNs in the liver and pancreas

INTRODUCTION

Intraductal papillary mucinous neoplasm (IPMN) is rare and mostly occurs in the liver or pancreas. Synchronous occurrence of IPMNs in the liver and pancreas is even more unusual. It is only described in the form of case reports in the literature^[1-5]. We present here a case of synchronous occurrence of IPMNs located respectively in the left lateral lobe of the liver and the tail of pancreas. These two lesions were resected by laparoscopic left lateral hepatectomy and spleen-preserving distal pancreatectomy. To the best of our knowledge, it is the first reported case treated by laparoscopic resection. We also summarized the features of five similar cases with detailed information reported in the English-language literature (Table 1).

CASE REPORT

A 68-year-old woman was admitted to our department in January 2012 because of epigastric pain for half a month. She had no fever, no nausea or vomiting, no hematemesis or melena, and no weight loss. She underwent open cholecystectomy for gallbladder stones 25 years ago. Physical examination on admission showed no abnormalities. Blood biochemistry and tumor markers (carcinoembryonic antigen, alpha fetoprotein, carbohydrate antigen 19-9, carbohydrate antigen 153, carbohydrate antigen 125) were all within normal ranges. Computed tomography (CT) of the abdomen with intravenous contrast revealed cystic dilatation of left intrahepatic bile ducts accompanied with stones (Figure 1A) and multiple cystic lesions in the pancreatic tail (Figure 1B). Magnetic resonance cholangiopancreatography revealed a diffuse dilated biliary tract with multiple filling defects in the left lateral lobe and segmental cystic dilatation of pancreatic duct in the pancreatic tail (Figure 2). According to the medical history and the imaging findings, left intrahepatic bile duct stones and pancreatic IPMN was first considered. Therefore, laparoscopic left lateral hepatectomy and spleen-preserving distal pancreatectomy were performed.

The patient was placed in supine position under general anesthesia. The operator and the second assistant who held the laparoscope stood on the right side of the patient and the first assistant stood on the left. Carbon dioxide pneumoperitoneum was established using a Veress needle to a pressure of 15 mmHg. One initial 10-mm trocar was placed for laparoscope below the umbilicus and another four trocars (one of 12 mm and three of 5 mm) were inserted into the left upper, left flank, right upper, and right flank quadrants, making the five trocars arrange in a V-shape (Figure 3). During laparoscopic exploration, severe adhesion in the right upper abdomen because of the former open cholecystectomy and the atrophy of left lateral lobe of the liver were found, but without abdominal metastasis.

After dissecting the adhesion, the gastrocolic omentum was divided for entrance to the lesser sac by ultrasonic coagulating shears (Harmonic Ace scalpel, Ethicon Endo-Surgery, Inc., Cincinnati, OH, United States). The stomach was reflected cephalad and the tumor was found in the tail of pancreas. According to the location of the tumor, the mobilization of the pancreas began at the upper border till the common hepatic artery and the proximal splenic artery were visualized. Then the pancreas was mobilized dorsally starting at the lower edge to visualize the splenic vein. Pancreas was transected 2 cm proximal to the right side of the tumor with an endoscopic linear staplers (Endocutter 60 staple, white cartridge; Ethicon, Endo-Surgery, Inc., Cincinnati, OH, United States) and the pancreatic tail was freely dissected from the splenic artery and vein by ligation of the small branches connected to the pancreas using small titanium vascular clips or ultrasonic coagulating shears.

The left lateral lobe of the liver was mobilized by

Figure 1 Computed tomography scan. A: A cystic dilatation of the left intrahepatic bile ducts accompanied with stones; B: Multiple cystic lesions in the pancreatic tail.

Figure 2 Magnetic resonance cholangiopancreatography reveals diffuse dilation of biliary tract with multiple filling defects in the left lateral lobe of the liver and segmental cystic dilatation of pancreatic duct in the pancreatic tail.

dissecting the round, falciform, left coronary and triangular ligaments. Liver parenchyma was also divided by ultrasonic coagulating shears 1 cm to the left side of the falciform ligament. The branches of left portal vein, hepatic artery and hepatic vein on the cut surface were ligated with hem-o-loks and divided. The dilated bile duct was cut and stones were found. However, it was surprising that a large amount of mucin outflowed from the bile duct, which implied the intraductal mucinous tumor. The common bile duct (CBD) was explored, because it was dilated to 2 cm. There was no stone but massive mucin.

Table 1 Summary of previous synchronous intraductal papillary mucinous neoplasms in the liver and pancreas

Source	Sex/age (yr)	IPMN-b					IPMN-p					Procedure

Figure 3 The location of trocars placement.

After inserting a No.24 T-tube, the CBD and bile duct in the cut surface were closed with a continuous suture of 3-0 Vicryl. The specimens were removed through the enlarged subumbilical port (Figure 4).

Intraoperative frozen section confirmed the mucinous tumors of the liver and pancreas and the resection margins were all negative. The operative time was 250 min and intraoperative bleeding was 150 mL. The post-operative course was uneventful, and the patient was discharged seven days later. She was followed up by abdominal CT six months later without signs of recurrence.

The gross finding was a 5 cm × 4 cm multiloculated cystic mass with stones in the left lateral lobe of liver, communicated with the dilated intrahepatic bile duct. Furthermore, multiple cystic lesions, ranging from 0.5 cm to 1.0 cm in diameter, were located in the pancreatic tail, in communication with the dilated pancreatic duct (Figure 4). All cystic lesions, in both the liver and pancreas, were filled with gelatinous transparent mucin. Microscopically, the cystic wall consisted of hyperplastic fibrous tissues lined by high columnar mucous epithelium demonstrating papillary growth, but no ovarian-like stroma was identified (Figure 5). There was no evidence of high-grade cellular dysplasia or stroma invasion suggesting malignancy in either specimen except for focal low-grade atypical

Figure 4 Resected specimens of intraductal papillary mucinous neoplasm-b (arrow head) and intraductal papillary mucinous neoplasm-p (arrow).

hyperplasia of epithelium in the liver lesion. The immunohistochemical staining of the liver lesion showed cytokeratin 7 (CK7): +/-, CK20: +, cadual type homeobox transcription factor-2 (CDX-2): +, mucin core protein 1 (MUC1): -, mucin core protein 2 (MUC2): + and mucin core protein 5 (MUC5): +, while the pancreas lesion showed CK7: +, CK20: -, CDX-2: -, MUC1: +, MUC2: - and MUC5: +, which were subsequently categorized into pancreaticobiliary and intestinal subtypes of IPMN.

DISCUSSION

IPMN is a rare but well-established disease, mostly occurs in the biliary tract or pancreas (IPMN-b or IPMN-p). It manifests as a cystic lesion in the imaging findings which make it difficult to differentiate from other cystic tumors preoperatively, such as cystadenoma or cystadenocarcinoma. The clinicopathological characteristics of IPMN can be summarized as follows: (1) Communicating with bile duct or pancreatic duct; (2) Dilated bile duct or pancreatic duct because of mucin hypersecretion and accumulation; (3) Lack of ovarian-like stroma characteristic of mucinous cystic tumor; and (4) Papillary proliferation

Figure 5 Histological features of intraductal papillary mucinous neoplasms by hematoxylin and eosin stain. A: Liver, $\times 20$; B: Liver, $\times 100$; C: Pancreas, $\times 40$; D: Pancreas, $\times 200$.

with delicate fibrovascular cores of ductal epithelium. The cystic lesions of the liver and pancreas in the present case possessed all the above characteristics, so a diagnosis of IPMN-b and IPMN-p was made. We believed that these two lesions were more likely to be the synchronous tumors arising in amenable ducts rather than metastasis, because each lesion was a definite benign tumor without lymph node involvement, and they were grossly and microscopically separate, without continuity between them. Besides, the IPMN-b and IPMN-p in the present case were categorized into different immunophenotypes, pancreaticobiliary and intestinal subtypes respectively, according to the results of immunohistochemical staining.

Although IPMN is frequently associated with malignancy of other organs, including the stomach, colon, esophagus and lung, the simultaneous occurrence of IPMN-b and IPMN-p is extremely rare^[6,7]. To the best of our knowledge, only five such cases have been reported in the English-language literature and the present case is the first one treated by total laparoscopic resection^[1-5]. Up till now, the origin of simultaneous occurrence of IPMN-b and IPMN-p is still unclear. However, similar clinicopathological findings supported the idea that both tumors might have the same pathogenesis. It was found that the multiple lesions of IPMN were consistent with the concept of field cancerization^[8], proposed by slaughter^[9], which has been invoked to explain the occurrence of multiple, independent and primary neoplasms^[10]. Because the pancreas and the bile duct develop embryonically from the same primordium^[11], the present case may

also fit the concept of field cancerization.

IPMN-b and IPMN-p are slow-growing tumors with a lower malignant potential than ductal cell carcinoma and mucinous cystadenocarcinoma^[12]. Regional lymph node metastasis was rarely found in previously reported cases and excellent prognosis can be expected after complete resection of tumors with negative margins, with a 5-year survival rate higher than 80%^[13-15]. Therefore, an accurate preoperative or intraoperative diagnosis is very important in this disease to ensure the curative resection. In contrast to IPMN-p, IPMN-b is more difficult to be diagnosed because of lacking full recognition, especially when it is accompanied with stones. Missed diagnosis of IPMN-b also occurred in our case till massive mucin in bile duct was found during liver resection. Preoperative endoscopic retrograde cholangiopancreatography is more useful than routine CT and magnetic resonance imaging, for the diagnosis of lesions with the characteristic findings of a patulous ampulla, hypersecreted mucin and diffusely dilated biliary tract.

It has been reported that laparoscopic hepatectomy or pancreatectomy is safe, valid, and minimally invasive. However, there are few reports on laparoscopic resection of synchronous liver and pancreatic tumors except one case of laparoscopic resection of a pancreatic polypeptidoma with solitary liver metastasis^[16]. In our case, two tumors were located separately in the left lateral lobe of liver and pancreatic tail, making the laparoscopic left lateral hepatolobectomy and distal pancreatectomy an optimal choice of treatment for the patient, since the

complicated lymphadenectomy, hilar dissection and gastrointestinal reconstruction were not needed. The spleen was preserved, for there was no evidence of malignancy or splenic vessel invasion according to the imaging findings and intraoperative pathological diagnosis.

Abstract

Extrathoracic solitary fibrous tumors (SFTs) have been described at almost every anatomic location of human body, but reports of SFT in the abdominal cavity are rare. We herein present a rare case of SFT originating from greater omentum. Computed tomography revealed a 15.8 cm × 21.0 cm solid mass located at superior aspect of stomach. Open laparotomy confirmed its mesenchymal origin. Microscopically, its tissue was composed of non-organized and spindle-shaped cells exhibiting atypical nuclei, which were divided up by branching vessel and collagen bundles. Immunohistochemical staining showed that this tumor was negative for CD117, CD99, CD68, cytokeratin, calretinin, desmin, epithelial membrane antigen, F8 and S-100, but positive for CD34, bcl-2, α -smooth muscle actin and vimentin. The patient presented no evidence of recurrence during follow-up. SFT arising from abdominal cavity can be diagnosed by histological findings and immunohistochemical markers, especially for CD34 and bcl-2 positive cases.

INTRODUCTION

Solitary fibrous tumor (SFT), a rare neoplasm occurring most often in the visceral pleura, was first described by Klemperer and Rabin in 1931^[1]. Extrathoracic SFT has been described at almost every anatomic location of the human body^[2-6], but reports of SFT in the abdominal cavity are rare^[7-11]. Five SFT cases involving omentum have been reported up till December 2011^[11-15]. Herein, we report a rare case of a giant SFT originating from greater omentum. The final diagnosis of the patient was established by pathological examination and immunohistochemical study after an open excision of the tumor.

CASE REPORT

A 29-year-old Chinese man was admitted to the Subei People's Hospital of Jiangsu Province, China on July 1, 2008. He complained of a mass in the upper abdomen and a gradual weight loss that started more than four months ago. He was a farmer. He had remained well until the day before admission, with no fever, no vomiting and no stomach-ache except for epigastric discomfort and compression. Physical examination showed a large abdominal mass lying between xiphoid process of the sternum and umbilicus without obvious tenderness. No abnormalities were found in laboratory data including tumor markers (Table 1). Abdominal contrast-enhanced

Table 1 Laboratory findings on admission

Tumor markers	Index	Normal range
CA199 (KU/L)	5.47	< 35.00
CA242 (KU/L)	1.31	< 20.00
CA125 (KU/L)	2.27	< 35.00

CA: Cancer antigen; NSE: Neuron-specific enolase; CEA: Carcinoembryonic antigen; β -HCG: β -human chorionic gonadotropin; AFP: Alphafetoprotein; PSA: Prostate specific antigen; HGH: Human growth hormone.

Figure 1 Abdominal computed tomography demonstrating a giant solitary tumor of 15.8 cm \times 21.0 cm in abdominal cavity.

computed tomography (CT) showed extrinsic multi-organ compression due to a giant solitary tumor of 15.8 cm \times 21.0 cm occupying the majority of abdominal cavity (Figure 1).

Laparotomy was performed and a giant tumor originating from greater omentum was discovered. The tumor was partly surrounded by greater omentum, and tightly adhered to the spleen and stomach (Figure 2). Abundant and extremely expanded blood vessels of greater omentum were present along the surface of tumor, leading to a blood loss of nearly 2000 mL when the tumor was totally excised. The excised mass was solitary and tenacious compassed with a complete envelope. The mass measured 28 cm \times 25 cm \times 11 cm in size and 5002.4 g in weight. Microscopically, the excised tumor tissue was composed of non-organized and spindle-shaped cells exhibiting atypical nuclei, which were divided up by branching vessel and collagen bundles (Figure 3). Immunohistochemical staining showed that the tumor was negative for CD117, CD99, CD68, cytokeratin, calretinin, desmin, epithelial membrane antigen, F8 and S-100, but positive for CD34, bcl-2, α -smooth muscle actin (α -SMA) and vimentin (VIM) (Figure 4). According to the mitotic index, this case was considered to have a low risk of malignancy.

Figure 2 Giant tumor. A: A giant tumor originating from greater omentum; B: A giant tumor originating from resected specimen.

The patient experienced no postoperative complications, and was discharged 10 d after surgery. During a 48-moSS follow-up by ultrasonography or CT, there was no evidence of recurrence.

DISCUSSION

SFT is a rare mesenchymal neoplasm often originating from the pleura, but occasionally from other parts of the body, including the peritoneum, mediastinum, extremities, orbit, and parotid gland^[1-6]. Intra-abdominal SFT is very rare; and SFT with the involvement of greater omentum is even more uncommon. We searched the PubMed and reviewed the relevant papers published till December 2011, and found only 5 SFT cases involving the omentum^[11-15].

SFT is a neoplasm derived from mesenchymal cells located in the sub-mesothelial lining of the tissue space, predominantly composed of spindle-shaped cells and collagen bundles^[16]. Approximately 78%-88% of SFTs are benign and 12%-22% are malignant^[17,18]. The clinical and pathological properties of SFT were first reported by Klempere *et al*^[1]. The earliest criteria for a judgment of malignancy of SFT by England *et al*^[19] were (1) high cellularity with crowding and overlapping of nuclei; (2) high mitotic activity (more than 4 mitotic figures per 10 high-power fields); and (3) pleomorphism judged as mild, moderate, or marked based on nuclear size, irregularity, and nucleolar prominence. In addition, some authors suggested a potential association of tumor size,

hemorrhage and necrosis with the clinical behavior of SFT^[19-21].

We summarized the clinical data of the 5 reported cases of SFT originating from omentum (Table 2). Of particular note, mitotic activity and tumor size may play a key role in predicting SFT. We suggest using risk assessment (very low risk, low risk, intermediate risk, and high risk) based on tumor size, mitotic activity, cellularity and pleomorphism to predict SFT behavior, rather than attempting to draw a sharp line between benign and malignant lesions. More frankly, malignant factors of SFT are associated with a higher risk for recurrence and metastasis. However, the small sample size limits us to draw a definite conclusion. And the detailed criteria still need to be discussed and validated by future studies.

In this case, no mitotic activity and necrosis were present, and there was low cellularity, resulting in a diagnosis of a possible benign entity according to the benign-malignant system. However, the only existing risk is the giant size, and multiple prognostic factors should be taken into account in predicting SFT behavior. In our opinion, it is reasonable to judge this case to be a low-risk lesion by clinical presentation, tumor size, mitotic activity, cellularity and pleomorphism. During a 48-mo follow-up, no evidence of local recurrence or metastasis was observed.

In cases of mesenchymal tumor presenting with

spindle-cell neoplasm, the differential diagnosis of SFT should be considered. It is absolutely necessary although sometimes it is difficult to clearly differentiate it from other malignant or benign entities such as hemangiopericytoma, neurofibroma, spindle cell lipoma, leiomyoma, fibrosarcoma, leiomyosarcoma, angiomyolipoma or fibroma (Table 3). Moreover, hemangiopericytoma must be included into differential diagnosis because of its vascular pattern. And electron microscopic examination can be used to exclude the presence of an external lamina, typically observed in hemangiopericytoma. Immunohistochemically, SFTs commonly express CD34 and bcl-2, and occasionally SMA. They are usually negative for S-100, desmin and cytokeratins^[22,23]. To our knowledge, few tumors of mesenchymal origin can express both CD34 and bcl-2, which are useful to differentiate SFT from other mesenchymal tumors, because approximately 82%-95% and 88%-100% of the SFTs are positive for CD34 and bcl-2, respectively^[24,25]. This report describes a giant SFT showing immunocytochemical reactivity for CD34, bcl-2, α-SMA and VIM, which is consistent with the results reported elsewhere. But what we are really concerned is how to make an exact diagnosis before operation.

The patients with SFT in abdominal cavity may complain of vomiting, abdominal pain or discomfort, but they are mostly asymptomatic. Tumor marker is not specific and sensitive for SFT. But in some patients with

the symptom of hypoglycemia, a high expression of serum insulin-like growth factor- II (IGF- II) was reported, which was found more in the tumor cystic fluid than in serum. Consequently, after total resection of the tumor, no abnormalities were found and the hypoglycemia was resolved^[26,27]. It was concluded that the tumor cells can secrete IGF- II, but the specificity and sensitivity need to be explored by further studies.

The best available diagnostic modalities are CT scanning and magnetic resonance imaging (MRI), which can demonstrate a proliferation of fibrous tissues in abdominal cavity and evaluate the relationship between the tumor and the neighboring structures so as to help the surgeons make a decision whether or not to excise the tumor. Nevertheless, CT scanning and MRI can not distinguish SFT from other mesenchymal tumors. Therefore, SFT may be misdiagnosed as stromal tumor as did in our case because of their homology.

Needle aspiration biopsy for SFT provides inconclusive results because the tumor is composed of acellular and hypercellular portions and it does not provide enough tissues for cytologic analysis. Although Apple *et al.*^[28] reported that accurate diagnosis could be established by fine needle aspiration, it still needs further investigation on a larger series of patients. The rare location of SFT often gives rise to difficulties in diagnosis or to misdiagnosis before operation. However, aspiration by Ryle's tube is a better option for large tumors and specimens could be obtained for immunohistochemical test, while for small tumors, samples can be collected through exploratory laparotomy for immunohistochemical test, thus a diagnosis can be done before operation.

Surgical treatment including local resection of this tumor is a definitive choice of treatment. Postoperative long-term follow-up is very important since SFT may recur locally. The malignant form pursues an aggressive course manifested by local invasion, recurrent growth, or metastasis^[29]. Therefore, postoperative chemotherapy is recommended for malignant SFT. Moreover, half of malignant SFT cases were positive for c-kit^[30] and tyrosine kinase inhibitors, such as imatinib and sunitinib, which are also effective against gastrointestinal stromal tumors^[31,32], have been used in the treatment of SFT^[33].

In summary, we report a rare case of a giant SFT originating from greater omentum. Abdominal imaging is helpful in the diagnosis of the tumor. If CT and MRI are not useful, immunohistochemical test can be performed in preoperative diagnosis using the tumor samples collected through Ryle's tube for small tumors and through exploratory laparotomy for large tumors. Long-term follow-up is necessary to assess the outcomes of the treatment, especially for the high-risk SFTs.

ACKNOWLEDGMENTS

Acknowledgments to reviewers of World Journal of Gastroenterology

We acknowledge our sincere thanks to our reviewers. Many reviewers have contributed their expertise and time to the peer review, a critical process to ensure the quality of our World Series Journals. Both the editors of the journals and authors of the manuscripts submitted to the journals are grateful to the following reviewers for reviewing the articles (either published or rejected) over the past period of time.

Arezoo Aghakhani, MD, PhD, Assistant Professor, Clinical Research Department Pasteur Institute of Iran, No 69, Pasteur Ave., Tehran 13164, Iran

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a weekly, open-access (OA), peer-reviewed journal supported by an editorial board of 1352 experts in gastroenterology and hepatology from 64 countries.

The biggest advantage of the OA model is that it provides free, full-text articles in PDF and other formats for experts and the public without registration, which eliminates the obstacle that traditional journals possess and usually delays the speed of the propagation and communication of scientific research results. The open access model has been proven to be a true approach that may achieve the ultimate goal of the journals, i.e. the maximization of the value to the readers, authors and society.

Maximization of personal benefits

The role of academic journals is to exhibit the scientific levels of a country, a university, a center, a department, and even a scientist, and build an important bridge for communication between scientists and the public. As we all know, the significance of the publication of scientific articles lies not only in disseminating and communicating innovative scientific achievements and academic views, as well as promoting the application of scientific achievements, but also in formally recognizing the "priority" and "copyright" of innovative achievements published, as well as evaluating research performance and academic levels. So, to realize these desired attributes of *WJG* and create a well-recognized journal, the following four types of personal benefits should be maximized. The maximization of personal benefits refers to the pursuit of the maximum personal benefits in a well-considered optimal manner without violation of the laws, ethical rules and the benefits of others. (1) Maximization of the benefits of editorial board members: The primary task of editorial board members is to give a peer review of an unpublished scientific article via online office system to evaluate its innovativeness, scientific and practical values and determine whether it should be published or not. During peer review, editorial board members can also obtain cutting-edge information in that field at first hand. As leaders in their field, they have priority to be invited to write articles and publish commentary articles. We will put peer reviewers' names and affiliations along with the article they reviewed in the journal to acknowledge their contribution; (2) Maximization of the benefits of authors: Since *WJG* is an open-access journal, readers around the world can immediately download and read, free of charge, high-quality, peer-reviewed articles from *WJG* official website, thereby realizing the goals and significance of the communication between authors and peers as well as public reading; (3) Maximization of the benefits of readers: Readers can read or use, free of charge, high-quality peer-reviewed articles without any limits, and cite the arguments, viewpoints, concepts, theories, methods, results, conclusion or facts and data of pertinent literature so as to validate the innovativeness, scientific and practical values of their own research achievements, thus ensuring that their articles have novel arguments or viewpoints, solid

evidence and correct conclusion; and (4) Maximization of the benefits of employees: It is an iron law that a first-class journal is unable to exist without first-class editors, and only first-class editors can create a first-class academic journal. We insist on strengthening our team cultivation and construction so that every employee, in an open, fair and transparent environment, could contribute their wisdom to edit and publish high-quality articles, thereby realizing the maximization of the personal benefits of editorial board members, authors and readers, and yielding the greatest social and economic benefits.

Aims and scope

The major task of *WJG* is to report rapidly the most recent results in basic and clinical research on esophageal, gastrointestinal, liver, pancreas and biliary tract diseases, *Helicobacter pylori*, endoscopy and gastrointestinal surgery, including: gastroesophageal reflux disease, gastrointestinal bleeding, infection and tumors; gastric and duodenal disorders; intestinal inflammation, microflora and immunity; celiac disease, dyspepsia and nutrition; viral hepatitis, portal hypertension, liver fibrosis, liver cirrhosis, liver transplantation, and metabolic liver disease; molecular and cell biology; geriatric and pediatric gastroenterology; diagnosis and screening, imaging and advanced technology.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: To introduce and comment on major advances and developments in the field; (2) Frontier: To review representative achievements, comment on the state of current research, and propose directions for future research; (3) Topic Highlight: This column consists of three formats, including (A) 10 invited review articles on a hot topic, (B) a commentary on common issues of this hot topic, and (C) a commentary on the 10 individual articles; (4) Observation: To update the development of old and new questions, highlight unsolved problems, and provide strategies on how to solve the questions; (5) Guidelines for Basic Research: To provide guidelines for basic research; (6) Guidelines for Clinical Practice: To provide guidelines for clinical diagnosis and treatment; (7) Review: To review systematically progress and unresolved problems in the field, comment on the state of current research, and make suggestions for future work; (8) Original Article: To report innovative and original findings in gastroenterology; (9) Brief Article: To briefly report the novel and innovative findings in gastroenterology and hepatology; (10) Case Report: To report a rare or typical case; (11) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (12) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (13) Guidelines: To introduce consensus and guidelines reached by international and national academic authorities worldwide on basic research and clinical practice gastroenterology and hepatology.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, Redit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homoge-

neous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/esps/>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval

of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision on acceptance is made only when at least two experts recommend publication of an article. All peer-reviewers are acknowledged on Express Submission and Peer-review System website.

Abstract

There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of "To investigate/study/..."), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g. 6.92 ± 3.86 vs 3.61 ± 1.67 , $P < 0.001$), and CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both. The main text format of these sections, editorial, topic highlight, case report, letters to the editors, can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Figures should be either Photoshop or Illustrator files (in tiff, eps, jpeg formats) at high-resolution. Examples can be found at: <http://www.wjgnet.com/1007-9327/13/4520.pdf>; <http://www.wjgnet.com/1007-9327/13/4554.pdf>; <http://www.wjgnet.com/1007-9327/13/4891.pdf>; <http://www.wjgnet.com/1007-9327/13/4986.pdf>; <http://www.wjgnet.com/1007-9327/13/4498.pdf>. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A....; B....; C....; D....; E....; F....; G: ...*etc.* It is our principle to publish high resolution-figures for the printed and E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. ^a*P* < 0.05, ^b*P* < 0.01 should be noted (*P* > 0.05 should not be noted). If there are other series of *P* values, ^c*P* < 0.05 and ^d*P* < 0.01 are used. A third series of *P* values can be expressed as ^e*P* < 0.05 and ^f*P* < 0.01. Other notes in tables or under illustrations should be expressed as ¹F, ²F, ³F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals ac-

cording to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability^[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references^[19,22-24], we know that..."

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean \pm SD or mean \pm SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as *v* (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 ± 24.5 μ g/L; CO₂ volume fraction, 50 mL/L CO₂, not 5% CO₂; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23 243 641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, *etc.*

Restriction enzymes: *EcoRI*, *HindII*, *BamHI*, *Kho I*, *Kpn I*, *etc.*

Biology: *H. pylori*, *E. coli*, *etc.*

RESUBMISSION OF THE REVISED MANUSCRIPTS

Authors must revise their manuscript carefully according to the revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade B certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to esps@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A or B.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm.

Proof of financial support

For papers supported by a foundation, authors should provide a copy of the approval document and serial number of the foundation.

Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

Science news releases

Authors of accepted original articles are suggested to write science news to promote their articles. The news will be released rapidly at EurekAlert/AAAS (<http://www.eurekalert.org>). The title for science news should be less than 90 characters; the summary should be less than 75 words; and main body less than 500 words. Science news should be lawful, ethical, and strictly based on your original content with an attractive title and interesting pictures.

Publication fee

WJG is an international, peer-reviewed, Open-Access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. The related standards are as follows. Publication fee: 1365 USD per article. Editorial, topic highlights, book reviews and letters to the editor are published free of charge.

Abstract

Esophageal cancer is mainly found in Asia and east Africa and is one of the deadliest cancers in the world. However, it has not garnered much attention in the Western world due to its low incidence rate. An increasing amount of data indicate that esophageal cancer, particularly esophageal adenocarcinoma, has been rising by 6-fold annually and is now becoming the fastest growing cancer in the United States. This rise has been associated with the increase of the obese population, as abdominal fat puts extra pressure on the stomach and causes gastroesophageal reflux disease (GERD). Long standing GERD can induce esophagitis and metaplasia and, ultimately, leads to adenocarcinoma. Acid suppression has been the main strategy to treat GERD; however, it has not been proven to control esophageal malignancy effectively. In fact, its side effects have triggered multiple warnings from regulatory agencies. The high mortality and fast growth of esophageal cancer demand more vigorous efforts to look into its deeper mechanisms and come up with better therapeutic options.

INTRODUCTION

While the incidence of most cancers is declining, esophageal cancer has been continuing its march as the fastest growing malignancy in the Western world^[1,2]. This rise is largely derived from gastroesophageal reflux disease (GERD), which is associated with the proliferation of obesity. The continuous growth of the obese population foreshadows a future increase of GERD and its associated esophageal cancer. This demands immediate and more rigorous research on the molecular mechanisms of this common disease and its pathways which lead to esophageal malignancy. Current GERD treatment mainly relies on acid suppression drugs which have not been proved to change the risk of cancer development. Although the debate is still going on whether gastric acid or bile acid is ultimately responsible for GERD malignancy, based on the data from human studies, animal modeling, and *in vitro* simulation, perhaps it is time to explore other options.

STATISTICS OF ESOPHAGEAL CANCER: RISING NUMBERS

Cancer is the second leading cause of death in the world^[3]

Figure 1 Top 10 leading causes of death worldwide. Cancer is the second highest one. Data extracted from World Health Organization documents. AIDS: Acquired immune deficiency syndrome.

after heart disease (21.09%), contributing 18.04% to the total number of deaths worldwide (Figure 1). Among all types of cancers, skin cancer is the most common one, which includes 2-3 million non-melanoma and 132 000 melanoma cases diagnosed each year, making up one third of the total cancer cases. According to Skin Cancer Foundation Statistics, one in every five Americans will develop skin cancer in their lifetime. This prevalence is largely due to depletion of ozone in the atmosphere, which weakens our planet's protective shield from the brunt of the sun's harmful rays. It is estimated that every 10% decrease in ozone levels will generate an additional 300 000 non-melanoma and 4500 melanoma cancer cases. However, the majority of skin cancer can be easily treated, while digestive cancers, such as esophageal cancer, are highly life-threatening.

Esophageal cancer is found more commonly in males than in females, with a ratio of approximately 7:1. Currently, it is the 7th leading cancer in men globally, contributing 6.51% to the total number of male cancer cases (Figure 2). There are two main subtypes of esophageal cancer: esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EAC). ESCC occurs most often in the middle portion of the esophagus and accounts for 90%-95% of all cases of esophageal cancer worldwide, while EAC is primarily found in the lower esophagus. The type and incidence of esophageal cancer varies dramatically depending on the geographical location (Figure 3). The top 10 countries with the highest age-standardized death rate due to esophageal cancer are Nauru (30.3), Sao Tome (26.4), Mongolia (18.6), South Africa (18.2), Malawi (18.2), China (15.5), Lesotho (15.5), Kenya (13.9), Mozambique (13.5) and Uganda (13.4) (the death rate being deaths per 100 000 people). The highest rates are found in Asia, stretching from northern Iran through the central Asian republics to north-central China, often referred to as the "esophageal cancer belt". For instance, in China, the majority of esophageal cancer diagnoses are ESCC and it is ranked as the 8th leading cause of death nationwide (Table 1), mostly in northern

Figure 2 Top 10 of the most common cancers in men (up) and women (below) worldwide. Esophageal cancer is No. 7 in men. Data extracted from World Health Organization documents.

China where the incidence rate can be as high as 800 cases per 100 000 people. On the other hand, in the United States, more than 50% of esophageal cancer cases are EAC, and the rate is less than 5 in 100 000, making it the 29th leading cause of death. For this reason, esophageal cancer is not even on the current list of common cancers in the United States, according to the National Cancer Institute. In order to be on the list, esophageal cancer has to have at least 40 000 cases a year, while the current estimate for 2012 is only 17 460. Although the reason for this geographic variation still needs investigation, several factors have been suggested that might all contribute to the issue to a certain degree, such as *Helicobacter* infection, dietary pattern, and life habits^[4]. As Eastern and Western countries become increasingly open to each other and people adapt more to each other, we expect this discrepancy will become less and less. As evident in China, EAC incidence was doubled from the 1970s to the 1980s, according to an examination of the medical records of esophageal cancer patients diagnosed from 1970 to 2001 in a local hospital^[5].

These numbers only tell one side of the story. Based on the annual reports on the status of cancer^[1,2], although esophageal cancer is low in Americans, it has been rising by 6-fold annually and its increase rate now exceeds that

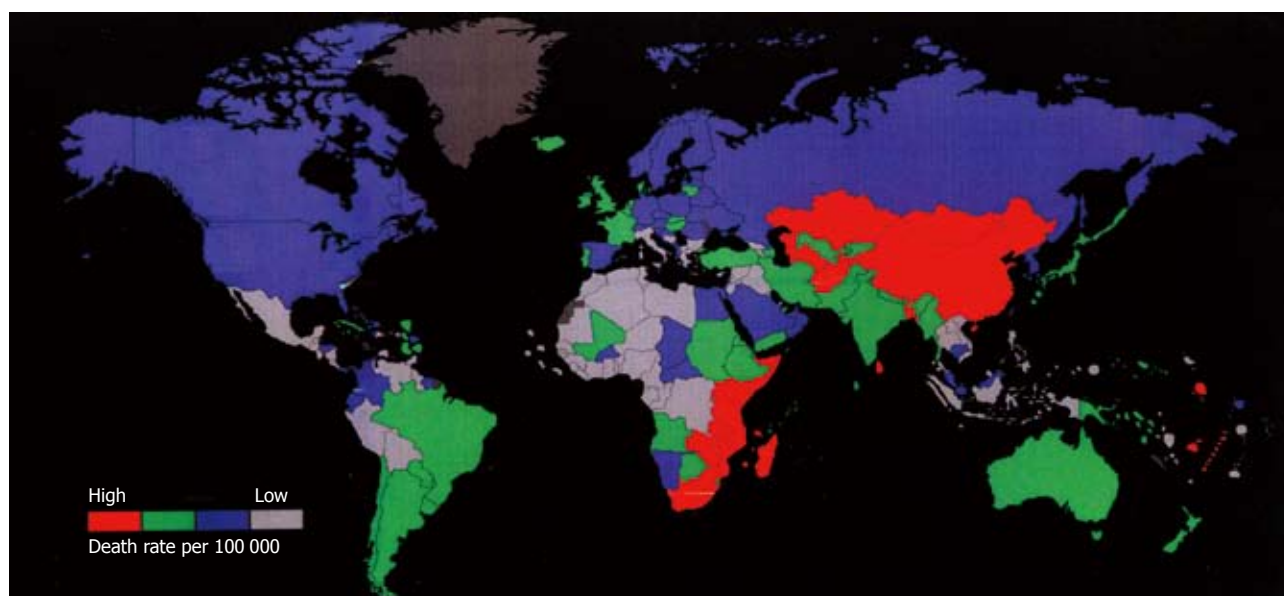

Figure 3 Geographic distribution of esophageal cancer. China is a hot spot. Data from World Health Organization documents.

Figure 4 Gastroesophageal reflux disease-induced esophagitis in human and rat (hematoxylin and eosin staining). Gastroesophageal reflux disease rats were created by surgically anastomosing the duodenum to the gastroesophageal junction. These rats can develop esophageal adenocarcinoma within a year, in a pathological sequence similar to human esophageal malignancy.

for any other type of cancer. There are several possible reasons for this rise, such as excessive alcohol consumption, smoking, stress, and a diet low in vegetables, but the leading factor is GERD, a term that frequently appears in the media as well as in general conversations. A recent study showed that GERD increases the risk of esophageal cancer by 8.6 fold^[6].

GERD: NOT A SMALL PROBLEM

GERD is the most common gastrointestinal diagnosis given during office visits and its direct medical costs, which primarily include drug costs, exceed \$10 billion a year in the United States^[7], whereas indirect costs resulting from reduced work productivity are estimated to be as much as \$75 billion a year^[8]. GERD occurs when the esophageal sphincter at the bottom of the esophagus weakens and allows stomach acid (often mixed with duo-

denal contents) to back up into the esophagus. The refluxate erodes the epithelial lining of the lower esophagus and gives a burning sensation in the middle of the chest, which is commonly described as “heartburn”. Patients with long standing GERD can develop esophagitis, an inflammation characterized histologically by a markedly thickened epithelium, elongation of the lamina propria papillae into the epithelium, and basal cell hyperplasia (Figure 4). Over time, this inflammation/injury cycle can induce esophageal mucosa transformation from squamous to a more protective intestinal columnar phenotype, known as Barrett’s esophagus (BE). From a physiological point of view, the secretory columnar epithelium is better prepared to withstand the erosive action of the acidic refluxate than squamous epithelium; however, this metaplastic change confers an increased risk of transformation to EAC. Studies have shown that people with BE can have as high as a 400-fold increased risk of EAC^[9,10]. Today, over 60% of Americans experience occasional episodes of acid reflux, and about 25% deal with the problem on a weekly basis. The prevalence of the condition in Americans is increasing by approximately 5% annually^[11]. Hospitalizations for all GERD-caused esophageal disorders doubled from 1998 to 2005, according to the United States Agency for Healthcare Research and Quality.

OBESITY: THE DEVIL

The rise in GERD is associated with the rapidly growing obese population^[12], which is usually measured by body mass index (BMI). BMI is calculated based on the weight and height of a person [$BMI = \text{weight}/(\text{height})^2$, kg/m²]. The World Health Organization regards a BMI of less than 18.5 as underweight and may indicate malnutrition, an eating disorder, or other health problems, while a BMI greater than 25 is considered overweight and above 30 is considered obese. A recent study showed that global obe-

Table 1 Top 10 leading causes of death in China *vs* the United States

Esophageal cancer is the No. 8 killer in China, while in the United States, it is No. 29. Here the death rate is the percentage of the total deaths nationwide. Data from World Health Organization, World Bank and National Institute of Health.

sity rates have doubled since 1980^[13]. The health care costs resulting from excess weight are estimated at greater than \$100 billion annually in the United States. According to the report released last year from the Centers for Disease Control and Prevention, more than 34% of adult Americans are obese, which is higher than Canadians (24%). It is predicted that by the year 2020, 77.6% of men will be overweight and 40.2% obese; the corresponding figures for women will be 71.1% and 43.3%, respectively^[14]. This problem has also affected children, whose obesity rate has tripled in the last 30 years^[15]. At the time of writing, 15.5% of children in the United States are obese. A recent study with a study population of 690 321 patients (age: 2-19 years) revealed that obese children have a 30%-40% higher risk of GERD, compared with children with a normal weight according to their BMI (BMI = $20 \pm 3.8 \text{ kg/m}^2$)^[16]. In adults, the situation is worse. In 2007, a study showed that the total number of GERD episodes was 48% higher in obese patients than those with a normal BMI^[17]. The link between increasing BMI and the presence of GERD was further strengthened by a meta-analysis of 20 independent studies, which established a dose-dependent association between these two conditions^[18]. A similar connection has also been drawn between increasing BMI and esophageal cancer^[19-23].

The precise pathophysiological pathway from obesity to GERD has not been fully elucidated. It has been shown that excess fat in the abdominal area can push on the stomach's contents to back up, relax the lower esophagus muscle^[24,25], disable the esophageal motor^[26], impair stomach accommodations^[27], and ultimately result in a higher frequency of esophageal acid exposure^[12,28,29]. Therefore, a potential causal pathway from body size to esophageal cancer may be from normal to GERD to esophagitis to BE, and ultimately to EAC. In such a direct pathway, obesity could act by increasing the prevalence of GERD, by increasing the prevalence of BE among the GERD population, or by enhancing the risk of malignant transformation from BE to EAC. Although obesity is a major contributor, other factors (e.g., smoking, drinking, diet, or genetics) may also influence the steps on this pathway. For example, GERD smokers

were found to have 12.3-fold higher risk of developing EAC than GERD non-smokers^[6]. While the issue is quite complex, since the main pathway starts with GERD, interventions aimed at GERD should be expected to proportionally lower the risk of the subsequent steps in the pathway: BE and EAC.

TREATMENT: NO WINNERS

Current treatment for GERD patients includes acid suppressive medications and lower esophageal repair surgery. Aside from traditional antacids (Alka-Seltzer and Tums) which have side effects such as diarrhea and constipation, there are now two categories of medications to treat GERD. H-2 blockers (e.g., Zantac 75, Pepcid AC, Tagamet HB and Axid AR) reduce the amount of histamine-2, which produces acid in the stomach, and are recommended for people with less frequent/severe heartburn. A second medication is the proton pump inhibitors or proton pump inhibitors (PPIs) (e.g., Prilosec, Prevacid, Protonix and Nexium), which directly shuts down the H^+/K^+ ATPase pump of the parietal cells in the stomach that produce acid. These drugs are stronger than H2 blockers and are recommended for people with more persistent/acute symptoms. Control of acid reflux with PPIs has been found extremely effective for healing reflux esophagitis, but not for prevention of BE development or its progression to EAC. As matter of fact, more and more evidence is emerging about the long-term side-effects associated with these drugs, such as decreased absorption of vitamins/minerals^[30], susceptibility to bacterial infections^[31], bone fracture^[32], and even elevated risk of developing EAC^[6,33]. The Food and Drug Administration of the United States has issued warnings repeatedly over the years on high-dose or long-term use of PPIs.

For people who have responded to medication but continue to experience GERD symptoms, surgery to reconstruct the lower esophageal sphincter is usually an option. However, only about 5% of GERD patients undergo surgery and a follow-up study showed that almost two-thirds of the surgical patients were back on medica-

Figure 5 National Institute of Health expenditure on cancer-related studies in 2011. Esophageal cancer barely shows on the pie chart. Data from National Institute of Health documents.

tion^[34]. A more recent study reported that although surgical therapy achieved better remission of GERD symptoms than Prilosec, 36% of surgical-treated GERD patients ultimately received PPI medication, while 14% of PPI-treated GERD patients underwent subsequent surgery^[35]. One final way to treat GERD is through endoscopic procedures, including stitching or using radio-frequency waves to reconstruct the lower esophageal sphincter, but in 2002 this was not recommended by the American Gastroenterological Association for GERD treatment.

CAUSE OF EAC: ACID OR BILE? WHAT TO BLAME?

The inadequacy of treatment options raises the question on the real scientific basis of acid suppression in GERD treatment. A direct chemical analysis of esophageal fluid showed that GERD patients contain about 10 times more bile acid in their lower esophagus than normal people^[36]. This might give us a clue as to why regular use of acid suppressants has not lowered the risk of GERD malignancy. In support of this notion, animal studies showed that gastric reflux alone does not cause EAC at all; it is the duodenal contents *per se* that ultimately lead to esophageal malignancy^[37-39]. Furthermore, some animal studies even suggested that gastric acid may play a protective role in GERD against malignancy. For example, one study showed that 87% of rats with surgically-created duodenal reflux alone developed EAC, while the percentage of rats with gastric-duodenal reflux was only 30%^[40]. In agreement with the animal studies, a recent systematic review^[41,42] examined publications indexed in MEDLINE from 1950 to 2010, and found 82 original human studies on the association of bile acids with GERD, among which, all *in vivo* studies detected bile acids in the esophageal aspirates of GERD patients, and what's more, their concentrations were significantly higher than in normal people. It is clear that the refluxate of GERD patients frequently contains bile acids, some-

times even in millimolar concentrations. In addition to human studies and animal modeling, *in vitro* experiments have shown that bile acids, at equivalent concentrations to the ones found in the esophagus of GERD patients, can stimulate esophageal epithelial cells to produce inflammatory cytokines and chemokines, to generate reactive oxygen species, and to express intestinal genes. All these factors have the ability to facilitate esophageal epithelial metaplasia and even malignancy.

CONCLUSION

Although skin cancer is the most common cancer in the world, 95% of cases are either basal cell carcinoma or squamous cell carcinoma, which have less than 0.5% mortality. Even for the most deadly type of skin cancer - melanoma, which is very rare - the death rate is only about 15%. So is prostate cancer, the second most common cancer in the United States. On the other hand, although esophageal cancer patients have a mortality rate of approximately 85%, since it is less common than either skin cancer or prostate cancer, it receives little attention from government agencies or the research community. This can be seen by looking at the annual budget of the National Institute of Health (NIH) of the United States. In 2011, the NIH spent \$284 million on 772 prostate cancer research projects, while only funding 30 esophageal cancer studies with \$13 million (Figure 5). Through this article, we hope to attract attention to this disease since, due to its high mortality and fast growth, esophageal cancer could be catastrophic in the near future if we do not prepare ourselves with the proper knowledge.

Abstract

Delayed gastric emptying (DGE) is a frequent complication after pylorus-preserving pancreatoduodenectomy (PpPD). Kawai and colleagues proposed pylorus-resecting pancreatoduodenectomy (PrPD) with antecolic gastrojejunostomy anastomosis to obviate DGE occurring after PpPD. Here we debate the reported differences in the prevalence of DGE in antecolic and retrocolic gastrojejunostomies after PrPD and PpPD, respectively. We concluded that the route of the gastrojejunostomy anastomosis with respect to the transverse colon; i.e., antecolic route or retrocolic route, is not responsible for the differences in prevalence of DGE after pancreatoduodenectomy (PD) and that the impact of the reconstructive method on DGE is related mostly to the angulation or torsion of the gastrojejunostomy. We report a prevalence of 8.9% grade A DGE and 1.1% grade C DGE in a series of 89 subtotal stomach-preserving PDs with Roux-en Y retrocolic reconstruction with anastomosis of the isolated Roux limb to the stomach and single Roux limb to both the pancreatic stump and hepatic duct. Retrocolic anastomosis of the isolated first jejunal loop to the gastric remnant allows outflow of the gastric contents by gravity through a "straight route".

INVITED COMMENTARY ON HOT ARTICLES

Delayed gastric emptying (DGE) is a major cause of early morbidity following pancreatoduodenectomy (PD). Although it has been recently reported that pylorus-preserving pancreatoduodenectomy (PpPD) and classical Whipple's PD are equal operations regarding the postoperative development of DGE^[1], the occurrence of this complication is usually considered to be associated with PpPD. DGE after PpPD was first described by Warshaw *et al*^[2] in 1985. DGE implies a state of postoperative gastroparesis and gastric stasis for which prolonged gastric drainage is necessary with delay to return to solid food intake. However, the pathogenesis of DGE is still unclear. Postoperative decrease in plasma motilin stimulation after duodenal resection^[3], devascularization and denervation of the pylorus with subsequent pylorospasm in PpPD^[4,5] and other operative factors such as the route of gastro-

duodeno-enteric reconstruction (antecolic *vs* retrocolic)^[6] and the type of reconstructive technique (Billroth I *vs* Billroth II reconstruction)^[7] may contribute to the occurrence of DGE. Moreover, intra-abdominal postoperative complications such as pancreatic fistula, peripancreatic collections, intraabdominal abscess or postoperative pancreatitis may increase the prevalence of DGE^[8-13]. The reported prevalence of DGE after pancreatic surgery is remarkably variable due to different adopted definitions of DGE^[10,14,15]. In fact, a consensus definition of DGE based on the impact on the clinical course and on postoperative management was proposed by the International Study Group of Pancreatic Surgery only in 2007^[16]. Kawai *et al*^[17] reported a prospective randomized controlled trial (RCT) on the prevalence of DGE in pylorus-resecting pancreatoduodenectomy (PrPD) *vs* PpPD. The authors proposed PrPD, in which the stomach is nearly entirely preserved and divided just adjacent to the pyloric ring, to obviate DGE occurring after PpPD and avoid the impairment of nutritional status occurring after classical Whipple's PD. They highlighted that the results of their RCT significantly favored PrPD over PpPD, considering the prevalence of DGE (4.5% *vs* 17.2%): in these procedures an antecolic gastro- or duodeno-jejunal reconstruction was adopted^[18]. A recent RCT comparing the occurrence of DGE after subtotal stomach-preserving pancreatoduodenectomy in pancreaticogastrostomy with retrocolic gastro-jejuno-stomy reconstruction and in pancreaticogastrostomy with antecolic gastro-jejuno-stomy reconstruction concluded that antecolic reconstruction, and not retrocolic reconstruction, decreases DGE prevalence. However, in this study, Billroth I (retrocolic) reconstructions were compared with Billroth II (antecolic) reconstructions^[19]. After subtotal stomach-preserving pancreatoduodenectomy with pancreaticogastrostomy, Oida *et al*^[20,21] considered retrocolic gastrojejunal reconstruction preferable to antecolic reconstruction for preventing DGE because pancreaticogastric anastomosis is located behind the stomach and the retrocolic route in gastroenteric reconstruction enables the gastric contents to easily reach the jejunum. In the study by Eshuis *et al*^[22], DGE was more frequent in retrocolic reconstructions, but in multivariable analysis no association between the route of reconstruction and DGE was found.

After PD, Billroth I reconstruction is considered to have a higher incidence of DGE than Billroth II reconstruction^[7], but Billroth I is considered to be a more physiologic procedure than Billroth II because Billroth I preserves the proximal jejunum in the alimentary circuit and maintains the hormonal stimuli on the remnant pancreas^[23]. In evaluation of the prevalence of DGE in antecolic and retrocolic reconstruction in gastro- and duodeno-jejuno-stomy after classical Whipple's PD and PpPD, respectively, the two compared procedures should differ only in the manner in which the jejunum is brought up in respect to the transverse colon. Kawai participated in a previously reported prospective RCT in which the adopted reconstructive procedures after PpPD were different only regarding

the route; i.e., antecolic or retrocolic, for Billroth II type duodeno-jejunal anastomosis. The prevalence of DGE was significantly lower in the antecolic duodeno-jejuno-stomy group than in the retrocolic duodeno-jejuno-stomy group^[6]. However, another recent RCT showed no difference in the prevalence of DGE between antecolic and retrocolic gastro/duodeno-jejuno-stomy following classical Whipple's PD/PpPD after standardization of both the antecolic and retrocolic types of Billroth II gastro/duodeno-jejuno-stomy with respect to the distance from the hepatico-jejuno-stomy and angulation of the jejunal loop. In this study, the occurrence of DGE was not affected by the type of performed PD; i.e., classical Whipple's PD *vs* PpPD, or the type of adopted reconstruction of the gastro/duodeno-jejuno-stomy; i.e., antecolic *vs* retrocolic^[24]. Ueno *et al*^[25] indicated that the transient torsion or angulation in the reconstruction of the alimentary tract is the main cause of DGE after PpPD. Several methods were proposed to promote the alimentary transit from the stomach through the jejunal loop, such as alignment of the stomach contour to avoid angulation of the jejunal loop distally to the duodeno-jejunal anastomosis in a Billroth I type of reconstructive procedure^[25], and straight antecolic duodeno-jejuno-stomy twisting the jejunum 30° counterclockwise to preserve the patency of the efferent jejunum and placing the stomach in the left subcolic fossa to straighten it in a Billroth II type of reconstruction^[26]. In the RCT by Chijiwa *et al*^[27] no significant difference in the prevalence of DGE was found between retrocolic vertically performed duodenojejuno-stomy and antecolic duodenojejuno-stomy (Table 1).

Regarding the resection method, Kawai *et al*^[17,18] highlighted that PrPD preserves the capacity of the stomach and obviates to pylorospasm, denervation and devascularization of the pylorus ring, which can occur in PpPD, and demonstrated that PrPD decreases the incidence of DGE in respect to PpPD. Recently, these surgical procedures of subtotal stomach-preserving (or pylorus-resecting) pancreatoduodenectomies have been adopted in surgical treatments of malignant tumors of the periampullary region and of the head of the pancreas. Our group has been adopting subtotal stomach-preserving pancreatoduodenectomy since 1995 for several considerations. After pancreaticoduodenectomy, gastric preservation favors adequate weight gain due to higher caloric intake; moreover, and most of all, normal acid secretion acts as a physiologic stimulus promoting the intestinal secretion of secretin and CCK-PZ, as well as the subsequent stimulation of pancreatic exocrine secretion with better digestion of protein and fat (weight gain). Lastly, preservation of the stomach with resection of the pylorus favors better gastric emptying^[28,29]. Regarding the impact of the reconstructive method on DGE, we think that the route of the gastro/duodeno-jejunal anastomosis with respect to the transverse colon (antecolic or retrocolic) or the type of reconstruction performed (Billroth I or Billroth II procedure) are not truly responsible for the differences in the prevalence of DGE after PD. We believe

Figure 1 Retrocolic gastro-jejunal anastomosis in Roux-en-Y reconstruction after subtotal stomach-preserving pancreaticoduodenectomy. M: Mesocolic window; GJ: Gastro-jejunal anastomosis. Dashed line indicates the level of jejunal division.

that, after a PD, the impact of reconstructive methods on DGE is related mostly to the angulation or torsion of the reconstruction of the gastro/duodeno-jejunostomy because all the reported modified procedures associated with lower DGE, in Billroth I as well Billroth II types of reconstruction, are related to the reconstructive anatomy of the alimentary circuit and are aimed to facilitate the outflow of the ingests from the gastric/duodenal remnant. An antecolic gastro/duodeno-jejunostomy can favor a straight construction and gastric emptying by gravity in a Billroth II reconstruction after PD or PpPD^[24] as well as a retrocolic Billroth II gastrojejunostomy after a subtotal stomach-preserving pancreaticoduodenectomy with pancreaticogastrostomy reconstruction can favor

the transit of the gastric contents towards the jejunum in consequence of the retrogastric site of pancreaticogastric anastomosis^[20,21]. A Billroth II reconstruction can avoid the jejunal angulation produced by a Billroth I procedure in which the anastomosis of the proximal jejunum to the gastric/duodenal stump is performed at first, followed by pancreatico-jejunostomy and hepatico-jejunostomy^[25] (or by hepatico-jejunostomy in a case in which a pancreaticogastrostomy is carried out).

According to the ISGPS clinical criteria^[16], we have recently reported a prevalence of 8.9% (8 cases) of grade A DGE and 1.1% (1 case) of grade C DGE in a series of 89 subtotal stomach-preserving PD followed by Roux-en-Y retrocolic reconstruction with anastomosis of the isolated Roux limb (i.e., first jejunal loop) to the stomach and single Roux limb (i.e., second jejunal loop) to the pancreatic stump and hepatic duct^[30] (Figure 1).

We chose anastomosing the isolated proximal jejunum to the gastric remnant because, after removal of the duodenal source of CCK and secretin, preservation of the first jejunal loop in the reconstruction of the alimentary circuit maintains the physiologic jejunal secretion of secretin and CCK-PZ subsequent to alimentary transit and can compensate (at least in part) for the abolished duodenal hormonal release^[29]. Then, the anastomosis of the isolated first jejunal loop to the gastric remnant, although retrocolic, avoided any angulation and torsion allowed the outflow of the gastric contents by gravity through a “straight route” (Figure 2). It is widely known that postoperative complications are related to the occurrence of DGE. Therefore, controlling the prevalence

Figure 2 Roux-en-Y retrocolic reconstruction. HJ: Hepatico-jejunal anastomosis; PJ: Pancreatico-jejunal anastomosis; GJ: Gastro-jejunal anastomosis; JJ: Jejunio-jejunal anastomosis; M: Mesocolic window.

of other postoperative complications can contribute to reduce the occurrence of DGE. Postoperative pancreatic fistula occurred in seven patients (7.8%) of our series. Six cases of grade A fistula resolved spontaneously and in only one grade B fistula was percutaneous drainage necessary. Postoperative hemorrhage occurred in two of 89 (2.2%) patients, biliary fistula in eight (8.9%) patients and acute pancreatitis in one (1.1%). One patient with pre-existing stenosis of the hepatic artery developed thrombosis of the hepatic artery.

In conclusion, PrPD may contribute to a decrease in the prevalence of DGE due to pylorospasm, denervation and devascularization of the pylorus ring, which may occur after PpPD. A “straight” route, not necessarily an “antecolic” route, may obviate to the prevalence of DGE due to torsion or angulation in the reconstruction of the alimentary tract.

has received much recent attention, particularly in the setting of CRC. Although its acceptance as a reportable factor has been held back by a lack of uniformity with respect to qualitative and quantitative aspects, tumor budding is now considered as an independent adverse prognostic factor in CRC that may allow for stratification of patients into risk categories more meaningful than those defined by tumor-node-metastasis staging alone, and also potentially guide treatment decisions, especially in T2-T3 N0 (stage II) CRCs.

Abstract

Colorectal cancer (CRC), the third most commonly diagnosed type of cancer in men and women worldwide is recognized as a complex multi-pathway disease, an observation sustained by the fact that histologically identical tumors may have different outcome, including various response to therapy. Therefore, particularly in early and intermediate stage (stages II and III, respectively) CRC, there is a compelling need for biomarkers helpful of selecting patients with aggressive disease that might benefit from adjuvant and targeted therapy. Histopathological examination shows that likely other solid tumors the development and progression of human CRC is not only determined by genetically abnormal cells, but also by intricate interactions between malignant cells and the surrounding microenvironment. This has led to reconsider the features of tumor microenvironment as potential predictive and prognostic biomarkers. Among the histopathological biomarkers, tumor budding (i.e., the presence of individual cells and small clusters of tumor cells at the tumor invasive front)

INVITED COMMENTARY ON HOT ARTICLES

We read with great interest the recent article by Lugli *et al*^[1] describing the morphology of "tumor budding" as a promising histopathological prognostic feature in colorectal cancer (CRC) and strongly recommend it to the readers.

Although in certain countries a decline in CRC incidence rate has been registered, attributed to increases in screening adhesion rates and linked detection and removal of precancerous polyps^[2], CRC remains one of the most

Figure 1 Colorectal cancer at the invasive front shows different growth patterns. Tumor budding denotes the presence of isolated single neoplastic cells or small clusters of cells scattered in the stromal compartment at the invasive tumor margin (A), although intra-tumoral budding is also reported. Tumor margin organized in larger tumor cell clusters (B) and a smooth infiltration tumor margin (C). Hematoxylin and eosin stain, objective magnification 20 \times .

common cancers^[3]. By its frequency, CRC ranks third in men and women worldwide^[3]. Explained as a multi-step dynamical disease in the last two decades, CRC develops slowly over several years and progresses through cytologically distinct benign and malignant states, from single crypt lesions through adenoma, to malignant carcinoma with the potential for local invasion and distant metastasis^[4,5]. According to the model of multi-step carcinogenesis, adenomatous cells accumulate a number of molecular abnormalities to eventually become fully malignant^[6,7]. In spite of unifying theories, genetic and epigenetic events during the carcinogenesis process differ considerably from tumor to tumor. Thus, CRC is not a unique disease; rather it encompasses different molecular and pathological entities with a wide range of clinical behaviors^[8]. At the molecular level, CRC encloses a complex array of gene alterations. Essentially, like individual fingerprints, each tumor arises and behaves in a distinctive fashion that is unlikely to be fully recapitulated by any other tumor. Nevertheless, molecular changes allow for a basic categorization of CRC, which is largely acknowledged, although likely over-simplistic. It has been demonstrated that genetic and epigenetic features, such as microsatellite instability (MSI), chromosomal instability, CpG island methylator phenotype or even global DNA hypomethylation, lead to alterations of gene function on a genome-wide scale. It is known that activation of oncogenes, including *KRAS*, *BRAF*, *TGFBR*, *PIK3CA* and *TP53*, affects complex intracellular signaling pathways^[9,10]. The suppressor pathway is disrupted in CRC with chromosomal instability occurring in the majority of CRCs (nearly, 85%), which have a molecular profile characterized by specific chromosomal amplifications and transformations, aneuploidy, and loss of heterozygosity^[8-10]. Differently, CRCs of the mutator pathway (roughly, 15%) have a defective DNA mismatch repair (MMR) system, which leads to accumulation of unrepaired mutations^[9], and harbor frameshift mutations in coding mononucleotide repeats of cancer-related genes (targets)^[11]. It is now accepted that MSI CRCs have a heterogeneous histological appearance, better prognosis due to a reduced metastatic potential, and a different response to 5-fluoro-uracil^[12-14].

Histopathology of CRC

Histopathological examination shows that likely other solid tumors, CRCs are infiltrated by various innate and adaptive immune cells^[15-17], and that in the cancer context, epithelial cells coexist with different extracellular matrix components and non-neoplastic cell types, including fibroblasts, myofibroblasts, adipocytes, endothelial cells, pericytes, which collectively form the tumor microenvironment^[18].

It is well known that histopathology reports usually include various features and including tumor grade, histological sub-type, state of resection margins and information on vascular and perineural invasion, but the tumor-border configuration (i.e., growth pattern) and especially tumor budding remain rarely described^[1]. The term “tumor budding” denotes the presence of isolated single neoplastic cells or small clusters of cells (conventionally, up to 5 cells) scattered in the stromal compartment at the tumor invasive margin (Figure 1)^[19-21].

Tumor stage as stated by the American Joint Committee on Cancer/International Union Against Cancer (AJCC/UICC) tumor-node-metastasis (TNM) system is currently considered as the most robust prognostic criterion for CRC patients. The inability of the AJCC/UICC staging system to accurately predict the outcome of individual patients with stage II and stage III CRC might be overcome by adding morphological, molecular or treatment-related features, that could stratify patients more accurately into different risk categories^[22]. Depth local tumor infiltration (pT), loco-regional lymph-node involvement (N status), venous and lymphatic invasion, and tumor grade, are currently recognized as the main histopathological characteristics associated with worse patient outcome.

Tumor budding and CRC

Tumor budding first introduced by Jass *et al.*^[23], as a reliable histopathological hallmark to estimate the aggressiveness of rectal cancer, was initially shown to have a superior prognostic value when compared to other histopathological characteristics, including tumor differentiation and venous invasion. Tumor grading based on the nature of the advancing tumor margins, which in the scoring sys-

tem proposed by Giger *et al.*^[24] divided rectal tumors into expanding type and infiltrating type, obtained wide acceptance among surgical pathologists worldwide. Although subsequent studies revealed a scarce reproducibility of Jass scoring system, several authors highlighted the potential role of tumor budding as a valid prognosticator also in tumors other than CRC, including lung cancer^[25,26], invasive ampullary adenocarcinomas^[27], and oesophageal and gastro-oesophageal junction cancers^[28]. In CRC, tumor budding is considered as a stage II B prognostic factor, and strictly associated with lymph-node metastasis^[1]. It has been shown that the presence of “buds” at the tumor invasive front represents an independent predictor of lymph node metastasis in patients with sub-mucosal invasive or early pT1 CRCs^[29]. It has also been suggested that the frequency of tumor budding increases with more advanced TNM stage^[1].

Tumor budding is virtually absent in MMR-deficient cancers^[30,31]. MSI CRCs have significantly more pronounced tumor infiltrating lymphocytes (i.e., CD3⁺ or CD8⁺ cells), peritumoral lymphocytes inflammation, and bundling edge (i.e., the ability of cells to adhere and to migrate) compared with microsatellite-stable CRCs, all factors contributing to the absence of tumor budding in MSI CRCs.

Tumor budding and the epithelial-mesenchymal transition

A parallel between tumor budding and the epithelial to mesenchymal transition (EMT) has also been recently proposed. This (potentially reversible) process thought to occur physiologically during embryological development (EMT subtype I), has been also associated with wound healing, tissue regeneration, organ fibrosis (EMT subtype II), and tumor invasion (EMT subtype III). Cells in EMT lose their epithelial phenotype (i.e., lack of E-Cadherin and cell polarity, expression of transcription factors including the zinc finger proteins SNAIL and SLUG, TWIST, ZEB 1/2 and SMAD) and dynamically acquire a mesenchymal phenotype (i.e., taking on a spindle-like, fusiform morphology, become motile, and start expressing mesenchymal markers including N-cadherin, fibronectin and vimentin)^[32]. While the mechanisms promoting distant metastasis are extremely wide and still under intense investigation, the presence of EMT features in cells of the tumor microenvironment has been associated with an increased metastatic potential^[32,33].

Assessing the tumor budding in colorectal cancer tissues

Rapidly growing insights into the cell biology of CRC and the recent developments of high-throughput technologies, gene sequencing and molecular diagnostics have led to practicable expectations for the identification of molecular biomarkers to be used in optimized and tailored treatment regimens. However, histopathological interpretation of CRC tissues remains the gold standard for cancer diagnosis. Tissue specimens, consisting of different cell types related to each other in complex spatial patterns, are important resources for both primary research

efforts and validation of biological findings that are made in laboratory^[34]. Working with human tissues poses several challenges to investigators, including: (1) tissue sampling (i.e., appropriate processing, histological variability, tissue heterogeneity with different areas of cancer, necrosis, inflammation and natural tissue); (2) selection of the proper preservation technique (i.e., maintenance of tissue morphology and molecular profile); (3) tissue complexity (i.e., requirement of an accurate histopathological interpretation); and (4) not least ethical and legal rules. However, an approach that integrates histopathology and molecular biology within a unique translational system is a mandatory strategy to pursue a better understanding of cancer. Such an effort can be achieved only through a more effective incorporation of pathology into clinical research, and conversely by integrating biological research into the pathological assessment, likely through efficient networks of translational researchers joining their data.

The morphology of the tumor invasive front has come into the focus of scientific studies because it appears to be intimately linked to cancer aggressiveness. Despite the established prognostic relevance of tumor budding in CRC, the reproducibility of actual methods proposed for its assessment, however, remains unstandardized, limiting its application in routine pathology practice^[35]. Diagnostic reproducibility is a prerequisite for the validation of a diagnostic test and is crucial for patient care. Tumor budding promises to be a histopathological prognostic factor in CRC, and although the level of agreement needs to be improved and further investigations are compulsory to confirm any association between the rates of tumor budding detection and clinical outcome, its evaluation can be improved first by an appropriate physician training. In addition, the use of immunohistochemistry (IHC) highlights budding cells by pan-cytokeratin antibodies leading to a significant increase of tumor budding-positive cases. Single tumor cells can be more accurately detected by immunological techniques than standard hematoxylin and eosin staining, even when they appear at the tumor boundary showing glandular disruption. Under these circumstances, dissociated tumor cells should not be interpreted as budding to avoid biasing tumor budding evaluation^[31].

As tumor budding has been shown as an independent prognostic factor in CRC, particularly in node-negative disease, its assessment has the potential to increase prognostic accuracy and influence treatment algorithms. When examined carefully, the majority of CRCs display some degree of budding; hence, attempts have been made at developing scoring systems to identify a prognostically significant degree of budding, commonly termed “high-grade” budding. Definitions of high-grade budding, however, vary substantially among different observers and even among different studies by the same observers^[31].

Final remarks

Consensus criteria for its evaluation must be better estab-

lished, to guide further research in this area and to provide the practicing pathologist with reporting guidelines. With respect to setting these criteria, studies focusing on budding should be designed to define objective cut-off for meaningful tumor budding. In mathematical terms, also tumor budding is a continuous variable; thus, a cut-off threshold should be less arbitrary as possible, and an attempt should be made to identify the budding threshold that results into relevant predictive information. Along this line, pathologist reporting on tumor budding should provide detailed information regarding the qualitative and quantitative criteria used to evaluate budding in order to allow for meaningful comparisons among different studies. Finally, the role of IHC in the evaluation of budding needs to be clarified. Although it might be impractical to perform IHC on all CRCs, there may be certain cases (i.e., in the context of a remarkable inflammatory reaction at the tumor invasive front), where it may reveal buds that are dubious when observed in standard hematoxylin and eosin stained histological sections.

It is indubitable that the substantial impediment to the adoption of tumor budding as a routinely reportable feature is the lack of a well defined, standardized and quantitative assessment. At any event, due to the forceful evidence that tumor budding is one of the most promising prognostic factors actually available, it is incumbent on the scientific community participating to the identification of CRC prognostic factors to move promptly to addressing it and removing the obstacles to its routine reporting and comparison with other predictive factors.

INVITED COMMENTARY ON HOT ARTICLES

Cancer is one of the major health problems worldwide, therefore constantly more effective therapeutic strategies are expected. Cancers arise from the uncontrolled proliferation and spreading of malignantly transformed cell clones with the obvious ability to evade protective immunity. In view of immune surveillance selective, specific and effective eradication of various cancer cells by a subsequent active host immune response serving as a widespread therapy option has still been remained unsolved.

Current therapies for cancer mainly are based on chemotherapeutic drugs that kill transformed, dividing cells or block cell division, but unfortunately these treatments may also attack normal proliferating cells, including immunocompetent ones. However, targeted immune responses (immunotherapy) to tumors may be specific, thus making the possibility to avoid normal cell injury. According to therapeutic vaccines killed tumor cells or tumor antigens can efficiently induce anticancer immunity.

So far less attention has been paid on the possible sub-cellular and molecular impact of chemotherapy-induced cell death regarding induction of host immune responses.

In a recent experimental study Michaud *et al*^[1] have underscored a new aspect of anticancer chemotherapy, that autophagy may contribute to action of certain drugs eliciting immunogenic tumor cell death. This type of cellular fate is characterized biochemically by pre- and postapoptotic events, like calreticulin exposure and high mobility group B-1 (HMGB-1) secretion, and by ATP release.

Autophagy

Besides the proteasomal degradation pathway autophagy represents an additional evolutionarily highly conserved multi-step process of cellular self-digestion due to sequestration of excessive, damaged, or aged proteins and

Abstract

Autophagy or self-digestion of cells is activated upon various stressful stimuli and has been found to be a survival and drug resistance pathway in cancer. However, genetic studies support that autophagy can act as a tumor suppressor. Furthermore, defective autophagy is implicated in tumorigenesis, as well. The precise impact of autophagy on malignant transformation has not yet been clarified, but recent data suggest that this complex process is mainly directed by cell types, phases, genetic background and microenvironment. Relation of autophagy to anticancer immune responses may indicate a novel aspect in cancer chemotherapy.

Figure 1 The process of macroautophagy and the types of autophagy (gray boxes).

intracellular organelles in double-membranous vesicles of autophagosomes, terminally self-digested in lysosomes^[2].

Different types of autophagy according to the route of delivery to lysosomes and the main physiological functions have been characterized, like macro- and microautophagy, and chaperon-mediated autophagy^[3]. Upon specific targeted degradation of cytosolic proteins, lipids, or organelles (e.g., ribosomes, nucleosomes, mitochondria), selective forms of autophagy can further be classified as lipophagy, or ribophagy, nucleophagy and mitophagy^[2].

Macroautophagy (hereafter simply termed autophagy) refers to cytoplasmatic bulk, non-selective degradation of subcellular constituents. Within this complex catabolic pathway regulated tightly by a limited number of autophagy genes (atgs) various morphologic stages are distinguishable starting with the formation of phagophore, followed by its elongation and maturation to autophagosome, and finally the fusion with lysosomes^[4]. The process of macroautophagy and the types of autophagy are summarized in Figure 1.

Autophagy is deeply implicated in regulation of numerous physiologic functions including cell development and differentiation, survival and senescence, and it also crucially affects inflammation and innate and adaptive immunity^[5]. On a basal level intact autophagy serves constantly and constitutively as a critical adaptive and surveillance mechanism in maintaining cellular homeostasis^[3]. However, autophagy is inducible, as well in response to different cellular metabolic stress conditions, including nutrient and growth factor deprivation in order to preserve cell viability. Defects in basal autophagy may yield accumulation of cytotoxic materials, damaged DNA, and thus, genomic instability, while alterations of induced autophagy especially lead to reduced cell survival^[4,5].

In general, defective autophagy by compromising cellular fitness has been ultimately related to several disease conditions, such as cancer, certain neurodegenerative, liver, and infectious disorders, aging, and inflammatory conditions, like Crohn's disease^[3,5-7].

Regarding tumorigenesis a dual-faced (Janus) role of

autophagy has been proposed, since on one side it may be critical for cancer cell survival and progression, in particular under stressful situations, however it may elicit tumor death signaling pathways. Direction of autophagy toward cytoprotection or tumor cell suppression, thus the pro-survival or pro-death function is context-dependent, and influenced by many intra- and extracellular factors, such as involved tissues, surrounding microenvironment, genetic background, and stages of tumor development, nevertheless its precise relation to cancer networks has not yet been fully elucidated^[5,6,8].

The involvement of autophagy in cell death, either in apoptosis (programmed, type I death) or in non-apoptotic or necrotic death, and their possible interactions are rather complicated. Autophagy in tumor cells usually displays a critical, programmed pro-survival function by inhibiting apoptosis or suppressing necrotic death, including programmed (or regulated) cell necrosis of caspase-independent necroptosis, and poly-ADP-ribose polymerase-mediated necrosis^[9].

In cases of autophagy deficiency, however, no tumor suppression, but on the contrary, accelerated tumorigenesis can be manifested. In autophagy-incompetent cells upon induced oxidative stress cell-autonomous mechanisms are exhibited in forms of accumulated DNA damage and chromatin instability^[10]. As a non-cell-autonomous mechanism, however, inflammatory events along with defective apoptosis could also contribute independently to cancer progression, partly by favouring cell necrosis^[11]. Similar situation has been found in human inflammatory bowel diseases (IBD) with high risk of malignancy, and in experimental cases of *atg5*^{-/-} or *atg7*^{-/-} mice displaying inflammatory Paneth cell abnormalities resembling human IBD^[7,12].

The *atg6/Beclin-1* gene, a Bcl-2/Bcl-xL interacting element has been found to be monoallelically lost in certain human cancers, and confirmed that it functions as a haploinsufficient tumor suppressor^[13]. However, this suppressive function of Beclin-1 may be tissue-specific, since even its higher expression has been detected in colorectal and gastric carcinomas^[14]. In addition to Beclin-1, alterations of other autophagy-associated genes, e.g., *atg4*, *atg5*, UV-irradiation resistance-associated gene (UVRAG), or Bax-binding protein-1 (Bif-1) have also been detected in various cancers, indicating that tumor suppression is attributed to different autophagy elements. Nonsense mutations of UVRAG, and downregulation of Bif-1 have been documented in colon and gastric carcinomas, and in colon adenocarcinomas, respectively^[15-17].

Hypothetically, increased autophagic flux *via* excessively induced autophagy may promote non-apoptotic (programmed, type II) autophagic cell death, acting like a tumor suppressor^[18]. Autophagy is also known to stimulate oncogene-induced senescence, thus providing another possible barrier against malignant transformation^[19]. Nevertheless, there is no direct evidence regarding the realistic anti-tumor capacity of autophagy.

In human cancers constitutive activation of Ras- and phosphoinositol 3-kinase/Akt-mammalian target of rapa-

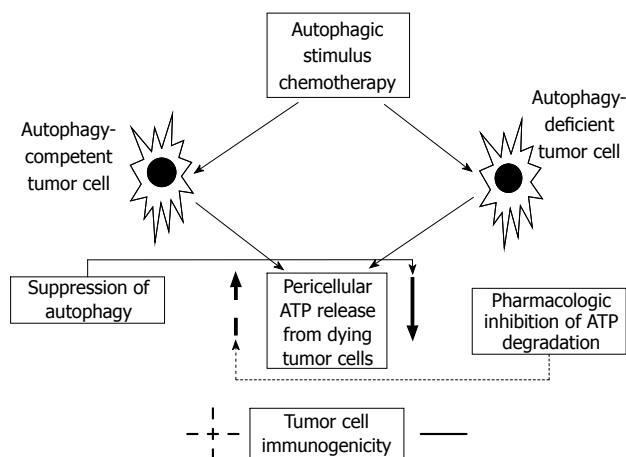

Figure 2 The relation of autophagy and anticancer immunity. Similarly to autophagy-deficient tumor cells inhibition of autophagy results in decreased pericellular ATP secretion, and thus suppressing anticancer immunity. Pharmacologic inhibition of ATP degradation, however, increases ATP level in the microenvironment of tumor cells, and favours tumor cell immunogenicity.

mycin (mTOR) pathway is a common phenomenon, and mTOR complex 1 seems to be the main negative regulator of autophagy^[20,21]. The tumor suppressor p53 gene exerts a typical dual role in autophagy regulation, depending primarily on its subcellular, nuclear or cytoplasmic distribution^[22]. Both stress-responsive cellular degradation pathways of intrinsic and extrinsic apoptosis and of autophagy can fundamentally affect, activate or inhibit each other *via* an extensive molecular crosstalk, and in fact, cell destiny is determined by their actual functional status and interplay^[6,23]. Their crosstalk is regulated primarily by the current status of the Bcl-2/Beclin-1 complex, dissociation of which can be achieved upon activation of mitogen activated phosphokinase-jun kinase or translocation of the damage-associated molecular pattern (DAMP) protein HMGB-1^[23]. Nuclear factor (NF)- κ B plays also a critical role in malignant transformation, and its constitutive, chronic activation has been observed in the majority of different tumor cells. There is also a complex interaction between autophagy and the NF- κ B signaling pathways *via* positive and negative feedback regulatory loops^[24]. The important autophagy selective substrate p62 acts as an adaptor protein to regulate NF- κ B, as well^[25].

Overall, there is no doubt that process of autophagy can be considered as an apparently quite difficult regulatory network, being in close connection with other signal transduction pathways and cellular programs. The complex and rather contradictory function of autophagy in tumorigenesis makes itself a promising but challenging therapeutic target both in cancer treatment and prevention. In autophagy-competent tumor cells autophagy increase can often be induced in response to different chemo- and radiotherapies, representing mainly an adaptive survival mechanism, but provoking simultaneously treatment resistance. Therefore it has been hypothesized that concurrent pharmacologic inhibition of autophagy, as an adjuvant may sensitize tumor cells to a spectrum of anticancer drugs^[22,26,27]. In cases of autophagy-deficient

tumors, however, due to their extreme susceptibility, metabolic stress- and DNA-damage-inducing therapeutic protocols are suggested. However, autophagy induction could also provide an alternative therapeutic option^[22,26,27]. Nevertheless, excessive autophagy can potentially act as an active cell death machinery, mainly along with inherent apoptosis defects, so induction of autophagy by antitumor drugs may also be considered as an efficient cytotoxic manipulation.

Michaud *et al*^[1] in their experiments, using transplantable murine tumors of CT26 colorectal carcinoma and of MCA205 fibrosarcoma treated either with mitoxantrone or oxaliptin have found that autophagy-competent tumor cells release more ATP comparing with autophagy-deficient ones. Furthermore, pharmacologic inhibition of autophagy reduced chemotherapy-induced ATP release, however induction of autophagy did not trigger it. ATP serves as a danger signal, it is a prominent DAMP molecule. In addition, unlike autophagy-deficient tumor cells chemotherapy in autophagy-competent cancer cells elicited a protective immune response, i.e., attraction of dendritic cells, CD4+ and CD8+ lymphocytes, and priming of T cells. Inhibition of autophagy decreased the immunogenic potential of tumor cells. The authors finally conclude, that upon chemotherapy premortem autophagy is required for tumor immunogenicity by releasing ATP from dying apoptotic cells, and consequently, in case of autophagy deficiency the ability of tumor cells to induce an adaptive anticancer immune response is significantly restricted. In that transplantable model dying cancer cells function as a therapeutic vaccine. Nevertheless, in autophagy-deficient tumors of immunocompetent hosts by pharmacologic inhibition of ATP degradation a compensatory increase in pericellular ATP content was achieved, thus successfully restoring the immunogenic capacity, and suggesting a novel adjuvant therapeutic possibility (Figure 2).

Findings of Michaud *et al*^[1] not only highlight on the complexity and many faces of autophagy in tumorigenesis, but emphasize the rationality of analyzing subcellular, molecular consequences of chemotherapy in respect of influencing host immunity, and thus propose a promising therapeutic strategy to compensate autophagy deficiency-related altered tumor immunogenicity.

Abstract

Solitary rectal ulcer syndrome (SRUS) is a benign and chronic disorder well known in young adults and less in children. It is often related to prolonged excessive straining or abnormal defecation and clinically presents as rectal bleeding, copious mucus discharge, feeling of incomplete defecation, and rarely rectal prolapse. SRUS is diagnosed based on clinical symptoms and endoscopic and histological findings. The current treatments are suboptimal, and despite correct diagnosis, outcomes can be unsatisfactory. Some treatment protocols for SRUS include conservative management such as family reassurance, regulation of toilet habits, avoidance of straining, encouragement of a high-fiber diet, topical treatments with salicylate, sulfasalazine, steroids and sucralfate, and surgery. In children, SRUS is relatively uncommon but troublesome and easily misdiagnosed with other common diseases, however, it is being reported more than in the past. This condition in children is benign; however, morbidity is an impor-

INVITED COMMENTARY ON HOT ARTICLES

Solitary rectal ulcer syndrome (SRUS) is an uncommon chronic and benign rectal disorder often related to abnormal defecation or straining. It was first described by Cruveilhier^[1] in 1829, when he reported four unusual cases of rectal ulcers. The term "solitary ulcers of the rectum" was used by Lloyd-Davis in the late 1930s and in 1969 the disease became widely recognized after a review of 68 cases by Madigan *et al*^[2] and few years later, a more detail pathogenic concept of the disease was reported by Rutter *et al*^[3]. SRUS is an infrequent or unrecognized or misdiagnosed disorder, with an estimated prevalence of 1 in 100 000 persons per year^[4]. Solitary rectal ulcer is a misnomer as ulcers are found in 40% of patients, while 20% of patients have a solitary ulcer, and the rest of the lesions are different in shape and size, including hyperemic mucosa to broad-based polypoid lesions^[5]. The disease process also may involve the sig-

moid colon^[6].

Although it is uncommon, it is well recognized in adult populations^[3]. SRUS seems to be rare in childhood^[7-10] and may masquerade as other more common conditions, causing difficult-to-manage lower gastrointestinal symptoms. Opinion differs regarding the best treatment for this troublesome condition, varying from conservative management and enema preparations to more invasive surgical procedures such as rectopexy^[11].

In this review article, several aspects of this syndrome will be evaluated with an especial focus on the condition in children. Detailed risk factors, causes, and treatment methods will help guide future treatment and prevention strategies in children.

Pathophysiology and clinical presentation

The pathophysiology of SRUS is incompletely understood; however, rectal hypersensitivity leading to the persistent desire to defecate and sensation of incomplete evacuation may have a role in SRUS^[12]. Inappropriate contraction of the puborectalis muscle and rectal mucosal prolapse have been commonly implicated, although trauma and ischemia have been suspected in some children^[7,13]. In children, secondary to chronic mechanical and ischemic trauma, inflammation by hard stools, and intussusception of the rectal mucosa, some histological features of SRUS can be seen such as fibromuscular obliteration of the lamina propria and disorientation of muscle fibers^[14].

In our previous study of 256 children who were evaluated endoscopically for recurrent lower gastrointestinal bleeding, 4.7% had this syndrome^[15]. In adult patients, men and women are affected equally, with a small predominance for women^[16], but 75%-80% of children with SRUS are boys^[15,17]. Suresh *et al*^[18] have evaluated 325 children aged < 18 years during 8 years for various indications such as bleeding, polyps and anal fissure. Twenty-two (6.8%) children were diagnosed with SRUS and ranged in age from 18 months to 18 years (median: 10 years), and 18 (81.8%) of these were \geq 8 years of age. The male to female ratio in this group was 1.4:1. To date, the youngest patient with SRUS was a child of 1.5 years^[18]; Gabra *et al*^[19] also have reported two boys with SRUS who were 2 and 3 years old.

The average time from the onset of symptoms to diagnosis is 5 years, ranging from 3 mo to 30 years in adults, which is longer than in pediatric patients (3.2 years, range: 1.2-5.5 years)^[15,17,20-22]. This syndrome results from obstructed defecation secondary to internal rectal prolapse with a collection of symptoms including rectal bleeding, passage of mucus and straining on defecation, perineal and abdominal pain, tenesmus, feelings of incomplete defecation, constipation, and rectal prolapse^[23-25]. The amount of blood varies from a little fresh blood to severe hemorrhage that requires blood transfusion^[26-28]. Up to 26% of patients can be asymptomatic and may not show the bleeding that is discovered incidentally while investigating other diseases^[5]. The use of

digital manipulation to assist with a bowel movement is variably reported in patients with SRUS^[15,29]. Bright-red blood from the rectum or mucoid rectal discharge, tenesmus, proctalgia, and constipation are the major symptoms. Some children present with apparent diarrhea (because of prolonged visits to the bathroom) and the associated bleeding, abdominal pain, and tenesmus may suggest to clinicians the presence of inflammatory bowel disease^[25].

Diagnosis

SRUS is a relatively uncommon but bothersome and easily misdiagnosed condition of childhood. Clinical suspicion and paraclinical evaluations are needed and diagnosis is via symptomatology in combination with endoscopic and histological findings^[17]. A complete and thorough history is most important in the initial diagnosis of SRUS. It is essential to differentiate SRUS from other devastating, chronic, and potentially lethal disorders such as inflammatory bowel disease, amebiasis, lymphogranuloma venereum, chronic ischemic colitis, endometriosis, colitis cystica profunda, and malignancy. Obstructive symptoms (anismus) in children may be interpreted by parents as constipation. Concomitant haematochezia may be misinterpreted as originating from an anal fissure caused by constipation, or as other causes of rectal bleeding such as a juvenile polyp^[30-32].

Defecography is a useful method for determining the presence of intussusception or internal or external mucosal prolapse and can demonstrate a hidden prolapse, as well as a non-relaxing puborectalis muscle and incomplete or delayed rectal emptying^[33]. Barium enema shows granularity of the mucosa, polypoid lesion, rectal stricture and ulceration, and thickened rectal folds; all of which are nonspecific findings^[33,34]. Temiz *et al*^[35] have recommended that defecography and anorectal manometry should be performed in all children with SRUS to define the primary pathophysiological abnormality and to select the most appropriate treatment protocol.

The endoscopic spectrum of SRUS varies from simple hyperemic mucosa to small or giant ulcers to broad-based polypoid lesions of different sizes. Macroscopically, SRUS typically appears as shallow ulcerating lesions on a hyperemic surrounding mucosa, most often located on the anterior wall of the rectum at 5-10 cm from the anal verge. Ulcers may range from 0.5 to 4 cm in diameter but usually are 1-1.5 cm in diameter^[5,15,30].

Histological examination of biopsy material is necessary to confirm a diagnosis of SRUS. The histological criteria for diagnosis are as follows: fibrous obliteration of the lamina propria, streaming of fibroblasts and muscle fibers between crypts, thickening of muscularis mucosa, branching and distorted glandular crypts and diffuse collagen infiltration of the lamina propria^[15,36-38].

Recent studies have shown the usefulness of anorectal ultrasound in assessing internal anal sphincter thickness, which is shown to be increased in patients with this syndrome^[37,39], and it has been suggested that

sonographic evidence of a thick internal anal sphincter is highly predictive of high-grade rectal prolapse and intussusception in patients with SRUS^[39].

There is a need for a high index of suspicion for the possibility of SRUS in young children with clinical picture of nonspecific proctitis.

Treatment

The most frustrating aspect of SRUS is the difficulty in treatment; experiences have shown that most therapeutic regimens are inadequate. There are few data on treatment and its outcome in children with SRUS. In most reported pediatric case series, active intervention using enemas^[15], laxatives^[40], and surgical approaches have been used more frequently than behavioral modification, mainly biofeedback therapy in adults^[11,41-45].

Some suggestions for the treatment of SRUS include reassurance of the patient and parents that the lesion is benign, encouragement of a high-fiber diet^[46], avoidance of straining, regulation of toilet habits, and attempt to discuss any psychosocial factors^[20,36,37,47,48]. The use of a high-fiber diet, in combination with stool softeners and bulking laxatives, and avoidance of straining have had varying responses^[4,46].

In children, primary medical treatment is proposed for most cases^[49]. Topical application of sucralfate can be effective for treatment of SRUS in some patients^[15,50]. Many medications that are useful in the treatment of patients with inflammatory bowel disease have been tried in those with SRUS, such as sulfasalazine and corticosteroids, with varying responses^[16,51]. In one study, oral salicylate and other topical agents such as mesalamine and steroids were not effective^[52]. Endoscopic application of human fibrin sealant^[53], laser therapy^[54], and biofeedback^[45,47,48] are some of the effective treatment methods for SRUS.

A therapeutic role for botulinum toxin injection into the external anal sphincter for the treatment of SRUS and constipation associated with dyssynergia of defecation dynamics has been reported by Keshtgar *et al*^[55]. The effect of botulinum toxin lasts approximately 3 mo, which may be more beneficial than biofeedback therapy^[55].

Surgical methods for treatment of SRUS are rectopexy^[42,43,56], excision^[4,5,16] and Delorme's procedure^[41,44,57,58].

The choice of treatment protocol depends on acuteness of symptoms and whether there is an underlying rectal prolapse or not^[25,31]. Maintaining compliance in children may prevent progression to the type of long-term morbidity and treatment resistance sometimes seen in adults with this condition^[25]. Recommended treatment in children by Abbas *et al*^[59] is initially conservative, but, if that fails, transrectal resection followed by a high-fiber diet. Conservative management including behavioral modification and reduction of time spent straining at defecation has been reported as a good method^[25,46,60].

Compliance with simple behavioral modification appears to produce a good outcome in childhood SRUS, probably because of the short disease duration compared with adults.

Early recognition and management of these patients may avoid some of the chronic long-term morbidity often associated with this condition; however, late relapse because of noncompliance is a substantial risk and children should be followed up long term.

SRUS is thought to be part of the bigger disease process known as mucosal prolapse syndrome, which incorporates inflammatory cloacogenic polyps, inflammatory cap polyps, and gastric antral vascular ectasia. In fact, all these syndromes have the same histological features^[61]. As a result of the wide endoscopic spectrum of SRUS and the fact that the condition may go unrecognized or, more commonly, misdiagnosed, it is crucial to take biopsy specimens from the involved area to make a positive confirmation of the diagnosis and to exclude other diagnoses including malignancy^[31,62].

The exact etiology is unknown^[30,63,64] but it has also been noted that this syndrome is often associated with trauma resulting in focal ischemia and ulceration, pelvic floor disorders^[64], mucosal prolapse^[14,52,64,65] and/or a larger systemic process^[66]. Also, it has been associated with perineal descent, nonrelaxing puborectalis syndrome, and rectal prolapse^[21,52]. In children, paradoxical contraction of pelvic floor and external anal sphincter muscles contributes to constipation, rectal prolapse, ischemia and finally rectal ulcer.

Diversity of the clinical presentation of SRUS requires a high index of suspicion of both the clinician and the pathologist for the definite diagnosis^[30].

The clinicopathological similarities between SRUS and inflammatory bowel disease and the limited pediatric experience of these conditions may lead to difficulties in differentiating these conditions, and could result in under-reporting of SRUS in this age group.

It can present as more common childhood intestinal conditions such as inflammatory bowel disease or constipation, causing difficult-to-manage lower gastrointestinal symptoms. Also, it may present as polypoid mass lesions^[67]. A biopsy is required for confirmation of diagnosis, because ulceration may not be apparent at the time of endoscopy. SRUS should be considered in children presenting with rectal bleeding, mucorrhea and excessive straining during defecation.

Biofeedback^[44,45,47,48], sucralfate enema^[15,50] and surgery seem to be ideal strategies because they aim to correct the underlying processes^[57,58]. Behavioral modification or biofeedback therapy improves both rectal blood flow and symptoms and includes bowel habit training, avoiding excessive straining, and normalization of pelvic floor coordination^[46-48,68,69]. Surgery is indicated in children with persistent bleeding per rectum not amenable to medical therapy and includes rectopexy, excision of ulcer, and rarely colostomy^[42-44,56]. In children, a multitude of procedures have been advocated for rectopexy and a cure rate of at least 90% has been reported for posterosagittal rectopexy^[43]. Also, El-Hemaly *et al*^[70] have reported that the results of surgery and biofeedback are satisfactory in comparison to conservative treatment.

Most patients with SRUS in childhood have a satisfactory outcome using a simple behavioral modification approach. Ongoing follow-up to reinforce behavioral modification is important and may avoid long-term, treatment-resistant disease into adulthood. Despite the previous reports about SRUS in children that indicate low prevalence of the disease in childhood, recently we have been faced with higher prevalence rates in this age group. It seems that detailed and effective diagnosis methods such as endoscopy and histological examinations, as well as more attention by clinicians to this syndrome in children, have improved the diagnosis rate of the disease. Despite this being a benign condition in children, morbidity remains a problem as reflected by persistence of symptoms especially bleeding per rectum. Therefore, we are faced with an important condition that needs more attention and attempts for prevention and treatment.

More studies are needed to evaluate all of the aspects of the syndrome in children and to recommend the best treatment protocol. Every child with SRUS must be assessed individually using all modalities of investigation to define clearly the underlying pathophysiology, and to select the appropriate treatment strategies.

Abstract

Nonalcoholic fatty liver disease (NAFLD) is common worldwide. The importance of genetic and epigenetic changes in etiology and pathogenesis of NAFLD has been increasingly recognized. However, the exact mechanism is largely unknown. A large number of single nucleotide polymorphisms (SNPs) related to NAFLD has been documented by candidate gene studies (CGSs). Among these genes, peroxisome proliferator-activated receptor- γ , adiponectin, leptin and tumor necrosis factor- α were frequently reported. Since the introduction of genome-wide association studies (GWASs), there have been significant advances in our understanding of genomic variations of NAFLD. Patatin-like phospholipase domain containing family member A3 (PNPLA3, SNP rs738409, encoding I148M), also termed adiponutrin, has caught most attention. The evidence that PNPLA3 is associated with increased hepatic fat levels and hepatic inflammation has been validated by a series of studies. Epigenetic modification refers to phenotypic changes caused by an adaptive

mechanism unrelated to alteration of primary DNA sequences. Epigenetic regulation mainly includes microRNAs (miRs), DNA methylation, histone modifications and ubiquitination, among which miRs are studied most extensively. miRs are small natural single stranded RNA molecules regulating mRNA degradation or translation inhibition, subsequently altering protein expression of target genes. The miR-122, a highly abundant miR accounting for nearly 70% of all miRs in the liver, is significantly under-expressed in NAFLD subjects. Inhibition of miR-122 with an antisense oligonucleotide results in decreased mRNA expression of lipogenic genes and improvement of liver steatosis. The investigation into epigenetic involvement in NAFLD pathogenesis is just at the beginning and needs to be refined. This review summarizes the roles of genetics and epigenetics in the development of NAFLD. The progress made in this field may provide novel diagnostic biomarkers and therapeutic targets for NAFLD management.

INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is one of the most common forms of chronic liver diseases and a cause of elevated serum aminotransferases worldwide. The prevalence of NAFLD in the general population of Western countries ranges from 20% to 30%^[1-3]. Due to the alterations of diet structure and life style, the prevalence of NAFLD in developing countries has been increasing rapidly^[4]. Recent studies, including one from our group indicate that the prevalence of NAFLD in Chinese population is about 15%^[5-7]. The term NAFLD encompasses a morphological spectrum of diseases, ranging from simple fatty liver (SFL) to nonalcoholic steatohepatitis (NASH) and hepatic cirrhosis, which may progress to hepatocellular carcinoma (HCC). SFL generally has a benign prognosis. Only a minority of them develop NASH, which is characterized by inflammation, fibrosis and liver cell injury^[8,9].

NAFLD has been shown to be associated with metabolic syndrome (MetS), which comprises obesity, type 2 diabetes, dyslipidemia and high blood pressure with insulin resistance being the central mechanism. NAFLD is presently considered the hepatic manifestation of MetS^[5,6,8,10].

It is generally believed that environmental and genetic factors interact to produce NAFLD phenotype and determine its progression. However, the detailed pathogenesis that determines which individual develops NAFLD remains unclear. Recently, the emerging field of epigenetics shed lights on the pathogenesis of chronic liver disease including NAFLD^[11,12]. Elucidation of genetic and epigenetic factors that predispose an individual to NAFLD may lead to development of noninvasive biomarkers for early diagnosis of NAFLD and may allow early preventive and therapeutic strategies for the people at the high risk. This review summarizes recent contributions to the field of the genetic and epigenetic variations that influence the development of NAFLD.

GENETIC VARIATIONS

Candidate gene studies

The genetic variations may result in conformational changes in the protein structures and functions of the genes. NAFLD is an exceedingly complex genetic disorder. Before 2008, the candidate genes based on the prior knowledge of MetS and NAFLD pathophysiology were selected for investigation^[11,13]. In comparison with NAFLD, the relationships between the genotypes and phenotypes of MetS have been examined more extensively. A large number of single nucleotide polymorphisms (SNPs) at the genes encoding proteins involved in insulin resistance has been revealed to be associated with the development of MetS^[14,15]. As there is substantial overlap in the pathogenesis of NAFLD and MetS, theoretically, many variations in candidate genes related to MetS may contribute to the pathogenesis of NAFLD: first, genes related to insulin resistance, such as adiponectin, resistin, insulin receptor, and peroxisome proliferator-activated receptors- γ

(PPAR- γ); second, genes influencing hepatic free fatty acid metabolism, such as hepatic lipase, leptin (or leptin receptor), adiponectin, microsomal triglyceride transfer protein, phosphatidylethanolamine N-methyltransferase (PEMT), PPAR- γ , cytochrome P 450, 2E1 and 4A; third, cytokine-related genes, such as tumor necrosis factor- α (TNF- α) and interleukin-10; fourth, genes affecting liver fibrogenic pathways, such as leptin, adiponectin, transforming growth factor beta1, connective tissue growth factor and angiotensinogen; and finally, genes encoding endotoxin receptors and oxidative stress responses, such as CD14, superoxide dismutase-2 and toll-like receptor-4. Among these genes, PPAR- γ , adiponectin, leptin and TNF- α were frequently reported in the field of MetS as well as NAFLD^[11,13,16]. It is noted that one gene may have a number of SNPs at several nucleotide loci. For example, the SNPs at the PPAR- γ gene involved in MetS may occur at the loci of C-681G, C-689T, Pro12Ala, G67222A, A69208G, G81556T, T95872C, T115432G, C127599T and C161T, but only a few of them have been investigated extensively^[17,18].

There is evidence supporting the theory that these genetic factors account for considerable variability in susceptibility to NAFLD. The SNPs may increase or decrease the function of the target genes and their encoding proteins. We have previously demonstrated that many candidate genes' SNPs mentioned above are associated with susceptibility to NAFLD. Some showed positive relationships (increased risk), i.e., TNF- α -238, adiponectin-45, leptin-2548, PPAR- γ -161 and PEMT-175. Other SNPs demonstrated a negative association (decreased risk), i.e., adiponectin-276 and hepatic lipase-514. Two were not relevant, i.e., TNF- α -380 and PPAR- γ coactivator-1a-482^[19]. Gene variations might affect the pathogenesis of NAFLD via blood cytokines (such as leptin and adiponectin) and insulin resistance pathways^[19,20]. Although many pathobiological candidacies of SNPs were reported, most studies in literature have not been well validated by larger replication cohorts. The findings in candidate gene studies might be influenced by specific ethnic groups or environmental conditions.

Genome-wide association studies

Since the introduction of genome-wide association studies (GWASs) to investigate genomic variations, there have been significant advances in our understanding of human genome and its clinical sequelae over a range of diseases. More than 3.1 million SNPs have been identified so far. The International HapMap Project (<http://hapmap.ncbi.nlm.nih.gov>) has characterized patterns of SNPs across individuals from diverse ethnic backgrounds^[16,21,22]. Although a number of GWASs has been published in the field of MetS (type 2 diabetes and insulin resistance)^[23], and other liver diseases (HCC, hepatitis B, hepatitis C, drug-induced liver injury and primary biliary cirrhosis)^[16,24,25], only a few studies were carried out on NAFLD.

In 2008, the first GWAS on NAFLD was reported by Romeo *et al*^[26]. In this population-based study, noninvasive

proton magnetic resonance spectroscopy (1H-MRS) was applied to assess hepatic steatosis. Totally, 2111 individuals comprising a mixed population of Hispanic, African American, and European American were enrolled. Non-synonymous sequence variations of 9229 SNPs were identified in NAFLD group compared with normal controls. An allele of patatin like phospholipase domain containing family member A3 (PNPLA3, SNP rs738409, encoding I148M), also termed adiponutrin, on chromosome 22 was shown to be strongly associated with increased hepatic fat levels and hepatic inflammation. This allele was most common in Hispanics, the group most susceptible to NAFLD, with hepatic fat content being more than twofold higher in G homozygous subjects than in non-carriers. G allele frequency was lower in people of European descents and lowest in African Americans, the group found to have the lowest level of hepatic triglyceride accumulation. These findings were validated by another GWAS. Totally 1117 individuals with histologically confirmed NAFLD were genotyped for six SNPs relevant to hepatic fat levels and liver enzymes. PNPLA3 was significantly associated with steatosis, portal inflammation, lobular inflammation, Mallory-Denk bodies, NAFLD activity score and fibrosis^[27]. Subsequently, the extension of the hepatic phenotype associated with the PNPLA3 genotype was independently replicated in both adult and pediatric subjects with simple steatosis, NASH and NASH-related fibrosis using different laboratory techniques^[28-33]. There was evidence that carriers of PNPLA3 exhibited more severe steatohepatitis and higher levels of fibrosis. PNPLA3 was consistent with the concept of NASH rather than the broader features of the MetS, such as body mass index, dyslipidemia, and type 2 diabetes mellitus. The influence of PNPLA3 on hepatic steatosis was not through insulin resistance pathway as assessed by hyperinsulinaemic, euglycaemic clamp and oral glucose tolerance testing^[27-29,32,34,35]. Recently a meta-analysis enrolling 16 studies (2937 subjects) was performed to evaluate the association of PNPLA3 with NAFLD. The results showed that PNPLA3 exerted a strong influence not only on liver fat accumulation (the GG homozygous subjects had a 73% higher lipid fat content compared with CC ones), but also on higher susceptibility to liver disorders (GG homozygous subjects had 3.24-fold higher risk of higher necro-inflammatory scores and 3.2-fold higher risk of developing fibrosis compared with CC homozygous ones). The PNPLA3 GG genotype *vs* the CC genotype was associated with a 28% increase in alanine transaminase (ALT) level. NASH was more frequently observed in GG than in CC homozygous subjects (odds ratio 3.488, 95%CI: 1.859-6.545). Nevertheless, carrying GG alleles did not seem to increase the risk of severe histological features^[36]. In a clinical study recruiting 302 subjects with 1H-MRS-confirmed NAFLD whose genotyping was determined with TaqMan polymerase chain reaction (PCR), a SNP (rs767870) at adiponectin receptors 2 (ADIPOR2), but not at *ADIPOR1* and *PPAR* gene, was found to link to a higher liver fat content. In this study, PNPLA3 was not tested^[37].

Although most studies supported the association be-

tween PNPLA3 and NAFLD, a few reports failed to validate this finding. In a GWAS enrolling 236 women with biopsy-confirmed NAFLD, no association for any feature of NAFLD with PNPLA3 was found. Another SNP (rs2645424) on chromosome 8 in the farnesyl diphosphate farnesyl transferase 1 gene, generating an enzyme with a role in cholesterol biosynthesis, was identified to relate to the severity of NAFLD histology including NAFLD activity score, liver fibrosis, lobular inflammation as well as increased ALT^[38].

The results from GWASs shed light on the understanding of the genetics in NAFLD, as the loci identified are frequently novel and have not previously been implicated. However, such findings require further detailed studies both to determine the activity and to validate the causality, as neither biological functions nor pathogenic mechanisms of these genetic variations are known.

EPIGENETIC MODIFICATIONS

During the past decade, the role of epigenetic mechanisms in the pathogenesis of disease has been increasingly recognized. Epigenetic modification, mainly including microRNAs (miRNAs, miRs), DNA methylation, histone modification and ubiquitination, refers to phenotypic changes caused by the mechanism that is unrelated to changes in the underlying DNA sequence. As an adaptive mechanism to alteration of genetic and environmental signal patterns and epigenetic regulation, which allows fine-tuning gene expression, is essential for the proper maintenance of cellular homeostasis. Disruption of the balance will lead to the development of a wide range of disorders. So far, epigenetic research has mainly focused on cancer, cardiovascular disease, mental illness and autoimmune disease. The roles of epigenetics in the pathogenesis of NAFLD are largely unknown^[39]. Among epigenetic modifications, miRs are studied most extensively in NAFLD. miRs are small naturally occurring single stranded RNA molecules regulating mRNA degradation or translation inhibition, subsequently altering protein expression of target genes. One miR can target multiple genes (multiplicity) and multiple miRs may target a single gene (cooperativity). Since the first discovery in 1993, many miRs in various organisms have been determined. To date, more than 1420 miRs have been identified in humans (miRBase v17). (<http://www.mirbase.org/>)^[40,41]. The expression of miRs is both organ-specific and dependent on the stage of development. miRs influence at least one-third of all human transcripts and are known regulators of important cellular processes, e.g., cell metabolism, cell proliferation, apoptosis, immune function, tissue development and differentiation^[42,43]. It has recently been shown that some 100 miRs are differentially expressed in human NASH. These miRs have diverse functions involved in the pathogenesis of NAFLD, including metabolisms of lipid and glucose, regulations of the unfolded protein response, endoplasmic reticulum stress, oxidative stress, cellular differentiation, inflammation, apoptosis and so on^[44,45]. In a

clinical study, the miR profiles of 15 patients with biopsy-proven NASH and 15 controls with normal liver histology were investigated. Out of a total of 474 tested miRs, 46 were differentially expressed in NASH with 23 being up-regulated (in particular, miR-34a and miR-146b), and 23 being down-regulated (in particular, miR-122). These differentially expressed miRs were further validated by quantitative real-time PCR^[45].

The miR-122, a highly abundant miR in the liver, has caught most attention in liver diseases. Accounting for nearly 70% of all miRs in the liver, miR-122 is significantly under-expressed (63%) in NASH subjects compared to controls^[45,46]. In addition to its role in lipid and cholesterol metabolism, miR-122 has been shown to promote adipocyte differentiation^[42]. Subsequently, the roles of miR-122 in the pathogenesis of NAFLD were confirmed by a number of studies. Inhibition of miR-122 in a diet-induced obesity mouse model with an antisense oligonucleotide treatment resulted in decreased mRNA expression of acetyl-coenzyme-A carboxylase-2, fatty acid synthetase, sterol regulatory element binding proteins 1-c, 2, stearoyl-CoA desaturase and 3-hydroxy-3-methyl-glutaryl coenzyme A (HMG CoA) reductase, all of which were key lipogenic factors in human NASH. The histology also showed substantial improvement in liver steatosis^[47]. The results were validated by another study in mice, in which the plasma cholesterol level, hepatic fatty-acid and cholesterol synthesis rate as well as HMG-CoA reductase level were significantly decreased after silencing miR-122^[42]. All these findings strongly suggested the significance of miR-122 in the regulation of lipid metabolism and the contribution to the development of NAFLD. A further study suggested that miR-122 was closely linked to the output system of the circadian clock by regulating circadianly expressed genes^[48]. Besides miR-122, some miRs have been demonstrated to be involved in NAFLD development. miR-34a and miR-146b were shown to be significantly over-expressed (99% and 80%, respectively) in human NASH^[45]. The expression of miR-335 in the liver and white adipose tissue was up-regulated in mice. The increased miR-335 expression was associated with increased body, liver and white adipose tissue weight, as well as elevated hepatic triglyceride and cholesterol levels. Furthermore, hepatic miR-335 level was closely correlated with the expression of adipocyte differentiation markers, i.e., PPAR- α and FAS in adipocyte^[49]. The presence of miR-181d significantly decreased lipid droplets in the liver (60%), and subsequently reduced cellular triglyceride and cholesterol^[50]. miR-10b regulated steatosis level through PPAR- α pathway in a steatotic hepatocyte (L02 cell line) model. The post-transcriptional regulation of PPAR- α by miR-10b was maintained by a single binding site^[51].

Aberrant methylation patterns of genomic DNA have been studied in many diseases. Hypermethylation of CpG islands is generally associated with gene silencing, and hypomethylation of global genomic DNA affects genomic

stability. Hypermethylation of multiple genes in CpG islands has been demonstrated in human HCC, in which CpG island methylator phenotype was involved in the promoter hypermethylation of multiple genes^[52]. However, the relation of DNA methylation to NAFLD development has not been well documented. A recent study enrolling 63 NAFLD patients confirmed by liver biopsies and 11 controls showed a tight interaction between the presence of NAFLD and hepatic DNA methylation of CpG in PPAR- γ coactivator 1 α (PPARGC1A) and mitochondrial transcription factor A (TFAM) promoters. The proportion of DNA methylation in PPARGC1A and TFAM was significantly higher in the NAFLD livers than in the controls. However, the histological severity and activity scores of NAFLD were not correlated to methylation level and methylated DNA/unmethylated DNA ratio either in PPARGC1A or TFAM promoter^[53]. The development of hepatic steatosis in a mouse model was accompanied by prominent epigenetic abnormalities, which comprised pronounced loss of genomic and repetitive sequences cytosine methylation, increased level of repeat-associated transcripts, aberrant histone modifications and alterations in expression of the maintenance DNA methyltransferase 1 (DNMT1) and *de novo* DNMT3A proteins in the livers^[54].

Ubiquitination and sumoylation (sumo: abbreviation of small ubiquitin-like protein) are recently demonstrated to be novel forms of post-translational modifications (PTMs). PTMs of transcription factors through the course of protein processing play important roles in controlling many biological events^[55]. The research of ubiquitination related to NAFLD is just at the beginning. In a study investigating the hepatic gene networks in morbidly obese patients with NAFLD, hepatic fibrosis signaling was found to be the most significant pathway in the up-regulated NAFLD gene cluster, whereas the endoplasmic reticulum stress and protein ubiquitination pathways to be the most significant pathways in the down-regulated NAFLD gene cluster^[56]. Besides ubiquitination, transcription factors can undergo several types of PTMs, including acetylation, phosphorylation, and glycosylation. Little is known about their role in NAFLD so far^[55].

In conclusion, environmental and genetic factors interact to produce NAFLD phenotype and to determine its progression. This review summarizes the current knowledge of genetic and epigenetic determinations on NAFLD. Genetic variations (e.g., SNPs) account for only a small fraction of environmental and heritable disease risks, whereas epigenetic modifications (e.g., miRs, DNA methylation histone modifications and ubiquitination) affect a bigger proportion of disease phenotypes. The investigation into the potential roles of epigenetics in NAFLD is just at the beginning and needs to be refined. The accumulation of genetic and epigenetic knowledge related to NAFLD has provided novel insight into disease pathogenesis, and may help to develop new diagnostic biomarkers and therapeutic targets for NAFLD management.

Abstract

The World Health Organization recommends that the daily intake of added sugars should make up no more than 10% of total energy. The consumption of sugar-sweetened beverages is the main source of added sugars. Fructose, together with glucose, as a component of high fructose corn syrups or as a component of the sucrose molecule, is one of the main sweeteners present in this kind of beverages. Data from prospective and intervention studies clearly point to high fructose consumption, mainly in the form of sweetened beverages, as a risk factor for several metabolic diseases in humans. The incidence of hypertension, nonalcoholic fatty liver disease (NAFLD), dyslipidemia (mainly hypertriglyceridemia), insulin resistance, type 2 diabetes mellitus, obesity, and the cluster of many of these pathologies in the form of metabolic syndrome is higher in human population segments that show high intake of fructose. Adolescent and young adults from low-income families are especially at risk. We recently re-

viewed evidence from experimental animals and human data that confirms the deleterious effect of fructose on lipid and glucose metabolism. In this present review we update the information generated in the past 2 years about high consumption of fructose-enriched beverages and the occurrence of metabolic disturbances, especially NAFLD, type 2 diabetes mellitus, and metabolic syndrome. We have explored recent data from observational and experimental human studies, as well as experimental data from animal and cell models. Finally, using information generated in our laboratory and others, we provide a view of the molecular mechanisms that may be specifically involved in the development of liver lipid and glucose metabolic alterations after fructose consumption in liquid form.

INTRODUCTION

At the end of 2011, the United Nations declared that, for the first time in the history of humanity, non-communicable diseases had outpaced infectious diseases as the main threat to human health globally. Among them, cardiovas-

cular diseases associated with metabolic disorders, such as obesity, metabolic syndrome, and type 2 diabetes mellitus, are of paramount importance. Changes in human dietary habits in recent decades have led to the consumption of hypercaloric diets that are rich in saturated fats and simple sugars (sucrose, glucose and fructose). This, combined with decreased physical activity, is one of the key factors contributing to the ever-increasing prevalence of metabolic disorders. This situation recently prompted Lustig *et al*^[1] to request the legal regulation of foodstuffs containing added sugars in a way similar to the control of tobacco and alcohol.

The World Health Organization recommends that the daily intake of added sugars should make up no more than 10% of total energy^[2]. The consumption of sugar-sweetened beverages is the main source of added sugars^[3]. Fructose, together with glucose, as a component of high fructose corn syrups (HFCSs) or as a component of the sucrose molecule, is mainly responsible for the metabolic disturbances associated with excessive consumption of added sugars. We recently reviewed evidence from experimental animals and human data that confirms the deleterious effect of fructose on lipid and glucose metabolism^[4]. Given the relevance of this issue to public health policies, in this review we update information on the effects of fructose on human health. We focus also on new experimental data from our laboratory and others on molecular mechanisms involved in the disturbance of liver metabolism by fructose.

FRUCTOSE: THE BENCH SIDE

Data from prospective and intervention studies clearly point to high fructose consumption, mainly in the form of sweetened beverages, as a risk factor for several metabolic diseases in humans. The incidence of hypertension, nonalcoholic fatty liver disease (NAFLD), dyslipidemia (mainly hypertriglyceridemia), insulin resistance, type 2 diabetes mellitus, obesity, and the cluster of many of these pathologies in the form of metabolic syndrome is higher in human population segments that show high intake of fructose. Adolescent and young adults from low-income families are especially at risk. We and others have recently reviewed the evidence of this relationship^[4-8]. In the present review, we provide an overview of recent data, from 2011 onwards that has not been discussed previously (Table 1). For readers interested in recent reviews on this subject, particularly regarding fructose consumption, uric acid metabolism and hypertension, we refer to two excellent reviews published in 2011^[9,10].

One of the ongoing controversies about fructose consumption in humans is related to the difficulty in identifying effects that are not strictly related to the simple consumption of an excess of daily calories. In a short (2 wk) dietary intervention study in NAFLD subjects, Browning *et al*^[11] showed that carbohydrate restriction (< 20 g/d) was significantly more effective in reducing hepatic triglyceride content than the restriction of calories

to 1200-1500 kcal/d (55% *vs* 28%, respectively), despite the fact that both interventions similarly reduced body weight (by about 4.3%). In a randomized intervention study comparing the consumption of sucrose-sweetened beverages (1 L/d for 6 mo) with other isocaloric beverages in obese subjects, Maersk *et al*^[12] demonstrated that sucrose significantly increased triglyceride deposition, not only in liver, but also in skeletal muscle and visceral adipose tissue.

In another intervention study in healthy people who consumed a balanced diet supplemented with 150 g/d fructose or glucose, Silbernagel *et al*^[13] showed that endogenous cholesterol synthesis was associated with visceral and liver fat content. However, in this study the strongest association was observed in glucose-consuming individuals. Nevertheless, in a well-conducted interventional study by Stanhope *et al*^[14], subjects who consumed fructose (at 25% of energy requirements), either as such or as HFCS, but not glucose, showed an increased fasting concentration of low density lipoprotein (LDL) cholesterol. Fructose consumption also increased the 24-h triglyceride area under the curve and the fasting apolipoprotein (apo)B concentration.

In a prospective cohort study that analyzed 40 389 healthy men over 20 years of follow up, de Koning *et al*^[15] clearly found an association between sugar-sweetened beverage consumption and an elevated risk of type 2 diabetes mellitus. Although it was suggested that fructose was mainly responsible for this association, Silbernagel *et al*^[16] did not find any differences between fructose and glucose in the reduction of insulin sensitivity when these sugars were administered to 20 healthy subjects in a small intervention study. However, plasma triacylglycerol concentrations only increased significantly in the fructose group.

Fructose-induced obesity is closely related to type 2 diabetes mellitus. In a well-conducted intervention study by Cox *et al*^[17] in overweight/obese male and female subjects, consumption of fructose (at 25% of energy requirements for 10 wk), but not glucose, clearly led to significant decreases in net postprandial fat oxidation and resting energy expenditure, thus contributing to the build-up of excess energy substrates. Furthermore, in one of the population segments at high risk of fructose-related obesity, Maier *et al*^[18] demonstrated that a significant reduction in fructose and/or general sugar intake over a short period of time (3 mo) in overweight and obese children may reduce the body mass index. Mainly through increases in visceral fat, fructose-induced obesity is positively associated in adolescents with cardio-metabolic risk markers, such as systolic blood pressure, fasting glucose, homeostasis model assessment-estimated insulin resistance index, and C-reactive protein^[19].

Cardiovascular accidents originate as thrombi deposits on atheromatous plaques, which obstruct blood circulation^[20]. Atherosclerosis is promoted by dyslipidemia, hypertension, and chronic low-grade inflammation. Besides increasing plasma triglycerides and LDL cholesterol^[14],

Table 1 Overview of fructose-related human studies

Authors	Subjects	Study characteristics	Sugar	Main results
Browning <i>et al</i> ^[11]	18 NAFLD (5 men, 13 women), BMI: 35 ± 7 kg/m ²	Intervention study 2 wk dietary carbohydrate and calorie restriction		Reductions in body weight (-4.6 ± 1.5 kg <i>vs</i> -4.0 ± 1.5 kg) and hepatic triglycerides ($-55\% \pm 14\%$ <i>vs</i> $-28\% \pm 23\%$) were significantly greater with dietary carbohydrate restriction than with calorie restriction
Maersk <i>et al</i> ^[12]	60 overweight/obese nondiabetic subjects	Randomized intervention study Ingestion of 4 different drinks (1 L/d, SSB, isocaloric semiskim milk, aspartame-sweetened and water) for 6 mo	S	Daily intake of SSB with sucrose increased ectopic fat accumulation (liver, skeletal muscle) and lipids (blood cholesterol and triglycerides) compared with the other beverages
Silbernagel <i>et al</i> ^[13]	Healthy male (12) and female (8) adults	Dietary intervention study 150 g/d for 4 wk	F and G	Visceral and liver fat content associated to cholesterol synthesis Cholesterol synthesis appeared to be dependent on fructose/glucose intake
Stanhope <i>et al</i> ^[14]	48 adults, BMI 18-35 kg/m ²	Dietary intervention study Consumption of simple sugars at 25% of energy requirements for 2 wk	F and G	F consumption increased cardiovascular risk factors (AUC-Tg, fasting LDL and apo B) more than G
de Koning <i>et al</i> ^[15]	40 389 healthy men	Prospective cohort study 20 yr of follow-up of SSB and artificially sweetened beverages consumption	F, G and S SSB	After adjustment for several confounders, the hazard ratio for the association of SSB with incident type 2 diabetes was 1.24 for the comparison of the top with the bottom quartile of SSB intake
Silbernagel <i>et al</i> ^[16]	Healthy male (12) and female (8) adults	Dietary intervention study 150 g/d for 4 wk	F and G	Insulin sensitivity decreased in both intervention groups, while plasma triglycerides were increased in the F group
Cox <i>et al</i> ^[17]	Overweight/obese male (16) and female (15) adults	Intervention study 10 wk supplementation with SSB at 25% of energy requirements	F and G SSB	F-consuming subjects had a significant reduction in net postprandial fat oxidation and resting energy expenditure
Maier <i>et al</i> ^[18]	15 overweight/obese children (5-8 yr)	Dietary intervention study parental training to reduce dietary sugar content (~50% from baseline, 12 wk) and 12 wk of follow-up	F, G and S	Reductions in sugar intake were related to significant reductions in BMI and BMI standard deviation scores
Pollock <i>et al</i> ^[19]	559 adolescents (14-18 yr)	Association study of F intake and cardiometabolic risk factors	F	After adjustment, higher F consumption directly associated to BP, fasting glucose, HOMA-IR and C-reactive protein, and inversely to HDL-cholesterol and adiponectin. The introduction of visceral fat as a covariate attenuated these trends
Cox <i>et al</i> ^[21]	Overweight/obese male (16) and female (15) adults	Intervention study 10 wk supplementation with SSB at 25% of energy requirements	F and G SSB	Fasting concentrations of MCP-1, PAI-1 and E-selectin as well as postprandial concentrations of PAI-1 increased in subjects consuming F but not in those consuming G
Brown <i>et al</i> ^[22]	2696 people	Cross-sectional association study	F, G and S SSB	Direct and independent associations of SSB intake and BP Greater sugar-BP differences for persons with higher sodium excretion
Friberg <i>et al</i> ^[25]	61 226 women	Population-based cohort study 18.4 yr of follow-up of total sucrose, high-sugar-foods	F, G and S	Total sucrose intake and consumption of sweet buns and cookies was associated with increased risk of endometrial cancer
Ye <i>et al</i> ^[26]	737 non diabetic adults	Association study of sugar intake and cognitive function	F, G and S	Greater intakes of total sugars, added sugars and SSB beverages, but not of sugar sweetened solid foods, were significantly associated with lower MMSE scores, after adjusting for covariates

F: Fructose; G: Glucose; S: Sucrose; SSB: Sugar-sweetened beverages; BP: Blood pressure; NAFLD: Nonalcoholic fatty liver disease; BMI: Body mass index; MCP-1: Monocyte chemoattractant protein-1; PAI-1: Plasminogen activator inhibitor-1; HOMA-IR: Homeostasis model assessment-estimated insulin resistance; HDL: High-density lipoprotein; AUC-Tg: 24 h area under the curve for plasma triglycerides; LDL: Low-density lipoprotein; MMSE: Mini-mental state examination.

fructose seems to promote a proinflammatory milieu that favors atherosclerosis development. In an intervention study in overweight/obese subjects, Cox *et al*^[21] demonstrated that fructose supplementation in liquid form (at 25% of energy requirements for 10 wk), but not glucose, clearly increases proinflammatory and prothrombotic mediators, such as monocyte chemoattractant protein-1, plasminogen activator inhibitor-1, and E-selectin. Fur-

thermore, in a cross-sectional study including 2696 participants in the International Study of Macro/Micronutrients and Blood Pressure, Brown *et al*^[22] found a direct association between sugar-sweetened beverage intake and systolic and diastolic blood pressure increases. Thus, fructose seems to contribute directly to increased prevalence in the three main risk factors for atherosclerosis-related cardiovascular diseases.

Besides the association between fructose consumption and common metabolic diseases, there is growing evidence of a relationship with other diseases, such as cancer and Alzheimer's disease, that are also closely connected to the cellular metabolic status^[23,24]. Very recently, Friberg *et al.*^[25] analyzed data on total sucrose and high-sugar food consumption during 18.4 years of follow-up in 61 226 women. They found a direct association with increased risk of endometrial cancer. In addition, high sugar intake has recently been associated with lower cognitive function among middle-aged and older Puerto Ricans without diabetes, in an analysis of data from a substudy of the Boston Puerto Rican Health Study 2004-9^[26]. Although a high fructose diet does not affect spatial water maze learning and memory in female rats^[27], the presence of NAFLD, which is one of the main consequences of fructose consumption in men and experimental animals, seems to somehow impair hippocampal-dependent memory in male rats^[28].

Thus, overall, it seems that a high intake of sugar-sweetened beverages containing fructose places a metabolic burden on humans that facilitates the development of metabolic and cardiovascular diseases. What molecular mechanisms are involved in the production of these effects by fructose?

FRUCTOSE: MOLECULAR INSIGHTS FROM ANIMAL STUDIES

Fructose administration, mainly in drinking water, to laboratory rats and mice reproduces almost all of the features of metabolic syndrome and associated diseases in humans. These include left ventricular hypertrophy^[29,30], insulin resistance^[30-33], hypertension and related hyperuricemia^[34-36], NAFLD^[37,38], and metabolic syndrome itself^[39].

London *et al.*^[40] have investigated the role of increased 11-hydroxysteroid dehydrogenase type 1 in liver and visceral adipose tissue in rats after fructose, but not glucose, consumption. Their results indicate that deregulated local glucocorticoid production plays a role at the onset of fructose-induced obesity^[40]. Morris *et al.*^[41] put forward the hypothesis that the timing of fructose intake, mainly during the daylight period, could induce a mismatch in caloric consumption that favors the development of obesity and other metabolic alterations, at least in C57BL mice. Furthermore, several possible hypotheses related to the development of NAFLD by fructose consumption have been pursued, including increased oxidative and inflammatory stress through nitric oxide synthase induction^[42] and tumor necrosis factor α production^[43]. A very concise and interesting review on the issue of possible molecular mechanisms involved in fructose induced lipogenesis was published in 2011^[44].

In the past few years, our laboratory has researched three main issues regarding the molecular effects of fructose on liver fat and glucose metabolism: (1) possible drug therapies for the prevention and/or correction of

fructose-induced metabolic pathologies; (2) molecular mechanisms that are responsible for early induction of glucose intolerance in female rats, as a previous step to developing insulin resistance and type 2 diabetes mellitus; and (3) molecular mechanisms leading to reduced peroxisome proliferator-activated receptor (PPAR) expression and activity in livers of female rats.

NAFLD is by far the most common cause of liver dysfunction. It is a spectrum of diseases ranging from fatty liver (steatosis) to steatohepatitis^[45]. To date, the only effective treatment for NAFLD is modest calorie restriction and gradual weight loss^[46]. Statins, hypolipidemic drugs that act by inhibiting the hydroxymethyl-glutaryl-CoA reductase enzyme, can be safely used in NAFLD patients^[47], and there is evidence of improved liver histology in NAFLD patients treated with atorvastatin^[48,49]. In a recently published study, we proposed a possible molecular mechanism for the therapeutic effect of atorvastatin on NAFLD^[50]. Besides its well-known anti-inflammatory effect^[51,52], atorvastatin reduced the liver expression of fructokinase in male rats supplemented with a 10% w/v solution of fructose for 14 d. Fructose consumption induces the expression of liver fructokinase in experimental animals^[53,54] and in NAFLD patients^[55]. As fructokinase is essential in controlling fructose metabolism, its induction establishes a vicious circle that progressively increases the deleterious effect of fructose on liver metabolism. Atorvastatin effectively facilitates the breaking of this circle. It contributes to an increase in fatty acid metabolism^[56] and to a reduction in fatty acid synthesis that is driven by increased carbohydrate response element binding protein (ChREBP) transcriptional activity^[57,58], which are necessary to revert the deposition of triglycerides in liver tissue.

We used the same experimental model of rats supplemented with a 10% w/v solution of fructose for 14 d, to show that female rats were more sensitive to the deleterious effect of fructose on glucose homeostasis than male rats, as only females showed signs of glucose intolerance^[54]. In the same study, we found a marked reduction in insulin receptor substrate (IRS)-2 in the livers of fructose-supplemented female rats. IRS-2 is the main transducer of insulin signaling in hepatic tissue^[59]. We have further pursued research of molecular changes related to fructose consumption in liver. We have confirmed that female rats supplemented with liquid fructose for 14 d, but not 7 d, are glucose intolerant (as shown by glucose tolerance test; GTT). This situation correlates with a decrease in the amount of IRS-2 protein expressed in liver. The same animals showed a marked increase in mammalian target of rapamycin (mTOR) activity and mitogen-activated protein kinase (p38-MAPK) activity.

p38-MAPK is a stress-related kinase^[60] whose activity can be increased by the metabolic burden imposed by fructose metabolism in hepatocytes through two mechanisms: increased activity of protein phosphatase A2^[54,61], and the presence of bacterial toxins in blood, as a result of fructose-related alteration of the intestinal barrier

Figure 1 X-box-binding protein-1, an endoplasmic reticulum stress transcription factor, plays an essential role in maintaining plasma glucose concentration and glucose tolerance. Indeed, in the liver samples from the fructose-fed rats used in the study, there was a marked increase in the spliced form of X-box-binding protein (XBP)-1 mRNA and nuclear protein, in accordance with the increased activity of mammalian target of rapamycin (mTOR) activity and mitogen-activated protein kinase (p38-MAPK). Thus, although the decreased expression of insulin receptor substrate-2 in liver represents an impairment of insulin signaling, the increased expression and activity of XBP-1 could compensate for this deficit and maintain appropriate gluconeogenesis. PEPCK G6Pc: Phosphoenolpyruvate carboxykinase and glucose-6-phosphatase; FoxO1: Forkhead box protein O1.

permeability^[43,62]. Furthermore, increased p38-MAPK activity, by phosphorylating the tuberous sclerosis 2 gene product or tuberin, could release its inhibitory activity on mTOR complex 1 (mTORC1)^[63]. This would explain the observed increase in mTOR activity. The mTOR signaling pathway transduces information from different signals, such as growth factors, amino acids and energy overload of the cell^[64]. Finally, as Guo *et al.*^[65] have shown that mTOR activation causes IRS-2 degradation, the increase in mTOR activity could be the final molecular factor resulting in a decreased liver expression of liver IRS-2 protein, as we have found^[54].

Surprisingly, although female rats supplemented with liquid fructose for 14 d, had reduced liver expression of IRS-2, were hyperinsulinemic and showed an altered GTT, they were normoglycemic and their liver expression of gluconeogenic genes was unchanged (glucose-6-phosphatase) or even decreased (phosphoenolpyruvate carboxykinase). An explanation for this discrepancy can be found in a recent report indicating that X-box-binding protein (XBP)-1, an endoplasmic reticulum stress transcription factor, plays an essential role in maintaining plasma glucose concentration and glucose tolerance^[66]. It has been described that mTORC1 activity increases the splicing of XBP-1^[67], while p38-MAPK phosphorylates the spliced-derived protein, facilitating its nuclear localization and activity^[68]. Indeed, in the liver samples from the fructose-fed rats used in our study, there was a marked increase in the spliced form of XBP-1 mRNA and nuclear protein, in accordance with the increased activity of mTOR and p38-MAPK. Thus, although the decreased expression of IRS-2 in liver represents an impairment of insulin signaling, the increased expression and activity of

XBP-1 could compensate for this deficit and maintain appropriate gluconeogenesis (Figure 1). Data from skeletal muscle that indicate a deficit in adiponectin receptor and signaling in 14-d fructose-supplemented rats, could explain the fact that these animals do not have increased liver gluconeogenesis, but do have significant glucose tolerance impairment, as evaluated by an GTT.

We have previously shown that there is a state of leptin resistance in livers of male rats supplemented with liquid fructose. This results in increased binding of unphosphorylated active forkhead box protein (Fox)O1 to the transcription factor PPAR α , which causes the inhibition of PPAR α transcriptional activity and, as a consequence, reduces the liver capacity to oxidize fatty acids^[57,58]. FoxO-1 is a transcription factor that is regulated by insulin and deeply involved in the control of liver gluconeogenesis^[65]. Female rats equally supplemented with liquid fructose respond similarly with a reduction in liver PPAR α activity and fatty acid oxidation. However, there is no involvement of leptin resistance and FoxO-1 interaction^[54]. Thus, we have pursued the search for a possible molecular mechanism involved in the downregulation of the PPAR α system in the liver of fructose-supplemented female rats.

ChREBP is a transcription factor responsible for inducing liver lipogenesis after carbohydrate ingestion^[69]. We have previously reported that ChREBP is the main factor responsible for the increase in rat liver lipogenesis following fructose supplementation^[50,54,57,58,70]. Unpublished results from our group indicate that there is also a close relationship between ChREBP activation and PPAR α downregulation across different experimental settings (*in vivo* studies in female rats, cultured FaO and HepG2 hepatoma cells, primary cultures of human hepatocytes). It has been described that ChREBP controls the expression of regulator of G protein signaling (RGS) 16, a regulator of G protein signaling that inhibits hepatic fatty acid oxidation^[71]. Although fructose markedly increased the mRNA level of RGS16 in livers of female rats, there was no change in the amount of the expressed protein. This suggests that increased expression of RGS16 is not involved in downregulation of the PPAR α system. In rat hepatoma FaO cells cultured in the presence of a high concentration of fructose (25 mmol/L), we are performing knock-down experiments with siRNA against ChREBP to demonstrate clearly the direct involvement of ChREBP in the production of the fructose effect on the PPAR system. Confirmation of this hypothesis will indicate that fructose can simultaneously switch on liver fatty acid synthesis and switch off liver fatty acid catabolism by a single molecular mechanism: the intense activation of ChREBP. This would explain the effectiveness of fructose in inducing fatty liver and hypertriglyceridemia. We are also exploring possible mechanisms to explain why fructose stimulates the activity of ChREBP with such intensity. We have found that fructose supplementation markedly reduces the amount of the NAD-dependent deacetylase sirtuin 1 protein in livers of female rats,

but not males. This reduction increases the amount of acetylated ChREBP. As it has been shown that ChREBP hyperacetylation increases its transcriptional activity^[72], the reduction of sirtuin 1 expression could be one mechanism involved in the intense activation of ChREBP by fructose in the liver of female rats.

Abstract

Gastrin is the main hormone responsible for the stimulation of gastric acid secretion; in addition, gastrin and its derivatives exert proliferative and antiapoptotic effects on several cell types. Gastrin synthesis and secretion are increased in certain situations, for example, when proton pump inhibitors are used. The impact of sustained hypergastrinemia is currently being investigated. *In vitro* experiments and animal models have shown that prolonged hypergastrinemia may be related with higher cancer rates; although, this relationship is less clear in human beings. Higher gastrin levels have been shown to cause hyperplasia of several cell types; yet, the risk for developing cancer seems to be the same in normo- and hypergastrinemic patients. Some tumors also produce their own gastrin, which can act in an autocrine manner promoting tumor

growth. Certain cancers are extremely dependent on gastrin to proliferate. Initial research focused only on the effects of amidated gastrins, but there has been an interest in intermediates of gastrin in the last few decades. These intermediates aren't biologically inactive; in fact, they may exert greater effects on proliferation and apoptosis than the completely processed forms. In certain gastrin overproduction states, they are the most abundant gastrin peptides secreted. The purpose of this review is to examine the gastrin biosynthesis process and to summarize the results from different studies evaluating the production, levels, and effects of the main forms of gastrin in different overexpression states and their possible relationship with Barrett's and colorectal carcinogenesis.

INTRODUCTION

The polypeptide hormone gastrin was discovered in 1905 and described as a major stimulant of acid secre-

tion from the stomach antral mucosa. In the last few decades, several studies have reported on the role of gastrin in stimulating cell division and inhibiting apoptosis, suggesting that gastrin and its derivatives might promote carcinogenesis^[1-5]. Gastrin and cholecystokinin (CCK) are members of a family of neuroendocrine peptides and are both physiological ligands of the CCK-B receptor (CCKBR).

Gastrin is secreted by antral G cells and interacts with the CCKBR on enterochromaffin-like (ECL) and parietal cells to induce gastric acid secretion.

Gastrin release from G cells is stimulated by the presence of food - mainly peptides^[6] in the stomach, vagal release of gastrin releasing peptide, and an increase in stomach pH, as seen in achlorhydria^[7]. *Helicobacter pylori* (*H. pylori*) infection is also known to cause hypergastrinemia, increasing mainly plasma levels of its amidated form gastrin-17. After eradication of the bacteria, plasma gastrin levels decrease to normal^[8-10]. Gastrin release is inhibited by secretion of gastric acid, and this serves as a negative feedback control that prevents excess acid secretion. Low pH values in the stomach inhibit gastrin release by G cells, stimulating the secretion of somatostatin by antral D cells^[11].

Gastrin is expressed in a variety of tissues under both normal and pathological conditions. Its main site of production are G cells from the antral mucosa, but it is also synthesized at lower levels in duodenal mucosa, fetal and neonatal pancreases, in pituitary corticotrophs, melanotrophs, and neurons, in spermatogenic cells, and in a variety of cancers.

The main products of the gastrin gene in the antrum are its amidated forms gastrin 17 and gastrin 34 (G17-NH₂ and G34-NH₂).

GASTRIN BIOSYNTHESIS

As with other peptide hormones, gastrin is synthesized initially as a large precursor molecule, which undergoes extensive post-translational modification prior to secretion. The gastrin gene spans 4.1 kb and is located on chromosome 17 (17q21). It produces a single mRNA (0.7 kb), which encodes the 101 amino acid precursor, preprogastrin^[12]. Preprogastrin is translated at the endoplasmic reticulum, where the signal peptide is removed by signal peptidase, giving rise to progastrin (80 amino acids)^[13]. Progastrin (PG) then progresses through the Golgi complex.

If the cell has a regulated secretory pathway, as with differentiated endocrine cells such as G-cells in the antrum, progastrin is fully processed and transported by secretory granules. It is then released by exocytosis, which is induced by secretagogues after G-cell stimulation. This is the secretory pathway of most of the amidated products, because the enzymes and conditions necessary for the processing of the immature gastrin forms are found inside secretory granules from the Golgi stack.

Progastrin is cleaved at paired amino acids by endo-

proteases belonging to the prohormone convertases (PC) family. PC1/3 cleavages at the dibasic sites arginine36-arginine37 and arginine73-arginine74 lead to the formation of an intermediate, which undergoes processing by carboxypeptidase E and yields glycine-extended gastrins (G-Gly) and the C-terminal flanking peptide (CTFP). The peptidylglycine α -amidating monooxygenase converts G34-gly to its amidated form and PC2 cleaves at lysine53-lysine54, producing bioactive gastrins of varying sizes (e.g., gastrin-34 and gastrin-17)^[13,14] (Figure 1).

Preprogastrin derivatives can also exit the cell *via* another pathway, known as the constitutive pathway. Molecules exiting cells *via* this pathway are transported in secretory vesicles that take their contents from the Golgi apparatus and continuously fuse with the plasma membrane. Intermediate products of gastrin processing are secreted mainly by this pathway since peptides exiting this pathway do not undergo extensive posttranslational processing.

Processing and final secretion of progastrin products differ markedly depending on the expression location. In healthy adults, the main gastrin production site is antroduodenal G-cells, so the proportion of circulating gastrins depends largely on the products exiting these cells. In G-cells, the regulated secretory pathway predominates; thus, these cells mostly secrete a mixture of amidated products (95%), including G17-NH₂ (85%-90%), G34-NH₂ (5%-10%), and a mix of gastrin-14, gastrin-52, gastrin-71, and short amidated C-terminal fragments^[15]. The remaining 5% of the secreted products correspond to non-amidated processing intermediates (mainly progastrin and G-Gly).

Although the majority of gastrins secreted by G-cells correspond to the amidated G17 form, peripheral blood contains almost equal amounts of G17-NH₂ and G34-NH₂ because the metabolic clearance of large gastrins is slower than for smaller forms of the peptide^[16-18].

On the other hand, the proportions of the gastrin intermediates may vary in certain gastrin overexpression states, such as when proton pump inhibitors (PPIs) are used or in the presence of gastrin-producing tumors. Most of these tumors are not able to completely process gastrin, resulting in less conversion to the mature peptide^[19-22].

The causes of incomplete gastrin processing during hormone overexpression are still unclear; although, it has been proposed that it might be caused by saturation of the enzymes that catalyze progastrin modifications, leading to an inability to process increasing amounts of the gene product.

Another possible reason is the lack of a well-developed regulated pathway of secretion, as in some tumor cells. In that case, progastrin exits the cell *via* the constitutive pathway directly from the Golgi terminal.

GASTRIN RECEPTORS

The actions of amidated gastrins and CCK peptides are mediated by two different receptors: CCKA and CCKB

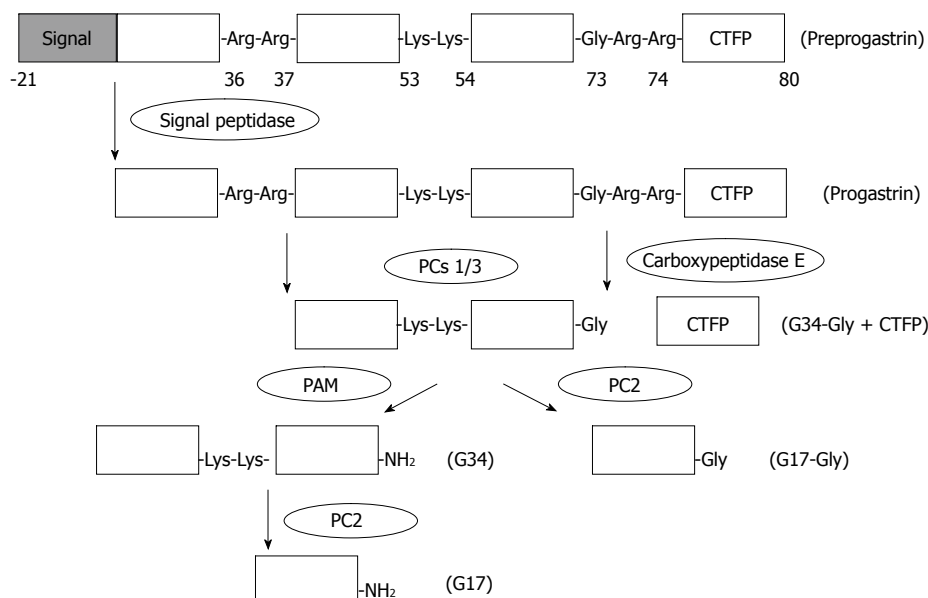

Figure 1 Main steps in pregastrin processing in antral G cells. Arg: Arginine; Lys: Lysine; CTFP: C-terminal flanking peptide; PC: Prohormone convertases; PAM: Peptidyl-glycine α -amidating monooxygenase.

receptors, which differ pharmacologically by their affinity for gastrin (low for CCKA receptors and high for CCKB receptors)^[23,24].

Gastrin and CCK peptides share a common C-terminal sequence, which has been well preserved during evolution. This conserved C-terminal active site is related to most of the known effects of these peptides, especially the tetrapeptide Trp-Met-Asp-Phe-NH₂. The specificity of the receptor binding and biological potency depends on N-terminal extensions of this common tetrapeptide.

Sulfation of the tyrosyl residue (in position six in gastrin peptides, counted from the C-terminal position, and in position seven in CCK peptides) determines the specificity for CCKA or CCKB receptors. The residue is totally sulphated in CCK peptides, so they are able to bind either CCKA or CCKB receptors with high affinity. It is partially sulphated in gastrin peptides, so they can only bind CCKB receptors.

Gastrin and CCK display similar affinities for the CCKB receptor; however, the gastrin concentration in plasma is 10- to 20-fold higher than CCK; therefore, CCKB receptors in the periphery are, in physiological terms, mainly receptors for gastrin.

The CCKB receptor has seven transmembrane domains and belongs to the superfamily of G-protein coupled receptors. CCKBR is abundantly expressed on enterochromaffin-like cells in the stomach, in the central nervous system and in some tumors, principally in the gastrointestinal tract.

Gastrin, at physiological levels, is the main mediator of meal-stimulated acid secretion. Once secreted by the antral G cells, gastrin is transported to the oxyntic mucosa of the stomach, where it interacts with the CCKBR on ECL cells, stimulating the release of histamine. Both gastrin and histamine then interact with the parietal cells, through the gastrin CCKB and histamine H₂ receptors to induce gastric acid secretion^[25].

Only amidated gastrins exert their effects through CCK-

BR activation, while intermediate precursors such as progastrin or G-Gly interact with other receptors^[3,26-28].
