**Key words:** Hepatocellular carcinoma; Mycotoxin; Aflatoxin; Ochratoxin; High-performance liquid chromatography

**Core tip:** Mycotoxins are one of the possible important carcinogens of hepatocellular carcinoma (HCC). Recently, a chromatographic separation technique based on high-performance liquid chromatography (HPLC) has been recognized as a useful method for the quantitative analyses of mycotoxins in the sera of individuals. Using this technique, the serum levels of ochratoxin A, a type of food mycotoxin widely spread in cereals, has been recently reported to be increased in the sera of HCC patients in Egypt. HPLC-based analysis of mycotoxins in the clinical samples would provide some new epidemiological information about non-viral HCC.

### Abstract

Hepatocellular carcinoma (HCC) is a common malignant disease with poor prognosis. To improve the clinical outcome, early diagnosis of HCC arising from nonviral agents and hepatitis virus is important. Among several etiological factors, mycotoxins defined as carcinogens by the International Agency for Research in Cancer (IARC) might be one of the critical risk factors for nonviral HCC. Aflatoxin B1 is the most well-known carcinogenic mycotoxin for HCC, but the role of the other types of mycotoxin remains unclear. Several studies have reported that a chromatographic separation technique based on high-performance liquid chromatography can successfully detect the concentration of mycotoxins in plasma. Recently, serum level of ochratoxin A (OTA), a widely distributed mycotoxin classified as Group 2B by IARC, was evaluated in HCC patients in Egypt. The results suggested that serum OTA levels

Matsuda Y, Wakai T, Kubota M, Osawa M, Sanpei A, Fujimaki S. Mycotoxins are conventional and novel risk biomarkers for hepatocellular carcinoma. *World J Gastroenterol* 2013; 19(17): 2587-2590 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i17/2587.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i17.2587>

### COMMENTARY ON HOT TOPICS

Hepatocellular carcinoma (HCC) is a common malignancy, with a high prevalence worldwide<sup>[1,2]</sup>. The prognosis of HCC has remained poor, because many of the patients also have chronic liver diseases and are not suitable for radical surgical treatment<sup>[1-3]</sup>. Another obstacle to HCC treatment is that hepatoma cells display strong

resistance against standard chemotherapeutic drugs<sup>[2,3]</sup>. To enable early diagnosis and treatment, understanding the etiological risk factors of HCC is desirable. Currently, approximately half of all HCC patients suffer from chronic hepatitis B and C virus (HBV and HCV) infection, and remaining cases are affected by various types of etiological factors including alcohol abuse, cigarette smoking, mycotoxins, obesity, and oral contraceptive drugs<sup>[4]</sup>. Intriguingly, growing evidence has suggested that the types of etiological risk factors for HCC might differ between geographic areas. For example, obesity-associated HCC has become one of the most important medical issues in developed countries<sup>[5]</sup>, while food contamination with mycotoxins remains a critical risk factor for HCC in developing countries, including South and East Africa, India and China<sup>[6]</sup>.

### **Mycotoxins as a major dietary risk factor for liver cancer**

In recent years, the relationship between cancer risk and mycotoxin has been universally publicized by global surveillance of food contamination. Mycotoxins are secondary metabolites produced by fungi and are present in various types of stored grains, and most of them are resistant against cooking, freezing and digestion after intake of contaminated food. Several food-contaminating mycotoxins have been defined as harmful carcinogens by the International Agency for Research in Cancer (IARC) (Table 1), that is, deoxynivalenol/nivalenol, zearalenone, ochratoxin, fumonisins and aflatoxins. Of these, aflatoxin B1 (AFB1) is the most well-known bioaccumulative toxin involved in the development of HCC<sup>[7]</sup>. AFB1 is produced by the fungi *Aspergillus flavus* and *Aspergillus parasiticus*, and mainly contaminates improperly stored cereals and peanuts. When individuals are exposed to AFB1 for a long time, mono-oxygenases produce reactive epoxide in the liver, leading to formation of toxic derivatives with nucleic acids and proteins<sup>[8]</sup>. AFB1 has a strong mutagenic effect, and induces G to T transversion within codon 249 of the tumor suppressor *p53* gene. Point mutation of *p53* has been observed in approximately half of all patients with AFB1-associated HCC<sup>[9-11]</sup>. It has also been reported that geographical distribution of aflatoxin exposure and HBV infection overlap, leading to a synergistic effect on the genetic mutation of *p53*<sup>[10,11]</sup>. AFB1 is now regarded as the representative of orally ingested carcinogens, and has been classified as a Group 1 carcinogen by IARC (IARC 7th Annual Report on Carcinogens, 1987).

### **Ochratoxin A: A possible diagnostic marker of HCC?**

Based on the clinical evidence of AFB1 in HCC, several researchers have turned their attention to the other type of mycotoxins. Ochratoxin A (OTA), which has been classified as a possible human carcinogen (Group 2B) by the IARC, is a secondary metabolite of *Aspergillus* and *Penicillium* fungi. OTA is widely spread in cereals such as barley, wheat, coffee and bread<sup>[12]</sup>, and is well known for its possible contribution to nephritic diseases. Although the evidence is still open to debate, several studies have

**Table 1 Classification of food mycotoxins as human carcinogens or potential human carcinogens**

| Group | Classification of food mycotoxins                               |
|-------|---|
| 1     | Aflatoxin B1, B2, G1, G2  |
| 2A    | -   |
| 2B    | Aflatoxin M1, ochratoxin A, sterigmatocystin                    |
| 3     | Citrinin, patulin, luteoskyrin, cyclochlorotine, deoxynivalenol |
| 4     | -   |

Group 1: Carcinogenic to humans; Group 2A: Probably carcinogenic to humans; Group 2B: Possibly carcinogenic to humans; Group 3: Not classifiable as to its carcinogenicity to humans; Group 4: Probably not carcinogenic to humans (classified by the International Agency for Research in Cancer).

reported that OTA might be a causative agent of Balkan endemic nephropathy<sup>[13]</sup>. Moreover, OTA is increased to high levels in the plasma of patients with nephropathy in specific regions such as Tunisia<sup>[14]</sup>, suggesting that OTA plays a critical role in the development of nephritic diseases.

Unfortunately, the role of OTA in hepatocarcinogenesis remains unclear. Although the results of relevant studies are controversial, several have suggested that the carcinogenic effect of OTA is due to increased hepatotoxicity and DNA damage. Ehrlich *et al.*<sup>[15]</sup> have tested the genotoxic effect of OTA in human hepatoma HepG2 cells using both micronucleus and single-cell gel electrophoresis assays, and have found that it causes pronounced dose-dependent effects on DNA damage. Renzulli *et al.*<sup>[16]</sup> have reported that OTA induces DNA damage through oxidative stress, and this could be prevented by rosmarinic acid, a natural phenolic compound contained in many Lamiaceae herbs. Bouaziz *et al.*<sup>[17]</sup> have reported that OTA triggers a p53- and caspase-dependent mitochondrial apoptotic pathway in HepG2 cells. In contrast, El Golli Bennour *et al.*<sup>[18]</sup> have reported that OTA does not induce significant reactive oxygen species generation in cultured HepG2 cells, but induces mitochondrial and caspase-dependent apoptotic cell death mediated by p53 transcription-independent activities. The aforementioned different and controversial studies suggest that etiological analysis of patients with HCC is indispensable for assessing the relationship between OTA and HCC.

Until recent decades, meta-analysis of etiological risk factors for carcinogenesis has been complicated because traditional methods for assessing toxin exposure were mainly performed by questionnaires or standard enzyme linked immunosorbent assay and these cannot assess minute quantities of environmental toxins. During the last decades, however, a chromatographic separation technique based on high-performance liquid chromatography (HPLC) has enabled us to assess the concentration of mycotoxins in clinical samples such as urine and plasma<sup>[19]</sup>. HPLC enables us to detect OTA at a low level of 0.005 ng/mL in plasma<sup>[20]</sup>, which is often less than the mean level in healthy individuals; therefore, this analytical method is preferable for evaluation of the

etiologic significance of OTA. For example, Grosso *et al.*<sup>[21]</sup> and Aslam *et al.*<sup>[22]</sup> have examined the levels of OTA in the serum of bladder cancer patients by HPLC, and have reported that OTA is unlikely to be a risk factor for bladder cancer in Tunisia and Karachi. di Giuseppe *et al.*<sup>[23]</sup> have examined serum OTA in patients in the Molise region in Italy, and have reported that the levels of OTA are significantly associated with C-reactive protein and cardiovascular risk score in men.

Until recently, there have been no studies investigating OTA in HCC patients using HPLC methods. Very recently, however, Ibrahim *et al.* performed a case-control study of HCC patients from 2010 to 2012 in Egypt, and found that OTA was frequently increased in the serum. They measured serum OTA in 39 HCC patients using HPLC and compared it with the level in healthy individuals in Egypt. The highest incidence of OTA was observed in the HCC group. The mean level of serum OTA in the HCC and normal groups was  $1.11 \pm 0.3$  ng/mL (0.129-10.93 ng/mL) and  $0.201 \pm 0.02$  ng/mL (0.005-0.50 ng/mL), respectively ( $P = 0.0002$ ). Multivariate analysis showed that serum OTA was an independent risk factor for HCC. The authors also found that OTA was well correlated with the levels of  $\alpha$ -fetoprotein, which is a major tumor marker for HCC. To date, to the best of our knowledge, there have been no studies regarding the etiologic relationship between OTA and HCC. Further studies on a large scale should be performed in different countries, and they might support the idea that mycotoxins, including OTA, are useful biomarkers of HCC.

### Summary

Recently, progress in the diagnosis and treatment of hepatitis virus infection has significantly improved the outcome of patients with HBV- and HCV-associated HCC. Early diagnosis of HCC arising in patients with nonviral disease, however, has been remained difficult. HPLC-based analysis of clinical samples might offer a useful tool for detecting minute concentrations of environmental toxins that have accumulated in the host. Although food contamination with mycotoxins has so far been recorded in specific geographic regions, it is conceivable that current advances in the transportation system could cause unexpected food contamination in a wide area. Therefore, to address whether OTA would be a real causal agent for HCC, assessment of the level of mycotoxins, including OTA, in clinical samples would be of value.

### Abstract

Tumor necrosis factor- $\alpha$  inhibitors (anti-TNFs) are effective in the treatment of inflammatory bowel disease (IBD) recalcitrant to conventional medical therapy. As the peak incidence of IBD overlaps with the prime reproductive years, it is crucial to establish pharmacologic regimens for women of childbearing age that achieve effective disease control without posing significant fetal harm. A systematic literature review was performed to identify all human studies with birth outcomes data after maternal exposure to infliximab, adalimumab, or certolizumab pegol within 3 mo of conception or during any trimester of pregnancy. Live births, spontaneous abortions or stillbirths, preterm or premature births, low birth weight or small for gestational age infants, and congenital abnormalities were recorded. Fifty selected references identified 472 pregnancy exposures. The subsequent review includes general information regarding anti-TNF therapy in pregnancy followed by a summary of our findings. The benefits of biologic modalities in optimizing disease control during pregnancy

must be weighed against the potential toxicity of drug exposure on the developing fetus. Although promising overall, there is insufficient evidence to prove absolute safety for use of anti-TNFs during pregnancy given the limitations of available data and lack of controlled trials.

**Key words:** Tumor necrosis factor- $\alpha$  inhibitors; Pregnancy; Congenital abnormalities; Safety; Infliximab; Adalimumab; Certolizumab

**Core tip:** A systematic literature review was performed to identify all human studies with birth outcomes data after maternal exposure to infliximab, adalimumab, or certolizumab pegol within 3 mo of conception or during any trimester of pregnancy. After systematic literature review investigating tumor necrosis factor- $\alpha$  inhibitor therapy and fetal risk, there is insufficient evidence to prove absolute safety for the use of biologics (specifically infliximab, adalimumab, and certolizumab pegol) during pregnancy.

### INTRODUCTION

Inflammatory bowel disease (IBD) encompasses the diagnoses of Crohn's disease (CD) and ulcerative colitis (UC). These are chronic relapsing gastrointestinal illnesses that involve proinflammatory molecules. The onset of IBD has a bimodal distribution with a higher peak in the younger population aged 15-30 years; fifty percent of patients afflicted by IBD are diagnosed before the age

of 35<sup>[1]</sup>. Hence, the peak incidence for developing these conditions overlaps with the prime reproductive years<sup>[2,3]</sup>.

Effective control of IBD is essential during pregnancy. Active disease or disease flares have been associated with adverse obstetrical outcomes<sup>[4]</sup>. About 50% of the pregnancies in North America are unplanned, and less than half of females realize their pregnancy status by week four of gestation<sup>[5]</sup>. Inadvertent fetal exposure to medications during the crucial stages of organogenesis is thus possible and common. For these reasons, preconception discussions addressing risks and benefits of pharmacologic therapy during pregnancy are clinically warranted for all patients of childbearing potential.

The decision to pursue or maintain certain drug regimens throughout the prenatal and pregnancy periods may pose a significant challenge; the risks of disease activity must be weighed against the potential side effects of medical therapy. Untreated disease may create greater risks to a pregnancy than the drugs themselves<sup>[2]</sup>. Identifying the safest management strategy is crucial, as medication use during pregnancy impacts maternal disease activity, fetal development, and pregnancy outcomes.

Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is a pleiotropic cytokine that plays a role both in pregnancy and in the pathophysiology of inflammatory conditions including IBD. Mouse models have demonstrated that TNF- $\alpha$  is one of several cytokines bearing a potent regulatory effect on early development<sup>[6]</sup>. It controls cyclooxygenases that affect blastocyst implantation, vascular permeability of the endometrium, and uterine decidualization<sup>[7]</sup>. TNF- $\alpha$  also contributes to the process of labor by stimulating uterine contractions in conjunction with other inflammatory cytokines<sup>[8]</sup>. The production of TNF- $\alpha$  increases throughout pregnancy and reaches a peak at the onset of labor. High levels of TNF- $\alpha$  have been implicated in such pregnancy complications as infection and fetal growth retardation and have even been linked to early and unexplained spontaneous abortions<sup>[8,9]</sup>.

There is a characteristic abundance of gut inflammation in IBD originating *via* various mechanisms at the cellular and subcellular levels. TNF- $\alpha$  is a key cytokine in the development and perpetuation of this abnormal immune response<sup>[10]</sup>. Several studies support the heightened production of TNF- $\alpha$  in the intestinal mucosa of patients with CD, and the levels are increased in both inflamed and histologically normal mucosa<sup>[11-13]</sup>. Increased TNF- $\alpha$  has also been linked to such rheumatologic and dermatologic conditions as rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, and psoriasis.

TNF- $\alpha$  inhibitors (anti-TNFs) are drugs that block the action of TNF- $\alpha$  and neutralize its biologic effect. This class has demonstrated efficacy in controlling disease activity associated with various inflammatory conditions. Infliximab (IFX), adalimumab (ADA), and certolizumab pegol (CTZ) are three such synthetic antibodies available in the United States for the treatment of IBD. Of these, infliximab has been the most highly studied.

Recognizing the effects of maternal drug use on fetal

development is an important aspect of providing care to pregnant patients and women of childbearing age with IBD. There is limited data, though, pertaining to the safety of biologic agents when used during pregnancy. The United States Food and Drug Administration (FDA) lists anti-TNF agents as category B drugs<sup>[14-16]</sup> (category B specifies that animal studies do not indicate fetal risk and there are no controlled studies in women or that animal studies have demonstrated adverse effects but controlled studies in women have failed to demonstrate risk). A recent consensus statement declared anti-TNF agents to be low risk during certain stages of pregnancy<sup>[17]</sup>. Some case reports and small case series reporting anti-TNF exposure and pregnancy outcomes have been published. However, large population-based studies are sparse, and there is a lack of prospective data in pregnant women. In addition, there is a relatively short number of post-marketing years since the advent of biologics, thus narrowing the safety information pool even further. The increasing use of antibody-based therapeutics fosters the need for further study in this group of patients.

A systematic literature review was performed to investigate fetal risks associated with maternal exposure to TNF- $\alpha$  inhibitors (IFX, ADA, and CTZ) during pregnancy.

## SEARCH STRATEGY

The search strategy was developed with the assistance of a medical librarian. Databases searched included MEDLINE, EMBASE, SCOPUS, and BIOSIS Previews through November 2011 and were restricted to studies published in English and performed in humans. Structured searches were conducted using both medical subject heading terms and keyword/exploded terms as follows: (“congenital abnormalities” OR “congenital disorders” OR “pregnancy” OR “safety”) AND (“infliximab” OR “adalimumab” OR “certolizumab”). Titles and abstracts were screened for relevance; reference lists of the applicable publications were hand-searched to identify additional studies.

## ELIGIBILITY CRITERIA

Case reports, case series, or observational studies published in article or abstract form were eligible for inclusion if there was documented female exposure to IFX, ADA, or CTZ within three months of conception or during any trimester of pregnancy and if > one of the following birth outcomes was assessed: live births, spontaneous abortions (SA), stillbirths (SB), preterm or premature births (PTB/PMB), low birth weight (LBW)/small for gestational age (SGA), or congenital abnormalities (CA). Studies were excluded if there was insufficient detail to link specific anti-TNF exposure with birth outcomes. One investigator independently performed the searches described above and reviewed the citations (titles and abstracts) to determine eligibility. Discrepancies were

resolved by the second investigator.

## DATA EXTRACTION

A standardized form was used to abstract the following data points from each study: anti-TNF drug exposure, indication for anti-TNF agent, pregnancy stage(s) of exposure by trimester, live births, and birth outcomes as aforementioned. Spontaneous abortions were defined as fetal death at < 20 wk, stillbirths as fetal death at > 20 wk or at weight > 350-500 g if gestational age unknown, preterm deliveries as < 37 wk gestation, premature deliveries as < 37 wk gestation and prior to completion of organ development, and low birth weight newborns as < 2500 g. Small for gestational age infants were described by authors as smaller than average size given the number of pregnancy weeks.

## SEARCH RESULTS

The initial search yielded 11452 citations. Fifty studies (Table 1)<sup>[18-68]</sup> met inclusion criteria for full review, including 13 case series, 36 case reports, and 2 prospective studies with control groups. Reports in Table 1 are categorized by biologic agent and study type, and details of maternal anti-TNF exposures and pregnancy outcomes are presented.

The total number of patients exposed to anti-TNFs was 472 (IFX 194/ADA 261/CTZ 17). Table 2<sup>[69-73]</sup> displays anti-TNF exposures and birth outcomes for the following categories: live births, spontaneous abortions, stillbirths, preterm/premature births, low birth weight/small for gestational age, and congenital abnormalities. Outcomes in Table 2 have been listed by anti-TNF exposure (IFX, ADA, and CTZ) and indication (for all medical conditions and for IBD patients alone), and results are compared to the general United States population.

Table 3 summarizes the reported congenital abnormalities associated with live births (4.1%). Among 19 congenital anomalies (IFX 9/ADA 10/CTZ 0), no specific pattern of birth defects was identified<sup>[74-76]</sup>.

## DISCUSSION

We performed a systematic literature review to assess the risk of adverse birth outcomes after maternal exposure to IFX, ADA, or CTZ and identified 50 references with a total of 472 fetal exposures.

The subsequent discussion highlights each biologic agent in the context of pregnancy and provides a summary of our data.

### Infliximab

Infliximab (Remicade) is a human-murine chimeric monoclonal antibody that neutralizes the activity of TNF- $\alpha$ . It is composed of a human immunoglobulin G1 (IgG1) constant region and a murine variable region. Its efficacy in IBD has been documented in randomized

controlled trials in the treatment of moderate to severe CD refractory to conventional therapy as well as enterocutaneous fistulae<sup>[77,78]</sup>. The drug can reduce the need for corticosteroids and, in patients who respond to initial dosing, IFX is effective for the maintenance of response and prolonged remission in CD<sup>[79,80]</sup>.

IFX is classified by the United States FDA as pregnancy category B. Murine models show no evidence of teratogenicity or embryotoxicity. However, anti-TNF- $\alpha$  antibodies vary among species; data cannot simply be paralleled to human pregnancy outcomes. Infliximab does not cross-react with TNF- $\alpha$  in species other than humans and chimpanzees, and it has not been tested in animal reproduction studies<sup>[14]</sup>.

IFX is not thought to cross the placenta in the first trimester due to its human IgG1 constant region<sup>[81]</sup>, but this subclass is known to efficiently cross in the late second and third trimesters<sup>[26]</sup>. Given this timing, the infant is somewhat shielded from drug exposure during the critical period of organogenesis. IFX levels can be detected in newborns of exposed mothers, and the drug remains in the system for up to six months after delivery<sup>[19,50]</sup>. This bears important consequences in terms of newborn infection risks and vaccination responses<sup>[17]</sup>. Discontinuing infliximab in the third trimester is an option to decrease late placental transport to the newborn.

### Adalimumab

Adalimumab (Humira) is a fully human monoclonal IgG1 antibody against TNF- $\alpha$ . It has proven effective for inducing and maintaining remission in CD<sup>[82,83]</sup>, especially in those who have lost response to or have become intolerant of infliximab<sup>[84]</sup>.

ADA is classified as an FDA pregnancy category B drug. In an embryo-fetal perinatal developmental toxicity study, cynomolgus monkeys were administered ADA at extreme dosages of up to 100 mg/kg [266 times human area under the curve (AUC) when dispensed as 40 mg subcutaneously with methotrexate weekly or 373 times human AUC when dispensed as 40 mg subcutaneously without methotrexate]. No evidence of fetal harm due to ADA was recorded. Adequate and well-controlled studies have not been conducted in pregnant women. Again, animal reproduction and developmental studies are not always indicative of human response, and ADA must be used with caution in pregnancy<sup>[15]</sup>. There is no long-term data regarding effects of adalimumab on the developing fetus.

Less information exists on the transplacental diffusion of ADA throughout the trimesters compared to infliximab. Determining the time course of drug administration and when to potentially discontinue ADA during pregnancy is not well-defined due to shorter dosing intervals and limited ability to commercially measure ADA levels. Withholding the drug in the third trimester may be considered to reduce late placental transport to the newborn. Mahadevan *et al*<sup>[17]</sup> suggests discontinuation 8-10 wk prior to estimated date of delivery.

IFX: Infliximab; ADA: Adalimumab; TNF: Tumor necrosis factor.

### Certolizumab pegol

Certolizumab pegol (Cimzia) is a recombinant humanized anti-TNF- $\alpha$  fragment antigen binding (Fab') fragment. The antibody fragment is bound to a polyethylene glycol molecule that extends the drug's half-life to approximately two weeks in the plasma, thereby reducing dosing frequency<sup>[85]</sup>. Studies have demonstrated the efficacy of CTZ for induction and maintenance of remission in CD<sup>[86]</sup>.

CTZ is a pregnancy category B drug. It does not cross-react with mouse or rat TNF- $\alpha$ . Reproduction studies in rats have thus been performed using a rodent anti-murine TNF- $\alpha$  pegylated Fab' fragment (cTN3 PF) that is similar in function to CTZ. These studies have been conducted using doses up to 100 mg/kg and have revealed no evidence of impaired fertility or fetal adversities due to cTN3 PF. Adequate and well-controlled studies have not been performed in pregnant women. As animal reproduction studies are not always indicative of human response, this drug must be used with caution in pregnancy<sup>[16]</sup>.

The molecular structure of CTZ lacks an Fc portion, so its cross-placental transfer is different from that of IFX and ADA. The Fab' fragment may passively cross the placenta in low levels during the first trimester, an event that is not expected with the IgG1 antibody. Although CTZ therapy would likely not need to be discontinued in the third trimester, it is important to recognize that the transplacental transfer of this drug occurs during a critical period of organogenesis in the first trimester.

In an animal model, pregnant rats received a murinized IgG1 TNF- $\alpha$  antibody and a PEGylated Fab' fragment of the antibody. Lower levels of the drug were detected in the infant and in breast milk with the Fab' fragment versus the full antibody<sup>[87]</sup>. Mahadevan *et al*<sup>[66]</sup> demonstrated these findings in two human patients receiving certolizumab during pregnancy. The drug was administered to both women two weeks prior to delivery. Although the mothers' drug levels were higher on the date of delivery, newborn cord blood levels were low.

There are few published reports on the use of CTZ during pregnancy. As with the other anti-TNF agents, it is possible that the Fab' fragment passively crosses the placenta at low levels in the first trimester. The drug must be further studied in humans to fully appreciate the course of drug transfer during gestation and subsequent effects on fetal development and pregnancy outcomes.

### SUMMARY OF DATA

Our review indicates that rates of SA and CA in anti-TNF-exposed patients are similar to rates in the general United States population<sup>[69-73]</sup> and in women with IBD unexposed to anti-TNF agents<sup>[74-76]</sup>. The live birth rate in the anti-TNF-exposed group (85.8%) is higher than that of the general United States population (64.6%); this holds true for all patients exposed to IFX or ADA regardless of underlying inflammatory disease and perhaps reflects a state of controlled disease activity. The live birth rate for patients exposed to CTZ (47.1%) is lower than that of the general population, although there is a very small collective sample size. The rates of SA and

SB for all groups are similar to the general United States population<sup>[72]</sup> with the exception of IFX-exposed patients, in whom the rate of SB is just slightly higher. The PTB/PMB rate in the anti-TNF-exposed group (19.9%) is higher than in the United States population (12.3%)<sup>[72]</sup>, perhaps due to an underlying predisposition as in the setting of IBD<sup>[76]</sup>. LBW/SGA infants are more common in ADA- and CTZ-exposed patients than in the general United States population<sup>[73]</sup>, again possibly reflecting the underlying disease itself or the severity of disease activity.

In general, pregnancy does not increase the risk of disease exacerbation in CD or UC<sup>[88,89]</sup>. Approximately one-third of women with inactive IBD at the time of conception are expected to flare during pregnancy and the puerperium<sup>[90]</sup>. Alternatively, if pregnancy overlaps with a period of active IBD, the disease may be difficult to control<sup>[91]</sup>. Active disease at the time of conception has been associated with increased rates of PTB<sup>[89]</sup> and fetal loss<sup>[92]</sup>, and disease flares during pregnancy have been associated with PTB and LBW<sup>[4,93]</sup>. Studies are mixed regarding the risk of congenital malformations among IBD progeny, with some data showing an increased risk for both CD and UC patients<sup>[94]</sup> or for UC patients alone<sup>[95,96]</sup> and other data showing no increased risk in CD or UC<sup>[97,98]</sup>. Regardless of disease activity, women with IBD have an increased risk for such adverse pregnancy outcomes as PTB, SB, LBW, SGA, and delivery complications such as cesarean sections compared to the general population<sup>[97-101]</sup>. In our study, no discernible increased risks for SA or CA were identified. Overall, unless there is a clear risk of fetal harm (*i.e.*, an FDA category X drug) that dictates otherwise, maintenance therapy is conventionally continued throughout pregnancy to optimize maternal disease control and prevent relapse or progression<sup>[102]</sup>.

This systematic review has limitations. Pooling data from different studies yields inherent heterogeneity based on study designs, study populations, and recording of birth outcomes data. As evidenced, there are a limited number of reported pregnancy exposures to anti-TNF agents, many published as case reports or case series with small sample sizes; these do not necessarily reflect outcomes that can be extracted to the general population. Our review is affected by the limitations of the individual studies, including the inability to adjust for maternal disease activity and severity, concomitant medication or substance use, comorbidities, or other maternal characteristics. Additionally, there exist potential publication bias against negative outcomes and recall bias involving drug exposure and timing of administration during conception and pregnancy. The decision to exclude studies based on the English language and on the inability to link specific anti-TNF exposure with birth outcomes may have discounted pertinent publications. Although care was taken to account for evident overlap, it is possible that repeated data exists given the nature of our information (for example, a case report that has also been reported within drug registry data).

A growing body of evidence supports that IFX, ADA, and CTZ are low risk in pregnancy<sup>[17]</sup>, and studies beyond those included in our data set are underway to further elucidate fetal risk and optimal timing of biologic administration during pregnancy<sup>[103,104]</sup>. Thus far, it is believed that IFX and ADA are most compatible for use during conception and at least the first and second trimesters considering mechanisms of placental transport<sup>[17,102]</sup>; further human data are needed to generate safety guidelines for the use of CTZ. In a recent study of pregnant women receiving biologic therapy, IFX and ADA were shown to be transplacentally transferred to infants at birth, with high levels of drug in cord blood and detectable drug levels up to six months after birth. CTZ was found to be least detectable in both cord blood and infant serum after birth. Of note, no CA or significant fetal complications were reported in this study<sup>[104]</sup>.

Future efforts are promising and include the expansion of drug safety data registries and the development of larger prospective trials to help definitively quantify fetal risk and to facilitate clinical decision-making in treating women with IBD during their childbearing years. One such project is the highly anticipated Pregnancy IBD and Neonatal Outcomes study, a prospective data collection from multiple IBD centers in the United States<sup>[105]</sup>. This large cohort registry not only accounts for maternal factors including IBD activity, medication use, delivery methods, and pregnancy complications but also tracks data over time from the neonatal period through children's first year of life. Similarly, post-marketing surveillance data may uncover additional consequences of fetal exposure to biologic agents over time.

While evidence in the field is mounting, caution should indefinitely be exercised. Given the limitations of the available data and lack of controlled trials, there is insufficient evidence to prove absolute safety for use of anti-TNFs during pregnancy. Although the benefits of therapy in optimizing disease activity during gestation may lend to more favorable pregnancy outcomes based on a controlled disease state, definitive safety of drug exposure on the developing fetus has not been confirmed.

Medical management decisions during the preconception and pregnancy periods will inevitably vary by case based on respective risk-to-benefit ratios, details of disease activity, response to alternative therapies, and individual preferences. Women and men of childbearing age should be educated about the effects of IBD on pregnancy and the potential implications of treatment on fetal development. In addition, patients should be encouraged to discuss reproductive plans with their physicians in order to achieve remission prior to conceiving. Ideally, the primary preconception goal should be quiescent disease, as this lends to the most favorable pregnancy outcomes.

## CONCLUSION

After systematic literature review investigating TNF- $\alpha$  inhibitor therapy and fetal risk, there is insufficient evi-

dence to prove absolute safety for the use of biologics (specifically infliximab, adalimumab, and certolizumab pegol) during pregnancy.

### Abstract

Colorectal cancer is one of the most common malignant tumors worldwide. A model of cancer development involving cancer stem cells has been put forward because it provides a possible explanation of tumor hierarchy. Cancer stem cells are characterized by their proliferation, tumorigenesis, differentiation, and self-renewal capacities, and chemoradiotherapy resistance. Due to the role of cancer stem cells in tumor initiation and treatment failure, studies of cancer stem cell markers, such as CD133, have been of great interest. CD133, a five-transmembrane glycoprotein, is widely used as a marker to identify and isolate colorectal cancer stem cells. This marker has been investigated to better understand the characteristics and functions of cancer stem cells. Moreover, it can also be used to predict tumor progression, patient survival, chemoradiotherapy resistance and other clinical parameters. In this review, we discuss the use of CD133 in the identification of colorectal cancer stem cell, which is currently controversial. Although the function of CD133 is as yet

unclear, we have discussed several possible functions and associated mechanisms that may partially explain the role of CD133 in colorectal cancers. In addition, we focus on the prognostic value of CD133 in colorectal cancers. Finally, we predict that CD133 may be used as a possible target for colorectal cancer treatment.

**Key words:** CD133; Colorectal cancer; Cancer stem cells; Prognosis; Chemoradiotherapy resistance

**Core tip:** CD133 is not a reliable marker to identify the entire population of cancer stem cells (CSCs). However, the abundance of CD133 may be a good indicator of CSC identity and consistent with the biological characteristics of CSCs; The expression of CD133 is correlated to the poor survival; CD133(+) cells exhibit more chemoresistant behavior than CD133(-) cells; Whether CD133-targeting therapies can be a specific or efficient treatment for colorectal cancer has not been confirmed.

### INTRODUCTION

Colorectal cancer is regarded as one of the most common cancers in the world, and a main cause of cancer-related death in western countries. In spite of progressing treatments, a large percentage of advanced tumors have poor prognosis. Recent studies have shown that a small population of tumor cells, known as cancer stem cells (CSCs), may be considered the main initiators of recurrence and metastasis. It is critical to find specific bio-

markers to identify and isolate CSCs as well as to predict patient prognosis. CD133 is one of the best-characterized markers of CSCs. However, its role in colorectal cancer needs further study. Here, we have attempted to elucidate the relationship between CD133 and colorectal cancer based on the results of previous studies.

## INTRODUCTION OF CD133

CD133, a five-transmembrane glycoprotein, was first found to be expressed in hematopoietic stem and progenitor cells by Yin *et al*<sup>[1]</sup>. The protein has a molecular weight of 120 kDa<sup>[1]</sup> and localizes to membrane protrusions. The protein may be expressed as one of two isoforms, CD133-1 and CD133-2. CD133-1 was the first to be discovered, by Yin *et al*<sup>[1]</sup>, and it is mainly expressed in human fetal liver, bone marrow and blood. CD133-2, first cloned and identified by Yu *et al*<sup>[2]</sup>, is another cell surface antigen that is recognized by anti-AC133 monoclonal antibodies. Relative to AC133-1 cDNA, a small exon of 27 nucleotides is deleted in AC133-2 by alternative mRNA splicing<sup>[2]</sup>. CD133-2 mRNA is prominently expressed in human fetal tissue, adult tissues and several carcinomas<sup>[2]</sup>. It has also been suggested that CD133-2 is expressed in multiple stem cell niches<sup>[2]</sup>. Based on these biological characteristics, CD133 is widely used to identify and isolate stem cells and cancer stem cells. However, its function is still unclear. It is hypothesized to be associated with the cell-cell interaction or signal transduction.

## CANCER STEM CELLS AND CD133

Tumor cells show heterogeneity in their morphology, inheritance, functions and other characteristics. However, some tumor cells present not only heterogeneity but also hierarchy. The increasing CSCs model represents a breakthrough in explaining this phenomenon. In this model, CSCs, despite being only a small subset of cancer cells, have the capability to self-renew and sustain the tumor. These CSCs also have the ability to proliferate, resulting in expansion of the CSC pool, and to differentiate into the heterogeneous cancer cell subgroups that may not themselves be tumorigenic but usually constitute the majority of the tumor<sup>[3]</sup>.

More and more studies have indicated that CD133 is a surface marker of CSCs. CD133 has been found in many tumors, including cancers of the brain<sup>[4]</sup>, colon<sup>[5,6]</sup>, liver<sup>[7]</sup>, pancreas<sup>[8]</sup>, kidney<sup>[9]</sup>, lung<sup>[10]</sup>, endometrium<sup>[11]</sup>, ovary<sup>[12]</sup> and bone<sup>[13]</sup>. The exploration of CD133 as a surface marker of colon cancer stem cells (Co-CSCs) is still in progress. In 2007, both O'Brien *et al*<sup>[14]</sup> and Ricci *et al*<sup>[15]</sup> found that CD133(+) cells in colon cancers had the ability to initiate tumor growth. The colon cancer-initiating cells (CC-ICs) represented enrichment in CD133(+) populations. These two studies strongly support CD133 as a marker of Co-CSCs based on the evidence that CD133(+) cells could produce tumors with preserved self-renewal and differentiation capabilities and without phenotypic alterations

after serial transplantation. The long-term tumorigenic potential of CD133(+) colon cancer cells has also been confirmed *in vitro*<sup>[15]</sup>. More importantly, CD133(-) colon cancer cells have no ability to form tumors. However, Shmelkov *et al*<sup>[16]</sup> discovered that CD133 was ubiquitously expressed in differentiated colonic epithelium rather than restricted to stem cells. Furthermore, *in vitro*, both CD133(+) and CD133(-) metastatic tumor subpopulations formed colonospheres. Both subpopulations maintained long-term tumorigenesis in a NOD/SCID serial xenotransplantation model. It should be noted that Shmelkov *et al*<sup>[16]</sup> used subpopulations from metastatic tumors. However, the distinction of CSCs and the function of CD133 in primary and metastatic tumors are still unknown. Despite this fact, the discovery challenged the view of CD133 as a marker of Co-CSCs, and further studies were performed to investigate the discrepancy.

Kawamoto *et al*<sup>[17]</sup> showed that although both CD133(+) and CD133(-) cells could form tumors after injection into NOD/SCID mice, the CD133(+) cells formed larger tumors. There remained a difference in these tumors. CD133(+) cells could not be found in tumors generated by the injection of CD133(-) cells but were observed in tumors from injections of CD133(+) cells, suggesting that CD133(+) cells had self-renewing capability whereas CD133(-) cells did not. The investigation is consistent with Shmelkov's finding that CD133(-) cells also have the ability to form tumors, although it seems that the CD133(+) cells were associated with stronger tumorigenesis than CD133(-) cells. Thus, the presence of CD133 may not be a reliable indicator of CSC *vs* non-CSC identity. A more appropriate distinction is the relative abundance of the CD133 protein<sup>[18]</sup>. Liao *et al*<sup>[19]</sup> attempted to confirm this hypothesis by sorting cancer cells according to the abundance of CD133. CD133 (High), CD133 (Mid), and CD133 (Low) subgroups of SW620 cells (a colorectal cancer cell line) were distinguished, and their biological characteristics were analyzed. The CD133 (High) subgroup exhibited a higher growth rate than the CD133 (Mid) and CD133 (Low) subgroups did. However, despite its much slower growth, the CD133 (Low) subgroup retained its tumorigenicity.

One likely explanation is that CD133 is expressed on not only CSCs but also differentiated tumor cells. However, during CSC differentiation, the specific epitopes recognized by AC133 are masked due to differential glycosylation<sup>[20]</sup>. The expression of CD133 could be modulated by factors in the microenvironment, such as energy supply<sup>[21]</sup>. In addition, the inactivation of CD133 during the progression of colorectal cancer can be considered a result of transcriptional repression, due to promoter hypermethylation of the CD133 CpG islands<sup>[22]</sup>. CD133(-) cells likely lack the AC133 epitopes, the expression of which is influenced by posttranslational modification under certain conditions. It appears that CD133 is not a reliable marker to identify the entire population of CSCs. However, the abundance of CD133 may be a good indicator of CSC identity.

**Table 1 Studies of the relationship between CD133 expression and survival**

| Ref.                                 | n   | Cancer category                       | Tumor stage                                       | Method | Did CD133 expression predict poor survival? |
|--------------------------------------|-----|---------------------------------------|---|--------|---|
| Choi <i>et al</i> <sup>[34]</sup>    | 523 | Colorectal adenocarcinomas            | Stages I-IV                                       | IHC    | No: overall survival                        |

| Kojima <i>et al</i> <sup>[69]</sup>  | 140 | Colorectal cancers                    | Stages I-IV (well- and moderately-differentiated) | IHC    | No: recurrence-free survival                |

IHC: Immunohistochemistry; RT-PCR: Reverse-transcription polymerase chain reaction; CRT: Chemoradiotherapy.

sion at the mRNA level, concluded that CD133 expression is inversely correlated with survival. The majority of these studies included post-chemoradiotherapy patients. However, all of these studies used small sample sizes. Although some studies had deficiency in their design, majority of them came to the similar conclusion that the expression of CD133 was correlated to the poor survival, and more uniform studies should be performed to demonstrate this confusion.

CD133 can be found in not only primary tumors but also metastatic tumors such as liver metastases. It was reported that the CD133(+)/CD44(+) subpopulation was responsible for this metastasis<sup>[30,71]</sup>. Neumann *et al*<sup>[72]</sup> reported that cases with MLH1(+), CD133 (high scores) and  $\beta$ -catenin (high scores) tumors were associated with a very high rate of distant metastases (94.4%). Thus, it seems that CD133, in combination with other markers, may be a good predictor of metastasis risk.

Several studies have investigated whether the CD133 mRNA level in peripheral blood is useful for prognosis in colorectal cancers. Lin *et al*<sup>[73]</sup> first described that an increased level of CD133 mRNA in the peripheral blood could predict colon cancer recurrence, independent of tumor-node-metastasis stage. Pilati *et al*<sup>[68]</sup> investigated patients with liver-confined hepatic metastasis from colorectal cancers. The level of CD133, used as a marker of circulating tumor cells, increased inversely with the survival. Iinuma *et al*<sup>[74]</sup> showed that in patients with Dukes' stage B and C cancer, CEA/CK/CD133 demonstrated significant prognostic value. In contrast, no significant differences were seen in patients with Dukes' stage A disease. These studies support the use of CD133 mRNA in peripheral blood as prognostic marker. However, Gazzaniga *et al*<sup>[75]</sup> reported that there was no correlation between the expression of CD133 in circulating tumor cells isolated from peripheral blood and outcomes in patients with metastatic colorectal cancers. All these studies used an reverse-transcription polymerase chain reaction approach, but this method may have low sensitivity and lead to a high rate of false positive results in detecting circulating tumor cells<sup>[76]</sup>. Due to the limitation of this method and the inclusion of early stage (stage I)

patients with better outcomes as well as advanced stage (stage IV) patients with worse outcomes, current studies may not accurately distinguish between the outcomes in patients with early and advanced stages of colorectal cancer. However, the prognostic value of CD133 mRNA in the peripheral blood of patients with middle-stage disease (stages II and III) has been confirmed by some studies.

Chemoradiotherapy (CRT) resistance is a major problem that affects the survival of patients with colorectal cancer. Furthermore, the acquired resistance has a long-term memory<sup>[77]</sup>. Conventional chemotherapy targets rapidly dividing cells, but CSCs divide slowly. Therefore, CSCs are likely to contribute to the resistance of cytotoxic systemic therapies<sup>[78]</sup>. Efforts have been made to demonstrate that the role of CD133(+) colorectal tumors are more resistant to 5-fluorouracil-based chemotherapy than CD133(-) tumors. Ong *et al*<sup>[79]</sup> conducted a clinical study containing 501 primary colorectal cancer cases that provided evidence supporting this hypothesis. Moreover, recent studies showed that the level of CD133 increased in post-CRT specimens<sup>[65]</sup> and that CD133 expression was detected in 27.5% of non-CRT and 70% of CRT specimens<sup>[80]</sup>. *In vitro*, CD133 was overexpressed in human colon cancer cell lines that were resistant to 5-fluorouracil and oxaliplatin, such as HT29/5FU-R and HT29/OxR<sup>[81]</sup>. These results suggest that CD133 is a good predictor of CRT resistance. However, Hongo *et al*<sup>[82]</sup> recently reported that CD133(-) cells are more resistant to 5-fluorouracil than CD133(+) cells, which challenged the previous view. However, these authors isolated CD133(+) and CD133(-) cells from a single colorectal cancer cell line, and the original characteristics may have been altered during long-term culture. Therefore, the clinical studies are more reliable than *in vitro* studies. Meanwhile, Ong's research was conducted in a large clinical sample size, and other clinical<sup>[57,80,83]</sup> and *in vitro* studies<sup>[81,84]</sup> supported their results. Considering that Hongo's study was based on a single cell line and that no further studies have drawn similar conclusions to date, we feel it is appropriate to conclude that CD133(+) cells exhibit more chemoresistant behavior than CD133(-) cells. However, more studies, especially

clinical studies, should be performed to clarify the role of CD133 in chemoresistance.

The mechanism of chemoresistance is still under investigation. Intrinsic factors such as antiapoptotic proteins and soluble microenvironmental molecules, including growth factors and cytokines, may cause the refractoriness of CSCs. Several studies have demonstrated that the interleukin 4 (IL-4) produced by cancer cells themselves negatively regulated apoptosis<sup>[85-87]</sup>. Todaro *et al*<sup>[88]</sup> reported that IL-4 protected CD133(+) cells from apoptosis in colon cancer. They later found that treatment with an IL-4 receptor alpha chain antagonist or anti-IL-4 neutralizing antibody strongly enhances the antitumor efficacy of standard chemotherapeutic drugs through selective sensitization of CD133(+) cells<sup>[89]</sup>. These studies highlight the importance of IL-4 in chemoresistance. In addition, the secretion of IL-4 induced an immunosuppressive state in the microenvironment of the tumor, which facilitates the tumor progression. These results indicate that IL-4 may be a good target of colorectal cancer treatment.

## COLORECTAL CANCER TARGET THERAPIES

There are two major targets for advanced colorectal cancer therapy: epidermal growth factor receptor and vascular endothelial growth factor. The Wnt pathway is an additional potential target. Data has shown that Wnt pathway activity could be responsible for the chemoresistance of CD133(+) cells in colorectal cancer cells. Deng *et al*<sup>[43]</sup> demonstrated that 5-fluorouracil upregulated Wnt activity in CD133(+) colon cancer stem-like cells. Dickkopf-1, an inhibitor of Wnt signaling, decreased the expression of CD133 and Lgr5. It also reduced the proliferation, migration, and invasion of colon cancer cells<sup>[90]</sup>. This indicates that blocking the Wnt pathway may be one possible solution to the problem of chemoresistance. Furthermore, other pathways, such as the Notch and Hedgehog signaling pathways involved in maintaining CSC identity, and other regulators, such as STAT3<sup>[53,91,92]</sup> and microRNAs, could be conceivable targets.

CSCs can be eliminated by targeting membrane proteins such as CD133 and then delivering medicines that can specifically induce to death. Several efforts have been made to utilize CD133 in the treatment of cancers. Damek-Poprawa *et al*<sup>[93]</sup> conjugated a CD133 monoclonal antibody (MAB) to a genetically modified cytolethal distending toxin (Cdt). The proliferation of CD133(+) cells in cell lines derived from head and neck squamous cell carcinomas was preferentially inhibited in a rate- and dose-dependent manner by the Cdt-MAB complex. Moreover, Rappa *et al*<sup>[94]</sup> decreased the number of CD133 molecules using two different short hairpin RNAs in FEMX-I melanoma cells. The cell growth, cell motility and spheroids-forming capacity were inhibited as a result of downregulation of CD133. In addition, Wang *et al*<sup>[95]</sup> investigated glioblastoma (GBM) using single-walled

carbon nanotubes (SWNTs) conjugated with CD133 monoclonal antibodies. GBM cells were exposed to these SWNTs and then irradiated with near-infrared laser light. They found that the CD133(+) cells were eliminated, and the tumorigenic and self-renewal characters of CD133(+) cells were also blocked. However, some have argued that CD133(-) cells can be reversed to CD133(+) cells through microenvironmental factors and that CD133 is not the only marker able to identify CSCs, indicating that targeting CSCs through CD133 alone is not sufficient to cure tumors. Whether CD133-targeting therapies can be a specific or efficient treatment for colorectal cancer requires further exploration.

## CONCLUSION

Although CD133 has been used as a CSC marker, it cannot be the only marker used to characterize CSCs in colorectal cancers. It seems that a small population of CD133(-) cells also have the biological characteristics of CSCs. Other markers should be used in combination to identify CSCs. Which combination of these markers is the best to identify CSC or shows consistent biological characters with CSC remains a question. Moreover, little is known about the function of CD133. Whether CD133 participates in the biological behavior of CSC or merely acts as a marker of the CSC phenotype is not clear. A variety of studies have confirmed the prognostic value of CD133 in colorectal cancers. However, these studies lack uniform samples, clinical conditions, methods and evaluations. Although CD133 is believed to be a target of advanced colorectal cancer, few efforts have been made to confirm this hypothesis directly. Regardless, it is desirable to explore new strategies of colorectal cancers by the use of CD133.

### Abstract

**AIM:** To determine the prevalence of celiac disease in a randomly selected population sample.

**METHODS:** A total of 2157 subjects (1036 males; 1121 females) participating in a population-based cross-sectional study underwent laboratory testing for tissue transglutaminase and antibodies to immunoglobulin A, endomysium and antigliadin. In a second step, all subjects who had been examined serologically were surveyed using a questionnaire that included questions

specific to celiac disease. Subjects with positive antibody titers and those with histories positive for celiac disease then underwent biopsy. At the first follow up, antibody titers were again determined in these subjects and subjects were questioned regarding symptoms specific for celiac disease and disorders associated with celiac disease. The second follow up consisted of a telephone interview with subjects positive for celiac disease.

**RESULTS:** Antibody tests consistent with celiac disease were reported in eight subjects, corresponding to an overall prevalence of 1:270 (8/2157). The prevalence among women was 1:224 and 1:518 in men. Classical symptoms were observed in 62.5% of subjects. Atypical celiac disease was present in 25.0%, and transient celiac disease in 12.5%. False-negative test results were returned in three subjects. This yields a sensitivity and specificity of 62.5% and 50.0%, respectively, for tissue transglutaminase immunoglobulin-A antibody; of 62.5% and 71.4% respectively, for endomysium antibody; and of 62.5% and 71.4%, respectively, for antigliadin antibody.

**CONCLUSION:** The prevalence rate in our collective lies within the middle tertile of comparable studies in Europe. The use of a single antibody test for screening purposes must be called into question.

**Key words:** Cross-sectional study; Celiac disease; Screening; Prevalence; Serology

**Core tip:** Only limited data on the prevalence of celiac disease in the adult European population are available. Aim of the study was to determine the prevalence of celiac disease in a randomly selected population sample in Germany and to assess the sensitivity and specificity of antibody tests. Eight of 2157 (1:270) subjects tested

positive for celiac disease. Tissue transglutaminase immunoglobulin-A antibody yielded a sensitivity of 62.5% (specificity 50.0%), endomysium antibody of 62.5% (71.4%) and anti gliadin antibody of 62.5% (71.4%). The prevalence rate lies within comparable European study results. The use of a single antibody test for screening purposes must be questioned.

Prevalence of celiac disease in Germany: A prospective follow-up study. *World J Gastroenterol* 2013; 19(17): 2612-2620 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i17/2612.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i17.2612>

## INTRODUCTION

The prevalence of celiac disease in population-representative collectives is reported between 1:42 and 1:558<sup>[1-10]</sup> (Table 1) depending on the size of the population studied and the nature of the antisera used for screening. Among blood donors, the reported range is from 1:37 to 1:681<sup>[11-19]</sup> (Table 1) and, for non-population representative samples, between 1:86 and 1:709<sup>[20-24]</sup> (Table 1).

Subjects suffering from celiac disease may present with typical clinical symptoms, such as diarrhea, weight loss and bloating; or, they may be completely asymptomatic or exhibit only unspecific symptoms. For example, anemia or iron deficiency may be the only initial signs of the disease. Age distribution of first onset shows a first peak between nine months and two years, and a second during the fourth decade<sup>[25]</sup>.

It has only been in recent years that the clinical manifestations of this very heterogeneous disorder have been arranged in subclasses<sup>[26]</sup>. The system of subtypes proposed by Holtmeier *et al*<sup>[26]</sup> for the first time integrates clinical symptoms, histology and antibody titers, thus facilitating reliable diagnosis and therapeutic management.

Celiac disease is associated with specific, often serious, complications, including the development of gastric ulcers with the risk of hemorrhage, perforation and stricture, as well as T cell lymphoma<sup>[25,27]</sup>. In fact, the risk of lymphoma in patients with celiac disease is about three times as high as that of the general population, with a peak age of onset at about 60 years<sup>[25]</sup>. The risk of complications and neoplasia is associated with all forms of celiac disease: hence, the recognition of non-classical disease forms is particularly crucial. A strict, gluten-free diet started as early as possible and maintained lifelong significantly reduces the risk of malignancy<sup>[28]</sup>. The protective effects of a gluten-free diet on the development of autoimmune disorders associated with celiac disease, such as diabetes mellitus or autoimmune thyroid diseases, however, remains controversial in the literature<sup>[29-33]</sup>.

Small bowel biopsy has been the conventional gold standard for the diagnosis of celiac disease. Today, however, greater importance is now attached to serological

studies, including antibodies to tissue transglutaminase (tTGA), endomysium (EMA) and gliadin (AGA)<sup>[8]</sup>.

To date, no prospective data on the prevalence of celiac disease in a representative adult population sample in Germany have been published. Objective of the present study was to determine the prevalence of celiac disease in a randomly selected population sample.

## MATERIALS AND METHODS

### Study population

The study "Echinococcus Multilocularis and other Internal Diseases in Leutkirch" (EMIL), a cross-sectional survey assessing the prevalence of *Echinococcus multilocularis* infection and other medical disorders, was conducted in Leutkirch, Germany in 2002. Initially, 4000 of the total 12475 residents were randomly selected by the staff of the municipal registry office from the roster of inhabitants. Out of these 4000 persons, 107 were excluded because their address was unknown or they had not given their informed consent. A total of 2445 individuals finally participated in the study, corresponding to a participation rate of 62.8%. Following exclusion of subjects less than 18 years and subjects with incomplete laboratory results, 2157 subjects were finally included in the present analysis (Figure 1).

The study was conducted in accordance with the principles of the Helsinki Declaration and Good Clinical Practice. It was approved by the ethics committee of the Landesärztekammer Baden-Württemberg. All subjects provided their written informed consent.

### Initial study

All subjects were interviewed by a trained interviewer using a standardized questionnaire. In order to reduce interviewer bias as much as possible, each interviewer underwent in-depth training by an interviewing specialist of the state health office<sup>[34]</sup>.

Because the original EMIL questionnaire did not include specific questions regarding celiac disease, in 2003 all subjects of the EMIL study were mailed a separate questionnaire addressing celiac disease. Subjects were questioned regarding celiac disease that had been diagnosed prior to the date of the EMIL study and were asked whether they were currently (*i.e.*, at the time of the study) prescribed a gluten-free diet. The response rate to this survey stood at 50%.

Each subject underwent phlebotomy of the cubital vein to obtain ca. 25 mL of venous blood. Total immunoglobulin A (IgA) concentration was determined by nephelometry (BN II, Dade Behring, Marburg, Germany). IgA to tTGA was measured using an indirect, non-competitive enzyme immunoassay (Pharmacia Diagnostics Freiburg, Germany). Human recombinant tTGA was used as the antigen. Titers of 5-8 U/mL were considered borderline, while titers > 8 U/L were considered positive. AGA was determined using ELISA (Vita Diagnostics Merzhausen, Germany). Titers of 12-16 U/mL were con-

tTGA: Tissue transglutaminase antibody; EMA: Endomysial antibody; AGA: Antigliadin antibody; NA: Not available; -: Positive.

sidered borderline, while titers > 16 U/L were considered positive. EMA was measured by means of an indirect immunofluorescence technique using a monkey esophagus immunofluorescence kit (The Binding Site, Ltd., Birmingham, United Kingdom). Positive samples exhibit an apple green fluorescence. IgG antibodies to tTGA were determined using an indirect, non-competitive enzyme immunoassay (Phadia GmbH, Freiburg, Germany) in which human recombinant tTGA antigen served as the solid phase. Titers of 7-10 U/mL were considered borderline, while titers > 10 U/L were considered positive.

All subjects testing positive for tTGA IgA underwent a confirmation test together with serological testing for antibodies to EMA and AGA. Subjects with low concentrations of total IgA were tested for tTGA IgG. Subjects with suspected celiac disease also underwent human leukocyte antigen (HLA) typing. Additional specific antibody testing was performed in order to assess the presence of other immunological disorders often associated with celiac disease (islet-cell antibody, anti-GAD, thyroid peroxidase antibody, auto-antibodies to adrenal cortex, parietal cell antibody).

Every effort was made to refer subjects with suspected celiac disease for esophagogastroduodenoscopy in order to obtain tissue samples from the duodenum.

The endoscopies and biopsies were performed by gastroenterologists in private practice. Between one and seven biopsy samples were obtained from each subject. The samples were examined histologically and classified according to the modified Marsh criteria<sup>[35]</sup>.

HLA loci were detected using the reverse sequence specific oligonucleotide (SSO) dot-blot method. The HLA-A, B and C loci were typed using the reverse SSO line-blot assay. Allele assignment was performed using the Helmberg score software with reference to the current nomenclature report and current literature<sup>[36-38]</sup>. Ambiguities were resolved following sequencing of amplicons obtained after SSP with appropriate primers.

### First follow-up screening

At the first follow-up assessment, conducted in December 2005, all antibody-positive subjects and subjects with histories suspicious for celiac disease underwent comprehensive re-examination. A total of 20 subjects were invited, of whom 14 (70%) participated (Figure 1). Subjects completed a diet and digestive symptoms questionnaire, antibody levels were rechecked and laboratory parameters routinely assessed in the work-up of celiac disease (blood count, coagulation parameters, iron, ferritin, hepatic enzymes, parathyroid hormone, calcium, magnesium, phos-

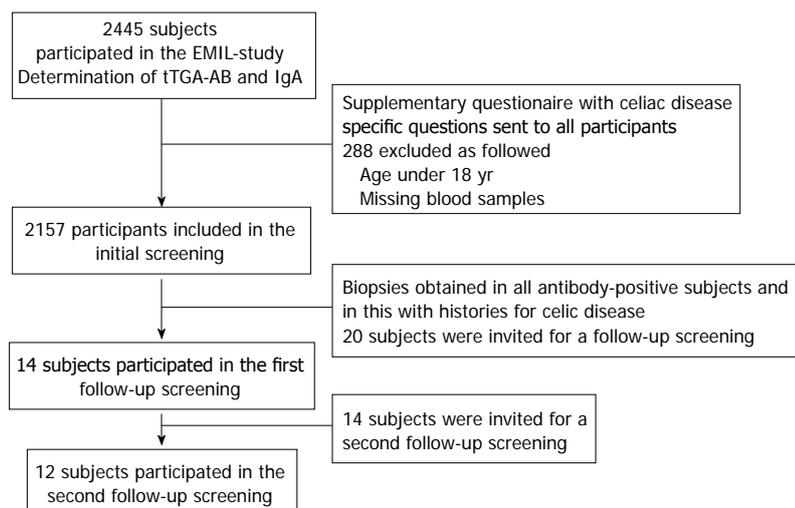

Figure 1 Flow of subjects across the study. tTGA: Tissue transglutaminase antibody; EMIL: Echinococcus Multilocularis and other Internal Diseases in Leutkirch; IgA: Immunoglobulin A.

phate) were obtained.

### Second follow-up screening

As a second follow-up screening, a telephone survey was conducted in March 2008. This survey focused on dietary habits, diet compliance and improvement in symptoms as a result of a gluten-free diet. In this follow-up all celiac positives subjects were included. Also included were the questionable celiac positives. Overall, 12 of 14 (86%) subjects participating in the 2005 follow up were contacted by telephone and re interviewed (Figure 1).

### Statistical analysis

Statistical calculations were performed with the assistance of the Faculty of Medical Documentation and Informatics of the University of Ulm using the SAS statistical software package (version 9.2; SAS Institute Inc., Cary, NC, United States). Data were analyzed descriptively with regard to absolute and relative frequencies, means and standard deviation. Sensitivity and specificity were calculated for all three antibody test methods. Because of the small number of cases, no statistical tests could be applied.

## RESULTS

The study collective available for assessing the prevalence of celiac disease consisted of 2157 subjects (48.0% men, 52.0% women), corresponding to 88% of the total study population. Subjects' age ranged from 18 to 65 years. Their mean age was 42.6 years (standard deviation 12.9 years).

### Initial screening

Fifty-five subjects exhibited a reduced total IgA concentration. However, elevated titers for tTGA IgG were not detected in any of these subjects. A total of 14 subjects (0.65%) were positive for tTGA IgA. Histological findings were available for 11 of these subjects. Celiac disease

was confirmed histologically in five cases (Figure 2).

Six subjects were seronegative but reported histories suspicious for celiac disease (Table 2). Histological findings were available for five of these subjects and confirmed the diagnosis of celiac disease in two cases. In two other subjects, the first diagnosis of celiac disease had already been made at a much earlier date and their histological findings were no longer available. Of these, one subject was HLA positive for DQA1 0101, DQB 0501 and was considered positive for celiac disease in our statistical analysis. The second subject was HLA negative for celiac disease and was considered negative for celiac disease in our statistical analysis (Figure 2). Thus, celiac disease was present in eight subjects, confirmed by biopsy in seven cases and by HLA typing in one case.

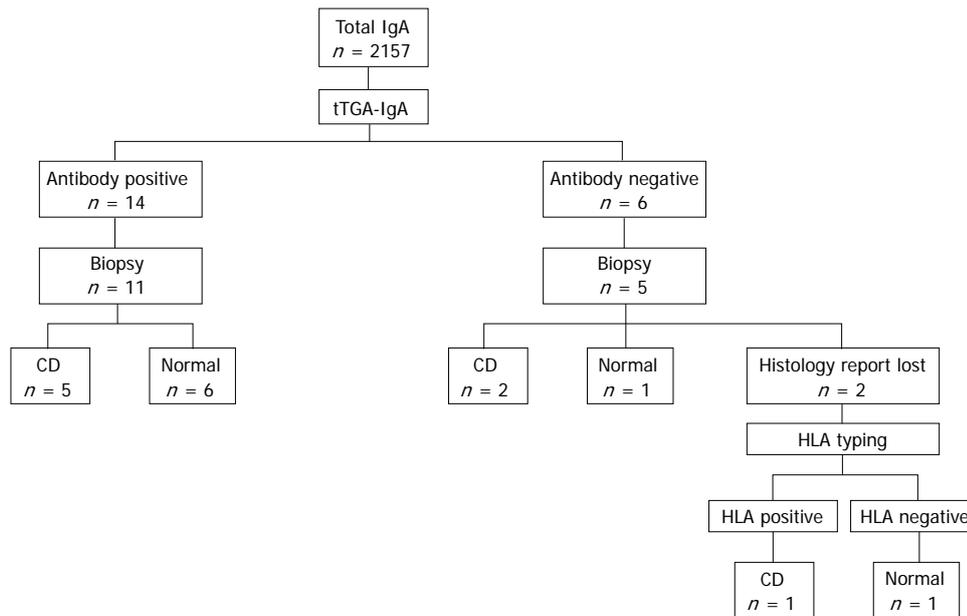

The sensitivity for tTGA IgA antibodies was 62.5%, with a specificity of 50.0%. EMA was associated with a sensitivity and specificity of 62.5% and 71.4%, respectively; and AGA with sensitivity and specificity of 62.5% and 71.4%, respectively. Confirmed false-negative findings were returned for tTGA IgA antibody in three cases, while false positive findings were documented in four cases. Both EMA and AGA were false negative in two cases and false positive in one case (Table 3).

### First follow-up screening

Fourteen of 20 invited subjects participated in the first follow-up screening, corresponding to a participation rate of 70%. tTGA IgA antibodies were detected in three subjects. AGA titers were definitely positive in two subjects. Two subjects were again positive for EMA. Of the six subjects who were initially seronegative but with histories suggestive of celiac disease, three took part in the first follow-up screening: of these, one exhibited positive AGA findings.

### Second follow-up screening

The participation rate at the second follow-up screening stood at 86%, 12 of 14 subjects being reached by tele-

phone and amenable to participation in the standardized interview. Five of eight subjects in our collective had developed classic celiac disease. All subjects maintained a gluten-free diet and reported significant improvement in their intestinal symptoms (Tables 3 and 4). Two further subjects developed atypical celiac disease, which is characterized by mild, atypical symptoms. One subject was monosymptomatic, exhibiting only psoriasis. Subjects were antibody positive and histology revealed changes consistent with Marsh 0-IIIc disease. Despite a strict gluten-free diet, the subject did not report any improvement in his psoriasis (Tables 3 and 4).

The second, female subject was completely asymptomatic. Lactose intolerance was suspected from the subject's history and she avoided all corresponding foods. The subject was antibody positive and histology was consistent with Marsh IIIc disease. Because she continued to be asymptomatic, the subject refused to maintain a gluten-free diet (Tables 3 and 4).

Transient celiac disease was diagnosed in one of the eight subjects. In this disease form, a gluten-free diet leads to complete remission. In this subject, celiac disease had been first diagnosed when she was nine months of age. The subject maintained a strict gluten-free diet until her sixth year; subsequent gastroscopic monitoring failed to return evidence of celiac disease. Since that time, the subject has returned to a diet containing gluten. The subject was negative for DQ2 and DQ8 at HLA typing, but returned positive findings for DQA1\*0101 and DQB1\*0501. This HLA pattern is observed in rare cases in patients with celiac disease. Lactose intolerance was diagnosed in 2004. Gastroscopy performed under the impetus of the present study revealed no evidence of celiac disease. Negative antibody titers during gluten exposure and biopsy findings consistently negative for celiac disease both initially and during the patient's subsequent course correspond to the subtype of transient celiac disease. Based on these HLA findings and improvement in

symptoms subsequent to starting a gluten-free diet, this patient was considered positive for celiac disease despite lack of initial histological findings.

No other autoimmune disorders were found in our collective of patients with celiac disease. Abnormal laboratory findings suggestive of celiac disease were only moderately pronounced. None of the subjects exhibited iron deficiency anemia. Parathyroid hormone levels were elevated in two subjects with celiac disease.

## DISCUSSION

To date, very few studies have prospectively investigated the prevalence of celiac disease in representative, population-based samples (Table 1). In fact, no corresponding data from a population-based study of adults are available for Germany.

The EMIL study was designed as a cross-sectional investigation in order to obtain a collective that most closely represented the general population. By contrast, a large number of recent studies<sup>[11-19]</sup> have drawn their collectives from blood donors, who are not necessarily representative of a population. A few other studies have investigated non-population representative collectives<sup>[20-24]</sup>.

Our findings correspond to a prevalence of 1:270 (0.37%) for adults in an urban population in Germany. Other population-based studies have reported prevalences between 0.18% and 2.4%<sup>[1-10]</sup>, while, for blood donor collectives, prevalences of 0.15%-2.7%<sup>[11-19]</sup> have been reported. Henker *et al.*<sup>[39]</sup> report a prevalence of 0.19% for asymptomatic celiac disease in children and blood donors. In another study, the same authors report a prevalence of 0.044% in children<sup>[40]</sup>. In a study of the incidence of celiac disease in Berlin, Sandforth *et al.*<sup>[41]</sup> report an incidence rate of 0.05%. Because of the nature of the collectives, however, these data cannot be compared with our findings. In fact, only one study (Monika Project) retrospectively investigated a representative population-based sample in Germany<sup>[10]</sup>. The prevalence of 0.3% reported

in that study is comparable to our findings.

Mustalahti *et al.*<sup>[10]</sup> identified large variability in the prevalence of celiac disease between European nations (Finland, 2.4%; Germany, 0.3%; Italy, 0.7%). Although the precise cause of this difference remains unclear, genetic and environmental factors have been discussed. The study by Mustalahti *et al.*<sup>[10]</sup> must be assessed critically due to its retrospective nature and the quality of the blood samples.

The antibody test methods utilized in the present study to assess for celiac disease have been shown in a comparison of 34 studies to possess both high sensitivity and quite good specificity (tTG-IgA: 93% *vs* 98%, EMA 93% *vs* 99%)<sup>[42]</sup>. The test method for AGA was associated with a lower sensitivity and specificity (80% *vs* 80%-90%)<sup>[43]</sup>. In contrast to these results, Dickey *et al.*<sup>[44]</sup> and Rostami *et al.*<sup>[45]</sup> report a lower sensitivity for AGA and EMA. The results of these tests depend on the severity of mucosal damage. If the damage is slight, the test results may be negative<sup>[45]</sup>. As a consequence, the prevalence of celiac disease is not only underestimated but treatment of affected individuals is delayed, which may be associated with an increased risk of malignancy<sup>[46]</sup>. Compared with data published by Lewis *et al.*<sup>[42]</sup>, the present study found a lower sensitivity (62.50%) and specificity (50%) for tTGA IgA antibody. In the present study, EMA and AGA showed comparably a high sensitivity (62.5%) and specificity (71.4%).

The findings of the present study suggest that the use of tTGA IgA antibody as a suitable method for screening a population for celiac disease should be reconsidered<sup>[42,47]</sup>. It was only by means of our follow-up examinations that we were able to identify subjects with celiac disease with false-negative antibody titers. Otherwise, the prevalence of celiac disease in our collective would have been too low. With the 50% response rate to our celiac disease questionnaire, it cannot be excluded that there may be other undetected false-negative antibody results. A definite conclusion regarding the reliability of this antibody test method is difficult: on the one hand, the number of patients in the different collectives is very small; also, there have been only very few studies to date in which all antibody-positive patients have been biopsied<sup>[2,8,23]</sup>.

Quantitative video capsule endoscopy has been described in the literature as a new method in diagnosing celiac disease<sup>[48,49]</sup>. The findings of these studies show that quantitative image analysis corresponds to the degree of villous atrophy. These studies, however, show some limitations; hence, the value of this new method must be investigated in further studies.

A limiting factor in the present study certainly relates to the study design itself. The EMIL study was not originally conceived to determine the prevalence of celiac disease. As a result, all study participants had to be sent a questionnaire following completion of the initial EMIL study, the response rate to which stood at only 50%. A further disadvantage is the inclusion in our collective of patients who had already been diagnosed with celiac

**Table 4 Clinical presentation, histology and human leukocyte antigen findings in subjects with celiac disease**

disease. Also problematic is the impact on the standardization of examination conditions of the retroactive refocusing of the study on determining the prevalence of celiac disease. Patients were referred for endoscopy to several gastroenterologists in private practice in Leutkirch. Biopsies returned between one and seven tissue samples. The histological assessment of the biopsy material was performed by pathologists in different centers.

In conclusion, the findings of the present study show a prevalence of 0.37% for celiac disease, which is comparable to that reported in other European studies. The use of a combination of several antibody test methods for screening examinations appears useful.

## ACKNOWLEDGMENTS

## COMMENTS

### Background

Celiac disease may present with typical clinical signs or patients may be oligo-symptomatic or completely asymptomatic. It is associated with specific, often serious complications. As all forms of celiac disease yield the same risk for complications and especially T cell lymphoma, it is paramount to detect not only the classical form but also patients with atypical disease manifestation.

### Research frontiers

Prevalence rates for celiac disease vary for different populations. This may also be due to the scarcity of data from representative samples. Serological antibody

tests constitute the most important screening tools. In the literature the sensitivity and specificity of transglutaminase immunoglobulin-A, endomysium antibody and antigliadin antibody tests differ.

### Innovations and breakthroughs

This is the first study to prospectively assess the prevalence of celiac disease in a representative population sample of adults in Germany. In comparison to results of the small bowel biopsy the sensitivity and specificity of serological antibody tests for celiac disease were lower than previously described in the literature.

### Applications

Their results add to an accurate estimate of the prevalence of celiac disease in the general population. The use of a single antibody test for screening purposes must be called into question.

### Peer review

Data over recent years have generally noted increased recognition and diagnosis of celiac disease (CD), with rates approaching 2% in some settings. Rates however, appear to vary between geographical regions. This study based in one German city examined several serological tests and gastroenterology symptoms in a large population of adults. The determined prevalence of less than 0.5% is consistent with some previous data, but substantially less than rates in other countries. Interestingly, only 2 of these 2157 adults had previously been thought to have CD, emphasising that CD is often not recognised in routine clinical practice.

### Abstract

**AIM:** The effects of vitamin D3 have been investigated on various tumors, including colorectal cancer (CRC). 25-hydroxyvitamin-D3-24-hydroxylase (CYP24A1), the enzyme that inactivates the active vitamin D3 metabolite 1,25-dihydroxyvitamin D3 (1,25-D3), is considered to be the main enzyme determining the biological half-life of 1,25-D3. During colorectal carcinogenesis, the expression and concentration of CYP24A1 increases significantly, suggesting that this phenomenon could be responsible for the proposed efficacy of 1,25-D3 in the treatment of CRC. The aim of this study was to investigate the anti-tumor effects of vitamin D3 on the human

CRC cell line Caco-2 after inhibition of the cytochrome P450 component of CYP24A1 activity.

**METHODS:** We examined the expression of CYP24A1 mRNA and the effects of 1,25-D3 on the cell line Caco-2 after inhibition of CYP24A1. Cell viability and proliferation were determined by means of sulforhodamine-B staining and bromodeoxyuridine incorporation, respectively, while cytotoxicity was estimated via the lactate dehydrogenase content of the cell culture supernatant. CYP24A1 expression was measured by real-time reverse transcription polymerase chain reaction. A number of tetralone compounds were synthesized to investigate their CYP24A1 inhibitory activity.

**RESULTS:** In response to 1,25-D3, CYP24A1 mRNA expression was enhanced significantly, in a time- and dose-dependent manner. Caco-2 cell viability and proliferation were not influenced by the administration of 1,25-D3 alone, but were markedly reduced by co-administration of 1,25-D3 and KD-35, a CYP24A1-inhibiting tetralone. Our data suggest that the mechanism of action of co-administered KD-35 and 1,25-D3 does not involve a direct cytotoxic effect, but rather the inhibition of cell proliferation.

**CONCLUSION:** These findings demonstrate that the selective inhibition of CYP24A1 by compounds such as KD-35 may be a new approach for enhancement of the anti-tumor effect of 1,25-D3 on CRC.

## INTRODUCTION

Epidemiologic studies have suggested that maintenance of an adequate level of vitamin D may reduce the incidence and development of several types of tumors, including breast, prostate and colorectal cancers (CRC)<sup>[1-4]</sup>. The role of vitamin D deficiency in the development of CRC, and the potential use of vitamin D in the treatment of CRC have been the focus of a number of studies, as CRC is one of the most common cancers<sup>[5]</sup>.

There is a vast array of evidence suggesting a protective effect of vitamin D against CRC<sup>[6-8]</sup>. There is an inverse association between the serum level of 25-hydroxy vitamin D3 (25-D3) and the risk of CRC<sup>[1,9]</sup>. In ulcerative colitis, low expression of the vitamin D receptor (VDR) is associated with an elevated risk of the development of CRC<sup>[10]</sup>. An inadequate dietary intake of vitamin D and a vitamin D deficiency promote the development and growth of CRC in mice<sup>[3,11]</sup>. In elderly women, higher plasma levels of 25-D3 are accompanied by a lower risk of CRC<sup>[12]</sup>. Further studies have shown that vitamin D may have a preventive role not only in CRC, but also in other cancers of the alimentary tract<sup>[13]</sup>. Nevertheless, the exact cellular pathway for the putative anti-tumor effect of vitamin D remains unclear. The action of 1,25-dihydroxyvitamin-D3 (1,25-D3) through the nuclear VDRs is delayed, but the immediate responses triggered from the cell by cytosolic VDRs acting through Ca<sup>2+</sup> influx might also play an important role in this process<sup>[14]</sup>. However, the application of 1,25-D3 in tumor treatment is restricted due to its tendency to cause hypercalcemia<sup>[15]</sup>.

The anti-tumor efficacy of vitamin D in tumor cell cultures is somewhat contradictory<sup>[16-19]</sup>. Some cancer cell lines are more susceptible to vitamin D treatment than others<sup>[19,20]</sup>, and the vitamin D-sensitive cell cultures have been shown to resemble early-stage tumors<sup>[20]</sup>. During the progression of the cancer, this susceptibility is gradually lost, but the underlying pathophysiological process of this loss is not clear. Though numerous clinical studies have been conducted with vitamin D or its analogs, the anti-tumor results were largely disappointing<sup>[21]</sup>. The current evidence suggests that a relationship does exist between vitamin D and cancer, but the strength of this relationship appears to weaken on progression from the preclinical to the clinical situation<sup>[22]</sup>. Thus, further examinations are needed to identify factors influencing the anti-tumor effect of vitamin D on tumor cells.

The mitochondrial enzyme cytochrome P450 component of 25-hydroxyvitamin-D3-24-hydroxylase (CYP24A1), which is the major 1,25-D3-inactivating enzyme, is considered to be an essential factor determining the biological half-life of 1,25-D3. Previous immunohisto-

chemical studies have shown that the level of CYP24A1 rises significantly as the course of colorectal carcinogenesis progresses<sup>[20,23]</sup>. This fact might explain why 1,25-D3 cannot exert its anti-tumor effect in many pathological situations. It has also been demonstrated that the higher the level of CYP24A1, the more malignant the CRC<sup>[24]</sup>. A concomitantly increased expression of the proliferation marker Ki-67 in human CRC samples suggests that the overexpression of CYP24A1 reduces the local availability of 1,25-D3, and hence its antiproliferative effect<sup>[24]</sup>. Other mechanisms to may be involved in the development of 1,25-D3 insensitivity such as the downregulation of the VDRs<sup>[25]</sup>.

In the present study, we set out to investigate the effects of 1,25-D3 on CRC cells after the inhibition of CYP24A1 activity.

## MATERIALS AND METHODS

### CYP24A1 inhibitors

The ability of tetralones to inhibit CYP24A1 is less than that of theirazole counterparts, but a greater degree of selectivity can be achieved with tetralones through the mechanism of their binding to the active site. Instead of binding to the heme iron, they interact with the active site if the enzyme through hydrogen bonds and van der Waals forces<sup>[26]</sup>. Thirteen new 2-substituted-benzyl-6-methoxy-1-tetralones synthesized in the Department of Organic Chemistry in Szeged were utilized in the present study.

The method employed for the preparation of the tetralones<sup>[27]</sup> involved the condensation of commercially available 6-methoxy-1-tetralone with benzaldehyde or a substituted benzaldehyde (Figure 1). 6-methoxy-1-tetralone (1) was dissolved in 4% ethanolic KOH solution, the appropriate benzaldehyde (2a-m) was added, and the reaction mixture was stirred at room temperature for 1-8 h until the starting material had disappeared (thin layer chromatography monitoring), and then allowed to stand overnight. The precipitate that formed was filtered off, washed with water, purified by flash chromatography on silica gel, and recrystallized from ethanol. The synthesis of the hydroxy derivative necessitated initial protection of the hydroxy group in the 4-hydroxybenzaldehyde with a tetrahydropyranyl group, which was stable under the basic ethanolic KOH condensation conditions. The protecting group was removed by heating with aqueous hydrochloric acid in a mixture of ethyl acetate and ethyl methyl ketone. In the next step, the 2-substituted-benzylidene-6-methoxy-1-tetralones (3a-m) were dissolved in ethyl acetate, and hydrogenated at 1 atm in the presence of Pd/C as catalyst for 1 h at room temperature. The catalyst was subsequently removed by filtration through a bed of silica gel, the solvent was evaporated *in vacuo*, and purification by flash chromatography on silica gel furnished the 2-substituted-benzyl-6-methoxy-1-tetralones (4a-m).

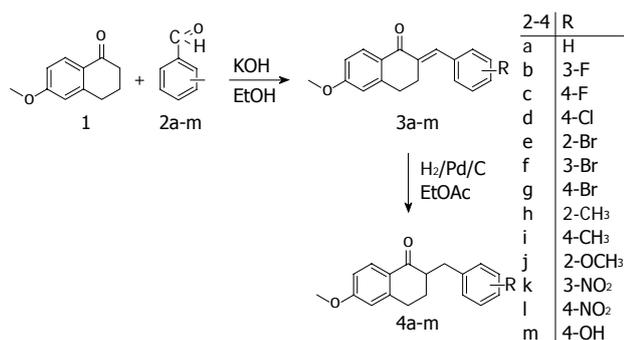

Figure 1 Outline of the procedure for the synthesis of the tetralones.

The resulting tetralones were dissolved individually in dimethyl sulfoxide at a concentration of 10 mmol/L and stored at 4 °C until use. In cell culture experiments, compounds (4a-m) were dissolved in sterile culture medium (GIBCO's OPTI-MEM, Life Technologies-Invitrogen, Carlsbad, CA, United States) to the desired concentration. 1,25-D3 at 1 and 10 nmol/L and an untreated control were also applied in these experiments.

### Cell culturing

The human epithelial colorectal adenocarcinoma cell line Caco-2 obtained from ECACC was maintained in Dulbecco's Modified Eagle Medium (D-MEM, Sigma, St. Louis, MO, United States) supplemented with 10% fetal calf serum (FCS, Sigma) and 1% antibiotic, antimycotic solution (Sigma) at 37 °C in a humidified atmosphere containing 5% CO<sub>2</sub>. Cells were cultured in 6-, 24- and 96-well plates, and all measurements were carried out in triplicate. The cell line was genotyped and identified as Caco-2 in 2011 on the basis of the results of STR analysis (DSMZ Profile Database, www.dsmz.de). Twenty-four hours before treatment, the medium was changed to GIBCO's OPTI-MEM (Life Technologies-Invitrogen, Carlsbad, CA, United States). All experiments were carried out with cells from passages 5-25.

### Cell viability assay

The protein dye sulforhodamine-B (SRB), was used to test various tetralone derivatives in various concentrations for various incubation times in 96-well plates to determine the effects of the compounds alone and in the presence of 1,25-D3 on the Caco-2 cell number. After removal of the culture medium, 100 µL of trichloroacetic acid was used to fix the cells during an incubation period of 30 min. The plates were then rinsed 5 times with distilled water. The cells were stained with a 0.4% solution of SRB (Sigma) in acetic acid for 30 min. After removal of the excess dye solution the plates were rinsed 4 times with 1% acetic acid solution and allowed to dry at room temperature. The bound SRB was dissolved in unbuffered Tris-Sol and the plates were shaken for 5 min. The plates were measured in an Infinite M200 reader (Tecan AG, Männedorf, Switzerland) at 520 nm.

### Cytotoxicity measurement

Levels of cytotoxicity were quantified after treatment through measurement of the lactate dehydrogenase (LDH) levels in the wells by using the Cytotoxicity Detection Kit<sup>PLUS</sup> (Roche, Indianapolis, IN, United States). The greater the number of cells that die due to the cytotoxic effect, the higher the amount of LDH in the medium. The experiments were carried out in accordance with the kit manufacturer's instructions.

### Cell proliferation assays

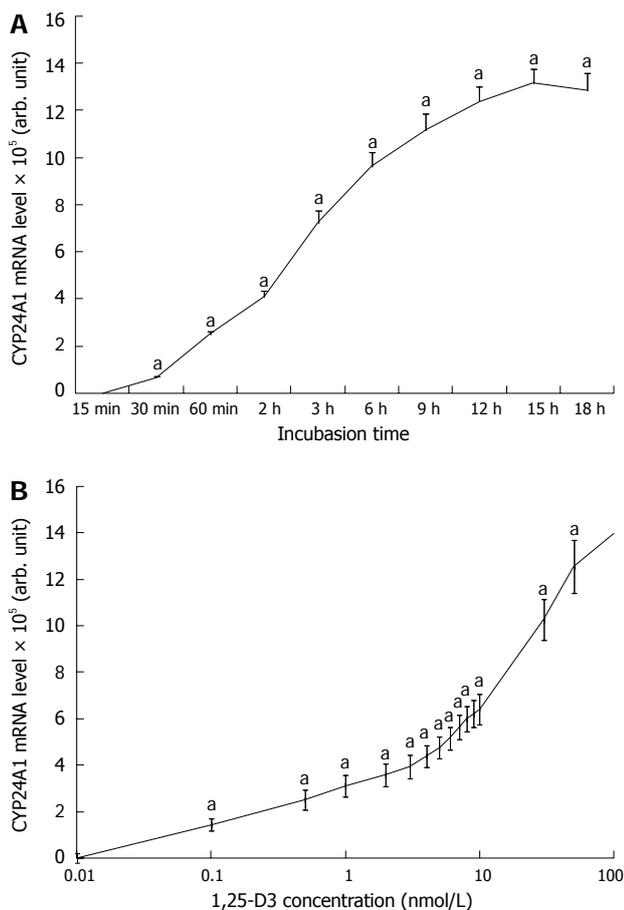

Cell proliferation was quantified by measurement of the incorporation of 5-bromo-2'-deoxyuridine (BrdU) into the cellular DNA by means of Cell Proliferation enzyme-linked immunosorbent assay, BrdU (colorimetric) (Roche). The experiments were carried out in accordance with the manufacturer's instructions.

### RNA isolation and Taqman probe-based real-time RT-PCR

RNA was isolated through use of the High Pure RNA Isolation Kit (Roche) as prescribed in the manufacturer's instructions. The isolated RNA was translated by using Moloney murine leukemia virus reverse transcriptase in accordance with the manufacturer's instructions (Promega, Madison, WI, United States). Predesigned and validated gene-specific TaqMan Gene Expression Assays from Life Technologies (Life Technologies, Foster City, CA, United States) were used in triplicate for quantitative real-time polymerase chain reaction (PCR) according to the manufacturer's protocol. Each set contained gene-specific forward and reverse primers and fluorescence-labeled probes. The probes span an exon junction and do not detect genomic DNA [ABI Taqman assay No's are hs00167999\_m1 and hs99999905\_m1, for CYP24A1 and glyceraldehyde-3-phosphate dehydrogenase (GAPDH), respectively]. The PCR assays were carried out with the following protocol: denaturation for 10 min at 95 °C, and 45 cycles of denaturation for 15 s at 95 °C, annealing and extension for 1 min at 60 °C. The PCR reaction volume of 20 µL contained 2 µL cDNA, 10 µL of TaqMan 2x Universal PCR Master Mix NoAmpErase UNG (Life Technologies), 1 µL of gene-specific TaqMan Gene Expression Assay Mix and 7 µL of water. GAPDH was used as a housekeeping gene to normalize for RNA loading. Samples were analyzed using the ABI Prism 7500 real-time PCR system (Life Technologies). Relative quantification (RQ) studies were carried out on collected data (threshold cycle numbers, referred to as Ct) with the 7500 System SDS software 1.3 (Life Technologies).

### Statistical analysis

Data were analyzed by using SPSS for Windows, release 18 (IBM, Armonk, NY, United States). Final data are presented as the means ± SD of at least three independent measurements. Statistical analysis was performed with the unpaired Student *t*-test; results with *P* ≤ 0.05 were con-

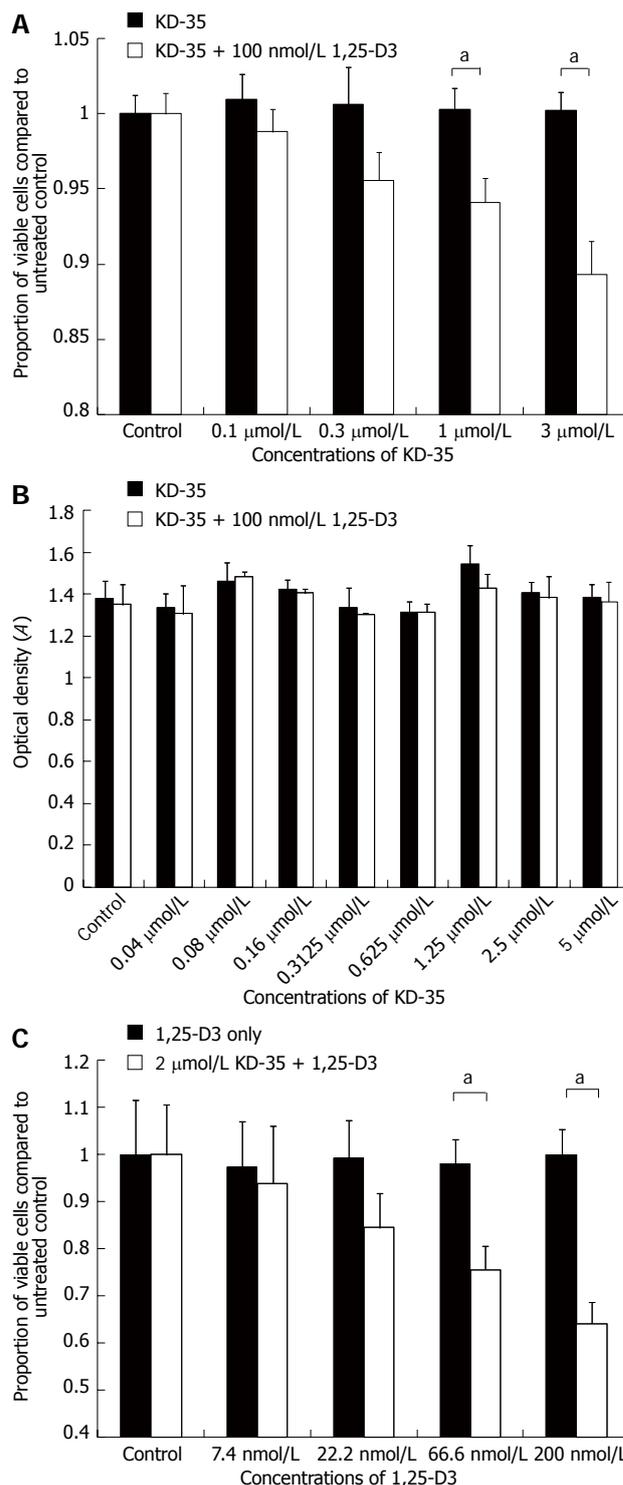

**Figure 2** Time and dose dependent-changes in CYP24A1 mRNA expression in response to 1,25-D3 administration. **A:** Time course of changes in the cytochrome P450 component of the 25-hydroxyvitamin D3-24-hydroxylase (CYP24A1) mRNA expression in Caco-2 cells after the addition of 100 nmol/L active vitamin D3 metabolite 1,25-dihydroxyvitamin D3 (1,25-D3) to the cell culture supernatant. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH)-normalized CYP24A1 expression levels are shown as a percentage of the CYP24A1 level of the untreated control cells. Points indicate means ± standard deviation (SD) (<sup>a</sup>*P* < 0.05 vs untreated control); **B:** Dose-dependent changes in CYP24A1 mRNA levels in Caco-2 cells after the addition of different amounts of 1,25-D3. GAPDH-normalized CYP24A1 expression levels are shown as a percentage of the CYP24A1 level of the untreated control cells. Points indicate means ± SD (<sup>a</sup>*P* < 0.05 vs untreated control).

sidered statistically significant.

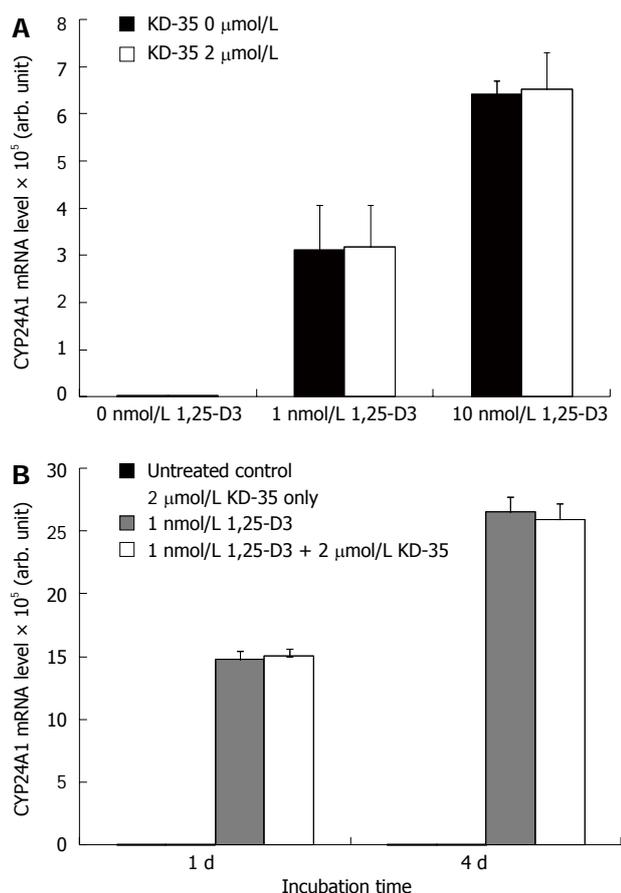

## RESULTS

### Time and concentration-dependent changes in CYP24A1 mRNA expression after vitamin D3 treatment

An increase in CYP24A1 mRNA level of six orders of magnitude was observed after a brief period of 1,25-D3 treatment. The increase in CYP24A1 mRNA expression was very rapid and it could be observed after 30 min of 1,25-D3 administration, and reached a maximum after 12-16 h of incubation (Figure 2A). After 4 h of incubation in the presence of 1 and 10 nmol/L 1,25-D3, the level of CYP24 mRNA was elevated to 311405-fold and 612801-fold, respectively, relative to the untreated controls (Figure 2B).

**Figure 3** Cell proliferation, lactate dehydrogenase activity and proliferation studies in the presence of KD-35 and 1,25-D3. **A:** Changes in the number of viable Caco-2 cells (sulforhodamine-B staining) in the presence of different concentrations of KD-35. Selected wells were treated with 100 nmol/L active 1,25-D3. Data are means ± SD (<sup>a</sup>*P* < 0.05 between KD-35 and KD-35 + 1,25-D3 treated cells); **B:** Changes in the lactate dehydrogenase (LDH) activity of the cell culture supernatant in response to KD-35 with or without 1,25-D3. Data are means ± SD. No significant changes in LDH activity were seen after treatment; **C:** Changes in the proliferation of Caco-2 cells (5-bromo-2'-deoxyuridine incorporation) in response to different concentrations of 1,25-D3. White bars indicate combined treatment with the given 1,25-D3 concentration + 2 μmol/L KD-35. Data are means ± SD. Significance levels were calculated between each sample and the untreated control sample (<sup>a</sup>*P* < 0.05 between 1,25-D3 and 1,25-D3 + KD-35 treated cells).

**Figure 4** KD-35 has no effect on CYP24A1 mRNA expression. A: Changes in CYP24A1 mRNA levels in Caco-2 cells incubated with different concentrations of 1,25-D3 for 4 h with or without KD-35. Data are means  $\pm$  SD. No significant changes in mRNA levels were seen with or without KD-35; B: Effects of KD-35 and KD-35 + 1,25-D3 on CYP24A1 mRNA expression in Caco-2 cells. Data are means  $\pm$  SD. No significant change in mRNA levels was seen with or without KD-35 at any time point.

#### Effects of tetralone derivatives on Caco-2 cell line

Certain of the tetralones were found to decrease the Caco-2 cell viability but only after 2-4 d of incubation with 1,25-D3. These compounds were tested at various concentrations for various periods to optimize the effect of 1,25-D3 in reducing the total Caco-2 cell count. Finally, compound KD-35 was selected for further and detailed investigations.

#### Effects of KD-35 on Caco-2 cell line

When Caco-2 cells were incubated for 4 d in the presence of 100 nmol/L 1,25-D3 with 0.1, 0.3, 1 or 3  $\mu$ mol/L KD-35, the cell number was reduced by 2.17%, 5.07%, 6.18% and 10.93%, respectively, relative to the controls treated with only 100 nmol/L 1,25-D3 or 3  $\mu$ mol/L KD-35 (Figure 3).

#### Results of the cytotoxicity test

To determine the cause of the decrease in viable cell number in the presence of KD-35 and 1,25-D3, we measured LDH concentration in the cell suspension. The concentration of KD-35 ranged between 0.04  $\mu$ mol/L

and 5  $\mu$ mol/L. Half of the wells were treated with KD-35 and 100 nmol/L 1,25-D3, the other half were treated with KD-35 only. All experiments were carried out in triplicate. Incubation lasted for 4 d. In all of the experimental setups, the LDH concentrations did not differ significantly in the presence of KD-35 alone or in combination with 1,25-D3 (Figure 3).

#### Results of the cell proliferation assay

In the presence of 2  $\mu$ mol/L KD-35, the following concentrations of 1,25-D3 were used: 7.4, 22.2, 66.6 and 200 nmol/L. Half of the wells were treated only with 2  $\mu$ mol/L KD-35. Incubation lasted for 4 d. After incubation, the 5-BrdU label was added for an additional 2 h. The reduction in cell number relative to the control was 3.43%, 14.81%, 22.49% and 35.81%, respectively, compared to the wells with 1,25-D3 only (Figure 3).

#### Changes in CYP24A1 mRNA expression

The amount of CYP24A1 mRNA expressed in the presence of various concentrations of KD-35 did not differ from that of the untreated controls. The CYP24A1 mRNA expression did not depend significantly on the duration of incubation with KD-35 (Figure 4).

## DISCUSSION

We have identified a new tetralone compound, KD-35, that effectively and markedly stimulates the anti-proliferative effect of 1,25-D3 in the CRC cell line Caco-2.

CYP24A1, a member of the cytochrome P450 (CYP450) enzyme superfamily is the key enzyme in the metabolism of vitamin D neutralizing the active metabolite 1,25-D3, and thereby controlling its concentration in the tissues. The CYP450 enzymes all display an iron-containing heme domain at the active site. There are two types of enzyme blockers: azoles and non-azoles<sup>[28]</sup>. The *N*-heterocyclic ring of azoles is linked directly to the iron in the heme domain and, although this inhibition is very potent, it is not selective. Since the other enzymes involved in vitamin D metabolism (CYP27A1 and CYP27B1) are also members of the CYP450 superfamily, this type of nonselective inhibition is not specific for CYP24A1.

The enzyme inhibitory effect of non-azoles is mediated through hydrogen bonds and hydrophobic interactions with the active site of the enzyme. This is a more flexible mechanism which may permit significant selectivity though the inhibitory effect may be less than that of azoles<sup>[20]</sup>. We investigated 13 tetralones (non-azoles) in a search for a compound that is effective locally in the colon and is not strongly absorbed, so that the risk of adverse systemic effects is minimized.

Most of the 13 tetralones were either toxic or ineffective, even in the presence of 1,25-D3. Only in the presence of KD-35 did 1,25-D3 markedly inhibit Caco-2 cell proliferation without pronounced cytotoxicity of the tetralone alone. Such inhibition was not observed in the absence of KD-35. Unfortunately, two of the three

most effective tetralones exhibited much higher cytotoxicity at higher concentrations than KD-35. The question arises as to whether KD-35 exerts its effect *via* CYP24A1 inhibition. We did not measure CYP24A1 enzyme activity directly since this is technically extremely difficult. It is also complicated to measure the intermediates of the CYP24A1 reaction. Moreover, a simple enzyme kinetic measurement would not reveal whether the compound enters the cell. We therefore chose an indirect approach: to prove the biological efficacy of the compound. KD-35 was found to exert an effect that allowed 1,25-D3 to reduce Caco-2 cell proliferation effectively, as reflected by an altered BrdU incorporation. Direct cytotoxicity was excluded by the LDH measurements, and no change in CYP24A1 mRNA expression was detected in response to KD-35, which ruled out alterations in protein synthesis. Obviously, no direct evidence was obtained to support direct enzyme inhibition, but an alternative mechanism is highly unlikely with this non-azole.

Two major pathways are mediated through the VDRs: the Wnt-beta-catenin pathway, which is responsible for the loss of adherent cell type, and the E-cadherin pathway, which is responsible for cell-to-cell adhesion and cell differentiation<sup>[29,30]</sup>. The administration of 1,25-D3 suppresses the Wnt-beta-catenin pathway and induces the expression of E-cadherin. The Wnt-beta-catenin pathway is constitutionally overregulated in most CRCs, due to the mutation of several members of the pathway (APC, AXIN2, *etc.*)<sup>[29]</sup>. There are other participants in colorectal carcinogenesis, such as estrogen receptors, which elevate the number of VDRs in the mucosal cells of the alimentary tract, or SNAIL, which inhibits the E-cadherin pathway and expression of VDRs<sup>[30-35]</sup>. Another important factor in the mucosal cell transition toward adenocarcinoma is an elevated level of CYP24A1, the intracellular concentration of which correlates with the dignity of the tumor<sup>[24]</sup>.

Our results corroborate the earlier finding<sup>[36]</sup> that the presence of 1,25-D3 dramatically stimulates the expression of CYP24A1 in CRC cells<sup>[24,37]</sup>. Two vitamin D-responsive elements are present in the promoter region of CYP24A1<sup>[38]</sup>. Through this pathway, 1,25-D3 stimulates its own destruction through metabolism into inactive forms by enhancing the expression of CYP24A1<sup>[39]</sup>.

Besides the genomic effects, there have also been reports of immediate nongenomic mechanisms. A possible mode of action is activation of the RhoA-ROCK-p38MAPK-MSK signaling pathway. This pathway mediates the induction of CST5, which is possibly responsible for tumor suppression and the level of CYP24A1; as a negative feedback mechanism, this eliminates 1,25-D3 from the cell<sup>[40]</sup>. VDRs found in other tumor cell membranes may bind 1,25-D3, and the complex could induce a rapid influx of Ca<sup>2+</sup> into the cell<sup>[40]</sup>, which activates RhoA-ROCK and then the p38MAPK-MSK-1 pathway. Besides the nongenomic activation of this pathway, a vitamin D-responsive element can also be identified in the -1k promoter region of the *RhoA* gene (<http://www.cbil.upenn.edu/cgi-bin/tess/tess>).

RhoA plays an important role in the induction of CDH1/E-cadherin, which is crucial for the acquisition of the polarity and adhesive phenotype of cancer cells<sup>[29]</sup>.

In view of these data, the elevation of CYP24A1 expression might be a self-defense mechanism of tumor cells. By inhibiting the inactivating enzyme, the amount of active vitamin D or its analogs required to elicit their marked anti-tumor effect could be reduced *in vivo*, thereby preventing elevation of the serum Ca<sup>2+</sup> level and avoiding hypercalcemia<sup>[36]</sup>. The inhibition of CYP24A1 may allow 1,25-D3 to exert its anti-tumor effect, in this way leading to a new approach in the treatment of CRC in the future.

## COMMENTS

### Background

The effects of vitamin D3 have been investigated on various tumors, including colorectal cancer (CRC). The cytochrome P450 component of 25-hydroxyvitamin D3-24-hydroxylase (CYP24A1), the enzyme that inactivates the active vitamin D3 metabolite 1,25-dihydroxyvitamin-D3 (1,25-D3) is considered to be the main enzyme determining the biological half-life of 1,25-D3. During colorectal carcinogenesis, the expression and concentration of CYP24A1 increases significantly, suggesting that this phenomenon could be responsible for the controversial efficacy of 1,25-D3 in the treatment of CRC. In the present study, authors set out to investigate the effects of 1,25-D3 on CRC cells after the inhibition of CYP24A1 activity.

### Research frontiers

The anti-tumor effect of vitamin D3 has been a focus of interest during the last 10-15 years. However, vitamin D3 cannot exert this important effect in a number of tumors. The reasons for this have been investigated intensively. One possible explanation for the reduced anti-tumor efficacy of vitamin D3 is the accelerated neutralization of the active vitamin D3 compound in certain cases, *e.g.*, CRC, liver and papillary thyroid cancers.

### Innovations and breakthroughs

The authors synthesized a number of compounds potentially able to inhibit the action of CYP24A1, the enzyme neutralizing the effects of vitamin D3. One of these compounds, KD-35, had inhibitory potential without an apparent toxic effect. In the presence of KD-35, vitamin D3 markedly inhibited the growth of CRC cells.

### Applications

Selective inhibition of the CYP24A1 by compounds such as KD-35 may permit a new approach to enhancement of the anti-tumor effect of 1,25-D3 on CRC.

### Peer review

The authors tackled an interesting topic for investigation. The manuscript is investigating the association between CYP24A1 inhibition and anti-tumor effect of 1a, 25-dihydroxyvitamin-D3 in Caco-2 CRC line. A careful assessment was considered using appropriate cell assays. A major finding of the study was that Caco-2 cell viability and proliferation were markedly reduced in response to 1,25-D3 when the CYP24A1 was inhibited (by KD-35, one of the tetralone compounds).

### Abstract

**AIM:** To establish novel intestinal myofibroblast (IMF) cell lines from mouse colonic mucosa and investigate their biological characters.

**METHODS:** Primary IMFs were isolated from mucosal tissues of mouse colon that was denuded of epithelial cells and smooth muscle layer. For immortalization, primary IMFs were transfected with simian virus 40 large T antigen (designated as LmcMF). We also isolated some primary IMFs that spontaneously became immortalized without transfection (designated as SmcMF). To check immortality and normality of these cells, we examined their proliferative ability and contact inhibition. Moreover, the expression levels of proteins characterizing IMFs [including  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA), vimentin, desmin, and type I collagen] and proteins associated with the immune response [such as toll-like

receptor 4 (TLR-4), CD14, MD2,  $I\kappa B\alpha$ , and p-p38] were determined by Western blotting. The localization of several myofibroblast protein markers was also detected by immunofluorescence staining.

**RESULTS:** The cell growth assay results show that both LmcMF and SmcMF cells proliferated logarithmically at least up to passage 20. In addition, the contact inhibition assays show that LmcMF and SmcMF stopped growing after the cells reached confluence. These data suggest that these 2 types of cells were immortalized without losing contact inhibition of growth. Moreover, both LmcMF and SmcMF, like primary IMFs, showed spindle-shaped appearance. The expression levels of key myofibroblast protein markers, including  $\alpha$ -SMA, vimentin, and desmin, were also examined by the Western blotting and immunofluorescence analyses. Our results show that these cells were positive for  $\alpha$ -SMA and vimentin, but not desmin, as well as that both LmcMF and SmcMF expressed type I collagen at a lower level than primary IMFs. Finally, we investigated the expression level of lipopolysaccharide (LPS) receptor-related proteins, as well as the response of the cells to LPS treatment. We found that the TLR4, CD14, and MD-2 proteins were present in LmcMF and SmcMF, as well as in primary IMFs, and that all these cells responded to LPS.

**CONCLUSION:** We established 2 novel IMF cell lines from mouse colonic mucosa, namely, LmcMF and SmcMF, both of which were able to respond to LPS.

## INTRODUCTION

The gastrointestinal mucosa is in contact with the extracorporeal environment and is exposed to various antigens and molecules that are mainly derived from ingested food and commensal bacteria<sup>[1]</sup>. Such antigens do not induce inflammation in healthy individuals, because intestinal epithelial cells form a physical barrier protecting against luminal bacteria and toxic substances. To achieve this protective function, differentiation and proliferation of epithelial cells need to be properly regulated. Accumulating evidence has recently revealed that subepithelial intestinal myofibroblasts (IMFs), which are located subjacent to the epithelium, play crucial roles in regulating epithelial cells<sup>[2-4]</sup>.

IMFs belong to the myofibroblast family, which includes several functionally related cells, such as lung contractile interstitial cells, pancreatic stellate cells, and orbital and synovial fibroblasts<sup>[5]</sup>. IMFs are spindle-shaped or stellate cells that exhibit phenotypic characteristics of both fibroblasts and smooth muscle cells<sup>[6,7]</sup>. In addition, it has been shown that IMFs, like other mesenchymal cells, synthesize collagen<sup>[6,8,9]</sup>. Notably, IMFs orchestrate diverse events in gastrointestinal health and diseases, including epithelial differentiation and development, mucosal repair, carcinogenesis, and inflammatory responses<sup>[3,4,10]</sup>. IMFs express toll-like receptor 4 (TLR-4), which is activated by lipopolysaccharide (LPS), a component of gram-negative bacteria, subsequently leads to secretion of proinflammatory mediators<sup>[10-13]</sup>. Moreover, IMFs, as nonprofessional antigen-presenting cells in the intestinal mucosa, induce proliferation of both resting CD4<sup>+</sup> T cells and regulatory T cells in a major histocompatibility complex (MHC) class II-dependent manner to maintain intestinal mucosal tolerance<sup>[14,15]</sup>. Furthermore, enterotoxins are known to engage MHC class II molecules on IMFs, which in turn leads to secretion of inflammatory mediators<sup>[16]</sup>.

Despite the crucial role of IMFs in gastrointestinal health and diseases, the understanding of their underlying regulatory mechanism is limited. One of the major issues that hinder the advance of IMF research is the lack of IMF cell lines that show myofibroblastic phenotypes without stimulation. Typically, primary IMFs isolated from intestine are used within passages 2-6, because their phenotypes change and the cells stop growing after repeated passages. In addition, CCD-18Co cells, which have been used as a human colon myofibroblast cell line, still need to be treated with transforming growth factor- $\beta$  (TGF- $\beta$ ) for the expression of  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA)<sup>[17]</sup>. In this present study, to address these issues, we separated mouse intestinal myofibroblast cell lines (namely, LmcMF and SmcMF) and examined their properties.

## MATERIALS AND METHODS

### Culture of mouse intestinal myofibroblasts and mouse embryonic fibroblasts

C57BL/6J mice purchased from Charles River Japan

(Yokohama, Japan) were maintained in compliance with the guidelines of the Animal Care and Use Committee of Yamaguchi University. Mouse IMFs were isolated as previously described, with slight modifications<sup>[18]</sup>. Briefly, a segment of the proximal colon was detached from the mesenterium, and mucosal layers were completely denuded of epithelial cells by repeated ( $\times 3$ ) 30-min incubation in 1 mmol/L EDTA-Hanks' balanced salt solution at 37 °C. Subsequently, smooth muscle layers were detached from mucosal layers with tweezers. De-epithelialized mucosal samples were cultured in Dulbecco's Modified Eagle Medium (DMEM; Invitrogen, Tokyo, Japan) containing 100 mL/L fetal bovine serum (FBS) at 37 °C in a 50 mL/L CO<sub>2</sub> atmosphere. Consequently, myofibroblast cells that migrated from mucosal tissues formed colonies. In this study, primary IMFs at passages 2-6 were used. Mouse embryonic fibroblasts (MEFs) isolated from embryos of C57BL/6J mice at embryonic day 11.5 were also grown under the same condition described above.

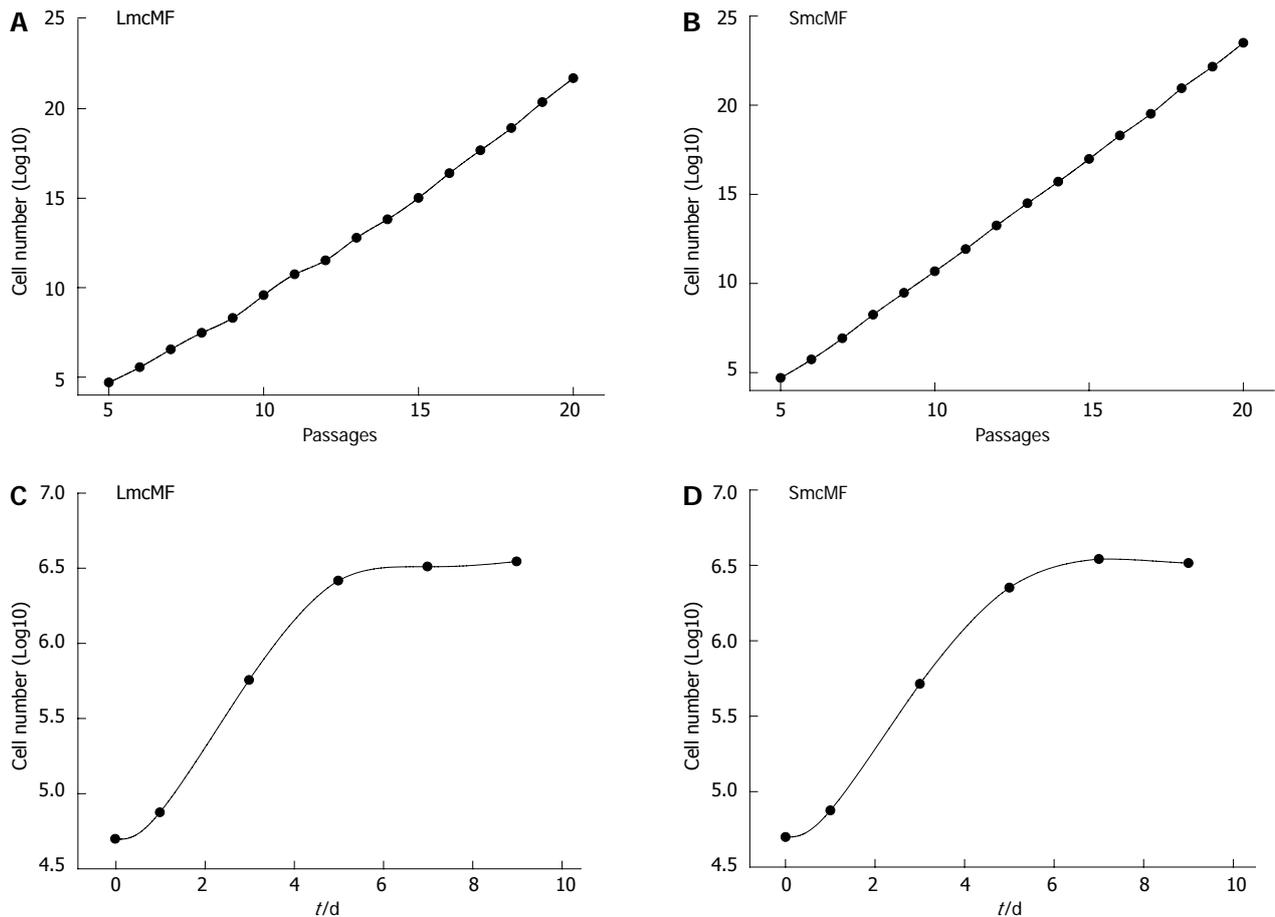

### Antibodies and cell lines

The following antibodies were used in this study: anti- $\alpha$ -SMA and anti-vimentin antibodies from Sigma (Tokyo, Japan); anti-desmin and anti-tubulin antibodies from Thermo Scientific (Yokohama, Japan); anti-TLR4, anti-CD14, and anti-actin antibodies from Santa Cruz (CA, United States); anti-MD2 antibody from AbD Serotec (Kidlington, United Kingdom); anti-I $\kappa$ B $\alpha$  and anti-p-38 antibodies from Cell Signaling (MA, United States); anti-Collagen type I antibody from Merck (Tokyo, Japan); anti-valosin-containing protein (VCP) antibody from Gene Tex (CA, United States); horseradish peroxidase (HRP)-conjugated mouse anti-rabbit Ig Light Chain from ECM biosciences (KY, United States); and HRP-conjugated donkey anti-mouse IgG from R and D Systems (MN, United States). A mouse mammary gland epithelial cell line, Eph4, and a mouse macrophage-like cell line, RAW264.7, were grown in DMEM supplemented with 100 mL/L FBS at 37 °C in a 50 mL/L CO<sub>2</sub> atmosphere.

### Immortalization of IMFs

EGIP-EF1a-Large T-IRES-Puro, a lentiviral plasmid expressing simian virus 40 (SV40) large T antigen (LT) but not small T antigen (ST), was obtained from Addgene (ID No. 18922; MA, United States)<sup>[19]</sup>. Using Lipofectamine LTX (Invitrogen), lentivirus was produced by transfecting Lenti-X 293T cells in 60-mm dishes with 3  $\mu$ g of EGIP-EF1a-Large T-IRES-Puro, 2.3  $\mu$ g of a packaging plasmid (psPAX2), and 1.3  $\mu$ g of a coat protein plasmid expressing vesicular stomatitis virus G protein (pDM2.G). Viral supernatants were collected after 48 h, and filtered (0.22  $\mu$ m). Primary IMFs were infected with virus for 8 h. With puromycin treatment for 6 d, immortalized LT-positive cells were selected and designated as LmcMF.

To obtain spontaneously immortalized IMFs, pri-

**Figure 1** Proliferation and contact inhibition of LmcMF and SmcMF. A, B: The cells were subcultured every 3 d, and the growth rate of LmcMF (A) and SmcMF (B) were assessed as described; C, D: Contact inhibition of LmcMF (C) and SmcMF (D).

many IMFs were repeatedly passaged until cells that kept proliferating emerged. These spontaneously immortalized cells were designated as SmcMF.

### Cell growth and contact inhibition assays

To determine the proliferative ability of IMF cells,  $5 \times 10^4$  cells were plated in 35-mm dishes and passaged every 3 d, and the number of cells was subsequently counted using a hemocytometer. For the contact inhibition assay,  $5 \times 10^4$  cells were plated in 35-mm dishes, and the number of cells was counted on the next day and then every other day.

### Immunofluorescence staining

Primary IMFs, as well as LmcMF and SmcMF, were grown on glass coverslips and subsequently fixed with 4% formaldehyde for 20 min at room temperature. Cells were permeabilized with 0.2% Triton X-100 in PBS-T (PBS containing 0.05% Tween 20) for 60 s and then blocked with 3% skim milk in PBS-T. After incubation with the first antibodies overnight at 4 °C, Alexa594-conjugated secondary antibodies (Alexa Fluor<sup>®</sup> 594 goat anti-mouse IgG or Alexa Fluor<sup>®</sup> 594 donkey anti-goat IgG; Invitrogen) were added and incubated for 1 h at room temperature. Nuclei were counterstained with SYTOX Green (Life Technologies, CA, United States).

Finally, fluorescence images were captured by a confocal laser-scanning microscope (LSM510; Zeiss, Tokyo, Japan).

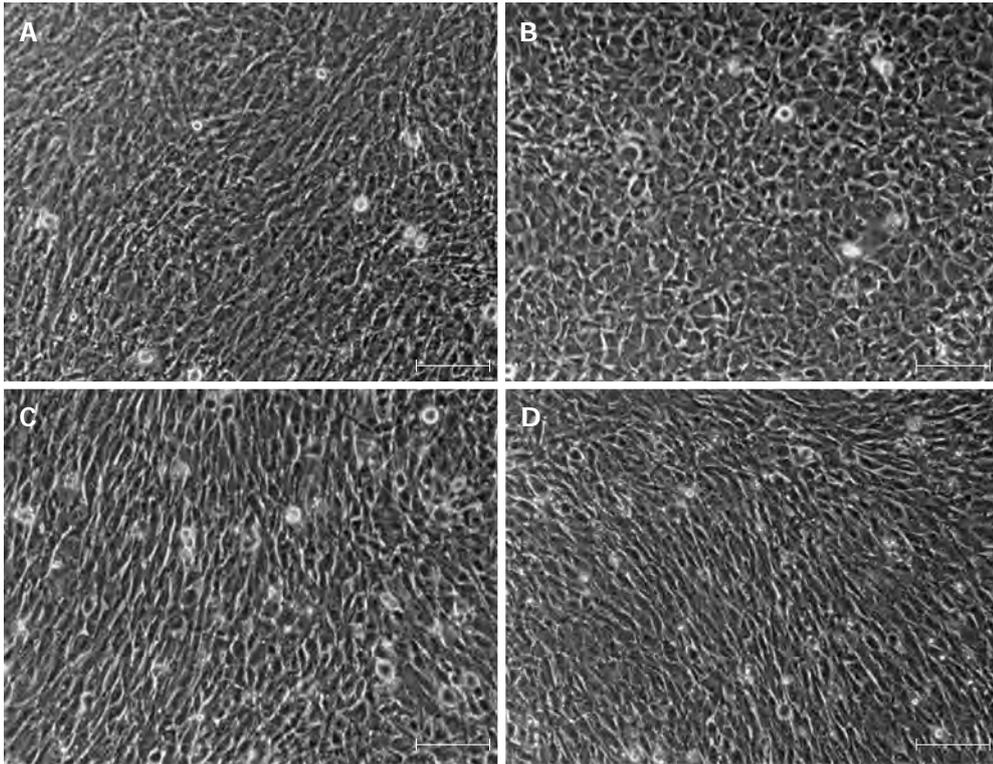

### Western blotting

The western blot analysis was performed as previously described<sup>[18]</sup>. Briefly, cells were lysed in a buffer consisting of 50 mmol/L Tris-HCl (pH 8.0), 5 mmol/L EDTA (pH 8.0), 5 mmol/L EGTA (pH 8.0), 1% Triton X-100, 1 mmol/L Na<sub>3</sub>VO<sub>4</sub>, 20 mmol/L sodium pyrophosphate, and Roche Complete Protease Inhibitor Cocktail (Roche, Tokyo, Japan). Amersham Hybond ECL Nitrocellulose Membranes (GE Healthcare, Buckinghamshire, United Kingdom) were blocked with 0.5% skim milk and treated with specific antibodies. Protein bands were detected using the ECL Western blotting Detection Reagents (GE Healthcare) or the Western Lightning ECL Pro (PerkinElmer, MA, United States) and visualized using a LAS-3000 mini luminescence imager (Fujifilm, Tokyo, Japan).

## RESULTS

### Immortalization of IMFs without losing contact inhibition of growth

First, we investigated the immortalization of 2 differ-

**Figure 2** Phase-contrast microscopic images of primary intestinal myofibroblasts, mouse embryonic fibroblasts, LmcMF, and SmcMF. A: Primary intestinal myofibroblasts; B: Mouse embryonic fibroblasts; C: LmcMF; D: SmcMF were cultured to confluence, and the phase-contrast microscopic images were taken. Representative images are shown. Scale bars indicate 200  $\mu\text{m}$ .

ent IMF cell lines, LmcMF and SmcMF. The cells ( $5 \times 10^4$  cells) were seeded in 35-mm dishes and subcultured every 3 d during the examination of the cell growth rate. As shown in Figure 1A and B, both LmcMF and SmcMF cells proliferated logarithmically at least up to passage 20, and their doubling times were 19.1 and 17.2 h, respectively. Primary IMFs, on the other hand, immediately stopped growing under this experimental condition, since they require a high cell density for proliferation.

For the contact inhibition assay, the cells ( $5 \times 10^4$  cells) were seeded in 35-mm dishes and cultured up to 9 d (Figure 1C and D). The cells became confluent around day 5 and reached the plateau phase by day 6 or 7. These data indicate that LmcMF and SmcMF were immortalized without losing contact inhibition of growth.

#### **LmcMF and SmcMF show myofibroblastic phenotypes**

IMFs have been defined as spindle-shaped or stellate cells that are positive for  $\alpha$ -SMA and vimentin, and very weakly positive or negative for desmin<sup>[7]</sup>. As shown in Figure 2A and B, primary IMFs exhibited spindle-shaped appearance, whereas MEFs were round-shaped. Both LmcMF and SmcMF, like primary IMFs, showed spindle-shaped appearance (Figure 2C and D).

The expression levels of key myofibroblast protein markers, including  $\alpha$ -SMA, vimentin, and desmin, were subsequently examined by the Western blotting and immunofluorescence analyses. We observed that primary IMFs and LmcMF expressed an equivalent amount of

$\alpha$ -SMA, whereas the  $\alpha$ -SMA protein level in SmcMF was relatively low (Figure 3A and B). As expected,  $\alpha$ -SMA was not detectable in the mouse mammary gland epithelial cell line, Eph4, which was used as a negative control. We also found that vimentin was present in both LmcMF and SmcMF, almost at the same level as that in primary IMFs, but was not detectable in the negative control RAW 264.7 cells (Figure 3C and D). Moreover, desmin, though not present in LmcMF, was detected at very low levels in SmcMF, compared to its expression level in intestinal smooth muscle tissues (positive control) (Figure 3E and F). Furthermore, both LmcMF and SmcMF expressed type I collagen, however, at a lower level than that in primary IMFs (Figure 3G). As the negative control, RAW 264.7 cells did not express type I collagen. Overall, these results suggest that LmcMF and SmcMF share almost the same characteristics with intestinal myofibroblasts.

To confirm the expression pattern of  $\alpha$ -SMA and vimentin in IMFs, we next performed the immunofluorescence analysis. In a cell, actin transits between its globular (G-) and filamentous (F-actin) states, and G-actin can be visualized by immunofluorescence microscopy in a spreading pattern, because they are monomeric actin<sup>[20]</sup>. As shown in Figure 4A, we observed strong filamentous  $\alpha$ -SMA expression in primary IMFs. While LmcMF also showed filamentous  $\alpha$ -SMA fibers, the amount of globular  $\alpha$ -SMA was higher than that in primary IMFs. Most of the  $\alpha$ -SMA protein in SmcMF existed in a

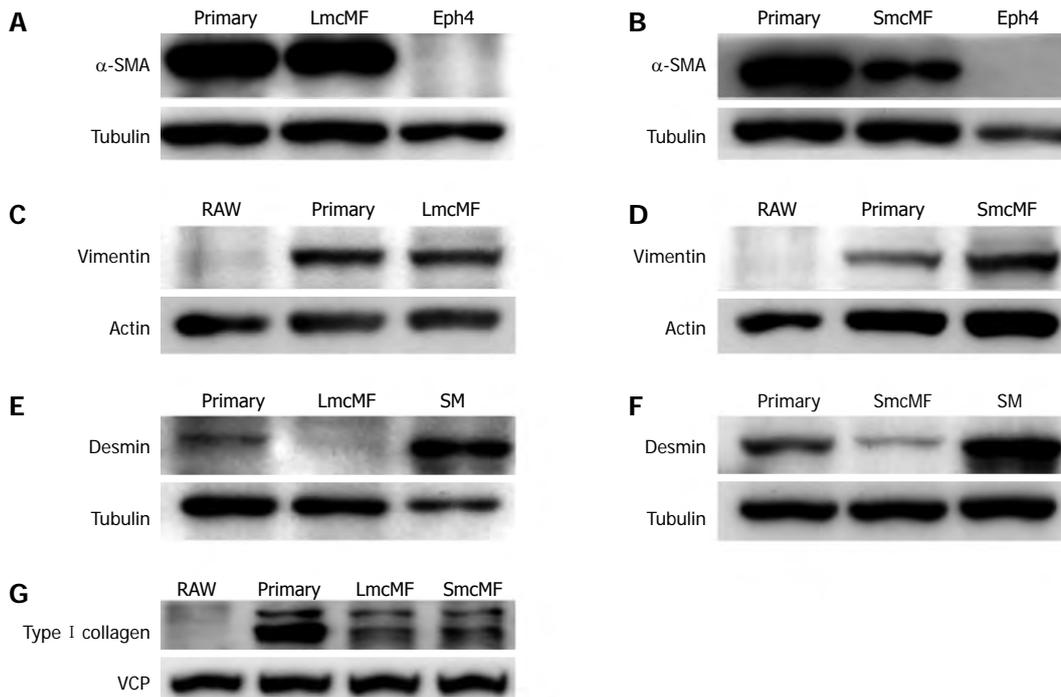

Figure 3 Expression levels of characteristic markers in LmcMF and SmcMF. A, B: The expression levels of  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA); C, D: Vimentin; E, F: Desmin; G: Type I collagen in primary intestinal myofibroblast (primary); LmcMF (A, C, and E), and SmcMF (B, D, and F) were investigated by Western blotting. Representative blots from 2 independent experiments are shown. Tubulin, actin, and valosin-containing protein (VCP) were used as loading controls.

globular  $\alpha$ -SMA form. On the other hand, vimentin was predominantly localized around the nucleus of primary IMFs and LmcMF but diffused throughout SmcMF cells (Figure 4B).

### Responses of LmcMF and SmcMF to LPS

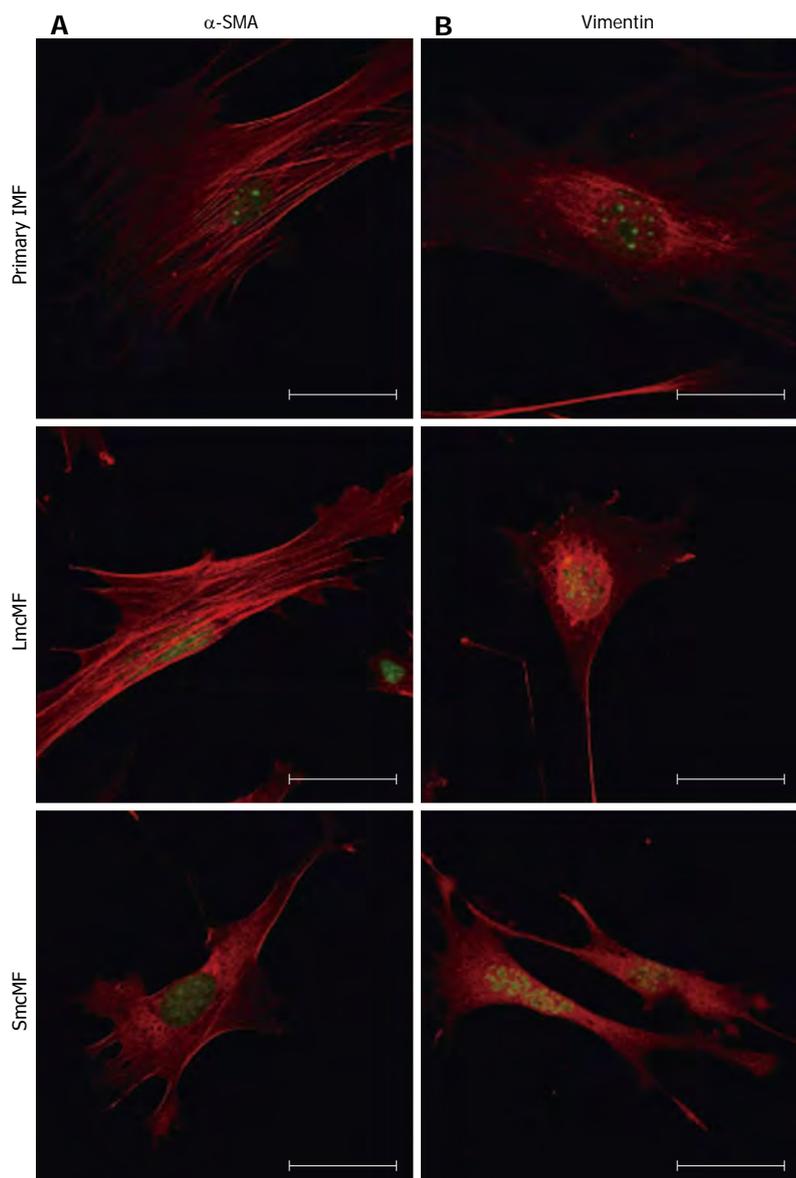

It is well known that the LPS receptor complex is composed of TLR4, CD14, and MD-2 and that both CD14 and MD-2 are required for the activation of TLR4<sup>[21]</sup>. A study has previously shown that primary IMFs expressed all these 3 components and that the exposure of cells to LPS activated the NF- $\kappa$ B and p38 MAPK pathways<sup>[10]</sup>; therefore, we assessed whether the same holds true for LmcMF and SmcMF. Our results show that although the expression level of TLR4 was low in primary IMFs, the levels in LmcMF and SmcMF were much higher (Figure 5A). As for CD14, the expression level was lower in LmcMF, compared to primary IMFs and SmcMF, and the expression level of MD-2 was relatively higher in primary IMFs and lower in SmcMF, compared to LmcMF.

Finally, we investigated the reactivity of primary IMFs, LmcMF, and SmcMF to LPS. We found that LPS treatment (20 ng/mL) induced the degradation of I $\kappa$ B $\alpha$ , as well as the phosphorylation of p38 MAPK (Figure 5B-D). While the maximal levels of I $\kappa$ B $\alpha$  degradation and p38 MAPK phosphorylation were detected at 30 min after LPS treatment, their expression was restored to basal levels within 2 h. Consistent with the previous study (performed in primary IMFs)<sup>[10]</sup>, our results demonstrate that both LmcMF and SmcMF preserve myofibroblastic phenotypes.

## DISCUSSION

IMFs play an important role in intestinal injury, inflammation, fibrosis, and tissue repair; however, their exact function and involvement are still not completely understood<sup>[6,8,10,22]</sup>. One issue that hinders the development of IMF research is the lack of IMF cell lines. In this present study, we established 2 IMF cell lines, namely, LmcMF and SmcMF, both of which were immortalized without losing contact inhibition of growth. LmcMF was established by transfecting primary IMFs with plasmid DNA encoding the LT of replication origin-defective SV40. It is known that 2 oncoproteins, LT and ST, encoded by the SV40 early region play an essential role in inducing transformation of mammalian cells<sup>[23]</sup>. In addition, previous studies have also shown that LT can immortalize cells but cannot induce neoplastic transformation without ST<sup>[23]</sup>. Moreover, it has been shown that immortalization of mouse cells can be achieved by transfecting only with LT<sup>[24]</sup>. Based on these findings, we used a plasmid that expresses LT, but not ST, for our immortalization experiments of IMFs. On the other hand, SmcMF was derived from cells that spontaneously immortalized. It has been reported that murine cells tend to immortalize spontaneously in culture, because mouse somatic cells have the telomerase activity<sup>[25]</sup>.

IMFs can be distinguished from other types of mesenchymal cells, such as smooth muscle cells and fibroblasts, by the expression of 3 protein markers:  $\alpha$ -SMA, vimentin, and desmin. It was reported that IMFs are positive for  $\alpha$ -SMA and vimentin, but negative or very

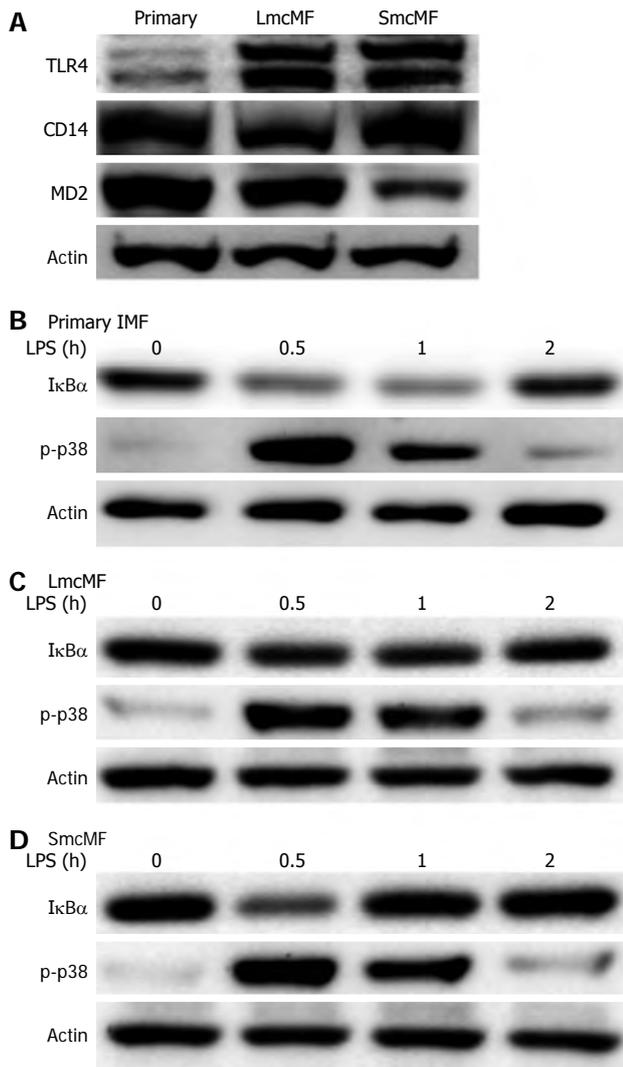

**Figure 4** Immunofluorescence staining for  $\alpha$ -smooth muscle actin and vimentin in primary intestinal myofibroblasts, LmcMF, and SmcMF. Primary intestinal myofibroblasts (IMFs), LmcMF, and SmcMF were immunostained with  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA) (A) and vimentin (B) (red). SYTOX Green was used for nuclear labeling (green). Representative images are shown. Scale bars indicate 40  $\mu$ m.

weakly positive for desmin<sup>[7]</sup>. In contrast, smooth muscle cells are  $\alpha$ -SMA-positive, vimentin-negative, and strongly positive for desmin, whereas typical fibroblasts, such as dermal fibroblasts, are negative for  $\alpha$ -SMA and desmin, but positive for vimentin<sup>[7,8,26]</sup>. In the present study, we observed that all 3 cell lines (primary IMFs, LmcMF, and SmcMF) expressed both  $\alpha$ -SMA and vimentin, suggesting that these cells share the same characteristics and that LmcMF and SmcMF can be used as intestinal myofibroblast cell lines. It is also noted that the doubling time of these cells is within a day, whereas that of human primary IMFs is about 5 d<sup>[27]</sup>. Therefore, the use of LmcMF and SmcMF will be helpful for improving the efficiency of IMF research.

There are, however, some differences among these cells. For instance, the  $\alpha$ -SMA expression level was

slightly lower in SmcMF, and  $\alpha$ -SMA was organized into stress fibers in primary IMFs and LmcMF, but not in SmcMF. The vimentin expression level was slightly higher in SmcMF, whereas the type I collagen levels in LmcMF and SmcMF were relatively lower than that in primary IMFs. We propose that these differences may depend on the differentiation stage of the cells. In the present study, very low levels of desmin were detected in primary IMFs and SmcMF. It has been reported that primary human colonic myofibroblasts and CCD-18Co cells do not express desmin<sup>[28]</sup>, whereas some lesion myofibroblasts do<sup>[7]</sup>. These differences in the desmin expression may occur by cell differentiation or by the differences between animal species tested (for example, mice *vs* humans); however, to clarify this, additional experiments are necessary.

**Figure 5** Expression of lipopolysaccharide-related proteins and responses of primary intestinal myofibroblasts, LmcMF, and SmcMF to lipopolysaccharide. **A:** The expression levels of indicated proteins in primary intestinal myofibroblasts (IMFs) (primary), LmcMF, and SmcMF were investigated by Western blotting; **B-D:** Primary IMFs (**B**), LmcMF (**C**), and SmcMF (**D**) were stimulated with lipopolysaccharide (LPS) (20 ng/mL) for indicated periods. The IκBα degradation and p38 MAPK phosphorylation were determined by Western blotting. Representative blots from 3-4 independent experiments are shown. Actin was used as a loading control.

The differentiation of fibroblasts into myofibroblasts is an important step in tissue repair and fibrosis<sup>[29]</sup>; however, it is a complex process and has not been completely elucidated. It was reported that CCD-18Co cells exhibit fibroblastic and myofibroblastic phenotypes and that TGF-β stimulates their differentiation into myofibroblasts<sup>[17]</sup>. CCD-18Co cells have also been used to investigate the mechanism of differentiation into myofibroblasts during wound healing processes. However, CCD-18Co cells poorly differentiate into myofibroblasts<sup>[30]</sup>; therefore, LmcMF and SmcMF may be useful to help reveal the role of differentiated myofibroblasts in tissue repair.

Accumulating evidence has shown that IMFs play a crucial role in local immune regulation in the intestine<sup>[10,14,15]</sup>; therefore, it is important that the developed cell lines show immune responses to external factors. Consistent with previous report<sup>[10]</sup>, all three types of IMF expressed TLR4, CD14, and MD-2. We also demonstrate that LmcMF and SmcMF, similar to primary IMFs, were able to respond to LPS stimulation.

In the present study, we observed that the TLR4 expression levels in LmcMF and SmcMF were higher than that in primary IMFs. It is possible that TLR4 was downregulated in primary IMFs and then recovered in LmcMF and SmcMF, since during the cell isolation procedure the intestinal tissues and cells were exposed to a large amount of LPS that existed in the intestinal lumen. Interestingly, although the TLR4 expression level in primary IMFs was low, LPS induced almost the same responses, including IκBα degradation and p38 MAPK phosphorylation, in all 3 types of IMFs. Together, our results indicate that the amount of TLR4 protein in primary IMFs was sufficient to respond to LPS.

In conclusion, we have successfully established 2 novel types of myofibroblast cell lines from mouse colon, namely, LmcMF and SmcMF, both of which expressed the key myofibroblast markers. Moreover, these cell lines were immortalized (rather than transformed to neoplastic cells) and were able to respond to LPS, like primary IMFs. Furthermore, these cell lines proliferate much faster than primary IMFs, and therefore they can be used efficiently. Nevertheless, for the development of IMF research using LmcMF and SmcMF, more experiments are necessary to determine their properties.

## COMMENTS

### Background

With respect to the gastrointestinal mucosa, accumulating evidence has shown that subepithelial intestinal myofibroblasts (IMFs), which are located subjacent to the epithelium, play crucial roles in regulating epithelial cells. IMFs orchestrate diverse events in gastrointestinal health and diseases, including epithelial differentiation and development, mucosal repair, carcinogenesis, and inflammatory responses. Therefore, it is important to establish IMF cell lines, which can be used for clarifying the role of IMFs.

### Research frontiers

Despite the crucial role played by IMFs in gastrointestinal health and diseases, the understanding of their underlying regulatory mechanism is limited. A major issue that hinders the advance of IMF research is the lack of IMF cell lines that exhibit myofibroblastic phenotypes. In this study, authors established 2 IMF cell lines, namely, LmcMF and SmcMF, both of which were immortalized without losing contact inhibition of growth, and were able to respond to lipopolysaccharide, like primary IMFs.

### Innovations and breakthroughs

For the IMF research, the 2 following cell types are available: freshly isolated IMFs (primary IMFs) and IMF-like cell lines (such as CCD-18Co cells). However, primary IMFs typically change phenotypes within passage 6 and stop growing after repeated passages. In addition, CCD-18Co cells need to be treated with TGF-β for the expression of key myofibroblast protein markers. To the best of our knowledge, this report is the first to establish novel types of myofibroblast cell lines from the mouse colon. Authors developed 2 cell lines, namely, LmcMF and SmcMF, both of which expressed the key myofibroblast markers without

stimulation.

### Applications

Because IMFs play crucial roles in regulating epithelial cells, it is important to develop IMF cell lines. The establishment of 2 cell lines is helpful for improving the efficiency of IMF research.

### Peer review

This study characterizes 2 IMF cell lines isolated from the mouse colon. This is a straightforward descriptive report and is methodological in nature; essentially, the authors have generated a potentially useful cell line resource that may be used to further myofibroblast research into tissue repair and fibrosis, immune regulation within the intestine, and other aspects of myofibroblast function. Because only a few good myofibroblast cell lines are currently available, it is important to create new myofibroblast cell lines for *in vitro* studies, and the authors have generated 2 IMF cell lines by using 2 different approaches.

by Western blotting.

**RESULTS:** Patients with active UC had significantly more IL-22, IL-23, IL-22R1 and p-STAT3-positive cells than the patients with inactive UC and normal controls. Furthermore, IL-22 and related proteins were closely related to the severity of the colitis. The expression of IL-22 and IL-22R1 in the tissue of initial UC was stronger than in that of chronic UC, whereas the expression of p-STAT3 was significantly increased in chronic UC tissues. In dysplasia tissues, the expression level of IL-22 and related proteins was higher compared with controls. Mouse colitis model showed that expression of IL-22, IL-22R1 and IL-23 was increased with time, p-STAT3 and the downstream gene were also remarkably upregulated.

**CONCLUSION:** IL-22/STAT3 signaling pathway may be related to UC and UC-induced carcinogenesis and IL-22 can be used as a biomarker in judging the severity of UC.

**Key words:** Ulcerative colitis; Ulcerative colitis-related carcinogenesis; Interleukin-22; Interleukin-22R1; STAT3

**Core tip:** This study investigates the expression of interleukin (IL)-22, IL-22R1, IL-23, and STAT3 in ulcerative colitis (UC) and UC-related carcinogenesis (UC-CRC) tissues from human and mouse. The results showed that IL-22 and related proteins were closely related to the severity of colitis, and the expression level of IL-22 and related proteins was higher in dysplasia tissues. IL-22/STAT3 signaling pathway was related to UC and UC-CRC. IL-22 can be used as a biomarker for determining the severity of UC and as an interesting therapeutic target in active UC and UC-CRC.

### Abstract

**AIM:** To investigate the expression of interleukin (IL)-22 and its related proteins in biopsy specimens from patients with ulcerative colitis (UC) and UC-related carcinogenesis.

**METHODS:** Biopsy specimens were obtained from patients with inactive ( $n = 10$ ), mild-to-moderately active ( $n = 30$ ), severely active ( $n = 34$ ), initial ( $n = 30$ ), and chronic UC ( $n = 44$ ), as well as UC patients with dysplasia ( $n = 10$ ). Specimens from patients without colonic abnormalities ( $n = 20$ ) served as controls. Chronic colitis in experimental mice was induced by 2.5% dextran sodium sulfate. The expression levels of IL-22, IL-23, IL-22R1 and phosphorylated STAT3 (p-STAT3) were determined by immunohistochemistry. Bcl-2, cyclin D1 and survivin expression was detected

ative colitis and related carcinogenesis. *World J Gastroenterol* 2013; 19(17): 2638-2649 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i17/2638.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i17.2638>

## INTRODUCTION

Ulcerative colitis (UC) is a subtype of chronic inflammatory bowel disease (IBD) of the large intestine. The disease is characterized by a dysregulated mucosal immune response. This aberrant immune response leads to the secretion of harmful cytokines that destroy the gastrointestinal tract epithelium, thereby causing further inflammation.

Several inflammatory cytokines have been associated with IBD, including the interleukins IL-1 and IL-6, tumor necrosis factor (TNF)- $\alpha$ , and interferon (IFN)- $\gamma$ . Among the inflammatory cytokines implicated in IBD pathogenesis, much interest has been focused on the recently-identified cytokine IL-22. IL-22 is a member of the IL-10 subfamily; its production is highly dependent on IL-23 in T-helper 17 (Th17)<sup>[1-3]</sup>, Th1<sup>[4,5]</sup>, NK-22<sup>[6,7]</sup>, and CD11c<sup>+</sup><sup>[8]</sup> cells. IL-22 is expressed by the novel Th22 cell lineages<sup>[9]</sup> and innate lymphoid cells (ILCs)<sup>[10]</sup>. IL-22-producing ILCs in humans are responsive to IL-23 signaling, as potentially important mediators of IBDs<sup>[10]</sup>. Th22 and Th17 cells may be implicated in the pathogenesis of several chronic inflammatory and autoimmune diseases such as IBD, psoriasis, ankylosing spondylitis, and rheumatoid arthritis<sup>[11-16]</sup>.

IL-22 signaling is established when the cytokine binds to a heterodimeric receptor complex of IL-22R1 and IL-10R2. Given that IL-10R2 is a ubiquitous protein, cellular IL-22 responsiveness is mainly determined by IL-22R1 expression. IL-22R1 is specifically expressed in nonleukocytic cells such as those of the pancreas, skin, kidney, liver, and colon. IL-22R1 expression is detectable in epithelial cells of these organs, but not in their immune cells<sup>[17-20]</sup>. Therefore, IL-22 is unique among the cytokines because it cannot mediate autocrine or paracrine functions among leukocytes. Instead, IL-22 transmits information between leukocytes and the nonleukocytic cell compartment.

The STAT3 pathway for transcription activation appears to be a major mode of IL-22 signal transduction. Activated STAT3 is translocated from the cytoplasm to the nucleus, where it regulates genes involved in cell apoptosis, proliferation, migration, and survival. STAT3 has important functions in several autoimmune diseases. IL-22 mediates IL-23-induced acanthosis and dermal inflammation in psoriasis and IBD through the activation of STAT3<sup>[21]</sup>. When activated by IL-22, STAT3 can aggravate colitis by promoting the expression of inflammatory factors such as IL-8, IFN- $\gamma$ , and the matrix metalloproteinases (MMPs)<sup>[22,23]</sup>. Previous studies investigated the role of IL-22 in UC and UC-related carcinogenesis (UC-CRC)<sup>[24-26]</sup>. These studies revealed that the IL-22/

STAT3 pathway is involved in UC pathophysiology and carcinogenesis through the activity of inducible nitric oxide synthase (iNOS), DMBT1, and REG $\alpha$ <sup>[24-26]</sup>. However, the IL-22-induced phosphorylated STAT3 (p-STAT3) was considered a defense mechanism because it enhanced mucus production and goblet cell replacement in mouse models for acute colitis and wound healing<sup>[27-29]</sup>. Thus, the role of the IL-22/STAT3 signaling pathway in UC remains unclear. The current study investigates the significance of IL-22 and the IL-22/STAT3 signaling pathway in UC and UC-CRC, as well as its value as a therapeutic target for both diseases.

## MATERIALS AND METHODS

### Patients and tissue samples

Colon biopsy *via* endoscopy was performed on 74 patients with UC, including 31 females and 43 males (median age, 45.9 years; range, 17-87 years). The controls included 6 females and 14 males (mean age, 45.6 years; range, 33-55 years). All samples were obtained at the First Affiliated Hospital of Nanjing Medical University from 2009 to 2011.

This study was approved by the Research Ethics Committee of the First Affiliated Hospital of Nanjing Medical University. Written informed consent was obtained from each patient. The diagnosis of UC was based on clinical, endoscopic, and histological findings. The patient characteristics and histological data are summarized in Table 1.

### Experimental mouse models of UC

The mouse experiments were conducted in strict accordance with the recommendations of the Guide for the Care and Use of Laboratory Animals of the United States National Institutes of Health. The protocol was approved by the Committee on the Ethics of Animal Experiments of Nanjing Medical University. Male ICR mice were purchased and maintained at the Centre of Animal Facility, Nanjing Medical University. The mice were sacrificed by cervical dislocation. All efforts were made to minimize suffering. Chronic colitis was induced by administering 2.5% dextran sodium sulfate (DSS; ICN Biomedicals Inc., Irvine, CA, United States) to the drinking water in three seven-day cycles, which had a five-day recovery period after each cycle. During the recovery period, mice drank only normal water. The age-matched control mice received only normal drinking water throughout the entire study.

### Immunohistochemistry

All the tissues were fixed overnight in 4% paraformaldehyde at 4 °C, processed, and cut into 5  $\mu$ m-thick sections. The sections were then deparaffinized in xylene and rehydrated. Endogenous peroxidase activity was blocked by 3% H<sub>2</sub>O<sub>2</sub> for 10 min at room temperature. Antigen retrieval was performed by 15 min of boiling in the preheated buffer (10 mmol/L of sodium citrate, pH = 6.0)

<sup>1</sup>The mean duration of disease in the chronic group (5.1 ± 0.6 years) was significantly longer than in the initial group (0.8 ± 0.6 years;  $P < 0.001$ ); <sup>2</sup>The mean duration of disease in the ulcerative colitis (UC) with dysplasia group (10.5 ± 1.4 years) was significantly longer than in other groups ( $P < 0.05$ ); <sup>3</sup>Data are expressed as mean ± SD.

at 200 W in a microwave. The slides were transferred to a humidifier and blocked by incubating in 5% normal goat serum at room temperature for 1 h. The polyclonal rabbit antibodies used in this study included anti-p-STAT3 tyrosine 727, anti-IL-22, anti-IL-22R1, and anti-IL-23 (ab30647, ab18499, ab5984 and ab115759, respectively); these antibodies were diluted in 5% normal goat serum at ratios of 1:200, 1:200, 1:200 and 1:400, respectively. The sections were incubated in the respective antibodies overnight at 4 °C. The slides were subsequently incubated in the secondary antibody goat anti-rabbit IgG-biotin (B8895; Sigma-Aldrich, St. Louis, MO, United States) at room temperature for 40 min. The sections were incubated in the ABC-peroxidase solution (Ultrasensitive™ S-P kit, kit 9719; Maixin-Bio, China) for 30 min at room temperature, followed by counterstaining with hematoxylin. The immunohistochemistry (IHC) results were analyzed using Image Pro-Plus.

### Western blotting analysis

Proteins were extracted from the mouse tissues and quantified using a commercial protein assay (Bio-Rad Laboratories, CA, United States). The protein samples (30 µg) were separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis and transferred onto a nitrocellulose membrane. Immunoblot analysis was conducted using antibodies against total STAT3, p-STAT3 (S727), Bcl-2, cyclin D1, and survivin (Abcam Inc, MA, United States). The results were visualized using the chemiluminescent Pierce ECL Substrate Western blotting detection system (Thermo Scientific, IL, United States) and exposure to autoradiography film (Kodak XAR film).

### Statistical analysis

The results were expressed as the mean ± SD. The two

groups were compared using the Student's *t* test or the Mann-Whitney *U* test, as appropriate. All statistical analyses were performed using the SPSS statistical software (version 13.0).  $P < 0.05$  was considered to be statistically significant.

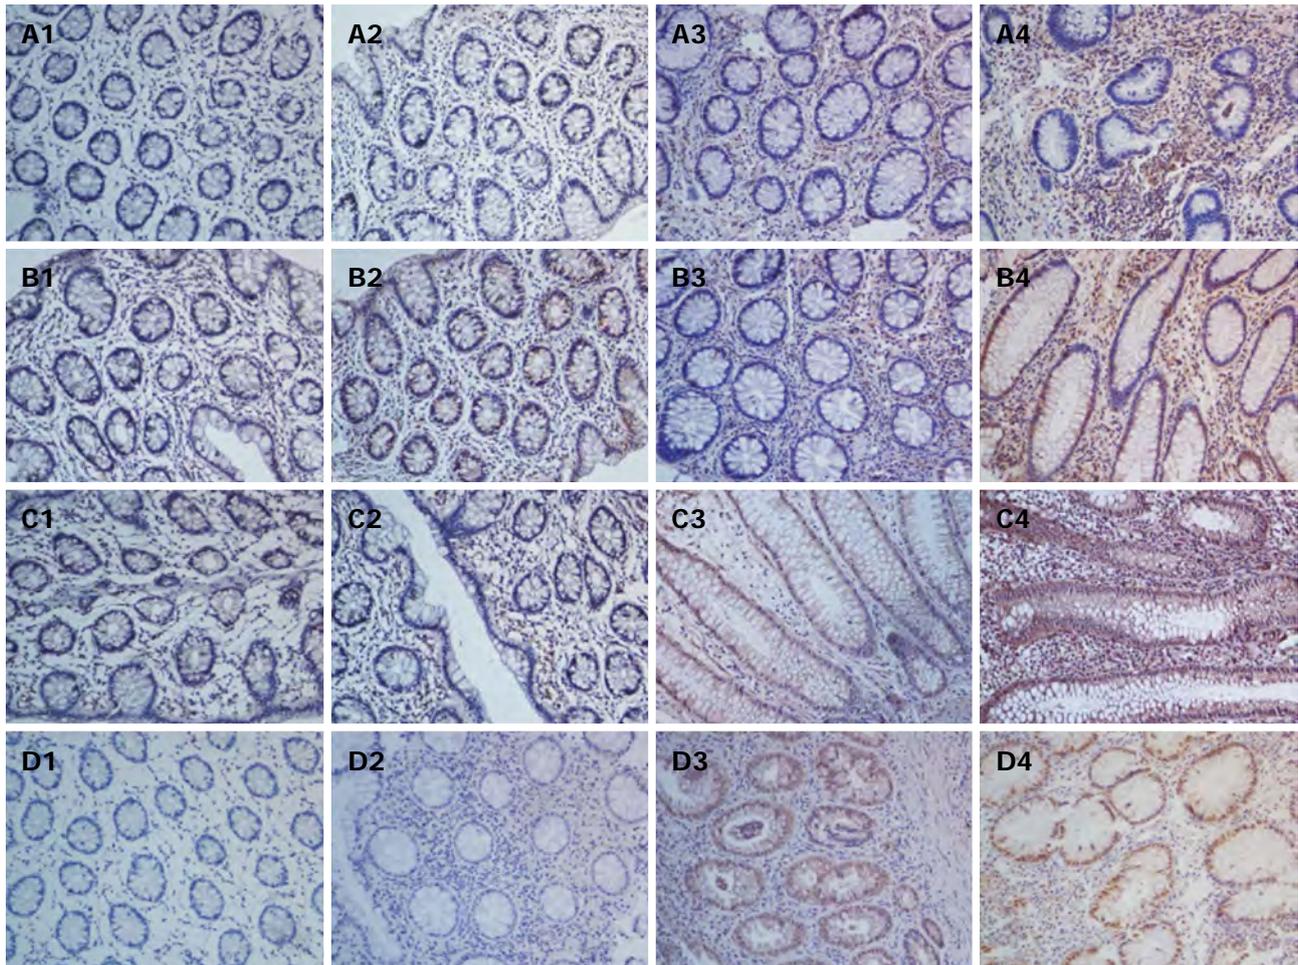

## RESULTS

### Patient characteristics

As shown in Table 1, we collected biopsy specimens from 20 healthy controls, 10 patients with inactive UC, 64 patients with active UC (including 30 patients with mild-to-moderate active UC and 34 patients with severely active UC), 30 patients with initial UC attacks, 44 patients with chronic UC, and 10 UC patients with dysplasia. The duration of disease was significantly longer in the groups with chronic UC and UC with dysplasia than in the other groups ( $P < 0.05$ ). No other significant differences were observed among the other groups, regardless of the treatment used.

### IL-22 expression in patients with different degrees of inflammation

Immunohistochemical analysis showed that the IL-22 protein was mainly expressed in inflammatory cells of the colonic lamina propria, but not in the normal controls (Figure 1A). Tissues with mild-moderate and severe UC had significantly higher expression levels than those with inactive UC and normal colon tissues (mild-moderate *vs* normal,  $P < 0.001$ ; mild-moderate *vs* inactive,  $P = 0.02$ ,  $P < 0.05$ ; severe *vs* normal,  $P < 0.001$ ; severe *vs* inactive,  $P < 0.001$ ; Figure 2A). Moreover, significantly more IL-22-positive cells were present in tissues of severe UC than in those of mild-moderate UC (severe *vs* mild-moderate,  $P < 0.001$ ; Figure 2A). The results indicate that

**Figure 1** Expression and distribution of interleukin-22 and its related proteins in colonic biopsy specimens as analyzed by immunohistochemistry ( $\times 200$ ). A1-A4: Expression and distribution of interleukin (IL)-22 in colonic biopsy specimens from the control, inactive ulcerative colitis (UC), mild-moderate UC, and severe UC tissues, respectively; B1-B4: The expression and distribution of IL-23 in colonic biopsy specimens from the control, inactive UC, mild-moderate UC, and severe UC tissues; C1-C4: The expression and distribution of IL-22R1 in colonic biopsy specimens from the control, inactive UC, mild-moderate UC, and severe UC tissues; D1-D4: The expression and distribution of p-STAT3 (S727) in colonic biopsy specimens from the control, inactive UC, mild-moderate UC, and severe UC tissues.

the expression of IL-22 was related to UC severity.

#### **Expression of IL-22-related proteins in patients with different degrees of inflammation**

Previous studies have demonstrated that IL-22 production is highly dependent on IL-23 in Th17, NK-22, and lymphoid tissue-inducer cells<sup>[1-3,6,7]</sup>. Thus, we analyzed IL-23 expression in UC tissues using IHC. The results indicated that IL-23 was significantly highly upregulated in active UC, as compared with inactive UC and the controls (mild-moderate *vs* normal,  $P < 0.001$ ; mild-moderate *vs* inactive,  $P < 0.001$ ; severe *vs* normal,  $P < 0.001$ ; severe *vs* inactive,  $P < 0.001$ ; Figure 2B). Similarly, the IL-23 expression was stronger with severe UC than with mild-moderate UC (severe *vs* mild-moderate,  $P = 0.01$ ,  $P < 0.05$ ; Figure 2B). The positive region of IL-23 in UC was mostly confined to the intestinal epithelial cells (IECs) and inflammatory cells of the colonic lamina propria (Figure 1B).

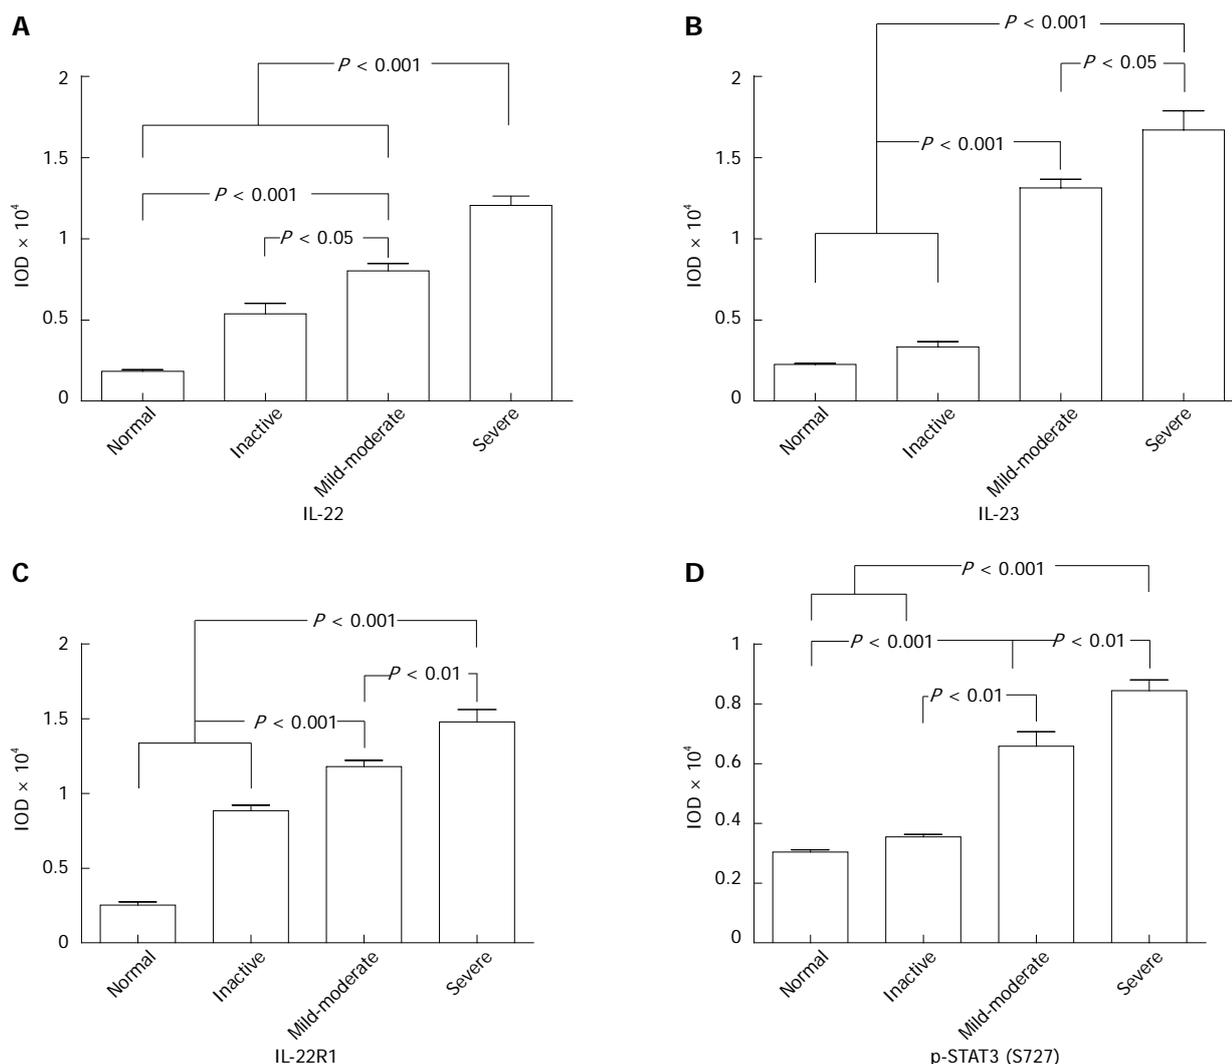

We identified IL-22R1, another key molecule that is necessary for signal transmission. IL-22R1 was mainly

localized in the IECs (Figure 1C). IL-22R1 was overexpressed in active UC (mild-moderate *vs* normal,  $P < 0.001$ ; mild-moderate *vs* inactive,  $P = 0.0002$ ,  $P < 0.001$ ; severe *vs* normal,  $P < 0.001$ ; severe *vs* inactive,  $P = 0.0002$ ,  $P < 0.001$ ; severe *vs* mild-moderate,  $P = 0.007$ ,  $P < 0.01$ ; Figure 2C).

Based on the downstream effects of IL-22, the activation of STAT3 was determined by staining with p-STAT3 at the S727 residue. IHC analysis showed that in the colon tissues resected from patients with UC, the p-STAT3 (S727) protein was mainly expressed in the nucleus of epithelial cells (Figure 1D). Its expression was significantly upregulated in the active UC tissues, particularly in severe UC (severe *vs* normal,  $P < 0.001$ ; severe *vs* inactive,  $P < 0.001$ ; severe *vs* mild-moderate,  $P = 0.0045$ ,  $P < 0.01$ ; mild-moderate *vs* normal,  $P < 0.001$ ; mild-moderate *vs* inactive,  $P = 0.0017$ ,  $P < 0.01$ ; Figure 2D).

#### **IL-22 expression in patients with different types of UC**

According to the clinical diagnostic standards, we classified UC into two types: initial and chronic UC. IHC

**Figure 2** Statistical evaluation of interleukin-22 and its related proteins in human colonic biopsy specimens from the controls and patients with inactive, mild-moderate, and severe ulcerative colitis. The average integrated optical density (IOD) was obtained by analyzing five random fields for each slide, which were evaluated using Image-Pro Plus software (v. 5.0), for the immunohistochemistry staining of interleukin (IL)-22 (A), IL-23 (B), IL-22R1 (C), and p-STAT3 (S727) (D) in human colonic biopsy specimens. The expression levels of IL-22 (A), IL-23 (B), IL-22R1 (C), and p-STAT3 (D) were positively correlated with colitis severity.

indicated that IL-22 was significantly upregulated in the initial UC tissues than in the chronic UC tissues (initial *vs* chronic,  $P = 0.0077$ ,  $P < 0.01$ ; Figures 3A and 4A).

**IL-22-related protein expression in patients with different types of UC**

Similar to IL-22, IL-22R1 was more strongly expressed in the tissues of initial UC than in those of chronic UC (initial *vs* chronic,  $P < 0.001$ ; Figures 3C and 4C). By contrast, the number of p-STAT3-positive cells was significantly higher in chronic UC tissues than in initial UC (chronic *vs* initial,  $P = 0.03$ ,  $P < 0.05$ ; Figures 3D and 4D). However, no significant differences were detected in terms of the IL-23 expression in these two groups (Figures 3B and 4B).

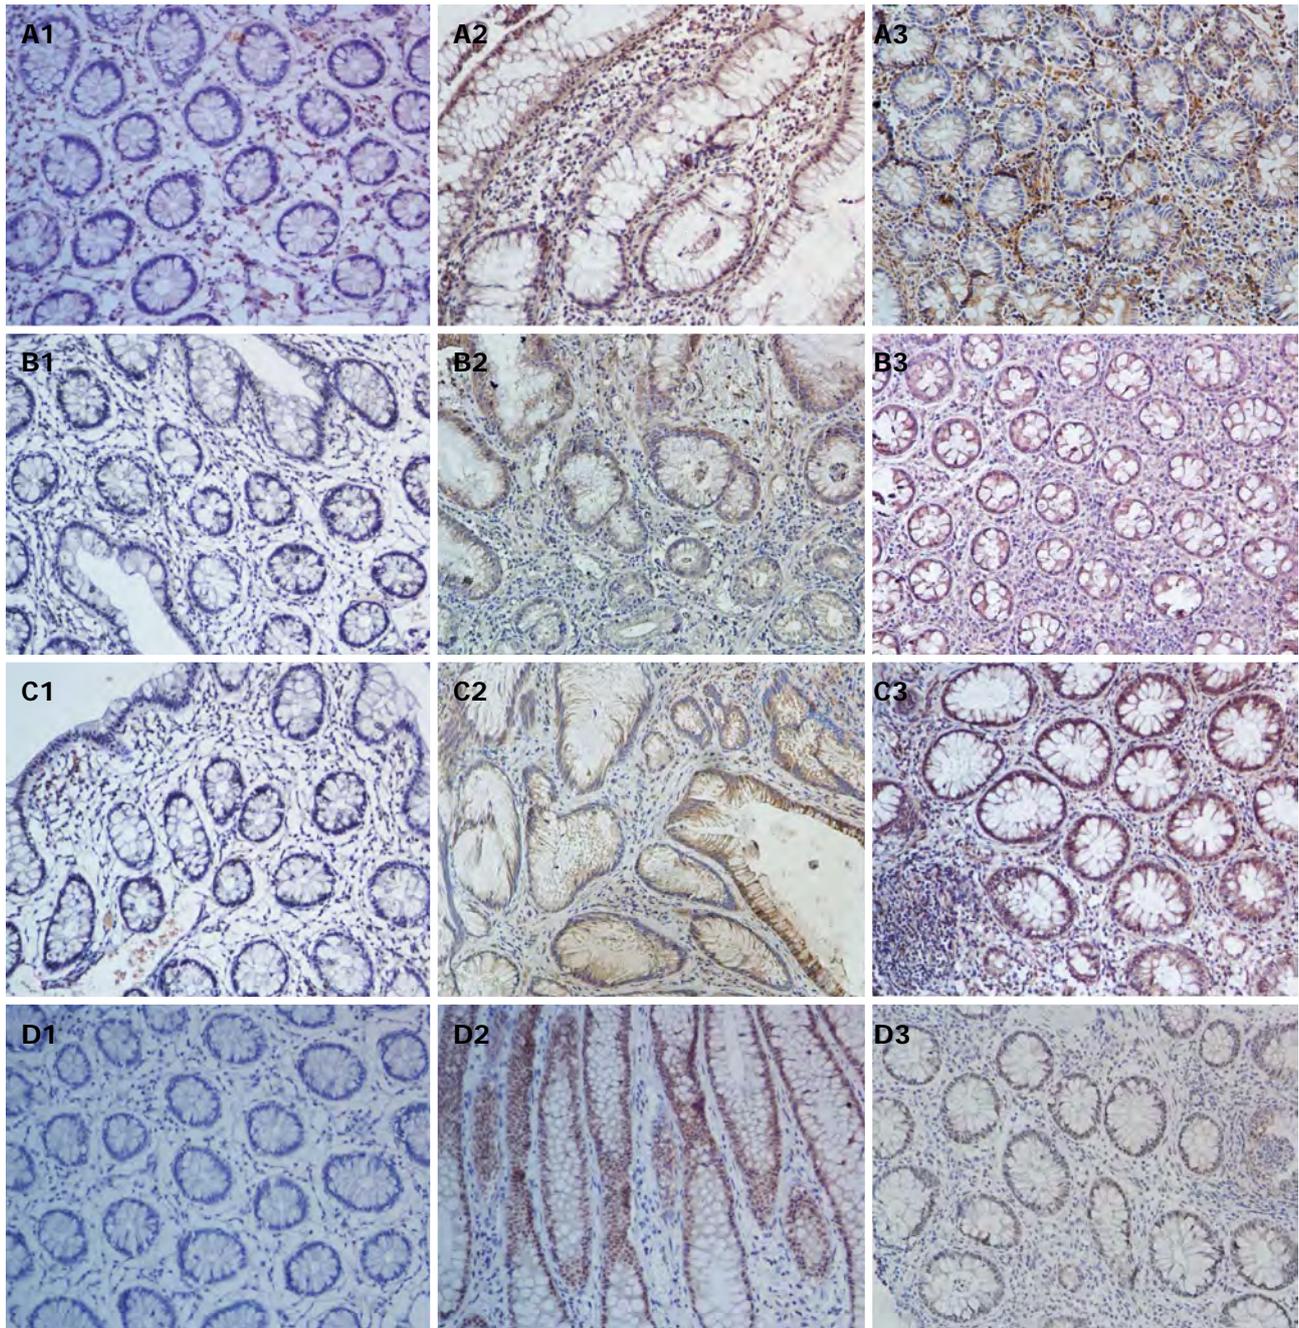

**IL-22 expression in patients with UC-CRC (dysplasia)**

A positive correlation exists between the IL-22-positive cells and the severity of colitis in patients with UC. We investigated IL-22 expression in biopsy specimens from

patients with UC-CRC (dysplasia) and analyzed the IL-22 levels in UC with dysplasia (Figure 5A). Significantly more IL-22-positive cells were observed in the dysplasia group than in the inflammatory group ( $P = 0.02$ ; Figure 6A).

**Expression of IL-22-related proteins in patients with UC-CRC (dysplasia)**

Given that IL-22 was highly upregulated in UC tissue with dysplasia, we studied the expression of the receptor IL-22R1, its upstream IL-23, and its downstream p-STAT3 (S727) in UC tissues with dysplasia, as compared with active and inactive UC tissues. The expression levels of IL-22R1, IL-23, and p-STAT3 were significantly higher in UC tissues with dysplasia than in the control group (IL-22R1: dysplasia *vs* active,  $P = 0.02$ ; IL-23: dysplasia *vs* active,  $P = 0.01$ ; p-STAT3: dysplasia *vs* active,  $P = 0.02$ ; Figure 6B-D). The increased expression was strictly found at the dysplastic tissues of the patients (Figure 5B-D).

**Figure 3** Expression and distribution of interleukin-22 and related proteins in human colonic tissues from controls and patients with chronic and initial ulcerative colitis as detected by immunohistochemistry ( $\times 200$ ). A1-A3: Expression and distribution of interleukin (IL)-22 in ulcerative colitis (UC) tissues from the control, chronic UC, and initial UC groups; B1-B3: Expression and distribution of IL-23 in UC tissues from the control, chronic, and initial UC groups; C1-C3: Expression and distribution of IL-22R1 in UC tissues from the control, chronic, and initial UC groups; D1-D3: Expression and distribution of p-STAT3 in UC tissues from the chronic and initial UC groups.

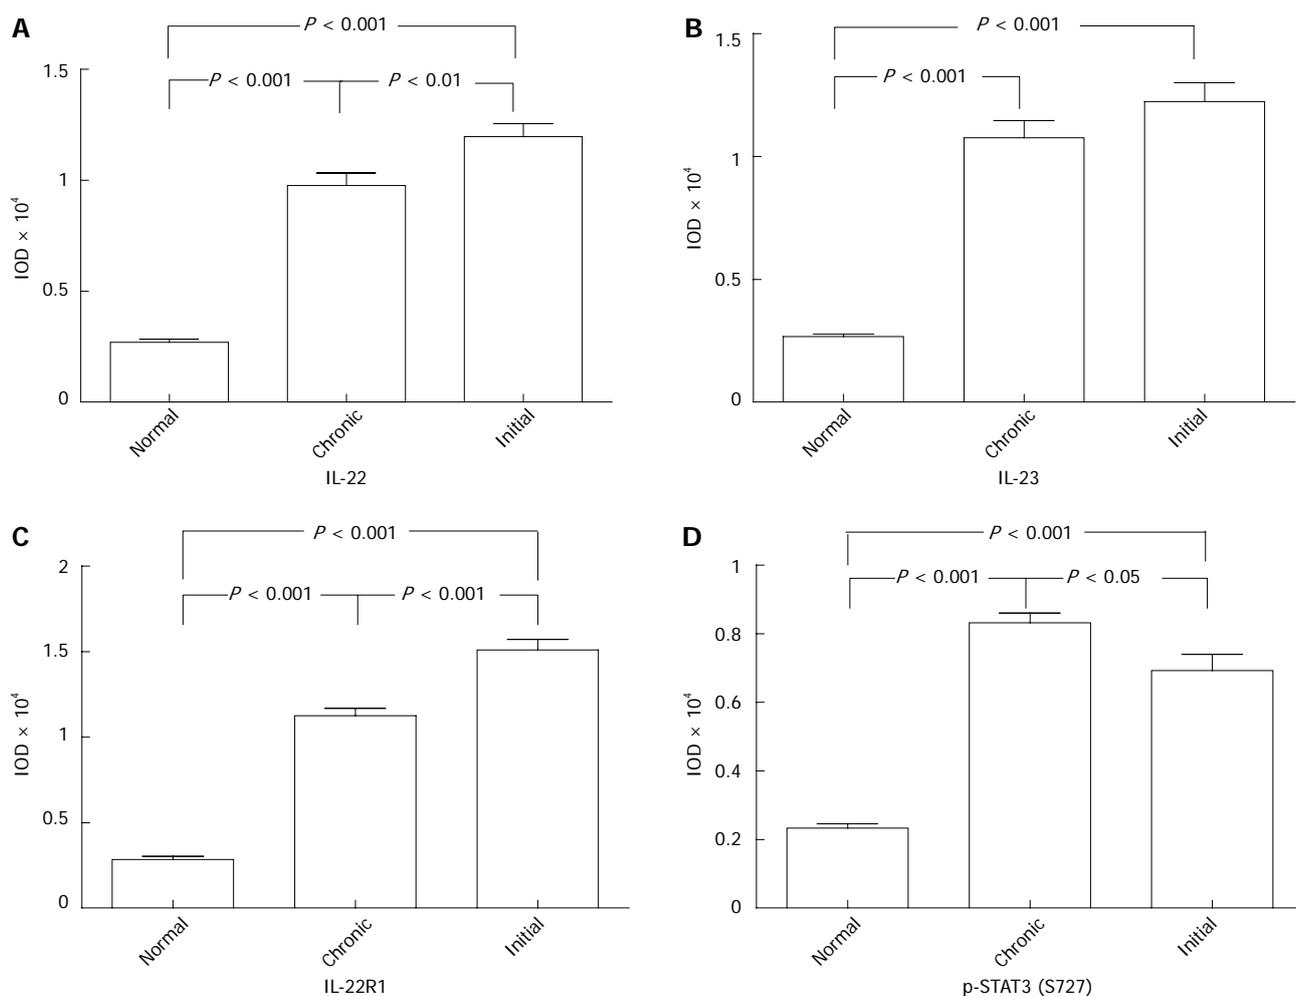

#### **Expression of IL-22 and its related proteins in DSS-induced mouse models of chronic colitis**

We induced experimental colitis by treating mice with DSS to study the role of IL-22 and its related proteins in the disease. Dynamic IL-22, IL-23, and IL-22R1 expression levels were investigated by IHC. p-STAT3 activity and its downstream gene expression were confirmed by Western blotting analysis at different time points (at days 40, 80, and 120). The expression levels of IL-22, IL-22R1, and IL-23 were increased with time (Figure 7A).

STAT3 activation and the activity of its downstream cell proliferation-related genes, such as Bcl-2, cyclin D1, and survivin, were also investigated. All these genes had sustained expression over time (Figure 7B).

## **DISCUSSION**

IBDs such as Crohn's disease and ulcerative colitis are chronic inflammatory disorders of the gastrointestinal tract. Although their etiology is not completely under-

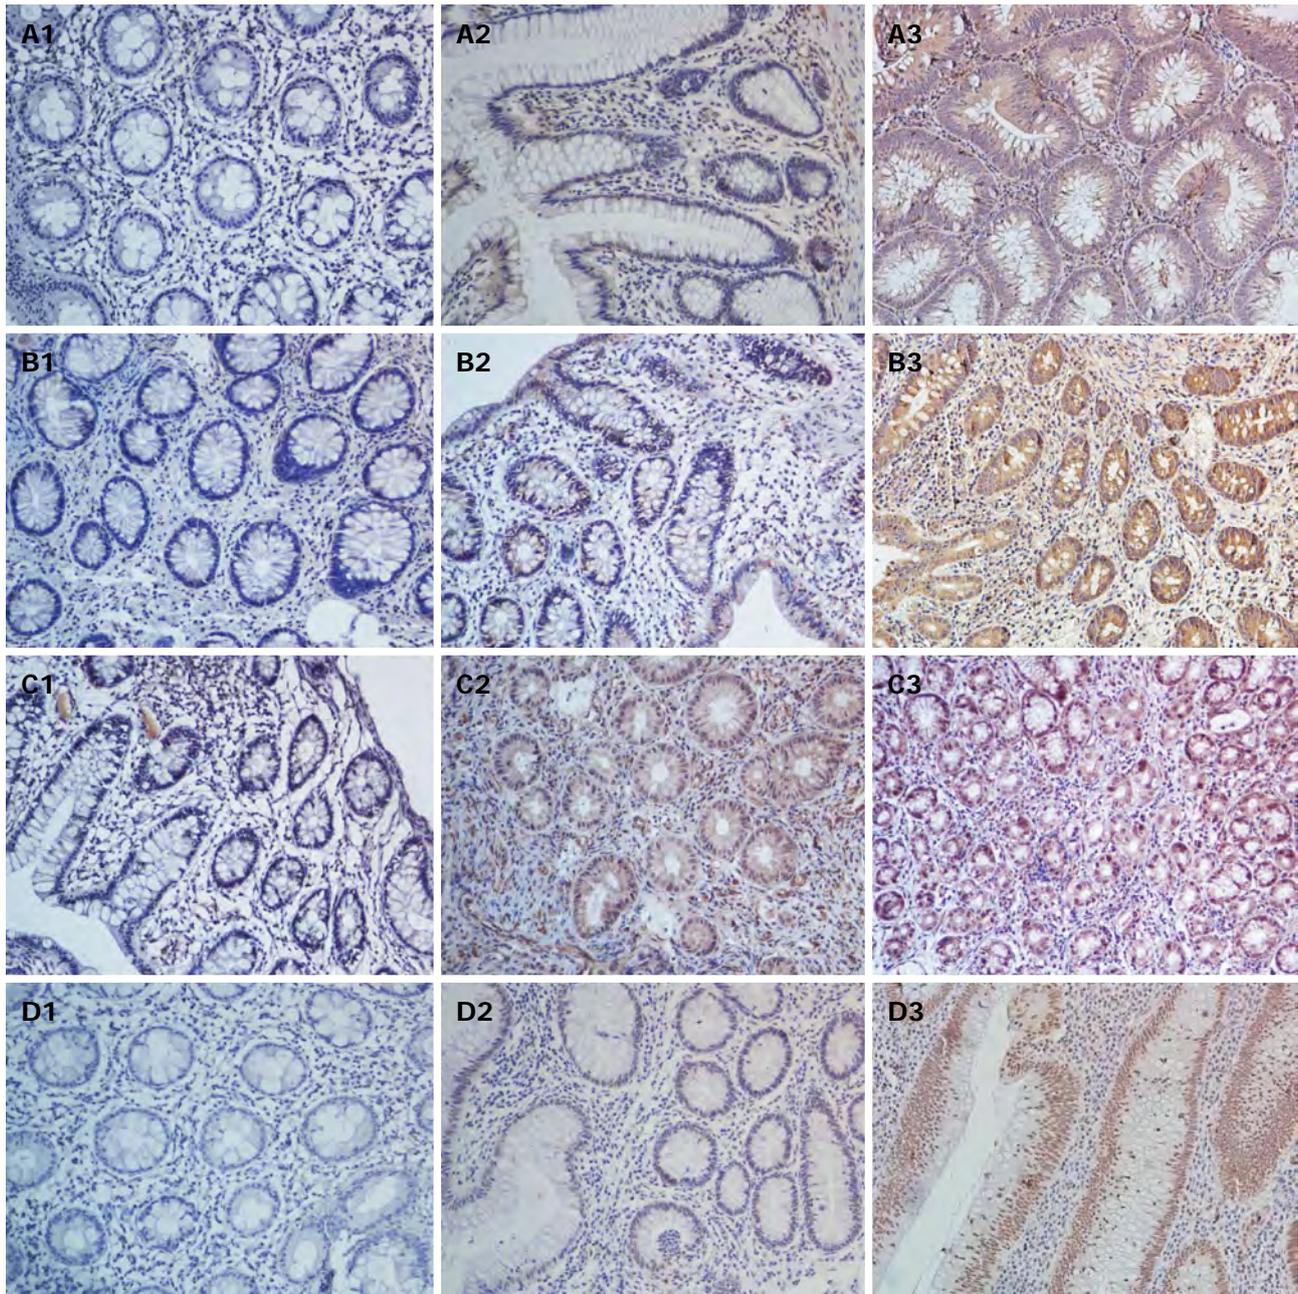

**Figure 4** Statistical evaluation of interleukin-22 and its related proteins in human colonic biopsy specimens from controls and patients with chronic and initial ulcerative colitis. The average integrated optical density (IOD) for the immunohistochemistry staining of interleukin (IL)-22 (A), IL-23 (B), IL-22R1 (C), and p-STAT3 (S727) (D) in colonic tissues with initial and chronic ulcerative colitis (UC). Significantly higher expression levels of IL-22 and IL-22R1 were observed in the initial UC group as compared with the chronic UC group. p-STAT3 was highly expressed in the chronic UC group.

stood, initiation and aggravation of the inflammatory process seem to be related to a massive local mucosal immune response. IL-22 belongs to the IL-10 family of cytokines; it has recently been shown to be preferentially expressed by Th17 and Th22 cells. These cells have been identified in the pathogenesis of certain chronic inflammatory diseases, including colitis, psoriasis, and rheumatoid arthritis. IL-22 targets innate immune pathways because of the restricted expression of IL-22 receptors on nonleukocytic cells, such as epithelial cells, keratinocytes, and hepatocytes; however, it does not recognize T- or B-cells<sup>[17-20]</sup>. Studies using genetically-engineered mice have demonstrated that epithelial STAT3 activation in DSS-induced colitis is dependent on IL-22, rather than on IL-6. Both IL-22 and STAT3 activation in epithelial cells is important for wound-healing, as demonstrated by *in vivo* experiments<sup>[27]</sup>. Sugimoto *et al.*<sup>[28]</sup> found that the IL-22/STAT3 pathway contributes to the rapid amelioration of local intestinal inflammation by enhancing the production of membrane-bound mucins (Muc1, -3, -10, and -13) in a mouse model of acute colitis. However, IL-22 is also considered an inflammatory driver in IBD

by acting on human colonic subepithelial myofibroblasts to stimulate secretion of proinflammatory cytokines such as MMPs, IL-1, IL-8, and INF- $\gamma$ <sup>[30]</sup>. Highly elevated serum levels of IL-22 were correlated with disease severity in patients with Crohn's disease (CD)<sup>[17]</sup>. Colitis mouse models have indicated that highly elevated IL-22 expression may directly or indirectly induce inflammation<sup>[31]</sup>. Moreover, the IL-22/STAT3 signaling pathway is important in inflammation and carcinogenesis during UC *via* its upregulation of iNOS and MMP production, respectively<sup>[23,24]</sup>. Here, we demonstrate that IL-22 contributes to the inflammatory severity of UC and UC-CRC by activating STAT3 in IECs.

The UC microenvironment is composed of IECs, macrophages, immunocytes, and so on. The interactions among these cells involve their secreted cytokines and consist of a positive feedback loop with persistent activation of the STAT3-enabling progression of UC. Similar to IL-23 and IL-22R1, an IL-22 positive feedback loop in the UC microenvironment was demonstrated in this study. Our results indicated the IL-22 overexpression in the inflammatory cells of the colonic lamina propria in

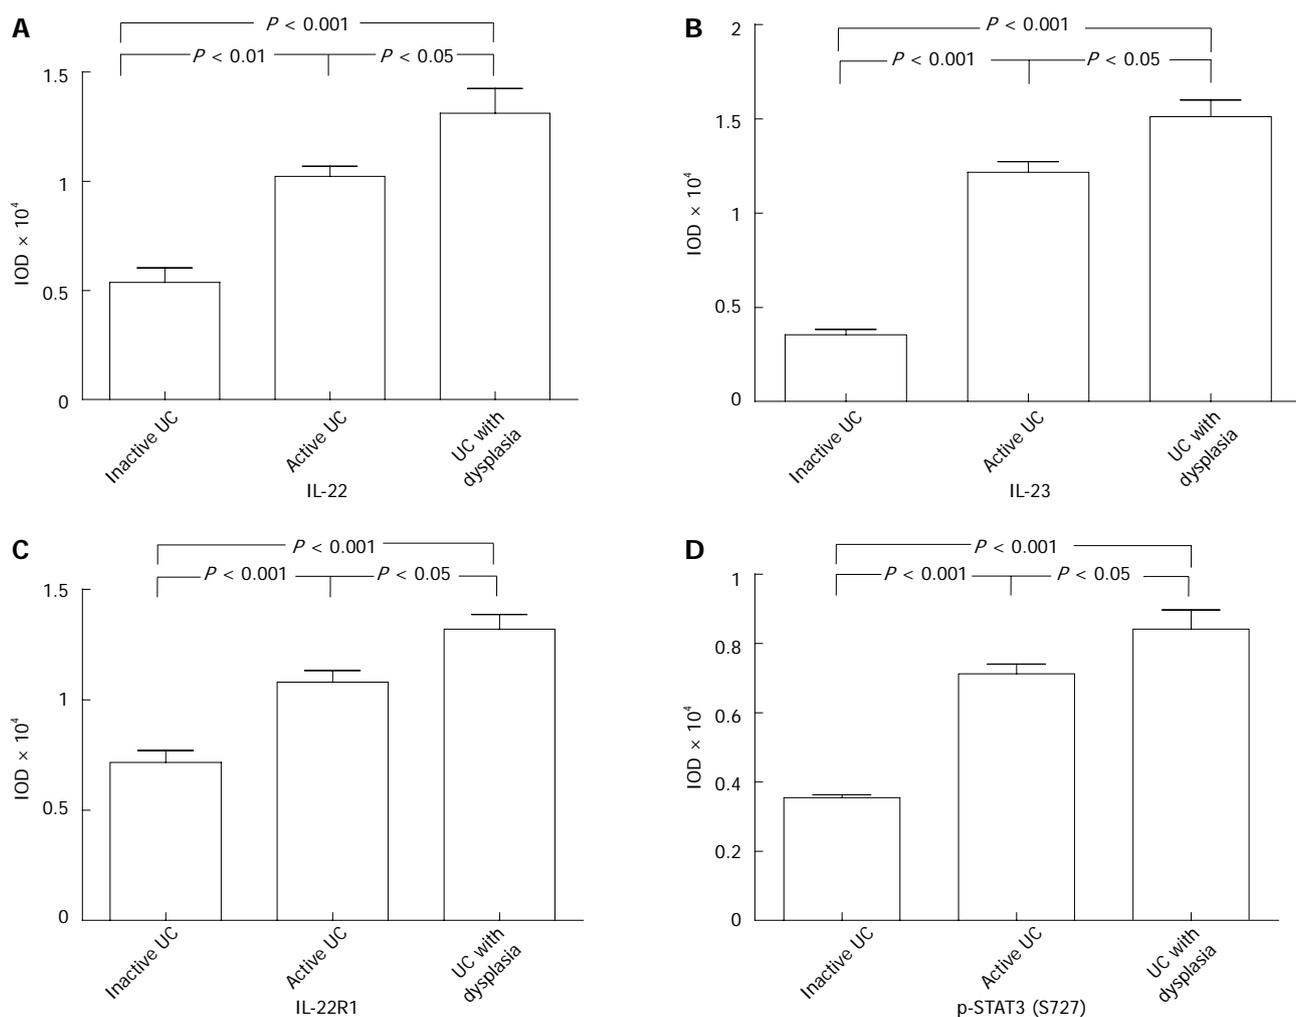

**Figure 5** Expression and distribution of interleukin-22 and its related proteins in human colonic tissues from patients with inactive ulcerative colitis, active ulcerative colitis, and ulcerative colitis with dysplasia, as detected by immunohistochemistry ( $\times 200$ ). A1-A3: Expression and distribution of interleukin (IL)-22 in inactive ulcerative colitis (UC), active UC, and UC with dysplasia tissues; B1-B3: Expression and distribution of IL-23 in inactive UC, active UC, and UC with dysplasia tissues; C1-C3: Expression and distribution of IL-22R1 in inactive ulcerative colitis (UC), active UC, and UC with dysplasia tissues; D1-D3: Expression and distribution of p-STAT3 (S727) in inactive UC, active UC, and UC with dysplasia tissues.

UC tissues. Moreover, the sustained activation of STAT3 signaling in IECs was verified. Simultaneously, IL-22R1 expression was enhanced in IECs, thereby ensuring the transmission of the IL-22 signal.

The STAT3-regulated proinflammatory cytokine IL-23<sup>[32]</sup> was likewise overexpressed in human UC. IL-23 activates innate immune cells to secrete pro-inflammatory cytokines such as IL-1 $\beta$ , TNF- $\alpha$ , and IL-6, as well as maintains the expansion of Th17 cells that express IL-22<sup>[33]</sup>.

IL-22 is increased in active Crohn's disease and pro-

motes proinflammatory gene expression<sup>[17]</sup>. We demonstrated that IL-22 is more highly expressed in active UC than in inactive UC and the normal control. Thus, the increased IL-22 signaling in active IBD supports the potential of an IL-22 signaling blockade as a therapeutic strategy for IBD. Furthermore, IL-23, IL-22, STAT3, and IL-22R1 are closely related to the colitis severity. Thus, positive feedback loops can further exacerbate inflammation. If left unchecked, these pathways may lead to the chronic immune pathology that is characteristic to IBD. Therefore, IL-22 could be used as a biomarker for deter-

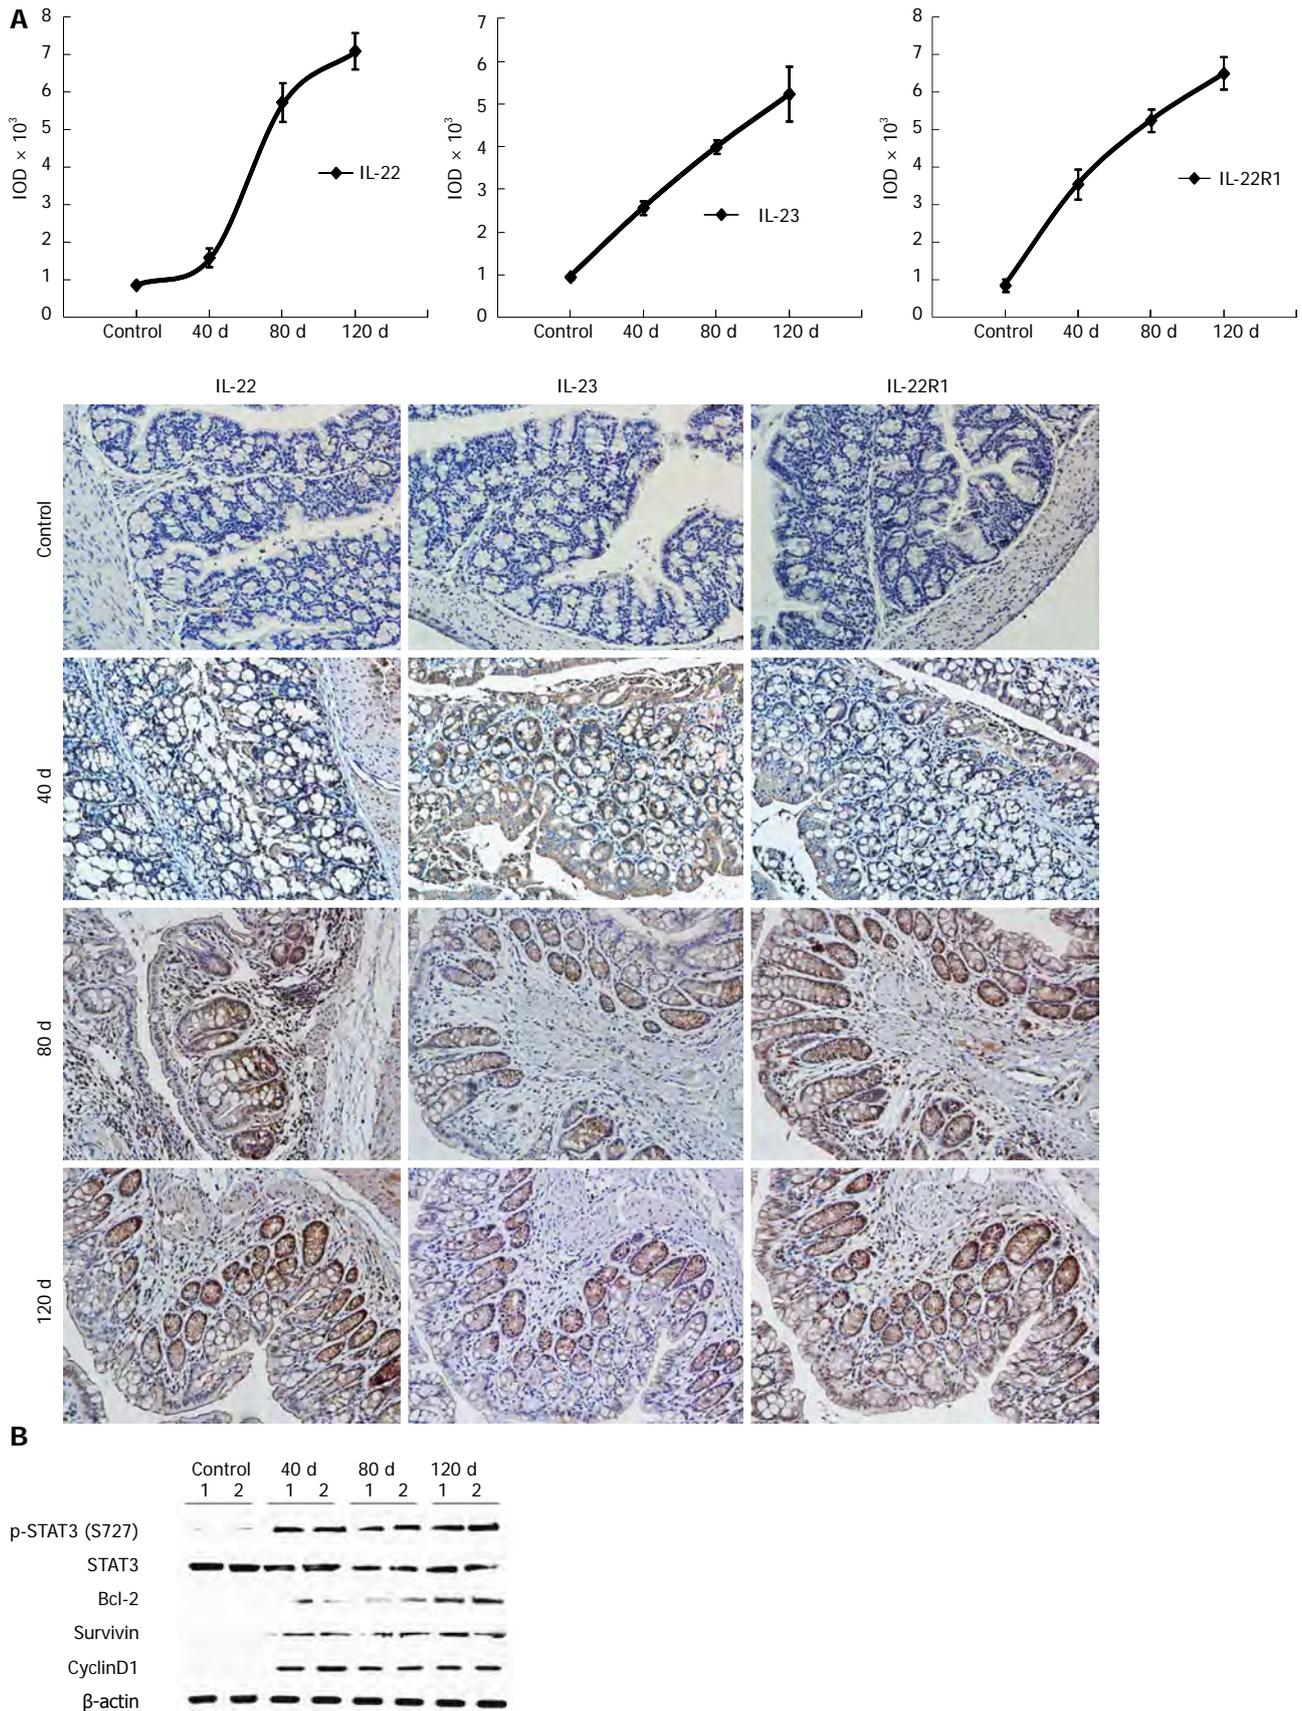

**Figure 6** Statistical evaluation of interleukin-22 and its related proteins in human colonic biopsy specimens from patients with inactive ulcerative colitis, active ulcerative colitis, and ulcerative colitis with dysplasia. The average integrated optical density (IOD) for immunohistochemistry staining of interleukin (IL)-22 (A), IL-23 (B), IL-22R1 (C), and p-STAT3 (S727) (D) in colonic tissues with ulcerative colitis (UC) and UC-related carcinogenesis (UC-CRC). Significantly higher expression levels of IL-22, IL-23, IL-22R1, and p-STAT3 were observed in the dysplasia group, as compared with the inactive and active UC groups.

mining UC severity.

STAT3 is a transcription factor that is activated by the binding of several cytokines, hormones, and growth factors to their respective receptors, including IL-22, IL-6, IL-23, and IL-1 $\beta$ <sup>[34]</sup>. We propose that STAT3 signaling is disrupted in chronic inflammation and carcinogenesis. The expression levels of total STAT3 and p-STAT3 in patients with UC were persistently elevated, with a positive correlation to the degree of inflammation<sup>[22]</sup>. Moreover, STAT3 is constitutively activated in a variety of human cancers, including colorectal cancer. This transcription factor is crucial in cancer cells because it regulates the transcription of genes involved in cell survival, apoptosis, and other cellular processes. Morikawa *et al*<sup>[34]</sup> found that p-STAT3 is significantly associated with poor prognosis in a data set of 724 colorectal cancers. Furthermore, STAT3 signaling has been reported to induce cancer-promoting inflammation and to inhibit antitumor immunity<sup>[35,36]</sup>. IL-6, a main activator of STAT3, has been proven to be important for promoting UC and UC-CRC<sup>[37]</sup>. IL-22, another inflammatory factor that

predominantly activates STAT3, has been verified in the chronic hepatitis and hepatocellular carcinoma (HCC) microenvironment; it induces tumor growth, inhibits apoptosis, and promotes metastasis *via* STAT3 activation<sup>[38]</sup>. Consistent with other studies on chronic hepatitis and HCC, our results demonstrated that the expression levels of IL-23, IL-22, IL-22R1, and STAT3 are consistently highly expressed in human UC tissues. IL-22 and p-STAT3, in particular, are more constitutively upregulated in the chronic colitis than in the controls. During the chronic phase of the DSS-induced mice colitis model, IL-22, IL-22R1, and IL-23 were highly expressed over time. Likewise, p-STAT3 and its downstream Bcl-2, cyclin D1, and survivin genes were remarkably upregulated. Furthermore, the expression of IL-22, p-STAT3, IL-23, and IL-22R1 were significantly elevated in human UC tissues with dysplasia, as compared with inactive and active UC tissues. Our results showed that the expression levels of IL-22 and IL-22R1 were more highly elevated in the acute colitis phase, which is in accordance with earlier studies<sup>[27,28]</sup>. We propose that IL-22 may ameliorate

**Figure 7** Expression of interleukin-22 and its related proteins in the mouse chronic colitis model. A: The average integrated optical density (IOD) for the immunohistochemistry staining of interleukin (IL)-22, IL-23, and IL-22R1 in mouse ulcerative colitis and normal tissues at different time points: days 40, 80, and 120. The expression of IL-22, IL-22R1, and IL-23 gradually increased with time; B: Western blotting detection of p-STAT3 (S727), total STAT3, Bcl-2, survivin, and cyclin D1 after DSS administration. Expression levels were all normalized to β-actin. All genes showed sustained expression over time.

intestinal inflammation by enhancing mucus production and goblet cell replacement in the early phase of inflammatory response. However, the persistent expression of IL-22 during the chronic phase of UC can strongly activate STAT3 phosphorylation in IECs, which is associated with the progression of human UC and UC-CRC<sup>[37]</sup> by upregulating genes for cell proliferation, anti-apoptosis, and survival.

In conclusion, our study provides clinical evidence that the IL-22/STAT3 signaling pathway is related to UC and UC-CRC. Moreover, IL-22 can be used as a biomarker for determining the severity of UC and as an interesting therapeutic target in active UC and UC-CRC.

## COMMENTS

### Background

It has been previously reported that interleukin (IL)-22, one of the cytokines secreted by Th17 cells, promotes a protective and inflammatory effect in inflammatory bowel disease (IBD) through STAT3 signaling activation.

### Research frontiers

The IL-22/STAT3 signaling pathway plays an important role in several autoimmune diseases, such as psoriasis, IBD, and so on. When activated by IL-22, STAT3 can aggravate colitis by promoting the expression of inflammatory factors such as IL-8, interferon- $\gamma$ , and matrix metalloproteinases. However, some studies have found that the IL-22 induced phosphorylation of STAT3 is a defense mechanism that enhances mucus production and goblet cell replacement in mouse models of acute colitis and wound-healing. Thus, the role of the IL-22/STAT3 signaling pathway in ulcerative colitis (UC) remains unclear.

### Innovations and breakthroughs

IL-22 may ameliorate intestinal inflammation by enhancing mucus production and goblet cell replacement during the early phase of the inflammatory response. However, the persistent expression of IL-22 in chronic phase of UC can strongly activate the phosphorylation of STAT3 in intestinal epithelial cells. p-STAT3 is associated with the progression of human UC and UC-related carcinogenesis (UC-CRC) because it upregulates the genes for cell proliferation, anti-apoptosis, and survival.

### Peer review

The authors report about the expression of IL-22, IL-22R1, IL-23, and STAT3 in biopsies of human UC and UC-related carcinogenesis. The study is well performed; it gives an overview on the expression of the before-mentioned factors in active and chronic UC and correlates IL-22 expression with disease severity.

### Abstract

**AIM:** To develop a prognostic model to predict survival of patients with colorectal cancer (CRC).

**METHODS:** Survival data of 837 CRC patients undergoing surgery between 1996 and 2006 were collected and analyzed by univariate analysis and Cox proportional hazard regression model to reveal the prognostic factors for CRC. All data were recorded using a standard data form and analyzed using SPSS version 18.0 (SPSS, Chicago, IL, United States). Survival curves were calculated by the Kaplan-Meier method. The log rank test was used to assess differences in survival. Univariate hazard ratios and significant and independent predictors of disease-specific survival and were identified

by Cox proportional hazard analysis. The stepwise procedure was set to a threshold of 0.05. Statistical significance was defined as  $P < 0.05$ .

**RESULTS:** The survival rate was 74% at 3 years and 68% at 5 years. The results of univariate analysis suggested age, preoperative obstruction, serum carcinoembryonic antigen level at diagnosis, status of resection, tumor size, histological grade, pathological type, lymphovascular invasion, invasion of adjacent organs, and tumor node metastasis (TNM) staging were positive prognostic factors ( $P < 0.05$ ). Lymph node ratio (LNR) was also a strong prognostic factor in stage III CRC ( $P < 0.0001$ ). We divided 341 stage III patients into three groups according to LNR values (LNR1,  $LNR \leq 0.33$ ,  $n = 211$ ; LNR2,  $LNR 0.34-0.66$ ,  $n = 76$ ; and LNR3,  $LNR \geq 0.67$ ,  $n = 54$ ). Univariate analysis showed a significant statistical difference in 3-year survival among these groups: LNR1, 73%; LNR2, 55%; and LNR3, 42% ( $P < 0.0001$ ). The multivariate analysis results showed that histological grade, depth of bowel wall invasion, and number of metastatic lymph nodes were the most important prognostic factors for CRC if we did not consider the interaction of the TNM staging system ( $P < 0.05$ ). When the TNM staging was taken into account, histological grade lost its statistical significance, while the specific TNM staging system showed a statistically significant difference ( $P < 0.0001$ ).

**CONCLUSION:** The overall survival of CRC patients has improved between 1996 and 2006. LNR is a powerful factor for estimating the survival of stage III CRC patients.

© 2013 Baishideng. All rights reserved.

**Key words:** Colorectal cancer; Prognostic factors; Cox proportional hazard regression; Lymph node ratio

**Core tip:** Recent reports and reviews have highlighted the importance of metastatic lymph node and Lymph

node ratio (LNR) in predicting prognosis of colorectal cancer (CRC). We found that the histological grade, depth of bowel wall invasion, and number of metastatic lymph nodes were the most important prognostic factor for CRC without consideration of the interaction of the tumor node metastasis staging system. LNR was a powerful factor for estimating the survival of stage III CRC. This paper presents new results on the 5-year overall survival and prognostic factors in Chinese CRC patients.

## INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies and one of the most common causes of cancer-related death worldwide<sup>[1]</sup>. An estimated 143460 new cases of CRC will be diagnosed this year, and 51690 patients will succumb to their disease in the United States alone<sup>[2]</sup>. Meanwhile, with the continuous aging of the population and an increased tendency to adopt a western lifestyle, the incidence of CRC and its related mortality is gradually increasing and it has become the fifth most common of all cancers in China<sup>[3,4]</sup>. Thus, the importance of CRC as a public health problem is increasing in China.

Over the past two decades, the 5-year overall survival of CRC patients has improved. Some advanced CRC patients have received clear survival benefits due to the practice of resecting liver metastases and advances in surgical techniques<sup>[5]</sup>. For those patients who have missed the opportunity for surgery, chemotherapy is still the main treatment. Although the overall survival of advanced CRC patients is still poorer than for early stage patients, it is encouraging that the combination of chemotherapy and targeted drugs may have the potential to improve survival.

In clinical practice, clinicians need an accurate outcome prediction of CRC patients to devise an appropriate therapeutic strategy. However, many variables may influence the prognosis, including both patient and tumor characteristics<sup>[6]</sup>. Therefore, we conducted the present study to explore the relevant factors affecting the prognosis of CRC patients using existing data in the Second Affiliated Hospital of Zhejiang University College of Medicine, China.

## MATERIALS AND METHODS

### *Patients and clinical data*

A total of 837 patients with CRC that underwent surgery

at the Department of Surgical Oncology at the Second Affiliated Hospital of Zhejiang University College of Medicine from January 1996 to December 2006 were enrolled from our database. All clinical cases and their follow-up data were recorded. The data included sex, age at diagnosis, clinical symptoms, severe complications, location of the primary tumor, histological type, tumor differentiation, lymphovascular invasion, depth of invasion, numbers of retrieved lymph nodes and metastatic lymph nodes, date of surgery, date of recurrence (if applicable), cause of recurrence (if applicable), date of death (if applicable), cause of death (if applicable), postoperative treatment, and date of follow-up. This study consisted of stages I-IV CRC patients. No local or systemic treatment had been conducted preoperatively. Patients' blood samples were collected before their operation and their carcinoembryonic antigen (CEA) levels were analyzed. Specimens were fixed in formalin and stained with hematoxylin-eosin (HE) and used for histopathological evaluation. The 6<sup>th</sup> and the 7<sup>th</sup> editions of the Union for International Cancer Control (UICC) classification were used to categorize colorectal carcinomas. Rectal cancer was defined as carcinomas with a distal margin of 15 cm from the anal verge measured with a rigid endoscope.

### *Follow-up duration*

All patients were followed up at 3-mo intervals for the first 2 years, and 6-mo intervals for 3-5 years. Follow-up was completed for the entire study population by March 2011, and the median follow-up period was 45 mo. The baseline of the study cases are shown in Table 1 (six cases of double primary CRC were excluded from Table 1).

### *Statistical analysis*

All data were recorded using a standard data form and analyzed using SPSS version 18.0 (SPSS, Chicago, IL, United States). Survival curves were calculated by the Kaplan-Meier method. The log rank test was used to assess differences in survival. Univariate hazard ratios and significant and independent predictors of disease-specific survival and were identified by Cox proportional hazard analysis. The stepwise procedure was set to a threshold of 0.05. Statistical significance was defined as  $P < 0.05$ .

## RESULTS

A total of 837 patients with CRC were enrolled. The 3-year and 5-year survival for all 837 patients was 74% and 68%, respectively. Table 2 summarizes the univariate analysis results of different clinical and pathological features.

Most patients ( $n = 808$ ) were diagnosed in middle age (median age: 60 years, range: 19-91 years) and 29 were diagnosed at  $\leq 35$  years of age. Patients were divided into four groups according to age at diagnosis: age1  $\leq 35$  years, age2 36-59 years, age3 60-74 years, and age4  $\geq 75$  years (Figure 1A). A significant difference in 5-year

**Table 1 Basic data for patients with colorectal cancer *n* (%)**

| Basic data                         | Colon cancer<br>( <i>n</i> = 437) | Rectal cancer<br>( <i>n</i> = 394) |

<sup>1</sup>Data are expressed as mean ± SD. Six cases of double primary colon and rectal cancer were not included.

survival was found between these four groups: age1 65%, age2 66%, age3 74%, and age4 53% (*P* = 0.002).

Among the 837 patients, 495 were male and 342 were female. There was no sex difference in survival (*P* = 0.834). Clinical features of 437 colon cancer patients and 394 rectal cancer patients were recorded. We also found six cases of double primary colon cancer and rectal cancer. In spite of a higher incidence of colon cancer, there were no significant differences in survival between patients with colon cancer and rectal cancer.

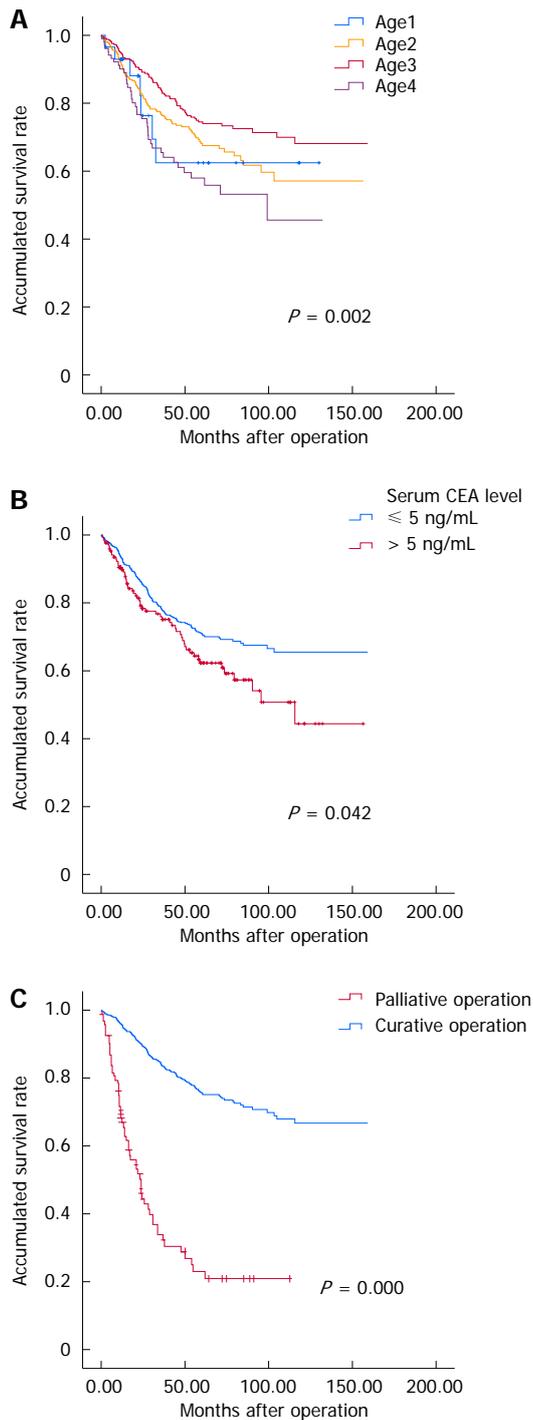

There were 25 patients who had a family history of CRC. It seemed that they had a trend toward better survival than the other 812 patients without a CRC-related family history. The difference was not statistically significant; 3-year survival was 91% *vs* 73% and 5-year survival was 82% *vs* 68% (*P* = 0.391).

According to the results of univariate analysis, patients with obvious clinical symptoms, such as tumor-related obstruction, perforation, diarrhea, constipation, and change of bowel habits had a shorter survival (Table 2). However, only the difference in tumor-related obstruction was statistically significant. The 3-year and 5-year

<sup>1</sup>*P* values were made by log-rank test. 3-YSR: 3-year accumulative survival rate; 5-YSR: 5-year accumulative survival rate; CEA: Carcino-embryonic antigen; CRC: Colorectal cancer.

**Figure 1** Survival curves of colorectal cancer patients. A: In different age groups; B: With different carcino-embryonic antigen levels; C: With different operation status. CEA: Carcinoembryonic antigen.

survival of 45 patients with preoperative bowel obstruction was 39% and 35% respectively *vs* 76% and 70% in patients without symptoms ( $P < 0.0001$ ). In addition to the clinical symptoms, serum carcino-embryonic antigen (CEA) level is commonly used as a screening and predictive factor for CRC patients (Figure 1B). In our study, the prognosis for patients with high CEA levels of  $> 5$  ng/mL at diagnosis was worse than those who with low CEA levels; 3-year survival was 71% *vs* 74% and 5-year

survival 62% *vs* 69% ( $P = 0.042$ ).

Surgery plays an important role in the treatment of CRC, and radical resection of tumors also has a major influence on prognosis. In our study, 711/837 CRC patients underwent curative surgery, while 95 had palliative surgery due to serious complications or for other reasons (Figure 1C). Compared with patients who had curative surgery, there was a significant decrease in postoperative survival in patients who had palliative surgery; 3-year survival of 80% *vs* 29% and 5-year survival of 74% *vs* 22% ( $P < 0.0001$ ). This confirms that curative surgery is one of the crucial factors affecting prognosis of CRC patients. In addition, the maximum length of the primary lesion, tumor differentiation, histological type, depth of bowel wall invasion, lymphovascular invasion, and invasion of adjacent organs may affect the prognosis of CRC patients ( $P < 0.05$ , Table 2).

Currently, the TNM staging system is widely accepted for tumor staging globally, and also represents the main staging system in our country. The 6<sup>th</sup> revision is regarded as being a significant improvement in CRC staging and the 7<sup>th</sup> revision is considered to be a major turning point in the evolution of cancer staging<sup>[7]</sup>. Regardless of the edition used for staging, survival of CRC patients gradually declined with increase in depth of infiltration of the primary tumor, the number of positive lymph nodes estimated, and status of distant metastases (Table 3, Figure 2). We also found that survival of stage IIIA patients was better than of stage IIB patients regardless of which edition was used to classify postoperative staging: with the 6<sup>th</sup> edition, 5-year survival of stage IIB and IIIA was 75% and 87% ( $P < 0.0001$ ), and for the 7<sup>th</sup> edition, 5-year survival of stages IIB and IIIA was 75% and 91% ( $P < 0.0001$ ).

LNR is defined as the ratio of positive lymph nodes divided by the total number of retrieved lymph nodes, and does not depend on the number of lymph nodes harvested<sup>[8]</sup>. It is considered to be an independent factor that reflects survival of CRC patients, especially those with stage III disease. We calculated the LNR values of 341 stage III cases. The mean LNR was 0.34 (median: 0.25, range: 0-1). Patients were divided into the following three LNR subgroups: LNR1, LNR  $\leq 0.33$ ,  $n = 211$ ; LNR2, LNR 0.34-0.66,  $n = 76$ ; and LNR3, LNR  $\geq 0.67$ ,  $n = 54$  (Figure 3). Survival among these three groups was significantly different ( $P < 0.0001$ ).

After we calculated the positive factors by univariate analysis, we used multivariate analysis (Cox proportional hazard model) to find the most significant prognostic factors (Table 4). First, we analyzed the interaction of the positive clinicopathological factors from univariate analysis, and multivariate analysis showed that histological grade, depth of bowel wall invasion, and number of metastatic lymph nodes affected the prognosis of CRC patients ( $P < 0.05$ ). We performed another two separate multivariate analyses with the 6<sup>th</sup> and 7<sup>th</sup> TNM staging systems. We found that histological grade was no longer a positive item when considering the interaction of the

3-YSR: 3-year accumulative survival rate; 5-YSR: 5-year accumulative survival rate; TNM: Tumor node metastasis.

TNM staging system (Table 4). Results for the 6<sup>th</sup> and 7<sup>th</sup> TNM staging systems in multivariate analysis showed significant differences (Table 4, *P* < 0.0001). Another two factors, the depth of bowel wall invasion and the number of metastatic lymph nodes, showed a positive statistical significance, regardless of which TNM staging system was used (Table 4, *P* < 0.05). Besides, with the increase in the number of metastatic lymph nodes with each level, the relative risk of death of CRC patients will increase 1.093 times without consideration of an exact clinical staging. However, this risk decreased to 1.037 times using the 6<sup>th</sup> TNM staging system and 1.047 times using the 7<sup>th</sup> system.

## DISCUSSION

CRC is the fifth most common cancer in China<sup>[3]</sup>. The morbidity and mortality of CRC have shown a clear upward trend in both urban and rural areas over the past 30 years. Although there has been an improvement in surgical techniques and treatment, the 5-year overall survival of CRC is still hovering around 60%. Park *et al*<sup>[9]</sup> have reported a 5-year survival rate of 67.2% in 2230 cases of CRC. In China, Lv *et al*<sup>[10]</sup> has reported 5-year survival rates of 58.4% and 64.5% 383 cases in colon and rectal cancer patients, respectively. In our study, the 3-year and 5-year survival of CRC patients was 74% and 68%, respectively.

The postoperative 5-year survival increased to 74% in our hospital, compared with 66% during 1980-1999<sup>[11,12]</sup>.

From 1980 to the 1990s, rectal cancer accounted for the main part of the incidence of CRC in China<sup>[4,11]</sup>. However, data from Table 2 showed a higher proportion of colon cancer than rectal cancer in our hospital from 1996 to 2006; with 437 cases *vs* 394 cases. Other researchers have reported similar results, which suggests that the proportion of rectal cancer cases is gradually declining<sup>[13-15]</sup>. Although the reason for the change is unclear, some experts have suggested that the higher incidence of colon cancer might be a complex result of changes in dietary habits, the higher rate of diagnosis of colon cancer, etiological changes, and the increased incidence of right colon cancer<sup>[16-20]</sup>.

In addition to the change in location of disease, the age at onset has also changed. Previously, CRC had a higher incidence in elderly people<sup>[21]</sup>. However, recent results at home and abroad have found that detection of CRC in the younger population is increasing<sup>[22]</sup>. CRC in young patients is generally considered a more aggressive disease, which presents at a later stage and has poorer pathological features<sup>[23,24]</sup>. Zhong *et al*<sup>[25]</sup> have reported only a 27.51% 5-year survival rate in young Chinese patients with CRC. In our study, the 5-year survival in the low-age group (age1) was 65%, which was slightly lower than the overall rate (68%), although it had improved

from the 5-year survival rate of 53% in patients aged  $\leq 40$  years at our hospital between 1980 and 1999<sup>[26]</sup>. It should be noted that there is no international standard definition of young or old, and the definition of low age in our study is different from that used by Cai *et al.*<sup>[26]</sup>. The overall survival between different age groups showed a significant difference in univariate analysis (Figure 1A), but failed to show a significant difference in the multivariate analysis.

Some reports have suggested that several clinicopathological features contribute to the unfavorable prognosis of CRC in young patients<sup>[27-29]</sup>. A review of the literature has suggested that younger patients with CRC, without relevant predisposing risk factors, have more advanced stages of disease, more aggressive histopathological characteristics, and a poorer prognosis compared with older patients<sup>[24]</sup>. However, there is also some evidence to show that cancer-related survival in young CRC patients seems no less favorable compared with older patients<sup>[30-32]</sup>.

The current international standard for CRC staging is the TNM system. The 7<sup>th</sup> edition of TNM staging, developed by the UICC and American Joint Committee on Cancer, has undergone some significant changes from the 6<sup>th</sup> edition. We tested which of the two versions could predict survival more accurately. Results of univariate analysis showed values in both staging systems were statistically significant prognostic factors ( $P < 0.05$ ). Figure 2D and H demonstrate the differences from stage I to stage IV disease. Similarly, both the 6<sup>th</sup> and 7<sup>th</sup> TNM staging systems were effective for judging the clinical survival and prognosis of CRC based on the results of multivariate analysis. The results also suggest a higher relative risk of death in CRC patients with more metastatic lymph nodes with an unclear clinical staging. It is worth noting that the patients with stage IIIA disease had a better survival than patients with stage IIB disease, as determined from the follow-up data. It might be explained by stage IIIA patients routinely receiving chemotherapy after their operation as part of current clinical practice, while stage IIB patients do not. Some authors also hold the view that lower survival of stage II CRC patients might be

RR: Relative risk; CEA: Carcino-embryonic antigen; TNM: Tumor node metastasis.

related to the particular biological behavior of stage II tumors<sup>[33-35]</sup>.

Lymph node metastasis is a significant component of TNM staging of CRC. Tumor stage and the number of lymph nodes retrieved at resection influence the accuracy of determining nodal status in CRC. They also influence the postoperative treatment strategy of CRC patients. In our study, we took the T, N and M stage as factors in univariate analysis and obtained positive results (Table 3, Figure 2). In addition, multivariate analysis demonstrated a strong relationship between the number of metastatic lymph nodes and survival of CRC patients (Table 4). The relative risk of death is increased with the number of metastatic lymph nodes. The number of lymph nodes found after surgical resection was positively associated with survival of patients with stage II and III colon cancer<sup>[36,37]</sup>. An underestimation of the nodal stage may lead to a high risk of local recurrence and influence decisions regarding adjuvant therapy, as well as influenc-

ing the overall prognosis<sup>[38-41]</sup>. According to the result of the INT-0089 trial, National Comprehensive Cancer Network Colon Cancer Clinical Practice Guidelines recommend that retrieval and examination of  $\geq 12$  lymph nodes can be regarded as adequate lymphadenectomy for accurate staging<sup>[42]</sup>.

There is a difference between the number of metastatic lymph nodes reported during surgery and the actual number of metastatic lymph nodes. The difference may result from many factors, including the extent of surgical dissection and the thoroughness of the pathologists. Cases with insufficient retrieval and undetected lymph nodes are not unusual in clinical practice, although the concept of taking a sufficient number of lymph nodes during surgery to ensure exact postoperative staging is currently agreed. Evaluating lymph node metastasis has become a prognostic factor for CRC, and LNR is an important component of staging. LNR has also been identified as being of significant prognostic value in breast and gastric cancer<sup>[43,44]</sup>. Berger *et al.*<sup>[45]</sup> were the first to suggest LNR as an important prognostic factor after curative resection for CRC. It was then established as a powerful independent index of CRC that reflected the probability of positive lymph nodes based on the number of retrieved lymph nodes<sup>[8,46-48]</sup>. In our study, we found a dramatic decrease in survival with an increase in LNR in stage III CRC patients ( $P < 0.0001$ , Figure 3).

Although the LNR has been emphasized as an important prognostic factor, quantification should be followed for clinical validity. Song *et al.*<sup>[49]</sup> have compared three prognostic factors of CRC and have concluded that LNR classification is a more reliable N classification than the nodal staging in the TNM system and LODDS:

$$\text{defined as } \log \frac{\text{pnod} + 0.5}{\text{tnod} - \text{nnod} + 0.5},$$

pnod is the number of positive lymph nodes, tnod is the total number of lymph nodes retrieved, and 0.5 is added to both numerator and denominator to avoid singularity<sup>[49]</sup>. They believe that LNR is superior to the other two indexes for the following reasons: (1) LNR could contribute to accuracy in prognostic assessment; (2) when the retrieved lymph node numbers is insufficient, TNM nodal staging will be inappropriate for staging migration and will even underestimate prognosis; and (3) as a novel indicator for predicting the status of lymph nodes, evidence of LODDS in CRC is inadequate and is more difficult to calculate and inconvenient for clinical practice<sup>[50]</sup>. When the number of examined lymph nodes is inadequate, LNR is a simple and powerful index to assess the prognosis of CRC patients.

In conclusion, based on the results from our study, we were delighted to find the overall survival in our hospital had improved between 1996 and 2006. Younger patients with CRC have attracted attention because of the increasing number of new cases, their adverse clinicopathological features, and poor prognosis. However, there is still a debate about the prognosis and clinicopathological

features of CRC in young compared to old patients. The pathogenesis and mechanism of disease are still unclear. The overall survival in patients with stage IIIA CRC was better than that in patients with stage IIB disease. This might be a combination of the special biological behavior of stage II CRC and the type of medical intervention for stage III CRC patients. The exact mechanisms of these problems and phenomena need further study.

By using multivariate analysis, we found that tumor histological grade, depth of bowel wall invasion, and metastatic lymph node numbers were independent prognostic factors for patients with CRC if we did not consider the exact clinical staging. We also found other important factors that could affect the prognosis of patients with CRC by univariate analysis, such as patient age, status of resection, and invasion of adjacent organs. The relative risk of death in CRC patients increases with the number of metastatic lymph nodes with an unclear clinical staging, which emphasizes the importance of correct clinical staging.

Surgeons know that a curative operation can greatly improve the overall survival of CRC patients, and resection of a sufficient number of lymph nodes is a necessity for proper postoperative staging. LNR is a powerful factor for assessment of prognosis in stage III CRC patients and is worthy of use in daily practice for evaluating a patient's risk of death. However, we should combine it with other complex factors that together can make a complete assessment so we can devise a proper plan for further treatment.

Besides appropriate treatment, a sensible follow-up plan should be given to CRC patients with full consideration of the factors mentioned above. Moreover, we should devise treatment strategies carefully based on the concept of individualized treatment according to each patient's clinical features, to improve survival and prognosis, especially for those patients with risk factors. In addition, early screening and surveillance by appropriate methods may improve the overall survival of CRC.

## COMMENTS

### Background

In recent years, the morbidity and mortality of colorectal cancer (CRC) has risen in the Chinese population. Although the 5-year overall survival of CRC patients has improved, the overall survival of advanced CRC patients is still poor. There are many impact factors that could influence the prognosis of CRC patients. Thus, a proper model for predicting the prognosis of CRC patients is necessary for both surgeons and physicians.

### Research frontiers

Nowadays, the tumor, node, metastasis (TNM) staging system is approved and widely used for clinical staging of CRC patients. As the latest version of TNM staging system, the 7<sup>th</sup> edition of TNM staging system is considered to represent a major turning point in the evaluation of CRC staging. However, less information of the real assessment validity between the 6<sup>th</sup> and 7<sup>th</sup> versions is available in Chinese populations.

### Innovations and breakthroughs

Recent reports and reviews have highlighted the importance of metastatic lymph node and lymph node ratio (LNR) in predicting prognosis of CRC patients. LNR is an easy but powerful index to evaluate prognosis in stage III CRC patients.

## Applications

Using univariate analysis and Cox proportional hazard regression model, we found that histological grade, depth of bowel wall invasion, and number of metastatic lymph nodes were the most important prognostic factors for CRC without consideration of the interaction of the TNM staging system. LNR is a powerful factor for estimating the survival of stage III CRC patients.

## Terminology

LNR is defined as the ratio of positive lymph nodes divided by the total number of retrieved lymph nodes, and does not depend on the number of lymph nodes harvested. It is considered an independent factor that reflects survival of CRC patients, especially those with stage III disease.

## Peer review

This article is helpful and creative for clinical significance. The results of this article verified the predictive affection of tumor invasion, lymph node metastasis and lymph node ratio. Meanwhile, it concludes that the 6<sup>th</sup> and 7<sup>th</sup> National Comprehensive Cancer Network TNM staging systems are both effective to predict the survival of colorectal cancer patients.

### Abstract

**AIM:** To evaluate short- and long-term efficacy of endoscopic balloon dilation in a cohort of consecutive patients with symptomatic Crohn's disease (CD)-related strictures.

**METHODS:** Twenty-six CD patients (11 men; median age 36.8 year, range 11-65 years) with 27 symptomatic strictures underwent endoscopic balloon dilation (EBD).

Both naive and post-operative strictures, of any length and diameter, with or without associated fistula were included. After a clinical and radiological assessment, EBD was performed with a Microvasive Rigiflex through the scope balloon system. The procedure was considered successful if no symptom reoccurred in the following 6 mo. The long-term clinical outcome was to avoid surgery.

**RESULTS:** The mean follow-up time was  $40.7 \pm 5.7$  mo (range 10-94 mo). In this period, forty-six EBD were performed with a technical success of 100%. No procedure-related complication was reported. Surgery was avoided in 92.6% of the patients during the entire follow-up. Two patients, both presenting ileocecal strictures associated with fistula, failed to respond to the treatment and underwent surgical strictures resection. Of the 24 patients who did not undergo surgery, 11 patients received 1 EBD, and 13 required further dilations over time for the treatment of relapsing strictures (7 patients underwent 2 dilations, 5 patients 3 dilations, and 1 patient 4 dilations). Overall, the EBD success rate after the first dilation was 81.5%. No difference was observed between the EBD success rate for naive ( $n = 12$ ) and post-operative ( $n = 15$ ) CD related strictures ( $P > 0.05$ ).

**CONCLUSION:** EBD appears to be a safe and effective procedure in the therapeutic management of CD-related strictures of any origin and dimension in order to prevent surgery.

## INTRODUCTION

In the last two decades, the medical therapy for Crohn's disease (CD) has remarkably improved and the introduction of biological therapies has dramatically changed the therapeutic approach in both adults and children<sup>[1,2]</sup>. However, CD still displays an unpredictable clinical course with high incidence of recurrence frequently leading to complications such as strictures, fistulas and abscesses<sup>[3]</sup>. At the time of diagnosis, intestinal strictures may occur throughout the gastrointestinal tract in about 5% of patients, whereas up to one third of the patients develop an intestinal strictures within 10 years of disease activity, with majority of them occurring at the terminal ileum, ileo-colonic, and colonic level<sup>[2,4,5]</sup>.

CD-related strictures is defined as a constant luminal narrowing, which can remain clinically silent or manifest with prestenotic dilatation and obstructive symptoms, such as abdominal bloating, distention, and pain. As the result of the continuous healing response to the chronic inflammation within the intestinal walls, the intestinal stricture induces a progressive narrowing of the lumen and an increased pressure gradient around the stricture, which might ultimately result into the development of internal fistula proximally to the obstruction<sup>[6]</sup>. Stricture-associated fistulas contribute to increase the disease severity and worsen the clinical management.

CD strictures generally show a poor response to medical therapies, and surgical bowel resection or surgical strictureplasty are often required<sup>[5,7,8]</sup>. In patients with CD, intestinal surgery is needed for as many as 80% of CD patients, and a permanent stoma is required in more than 10% of CD patients<sup>[3]</sup>. However, high rate of relapse (defined by recurrence of clinical symptoms) is also observed after surgical resection: 40% at 4 years after bowel resection<sup>[9,10]</sup>, and 50% at 10 to 15 years after ileocecal resection<sup>[11,12]</sup>. Strictureplasty has also been associated with a risk of stricture relapse in 34% of the cases at 7.5 years<sup>[13]</sup>. This implies that up to one third of CD patients will undergo more than one surgery in their life course<sup>[14-16]</sup>. Patients with an early onset disease have an increased risk of surgical relapse and need of repeated resections, which in turn may result in a short bowel syndrome<sup>[13,17-20]</sup>.

Endoscopic balloon dilation (EBD) is a minimally invasive technique that can reduce or delay the need of surgery in patients with CD-related strictures<sup>[21,22]</sup>. With the new generation of double or single endoscopic balloon enteroscopy, this procedure can be performed at almost any level of the gastrointestinal tract. Moreover, the EBD in CD strictures appears to be a safe technique with a low complication rate (0% to 10%)<sup>[22-24]</sup>. It has been shown that the technical success rate of the endoscopic bal-

loon dilation is 95%<sup>[25-27]</sup>, with up to 47% of CD patients showing a long-term global benefit, *i.e.*, a surgery-free period at 3 year follow-up<sup>[22,24]</sup>.

In this prospective study, we aimed to assess the effectiveness and safety of the EBD in a cohort of consecutive CD patients with symptomatic intestinal strictures.

## MATERIALS AND METHODS

### Study cohort

Twenty-six consecutive CD patients (11 males, 15 females), presenting 27 symptomatic strictures (one patient was treated for two strictures), and complaining up to two intestinal symptomatic obstructive episodes as suspected by plain abdominal X-rays or contrast study in the preceding 6 mo, were prospectively enrolled into the trial between March 2004 and March 2011. Diagnosis of CD in both adult and children was based on widely agreed endoscopic and histological criteria<sup>[28,29]</sup>, and disease classification was done according to the Montreal criteria for adults and Paris criteria for children<sup>[30,31]</sup>. A detailed personal and family history was obtained from each patient. The clinical assessment of the patients was performed through the pediatric Crohn's disease activity index (PC-DAI) in children, and through the Crohn's disease activity index (CDAI) in adult<sup>[32,33]</sup>. An PCDAI  $\leq 10$  and a CDAI  $\leq 150$  indicate inactive disease.

Prior to the endoscopic procedure, all patients underwent radiological assessment by abdominal ultrasound with eco-color doppler of mesenteric and the ileocecal region, and magnetic resonance imaging with contrast enhancement to confirm the suspected stricture and to investigate the presence of concomitant fistula or abscess. No exclusion criterion was applied in the selection of strictures to be treated with EBD. Naive and post-surgical strictures, strictures associated with fistula or abscess, and strictures of any length and diameter were included in the study. In all patients surgery was considered for treatment.

### EBD technique

Before the endoscopic procedure, all patients underwent the following tests and medications: standard laboratory blood tests including coagulation tests; mechanical intestinal bowel preparation (approximately 36 h before); and liquid diet (starting at least 12 h before).

The endoscopic dilations were performed under unconscious sedation, obtained by administering IV midazolam +/- meperidine or propofol, under constant monitoring of the vital parameters. All procedures were performed by the same endoscopist (de'Angelis GL), and lasted approximately 1 h. The EBD was carried out using Olympus PCF 140 (Olympus, Germany) and Olympus Ileoscopy single balloon SIF 180 (Olympus, Germany) (according to the stricture site).

The EBD was carried out with a hydrostatic Microvative Rigidflex through the scope balloon system (Microvative Endoscopic, Boston Scientific Corporation<sup>®</sup>, Natick,

CD: Crohn's disease; PCDAI: Pediatric Crohn's disease activity index; CDAI: Crohn's disease activity index.

Massachusetts, United States), with a diameter of 15-18 mm. The correct insertion and positioning of the balloon was checked by fluoroscopic control. After reaching the optimal placement through the stricture, the balloon was gradually inflated with water and gastrografin up to 15 mm of diameter, held for 90 s and then deflated. A second inflation up to 18 mm diameter for 90 s was always performed. In case of resilient strictures, the process of inflation was repeated up to 6 times in the same session, reaching progressively larger balloon diameters. Once the balloon dilation was accomplished, a combination of methylprednisolone (40 mg) diluted in 5 mL of normal saline solution were injected intra-lesionally with Olympus single use injector 0, 5 mm (Olympus, Japan). The ultimate step of the procedure consisted in examining the proximal bowel (30 cm above the stricture) in order to detect others possible lesions that were undetected by the pre-procedural assessing imaging.

In combination with underlying treatment, after EBD each patient was treated by administering prednisolone with a dosing scheme determined by body weight: 1.5 mg/kg daily (maximum allowed dose 60 mg daily) for 2 wk, followed by a 4 wk tapering course.

### Clinical outcomes

The technical success of the procedure was defined as the passage of the endoscope through the stricture, reaching a diameter of approximately 15 mm. Procedure-related complications were defined as intestinal perforation, and active bleeding requiring surgery or blood transfusions. The long-term clinical success was defined as surgery was avoided all long the follow-up period by obtaining symptom relief with repeated EBD procedures. The short-term clinical success was defined as 6 mo symptom-free period after the EBD. The need of re-dilation was determined based on clinical and imaging criteria in association with persistence or reoccurrence of

obstructive symptoms. Surgery was reserved for strictures that did not respond to the medical and the endoscopic therapy.

### Ethical considerations

The work carried out was in accordance with the principles laid down in the Declaration of Helsinki for biomedical research involving humans. All adult patients included in the study gave their consent for the use of their clinical data. For children, written consent was obtained from both parents and those older than 12 year signed a statement of assent.

### Statistical analysis

Data were analyzed by using SPSS (IBM SPSS Statistics, Version 17.0.0 for Macintosh, Chicago, IL, United States). Kaplan-Meier analysis was performed for periods free of surgery and free of endoscopic re-dilation. Regression statistics were used to relate the clinical and demographic variables to the main outcome (*i.e.*, need of surgery). *P* value ≤ 0.05 was considered significant. Data are expressed as median and range, or mean ± SE, unless otherwise stated.

## RESULTS

The patients' demographic and clinical characteristics, and the stricture characteristics are summarized in Tables 1 and 2 respectively. Forty-six EBD were performed for 27 symptomatic strictures occurred in the 26 CD patients. Of these, 15 patients had post-surgical strictures and 11 had naive strictures. The technical success of the endoscopic procedure was achieved in all patients without any endoscopic related complication (Figure 1).

The mean follow-up time of the cohort was 40.7 ± 5.7 mo (range 10-94 mo). All patients survived during the follow-up period. Of the 26 CD patients that were treated with EBD, only two failed to respond to the treat-

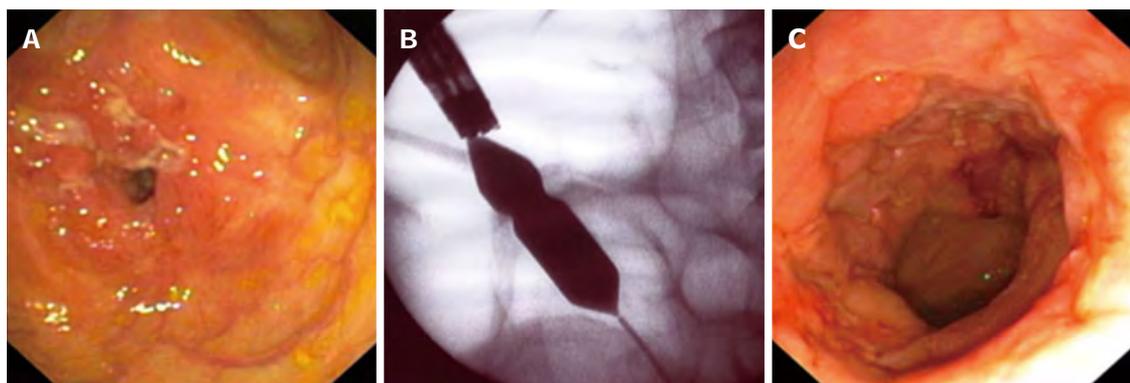

Figure 1 Images of Crohn's disease-related stricture in one patient. A: Direct visualization of the ileal stricture; B: Inflation of the endoscopic balloon under fluoroscopic control; C: Direct visualization of the bowel site after the endoscopic balloon dilation.

ment and underwent elective surgical laparoscopic stricture resection. Both patients requiring surgery presented ileocecal strictures associated with fistula. The overall long-term clinical success rate was 92.6% (24/26 patients remained free of surgery) (Figure 2A).

Of the 24 patients who did not undergo surgery all long the follow-up period, 11 patients received only 1 EBD, and 13 required further dilations over time for the treatment of relapsing strictures (7 patients underwent 2 dilations, 5 patients 3 dilations, and 1 patient 4 dilations). The mean time free of re-dilation between the first and the second EBD was  $21.2 \pm 5$  mo. The cumulative percentages of patients free of re-dilation over the entire follow-up period are shown in Figure 2B.

Throughout the study population, the short-term clinical success rate was 81.5% (2 patients required surgery; 3 patients did not have symptom-free 6 mo) after the first EBD. After the second EBD, the clinical success rate was 92.3% (12/13 patients); after the third EBD, the clinical success rate was 83.3% (5/6 patients). Only one patient underwent a fourth EBD showing a clinical success. The subgroup analysis dividing the study population into two groups based on the nature of the strictures, *i.e.* naive vs post-operative, showed no statistical difference between groups in term of clinical success after repeated EBD. Indeed, after the first dilation, short-term clinical success was obtained in 93.3% of the post-operative strictures and 66.7% of the naive strictures [not significant (NS)]; after the second EBD, success was obtained in 100% of the post-operative strictures and in 80% of the naive ones (NS); after the third EBD, success was observed in 100% of the post-operative strictures and 66.7% of the naive strictures (NS). The cumulative percentages of patients free of re-dilation over the entire follow-up period for both naive and post-operative strictures are shown in Figure 2C.

Of the variables evaluated, the presence of stricture-associated fistula and the stricture location at the ileocecal level resulted significant predictive factors on the long-term negative clinical outcome, *i.e.*, the need of surgery (both  $P = 0.002$ ). In fact, the 2 strictures that required surgery after the first EBD due to the failure of the

endoscopic procedure (*i.e.*, persistency of subocclusion symptoms) were sited at the ileocecal level and were associated with fistula. On the contrary, the sex and age of the patient, the nature of the strictures (naive *vs* post-surgical), the severity of CD activity, the dimension of the strictures (lengths and diameters), and the medical therapy did not influence the long-term clinical outcomes (Table 3).

## DISCUSSION

The present study describes the clinical follow-up of a cohort of 26 CD patients presenting with symptomatic strictures and treated with EBD. The EBD appeared to be a safe technique that prevented the need of surgery in 92.6% of the patients during our follow-up period. The endoscopic treatment associated with the medical therapy influenced the natural history of the disease and thus it can be considered an effective strategy in the management of symptomatic strictures in CD patients.

EBD has become more and more used in the treatment of CD strictures since it demonstrated to be a safe and minimally invasive technique, while conserving the intestinal length. At the same time, the medical therapy is largely applied to manage the clinical course of this inflammatory disease and to control its clinical evolution. A combined medical and endoscopic therapy has shown to be effective in the treatment of CD-related strictures<sup>[22,34]</sup>. However, standardized clinical guidelines and protocols are missing.

Our cohort study presents some points of strength and novelty. In fact, to describe the effectiveness of EBD and its influence of the natural history of the disease, we decided to recruit in the study consecutive CD patients without any strictures related exclusion criterion. Conversely to the other studies<sup>[21,22,34,35]</sup>, we considered strictures of any nature and lengths (up to 12 cm), with and without associated fistula. The objective was to analyze a population that is the most often seen in the everyday clinical practice compared to the highly selected cohorts of patients that are usually described in the literature. Our results demonstrated that the EBD can be

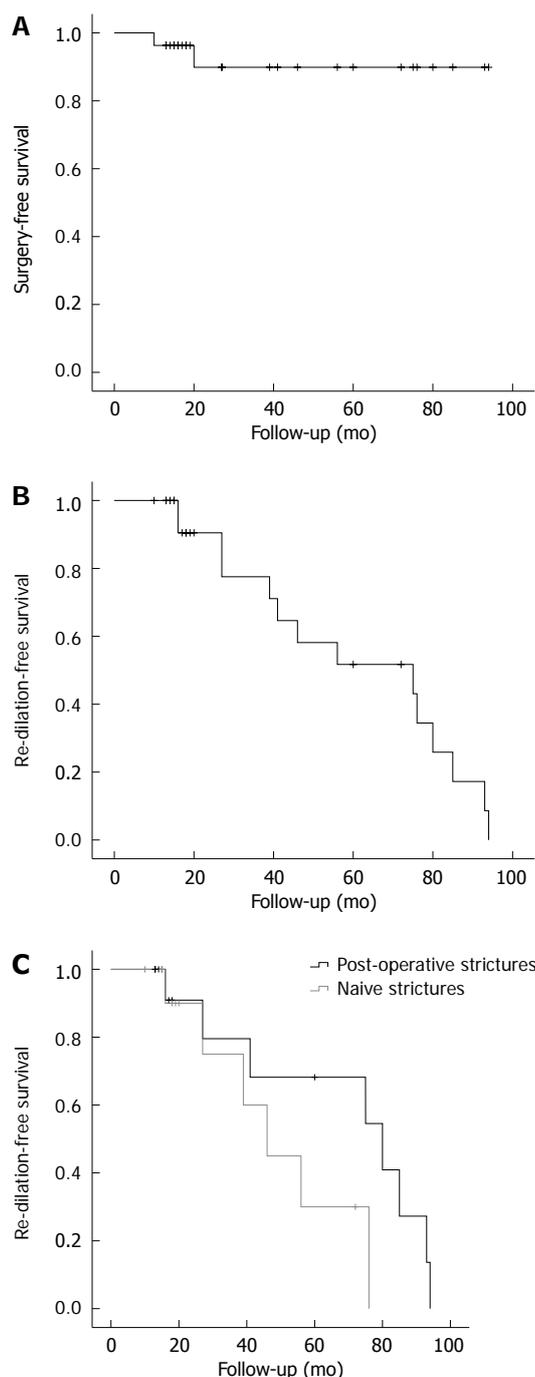

Figure 2 Kaplan-Meier curves for intervals free of surgery or endoscopic dilation. A: Kaplan-Meier curve for interval free of surgery after endoscopic balloon dilation or re-dilation; B: Kaplan-Meier curve for interval free of re-dilation during the follow-up period; C: Kaplan-Meier curve for the interval free of re-dilation over the follow-up period for patients with naive (in gray) and post-operative (in black) strictures.

effectively used also in CD related strictures longer than 4 cm in order to avoid or postpone surgery. The lengths of the strictures did not appear to be a contraindication for performing EBD as a first line treatment in contrast to previous studies<sup>[24,34]</sup>. The EBD overall long-term success rate in our study is higher than the values of Hassan *et al.*<sup>[34]</sup> in a recent systematic review, which reported a cumulative mean success rate of 67% (ranging from 41%

**Table 3 Analyses of the influence of the clinical variables on the occurrence of surgery**

| Variables                              | No surgery (n) | Surgery (n) | P value |
|--|----------------|-------------|---------|
| Male sex                               | 10             | 1           | NS      |
| Adult patients                         | 21             | 2           | NS      |
| Naive strictures                       | 10             | 2           | NS      |
| Moderate disease activity              | 12             | 2           | NS      |
| Strictures length > 4 cm               | 11             | 1           | NS      |
| Strictures diameters ≤ 5 mm            | 24             | 2           | NS      |

NS: Not significant.

to 100%) over an average follow-up time very close to one in the present study. In order to avoid surgery, EBD was repeated-up up to 4 times during the follow with a high short-term clinical success rate after each procedure and a technical success rate of 100% with no procedure-associated complication. This result may be also related to the high-volume endoscopy center in which EBD were performed.

Based on these findings and in accordance with other studies<sup>[22,24,34,35]</sup>, EBD appeared to be a safe procedure with a very low complication rate when an endoscopist experienced in the management of bowel stricture performs it. In our study, we showed that EBD is safe and feasible even in a non-selected sample of CD patients. Moreover, the safety of the procedure may be related to the diameters of the endoscopic balloon used. In our study the 18 mm balloon was the largest applied, for not more than 90 s inflations and no more than 6 dilations per session. If prudence is respected in the selection of balloon dimensions, number of dilations, and progressive inflations, the intra-operative complications may be minimized<sup>[22,23,36]</sup>. The procedural safety is essential in consideration of the need of frequent re-dilations over time in the same patient in order to obtain and maintain symptomatic relief.

EBD can be considered a valuable and safe alternative of surgical resection, but EBD and surgery must not be seen as mutually exclusive solutions for CD strictures. Rather EBD may be a complementary procedure that should be considered in both adult and pediatric patients in order to reach a symptom-free condition with a low risk associated.

As previously reported, we found that the stricture location at the ileocecal level appeared to be a significant negative predictor on the long-term clinical outcome, *i.e.*, the need of surgery<sup>[24]</sup>. In our study, also the presence of fistula was associated with the occurrence of surgery. Notwithstanding, three patients with fistulizing phenotype (2 located at the colo-rectal anastomosis and 1 in the sigma), showed good clinical short and long-term outcomes after EBD, suggesting that the analysis results may represent a type II error and that larger groups could provide different results. Studies on EBD in CD

patients presenting strictures associated with fistula are scarce in the literature, since the majority of the previously published case series considered the presence of fistula as a patient's exclusion criterion<sup>[21,27,35,37]</sup>. Although the paucity of data, in a similar clinical scenario the EBD should not be excluded a priori. Furthermore, it could be used, together with the medical therapy, as an option to bridge the patient to surgery in better performance conditions (*e.g.*, nutrition, inflammatory status), shifting from an emergency to an elective surgery. It is noteworthy that in patients with an adequate nutrition status in which the intestinal obstructive condition has been endoscopically managed (even if suboptimally), the response to surgery and the post-surgical complication rate (*e.g.*, anastomotic leakage) are generally improved<sup>[38,39]</sup>. The other examined variables seem to not affect the clinical outcomes. However, we were not able to detect which variables are associated with clinical success after only one EBD, and which can predict the need of further dilations. These aspects should be studied in a larger sample of patients.

In our cohort, both naive and post-surgical strictures responded to the EBD treatment, without significant difference on the clinical outcomes as seen by other authors<sup>[24,25]</sup>. Thus, EBD can be considered a valuable strategy in the management of both naive and post-surgical CD related strictures. In parallel, EBD resulted equally effective in adult and pediatric CD patients. It must be emphasized that the endoscopic management of CD strictures is cardinal in pediatrics because of the long life expectancy of these patients, who would more probably develop a short bowel syndrome if repeated surgical resections are performed. Moreover, many clinical concerns are related to the malnutrition and subsequent failure to thrive that will follow the obstructive condition in children if this is not immediately managed<sup>[40]</sup>.

Interestingly, all our patients were still medically both before and after the endoscopic treatment, mainly with azathioprine and/or biological therapy. Factors determining the development of strictures are not fully understood, but chronic and trans-mural inflammation probably plays a major role<sup>[41-43]</sup>. Although the lack of data in the literature, azathioprine has been shown to reverse the inflammatory changes at the anastomotic site and to maintaining remission in CD patients<sup>[44,45]</sup>. Conversely, because of reports of complete obstruction after infliximab in patients with or without initial stricture, its use has been contra-indicated in stenotic forms of CD<sup>[46]</sup>. Theoretically, the rapid tissue healing induced by infliximab administration may result in marked architectural changes in the intestinal wall, which may lead to wall stricturing. However, strictures do not occur without inflammation, and chronic inflammation *per se* may lead to strictures. In fact, a long-term inflammatory process sustained by increased cytokine production leads to an excess of fibrotic response. On the other hand, substantial thickening of the mesenchymal layers is observed during mucosal repair. The control of chronic inflammation to prevent fibrosis and stenosis seems more important than the risk of fibrosis induced by treatment, thus justifying inflix-

imab infusions<sup>[41]</sup>. However, the role of biological therapy in case of CD strictures remains controversial<sup>[47,48]</sup>. In our cohort, we were not able to define the role and support of the two medical therapies on the clinical outcomes evaluated. With this objective, multicenter, randomized, controlled, blind clinical trials should be performed. The use of EBD is supported not only by the clinical risk/benefit ratio, but also by the costs associated to this procedure. In Italy, the entire EBD procedure (pre-endoscopy exams; hospitalization; medications; balloon dilation kit) is comprised between 1000 and 1200 Euros (reimbursed by the National Health System).

In conclusion, the EBD is not just an attractive treatment option in the management of CD-related strictures. The available literature provides quite enough evidence to support its use. However, clinical guidelines, especially on the combined medical and endoscopic therapy, are still lacking. Time has come to investigate EBD clinical benefits and success in large clinical studies in order to define and standardize the protocol of use.

## COMMENTS

### Background

Crohn's disease (CD)-related strictures are scarcely responsive to medical therapy and thus they are mainly treated surgically. Recently, endoscopic balloon dilation has been increasingly used in the treatment of CD-related strictures.

### Innovations and breakthroughs

The present study evaluated the efficacy of endoscopic balloon dilation (EBD) in CD-related strictures of any length (up to 12 cm), both naive and post-operative, with or without associated fistula, and in both adult and pediatric patients. Strictures located in both upper and lower gastrointestinal were successfully treated using gastroscope, colonoscope or ileoscope according to the stricture site. Their results confirmed that over a mean follow-up period of 40.7 mo multiple endoscopic balloon dilations were safe and effective to manage CD-related strictures.

### Applications

The present study supports EBD as a valuable option in the treatment of symptomatic CD patients. Moreover, EBD demonstrated as a safe technique, which can be repeated over time in order to avoid surgery, since it can be performed successfully also in relapsing patients who were previously endoscopically dilated. The associated complications are very rare (none in this study).

### Terminology

EBD is an operative endoscopy procedure used to dilate intestinal strictures in unconscious patients. The dilation is carried out with a hydrostatic through the scope balloon system, which, once inserted and positioned through the stricture, is gradually inflated with water, held for 90 s and then deflated to obtain stricture dilation.

### Peer review

de'Angelis *et al* report an interesting series of EBD of strictures in CD. The inclusion of both naive and postoperative strictures with or without associated fistula reflects the usual clinical scenario in CD strictures. Although the number of the cases included in the study is not so large, the conclusions are well presented and discussed. I agree with the authors that until clinical guidelines are available EBD would be a treatment option before surgery in this kind of patients.

### Abstract

**AIM:** To investigate the predictive value of narrow-band imaging with magnifying endoscopy (NBI-ME) for identifying gastric intestinal metaplasia (GIM) in unselected patients.

**METHODS:** We prospectively evaluated consecutive patients undergoing upper endoscopy for various indications, such as epigastric discomfort/pain, anaemia, gastro-oesophageal reflux disease, suspicion of peptic ulcer disease, or chronic liver diseases. Patients underwent NBI-ME, which was performed by three blinded, experienced endoscopists. In addition, five biopsies (2 antrum, 1 angulus, and 2 corpus) were taken and examined by two pathologists unaware of the endoscopic

findings to determine the presence or absence of GIM. The correlation between light blue crest (LBC) appearance and histology was measured. Moreover, we quantified the degree of LBC appearance as less than 20% (+), 20%-80% (++) and more than 80% (+++) of an image field, and the semiquantitative evaluation of LBC appearance was correlated with IM percentage from the histological findings.

**RESULTS:** We enrolled 100 (58 F/42 M) patients who were mainly referred for gastro-esophageal reflux disease/dyspepsia (46%), cancer screening/anaemia (34%), chronic liver disease (9%), and suspected celiac disease (6%); the remaining patients were referred for other indications. The prevalence of *Helicobacter pylori* (*H. pylori*) infection detected from the biopsies was 31%, while 67% of the patients used proton pump inhibitors. LBCs were found in the antrum of 33 patients (33%); 20 of the cases were classified as LBC+, 9 as LBC++, and 4 as LBC+++. LBCs were found in the gastric body of 6 patients (6%), with 5 of them also having LBCs in the antrum. The correlation between the appearance of LBCs and histological GIM was good, with a sensitivity of 80% (95%CI: 67-92), a specificity of 96% (95%CI: 93-99), a positive predictive value of 84% (95%CI: 73-96), a negative predictive value of 95% (95%CI: 92-98), and an accuracy of 93% (95%CI: 90-97). The NBI-ME examination overlooked GIM in 8 cases, but the GIM was less than 5% in 7 of the cases. Moreover, in the 6 false positive cases, the histological examination showed the presence of reactive gastropathy (4 cases) or *H. pylori* active chronic gastritis (2 cases). The semiquantitative correlation between the rate of LBC appearance and the percentage of GIM was 79% ( $P < 0.01$ ).

**CONCLUSION:** NBI-ME achieved good sensitivity and specificity in recognising GIM in an unselected population. In routine clinical practice, this technique can reliably target gastric biopsies.

**Key words:** Narrow-band imaging; Magnification; Gastric intestinal metaplasia; Light blue crest; Gastric cancer; Endoscopy; Precancerous conditions; Gastric biopsy

**Core tip:** Gastric cancer is one of the most common neoplastic diseases in the Western world and has a poor prognosis and inconsistent signs and symptoms in the early phases. Narrow-band imaging with magnifying endoscopy was shown to be a valid method for intestinal metaplasia (IM) detection, this technique can reliably target which patients should be biopsied to evaluate IM and those who do not need biopsies. Moreover, a semi-quantitative evaluation of light blue crest appearance was feasible as there was a good correlation with the histological assessment of IM percentage.

Narrow-band imaging with magnifying endoscopy is accurate for detecting gastric intestinal metaplasia. *World J Gastroenterol* 2013; 19(17): 2668-2675 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i17/2668.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i17.2668>

## INTRODUCTION

Gastric cancer is the fourth most common cancer and the second leading cause of cancer-related death worldwide<sup>[1,2]</sup>. However, the mechanism of gastric carcinogenesis is unknown. The intestinal type tumour, according to the Lauren classification, is characterised by the presence of malignant cells forming glandular structures; in contrast to diffuse type carcinomas, these tumours are generally thought to be preceded by a sequence of precursor lesions. In this multistep model of gastric carcinogenesis, described several years ago by Correa *et al*<sup>[3]</sup>, *Helicobacter pylori* (*H. pylori*) causes chronic inflammation of the gastric mucosa, which slowly progresses through the premalignant stages of atrophic gastritis, intestinal metaplasia and dysplasia, intramucosal carcinoma and invasive neoplasia<sup>[4]</sup>.

Intestinal metaplasia (IM) is generally considered as the “field cancerization” in the gastric mucosa. At the cell level, intestinalized glands provide the cellular substrate that allows the gastric non-invasive neoplasia to develop. The reported progression rates of IM and dysplasia to cancer vary greatly from 0% to 10% per year for IM and from 0% to 73% per year for dysplasia<sup>[1]</sup>. The prevalence of this condition in Europe varies by country<sup>[5-9]</sup>; for instance, a Swedish group reported an IM prevalence of 23% in the general population<sup>[10]</sup>, while the prevalence has been estimated to be up to 25% in the Italian population, mainly occurring in the gastric antrum<sup>[7,11-13]</sup>.

In Western countries, premalignant gastric lesions and

early gastric cancer are generally diagnosed upon histologic examination of random biopsies, whereas in Asian countries, especially in Japan, the presence and extension of these lesions are frequently established during an endoscopy<sup>[14-16]</sup>. These remarkable differences are explained by different training and attitudes towards the inspection of the stomach in countries with a high gastric cancer incidence.

The narrow-band imaging system (NBI) is based on the modification of optical filter spectral characteristics in the light source, which improves the visibility of mucosal structures. NBI may be combined with magnification endoscopy to obtain a clear visualisation of surface and vascular patterns<sup>[1,2]</sup>. Earlier studies using the NBI system with magnification endoscopy (NBI-ME) in the gastric mucosa showed that the appearance of a light blue crest (LBC) in the mucosa is a distinctive endoscopic finding that suggests an increased likelihood of detecting IM in the stomach. More precisely, blue-whitish patchy areas are often observed in NBI images of the antrum in patients with gastric IM. Uedo *et al*<sup>[16]</sup> tested NBI-ME on 34 patients with atrophic gastritis and found that the LBC appearance was frequently observed in gastric antrum as blue-white lines visible on the epithelial surface. These authors demonstrated that the appearance of LBCs correlated with histological evidence of IM, with a sensitivity of 89% (95%CI: 83-96), a specificity of 93% (95%CI: 88-97), a positive predictive value of 91% (95%CI: 85-96), a negative predictive value of 92% (95%CI: 87-97) and an accuracy of 91% (95%CI: 88-95).

Despite these promising findings, the added value of NBI-ME in the stomach, and more precisely in detecting premalignant and malignant gastric lesions, requires confirmation from controlled longitudinal trials. Furthermore, a uniform and validated classification system is needed. Thus, the aim of our study was to define the value of NBI-ME for identifying gastric IM in an unselected population through the visualisation of LBC appearance. A secondary aim was to provide a semiquantitative evaluation of LBC appearance and to verify a correlation with the histological measurement of IM percentage.

## MATERIALS AND METHODS

### Subjects

This prospective, blinded study included unselected consecutive patients presenting to the endoscopy unit of the University Hospital of Genoa, Italy. Patients underwent an upper endoscopy for various indications, such as epigastric discomfort/pain, anaemia, gastro-oesophageal reflux disease, suspicion of peptic ulcer disease, or chronic liver diseases. Exclusion criteria included a previous gastrectomy or partial gastric resection; treatment with antiplatelet medication, anticoagulant medication or non-steroidal anti-inflammatory drugs; and the presence of haemorrhagic diseases. The study protocol was approved by the local Ethics Committee and was performed according to the Declaration of Helsinki. All patients pro-

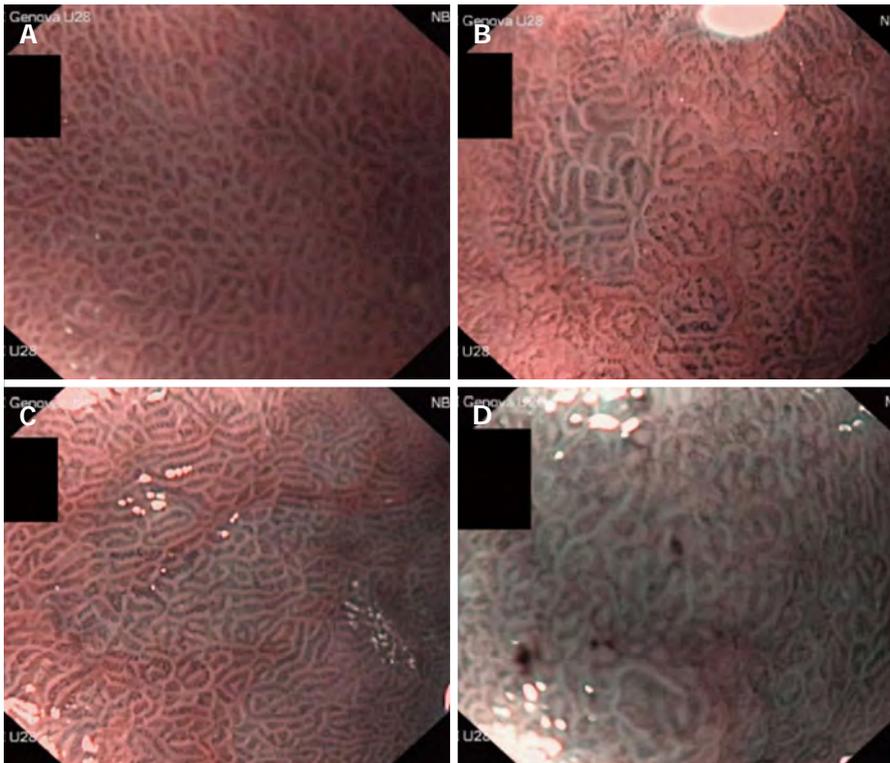

Figure 1 Normal mucosal aspects. A: Narrow-band-imaging with magnification endoscopy examination and the degree of light blue crest appearance; B: Light blue crest (LBC) +, less than 20%; C: LBC ++, 20%-80%; D: LBC +++, 80% or more.

vided written informed consent before the start of the study.

### Study protocol

All subjects who agreed to participate in our investigation underwent a thorough physical and clinical examination, a careful collection of their medical history (including current medications, tobacco use, and alcohol and coffee consumption) and an upper gastric intestinal (GI) endoscopy with the NBI-ME system to determine the presence or absence of gastric IM. Five biopsies (2 antrum, 1 angulus and 2 corpus) were collected from all patients according to the updated Sydney classification<sup>[17]</sup>.

### Endoscopic procedure

The endoscopic examinations were performed by experienced endoscopists (Corbo M, Savarino E, and Dulbecco P) who were blinded to the conditions and medical histories of the patients. Before starting the study, each endoscopist underwent training to obtain good expertise in the detection of IM using NBI-ME. Each endoscopist performed > 300 NBI-ME gastroscopies in patients selected independently of a previous diagnosis of IM and compared their NBI-ME findings with those obtained after a histologic evaluation. At the end of this training, the overall ability to detect histologic IM using NBI-ME was very high (92%). The procedure was conducted with a magnifying endoscope (GIF-Q160Z; Olympus Medical Systems, Tokyo, Japan; 10.9 mm outer diameter insertion tube with a 2.8 mm channel diameter; optical magnifica-

tion  $\times 115$ ). A disposable attachment was fitted to the scope tip to maintain focal distance from the mucosa for magnifying observation (approximately 2 mm). A conscious sedation was performed at the request of the patient. Before the procedure, all patients ingested 66.6 mg of simethicone diluted in 40 mL of water (Istituto Biochimico Italiano Giovanni Lorenzini S.p.A., Aprilia, Italy). If poor visualisation persisted, the gastric mucosal surface was rinsed with an additional 30-60 mL of the simethicone solution. After white light examination, the gastric antrum and body were examined by NBI for blue-whitish patchy areas and then by NBI-ME observation at the maximum magnification, as LBC was frequently observed in these areas. If no blue-whitish areas were observed, NBI-ME was conducted at the proximal and distal portions of the following areas: the anterior wall, the lesser curvature, the posterior wall, and the greater curvature, as previously described<sup>[16]</sup>. During NBI-ME observation, we assessed for the presence or absence of LBCs, defined as a fine, blue-white lines on the crests of the epithelial surface that are similar in appearance to the light reflected from a mirror. The patient was defined as LBC-negative if LBCs were not observed in any of the image fields and as LBC-positive if LBCs were observed in any of the image fields. Moreover, we quantified the degree of LBC appearance as less than 20% (+), 20%-80% (++) and more than 80% (+++) of an image field (Figure 1). In each examination, six pictures were taken and stored (one during NBI and two during NBI-ME observation, both in the antrum and in the corpus).

**Table 1** Demographic and clinical characteristics of unselected patients ( $n = 100$ ) included in the study  $n$  (%)

| Demographic and clinical features | Patients    |
|-----------------------------------|-------------|
| Age, yr (mean $\pm$ SD)           | 67 $\pm$ 12 |

| Non-drinker                       | 75 (75)     |
| Current drinker                   | 25 (25)     |
| Medication                        |             |
| PPI users                         | 67 (67)     |
| Light blue crests                 |             |
| Present                           | 33 (33)     |
| Absent                            | 67 (67)     |

Data are expressed as absolute numbers (percentages) or mean  $\pm$  SD. *H. pylori*: *Helicobacter pylori*; PPI: Proton-pump inhibitors.

A five biopsy set (2 antrum, 1 angulus, and 2 corpus) of LBC-positive areas was collected in all LBC-positive examinations; biopsy samples were taken from the non-LBC mucosa in the LBC-negative patients.

### Histological assessment

All biopsy specimens were immersed in formalin and then embedded in paraffin. Sections cut from the paraffin blocks were stained with haematoxylin and eosin, Alcian blue PAS and Giemsa. The histological findings were evaluated by two expert pathologists who specialised in GI pathology; the pathologists were unaware of the medical history of the patients and of the endoscopic findings regarding LBC appearance. Inflammation, atrophy, metaplasia and dysplasia were classified according to the updated Sydney system<sup>[17]</sup> and the revised Vienna classification<sup>[18]</sup>. Intestinal metaplasia was also expressed as the percentage of metaplastic glands on the entire antral or oxyntic mucosa specimens. Moreover, each sample was evaluated for the presence of *H. pylori*.

### Statistical analysis

Based on prior studies reporting a sensitivity of more than 80% and a specificity of more than 90%, we determined that a cohort of 100 patients was needed to detect an effect with a confidence interval of 95%, a sensitivity of 80% (interval width of 17%), and a specificity of 90% (interval width of 13%) (calculated with the Clopper-Pearson method using PASS 11; NCSS, LLC, Kaysville, Utah, United States; www.ncss.com). The sensitivity, specificity, positive and negative predictive values and accuracy were calculated and expressed as percentages and 95%CI. Pearson correlation analysis was used to compare the LBC grading with the percentage of histologically as-

**Table 2** Relationship between narrow-band-imaging with magnification endoscopy ranking and the percentage of gastric intestinal metaplasia detected by histological assessment

| Intestinal metaplasia | LBC ( $n$ ) |   |    |     | Total ( $n$ ) |
|-----------------------|-------------|---|----|-----|---------------|
|                       | Negative    | + | ++ | +++ |               |

sessed metaplasia.

## RESULTS

The study included 100 consecutive patients (58 F/42 M, mean age 67  $\pm$  12 years) who presented at our endoscopy unit between December 2010 and February 2012. The demographic and clinical characteristics of the patients are shown in Table 1. The patients were referred to our endoscopy unit mainly because of gastro-oesophageal reflux disease and/or dyspepsia symptoms (46%); 34% underwent the endoscopic procedure for cancer screening, anaemia, a positive faecal occult blood test or suspicion of a peptic ulcer; 9% for chronic liver disease; 6% for suspected celiac disease and the remaining patients for other indications. The prevalence of *H. pylori* infection on the biopsies was 31%; in addition, 67% of the patients used proton pump inhibitors, 16% were current smokers, and 25% of the patients were alcohol consumers.

### Endoscopic and histological findings

During the upper NBI-ME procedure, we observed LBC appearance in the gastric antrum of 33 patients (33%); 20 of the LBCs were classified as LBC+, 9 as LBC++, and 4 as LBC++++. Moreover, we detected LBC appearance in the gastric body in only 6 patients (6%), and 5 of the patients also had LBC appearance in the antrum; of these, 3 cases were classified as LBC+, 2 as LBC++, and 1 as LBC++++.

Intestinal metaplasia in the biopsy specimens (2 antrum, 1 angulus and 2 corpus) obtained during the endoscopy from both LBC-positive and -negative patients was classified as complete and incomplete based on special staining. Gastric IM was histologically detected in 35 (35%) patients, and 27 cases were LBC-positive. In five patients, histological IM was found in both the antrum and body, and this finding correlated with LBC appearance at both sites. A percentage of IM greater than 20% was observed in 13 (13%) of the cases.

### Accuracy of LBC presence for diagnosing gastric intestinal metaplasia

For the diagnosis of IM, compared to histological assessment, the NBI-ME findings had an accuracy of 93%

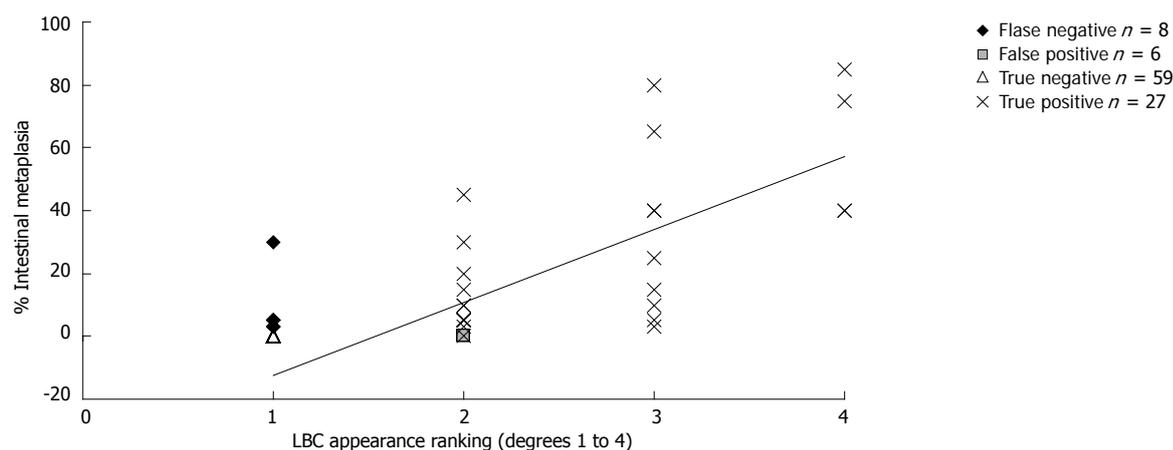

Figure 2 Graphic representation of the correlation between the degree of light blue crest appearance during narrow-band imaging with magnifying endoscopy examination and the percentage of gastric intestinal metaplasia detected by histological examination. LBC: Light blue crest.

(95%CI: 90-97), a sensitivity of 80% (95%CI: 67-92), a specificity of 96% (95%CI: 93-99), a positive predictive value of 84% (95%CI: 73-96), and a negative predictive value of 95% (95%CI: 92-98).

Interestingly, in our study, the NBI-ME examination overlooked the presence of gastric IM in 8 cases (false negative cases), and 7 out of the 8 cases had an IM that was less than 5%. Moreover, in the 6 false positive cases, the histological examination showed the presence of reactive gastropathy (4 cases) or *H. pylori* active chronic gastritis (2 cases).

The semiquantitative correlation between the grades of LBC appearance and the percentage of histological IM is shown in Table 2 and Figure 2; the correlation index was 79% ( $P < 0.01$ ).

## DISCUSSION

Intestinal metaplasia has been widely studied as the main mucosal background for the development of oesophageal and gastric adenocarcinomas. However, to date, no endoscopic patterns that clearly define IM or dysplasia in the stomach have been found. Kaminishi *et al*<sup>[19]</sup> evaluated the accuracy of endoscopic findings for diagnosing chronic gastritis and found that ash-coloured nodular changes were highly specific (98%  $\pm$  99%) but had a very poor sensitivity (6%  $\pm$  12%) for detecting histological IM; the authors concluded that conventional endoscopy is not really useful for diagnosing gastric IM. Later, Dinis-Ribeiro *et al*<sup>[20]</sup> observed that magnifying chromoendoscopy with methylene blue staining had good sensitivity (76%) and specificity (87%) for detecting gastric IM. Moreover, methylene blue chromoendoscopy has been found to be useful for assessing the extent of IM<sup>[21]</sup>. However, this latter technique is time consuming and has some limitations, including the need for preparation with mucolytic agents, dye spraying and vigorous irrigation of the mucosal surface; furthermore, a recent report suggests that methylene blue chromoendoscopy induced questionable oxidative DNA damage in a patient with Barrett's

mucosa<sup>[22]</sup>. Therefore, collecting biopsies for subsequent histological evaluation remains the current gold standard for diagnosing IM. However, the fact that premalignant gastric lesions may occur multifocally represents a limitation of random biopsy sampling.

Several new imaging techniques have been developed recently to improve the diagnostic yield of endoscopy. The NBI-ME system has the practical advantage of not requiring complex preparation procedures, the use of any staining technique or a long duration. The additional value of NBI-ME in the detection of gastric pre-malignant lesions is still unclear, especially in countries with a low gastric cancer incidence<sup>[7]</sup>.

Recently, Capelle *et al*<sup>[23]</sup> compared the yield of NBI alone to that of white light endoscopy (WLE) in the surveillance of 43 patients with IM and dysplasia. The authors concluded that NBI alone considerably increased the detection of premalignant gastric lesions compared to routine WLE and appeared to be superior to WLE for the surveillance of patients with these advanced gastric lesions. However, a combination of NBI and magnification is likely to provide the best alternative to current endoscopic practice. Previous studies have already demonstrated a high correlation between the microvascular patterns found with NBI-ME and the diagnosis of gastric cancer<sup>[24,25]</sup>. Moreover, the combined optical technology of NBI with ME has been shown to identify with great accuracy the presence of gastric IM through the visualisation of LBC appearance on the epithelial surface<sup>[16]</sup>. However, the main limitations of the above-mentioned studies are that they were all conducted in patients with already known diagnoses of intestinal metaplasia/dysplasia/gastric cancer or in a population at a high risk for developing gastric cancer. Other limitations included the small sample sizes and the limited assessment of the gastric antrum and angulus with the exclusion of the gastric body.

Therefore, no prospective data are available on the diagnostic utility and accuracy of NBI-ME for detecting IM in an unselected population presenting at an endos-

copy unit in routine clinical practice. Our study showed that NBI-ME allowed us to detect gastric IM areas with an accuracy of 93%, a sensitivity of 80%, a specificity of 96%, a positive predictive value of 84% and a negative predictive value of 95%. These results are similar to those recently published by Pimentel-Nunes *et al.*<sup>[26]</sup>, who found a sensitivity of 68% and a specificity of 87% using the same method and a simplified classification system for NBI in the diagnosis of gastric lesions. In our investigation, NBI-ME underestimated the presence of IM in 8 patients; for 7 of these patients, metaplasia was histologically estimated to be less than 5%. The fact that NBI-ME has its major limitation in identifying gastric IM lower than 5% when performed by experienced endoscopists represents a new finding about the diagnostic yield of this technique; at this stage, we can assume that this value constitutes the sensitivity limit of this technique. The false positive cases (6 patients) presented with a histological diagnosis of reactive gastropathy (4 cases) or *H. pylori* active chronic gastritis (2 cases). Both of these conditions may sometimes represent a confounding factor because they show endoscopic features similar to those of gastric IM.

The prevalence of histologically observed IM in our cohort (35%) was slightly higher than the prevalence estimated in the general Western population (25%)<sup>[5-9]</sup> and in other studies on the Italian population (20%-30%)<sup>[5,8,11-13]</sup>. A possible explanation for our findings may be related to the higher mean age and prevalence of *H. pylori* infection in our patients, as it is well known that *H. pylori* infection, increased age and smoking (> 20 cigarettes/daily) are the main risk factors<sup>[27]</sup> for the development of premalignant gastric lesions. However, the prevalence of IM in the general population is reported to be highly variable. Additionally, the majority of data come from studies on patients with dyspeptic symptoms and/or suspected *H. pylori* infections, while information derived from unselected patients (*i.e.*, consecutive patients enrolled independently of GI symptoms or clinical status) is limited.

The semiquantitative evaluation of LBC appearance in our study and its correlation with the histological measurement of IM percentage shows that the agreement was high (79%). Previously, Uedo *et al.*<sup>[16]</sup> also found a significant correlation between the diffuse positivity of LBC (+++) mucosa and the presence of histological markers of IM, such as immunohistochemical staining for CD10 and Alcian blue/high iron diamine. However, these authors did not assess the correlation between LBC appearance and the percentage of histologic IM. Therefore, to the best of our knowledge, our study is the first to show a good correlation between the degree of IM detected by NBI-ME and the severity of IM identified by histological measurement in a series of consecutive patients without specific indications to perform an upper GI endoscopy.

In contrast to Uedo *et al.*<sup>[16]</sup> who used NBI-ME and Capelle *et al.*<sup>[23]</sup> who performed NBI alone, we opted to evaluate not only the antrum and the angulus of the stomach but also the body; including the body was re-

cently emphasised in the ESGE guidelines<sup>[28]</sup>, despite the significantly longer examination time. This measurement was included because our intention was to demonstrate the potential application of NBI-ME in a population-based screening and surveillance setting, and we thought that gastric assessment of only one region of the stomach was not adequate and fully informative. However, IM is predominantly found in the antrum, which was confirmed in our study. Therefore, limiting the endoscopic evaluation to the antrum permits an accurate observation and a shorter duration of the examination. Moreover, it has been shown that three biopsies (two antral and one angular) appear to be the best compromise between acceptable accuracy<sup>[29]</sup> and ease of use in the detection of IM by endoscopy.

Our study had some limitations. First, the study included only a single centre. Further research in larger multicentre prospective studies is necessary to evaluate whether NBI-ME yields adequate results in the detection and grading of gastric IM. Second, the endoscopic procedure of WLE and NBI-ME was performed by the same endoscopist; thus, detection of IM by NBI-ME could possibly be biased by the previous WLE observations. Third, as a learning curve must still be defined, regular training is mandatory to improve our findings. Indeed, despite our prolonged training, we obtained a value of sensitivity that was lower than the value obtained by Uedo *et al.*<sup>[16]</sup>. This difference was likely the result of differences in training between Japanese and Western gastroenterologists. Due to the higher gastric cancer incidence, Japanese endoscopists are trained to scrutinise gastric mucosal areas that are compatible with atrophy and early cancer and spend more time on a thorough mucosal examination than in Western countries. In addition, uniform criteria for this technique must be adopted in large controlled trials in Western or Eastern countries.

In conclusion, NBI-ME was shown to be a valid method for IM detection, except in those cases with IM lower than 5%, which may not be clinically relevant. In routine clinical practice, this technique can reliably target which patients should be biopsied to evaluate IM and those who do not need biopsies. Moreover, a semi-quantitative evaluation of LBC appearance was feasible as there was a good correlation with the histological assessment of IM percentage.

## COMMENTS

### Background

Gastric cancer is one of the most common neoplastic diseases in the Western world and has a poor prognosis and inconsistent signs and symptoms in the early phases. Therefore, adequate screening and prevention are needed to improve the diagnostic process and to identify this condition and its risk factors earlier. Recently, upper gastric intestinal endoscopy has been enhanced with the addition of the narrow band imaging with magnification endoscopy (NBI-ME) technique, which was found to identify precancerous lesions, such as gastric intestinal metaplasia (GIM).

### Research frontiers

Light blue crests (LBCs) are light-blue patches or lines visible on gastric mucosa by NBI endoscopy. Several studies have demonstrated that LBCs are a sign

of underlying intestinal metaplasia, with a good correlation between endoscopic findings and histological assessments. Therefore, authors have assessed the predictive values of the NBI-ME technique to identify and estimate the extension of GIM to biopsies of the antrum, angulus and corpus in the stomach. Authors also studied the correlation between the appearance of LBCs and the histological detection of GIM in prospectively recruited consecutive unselected patients.

### Innovations and breakthroughs

One hundred consecutive patients were studied. NBI-ME-aimed gastric bioptic samples were collected (2 in the antrum, 1 in the angulus, and 2 in the corpus) from each patient and compared with the presence or absence of LBCs as stated by skilled endoscopists; the biopsies were assessed according to the pathologists' expertise in the upper digestive tract. They determined a correlation of 79% between the appearance of LBCs and histologically assessed GIM. Moreover, authors observed that the appearance of LBCs correlated with the histological evidence of intestinal metaplasia, with a sensitivity of 80%, a specificity of 96%, a positive predictive value of 84%, a negative predictive value of 95% and an overall accuracy of 93%. Their results are similar, if not superior, to those of previously published studies in selected populations.

### Applications

NBI-ME is a good technique to identify areas suggestive of GIM in the stomach and can be used to take adequate biopsies from the stomach to provide the pathologist with a useful sample. This technique is easy to learn and provides an accuracy of greater than 90% for diagnosing GIM.

### Terminology

NBI-ME is an endoscopic technique that uses narrow band imaging to produce superior image contrast combined with a magnification of the image up to  $\times 115$ ; this technique enables a more accurate observation of the gastric epithelium. Gastric intestinal metaplasia is a condition characterised by the replacement of gastric epithelial cells with cells of intestinal morphology. GIM is a pre-cancerous condition that can progress towards gastric cancer, especially the intestinal-type according to the Lauren classification. This progress varies from 0% to 10% according to different studies, with a prevalence of more than 20% in Western countries, and is considered to be the "breaking point" in the Correa sequence of carcinogenesis. Identifying this condition could halt or reverse the neoplastic progression.

### Peer review

This research was performed by endoscopists who belong to single medical center in Italy. This article should be helpful for understanding the efficacy of NBI-magnifying endoscopy in detecting the presence of intestinal metaplasia of stomach.

### Abstract

**AIM:** To assess adalimumab's efficacy with concomitant azathioprine (AZA) for induction and maintenance of clinical remission in Japanese Crohn's disease (CD) patients.

**METHODS:** This retrospective, observational, single-center study enrolled 28 consecutive CD patients treated with adalimumab (ADA). Mean age and mean disease duration were  $38.1 \pm 11.8$  years and  $11.8 \pm 10.1$  years, respectively. The baseline mean Crohn's disease activity index (CDAI) and C-reactive protein were  $177.8 \pm 82.0$  and  $0.70 \pm 0.83$  mg/dL, respectively. Twelve of these patients also received a concomitant stable dose

of AZA. ADA was subcutaneously administered: 160 mg at week 0, 80 mg at week 2, followed by 40 mg every other week. Clinical response and remission rates were assessed *via* CDAI and C-reactive protein for 24 wk.

**RESULTS:** The mean CDAI at weeks 2, 4, 8, and 24 was 124.4, 120.2, 123.6, and 135.1, respectively. The CDAI was significantly decreased at weeks 2 and 4 with ADA and was significantly suppressed at 24 wk with ADA/AZA. Overall clinical remission rates at weeks 4 and 24 were 66.7% and 63.2%, respectively. Although no statistically significant difference in C-reactive protein was demonstrated, ADA with AZA resulted in a greater statistically significant improvement in CDAI at 24 wk, compared to ADA alone.

**CONCLUSION:** Scheduled ADA with concomitant AZA may be more effective for clinical remission achievement at 24 wk in Japanese Crohn's disease patients.

**Key words:** Crohn's disease; Adalimumab; Immuno-modulator; Azathioprine; Inflammatory bowel disease

**Core tip:** In this study, the authors found that adalimumab (ADA) treatment with concomitant azathioprine usage significantly suppressed the Crohn's disease activity index and increased the remission rate at 24 wk after the initiation of therapy, compared with ADA treatment alone.

## INTRODUCTION

Tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) is a proinflammatory cytokine implicated in the pathogenesis of inflammatory bowel disease (IBD)<sup>[1-3]</sup>. Thus far, a variety of therapeutic approaches have been used to inhibit TNF- $\alpha$  in patients with IBD, including infliximab (IFX), which was the first biologic agent approved for the treatment of IBD<sup>[4]</sup>. IFX is a mouse and human chimeric immunoglobulin G1 (IgG1) monoclonal antibody directed against TNF- $\alpha$ ; it binds to both the soluble and transmembrane forms of TNF- $\alpha$  and is effective as both an induction and maintenance therapy in patients with Crohn's disease (CD), including patients who have draining fistulas<sup>[5-8]</sup>. However, IFX has a 25% murine fraction that has potent immunogenicity and can cause the formation of human anti-chimeric antibodies (HACA)<sup>[9]</sup>. Furthermore, this potent immunogenicity may lead to the loss of efficacy, hypersensitivity reactions, or infusion reactions<sup>[10]</sup>.

Adalimumab (ADA) is the second biologic agent approved for use in the treatment of IBD. It is a subcutaneously administered, recombinant, fully human, IgG1 monoclonal antibody that binds with a high affinity and specificity to TNF- $\alpha$  and was found to be effective in refractory CD patients who were either naïve to or previously treated with IFX<sup>[11-15]</sup>. Combination therapy with IFX and an immunosuppressant demonstrated increased efficacy compared with nonconcomitant use of immunosuppressants<sup>[16,17]</sup>. Nonetheless, limited data are available for ADA. In the pivotal registration study of ADA (Crohn's trial of the fully Human antibody ADA for Remission Maintenance, CHARM), post-hoc analysis did not detect an impact of coadministration of immunosuppressants on the remission rates achieved at 1 year<sup>[12]</sup>. Ardizzone *et al.*<sup>[18]</sup> reported that ADA with concomitant immunosuppressant treatment was not associated with the loss of response or the need for dose escalation. However, Reenaers *et al.*<sup>[19]</sup> reported that there may be a benefit from using immunosuppressive drugs during the first semester of initiating ADA treatment, with a slight decrease in ADA failure and lower need for ADA dosage escalation.

In Japan, ADA was approved for the treatment of CD; however, only limited data have been collected on its optimal usage. Therefore, this study aimed to assess the impact of ADA with concomitant azathioprine (AZA) therapy on the rate of clinical remission during maintenance with ADA in CD patients at the Osaka Medical College Hospital during routine clinical practice.

## MATERIALS AND METHODS

### Study participants

Between November 2010 and March 2012, about 28 CD

patients who were diagnosed by clinical, endoscopic, and histological criteria and who received ADA at the Osaka Medical College Hospital, Osaka, Japan, were consecutively enrolled in this retrospective, observational, single-center study. The patients were informed about the potential risks and benefits of ADA therapy and were provided and signed informed consent forms before all procedures. The medical records of all participating patients were reviewed by two senior investigators (Ishida K and Inoue T) for the following information: demographics; disease duration; disease location; prior surgical history; perianal disease presence; smoking behavior; previous IFX treatment and response to IFX treatment; Crohn's disease activity index (CDAI); C-reactive protein (CRP) levels; and concomitant medications (corticosteroids, AZA, mesalazine, and elemental diet).

All patients received 160 mg of ADA subcutaneously at week 0, 80 mg at week 2, followed by 40 mg every other week. A clinical response was defined as a  $\Delta$ CDAI > 70 points, whereas a clinical remission was defined as a CDAI < 150 points. The loss of response to IFX was defined as a loss of therapeutic efficacy after > 2 IFX infusions.

### Statistical analysis

Categorical data were compared by the  $\chi^2$  test or the Fisher's exact test, and continuous variables were compared by the Student *t* test. The results were expressed as the mean  $\pm$  SD. *P* values less than 0.05 were considered to be statistically significant. All calculations were made using the StatView system (SAS Institute, Cary, NC, United States).

## RESULTS

### Patient characteristics

ADA was administered to 28 consecutive patients with CD from November 2011 to March 2012 at the Osaka Medical College Hospital (male-to-female ratio: 22/6; age at presentation:  $38.1 \pm 11.8$  years; and disease duration:  $11.8 \pm 10.1$  years). The patients' baseline characteristics and demographics are listed in Table 1. According to the Montreal classification, patients presented with CD in the following locations: about 10.7% (3/28) in an isolated ileal location; 17.9% (5/28) in an isolated colonic location; and 71.4% (20/28) in an ileocolonic location. Of the patients, 60.7% (17/28) had a history of bowel resection, 57.1% had perianal disease, and 17.9% had an associated fistulizing disease. Two patients (7.1%) were current smokers.

Seventeen (60.7%) patients had previously taken IFX, and 6 patients did not have a response to IFX, including no primary response in one patient and emergent allergic reaction in another patient. Twelve of the 28 patients were treated with ADA and a concomitant stable dose of AZA throughout the observational period. The mean CDAI and mean CRP at baseline were  $177.8 \pm 82.0$  and  $0.70 \pm 0.83$  mg/dL, respectively.

### Clinical efficacy of ADA therapy

The overall clinical response and remission rates are shown in Table 2. The rates of clinical remission at weeks 2, 4, 8, and 24 were 60%, 66.7%, 69.6%, and 63.2%, respectively. The mean CDAI of all patients at weeks 2, 4, 8, and 24 was 124.4 ± 60.2, 120.0 ± 66.8, 123.6 ± 73.5, and 135.1 ± 74.4, respectively. The CDAI was significantly decreased commencing 2 wk after the initiation of ADA treatment and remained low for 24 wk (Table 2).

### Impact of ADA/AZA on the clinical remission compared to ADA maintenance

Regarding the concomitant use of immunosuppressive agents, 12 patients (42.9%) were treated with a stable dose of AZA (50.0 ± 21.3 mg/d, 1.0 ± 0.5 mg/kg/d) before the initiation of ADA. The concomitant use of AZA was well tolerated, with only minor side effects. Although there were no statistically significant differences seen until 12 wk into ADA and AZA treatment (compared with ADA treatment), combinational therapy with ADA and AZA significantly increased the clinical remission rate (Figure 1) and reduced the CDAI, compared with nonconcomitant use at week 24 (Figure 2A).

Sixteen of the 28 patients were found to have increased CRP serum levels (> 0.25 mg/dL) before starting ADA therapy. The mean serum CRP of all of the patients at weeks 2, 4, 8, and 24 were 0.27 ± 0.40, 0.28 ± 0.51, 0.46 ± 0.69, and 0.51 ± 0.94 mg/dL, respectively.

ADA significantly reduced the CRP levels at weeks 2 and 4 after the initiation of treatment. The concomitant use of AZA tended to maintain low CRP levels for 24 wk, even though the result was not statistically significant (CRP levels at weeks 0 and 24 were 0.66 ± 0.73 and 0.27 ± 0.44 mg/dL, respectively; *P* = 0.09, Figure 2B).

## DISCUSSION

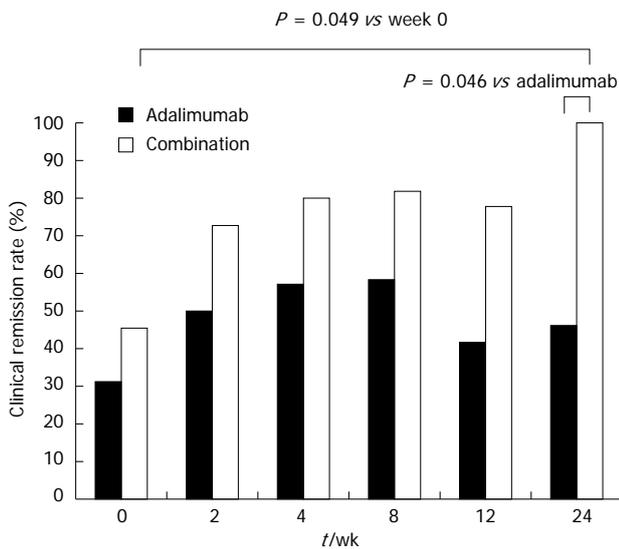

The effectiveness of AZA in CD patients treated with IFX has been clearly reported by many investigators. However, few reports have demonstrated the benefits of ADA and AZA combination therapy. In this study, we analyzed the use of ADA and AZA in patients with mild to moderate CD at our clinical practice and found that scheduled ADA with concomitant use of AZA was more effective in inducing and maintaining remission for 24 wk after the initiation of ADA treatment, compared with ADA monotherapy. Although ADA monotherapy was also able to induce and maintain clinical remission from 2 to 24 wk compared to the baseline, the effects of the combination therapy were better. Since previous IFX nonresponse and previous treatment with an anti-TNF agent were reported to be associated with a decreased clinical efficacy and a loss of response<sup>[20]</sup>, we also compared the CDAI between anti-TNF-naïve patients and anti-TNF-treated patients in this study, but there was no significant difference.

ADA is a human monoclonal IgG1 antibody that has demonstrated efficacy in the induction and maintenance of clinical remission in patients with moderate to severe CD and is useful in patients who have lost responsiveness to IFX<sup>[11-15]</sup>. IFX, a chimeric anti-TNF-α antibody, has potent immunogenicity; repeated administration of IFX could result in the development of antibodies that may lead to the loss of response<sup>[21]</sup>. Although no consensus has yet been established on the appropriateness of concomitant immunomodulators with anti-TNF-α antibody therapy for CD<sup>[22-24]</sup>, immunosuppressants were shown to inhibit the development of HACA<sup>[10]</sup>. Moreover, since the clearance of IFX is affected by the presence of HACA, IFX serum levels were significantly higher in patients with concomitant immunosuppressive therapy, as this concomitant usage reduces the frequency of HACA formation<sup>[4,25]</sup>. Sokol *et al.*<sup>[17]</sup> assessed the efficacy of immunosuppressants with scheduled IFX in patients with IBD and reported that IBD flares, perianal complications, and switching to ADA were less frequently observed in patients with combined immunosuppressant and biologic agent use than in those patients who were not concomitantly treated with immunosuppressants<sup>[22]</sup>. Furthermore, in the SONIC study, Colombel *et al.*<sup>[16]</sup> compared the efficacy and safety of IFX monotherapy and IFX plus AZA combination therapy for CD and showed that the combination therapy provided a significantly greater benefit than that of IFX monotherapy at weeks 26 and 50. These studies suggest

**Figure 1 Clinical remission rate.** Combinational therapy with adalimumab and azathioprine significantly increased the clinical remission rate vs nonconcomitant use at week 24.

that combination therapy with IFX and AZA may have an added benefit in maintaining the remission of CD. With regard to ADA, a substantial proportion of patients, including previously treated anti-TNF- $\alpha$  patients and anti-TNF- $\alpha$  treatment-naïve patients, needed dose escalation during ADA treatment<sup>[12,26]</sup>. However, concomitant immunosuppressive therapy was not associated with a loss of response or a need for dose escalation and did not influence the development of ADA antibodies<sup>[27-29]</sup>. Recently, Reenaers *et al.*<sup>[19]</sup> reported that usage of ADA with immunosuppressive drugs, such as AZA, during the first semester of initiating ADA demonstrated a slight decrease in ADA failure and a lower need for ADA dose escalation. Moreover, the presence of anti-ADA antibodies and a low serum ADA concentration have been reported to be associated with a diminished clinical response in rheumatoid arthritis patients, and the concomitant use of an immunomodulator significantly suppresses the concentration of anti-ADA antibodies<sup>[30,31]</sup>. Interestingly, in this study, AZA in the presence of ADA provides better efficacy in patients it has previously failed. However, some patients with IFX had not early received concomitant AZA. Therefore, we consider that ADA and AZA combination therapy may be more effective than ADA monotherapy via the inhibition of the development of anti-ADA antibodies. Prospective

**Figure 2 Mean Crohn's disease activity index and C-reactive protein through week 24.** A: Combinational therapy with adalimumab (ADA) and azathioprine (AZA) significantly reduced the Crohn's disease activity index (CDAI), compared with nonconcomitant use at week 24. <sup>a</sup>*P* < 0.05 vs week 0; <sup>c</sup>*P* < 0.05 vs adalimumab; B: The concomitant use of AZA tended to maintain low C-reactive protein (CRP) levels for 24 wk (CRP levels at weeks 0 and 24 were 0.66 ± 0.73 and 0.27 ± 0.44, respectively, *P* = 0.09).

studies, combined with anti-ADA antibody and ADA trough level measurements, are required<sup>[19]</sup>.

In this study, we found that ADA treatment with concomitant AZA usage significantly suppressed the CDAI and increased the remission rate at 24 weeks after the initiation of therapy, compared with ADA treatment alone. Furthermore, these results were not consistent with previous reports showing that the efficacy of ADA is independent of the use of concomitant immunosup-

pression<sup>[27-29]</sup>. One possible explanation for this discrepancy is that these previous studies assessed the efficacy of ADA in patients with moderate to severe CD, whereas the present study included mild to moderate CD patients. Notably, the CDAI at the beginning of this study was relatively low ( $177.8 \pm 82.0$ ). Since the CDAI scores were gradually increasing, some patients were switched from IFX treatment to ADA treatment, even though their CDAI scores were still in remission (CDAI < 150 at the initiation of ADA treatment). Indeed, Zheng *et al.*<sup>[32]</sup> evaluated the efficacy of AZA in controlling the relapse of disease in patients with CD for at least 6 months and showed that AZA treatment decreased the CDAI from  $187.3 \pm 23.4$  to  $96.1 \pm 13.5$ . Actually, the finding of a significant efficacy with ADA plus AZA combination therapy compared to ADA monotherapy is revealed only after week 24 in this study. Generally, thiopurines require a lag time of approximately 6 mo before expressing full activity. Taken together, we consider that the combination of ADA and AZA may have an added benefit in inducing long-term remission compared with ADA alone, even though ADA has shown less immunogenicity compared with IFX.

Our study had some major limitations. The patients were not randomized between ADA monotherapy and ADA plus AZA combination therapy. Also, the mean age was significantly different between these two groups due to the nature of retrospective study. Therefore, these two groups were not strictly comparable. In addition, the patient numbers were limited, as we only analyzed the data in our own hospital. Moreover, recent studies have revealed that Japanese and Caucasian CD patients genetically differ, as Japanese CD patients lack the polymorphism in the *NOD2* gene<sup>[33-36]</sup>. Genetic differences might have affected the results in this study. An additional, larger, long-term multicenter study should be conducted to determine the effect of combination therapy with ADA and AZA for patients with CD.

So far, there have been few reports demonstrating that CD patients could achieve a better clinical remission with ADA and immunomodulator combination therapy, compared with ADA monotherapy<sup>[19,37]</sup>. This study may help physicians decide whether to use combination therapy. In conclusion, scheduled ADA with concomitant AZA is more effective for clinical remission achievement at 24 wk in Japanese CD patients. Although further long-term studies evaluating the efficacy of combination therapy with ADA and AZA are required, our data suggest that ADA with concomitant AZA therapy may provide clinical benefit in inducing long-term remission.

## COMMENTS

### Background

The benefits of azathioprine (AZA) in Crohn's disease (CD) with infliximab as scheduled anti-tumor necrosis factor- $\alpha$  maintenance therapy have been established but remain unclear with adalimumab (ADA).

### Research frontiers

So far, there have been few reports demonstrating that CD patients could achieve better clinical remission with ADA and immunomodulator combination therapy, compared with ADA monotherapy.

### Innovations and breakthroughs

This is the first study reported in Asia on the effect of ADA with concomitant AZA for induction and maintenance of clinical remission in CD patients. The results of this study showed that ADA treatment with concomitant AZA usage significantly suppressed the Crohn's disease activity index and increased the remission rate at 24 wk after the initiation of therapy, compared with ADA treatment alone.

### Applications

Although further long-term studies evaluating the efficacy of combination therapy with ADA and AZA are required, this study suggests that ADA with concomitant AZA therapy may provide clinical benefit in inducing long-term remission. The results of this study may help physicians decide whether to use combination therapy.

### Peer review

This is an interesting small retrospective, observational, study assessing the effect of effects of ADA treatment with concomitant AZA in CD patients.

### Abstract

**AIM:** To investigate the associations between dietary intake of polyphenols and colorectal cancer.

**METHODS:** The study subjects were derived from the Fukuoka colorectal cancer study, a community-based case-control study. The study subjects were 816 cases of colorectal cancer and 815 community-based controls. The consumption of 148 food items was assessed by a computer-assisted interview. We used the consumption of 97 food items to estimate dietary intakes of total, tea and coffee polyphenols. The Phenol-Explorer database was used for 92 food items. Of the 5 foods which were not listed in the Phenol-Explorer Database, polyphenol contents of 3 foods (sweet potatoes, satsumo and daikon) were based on a Japanese study and 2 foods (soybeans and fried potatoes) were estimated by ORAC-based polyphenol contents in the United States Department of Agriculture Database. Odds ratios (OR) and 95%CI of colorectal cancer risk according to quintile categories of intake were obtained by using logistic regression models with adjustment for age, sex, residential area, parental history of colorectal cancer, smoking, alcohol consumption, body mass index 10 years before, type of job, leisure-time physical activity and dietary intakes of calcium and n-3 polyunsaturated fatty acids.

**RESULTS:** There was no measurable difference in total or tea polyphenol intake between cases and controls, but intake of coffee polyphenols was lower in cases than in controls. The multivariate-adjusted OR of colorectal cancer according to quintile categories of coffee polyphenols (from the first to top quintile) were 1.00 (referent), 0.81 (95%CI: 0.60-1.10), 0.65 (95%CI: 0.47-0.89), 0.65 (95%CI: 0.46-0.89) and 0.82 (95%CI: 0.60-1.10), respectively ( $P_{\text{trend}} = 0.07$ ). Similar, but less pronounced, decreases in the OR were also noted for the third and fourth quintiles of total polyphenol intake. Tea polyphenols and non-coffee polyphenols showed no association with colorectal cancer risk. The site-specific analysis, based on 463 colon cancer cases and 340 rectal cancer cases, showed an inverse association between coffee polyphenols and colon cancer. The multivariate-adjusted OR of colon cancer for the first to top quintiles of coffee polyphenols were 1.00 (referent), 0.92 (95%CI: 0.64-1.31), 0.75 (95%CI: 0.52-1.08), 0.69 (95%CI: 0.47-1.01), and 0.68 (95%CI: 0.46-1.00), respectively ( $P_{\text{trend}} = 0.02$ ). Distal colon cancer showed a more evident inverse association with coffee polyphenols than proximal colon cancer. The association between coffee polyphenols and rectal cancer risk was U-shaped, with significant decreases in the OR at the second to fourth quintile categories. There was also a tendency that the OR of colon and rectal cancer decreased in the intermediate categories of total polyphenols. The decrease in the OR in the intermediate categories of total polyphenols was most pronounced for distal colon cancer. Intake of tea polyphenols was not associated with either colon or rectal cancer. The associations of coffee consumption with colorectal, colon and rectal cancers were almost the same as observed for coffee polyphenols. The trend of the association between coffee consumption and colorectal cancer was statistically significant.

**CONCLUSION:** The present findings suggest a decreased risk of colorectal cancer associated with coffee consumption.

## INTRODUCTION

Colorectal cancer is one of the most common cancers in

the world and the second most common cause of cancer death in developed countries<sup>[1]</sup>. In Japan, the incidence rate of colorectal cancer, especially of colon cancer, has increased dramatically until the 1990s<sup>[2]</sup>. Lifestyle factors such as physical inactivity, obesity and alcohol use are known to confer increased risk of colorectal cancer. Of dietary factors, high intake of red meat has been related to increased risk of colorectal cancer, and fiber-containing plant foods and calcium have been considered to be protective<sup>[3]</sup>.

Polyphenols are the most abundant antioxidants in foods and have drawn much interest as potentially anticarcinogenic compounds. The flavonoids have been identified as potential cancer-preventive components of fruits and vegetables<sup>[4]</sup>. Catechins and tea polyphenols inhibit tumorigenesis at initiation, promotion, and progression stages in animal experiments<sup>[5]</sup>. Coffee is the major source of polyphenol intake in populations in which coffee is commonly consumed<sup>[6]</sup>, and phenolic compounds in coffee such as chlorogenic acids also have anticarcinogenic effects in animal models<sup>[7]</sup>. Epidemiological studies have suggested that polyphenol-rich foods such as fruits and vegetables<sup>[3,8]</sup> and beverages such as tea<sup>[9-13]</sup> and coffee<sup>[14,15]</sup> may be protective against colorectal cancer. Experimental studies on colorectal cancer cell lines also support a protective role of polyphenols in carcinogenesis by exerting antioxidant and anti-proliferative effects and by inducing cell cycle arrest<sup>[16]</sup>. In the study reported here, we addressed the association of dietary intake of polyphenols with colorectal cancer risk using data from a community-based case-control study in Japan<sup>[17]</sup>.

## MATERIALS AND METHODS

The present data were derived from the Fukuoka colorectal cancer study, a community-based case-control study in Fukuoka, Japan. The research protocol was approved by the ethics committee of Kyushu University and collaborating hospitals. Details of the design and conduct of the study have been described elsewhere<sup>[17]</sup>.

### Study subjects

Cases were histologically confirmed incident cases of colorectal adenocarcinomas who were admitted for surgical treatment to one of the collaborating hospitals in Fukuoka City and three adjacent areas during the period from September 2000 to December 2003. Of 1053 eligible cases, a total of 840 cases (80%) participated in the interview; the eligible cases were aged between 20-74 years at the time of diagnosis; lived in the study area; had no prior history of partial or total removal of the colon, familial adenomatous polyposis or inflammatory bowel disease; and were mentally competent to give informed consent and to complete the interview. Research staff visited each hospital regularly, determined the eligibility of cases by referring to admission logs and medical records, and interviewed him/her if written informed consent was obtained.

Eligibility criteria for controls were the same as described for the cases except that they had no history of colorectal cancer. A total of 1500 control candidates were randomly selected by a two-stage random sampling on the basis of a resident registry with the frequency by sex and 10-year age class matched to expected sex- and age-specific frequencies of cases. Recruitment was initiated by a letter of invitation, which was followed by phone calls if available. After exclusion of 113 who were found to be ineligible and 5 who were diagnosed with colorectal cancer after the interview, 833 (60%) participated in the interview.

In the analysis, we excluded those who were in the top 1% or bottom 1% of total energy intake within each stratum of sex and age class (< 55, 55-64, and  $\geq$  65 years of age). A total of 816 cases and 815 controls remained.

### Lifestyle questionnaire

Cases and controls were interviewed in person regarding smoking, alcohol use, physical activity and other factors using a uniform questionnaire. The index date was taken as the date of onset of symptoms or the screening leading to the diagnosis of colorectal cancer for cases and the date of interview for controls. Anthropometric questions inquired about height (cm) and body weight (kg) at the time of interview and 10 years earlier. Body mass index ( $\text{kg}/\text{m}^2$ ) 10 years earlier was used in the analysis because the current body mass index was unrelated to the risk<sup>[18]</sup>. For 4 cases and 11 controls, body weight 10 years before was not ascertained, and the current body weight was used for substitution. The amount of alcohol was expressed using the conventional Japanese unit; one go (180 mL) of sake, one large bottle (633 mL) of beer and half a go (90 mL) of shochu were each expressed as one unit; and one drink (30 mL) of whisky or brandy and one glass (100 mL) of wine were each converted to half a unit. Regarding smoking, ever smokers reported years of smoking and the numbers of cigarettes per day for each decade of life, and we calculated the cumulative exposure to cigarette smoking until the beginning of the previous decade of age. Types of job and non-job physical activities 5 years before were ascertained. The amount of non-occupational physical activity was expressed as a sum of metabolic equivalents (MET) multiplied by the hours of weekly participation in each activity, *i.e.*, MET-hours per week. History of parental colorectal cancer also was obtained.

### Dietary assessment

Consumption frequencies and portion sizes of 148 food and beverage items were ascertained by a computer-assisted interview. Details of the dietary interview have been described elsewhere<sup>[19]</sup>. Participants were asked to report their usual consumption during the past 12 mo. Intakes of nutrients were calculated based on the food composition tables in Japan<sup>[20]</sup>. To estimate dietary intake of polyphenols, we used 97 food items, including cereals, soybeans, vegetables, fruits, beverages and condiments.

**Table 1** Characteristics of colorectal cancer cases and controls

| Variables                                 | Cases (n = 816) | Controls (n = 815) |
|---|-----------------|--------------------|
| Male                                      | 60%             | 62%                |
| Age (yr), mean $\pm$ SD                   | 60.5 $\pm$ 9.1  | 58.9 $\pm$ 10.7    |
| Dietary intake, median (IQR) <sup>1</sup> |                 |                    |
| Total polyphenols (mg/d)                  | 1025 (698-1487) | 1047 (736-1431)    |
| Tea polyphenols (mg/d) <sup>2</sup>       | 432 (226-576)   | 397 (215-509)      |
| Coffee polyphenols (mg/d) <sup>3</sup>    | 187 (0.2-619)   | 260 (39-643)       |

<sup>1</sup>Polyphenols and food intakes were energy-adjusted to 2000 kcal/d;

<sup>2</sup>Included green tea, black tea and oolong tea; <sup>3</sup>Included coffee infusion, instant coffee and coffee drinks. IQR: Interquartile range.

Polyphenols for 92 food items were derived from the Phenol-Explorer Database, which is a compilation of polyphenol contents of 452 daily foods and beverages based on 638 published analytical studies<sup>[21]</sup>. As for the remaining 5 foods which were not listed in the Phenol-Explorer Database, polyphenol contents of 3 foods (sweet potatoes, satoimo and daikon) were based on a Japanese study<sup>[22]</sup>, and 2 foods (soybeans and fried potatoes) were estimated by ORAC-based polyphenol contents in the United States Department of Agriculture Database<sup>[23]</sup>.

### Statistical analysis

Dietary intakes of the nutrients and polyphenols were transformed to a natural log-scale and were adjusted to a total energy intake of 2000 kcal/d by the regression residual method<sup>[24]</sup>. Subjects were divided into quintile categories according to intakes of polyphenols among controls. Logistic regression analysis was used to estimate odds ratios (OR) and 95%CI of colorectal cancer for each category with the lowest quintile category as the referent group. We also calculated the OR according to coffee consumption in terms of the number of cups per week or day, with an assumption that one cup corresponded to 150 g of coffee infusion.

Confounding variables under consideration were age, sex, residential area (Fukuoka City or others), parental history of colorectal cancer, smoking (0, 1-399, 400-799 or  $>$  800 cigarettes/year), alcohol consumption (0, 0.1-0.9, 1.0-1.9 or  $\geq$  2 units per day), body mass index 10 years before (< 22.5, 22.5-24.9, 25.0-27.4 or  $\geq$  27.5  $\text{kg}/\text{m}^2$ ), type of job (sedentary or non-sedentary), leisure-time physical activity (0, 1-5.9 or  $\geq$  6 MET-h/wk) and dietary intakes of calcium and n-3 polyunsaturated fatty acids (PUFA). Calcium and n-3 PUFA intakes were related to decreased risk of colorectal cancer in the study population<sup>[25-29]</sup>. Trends of the associations were assessed with ordinal scores assigned to quintile categories of intake. Statistical significance was declared with the two-sided  $P < 0.05$ . Statistical analyses were performed using SAS version 9.2 (SAS Institute Inc., Cary, NC, United States).

## RESULTS

Demographic and lifestyle characteristics of colorectal

**Table 2 Association of dietary polyphenol intakes with colorectal cancer risk**

| Nutrient (unit)                      | Quintile of intake |                   |                   |                   |                   | <i>P</i> <sub>trend</sub> |
|--------------------------------------|--------------------|-------------------|-------------------|-------------------|-------------------|---------------------------|
|                                      | Q1 (low)           | Q2                | Q3                | Q4                | Q5 (high)         |                           |

<sup>1</sup>Adjusted for age, sex, residence area, parental history of colorectal cancer, smoking, alcohol drinking, body mass index 10 years before, type of job and leisure-time physical activity; <sup>2</sup>Further adjusted for calcium and n-3 polyunsaturated fatty acids. OR: Odds ratio.

cancer cases and controls were previously described<sup>[25-29]</sup>. The two groups did not differ much with respect to sex, age, residence area and most other factors. Body mass index was greater and a history of parental colorectal cancer was slightly more frequent in the cases than in the controls. There was no measurable difference in total or tea polyphenol intake between cases and controls, but intake of coffee polyphenols was lower in cases than in controls (Table 1). In the whole sample, intake of total polyphenols derived from tea and coffee was 38% and 34%, respectively.

The associations of intakes of total, tea and coffee polyphenols with colorectal cancer are shown in Table 2. Statistically significant decreases in the OR were observed in those with high intake of coffee polyphenols (the third and fourth quintile categories) compared with the lowest quintile, but the OR for the top quintile did not decrease further, showing an upward tendency. Similar, but less pronounced, decreases in the OR were also noted for the third and fourth quintiles of total polyphenol intake. Tea polyphenols and non-coffee polyphenols showed no clear association with colorectal cancer risk regardless of adjustment for the dietary factors.

Multivariate-adjusted ORs in the subsite-specific analysis are summarized in Table 3. Cases of colon and rectal cancers numbered 463 and 340, respectively. There were 188 cases who had proximal colon cancer only and 272 cases with distal colon cancer alone. The OR of colon cancer decreased with increasing intakes of coffee polyphenols; although the individual OR for the third to fifth quintiles were not significantly different from unity, a decreasing trend was statistically significant. Distal colon cancer showed a more evident inverse association with coffee polyphenols than proximal colon cancer. The

association between coffee polyphenols and rectal cancer was U-shaped, with significant decreases in the OR at the second to fourth quintile categories. Again, there was a tendency for the OR of colon and rectal cancer to decrease in the intermediate categories of total polyphenols. The decrease in the OR in the intermediate categories of total polyphenols was most pronounced for distal colon cancer. Intake of tea polyphenols was not associated with either colon or rectal cancer.

Additionally, we analyzed the associations of coffee consumption with colorectal cancers (Table 4). The associations of coffee consumption with colorectal, colon, and rectal cancers were almost the same as observed for coffee polyphenols. Nonetheless, the trend of the association between coffee consumption and colorectal cancer was statistically significant. The trend of an inverse association with coffee was also statistically significant for distal colon cancer. The OR of proximal colon cancer tended to decrease with increasing consumption of coffee, but the trend failed to reach statistical significance.

## DISCUSSION

The present study showed protective associations of coffee polyphenols and coffee consumption with the risk of colorectal cancer, especially of colon cancer. Non-coffee polyphenols showed no measurable association with the overall or site-specific risk of colorectal cancer. Thus, a modestly decreased risk of colorectal cancer associated with total polyphenol intake was probably ascribed to coffee polyphenols.

The association between coffee consumption and colorectal cancer has been examined in many studies in different populations. A meta-analysis of 12 cohort stud-

**Table 3** Multivariate-adjusted odds ratio (95%CI) of colon and rectal cancers according to polyphenols intake

<sup>1</sup>Adjusted for age, sex, residence area, parental history of colorectal cancer, smoking, alcohol drinking, body mass index 10 years before, type of job, leisure-time physical activity, calcium and n-3 polyunsaturated fatty acid. OR: Odds ratio.

ies found a relative risk (RR) of 0.91 (95%CI: 0.81-1.02) of colorectal cancer for the highest versus lowest coffee consumption<sup>[15]</sup>. A slightly pronounced decrease in the RR of colorectal cancer for the highest versus lowest consumption was noted in a combined analysis of 3 Japanese cohort studies (RR = 0.83, 95%CI: 0.62-1.10)<sup>[15]</sup>. On the other hand, a decrease in the risk of colorectal cancer associated with coffee use was more pronounced in a meta-analysis of 24 case-control studies<sup>[14]</sup>. The pooled OR for the highest versus non/low consumption was 0.70 (95%CI: 0.60-0.81) for colorectal cancer, 0.75 (95%CI: 0.60-0.81) for colon cancer and 0.87 (95%CI: 0.75-1.00) for rectal cancer<sup>[14]</sup>. A weaker association in the cohort studies is probably ascribed to a different time of exposure under consideration<sup>[14]</sup>. Coffee consumption in the recent past was assessed in most case-control studies. In the cohort studies, a follow-up shorter than 10 years was more likely to result in an inverse association between

coffee consumption and colorectal cancer risk than a longer follow-up<sup>[15]</sup>. In a recent large cohort study<sup>[30]</sup>, coffee consumption was associated with a decreased risk of proximal colon cancer, but not of distal colon cancer. The present study showed no such site-specific association with coffee.

Coffee polyphenolic compounds include chlorogenic, caffeic, ferulic and cumaric acids, and diterpenes (cafestol and kahweol) have been shown to possess anticarcinogenic properties<sup>[7]</sup>. Possible mechanisms by which coffee polyphenols are protective against colorectal cancer include reduction in bile acid secretion<sup>[31]</sup>, reduction in the synthesis of bile by down-regulation of the expression of bile acid homeostatic genes<sup>[32]</sup> and increase in colonic motility<sup>[33]</sup>.

The present study did not provide any evidence for a decreased risk of colorectal cancer associated with dietary intake of tea polyphenols. Tea polyphenols have been

**Table 4 Association of frequency of coffee consumption with colorectal cancer risk**

shown to have anti-cancer properties in numerous *in vitro* and *in vivo* studies<sup>[34,35]</sup>, but epidemiologic findings are inconsistent as regards tea and colorectal cancer risk. In China, regular green tea consumption was associated with a reduced risk of colorectal cancer in male non-smokers, but not in male smokers<sup>[9]</sup> and in women<sup>[10]</sup>. On the other hand, in cohort studies of Chinese in Singapore<sup>[11]</sup> and Japan<sup>[13]</sup>, green tea consumption was unrelated to colorectal cancer risk in men and women combined. A pooled analysis of 13 cohort studies in Western countries showed an increased risk associated with tea consumption; the RR for a consumption of > 900 g in liquid/d versus no consumption was 1.28 (95%CI: 1.02-1.61) in men and women combined<sup>[12]</sup>. A combined analysis of two Japanese prospective studies found no association between green tea consumption and colorectal cancer risk<sup>[13]</sup>.

We examined the associations with polyphenol and coffee for proximal and distal colon cancer separately, because these two cancers have distinct molecular mechanisms in carcinogenesis<sup>[36]</sup>. It was recently suggested that molecular changes in colorectal cancer were continuous, rather than dichotomous, from rectum to ascending colon<sup>[37]</sup>. The number of colorectal cancer cases was not large enough to perform a detailed subsite analysis in the present study. It should be noted that the difference in the molecular changes among the detailed subsites of proximal colon was less marked as compared with the difference between proximal and distal colon cancer.

In addition to a large sample size and the use of community controls, the detailed dietary assessment was a notable strength in the present study. The dietary interview was conducted as an in-person interview with typical dishes and serving sizes shown on a computer display. The present study had some weaknesses to be mentioned. The retrospective assessment of diet is a problem inherent to case-control studies. Dietary intakes in the past year may not have captured a habitual consumption

relevant to the development of colorectal cancer. Additionally, the participation rate was lower in the controls (60%) than in the cases (80%), and this may have caused a selection bias.

In conclusion, a case-control study in Japan showed protective associations of coffee polyphenols and coffee consumption with the risk of colorectal cancer, especially of colon cancer.

## ACKNOWLEDGMENTS

The authors acknowledge support from Emeritus Professors Keizo Sugimachi, Seiyo Ikeda, Sumitaka Arima, and Takayuki Shirakusa and from Drs. Motonori Saku, Yoichi Ikeda, Soichiro Maekawa, Kazuo Tanoue, Kinjiro Sumiyoshi, and Shoichiro Saito in conducting the survey of cases. The following physicians kindly supervised the survey of controls at their clinics: Drs. Hideaki Baba, Tomonori Endo, Hiroshi Hara, Yoichiro Hirokata, Motohisa Ikeda, Masayoshi Ishibashi, Fumiaki Itoh, Yasuhiro Iwanaga, Hideki Kaku, Shoshi Kaku, Minoru Kanazawa, Akira Kobayashi, Ryunosuke Kumashiro, Shinichi Matsumoto, Soukei Mioka, Umeji Miyakoda, Osamu Nakagaki, Nobuyoshi Nogawa (deceased), Nobuyuki Ogami, Toyooki Okabayashi, Hironao Okabe, Nishiki Saku, Masafumi Tanaka, Masahiro Ueda, Bunichi Ushio, and Koheisho Yasunaga.

## COMMENTS

### Background

Polyphenols are the most abundant antioxidants in foods and have drawn much interest as potentially anticarcinogenic compounds. Epidemiological studies have suggested that polyphenol-rich foods and beverages may be protective against colorectal cancer.

### Research frontiers

The Phenol-Explorer Database has enabled researchers to study the association between polyphenol intake and cancer risk. Evidence from meta-analyses

indicates that coffee may be protective against colorectal cancer.

### Innovations and breakthroughs

This was the first Japanese epidemiological study reporting that coffee polyphenol intake was associated with a decreased risk of colorectal cancer, particularly of colon cancer.

### Applications

Understanding the role for coffee polyphenols in colorectal carcinogenesis may advance a future strategy in the prevention of colorectal cancer.

### Terminology

The flavonoids are plant antioxidative compounds and possess anticarcinogenic properties. Tea catechins are a class of flavonoids, and are shown to inhibit tumorigenesis in animal experiments. Coffee is the major source of polyphenol intake such as chlorogenic and caffeic acids.

### Peer review

The present study is a very timely and well performed study that investigates the associations between intake of dietary polyphenols and colorectal cancer. The authors have done a tremendous job of designing and executing the project, and the data analysis and interpretations are very logical. I think these data are very important and provide another dimension and validity to the growing awareness of diet and its link to colorectal cancer.

### Abstract

**AIM:** To assess whether schistosomiasis coinfection with chronic hepatitis C virus (HCV) influences hepatic fibrosis and pegylated-interferon/ribavirin (PEG-IFN/RIB) therapy response.

**METHODS:** This study was designed as a retrospective analysis of 3596 chronic HCV patients enrolled in the Egyptian National Program for HCV treatment with PEG-IFN/RIB. All patients underwent liver biopsy and anti-schistosomal antibodies testing prior to HCV treatment. The serology results were used to categorize the patients into group A (positive schistosomal serology) or group B (negative schistosomal serology). Patients in group A were given oral antischistosomal treatment

(praziquantel, single dose) at four weeks prior to PEG-IFN/RIB. All patients received a 48-wk course of PEG-IFN (PEG-IFN $\alpha$ 2a or PEG-IFN $\alpha$ 2b)/RIB therapy. Clinical and laboratory follow-up examinations were carried out for 24 wk after cessation of therapy (to week 72). Correlations of positive schistosomal serology with fibrosis and treatment response were assessed by multiple regression analysis.

**RESULTS:** Schistosomal antibody was positive in 27.3% of patients (15.9% females and 84.1% males). The patients in group A were older ( $P = 0.008$ ) and had a higher proportion of males ( $P = 0.002$ ) than the patients in group B. There was no significant association between fibrosis stage and positive schistosomal serology ( $P = 0.703$ ). Early virological response was achieved in significantly more patients in group B than in group A (89.4% vs 86.5%,  $P = 0.015$ ). However, significantly more patients in group A experienced breakthrough at week 24 than patients in group B (36.3% vs 32.3%,  $P = 0.024$ ). End of treatment response was achieved in more patients in group B than in group A (62.0% vs 59.1%) but the difference did not reach statistical significance ( $P = 0.108$ ). Sustained virological response occurred in significantly more patients in group B than in group A (37.6% vs 27.7%,  $P = 0.000$ ). Multivariate logistic regression analysis of patient data at treatment weeks 48 and 72 showed that positive schistosomal serology was associated with failure of response to treatment at week 48 (OR = 1.3,  $P = 0.02$ ) and at week 72 (OR = 1.7,  $P < 0.01$ ).

**CONCLUSION:** Positive schistosomal serology has no effect on fibrosis staging but is significantly associated with failure of response to HCV treatment despite anti-schistosomal therapy.

**Key words:** Hepatitis C virus; Schistosomiasis; Coinfection; Fibrosis; Treatment response

**Core tip:** Both hepatitis C virus (HCV) and schistosomiasis are highly endemic in Egypt and coinfection is frequently encountered. The effect of such coinfection on hepatic fibrosis and response to pegylated-interferon and ribavirin therapy (PEG-IFN/RIB) remains unclear. Our study aimed to assess the impact of schistosomiasis on hepatic fibrosis and response to PEG-IFN/RIB therapy in chronic HCV Egyptian patients. Antischistosomal antibody was positive in 27.3% of 3596 chronic HCV patients. Findings suggest positive schistosomal serology has no effect on fibrosis stage but is significantly associated with failure of response to HCV treatment despite antischistosomal therapy.

## INTRODUCTION

The hepatitis C virus (HCV) is a major public health problem and a leading cause of chronic liver disease<sup>[1]</sup>. In fact, Egypt has the largest epidemic of HCV in the world with an overall serum positive prevalence of 14.7% as reported by the Egyptian demographic health survey<sup>[2]</sup>. It also is a major cause of liver fibrosis, which is associated with significant morbidity and mortality<sup>[3]</sup>.

Schistosomiasis is also of significant concern as it is endemic in Egypt<sup>[4,5]</sup>. *Schistosoma haematobium* is endemic in Upper Egypt (7.8% prevalence), while *Schistosoma mansoni* has greater prevalence in Lower Egypt (36.4%)<sup>[6]</sup>. The presence of both HCV and *Schistosoma* spp. is of significant concern as patients with coinfections have been shown to have higher HCV RNA titers, increased histological activity, greater incidence of cirrhosis/hepatocellular carcinoma, and higher mortality rates than patients suffering from single infections<sup>[7]</sup>. In addition, patients diagnosed with hepatosplenic schistosomiasis have increased opportunities for additional infections and medical abnormalities. These may include up to a 10-fold opportunity for coinfection with hepatitis B virus (HBV) (compared to healthy counterparts), chronic hepatitis on liver biopsy, persistent antigenemia, and increased frequency of liver failure<sup>[8]</sup>.

The aim of this study was to evaluate the impact of schistosomiasis on hepatic fibrosis and on response to pegylated-interferon combined with ribavirin (PEG-IFN/RIB) therapy in Egyptian patients with chronic HCV.

## MATERIALS AND METHODS

### Patient characteristics and study design

This retrospective study included 3596 Egyptian patients

with chronic HCV treated with PEG-IFN/RIB at Cairo-Fatemic Hospital (Cairo, Egypt). Study enrollment inclusion and exclusion criteria are listed in Table 1.

All patients received PEG-IFN $\alpha$ 2a (180  $\mu$ g/wk dose) or PEG-IFN $\alpha$ 2b (1.5  $\mu$ g/kg/wk dose) via subcutaneous injection and oral RIB (800-1200 mg/d) for 48 wk as genotype 4 causes approximately 90% of HCV infections in Egypt<sup>[9]</sup>. Patients were followed for 24 wk after cessation of therapy (to week 72).

The study was approved by the ethical committee of the Ministry of Health (Cairo, Egypt), and all patients consented to blood sampling and data usage in future research. Anti-schistosomal antibody testing was completed for all patients. Patients were stratified according to their schistosomal serological status; group A, HCV patients with positive schistosomal serology; group B, HCV patients with negative schistosomal serology. Study participants with positive schistosomal serology were given praziquantel (PZQ) therapy (oral, 40 mg/kg, single dose) at four weeks prior to initiation of the PEG-IFN/RIB therapy. Liver biopsies were performed for all patients to determine the grade of necroinflammation and stage of fibrosis (Table 2) (based on the METAVIR scoring system<sup>[10]</sup>).

Quantitative real-time reverse transcription-polymerase chain reaction was used to detect HCV RNA (detection limit  $\geq$  50 IU/mL) at baseline and weeks 12, 24, 48 and 72 after initiation of anti-viral therapy. Clinical and laboratory follow-up examinations were carried out to identify the presence of adverse side effects and treatment response. A total of 845 patients were lost to follow-up, so that 2751 participants completed the follow-up to week 72. Patients with early virologic response (EVR) continued follow-up to identify subsequent non-responders. Patients with detectable HCV-RNA at week 24 or those with less than 2 log decrease in viral load at week 12 were designated as treatment failure. HCV therapy was discontinued prematurely in those patients.

### Statistical analysis

Quantitative data were described by averaging and calculating the SD. Intergroup differences were assessed by the Student's *t*-test,  $\chi^2$  or Fisher's exact tests were used for comparisons when appropriate. Multivariate logistic regression was performed with failure of treatment set as the dependent variable. In all tests, a *P*-value of  $<$  0.05 was considered as the threshold for significance.

## RESULTS

No statistically significant differences were found in the baseline characteristics of the two groups of patients, with the exceptions of age and sex (Table 3). HCV patients with positive schistosomal serology were older than the negative schistosomal group ( $P = 0.008$ ) and showed a higher rate of males ( $P = 0.002$ ). Of the 27.3% of the patients with positive schistosomal serology, 15.9% were

Cited from reference 10. A: Activity; F: Fibrosis.

females and 84.1% were males.

There were no significant differences between groups regarding fibrosis staging (Figure 1) or end of treatment response (ETR) (Table 4). However, the EVR and virological response at week 24 were significantly higher in patients with negative schistosomal serology ( $P = 0.015$  and  $P = 0.024$ , respectively).

Of the 2751 patients that were followed-up to week 72, those with negative schistosomal serology had achieved a higher sustained virological response (SVR) than the other group (37.6% *vs* 27.7%,  $P = 0.000$ ).

Multivariate logistic regression analyses indicated that patients with positive schistosomal serology were more likely to fail treatment (OR = 1.3,  $P = 0.02$ ) at week 48 and (OR = 1.7,  $P < 0.01$ ) at week 72 (Table 5).

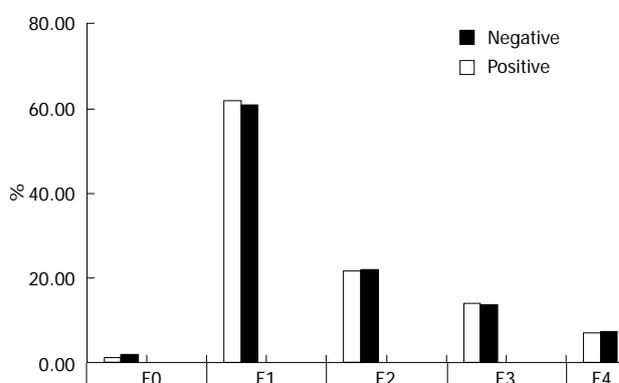

Figure 1 Fibrosis stages in relation to schistosomal serology.

## DISCUSSION

This study was undertaken to determine a correlation between HCV and schistosomiasis infection in relation to hepatic fibrosis stages and antiviral treatment response.

Our findings showed a correlation of positive schistosomal serology in reference to sex, with the predominance involving males. HCV patients with positive schistosomal serology were also found to be older than those with negative serology. This finding is suspected to be due to the reservoir of HCV infection in Egypt, for which intravenously administered tartar emetic was used as a primary treatment<sup>[11]</sup>.

While this study showed no significant difference between the two groups in terms of fibrosis staging, other studies report HCV/schistosomiasis coinfecting patients have more rapid progression of hepatic fibrosis than those with HCV mono-infection<sup>[12]</sup>, as evidenced by increased fibrosis scores for the liver biopsies taken at 96.0 ± 4.6 mo of follow-up. Moreover, another study demonstrated that serum transforming growth factor-β (TGF-β) and tumor necrosis factor-α (TNF-α) levels are higher in coinfecting groups<sup>[13]</sup>.

Ahmad *et al.*<sup>[14]</sup> showed that schistosomiasis coinfection with HCV and/or non-alcoholic steatohepatitis had no significant impact on fibrosis stage. Results involving differences in fibrosis stages may be explained by several

**Table 4** Virological response at weeks 12, 24, 48 in relation to schistosomal serology *n* (%)

EVR: Early virologic response; ETR: End of treatment response.

factors. Genetic predisposition may play a role, whereby only a minority of the individuals infected with *Schistosoma mansoni* may develop hepatic fibrosis or be more sensitive to infection(s). Moreover, frequency of exposure is directly correlated with the presence and amount of fibrosis<sup>[15]</sup>. In addition, several clinical and pathological studies have shown that schistosomal hepatopathy is a reversible condition and that resolution of the schistosomiasis disease is accompanied by subsequent fibrosis resorption<sup>[16,17]</sup>.

Moreover, HCV patients with evidence of coinfection or previous exposure to schistosomiasis received oral antischistosomal treatment of PZQ prior to starting the anti-viral therapy. PZQ is believed to exert antifibrotic effects by affecting (decreasing) activation of hepatic stellate cells through inhibition of profibrotic gene expression<sup>[18]</sup>. Morcos *et al*<sup>[19]</sup> demonstrated that PZQ treatment could induce resolution of schistosoma-induced pathology, showing partial reversal of liver fibrosis in *Schistosoma mansoni* infected mice. Improvements and/or resolutions of schistosomal-induced periportal thickening/fibrosis in PZQ treated models have also been demonstrated by Berhe *et al*<sup>[20]</sup> and Frenzel *et al*<sup>[21]</sup>. It is theorized that the beneficial effects are likely related to the clearance of schistosomal worms and subsequent reduction of egg deposition.

Other limiting issues for the use of liver biopsy as a clinical tool for assessing fibrosis in schistosomiasis include ethical considerations and the risk of sampling errors, which may be especially evident for small-volume biopsies<sup>[22]</sup>.

In our current study, the EVR, virological response at week 24, and SVR were significantly higher in patients with negative schistosomal serology. This finding may be attributed to coinfecting patients with a down-regulated immune response to HCV leading to reduced IFN $\gamma$ , interleukin (IL)-4 and IL-10 secreted by HCV-specific T cells. Early reports by Kamal *et al*<sup>[23]</sup> using standard IFN in the treatment of chronic HCV patients reported that Egyptian patients with coinfections have higher HCV RNA titers, more advanced liver disease, more hepatic complications and greater mortality rates than those infected with HCV alone.

In light of the previous real time PCR findings from Bahgat *et al*<sup>[24]</sup>, soluble egg antigen (SEA) should be considered as a potential stimulatory factor for HCV RNA that may have influenced the early detection of HCV RNA as SEA can stimulate viral replication. The higher morbidity that is observed in patients coinfecting with schistosomiasis and HCV is related, at least in part, to direct stimulation of viral replication by SEA<sup>[25]</sup>.

It is interesting to consider that Derbala *et al.* found no significant difference in the treatment responses of patients treated with and without bilharziasis<sup>[26]</sup>. This finding might be explained by phenotypic variations in Egyptian patients infected with HCV genotype 4, whereby some patients may mount HCV-specific T cell responses, both CD4+ and CD8+, despite the prevalence of concomitant schistosomiasis<sup>[27]</sup>.

A major limitation of this study was the need to diagnose schistosomiasis in patients by using an antischistosomal serology approach with a commercially available indirect hemagglutination test (IHAT). While the IHAT is sensitive in detecting bilharziasis, it cannot differentiate between past and current infection status nor between *Schistosoma mansoni* and *Schistosoma haematobium* species. While rectal snips are the preferred method of schistosomiasis diagnosis, this approach was not possible in our study population due to the large number of participants. Finally, genotyping for HCV was not performed on the patients in our study, since approximately 90% of infections in Egypt are due to genotype 4<sup>[9]</sup> and the Egyptian National Committee for Control of Viral Hepatitis does not recommend routine genotyping.

In conclusion, positive schistosomal serology has no effect on fibrosis stage but it is significantly associated with failure of response to HCV treatment despite antischistosomal therapy.

## COMMENTS

**Background**

Hepatitis C virus (HCV) is a major public health problem and is the primary cause of liver fibrosis and chronic liver disease worldwide. Both HCV and schistosomiasis are highly endemic in Egypt and cases of coinfection are frequently encountered. Intriguingly, HCV prevalence shows a direct correlation to the amount of intravenous tartar emetic used to control schistosomiasis in some geographic regions of Egypt. Moreover, patients with hepatosplenic schistosomiasis show a higher susceptibility to coinfection with hepatitis B virus and HCV than healthy individuals.

**Research frontiers**

HCV/Schistosomiasis coinfecting patients are characterized by higher HCV RNA titers, histological activity, incidence of cirrhosis and hepatocellular carcinoma, as well as higher mortality rates than monoinfected patients. This research aimed to assess the influence of schistosomiasis on hepatic fibrosis and to evaluate the response to pegylated-interferon/ribavirin (PEG-IFN/RIB) therapy in patients with chronic HCV infection.

**Innovations and breakthroughs**

Results showed that 27.3% of the patients had positive schistosomal serology, with a prevalence towards males (15.9% female and 84.1% male). The extent of fibrosis was not significantly different between patients with HCV/schistosomiasis coinfection and patients with chronic HCV mono-infection. Patients with HCV/schistosomiasis coinfection showed lower rates of early virologic response and virological response at week 24 of antiviral treatment, as well as lower rates of end-treatment response and sustained virological response. Schistosomiasis appears to be significantly associated with failure to respond to HCV treatment despite antischistosomal therapy.

**Applications**

Schistosomiasis appears to be significantly associated with failure to respond to HCV treatment. Authors propose that mandatory schistosomal serology should be considered for chronic HCV patients prior to initiating PEG-IFN/RIB therapy. In those patients with positive schistosomal serology, administration of anti-schistosomal therapy (praziquantel at 40 mg/kg single dose) four weeks prior to antiviral therapy (PEG-IFN/RIB) may decrease the effect of schistosomiasis, reduce subsequent complications and improve response to treatment.

**Terminology**

Early virological response is defined as a  $\geq 2$  log reduction or complete absence of serum HCV RNA at week 12 of therapy, as compared to the baseline level. End-of-treatment response is defined as an undetectable level of virus (by polymerase chain reaction) in serum at the end of a 48-wk course of therapy (for patients infected with HCV genotype 4). Sustained virological response is defined as an undetectable level of HCV RNA in serum at 24 wk after the discontinuation of therapy. Virological breakthrough refers to the reappearance of HCV RNA during the ongoing course of therapy.

**Peer review**

This study analyzes the impact of schistosomiasis on hepatic fibrosis and response to PEG-IFN/RIB therapy in patients with chronic HCV. The results suggest that positive schistosomal serology has no effect on fibrosis stage, but is significantly associated with failure to respond to HCV treatment.

### Abstract

**AIM:** To investigate the expression of distal-less homeobox 2 (DLX2) in gastric adenocarcinoma and its clinicopathological significance.

**METHODS:** Gastric adenocarcinoma tissues were obtained from gastrectomy specimens of 129 patients from the Department of Surgery and Pathology, the Second Affiliated Hospital of Kunming Medical University. Sixty cases of normal gastric tissues were collected from gastrectomy specimens of adjacent gastric cancer margins greater than 5 cm. Patient diagnosis was established pathologically, and no patient had received chemotherapy or radiotherapy before surgery. All tissue specimens were formalin-fixed and paraffin-embedded. Immunohistochemistry was carried out to investigate the expression of DLX2 in 129 gastric adenocarcinoma tissues and 60 adjacent normal tissues. The immunos-

taining reaction was semiquantitatively evaluated based on the proportion of positive cells and the median staining intensity in normal gastric epithelial cells or tumor cells. All patients had follow-up records for more than 5 years. Correlations of DLX2 expression with clinicopathological features and prognosis of patients with gastric adenocarcinoma were analyzed. All statistical analyses were performed using the SPSS 17.0 software.

**RESULTS:** The positive expression of DLX2 was detected in 68 (52.7%) cases of 129 gastric adenocarcinoma tissues and 14 (23.3%) cases of 60 adjacent normal tissues. The difference in DLX2 expression between gastric adenocarcinoma tissues and adjacent normal tissues was statistically significant ( $\chi^2 = 14.391$ ,  $P < 0.001$ ). Moreover, high expression of DLX2 was detected in 48 (37.2%) cases of 129 human gastric cancer tissues, but not in adjacent normal tissues. The expression of DLX2 correlated with the size of tumor ( $P = 0.001$ ), depth of invasion ( $P = 0.008$ ), lymph node metastasis ( $P = 0.023$ ) and tumor-node-metastasis stages ( $P = 0.020$ ), but was not correlated with age, gender, histological differentiation and distant metastasis. The Kaplan-Meier survival analysis revealed that survival time of patients with high DLX2 expression was significantly shorter than that with low DLX2 expression. However, the multivariate analysis showed that invasion depth ( $P < 0.001$ ), lymph nodes metastasis ( $P = 0.001$ ) and distant metastasis ( $P < 0.001$ ) were independent prognostic factors for patients with gastric adenocarcinoma, but DLX2 expression, tumor location and tumor size were not.

**CONCLUSION:** These results suggest that increased expression of DLX2 may correlate with the advanced stage of gastric adenocarcinoma, and it may contribute to tumor development.

## INTRODUCTION

Gastric cancer is one of the leading causes of cancer-related death worldwide due to its frequency, poor prognosis and limited treatment options<sup>[1]</sup>. Although the incidence of gastric cancer has been declining for several decades in most Western countries, it remains a crucial public health problem in developing countries<sup>[2,3]</sup>. In China, gastric cancer is the second most common malignancy and was the third leading cause of death from cancer in 2007, representing a major disease burden on health services<sup>[4]</sup>. Several studies have shown that various genetic and epigenetic alterations are involved in the course of carcinogenesis and progression of gastric cancer<sup>[5-8]</sup>. However, the molecular mechanism involved in the development of gastric cancer remains unclear.

The distal-less homeobox (*DLX*) gene family, a homolog of *Drosophila* distal-less, comprises six *DLX* genes in humans, of which three exist as bigene clusters: *DLX-1/DLX-2*, *DLX-3/DLX-4*, *DLX-5/DLX-6*<sup>[9]</sup>. The *DLX* gene family has crucial roles in regulating embryonic development, tissue homeostasis, lymphocyte development, cell cycle and apoptosis<sup>[10-14]</sup>. However, the role of the *DLX* gene family in tumor development has only recently been explored. As a member of *DLX* gene family, the abnormal expression of *DLX2* has been reported in many human hematological malignancies and solid tumors, including acute lymphoblastic leukemia, acute myeloid leukemia, melanoma, glioma, breast, lung, prostate, ovarian and colon cancer<sup>[9,14-17]</sup>. A recent study showed that the expression of *DLX2* plays a critical role in shifting transforming growth factor  $\beta$  (TGF- $\beta$ ) from its tumor suppressive to its tumor-promoting functions<sup>[13]</sup>. Moreover, abnormal TGF- $\beta$  expression is involved in tumor progression, metastasis, angiogenesis and poor survival of gastric cancer<sup>[18,19]</sup>. These studies led us to investigate the possible role of *DLX2* in the development of gastric adenocarcinoma.

In the present study, we assessed the expression of *DLX2* in gastric adenocarcinoma tissues and adjacent normal tissues by immunohistochemistry. Correlations of *DLX2* expression with clinicopathological features and survival of gastric adenocarcinoma patients were then analyzed.

## MATERIALS AND METHODS

### Patients and tissue samples

Gastric adenocarcinoma tissues were obtained from gastrectomy specimens of 129 patients from the Depart-

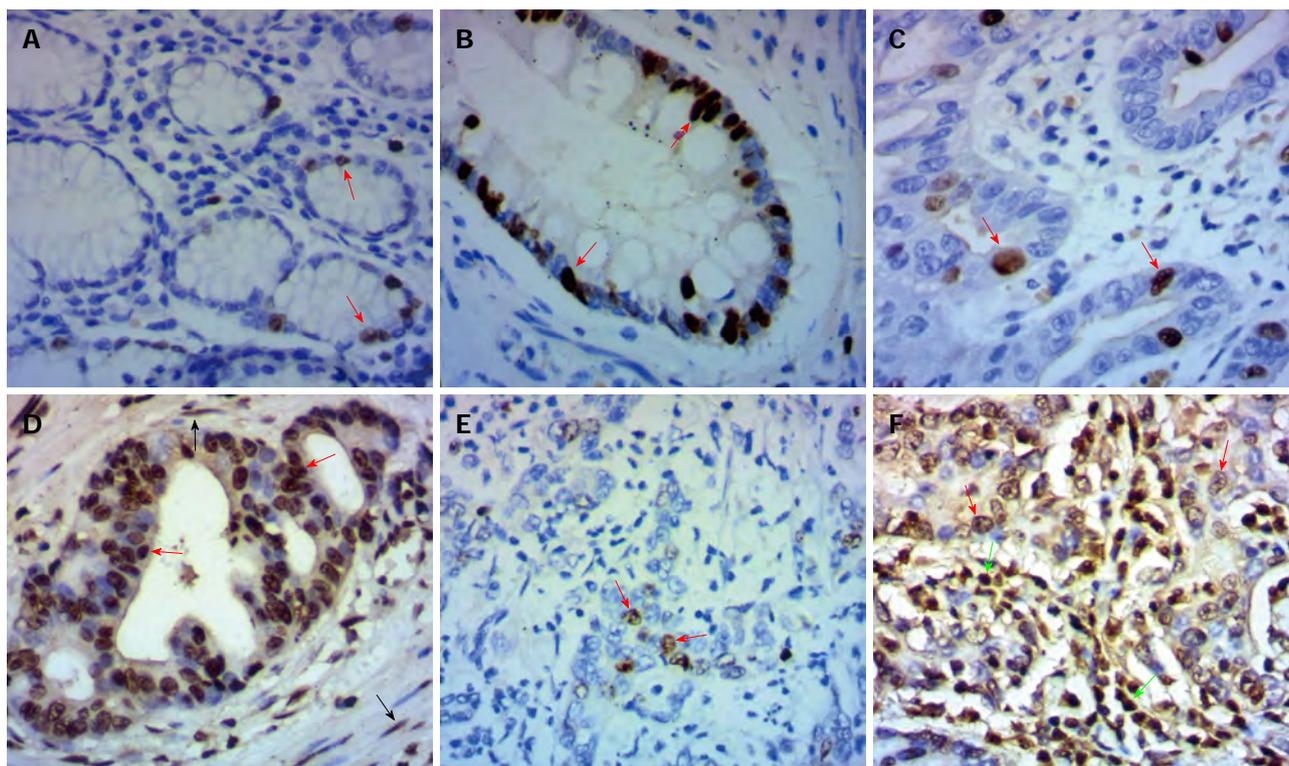

ment of Surgery and Pathology, the Second Affiliated Hospital of Kunming Medical University. Sixty samples of normal gastric tissues were collected from gastrectomy specimens of adjacent gastric cancer margins greater than 5 cm and served as controls. All operations were performed between January 2001 and June 2007. Patient diagnosis was established pathologically, and no patient had received chemotherapy or radiotherapy prior to surgery. All tissue specimens were formalin-fixed and paraffin-embedded. There were 87 males and 42 females (mean age, 57.6 years; range, 26-84 years). The age and gender of patients, tumor size, tumor location, histological differentiation, depth of invasion, status of lymph node metastasis and distant metastasis were obtained from histopathology records. The stage was determined according to the 7<sup>th</sup> edition of the AJCC Tumor Staging Manual and Japanese Classification 2011 in gastric cancer<sup>[20,21]</sup>. Forty-three cases were categorized as stage I, 43 were stage II, 34 were stage III and nine were stage IV. All patients had follow-up records for more than 5 years. The follow-up deadline was July 2012. The survival time was determined from the date of surgery to the follow-up deadline or date of death, which was mostly caused by recurrence or metastasis. The hospital's ethics committee approved this study.

### Immunohistochemistry

Immunohistochemical analysis was used to investigate *DLX2* expression in 129 cases of gastric adenocarcinoma tissues and 60 cases of adjacent normal tissues. According to protocol<sup>[22,23]</sup> for immunohistochemistry on paraffin-embedded tissue sections, paraffin-embedded blocks were sectioned at about 4  $\mu$ m thickness. Slides were baked at 60 °C for 2 h, deparaffinized with xylene and rehydrated using an alcohol gradient (100% alcohol, 95% alcohol, 80% alcohol, and 70% alcohol). After microwave pretreatment in citrate buffer (pH 6.0) for antigen retrieval, sections were treated with 3% hydrogen peroxide in methanol to block endogenous peroxidase activity. Sections were incubated with 1% bovine serum albumin to block nonspecific binding, and then incubated overnight at 4 °C with the polyclonal antibody against *DLX2* (Epitomics, Inc., California, United States) at a dilution of 1:100. Phosphate buffer solution (PBS) was used as a negative control. After rinsing 3  $\times$  3 min with PBS, tissue sections were treated with peroxidase-linked secondary antibody (Maixin-Bio, Inc., Fuzhou, China) for 30 min at room temperature. Staining was carried out with diaminobenzidine chromogen (Maixin-Bio, Inc., Fuzhou, China) and counterstained with hematoxylin. All slides were then dehydrated using an alcohol gradient, and mounted with a coverslip.

### Scoring of immunohistochemical staining

The results of immunostaining were reviewed and scored independently by two observers in a blinded fashion without knowledge of clinical and pathological information. To avoid artifactual effects, the cells on the margins

**Figure 1** Immunohistochemical staining for distal-less homeobox 2 in gastric adenocarcinoma tissues and adjacent normal gastric tissues. A: Low expression of distal-less (DLX2) in normal gastric mucosa; B: High expression of DLX2 in intestinal metaplasia cells; C: Low expression of DLX2 in gastric adenocarcinoma tissue with well differentiation; D: High expression of DLX2 in gastric adenocarcinoma tissue with well differentiation; E: Low expression of DLX2 in gastric adenocarcinoma tissue with poor differentiation; F: High expression of DLX2 in gastric adenocarcinoma tissue with poor differentiation. DLX2 staining was detected mainly in nucleus of normal gastric epithelial cells (Figure 1A, red arrows) or tumor cells (Figure 1C-F, red arrows). Besides, increased expression of DLX2 was detected in intestinal metaplasia cells (Figure 1B, red arrows), fibroblasts (Figure 1D, black arrows) and inflammatory cells (Figure 1F, green arrows) around tumor cells. Original magnification,  $\times 200$ .

of sections and areas with poorly presented morphology were not counted. Five fields ( $\times 400$  magnification) per tissue section, chosen at random, were counted. The immunostaining reaction was semiquantitatively evaluated based on the proportion of positive cells and the median staining intensity in normal gastric epithelial cells or tumor cells. The proportion of positive cells was scored as follows: 0,  $\leq 5\%$ ; 1, 6%-25%; 2, 26%-50% and 3,  $\geq 51\%$ . The sections were considered to be positively stained when there were more than 5% of observed cells with immunostaining. Staining intensity was graded according to the following criteria: 0, no staining; 1, weak staining, light yellow; 2, moderate staining, yellow brown; and 3, strong staining, brown. The immunoreactive score was calculated based on the proportion score multiplied by the staining intensity score. All immunoreactive scores were less than 4 in adjacent normal tissues; therefore, the results of immunostaining in tumor tissues were divided into two groups, low expression (immunoreactive score  $\leq 3$ ) and high expression (immunoreactive score  $\geq 4$ ).

### Statistical analysis

All statistical analyses were performed using the SPSS 17.0 software. Correlation of DLX2 expression with clinicopathological parameters was calculated by Pearson  $\chi^2$  test,  $\chi^2$  test with continuity correction and Spearman's rank

correlation test, respectively. Univariate survival analysis was assessed by the Kaplan-Meier method and the difference in survival curves was analyzed by the log-rank test. The Cox proportional hazards regression model was used to analyze independent prognostic factors. All reported *P* values were two-sided and *P* < 0.05 was considered statistically significant.

## RESULTS

### Expression of DLX2 in gastric cancer and adjacent normal tissues

In the present study, immunohistochemical analysis was carried out to investigate the DLX2 expression in 129 gastric adenocarcinoma tissues and 60 adjacent normal tissues. Positive expression of DLX2 was detected in 68 (52.7%) cases of 129 gastric cancer tissues and in 14 (23.3%) cases of 60 adjacent normal tissues. The difference of DLX2 expression between gastric cancer tissues and adjacent normal tissues was statistically significant ( $\chi^2 = 14.391$ , *P* < 0.001). Moreover, high expression of DLX2 was detected in 48 (37.2%) cases of 129 human gastric cancer tissues, but not in adjacent normal tissues. DLX2 staining was detected mainly in the nuclei of normal gastric epithelial cells (Figure 1A) or tumor cells (Figure 1C-F). In addition, increased expression of

DLX2: Distal-less homeobox 2.

DLX2 was detected in intestinal metaplasia cells (Figure 1B), fibroblasts (Figure 1D) and inflammatory cells (Figure 1F) around tumor cells.

**Expression of DLX2 and clinicopathological features**

The expression of DLX2 in gastric adenocarcinoma was significantly correlated with tumor size (*P* = 0.001), depth of invasion (*P* = 0.008), lymph node metastasis (*P* = 0.023) and TNM stages (*P* = 0.020), but was not correlated with age, gender, histological differentiation and distant metastasis (*P* > 0.05, Table 1). Spearman’s rank correlation test showed that DLX2 expression was positively related to tumor size (*P* < 0.001), depth of invasion (*P* = 0.010), lymph node metastasis (*P* = 0.013) and TNM stages (*P* = 0.004).

To investigate whether the ranks of percentage or staining intensity of DLX2 expression was more prominent for the immunoreactive assessment, the statistical analysis of the correlation between clinicopathological parameters and the proportion score or staining intensity

**Figure 2 Kaplan-Meier curves with univariate analysis (log-rank) for patients with low distal-less homeobox 2 expression vs high distal-less homeobox 2 expression.**

score of DLX2 expression was calculated separately. As shown in Table 2, the proportion score of DLX2 expression was significantly correlated with tumor size (*P* = 0.002), depth of invasion (*P* = 0.016) and lymph node metastasis (*P* = 0.002). The staining intensity score was significantly correlated with tumor size (*P* = 0.029) and lymph node metastasis (*P* = 0.044). These results suggest that the ranks of percentage of DLX2 expression in gastric cancer tissues may be more prominent than staining intensity for the immunoreactive assessment.

**Correlation between DLX2 expression and patient prognosis**

The Kaplan-Meier survival analysis revealed that survival time of patients with high DLX2 expression was significantly shorter than for those with low DLX2 expression ( $\chi^2 = 4.986, P = 0.026$ ; Figure 2). The mean survival time of the former was only 39.216 mo (95%CI: 34.030-44.402), whereas the mean survival time of latter was 45.669 mo (95%CI: 41.426-49.912). For patients with high DLX2 expression, the cumulative 3- and 5-year survival rates were 58.3% and 16.7%, respectively, which was significantly lower than those for patients with low DLX2 expression (70.4% and 29.6%, respectively).

Additionally, the clinicopathological features for possible prognostic effects in gastric cancer were analyzed by Cox regression analysis. The following six clinicopathological features were selected for evaluation: tumor size, tumor location, depth of invasion, lymph nodes metastasis, distant metastasis and DLX2 expression (all *P* < 0.05 in univariate survival analysis). The multivariate analysis showed that invasion depth (*P* < 0.001), lymph nodes metastasis (*P* = 0.001) and distant metastasis (*P* < 0.001) were independent prognostic factors for patients with gastric adenocarcinoma, but DLX2 expression, tumor location and tumor size were not independent prognostic factors (Table 3).

**DISCUSSION**

In the present study, DLX2 expression levels were in-

**Table 2** Relationship of proportion score or staining intensity of distal-less homeobox 2 expression with clinicopathological features of gastric adenocarcinoma

| Clinicopathological features | Cases | Proportion score |    |      | $\chi^2$ test | P value | Staining intensity |      |    | $\chi^2$ test | P value |

investigated in 129 gastric adenocarcinoma tissues and 60 adjacent normal tissues by immunohistochemistry. We showed that DLX2 expression was more frequent in gastric cancer tissues than in adjacent normal tissues. The expression of DLX2 in gastric cancer tissues was significantly associated with the size of the tumor, the depth of invasion, lymph node metastasis and TNM stages. Based on these results, we suggest that increased expression of DLX2 may correlate with the advanced stage of gastric adenocarcinoma.

In several investigations, it has been shown that the abnormal expression of DLX2 in cancer cells is associated with tumor progression. However, the mechanism of DLX2's involvement in tumor progression is not clear. Yilmaz *et al*<sup>[4]</sup> showed that expression of DLX2 correlated significantly with advanced tumor progression and with the metastatic potential of melanoma, glioma, lung, and prostate cancers. In their research, they found that DLX2 counteracted TGF- $\beta$ -induced cell-cycle arrest and apoptosis in mammary epithelial cells, and DLX2 ex-

pression supported experimental tumor growth and metastasis of B16 melanoma cells. These results established that DLX2 has an important role in shifting TGF- $\beta$  from its tumor suppressive to its tumor-promoting functions. Additionally, Lee *et al*<sup>[16]</sup> found that DLX2 expression was higher in breast and ovarian cancer tissues compared with the adjacent normal tissues. Furthermore, DLX2 expression was related to poor differentiation grade of ovarian cancer. DLX2 short hairpin RNA inhibited the metabolic stress-induced increase in propidium iodide-positive cell population and high mobility group box 1 and lactate dehydrogenase release. They concluded that DLX2 might be involved in tumor progression *via* the regulation of metabolic stress-induced necrosis.

In our research, high expression of DLX2 was detected in intestinal metaplasia, which is a risk factor for development of gastric cancer<sup>[24,25]</sup>, indicating that increased expression of DLX2 might contribute to an early event of gastric cancer development. In addition, we found that increased expression of DLX2 was detected in inflammatory cells around tumor cells. Recent studies have expanded the concept that inflammation is a critical component of tumor progression<sup>[26]</sup>. Moreover, the mediators and cellular effectors of inflammation are important constituents of the local environment of tumors<sup>[27]</sup>. These results further support the hypothesis that DLX2 is involved in the development of gastric adenocarcinoma.

In 2010, Morini *et al*<sup>[9]</sup> found that expression of DLX2 was detected in 21.6% of the patients with breast cancer, and was significantly correlated with prolonged disease-free survival and reduced incidence of relapse. DLX5 expression was detected in 2.2% of all cases, displaying reduced disease-free survival and high incidence

of relapse. In all cases, they found mutually exclusive expression of DLX2 and DLX5. Their study suggested that *DLX* genes were involved in human breast cancer progression, and that *DLX2* and *DLX5* genes might serve as prognostic markers. In our research, the Kaplan-Meier survival analysis revealed that the survival times of gastric adenocarcinoma patients with high DLX2 expression were significantly shorter than those with low DLX2 expression. However, the multivariate analysis showed that DLX2 expression was not an independent prognostic factor in gastric adenocarcinoma. The multivariate analysis might mask DLX2's contribution to survival rate. Therefore, DLX2 expression might not be related with poor prognosis in patients with gastric adenocarcinoma.

In conclusion, our study demonstrates that increased expression of DLX2 may correlate with the advanced stage of gastric adenocarcinoma, and it may contribute to tumor development. These findings further support the hypothesis that, as a key regulator of embryogenesis, DLX2 may also play a critical role in tumor development. Consequently, further investigation is necessary to clarify the role of DLX2 in the development of gastric adenocarcinoma.

## COMMENTS

### Background

Gastric cancer is one of the leading causes of cancer-related death worldwide because of its frequency, poor prognosis and limited treatment options. Although the incidence of gastric cancer has been declining for several decades in most Western countries, it remains a crucial public health problem in developing countries. Several studies have demonstrated that various genetic and epigenetic alterations are involved in the course of carcinogenesis and progression of gastric cancer.

### Research frontiers

The distal-less homeobox (*DLX*) gene family exerts an important role in regulating embryonic development, tissue homeostasis, lymphocyte development, cell cycle and apoptosis. However, the role of the *DLX* gene family in tumor development has only recently been explored. As a member of *DLX* gene family, the abnormal expression of distal-less homeobox 2 (*DLX2*) has also been reported in many human solid tumors and hematological malignancies.

### Innovations and breakthroughs

This is the first study attempt to explore the expression of DLX2 in gastric adenocarcinoma and its clinicopathological significance. This study suggests that increased expression of DLX2 may correlate with the advanced stage of gastric adenocarcinoma, and it may contribute to tumor development.

### Applications

By understanding the expression of DLX2 and its correlation with clinicopathological features of gastric adenocarcinoma, this study will form the basis for further research to explore the mechanism of tumor development, and may represent a potential therapeutic target of gastric adenocarcinoma.

### Terminology

Homeobox genes encode transcription factors that play essential roles in controlling cell growth and differentiation during embryonic development. These genes are characterized by a highly conserved 61-amino acid homeodomain that binds DNA elements containing a TAAT core motif. Many homeobox genes are aberrantly expressed in a wide variety of solid tumors and hematological malignancies.

### Peer review

The authors investigated the expression of DLX2 in gastric adenocarcinoma tissues and adjacent normal tissues by immunohistochemistry. Correlations of DLX2 expression with clinicopathological features and prognosis of patients with gastric adenocarcinoma were then analyzed. This study has shown that

increased expression of DLX2 may correlate with the advanced stage of gastric adenocarcinoma, and it may contribute to tumor development. These results are interesting and may represent a novel molecular mechanism of gastric adenocarcinoma development.

### Abstract

**AIM:** To evaluate the use of medical adhesive spray in endoscopic submucosal dissection (ESD).

**METHODS:** Patients who underwent ESD between January 2009 and June 2012 ( $n = 173$ ) were enrolled in the prospective randomized study. Two patients undergoing surgery due to severe intraoperative hemorrhage and failed hemostasis were excluded, and the remaining 171 patients were randomly divided into two groups: group A (medical adhesive group,  $n = 89$ ) and group B (control group,  $n = 82$ ). In group A, a medical adhesive spray was evenly applied after routine electrocoagulation and hemostasis using hemostatic clip after ESD. Patients in group B only treated with routine wound management. Intraoperative and postoperative data were collected and compared.

**RESULTS:** In all 171 patients, ESD was successfully

completed. There was no significant difference in the average treatment time between groups A and B (59.4 min vs 55.0 min, respectively). The average length of hospital stay was significantly different between group A and B (8.89 d vs 9.90 d, respectively). The incidence of intraoperative perforation was 10.1% in group A and 9.8% in group B, and was not significantly different between the two groups. In all cases, perforations were successfully managed endoscopically and with conservative treatment. The incidence of postoperative delayed bleeding in group A was significantly lower than that in group B (0.00% vs 4.88%, respectively).

**CONCLUSION:** ESD is an effective minimally invasive treatment for gastrointestinal precancerous lesions or early-stage gastrointestinal cancer. Medical adhesive spray is effective in preventing delayed bleeding after ESD, and can thus reduce the average length of hospital stay.

**Key words:** Endoscopic submucosal dissection; Medical adhesive; Early-stage gastrointestinal cancer; Postoperative delayed bleeding; Intraoperative hemorrhage

**Core tip:** This is the first report to use medical adhesive after endoscopic submucosal dissection (ESD), and results were exciting. Application of medical adhesive spray can prevent complications of ESD, especially the delayed bleeding, consequently reducing the average length of hospital stay, and avoiding additional health care expenditures.

Effects of medical adhesives in prevention of complications after endoscopic submucosal dissection. *World J Gastroenterol* 2013; 19(17): 2704-2708 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i17/2704.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i17.2704>

## INTRODUCTION

In endoscopic submucosal dissection (ESD), special instrument and other ancillary equipment are used to resect and strip gastrointestinal precancerous lesions and early-stage cancer on the basis of endoscopic mucosal resection (EMR). ESD has been widely performed in clinical practice due to its advantages of complete resection and reduced recurrence rates. However, compared to EMR, ESD is associated with a high incidence of complications such as perforation and bleeding, which has limited the utility of ESD. Currently, ESD is only performed at some institutions in China. Medical adhesives (spray type) have been widely used in surgery and for the treatment of gastric varices because of their adhesive, reinforcement, and leak proofing functions<sup>[1,2]</sup>. However, there has been no report of their use in gastrointestinal (GI) endoscopy. This study investigated the use of medical spray adhesives for the prevention of complications in patients undergoing ESD.

## MATERIALS AND METHODS

### Patients

Patients who underwent ESD at the department of digestive endoscopy of our hospital between January 2009 and June 2012 ( $n = 173$ ) were enrolled. Two patients undergoing surgery due to severe intraoperative hemorrhage and inability to achieve adequate hemostasis were excluded. The remaining 171 patients completed the ESD treatment and were included in the analysis. There were 75 males and 96 females with an average age of  $57.21 \pm 12.22$  years (range, 18-82 years). There were 37 cases of esophageal lesions, 110 cases of gastric lesions, and 24 cases of colorectal lesions diagnosed by routine preoperative endoscopy, endoscopic ultrasonography, and histopathological examination of biopsy specimens. There were 50 cases of mucosal or submucosal lesions (early-stage cancer or precancerous lesions) and 121 cases of muscularis propria lesions (stromal tumors). The pathological examination revealed 92 cases of leiomyoma, 61 cases of stromal tumor and 18 cases of early-stage cancer. The average size of lesions was  $4.42 \pm 1.28$  cm.

### Instruments and adhesives

An Olympus GIF-Q260J electronic gastroscope and CF-Q260 colonoscopy system were used. In addition, an NM-4L-1 injection needle, triangle-tip knife, FD-1U-1 hot biopsy forceps, snare, Poko hemostatic clip, HX-610-135 hemostatic clip, and ERBE ICC-200 high-frequency electric cutting device were also employed. The medical adhesive (Compont Medical Adhesive) is a spray-type adhesive and the primary ingredient is butyl  $\alpha$ -cyanoacrylate. During ESD, a transparent cap was added at the end of the lens and carbon dioxide insufflation was adopted.

### ESD

After conventional therapeutic steps, patients were ran-

domly divided into group A (medical adhesive group,  $n = 89$ ) and group B (control group,  $n = 82$ ) according to a computer-generated random number table. There was no significant difference in age, gender, or lesion type between the two groups (Table 1). Patients receiving anticoagulant drugs such as aspirin underwent ESD 5-7 d after drug withdrawal.

All patients underwent the following operations under intubation anesthesia or intravenous anesthesia: (1) Staining: During endoscopy, the lesions were identified and stained with methylene blue. After staining, the lesion boundary was obvious; (2) Marking: A needle knife or argon plasma coagulation (APC) was used to mark at the lesion edges; (3) Injection: An epinephrine/saline solution (1:10000) containing a small amount of methylene blue was injected submucosally at multiple places lateral to the marked points at the lesion edges; (4) Pre-cut: A needle knife was used to cut open the mucosa at the marked points at the lesion edges; (5) Cut: The TT knife was used to make a circular incision on the lesion edge along the marker; (6) Stripping: The TT knife was used to cut open the submucosa layer by layer, and the lesion was peeled off. For the muscularis propria lesions, the lesions were completely stripped from the nearby tissue after the lesion was exposed. In some cases, when the lesion was almost completely peeled off, the snare was used to trap the lesion root so that the lesion could be resected completely; and (7) Wound treatment: After resection of the lesion, small visible blood vessels were treated with argon plasma coagulation (APC) or hot biopsy forceps. The perforated wound surface was closed with metal hemostatic clips. In addition, medical adhesive was sprayed onto the wound surface *via* a spray catheter in group A patients.

Patients with severe intraoperative bleeding or perforation who were unable to undergo endoscopic treatment received surgical treatment. All the patients receiving ESD were maintained *non per os* (NPO) postoperatively and received a nasogastric tube and low flow suction. Antacids and necessary hemostatic drugs (Ethamsylate, PAMBA) were administered, together with the prophylactic antibiotics. Abdominal signs such as abdominal pain and distension were monitored closely. Endoscopy was repeated 1, 3, and 6 mo after surgery to examine wound healing, residual lesions, and recurrence.

The postoperative abdominal signs, recurrence, length of hospital stay, and incidence of complications including delayed bleeding, perforation and infection were compared between the two groups.

### Statistical analysis

Categorical data were analyzed using the  $\chi^2$  test, and quantitative data were analyzed using the *t* test. SPSS 10.0 statistical software was used for analysis and the significance level  $\alpha$  was set at 0.05.

## RESULTS

A total of 173 patients underwent ESD treatment. There

<sup>1</sup>Data are expressed as mean ± SD. NS: Not significant.

were two patients with muscularis propria lesions with a diameter of 4 or 5 cm, respectively, protruding toward the abdominal cavity. During ESD, the bleeding was difficult to control and these two patients received surgical treatment. The lesions were completely stripped off in the remaining 171 patients. Patient clinical data are shown in Table 1.

The average duration of ESD (from submucosal injection to complete stripping of lesions) was 59.44 min (range, 36-150 min) in group A and 55.00 min (range, 35-140 min) in group B and the difference was not statistically significant. The average length of hospital stay was 8.89 d (range, 6-15 d) in group A and 9.90 d (range, 5-21 d) in group B and the difference was statistically significant. In group B, four patients experienced delayed bleeding and were hospitalized for 19, 19, 20, and 21 d, respectively. Excluding those patients, the average length of hospital stay in group B was 9.40 d (ranged, 5-15 d), which was not significantly different compared with group A (Table 2).

All the 171 patients treated with ESD, with the exception of two patients who were lost to follow-up after treatment, underwent repeat endoscopy 1, 3, 6, and 12 mo after treatment. To date, no recurrence has been noted.

During ESD, bleeding (< 40 mL) occurred in all patients, and hemostasis was successful after electrocoagulation, APC, and application of the hemostatic clip. No delayed bleeding occurred in group A (0.00%, 0/89), whereas delayed bleeding occurred in four patients in group B (4.88%, 4/82), which was significantly different from that in group A. In group B, one patient with an esophageal lesion, two patients with gastric lesions, and one patient with colon lesions experienced bleeding 3, 5, 10 and 7 d after surgery. One patient had symptoms of shock including progressive drop in blood pressure and cold sweats, and the vital signs became stable after transfusion and active medical treatment. Gastric endoscopy and colonoscopy revealed active bleeding at the location of the ESD. After norepinephrine saline flush, APC, ap-

|   | Group A<br>(medical<br>adhesive group) | Group B<br>(control<br>group) | P value |
|---|--|-------------------------------|---------|
| Average duration of ESD treatment (min)   | 59.44 ± 18.46                          | 55.00 ± 21.00                 | 0.143   |
| Average length of hospital stay (d)   | 8.89 ± 2.33                            | 9.90 ± 3.30                   | 0.021   |
| Average length of hospital stay when patients with delayed bleeding were excluded (d) | 8.89 ± 2.33                            | 9.40 ± 2.47                   | 0.172   |

Data are expressed as mean ± SD. ESD: Endoscopic submucosal dissection.

plication of hemostatic clips, and the endoscopic application of medical spray adhesive, hemostasis was successful. No patients underwent surgical intervention for the control of bleeding.

Perforation occurred in nine of 89 (10.1%) patients in group A. Of these patients, one had an esophageal lesion, seven had gastric lesions, and one patient had colon lesions. Perforation occurred in 8 (9.8%) of 82 patients in group B. Of these patients, two had esophageal lesions and six had gastric lesions. The incidence of perforation was not significantly different between the two groups. Among the nine patients who experienced perforation in group A, seven patients had muscularis propria lesions, one patient had ulcer scars, and the remaining patient had non-ulcer scar lesions. All of the eight patients who experienced perforation in group B had muscularis propria lesions, and none had ulcer scar formation or non-ulcer scar lesions. The diameter of perforation ranged from 0.2 to 2.0 cm, and the wound surface was clipped using hemostatic clips in all the cases. Abdominal paracentesis was performed to release gas in patients with obvious abdominal distension. All perforations resolved after fasting, placement of an indwelling nasogastric tube and gastrointestinal decompression in patients who received gastric procedures, absolute bed rest, and treatment with antibiotics. No patient underwent surgical treatment.

After ESD, 12 patients in group A and 10 patients in group B experienced varying degrees of abdominal distension and abdominal pain, and the incidence was 13.5% and 12.2%, respectively (*P* > 0.05). Eight of the 12 patients with abdominal distension and abdominal pain in group A experienced intraoperative perforation, and the remaining four patients had no intraoperative perforation. Six of the 10 patients with abdominal distension and abdominal pain in group B experienced intraoperative perforation, and the remaining four patients did not. The symptoms resolved in all patients within 1-3 d after conservative treatment including gastrointestinal decompression, fasting, antacids, and antibiotics. Anal pain during defecation occurred in two patients (2.25%) in group A 8-10 d after treatment, which was followed by the discharge of solid medical adhesive. A summary of complications is presented in Table 3.

Table 3 Complications

## DISCUSSION

ESD is a technique that uses special instruments and other equipment to resect and strip gastrointestinal precancerous lesions and early-stage tumors on the basis of EMR. ESD can be used for the one-time complete resection of lesions with a diameter greater than 2 cm, and the high *en bloc* resection rate can reduce residual lesions and the chances of recurrence, thus achieving a radical cure<sup>[3-6]</sup>. The indications for ESD are still controversial; however, some scholars believe that as long as there is no lymphatic and blood vessel invasion or metastasis, the lesion can be resected using ESD regardless of lesion location and size<sup>[7]</sup>. With improvement in the management of endoscopic complications, the depth of lesions treated with ESD has gradually increased and ESD has been used to treat some muscularis propria lesions and stromal tumors. Some authors have even proposed a concept of ESE<sup>[8,9]</sup>. However, the incidence of major complications with ESD, including bleeding and perforation, is still relatively high which has limited the generalization of ESD to a larger extent.

The main ingredient of the medical adhesive used in this study is butyl  $\alpha$ -cyanoacrylate. As an adhesive with special biomedical function, it has biomedical functions in addition to the common gluing function and mechanical function. It has been confirmed that butyl  $\alpha$ -cyanoacrylate is non-toxic to the human body and not mutagenic, teratogenic, or carcinogenic, and will not cause an irritant reaction. Medical adhesives are widely used in surgery, and can rapidly solidify in the presence of anionic substances such as tissue fluid and blood. The adhesive used has a similar strength as tissues, and therefore is not likely to fall off during extension and flexion movement. The adhesive strength is greater than the physiological strength of human body; therefore, its tissue adhesive function is reliable<sup>[1,2]</sup>.

Manner *et al*<sup>[10]</sup> reported an incidence of delayed bleeding after ESD of 6.5%, and Sugimoto *et al*<sup>[11]</sup> in a

multi-center study reported an incidence of 3.7%. In our study, the incidence of delayed bleeding in the control group was 4.88%, similar to that previously reported. However, no delayed bleeding occurred in the medical adhesive group, and this was significantly different from the incidence in the control group.

Ono *et al*<sup>[12]</sup> reported a perforation rate of 5% among 906 patients who were treated with ESD. Sugimoto *et al*<sup>[11]</sup> reported a perforation rate of 10.3% in patients with scar lesions and 3.5% in patients without scar lesions. In our study, the perforation rates in groups A and B were 10.1% and 9.8%, and the difference was not statistically different. The incidence of perforation in our study was slightly higher than that in the report by Ono *et al*<sup>[12]</sup>, but it was similar to the incidence of perforation in patients with scar lesions in the study by Sugimoto *et al*<sup>[11]</sup>. We analyzed the depth of the perforated lesions, and found that among the 17 cases of perforation in the two groups, there were 15 cases of muscularis propria lesions, one case of scar formation, and one case of a non-scar forming lesion. Therefore, the relatively high incidence of perforation in our study was due to relatively deep lesions. Generally, perforation was managed successfully with conservative treatment including fasting and antibiotics<sup>[13]</sup>.

As for other complications of ESD, 12 patients in group A (medical adhesive group) and 10 patients in group B (control group) experienced varying degrees of abdominal distension, and the incidence was 13.5% (12/89) and 12.2% (10/82), respectively, and was not different between the groups. Anal pain during defecation occurred in two patients in group A 8-10 d after treatment, which was followed by discharge of solid medical adhesive. Medical adhesive was not used in group B, so no difficulty in excreting the medical adhesive occurred.

The average duration of ESD in group A was 59.44 min (range, 36-150 min) and in group B was 55.00 min (range, 35-140 min) and the times were not statistically different. However, the average treatment time in group A was slightly more than that in group B, and we believe this is because of the extra time needed to apply the medical adhesive. Our results are consistent with a treatment time of 35-180 min reported by Sano *et al*<sup>[4]</sup>. With improvement of techniques and accumulation of experience, the operation time will be gradually shortened, while treating larger and deeper lesions may increase the operation time.

The average length of hospital stay was 8.89 d (range, 6-15 d) in group A and 9.90 d (range, 5-21 d) in group B, and the differences were statistically significant. In group B, four patients experienced delayed bleeding and were hospitalized for 19, 19, 20 and 21 d, respectively. Excluding those patients, the average length of hospital stay in group B was 9.40 d (ranged, 5-15 d), and this was not significantly different compared with group A, indicating that delayed bleeding may significantly increase the length of hospital stay.

In summary, application of spray-type medical adhe-

sive may cause difficulty in excreting the medical adhesive in a few patients, but it does not affect the overall therapeutic effects and prognosis. Use of a spray-type medical adhesive can prevent complications of ESD, especially delayed bleeding. Application of a spray-type medical adhesive can reduce the average length of hospital stay, thereby avoiding additional health care expenditures.

## COMMENTS

### Background

Endoscopic submucosal dissection (ESD) is an effective minimally invasive treatment for gastrointestinal precancerous lesions or early-stage gastrointestinal cancer. Medical adhesive spray can be effective in preventing delayed bleeding after ESD, and can thus reduce the average length of hospital stay.

### Research frontiers

ESD is associated with a high incidence of complications such as perforation and bleeding, which has limited the utility of ESD. Medical adhesives (spray type) have been widely adopted in surgery and for the treatment of gastric varices because of their adhesive, reinforcement, and leak proofing functions.

### Innovations and breakthroughs

This is the first report to use medical adhesive after ESD, and results were exciting. Use of a spray-type medical adhesive can prevent complications of ESD, especially delayed bleeding. Application of a spray-type medical adhesive can reduce the average length of hospital stay, thereby avoiding additional health care expenditures.

### Applications

Medical adhesive spray can be effective in preventing delayed bleeding after ESD, and can thus reduce the average length of hospital stay.

### Terminology

ESD is an effective minimally invasive treatment for gastrointestinal precancerous lesions or early-stage gastrointestinal cancer.

### Peer review

This is a good prospective randomized study in which authors analyzed the effect of medical adhesive spray in preventing delayed bleeding after ESD. The results are interesting and suggest that the use of medical adhesive spray may be a useful therapeutic approach in the prevention of delayed bleeding after ESD.

### Abstract

**AIM:** To evaluate the association between *HLA-DRB1* alleles and Han and Uyghur ulcerative colitis (UC) patients residing in the Xinjiang Uyghur Autonomous Region of China.

**METHODS:** In this study, 102 UC patients (53 Han including 22 men and 31 women, and 49 Uyghur patients including 25 men and 24 women; aged  $48.07 \pm 15.83$  years) and 310 age- and sex-matched healthy controls were enrolled in the Department of Gastroenterology, Xinjiang People's Hospital of China from January 2010 to May 2011. UC was diagnosed based on the clinical, endoscopic and histological findings following Lennard-Jones criteria. Blood samples were collected and genomic DNA was extracted by routine laboratory methods, and both polymerase chain reaction and gene sequencing were used to identify *HLA-DRB1* allele variants. The potential association between genetic varia-

tion and UC in Han and Uyghur patients was examined. There were no statistical differences in *HLA-DRB1* allele frequencies in Han UC patients.

**RESULTS:** There was no significant difference in the sex ratio between the controls and UC patients ( $P = 0.740$ ). In Han patients with UC ( $n = 53$ ), *HLA-DRB1*\*03, \*13 allele frequencies were lower than in healthy controls ( $n = 161$ ), but not statistically significant, and *HLA-DRB1*\*04\*11\*14 allele frequencies were higher than in healthy controls, but without statistical significance. Differences between Uyghur UC patients and the control group were observed for *HLA-DRB1*\*04 and *HLA-DRB1*\*13, both showed a greater frequency in UC patients (10.21% vs 2.69%,  $P = 0.043$ ; 14.29% vs 4.03%,  $P = 0.019$ ). *HLA-DRB1*\*14 also showed a greater frequency in UC patients (14.29% vs 2.69%,  $P = 0.006$ ). The frequencies of *DRB1*\*04, \*13\*14 alleles were increased in Uyghur UC patients compared with normal controls. The frequency of *DRB1*\*08 was decreased in Uyghur UC patients compared with normal controls. *HLA-DRB1* alleles showed no association with UC in Han patients. There were no statistical differences in *HLA-DRB1* allele frequencies in Han UC patients. The frequencies of *DRB1*\*04, \*13\*14 alleles were increased in Uyghur UC patients compared with normal controls. The frequency of *DRB1*\*08 was decreased in Uyghur UC patients compared with normal controls. Polymorphism of the *HLA-DRB1* gene may contribute to the clinical heterogeneity of UC between Han and Uyghur UC patients in China.

**CONCLUSION:** *HLA-DRB1*\*04\*13\*14 and *DRB1*\*08 may contribute to the clinical heterogeneity of UC between Han and Uyghur UC patients.

**Key words:** Ulcerative colitis; *DRB1*\* gene polymorphisms; Han and Uyghur

**Core tip:** This study evaluated the association between

*HLA-DRB1* alleles and Han and Uyghur ulcerative colitis (UC) patients residing in the Xinjiang Uyghur Autonomous Region of China. The authors found that polymorphism of the *HLA-DRB1*\* gene differed between the Han and Uyghur patients with UC. Polymorphism of the *HLA-DRB1* gene may contribute to the clinical heterogeneity of UC between Han and Uyghur UC patients in North-West China.

## INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease are often grouped together as inflammatory bowel disease (IBD). IBD is the term used to describe idiopathic disorders associated with chronic inflammation of the gastrointestinal tract<sup>[1,2]</sup>. Clinical features common to both disorders include abdominal pain, diarrhea, weight loss, and increased risk of developing colorectal cancer<sup>[3,4]</sup>. The etiology of UC is still not known. However, underlying genetic, environmental, and lifestyle issues can affect an individual's predisposition to these diseases<sup>[5,6]</sup>. Genetic factors involved in the regulation of the immune system are thought to play a significant role in the pathogenesis of UC<sup>[7]</sup>. Human leukocyte antigens (HLA), located on chromosome 6, play an important role in the immune response and several immune-mediated diseases. Several studies have shown that HLA alleles are associated with UC<sup>[8]</sup>. We previously compared the clinical characteristics of UC in the Han and Uyghur populations residing in the Xinjiang Uyghur Autonomous Region of China. We showed some differences between the Uyghur and Han populations living in the same region, which included a higher prevalence of UC, a younger age of onset, an increased prevalence of the chronic persistent and acute outbreak type, more moderate and severe forms, a higher complication rate, and an increased frequency of positive antineutrophilic cytoplasmic antibodies (ANCA) in the Uyghur population<sup>[9]</sup>. However, to date, hardly a research shows that there is association between *HLA-DRB1* alleles and UC in the Uyghur population. It would be interesting to know what causes the clinical heterogeneity of UC between Han and Uyghur UC patients in China.

## MATERIALS AND METHODS

### Patients and controls

Consecutive patients with UC were recruited from the Department of Gastroenterology, Xinjiang People's Hospital of China. The diagnosis of UC was made based on clinical, endoscopic, and histological findings in accordance with Lennard-Jones criteria<sup>[10]</sup>. The extent of

**Table 1** The 5' amplification primer mix included the following primers

| 5'-TCGTTCTGTGGCAGGGTAAGTATA-3'    |
| 5'-AGCCGTTTCTGAAGCAGGATAAGTT-3'   |
| 5'-CCAAGCACGTTTCTTGGAGGAGG-3'     |
| 5'-TCGTTCTGTGGCAGCTAAGA-3'        |
| 5'-AGCCGTTTCTTGGAGCAGGTTAAAC-3'   |

disease was assessed by colonoscopy at initial diagnosis and at follow-up. Extensive colitis was defined as lesions located beyond the splenic flexure. Distal colitis was defined as lesions limited to the region distal to the splenic flexure<sup>[11,12]</sup>. Age- and sex-matched healthy controls were also recruited from the Health Examination Center of Xinjiang People's Hospital. The study protocol was approved by the Ethics Committee of Xinjiang Uyghur Autonomous Region of China, and individuals selected from the populations sampled were Chinese and Uyghur UC patients from Urumqi, Xinjiang. Informed consent was obtained from all patients.

Genomic DNA was isolated using a QIAamp DNA Blood Mini Kit according to the manufacturer's instructions (Qiagen, Germany). DNA samples were quantified by *ultraviolet* measurements at  $A_{260}$ .

### Polymerase chain reaction amplification

Polymerase chain reaction (PCR) amplifications were performed in a volume of 20  $\mu$ L consisting of 20 ng of genomic DNA, PCR buffer (1.5 mmol/L MgCl<sub>2</sub>, 10 mmol/L Tris-HCl pH 8.4, 50 mmol/L KCl, 0.1 mg/mL of Gelatin, 0.02% of NP-40), 200 mmol/L of each dNTP (Life Technologies, Rockville, MD, United States) and 1 unit of Taq Platinum polymerase (Life Technologies, Grand Island, NY, United States). Seven sense primers and 1 antisense primer were used to amplify *HLA-DRB1* alleles (Table 1).

The 3' amplification primer was 5'-CTGTTACCTC-GCCACTGCAC-3'. PCR amplification was performed in an ABI 9700. The DNA was amplified following initial denaturation at 95 °C for 120 s followed by 35 cycles at 95 °C for 30 s, 60 °C for 30 s and 72 °C for 60 s. PCR amplification was confirmed following electrophoresis on a 2.0% agarose gel. Samples were electrophoresed at 10 V/cm for 36 min. PCR products were purified using the High Pure PCR Purification Kit (Roche Diagnostics, Basel, Switzerland).

### DNA sequencing and analysis

PCR products were sequenced using BigDye Terminator v3.1 kits (ABI, United States) and automated ABI 3730XL DNA sequencers. The 5' sequence primer was 5'-TTGCAATTCTTCAATGGGAC-3' and the 3' primer was 5'-ACCACCCGGTAGTTGTGTC-3'. The DNA was sequenced following initial denaturation at 95 °C for 120 s followed by 25 cycles at 95 °C for 10 s, 50 °C for 5 s and 60 °C for 60 s. The sequence within the 5' primer sites was included in the analysis to prevent the mistyping of

<sup>1</sup>Data are expressed as mean ± SD. UC: Ulcerative colitis.

novel alleles that may have arisen due to recombination within the first variable region. DRB1 genotyping was assigned using Qiagen SBTengine HLA Typing software that compares an unknown sequence against a library of allele sequences (Figure 1).

**Statistical analysis**

Hardy-Weinberg disequilibrium was assessed with  $\chi^2$  tests and clinical records including age were analyzed with *t* tests.  $\chi^2$  tests were used to compare genotype and allele frequencies between patients and normal controls. Fisher exact tests with 95%CI were used when the number of samples was less than 5. *P* values less than 0.05 were con-

sidered statistically significant.

**RESULTS**

**Clinical characteristics of UC patients**

DNA was obtained from 102 consecutive UC patients and 310 healthy individuals well matched for sex and age. The main clinical characteristics of the UC patients are summarized in Table 2. UC patients included 47 males and 55 females and the controls included 137 males and 173 females. The average age of UC patients and controls was 48.07 ± 15.83 years and 47.37 ± 14.49 years, respectively. There was no significant difference in the sex ratio between the controls and UC patients (*P* = 0.740, Table 2).

**Comparison of DRB1\*genotype variants between UC patients and healthy controls in the Han population**

The HLA-DRB1 allele frequencies in the patients and controls are shown in Table 3. In Han patients with UC (*n* = 53), HLA-DRB1\*03, \*13 allele frequencies were lower than in healthy controls (*n* = 161), but not statistically significant (*P* > 0.05), and HLA-DRB1\*04\*11\*14 allele frequencies were higher than in the healthy controls, but without statistical significance (*P* > 0.05) (Figure 2).

**Comparison of DRB1\*genotype variants between the UC patients and healthy controls in the Uyghur population**

Differences between Uyghur UC patients and the control group were observed for HLA-DRB1\*04 and HLA-

UC: Ulcerative colitis.

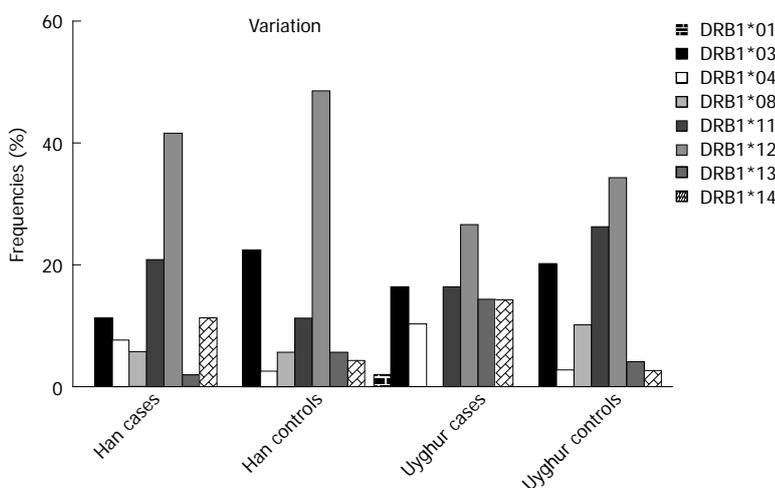

Figure 2 Comparison of the *DRB1*\* genotype variants between ulcerative.

*DRB1*\*13, both showed a greater frequency in UC patients (10.21% vs 2.69%,  $P = 0.043$ ; 14.29% vs 4.03%,  $P = 0.019$ ). *HLA-DRB1*\*14 also showed a greater frequency in UC patients (14.29% vs 2.69%,  $P = 0.006$ ), however, *HLA-DRB1*\*08 showed a lower frequency in UC patients than in the controls (0% vs 10.07%,  $P = 0.024$ ), Table 3.

## DISCUSSION

UC was previously uncommon in China, however, in the last 10 years more cases have been identified and the incidence of this disease has increased<sup>[13]</sup>. The clinical characteristics of UC in the Han and Uyghur populations residing in the Xinjiang Uyghur Autonomous Region of China were shown to be different<sup>[14]</sup>. The genetic factors possibly associated with UC and its clinical characteristics in these two ethnic groups are unknown. A number of *HLA* alleles have been shown to be associated with variations in immune response diseases (e.g., celiac disease<sup>[15]</sup>, longitudinally extensive transverse myelitis<sup>[16]</sup>, and Behçet's disease<sup>[17]</sup>). Several genome-wide scans have shown that the susceptibility locus of UC and Crohn's disease is on chromosome 16q (IBD1)<sup>[18]</sup>. In the present study, we evaluated the association between the *HLA-DRB1* alleles and UC in Han and Uyghur populations from north-west China. We did

not find any association between *HLA-DRB1* alleles and UC in the Han population, and these results were consistent with previous Chinese studies. Lü *et al*<sup>[19]</sup> showed that polymorphism of the *HLA-DRB1* gene did not have a strong association with UC in Chinese patients. Lee *et al*<sup>[20]</sup> found that *HLA-DQA1c*, but not *HLA-DRB1* alleles, was associated with ANCA-positive UC in southern China.

We found differences between Uyghur UC patients and healthy controls, in whom *HLA-DRB1*\*04, *HLA-DRB1*\*13 and *HLA-DRB1*\*14 showed a greater frequency in UC patients than in controls. These results were consistent with previous Japanese studies<sup>[21]</sup>. In contrast to previous Chinese studies *HLA-DRB1*\*08 showed a lower frequency in UC patients than in controls<sup>[22]</sup>. Polymorphism of the *HLA-DRB1* gene may contribute to the clinical heterogeneity of UC between Han and Uyghur UC patients in China. The results in the present study were different probably due to the statistical methods used and the genetic heterogeneity of the ethnic populations. In future studies, we will continue to explore other *HLA* genes and amplify our sample size to identify the genes associated with UC in different ethnic groups in China and to provide more evidence for the genetic susceptibility of UC.

## COMMENTS

**Background**

Previous studies have shown that human leukocyte antigens (HLA) alleles are associated with ulcerative colitis (UC). The clinical characteristics of UC in the Han and Uyghur populations residing in the Xinjiang Uyghur Autonomous Region of China were shown to be different. In this study, the authors examined whether polymorphism of the *HLA-DRB1\** gene differed between Han and Uyghur patients with UC.

**Research frontiers**

Studies have found that disease distribution and phenotypic appearance differ significantly between ethnic groups and even within populations. The genetic and clinical heterogeneity of UC between the two ethnic groups, Chinese Han and Uyghur, were investigated.

**Innovations and breakthroughs**

This study found that polymorphism of the *HLA-DRB1\** gene differed between Han and Uyghur patients with UC. Polymorphism of the *HLA-DRB1* gene may contribute to the clinical heterogeneity of UC between Han and Uyghur UC patients in north-west China.

**Applications**

The effects of different genotypes in normal controls and patients with UC are still unknown and likely represent a potentially productive area for future research to better understand the pathogenesis and treatment of UC.

**Terminology**

UC is a form of *inflammatory bowel disease*. It is a refractory, chronic, and non-specific disease which usually occurs in the rectum and the entire colon. HLA, located on chromosome 6, play an important role in the immune response and several immune-mediated diseases.

**Peer review**

The authors investigated the contribution of *DRB1\** gene polymorphism to the genetic susceptibility and clinical heterogeneity of UC between Han and Uyghur patients. This manuscript contains potentially interesting findings.

### Abstract

We report a case of life-threatening hematemesis due to portal hypertension caused by an isolated arterioportal fistula (APF). Intrahepatic APFs are extremely rare and are a cause of presinusoidal portal hypertension. Etiologies for APFs are comprised of precipitating trauma, malignancy, and hereditary hemorrhagic telangiectasia, but these were not the case in our patient. Idiopathic APFs are usually due to congenital vascular abnormalities and thus usually present in the pediatric

setting. This is one of the first cases of adult-onset isolated APF who presented with portal hypertension and was successfully managed through endoscopic hemostasis and subsequent interventional radiological embolization.

Isolated arterioportal fistula presenting with variceal hemorrhage. *World J Gastroenterol* 2013; 19(17): 2714-2717 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i17/2714.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i17.2714>

### INTRODUCTION

Portal hypertension is defined as the increase in porto-systemic resistance and/or flow<sup>[1]</sup>. The causes of portal hypertension can be divided into pre-, intra-, and posthepatic causes. Moreover, intrahepatic portal hypertension can be further categorized into three groups: pre-, intra-, and postsinusoidal causes. The most common etiology of portal hypertension is due to liver cirrhosis which accounts for 90% of the cases in the United States<sup>[2]</sup>. It is a cause of intrasinusoidal portal hypertension due to distortion of the hepatic lobular architecture and results in hyperdynamic splanchnic circulation. The second major cause of portal hypertension is due to extrahepatic portal vein thrombosis, accounting for 7% of cases. The remaining 3% of causes of portal hypertension encompasses a variety of rare etiologies, including our case of intrahepatic presinusoidal portal hypertension<sup>[2]</sup>. While infrequent, the causes for presinusoidal portal hypertension comprise of schistosomiasis, myeloproliferative diseases, sarcoidosis, hepatic portal fibrosis, primary biliary cirrho-

sis, arsenic toxicity, idiopathic portal hypertension<sup>[3]</sup>.

## CASE REPORT

The patient is a 30 year old male who presented to Los Angeles County-University of Southern California Medical Center with a two day history of hematemesis. The physical examination on arrival showed vital signs of a blood pressure of 93/61 mmHg, a heart rate of 135 beats per minute with exam findings significant for splenomegaly and left femoral artery bruit, but otherwise negative for shifting dullness, spider angiomas, palmar erythema, asterix, and jaundice. Pertinent laboratory values were as follows: alkaline phosphatase 175 units/L, total protein 6.3 g/dL, albumin 3.9 g/dL, total bilirubin 0.6 mg/dL, aspartate aminotransferase 39 units/L, alanine transaminase 72 units/L, prothrombin 14.5 s, INR 1.16, hemoglobin 13.5 g/dL, white blood cells 8.0 k/cumm, and a platelet count of  $79 \times 10^3$ /cumm. Further testing was done and showed all viral hepatitis, autoimmune, and metabolic liver disease markers to be negative. No history of alcohol intake and no history of prescribed, over the counter or supplement medications. His family history was negative for liver disease.

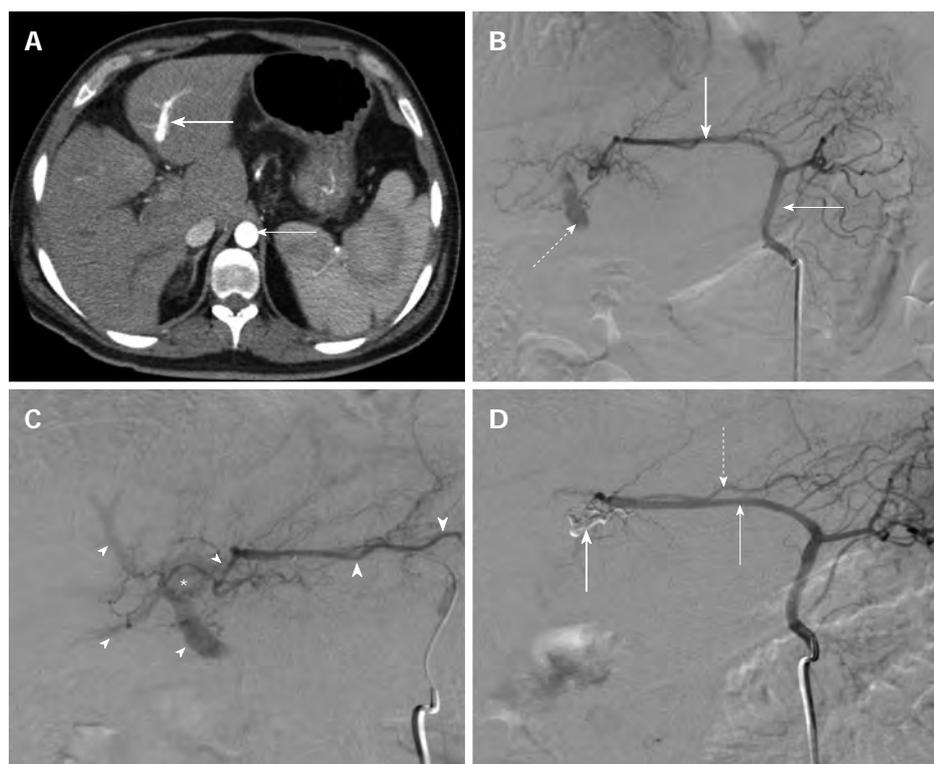

Upon presentation, the patient underwent an emergent esophagogastroduodenoscopy, which showed four columns of esophageal varices with active bleeding. Band ligation of the varices was performed successfully. Subsequent abdominal ultrasound demonstrated splenomegaly (length 14.8 cm) but a normal size, smooth liver surface and homogeneous liver parenchyma, suggesting a non-cirrhotic etiology for the portal hypertension. A multi-phase computed tomography (CT) examination of the liver demonstrated the left portal vein was highlighted at the arterial phase, strongly suggesting the existence of a hepatic arteriportal communication (Figure 1A). Based upon this finding, it was speculated that the overflowing of the portal vein due to the shunt between the hepatic artery to the portal vein was causing presinusoidal portal hypertension. In order to further confirm this, a hepatic venous pressure gradient (HVPG) measurement was performed and indicated normal value; 2 mmHg (< 5 mmHg is normal). Along with the signatures of portal hypertension-variceal bleeding and splenomegaly-the normal HVPG was consistent with pre-sinusoidal portal hypertension. To further confirm this, an angiogram was performed. A brisk contrast opacification of the left portal vein was noted upon contrast injection into the left hepatic artery, which branched from left gastric artery, confirming arteriportal shunting (Figure 1B). The shunting was determined not to be direct, but passing through a network of small capillary-like “fuzz” prior to brisk drainage into the portal system (Figure 1C). Furthermore, angiography showed the right superficial femoral artery with pseudoaneurysm and fistula and this additional vascular abnormality support our diagnosis of arteriportal fistulas (APFs) of congenital etiology. Taken all together, it was concluded that the arteriportal fistula is the cause

of this patient’s non-cirrhotic portal hypertension. The arteriportal and femoral artery fistulas were also closed with catheter directed embolization utilizing the liquid embolic agent Onyx<sup>®</sup> (ev3 Endovascular Inc., Plymouth, MN, United States). Following the embolization, no further early portal vein enhancement was seen during left hepatic arteriogram (Figure 1D). Finally, a liver biopsy was performed showing focal portal venule dilatation with dilated outflow vessels, but was otherwise normal, compatible with the clinical diagnosis of presinusoidal portal hypertension secondary to the hepatic artery and portal vein shunt (Figure 2). Post-embolization recovery of the patient has been uneventful, and no additional episodes of upper gastrointestinal bleeding have been reported by the patient on two subsequent clinic visits during the last four months.

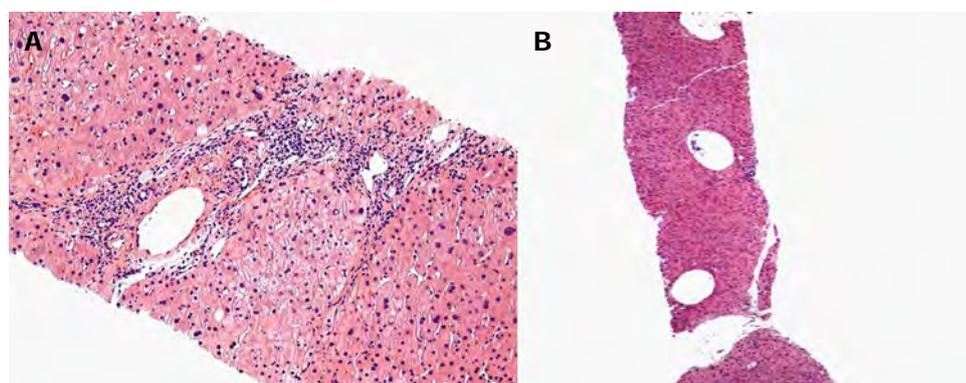

## DISCUSSION

HVPG measurements often provide valuable information in identification of the site or cause of the portal hypertension<sup>[4]</sup>. The HVPG is the difference between the wedged and free hepatic venous pressures, which has been shown to correlate well with actual portal vein pressure<sup>[5]</sup>. Its increase is consistent with sinusoidal portal hypertension and is known to be a predictor of development of varices and ascites<sup>[6]</sup>. Upon visualization of the hepatic artery and portal vein communication through CT, the measurement of HVPG was conducted. The classic pattern of the prehepatic or intrahepatic presinusoidal portal hypertension shows normal HVPG and free hepatic vein pressure (FHVP) along with the stigmata of portal hypertension. The pathophysiology consists of a presinusoidal block preventing the transmission of the elevated portal pressure to the sinusoid, thus resulting in a normal wedged hepatic vein pressure<sup>[5]</sup>. In our case, the HVPG value was consistent to the pathophysiology of presinusoidal portal hypertension.

Most of the literature regarding APFs is focused on the following etiologies: precipitating trauma, hepatocellular carcinoma (HCC), congenital, and in the context of hereditary hemorrhagic telangiectasia (HHT)<sup>[7]</sup>. Clinical presentation of APFs varies from asymptomatic to symptoms related to congestive heart failure (40%-60%), portal hypertension (20%-40%), and diarrhea with abdominal pain secondary to a “steal” phenomenon (20%)<sup>[8]</sup>. Hepatic trauma is a common cause for APFs. It may be from penetrating trauma such as gunshot wounds, a complication of liver transplantation or from previous liver biopsies<sup>[9,10]</sup>. HCC can cause APFs and two studies have shown that APFs may occur in up to 60% of patients with HCC<sup>[10,11]</sup>. Congenital APFs are associated with portal hypertension, failure to thrive, and gastrointestinal hemorrhage in infancy or early childhood<sup>[7,12]</sup>. In general, it is noted that less than 10% of all APFs are congenital<sup>[13]</sup>. As for HHT, hepatic involvement has been reported in 8%-78% of cases in retrospective and prospective studies<sup>[14]</sup>. Our patient did not have the any his-

**Figure 1** Intrahepatic communication between hepatic artery and portal vein. A: Contrast enhanced axial computed tomography of the abdomen demonstrating similar contrast opacification of the aorta (thin arrow) and the left portal vein (thick arrow); B: Left gastric arteriogram demonstrates gastrohepatic trunk (thin arrow) giving rise to aberrant left hepatic artery (thick arrow). Note early opacification of the portal vein (dashed arrow); C: Selective arteriogram with coaxial microcatheter in the left hepatic artery demonstrates medial branch of the left hepatic artery (large arrowheads) contributing to a parenchymal blush (star) and leading to opacification of the portal veins (small arrowheads). Note the normal appearance of the lateral branch of the left hepatic artery (thick arrow); D: Post-embolization arteriogram in the gastrohepatic trunk demonstrates opacification of the left hepatic artery (thin arrow). Onyx cast (thick arrow) is seen occupying the previously seen medial branch of the left hepatic artery. No further opacification of the portal veins is seen. Note the preserved lateral branch of the left hepatic artery (dashed arrow).

**Figure 2** The hepatic histology of arterioportal fistula. A: This low power image shows a small portal tract in the center of the field that has a markedly dilated portal venule. The terminal hepatic (central) venules above and below the portal tract are markedly dilated; B: The portal venule is slightly dilated and there are increased numbers of small portal venous radicals.

tory suggestive of congenital APF or signatures of HHT. Furthermore, he had no abdominal trauma or surgery, malignancy and no previous liver biopsies. Moreover the incidental finding of the femoral arteriovenous fistula and unique variation of hepatic artery further imply the congenital etiology. Therefore, we believe that this is a case of adult onset congenital APF that likely did not present in infancy or childhood because his fistula is through a capillary connection and probably took multiple decades

to develop clinical manifestation. Based our intensive literature search, this is one of the first cases reported to be adult onset portal hypertension due to congenital APFs.

Treatment of the APFs through shunt reduction is either surgical or minimally invasive though interventional radiology (IR) techniques. In the past, surgical ligation of the supplying artery was performed, however with the advancement of interventional radiology techniques, the trend has now shifted to endovascular catheter directed

therapy<sup>[15]</sup>. IR directed therapy offers many advantages over the conventional surgical treatment and is now the preferred technique for treatment. These advantages include decreased morbidity and mortality, reduced risk of subsequent complications, and significant reduction in the time required for recovery. IR directed therapy is accomplished through hepatic artery embolization (HAE)<sup>[16]</sup>. Embolization is usually performed with metal coils, detachable balloons, or gelfoam<sup>[17,18]</sup>. However at selected centers such as ours, liquid embolic agents are also utilized. Types of liquid embolic agents include ethylene vinyl alcohol (Onyx<sup>®</sup>) and *N*-butyl cyanoacrylate, both of which are predominantly used in congenital APFs per the literature<sup>[17,18]</sup>. HAE complications do occur, and include non-target embolization, hepatic infarction, and ischemic cholangitis. In a series of 15 patients studied by Chavan *et al*<sup>[19]</sup> ischemic cholangitis and/or cholecystitis occurred in three patients and one patient died of hepatic necrosis leading to multi-organ failure. Nevertheless, due to the dual blood supply of the liver (hepatic artery and portal vein), infarctions are rare<sup>[16]</sup>. In our limited experience with IR therapy of hepatic APFs, no such complications have occurred.

In summary, we described a case of lethal variceal bleeding due to an adult onset congenital APF. The patient was successfully treated through radiological interventional therapy and is being monitored regularly in our outpatient clinic without any further episodes of bleeding.

### Abstract

Ulcerative colitis (UC) is a chronic inflammatory bowel disease that may become intractable when treated with conventional medications such as aminosalicylates, corticosteroids, and azathioprine. The herbal medicine Qing Dai has traditionally been used in Chinese medicine to treat UC patients, but there is a lack of published data on the efficacy of Qing Dai in UC treatment. We report several cases of patients with intractable UC who take Qing Dai in a retrospective observational study. Furthermore, we explore the mechanisms of action of Qing Dai. Nine patients with active UC who received conventional medications but wished to receive Qing Dai as an alternative medication were included in our analysis. The UC severity level was determined based on the clinical activity index (CAI). Additionally, 5 of the 9 patients were endoscopically evaluated according to the Matts grading system. Each patient received

2 g/d of Qing Dai orally and continued taking other medications for UC as prescribed. Electron spin resonance was applied to explore the mechanisms of action of Qing Dai. After 4 mo of treatment with Qing Dai, the CAI score decreased from  $8.3 \pm 2.4$  to  $2.4 \pm 3.4$  (mean  $\pm$  SD;  $P < 0.001$ ). Similarly, the endoscopic Matts grade decreased from  $3.4 \pm 0.5$  to  $2.2 \pm 0.8$  ( $P = 0.02$ ). Six of 7 patients who were on prednisolone upon enrollment in the study were able to discontinue this corticosteroid. Electron spin resonance revealed that Qing Dai possesses strong hydroxyl radical scavenging activity. Qing Dai showed significant clinical and endoscopic efficacy in patients who failed to respond to conventional medications. Scavenging of hydroxyl radicals appears to be a potential mechanism through which Qing Dai acts, but the significance of the scavenging ability of Qing Dai with respect to the anti-inflammatory effect in UC patients warrants further investigation.

Therapeutic efficacy of the Qing Dai in patients with intractable ulcerative colitis. *World J Gastroenterol* 2013; 19(17): 2718-2722 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i17/2718.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i17.2718>

## INTRODUCTION

The prevalence of ulcerative colitis (UC) is increasing worldwide and has reached a total of 130000 cases in Japan. Clinical practice guidelines issued by the Japanese Ministry of Health, Labor and Welfare recommend aminosalicylates, sulfasalazine, or 5-aminosalicylic acid (5-ASA) followed by corticosteroids [prednisolone (PSL)] or azathioprine (AZA) as the standard treatment for UC patients. Recently, infliximab (IFX) and tacrolimus have become available and are used clinically as novel medications for patients with UC. However, some patients do not respond to these pharmacological interventions; UC in such patients is called refractory or intractable. The herbal medicine Qing Dai is also known as Indigo naturalis and is extracted from plants such as *Strobilanthes cusia* and *Isatis tinctoria*. Qing Dai contains natural ingredients such as indigo, indirubin, isoindirubin, and nimboesterol. In China, Qing Dai has been traditionally used as an antipyretic, an antiphlogistic, and as a hemostatic remedy. Qing Dai enemas have been used for ulcerative proctitis and are currently described in Chinese medical guidelines for the treatment of UC. However, until now, no report has been published describing the efficacy of orally administered Qing Dai in UC patients.

## CASE REPORT

### Cases

Nine UC patients (7 men and 2 women, listed in Table 1) who voluntarily received Qing Dai between 2008 and 2011 were retrospectively evaluated. Patients who did not respond to 5-ASA and PSL or IFX were defined as “intractable”. One patient who was not intractable but refused to add PSL or IFX was included in the analysis. The average age of the patients was 34 years with a range of 16–75 years. All patients purchased Qing Dai from Seishinshoyakudo (Tokyo, Japan), a company that imports Qing Dai from China and sells it at a price of 4200 Japanese yen (US \$50) per 500 g. Qing Dai was provided as powder, and each patient took 1 g of Qing Dai orally twice a day without wrapping, according to the manufacturer’s recommendations. All 9 patients were on 5-ASA, and 7 patients were also on PSL. 5-ASA and PSL were taken at the recommended dose for at least 8 wk prior to the initiation of Qing Dai; however, unique cases include patient D, whose pharmacological regimen was changed from 3 g/d of Pentasa (Ferring Pharmaceuticals, Malmö, Sweden) to 3.6 g/d of Asacol (Warner Chilcott, Dublin, Ireland) 4 d before the start of Qing Dai and patient F, whose prescription was changed from 4 g/d of Pentasa to 3.6 g/d of Asacol 3 d before taking Qing Dai. The clinical activity index (CAI)<sup>[1]</sup> of the patients before taking Qing Dai and 1, 2, and 4 mo after initially taking Qing Dai and the endoscopic Matts grade<sup>[2]</sup> before and after treatment with Qing Dai were retrospectively collected from clinical records because those data had been routinely recorded for all UC patients.

**Table 1 Patient characteristics including lesion type and ulcerative colitis duration and treatment**

| Patient | Sex | Age (yr) | Type of UC Lesion  | Duration of UC (mo) | Ongoing treatment at time of Qing Dai initiation |
|---------|-----|----------|--------------------|---------------------|--|
| A       | M   | 16       | Proctitis          | 18                  | 5-ASA, PSL                                       |
| B       | M   | 36       | Left-sided colitis | 65                  | 5-ASA, IFX                                       |
| C       | M   | 35       | Proctitis          | 96                  | 5-ASA, PSL, CAP                                  |
| D       | M   | 33       | Pancolitis         | 60                  | 5-ASA, PSL, AZA, IFX                             |
| E       | M   | 31       | Left-sided colitis | 40                  | 5-ASA, PSL, AZA                                  |
| F       | M   | 27       | Left-sided colitis | 32                  | 5-ASA, PSL, CAP, IFX                             |
| G       | F   | 26       | Proctitis          | 6                   | 5-ASA  |
| H       | F   | 29       | Left-sided colitis | 8                   | 5-ASA, PSL                                       |
| I       | M   | 75       | Left-sided colitis | 74                  | 5-ASA, PSL, AZA                                  |

Nine UC patients (7 men and 2 women) were included in this study. The type of colitis lesion, the duration of UC and the ongoing treatment at the time of Qing Dai initiation are shown. UC: Ulcerative colitis; M: Male; F: Female; 5-ASA: 5-aminosalicylates; PSL: Prednisolone; IFX: Infliximab; CAP: Cytopheresis; AZA: Azathioprine.

### Electron spin resonance

To investigate the mechanisms of action of Qing Dai, we performed electron spin resonance (ESR) spectroscopy by using the spin-trapping reagent 5-(2,2-dimethyl-1,3-propoxy cyclophosphoryl)-5-methyl-1-pyrroline *N*-oxide (CYPMPO)<sup>[3]</sup>. Hydroxyl radicals were produced in an aqueous solution containing 50  $\mu$ L of 2 mmol/L H<sub>2</sub>O<sub>2</sub> dissolved in 0.1 mol/L phosphate buffer. Fifty microliters of 8.9 mmol/L DMPO with or without 2.5, 25, or 250  $\mu$ g/mL Qing Dai was incubated for 60 s after the addition of 50  $\mu$ L of 0.2 mmol/L FeSO<sub>4</sub>, and results were obtained using a JEOL-TE X-Band spectrometer (JEOL, Tokyo, Japan).

### Ethical consideration

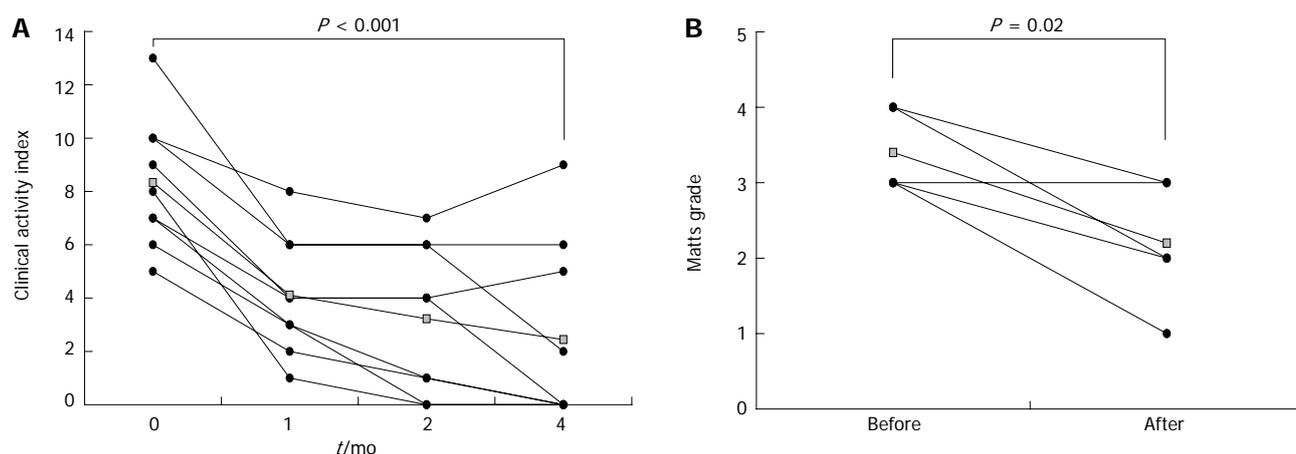

All 9 patients began taking Qing Dai voluntarily. Nonetheless, for this paper, written informed consent was obtained from all of the patients included in the analysis.

### Statistical analysis

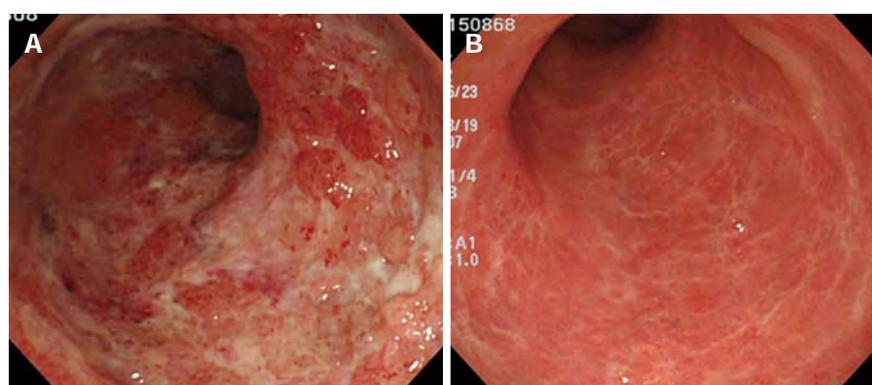

The data for CAI and Matts grade score were analyzed by a paired *t*-test using Excel 2010 (Microsoft, United States) with the add-in software Statcel 3 (OMS publishing Co., Saitama, Japan). Differences corresponding to a *P* value < 0.05 were considered statistically significant.

### Clinical and endoscopic efficacy of Qing Dai

The average CAI score (mean  $\pm$  SD) decreased from 8.3  $\pm$  2.4 to 2.4  $\pm$  3.4 (*P* < 0.001) (Figure 1A). This effect persisted unless the patient withdrew from Qing Dai treatment. Patients A and C showed recurrence of UC after cessation of Qing Dai. However, their CAI score immediately recovered upon re-administration of Qing Dai.

**Figure 1** The clinical activity index score and endoscopic Matts grade before and after Qing Dai initiation. A: The score markedly improved from  $8.3 \pm 2.4$  to  $2.4 \pm 3.4$  (mean  $\pm$  SD; *t*-test,  $P < 0.001$ ) after the initiation of Qing Dai. The line plotted in gray shows the average; B: The Matts grade significantly improved from  $3.4 \pm 0.5$  to  $2.2 \pm 0.8$  (mean  $\pm$  SD; *t*-test,  $P = 0.02$ ) after the initiation of Qing Dai treatment. The line plotted in gray shows the average.

**Figure 2** Endoscopic finding before and after treatment. A: Before the initiation of Qing Dai, endoscopic examination showed severe ulcers and erosions in the rectum; B: After 3 mo of Qing Dai treatment, the mucosal damage completely disappeared.

Five patients, including 3 patients with left-sided colitis, 1 patient with pancolitis and 1 patient with proctitis, were monitored by endoscopy. The average time interval between endoscopies was 7 mo (range 2-10 mo). The endoscopic Matts grade (Figure 1B) also decreased from  $3.4 \pm 0.5$  to  $2.2 \pm 0.8$  ( $P = 0.02$ ). Six of the 7 patients (86%) who were also taking PSL were able to discontinue this corticosteroid.

Patient E, a 28-year-old man who presented with hematochezia was diagnosed as having left-sided UC and demonstrated remarkable benefit from Qing Dai therapy. Initially, patient E was prescribed 4 g/d sulfasalazine and 40 mg/d PSL for the treatment of UC, and the hematochezia rapidly disappeared. However, the hematochezia recurred as the patient reduced his intake of PSL. Thus, patient E required the dose of PSL to be increased several times, and treatment with AZA and cytapheresis failed to provide long-term improvement. Patient E met our criteria for refractory UC. After 3 years of treatment, patient E began to use Qing Dai of his own volition. One month after treatment with Qing Dai, hematochezia in patient E was resolved, and the CAI score decreased from 9 to 4. The serum C-reactive

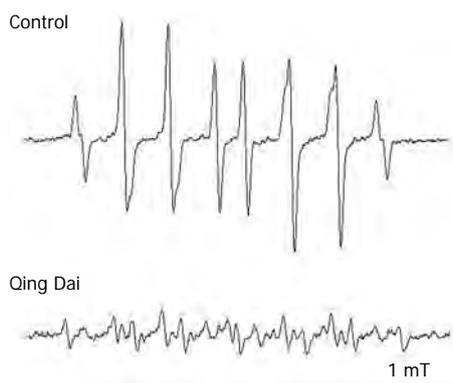

protein level also decreased from 1.33 mg/dL to 0.11 mg/dL. The CAI score fell to 0 after 3 mo of treatment with Qing Dai, and patient E was withdrawn from PSL and AZA after 8 mo of Qing Dai treatment. Notably, this effect of Qing Dai therapy persisted for more than 2 years. The endoscopic findings are shown in Figure 2A and B. The ulcers completely disappeared and only erythema was observed. In contrast, patient D did not respond to Qing Dai, and required the administration of conventional medications.

**Safety**

Although no serious adverse side effects were reported in patients consuming Qing Dai, 2 patients developed mild headaches while taking Qing Dai. The headaches disappeared upon reduction of the dose of Qing Dai by half.

**Hydroxyl radical scavenging effect of Qing Dai**

As shown in Figure 3, without Qing Dai, the ESR spectrum agreed with CYPMPO-OH, a hydroxyl radical adduct trapped by CYPMPO. The reduction in the signal intensity of CYPMPO-OH reflected the hydroxyl radical scavenging ability of Qing Dai, and the results of treat-

**Figure 3** Electron spin resonance of Qing Dai. Representative electron spin resonance spectra of CYPMPPO-OH (for hydroxyl radical determination) obtained by the addition of solvent control or an ethanol extract of Qing Dai at a concentration of 25  $\mu\text{g}/\text{mL}$ . The test was repeated in five independent trials, and a representative result is presented.

ment with 25  $\mu\text{g}/\text{mL}$  Qing Dai are shown in Figure 3. The 250 and 2.5  $\mu\text{g}/\text{mL}$  concentrations of Qing Dai showed a similar hydroxyl radical scavenging effect in a dose-dependent manner (data not shown).

## DISCUSSION

Approximately 21% of patients with inflammatory bowel disease reportedly use alternative treatment outside of the medications typically prescribed to treat inflammatory bowel disease in a clinical setting<sup>[4]</sup>. Consistent with this statistic, several herbal medications have shown promising efficacy and safety in patients with UC, including preparations that contain a sulfhydryl group in their structure<sup>[5]</sup>. Evidence of the clinical efficacy of Qing Dai and its constituent substances has been previously reported. Yuan *et al*<sup>[6]</sup>, reported that Qing Dai enemas are associated with significant clinical efficacy in the treatment of chronic hemorrhagic radiation proctitis. Likewise, Xilei-san, which is a major ingredient in Qing Dai, has traditionally been used for the treatment of UC in China and, more recently, in Japan<sup>[7,8]</sup>. Accordingly, in a double blind, randomized clinical trial setting, Fukunaga *et al*<sup>[9]</sup> reported that suppositories of Xilei-san showed significant efficacy in patients with ulcerative proctitis refractory to conventional medications. In the current study, we found a good clinical response to Qing Dai with no serious adverse side effect in patients with intractable UC. Ferber has also reported very low toxicity for Qing Dai<sup>[10]</sup>.

There are few reports on the pharmacokinetics of Qing Dai. Because Qing Dai appears in the stool without significant digestion, the mucosal healing effect could be associated with the ability of Qing Dai to provide a protective coating to the injured mucosa. Qing Dai has been reported to have anti-inflammatory effects on human neutrophils based on its ability to suppress superoxide generation<sup>[11]</sup>. The same authors reported efficacy of Qing Dai in patients with recalcitrant psoriasis in a randomized study<sup>[12]</sup>. Indirubin, a constituent of Qing Dai, has been reported to produce anti-inflamma-

tory effects by suppressing interferon- $\alpha$ , interleukin-6<sup>[13]</sup>, and nuclear factor  $\kappa\text{B}$  (NF- $\kappa\text{B}$ ) production<sup>[14]</sup>. Xilei-san was also reported to decrease the expression of toll-like receptor 4, NF- $\kappa\text{B}$ , and tumor necrosis factor- $\alpha$  in mice with oxazolone-induced colitis<sup>[15]</sup>. Interestingly, cytaferesis, which has been used in patients with active UC as a highly effective therapeutic, possesses a similar mechanism of action by decreasing reactive oxygen-producing neutrophils and interleukin-6 secretion<sup>[16]</sup>. In the present investigation, although we observed a strong hydroxyl radical scavenging effect in Qing Dai, further studies are warranted to fully understand the mechanisms of action in UC patients.

This study has several limitations. First, this was not a double-blind placebo-controlled trial. Second, basic experiments using animal models were not conducted. In light of these limitations, we are planning an *in vivo* study and a prospective multicenter double-blind placebo-controlled trial to investigate the effects of Qing Dai in patients with inflammatory bowel disease.

In conclusion, this investigation showed that oral Qing Dai is associated with significant clinical and endoscopic improvement of UC in patients who maintain active disease despite receiving conventional medications. The hydroxyl radical scavenging effect appears to be one mode of action of Qing Dai. Our results suggest that Qing Dai may represent a clinically relevant intervention for patients with inflammatory bowel disease. Additional controlled trials using larger cohorts of patients should be conducted to verify the findings of this investigation.

### Abstract

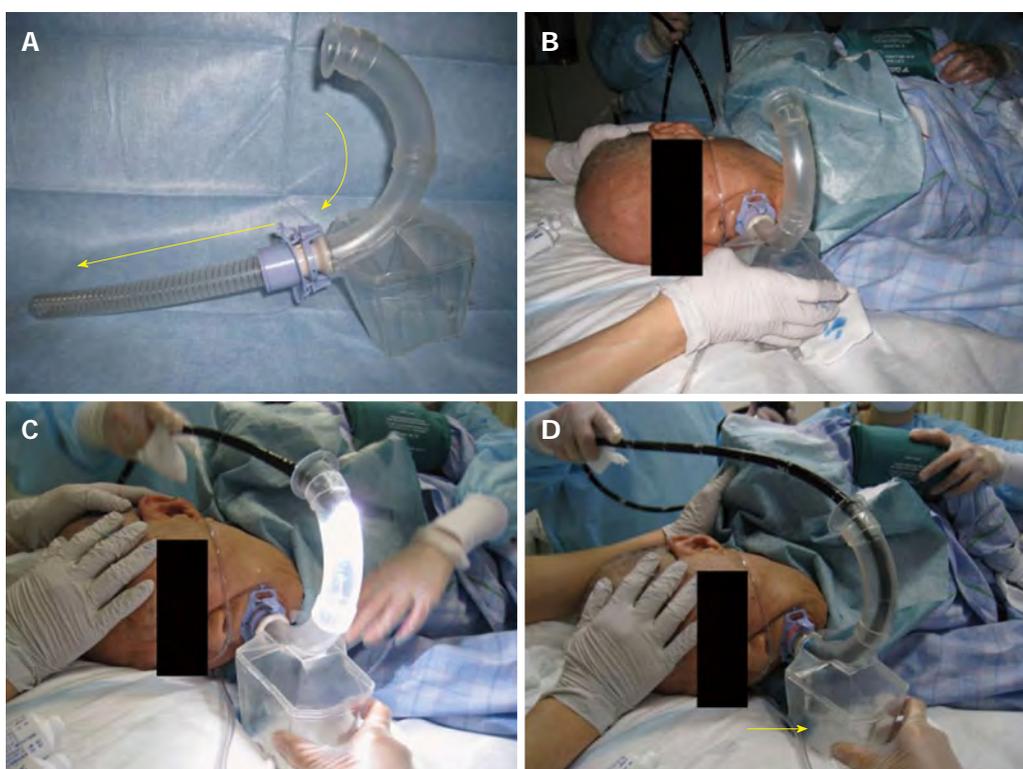

Endoscopic hemostasis performed in the emergency room is difficult due to the presence of blood clots and food residue that makes obtaining a clear view of the bleeding vessel difficult. We experienced the efficacy of a newly developed inverted overtube to shorten the hemostatic time and obtain a clear endoscopic view with upper gastrointestinal bleeding patient who were transferred by ambulance car and required emergency endoscopy. The technique improved the endoscopic views and enabled us to perform the hemostatic procedures from the conventional standing position while freely and easily changing the patient's position. The presence of blood clots and food residue in the gastric fornix or upper gastric body makes identifying a bleeding exposed vessel impossible. This set-up significantly shortened the procedure time. The inverted overtube helped us obtain a clear view in patients who were laid in the right lateral position. Rapid identification of ex-

### INTRODUCTION

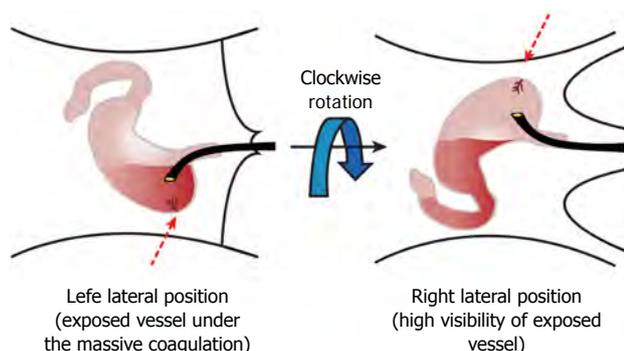

Patients with upper gastrointestinal bleeding who are transferred by an ambulance commonly present in emergency rooms and require an emergency endoscopy to achieve hemostasis. Although the significance, indication and timing of emergency endoscopies are controversial<sup>[1,2]</sup>, in the case of esophageal or gastric varix or Dieulafoy's ulcer, exposed vessels with spurting bleeding require prompt hemostasis, and failure to achieve hemostasis may lead to a serious condition. Endoscopists are under pressure to perform these emergency endoscopic treatments, especially in patients with cardiovascular or cerebrovascular diseases who are being treated with antiplatelet and anticoagulant agents<sup>[3]</sup> or in seriously ill patients who require rapid and reliable hemostasis<sup>[4]</sup>. In almost all cases, once the bleeding site is visually identified

**Figure 1** Emergency endoscopic view. A: The presence of large amounts of blood clots; B: The presence of food residue in the stomach complicated the observation of the region from the gastric fornix to the upper corpus.

**Figure 2** Outer appearance and procedures of using the inverted overtube. A: Outer appearance of the inverted overtube; B: Switching the patient from the conventional left lateral decubitus position to the right lateral decubitus position using the inverted overtube to dislodge blood clots during emergency endoscopic hemostasis; C: Insertion of the endoscope into the stomach through the inverted overtube in the right lateral decubitus position; D: Continuous aspiration from the bottom of the box (yellow arrow) enabled massive blood clots to be eliminated from the overtube, which maintained a clear endoscopic view during hemostasis.

**Figure 3** The schema of the visibility differences between 2 positions. We clockwise rotated the patient's position to a right lateral decubitus position to dislodge any massive clots and food residue.

**Figure 4** Obtaining a clear view of the gastric fornix and exposed vessels of a Dieulafoy's ulcer. Obtaining a clear view of the gastric fornix and upper gastric corpus, with all of the blood clots and food residue dislodged into the gastric antrum and duodenum. The exposed vessels of a Dieulafoy's ulcer were revealed (yellow arrows). The schema of the inverted overtube is shown in the center.

by endoscopy, hemostasis can be achieved using current endoscopic techniques and hemostatic forceps<sup>[5]</sup>; however, if it cannot be visually identified, a surgical procedure is required<sup>[6-8]</sup>. The presence of blood clots and food residue in the gastric fornix or upper gastric body makes identifying a bleeding exposed vessel impossible. In the case of gastric variceal bleeding, erythromycin or somatostatin has a beneficial effect on upper gastrointestinal bleeding by inducing rapid gastric emptying<sup>[9,10]</sup>. However, even with such drugs, obtaining a clear endoscopic view to rapidly identify the bleeding exposed vessels in an emergency situation is still difficult. This case series demonstrates a method for shortening the hemostasis time and reducing stress for both patients and endoscopists.

## CASE REPORT

A 55-year-old woman who was transported to our emergency room in shock after feeling nauseous and experiencing sudden massive hematemesis in June 2012. Although her family informed us that a blood test 6 mo prior had shown no signs of anemia, a blood examination revealed severe anemia (hemoglobin, 5.5 g/dL). Emergency endoscopic hemostasis and a blood transfusion were performed. Large amounts of blood and food residue were observed in the stomach. Because the patient appeared drowsy, an emergency endoscopy to detect the bleeding vessel was immediately performed in the areas that could be observed in the left lateral decubitus position. The bleeding vessel could not be identified in the duodenum or gastric antrum. As the amount of fresh blood increased, obtaining a clear endoscopic view to identify the bleeding vessel gradually increased in difficulty (Figure 1). Assuming that the bleeding vessel was located in either the upper gastric body or gastric fornix, which was not visible due to the blood clot, we immediately switched from the conventional observation position to the right lateral decubitus position using newly developed inverted overtube (Figure 2). The inverted overtube was approved by the Institutional Ethics Committee of Kagawa University Hospital, Kagawa, Japan. Additionally, the inverted overtube was approved by the

Japanese Pharmaceutical Law.

The blood clot and food residue in the gastric corpus and fornix were immediately dislodged to the right into the duodenum by gravity (Figure 3), allowing for the visual identification of an exposed blood vessel in the fornix (Figure 4). Up to this point, no spurting bleeding had been observed due to the decreased blood pressure. However, massive spurting bleeding occurred immediately after the exposed blood vessel was pinched with hemostatic forceps. The pinched vessel was then completely cauterized by coagulation mode to achieve hemostasis. No bleeding was observed thereafter.

## DISCUSSION

Despite the dramatic progress made in endoscopic hemostatic techniques<sup>[1,4]</sup>, hematemesis from an esophageal or gastric varix or Dieulafoy's ulcer can lead to serious consequences if hemostasis is not achieved<sup>[8]</sup>. Achieving accurate and reliable hemostasis is difficult without a clear view of the bleeding vessel. Although hemostasis *via* a laparotomy can be performed as a last resort, surgery in a patient with a poor systemic condition carries a high risk. Thus, emergency endoscopic hemostasis remains the first-line treatment of choice<sup>[2,6]</sup>.

During endoscopic hemostatic procedures performed in the emergency room, where pretreatment is not performed, the presence of blood clots and food residue makes obtaining a clear view of the bleeding vessel difficult<sup>[5]</sup>. The removal of blood clots from the stomach has conventionally been achieved by gastric suction with a gastric tube and/or by manual removal of the clot with grasping forceps. However, the use of gastric suction and/or grasping forceps currently requires a great deal of time. Thus, endoscopists have adopted a procedure in which the patient's posture is rotated to the right lateral decubitus position to dislodge the blood clots and enable the identification of the bleeding vessel. Because most endoscopists perform conventional endoscopic examinations and treatment procedures with the patient lying in the left lateral decubitus position, they find that performing accurate hemostatic procedures from the opposite

side, with the patient lying in the right lateral decubitus position, to be difficult. Thus, the use of the inverted overtube is the best method to help endoscopists perform an emergency endoscopy with less stress because they are in their conventional standing position relative to patients who are rotated to the right lateral decubitus position, without changing the positions of the endoscopy unit and light source. This technique is the most effective way to dislodge blood clots and food residue by gravity in these patients. The present technique dramatically improved the clarity of the endoscopic views and enabled the endoscopist to perform the hemostatic procedures from the conventional standing position while freely and easily changing the patient's position. This set-up significantly shortened the procedure time. The inverted overtube, with its very simple structure, helped the endoscopist acquire a clear view in patients who were laid in the right lateral position. This clear view contributed to the rapid identification of the bleeding vessels and the subsequent rapid achievement of hemostasis.

### Abstract

Although the introduction of double-balloon enteroscopy has greatly improved the diagnostic rate, definite diagnosis of Meckel's diverticulum far from the ileocecal valve is still impossible in most cases. We explored the role of magnetic resonance (MR) enterography in detecting bleeding from Meckel's diverticulum that can not be confirmed *via* double-balloon enteroscopy. This study describes a case of male patient with bleeding from Meckel's diverticulum diagnosed with MR enterography of the small intestine. No bleeding lesion was found *via* colonoscopy, anal enteroscopy, or oral colonoscopy. MR enterography of the small intestine revealed an occupying lesion of 3.0 cm in the lower segment of the ileum. The patient was transferred to the Department of Abdominal Surgery of our hospital for surgical treatment. During surgery, a mass of 3 cm × 2 cm was found 150 cm from the ileocecal valve, in conjunction with congestion and edema of the corresponding mesangium. Intraoperative diagnosis was small bowel diverticulum with bleeding. The patient underwent partial resection of the small intestine. Postopera-

tive pathology showed Meckel's diverticulum containing pancreatic tissues. He was cured and discharged 7 d after operation. We conclude that MR enterography of the small intestine has greatly improved the diagnosis rate of Meckel's diverticulum, particularly in those patients with the disease which can not be confirmed *via* double-balloon enteroscopy.

### INTRODUCTION

Gastrointestinal bleeding of unknown cause is mostly a result of lesions located in the small intestine, for which the diagnosis and treatment can be challenging<sup>[1,2]</sup>. Meckel's diverticulum is a common congenital malformation of the small intestine, with gastrointestinal bleeding being the most common symptom. Preoperative diagnosis of this condition is difficult. Although the introduction of double-balloon enteroscopy has greatly improved the diagnostic rate, definite

diagnosis of Meckel's diverticulum far from the ileocecal valve is still impossible in most cases. This study describes a case of bleeding from Meckel's diverticulum diagnosed with magnetic resonance (MR) enterography of the small intestine in our department.

## CASE REPORT

A 25-year-old man was first admitted to the hospital for lower abdominal pain on March 25, 2011. No abnormality was found through enhanced computed tomography (CT) scan of the whole abdomen on admission. No positive finding was reported on anal enteroscopy. Barium meal examination of the entire digestive tract showed multiple fluid levels in segments 4 and 5 of the small intestine. His condition improved with anti-inflammatory therapy, intestinal spasmolysis, and nutritional support. He was then discharged on April 3, 2011. After that, he was diagnosed as having "appendicitis" and underwent appendectomy in a local hospital. Encapsulated fluid was present in the right lower quadrant, which was improved after puncture and drainage. Later, he was again admitted to our hospital on February 17, 2012 due to melena for two days after recurrent abdominal pain for nearly a year. Examinations on admission showed a positive fecal occult blood test, stool red blood cell (RBC) +++/HP, C-reactive protein: 30.9 mg/L; abdominal CT revealed a small amount of fluid in the pelvic cavity. Routine examination of the ascites fluid collected by ultrasound-guided puncture showed red fluid, specific gravity > 1.018, positive Rivalta test, RBC ++++/HP, and nucleated cell count of  $1.8 \times 10^9/L$ . Ascites smears revealed no acid-fast bacilli. Bacterial culture indicated *Streptococcus sanguis*. No bleeding lesion was found *via* colonoscopy, anal enteroscopy, or oral colonoscopy. His condition improved after hemostatic, anti-infective and symptomatic treatment, and he was discharged on March 4, 2012. His condition remained stable after discharge until three days prior to admission when he experienced lower abdominal pain after eating spicy food, and had dark red bloody stools, 2-3 times a day. He was admitted for a third time on April 24, 2012. Blood tests upon admission showed hemoglobin (HGB) of 96 g/L; MR enterography of the small intestine showed an occupying lesion of 3.0 cm in the lower segment of the ileum. He was transferred to the Department of Abdominal Surgery for surgical treatment. During surgery, a mass of 3 cm  $\times$  2 cm was found 150 cm from the ileocecal valve, in conjunction with congestion and edema of the corresponding mesangium. Intraoperative diagnosis was small bowel diverticulum with bleeding. Postoperative pathology showed Meckel's diverticulum containing pancreatic tissues. The patient underwent partial resection of the small intestine, and was cured and discharged 7 d after operation (Figure 1).

## DISCUSSION

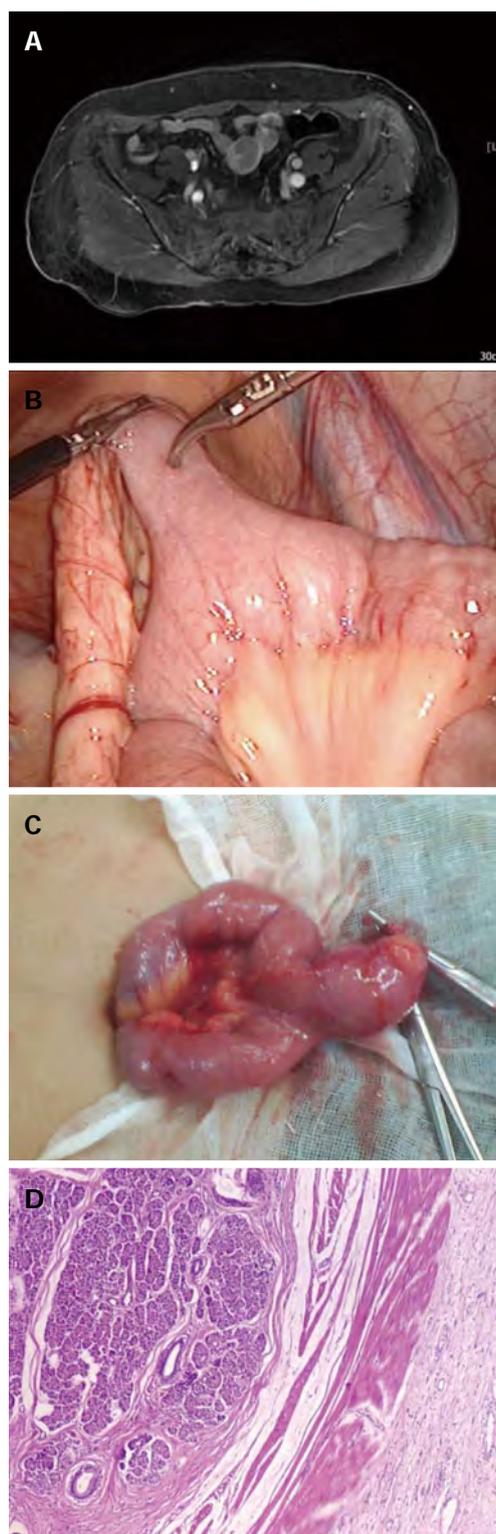

Meckel's diverticulum is the most common congenital

malformation of the small intestine, with an incidence of 1% to 4%<sup>[3]</sup>. It usually occurs in the ileum within 100 cm of the ileocecal valve<sup>[4]</sup>, and is a true diverticulum consisting of all layers of the bowel wall. Meckel's diverticulum harbors various ectopic tissues, with gastric mucosa being the most common (about 50%), followed by pancreatic tissues (about 5%)<sup>[5]</sup>. The majority of people afflicted with Meckel's diverticulum are asymptomatic, and 4% to 6% of the patients are detected due to symptoms of related complications<sup>[6-10]</sup>. Gastrointestinal bleeding is the most common symptom of Meckel's diverticulum<sup>[11]</sup>, followed by intussusception, and intestinal obstruction.

Such bleeding occurs from larger vessels invaded by erosion and ulceration of normal intestinal mucosa in the diverticulum, as a result of the secretion of gastric acid or alkaline pancreatic fluid from the ectopic mucosa<sup>[12-15]</sup>. Consisting mainly of fundic glands, where parietal cells secrete gastric acid and chief cells secrete pepsin, the ectopic gastric mucosa is closely related to gastrointestinal bleeding, as the acid does not only directly cause corrosion of the diverticulum and intestinal mucosa, but also promotes the conversion of pepsinogen secreted by ectopic chief cells into pepsin, which in turn induces tissue digestion and leads to ulceration and bleeding.

Preoperative diagnosis is difficult when Meckel's diverticulum is complicated by small intestinal bleeding<sup>[15]</sup>. Gastroscopy, colonoscopy, barium meal and ultrasound lack specificity, but they can be used to exclude lower gastrointestinal bleeding from other sites. Due to its high-density resolution, CT scanning can detect and accurately locate stones of low density in Meckel's diverticulum<sup>[16,17]</sup>. CT enterography of the small intestine has been proven to be more useful than conventional CT in patients suspected of having small bowel lesions, as it not only maximizes the visibility of the mucosa and intestine structure with the aid of contrast agents, but also detects parenteral abnormalities<sup>[18-22]</sup>. MR enterography is a radiation-free technique developed based on CT enterography, which allows evaluation of intestinal functionalities using MR fluoroscopy.

MR enterography is a novel technique that combines the advantages of both the conventional enterography and the morphological imaging of magnetic resonance imaging, thus making it an examination for both the functions and the morphologies of small intestine. Before MR enterography is done, the bowel must be completely cleansed and the intestinal canal distended. Therefore, it is critically important to select a contrast agent that can thoroughly distend the intestinal canal and clearly demonstrate the enteric cavity and intestinal wall, and does not produce artifacts or pose a hazard to human health. Although the double-contrast imaging of the small intestine is helpful for observing the early mucosal changes, it cannot visualize the lesions around the intestinal wall or in the mesentery. In contrast, MR enterography, with three-dimensional imaging capabilities and excellent soft-tissue contrast, can be used to observe the mucosa and analyze the changes around the intestinal canal<sup>[23-25]</sup>.

**Figure 1** The patient underwent partial resection of the small intestine, and was cured and discharged 7 d after operation. A: Magnetic resonance enterography of the small intestine. An occupying lesion of 3.0 cm was found in the lower segment of the ileum; B: A mass of 3 cm × 2 cm was found 150 cm from the ileocecal valve during surgery; C: Removed lesion during surgery; D: Postoperative pathology showed Meckel's diverticulum containing pancreatic tissues.

The introduction of capsule endoscopy and double-balloon enteroscopy has made observation of the entire

small bowel mucosa possible, and the latter technique also enables biopsy for pathological diagnosis and endoscopic treatment<sup>[26-28]</sup>. Compared with traditional push enteroscopy (90-150 cm) and retrograde terminal ileoscopy (50-80 cm), double-balloon enteroscopy has a longer average depth (240-360 cm orally and 102-140 cm anally); compared with capsule endoscopy, it enables more pathological and endoscopic applications, such as hemostasis, polypectomy, dilatation treatment, and removal of foreign substances<sup>[29,30]</sup>. Heine *et al*<sup>[31]</sup> demonstrated in their study that double-balloon enteroscopy has a diagnosis rate of 63% for obscure gastrointestinal bleeding, and complete small bowel examination is achievable for about 1/3 of these cases.

Although double-balloon enteroscopy has a high diagnosis rate for unexplained gastrointestinal bleeding, since a complete small bowel examination can be done in only a few patients, the causes of bleeding still remain unknown in many other patients before surgery. In the present case, the lesion was up to 150 cm from the ileocecal valve, which was undetectable by anal colonoscopy with an average insertion depth of about 102-140 cm, therefore, no definite diagnosis could be made. In view of this, MR enterography of the small intestine was performed and an occupying lesion of 3.0 cm was found in the lower segment of the ileum, with clear boundaries, showing mixed signals. He was transferred to the Department of Abdominal Surgery for surgical treatment. During surgery, a mass of 3 cm × 2 cm was found 150 cm from the ileocecal valve, in conjunction with congestion and edema of the corresponding mesangium. Intraoperative diagnosis was small bowel diverticulum with bleeding. Postoperative pathology showed Meckel's diverticulum containing pancreatic tissues. The patient underwent partial resection of the small intestine, and was cured and discharged 7 d after operation.

In summary, Meckel's diverticulum is the most common congenital malformation of the small intestine that is easily complicated by small intestinal bleeding, for which preoperative diagnosis is difficult. The introduction of double-balloon enteroscopy has greatly improved the diagnostic rate, but definite diagnosis is still challenging in some patients, especially when the lesion is far from the ileocecal valve. MR enterography is a radiation-free technique developed based on CT enterography, which maximizes the visibility of the mucosa and intestine structure with the aid of contrast agents. MR enterography of the small intestine has greatly improved the diagnosis rate of Meckel's diverticulum, particularly in those patients with the disease which can not be confirmed *via* double-balloon enteroscopy.

## GENERAL INFORMATION

*World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access (OA) journal. *WJG* was established on October 1, 1995. It is published weekly on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup>, and 28<sup>th</sup> each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

### Aims and scope

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

*WJG* is published by Baishideng Publishing Group (BPG) in both electronic and online forms. All *WJG* articles are published in *WJG* website and PubMed Central. The major advantages of OA journals are faster release and delivery, no page or graph restrictions, and increased visibility, usage and impact. Full-text PDF articles and electronic/online versions are freely available to global readers. After the paper is published, the author(s) can obtain high-quality PDF files, which contain the journal cover, a list of editorial board members, table of contents, text, and back cover of the journal. BPG has a strong professional editorial team composed of editorial board members, editors-in-chief, science editors, language editors, and electronic editors. BPG currently publishes 42 OA clinical medical journals, including 41 in English, has a total of 15 471 editorial board members or peer reviewers, and is a world first-class publisher.

### Columns

The columns in the issues of *WJG* will include: (1) Editorial: The editorial board members are invited to make comments on an important topic in their field in terms of its current research status and future directions to lead the development of this discipline; (2) Frontier: The editorial board members are invited to select a highly cited cutting-edge original paper of his/her own to summarize major findings, the problems that have been resolved and remain to be resolved, and future re-

search directions to help readers understand his/her important academic point of view and future research directions in the field; (3) Diagnostic Advances: The editorial board members are invited to write high-quality diagnostic advances in their field to improve the diagnostic skills of readers. The topic covers general clinical diagnosis, differential diagnosis, pathological diagnosis, laboratory diagnosis, imaging diagnosis, endoscopic diagnosis, biotechnological diagnosis, functional diagnosis, and physical diagnosis; (4) Therapeutics Advances: The editorial board members are invited to write high-quality therapeutic advances in their field to help improve the therapeutic skills of readers. The topic covers medication therapy, psychotherapy, physical therapy, replacement therapy, interventional therapy, minimally invasive therapy, endoscopic therapy, transplantation therapy, and surgical therapy; (5) Field of Vision: The editorial board members are invited to write commentaries on classic articles, hot topic articles, or latest articles to keep readers at the forefront of research and increase their levels of clinical research. Classic articles refer to papers that are included in Web of Knowledge and have received a large number of citations (ranking in the top 1%) after being published for more than years, reflecting the quality and impact of papers. Hot topic articles refer to papers that are included in Web of Knowledge and have received a large number of citations after being published for no more than 2 years, reflecting cutting-edge trends in scientific research. Latest articles refer to the latest published high-quality papers that are included in PubMed, reflecting the latest research trends. These commentary articles should focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions. Basic information about the article to be commented (including authors, article title, journal name, year, volume, and inclusive page numbers); (6) Minireviews: The editorial board members are invited to write short reviews on recent advances and trends in research of molecular biology, genomics, and related cutting-edge technologies to provide readers with the latest knowledge and help improve their diagnostic and therapeutic skills; (7) Review: To make a systematic review to focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions; (8) Topic Highlight: The editorial board members are invited to write a series of articles (7-10 articles) to comment and discuss a hot topic to help improve the diagnostic and therapeutic skills of readers; (9) Medical Ethics: The editorial board members are invited to write articles about medical ethics to increase readers' knowledge of medical ethics. The topic covers international ethics guidelines, animal studies, clinical trials, organ transplantation, etc.; (10) Clinical Case Conference or Clinicopathological Conference: The editorial board members are invited to contribute high-quality clinical case conference; (11) Original Articles: To report innovative and original findings in gastroenterology and hepatology; (12) Brief

## Instructions to authors

Articles: To briefly report the novel and innovative findings in gastroenterology and hepatology; (13) Meta-Analysis: To evaluate the clinical effectiveness in gastroenterology and hepatology by using data from two or more randomised control trials; (14) Case Report: To report a rare or typical case; (15) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (16) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (17) Autobiography: The editorial board members are invited to write their autobiography to provide readers with stories of success or failure in their scientific research career. The topic covers their basic personal information and information about when they started doing research work, where and how they did research work, what they have achieved, and their lessons from success or failure.

## SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

### Biostatistical editing

Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t*-test (group or paired comparisons), chi-squared test, ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word 'significantly' should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

### Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they

might have reviewing a particular paper. Before submitting, authors are suggested to read “Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest” from International Committee of Medical Journal Editors (ICMJE), which is available at: [http://www.icmje.org/ethical\\_4conflicts.html](http://www.icmje.org/ethical_4conflicts.html).

### **Statement of informed consent**

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

### **Statement of human and animal rights**

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator’s national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

## **SUBMISSION OF MANUSCRIPTS**

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted

manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is <http://www.clinicaltrials.gov> sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author’s organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

### **Online submissions**

Manuscripts should be submitted through the Online Submission System at: <http://www.wjgnet.com/esps/>. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS ([http://www.wjgnet.com/1007-9327/g\\_info\\_20100315215714.htm](http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm)) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to [wjg@wjgnet.com](mailto:wjg@wjgnet.com), or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

## **MANUSCRIPT PREPARATION**

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

### **Title page**

**Title:** Title should be less than 12 words.

**Running title:** A short running title of less than 6 words should be provided.

**Authorship:** Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

**Institution:** Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Visceral, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

## Instructions to authors

**Author contributions:** The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

**Supportive foundations:** The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

**Correspondence to:** Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomerybissell@ucsf.edu

**Telephone and fax:** Telephone and fax should consist of +, country number, district number and telephone or fax number, e.g. Telephone: +86-10-59080039 Fax: +86-10-85381893

**Peer reviewers:** All articles received are subject to peer review. Normally, three experts are invited for each article. Decision on acceptance is made only when at least two experts recommend publication of an article. All peer-reviewers are acknowledged on Express Submission and Peer-review System website.

### Abstract

There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of “To investigate/study/...”), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, e.g.  $6.92 \pm 3.86$  vs  $3.61 \pm 1.67$ ,  $P < 0.001$ ), and CONCLUSION (no more than 26 words).

### Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

### Core tip

Please write a summary of less than 100 words to outline the most innovative and important arguments and core contents in your paper to attract readers.

### Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in

Figures and Tables, but not in both.

### Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: ...*etc.* It is our principle to publish high resolution-figures for the E-versions.

### Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

### Notes in tables and illustrations

Data that are not statistically significant should not be noted. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  should be noted ( $P > 0.05$  should not be noted). If there are other series of *P* values, <sup>c</sup> $P < 0.05$  and <sup>d</sup> $P < 0.01$  are used. A third series of *P* values can be expressed as <sup>e</sup> $P < 0.05$  and <sup>f</sup> $P < 0.01$ . Other notes in tables or under illustrations should be expressed as <sup>1</sup>F, <sup>2</sup>F, <sup>3</sup>F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

### Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

## REFERENCES

### Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, “Crohn's disease (CD) is associated with increased intestinal permeability<sup>[1,2]</sup>”. If references are cited directly in the text, they should be put together within the text, for example, “From references<sup>[19,22-24]</sup>, we know that...”.

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

### PMID and DOI

Please provide PubMed citation numbers to the reference list,

e.g. PMID and DOI, which can be found at <http://www.ncbi.nlm.nih.gov/sites/entrez?db=pubmed> and <http://www.crossref.org/SimpleTextQuery/>, respectively. The numbers will be used in E-version of this journal.

### Style for journal references

Authors: the name of the first author should be typed in bold-faced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

### Style for book references

Authors: the name of the first author should be typed in bold-faced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

### Statistical data

Write as mean  $\pm$  SD or mean  $\pm$  SE.

### Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as  $\chi^2$  (in Greek), related coefficient as *r* (in italics), degree of freedom as  $\nu$  (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

### Units

Use SI units. For example: body mass, *m* (B) = 78 kg; blood pressure, *p* (B) = 16.2/12.3 kPa; incubation time, *t* (incubation) = 96 h, blood glucose concentration, *c* (glucose) 6.4  $\pm$  2.1 mmol/L; blood CEA mass concentration, *p* (CEA) = 8.6 24.5  $\mu$ g/L; CO<sub>2</sub> volume fraction, 50 mL/L CO<sub>2</sub>, not 5% CO<sub>2</sub>; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, etc. Arabic numerals such as 23, 243, 641 should be read 23243641.

## Instructions to authors

The format for how to accurately write common units and quantum numbers can be found at: [http://www.wjgnet.com/1007-9327/g\\_info\\_20100315223018.htm](http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm).

### Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

### Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.

Genotypes: *gyrA*, *arg 1*, *c myc*, *c fos*, etc.

Restriction enzymes: *EcoRI*, *HindI*, *BamHI*, *Kbo I*, *Kpn I*, etc.

Biology: *H. pylori*, *E. coli*, etc.

### Examples for paper writing

All types of articles' writing style and requirement will be found in the link: <http://www.wjgnet.com/esps/Navigation-Info.aspx?id=15>.

## RESUBMISSION OF THE REVISED MANUSCRIPTS

Authors must revise their manuscript carefully according to the revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade A certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to [esps@wjgnet.com](mailto:esps@wjgnet.com).

### Language evaluation

The language of a manuscript will be graded before it is sent for

revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A.

### Copyright assignment form

Please download a Copyright assignment form from [http://www.wjgnet.com/1007-9327/g\\_info\\_20100315222818.htm](http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm).

### Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: [http://www.wjgnet.com/1007-9327/g\\_info\\_20100315222607.htm](http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm)

### Proof of financial support

For papers supported by a foundation, authors should provide a copy of the approval document and serial number of the foundation.

### Links to documents related to the manuscript

WJG will be initiating a platform to promote dynamic interactions between the editors, peer reviewers, readers and authors. After a manuscript is published online, links to the PDF version of the submitted manuscript, the peer-reviewers' report and the revised manuscript will be put on-line. Readers can make comments on the peer reviewer's report, authors' responses to peer reviewers, and the revised manuscript. We hope that authors will benefit from this feedback and be able to revise the manuscript accordingly in a timely manner.

### Publication fee

WJG is an international, peer-reviewed, open access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non-commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. Publication fee: 1365 USD per article. All invited articles are published free of charge.

**APPENDIX I-VI** Instructions to authors

**ABOUT COVER** Editorial Board Member of *World Journal of Gastroenterology*, Chi Hin Cho, Professor, School of Biomedical Sciences, Faculty of Medicine, the Chinese University of Hong Kong, Lo Kwee Seong Integrated Biomedical Sciences Building, Shatin, Hong Kong, China

**AIMS AND SCOPE** *World Journal of Gastroenterology* (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7<sup>th</sup>, 14<sup>th</sup>, 21<sup>st</sup>, and 28<sup>th</sup> each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

**INDEXING/ABSTRACTING** *World Journal of Gastroenterology* is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2011 Impact Factor: 2.471 (32/74); Total Cites: 16951 (7/74); Current Articles: 677 (1/74); and Eigenfactor® Score: 0.06035 (5/74).

### Abstract

Cathelicidins, are host defense peptides synthesized and stored in circulating leukocytes and numerous types of epithelial tissues in particular the gastrointestinal (GI) tract and skin. They have been known for their antimicrobial activities against a variety of microbes. Recently it was discovered that they have other significant biological functions and produce appealing pharmacological actions against inflammation and cancer in the GI tract through defined mechanisms. Experimental evidence shows that these actions could be tissue and disease specific and concentration dependent. This article reviews some of the physiological functions of cathelicidins and also their therapeutic potential in the treatment of inflammation and cancer and also the delivery system for this peptide as targeted therapy for various disorders in the GI tract both in animals and humans.

### Biography

Professor Chi Hin Cho received his under- and post-graduate trainings in Taiwan, Canada, United States and Hong Kong and obtained his PhD in Pharmacology from the University of Hong Kong (HKU) in 1978. He had postdoctoral training in Canada and started his first faculty position in the Yang Ming Medical College and Veterans General Hospital, Taiwan in 1981. He returned to Hong Kong and joined HKU in the Department of Pharmacology, Faculty of Medicine from 1984 and became Chair Professor of Pharmacology in 2000. He joined the Chinese University of Hong Kong (CUHK) in 2007 as a chairman of the Department of Pharmacology. Currently, he is the Professor of Pharmacology and Associate Director of the School of Biomedical Sciences, Faculty of Medicine in CUHK. Professionally he was the President (2006-2010) and is now the Chair of Presidential Council (2012-2014) of the Gastrointestinal Pharmacology Section of the International Union of Basic and Clinical Pharmacology and visiting and honorary professors of Peking University, Fudan University, Zhejiang University, Beijing Capital University of Medical Science, the Fourth Military Medical University, Virginia Tech, University of Maryland and University of California. His current research interests focus on drug development for inflammation and cancers in the gastrointestinal (GI) tract. His recent work in the discovery of novel peptides including small peptides and cathelicidin as shown in this review have promising potential for drug targeting against inflammatory and cancerous diseases in the stomach and colon. These findings received prominent recognition, had significant impact on biomedical and clinical sciences and attracted international pharmaceutical industry's interest in the development of drugs and agents for the treatment and diagnosis of GI disorders. Professor Cho trained more than 50 PhD and master students and 11 postdoctoral fellows so far in his academic career. He is also the editorial board member and editor in more than 30 journals in the fields of Gastroenterology and Pharmacology. He published more than 355 peer-reviewed articles and 48 reviews in scientific journals and is the editor of six books in GI ulcer and cancer. He also holds 2 patents related to therapeutic agents for GI disorders in CUHK.

**Core tip:** Cathelicidin is one of the most important host defense peptides known today. It carries multiple and yet unique biological functions against pathogens which contribute to the induction and also progression of infection, inflammation and cancer, the three major types of diseases in mankind. Deficiency of such peptide would cause multiple dysfunctions in the body. In this review we highlight the physiological role and therapeutic potential of cathelicidin in inflammation and cancer and also mucosal repair in the gut. All these information would shed new lights on the development of cathelicidin as therapeutic agent for different disorders in the gastrointestinal tract.

## INTRODUCTION

Cathelicidins are innate immunity peptides. They are antimicrobial peptides (AMPs) that are produced by organisms as part of the defensive mechanism against various pathogenic microbes in humans and animals<sup>[1,2]</sup>. This class of pleiotropic peptides provides the first-line defense against infection by eliminating pathogens. Each AMP is encoded by a distinct gene. They show a great diversity in structures but have some common features, including: (1) relatively small molecular sizes (usually less than 50 amino acid residues); (2) cationic nature; (3) amphipathic helix structure; and (4) a substantial portion of hydrophobic amino acids<sup>[2,3]</sup>. Human cathelicidin (LL-37) consists of a long amphipathic helix spanning residues 2-31 with the C-terminal residues 32-37 unstructured. Another feature is that the structure is curved with a train of hydrophobic side chains. Such a cationic structure is perfect to associate with anionic micelles<sup>[4]</sup>. Indeed the cationic cathelicidin reacts electrostatically with anionic membrane components in particular cancer cells and microbes to disrupt cell membranes and induce cell death, while normal cells are neutral<sup>[5,6]</sup>. This specific property would enable cathelicidins directly and selectively attack membranes of microbes and cancer cells but spare the normal cells<sup>[7]</sup>. This uniqueness would make these peptides naturally exist and relatively non-toxic to normal mammalian system and have significant clinical implications as therapeutic agents for various diseases in particular those bacterial-related inflammation and cancer in the gastrointestinal (GI) tract<sup>[1,4,8]</sup>.

## CATHELICIDIN IN THE GI TRACT

Cathelicidins, a family of host defense peptides naturally expressed by cells of the GI tract. LL-37 is the mature

form of human cathelicidin. It is produced constitutively by differentiated surface and upper crypt epithelial cells in the colon and by the Brunner glands in the duodenum<sup>[9]</sup>. In normal stomach, the expression of the peptide is restricted to differentiated surface of various types of cells including epithelial cells, chief cells and parietal cells and is also present in the gastric secretion. They are upregulated during infection, inflammation and wound healing both in animals and humans<sup>[9-12]</sup>. These biological responses to external challenges could have significant implications as a host defense in protection against different disorders in the GI tract.

One good example is in the course of *Helicobacter pylori* (*H. pylori*) infection in which the expression of LL-37 is induced along the gastric glands. Induction of LL-37 may help to fight against bacterial infection at the early stage. However, the expression of LL-37 is dysregulated during *H. pylori*-associated gastric carcinogenesis. During the progression from atrophic gastritis to adenocarcinoma, the expression of LL-37 is reduced<sup>[12]</sup>. All these findings indicate that cathelicidin could play a significant role in preventing bacteria related inflammation and perhaps also carcinogenesis in the GI tract. It is envisaged that deficiency of this host defense peptide could facilitate the formation of inflammation and cancer.

## CATHELICIDIN AND GI REPAIR

Wound repair is a crucial adaptation to tissue damage. Based on the above information it comes to no surprise that soluble peptides like cathelicidins could evolve to orchestrate wound healing in response to mucosal damage in the GI tract. Along this line, LL-37 and mouse cathelicidin (mCRAMP) are strongly expressed in skin epithelium during wound healing in humans and mice<sup>[13]</sup>. In addition, the expression of LL-37 is low or absent in chronic ulcers, and antibodies to this peptide inhibit post-wounding re-epithelialization<sup>[14]</sup>.

Induction of angiogenesis by cathelicidin further highlights its potential role in wound repair<sup>[15]</sup>. In this context, it has been proposed that the healing-promoting effect of the peptide may be mediated through modification of growth factor and receptor interactions<sup>[16,17]</sup>. However the exact mechanisms by which cathelicidins promote wound healing have not yet been fully clarified. A recent study conducted by Yang *et al.*<sup>[11]</sup> in 2006 showed that rat cathelicidin can promote gastric ulcer healing in rats through induction of cell proliferation and angiogenesis. The same peptide stimulates cultured gastric epithelial cells through a transforming growth factor  $\alpha$ -dependent transactivation of epidermal growth factor and its related pathway to induce proliferation of gastric cells<sup>[11]</sup>.

## CATHELICIDIN AND INFLAMMATION

Experimental evidence shows that cathelicidin can modulate inflammation by altering cytokine response and chemoattraction of inflammatory cells in diseased tissues<sup>[1,18,19]</sup>. A recent study demonstrates that bacterial DNA

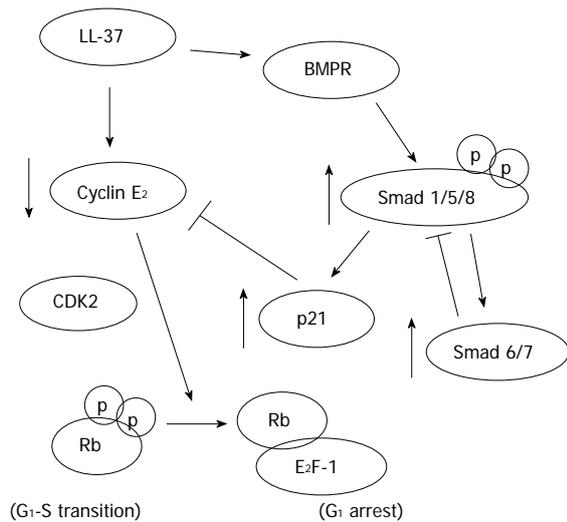

Figure 1 The possible signal pathway activated by cathelicidin (LL-37) to inhibit cell proliferation in gastric cancer cells. BMPR: Bone morphogenetic protein.

upregulates cathelicidin expression *via* a Toll-like receptor and mitogen-activated protein kinases/Erk pathway in colonic murine mucosa<sup>[20]</sup>. Clinical study also showed that cathelicidin expression was altered in inflammatory bowel diseases (IBD) patients. It was increased in both inflamed and non-inflamed mucosa in ulcerative colitis (UC) patients but not in Crohn's disease patients. The distribution of cathelicidin was also changed. Cathelicidin mainly expressed in the upper crypt of colons in healthy people in contrast to the basal part in IBD patients<sup>[21]</sup>. In another study, deficiency of cathelicidin in mCRAMP-knockout mice present more severe symptoms and mucosal disruption than the wild-type mice in response to dextran sulfate sodium challenge to induce UC. The inflammatory cytokines and the number of apoptotic cells are increased together with mucus secretion and gene expression are impaired. All these abnormalities are reversed by intrarectal administration of mCRAMP or mCRAMP-encoding plasmid<sup>[22]</sup>. On the other hand the increase of endogenous cathelicidin by agents such as butyrate and vitamin D has been suggested to modulate inflammatory responses either induced by chemical or bacteria in colonic cells<sup>[21,23-26]</sup>. Indeed butyrate treatment has been demonstrated to improve rectal histopathology in humans and eradicate *Shigella in vitro*<sup>[23,24]</sup> and vitamin D can prevent mucosal injury in chemical-induced acute colitis in mice<sup>[25]</sup>.

The peptide also significantly reduces the increased number of fecal microflora in UC animals<sup>[27]</sup>. Indeed exogenous cathelicidin modulates *Clostridium difficile* (*C. difficile*) colitis. In addition, *C. difficile*-induced colitic mice treated with cathelicidin inhibits toxin A-associated intestinal inflammation<sup>[28]</sup>. In view of the current UC therapies mainly focus on relieving the inflammatory responses or reducing the pathogenic microbes, cathelicidin would have both actions, and it further promotes the mucosal defensive mechanism through mucus secretion *via* a MAP kinase pathway<sup>[29]</sup>. All these actions would provide us a better therapeutic option in the treatment of inflamma-

tion in the colon. In this context, Cho and his group develop a new form of transporting system for this peptide by combining a probiotic *Lactococcus lactis* with cathelicidin gene into a single preparation. This preparation given orally instead of intrarectal administration<sup>[22]</sup> produces similar protection against UC in mice<sup>[30]</sup>. In a similar approach, we have applied the same mCRAMP-secreting strain of *Lactococcus lactis* to reduce *H. pylori* density in the stomach as well as the associated inflammatory cell infiltration and cytokine production<sup>[31]</sup>. These findings show the feasibility of using the transformed food-graded probiotic to deliver cathelicidin to the diseased organs and exert targeted therapy. This new biological preparation would have significant clinical applications in the future as potential therapeutic agent to alleviate inflammation induced by *H. pylori* infection in the stomach and bacteria overgrowth in the colon.

## CATHELICIDIN AND CANCER

Although studies have demonstrated that LL-37 could promote tumorigenesis in some cancers including lung and breast cancers as well as epithelial ovarian cancer<sup>[32-34]</sup>. Other reports have shown that LL-37 may induce cell death in many tissues. In human airway epithelial cells, LL-37 has been shown to result in apoptotic TUNEL positive cells in a caspases-dependent manner<sup>[35]</sup>. Analogue of LL-37 could induce the caspase-independent apoptosis in an oral squamous cell line SAS-H1 but not normal cells<sup>[36]</sup>. The anti-tumorigenic effect of LL-37 is dependent on its ability to induce DNA break and mitochondrial damage in Jurkat T leukemia and A549 cells which are independent of caspase activation<sup>[37]</sup>. It is likely that low tissue expression of LL-37 could promote tumor formation. Indeed downregulation of LL-37 in cancer tissues has also been reported in the GI tract. In normal gastric mucosa, LL-37 is expressed in surface epithelial cells and chief cells as well as parietal cells in the fundic glands. Immunochemical staining of LL-37 has revealed that the expression of LL-37 is down-regulated in gastric hyperplastic polyps, tubular adenomas, and adenocarcinomas<sup>[12]</sup>. After *H. pylori* infection, LL-37 is markedly up-regulated in the epithelium and gastric secretions. Such upregulation could not be detected in patients with *H. pylori*-independent gastric inflammation. Moreover, a higher level of LL-37 expression has been demonstrated in wild-type *H. pylori* infection of cultured gastric epithelial cells and this higher production of LL-37 requires an intact type IV secretion system<sup>[4,12]</sup>. Therefore, it is indicated that expression of LL-37 may be in a tissue- and disease-specific manner.

Our recent study shows that LL-37 may function as a putative tumor-suppressing gene in gastric carcinogenesis. We found that exogenous LL-37 inhibits proliferation and induces G<sub>0</sub>/G<sub>1</sub>-phase cell cycle arrest through a defined signal pathway in gastric cancer cells (Figure 1). Furthermore depletion of endogenous LL-37 stimulates gastric cancer cell DNA synthesis suggesting that the

**Table 1** Possible functional effects and mechanisms of action of cathelicidins in different gastrointestinal disorders

| Type of GI disorders | Functional effects   | Mechanisms   | Ref.       |
|----------------------|--|--|------------|
| Ulcer                | Increases of cell proliferation, re-epithelialization and angiogenesis                             | Activation of growth factors and their receptors   | [11,13-17] |
| Inflammation         | Decrease of pathogenic microbes, inflammatory cytokines and apoptosis; increase of mucus secretion | Activation of MAP kinase, formyl peptide receptor and mucin genes; electrostatic interaction on microbial membrane | [1,5,8,23] |
| Cancer               | Induction of apoptosis and cell cycle arrest   | Release of AIF/EndoG; activation of BMPR and Smads   | [29,30]    |

GI: Gastrointestinal; MAP: Mitogen-activated protein; AIF: Apoptosis-inducing factor; BMPR: Bone morphogenetic protein.

antiproliferative effect of LL-37 occurs at physiological concentrations. The direct anti-cancer action has also been confirmed in a gastric xenograft cancer model in nude mice<sup>[38]</sup>. In the lower GI tract, it has been shown that LL-37 is strongly expressed in the human normal colon mucosa but downregulated in colon cancer tissues. In both settings it is correlated with the number of apoptotic cells in colonic mucosa. To this end, the pro-apoptotic activity of LL-37 is confirmed in colon cancer cells in which the peptide activates a GPCR-p53-Bax/Bak/Bcl-2 signaling cascade that triggers off the AIF/EndoG-mediated apoptosis in colon cancer cells<sup>[39]</sup>. All these findings suggest that cathelicidin could be a tumor suppressor gene in the stomach and colon. Supplementation of which would have a great potential as a therapeutic agent for gastric and colon cancers.

## PERSPECTIVES AND CONCLUSION

The host defense peptide cathelicidin is highly expressed in the GI mucosa. This peptide and its recombinant protein in a deliverable preparation represent an appealing option for the treatment of inflammation and cancer and also promotion of mucosal repair in the GI tract (Table 1). This is especially true for those diseases associated with bacteria including gastritis and UC. Depletion of cathelicidin by unknown epigenetic mechanisms in the gastric and colonic tissues could be one of the causative factors in the promotion of inflammation and carcinogenesis in both organs. Supplementation with this host defense peptide orally through an effective delivery system seems to be a promising approach to treat different disorders in the GI tract.

### Abstract

Barrett's esophagus (BE) is characterized by intestinal metaplasia with the differentiated epithelium replaced by another type of epithelium morphologically similar to normal intestinal epithelium. The metaplasia is preceded by bile and acid reflux into the esophagus. BE is a premalignant condition associated with increased risk of esophageal cancer, especially esophageal adenocarcinoma. The Caudal-related homeodomain transcription factors Caudal-related homeodomain transcription factor CDX1 and CDX2 are expressed exclusively in the small and large intestine, playing important roles in proliferation and differentiation of intestinal epithelial cells. Ectopic expression of CDX1 and CDX2 occurs in BE. The apical sodium-dependent bile acid transporter (ASBT) is expressed primarily in terminal ileum where it is a key factor for intestinal reabsorption of bile salts. In addition to upregulation of CDX1 and CDX2, ASBT expression is up-regulated in BE. Furthermore, both CDX1/CDX2 and ASBT expressions are down-regulated in high-grade esophageal dysplasia. The alteration of the above-mentioned factors calls for attention: what is the relationship between CDXs and ASBT aberrant

expression in BE? In this commentary, we discuss this issue on basis of the recent study done by Ma *et al*.

**Key words:** Esophagus; Intestinal metaplasia; Caudal-related homeodomain transcription factors; Apical sodium-dependent bile acid transporter; Aberrant expression

**Core tip:** Aberrant co-expression of Caudal-related homeodomain transcription factors (CDXs) and apical sodium-dependent bile acid transporter (ASBT) in the epithelium of Barrett's esophagus (BE) indicates association among these factors. Acid and bile reflux induce CDXs gene expression and can lead to formation of BE. CDX-mediated promoter activation can lead to aberrant expression of ASBT. The BE phenotype may be better than squamous epithelium to protect against refluxed acid and bile. On the other hand the BE phenotype is associated with increased risk of esophageal adenocarcinoma (EAC). Furthermore, the decreased expressions of CDXs and ASBT in high-grade esophageal dysplasia indicate that CDXs and ASBT are inhibitory factors to the progression of EAC.

### COMMENTARY ON HOT TOPICS

Recently, an interesting study by Ma *et al*<sup>[1]</sup> demonstrated that short interfering RNA-mediated knockdown of Caudal-related homeodomain transcription factors (CDXs) resulted in reduced apical sodium-dependent bile acid transporter (ASBT) mRNA expression in intestinal cells.

CDXs strongly induced activity of the ASBT promoter of esophageal and intestinal cells. Association with ASBT expression was found for CDX1, CDX2 and hepatocyte nuclear factor-1 $\alpha$  in Barrett's esophagus (BE) biopsies. Ma *et al*<sup>[1]</sup> concluded that CDX1 and CDX2 activate the human ASBT promoter by transcription. For the first time ASBT is added to the list of genes regulated by CDXs. We strongly recommend this paper to the readers.

BE is a clinically important disease. The human esophagus is lined by a multilayered squamous epithelium which withstands the potential damage from rapidly propelling food boluses through the esophagus and also from intermittent exposure to refluxed contents from the stomach. However, the esophageal epithelium, usually at the gastroesophageal junction, can be inflamed and injured if the esophageal epithelium chronically and repeatedly is in contact with refluxed bile and acid. This can result in intestinal metaplasia where the esophageal squamous epithelium is replaced by intestinal-type epithelium, which is the key feature of BE<sup>[2]</sup>. BE is characterized not only by the morphological intestinalization but also by changes in gene expression patterns. The intestinal specific transcription factors CDX1 and CDX2 and other intestinal proteins such as villin, sucrase isomaltase, and acidic mucins/MUC2 can be detected in human BE tissue<sup>[3]</sup>. BE is an important risk factor for esophageal adenocarcinoma (EAC)<sup>[4,5]</sup>. The molecular mechanisms related to BE are not yet fully understood. Currently, it is believed that the BE cell emerges from (1) the esophageal squamous epithelium; (2) the distal esophagus submucosal gland epithelium; (3) the proximally-migrating gastric cardia epithelium; or from (4) infiltrating bone marrow stem cells<sup>[6,7]</sup>. Hence, the mechanism of BE formation is not well understood.

ASBT is a 48-kDa transmembrane protein. At the apical membrane of ileal enterocytes, ASBT is the chief mediator of active sodium-dependent intestinal bile acid absorption<sup>[8]</sup>. The roles of ASBT on bile acid reabsorption, regulation of *ASBT* gene expression and its association with some diseases have been reviewed in detail<sup>[8-11]</sup>. ASBT is mainly expressed in the terminal ileum but is also expressed in renal tubule cells, cholangiocytes, and the gallbladder<sup>[10]</sup>. It was recently shown that the expression of ASBT is elevated in esophageal epithelial cells from BE patients whereas ASBT expression was decreased in esophageal adenocarcinoma at both mRNA and protein levels<sup>[12]</sup>. CDX1 and CDX2 are expressed exclusively in the small and large intestine, playing important roles in proliferation and differentiation of intestinal epithelial cells. The role of *CDX* genes in the gut has recently been reviewed<sup>[13]</sup>. In adults, CDX1 is expressed primarily in intestinal crypts<sup>[14,15]</sup> whereas CDX2 is expressed in the paracaecal region of the intestine. Furthermore, CDX2 is expressed relatively more in the villi than in the crypts<sup>[14]</sup>. CDX1 and CDX2 are not expressed in the normal human esophagus<sup>[16]</sup>. However, CDX1 and CDX2 levels are elevated in the epithelium of BE<sup>[16,17]</sup>. CDX2 expression has been demonstrated in all biopsy

specimens from BE without and with dysplasia, and from BE-associated adenocarcinomas<sup>[18,19]</sup>. Expression of CDX1 mRNA and protein was found in biopsy specimens from patients with BE but not from epithelium of normal esophagus<sup>[20]</sup>. Furthermore, similar to expression of ASBT, CDX2 expression decreased esophageal metaplasia progressed into adenocarcinoma<sup>[21,22]</sup>.

The aberrant co-expression of CDXs and ASBT in the BE epithelium makes us ask what is the relationship between CDXs and ASBT, how do these factors relate to BE, BE with dysplasia and BE-associated adenocarcinomas. In order to study the relationship between CDXs and ASBT, Ma *et al*<sup>[1]</sup> conducted a test series to (1) study whether endogenous human ASBT mRNA levels are regulated by CDX1 and CDX2; (2) study the possible direct role for CDX1 and CDX2 in the regulation of the ASBT promoter; (3) identify putative CDX response elements (CDXREs) within the ASBT; (4) study whether the proximal promoter region containing the predicted CDXREs mediate the CDX-dependent activation; (5) study the potential *in vitro* interaction between CDX1 and CDX2 with their predicted binding motifs within the ASBT promoter; and to (6) confirm the interaction between CDX1 and CDX2 with the ASBT promoter also within living cells. Ma *et al*<sup>[1]</sup> found in human esophageal and intestine-derived cell lines that the human ASBT promoter is a direct target for transcriptional activation by the transcription factors CDX1 and CDX2. In other words, ASBT expression is regulated by CDXs. Therefore, their study adds a new piece of knowledge to the already known complexity of transcriptional regulation of *ASBT* gene expression. Furthermore, Ma *et al*<sup>[1]</sup> discover close association of CDX and ASBT expression levels in human BE tissue. This indicate that CDX-mediated ASBT promoter activation can lead to aberrant esophageal expression of the bile acid uptake system ASBT and consequently to an increase in epithelial bile acid uptake activity by the BE mucosa.

It is well known that BE is closely associated with gastro-esophageal reflux disease (GERD). In animal models, GERD caused increased *Cdx2* expression in cells of the basal layer of esophageal squamous epithelium. The increased *Cdx2* expression preceded the development of intestinal metaplasia<sup>[23,24]</sup>. In esophageal biopsy specimens from patients with BE, Vallböhmer *et al*<sup>[17]</sup> found high levels of CDX2 mRNA in specialized intestinal metaplasia. A recent study done by Kazumori *et al*<sup>[25]</sup> shows that *Cdx1* is over-expressed in esophageal metaplastic tissue and that bile acids increase promoter activity in cultured esophageal epithelial cells. This in turn appears to induce production of *Cdx2* sufficient to cause intestinal metaplasia. It has been proposed that bile acids in refluxed contents cause tight junctions in squamous cells to break, allowing the bile acids to leak into the basal layer, resulting in cell transdifferentiation<sup>[26]</sup>.

From the above-mentioned studies it is evident that acid reflux and bile reflux contribute to increased CDX expression levels. The induction of *CDXs* genes precedes

the morphologic changes in BE. The BE phenotype may be better than squamous epithelium to protect against exposure to refluxed acid and bile. Furthermore, CDX-mediated promoter activation leads to aberrant expression of ASBT, resulting in increased epithelial bile acid uptake by the BE mucosa. However, the BE phenotype has 30-125 times increased risk of EAC compared to that of the general population<sup>[27]</sup>. Furthermore, although CDXs expression can be detected in well or moderately well differentiated EAC, expression of CDXs is decreased and may even be undetectable in poorly differentiated EAC<sup>[28,29]</sup>. Ma *et al*<sup>[11]</sup> found that ASBT like CDXs decrease its expression in high-grade esophageal dysplasia. All together this suggests that CDXs and ASBT expression have an inhibitory role for the progression of EAC. However, the exact mechanism about the effect of CDX1, CDX2 and ASBT on BE and BE-associated esophageal dysplasia is not well understood yet and need further study.

In summary, aberrant co-expression of CDXs and ASBT in BE epithelium stimulates further interest into learning more about the relationship between CDXs and ASBT and how they relate to BE. Based on reviewing the study by Ma *et al*<sup>[11]</sup> and other relevant literature, it is anticipated that ASBT gene expression is regulated by CDXs. Acid and bile reflux as well as inflammation induce CDXs gene expression preceding BE. CDX-mediated promoter activation can lead to aberrant expression of ASBT. The BE phenotype may be better than squamous epithelium to protect against refluxed acid and bile. On the other hand, BE phenotype is associated with increased risk of EAC. Furthermore, CDXs and ASBT expressions decrease in high-grade esophageal dysplasia. This indicates that CDXs and ASBT expression may be inhibitory factors for progression of EAC. Further research is needed for understanding the exact mechanism and effects of CDX1, CDX2 and ASBT on BE and BE-associated esophageal dysplasia.

### Abstract

We aimed to examine the major causes of isolated chronic hypertransaminasemia in asymptomatic children and develop a comprehensive diagnostic flow diagram. A MEDLINE search inclusive of publications throughout August 2012 was performed. We found only a small number of publications that had comprehensively investigated this topic. Consequently, it was difficult to construct a diagnostic flowchart similar to those already available for adults. In children, a "re-testing panel" prescription, including gamma-glutamyl transpeptidase and creatine kinase in addition to aminotransferases, is considered a reasonable approach for proficiently confirming the persistence of the abnormality, ruling out cholestatic hepatopathies and myopathies, and guiding the subsequent diagnostic steps. If re-evaluation of physical and historical findings suggests specific etiologies, then these should be evaluated in the initial enzyme retesting panel. A simple multi-step diagnostic algorithm incorporating a large number of possible pediatric scenarios, in addition to the few common to adults, is available. Accurately classifying a child with asymptomatic persistent hypertransaminas-

emia may be a difficult task, but the results are critical for preventing the progression of an underlying, possibly occult, condition later in childhood or during transition. Given the high benefit/cost ratio of preventing hepatic deterioration, no effort should be spared in diagnosing and properly treating each case of persistent hypertransaminasemia in pediatric patients.

Vajro P, Maddaluno S, Veropalumbo C. Persistent hypertransaminasemia in asymptomatic children: A stepwise approach. *World J Gastroenterol* 2013; 19(18): 2740-2751 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i18/2740.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i18.2740>

### INTRODUCTION

The measurement of serum transaminase levels has become part of the routine biochemical evaluation that takes place before surgery or for the investigation of pathologies not necessarily related to liver injury in many countries. An investigation of unexpected hypertransaminasemia is important for differentiating muscular and hepatic disease; to institute timely and specific treatment for progressive, but still asymptomatic, treatable liver conditions [*e.g.*, Wilson's disease, autoimmune hepatitis (AIH), and non-alcoholic fatty liver disease (NAFLD)]; to furnish genetic counseling for hereditary disorders; and/or to setup appropriate preventive measures (*e.g.*, avoidance of viral hepatitis transmission). Moreover, prevention of possible hepatic deterioration has a high benefit/cost ratio by avoiding the need for eventual liver transplantation<sup>[1]</sup>.

Currently, the most frequent cause of hypertransaminasemia in both adults and children is obesity, although obesity-related liver disease is still sometimes erroneously

considered cryptogenic because of a poor perception of obesity among medical practitioners<sup>[2,4]</sup>. In adults, the causes of isolated hypertransaminasemia other than obesity-related liver disease are limited to viral hepatitis, toxic damage, autoimmune hepatobiliary diseases, celiac disease, Wilson's disease, and hereditary hemochromatosis<sup>[5,6]</sup>, whose diagnostic work-up is well established<sup>[4,6-11]</sup>. The problem is more complex in children, in whom individually rare genetic/metabolic conditions collectively constitute 20%-30% of liver diseases<sup>[12,13]</sup>. Therefore, persistent hypertransaminasemia in a child should alert the physician to the possibility of an underlying hepatic or multisystem metabolic disorder and prompt a referral to a specialized center for diagnostic evaluation. However, despite extensive investigation, the etiology of some cases may have to be defined as truly unknown (cryptogenic)<sup>[12,14]</sup>.

There are only a few reports examining the possible causes of isolated chronic hypertransaminasemia in asymptomatic pediatric populations<sup>[12,14-16]</sup>, and often these studies are biased by flawed inclusion and exclusion criteria, and/or an inadequate diagnostic work-up. Consequently, there is no diagnostic algorithm for the differential diagnosis of unexpected chronic hypertransaminasemia in pediatric patients.

The aim of this report is to develop a comprehensive diagnostic algorithm that includes many of the frequent causes of isolated asymptomatic hypertransaminasemia in children and adolescents. We examined current adult guidelines and expert opinions, and then performed a MEDLINE search inclusive of publications throughout August 2012 using the key words: transaminase, aminotransferase, hypertransaminasemia, liver disease, and children. We also evaluated reports from specialized tertiary pediatric hepatology centers. A secondary aim was to provide a basis for future studies on the cost/benefit ratio of diagnostic assessment procedures.

## TRANSAMINASES: BACKGROUND ON ORIGINS, LEVELS, AND THRESHOLD LEVELS

Aminotransferases are normally present in circulation at low levels. They are intracellular enzymes produced principally by hepatocytes, and their increase in serum is therefore indicative of liver cell injury. However, aspartate aminotransferase (AST) is also found in cardiac and skeletal muscles, the kidneys, brain, pancreas, and lungs, and in erythrocytes, in decreasing order of concentration. Additionally, alanine aminotransferase (ALT) is present in skeletal muscle and kidneys, but at low concentrations, and its increase in the circulation is more specific for liver damage than AST. Aminotransferase serum levels depend not only on the tissue of origin, but also on the enzyme half-life, which is longer for ALT than AST. Thus, in diseases such as muscular dystrophy, patients can have AST and ALT serum values that are elevated to the same degree, instead of the expected prevalent elevation of AST<sup>[17]</sup>.

In clinical practice, normal parameter values are within 2 standard deviations of the mean value obtained in healthy individuals. This implies that 5% of the results of healthy subjects fall outside this range. While transaminase reference intervals for adults have recently been revised<sup>[18,19]</sup>, this has not occurred for children. England *et al*<sup>[20]</sup> recently proposed ALT centiles stratified by sex and age in a healthy European population. They propose an ALT upper limit of normal of 60 IU/L in boys and 55 IU/L in girls during the first 18 mo of life. The range changes to 40 IU/L in boys and 35 IU/L in girls after the age of 18 mo. The Screening ALT for Elevation in Today's Youth (SAFETY) study conducted on a population of North American patients aged between 12 and 17 years shows that the upper limit of normal used by most laboratories for ALT is too high to detect chronic liver disease and that less than half of North American hospitals utilize gender-specific values. In that study, the ALT thresholds in use had a low sensitivity for the detection of chronic liver damage (30%-40%). Using the National Health and Nutrition Examination Survey (NHANES) ALT threshold of 25.8 IU/L for boys and 22.1 IU/L for girls, the sensitivity improved to 70%-80%, while the specificity was only reduced from approximately 90% to approximately 80%<sup>[21]</sup>.

### Clinical recommendation

In the pediatric population, there is no established reference range of ALT and AST. ALT thresholds currently in use have a low sensitivity for the detection of chronic liver damage. In teenagers, the biologically-determined and gender-specific ALT threshold of 25.8 U/L for boys and 22.1 U/L for girls established by NHANES increases this sensitivity, with only a modest specificity reduction.

## APPROACH TO ASYMPTOMATIC HYPERTRANSAMINASEMIA

Table 1 summarizes the most frequent causes of persistently-elevated transaminase levels in asymptomatic children, schematically classified under the categories of viral, autoimmune, metabolic, and other types of hepatobiliary diseases or extrahepatic causes of hypertransaminasemia.

A detailed evaluation of medical and family history and an accurate clinical examination are crucial in determining the likely etiology of hypertransaminasemia, as they may indicate towards possible muscle or liver conditions.

### Initial step: The retesting panel

A stepwise approach contemplates repeating the tests to confirm the results<sup>[5,9,10]</sup>. In adults, timing of retesting is not firmly established because it has usually been empirically guided by the degree of transaminase alterations found {mild [ $< 5$  times upper limit of normal ( $\times$  ULN)]; moderate ( $5-10 \times$  ULN); marked ( $> 10 \times$  ULN)}.

In pediatric patients, information about gamma-glutamyl transferase (GGT) rather than alkaline phosphatase values might help to determine whether the liver injury

**Table 1 Main causes of asymptomatic hypertransaminasemia in children**

| Hepatic origin  | Extrahepatic origin   |
|---|---|
| Obesity (non-alcoholic fatty liver disease)   | Duchenne/Becker muscular dystrophy (prevalence: 1:4700)                               |
| Viral infections (major and minor hepatotropic viruses)                                   | Other myopathies ( <i>e.g.</i> , caveolinopathies; prevalence: 1:14000 to 1:120000)   |
| Autoimmune liver disease (prevalence: 1:200000)   | Myocardiopathies  |
| Celiac disease and inflammatory bowel disease   | Nephropathies   |
| Wilson's disease (prevalence: 1:30000)  | Hemolytic disorders   |
| Cystic fibrosis (prevalence: 1:2500) and Shwachman-Diamond syndrome (prevalence: 1:50000) | Macro - AST (prevalence: 30% of children with isolated aspartate aminotransferasemia) |
| Alpha1 antitrypsin deficiency (prevalence: 1:7000)  |   |
| Other genetic and metabolic diseases <sup>1</sup>   |   |
| Toxic: Drugs and alcohol  |   |
| Cryptogenic hypertransaminasemia  |   |

<sup>1</sup>Refer to Table 3. AST: Aspartate aminotransferase.

is predominantly hepatocellular or cholestatic<sup>[5]</sup>. Creatine phosphokinase (CPK) should also be evaluated to rule out occult muscle disease<sup>[22]</sup>.

As in adults<sup>[5,10,23]</sup>, in many asymptomatic children, abnormal values can show normal values when retested<sup>[12,14-16,23]</sup>. The reported percentage of patients who normalize aminotransferase serum values within 6 mo from the first detection of abnormality ranges from 26% to 73.6%<sup>[12,14-16]</sup>. A fluctuating pattern (transient/self-limiting or intermittent) is frequently observed at all ages, and more than one retesting may be warranted even for a mild increase of transaminases. In areas with a high prevalence of hepatitis B (HBV) and C (HCV) virus infection and in high-risk populations, it is advisable to request viral markers at the time of repeat testing to accelerate the screening protocol<sup>[9,10]</sup>. Recently, Senadhi<sup>[24]</sup> recommended that HBV and HCV screening is warranted in all asymptomatic patients with mild transaminase elevations.

In selected patients who participate in strenuous sports, liver tests should be repeated after at least one week without exercise, especially if hypertransaminasemia was associated with high CPK or with elevation of other enzymes of muscle origin<sup>[25]</sup>. If high CPK and hypertransaminasemia are confirmed, it is mandatory to exclude muscular diseases, which are often clinically asymptomatic during the first 5-6 years of life and can be recognized only after a detailed and oriented neurologic examination<sup>[22]</sup>. In addition to the well-known muscular dystrophies, myocyte injury, necrosis induced by drugs or toxins, and increased exercise are possible causes of high CPK and hypertransaminasemia. Additionally, some mitochondrial, endocrine and metabolic myopathies, and gluten enteropathy are also causes of high CPK and hypertransaminasemia. A serum elevation of CPK ranging from 450 to 5000 U/L (normal upper limit: 150 U/L) accompanying isolated asymptomatic hypertransamina-

semia can also be a marker of a caveolinopathy, a group of newly described and still poorly understood muscle diseases that affect the limb-girdle, distal muscles, and heart. A diagnosis may be particularly challenging in pediatric patients that are only mildly symptomatic<sup>[26]</sup>.

### First, second, and third line investigations

The evaluation of patients with confirmed hypertransaminasemia should include first (and eventually second and third) line investigations (Table 2). If the patient's history or physical examination suggests a particular disease, selected first-line investigations should already be part of the retesting panel. However, some authors suggest that first-line exams for hepatocellular causes of liver disease should be performed without the need to confirm hypertransaminasemia in patients with increased serum levels of ALT > 3-5 × ULN<sup>[27]</sup>. Historically, a hypertransaminasemia duration of approximately 6 mo has been arbitrarily used to determine chronic liver disease. However, it is unwise to wait for 6 mo before investigating a possible cause of liver damage, as some hepatopathies, such as autoimmune liver disease or Wilson's disease, can become rapidly life-threatening without appropriate treatment<sup>[28]</sup>.

In the case of protracted isolated AST elevation, the possibility of macro-AST should be investigated by polyethylene glycol and/or electrophoresis testing. Macro-AST is a condition characterized by the presence in serum of a macromolecular complex formed by association with other plasma components [*e.g.*, immunoglobulin G (IgG)] or by self-polymerization. Due to their large size, macro-AST components cannot be filtered by renal glomeruli and are retained in the plasma. The condition is benign, but may cause diagnostic uncertainty and lead to useless, invasive, expensive, and time-consuming testing<sup>[29]</sup>.

### Clinical recommendation

Aminotransferase levels should be retested upon finding hypertransaminasemia in asymptomatic patients. At this time, the levels of CPK (for muscular disease) and GGT (for biliary involvement) should also be evaluated. An accurate clinical history and physical examination are of paramount importance for guiding an appropriate investigation and avoiding expensive and unnecessary tests.

## MOST COMMON LIVER DISEASES

### Non-alcoholic fatty liver disease

NAFLD is the most common cause of hypertransaminasemia in children and adolescents<sup>[12,14,16,21]</sup>. In clinical practice, NAFLD is usually suspected by the finding of hypertransaminasemia and ultrasonographic fatty liver in an obese child<sup>[30,31]</sup>. Although the ALT serum level is a useful diagnostic tool, it is not a sensitive marker of NAFLD. It is common to observe the entire histological spectrum of NAFLD in patients with normal ALT levels<sup>[22,32]</sup>. The evaluation of both AST and ALT values is important because an increased AST/ALT ratio has been reported to reflect a progressive and more serious condition [fibrotic

**Table 2 Retesting panel; first, second, and third line investigations in children with asymptomatic mild hypertransaminasemia**

| Retesting panel <sup>1</sup> | First line panel   |   | Second and third line panels  |
|------------------------------|--|---|---|
|                              | Liver function tests   | Etiology tests  |   |
| ALT                          | Conjugated and unconjugated bilirubin  | Viral markers (HAV, HBV, HCV)                           | Urinary copper, molecular ATP B7 analysis   |
| AST                          | Protein electrophoresis  | Minor hepatotropic viruses serology                     | HCV RNA, HBV DNA  |
| CPK                          | Serum albumin  | ( <i>e.g.</i> , EBV, CMV)                               | Genetic and metabolic enlarged screening <sup>2</sup> (“non-alcoholic fatty liver disease bin”) |
| GGT                          | Prothrombin time and partial thromboplastin time                               | Ceruloplasmin, serum copper                             | Sweat test  |
|                              | Blood cell count   | ANA, SMA, LKM, LCI, anti-SLA, total IgG                 | Fecal elastase, steatocrit  |
|                              | Hepatic ultrasonography  | Serum $\alpha$ 1 antitrypsin                            | Other hepatic imaging techniques (MRI, ERCP, CT, <i>etc.</i> )                                  |
|                              | If only AST elevation is confirmed: PEG test and electrophoresis for macro-AST | EMA, tTgasi IgA, deamidated AGA IgA (< 2 yr), total IgA | Liver biopsy <sup>3</sup><br>Jejunal biopsy (after celiac disease serology)                     |

<sup>1</sup>After at least one week off from exercise; <sup>2</sup>Genetic and metabolic enlarged screening: blood gases, lactic acid, serum ammonium concentrations, blood and urinary amino acids, urinary reducing substances, urinary organic acids, transferrin isoforms, screening test for congenital disorders of glycosylation,  $\alpha$ 1 antitrypsin phenotype; <sup>3</sup>Modified from the reference of 28. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; PEG: Polyethylene glycol; CPK: Creatine kinase; GGT: Gamma-glutamyl transferase; HAV: Hepatitis A virus; HBV: Hepatitis B virus; HCV: Hepatitis C virus; EBV: Epstein-Barr virus; CMV: Cytomegalovirus; ANA: Antinuclear antibodies; SMA: Smooth muscle antibodies; LKM: Anti-microsomal antibodies; LCI: Anti-liver cytosol antibodies type 1; SLA: Soluble liver antigen; IgG: Immunoglobulin G; EMA: Anti-endomysial antibodies; tTgasi: Anti-tissue transglutaminase antibodies; AGA: Anti-gliadin antibodies; IgA: Immunoglobulin A; ATP B7: ATP binding protein 7; MRI: Magnetic resonance imaging; ERCP: Endoscopic retrograde cholangiopancreatography; CT: Computed tomography.

**Table 3 Fatty liver disease; possible causes in likely asymptomatic children and adolescents**

| General or systemic                   | Genetic-metabolic causes                     | Drugs/chemicals               |

|                                       | Turner syndrome                              |                               |

Modified from the references of 30 and 38. HIV: Human immunodeficiency virus.

non-alcoholic steatohepatitis (NASH)]<sup>[33]</sup>.

Due to the worldwide obesity epidemic, obesity may be erroneously accepted as a normal condition even in the presence of abnormal liver function tests<sup>[2]</sup>. Conversely, in the presence of obesity, all other conditions associated with abnormal transaminase levels, such as celiac disease<sup>[34,35]</sup>, Wilson’s disease<sup>[36]</sup>, autoimmune hepatitis<sup>[37]</sup>, or muscular diseases<sup>[22]</sup>, must be investigated and excluded. In many of these diseases, prompt treatment will avoid irreversible disease progression<sup>[38]</sup> (Table 3).

Abdominal ultrasound and liver function tests should be performed as a first step in the diagnosis of possible NAFLD in children<sup>[39]</sup>. Ultrasonography, however, detects fat levels above 30% only. Waist circumference is a valid surrogate marker of central obesity, which is closely correlated with liver involvement<sup>[40]</sup>. When pediatric NAFLD is suspected, other liver diseases should be excluded

based on an age-driven algorithm<sup>[39]</sup>. In obese children and adolescents with disordered breathing during sleep, sleep apnea syndrome should be viewed as a risk factor for NAFLD. Interestingly, weight loss, avoidance of a sedentary life, and effective treatment of sleep apnea syndromes resulted in a significant improvement of liver enzyme levels<sup>[41,42]</sup>.

**Clinical recommendation:** NAFLD and NASH are diagnoses of exclusion even in obese children with hypertransaminasemia. Other fatty liver causing diseases should be investigated based on the patient’s age and clinical features.

**Viral infections**

Serological markers of hepatitis viruses are part of the first-line etiology investigation panel (Table 2). A positive

history of blood or blood-derivative transfusion, tattooing, ingestion of potentially-contaminated food, and the ethno-geographic origin of the patients give a clue as to a possible infectious etiology. Although immigration and international adoption from endemic areas are well-recognized risk factors, hepatitis B shows an emerging presentation of subclinical chronic hepatitis B in children<sup>[43]</sup>.

In countries where universal vaccination against HBV has been introduced, a significantly-reduced rate of HBV infection in children and mother-to-infant transmission has been observed. However, international adoption and immigration maintain an ample reservoir of HBV infection. Although significantly less infectious than HBV, HCV infection remains a widespread problem in the absence of an effective vaccine. In Western countries, perinatal transmission is currently the primary mode of HCV spread in children, which accounts for approximately 65% of cases<sup>[44]</sup>. Although hypertransaminasemia may suggest HCV infection, adult<sup>[45]</sup> and pediatric HCV carriers<sup>[46]</sup> may have normal or fluctuating aminotransferase levels even in the presence of serious liver damage.

Among the conditions falling within the category of adult cryptogenic hypertransaminasemia is a new entity called “occult” HCV infection. Said entity is characterized by fluctuating serum levels of HCV RNA, while the virus genome and its replicative intermediate RNA-negative strand are detectable in the liver and in peripheral blood mononuclear cells with or without antibodies to HCV<sup>[47]</sup>. Similarly, “occult” HBV infection has been recognized in patients with cryptogenic hepatitis B surface antigen (HBsAg)-negative chronic liver disease<sup>[48]</sup>. Intrahepatic replicative activity (HBV covalently closed circular DNA and pregenomic RNA) has recently been described in adults with occult hepatitis B infection. HBV occult infection seems to be relatively frequent in immunized children born to HBsAg-positive mothers. HBsAg negativity is not sufficient for excluding the presence of HBV DNA. These findings emphasize the importance of considering occult HBV infection in hypo-endemic areas<sup>[49]</sup>.

In pediatric patients, hepatitis A virus infection may be followed by up to 1 year intermittent hypertransaminasemia due to relapsing viremia, which does not evolve to chronic liver damage<sup>[50]</sup>. Other hepatotropic viruses are a frequent cause of liver disease. Epstein-Barr virus and/or cytomegalovirus should be excluded in patients with a history of fever, lymphadenopathy (mainly latero-cervical), pharyngitis, asthenia, and/or hepatosplenomegaly. In patients with paucisymptomatic immunodeficiency, coxsackievirus and adenovirus may be the cause of liver enzyme alteration. Gastrointestinal infection by rotavirus can be accompanied by self-limiting hepatic and non-hepatic transaminase elevation in 20% of infected patients<sup>[51]</sup>.

Currently minor, rather than major, hepatotropic viruses are a common cause of hypertransaminasemia in children in developed countries<sup>[12,15,16]</sup>.

**Clinical recommendation:** Viral serological markers are part of the first-line investigation panel.

### Toxic causes

An accurate medical history is crucial in determining the possible role of toxin-induced hepatotoxicity in children with hypertransaminasemia<sup>[52]</sup>. In adults, diagnostic scores have been proposed and evaluated to define the association between drugs and liver disease<sup>[53,54]</sup>. Alcohol abuse can induce liver disease and hypertransaminasemia even in childhood, especially in adolescents<sup>[6]</sup>. It has been suggested that elevated serum GGT levels, and/or an AST/ALT ratio > 1, and/or an increase in mean corpuscular volume may help in identifying excessive drinking<sup>[55]</sup>. Carbohydrate deficient transferrin is another tool for identifying unhealthy occult drinking<sup>[56]</sup>. If medication or alcohol are suspected causes of hypertransaminasemia in an adolescent, aminotransferases should be retested after 6-8 wk of controlled or monitored abstinence<sup>[57]</sup>. In addition to prescribed or over-the-counter medications and herbal remedies, illegal drugs or substances of abuse should be considered in differential diagnoses and be carefully investigated<sup>[58,59]</sup>.

### Autoimmune liver disease

AIH is a progressive inflammatory liver disease without a known etiology, and is characterized histologically by interface hepatitis and serologically by high levels of transaminases, IgG, and positive autoantibodies<sup>[60]</sup>. The exact prevalence of autoimmune hepatitis is unknown, but it is approximately one in 200000 in the general population of the United States<sup>[61]</sup>. Sometimes, the histology of autoimmune hepatitis is associated with bile duct injury-determining overlap syndrome or autoimmune sclerosing cholangitis (ASC); this condition is different from primary sclerosing cholangitis, which is characterized by inflammation and fibrosis in the intrahepatic and/or extrahepatic bile load in the absence of interface hepatitis<sup>[62,63]</sup>. It is important to perform a cholangiography in all children with the histological features of autoimmune hepatitis, as ASC is as prevalent as AIH in childhood, and thus only cholangiography can differentiate between these conditions<sup>[64]</sup>. There are two types of AIH classified according to antibody profile: type 1 [anti-nuclear antibodies and anti-smooth muscle antibodies (SMA)] and type 2 [anti-liver kidney microsomal antibody (LKM1); and/or antibodies to liver cytosol type 1 (anti-LC1)]<sup>[65]</sup>. Anti-soluble liver antigen (anti-SLA) antibodies can be positive in otherwise autoAb-negative patients. These antibodies cannot be detected by immunofluorescence, and require enzyme-linked immunosorbent assay and immunoassays for identification. Type 2 may tend to be more severe and prevalent in children, adolescents, and young adults than in the older population<sup>[60]</sup>. The absence of autoantibodies in a child with hypertransaminasemia does not exclude the diagnosis of autoimmune hepatitis. In fact, seronegative but empirically steroid-responsive autoimmune hepatitis has been reported<sup>[66-68]</sup>. Conversely, the increase in serum gamma-globulins is not universal in AIH. As for Wilson's disease, the diagnosis of autoimmune hepatitis may be difficult because it is not based on specific markers. Consequently, a scoring system

has been devised<sup>[69,70]</sup> that gives positive predictive values for females, the presence of other autoimmune diseases, hypergammaglobulinemia, and positivity for ANA, SMA, LKM1, LC1 and ASLA. It also gives negative scores for viral markers and a positive history for drugs and alcohol use. A simpler score based on only four items<sup>[71]</sup> has not yet been fully validated in children. Primary biliary cirrhosis is not observed during childhood, although very rare cases of anti-mitochondrial autoantibody positivity have been reported<sup>[72]</sup>.

AIH (and ASC) may present with only hypertransaminasemia, which can occur in children with apparent good health. It should therefore be investigated with appropriate examinations; if left untreated, cirrhosis may develop.

**Clinical recommendation:** Autoimmune hepatitis should be rapidly identified in order to administer prompt therapy and avoid cirrhotic evolution. Hypertransaminasemia and hypergammaglobulinemia may be the only findings of seronegative autoimmune hepatitis. It is important to perform a cholangiography in all children with the histological features of autoimmune hepatitis because, in childhood, autoimmune sclerosing cholangitis is as prevalent as autoimmune hepatitis.

### *Celiac disease and hypertransaminasemia*

Celiac disease may be associated with liver involvement in both adults and children. Isolated hypertransaminasemia may be the first manifestation of clinically silent celiac disease<sup>[73,74]</sup>. It is currently controversial<sup>[75]</sup> as to whether, in children less than 2 years old, AGA-IgA and IgG should be tested, because of a diagnostic sensitivity higher than that of anti-endomysium antibodies and anti-transglutaminase antibodies at that age. Selective non-responsiveness to HBV immunization in a hypertransaminasemic child may be a clue to undiagnosed celiac disease<sup>[76]</sup>.

So-called “celiac hepatitis” is the most common hepatopathy in celiac patients and is characterized by a moderate increase of transaminase levels usually associated with minimal and non-specific liver lesions of the lobule and portal tracts. A gluten-free diet generally results in normalization of the liver enzymes and repair of histological damage. Due to high disease prevalence, patients with a known diagnosis of celiac disease and persistent hypertransaminasemia should be tested for other possible causes of liver damage before ascribing liver function test abnormalities to celiac disease. Co-existing causes of hepatopathy have been reported<sup>[77]</sup>. Celiac disease may present as hepatic steatosis in obese children with hypertransaminasemia resistant to weight loss. In such cases, the addition of a gluten-free diet is necessary to resolve their liver abnormalities<sup>[34]</sup>.

Celiac disease can be associated with a variety of autoimmune liver diseases, including AIH, autoimmune cholangitis, and overlap syndromes, with a frequency of AIH peaking at 2.9% in celiac disease children less than 10 years old<sup>[74]</sup>. Autoimmune hepatic involvement can ei-

ther precede or follow the diagnosis of celiac disease. It is necessary to diagnose AIH associated with celiac disease promptly, because it is not responsive to a gluten-free diet alone and requires long-term associated immunosuppressive therapy<sup>[78]</sup>.

### *Wilson's disease and hypertransaminasemia*

The prevalence of Wilson's disease is estimated at one in 30000 in most populations (Table 4). The prevalence is as high as one in 10000 in China, Japan, and Sardinia<sup>[79]</sup>. It may present at any age. Usually, the onset of symptomatic liver disease is at approximately 12 years of age<sup>[80]</sup>. It is only during adolescence or early adult life that patients usually present with complicating neurological and psychiatric manifestations. The most important laboratory diagnostic clues are hypoceruloplasminemia (< 20 mg/dL in 85%-95% cases), increased free serum copper, increased intrahepatic copper (> 250 µg/g dry weight), and increased basal and post-penicillamine challenge urinary copper excretion<sup>[81,82]</sup>. These findings are not specific if considered individually, and several conditions may be responsible for false negative and false positive results. Therefore, a score (the “Ferenci score”), which takes into account the Kayser-Fleischer ring, neuropsychiatric symptoms, the occurrence of Coombs negative hemolytic anemia, increased urinary copper, decreased serum ceruloplasmin, increased copper content of hepatocytes, and the presence of causative mutations, has been devised to distinguish between an unlikely/probable/highly-likely diagnosis of Wilson's disease<sup>[81]</sup>. More recently, a new cut-off value for urinary copper excretion in asymptomatic children with Wilson's disease has been suggested. The new value of 40 µg/24 h replaces the previously-used 100 µg/24 h<sup>[83,84]</sup>. The post-penicillamine challenge urinary copper estimation has been reported to be poorly sensitive in asymptomatic children<sup>[84]</sup>. A molecular diagnosis and/or haplotype analysis of the region surrounding ATP7B on chromosome 13 should be considered in children with enigmatic liver disease, especially those with features of NAFLD<sup>[84,85]</sup>. Wilson's disease-like hypoceruloplasminemic liver disease has been recently described in congenital disorders of glycosylation (CDG) type X<sup>[84,86,87]</sup>. Non-Wilsonian high urinary copper excretion has been reported in pediatric nodular regenerative hyperplasia<sup>[84]</sup>.

**Clinical recommendation:** The criteria adopted for the diagnosis of Wilson's disease are non-specific if considered individually. The Ferenci score will distinguish between unlikely, probable, and highly-likely diagnoses of Wilson's disease. New pediatric cut-off values and the real value of post-penicillamine urinary test in asymptomatic cases need careful consideration.

## **OTHER DISEASES**

Disorders, such as inborn errors of metabolism and/or congenital conditions affecting the liver, are much more

**Table 4 Clinical and laboratory findings for orienting diagnosis of some genetic metabolic liver diseases**

| Clinical/laboratory findings                                 | Possible genetic-metabolic cause             | Prevalence                 | Liver involvement |
|--|--|----------------------------|-------------------|
| Pancreatic failure, hematological disorders                  | Shwachman syndrome                           | 1:50000                    | +++ <sup>1</sup>  |
| Asymptomatic, hemolysis                                      | Wilson's disease                             | 1:30000                    | +++               |
| Previous neonatal cholestasis, hepatomegaly                  | Alpha 1 antitrypsin deficiency               | 1:7000                     | +++               |
| Hypoglycemia, hepatomegaly                                   | Glycogen storage disease (type I, VI and IX) | From 1:100000 to 1:1000000 | +++               |
| Fructose refusal, hepatomegaly                               | Hereditary fructose intolerance              | 1:20000                    | +++               |
| Lethargy, increased serum ammonia levels                     | Urea cycle defects                           | 1:30000 (all disorders)    | ++                |
| Lethargy, increased serum ammonia levels                     | Urea cycle defects                           | 1:30000 (all disorders)    | ++                |
| Chubby face, fatty liver, specific serum amino acids pattern | Citrin deficiency                            | 1:20000 in East Asia       | ++                |
| Failure to thrive, lactic acidosis                           | Mitochondrial diseases                       | 1:8500 (all disorders)     | +                 |
| Failure to thrive, ketoacidosis, hypoglycemia                | Organic acidosis                             | 1:1000 (all disorders)     | +                 |
| Mild coagulopathy, clinical phenotype                        | Congenital disorders of glycosylation        | From 1:10000 to 1:100000   | +                 |
| Short stature, female gender, karyotype                      | Turner syndrome                              | 1:2000                     | +                 |
| Failure to thrive, positive sweat test                       | Cystic fibrosis                              | 1:2500                     | +                 |

<sup>1</sup>First 1-2 yr of life; +: Possible; ++: Frequent; +++: Almost always.

common in pediatric patients than in adults (Table 3). These diseases are rare when considered individually, but represent a large group if considered collectively. It is difficult to establish their incidences; in most cases, they are relatively asymptomatic and may therefore remain undiagnosed<sup>[88]</sup>. Although many etiologies present in the neonatal period with cholestasis or acute illness, several may become manifest only later in infancy or childhood. Extreme care is required to avoid misdiagnosing these cases. This is particularly true if the patients have NAFLD-like symptoms that risk being considered part of the NASH syndrome<sup>[58]</sup>. Laboratory investigations for genetic metabolic diseases that may often be responsible for a NAFLD-like fatty liver picture should be guided by age and clinical/family history (Table 4). We will comment only on the most relevant metabolic liver diseases and refer the reader to a series of comprehensive reviews for specific information regarding the less common ones<sup>[89,90]</sup>.

Hepatic derangement with severe, but self-limiting, hypertransaminasemia and variable histological patterns may be the sole initial evident manifestation of Shwachman-Diamond syndrome (incidence: 1:50000 worldwide). The mechanisms that can contribute to liver damage in these patients are not known<sup>[91]</sup>. Citrin deficiency (incidence: 1:20000 in East Asia), a condition now also recognized in Western countries, may present with a pattern of neonatal cholestasis and increased levels of blood citrulline, or NAFLD in children and adolescents<sup>[92]</sup>. Hereditary fructose intolerance (incidence: 1:20000 worldwide) typically occurs with a pattern of early-onset cholestasis during weaning. However, it may present later in patients who spontaneously follow a low fructose diet because of instinctive fructose refusal/dislike or avoidance. In these cases, medical observation may be dictated by the incidental finding of hypertransaminasemia, hepatomegaly, and/or bright liver by ultrasound observation. Feeding history is crucial for the diagnosis, which is confirmed by molecular analysis of gene mutations<sup>[93]</sup>. Mitochondrial diseases are often multisystem, but some cases may present with exclusive or prevalent mild liver involvement [*e.g.*, mitochondrial DNA depletion syndrome due

to deoxyguanosine kinase (DGUOK, OMIM 251880)]. Some congenital disorders of glycosylation (incidence: 1:50000-1:100000) may present as chronic isolated hypertransaminasemia. Children with clinically asymptomatic, cryptogenic hypertransaminasemia with liver steatosis-fibrosis and mild coagulopathy should be screened for CDG<sup>[86,87]</sup>. Congenital hepatic fibrosis (CHF, incidence: unknown) is a developmental disorder of the portobiliary system. It is one of the fibropolycystic diseases, which include Caroli disease, autosomal dominant polycystic kidney disease, and autosomal recessive polycystic kidney disease. Clinically, it is characterized by non-cirrhotic portal hypertension, and rarely complicated by (porto-) pulmonary hypertension and hepatopulmonary syndrome. Hepatocellular function is relatively well-preserved, unless cholangitic episodes are present. Hereditary familial hemochromatosis (incidence: 1:20000 worldwide) most often presents after the transition to maturity, and is well-discussed in studies on adult patients and outside the scope of this article. Alpha 1-antitrypsin deficiency (incidence: 1:7000) presents clinical symptoms only in a minority of affected people. In infancy, the most common presentation is cholestasis. During childhood, it may present with minimally symptomatic disease that becomes significant liver disease only in 10%-15% of patients, often after several years of a near-normal quality of life, and may progress to decompensated liver disease<sup>[94]</sup>. Glycogenosis types VI and IX may be associated with elevated ALT and a soft hepatomegaly that is often not discernible at clinical examination, but without the gross metabolic abnormalities that are typically observed in the other types of glycogenosis. Cystic fibrosis rarely has a prevalent or exclusive hepatic presentation<sup>[95]</sup>. Nodular regenerative hyperplasia is an infrequently-identified liver disease characterized by non-fibrotic nodular hepatocyte regeneration, secondary portal hypertension, and mild stable abnormalities of liver function tests. In adults, it is usually associated with malignant prothrombotic or rheumatological conditions. These associations are rarely encountered in pediatric practice. The diagnosis is sometimes suggested by minimal histological changes

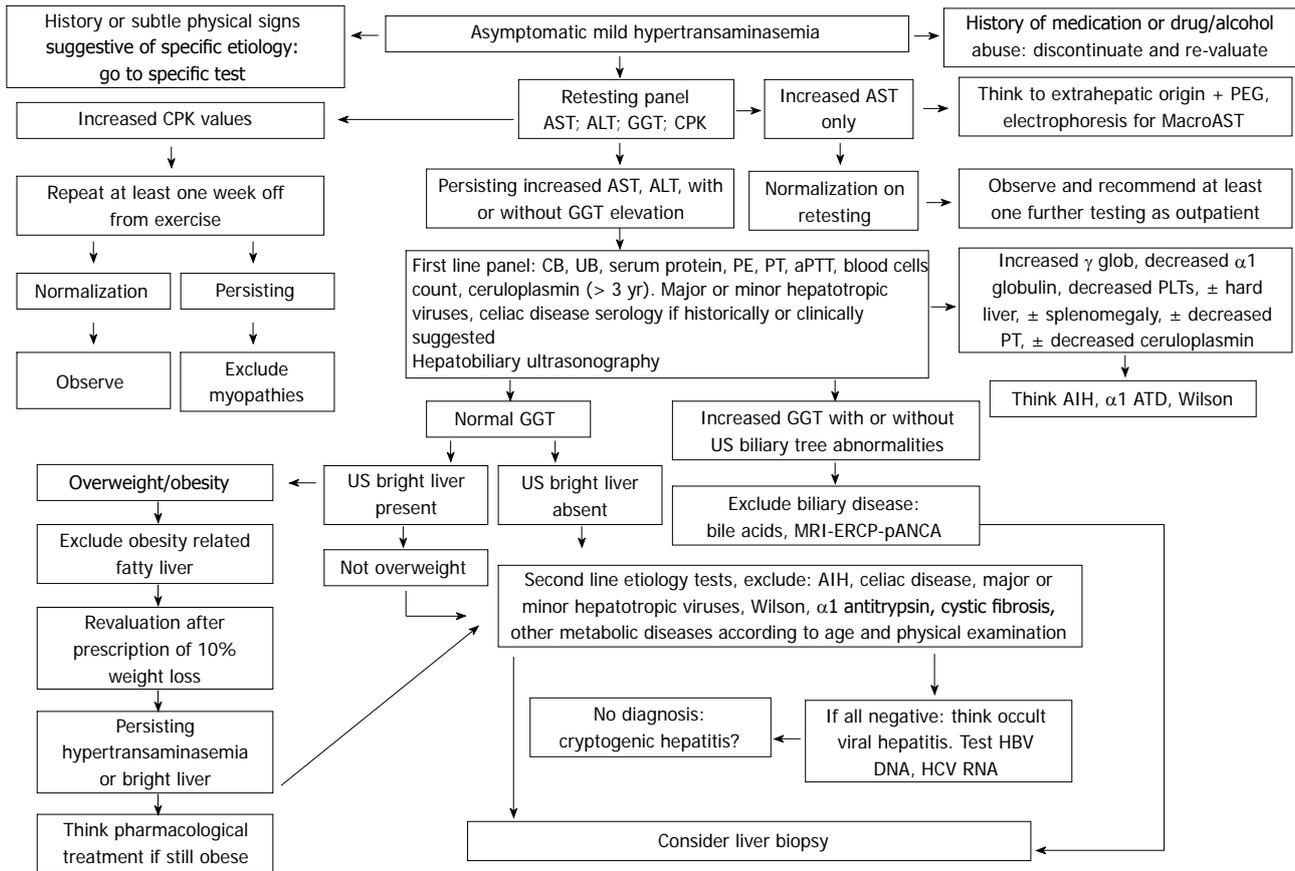

Figure 1 Diagnostic algorithm for the diagnosis of pediatric mild chronic asymptomatic hypertransaminasemia. Modified from the reference of 28. ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; CB: Conjugated bilirubin; UB: Unconjugated bilirubin; CPK: Creatine kinase; GGT: Gamma-glutamyl transferase; PE: Pulmonary embolism; PEG: Polyethylene glycol; PT: Prothrombin time; PTT: Partial thromboplastin time; US: Ultrasound; MRI: Magnetic resonance imaging; ERCP: Endoscopic retrograde cholangiopancreatography; pANCA: Perinuclear anti-neutrophil cytoplasmic antibodies; HBV: Hepatitis B virus; HCV: Hepatitis C virus; AIH: Autoimmune hepatitis;  $\alpha$ 1 ATD:  $\alpha$ 1-antitrypsin deficiency.

(*e.g.*, sinusoidal dilation)<sup>[96]</sup>.

## TRANSAMINITIS AND CRYPTOGENIC HEPATITIS

The term “transaminitis” was coined to describe overall liver enzyme leakage without hepatotoxic consequences in adult patients receiving drug therapy of any type. Hypertransaminasemia is due to an unknown effect of the drug (*e.g.*, changes in hepatocellular membranes due to lipid lowering) or underlying conditions (*i.e.*, fatty liver)<sup>[97]</sup>. Childhood “cryptogenic” hepatitis appears to be a symptomless disease characterized by isolated hypertransaminasemia that onsets during the first 4 years of life, and mild to moderate histologic liver lesions. Although the frequency of spontaneous remissions is low, childhood chronic cryptogenic hepatitis appears, in the short-term, to be a non-progressive disease. This diagnosis can only be attempted once all other known causes of liver disease are excluded<sup>[14,15]</sup>.

## DISCUSSION AND CONCLUSION

Given the large number of pediatric conditions that may

be responsible for isolated persistent hypertransaminasemia, one can conclude that even asymptomatic children should undergo an intensive liver work-up. Based on the possibility of a fluctuating pattern, it seems reasonable to repeat ALT and AST testing to confirm hypertransaminasemia, rather than embarking on expensive investigations that may prove to be useless. An enzyme panel costs approximately \$30, whereas tests to identify only some of the most common causes of elevated liver enzymes (such as serology for hepatitis B and C infection and ultrasonography for NAFLD) cost approximately \$400<sup>[10]</sup>. However, the cost-benefit considerations of a stepwise diagnostic approach *vs* a simultaneous (and timesaving) testing approach in children should not deter from the need to avoid repeated vein punctures, which is often a traumatic experience. As seen in patients with a fever of unknown origin, in asymptomatic children with cryptogenic hypertransaminasemia, ordering investigations as screening procedures in the hope that something abnormal will be identified might have a number of disadvantages. These disadvantages include: possible adverse reactions or complications, loss of the patient’s faith in the medical staff, high testing costs, and a soporific effect on the doctor’s diagnostic mental activities<sup>[98]</sup>.

The prescription of a “retesting panel”, which in-

cludes the determination of GGT and CPK in addition to aminotransferase levels, has the advantage of confirming the persistence of the abnormality, helping to rule out, at least in part, cholestatic hepatopathies and myopathies, and guiding the subsequent diagnostic steps that are shown in Figure 1. Testing serum bile acids and cholangiography are other means to better assess cholestasis. If reassessment of physical and anamnestic findings suggests specific etiologies, these should be checked in the initial enzyme retesting panel (*e.g.*, viral serologies or hepatorenal ultrasonography for viral hepatitis and NAFLD, respectively). In the presence of even subtle symptoms or signs (*e.g.*, jaundice, ascites, pruritus, hepatomegaly, and/or splenomegaly), complete testing to identify the possible cause of liver disease should be included in the initial retesting.

The first line panel in asymptomatic hypertransaminasemic patients should consist of liver ultrasonography, liver function tests, and a number of investigations for the most frequent etiologies. Second and third line investigations are justified either by the inconclusive first line panel or to explore specific plausible conditions. Liver biopsy is part of these panels, but its exact timing and role remains a controversial issue<sup>[28,39,99-101]</sup>. It has been shown that in those patients with negative etiological investigations, a liver biopsy will most likely not add further useful information<sup>[10,15]</sup>, and considering that a percutaneous liver biopsy samples only 1:50000 of the liver, sampling error is an obvious limitation which can lead to misdiagnosis and staging inaccuracies<sup>[102]</sup>. The competence of the pediatric liver disease pathologist is paramount. Steatosis of the liver in a non-obese individual may suggest a metabolic/genetic hepatopathy<sup>[14,38]</sup>.

In conclusion, here we provide an overview of pediatric persistent hypertransaminasemia and list a series of metabolic, genetic, gastrointestinal, and extrahepatic causes that should be taken into account in clinical practice. The number of these etiologies constitutes a wider field of what one usually considers in adulthood. Importantly, information derived from the combination of the patient's history, physical examination, and basic laboratory data are necessary to reach a timely and correct diagnosis. We also provide a stepwise approach that should always be guided by clinical scenarios.

## ACKNOWLEDGMENTS

We are grateful to Professor Giorgina Mieli Vergani (London) for thoughtful discussion and suggestions.

### Abstract

**AIM:** To retrospectively review the results of over-the-scope clip (OTSC) use in our hospital and to examine the feasibility of using the OTSC to treat perforations after endoscopic submucosal dissection (ESD).

**METHODS:** We enrolled 23 patients who presented with gastrointestinal (GI) bleeding, fistulae and perforations and were treated with OTSCs (Ovesco Endoscopy GmbH, Tuebingen, Germany) between November 2011 and September 2012. Maximum lesion size was defined as lesion diameter. The number of OTSCs to be used per patient was not decided until the lesion was completely closed. We used a twin grasper (Ovesco Endoscopy GmbH, Tuebingen, Germany) as a grasping device for all the patients. A 9 mm OTSC was chosen for use in the esophagus and colon, and a 10 mm device was used for the stomach, duodenum and rectum. The overall success rate and complications were evaluated, with a particular emphasis on patients who had

undergone ESD due to adenocarcinoma. In technical successful cases we included not only complete closing by using OTSCs, but also partial closing where complete closure with OTSCs is almost difficult. In overall clinical successful cases we included only complete closing by using only OTSCs perfectly. All the OTSCs were placed by 2 experienced endoscopists. The sites closed after ESD included not only the perforation site but also all defective ulcers sites.

**RESULTS:** A total of 23 patients [mean age 77 years (range 64-98 years)] underwent OTSC placement during the study period. The indications for OTSC placement were GI bleeding ( $n = 9$ ), perforation ( $n = 10$ ), fistula ( $n = 4$ ) and the prevention of post-ESD duodenal artificial ulcer perforation ( $n = 1$ ). One patient had a perforation caused by a glycerin enema, after which a fistula formed. Lesion closure using the OTSC alone was successful in 19 out of 23 patients, and overall success rate was 82.6%. A large lesion size (greater than 20 mm) and a delayed diagnosis (more than 1 wk) were the major contributing factors for the overall unsuccessful clinical cases. The location of the unsuccessful lesion was in the stomach. The median operation time in the successful cases was 18 min, and the average observation time was 67 d. During the observation period, none of the patients experienced any complications associated with OTSC placement. In addition, we successfully used the OTSC to close the perforation site after ESD in 6 patients. This was a single-center, retrospective study with a small sample size.

**CONCLUSION:** The OTSC is effective for treating GI bleeding, fistulae as well as perforations, and the OTSC technique proved effective treatment for perforation after ESD.

**Key words:** Over-the-scope clip; Gastrointestinal bleed-

ing; Endoscopic submucosal dissection complications; Gastrointestinal fistulae; Gastrointestinal perforation

**Core tip:** We have reported our experiences with the over-the-scope clip (OTSC) and the outcomes of several cases in Japan. The aims of the present study were to retrospectively review the results of OTSC use in our hospital and to examine the feasibility of using the OTSC to completely close perforations after endoscopic submucosal dissection for early gastrointestinal cancers.

## INTRODUCTION

Historically, the standard treatment for gastrointestinal (GI) perforations has been surgery. Recent, invasive endoscopic treatments, such as endoscopic submucosal dissection (ESD) and natural orifice transluminal endoscopic surgery (NOTES), have provided alternative approaches to surgery. Our recent attempts to develop a new device, such as a full-thickness suturing device, constitute progress in the development of NOTES<sup>[1-4]</sup>. In addition, several devices are currently available for endoscopic management<sup>[5,6]</sup>. However, there is little convenient, safety and perfect device for complication of endoscopic treatment<sup>[7,8]</sup>. Since its introduction, the over-the-scope clip (OTSC) (Ovesco Endoscopy GmbH, Tuebingen, Germany) has been used to treat GI bleeding, fistulae and perforations in the United States and several European countries. Reports describing the use and value of OTSCs have primarily consisted of animal studies and clinical cases<sup>[9-14]</sup>. Retrospective studies have demonstrated the feasibility and the preliminary safety of the OTSC for the treatment of GI bleeding and fistulae, as well as for the closure of acute GI perforations<sup>[15,16]</sup>. The OTSC was approved by the Japanese Drug Administration and was made commercially available in November 2011. We have reported on our experiences with the OTSC and the outcomes of several cases involving its use since this device became available in Japan. Here, we retrospectively report the results of using the OTSC in our hospital. We also describe the potential use of the OTSC to completely close perforations after ESD for early GI cancers.

## MATERIALS AND METHODS

We retrospectively analyzed our database of all 23 patients who underwent OTSC placement (Ovesco Endoscopy GmbH, Tuebingen, Germany) in our hospital from November 2011 to September 2012, as summarized in Table 1. The indications for OTSC placement were GI

bleeding, perforations, fistulae and the prevention of post-ESD duodenal artificial ulcer perforation. ESD were performed because of dissection of adenocarcinoma. Maximum lesion size was defined as lesion diameter, not lesion surface area. The number of OTSCs to be used per patient was not decided until the lesion was completely closed. We used a twin grasper (Ovesco Endoscopy GmbH, Tuebingen, Germany) as a grasping device for all the patients. A 9-mm OTSC was chosen for use in the esophagus and colon, and a 10-mm device was used for the stomach, duodenum and rectum. Clinical success was defined by the results of a computed tomography scan and a blood analysis. Cases considered to be failures were those requiring hemostasis to control GI bleeding. In technical successful cases we included not only complete closing by using OTSCs, but also partial closing where complete closure with OTSCs is almost difficult. In overall clinical successful cases we included only complete closing by using only OTSCs perfectly.

All the OTSCs were placed by 2 experienced endoscopists. The sites closed after ESD included not only the perforation site but also all defect ulcers.

We obtained written, informed consent related to the use of OTSCs from all the patients.

### *Institution participating in the study*

Kagawa University Hospital, Kagawa, Japan, participated in the study.

## RESULTS

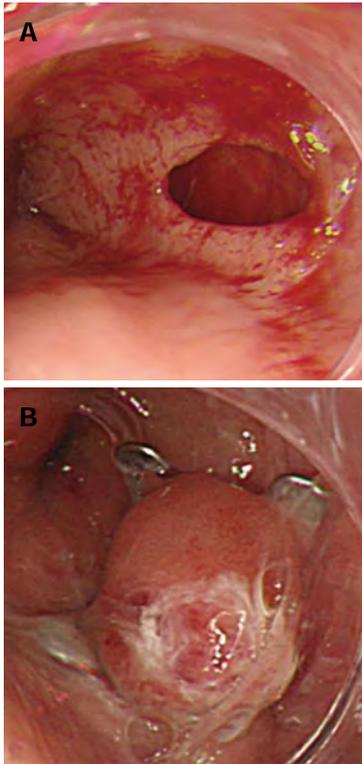

A total of 23 patients [mean age 77 years (range 64-98 years)] underwent OTSC placement during the study period. Of the 23 patients, 14 were male (60%) and 9 were female (40%). The indications for OTSC placement were GI bleeding ( $n = 9$ ), perforation ( $n = 10$ ), fistula ( $n = 4$ ) and the prevention of post-ESD duodenal artificial ulcer perforation ( $n = 1$ ). One patient had a perforation caused by a glycerin enema, after which a fistula formed. The perforations that were observed included iatrogenic perforations ( $n = 8$ ) and hemorrhagic peptic ulcers ( $n = 2$ ). The iatrogenic perforations included post-ESD artificial ulcer perforations ( $n = 6$ ), a perforation by a local steroid injection into an ulcer following ESD to prevent gastric stenosis ( $n = 1$ ), an esophageal perforation by a nasogastric tube ( $n = 1$ ) (Figure 1) and a rectal perforation by a glycerin enema ( $n = 1$ ). The fistulae included rectal fistulae ( $n = 2$ ), a stomach-to-skin fistulae following percutaneous endoscopic gastronomy (PEG) tube removal ( $n = 1$ ) (Figure 2) and a stomach-to-brachial tube fistula ( $n = 1$ ) (Figure 3).

The mean maximum size of the lesions was 23.1 mm (range 5 to 50 mm). The lesions were located in the esophagus ( $n = 1$ ), the stomach ( $n = 10$ ), the duodenum ( $n = 5$ ), the sigmoid colon ( $n = 3$ ) and the rectum ( $n = 4$ ). The time required for the procedure was measured from the time that the OTSC was applied to the time that it was released in the lesion. The median operation time for the successful cases was 18 min (range 5 to 51 min). The

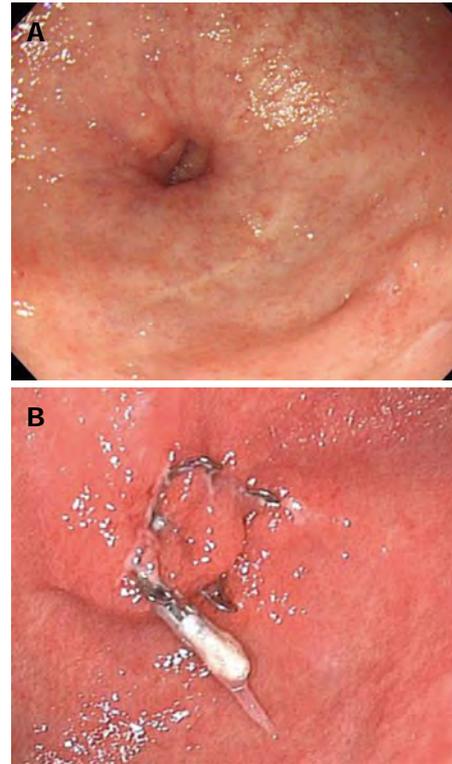

**Table 1 Database of patients who underwent over-the-scope clip device placement**

| No. | Sex | Age | Location                            | Primary disease                                | Maximum lesion size (mm) | Prior treatment history      | No. of OTSCs | Operation time (min) | Time from diagnosis (wk) | Technical/overall clinical successful | Additional treatment   | Complication | Stay in hospital after OTSC placement (d) | Duration of follow-up (d) |

OTSC: Over-the-scope clip; ESD: Endoscopic submucosal dissection; M: Male; F: Female; N/A: Not available; HSE: Hypertonic saline-epinephrine injection therapy.

**Figure 1** Esophageal perforation caused by a nasogastric tube. A: During the insertion of a nasogastric tube, the tip of the tube perforated the lower esophagus; B: The wound was successfully closed with a single over-the-scope clip, and there was no leakage.

**Figure 2** Gastrocutaneous fistula that occurred after percutaneous endoscopic gastrostomy removal. A: After the removal of a gastrostomy tube, the patient was able to eat orally, but a gastrocutaneous fistula was diagnosed; B: The wound was slightly hardened, but was successfully closed with a single over-the-scope clip.

numbers of OTSC devices used per session were one ( $n = 11$  patients), two ( $n = 8$  patients) and three ( $n = 2$  patients). The post-OTSC placement mean observation period was 67 d (range 8-210 d).

The technical success rate for OTSC placement was 91.3% (21/23). The OTSC was successfully and safely released in all the cases except for 2, in which we did not release the OTSC because the ulcer was extremely stiff due to being a chronic hemorrhagic gastric ulcer. We could not include the entire thickness of the mucosa of these ulcers within the applicator cap. Ultimately, we stopped the bleeding by reapplying the hemostatic forceps (Coagrasper, FD-410LR, Olympus, Tokyo, Japan). The overall clinical success rate using the OTSC alone was 82.6% (19/23). A large lesion size (greater than 20 mm) and a delayed diagnosis (more than 1 wk) were the major contributing factors in the overall unsuccessful clinical cases. The location of the unsuccessful lesion was in the stomach (Table 2). In 2 patients, we were unable to place the OTSC on the refractory peptic ulcer. In 1 patient, a perforation occurred because of a local steroid injection into the artificial ulcer after ESD to prevent stenosis. We could not place the OTSC correctly because the wound was large and the ulcer was exceptionally stiff. In another patient, who was suffering from a gastrobrachial fistula (Figure 3), we were able to place only one OTSC, but not the additional OTSCs necessary for the complete closure of the fistula.

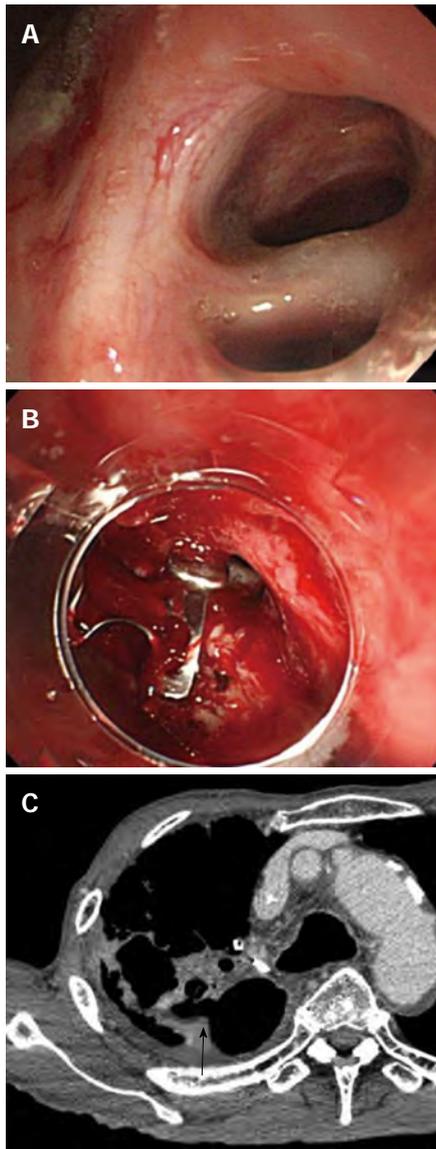

There was no adjunct therapy used for OTSC placement in the 19 overall clinical success cases. In the two technical failure cases, we used coagulation forceps for additional hemostasis. All the patients were hospitalized for observation after the OTSC placement. The median hospital stay was 9 d (range 6-21 d).

### Complications

During the observation period, none of the patients experienced any complications associated with OTSC placement.

## DISCUSSION

The development of new NOTES devices has introduced advanced therapeutic techniques that can be used in minimally invasive treatments<sup>[1-3]</sup>, including various full-thickness suturing devices that are applied in clinical practice. One of these devices is the OTSC system, the clinical utility of which has been reported in Europe and the United States. The OTSC system shows great potential for use in endoscopic treatments that require speed and simplicity<sup>[2,3,17,18]</sup>. This system received a pharmaceutical license in Japan in November 2011. Although animal experiments and clinical studies have been performed in Europe and the United States, few clinical cases have been reported in Japan<sup>[13,14]</sup>. We used the OTSC in NOTES animal experiments prior to its approval for

**Figure 3** A gastric tube bronchial fistula following a subtotal esophagectomy for esophageal cancer. A: A gastric tube bronchial fistula occurred after a subtotal esophagectomy for esophageal cancer. Bronchial embolization was performed, but it failed to close the fistula; B: The authors attempted to close the fistula using over-the-scope clip (OTSC) but were unsuccessful. Although 1 OTSC was placed, mucosal hardening (resulting from the prolonged duration of the untreated ulcer) prevented the placement of the additional OTSCs required for closure; C: A chest-abdominal computed tomography scan revealed a gastrobronchial fistula (arrow).

humans. Recognizing its potential for use in Japan, we began using the OTSC clinically immediately after the pharmaceutical license was granted. We have employed this device in 23 patients within a short period in our hospital, with an overall success rate of 82%. Animal and clinical studies of the OTSC have demonstrated that gastric, duodenal or colonic perforations up to 15 mm in diameter can be completely closed with a single OTSC. For perforations up to 20 mm in diameter, closure can also be achieved using some OTSCs, which indicates that there is sufficient working space for the unobstructed use of the endoscope during NOTES<sup>[17]</sup>. There are reports that

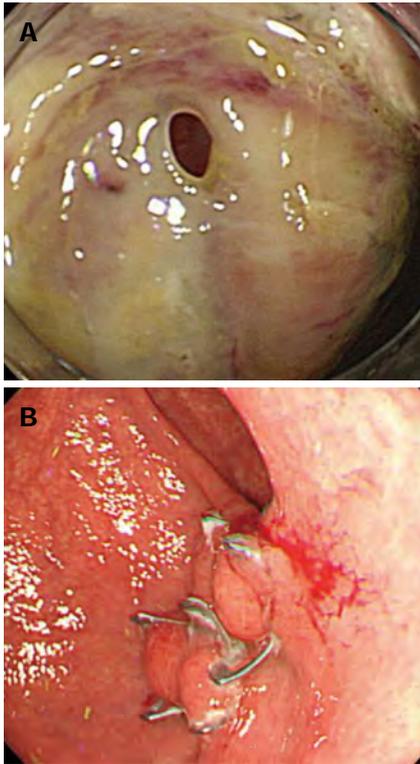

**Table 2** Relationship between each characters and overall clinical success rate *n* (%)

|                          | Patients | Overall clinical success |
|--------------------------|----------|--------------------------|
| Location                 |          |                          |

| 1-4                      | 3        | 0 (0)                    |
| > 4                      | 2        | 1 (50)                   |

full-thickness closures of defects 18-27 mm in diameter can be performed using OTSC; however, it is difficult to completely close defects > 30 mm in diameter<sup>[18]</sup>.

In the present series, OTSC closure was successful for wounds with a maximum diameter of ≤ 30 mm but unsuccessful in 1 case of refractory GI bleeding and 1 case of gastrobronchial fistula (Figure 3). Even in cases with a maximum wound diameter of > 30 mm, we placed the OTSC successfully because the tissue was well extensible and not hardened. In our clinical experience, unsuccessful OTSC closure had a chronic course and OTSC failures were due to chronic fibrotic changes and scarring at the perforation site. Specifically, we used OTSCs in 4 chronic patients and failed to close the perforation site in 3 of them (75%). It appears that wound closure with the OTSC is suitable for wounds with easy extensibility of the surrounding tissues; such lesions have little fibrosis and can be easily grasped by the twin grasper. Considering that successful closure was also achieved in cases with a rectal fistula < 20 mm in diameter or a gastrocutaneous fistula after PEG removal (Figure 2), we believe that OTSC use should be considered when surgery is the only remaining option, provided that the lesion (even if presumably hardened) is ≤ 30 mm in diameter and can be sucked into the cap to lift the mucosa. In addition, the success of the OTSC closures in 4 cases with lesions > 30 mm suggests that this device can be used in acute cases with good extensibility of surrounding mucosa.

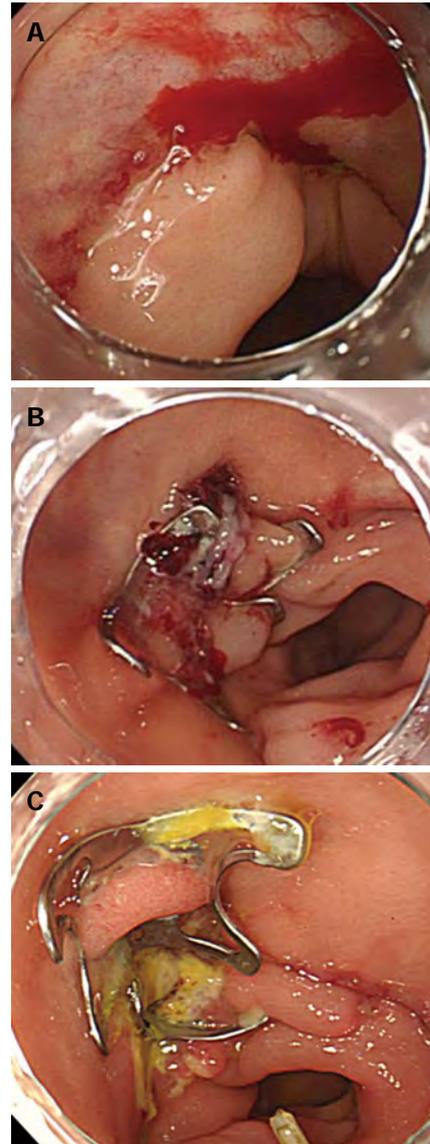

ESD was developed for *en bloc* removal of large gastric cancer, which decrease the risk of local recurrence, and specimens can be accurately evaluated by histological examination<sup>[19]</sup>. However, the procedure is associated with a high incident of complication with bleeding and perforation<sup>[20-22]</sup>. Now, bleeding has been good controlled with new hemostatic forceps and clips<sup>[23]</sup>. We also used the OTSC for the complete wound closure of post-ESD perforations in the stomachs of 2 patients who had undergone ESD for early gastric cancer. In both cases,

**Figure 4** Iatrogenic perforation after endoscopic submucosal dissection for early gastric cancer in the greater curvature of the stomach. A: A post-endoscopic submucosal dissection ulcer was found in the greater curvature of the stomach. An examination by retroflex view revealed that the muscle layer was separated and perforated; B: The wound was successfully closed using an over-the-scope clip (OTSC). An upper endoscopy performed 2 mo after the closure revealed no displacement of the OTSC or complications, such as ulceration or deformation.

the lesions were located in the greater curvature of the stomach (Figure 4). Because it is anatomically thinner than other parts of the stomach, the greater curvature of the stomach is considered to be easy to perforate<sup>[24-29]</sup>. In addition, because the knife is applied vertically to the mucosa during ESD, it is difficult to perform the procedure while maintaining an appropriate dissection depth into the submucosal layer. The endoscope must also be retroflexed<sup>[24]</sup>. These limitations have led to several cases in which our attempts to create a partial closure of an ulcer base using conventional clips caused the further extensive separation of the muscle layer and the subsequent need for surgery. In such cases, complete closure using the OTSC is thus preferred for a post-ESD ulcer in the greater curvature of the stomach, even if perforation is suspected.

The use of duodenal ESD is controversial among Japanese endoscopists because the narrow lumen of the duodenum makes it difficult to perform the procedure, and the base of a post-ESD duodenal ulcer is continuously exposed to bile, causing an increased incidence of delayed perforation compared with other ESD sites<sup>[30-35]</sup>. Nevertheless, duodenal surgery is highly invasive because of the anatomical position. ESD should be preferentially performed instead of surgery if clinically indicated. The

**Figure 5** Bleeding from an anastomotic ulcer caused by a sigmoidectomy for sigmoid cancer. A: Bleeding was observed from the anastomotic site after surgery for sigmoid colon cancer; B: The wound was successfully closed using an over-the-scope clip; C: The postoperative course has been uneventful, with no rebleeding.

Japan Gastroenterological Endoscopy Society reported in April 2009 that the complete closure of a post-ESD duodenal ulcer using conventional clips helps prevent delayed perforation. However, conventional clips are too small and do not provide sufficient grip strength to achieve the complete closure of an ulcer base. Therefore, the OTSC, which is larger and provides greater grip strength, is recommended for the complete closure of post-ESD duodenal ulcers<sup>[36]</sup>.

At our hospital, patient 11 (Table 1) experienced a small perforation of a post-ESD ulcer that formed in the duodenal bulb, and the OTSC was used for its closure. In patient 12 (Table 1), the lesion occurred in the descending portion of the duodenum and was exposed to bile, indicating an increased risk of delayed perforation. Thus,

the ulcer was closed using the OTSC, which helped prevent perforation and bleeding.

We experienced 2 cases of OTSC closure for post-ESD ulcers in the colon. In both cases, the lesions were located in the sigmoid colon, with post-ESD perforations requiring complete wound closure. The wound was > 30 mm in diameter in both cases and was successfully closed using the OTSC.

We experienced 9 cases of GI bleeding that were treated with OTSCs. Widely used hemostatic procedures, such as hemostatic clips and local injections, are economically advantageous but sometimes fail to achieve complete primary hemostasis. The use of coagulation hemostasis with hemostatic forceps is also increasing because the reliable coagulation of exposed vessels under direct visualization can minimize the risk of rebleeding. However, the application of coagulation hemostasis to a deep ulcer or a thin wall of the duodenum is associated with a risk of perforation. For patients who do not tolerate surgery well and are in shock due to rebleeding or who do not respond to conventional treatment, the use of the OTSC should be considered. Based on these criteria, we applied OTSCs to the 9 patients with GI bleeding and achieved complete hemostasis in 7 of them. The remaining 2 patients with failed hemostasis using the OTSC system had a personal status  $\geq 3$  and could not tolerate open abdominal surgery. One of the patients had a large ulcer (50 mm in diameter) to which hemostasis with hemostatic forceps was applied. However, the patient experienced 2 episodes of shock due to bleeding from other sites of neovascularization. During the third episode of bleeding, ulcer closure with the OTSC was attempted but was unsuccessful due to a hardened ulcer base. Hemostasis with hemostatic forceps was again performed, after which no rebleeding was observed.

Hemostatic treatment of an anastomotic ulcer using the OTSC for was successful in 1 patient with a duodenal lesion and for 2 patients with lesions in the sigmoid colon (Figure 5). The aggressive treatment of bleeding with hemostatic forceps may cause perforations because anastomotic sites are usually thin and fragile. We consider the OTSC to be an effective tool for the treatment of lesions at anastomotic sites.

Regarding safety and complications, none of our patients treated with the OTSC reported any complications. Assessments performed 7 d after closure using the OTSC also revealed no displacements of the OTSC or tissue necrosis at the wound sites. Endoscopic examinations revealed OTSC losses in 2 cases: 1 occurred 1 mo after OTSC placement for duodenal lesions, and the other occurred 2 mo after OTSC placement for colonic lesions. No associated complications were observed in either case. Other possible complications include mucosal damage caused by the teeth of the OTSC protruding out of the hood top during insertion. Therefore, special care should be taken when the OTSC is inserted into physiologically narrow sites, such as the esophageal entrance, pyloric ring or anal ring. There have been no reports of

OTSCs causing mucosal deformation or stenosis of the gastrointestinal<sup>[9]</sup>. However, we must consider the possibility that a failure to extract the fibrotic mucosa may result in the tissue being crushed by the twin grasper during the extraction of hardened tissue.

Based on our 23 cases and those reported in the literature, we consider OTSC to be a highly useful device that can be safely utilized in the treatment of GI perforations, fistulae and refractory bleeding. However, OTSC is not suitable for the closure of chronic lesions with hard, severely fibrotic wounds because it is difficult to draw such a lesion into the top of the device. However, we have used the OTSC to close post-ESD perforations with a 100% success rate. Although our sample size was small, we believe that the OTSC is a viable treatment option for post-ESD perforation.

## COMMENTS

### Background

Recently, over-the-scope clip (OTSC) devices have been used for gastrointestinal (GI) bleeding, fistulae and perforations in the United States and several European countries. OTSC devices became pharmaceutically licensed in Japan in August 2011. The authors have reported their experiences with the OTSC and the outcomes of several cases in Japan. The aims of the present study were to retrospectively review the results of OTSC use in the authors' hospital and to examine the feasibility of using the OTSC to completely close perforations after endoscopic submucosal dissection (ESD) for early GI cancers.

### Research frontiers

Historically, the standard treatment for GI perforations has been surgery. Recently, invasive endoscopic treatments, such as ESD and natural orifice transluminal endoscopic surgery (NOTES), have provided alternative approaches to surgery. However, the devices used to treat complications following endoscopic treatments are less convenient and not as safe. OTSCs have been used to treat GI bleeding, fistulae and perforations in several countries. In this study, the authors retrospectively report the results of using the OTSC in their hospital. They also discuss the potential use of the OTSC to completely close perforations after ESD for early GI cancers.

### Innovations and breakthroughs

This is the first retrospective study of the OTSC in Japan, and it includes more cases of post-ESD perforation closure compared with other published reports on OTSC. All the post-ESD perforation closure cases in the present study were successes. Thus, the authors consider OTSC to be a possible tool for the treatment of perforations after ESD.

### Applications

Based on the present 23 cases and those reported in the literature, the authors assert that the OTSC is useful and safe for the treatment of GI perforations, fistulae and refractory bleeding.

### Terminology

ESD is the only nonsurgical, endoscopic method of treating early GI cancers; NOTES, a fusion of flexible endoscopy and operative techniques, is a less invasive form of treatment than surgery.

### Peer review

The OTSC is an interesting and novel device that enhances the armamentarium of therapeutic gastroenterologists. This report illustrates the use of this novel device, which facilitates interventions that were previously impossible to perform endoscopically.

### Abstract

**AIM:** To examine the effect of  $\alpha$ -lipoic acid (LA) on mild portal endotoxemia-induced steatohepatitis and associated pancreatic abnormalities in fructose-fed rats.

**METHODS:** Rats were randomly assigned into two groups with a regular or 60% fructose-enriched diet for 8 wk. After fructose feeding for 4 wk, rats were further divided into four subgroups: with intraportal saline (F<sub>PV</sub>), with intraportal saline plus administration of LA (F<sub>PV</sub> + LA), with lipopolysaccharide (LPS) infusion (F<sub>PLPS</sub>), and with LPS infusion plus administration of LA

(F<sub>PLPS</sub> + LA). Rats were treated with LPS using intraportal infusion while LA was administered orally. Metabolite levels, superoxide levels, inflammatory markers, malondialdehyde content, glutathione content and toll-like receptor 4 (*TLR4*) gene expression were all measured using standard biochemical techniques. Pancreatic insulin secretion was evaluated by a hyperglycemic clamp technique. Histology of liver and pancreas tissues were evaluated using hematoxylin and eosin staining and immunohistochemistry.

**RESULTS:** Fructose-induced elevation in plasma C-reactive protein, amylase, superoxide, white blood cell count as well as in hepatic and pancreatic contents of malondialdehyde, tumor necrosis factor alpha and interleukin-6 were increased in animals treated with LPS and reversed with LA administration. The augmented hepatic gene expression of *TLR4* in fructose-fed rats was further increased in those with intraportal LPS infusion, which was partially reversed by LA administration. Pathological examination showed inflammatory changes and leukocyte infiltration in hepatic and pancreatic islets of animals treated with LPS but were rarely observed in those with LA treatment. In addition to effects on the liver, impaired pancreatic insulin secretion seen in fructose-fed rats was deteriorated in with LPS treatment and partially reversed with LA administration.

**CONCLUSION:** These data suggest LA could significantly suppress mild portal-endotoxemia but not fructose-induced liver and pancreatic abnormalities in a rodent model for metabolic syndrome.

**Key words:** Lipoic acid; Oxidative stress; Steatohepatitis; Portal endotoxemia; Insulin secretion; Fructose

**Core tip:**  $\alpha$ -lipoic acid (LA), a potent antioxidant and also an inducer of endogenous antioxidants has been

reported to protect the liver and pancreas from injury. Our observations suggest that LA could significantly suppress inflammatory change of steatosis induced by low-dose intraportal lipopolysaccharide infusion and associated deterioration of insulin secretion in this metabolic syndrome rodent model. In addition, our data suggest that hepatic toll-like receptor 4 signaling might not only play a significant role in chronic fructose-feeding-induced hepatic steatosis but also in its subacute inflammatory change induced by mild portal endotoxemia and associated extrahepatic disorders.

Lipoic acid suppresses portal endotoxemia-induced steatohepatitis and pancreatic inflammation in rats. *World J Gastroenterol* 2013; 19(18): 2761-2771 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i18/2761.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i18.2761>

## INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is currently the most common liver disease in the world<sup>[1]</sup>. NAFLD is mainly associated with obesity, diabetes, hyperlipidemia and insulin resistance, which are the main characters of metabolic syndrome<sup>[1,2]</sup>. The development of liver inflammation in NAFLD, defined as non-alcoholic steatohepatitis (NASH), is one of the crucial steps in causing liver-related morbidity and mortality<sup>[3]</sup>. Moreover, a pathological link between portal endotoxemia and NASH and also alcoholic liver disease has been speculated in several animal and human studies<sup>[4-8]</sup>. For instance, genetically obese fatty/fatty rats and *ob/ob* mice showed increased sensitivity to endotoxin hepatotoxicity, quickly developing steatohepatitis after exposure to low doses of lipopolysaccharide (LPS)<sup>[5]</sup>. These studies implicate that portal endotoxemia might significantly contribute to the pathogenesis of chronic hepatic inflammation, especially in NAFLD.

The release of liver-derived acute-phase proteins and inflammatory cytokines under chronic liver injury significantly contributes to the extrahepatic effect of inflamed liver and the pathogenesis of metabolic syndrome<sup>[9,10]</sup>. We have shown that mild portal endotoxemia induced by low-dose intraportal LPS infusion could significantly cause chronic hepatic and pancreatic inflammation, and impair pancreatic insulin secretion in rats<sup>[11]</sup>. Furthermore, low-dose intraportal LPS infusion could also accelerate the process of NAFLD to NASH in fructose-fed rats, an animal model of metabolic syndrome with NAFLD<sup>[4]</sup>. However, the possible underlying mechanisms behind the detrimental effects of mild portal endotoxemia on liver and pancreas remain unclear.

Chronic stress such as portal endotoxemia has been documented to activate hepatic Kupffer cells and cause the release of reactive oxygen species, potentially inducing inflammatory changes in the liver and impairing

pancreatic functions<sup>[5,12]</sup>.  $\alpha$ -lipoic acid (LA) is a potent antioxidant and an inducer of endogenous antioxidants<sup>[13,14]</sup>. It also has a protective effect on hepatic and pancreatic injury<sup>[15-18]</sup>. In this study, we sought to test the potential therapeutic effect of LA on mild portal endotoxemia and fructose-induced inflammatory changes of fatty liver and impaired pancreatic insulin secretion in rats.

## MATERIALS AND METHODS

### Animals

Male Sprague-Dawley rats aged five to six weeks were purchased from the National Laboratory Animal Breeding and Research Center (Taipei, Taiwan). The rats were housed in an animal center certified by Association of Assessment and Accreditation of Laboratory Animal Care. All animals were handled according to the guidelines and manual of the institutional animal care and use committee of this institute. Rats weighing 250-300 g were randomly assigned into six groups: (1) two control groups: on regular chow diets for 4 wk and then separated into those combined with or without intraportal vehicle (saline) infusion (C<sub>PV</sub> vs C) for another 4 wk; (2) four experimental groups: on high-fructose enriched diet (60% of the calories from fructose, TD89247, Teklad Primer Labs, Madison, WI) for 4 wk and thereafter (F<sub>PV</sub>), those combined with intraportal vehicle or low-dose LPS infusion (F<sub>LPS</sub>), cotreated with vehicle or LA ( $\alpha$ -LA in saline, pH 7.8, Sigma Co. Germany, 60 mg/kg per day, oral gavage) for additional 4 wk (F<sub>PV</sub> + LA and F<sub>LPS</sub> + LA respectively)<sup>[19]</sup>. In the time-course study, blood samples were taken by tail bleeding method after overnight fasting. At the end of week 8, one set of rats from the above grouping ( $n = 6$  per group) was used for an *in vivo* hyperglycemic clamp study. The second set ( $n = 6$  per group) was euthanized by overdose pentobarbital injection (100 mg/kg, intraperitoneal) immediately after overnight fasting and blood sampling by cardiac puncture was carried out for the measurement of plasma C-reactive protein (CRP), superoxide, white blood cell (WBC) count and endotoxin levels. Tissue samples were dissected for further analysis. The liver and pancreas dissected from the third set of rats ( $n = 6$  per group) were fixed by perfusion with 4% paraformaldehyde. The tissues were embedded in paraffin for further staining. Notably, the metabolic and hemodynamic parameters and histopathological examination of group C<sub>PV</sub> were similar to those without intraportal vehicle infusion (data not shown). The group C<sub>PV</sub> was used as the only control group on regular chow diet in the following result section.

### Intraportal infusion

A laparotomy was performed under anesthesia (sodium pentobarbital 25 mg/kg, intraperitoneal injection) in rats with intraportal infusion. A catheter (PE-5 tubing, 0.008 inch inner diameter  $\times$  0.020 inch outer diameter, SCI micro medical grade polyethylene; Scientific Commodities Inc., Lake Havasu City, AZ, United States) was inserted

into the distal end of a colic vein and the tip of the catheter was placed about 3 mm distal to the point at which the catheterized vein enters portal vein. After insertion, the catheters were filled with LPS-saline solution or saline alone and were connected to osmotic mini-pumps (model 2004, Alzet corporation, Cupertino, CA, United States) filled with LPS, 0.42 ng/kg per minute or saline as shown in our previous study<sup>[20]</sup>. Three days before the surgery, a safe dosage of LA was orally administered once per day for 4 wk<sup>[21,22]</sup>.

### **Hyperglycemic clamp**

In one set of rats, vascular catheters were placed in the left femoral artery and right femoral vein under anesthesia and their proximal ends were placed in subcutaneous pockets under scapular area at the end of week 8. The hyperglycemic clamp experiment was performed after recovery for 3 to 4 d, as described elsewhere<sup>[23,24]</sup>. The insulin secretions of the first and second phases were indicated by the incremental plasma insulin values during time 0-10 and 10-240 min in the glucose clamp period, respectively.

### **Plasma metabolic parameters**

The WBC count was determined by using a Bright-Line-hemocytometer (Hausser Scientific, Horsham, PA, United States). Whole blood glucose levels were measured by the glucose oxidase method. Plasma and tissue triglyceride levels were determined by using appropriate enzymatic colorimetric method (Randox Laboratories, Antrim, United Kingdom). Plasma insulin levels were determined by commercial rat enzyme-linked immuno sorbent assay (ELISA) kits (MercoDIA AB, Uppsala, Sweden). Serum aspartate aminotransferase (AST) and alanine aminotransferase (ALT), albumin and amylase levels were measured by Randox reagent kits (Randox Laboratories Antrim, United Kingdom). CRP levels were measured by a commercial rat ELISA kit (Alpha Diagnostic, San Antonio, TX, United States). Arterial plasma endotoxin level was assayed by using the limulus amoebocyte lysate test (Kinetic-QLC; Whittaker Bioproducts, Walkersville, MD, United States).

### **Plasma superoxide levels**

A lucigenin-dependent chemiluminescence assay (Sigma Chemical Co. St. Louis, MO, United States) was used to quantify plasma superoxide levels with the MLA-GOLDS chemiluminescence analyzing system (Tohoku Electronic Industrial Co., Sendai, Japan) as described previously<sup>[4]</sup>. The total amount of chemiluminescence was calculated by integrating the area under the curve and subtracting it from the background level during the 10 min counting period.

### **Tissue tumor necrosis factor alpha and interleukin-6 contents**

Tissues were prepared as described previously<sup>[25]</sup>. The supernatant was subjected to tumor necrosis factor alpha (TNF- $\alpha$ ) and interleukin-6 (IL-6) assays using commercial rat ELISA kits (R and D Systems, Minneapolis, MN,

United States).

### **Tissue malondialdehyde content**

Lipid oxidation of the liver and pancreas was detected by a commercial malondialdehyde (MDA) assay kit (Cayman Chemical Co., Ann Arbor, MI, United States). In brief, MDA, the breakdown product of oxidative degradation of lipids, reacted with thiobarbituric acid (TBAR) to form MDA-TBAR, and its levels were expressed as nmol/g protein.

### **Tissue glutathione content**

The total glutathione in the liver was measured by using commercial glutathione assay kit (Cayman Chemical Co., Ann Arbor, MI, United States). In brief, the liver was homogenized in RIPA buffer (0.5 mol/L Tris-HCl, pH 7.4, 1.5 mol/L NaCl, 2.5% deoxycholic acid, 10% NP-40, 10 mmol/L EDTA) by using a Polytron homogenizer to obtain tissue lysates and centrifuged at 10000 g for 10 min. Subsequently, the supernatant was collected and added HPO<sub>3</sub> (v/v = 1/1) to deproteinize. The glutathione (GSH) content of deproteinized supernatant of liver (50 L) was measured by the reductive rate of 5,5'-dithio-bis-2-nitrobenzoic acid to 5-thio-2-nitrobenzoic acid according to the instructions with absorption at 405 nm. The GSH level was expressed as  $\mu$ mol/g protein.

### **Toll-like receptor 4 gene expression in the liver and pancreas**

RNA was extracted from the liver and pancreas of experimental rats using Trizol (Ambion, Austin, TX, United States) at the end of the study. TaqMan gene expression assay kits for toll-like receptor 4 (TLR4) (Rn00569848\_m1) and the TATA box binding protein (Rn01455648\_m1) were used in conjunction with a universal master mix in a 7500 real-time polymerase chain reaction system (Applied Biosystems, Foster City, CA, United States). Gene expression was normalized to the TATA box binding protein expression level measured in each sample and expressed as fold increases or decreases from control values for each gene of interest.

### **Hematoxylin and eosin stain**

The third set of rats ( $n = 5-6$  per group) was grouping as the hyperglycemic clamp experiment. The perfused liver and pancreas were then fixed in 5% zinc-formalin solution and embedded in paraffin. These tissue slices were then prepared for staining with hematoxylin and eosin (HE) (liver, pancreas) to evaluate pathological changes.

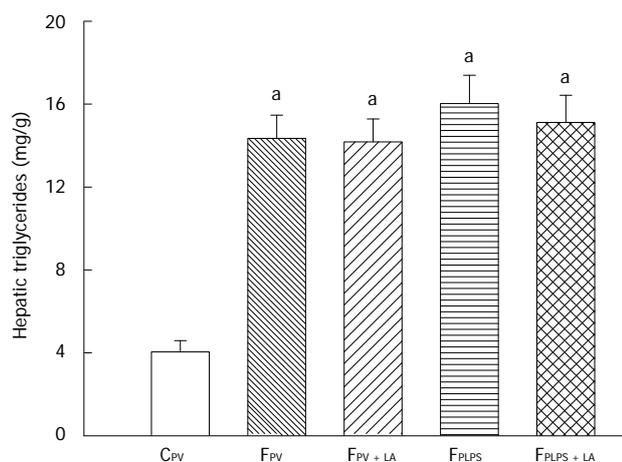

### **Immune cell immunohistochemistry and scoring**

Tissue samples were fixed in formalin, and cut into 4  $\mu$ m sections. Immunohistochemistry was performed on an automated stainer (Autostainer; Dako, Glostrup, Denmark). Then, sections were incubated with anti-CD68 antibody (ED1 mouse anti-rat CD68, Serotec, 1:100, MorphoSys UK Ltd., Oxford, United Kingdom), followed by incubation with goat anti-mouse secondary antibody and

Rats were on regular (C) or high-fructose enriched diet (F) for 4 wk and then further divided into those with intraportal infusion of saline or lipopolysaccharides (LPS), combined with vehicle or  $\alpha$  lipoic acid (LA) for additional 4 wk (C<sub>PV</sub>, F<sub>PV</sub>, F<sub>PV</sub> + LA, F<sub>PLPS</sub>, F<sub>PLPS</sub> + LA). Values are expressed as mean  $\pm$  SE,  $n = 6$  per group. <sup>a</sup> $P < 0.05$  vs C<sub>PV</sub>; <sup>c</sup> $P < 0.05$  vs F<sub>PV</sub>; <sup>e</sup> $P < 0.05$  vs F<sub>PLPS</sub> for each corresponding time point. TG: Triglycerides; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; CRP: C-reactive protein; WBC: White blood cell.

**Figure 1** Effects of  $\alpha$ -lipoic acid on hepatic triglyceride contents. Hepatic triglyceride levels were measured from the blood of each group of fructose-fed rats and the control group. Values are expressed as mean  $\pm$  SE,  $n = 6$  per group. <sup>a</sup> $P < 0.05$  vs C<sub>PV</sub>. C: Regular diet; F: High-fructose enriched diet; LA: Lipoic acid; LPS: Lipopolysaccharides.

visualized with HRP substrate (REAL EnVision Detection System; Dako).

A total of  $100 \pm 25$  islets per experimental group were blindly scored for CD68-positive cells around the periphery and/or within islets from five or six different animals by two investigators. Islet area was measured as the area of islet capsule in pancreatic section with HE stain and computed using AxioVision LE 4.8.2.0 software.

### Statistical analysis

Statistical analysis was performed according to the repeated measurements of one-way analysis of variance fol-

lowed by Bonferroni test. A probability of  $P < 0.05$  was taken to indicate a significant difference between means. Values are expressed as mean  $\pm$  SE.

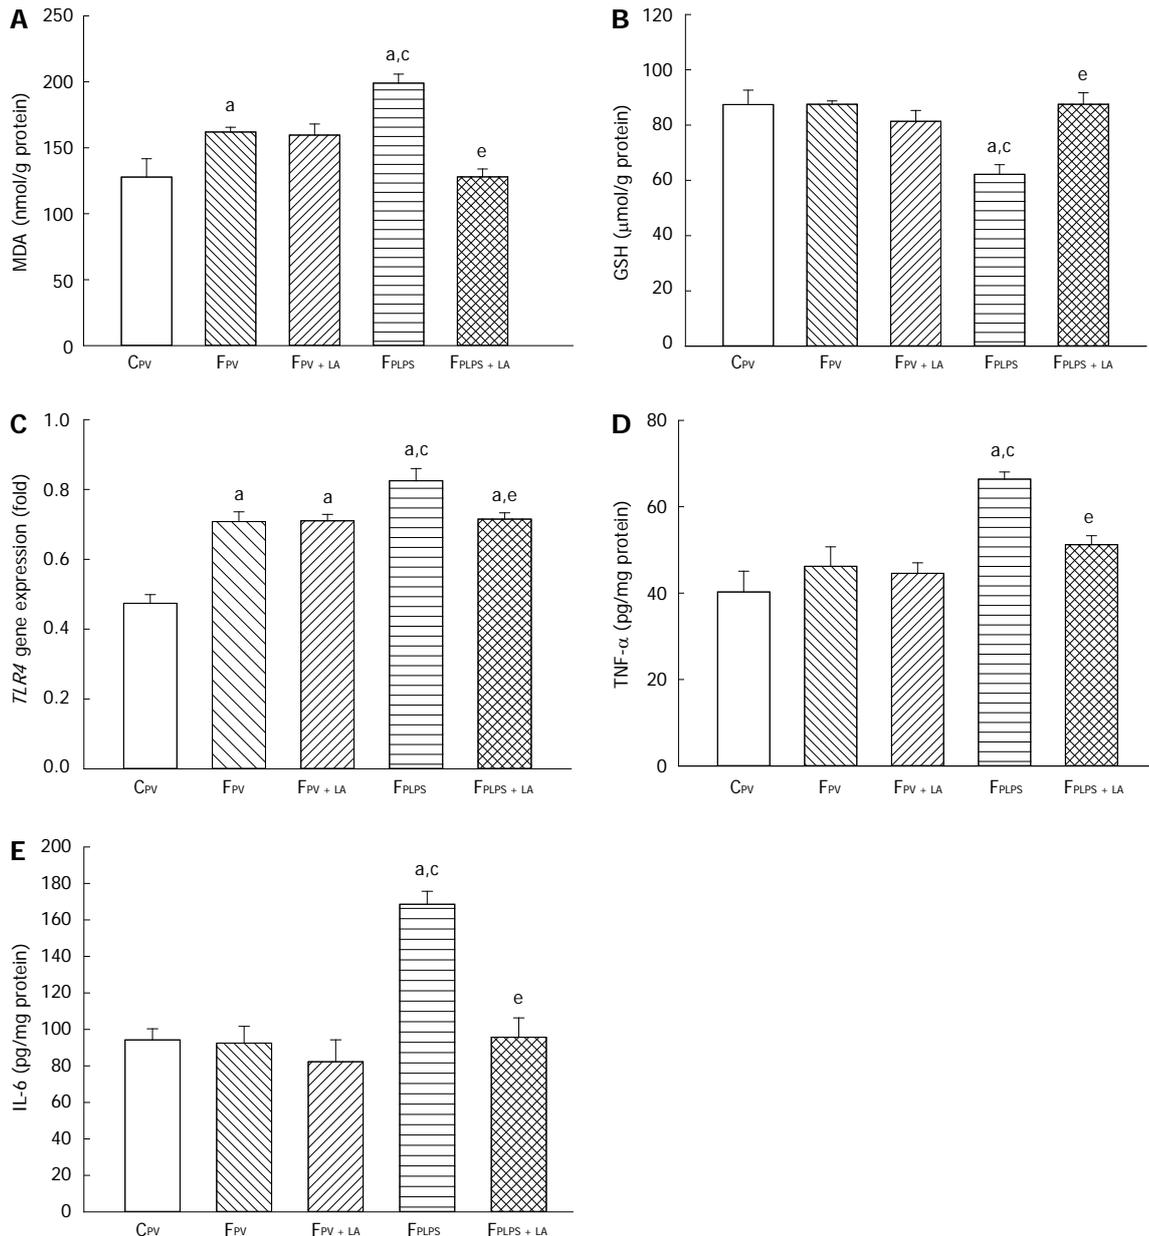

## RESULTS

### Metabolic and hemodynamic parameters

We first measured the effect of fructose feeding and LPS treatment on rats with and without LPS infusion. After high-fructose feeding for 4 wk, fasting plasma insulin levels in fructose-fed groups were significantly increased as compared with controls, but not different among fructose-fed groups. Plasma CRP, amylase, superoxide and white blood cells were also significantly increased in fructose-fed rats and further increased after intraportal LPS infusion for 4 wk. The above LPS-induced responses were suppressed in those co-treated with LA to levels similar to those in fructose-fed untreated controls. On the other hand, there were no significant differences in fasting plasma glucose, AST, ALT, albumin and endotoxin concentrations among experimental groups (Table 1).

### Triglyceride contents, oxidative parameters and inflammatory parameters in hepatic tissue

To measure the liver response to our conditions, we measured triglyceride levels, oxidative parameters, and inflammatory parameters. Fructose feeding resulted in elevated triglyceride levels in all groups when compared to the control groups. Administration of LA had no effect on these levels (Figure 1). As shown in Figure 2A, MDA levels in the liver were significantly increased in fructose-fed rats as compared with controls and further elevated in animals treated with LPS. However, the increase of

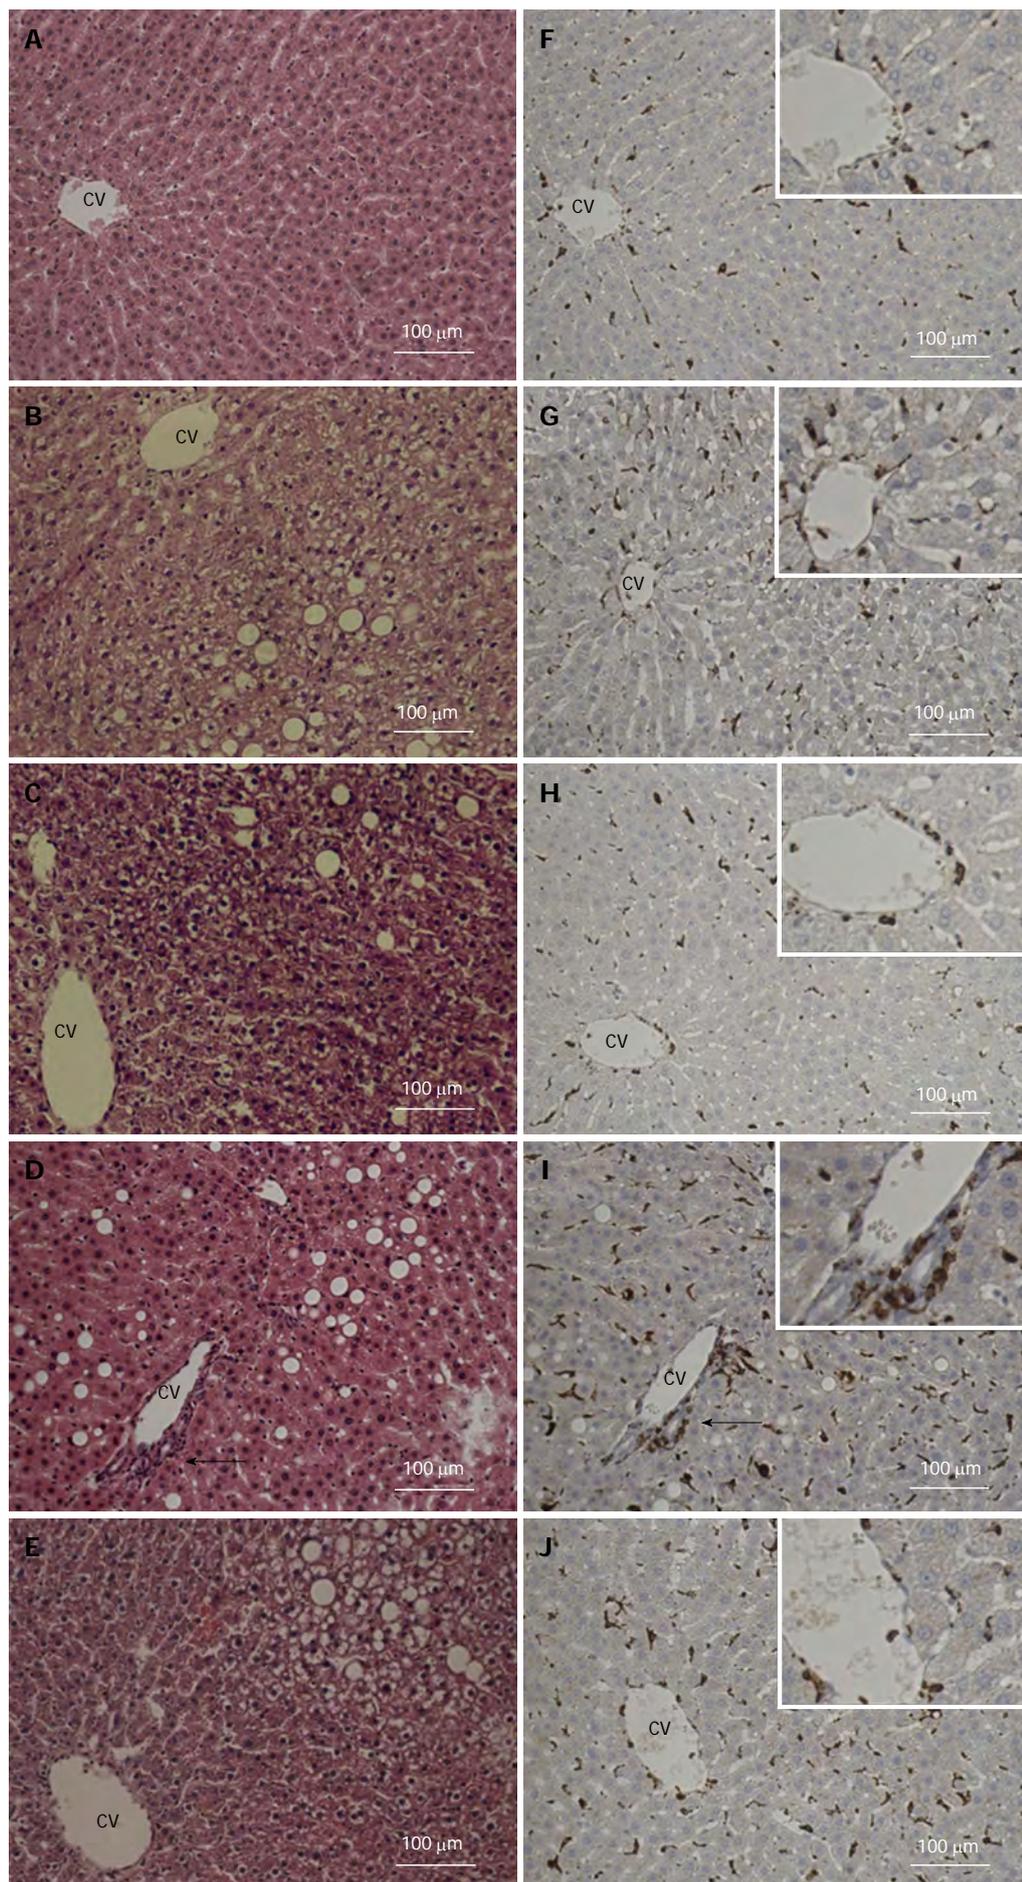

**Figure 2** Effect of  $\alpha$ -lipoic acid on portal endotoxemia-induced changes in hepatic oxidative and inflammatory markers. The following parameters were measured from liver of each group of fructose-fed rats and the control group: (A) Malondialdehyde (MDA) content; (B) Glutathione (GSH) content; (C) Toll-like receptor 4 (*TLR4*) gene expression; (D) Tumor necrosis factor alpha (TNF- $\alpha$ ) protein; and (E) Interleukin-6 (IL-6) protein. Values are expressed as mean  $\pm$  SE,  $n = 6$  per group. <sup>a</sup> $P < 0.05$  vs Cpv; <sup>b</sup> $P < 0.05$  vs Fpv; <sup>c</sup> $P < 0.05$  vs FPLPS. C: Regular diet; F: High-fructose enriched diet; LA: Lipoic acid; LPS: Lipopolysaccharides.

hepatic MDA contents in fructose-fed rats following intraportal LPS infusion was significantly reversed in those with LA administration. Liver GSH levels were significantly decreased following LPS infusion, but were significantly reversed in those treated with LA (Figure 2B). Additionally, the enhanced hepatic *TLR4* gene expression by chronic high-fructose feeding was further increased in those with intraportal LPS infusion. LA administration suppressed the augmentation of *TLR4* gene expression induced only by mild portal endotoxemia and not by high-fructose feeding (Figure 2C). The significant increase of TNF- $\alpha$  and IL-6 protein levels in the liver of LPS-infused rats was reflective of the hepatic inflammatory response. These levels were significantly suppressed with LA treat-

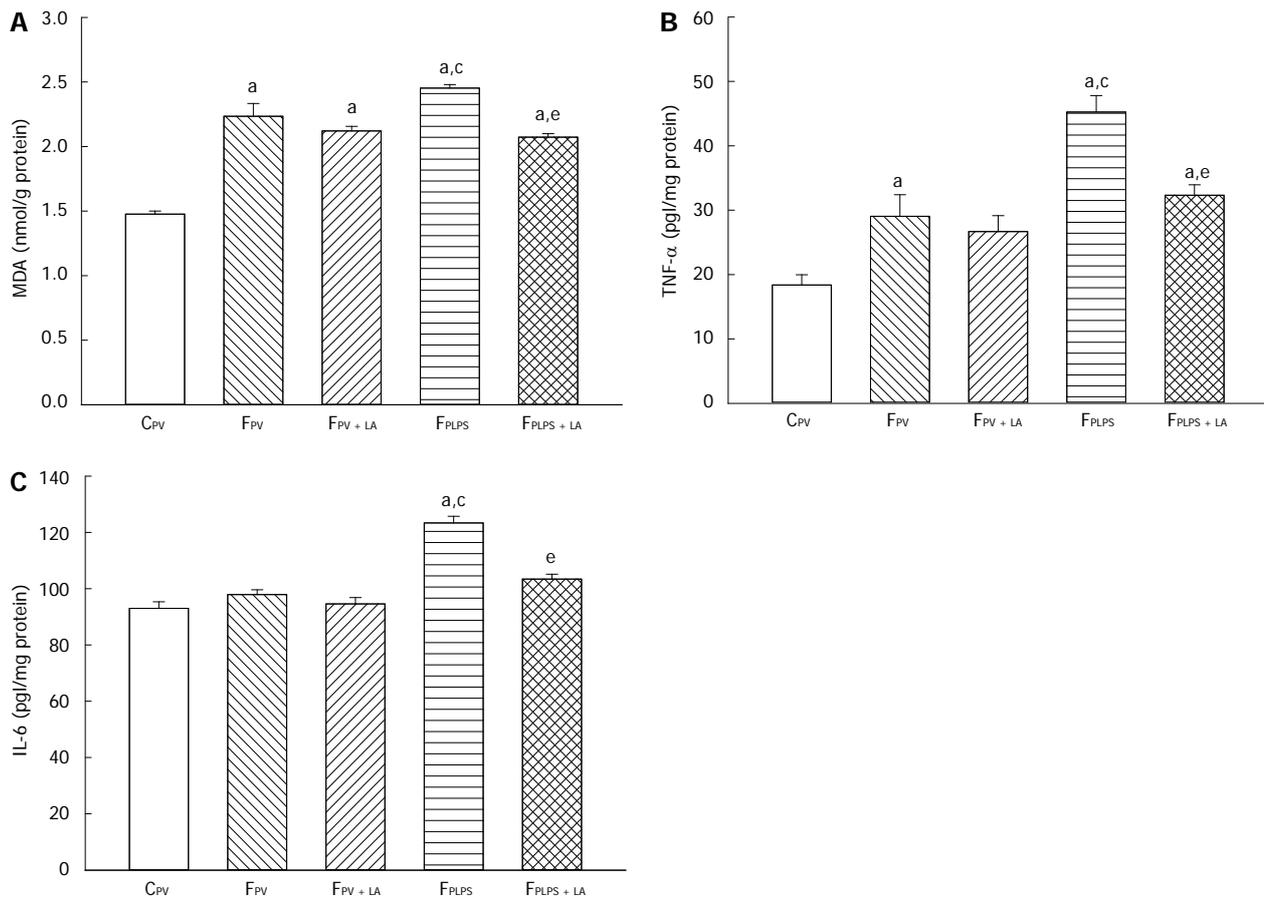

ment (Figure 2D and E). LPS infusion had no effect on triglyceride levels, but did have an effect on MDA, GSH, *TLR4*, TNF- $\alpha$  and IL-6. LA administration significantly reversed these effects.

#### Histopathological changes in the liver

Following analysis of the liver response to our treatments, we sought to examine the liver for histopathological changes. Not surprisingly, steatosis was noted in fructose-fed groups but was not different between groups. On the other hand, the infiltration of monocytes in liver was markedly exhibited in LPS-treated animals (Figure 3D), a phenotype not seen in any other treatment group (Figure 3A-C), and alleviated by the administration of LA

**Figure 3** Histopathological examination of liver in rats with regular or high-fructose feeding. Lipid accumulation in: (A) C<sub>PV</sub> rats; (B) F<sub>PV</sub> rats; (C) F<sub>PV+LA</sub>; (D) F<sub>PLPS</sub>; and (E) F<sub>PLPS+LA</sub> rats. CD-68 positive cell infiltration in: (F) C<sub>PV</sub> rats; (G) F<sub>PV</sub> rats; (H) F<sub>PV+LA</sub>; (I) F<sub>PLPS</sub>; and (J) F<sub>PLPS+LA</sub> rats. Slides were stained with hematoxylin and eosin (A-E) and immunostained with an anti-CD68 antibody (F-J). Arrows indicate CD68 positive cells. C: Regular diet; F: High-fructose enriched diet; LA: Lipoic acid; LPS: Lipopolysaccharides; CV: Central vein.

**Figure 4** Effect of  $\alpha$ -lipoic acid on portal endotoxemia-induced changes in the pancreas. The pancreata from experimental animals were harvested and tested for: (A) Malondialdehyde (MDA) content; (B) Tumor necrosis factor alpha (TNF- $\alpha$ ) protein level; and (C) Interleukin-6 (IL-6) protein level. Values are expressed as mean  $\pm$  SE,  $n = 6$  per group. <sup>a</sup> $P < 0.05$  vs CPV; <sup>c</sup> $P < 0.05$  vs FPLPS; <sup>e</sup> $P < 0.05$  vs FPLPS + LA. C: Regular diet; F: High-fructose enriched diet; LA: Lipoic acid; LPS: Lipopolysaccharides.

(Figure 3E). Accordingly, immunohistochemical staining showed that the observed CD68-positive cell infiltration was observed in areas around the central vein in LPS infused animals (Figure 3I), but significantly attenuated in those with LA administration (Figure 3J). Therefore, LPS treatment resulted in marked histopathological changes in the liver of fructose-fed animals, a phenotype that was reversed by the administration of LA.

#### Content of MDA and inflammatory markers in the pancreas

To measure the pancreas response to our conditions, we tested for MDA, TNF- $\alpha$  and IL-6 levels. Fructose feeding increased all three parameters, while fructose feeding with infusion of LPS significantly increased each (Figure 4A-C). Administration of LA resulted in each parameter returning back to original fructose-fed levels. *TLR4* gene expression was not detected in pancreas in experimental groups. Therefore, immunological markers including TNF- $\alpha$  and IL-6, but not *TLR4*, are increased upon fructose feeding and LPS infusion, a phenotype that can be reversed with administration of LA.

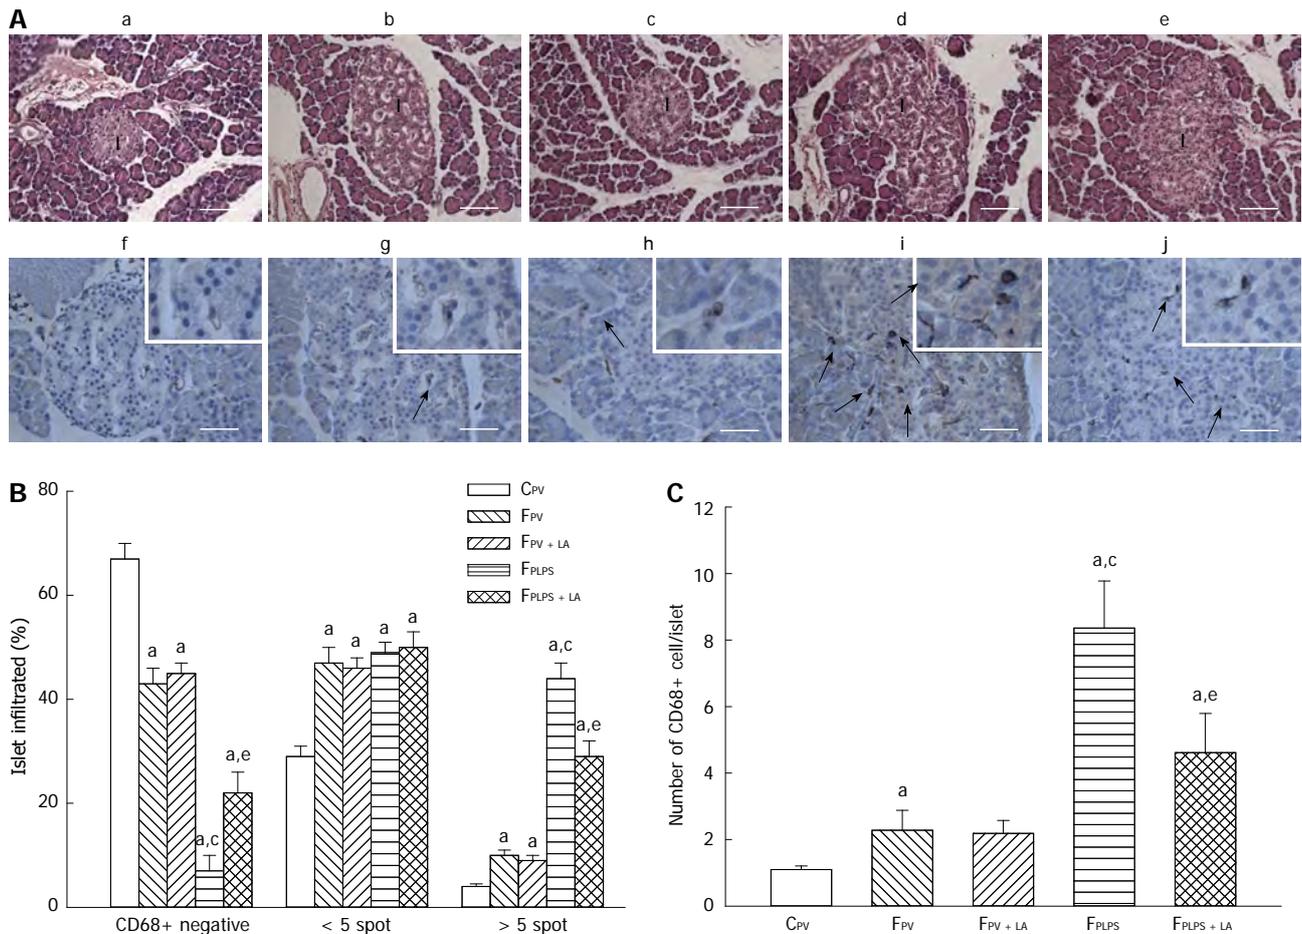

#### Histopathologic changes in the pancreatic islets

We then examined the histopathological response to our

treatments in the pancreas. Following LPS treatment, pancreatic islets exhibited damage that was attenuated with LA administration (Figure 5, top panels). Consistently, the frequency and CD68-positive cell infiltration in fructose-fed animals was only slightly increased as compared to controls. However, they were markedly increased in following LPS infusion and attenuated with LA administration (Figure 5, bottom panels). Quantitation of this data shows the frequency of CD68-positive islets and numbers of CD68-positive cells/islet in fructose-fed rats were further elevated following LPS infusion and partially suppressed in those with LA administration.

#### Glucose-stimulated insulin secretion

Hyperglycemic clamp is the gold-standard method to evaluate glucose-stimulated insulin secretion *in vivo*<sup>[26]</sup>. Plasma glucose levels were not different during the basal period and maintained similar hyperglycemia during the clamp periods among experimental groups (Figure 6A). Increases in plasma insulin levels from baseline in fructose-fed animals were significantly lower than those in controls and further decreased in those infused with LPS under similar hyperglycemic conditions (Figure 6B). The diminished glucose-stimulated insulin secretion shown in fructose-fed controls was not significantly changed with

**Figure 5** Histopathological examination of pancreatic islets. A: Tissue samples from each subset of animals were analyzed by hematoxylin and eosin (HE) staining (a-CpV, b-FpV, c-FpV + LA, d-FpLPS, e-FpLPS + LA) and immunostaining with an antibody against CD68 (f-CpV, g-FpV, h-FpV + LA, i-FpLPS, j-FpLPS + LA); This data was then quantitated as (B) percentage of islets infiltrated and (C) number of CD68+ cells per islet. Arrows indicated CD68-positive cells. I: Islet. A total of 100 ± 25 islets per experimental group were blindly scored for CD68-positive cells around the periphery and/or within islets from 5 to 6 different animals. Islet area was measured by the area of islet capsule in pancreatic section with HE stain and computed using AxioVision LE 4.8.2.0 software. Values are expressed as mean ± SE, n = 6 per group. Line bar: 50 μm. <sup>a</sup>P < 0.05 vs CpV; <sup>c</sup>P < 0.05 vs FpV; <sup>e</sup>P < 0.05 vs FpLPS. C: Regular diet; F: High-fructose enriched diet; LA: Lipoic acid; LPS: Lipopolysaccharides.

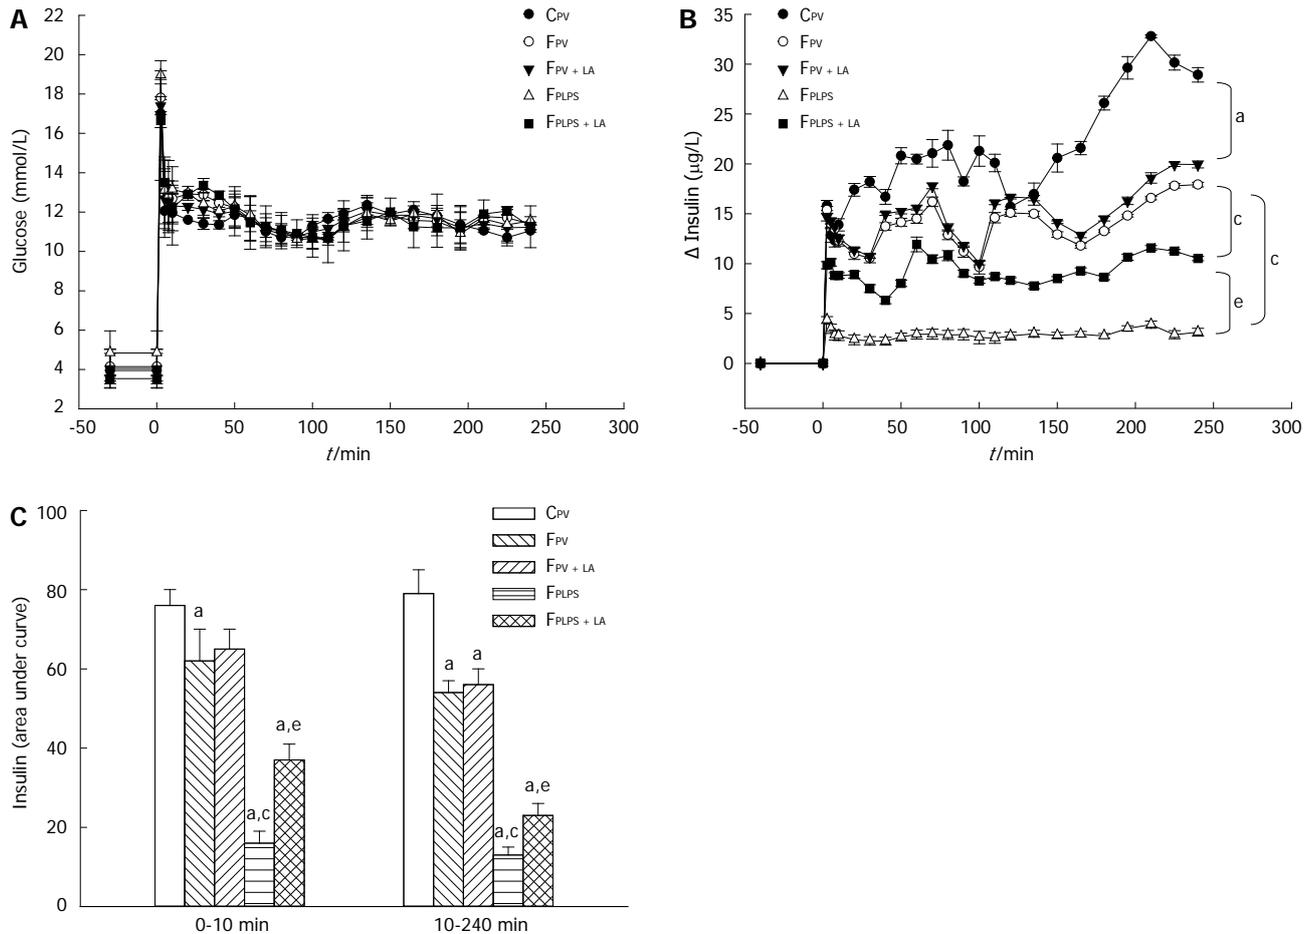

LA administration. However, intraportal LPS infusion significantly impaired the glucose-stimulated insulin secretion shown in fructose-fed controls, which was significantly reversed in those with LA treatment (Figure 6B). In addition, the first-phase insulin secretion (0-10 min post glucose treatment) and the second-phase insulin secretion (10-240 min post glucose treatment) were significantly lower in fructose-fed animals when compared with controls. This was further exacerbated following intraportal LPS infusion, a phenotype that was partially reversed when treated with LA (Figure 6C).

## DISCUSSION

Nonalcoholic steatohepatitis is not only highly correlated with the development of metabolic syndrome and type 2 diabetes mellitus, but is also a crucial factor in progression to cirrhosis and hepatocellular carcinoma<sup>[5]</sup>. In addition, mild portal endotoxemia has been speculated as a crucial risk factor to induce hepatic inflammation in the state of steatosis and impaired pancreatic β cell func-

tion<sup>[4]</sup>. This study explored the potential therapeutic role of the potent antioxidant α-LA in liver disease and associated pancreatic abnormalities. Using the animal model for metabolic steatohepatitis, fructose-fed rats, we found administration of LA reversed mild portal endotoxemia-induced inflammation. Further, portal endotoxemia also decreased glucose-stimulated insulin secretion, a phenotype that was reversed following LA treatment.

LA has been reported to scavenge free radicals, chelate metals and restore intracellular GSH, all factors associated with increasing age<sup>[13]</sup>. In addition, it is used as a therapeutic agent in several liver-related diseases such as alcohol-induced liver damage<sup>[27]</sup> and fatty liver disease<sup>[16]</sup> through multiple mechanisms. Our observations further establish LA as a therapeutic for liver disease. Specifically, our animal model shows LA improves endotoxin-induced hepatic disorders in addition to its established role as a treatment for chronic high-fructose feeding. These antioxidant and anti-inflammatory characteristics may be in the ability of LA to restore tissue GSH-dependent antioxidant defenses during portal endotoxin attack.

**Figure 6** Effect of  $\alpha$ -lipoic acid on plasma glucose and insulin levels. A hyperglycemic clamp technique was used to evaluate glucose-stimulated insulin secretion. A: Plasma glucose levels during the clamp period; B: Change in insulin levels during clamp period; C: The insulin level averages during the first phase (0-10 min) and the second phase (10-240 min) of the clamp period. Values are expressed as mean  $\pm$  SE,  $n = 6$  per group. <sup>a</sup> $P < 0.05$  vs CpV; <sup>b</sup> $P < 0.05$  vs FpV; <sup>c</sup> $P < 0.05$  vs FpLPS. C: Regular diet; F: High-fructose enriched diet; LA: Lipoic acid; LPS: Lipopolysaccharides.

Furthermore, these data show LA administration significantly suppressed the augmented *TLR4* gene expression induced by mild portal endotoxemia but not chronic fructose feeding. Hepatic *TLR4* is activated by gut-derived LPS and attributed to the pathogenesis of liver inflammation<sup>[28]</sup>. In addition, *TLR4* signaling is involved in the development of fructose-induced steatosis in mice<sup>[29]</sup> and also required for liver steatosis, inflammation and a fibrogenic response after chronic alcohol treatment in *TLR4* transgenic mice<sup>[30]</sup>. In addition to LPS, other potential agents including saturated fatty acids (*i.e.*, palmitate) and alarmins (*i.e.*, HMGB1) have also been shown to stimulate the inflammatory response in a *TLR4*-dependent manner<sup>[31,32]</sup>. Hepatic *TLR4* signaling occurs not only in Kupffer cells but also in hepatic non-immune cell populations including hepatocytes, biliary epithelial cells, endothelial cells and hepatic stellate cells<sup>[33]</sup>. In brief, these observations implicate *TLR4*-mediated inflammatory signaling in hepatic cell populations are crucially involved in the development of NAFLD, affected individually by diet components and portal endotoxemia.

Our observations showed that LA not only significantly improved the inflammatory changes in fructose-

induced NASH but also diminished the detrimental inflammatory response of the pancreas. Consistent with our results, LA has a protective effect on cholecystokinin-octapeptide induced acute pancreatitis in rats<sup>[15]</sup>. LA was reported to have a dose-related cytoprotective effect on hydrogen peroxide-induced oxidative stress on pancreatic beta cells. On the other hand, LA could also directly suppress insulin secretion in pancreatic beta cells at high concentrations by inducing AMP-activated protein kinase activation<sup>[34]</sup>. Taken together, data from these studies combined with our observations implicate a beneficial effect of LA on impaired pancreatic insulin secretion. This effect might be attributed to its anti-oxidative and anti-inflammatory actions on mild portal endotoxemia-induced liver inflammation and subsequent pancreatic damage, but not its direct effect on pancreatic beta cell secretion.

Nevertheless, the selected dose of intraportal LPS infusion was based on evaluating its effects on the mortality rate and systemic endotoxin levels during 4-wk infusion period in our previous study<sup>[11]</sup>. Consistently, this low-dose LPS infusion caused subacute hepatic inflammation that could be almost completely be cleared by Kupffer cells once it passed through the liver, so that the arterial

plasma endotoxin levels were not different among experimental groups.

The present study showed that administration of LA could protect liver from LPS-induced oxidative stress and inflammation while reversing the subsequent impairment of the pancreas in rats with fructose-associated fatty liver disease. However, LA had no effect on oxidative stress induced by high-fructose feeding. Clinical implications of this observation suggest both the suppression of portal endotoxemia-induced oxidative stress and dietary interventions are crucial for improving symptoms of NASH.

Although both oxidative stress induced by low-dose intraportal LPS infusion and high-fructose feeding have been demonstrated to contribute to the development of steatohepatitis in fructose-fed rats, the possible involvement of TLR4 signaling in individual hepatic cell populations remain elusive in the present study.

In conclusion, the present study demonstrates that LA can significantly reduce intraportal LPS-induced liver inflammation and associated deterioration of insulin secretion function in this metabolic syndrome rodent model. In addition, it is also implicated that hepatic TLR4 signaling might not only play a significant role in chronic-fructose-feeding induced hepatic steatosis but also in its subacute inflammatory change induced by mild portal endotoxemia and associated extrahepatic disorders in this model.

## COMMENTS

### Background

$\alpha$ -lipoic acid (LA), a potent antioxidant and also an inducer of endogenous antioxidants has been reported to protect the liver and pancreas from injury.

### Research frontiers

Chronic stress such as portal endotoxemia has been documented to activate hepatic Kupffer cells and cause the release of reactive oxygen species, potentially inducing inflammatory changes in the liver and impairing pancreatic functions. The potential therapeutic effect of LA on mild portal endotoxemia and fructose-induced inflammatory changes of fatty liver and impaired pancreatic insulin secretion in rats remain controversial.

### Innovations and breakthroughs

LA has been documented to have a protective effect on hepatopancreatic damage. However, the effect of LA on lipopolysaccharide-induced non-alcoholic steatohepatitis (NASH) remains unclear. The present result in this manuscript has a significant contribution to clarify this issue.

### Applications

The present study implicates that LA might suppress inflammatory change of steatosis and associated deterioration of insulin secretion in the patients with metabolic syndrome.

### Terminology

Alpha LA is a potent antioxidant and an inducer of endogenous antioxidants. It also has a protective effect on hepatic and pancreatic injury.

### Peer review

The authors found that LA quenches inflammation and oxidative stress, leading to attenuation of NASH. So far a few reports describe the effect of LA on lipopolysaccharide-induced NASH. The manuscript represents a major effort to fill the gap.

### Abstract

**AIM:** To identify the downstream regulated genes of *GAEC1* oncogene in esophageal squamous cell carcinoma and their clinicopathological significance.

**METHODS:** The anti-proliferative effect of knocking down the expression of *GAEC1* oncogene was stud-

ied by using the RNA interference (RNAi) approach through transfecting the *GAEC1*-overexpressed esophageal carcinoma cell line KYSE150 with the pSilencer vector cloned with a *GAEC1*-targeted sequence, followed by MTS cell proliferation assay and cell cycle analysis using flow cytometry. RNA was then extracted from the parental, pSilencer-*GAEC1*-targeted sequence transfected and pSilencer negative control vector transfected KYSE150 cells for further analysis of different patterns in gene expression. Genes differentially expressed with suppressed *GAEC1* expression were then determined using Human Genome U133 Plus 2.0 cDNA microarray analysis by comparing with the parental cells and normalized with the pSilencer negative control vector transfected cells. The most prominently regulated genes were then studied by immunohistochemical staining using tissue microarrays to determine their clinicopathological correlations in esophageal squamous cell carcinoma by statistical analyses.

**RESULTS:** The RNAi approach of knocking down gene expression showed the effective suppression of *GAEC1* expression in esophageal squamous cell carcinoma cell line KYSE150 that resulted in the inhibition of cell proliferation and increase of apoptotic population. cDNA microarray analysis for identifying differentially expressed genes detected the greatest levels of downregulation of calpain 10 (*CAPN10*) and upregulation of trinucleotide repeat containing 6C (*TNRC6C*) transcripts when *GAEC1* expression was suppressed. At the tissue level, the high level expression of calpain 10 protein was significantly associated with longer patient survival (month) of esophageal squamous cell carcinoma compared to the patients with low level of calpain 10 expression ( $37.73 \pm 16.33$  vs  $12.62 \pm 12.44$ ,  $P = 0.032$ ). No significant correction was observed among the *TNRC6C* protein expression level and the clinicopathological features of esophageal squamous cell carcinoma.

**CONCLUSION:** *GAEC1* regulates the expression of

*CAPN10* and *TNRC6C* downstream. Calpain 10 expression is a potential prognostic marker in patients with esophageal squamous cell carcinoma.

Chan D, Tsoi MYT, Liu CD, Chan SH, Law SYK, Chan KW, Chan YP, Gopalan V, Lam AKY, Tang JCO. Oncogene *GAEC1* regulates *CAPN10* expression which predicts survival in esophageal squamous cell carcinoma. *World J Gastroenterol* 2013; 19(18): 2772-2780 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i18/2772.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i18.2772>

## INTRODUCTION

Esophageal squamous cell carcinoma (ESCC) has a multifactorial etiology which involves environmental and/or genetic factors<sup>[1,2]</sup>. The incidence of ESCC also shows marked variation in its geographic distribution and occurs at relatively high frequency in Asian regions including China<sup>[3]</sup>. Current modalities of therapy for this disease offer relatively poor survival and cure rates<sup>[4]</sup>, thus more investigations at the molecular level are essential for a better understanding the molecular pathogenesis of this disease and for making further improvements in diagnosis and treatment of ESCC.

Gene amplification and overexpression have been suggested as the major genomic aberrations involved in the pathogenesis of ESCC<sup>[5,6]</sup>. We previously employed the method of comparative DNA fingerprinting using inter-simple sequence repeat polymerase chain reaction (ISSR-PCR) and revealed that amplifications or deletions of chromosomal sequences are common events in both the preneoplastic lesions and carcinomas<sup>[7]</sup>. An analysis of the frequency of amplification or loss of individual ISSR-PCR profile bands led to the identification of a novel expressed sequence tag database entry of a cDNA clone from a chromosome 7 placental cDNA library<sup>[7,8]</sup>. Moreover, the ISSR-PCR fragment also showed 98% homology to a Homo sapiens chromosome 7 P1-derived artificial chromosome clone (approximately 125 kb) which has been mapped to chromosome band 7q22<sup>[9]</sup>. The amplification of chromosomal segment 7q22 has been implicated in many types of cancer. Reported examples include ESCC<sup>[10]</sup>, breast carcinoma<sup>[11]</sup>, pancreatic carcinoma<sup>[12]</sup>, renal-cell carcinomas<sup>[13]</sup> and T-cell leukemia<sup>[14]</sup>. Thus, further investigation on the newly identified ESCC-related genomic and expressed sequences mapped to chromosomal region 7q22 can be a fruitful approach for identifying new candidate genes crucial to the disease. We subsequently identified and characterized the role of a novel oncogene *GAEC1* which is located at 7q22 region, encodes a nuclear protein and shows a high frequency of gene amplification and overexpression in ESCC cell

lines and primary tumors<sup>[15]</sup>, as well as in colorectal adenocarcinoma<sup>[16]</sup>. Overexpression of *GAEC1* in 3T3 mouse fibroblasts caused increased cell proliferation, foci formation and colony formation in soft agar, comparable to *H-ras* overexpression. Further, injection of *GAEC1*-transfected 3T3 cells into athymic nude mice formed undifferentiated sarcoma *in vivo*, providing the first evidence about the oncogenic nature of *GAEC1*<sup>[15]</sup>. An increased *GAEC1* DNA copy number was also reported in 79% of colorectal adenocarcinomas and the copy numbers were significantly different among colorectal adenocarcinomas, adenomas, and non-neoplastic colorectal tissues<sup>[16]</sup>.

In this report, *GAEC1* was further characterized by identifying the downstream partners using cDNA microarray analysis on *GAEC1*-suppressed human esophageal carcinoma cell line KYSE150 which shows *GAEC1* overexpression. The prominently downstream-regulated genes were then studied by immunohistochemistry on a tissue microarray (TMA) of ESCC to determine their clinicopathological significance.

## MATERIALS AND METHODS

### ESCC specimens and cell lines

One hundred and thirty-two paired non-tumor and tumor fresh tissue samples were collected after esophagectomy with patients' consent at the Department of Surgery, Queen Mary Hospital, Hong Kong from 2001 to 2006. They were collected consecutively from esophagectomy specimens performed on patients who had received no prior treatment directed to the primary ESCC. The histopathological features were reported by specialist pathologists of the Department of Pathology, Queen Mary Hospital, Hong Kong. The clinicopathological parameters of the patients were collected prospectively and they included age, gender, tumor-node-metastasis pathological stages and histological grades. The actuarial survival rate of the patients was calculated from the date of surgical resection of the ESCC to the date of death or last follow-up. Management was by a pre-agreed standardized multidisciplinary protocol supervised by a senior specialist surgeon. The ESCC cell line KYSE150 is of Japanese origin. It was purchased from DSMZ (Braunschweig, Germany) and cultured as described<sup>[17]</sup>. The non-tumor esophageal epithelial cell line NE1 was used as the control to confirm the overexpression of *GAEC1* in KYSE150 and was cultured as previously described<sup>[18]</sup>.

### Preparation of small interfering RNA expression vector

A vector based RNA interference (RNAi) approach was used for suppressing the expression of *GAEC1* in KYSE150 ESCC cells. The pSilencer2.1-U6 neo vector (Ambion) was used to express the siRNA which is specific for targeting *GAEC1* expression. The pSilencer2.1-U6 neo Negative Control vector (Ambion) was used as the negative control which expressed a hairpin small interfering RNA (siRNA) with limited homology to any known sequences in the human, mouse and rat genomes. The siRNA target sequence of *GAEC1*

and the insert sequence were determined by the programs siRNA Target Finder and Insert Design Tool for the pSilencer™ Vectors (Ambion). The top strand of the insert sequence (P3-4) is 5'-GATCCGAAGTGGCTTCTGGATTAATTCAAGAGATTAATC-CAGAAGCCACTTCTTTTGGAAA-3' and the bottom strand is 5'-AGCTTTTCCAAAAAGAAGTGGCTTCTGGATTAATCTCTTGAATTAATC-CAGAAGCCACTTCG-3'. The top and bottom strands were annealed and cloned into the pSilencer2.1-U6 neo vector according to the manufacturer's instruction. The vectors were transfected into the KYSE150 cells as previously described<sup>[15]</sup> using FuGene HD (Roche Diagnostics GmbH) with G418 selection.

#### **RNA extraction and reverse transcription-polymerase chain reaction analysis**

RNA was extracted from the parental, pSilencer-P3-4 and pSilencer-negative control vectors transfected KYSE150 cells using the RNeasy mini Kit (Qiagen) after 2 mo selection under G418. About 2 µg DNA-free RNA from each sample was used for the multiplex semi-quantitative reverse transcription-polymerase chain reaction (RT-PCR) analysis with β-actin as the internal control to show the expression level of *GAEC1* as previously described<sup>[15]</sup>. Densitometry analysis was performed to compare the intensity of the PCR products after agarose gel electrophoresis under UV using Quantity-One program (Bio-Rad).

#### **Cell proliferation assay**

The cell proliferation of the parental, pSilencer-P3-4 and pSilencer-negative control vectors transfected KYSE150 cells was determined by MTS assay using the CellTiter 96 Aqueous One Solution (Promega) as previously described<sup>[15]</sup>.

#### **Cell cycle analysis**

The parental, pSilencer-P3-4 and pSilencer-negative control vectors transfected KYSE150 cells were resuspended in 500 L 1 × phosphate buffered saline and fixed with 500 L 70% ethanol. The cells were then suspended in 1 mL PI (20 µg/mL)/Triton X-100 (0.1% v/v) staining solution with RNase A (200 µg/mL) and then analyzed by the BD FACSCalibur flow cytometer. Different fractions of cell cycles were analyzed using the Modfit LT software (Verity Software House).

#### **cDNA microarray analysis**

The differentially expressed genes of the pSilencer-P3-4 vector transfected KYSE150 cells with suppressed *GAEC1* expression were identified using cDNA microarray analysis by making comparisons between the parental cells, pSilencer-negative control vectors transfected cells, and pcDNA3.1-*GAEC1* transfected cells with *GAEC1* overexpression<sup>[15]</sup>. The cDNA microarray analysis and the associated quality control using Human Genome U133 Plus 2.0 arrays (Affymetrix) were performed in the Genome Research Centre of the University of Hong Kong according to the Affymetrix's protocol. Briefly, to-

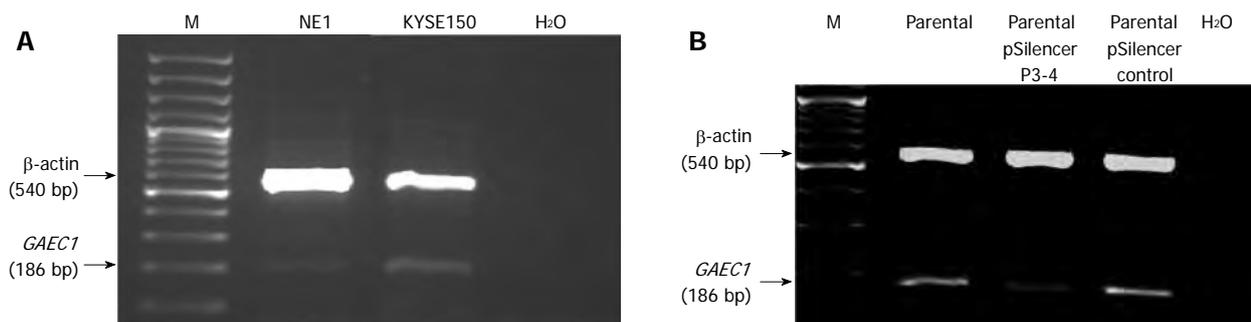

tal RNA was extracted from  $2 \times 10^6$  cells of each sample using RNeasy mini Kit (Qiagen). The RNA integrity was measured by the ratio of 28S/18S ribosomal RNA using Agilent 2100 Bioanalyzer. One microgram total RNA from each source was then reverse transcribed to the first-stranded cDNA by using oligo-dT linked-T7 RNA polymerase promoter sequence and the double-stranded cDNA was synthesized by using RT Kit (Invitrogen). The biotin labelled-cRNA was produced by *in vitro* transcription kit (Invitrogen) and purified by RNeasy mini columns (Qiagen). About 15 µg denatured cRNA was hybridized to each Human Genome U133 Plus 2.0 array (Affymetrix) and then stained with a streptavidin-phycoerythrin conjugate and the signals were detected with GeneArray scanner (Agilent). The microarray signals were analyzed by using Agilent Genespring GX and Affymetrix GeneChip Operating Softwares. The signal of each differentially expressed gene in the pSilencer-P3-4 transfected cells was determined by comparing with the parental cells and normalized with the pSilencer-negative control vector transfected cells. The threshold level of the corresponding up- or down-regulated genes with transfected pcDNA3.1-*GAEC1* vector is  $\geq 2$  folds.

#### **Tissue microarray and immunohistochemical staining**

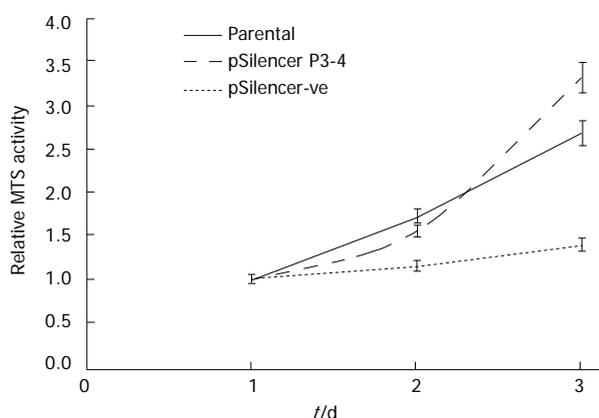

A TMA containing the 132 paired non-tumor esophageal epithelia and ESCC specimens were constructed as described previously<sup>[19]</sup>. The archival paraffin-embedded ESCC tissues were used under the ethical guidelines in the Department of Pathology of The University of Hong Kong. Immunohisto-chemical staining on the TMA sections was performed using the calpain 10 (0.03 mg/mL; Sigma-Aldrich) rabbit polyclonal antibody and *TNRC6C* (1 mg/mL; Abnova) mouse monoclonal antibody using the previously described methodology<sup>[19]</sup>. The dilution factors for the calpain 10 and *TNRC6C* antibodies were 1:50 and 1:150 respectively. The percentage of tumor cells positively stained formed the basis of grading as follows: Grade 0: less than 5%, Grade I: 5% to less than 25%, Grade II: 25% to less than 50% and Grade III: more than 50%. For each tissue sample, the tissue core with the highest grade was selected for subsequent statistical analysis. The high expression group combined those tumors with Grade II or III, and the low expression group combined those tumors with Grade 0 or I.

#### **Statistical analysis**

The Student's *t* test was used to evaluate the statistical significance of the differences in calpain 10 and *TNRC6C* expression between tumor and non-tumor tissues. The  $\chi^2$  test and *t* test were used to examine the statistical significance of the correlations between calpain 10 and *TNRC6C* expression with clinicopathological parameters. Kaplan-Meier plots and Cox multi-variant analysis were produced for overall patient survival, and statistical significance was evaluated by using Wilcoxon's signed-rank test. Statistical analysis were performed using SPSS Ver. 20.0 (SPSS, Chicago, IL, United States). Differences were

**Figure 1** Expression level of *GAEC1* in KYSE150 cells. A: Multiplex reverse transcription-polymerase chain reaction (RT-PCR) analysis showed the overexpression of *GAEC1* in KYSE150 compared with the non-tumor esophageal epithelial cell line NE1; B: Multiplex RT-PCR analysis demonstrated the down-regulation of *GAEC1* expression in KYSE150 cells transfected with pSilencer P3-4 vector compared with the parental cells and those transfected with pSilencer control vector. The amount of RNA in each lane was normalized with the amplification of  $\beta$ -actin. M: 100 bp ladder marker; H<sub>2</sub>O: Water control.

**Figure 2** MTS cell proliferation assays for esophageal squamous cell carcinoma cell line KYSE150. Cells were transfected with pSilencer vector cloned with the P3-4 sequence (pSilencer P3-4) or control vector (pSilencer-ve). MTS assays were then performed every 24 h for 3 d on each type of transfected cells and the parental cells. The respective MTS activities on each day were compared with the corresponding activities of day 1. Representative data from 3 independent experiments are shown.

considered statistically significant when the relevant *P* values were < 0.05.

## RESULTS

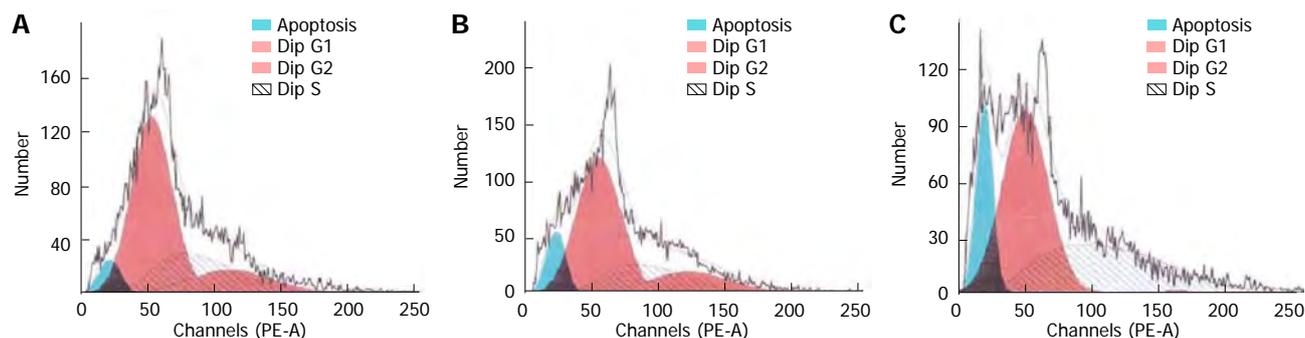

The overexpression of *GAEC1* in KYSE150 over NE1 was confirmed by multiplex semi-quantitative RT-PCR and densitometry analysis (Figure 1A). The expression level of *GAEC1* in pSilencer-P3-4 transfected KYSE150 cells was also determined by comparing with the parental and pSilencer-negative control vector transfected cells using densitometry measurement. The results indicated that the pSilencer-P3-4 transfected KYSE150 cells showed a down-regulation of *GAEC1* expression compared with the parental cells and the control. The comparison of the band intensities among the samples by densitometry measurement showed that the *GAEC1* expression level was down-regulated in the pSilencer-P3-4 transfected cells by about three folds (Figure 1B).

To assess the effect on cell proliferation with suppressed *GAEC1* expression, a comparison was made

between the MTS activities generated from the parental cells and the cells transfected with the pSilencer-negative control vector. The results indicated that the KYSE150 cells with down-regulated *GAEC1* showed an obvious reduction in proliferation rate compared with the parental and control-vector transfected cells (Figure 2). Further analysis on the cell cycle related changes using flow cytometry demonstrated an approximately 50% increase in apoptotic population with suppressed *GAEC1* expression, compared with the parental and control-vector transfected cells (Figure 3).

To identify the downstream candidate genes which are regulated by the suppressed *GAEC1* expression, cDNA microarray analysis was performed using the Human Genome U133 Plus 2.0 array (Affymetrix) which comprises of more than 47000 transcripts and variants in each chip. The results of the identified lists of more than 5-fold down-regulated (total 10 genes) and more than 3-fold up-regulated (total 9 genes) targets were shown in Table 1 respectively. All the listed genes were selected based on more than 2-fold expression signals of the corresponding up- or down-regulation of the respective genes when the cells were transfected with the pcDNA3.1-*GAEC1* vector and no significant fold change was detected with transfected pSilencer-negative control vector compared with parental cells. With suppressed *GAEC1* expression, calpain 10 (*CAPN10*) was identified to have the highest level (> 15 folds) of down-regulation (Table 1), while trinucleotide repeat containing 6C (*TNRC6C*) was shown to have the highest level (> 7 folds) of up-regulation (Table 1). These two *GAEC1*-regulated target genes with the greatest changes in expression level were followed up by the immunohistochemical analysis using the ESCC tissue microarray.

The expression of *CAPN10* and *TNRC6C* proteins in TMA sections sampling 132 paired tumor and non-tumor tissues from ESCC specimens was investigated using immunohistochemistry. Fourteen out of 132 tumors (10.61%) were found to belong to the high expression group of *CAPN10* expression. However, *TNRC6C* did not show any significant expression signals in all the ESCC cases analyzed except eight non-tumor esopha-

**Figure 3** Flow cytometry analyses for KYSE150 cells. KYSE150 transfected with pSilencer cloned with P3-4 sequence demonstrated an increased apoptotic population by approximately 50% (C) compared with the parental cells (A) and cells transfected with pSilencer-ve control vector (B).

All the listed genes were selected based on more than 2-fold of the corresponding up-regulation when *GAEC1* was overexpressed with transfected pcDNA3.1-*GAEC1* vector and no significant fold change with transfected pSilencer-negative control vector compared with parental cells.

geal tissues which also served as the positive controls. Representative examples of immunohistochemical staining of *CAPN10* and *TNRC6C* are shown in Figure 4. Correlation between expression level of *CAPN10* and clinicopathological features are summarized in Table 2. There was no significant correlation of any clinicopathological features with the expression level of *CAPN10*. The median survival of patients with high expression level of *CAPN10* was 38 mo whereas that of low expression level was 13 mo, and the survival range is from 0.72 to 65.15 mo. The difference was significant on both univariate and multi-variate analysis ( $P = 0.032$  and  $0.035$  respectively; Figure 5).

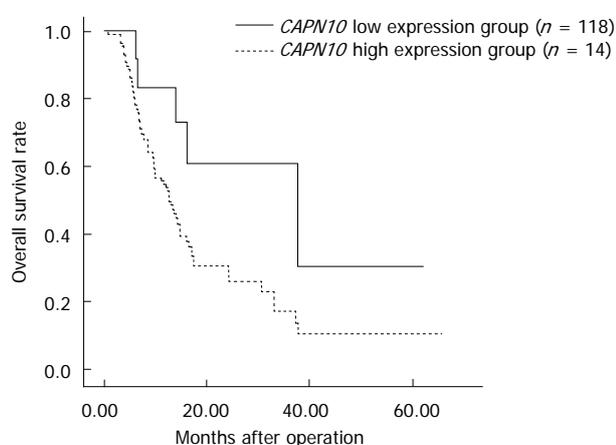

## DISCUSSION

Our previous study reported the oncogenic role of *GAEC1* in esophageal carcinogenesis and high expres-

sion level of *GAEC1* caused malignant transformation of normal cells<sup>[15]</sup>. High DNA copy number of *GAEC1* was also observed in colorectal adenocarcinoma and significant difference was reported in cancer sub-sites and tumor types<sup>[16]</sup>. From our previous study<sup>[15]</sup>, however, no significant correlation was observed between *GAEC1* amplification and clinicopathological parameters and prognosis in ESCC tumors, and thus the DNA amplification study of *GAEC1* is not included in this report. In the present study, an attempt was made to investigate the downstream-regulated genes when *GAEC1* expression was suppressed in an ESCC cell line KYSE150. Our group also investigated the ESCC cell lines which showed overexpression of *GAEC1* as we reported previously<sup>[15]</sup>. KYSE150 showed the more stable and consistent overexpression with time compared among the ESCC cell lines. Reduction of proliferation rate and increase in apoptotic population were observed in association with reduced

**Figure 4** Immunohistochemical staining of *CAPN10*. A: In normal esophageal epithelial tissue showing weak *CAPN10* staining; B: esophageal squamous cell carcinoma (ESCC) tissue showing strong *CAPN10* staining; C: ESCC tissue showing weak *CAPN10* staining in tumor. *CAPN10* was mainly localized in the cytoplasm of the cancer cells (original magnification, ×100).

**Figure 5** Overall 5-year survival rates as determined by the expression level of *CAPN10* in esophageal squamous cell carcinoma patients. Low expression group of *CAPN10* in ESCC patients showed a significantly lower 5-year survival rate than those of high expression group.

*GAEC1* expression in ESCC cells. Thus our study is the first report to demonstrate the significance of suppressing *GAEC1* as a target of reducing the malignant properties of ESCC. In order to assess whether the tumors are more proliferative, the use of other histological markers for assessing proliferation, such as Ki-67<sup>[20]</sup> and AgNOR<sup>[21]</sup>, in parallel to *CAPN10* is suggested in future studies to determine whether the *CAPN10* level is associated with progression of the disease. Similar targeting approach against potential oncogenes is now being explored intensively in the direction of gene therapy for various types of cancers<sup>[22]</sup>. Examples include the suppression of *MTA1* in esophageal carcinoma<sup>[23]</sup>, alpha-actinin-4 in oral carcinoma<sup>[24]</sup>, osteopontin in colon carcinoma<sup>[25]</sup> and *EGFR* in hepatocellular carcinoma<sup>[26]</sup>. The application of RNAi approach has been recognized as having high potential for the clinical application of targeted cancer therapy<sup>[27]</sup>. To date, clinical trials at different stages were reported and they targeted against various oncogenic components in various cancers, including metastatic melanoma, liver cancer, chronic myelogenous leukemia, pancreatic cancer and colon cancer<sup>[22]</sup>. Moreover, the

RNAi approach for targeting specifically on transforming growth factor-β has been developed as a “cancer vaccine” against ovarian cancer<sup>[22]</sup>. Thus our present study offers a new direction for exploring the application of RNAi-based method for suppressing the oncogenic target *GAEC1* as a novel gene therapy approach in our future investigations.

Calpain 10 (*CAPN10*) is a member of the mitochondrial calpain system<sup>[28]</sup>. Mitochondrial calpain system has been shown to promote caspase-independent programmed cell death *via* the apoptotic inducing factor-mediated mechanism<sup>[28]</sup> and its expression has been correlated to insulin-stimulated glucose uptake<sup>[29]</sup> and type 2 diabetes<sup>[30]</sup>. However, the correlation and functional roles of *CAPN10* in tumorigenesis are still not fully understood, although *CAPN10* has been linked to laryngeal<sup>[31]</sup>, colorectal<sup>[32]</sup> and pancreatic cancers<sup>[33]</sup>. In the present study, the RNAi-based suppression of *GAEC1*

in KYSE150 resulted in the suppression of *CAPN10* expression (approximately 15-fold compared with the parental cells). For those ESCC tumors belonging to the *CAPN10* low expression group, the 5-year survival rate is significantly lower than those belonging to the *CAPN10* high expression group. From the study of Moreno-Luna *et al.*<sup>[31]</sup>, *CAPN10* genotype 12 was reported to be related with a worse prognosis in laryngeal cancer, which is similar to our present study which is newly described in ESCC. Our observation from the low *CAPN10* expression group implied the possibility that the oncogene *GAEC1* overexpression within this group might involve more prominently at the initial stage of molecular carcinogenesis, so that the expression level of *CAPN10* was lower in ESCC at the time of operation. Similar pattern of oncogenic expression happening at the earlier stage of carcinogenesis was also observed from fibroblast growth factor-2 in melanoma<sup>[34]</sup> and *KLF4* in cutaneous squamous epithelial neoplasia<sup>[35]</sup>. The verification of this hypothesis can be followed up with the future development of *GAEC1*-specific antibody, which is still unavailable in market, for the future analysis of *GAEC1* expression in various stages in ESCC. This important finding also paves the path for the further investigation for the roles of *CAPN10* in the molecular pathogenesis of esophageal carcinoma. Moreover, in the present study, no significant correlation of any other clinicopathological features with the expression level of *CAPN10* was found, but *CAPN10* predicted the poor survival of ESCC patients. Similar results were also reported previously in which the overexpression of a chemokine *CXCL12* in ovarian cancer<sup>[36]</sup> and a protein Rad51 for homologous recombination in ESCC<sup>[37]</sup> also showed a correlation to the survival of patients, but no correlation to other clinicopathological features was found. The level of *CAPN10* is also not associated with local lymph node and distant metastasis in the ESCC cases, implying the possibility that *GAEC1* expression may not be relevant to the control of metastasis in ESCC.

*TNRC6C* has been reported to be the miRNA regulation-related genes and their mutation was correlated to cancer development through deregulating the miRNA regulation<sup>[38]</sup>. *TNRC6C* was also shown in the present study to undergo up-regulation with the suppression of *GAEC1* expression by the RNAi approach, but there was no significant expression of *TNRC6C* in the ESCC cases studied. This may be due to the down-regulation of *TNRC6C* in ESCC by other unknown mechanisms which are subjected to further investigation. Future study of *TNRC6C* mutation in ESCC is required to investigate the possible roles of *TNRC6C* in carcinogenesis. Moreover, among the down-regulated genes identified by cDNA microarray with suppressed *GAEC1* expression, activation-induced cytidine deaminase (AID) was reported to show overexpression in Barrett's esophagus and Barrett's adenocarcinoma<sup>[39]</sup>, but there was no investigation on the roles of AID in molecular pathogenesis in ESCC. AID has been shown to induce somatic mutations in host genes and implicated in the carcinogenesis of lung<sup>[40]</sup>,

colorectal<sup>[41]</sup> and gastric cancers<sup>[42]</sup>. Therefore, our findings provide a new evidence for prompting future study on the role of AID in the development of ESCC.

In conclusion, the suppression of *GAEC1* expression resulted in reduced tumor cell proliferation, increased apoptotic population in ESCC cells and also regulated *CAPN10* and *TNRC6C* expression. The low expression of *CAPN10* predicted the poor survival of ESCC patients.

## ACKNOWLEDGMENTS

Special thanks are given to Professor George SW Tsao of the Department of Anatomy of The University of Hong Kong for giving us the cell line NE1 as the control. Tang JCO would also like to thank the Griffith University of Australia for awarding the Visiting Research Fellowship (2012).

## COMMENTS

### Background

Esophageal squamous cell carcinoma (ESCC) has a multifactorial etiology which involves environmental and/or genetic factors. More investigations at the molecular level are essential for a better understanding the molecular pathogenesis of this disease. Authors subsequently identified and characterized the role of a novel oncogene *GAEC1* which is located at 7q22 region. In this report, *GAEC1* was further characterized by identifying the downstream partners. The prominently downstream-regulated genes were then studied by immunohistochemistry on ESCC tissues to determine their clinicopathological significance.

### Research frontiers

The anti-proliferative effect of knocking-down the expression of *GAEC1* in ESCC cells was studied. The research hotspot is to find out the target genes which are most regulated by *GAEC1* and to determine their clinicopathological significance in ESCC.

### Innovations and breakthroughs

The RNA interference (RNAi) approach showed effective suppression of *GAEC1* expression in ESCC cells to inhibit cell proliferation and increase apoptosis. cDNA microarray analysis for differentially expressed genes identified the greatest levels of downregulation of calpain 10 (*CAPN10*) and upregulation of trinucleotide repeat containing 6C when *GAEC1* expression was suppressed. High level expression of calpain 10 was significantly associated with longer patient survival. This is the first study to explore the regulatory roles of *GAEC1* on the downstream targets and to report the association of *CAPN10* to the survival of ESCC patients.

### Applications

This study suggested that the potential use of *CAPN10* as a prognostic marker to predict the survival of ESCC patients after operation. The findings of the present study pave the path for the future related studies in other human cancers.

### Terminology

Squamous cell carcinoma: It is a cancer of a kind of epithelial cell called squamous cell. Squamous cells also occur in the lining of the digestive tract, such as the esophagus; Oncogene: An oncogene is a gene that has the potential to cause cancer. In tumor cells, they are often mutated or expressed at high levels.

### Peer review

This is a good study in which the authors employed *GAEC1* RNAi to knockdown the expression of *GAEC1*, investigated its effects on *GAEC1*-overexpressed esophageal carcinoma cell line KYSE150, and then explored the possible mechanisms. The study design is reasonable, statistical methods are appropriate.

### Abstract

**AIM:** To investigate role of putative mitogen-activated protein kinase activator with WD40 repeats (MAWD)/MAWD binding protein (MAWBP) in gastric cancer (GC).

**METHODS:** MAWBP and MAWD mRNA expression level was examined by real-time reverse transcriptase-polymerase chain reaction and semi-quantitative polymerase chain reaction in six GC cell lines. Western blotting was used to examine the protein expression levels. We developed GC cells that stably overexpressed MAWBP and MAWD, and downregulated expression by RNA interference assay. Proliferation and migration

of these GC cells were analyzed by 3-(4,5-dimethyl-2-thiazolyl)-2,5-diphenyl tetrazolium bromide (MTT), soft agar, tumorigenicity, migration and transwell assays. The effect of expression of MAWBP and MAWD on transforming growth factor (TGF)- $\beta$ 1-induced epithelial-mesenchymal transition (EMT) was examined by transfection of MAWBP and MAWD into GC cells. We detected the levels of EMT markers E-cadherin, N-cadherin and Snail in GC cells overexpressing MAWBP and MAWD by Western blotting. The effect of MAWBP and MAWD on TGF- $\beta$  signal was detected by analysis of phosphorylation level and nuclear translocation of Smad3 using Western blotting and immunofluorescence.

**RESULTS:** Among the GC cell lines, expression of endogenous MAWBP and MAWD was lowest in SGC7901 cells and highest in BGC823 cells. MAWBP and MAWD were stably overexpressed in SGC7901 cells and knocked down in BGC823 cells. MAWBP and MAWD inhibited GC cell proliferation *in vitro* and *in vivo*. MTT assay showed that overexpression of MAWBP and MAWD suppressed growth of SGC7901 cells ( $P < 0.001$ ), while knockdown of these genes promoted growth of BGC823 cells ( $P < 0.001$ ). Soft agar colony formation experiments showed that overexpression of MAWBP and MAWD alone or together reduced colony formation compared with vector group in SGC7901 ( $86.25 \pm 8.43$ ,  $12.75 \pm 4.49$ ,  $30 \pm 6.41$  vs  $336.75 \pm 22.55$ ,  $P < 0.001$ ), and knocked-down MAWBP and MAWD demonstrated opposite effects ( $131.25 \pm 16.54$ ,  $88.75 \pm 11.12$ ,  $341.75 \pm 22.23$  vs  $30.25 \pm 8.07$ ,  $P < 0.001$ ). Tumorigenicity experiments revealed that overexpressed MAWBP and MAWD inhibited GC cell proliferation *in vivo* ( $P < 0.001$ ). MAWBP and MAWD also inhibited GC cell invasion. Transwell assay showed that the number of traverse cells of MAWBP, MAWD and coexpression group were more than that in vector group ( $84 \pm 16.57$ ,  $98.33 \pm 9.8$ ,  $29 \pm 16.39$  vs  $298 \pm 11.86$ ,  $P < 0.001$ ). Coexpression of MAWBP and MAWD significantly decreased the cells traversing the matrix membrane. Conversely, knocked-down MAWBP

and MAWD correspondingly promoted invasion of GC cells ( $100.67 \pm 14.57$ ,  $72.66 \pm 8.51$ ,  $330.67 \pm 20.55$  vs  $27 \pm 11.53$ ,  $P < 0.001$ ). More importantly, coexpression of MAWBP and MAWD promoted EMT. Cells that coexpressed MAWBP and MAWD displayed a pebble-like shape and tight cell-cell adhesion, while vector cells showed a classical mesenchymal phenotype. Western blotting showed that expression of E-cadherin was increased, and expression of N-cadherin and Snail was decreased when cells coexpressed MAWBP and MAWD and were treated with TGF- $\beta$ 1. Nuclear translocation of p-Smad3 was reduced by attenuating its phosphorylation.

**CONCLUSION:** Coexpression of MAWBP and MAWD inhibited EMT, and EMT-aided malignant cell progression was suppressed.

**Key words:** Gastric cancer; Mitogen-activated protein kinase activator with WD40 repeats binding protein; Mitogen-activated protein kinase activator with WD40 repeats; Invasion; Transforming growth factor- $\beta$ ; Epithelial-mesenchymal transition

**Core tip:** Our previous study revealed that mitogen-activated protein kinase activator with WD40 repeats (MAWD) and MAWD binding protein (MAWBP), acting as a complex, were differentially expressed in gastric cancer (GC) tissues compared with that in normal gastric tissues. The present study provided direct evidence that MAWBP and MAWD inhibited proliferation and migration of GC cells. Importantly, interaction of MAWBP and MAWD influenced expression of epithelial-mesenchymal transition (EMT) markers induced by transforming growth factor (TGF)- $\beta$ 1 in GC cells. It indicated that coexpression of MAWBP and MAWD inhibited TGF- $\beta$ 1-induced EMT, thus suppressing EMT-aided GC malignant progression.

MAWBP and MAWD inhibit proliferation and invasion in gastric cancer. *World J Gastroenterol* 2013; 19(18): 2781-2792 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i18/2781.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i18.2781>

## INTRODUCTION

Gastric cancer (GC) is the second most common cause of cancer death worldwide and is especially common in China<sup>[1]</sup>. Multiple factors are involved in the development of GC carcinogenesis. Molecular genetic studies have addressed accumulation of multiple genes and proteins alteration involved in GC development<sup>[2,3]</sup>. Investigation of GC biomarkers has focused on discovering differential protein signatures and has explored their biology

mechanisms. The genes involved include activation of *c-myc*, *erbB-2*, *c-met*, and *k-ras*<sup>[4-7]</sup> oncogenes and inactivation of tumor suppressor genes *p53*, *APC*, *E-cadherin* and *RUNX3*<sup>[8-10]</sup>.

Our laboratory previously found (using 2D gel electrophoresis and mass spectrometry) that expression of mitogen-activated protein kinase activator with WD40 repeats (MAWD) and MAWD binding protein (MAWBP) were differentially expressed in GC tissues. MAWD interacts with MAWBP and forms complexes in GC cell lines<sup>[11]</sup>, which suggests that these proteins are involved in GC carcinogenesis. Combined analysis of MAWBP and MAWD expression would provide useful information in uncovering their roles in GC.

The proteins MAWBP and MAWD were discovered in 2000 and 2001, respectively<sup>[12,13]</sup>. MAWD is widely expressed in many tissues and sequence analysis has indicated that MAWD contains a WD40 repeat domain. Datta *et al*<sup>[14]</sup> have shown that MAWD-homolog protein serine-threonine kinase receptor-associated protein (STRAP) recruits Smad7, forming a complex that increases inhibition of transforming growth factor (TGF)- $\beta$  signaling. Iriyama *et al*<sup>[13]</sup> tried to detect MAWD-related protein using a conventional two-hybrid technique and found MAWBP had an affinity for MAWD. The effects of MAWD in cancer have been reported in breast, colon and lung cancer but views about its role in cancer are divergent<sup>[15]</sup>. However, there is no current report on the function of MAWD in GC, and little is known about MAWBP other than its affinity for MAWD.

We hypothesize that MAWBP and MAWD interactions have a key role in GC tumorigenesis, and therefore investigated their biological function in GC cell lines. We found that these two proteins inhibited cell proliferation, and coexpression of MAWBP and MAWD obviously suppressed migration as well as invasive behavior of GC cells. Recent evidence implies that epithelial-mesenchymal transition (EMT) contributes to cancer progression, invasion and metastasis in various cancers<sup>[16,17]</sup>. TGF- $\beta$  is the main and best-characterized inducer of EMT during embryogenesis and cancer pathogenesis<sup>[18]</sup>. MAWBP and MAWD are involved in the TGF- $\beta$  signaling pathway<sup>[14]</sup>. We further sought to determine whether coexpression of MAWBP and MAWD could inhibit TGF- $\beta$ 1-induced EMT.

The canonical EMT program is characterized by complex proteome changes, leading to loss of epithelial markers such as E-cadherin, and expression of mesenchymal markers such as vimentin and N-cadherin<sup>[19]</sup>. Transcriptional regulator Snail is also activated in EMT. TGF- $\beta$  signaling regulates expression of Snail, SOX2 and SOX4<sup>[20]</sup>.

In this study, we analyzed the effect of MAWBP and MAWD on expression of E-cadherin, N-cadherin and Snail. We further demonstrated the relationship of this effect with TGF- $\beta$  signalling pathway via detection of the phosphorylation level and nuclear translocation of Smad3. Our findings suggest that coexpression of MAWBP and MAWD inhibits TGF- $\beta$ 1-induced EMT

and suppresses EMT-aided GC cell invasion.

## MATERIALS AND METHODS

### Cell lines and cell culture

GC cell lines BGC823, MGC803, SGC7901, AGS, N87 and MKN45 were cultured in Dulbecco's Modified Eagle's Medium (DMEM; Gibco BRL, Gaithersburg, MD, United States), supplemented with 5% fetal bovine serum (FBS). All cell lines were maintained at 37 °C in 5% CO<sub>2</sub> as previously described<sup>[21,22]</sup>.

### Plasmid construction

We constructed MAWBP and MAWD expression plasmids using pcDNA3.1B(-). Total RNA was extracted from 19-wk-old fetal liver. MAWBP and MAWD cDNA was produced by reverse-transcriptase polymerase chain reaction (RT-PCR). The reaction was initiated by 5-min incubation at 94 °C; 35 cycles of 94 °C for 45 s, 56 °C for 45 s, 72 °C for 60 s; and terminated after a 10-min extension at 72 °C. Products were purified by gel extraction. Recombinant plasmids were transferred into *Escherichia coli* DH5 $\alpha$ , and identified by restriction enzymes digestion and sequencing analysis. Then, we constructed MAWBP and MAWD short hairpin RNA (shRNA) plasmids. Oligonucleotides were annealed and ligated to pSilencer3.1-H1-Neo. All of the primers are shown on Table 1.

### Real-time PCR

Total RNA was extracted using Trizol (Invitrogen, Carlsbad, CA, United States), and subjected (5  $\mu$ g) to RT-PCR (Table 1). The internal control,  $\beta$ -actin, was processed with all specimens simultaneously. Real-time PCR was performed using Applied Biosystem 7500 Real-Time PCR System (Foster City, CA, United States). Data were analyzed using the relative standard curve method.

### Western blotting

Proteins were extracted from cells for western blotting. Proteins (50  $\mu$ g) were separated on sodium dodecyl sulfate polyacrylamide gel electrophoresis and transferred to polyvinyl difluoride membranes (Bio-Rad, Hercules, CA, United States). Immunoreactivity was tested with anti-MAWD (1:500, our laboratory), anti-MAWBP (1:500, our laboratory)<sup>[11]</sup>, E-cadherin (1:500, BD, Franklin Lakes, NJ, United States), N-cadherin (1:500, BD), Snail (1:500, Cell Signaling, Danvers, MA, United States), diluted in blocking buffer at 4 °C overnight. The signal was detected by Super Signal West Dura Extended Duration Substrate (Thermo Scientific, Rockford, IL, United States).

### Transfection studies

SGC7901 cells were transfected with overexpression plasmids, while BGC823 cells were transfected with shRNA plasmids. Cells were cultured at 60%-70% confluence in 35-mm plates and were transfected using Lipofectamine 2000 (Invitrogen). Except that mono-plasmids and empty vector were transfected into GC cells, overexpressed

**Table 1** List of oligonucleotide primers

MAWD: Mitogen-activated protein kinase activator with WD40 repeats; MAWBP: MAWD binding protein; shRNA: Short hairpin RNA.

plasmids of MAWBP and MAWD were cotransfected into SGC7901 cells. shRNA plasmids of MAWBP and MAWD were cotransfected into BGC823 cells. At 48 h post-transfection, cells were seeded for 21 d in selection medium containing 400  $\mu$ g/mL G418, to screen for stable clones. The efficacy of transfection was identified by RT-PCR and Western blotting.

### 3-(4,5-Dimethyl-2-thiazolyl)-2,5-diphenyl tetrazolium bromide assay

Stable transfected cells ( $1 \times 10^3$ ) in 200  $\mu$ L DMEM supplemented with 5% FBS were seeded in duplicate into each well of 96-well culture plates, and 10  $\mu$ L 3-(4,5-Dimethyl-2-thiazolyl)-2,5-diphenyl tetrazolium bromide (MTT, GenView, Jacksonville, FL, United States) (5 mg/mL) was added at 0, 24, 48, 72 and 96 h. The MTT was removed after 4 h incubation, and 100  $\mu$ L dimethylsulfoxide (Amresco, Solon, OH, United States) was pipetted into each well and incubated for 30 min. Absorbance was measured at 570 nm using an iMark Microplate Reader (Bio-Rad, Hercules, CA, United States).

### Soft agar colony formation assay

Cells ( $3 \times 10^3$ ) were trypsinized and resuspended in 4 mL 0.3% agar in DMEM containing 10% FBS, and overlaid with 0.6% agar in 60-mm culture dishes. The dishes were incubated routinely for 21 d. Colonies were stained with 0.2% p-iodonitrotetrazolium violet, photographed,

and counted.

### **Tumorigenicity assay in nude mice**

Animal experiments were carried out in strict accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the Ethics Committee of Peking University. All efforts were made to minimize suffering. Transfected cells were resuspended in  $1 \times$  Hank's Buffer at a concentration of  $5 \times 10^5$  cells/mL. A 100- $\mu$ L suspension was injected subcutaneously into the left dorsal flank of 15 5-wk-old female nude mice, and the right side was inoculated with GC cells transfected by vector alone as a control. The mice were checked every 3 d for tumor appearance, and the large (a) and small (b) diameters of the palpable tumors were recorded for tumor volume calculation according to  $a \times b^2 \times 0.5$ .

### **Wound healing assay**

Cells were cultured at 80%-90% confluence in 60-mm dishes. Cells were scratched with a pipette tip to produce a straight line. The detached cells were washed three times with phosphate buffered solution (PBS) and incubated for a further 24 h. The scratched gap was inspected at 0, 2, 4, 6, 12 and 24 h. Photographs were taken at  $\times 200$  magnification, using a TS100 inverted microscope (Nikon, Tokyo, Japan).

### **Transwell assay**

The invasion assay was performed using a BD Matrigel Invasion Chamber. Cells ( $1 \times 10^5$ ) were suspended in serum-free DMEM and seeded on matrix membranes. DMEM supplemented with 10% FBS was used as a chemoattractant. After 48 h incubation, cells were fixed with methanol and stained with crystal violet for 20 min. Cells that penetrated the membrane were counted.

### **Immunofluorescence**

Cells were grown on glass slides, washed with PBS, fixed in methanol for 10 min, and processed for immunofluorescence. Cells were exposed to anti-p-Smad3 overnight at 4 °C, incubated for 1 h with rhodamine-conjugated anti-rabbit secondary antibodies, and nuclei were stained with 4',6-diamidino-2-phenylindole. Cells were studied with a confocal fluorescence imaging microscope (TCS-SP5; Leica, Mannheim, Germany).

### **Analysis of TGF- $\beta$ pathway responses**

Cells were starved for 24 h, and then incubated in 5% FBS-DMEM containing 2 or 4 ng/mL TGF- $\beta$  for 24 or 48 h. Plasminogen activator inhibitor (PAI)-1 promoter assays were used to select the optimum TGF- $\beta$  conditions. Transfected cells were cultured in 5% FBS-DMEM containing 4 ng/mL TGF- $\beta$  for 24 h. PhosphoSafe Extraction Reagent (Merck, San Diego, CA, United States) was used to extract phosphoprotein. P-Smad3 (1:1000, Abcam, Cambridge, United Kingdom) and p-Smad2 (1:500, Millipore, Temecula, CA, United States) were analyzed by western blotting as described above. Smad2

(1:500, Bioworld, Boston, MA, United States) and Smad3 (1:500, Bioworld) were detected at the same time. We then separated the cytosolic and nuclear fractions according to the protocol of the Nuclear-Cytosol Extraction Kit (Applygen Technologies Inc., Beijing, China) and detected p-Smad3 levels. Nuclear translocation ability of p-Smad3 (1:50) was analyzed by confocal microscopy as described above.

### **Ethics**

The study has been examined and approved ethically by the Ethics Committee of Beijing Cancer Hospital.

### **Statistical analysis**

Statistical analysis used SPSS version 16.0. Student's *t* test and analysis of variance were used for data measurement. Quantitative values were presented as mean  $\pm$  SD. Differences with  $P < 0.05$  were considered statistically significant.

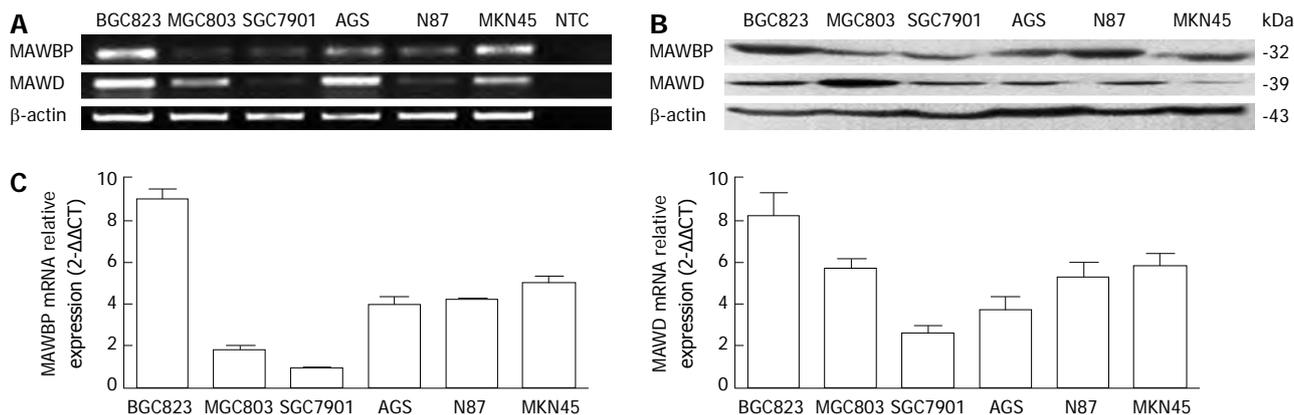

## **RESULTS**

### **MAWBP and MAWD inhibited proliferation and tumorigenicity of GC cells**

BGC823, MGC803, SGC7901, AGS, N87 and MKN45 GC cell lines were used to detect MAWBP and MAWD expression, which was found to differ between the cell types. RT-PCR and real-time PCR revealed low levels of endogenous MAWBP and MAWD mRNA in SGC7901 cells but high levels in BGC823 cells, and Western blotting confirmed these results (Figure 1). These two cell lines were selected for the following experiments.

To investigate further biological function of MAWBP and MAWD in GC cells, MAWBP-pcDNA3.1 and MAWD-pcDNA3.1, alone or in combination, and empty vector were transfected into SGC7901 cells, in which these two proteins were expressed at a lower level compared with other GC cells. G418-resistant clones were isolated, which were stably transfected cells. These cells were termed as MAWBP, MAWD, MAWBP/D (MAWBP and MAWD cotransfected cells) and vector, respectively. shRNA plasmid MAWBP-pSilencer3.1 and MAWD-pSilencer3.1, alone or in combination, and empty vector were transfected into BGC823 cells, in which they were expressed at a higher level compared with other GC cells. The stably transfected cells were termed as sh-MAWBP, sh-MAWD, sh-MAWBP/D (MAWBP and MAWD co-downregulated groups) and sh-vector, respectively. We analyzed MAWBP and MAWD expression at the mRNA and protein levels by semi-quantitative RT-PCR and Western blotting, respectively.

In the MTT assay, cell growth in the overexpressed group was suppressed in the MAWBP, MAWD and MAWBP/D groups, compared with the vector group (Figure 2A,  $P < 0.001$ ). Knockdown of MAWBP and MAWD in BGC823 cells using RNA interference (RNAi) increased cell growth (Figure 2B,  $P < 0.001$ ). The soft agar assay in overexpressed cells showed reduced colony formation for the MAWBP, MAWD, and MAWBP/D

**Figure 1** Analysis of expression of mitogen-activated protein kinase activator with WD40 repeats binding protein and mitogen-activated protein kinase activator with WD40 repeats in six gastric cancer cell lines. A: mRNA expression for mitogen-activated protein kinase activator with WD40 repeats (MAWD)/MAWD binding protein (MAWBP) in BGC823, MGC803, SGC7901, AGS, N87 and MKN45 six gastric cancer cell lines was detected by reverse transcription-polymerase chain reaction (PCR). There was a low level of endogenous MAWBP and MAWD mRNA in SGC7901 cells, and a high level in BGC823 cells; B: Expression of MAWBP and MAWD proteins was detected by Western blotting. The expression level was lower in SGC7901 cells than in the other cell lines. Expression of MAWBP and MAWD was higher in BGC823 cells than in the other cells; C: mRNA expression for MAWBP and MAWD was detected by real-time PCR. There were lower levels of endogenous MAWD and MAWBP mRNA in SGC7901 cells, and higher levels in BGC823 cells. NTC: No template control.

groups for cell number and size compared with the vector group (Figure 2C, clones number:  $86.25 \pm 8.43$ ,  $12.75 \pm 4.49$ ,  $30 \pm 6.41$  vs  $336.75 \pm 22.55$ ,  $P < 0.001$ ). The corresponding knockdown group demonstrated the opposite effects (Figure 2D,  $131.25 \pm 16.54$ ,  $88.75 \pm 11.12$ ,  $341.75 \pm 22.23$  vs  $30.25 \pm 8.07$ ,  $P < 0.001$ ). These results suggested that expression of MAWBP and MAWD play a role in inhibiting proliferation of GC cells.

*In vivo* experiments, tumor growth appeared to be slow in nude mice injected with MAWBP, MAWD, and MAWBP/D compared with the control group. Tumors from MAWD-transfected cells were smaller than those from the other groups (Figure 2E and F,  $P < 0.001$ ).

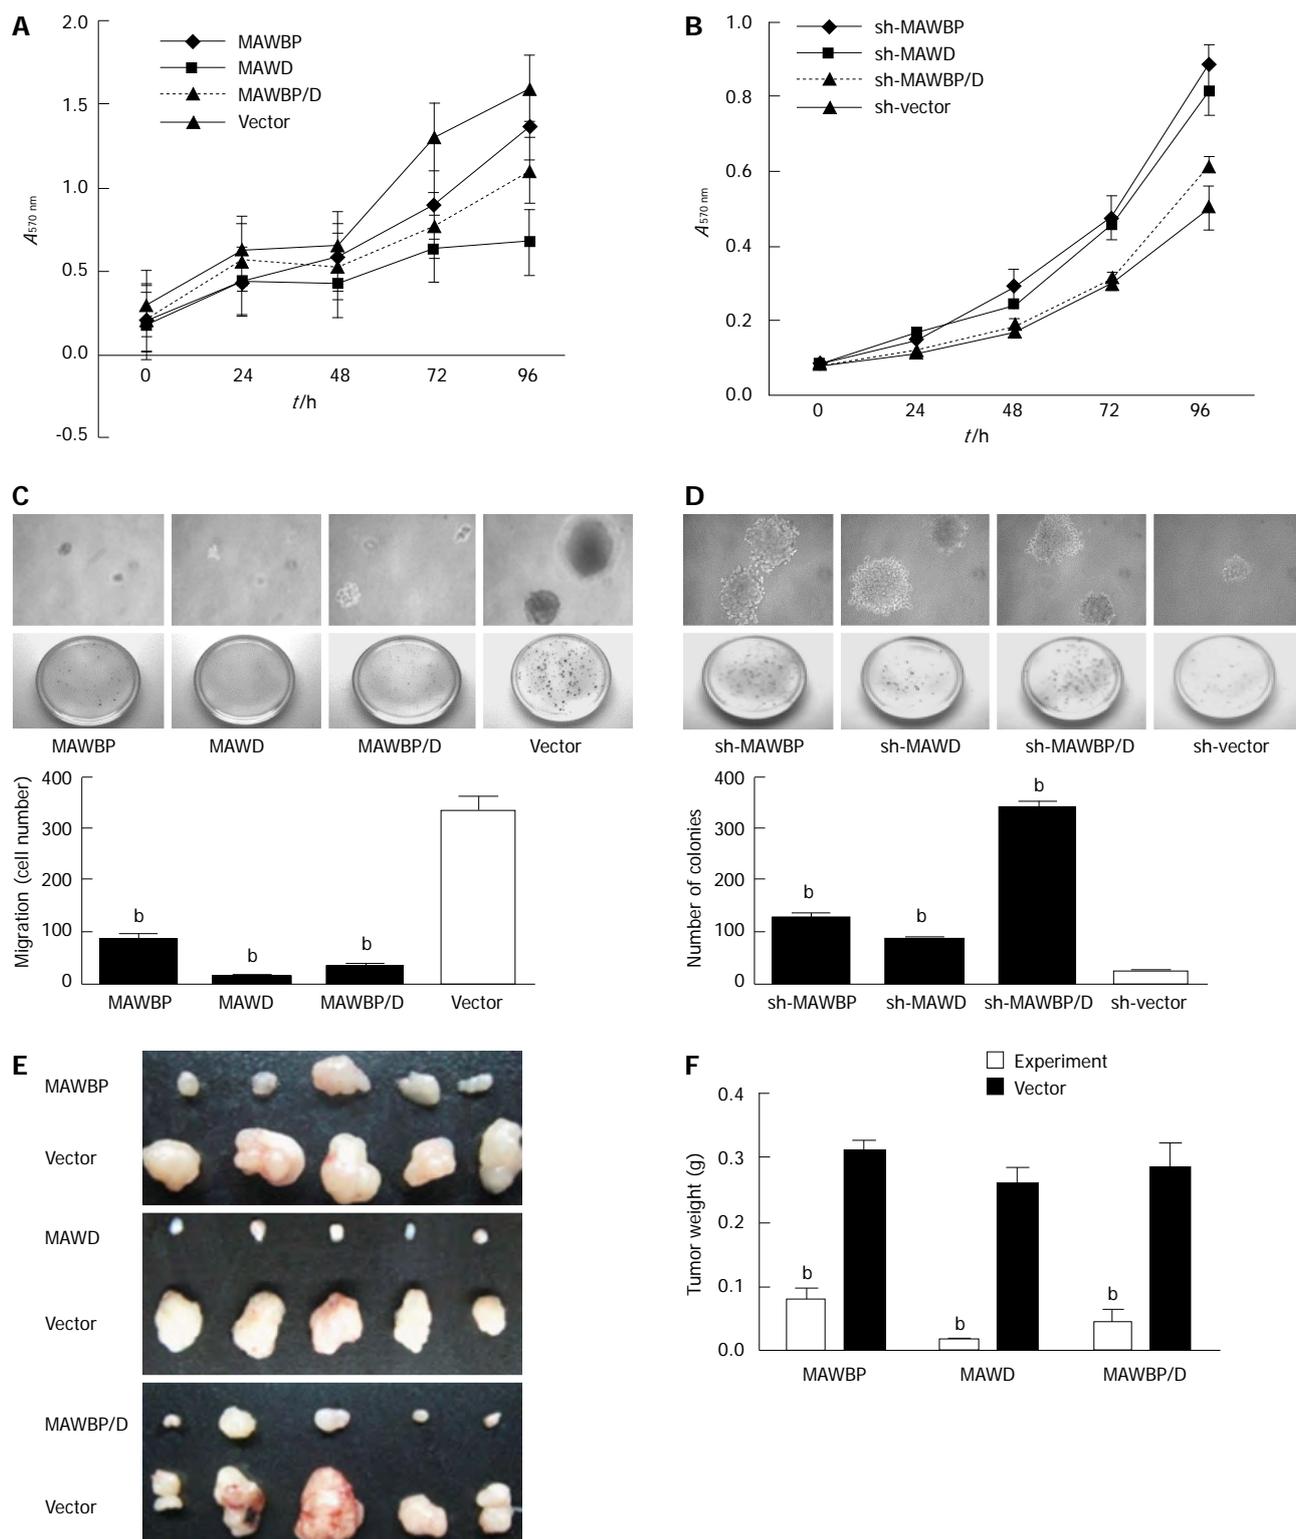

#### Co-expression of MAWBP and MAWD suppressed migration and invasion of GC cells

To explore the potential role of MAWBP and MAWD in GC metastasis and invasion, we evaluated the effects of the stably transfected cells on migration and invasion using a wound healing assay and transwell invasive activity assay, respectively. In the wound healing assay, the scratch gap of vector transfected cells was almost closed at 24 h in the overexpressed group. Cells with co-overexpression of MAWBP and MAWD showed the slowest rate of migration (Figure 3A). In the knockdown group, the cells with combined downregulation of MAWBP and MAWD expression migrated faster than the other cells. Migration of sh-vector cells was slowest (Figure 3B). In the transwell assay, there was significant difference in the number of the cells traversing the matrix membrane between the vector and other groups. Combined overexpression of MAWBP and MAWD decreased the invasive ability of GC cells (Figure 4A). The number of traverse cells of MAWBP, MAWD and co-expression group was higher than that in the vector group (Figure 4C,  $84 \pm 16.57$ ,  $98.33 \pm 9.8$ ,  $29 \pm 16.39$  vs  $298 \pm 11.86$ ,  $P < 0.001$ ).

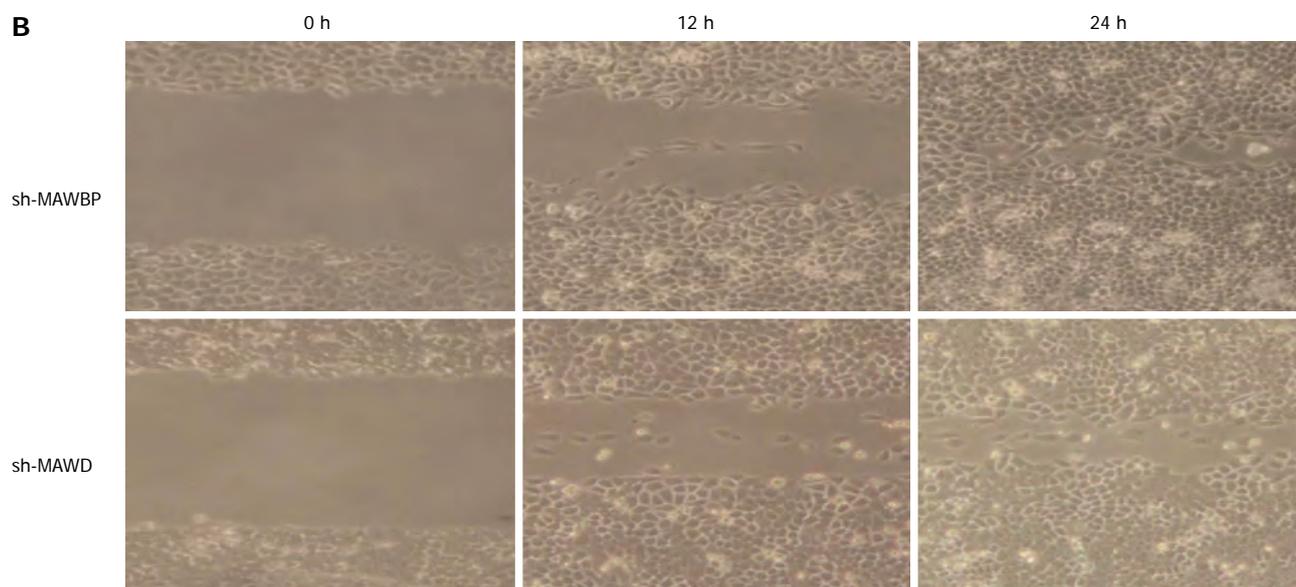

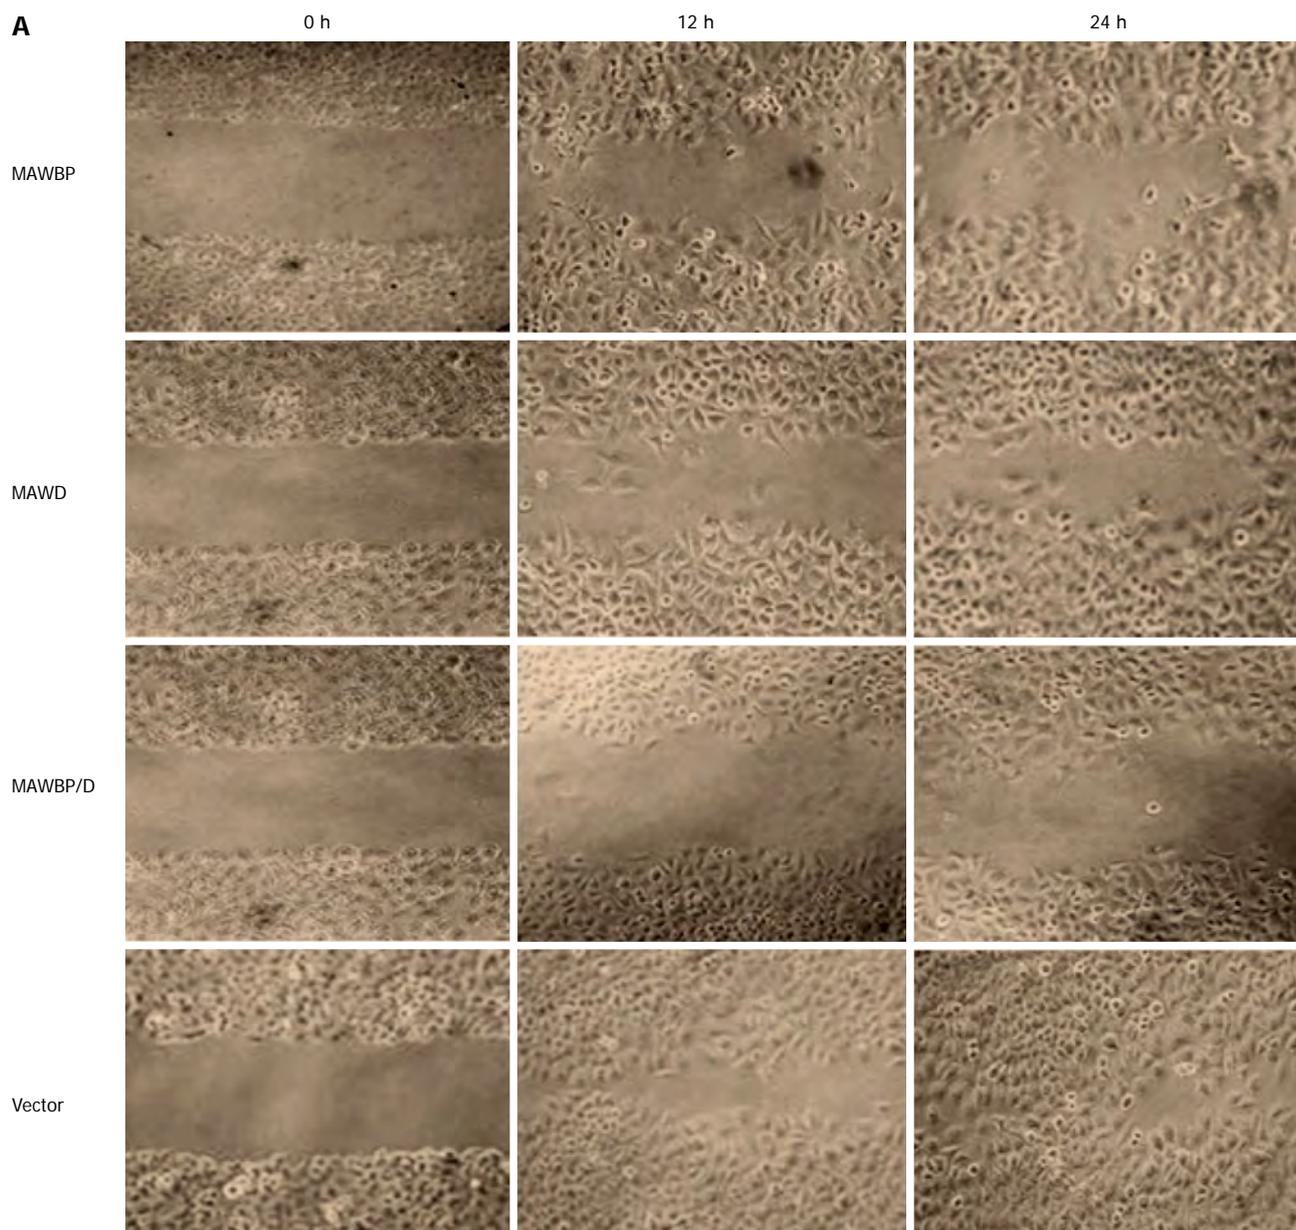

Knockdown of expression of MAWBP and MAWD increased the number of cells that traversed the matrix membrane (Figure 4B). Cells with combined downregulation of MAWBP and MAWD expression migrated faster than the other cells (Figure 4B). Invasion of sh-vector cells was slowest (Figure 4C,  $100.67 \pm 14.57$ ,  $72.66 \pm 8.51$ ,  $330.67 \pm 20.55$  vs  $27 \pm 11.53$ ,  $P < 0.001$ ). These data showed that MAWBP and MAWD inhibited migration and invasion of GC cells.

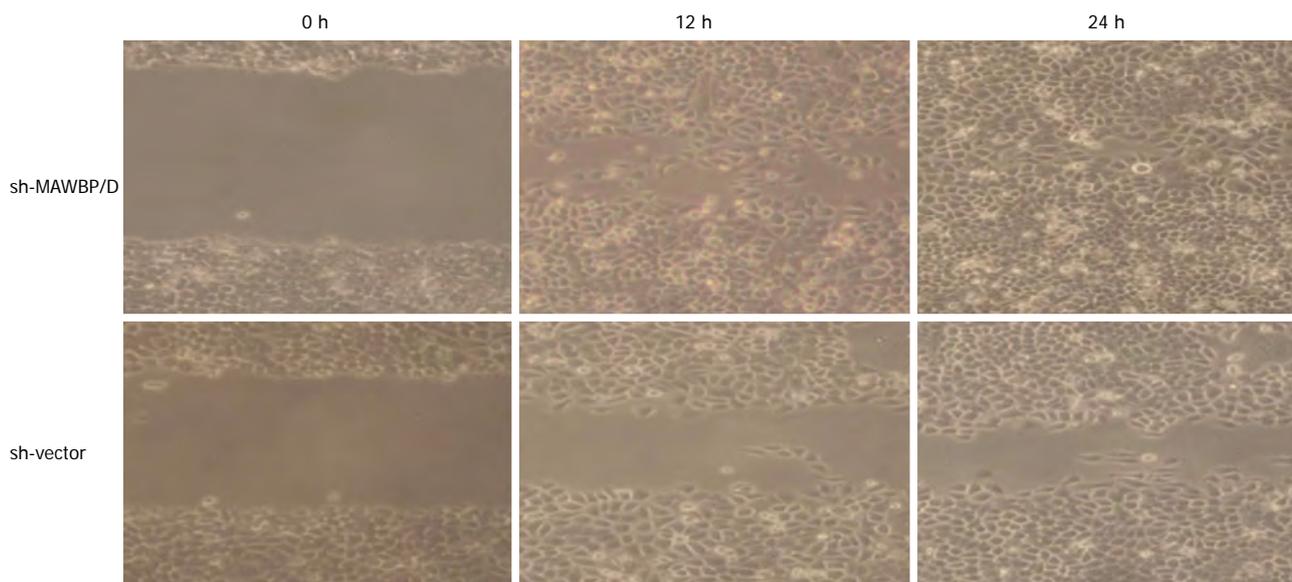

#### Co-expression of MAWBP and MAWD influenced expression of EMT markers induced by TGF- $\beta$ 1 in GC cells

EMT contributes to cancer progression and metastasis. TGF- $\beta$  is the main and best-characterized inducer of EMT. We sought to determine whether co-expression of MAWBP and MAWD inhibited TGF- $\beta$ 1-induced EMT, thus suppressing migration and transwell behavior of GC cells. We detected a relationship between the expression of MAWBP and MAWD and the EMT markers induced by TGF- $\beta$ 1, such as E-cadherin, N-cadherin, and transcription factor Snail. We established the optimum TGF- $\beta$ 1 concentration and treatment time to stimulate cells. We used the expression of TGF- $\beta$  reporter gene PAI-1 to indicate that the optimum TGF- $\beta$ 1 concentration and treatment time was 4 ng/mL for 24 h (Figure 5A). We stimulated GC cells that overexpressed MAWBP and MAWD with TGF- $\beta$ 1, and observed their morphology. We found that cells that overexpressed both MAWBP and MAWD displayed a pebble-like shape and tight cell-cell adhesion, while vector-treated cells showed a classical mesenchymal phenotype (Figure 5B). That means that co-expression of MAWBP and MAWD inhibited morphological changes of TGF- $\beta$ 1-induced EMT. We next detected expression of E-cadherin, N-cadherin and Snail in cells overexpressing MAWBP and MAWD. Ex-

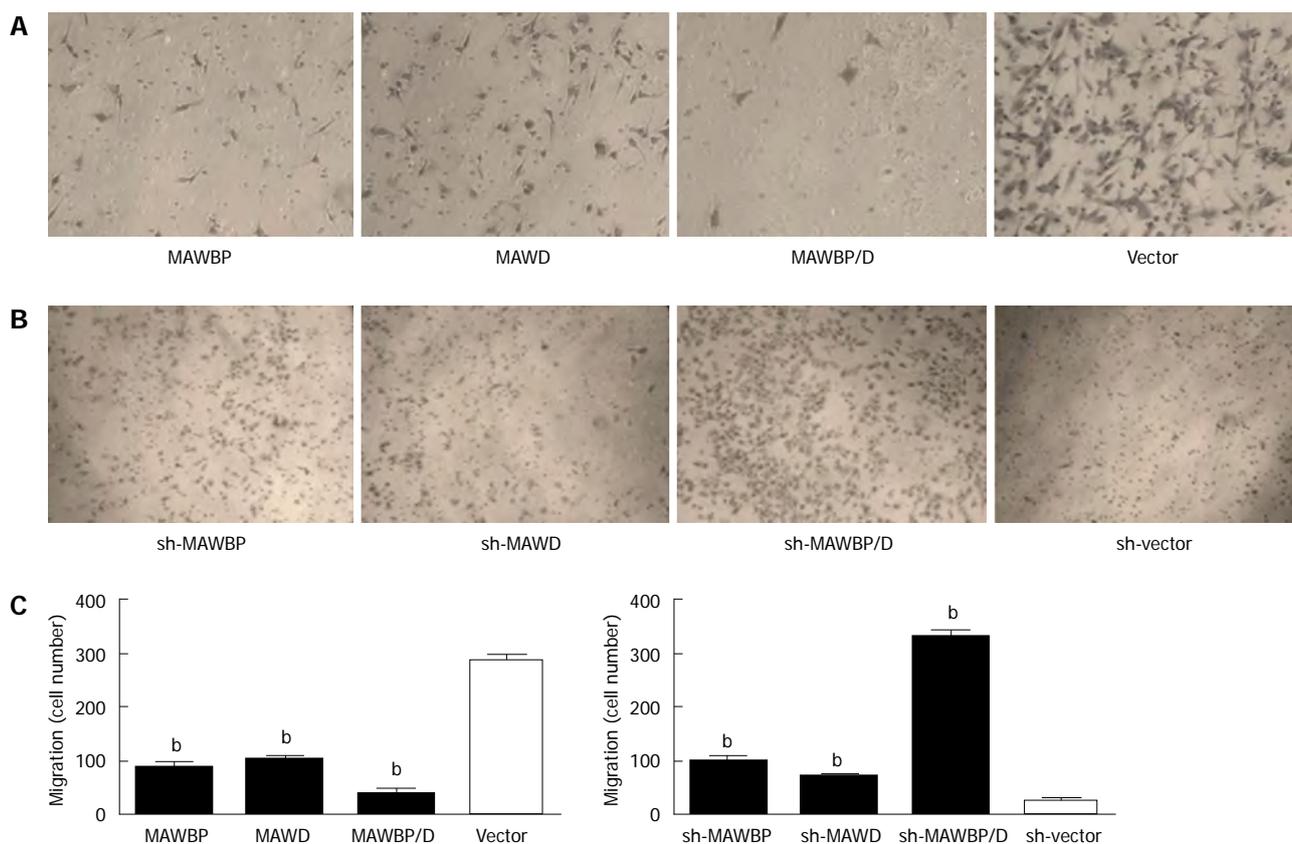

**Figure 2** Effect of mitogen-activated protein kinase activator with WD40 repeats binding protein and mitogen-activated protein kinase activator with WD40 repeats on proliferation and tumorigenicity of gastric cancer cells. **A:** 3-(4,5-Dimethyl-2-thiazolyl)-2,5-diphenyl tetrazolium bromide assay showed that growth of SGC7901 cells overexpressing mitogen-activated protein kinase activator with WD40 repeats (MAWD)/MAWD binding protein (MAWBP) was markedly inhibited; **B:** In BGC823 cells with inhibition of expression of MAWBP and MAWD, cell growth was inversely increased; **C:** In soft agar assay, colonies of cells with overexpression of MAWBP, MAWD and MAWBP/D were reduced in number and size compared with cells transfected with vectors alone (original magnification of clones:  $\times 100$ ); **D:** Knockdown group demonstrated the opposite effects. There was an increase in the number and size of sh-MAWBP, sh-MAWD, sh-MAWBP/D cells compared with cells transfected with vectors alone; **E:** Nude mouse xenografts. Tumors induced by MAWBP, MAWD and MAWBP/D cotransfected cells were smaller than those of the vector group; **F:** Xenograft weight. The average tumor weight were calculated from five nude mice in every group. Data are presented as the mean  $\pm$  SD from three independent experiments. <sup>b</sup> $P < 0.01$  vs vector group.

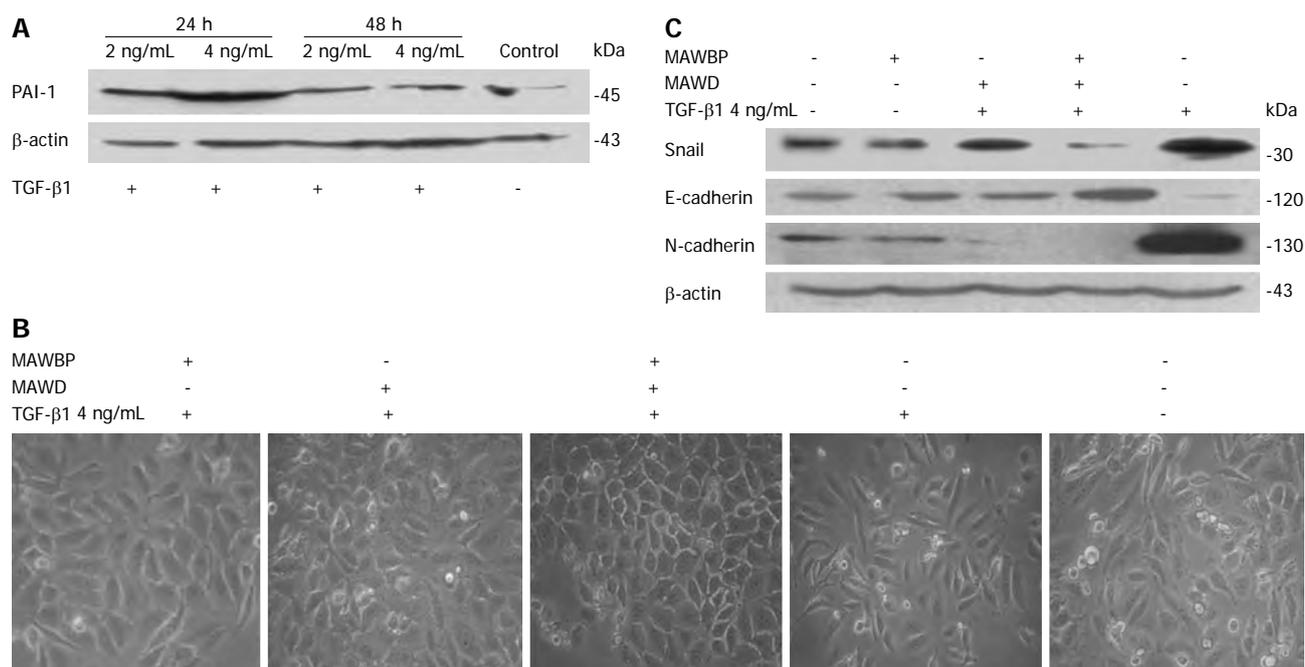

**Figure 3** Effect of mitogen-activated protein kinase activator with WD40 repeats binding protein and mitogen-activated protein kinase activator with WD40 repeats on migration of gastric cancer cells. A: Wound healing assay showed that migration of vector-transfected cells was faster than that of cells overexpressing mitogen-activated protein kinase activator with WD40 repeats (MAWD)/MAWD binding protein (MAWBP). The scratch gap in vector group was almost closed at 24 h. The migration of MAWBP/D cotransfected cells was slowest; B: Cells with combined downregulation of MAWBP and MAWD expression migrated faster than the other cells. Migration of sh-vector cells was slowest (original magnification,  $\times 100$ ).

**Figure 4** Effect of mitogen-activated protein kinase activator with WD40 repeats binding protein and mitogen-activated protein kinase activator with WD40 repeats on invasive ability of gastric cancer cells. A: Transwell assay showed that invasive ability of mitogen-activated protein kinase activator (MAWD) with WD40 repeats binding protein (MAWBP)/D cotransfected cells was weakest, with the lowest number of cells to cross the matrix membranes. Vector-transfected cells migrated farthest; B: Knockdown of MAWBP and MAWD increased the invasive ability of gastric cancer (GC) cells (original magnification:  $\times 100$ ); C: Number of cells that traverse the matrix membrane in the different groups. Data are presented as the mean  $\pm$  SD from three independent experiments. <sup>b</sup> $P < 0.01$  vs vector group.

**Figure 5** Effect of mitogen-activated protein kinase activator with WD40 repeats binding protein and mitogen-activated protein kinase activator with WD40 repeats on expression of biomarkers specific for epithelial-mesenchymal transition induced by transforming growth factor- $\beta$ 1. A: According to the expression of transforming growth factor (TGF)- $\beta$  downstream reporter gene plasminogen activator inhibitor (PAI)-1, the optimum TGF- $\beta$ 1 concentration and time were confirmed as 4 ng/mL for 24 h; B: SGC7901 cells overexpressing mitogen-activated protein kinase activator with WD40 repeats (MAWD)/MAWD binding protein (MAWBP) were stimulated by 4 ng/mL TGF- $\beta$ 1 for 24 h. Cells that overexpressed both MAWBP and MAWD displayed a pebble-like shape, while vector cells showed a classical mesenchymal phenotype (original magnification,  $\times 400$ ); C: Expression of E-cadherin was strongest in the MAWBP/D cotransfection group and weakest in the vector group, using Western blotting. Snail and N-cadherin were inversely associated with E-cadherin expression.

pression of E-cadherin was strongest in the MAWBP/D group and weakest in the vector group. N-cadherin and Snail expression was inversely associated with E-cadherin expression (Figure 5C). Collectively, these data demonstrated that MAWBP and MAWD were involved in TGF- $\beta$ 1-induced EMT through upregulating E-cadherin and downregulating N-cadherin and Snail in GC cells.

#### Co-expression of MAWBP and MAWD suppressed phosphorylation and nuclear translocation of p-Smad3

Following MAWBP and MAWD overexpression in cells stimulated with TGF- $\beta$ 1, the level of p-Smad3 was lowest in the MAWBP/D group and highest in the vector group (Figure 6A). The level of p-Smad2 was also lower in the MAWBP/D group. Furthermore, we separated the proteins in the cytoplasm and nucleus and found that p-Smad3 in the nucleus had the lowest level, as shown by Western blotting (Figure 6B) and confocal microscopy (Figure 6C). That means that the nuclear translocation capability of p-Smad3 in cotransfected cells was weakest. These results imply that the MAWBP/D complex suppressed TGF- $\beta$  signaling by inhibiting downstream phosphorylation.

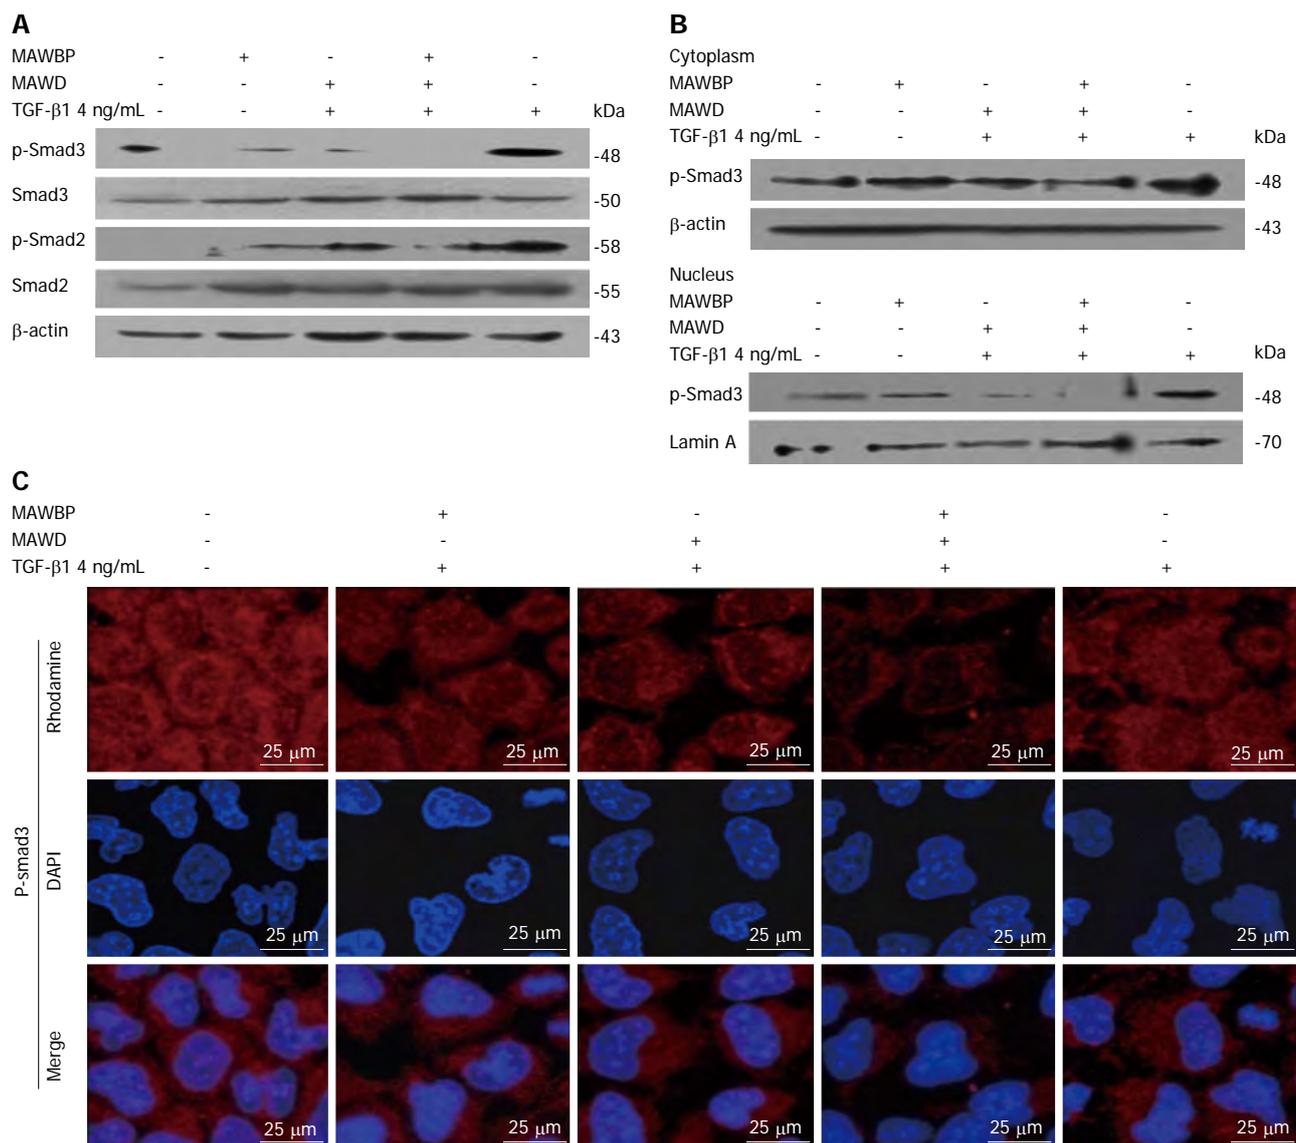

## DISCUSSION

From the outset of this study, we analyzed the biological function of MAWBP and MAWD in GC cell lines. We found that MAWBP and MAWD inhibited prolifera-

tion and migration of GC cells. Importantly, combined overexpression of MAWBP and MAWD in GC cells suppressed TGF- $\beta$ 1-induced EMT by attenuating phosphorylation of Smad3 and reducing its nuclear translocation.

In a previous study, we reported proteomic data acquired from screening protein profiles from GC tissues, including MAWBP and MAWD, and showed that they formed a complex in GC cells by co-immunoprecipitation<sup>[11]</sup>. MAWD has been reported to have divergent effects in cancer. Some researchers have suggested that MAWD promotes cancer development. Matsuda *et al.*<sup>[12]</sup> found that MAWD was overexpressed in 45.6% (21/46) of human breast tumor tissues, and promoted anchorage-independent cell growth. Kim *et al.*<sup>[15]</sup> reported MAWD upregulation in 50.8% (30/59) of adenomas and 70.7% (87/123) of colorectal cancers. Halder *et al.*<sup>[23]</sup> found that STRAP was upregulated in 60% (12/20) of colon and 78% (11/14) of lung carcinomas. However, other researchers have found that MAWD suppressed development of malignant cells. Buess *et al.*<sup>[24]</sup> reported complete or partial allelic loss of MAWD in 45.2% (75/166) of colorectal cancer patients. Jung *et al.*<sup>[25]</sup> found that MAWD was a binding partner of NM23-H1, creating a complex that interacted with and potentiated p53. Dong *et al.*<sup>[26]</sup> detected chromosomal deletions in prostate cancer that overlapped MAWD gene locations. Zhao *et al.*<sup>[27]</sup> reported that MAWBP was down-regulated in ulcerative colitis. The function of MAWBP and MAWD in GC has not been reported.

In the present study, we investigated the biological

**Figure 6** Combination of mitogen-activated protein kinase activator with WD40 repeats binding protein and mitogen-activated protein kinase activator with WD40 repeats inhibited the transforming growth factor- $\beta$  pathway. **A:** The level of p-Smad3 was lowest in the mitogen-activated protein kinase activator (MAWD) with WD40 repeats binding protein (MAWBP)/D cotransfected group and highest in the vector group. p-Smad2 was also lower in the MAWBP/D group; **B, C:** Nuclear translocation capability of p-Smad3 in cotransfected cells was weakest that means the activity of transforming growth factor (TGF)- $\beta$  pathway in co-expression group was inhibited. DAPI: 4',6-diamidino-2-phenylindole.

role of MAWBP and MAWD in GC. We first investigated expression levels of MAWBP and MAWD in six GC cell lines at the RNA and protein levels. We found that expression was lowest in SGC7901 cells and highest in BGC823 cells. Thus, we selected SGC7901 for overexpression of MAWBP and MAWD and BGC823 for RNAi assay, and constructed the eukaryotic expression plasmid and RNAi plasmid for these two proteins for cell transfection. We generated MAWBP/D-cotransfected cells to establish whether one complements the function of the other. We found that MAWBP and MAWD acted as tumor suppressors. Our results showed that overexpression of MAWBP and MAWD suppressed growth of SGC7901 cells. Knockdown of their expression enhanced proliferation of BGC823 cells. The suppressive ability of MAWD was more pronounced than that of MAWBP.

Interestingly, the results from the migration and transwell assays indicated that combined overexpression of these two proteins more obviously limited migration and invasive behavior of GC cells. The cotransfected cells showed mixed characteristics for proliferation and migration, meaning that MAWBP and MAWD had a synergetic role in regulating migration and invasion of GC cells.

EMT is thought to be a key step in the progression of tumors toward invasion and metastasis<sup>[28]</sup>. EMT is a cellular process during which epithelial polarized cells become motile mesenchymal-appearing cells. This process can lead to loss of epithelial markers - especially E-cadherin - and expression of mesenchymal markers such as vimentin and N-cadherin<sup>[29]</sup>. E-cadherin is a cell-adhesion protein that is regulated by transcription factors including Snail and Slug. Snail act as a repressor and blocks E-cad-

herin transcription, and has emerged as an essential regulator of physiological and pathological EMT processes<sup>[30]</sup>. It has been shown that TGF- $\beta$  induces changes in cell morphology that are consistent with the acquisition of the EMT phenotype<sup>[31]</sup>.

In this study, we sought to determine whether co-expression of MAWBP and MAWD inhibited TGF- $\beta$ 1-induced EMT, thus suppressing migration and transwell behavior of GC cells. We stimulated GC cells with over-expression of MAWBP and MAWD with TGF- $\beta$ 1 and detected the expression level of epithelial and mesenchymal markers and transcription factors. We found that E-cadherin was upregulated in the co-expression group and N-cadherin and Snail expression was inversely associated with E-cadherin expression. This revealed that MAWBP and MAWD had a synergetic function in inhibiting TGF- $\beta$ 1-induced EMT.

TGF- $\beta$ 1 stimulation induces upregulation of Snail and induces EMT in Smad-dependent signaling<sup>[30]</sup>. MAWD was found to recruit Smad7 and form a complex that inhibited TGF- $\beta$  signaling. To confirm whether the MAWBP and MAWD complex further suppressed TGF- $\beta$ 1 and decreased Snail expression, we evaluated TGF- $\beta$  activity in MAWBP and MAWD overexpressed cells. Phosphorylation of effector molecules is often essential for downstream receptor kinase signaling<sup>[31]</sup>. Thus, we detected the phosphorylation level and nuclear translocation of p-Smad2 and p-Smad3 to indicate TGF- $\beta$  activity. We found that the level of p-Smad3 was lowest in the combined overexpression group and highest in the vector group. Nuclear translocation of p-Smad3 was weakest in cells with combined overexpression. These results imply that the MAWBP/D complex suppresses TGF- $\beta$  signaling, and therefore downregulates Snail level and inhibits EMT.

All together, the present study demonstrates that MAWBP and MAWD have a suppressive role in progression of tumor growth and invasion of GC. Co-expression of MAWBP and MAWD inhibits TGF- $\beta$ 1-induced EMT, which suppresses EMT-assisted GC cell malignant progression. In future research, we should attempt to find the mechanisms mediating MAWBP and MAWD expression in GC. MAWBP and MAWD interaction domains will be predicted by biological information analysis and tested in cell assays.

## COMMENTS

### Background

Gastric cancer (GC) is the second most common cause of cancer death worldwide. GC incidence in Asian countries, particularly in East Asia, is significantly higher than that in other parts of the world. GC creates a serious public health problem. Early diagnosis is important for therapy and prognosis of patients. Therefore, investigation of sensitive biomarkers and analysis of their function

are important.

### Research frontiers

During the past decade, a great effort has been made to define better the biological profile of GC. Molecular genetic studies have investigated the accumulation of mutations and alterations in proteins involved in GC. These include activation of c-myc, erbB-2, c-met, and k-ras oncogenes and inactivation of tumor suppressor genes *p53*, *APC*, *E-cadherin* and *RUNX3*. Their previous study found that mitogen-activated protein kinase activator with WD40 repeats (MAWD) and MAWD binding protein (MAWBP) were differentially expressed and interacted in GC.

### Innovations and breakthroughs

The present study provided direct evidence that MAWBP and MAWD inhibited proliferation and migration of GC cells. Importantly, interaction of MAWBP and MAWD influenced expression of epithelial-mesenchymal transition (EMT) markers induced by transforming growth factor (TGF)- $\beta$ 1 in GC cells. It also reduced nuclear translocation of p-Smad3. This means that co-expression of MAWBP and MAWD inhibits TGF- $\beta$ 1-induced EMT and suppresses EMT-aided GC malignant progression.

### Applications

The authors found that interaction between MAWBP and MAWD could shed new light on the carcinogenic mechanisms of GC. MAWBP and MAWD as biomarkers might be diagnostic and therapeutic targets for GC.

### Terminology

MAWD is a protein that is evolutionarily conserved and is widely expressed in many tissues. Sequence analysis indicates that the protein structure of MAWD contains a WD40 repeat domain. WD repeat proteins help to assemble macromolecular complexes, such as shown for the  $\beta$ -subunit of G proteins. The homologous protein of MAWD, serine-threonine kinase receptor-associated protein recruits Smad7 to the activated type I receptor and forms a complex. MAWBP is a MAWD binding protein. EMT is the morphological and molecular changes that occur when epithelial cells lose their characteristics, gain mesenchymal properties and become motile, which is a key event in tumor invasion and metastasis.

### Peer review

The authors analyzed MAWD and MAWBP in a series of GC cell lines. They found that co-expression of both genes is potentially involved in the suppression of migration and invasion in their selected cell lines. This study was a straightforward continuation of the authors' own work and they have recently reported differential expression of both genes in GC tissues. Now, they have analyzed the functional consequences of suppression or overexpression of both genes in an *in vitro* setting.

### Abstract

**AIM:** To evaluate the long-term eradication of hepatitis C virus (HCV) infection and liver-related complications in chronically infected patients that have achieved sustained virological response.

**METHODS:** One hundred and fifty subjects with chronic hepatitis C (CHC) or cirrhosis and sustained virological response (SVR) between the years of 1989 and 2008 were enrolled in a long-term clinical follow-up study at the Gastrointestinal and Liver Unit of the University Hospital of Naples "Federico II". At the beginning of the study, the diagnosis of HCV infection was made on the basis of serum positivity for antibodies to HCV

and detection of HCV RNA transcripts, while a diagnosis of chronic hepatitis was formulated using imaging techniques and/or a liver biopsy. SVR was achieved by interferon-based therapy, both conventional and pegylated, with and without ribavirin treatment. The patients were evaluated for follow-up at a median length of 8.6 years, but ranged from 2-19.9 years. Among them, 137 patients had pre-treatment CHC and 13 had cirrhosis. The patients were followed with clinical, biochemical, virological, and ultrasound assessments on a given schedule. Finally, a group of 27 patients underwent a liver biopsy at the beginning of the study and transient elastography at their final visit to evaluate changes in liver fibrosis.

**RESULTS:** The median follow-up was 8.6 years (range 2-19.9 years). HCV RNA remained undetectable in all patients, even in patients who eventually developed liver-related complications, indicating no risk of HCV recurrence. Three liver-related complications were observed: two cases of hepatocellular carcinoma and one case of bleeding from esophageal varices resulting in an incidence rate of 0.23%/person per year. Further, all three complications took place in patients diagnosed with cirrhosis before treatment began. Only one death due to liver-related causes occurred, resulting in a mortality rate of 0.077% person per year. This amounts to a 99.33% survival rate in our cohort of patients after therapy for HCV infection. Finally, of the 27 patients who underwent a liver biopsy at the beginning of the study, a reduction in liver fibrosis was observed in 70.3% of the cases; only three cases registering values of liver stiffness indicative of significant fibrosis.

**CONCLUSION:** Patients with CHC and SVR show an excellent prognosis with no risk of recurrence and a very low rate of mortality. Our data indicate that virus-eradication following interferon treatment can last up to 20 years.

**Key words:** Antiviral therapy; Cirrhosis; Hepatitis C virus; Sustained virological response; Fibrosis

**Core tip:** This study represents one of the longest follow-up studies on the natural history of successfully treated chronically hepatitis C virus (HCV) infected individuals. The outcome of the study was very positive, as it revealed an extremely high survival rate, an extremely low rate of liver complications, and a significant reduction in liver fibrosis in patients who have achieved sustained virological response (SVR). All of the patients without cirrhosis before starting the treatment showed no signs of evolution or decompensation over the years of observation, proving that SVR positively changes the natural history in individuals with HCV-infection.

Sustained virological response: A milestone in the treatment of chronic hepatitis C. *World J Gastroenterol* 2013; 19(18): 2793-2798 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i18/2793.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i18.2793>

## INTRODUCTION

Hepatitis C virus (HCV) infection represents a serious challenge to global health, with an estimated 170 million carriers worldwide<sup>[1]</sup>. A significant complication in chronically infected individuals is the development of liver inflammation and fibrosis, which may progress to liver cirrhosis and hepatocellular carcinoma (HCC)<sup>[2-10]</sup>.

For nearly 20 years, interferon-based therapy has been the standard therapy for chronic hepatitis C (CHC), with the optimal treatment of the combination of pegylated-interferon and ribavirin dating back ten years. The primary goal of HCV treatment is to achieve a sustained virological response (SVR). SVR is defined by undetectable HCV RNA levels 24 wk after completing treatment<sup>[11]</sup>. The achievement of the SVR in patients with CHC represents a milestone because it has been associated with the eradication of the infection, improvement in liver histology, improvement in quality of life, and reduced risk of cirrhosis and hepatocellular carcinoma<sup>[12-15]</sup>. Short term SVR in patients with chronic HCV-infection is well established, however, knowledge regarding long-term SVR remains to be elucidated. There are limited long-term studies observing chronically infected patients who have achieved SVR, all with a limited number of patients<sup>[12,16]</sup>. Further, studies that do have a large cohort of patients have a fairly short follow-up period<sup>[17,18]</sup>. Finally, the data gathered thus far lack real world examples as data gathered by subjects with SVR are usually limited to those participating in pivotal clinical trials.

The aim of this study was to evaluate the long-term

outcomes of patients who obtain a SVR after antiviral therapy, regardless of the type treatment, in a monocentric cohort of patients representing a real world population with CHC during the last 20 years.

## MATERIALS AND METHODS

### Patients

From January 1989 to April 2008, 150 HCV-positive patients who achieved SVR after interferon-based therapy at the Gastroenterology Unit of the University of Naples "Federico II" were enrolled in this cohort study. There were 100 men and 50 women (mean age,  $56.37 \pm 12.05$  years; range 22-67 years). The main characteristics of our study population at baseline are reported in Table 1.

In this cohort, 137/150 (91.3%) patients had chronic hepatitis and 13 had liver cirrhosis. Before treatment, 21 patients had normal alanine transaminase (ALT) values and 129/150 (86%) had elevated ALT values ranging between 1.2 and 15.87 times the upper normal limit. A histological examination was performed in 103/150 (68.6%) of patients at baseline, while 47/150 (31.3%) patients refused the biopsy procedure and 27 patients showed comorbidities (Table 1). Nine patients had a diagnosis of arterial hypertension and two had an incomplete right bundle branch block. One patient had a medical history of previous angina pectoris and another suffered from a previous myocardial infarction, however, there was no cardiologic contraindication at the time the therapy started. Seven patients had thyroid disease; two patients had type II diabetes; two had gastroesophageal reflux disease, and two had a co-infection of hepatitis B. One patient had a history of non-Hodgkin lymphoma that had been in remission for five years since the time the antiviral therapy started.

### Modality of diagnosis

The diagnosis of HCV infection was made on the basis of serum positivity for antibodies to HCV and detection of HCV RNA transcripts. The diagnosis of chronic hepatitis was formulated by a histological assessment and scored according to the internationally accepted criteria<sup>[19]</sup>. The liver biopsy was not performed if the patients refused the procedure or had evidence of clinical, biochemical, ultrasound and endoscopic signs of liver cirrhosis. Transient elastography (TE), a non-invasive method of quantifying fibrosis developed as an alternative to liver biopsy, was carried out using FibroScan. Ultrasound elastography analyzes ultrasound frequency waves related to the elasticity (deforming capacity) of the liver. The methodology is simple, highly reproducible and can be completed in ten minutes. The diagnostic accuracy of TE is not as high as a liver biopsy, which remains the gold standard for evaluation of fibrosis. Nonetheless, in this context, TE is both highly sensitive and specific (79%-83% and 83%-89%, respectively)<sup>[20]</sup>.

### Therapy schedules

All patients were treated with interferon-based therapy,

either in mono-therapy or in combination with ribavirin. Sixty-six subjects received conventional interferon mono-therapy. Twenty-five patients were treated with conventional interferon plus ribavirin and 59 patients were treated with pegylated interferon plus ribavirin. Conventional interferon was used at doses ranging between 3 and 6 MU every 2 d for a mean period of  $49 \pm 3.12$  wk. The treatment regimen with pegylated interferon was carried out by international guideline recommendations and method indicated in the relevant product data sheets (Pegasys<sup>®</sup> 180 µg once weekly, subcutaneously; Peginteron<sup>®</sup> 1.5 µg/kg per week, subcutaneously; ribavirin 800, 1000 or 1200 mg/week orally, depending on body weight and virus genotype). The mean duration of the therapy was  $47 \pm 13$  wk.

### Follow-up

All patients were followed and analyzed for clinical, biochemical, virological and ultrasound parameters. All assessments were performed every 6 mo for the first two years of observation. In patients with cirrhosis at baseline, we continued to perform sequential clinical, biochemical and ultrasound follow-up every 6 mo, while the same panel of tests was conducted once a year in patients without cirrhosis. HCV RNA assessment was performed once per year during follow-up for all patients and whenever a decompensation or a progression of the liver disease occurred. At each medical visit, life-sign assessments and potential therapy-adverse effects were investigated. Biochemical evaluations measuring haemocrome (blood count), transaminases, bilirubin,

alkaline phosphatase and renal function were performed. All patients underwent abdominal ultrasound every 6 mo. If a new space-occupying lesion was suspected, it was first analyzed by ultrasonography to determine if it was unquestionably benign (*e.g.*, cysts or hemangioma). If necessary, the lesion was further examined by computed tomography, magnetic resonance imaging, arteriography, or liver biopsy. In a group of 27 patients with liver biopsy at baseline, liver stiffness was assessed during the last visit. During this follow-up, cirrhotics were considered to have progression if they showed any of the following findings: ascites, bleeding varices, hepatic encephalopathy and HCC. The diagnosis of HCC was formulated using imaging techniques and/or biopsy, according to the Barcelona Clinical Liver Cancer standardized staging system for hepatocellular carcinoma<sup>[21]</sup>.

### Laboratory analysis

Serum was collected for detection of HCV RNA once per year after SVR was obtained. Qualitative detection of HCV-RNA was performed by a standardized qualitative assay, Cobas AmpliPrep/Cobas Taqman (CAP/CTM). This assay is based on the reverse transcription-polymerase chain reaction (RT-PCR) method, followed by HCV RNA real-time fluorescent detection from 850 µL of serum. HCV RNA concentration was read in IU/mL. The CAP/CTM assay has a sensitivity of 15 IU/mL, with a linear quantification range of  $43-6.9 \times 10^7$  IU/mL.

## RESULTS

### Follow-up

The median duration of follow-up was 8.6 years (range 2-19.9 years). One hundred and fifteen/150 (76.6%) patients were followed for more than 4 years. Fifty-two/150 (34.6%) patients were followed for more than 10 years.

### Virological outcomes

Zero of the 150 patients had a recurrence of HCV infection during the follow-up period. HCV RNA was evaluated in all patients with CAP/CTM assay, using at least four blood samples taken in different times (including the last sample available for each patient). No patient had detectable HCV-RNA in serum by RT-PCR in any sample, even in the patients who developed liver-related complications.

### Survival and complication rates

The results from this study indicate the risk of liver-related death was only 0.67%, as only one patient died from liver-related causes. In addition, liver-related complications were observed in only three patients with a global complication incidence rate of 2%, while the complication incidence/person per year was 0.08%. These three complications included two patients with HCCs and one patient experiencing bleeding from esophageal varices. All three patients who developed complications had pre-treatment cirrhosis. Both patients who developed HCC were males, aged 61 developing the complication

**Table 2** Liver fibrosis with paired assessment at baseline *vs* the end of follow-up

| Patients | Baseline           |                                      | End of follow-up               |                     |                                   |

LS: Liver stiffness.

five years after follow-up, and aged 65 developing the complication nine years after follow-up, respectively. The 65-year-old male eventually died from liver-related complications. A 66-year-old female patient developed esophageal 17 bleeding years after the follow-up.

### Regression of liver fibrosis

During the final visit, we performed TE on 27 patients who underwent a liver biopsy at baseline. The histological staging at baseline and the mean values of liver stiffness at the end of follow-up are reported in Table 2. Only in three cases were the values of liver stiffness higher than 7.3 kPa, the threshold indicative of significant fibrosis (F2 according to Metavir score). None of the patients had a liver stiffness score higher than 14.5 kPa, suggestive of cirrhosis. We observed regression of the fibrosis in 19/27 patients (70% of the cases).

## DISCUSSION

The aim of this study was to assess the long-term effect of antiviral treatment in a large cohort of patients chronically infected with hepatitis C who had achieved SVR. This is one of the largest and longest studies on the natural history of successfully treated patients with chronic HCV infection in a real world setting. In the majority of the cases reported in the literature, the median follow-up duration is less than 5 years. In our study however, we observed 50 patients for up to 10 years and 21 patients for up to 15 years, with the median duration of the follow-up being 8.6 years. Overall, the clinical outcome of this study was very positive, indicating that prognosis in patients who obtained SVR is extremely promising.

The overall hepatic complication rate in our population was only 2%; a figure that is in agreement with other studies. Veldt *et al*<sup>[22]</sup> reported 3 cases of HCC in a population of 142 patients (2%) with SVR and a baseline fibrosis score that ranged between 4 and 6 according to the Ishak index<sup>[19]</sup>. Turner *et al*<sup>[23]</sup> reported 2 cases of HCC in a population of 152 patients (1.3%) with SVR and no cirrhosis. Ikeda *et al*<sup>[24]</sup> reported 30 cases of HCC in a population of 1097 patients (2.7%), of which 97 had cirrhosis and obtained SVR; but it was a retrospective, multicentric study with a median follow-up of 4.6 years. The high survival rate observed in our study (99.3%) is very consistent with values observed by George *et al*<sup>[18]</sup>

(99.4%) and Imazeki *et al*<sup>[25]</sup> (99.97%).

We could not detect HCV-specific RNA transcripts in any of the patients at each follow-up, confirming that a durable SVR can be achieved with both conventional and pegylated interferon treatment<sup>[7-9]</sup>. Although a low rate of HCV-recurrence detected through RT-PCR assays has been reported, these data are in agreement with more recent studies on the topic<sup>[26-28]</sup>. The sensitivity of laboratory assays for HCV RNA detection has significantly increased throughout the years, and we can hypothesize that low serum levels of HCV RNA may not have been detected by a low sensitivity assay in the past, leading to a misclassification of SVR subjects. In fact, 5%, 9.7%, and 8% rates of HCV recurrence have been observed in previous studies<sup>[26-28]</sup>. In our study, HCV RNA was assessed through the most sensitive assay available (RT-PCR with sensitivity < 50 IU/mL). This sensitivity adds validity to our hypothesis that the hepatic complications observed in patients in our study were not directly related to ongoing HCV replication, but rather other complicating factors.

Of the 27 patients where fibrosis was evaluated, no patient with pre-treatment chronic hepatitis showed progression to cirrhosis, including those with advanced fibrosis (Ishak score 3-4/6). Moreover, a regression of fibrosis was reported in 70% of the cases. These results correlate well with the work by Poynard *et al*<sup>[29]</sup> showing that SVR (regardless of the therapy with which it is obtained) not only stops liver damage progression, but can also induce its regression. In this cohort, 1904 patients with CHC and SVR and with paired pre-treatment and post-treatment biopsies were observed; 86% of patients showed an improvement in fibrosis stage while 12% showed no change, even when the mean time between biopsies was only 20 mo<sup>[29]</sup>. Our data also comply with two recent studies with mean follow-up times of 5 and 6.5 years reporting 83% and 61% rates of fibrosis regression, respectively<sup>[18,30]</sup>. In these studies, the regression of fibrosis was assessed through liver biopsy. Although a liver biopsy is considered the gold standard; it does have limitations including sampling errors and interpretation of results influenced by intra- and inter-observer variation, implying that distinguishing real changes in fibrosis, longitudinally, is a difficult task<sup>[31]</sup>. Ellis *et al*<sup>[32]</sup> suggested that the most convincing evidence for regression of liver fibrosis derives from large-scale studies on post-treatment natural history. In fact, long-term follow-up studies indicate that regression of liver fibrosis is

associated with improved clinical outcomes, strengthening the perception that histological regression is a real phenomenon. Even though there is no universal parameter to define fibrosis regression, it is suggested that a long term assessment of clear clinical outcomes combined with non-invasive testing for fibrosis could help with the interpretation of the results<sup>[32]</sup>.

In conclusion, our study documents that progression of liver damage and HCV infection relapse are virtually non-existent in patients with chronic hepatitis C infection who have achieved sustained virological response. Further, patients with pre-treatment evidence of cirrhosis show a rate of complications that cannot be neglected, but are hypothesized to occur due to complicating factors separate from HCV infection.

## COMMENTS

### Background

Sustained virological response (SVR) is by defined by undetectable hepatitis C virus (HCV) RNA levels 24 wk after completing treatment. The achievement of the SVR in patients with chronic hepatitis C (CHC) represents a milestone because it has been associated with the eradication of the infection, improvement in liver histology, improvement in quality of life, and reduced risk of cirrhosis and hepatocellular carcinoma. Short term SVR in patients with chronic HCV-infection is well established, however, knowledge regarding long-term SVR remains to be elucidated. There are limited long-term studies observing chronically infected patients who have achieved SVR, all with a limited number of patients.

### Innovations and breakthroughs

This study represents one of the longest follow-up studies on the natural history of successfully treated chronically HCV infected individuals. The outcome of the study was very positive, as it revealed an extremely high survival rate, an extremely low rate of liver complications, and a significant reduction in liver fibrosis in patients who have achieved SVR.

### Applications

The aim of this study was to evaluate the long-term outcomes of patients who obtain a SVR after antiviral therapy, regardless of the type treatment, in a monocentric cohort of patients representing a real world population with CHC during the last 20 years.

### Peer review

It is a well planned study with sound methodology.

### Abstract

**AIM:** To examine the long-term therapeutic efficacies of endoscopic cauterization for gastric vascular ectasia, according to the type of lesion.

**METHODS:** Thirty-eight patients with hemorrhagic gastric vascular ectasia (VE) were treated by endoscopic cauterization: 13 by heater probe coagulation and 25 by argon plasma coagulation. Depending on the number of lesions, 14 and 24 patients were classified into localized VE ( $\leq 10$ ; LVE) and extensive VE ( $> 10$ ; EVE), respectively. The patients were followed-up by repeated endoscopic examinations after the therapy, and the incidences of VE recurrence and re-bleeding from the lesions were evaluated.

**RESULTS:** Although the VE lesions disappeared initially in all the patients after the therapy, the recurrence of VE developed in 25 patients (66%) over a mid-term observation period of 32 mo, and re-bleeding occurred in 15 patients (39%). The recurrence of VE was found in

all patients with EVE, with re-bleeding occurring in 14 patients (58%). In contrast, only 1 patient (7%) with LVE showed recurrence of the lesions and complicating hemorrhage. Both the cumulative recurrence-free rates and cumulative re-bleeding-free rates were significantly lower in the EVE group than in the LVE group ( $P < 0.001$  and  $P < 0.001$ , respectively). Moreover, the cumulative re-bleeding-free rate in the EVE group was 47.6% at 1 year and 25.4% at 2 years in patients with chronic renal failure, which were significantly lower than the rates in the patients without chronic renal failure (83.3% and 74.1%, respectively) ( $P < 0.05$ ).

**CONCLUSION:** The recurrence of VE and re-bleeding from the lesions was more frequent in the patients with EVE, especially in those with complicating renal failure.

**Key words:** Gastric vascular ectasia; Heater probe coagulation; Argon plasma coagulation; Renal failure; Recurrence

**Core tip:** The aim of this study was to examine the long-term therapeutic efficacies of endoscopic cauterization for gastric vascular ectasia (VE), according to the type of lesion. Depending on the number of lesions, 14 and 24 patients were classified into localized vascular ectasia ( $\leq 10$ ) and extensive VE ( $> 10$ ; EVE), respectively. The incidences of VE recurrence and re-bleeding from the lesions were evaluated. The recurrence of VE and re-bleeding from the lesions was more frequent in the patients with EVE, especially in those with complicating renal failure, even after the initial successful arrest of bleeding and disappearance of the lesions by the endoscopic therapy.

coagulation for different types of gastric vascular ectasia. *World J Gastroenterol* 2013; 19(18): 2799-2805 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i18/2799.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i18.2799>

## INTRODUCTION

Vascular ectasia (VE) of the stomach has been recognized as a rare cause of hemorrhage from the upper gastrointestinal tract<sup>[1-4]</sup>. Patients may present with either evidence of chronic occult bleeding, *i.e.*, iron deficiency anemia, or with acute hematemesis or melena. VE is a term that encompasses a broad spectrum of lesions visualized on endoscopic examination, including angiodysplasia, watermelon stomach, diffuse antral VE (DAVE) and telangiectasis associated with Osler-Weber-Rendu disease<sup>[5]</sup>. In general, angiodysplasia is defined as VE with a limited number of red flat spots or reticulated vascular areas in the gastric mucosa on endoscopic examination. In contrast, gastric antral VE (GAVE) is diagnosed as watermelon stomach when the lesions are visualized as stripes radiating outwards from the pylorus and as DAVE in cases with diffuse red spots in the gastric antrum.

Various therapeutic procedures have been employed for hemorrhagic gastric VE. Surgical resection of the stomach is the most curative therapeutic procedure, but it is a highly invasive procedure that maybe associated with high mortality, especially in elderly patients with underlying diseases such as metabolic syndrome. Thus, endoscopic cauterization has generally been performed for the treatment of gastric VE. Several types of coagulation procedures may be employed for endoscopic cauterization, including heater probe coagulation<sup>[6]</sup>, laser coagulation<sup>[7-10]</sup> and argon plasma coagulation<sup>[10-16]</sup>, and these devices have been reported to be useful for the temporary arrest of bleeding from any type of gastric VE. However, the long-term prognosis of patients undergoing endoscopic cauterization has to be elucidated. In the present paper, we examined the long-term therapeutic efficacies of endoscopic cauterization, including the recurrence rate of the lesions and the rates of re-bleeding, in patients with hemorrhaging from gastric VE, according to the type of lesion.

## MATERIALS AND METHODS

### Patients

The subjects included 42 patients with gastrointestinal bleeding from gastric VE lesions, which were diagnosed by gastrointestinal endoscopic examination between October 1996 and December 2007. Among them, 4 patients, who moved to a different institution for follow-up following discharge from our hospital after the successful arrest of bleeding from the VE, were excluded from the analysis. The remaining 38 patients consisted of 21 men and 17 women, with a median age of 69 years (range, 48-85 years). Twenty patients (53%) had underlying liver cirrhosis, and 15 patients (39%) were undergoing mainte-

nance hemodialysis for chronic renal failure.

On endoscopic examination, bleeding from the gastric VE lesions was observed in 21 patients (55%). In the remaining 17 patients, other gastrointestinal lesions that could serve as the possible source of the bleeding were not detectable by the endoscopic examinations, including small intestinal endoscopy, despite the patient presenting with hematemesis or melena. The patients were classified into 2 groups: 14 patients with  $\leq 10$  VE lesions (localized VE, the LVE group) and 24 patients with  $> 10$  VE lesions (extensive VE, the EVE group). The LVE group comprised 9 patients with a single lesion and 5 patients with multiple lesions (range, 3 to 10 lesions), including one patient with Osler-Weber-Rendu disease showing 3 lesions in the stomach. In contrast, the EVE group consisted of 5 patients with watermelon stomach and 19 patients with DAVE, including one patient with radiation-induced DAVE.

All patients were treated by endoscopic cauterization. Thereafter, follow-up endoscopic examinations were performed at intervals ranging from 1 to 6 mo, depending on the clinical features of each patient, and the rate of the recurrence of VE with or without re-bleeding from the lesions was evaluated. The recurrence of VE was defined as the presence of  $> 10$  lesions in the EVE group, and of at least one lesion in the LVE group. The diagnosis of re-bleeding was conducted when the patients showed hematemesis or melena and/or hemorrhagic features of the gastric VE lesions on endoscopic examination irrespective of the number of lesions. Fifteen and twenty patients received treatment with a proton pump inhibitor and H<sub>2</sub>-receptor antagonist, respectively, during the observation period. Written informed consent for the endoscopic procedures was obtained from all the patients. This study was retrospectively performed with the approval of the Institutional Review Board of the Hospital.

### Endoscopic cauterization therapies

Thirteen patients seen between October 1996 and March 2000 were treated by heater probe coagulation, and twenty-five patients seen after April 2000 were treated by argon plasma coagulation. The therapies were repeated until the VE lesions completely disappeared from the stomach following the arrest of hemorrhaging. Heater probe coagulation was performed using a heater probe unit (Olympus Co., Tokyo, Japan) at 15 J for patients with bleeding VE and/or those with VE lesions with a diameter of  $> 3$  mm and at 10 J for those with non-bleeding VE lesions with a diameter of  $\leq 3$  mm. Argon plasma coagulation was performed using a high-frequency generator (Erbotom ICC200; ERBE, Tübingen, Germany) with an automatically regulated argon source (APC300; ERBE) and a flexible APC probe (ERBE) with a high-frequency output at 60 W. Argon gas was delivered at a flow rate of between 1.0 and 2.0 L/min.

### Statistical analysis

The differences in the characteristics between the 2 groups

were analyzed by Mann-Whitney's *U* test, Fisher's exact test and the  $\chi^2$  test. The cumulative recurrence-free and rebleeding-free rates were analyzed by the Kaplan-Meier method. Factors associated with the type of VE and the treatment methods were compared by the log-rank test. *P* values of less than 0.05 were considered to be statistically significant.

## RESULTS

### Demographic and clinical features of the patients in the LVE and EVE groups

As shown in Table 1, there were no significant differences in the sex distribution or age of the patients between the LVE and EVE groups. Hemorrhaging from the VE lesions was observed in 43% (6/14) and 63% (15/24) of the patients in the LVE and EVE groups, respectively. Additionally, 21% (3/14) and 36% (5/14) of the patients in the LVE group and 50% (12/24) and 63% (15/24) of the patients in the EVE group had underlying liver cirrhosis and chronic renal failure, respectively, but the prevalences of the 2 underlying diseases were not significantly different between the two groups.

### Therapeutic efficacies of the endoscopic coagulation procedures

Among the 21 patients in whom active bleeding from the VE lesions was observed, heater probe coagulation was performed in 3 LVE and 4 EVE patients, and argon plasma coagulation in 3 LVE and 11 EVE patients. Hemostasis was obtained in all patients after either endoscopic coagulation procedure. Although the VE lesions diminished

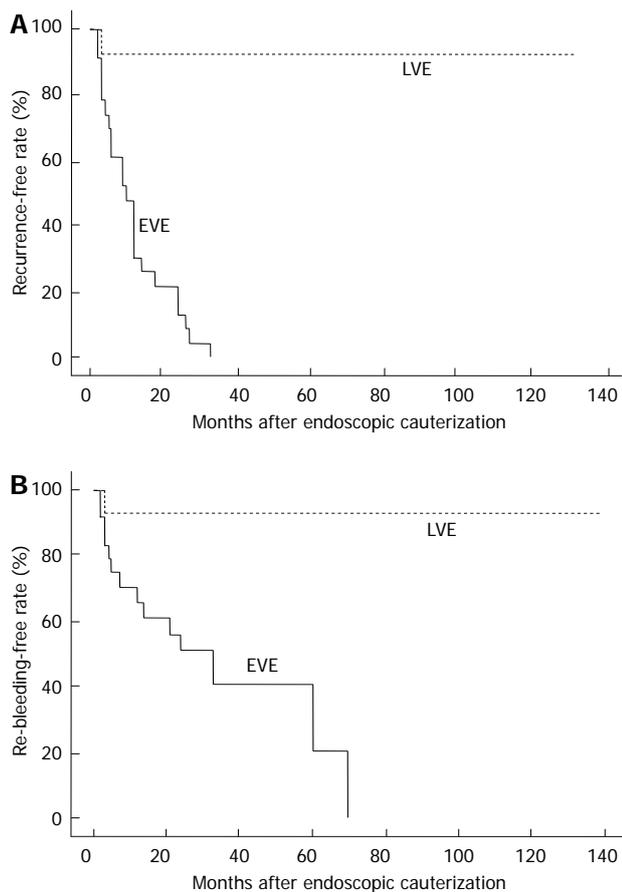

**Table 2** Long-term efficacies of endoscopic cauterization therapies in the patients with gastrointestinal bleeding caused by gastric vascular ectasia *n* (%)

| Groups      | Recurrence rate | Re-bleeding rate |
|-------------|-----------------|------------------|
| LVE         | 1 (7.1)         | 1 (7.1)          |
| Without CRF | 0 (0.0)         | 0 (0.0)          |
| With CRF    | 1 (33.3)        | 1 (33.3)         |
| EVE         | 24 (100.0)      | 14 (58.3)        |
| Without CRF | 12 (100.0)      | 6 (50.0)         |
| With CRF    | 12 (100.0)      | 8 (66.7)         |

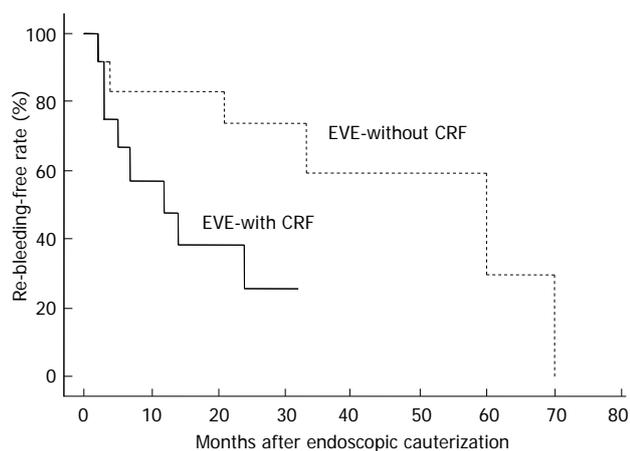

LVE: Localized vascular ectasia, EVE: Extensive vascular ectasia; CRF: Chronic renal failure.

after the procedures in all patients, the number of treatment sessions required for the complete disappearance of the lesions in the stomach differed between the LVE and EVE groups (Table 1). A single treatment session was sufficient to achieve the complete disappearance of the VE lesions in all the patients of the LVE group, except one, who required 2 sessions of heater probe coagulation. In contrast, the patients in the EVE group needed a mean of 3.0 treatment sessions (range, 2-7 treatment sessions) for the complete disappearance of the lesions. No complications of the endoscopic coagulation treatments were encountered in either treatment group.

In all patients, the recurrence of VE and of re-bleeding was examined by repeated follow-up endoscopic examinations for more than 6 mo after the final session of endoscopic cauterization therapy; the median observation period was 32 mo (range, 6-139 mo). As shown in Table 1, however, the observation periods were significantly longer in the LVE group than in the EVE group (*P* < 0.01). The medications prescribed for the patients during the observation period were similar between the two groups. The endoscopic examination revealed recurrence of the VE in 25 of 38 patients (66%), and re-bleeding from the recurrent gastric VE lesions in 15 of these patients (39%) over a median observation period of 5 mo (range, 2-70 mo) after the final session of the coagulation therapy. Particularly in the EVE group, the VE recurred in all the patients, and re-bleeding from the recurrent lesions developed in 14 of these patients (58%) (Table 2). No patients in the EVE group developed re-bleeding with the re-appearance of  $\leq 10$  VE lesions. All of the patients showing re-bleeding in the EVE group had underlying diseases: 8 with chronic renal failure, 5 with liver cirrhosis and 1 with radiation-induced mucosal damage of the gastrointestinal tract. In contrast, in the LVE group, the recurrence of the gastric VE was found in only 1 patient (7%), who had a single lesion that was found before the first session of argon plasma coagulation therapy. This patient also had underlying renal failure and was under long-term maintenance hemodialysis. Consequently, re-bleeding from the recurrent VE lesions developed in 60% (9/15) of the patients with chronic renal failure, which was significantly higher than the percentage in the patients without chronic renal failure (26%; 6/23) (*P* = 0.036).

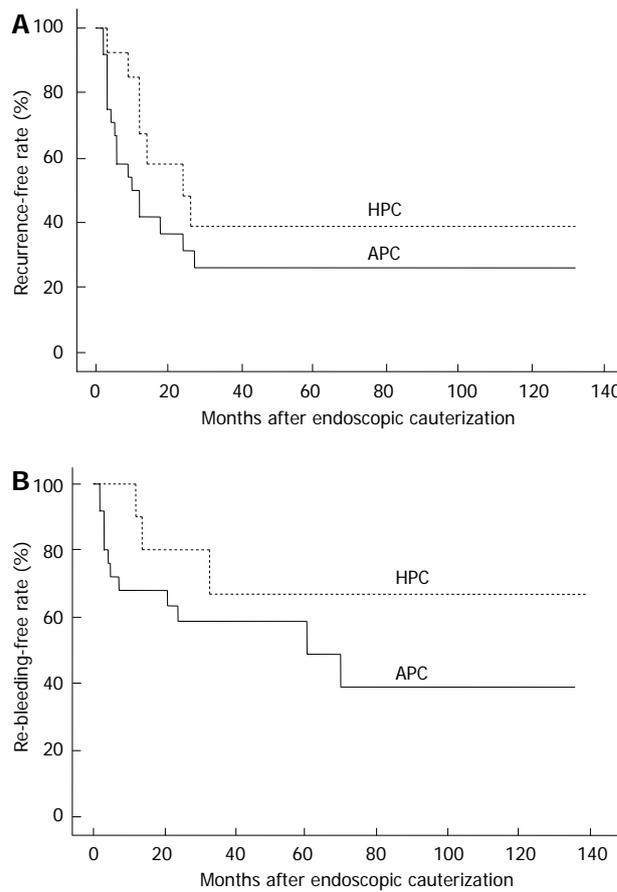

**Figure 1** Long-term outcomes of the patients with hemorrhaging gastric vascular ectasia treated by endoscopic cauterization, depending on the number of lesions. A: Cumulative recurrence-free rates; B: Cumulative re-bleeding-free rates. Both rates were significantly higher in the localized vascular ectasia (LVE) group than in the extensive vascular ectasia (EVE) group ( $P < 0.001$ ).

**Figure 2** Cumulative re-bleeding-free rates in the patients with extensive vascular ectasia treated by endoscopic cauterization. The rates were significantly higher in the patients without chronic renal failure (CRF) than in those with CRF ( $P < 0.05$ ). EVE: Extensive vascular ectasia.

Kaplan-Meier analysis revealed that the cumulative recurrence-free rates of the patients with VE were 29.2% and 0% at 1 and 3 years, respectively, after the endoscopic coagulation therapy in the EVE group (Figure 1A), and

**Figure 3** Long-term outcomes of the patients with hemorrhaging gastric vascular ectasia treated by endoscopic cauterization, depending on the type of procedure. A: Cumulative recurrence-free rates; B: Cumulative re-bleeding-free rates. Both the rates were comparable between the patients treated by heater probe coagulation (HPC) and those treated by argon plasma coagulation (APC).

the cumulative re-bleeding-free rates in these patients were 65.9%, 40.8% and 20.4% at 1, 3 and 5 years, respectively, after the therapy (Figure 1B). Both the recurrence-free rates and re-bleeding-free rates were significantly lower in the EVE group than in the LVE group. Moreover, the cumulative re-bleeding-free rate in the EVE group was 47.6% at 1 year and 25.4% at 2 years after the therapy in patients with chronic renal failure, which were significantly lower than the rates in the patients without chronic renal failure (83.3% and 74.1%, respectively) (Figure 2). There were no significant differences in either the recurrence-free rates or re-bleeding-free rates between the patients treated by heater probe coagulation and those treated by argon plasma coagulation, as shown in Figure 3.

## DISCUSSION

In the present study, we examined the long-term prognosis of 38 patients with hemorrhagic gastric VE treated by endoscopic coagulation procedures, with a medium observation period of 32 mo after the therapies. Although both heater probe coagulation and argon plasma coagulation were useful to achieve the arrest of bleeding and

disappearance of the VE lesions, the recurrence of VE and re-bleeding from the recurrent lesions were noted in 66% and 39% of the patients, respectively. Additionally, we found that the recurrence of VE and/or re-bleeding from the recurrent lesions were more frequent in patients with EVE, especially those with underlying chronic renal failure undergoing maintenance hemodialysis, than in those with LVE. We also found that neither the lesion recurrence rate nor the re-bleeding rate differed significantly between the patients treated by heater probe coagulation and those treated by argon plasma coagulation, although the number of patients evaluated in the study was relatively small.

In Japan, endoscopic laser therapy has not been widely employed for the treatment of VE in the gastrointestinal tract because of the high risk of severe complications, such as perforation<sup>[8]</sup>. Thus, endoscopic cauterization either with heater probe coagulation or argon plasma coagulation is the standard therapeutic strategy used for gastric VE with or without bleeding. However, few studies have been performed to determine the long-term outcomes of such therapies. Olmos *et al.*<sup>[13]</sup> reported that argon plasma coagulation was effective for the prevention of recurrent bleeding from VE in the gastrointestinal tract. Although they showed that re-bleeding did not occur from recurrent lesions in 83% of the patients over a median observation periods of 18 mo, only 10 patients with hemorrhagic gastric VE were included in their study after the exclusion of patients with chronic renal failure, liver cirrhosis and GAVE, including patients with the lesions caused by radiation. Moreover, Zushi *et al.*<sup>[14]</sup> examined the outcomes in 16 patients with liver cirrhosis with hemorrhagic GAVE treated by endoscopic cauterization and reported that 25% of the patients showed re-bleeding from recurrent lesions. In their study, however, the mean observation period was only 10 mo, which is too short to evaluate the long-term outcomes of therapy in these patients. In contrast, Nakamura *et al.*<sup>[15]</sup> evaluated the long-term efficacy of argon plasma coagulation in 22 patients with GAVE and reported that the cumulative re-bleeding rates at 1, 2 and 3 years after the therapy were 50.3%, 64.5% and 64.5%, respectively, over a mean observation period of 23.5 mo. Herrera *et al.*<sup>[17]</sup> examined the therapeutic efficacy of argon plasma coagulation in patients with VE depending on the type of lesion, and reported that there were no cases of re-bleeding from recurrent lesions among the patients with LVE. Our results regarding the EVE group were in line with those reported by Nakamura *et al.*<sup>[15]</sup> but not with those by Herrera *et al.*<sup>[17]</sup>, in which re-bleeding after the therapies developed only in 1 of 8 patients with GAVE. In our study, re-bleeding from recurrent VE was especially frequent in patients with EVE and in those with chronic renal failure undergoing maintenance hemodialysis, whereas underlying diseases such as chronic renal failure were found only in 3 patients with GAVE in the study by Herrera *et al.*<sup>[17]</sup>. These differences in the clinical features of the patients

may have produced the discrepancies in the results by Herrera *et al.*<sup>[17]</sup>, those by Nakamura *et al.*<sup>[15]</sup> and those in the present study.

Both LVE and EVE have been reported to develop at a high frequency in association with chronic renal failure<sup>[18]</sup>. Clouse *et al.*<sup>[3]</sup> reported that 18 of 30 patients (60%) with hemorrhagic angiodysplasia had underlying renal failure, with 10 of these patients (33%) under long-term maintenance hemodialysis and/or who underwent renal transplantation. The present study demonstrated that endoscopic cauterization did not provide satisfactory long-term outcomes in patients with EVE complicated with chronic renal failure, even after the successful initial arrest of bleeding had been achieved by the endoscopic cauterization therapy. Notably, the VE developed again after the therapies in all of the patients with EVE, even in the absence of underlying chronic renal failure, followed by re-bleeding from the recurrent lesions in half of these patients, with a cumulative re-bleeding rate of approximately 40% at 3 years. These observations prompted us to postulate that the etiology and the clinical characteristics may be different between the LVE and EVE groups, and also between VE patients with and without chronic renal failure. Based on the findings, careful endoscopic follow-up after the initial successful cauterization therapy is required for patients with EVE, regardless of the presence/absence of underlying diseases, including chronic renal failure.

With respect to the endoscopic cauterization procedures available, argon plasma coagulation has been employed more frequently compared with heater probe coagulation for the treatment of gastric VE in Japan. Similarly, at our institution, almost all patients seen after the year 2000 have been treated by argon plasma coagulation. As shown in Figure 3, both the cumulative recurrence and re-bleeding rates were equivalent between patients with gastric VE treated by argon plasma coagulation and those treated by heater probe coagulation. The limitation of our evaluation is that it is a retrospective and single cohort study. A randomized controlled study would be required to confirm our results. Additionally, the safety, including the frequency of complications, convenience of instrument handling, and number of sessions required for the treatment, has been reported to not be significantly different between the patients treated by the two procedures<sup>[19-22]</sup>. Thus, the criteria for the selection of either procedure for patients with gastric ectasia need to be established in the future. Recently, endoscopic band ligation was shown to be useful for the treatment of GAVE<sup>[23-27]</sup>. Wells *et al.*<sup>[25]</sup> reported that endoscopic band ligation was superior to thermal therapies, including argon plasma coagulation, in terms of the therapeutic efficacy to arrest bleeding, the volume of blood transfusion needed after the procedure and the duration of hospitalization in 22 patients with GAVE. Sato *et al.*<sup>[26]</sup> also reported the superiority of endoscopic band ligation compared with argon plasma coagulation for GAVE as-

sociated with liver diseases. Moreover, a novel endoscopic ablation method, the HALO<sup>90</sup> system, has been reported to be useful for the treatment of GAVE in a few patients. A large-scale study would be required to compare the efficacy and safety of these novel procedures with those of argon plasma coagulation and heater probe coagulation.

In conclusion, the recurrence of VE and re-bleeding from the lesions was frequent in patients with EVE, especially in those with underlying chronic renal failure after the initial successful control of the bleeding and disappearance of the lesions by endoscopic cauterization. Therefore, careful observation by endoscopy is important for these patients even after initial successful therapy.

## COMMENTS

### Background

Vascular ectasia (VE) of the stomach has been recognized as a rare cause of hemorrhage from the upper gastrointestinal tract. Endoscopic coagulation has been reported to be useful for the temporary arrest of bleeding from any type of gastric VE. However, the long-term prognosis of patients undergoing endoscopic coagulation has not yet been elucidated.

### Innovations and breakthroughs

The recurrence of VE and re-bleeding from the lesions was frequent in patients with extensive VE, especially in those with underlying chronic renal failure, after the initial successful control of the bleeding and disappearance of the lesions by endoscopic cauterization.

### Applications

The findings of this study may help establish the treatment and follow-up strategy for the patients with bleeding gastric VE.

### Terminology

VE is a term encompassing a broad spectrum of lesions visualized on endoscopic examination, including angiodysplasia, watermelon stomach and diffuse antral VE. In this study, VE lesions were classified into 2 subtypes: localized VE with ≤ 10 VE lesions and extensive VE with > 10 VE lesions.

### Peer review

This is a paper on the treatment of VE of the stomach with some novel findings. The cohort is large and well described. It is worth publishing to demonstrate the novel finding of worse outcomes in those patients with chronic renal failure.

### Abstract

**AIM:** To revealed the prevalence of *Helicobacter pylori* (*H. pylori*) infection in the Bhutanese population.

**METHODS:** We recruited a total of 372 volunteers (214 females and 158 males; mean age of  $39.6 \pm 14.9$  years) from three Bhutanese cities (Thimphu, Punaka, and Wangdue). The status of *H. pylori* infection was determined based on five different tests: the rapid urease test (CLO test), culture, histology, immunohistochemistry (IHC), and serum anti *H. pylori*-antibody.

**RESULTS:** The serological test showed a significantly higher positive rate compared with the CLO test, culture, histology and IHC ( $P < 0.001$ ,  $P < 0.001$ ,  $P = 0.01$ , and  $P = 0.01$ , respectively). When the subjects were considered to be *H. pylori* positive in the case of at least one test showing a positive result, the overall prevalence of *H. pylori* infection in Bhutan was 73.4%. The prevalence of *H. pylori* infection significantly decreased with age ( $P < 0.01$ ). The prevalence of *H. pylori* infection was lower in Thimphu than in Punakha and Wangdue ( $P = 0.001$  and  $0.06$ , respectively). The prevalence of *H. pylori* infection was significantly higher in patients with peptic ulcers than in those with gastritis ( $91.4\%$  vs  $71.3\%$ ,  $P = 0.003$ ).

**CONCLUSION:** The high incidence of gastric cancer in Bhutan may be attributed to the high prevalence of *H. pylori* infection.

**Key words:** *Helicobacter pylori*; Bhutan; Prevalence

**Core tip:** The high prevalence of *Helicobacter pylori* (*H. pylori*) infection in Bhutan may contribute to the high incidence of peptic ulcers and gastric cancer. The prevalence of *H. pylori* infection in the capital city, Thimphu, was significantly lower than that of other rural areas. Therefore, performing eradication therapy of *H. pylori* and improving the sanitary conditions to decrease the rate of *H. pylori* infection in Bhutan can contribute to decreasing *H. pylori*-related diseases such as peptic ulcers and gastric cancer.

Vilaichone R, Mahachai V, Shiota S, Uchida T, Ratanachu-ek T, Tshering L, Tung NL, Fujioka T, Moriyama M, Yamaoka Y. Extremely high prevalence of *Helicobacter pylori* infection in Bhutan. *World J Gastroenterol* 2013; 19(18): 2806-2810 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i18/2806.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i18.2806>

## INTRODUCTION

*Helicobacter pylori* (*H. pylori*) is a spiral, Gram-negative bacterium that chronically colonizes the human stomach and is currently recognized to play a causative role in the pathogenesis of various gastroduodenal diseases, including gastritis, peptic ulcers, gastric cancer, and mucosa-associated lymphoid tissue lymphoma<sup>[1,2]</sup>. Infection with *H. pylori* almost always results in chronic gastritis, but only a small population of infected patients develop more severe diseases, such as peptic ulcers and gastric cancer<sup>[2,3]</sup>. In Asia, gastric cancer is still a significant health problem, and the incidence of gastric cancer geographically varies greatly. Based on the age-standardized incidence rate (ASR) of gastric cancer, Asian countries can be categorized as high-risk (e.g., Japan, South Korea and China), intermediate-risk (e.g., Vietnam) or low-risk (e.g., Thailand and Indonesia) countries for gastric cancer<sup>[4]</sup>. Although the association between *H. pylori* infection and gastric cancer has been well-established<sup>[5,6]</sup>, a high prevalence of *H. pylori* infection is not always associated with a high incidence of gastric cancer. For example, despite the high infection rate in India, the incidence of gastric cancer there is low, which is known as an "Asian enigma"<sup>[7]</sup>.

Bhutan is a small landlocked country in South Asia, located at the eastern end of the Himalayas and bordered on the South, East and West by India and on the North by China. The ASR of gastric cancer in Bhutan was reported to be 24.2/100000, which is relatively high among Asian countries<sup>[4]</sup>. Although several studies focused on the prevalence of *H. pylori* infection have been conducted in many countries with different socio-economic, cultural, and racial groups<sup>[8-10]</sup>, the prevalence of *H. pylori* infection in Bhutan has not been investigated yet. In this study, we first disclosed the infection rate of *H. pylori* in Bhutan, and the findings from this study can be used as baseline epidemiological data for further research to understand the epidemiology of *H. pylori* infection in Bhutan and other Asian countries.

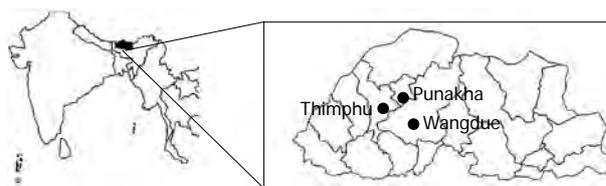

Figure 1 Geographic location in Bhutan.

## MATERIALS AND METHODS

### Study population

We recruited a total of 372 volunteers with dyspeptic symptoms (214 females and 158 males; mean age of  $39.6 \pm 14.9$  years) during four days (December 6 to 9) in December 2010. The survey was conducted in Thimphu ( $n = 194$ ), the capital city, and in two other cities within a 200 km radius of the capital, Punakha ( $n = 119$ ) and Wangdue ( $n = 59$ ) (Figure 1). Written informed consent was obtained from all participants, and the protocol was approved by the Ethics Committee of Jigme Dorji Wangchuk National Referral Hospital, Bhutan.

During each endoscopy session, four gastric biopsy specimens were obtained (three from the antrum and one from the corpus). The three specimens from the antrum were used for *H. pylori* culture, rapid urease test and histological examination. The specimen from the corpus was used for histological examination. Peptic ulcers and gastric cancer were identified by endoscopy, and gastric cancer was further confirmed by histopathology. Gastritis was defined as *H. pylori* gastritis in the absence of a peptic ulcer or gastric malignancy.

### Status of *H. pylori* infection

To maximize the diagnostic accuracy, 5 different methods were combined for the diagnosis of *H. pylori* infection, including culture, histology, immunohistochemistry (IHC), the rapid urease test and serum *H. pylori* antibody. For the *H. pylori* culture, one biopsy specimen from the antrum was homogenized in saline and inoculated onto Mueller Hinton II Agar medium (Becton Dickinson, NJ, United States) supplemented with 7% horse blood without antibiotics. The plates were incubated for up to 10 d at 37 °C under microaerophilic conditions (10% O<sub>2</sub>, 5% CO<sub>2</sub> and 85% N<sub>2</sub>). *H. pylori* was identified on the basis of colony morphology, Gram staining and positive reactions for oxidase, catalase, and urease. Isolated strains were stored at -80 °C in Brucella Broth (Difco, NJ, United States) containing 10% dimethylsulfoxide and 10% horse serum. For histology, all biopsy materials were fixed in 10% buffered formalin for 24 h and then embedded in paraffin. Serial sections were stained with hematoxylin and eosin and with May-Giemsa stain. The state of the gastric mucosa was evaluated according to the updated Sydney system<sup>[11]</sup>. The degree of the bacterial load was classified into four grades: 0, "normal"; 1, "mild"; 2, "moderate"; and 3, "marked". A bacterial load grade greater than or equal to 1 was defined as *H. pylori* positive. *H. pylori* seropositivity was evaluated with a commercially available ELISA kit (Eiken Co., Ltd.,

**Table 1** Prevalence of *Helicobacter pylori* infection in each diagnostic test *n* (%)

CLO: The rapid urease test; IHC: Immunohistochemistry.

Tokyo, Japan) according to the manufacturer's instructions. Patients were considered to be *H. pylori*-negative when all five tests were negative, and a *H. pylori*-positive status required at least one positive test result.

### Immunohistochemistry

IHC was performed as described previously<sup>[12]</sup>. Briefly, after antigen retrieval and inactivation of endogenous peroxidase activity, tissue sections were incubated with the  $\alpha$ -*H. pylori* Ab (DAKO, Denmark) overnight at 4 °C. After washing, the sections were incubated with biotinylated goat anti-rabbit IgG (Nichirei Co., Japan), followed by incubation with a solution of avidin-conjugated horseradish peroxidase (Vectastain Elite ABC kit; Vector Laboratories Inc., Burlingame, CA, United States). Peroxidase activity was detected using a H<sub>2</sub>O<sub>2</sub>/diaminobenzidine substrate solution. For all cases, we performed Giemsa staining using a serial section to identify the presence of *H. pylori*. If the *H. pylori* identified by Giemsa staining was found to be positively immunostained, we judged the case to be positive.

### Statistical analysis

The statistical analysis were conducted using the chi-square test to compare discrete variables and Cochran-Armitage analysis to compare the prevalence of *H. pylori* infection. Differences in the prevalence in each group were analyzed using the Mantel-Haenszel method. To match age and sex, multiple backward stepwise logistic regression analyses were used to examine the associations of peptic ulcers with the main predictor variables. The predictor variables for peptic ulcers were age, sex and *H. pylori* status. For each variable, the OR and 95%CI were calculated. Differences at  $P < 0.05$  were regarded as statistically significant. The data analysis was performed using JMP® 9 statistical software (SAS Institute Inc., Cary, NC, United States) and SPSS version 19 (SPSS Inc., Chicago, IL, United States).

## RESULTS

A total of 372 subjects were recruited, comprising 107 who were ≤ 29 years old, 96 who were 30-39 years old, 80 who were 40-49 years old, 45 who were 50-59 years old, and 44 who were ≥ 60 years old. Table 1 shows the *H. pylori*-positive rate for each test. The serological test showed a significantly higher positive rate compared with the CLO

test, culture, histology and IHC ( $P < 0.001$ ,  $P < 0.001$ ,  $P = 0.01$ , and  $P = 0.01$ , respectively). The prevalence of *H. pylori* infection by the serological test was as follows: 74.8% (80/107) for the ≤ 29 years old group, 83.3% (80/96) for the 30-39 years old group, 58.8% (47/80) for the 40-49 years old group, 66.7% (30/45) for the 50-59 years old group, and 54.5% (24/44) for the ≥ 60 years old group. When the subjects were considered to be *H. pylori* positive in the case of at least one positive test, the prevalence of *H. pylori* was 80.4% (86/107) for the ≤ 29 years old group, 83.3% (80/96) for the 30-39 years old group, 61.3% (49/80) for the 40-49 years old group, 71.1% (32/45) for the 50-59 years old group, and 59.1% (26/44) for the ≥ 60 years old group; thus, the prevalence was significantly decreased with age ( $P < 0.01$ ). This phenomenon was significant in the Thimphu area. Because the number of subjects older than 50 years old in Punakha and Wangdue was too small for the statistical analysis, this trend was not observed in these two areas. Overall, the prevalence of *H. pylori* infection in Bhutan was 73.4% (273/372). Figure 2 shows the prevalence of *H. pylori* infection according to the various range age groups. There was no significant difference between men and women (data not shown).

The prevalence of *H. pylori* infection in the three cities was analyzed by the Mantel-Haenszel method to adjust for age. It differed among the three cities, with the highest in Punakha (102/119, 85.7%), followed by Wangdue (44/59, 74.5%) and Thimphu (127/194, 65.4%). The prevalence of *H. pylori* infection was significantly lower in Thimphu than in Punakha even after the adjustment for age ( $P = 0.001$ ). Although there was no significant difference, the prevalence tended to be lower in Thimphu than in Wangdue even after the adjustment for age ( $P = 0.06$ ).

In the endoscopic diagnosis, gastritis was the most common finding (307/372, 82.5%). Gastric and duodenal ulcers were found in 25 (6.7%) and 22 (5.9%) cases, respectively. Gastric cancer was found in 5 cases (1.3%). Duodenal erosion, duodenal tumor, and reflux esophagitis were found at 5, 1 and 7 cases, respectively. Table 2 shows the prevalence *H. pylori* infection in each diagnosis. A high infection rate was detected among patients with gastric ulcers (92.0%) and duodenal ulcers (90.9%). In addition, 71.3% of the subjects with gastritis were *H. pylori*-positive. When gastric and duodenal ulcers were defined as peptic ulcers, the prevalence of *H. pylori* infection in peptic ulcers was significantly higher than that in gastritis (91.4% *vs* 71.3%,  $P = 0.003$ ). The percentage of

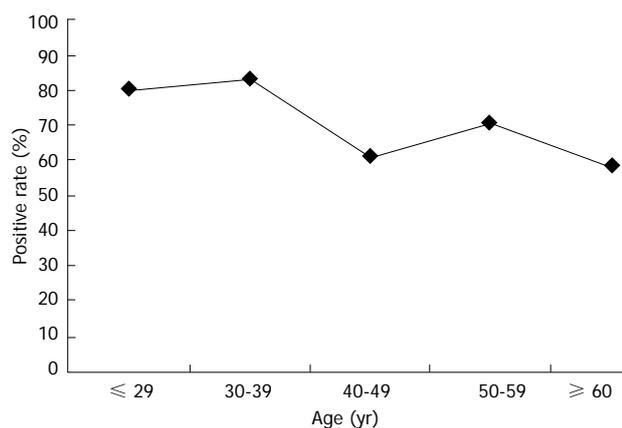

Figure 2 Prevalence of *Helicobacter pylori* infection by age group in Bhutan.

men was also significantly higher in patients with peptic ulcers than in those with gastritis (72.3% vs 37.1%,  $P < 0.001$ ). Multiple logistic analysis after adjusting for age and gender showed that *H. pylori*-positivity in addition to male gender was significantly associated with peptic ulcers (OR = 3.89, 95%CI: 1.33-11.33).

## DISCUSSION

We first revealed that the prevalence of *H. pylori* in Bhutan was 73.4%. In contrast with developed countries, *H. pylori* infections occur earlier in life and with a higher frequency in the developing world<sup>[8]</sup>. The prevalence of infection with *H. pylori* infection exceeds 50% by 5 years of age, and by adulthood, infection rates exceeding 90% are not unusual in developing countries<sup>[13]</sup>. Although the prevalence of infection has dropped significantly in many parts of North America, Western Europe and Asia, no such decline has been noted in the developing world<sup>[13]</sup>. The present study showed that a high prevalence was detected in younger age groups and that the prevalence significantly decreased with age in Bhutan. The decrease in the *H. pylori* infection rate with age might be due to the overuse of antibiotics in Bhutan. Antibiotics are frequently used in any infectious diseases in Bhutan (Dr. Lotay, personal communication). Even under these conditions, the prevalence of *H. pylori* infection was relatively high in all age groups.

Several clinical tests have been developed to diagnose *H. pylori* infection. However, there is still no established "gold standard" for the diagnosis of *H. pylori*, and thus the combination of two or more tests should be applied to determine the accurate prevalence of infection. In this study, we combined 5 different tests and considered *H. pylori*-positivity to be at least one positive test among the five tests. In this study, the serological test showed the highest positive rate compared with the other 4 tests. Although the serological test is widely used in epidemiological studies and not affected by local changes in the stomach that could lead to false-negatives, as in the other tests, this test cannot distinguish between current and past infections because *H. pylori* IgGs persist even after the disappearance of this bacterium<sup>[9,14]</sup>. Therefore,

Table 2 Prevalence of *Helicobacter pylori* infection in each diagnosis *n* (%)

| Diseases           | <i>n</i> | Positive   |
|--------------------|----------|------------|
| Gastritis          | 307      | 219 (71.3) |
| Gastric ulcer      | 25       | 23 (92.0)  |
| Duodenal ulcer     | 22       | 20 (90.9)  |
| Gastric cancer     | 5        | 3 (60.0)   |
| Duodenal erosion   | 5        | 3 (60.0)   |
| Duodenal tumor     | 1        | 1 (100.0)  |
| Reflux esophagitis | 7        | 4 (57.1)   |

results that are positive in the serological test and negative in the endoscopic tests may indicate a past infection. Culture from biopsy specimens has the potential of leading to a high sensitivity, given that only one bacterium can multiply and provide billions of bacteria. However, both strict transport conditions and careful handling in the laboratory are necessary<sup>[14]</sup>. Histopathological positivity depends on the density of *H. pylori* biopsy sites; thus, these tests can occasionally show false negative results<sup>[14]</sup>. In addition, the histological diagnosis of *H. pylori* infection is very much dependent on the expertise of the pathologists. The rapid urease test, such as the CLO test, can be useful as a rapid diagnostic method. However, these results can also be affected by the bacterial load<sup>[14]</sup>. A high proportion of the elderly population develops gastric atrophy and intestinal metaplasia, which can lead to a hostile environment for *H. pylori* and thus fewer bacteria and potentially a negative result. A detailed study in histological scoring is necessary for further study. Moreover, endoscopic tests, including the CLO test, culture and histological examination, can be affected in bleeding patients with peptic ulcers<sup>[10]</sup>. However, although the reason is not clear, all peptic ulcer cases in our study were not in the active bleeding phase, indicating that we do not need to consider any effects of bleeding.

The lowest infection rate was found in Thimphu, which is the capital city of Bhutan. The prevalence of *H. pylori* infection in Thimphu was significantly lower than that of the rural cities of Punakha and Wangdue. In Thimphu, the sanitary conditions are better than those of Punakha and Wangdue, which supports the possibility that sanitary conditions may be important factors for *H. pylori* infection. In fact, the prevalence of *H. pylori* infection was very low in individuals less than 10 years old (*i.e.*, approximately 5%) and increased with age in Japan<sup>[15]</sup>. Overall, it was higher among individuals born before 1950 and lower in those born thereafter. There was a rapid change in the sanitary conditions and standard of living in Japan after World War II, and clean public water systems were introduced in Japan in the 1950s. Therefore, sanitary conditions, such as a full equipment rate of water and sewage, are considered to be important factors for *H. pylori* infection<sup>[8]</sup>.

The prevalence of *H. pylori* in patients with peptic ulcers was significantly higher than that in patients with gastritis, which is consistent with previous reports<sup>[16-18]</sup>. This observation suggests that *H. pylori* infection is a risk factor for the development of peptic ulcers and gastric cancer, even in Bhutan. In addition, we found 5 gastric

cancer patients among the 372 volunteers. The ASR of gastric cancer in Bhutan was reported to be 24.2/100000 based on the small number in the registry (114 cases) in 2008<sup>[4]</sup>. This observation supports the high incidence of gastric cancer in Bhutan.

In conclusion, the high incidence of gastric cancer in Bhutan may be attributed to the high prevalence of *H. pylori* infection. Therefore, the eradication therapy of *H. pylori* can contribute to a decrease in *H. pylori*-related diseases, such as peptic ulcers and gastric cancer. However, we should be cautious regarding eradication therapy in Bhutan. Even when eradication therapy for *H. pylori* has succeeded, the infection frequently recurs in patients in developing countries, where there is a high prevalence of *H. pylori* infection<sup>[19]</sup>. Such repeat infections are either due to a recurrence of the original infection or reinfection with a new strain. Improving the sanitary conditions to decrease the prevalence of *H. pylori* in Bhutan is important.

## ACKNOWLEDGMENTS

We thank Kudo Y, Yano K and Chaithongrat S for their technical assistance.

## COMMENTS

### Background

Bhutan is a small landlocked country in South Asia and the prevalence of *Helicobacter pylori* (*H. pylori*) infection in Bhutan has not been investigated.

### Research frontiers

The prevalence of *H. pylori* in Bhutan was 73.4% and the high incidence of gastric cancer and peptic ulcer disease in Bhutan may be attributed to the high prevalence of *H. pylori* infection.

### Innovations and breakthroughs

This is the first study exploring the extremely high prevalence of *H. pylori* infection in Bhutan. Many tests for *H. pylori* detection such as serological test rapid urease test, culture, histology and immunohistochemistry were performed and analyzed.

### Applications

The study results suggest that high incidence of gastric cancer and peptic ulcer disease in Bhutan may be attributed to the high prevalence of *H. pylori* infection. Therefore, *H. pylori* eradication therapy can contribute to reduce these *H. pylori*-related diseases.

### Peer review

This is a study in which authors analyzed the prevalence of *H. pylori* infection in different cities, age group and each disease. The results are very interesting and suggest that *H. pylori* eradication and improve of sanitation should be considered to reduce *H. pylori* infection and related diseases in Bhutan.

### Abstract

**AIM:** To evaluate whether preoperative mean corpuscular volume (MCV) is a prognostic indicator in patients with resectable esophageal squamous cell carcinoma (ESCC).

**METHODS:** A total of 298 consecutive, prospectively enrolled patients with histologically diagnosed ESCC who underwent surgery with curative intent from 2001 to 2011 were retrospectively evaluated. Patients were excluded if they had previous malignant disease, distant metastasis at the time of primary treatment, a history of neoadjuvant treatment, had undergone non-radical resection, or had died of a non-tumor-associated

cause. Survival status was verified in September 2011. Pathological staging was performed based on the 2010 American Joint Committee on Cancer criteria. Preoperative MCV was obtained from blood counts performed routinely within 7 d prior to surgery. Receiver operating characteristic (ROC) curve analysis was used to determine a cutoff for preoperative MCV.

**RESULTS:** The 298 patients consisted of 230 males and 68 females, with a median follow-up of 30.1 mo. ROC analysis showed an optimal cutoff for preoperative MCV of 95.6 fl. Fifty-nine patients (19.8%) had high (> 95.6 fl) and 239 (80.2%) had low ( $\leq$  95.6 fl) preoperative MCV. Preoperative MCV was significantly associated with gender ( $P = 0.003$ ), body mass index ( $P = 0.017$ ), and preoperative red blood cell count ( $P < 0.001$ ). The predicted 1-, 3- and 5-year overall survival (OS) rates were 72%, 60% and 52%, respectively. Median OS was significantly longer in patients with low than with high preoperative MCV (27.5 mo vs 19.4 mo,  $P < 0.001$ ). Multivariate analysis showed that advanced pT ( $P = 0.018$ ) and pN ( $P < 0.001$ ) stages, upper thoracic location ( $P = 0.010$ ), lower preoperative albumin concentration ( $P = 0.002$ ), and high preoperative MCV ( $P = 0.001$ ) were negative prognostic factors in patients with ESCC. Preoperative MCV also stratified OS in patients with T3, N1-N3, G2-G3 and stage III tumors.

**CONCLUSION:** Preoperative MCV is a prognostic factor in patients with ESCC.

© 2013 Baishideng. All rights reserved.

**Key words:** Preoperative markers; Mean corpuscular volume; Prognosis; Resectable; Esophageal neoplasms

**Core tip:** Elevated mean corpuscular volume (MCV) has been shown to predict the risk of esophageal squamous cell carcinoma (ESCC). We hypothesized that pretreatment MCV could predict prognosis. In analyzing 298 patients with ESCC, we found that the optimal cut-off

for preoperative MCV was 95.6 fl. Multivariate analysis showed that high (> 95.6 fl) preoperative MCV was a negative prognostic factor, along with advanced stage, upper thoracic location and lower preoperative albumin, in patients with ESCC. Median overall survival was significantly longer in patients with low ( $\leq$  95.6 fl) than high preoperative MCV (27.5 mo *vs* 19.5 mo,  $P < 0.001$ ).

Prognostic value of preoperative mean corpuscular volume in esophageal squamous cell carcinoma. *World J Gastroenterol* 2013; 19(18): 2811-2817 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i18/2811.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i18.2811>

## INTRODUCTION

Elevated mean corpuscular volume (MCV) has long been recognized as a biomarker for alcoholic and folate deficient patients<sup>[1-3]</sup>. Although the nature of the relationship between them remains unclear, recent reports suggested that alcohol-induced folate deficiency can lead to macrocytosis<sup>[4]</sup>. In addition, MCV was found to be higher in Asian heavy drinkers with inactive aldehyde dehydrogenase-2 (ALDH2)<sup>[5,6]</sup> and to be a marker for alcohol abuse with inactive heterozygous ALDH2<sup>[7,8]</sup>, suggesting that acetaldehyde is an important contributor to macrocytosis.

Alcohol abuse, and acetaldehyde and folate deficiency, all indicative of poor physical condition, were found to increase susceptibility to esophageal carcinoma<sup>[3,9-12]</sup>, as was macrocytosis<sup>[7,13]</sup>. In addition, patients with more advanced malignancies frequently present with more severe hematological anomalies<sup>[14,15]</sup>. These findings led us to hypothesize that pretreatment MCV may predict the prognosis of patients with esophageal carcinoma. We therefore analyzed the association between preoperative MCV and different clinicopathological parameters, as well as the prognostic significance of preoperative MCV in patients with esophageal squamous cell carcinoma (ESCC).

## MATERIALS AND METHODS

### Patients selection

This study was a retrospective analysis of a prospectively collected database (2001-2011) of 298 consecutive patients with histologically diagnosed ESCC who underwent surgery with curative intent at the Cancer Center of Sun Yat-Sen University, Guangzhou, China. Patients with previous malignancy, distant metastasis, neoadjuvant treatment, non-radical resection (R1/R2), or non-tumor-associated death were excluded. Tumors were pathologically staged using the American Joint Committee on Cancer (2010) staging system. Patients were followed-up in the outpatient clinic every 3-6 mo during the first 3 years and every 12 mo thereafter. Demography and clinical details were extracted from the database (Table 1). Survival status

was verified in September 2011 using the best available methods. The study protocol was approved by the medical ethics committee of the Cancer Center of Sun Yat-Sen University, which waived the requirement for informed consent due to the retrospective nature of the study.

### Preoperative MCV

Preoperative MCV was determined from preoperative blood counts, performed routinely within 7 d prior to surgery, using a Beckman Counter blood analyzer (version STKS, Beckman Counter Inc., Fullerton, CA, United States). The cut-off for preoperative MCV was defined by receiver operating characteristic (ROC) curve analysis, with the point maximizing the area under the curve being selected.

### Statistical analysis

All statistical analysis were performed using the SPSS 19.0 software package (SPSS, Inc., Chicago, IL, United States). The ROC curve was generated and analyzed using MedCalc statistical software package 11.0.1 (MedCalc Software bvba, Mariakerke, Belgium). Correlations between preoperative MCV and clinicopathological characteristics were assessed using the Pearson's  $\chi^2$  test. Overall survival (OS) was defined as the interval from the date of surgery to the date of death, or last follow-up. Multivariate Cox regression analysis was performed for all parameters found to be significant by the univariate analysis. Survival was analyzed using the Kaplan-Meier method, and differences between curves were assessed by the Log-Rank test. Statistical significance was defined as a  $P$  value < 0.05.

## RESULTS

### Patient baseline characteristics and preoperative MCV

The 298 patients consisted of 230 males and 68 females, with a median preoperative MCV of 91.0 fl (range: 61.4-112.4 fl). ROC curve analysis showed that the optimal cut-off point maximizing (0.588) was 95.6 fl ( $P = 0.0123$ ), with a sensitivity of 0.867 and a specificity of 0.324. Using this cut-off, 59 patients (19.8%) had high (> 95.6 fl) and 239 (80.2%) had low ( $\leq$  95.6 fl) preoperative MCV. The correlations between preoperative MCV and clinicopathologic parameters are summarized in Table 1. Preoperative MCV was significantly associated with gender ( $P = 0.003$ ), body mass index (BMI) ( $P = 0.017$ ), and preoperative red blood cell (RBC) count ( $P < 0.001$ ; Figure 1).

### Survival and preoperative MCV

Over a median follow-up of 30.1 mo, 102 of the 298 patients (34.2%) died of cancer-related causes, whereas the other 196 (65.8%) survived. The median survival time was 25.8 mo (range: 1.6-116.1 mo), and the predicted 1-, 3- and 5-year OS rates after primary surgery were 72%, 60%, and 52% respectively. Median OS was significantly longer in patients with low than high preoperative MCV (27.5 mo *vs* 19.4 mo,  $P < 0.001$ ; Figure 2).

<sup>1</sup>Normal limit of red blood cell count; <sup>2</sup>Mean value of preoperative hemoglobin. MCV: Mean corpuscular volume; Low: Low preoperative MCV ( $\leq 95.6$  fl); High: High preoperative MCV ( $> 95.6$  fl); BMI: Body mass index; RBC: Red blood cell; UICC: Union for International Cancer Control.

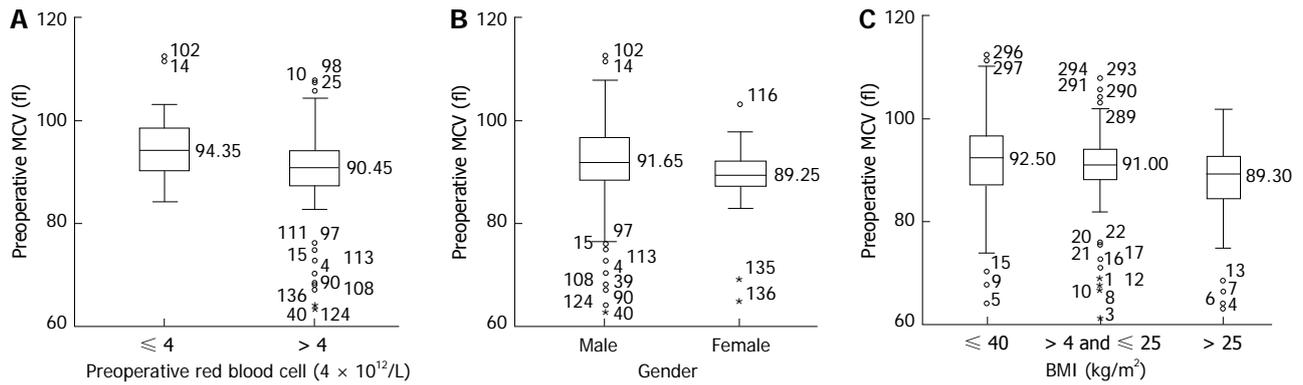

tient survival, we analyzed OS using a Cox proportional hazards model. All parameters found to be potentially significant in univariate analysis were included in a multivariate analysis. We found that pT status ( $P = 0.018$ ), pN status ( $P < 0.001$ ), tumor location ( $P = 0.010$ ), preoperative albumin concentration ( $P = 0.002$ ), and preoperative MCV ( $P = 0.001$ ) were significantly prognostic of survival in this patient cohort (Table 2). When we analyzed the effect of preoperative MCV on OS in patients classified by clinicopathological factors, preoperative MCV was predictive of OS in patients with T3 ( $P < 0.001$ ), N1-N3 ( $P < 0.001$ ), G2-G3 ( $P < 0.001$ ), and stage III ( $P = 0.001$ ) tumors (Figure 2 and Table 3).

## DISCUSSION

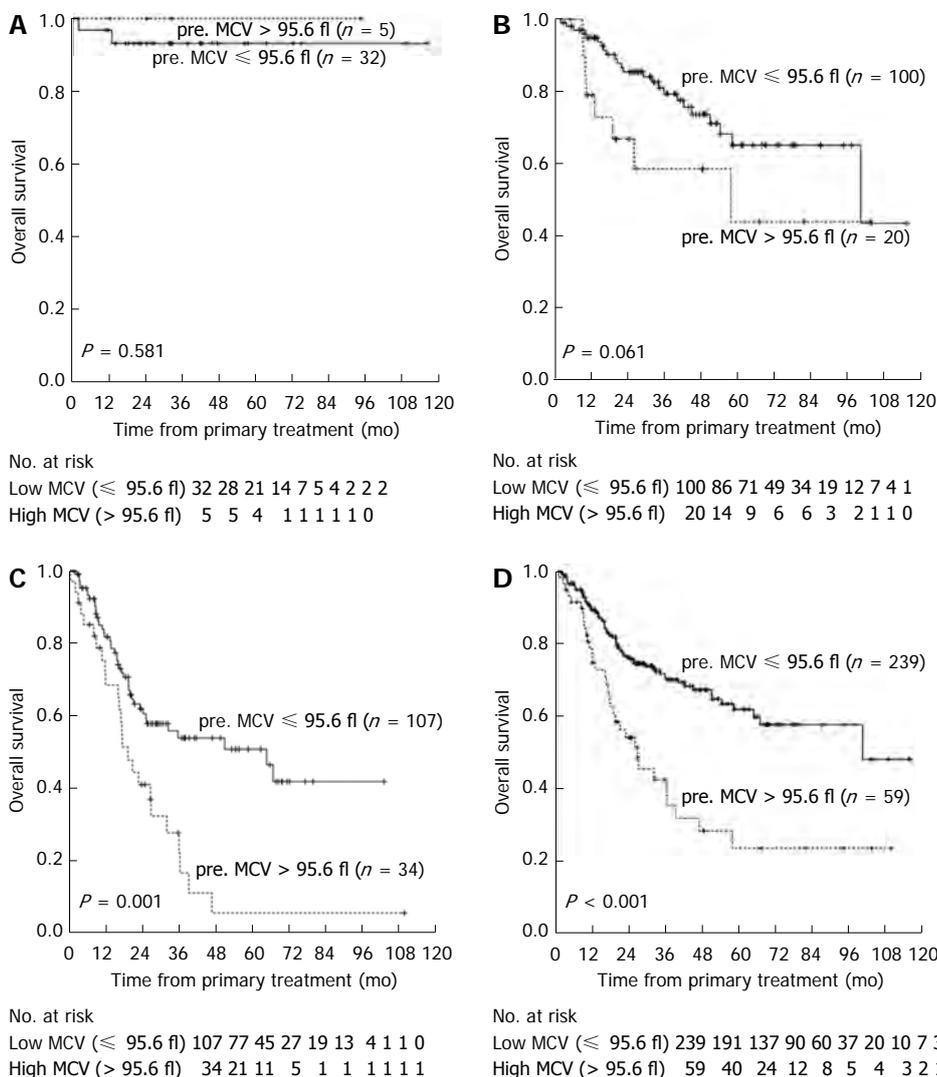

Hematologic parameters have been reported to correlate significantly with prognosis in patients with advanced

malignant disease<sup>[15-18]</sup>. MCV is considered a sensitive indicator of alcohol abuse and folate deficiency<sup>[1,2,4,6,19]</sup>. Recently, MCV was found to be a biomarker for alcohol abuse accompanied by inactive heterozygous ALDH2, and also allowed for the prediction of ESCC risk<sup>[8]</sup>. To our knowledge, however, no previous study has assessed the relationship between MCV and the prognosis of patients with ESCC.

Using ROC curve analysis, we found that a cut-off of 95.6 fl was a statistically significant predictor of OS. Moreover, high ( $> 95.6$  fl) MCV was significantly correlated with male gender, lower BMI, and RBC  $\leq 4 \times 10^{12}$ /L. Folate deficiency has been shown to inhibit red cell maturation, as well as increasing erythrocyte fragility, resulting in increased hemolysis and lower RBC count, which consequently results in macrocytosis<sup>[20]</sup>. Lower BMI may accompany poor nutritional status, which was associated with elevated MCV<sup>[13,21]</sup>. The significant correlation

**Figure 1** Box plot of preoperative mean corpuscular volume stratified by preoperative red blood cell count (A), gender (B) and body mass index (C). MCV: Mean corpuscular volume; BMI: Body mass index.

between high MCV and male gender may be related to the association between macrocytosis and alcohol abuse, since overdrinking is much more frequent in males than in females<sup>[6-8]</sup>. Furthermore, MCV tended to be associated with pT status ( $P = 0.051$ ), consistent with findings showing that preoperative MCV may provide a complementary advantage in assessing tumor invasiveness<sup>[17]</sup>.

Although TNM stage is the best predictor of survival in cancer patients, OS may differ widely in patients with the same TNM stage tumors who receive the same treatment, suggesting that other, as yet undetermined factors may affect prognosis. Since preoperative hematologic parameters have been predictive of patient prognosis<sup>[15,22-25]</sup>, we performed univariate and multivariate analyses of

Low: Low preoperative mean corpuscular volume ( $\leq 95.6$  fl); High: High preoperative mean corpuscular volume ( $> 95.6$  fl).

factors predictive of OS in patients with ESCC. We found that pathological stage, tumor location, preoperative albumin concentration, and preoperative MCV were prognostic factors in our patient cohort.

We also found that OS was significantly shorter in patients with upper-thoracic cancer than those with middle and lower-thoracic esophageal cancer. A study of 605 patients with ESCC also found that median OS was significantly shorter in patients with upper thoracic cancer than in those with middle and lower thoracic tumors (45.9 mo *vs* 82.2 and 93.8 mo;  $P < 0.001$ )<sup>[26]</sup>. Due to their anatomical location, carcinomas of the upper thoracic esophagus often result in early invasion of adjacent structures and extensive lymph node metastasis<sup>[27]</sup>. The prognostic significance of preoperative albumin concentration may be due to it being a sensitive indicator of nutrition, liver function, and metabolic response to disease; thus patients with lower albumin concentrations may present with poorer physical status, decreasing both their response and tolerance to treatment<sup>[28,29]</sup>. Similar findings were reported in patients with adenocarcinoma of the gastric cardia<sup>[30]</sup>.

Although we found that preoperative MCV was prognostic in patients with ESCC, there is no evidence that MCV has a direct effect on tumor progression or patient prognosis. MCV, however, is a marker of internal folate concentration. Folate acts to transfer one-carbon moieties, thus playing a central role in DNA synthesis, replication, repair, and methylation<sup>[31]</sup>. Folate deficiency leads to aberrant DNA methylation, which has been reported to be a predictor of clinical outcome in patients with esophageal cancer<sup>[32]</sup>. A recent study of 125 ESCC patients who underwent surgical resection showed that median OS was significantly longer in patients with high than with low/moderate folate intake (4.59 years *vs* 3.06 years;  $P = 0.007$ )<sup>[33]</sup>. Similar results were reported in patients with advanced gastric cancer who were treated with chemotherapy<sup>[34]</sup>.

Another factor linking MCV with prognosis in ESCC is macrocytosis, which may be an indicator of malnutrition, a negative prognostic factor in various human cancers<sup>[21,35,36]</sup>. In addition, crystal osmotic pressure was shown to be a major regulator of red cell volume in internal environments<sup>[37]</sup>. Dysphagia, a frequently observed symptom in patients with advanced esophageal cancer,

restricts intake, thus reducing serum concentrations of electrolytes, glucose, and amino acids. This, in turn, may decrease crystal osmotic pressure, leading to red cell dilation. Our finding, that preoperative MCV was related to pT stage and BMI, was consistent with results suggesting that increased MCV was associated with tumor invasiveness and nutritional status<sup>[3,17]</sup>. Thus, taken together, these results suggest that preoperative MCV may be a marker reflecting internal folate concentration, nutritional status, and tumor invasiveness, thus comprehensively predicting prognosis in patients with ESCC. MCV assays are also convenient and inexpensive to perform, allowing for wide clinical application and suggesting that they may be crucial in preoperative assessment.

To further evaluate the prognostic significance of preoperative MCV, we performed subgroup analysis in patients with ESCC. We found that MCV resulted in the stratification of OS in patients with T3, N1-N3, G2-G3, and stage III tumors, but not in patients with T1-T2, N0, G1, or stage I / II tumors. These findings, however, may be due to the small sample size of these subgroups. Moreover, the relatively good prognosis in patients with T1/2, N0, G1, and stage I / II tumors may mask the significance of preoperative MCV.

This study has limitations and potential biases. Due to its retrospective nature, records of alcohol consumption by patients were incomplete and folic acid concentrations were not tested in most patients. Furthermore, we could not determine whether preoperative MCV was a better predictor of OS than conventional prognostic factors. Finally, our small sample size may reflect a selection bias to some extent.

In conclusion, in patients with resectable ESCC, OS was significantly longer in patients with low ( $\leq 95.6$  fl) than high ( $> 95.6$  fl) preoperative MCV. Additional studies, however, are required to validate our results.

## COMMENTS

### Background

Surgical resection remains the treatment of choice for patients with localized esophageal carcinoma. Routine preoperative blood tests of red blood cells, white blood cells, and platelet counts can help estimate surgical risk. Significant hematologic variations frequently observed in patients with advanced malignant diseases may predict prognosis.

### Research frontiers

Elevated mean corpuscular volume (MCV) has long been recognized as a biomarker for alcohol abuse and folate deficiency. In addition, MCV was reported to be higher in Asian heavy drinkers with inactive aldehyde dehydrogenase-2 (ALDH2), and was found to be a marker of alcohol abuse in individuals with inactive heterozygous ALDH2, suggesting that acetaldehyde may be an important contributor to macrocytosis. A recent study showed that macrocytosis was a risk factor for esophageal carcinoma.

### Innovations and breakthroughs

The authors observed a correlation between macrocytosis and prognosis in patients with esophageal carcinoma. Overall survival was significantly shorter in patients with elevated MCV than those with lower MCV. Utilizing receiver operating characteristic curve analysis, the authors determined an optimal cut-off point for MCV, which was both reasonable and objective.

### Applications

These results suggest that preoperative MCV may be used to predict prognosis in patients with esophageal cancer. Routine blood tests should be performed

shortly before surgery in these patients, and those with elevated MCV, especially greater than 95.6 fl, should be carefully evaluated to assess the risks and feasibility of surgery.

### Terminology

MCV, representing the mean volume of a single red blood cell, is determined by indirect calculation. Clinically, this parameter is often used in the differential diagnosis of various type of anemia.

### Peer review

This is an article on an unusual topic. The value of MCV has been known up to now as risk factor for esophageal carcinoma, but it is not known as prognostic factor.

### Abstract

**AIM:** To assess CD163 expression in plasma and peripheral blood and analyze its association with disease in acute-on-chronic hepatitis B liver failure (ACHBLF) patients.

**METHODS:** A retrospective study was conducted from January 1, 2011 to January 1, 2012. Forty patients with ACHBLF (mean age  $44.48 \pm 12.28$  years, range 18-69 years), 40 patients with chronic hepatitis B (CHB) (mean age  $39.45 \pm 12.22$  years, range 21-57 years) and 20 age- and sex-matched healthy controls (mean age  $38.35 \pm 11.97$  years, range 28-60 years) were included in this study. Flow cytometry was used to analyze the frequency of CD163+ peripheral blood mononuclear cells (PBMCs) and surface protein expression of CD163. Real-time transcription-polymerase chain re-

action was performed to assess relative CD163 mRNA levels in PBMCs. Plasma soluble CD163 (sCD163) levels were measured by enzyme-linked immunosorbent assay. Clinical variables were also recorded. Comparisons between groups were analyzed by Kruskal-Wallis *H* test and Mann-Whitney *U* test. Statistical analyses were performed using SPSS 15.0 software and a *P* value < 0.05 was considered statistically significant.

**RESULTS:** Flow cytometry showed that the population of CD163+ PBMCs was significantly greater in ACHBLF patients than in CHB patients and healthy controls ( $47.9645\% \pm 17.1542\%$ ,  $32.0975\% \pm 11.0215\%$  vs  $17.9460\% \pm 6.3618\%$ ,  $P < 0.0001$ ). However, there were no significant differences in mean fluorescence intensity of CD163+ PBMCs within the three groups ( $27.4975 \pm 11.3731$ ,  $25.8140 \pm 10.0649$  vs  $20.5050 \pm 6.2437$ ,  $P = 0.0514$ ). CD163 mRNA expression in ACHBLF patients was significantly increased compared with CHB patients and healthy controls ( $1.41 \times 10^{-2} \pm 2.18 \times 10^{-2}$ ,  $5.10 \times 10^{-3} \pm 3.61 \times 10^{-3}$  vs  $37.0 \times 10^{-4} \pm 3.55 \times 10^{-4}$ ,  $P = 0.02$ ). Plasma sCD163 levels in patients with ACHBLF were significantly increased compared with CHB patients and healthy controls ( $4706.2175 \pm 1681.1096$  ng/mL,  $1089.7160 \pm 736.8395$  ng/mL vs  $435.9562 \pm 440.8329$  ng/mL,  $P < 0.0001$ ). In ACHBLF patients, plasma sCD163 levels were significantly positively associated with model for end-stage liver disease scores ( $r = 0.5075$ ,  $P = 0.008$ ), hepatitis B virus-DNA ( $r = 0.6827$ ,  $P < 0.0001$ ), and negatively associated with prothrombin activity ( $r = -0.3348$ ,  $P = 0.0347$ ), but had no correlation with total bilirubin ( $r = 0.2551$ ,  $P = 0.1122$ ). Furthermore, sCD163 was obviously elevated in non-surviving patients compared with surviving patients with ACHBLF ( $5344.9080 \pm 1589.5199$  ng/mL vs  $3641.7333 \pm 1264.5228$  ng/mL,  $P = 0.0321$ ).

**CONCLUSION:** CD163 and sCD163 may be related to disease severity and prognosis in ACHBLF patients.

**Key words:** Acute-on-chronic hepatitis B liver failure; Model for end-stage liver disease; CD163; Soluble CD163; Real-time transcription-polymerase chain reaction

**Core tip:** This study included three groups, acute-on-chronic hepatitis B liver failure (ACHBLF) patients, chronic hepatitis B (CHB) patients and healthy controls. Flow cytometry was used to analyze the frequency of CD163+ peripheral blood mononuclear cells (PBMCs) and surface protein expression of CD163. Real-time transcription-polymerase chain reaction was performed to assess relative CD163 mRNA levels in PBMCs. The population of CD163+ PBMCs was significantly larger in ACHBLF patients than in CHB patients and healthy controls. CD163 mRNA expression in ACHBLF patients was significantly increased compared with healthy controls. Plasma soluble CD163 (sCD163) levels were markedly increased and correlated with disease severity and prognosis in ACHBLF patients. CD163 and sCD163 may be useful biomarkers for ACHBLF.

## INTRODUCTION

Hepatitis B virus (HBV) infection is a major health problem worldwide. It is thought to be one of the main causes of liver-related chronic and acute diseases<sup>[1]</sup>. With severe acute exacerbation of the disease, some chronic hepatitis B (CHB) patients may progress to liver failure. We define this progression as acute-on-chronic hepatitis B liver failure (ACHBLF), and constitutes about 70% of all acute-on-chronic liver failure in areas with a high incidence of hepatitis B<sup>[2]</sup>. ACHBLF has an extremely poor prognosis due to a lack of understanding of its pathogenesis. Currently, clinical observations have shown that ACHBLF may be related to strong immune responses. Therefore, it is important to fully understand the course of the immune pathogenesis of ACHBLF. If we can identify efficient markers which predict disease progression, this may be of great help in the treatment of ACHBLF<sup>[3]</sup>.

Innate immune cells such as macrophages can be activated by acute and chronic inflammation and produce various cytokines. These immunological cytokines induce and cause liver tissue injury. Activated macrophages play important roles in the production of these immune cytokines. Monocytes and macrophages can be activated into M1 and M2 subpopulations in response to different environmental signals which are mainly derived from inflammatory diseases. Those of the M2 subpopulation inhibit the inflammatory state<sup>[4-6]</sup>.

CD163 is a member of a scavenger receptor family and is expressed mainly on activated macrophages.

It is a specific M2 macrophage marker. Soluble CD163 (sCD163) emerges from the shedding of CD163 from the cell surface in the plasma<sup>[6-9]</sup>. It is now evident that sCD163 and CD163 are very useful as biomarkers of macrophage activation in various inflammatory diseases. It is strongly indicated that CD163 and sCD163 may be involved in the pathogenesis of liver failure. However, the exact expression of CD163 and sCD163 in ACHBLF patients has not been fully elucidated<sup>[10,11]</sup>.

This study aimed to evaluate peripheral blood CD163 and plasma sCD163 expression in macrophages from patients with ACHBLF.

## MATERIALS AND METHODS

### Patients

Forty patients with ACHBLF, 40 patients with CHB and 20 healthy controls from Qilu Hospital of Shandong University, were included in this retrospectively study.

Blood samples collected from January 2011 to January 2012 at the Department of Hepatology, Qilu Hospital of Shandong University, were separated into plasma and stored at -70 °C until use.

Patients with CHB had more than twice the normal alanine aminotransferase level. All groups were matched for sex and age. ACHBLF patients had a history of CHB, with plasma total bilirubin (TBIL)  $\geq 85$   $\mu\text{mol/L}$ , prothrombin activity (PTA)  $< 40\%$ , and complications such as hepatic encephalopathy (no less than grade II), ascites or hepato-renal syndrome. According to the Asian Pacific Association for the Study of the Liver guideline, all ACHBLF patients received inpatient treatment. We excluded patients who underwent liver transplantation, had hepatocellular carcinoma or other metastatic liver tumors or who had received immunotherapy or anti-viral treatment within 6 mo. Patients with a history of alcohol abuse, intravenous drug abuse, pregnancy, concomitant chronic hepatitis C, human immune deficiency virus infection or autoimmune hepatitis were also excluded. Hepatitis B surface antigen in healthy controls ( $n = 20$ ) (age-, sex- and race-matched) was negative. Experiments and procedures were conducted with the guidance of the Helsinki Declaration of 1975<sup>[12]</sup>. The study was approved by the local Ethical Committee of Qilu Hospital of Shandong University. Prior to the collection of blood, informed consent was obtained from each patient. The characteristics of the enrolled subjects are summarized in Table 1.

### RNA extraction and real-time reverse-transcriptase polymerase chain reaction

Six milliliters of peripheral venous blood were collected from each subject and Ficoll-Paque Plus (GE Healthcare, Uppsala, Sweden) was used for isolation of PBMCs. Total RNA in PBMCs was extracted using Trizol (Invitrogen, Carlsbad, CA, United States) according to the manufacturer's instructions. Two micrograms of total RNA were converted into cDNAs using the RevertAid™ First

**Table 1** Baseline characteristics of the subjects enrolled in the present study

| Patients                             | ACHBLF          | CHB           | Healthy control |
|--------------------------------------|-----------------|---------------|-----------------|
| Cases                                | 40              | 40            | 20              |

ACHBLF: Acute-on-chronic hepatitis B liver failure; CHB: Chronic hepatitis B; HBeAg: Hepatitis B e antigen; PTA: Prothrombin activity; TBIL: Total bilirubin; HBV: Hepatitis B virus; NA: Not available.

Strand cDNA Synthesis Kit (Fermentas, Lithuania) and real-time polymerase chain reaction (RT-PCR) was carried out on a Lightcycler (Roche Diagnostics, Germany). RT-PCR amplification mixtures (20 μL) contained 75 ng template cDNA, 10 μL 2 9 SYBR<sup>®</sup> Premix Ex Taq<sup>™</sup> (Takara, Japan) and 200 nmol/L forward and reverse primer. The real-time PCR reaction was performed as follows: the initial step was 95 °C for 30 s, followed by 40 cycles at 95 °C for 5 s, 60 °C for 30 s and 72 °C for 30 s. β-actin was used as the endogenous control for the normalization of RNA quantity and quality differences in all samples.

The primers were as follows: CD163 forward 5'-TCTGGCTTGACAGCGTTTC-3'; CD163 reverse 5'-TGTGTTTGTTCCTGGATT-3'; β-actin forward 5'-CGGGAAATCGTGCGTGACATT-3'; β-actin reverse 5'-GGAGTTGAAGGTAGTTTCGTGG-3' (Fermentas, Lithuania). Gene specific amplifications were demonstrated with melting curve data and gel-migration analyses.

### Flow cytometric analysis

Freshly drawn peripheral whole blood samples of 200 μL were stained with isotype-matched control antibody or a relevant antibody (CD14, CD163) for 30 min at room temperature in the dark. Anti-human CD163 PE, anti-human CD14 APC and isotype-matched control antibody were purchased from eBioscience (San Diego, CA, United States). Following incubation, erythrocytes were lysed with RBC lysis buffer (Whole Blood Lysing Kit, R and D Systems, United States). Finally, the cells were washed three times, resuspended in 500 μL of PBS containing 0.5% formaldehyde, and analyzed using a FACS Calibur (BD Bioscience, PharMingen). The samples were analyzed with a Becton-Dickinson FACS Calibur machine. Separate gates were established for the macrophages. The amount of CD163 in peripheral blood was assessed using flow cytometry (Coulter counter)<sup>[13-15]</sup> (Figure 1).

### Determination of plasma levels of sCD163

SCD163 was determined by enzyme-linked immunosorbent assay (ELISA) according to the manufacturer's instructions (R and D, Minneapolis, MN, United States). All

samples were analyzed in duplicate following the manufacturer's protocol. The sensitivity of the assay was 0.1 ng/mL, and the intra-assay and inter-assay coefficients of variation were less than 3% and 6%, respectively.

### Clinical and laboratory parameters

Measurement of liver function tests: TBIL and hematological tests including PTA were performed using standard methods in a clinical setting. Hepatitis B markers were tested using a commercially available radioimmunoassay (Abbott). The level of HBV DNA was quantified using a DNA assay (sensitivity > 500 copies/mL). Model for end-stage liver disease (MELD) scores were calculated according to the Malinchoc formula:  $r = 9.57 \times \log_e [\text{creatinine (mg/dL)}] + 3.78 \times \log_e [\text{bilirubin (mg/dL)}] + 11.2 \times \log_e (\text{INR}) + 6.43 \times (\text{etiology: } 0 \text{ if cholestatic or alcoholic, } 1 \text{ otherwise})$ <sup>[16,17]</sup>.

### Statistical analysis

Statistical analysis were performed using SPSS 15.0 software (SPSS Inc., Chicago, IL, United States). Comparisons between groups were analyzed by Kruskal-Wallis *H* test and Mann-Whitney *U* test. The Spearman rank correlation test was used for correlation analysis. All statistical analysis were two-sided, and a *P* value < 0.05 was considered statistically significant.

## RESULTS

### Frequency of circulating CD163+ PBMCs and mean fluorescence intensity

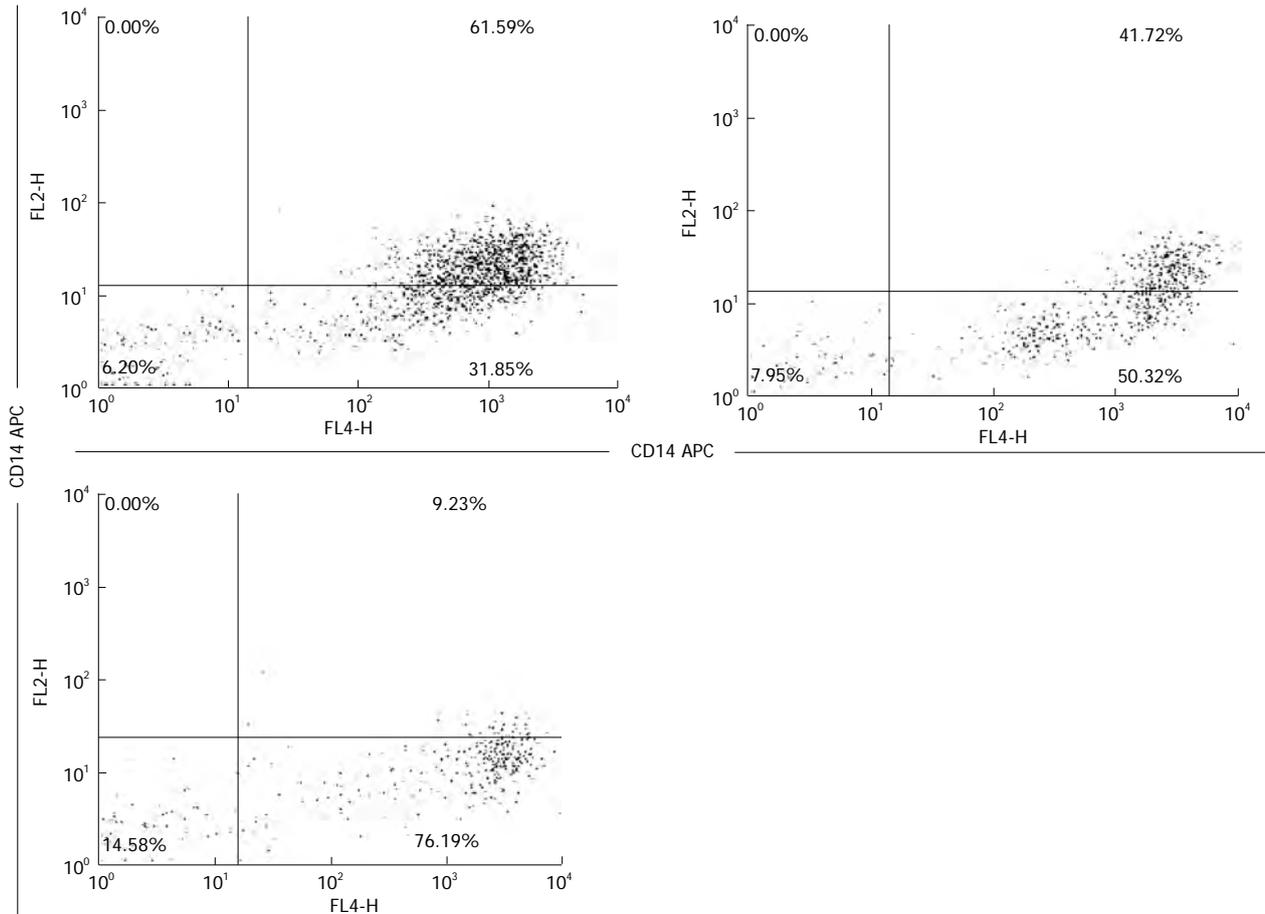

We determined the frequency of CD163+ PBMCs using flow cytometry and found that in ACHBLF patients, the frequency was markedly higher than that in the healthy control group and CHB patients, respectively (Figure 2A). There was a significant difference in the frequency of CD163+ PBMCs within the three groups (47.9645% ± 17.1542%, 32.0975% ± 11.0215% *vs* 17.9460% ± 6.3618%, *P* < 0.0001). We also evaluated the average mean fluorescence intensity (MFI) of CD163+ PBMCs using flow cytometric analysis. However, there were no significant differences in MFI in CD163 + PBMCs within the three groups (27.4975 ± 11.3731, 25.8140 ± 10.0649 *vs* 20.5050 ± 6.2437, *P* = 0.0514) (Figure 2B).

### Plasma levels of sCD163 in ACHBLF patients

We evaluated the plasma levels of sCD163 by ELISA. The results showed that the levels of sCD163 in ACHBLF patients were markedly higher than those in CHB patients and the healthy control group. Significant differences in plasma sCD163 were found within ACHBLF patients, CHB patients and healthy controls (4706.2175 ± 1681.1096 ng/mL, 1089.7160 ± 736.8395 ng/mL *vs* 435.9562 ± 440.8329 ng/mL, *P* < 0.0001) (Figure 2C).

### Increased mRNA expression of CD163 in PBMCs from ACHBLF patients

We also determined the mRNA level of CD163 in PBMCs

**Figure 1** Percentage of CD163+ peripheral blood mononuclear cells. The representative results of CD163+ peripheral blood mononuclear cells are shown. ACH-BLF: Acute-on-chronic hepatitis B liver failure; CHB: Chronic hepatitis B.

using RT-PCR. No significant differences in the mRNA level of CD163 were found within the three groups ( $1.41 \times 10^{-2} \pm 2.18 \times 10^{-2}$ ,  $5.10 \times 10^{-3} \pm 3.61 \times 10^{-3}$  vs  $37.0 \times 10^{-4} \pm 3.55 \times 10^{-4}$ ,  $P = 0.02$ ). The mRNA levels of CD163 in ACHBLF patients and CHB patients were significantly higher than those in healthy controls. No significant difference in the mRNA level of CD163 was observed in ACH-BLF and CHB patients ( $P > 0.05$ ) (Figure 2D).

#### **Increased plasma sCD163 levels in patients with ACHBLF**

To determine whether the increase in plasma levels of sCD163 correlated with liver injury, we analyzed the plasma levels of sCD163 in ACHBLF patients with clinical and laboratory parameters which indicated liver function or DNA replication in ACHBLF. The results showed that plasma levels of sCD163 were positively correlated with MELD score ( $r = 0.5075$ ,  $P = 0.008$ ), plasma HBV-DNA levels ( $r = 0.6827$ ,  $P < 0.0001$ ) and negatively correlated with PTA ( $r = -0.3348$ ,  $P = 0.0347$ ), but had no correlation with TBIL ( $r = 0.2551$ ,  $P = 0.1122$ ) (Figure 3A-D).

#### **Plasma levels of sCD163 influence disease progression in ACHBLF patients**

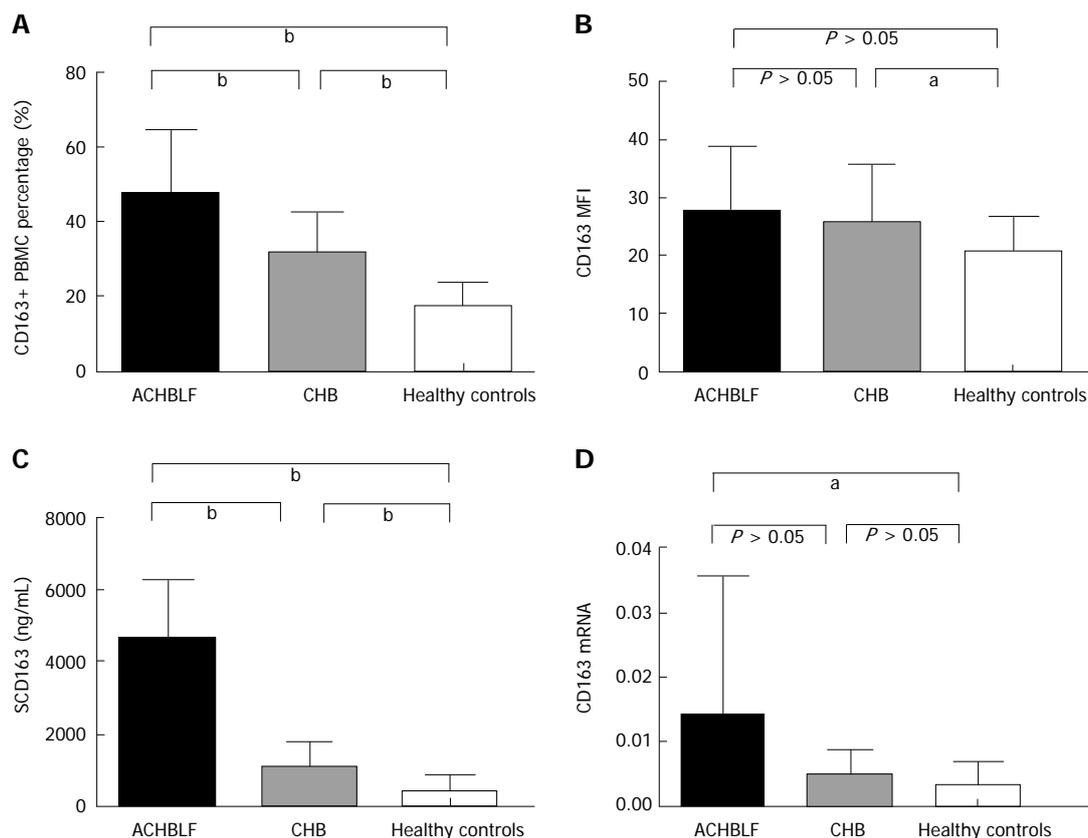

ACHBLF patients were grouped into survivors and non-

survivors after 3 mo of follow up. The plasma levels of sCD163 were increased in non-survivors compared with survivors ( $5344.9080 \pm 1589.5199$  ng/mL vs  $3641.7333 \pm 1264.5228$  ng/mL,  $P = 0.0321$ ) (Figure 3E).

## **DISCUSSION**

Although sCD163 is thought to play an important role in the pathogenesis of liver failure, this is the first study on the frequency of CD163+ PBMCs and CD163 mRNA level in ACHBLF patients<sup>[18,19]</sup>. Increased plasma sCD163 levels were correlated with disease severity in ACHBLF patients. These results strongly suggest that the role of CD163 in the immune response might affect the prognosis of ACHBLF.

CD163 is a scavenger receptor, and its expression has been proved to be associated with inhibition of inflammation. Furthermore, during the innate immune response, CD163 plays an important role in the host defense against inflammation<sup>[5,20,21]</sup>. The soluble form of CD163 is also a biomarker associated with inflammation<sup>[18]</sup>. In the present study, we first found that the frequency of CD163+ PBMCs and CD163 mRNA expression in PBMCs were dramatically increased in ACHBLF patients compared with healthy controls. These results could be interpreted together with previous reports to suggest that CD163 might

**Figure 2** Acute-on-chronic hepatitis B liver failure ( $n = 40$ ), chronic hepatitis B ( $n = 40$ ) and healthy controls ( $n = 20$ ). A: The frequency of CD163+ peripheral blood mononuclear cells (PBMCs) in acute-on-chronic hepatitis B liver failure (ACHBLF) patients was significantly higher than that in chronic hepatitis B (CHB) patients and healthy controls ( $P < 0.01$ ); B: There were no significant differences in mean fluorescence intensity (MFI) of CD163+ PBMCs within the three groups ( $P > 0.05$ ); C: The plasma levels of soluble CD163 (sCD163) in ACHBLF patients were significantly higher than those in CHB patients and healthy controls ( $P < 0.01$ ); D: The mRNA levels of CD163 in ACHBLF patients and CHB patients were significantly higher than those in healthy controls ( $P < 0.01$ ). Significant differences were calculated using the Kruskal-Wallis  $H$  test and Mann-Whitney  $U$  test ( $^aP < 0.05$ ,  $^bP < 0.01$  between the two groups).

have a key position in the immunolesion of ACHBLF.

There were no significant differences in MFI of CD163+ PBMCs within the three groups. This result is very interesting. From previous literature, which mainly included randomly selected patients, CD163 was inversely correlated with sCD163 plasma levels<sup>[22]</sup>. Lipopolysaccharide and other pro-inflammatory cytokines induce shedding of CD163 from the surface of isolated monocytes. During infection, the expression of monocyte surface CD163 decreases. In contrast, some studies have shown that with chronic and acute inflammation, the expression of surface CD163 increased. Through CD163 shedding, decreased surface CD163 was followed by recovery and induction of surface CD163 to higher levels<sup>[23-25]</sup>. We speculate that surface CD163 expression might vary according to different inflammatory states in patients and different stages of inflammation. More research is needed to confirm this.

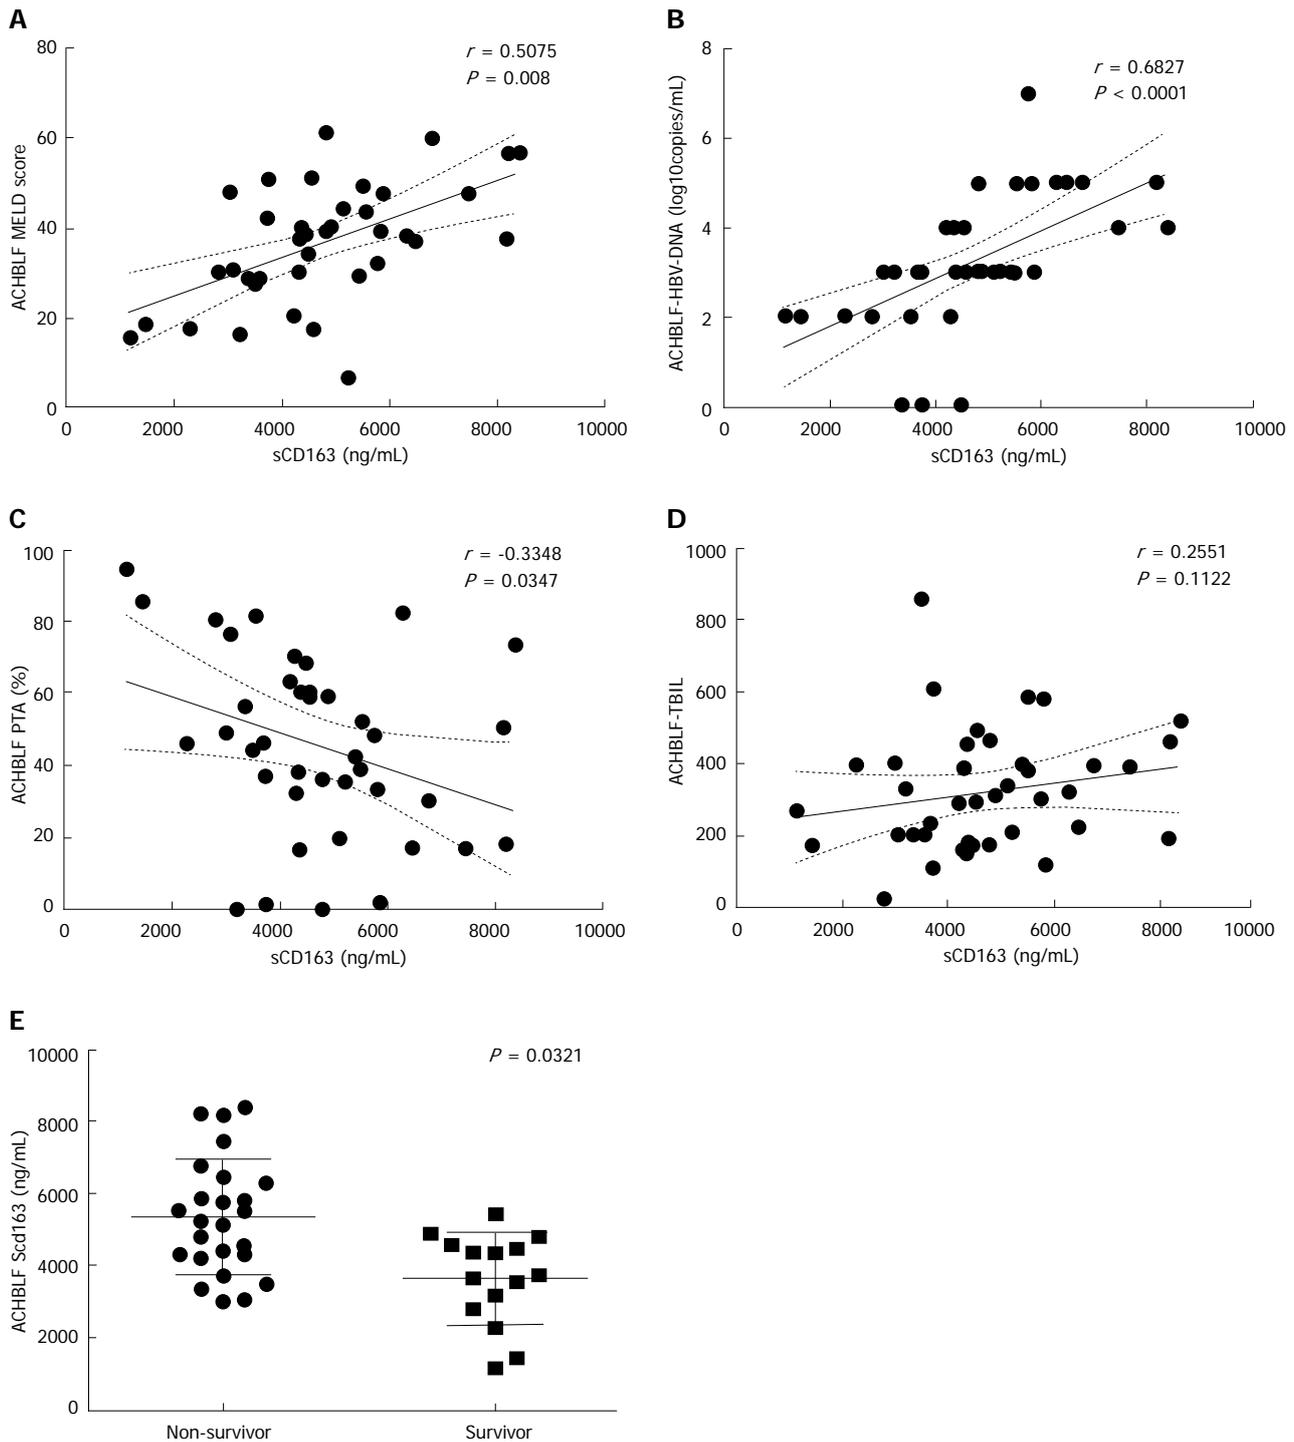

In this study, we observed that peripheral mRNA levels of CD163 in ACHBLF patients were high and there was a significant difference between the three groups, however, mRNA levels of CD163 in ACHBLF patients were not significantly different to those in CHB patients. During inflammation, we speculate that plasma sCD163

levels might increase dramatically, but mRNA levels increase slowly<sup>[26-28]</sup>.

In the present study, we found that plasma sCD163 levels were significantly increased in patients with ACHBLF compared to CHB patients and healthy controls. Plasma sCD163 levels were positively associated with HBV DNA levels, MELD scores and were negatively correlated with PTA. In addition, there were no associations with TBIL. It was demonstrated that plasma sCD163 correlated with the severity of ACHBLF<sup>[29-31]</sup>.

The MELD scoring system is widely accepted and is used to predict prognosis in patients with liver failure. We chose the MELD scoring system to evaluate the prognosis of ACHBLF patients over a three month period. The results strongly indicated the potential role of plasma sCD163 levels in forecasting the prognosis of ACHBLF patients. Furthermore, plasma sCD163 levels were obviously elevated in ACHBLF patients who did not survive compared with surviving ACHBLF patients<sup>[16,17]</sup>.

We found significant associations between plasma sCD163 levels and HBV DNA in ACHBLF patients. These results indicate that HBV may contribute to the aggravated macrophage immune response besides activation of HBV<sup>[32,33]</sup>. HBV might play a key role in promot-

**Figure 3** Linear correlation of plasma CD163 levels with disease severity markers in acute-on-chronic hepatitis B liver failure patients. A-C: Plasma CD163 was positively correlated with model of end stage liver disease (MELD) score, hepatitis B virus (HBV)-DNA and negatively correlated with prothrombin activity (PTA); D: There was no correlation between plasma CD163 levels and total bilirubin (TBIL); E: In acute-on-chronic hepatitis B liver failure (ACHBLF) patients, non-survivors had elevated plasma CD163 levels compared with survivors.

ing disease progression during host immune responses caused by the infection in ACHBLF patients. The exact role of HBV in CD163 immune response requires further clarification<sup>[34-36]</sup>.

The present study has limitations, and it would be very interesting to determine the dynamic and histologic expression of CD163 in a future study.

In conclusion, our study demonstrated three major findings. First, the population of CD163+ PBMCs was significantly greater in ACHBLF patients than in CHB patients and healthy controls. Second, CD163 mRNA expression in ACHBLF patients was significantly increased compared with CHB patients and healthy controls. Third, plasma sCD163 levels were markedly increased and cor-

related with disease severity and prognosis in ACHBLF patients. Our findings indicate that CD163 and sCD163 may serve as useful biomarkers and new therapeutic targets for ACHBLF.

## COMMENTS

### Background

Acute-on-chronic hepatitis B liver failure (ACHBLF) constitutes about 70% of all acute-on-chronic liver failure (ACLF) in areas with a high incidence of hepatitis B. ACHBLF has an extremely poor prognosis due to a lack of understanding of its pathogenesis.

### Research frontiers

ACHBLF has an extremely poor prognosis due to a lack of understanding of its pathogenesis. It is important to fully understand the course of the immune pathogenesis of ACHBLF. It may be very helpful to identify a new biomarker which indicates the prognosis of ACHBLF.

### Innovations and breakthroughs

This is the first study on the frequency of CD163+ peripheral blood mononuclear cells and CD163 mRNA level in ACHBLF patients. Authors found that increased plasma soluble CD163 (sCD163) levels were correlated with disease severity in ACHBLF patients. These findings strongly suggest that the role of CD163 and sCD163 in the immune response might affect the prognosis of ACHBLF.

### Applications

Their findings indicate that CD163 and sCD163 may serve as useful biomarkers and new therapeutic targets for ACHBLF. These biomarkers should be determined as early as possible in ACHBLF patients.

### Terminology

ACLF was first used in 1995 to describe a rapid deterioration of liver function due to acute insult to the liver in patients with ongoing or chronic liver disease. Diagnosis of ACLF may be based on the following: acute hepatic insult manifesting as jaundice (serum bilirubin  $\geq 85$   $\mu\text{mol/L}$  and coagulopathy international normalized ratio  $> 1.5$  or prothrombin activity  $< 40\%$ ) complicated within 4 wk by ascites and/or encephalopathy in a patient with previously diagnosed or undiagnosed chronic liver disease. ACHBLF is ACLF with acute or chronic hepatitis B.

### Peer review

Overall, this paper is of a very good quality. Study design is appropriate and clear, and helps to answer a clinical relevant question. Data analysis is sufficient. Manuscript is well structured, language is of sufficient quality.

### Abstract

Right portal vein ligation (PVL) is a safe and widespread procedure to induce contralateral liver hypertrophy for the treatment of bilobar colorectal liver metastases. We report a case of a 60-year-old man treated by both right PVL and ligation of the glissonian branches of segment 4 for colorectal liver metastases surrounding the right and median hepatic veins. After surgery, the patient developed massive hepatic necrosis with secondary pulmonary and renal insufficiency requiring transfer to the intensive care unit. This so-called toxic liver syndrome finally regressed after hemofiltration and positive oxygen therapy. Diagnosis of acute congestion of the ligated lobe was suspected. The mechanism suspected was an increase in arterial inflow secondary to portal vein

ligation concomitant with a decrease in venous outflow due to liver metastases encircling the right and median hepatic vein. This is the first documented case of toxic liver syndrome in a non-cirrhotic patient with favorable issue, and a rare complication of PVL.

Massive hepatic necrosis with toxic liver syndrome following portal vein ligation. *World J Gastroenterol* 2013; 19(18): 2826-2829 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i18/2826.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i18.2826>

### INTRODUCTION

Portal vein embolization (PVE) was first used by Makuuchi *et al*<sup>[1]</sup> to induce liver hypertrophy before major hepatectomy in biliary cancers. The technique was then applied to hepatocellular carcinoma and colorectal liver metastases (CRLM) to decrease postoperative morbidity and mortality<sup>[2,3]</sup>. PVL and portal vein embolization (PVE) are generally safe with few side effects in non-cirrhotic patients<sup>[4]</sup>. Suppression of the right portal flow causes atrophy of the right lobe, and induces the production of various growth factors and proinflammatory cytokines that prepare hepatocytes for growth (for review, see<sup>[5]</sup>). Whereas arterial ischemia can induce massive liver necrosis, the suppression of portal flow leads to progressive apoptosis with minor consequences for liver function<sup>[6]</sup>, owing mainly to a compensatory increase in arterial blood flow in the deprived lobe, a phenomenon called “hepatic arterial buffer response (HABR)”<sup>[7]</sup>. Here we report a case of massive hepatic necrosis of both the right lobe

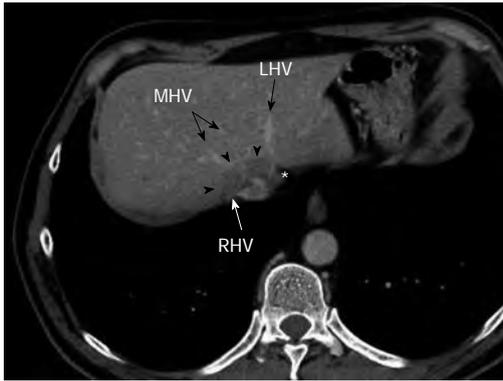

Figure 1 Preoperative multidetector computed tomograph at portal venous phase showing a large metastasis (arrowheads) encircling the confluence of the right hepatic vein and middle hepatic vein, without any thrombosis, and displacing the end of the left hepatic vein (asterisk). RHV: Right hepatic vein; MHV: Middle hepatic vein; LHV: Left hepatic vein.

and segment 4 after PVL in a patient treated for CRLM, with secondary cardiac, pulmonary and renal insufficiency due to toxic liver syndrome.

## CASE REPORT

A 60-year-old man was referred to our tertiary center for treatment of metachronous bilobar colorectal liver metastases. He had no medical history. Two years before he had undergone right colectomy for stage II colon cancer with no adjuvant anticancer therapy. During oncologic follow-up, three CRLM were detected by multidetector computed tomography scan: two in the right lobe, and one large one encircling the right and middle hepatic veins and displacing the left hepatic vein (Figure 1). Neoadjuvant chemotherapy (six courses of FOLFOX with cetuximab) was administered, with control imaging showing objective response according to RECIST criteria<sup>[8]</sup>. Radical resection required right hepatectomy enlarged to segment 4 (right trisectionectomy according to the Brisbane terminology<sup>[9]</sup>). To improve left lobe hypertrophy, we decided to perform a two-stage surgical procedure: first, right PVL with ligation of the glissonian branches of segment 4, and assessment of resectability using intraoperative liver ultrasonography (US) followed by right trisectionectomy. At first stage laparotomy, the liver was normal with no sign of chemotherapy-related injury. CRLM were confined to the right lobe and did not involve the left hepatic vein. A right PVL was performed with ligation of the glissonian branches of segment 4.

The immediate postoperative course was marked by a massive peak of transaminase and moderate liver insufficiency (Figure 2). The patient developed pulmonary and renal insufficiency with oligoanuria necessitating transfer to the intensive care unit (ICU) for non-invasive positive pressure ventilation and hemofiltration. US of the hepatic pedicle did not show any vascular thrombosis. Multidetector computed tomography (MD-CT) performed at postoperative day (POD) 2 showed massive hepatic necrosis of segment 4 and of a large part of the right hemi-

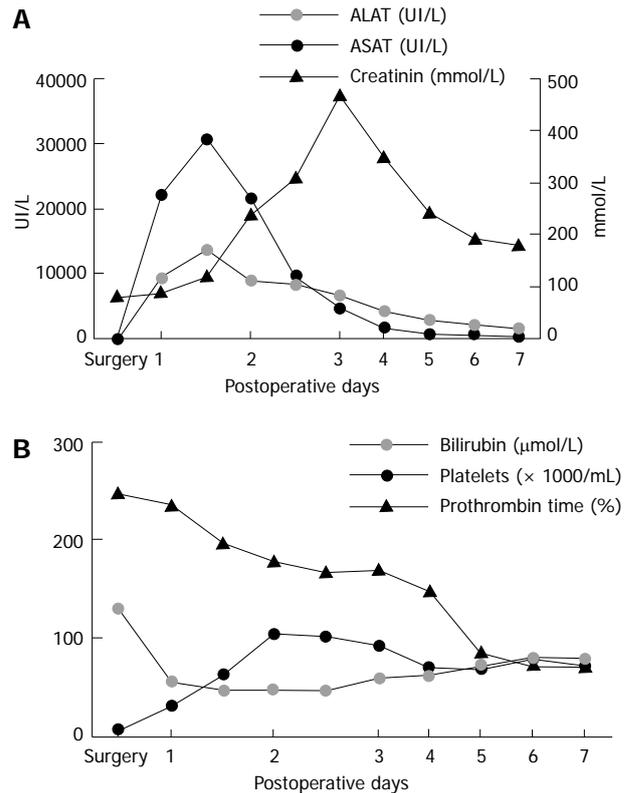

Figure 2 Postoperative blood tests. A: Transaminases increased from postoperative day 1, reached a peak at postoperative day 3, then returned to normal value on postoperative day 7. Serum creatinin started to increase after the peak of transaminases, as observed in the toxic liver syndrome, and decreased after hemofiltration; B: Platelets decreased regularly as from the first postoperative day. Total bilirubin increased from the first postoperative day and reached a plateau around 100 μmol/L. Prothrombin time fell rapidly to 47% at postoperative day 1 and thereafter increased progressively. ASAT: Aspartate amino transferase; ALAT: Alanine amino transferase.

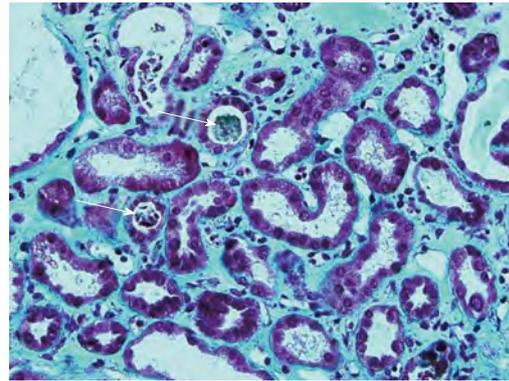

liver, hypertrophy of the left lobe and ascites (Figure 3). Renal biopsy revealed acute tubular necrosis without any particularity (Figure 4). Liver biopsy was not performed because of relative liver insufficiency and ascites. The level of transaminases started to decrease progressively from POD 2, and hemofiltration was stopped after recovery of renal function at POD 12. Finally, the patient was discharged from ICU at POD 15. A liver abscess developed in segment 8 near the necrotic area. Percutaneous drainage showed infected collection without biliary leak, with favorable outcome after appropriate antibiotic treatment. The patient was discharged from hospital after 52 d.

## DISCUSSION

Portal vein occlusion by ligation or embolization is a safe procedure widely used to induce liver hypertrophy of the future remnant liver before major liver resection. The mortality of this procedure is these procedures nil and major morbidity is about 1%<sup>[6]</sup>. In the event of post-procedure symptoms, which occur in more than 50% of patients, transaminase levels peak at a level less than three times baseline 1 to 3 d after embolization and return to baseline in 7-10 d<sup>[10]</sup>. Fever and post-embolization syn-

**Figure 3** Postoperative day 2 non-enhanced multidetector computed tomograph scan. Massive hepatic necrosis of the medial segment of the left lobe (segment 4, white arrowhead) and of a large part of the right lobe (black arrowhead) are shown, with remarkable hypertrophy of the lateral segments of the left lobe (red zone). Note also ascites (asterisk).

**Figure 4** Renal biopsy showing acute tubular necrosis: Tubules dilated with sometimes a low-lying epithelium and pleomorphic nuclei. The brush border of the proximal tubular cells is missing. The lumen of some tubules contains rare tubular cell necrosis (white arrows). There is a diffuse interstitial edema (Masson's trichrome,  $\times 40$ ).

drome, which are frequently observed after trans-arterial chemoembolization, are rare in PVE or PVL. Markers of liver insufficiency (bilirubin, prothombin time) are usually not affected. Hepatic necrosis of the ligated lobe has never been reported as a major complication<sup>[4]</sup>. Despite having different courses within the liver, arterial and portal blood flow drain in a common terminal hepatic veinule<sup>[11]</sup>. Thus, occlusion of a branch of the portal vein induces an ipsilateral HABR that guarantees rapid normalization of overall blood flow in the ligated lobe<sup>[12]</sup>. Flow in the hepatic artery of the ligated lobe increases by more than 3-fold for this compensatory effect and is usually well tolerated as venous outflow can absorb the overflow<sup>[13]</sup>. Hepatic necrosis involves the interruption of hepatic arterial flow with secondary damage due to liver hypoxemia. Interestingly, portal arterialization by arterioportal shunting restores normal oxygen supply within the liver and can prevent liver necrosis<sup>[14]</sup>. Hence, hypoxemia is the main cause of liver necrosis and explains why portal vein obstruction alone cannot induce hepatic necrosis. In contrast, impairment of venous outflow following compression by liver tumors may be very deleterious in this situation. Studies on venous drainage of right lobe grafts in living donor liver transplantation have demonstrated that non reconstruction of the middle hepatic vein can lead to congestion of the anterior sector, with possible severe liver dysfunction<sup>[15,16]</sup>. In such cases, assessment of hepatic tissue oxygenation using near-infrared spectrometry has confirmed congestion with hypoxemia of the anterior sector<sup>[17]</sup>. As a consequence, portal veins can become the draining veins to ensure adequate venous outflow, *via* a mechanism of regurgitation<sup>[18]</sup>. Finally, it can be speculated that compression of the right and median hepatic veins by liver metastases silently reduced the flow in these veins, with partial recovery of liver outflow through the portal system. PVL in this condition could have induced acute congestion with secondary necrosis of the right liver. Congestion was probably worsened by increased hepatic arterial inflow due to hepatic arterial buffer response secondary to PVL.

Acute congestion probably led to massive hepatic ne-

crosis of the right lobe with partial liver insufficiency. In our patient, massive hepatic necrosis caused renal, cardiac and respiratory dysfunction. This so-called “toxic liver syndrome (TLS)” was first described by Ringe *et al*<sup>[19]</sup> in fulminant hepatic failure. Definition is based on complete liver necrosis associated with cardiovascular shock, renal, and possibly respiratory failure requiring vasopressor support, hemodialysis, and mechanical ventilation<sup>[19]</sup>. The pathophysiology is still unclear but seems to involve toxic metabolites released from the necrotic liver, such as cytokines or cardiosuppressive factors, known to play a role in cardiac and pulmonary instability after liver ischemia-reperfusion syndrome<sup>[20,21]</sup>. Furthermore, intra-abdominal hypertension related to an increase in the volume of the intra-abdominal organs and ascites can impair cardiac preload by reduced venous return and pulmonary function and by limitation of abdominal wall expansion<sup>[22]</sup>. TLS is invariably fatal, and all the studies on the topic have been published in the setting of two-stage liver transplantation<sup>[19,23-26]</sup>. To the best of our knowledge, there are no documented cases of reversible TLS. The syndrome usually develops following graft failure or acute rejection in liver transplantation, but can also have traumatic, toxic or postoperative causes<sup>[19]</sup>. Spontaneous evolution of TLS is fatal mainly because of its association with liver failure<sup>[19]</sup>. One approach is wo-stage liver transplantation, which consists in (1) removing the necrotic liver to avoid toxic syndrome and stabilize the patient; and (2) restoring hepatic function with transplantation<sup>[27]</sup>. In our case, the patient did not develop fatal complications, for at least two reasons. First, only a part of the liver was involved by necrosis so that TLS was comparatively moderate. Second, the remnant liver spared by necrosis was neither cirrhotic nor fibrotic and was able to ensure sufficient hepatic function to minimize liver insufficiency, as demonstrated by the rapid hypertrophy visualized on MD-CT. Taken together, these two factors may have limited the consequences of TLS and directly contributed to the patient's favorable clinical evolution.

Portal vein ligation must be avoided when impaired venous return is suspected. There is the risk of massive

hepatic necrosis occurring due to hepatic congestion and secondary toxic liver syndrome, which can be fatal. This is the first documented observation of a spontaneously reversible toxic liver syndrome with minor hepatic failure.

### Abstract

The differential diagnosis of acute abdomen is typically extremely broad in range, with vasculitis posing a rare but potentially life-threatening cause of acute abdomen. Here, we report a case of acute abdomen with bowel wall thickening limited to jejunum, accompanied by unexplained renal dysfunction. Later, the patient was diagnosed as having polyarteritis nodosa based on surgically resected jejunal necrosis. Despite aggressive treatment, including the use of steroid pulse therapy and continuous hemodiafiltration, the patient died. Although polyarteritis nodosa is extremely rare in patients with acute abdomen, acute abdomen is relatively common manifestation of that. And it is reported that involvement of small intestine suggests poorer prognosis. Our case highlights the importance of vasculitis as a differential diagnosis of patients with atypical acute abdomen. In this report, we not only

review possible clues that might have led to an earlier diagnosis in this case, but also attempt to draw some lessons for treating similar cases in the future.

**Key words:** Acute abdomen; Polyarteritis nodosa; Jejunal necrosis

**Core tip:** Our case shows the importance of vasculitis, including polyarteritis nodosa, as a differential diagnosis in case of acute abdomen. Here we provide comprehensive review of gastrointestinal organ involvement in Polyarteritis nodosa, and concluded that gastrointestinal lesions, especially small intestinal lesion, is relatively common manifestation and that suggests high mortality. Then we draw two findings, bowel wall thickening limited to jejunum and unexplained renal dysfunction, as possible clues that might led us to earlier diagnosis in this case. Additionally, we discuss possible relationship between pathophysiology of intestinal ischemia and radiological findings.

### INTRODUCTION

Polyarteritis nodosa is a systemic vasculitis affecting medium- and small-sized arteries<sup>[1,2]</sup>. The affected sites can include the kidneys, gastrointestinal tract, heart, peripheral and central nervous system, and skin. Accurately diagnosing the disease is difficult because there are no

known markers, making biopsy a mandatory procedure. Here we report the case of a patient with acute abdomen diagnosed as polyarteritis nodosa based on surgically resected jejunal necrosis.

## CASE REPORT

A 70-year-old female with a history of diabetes mellitus, hypertension, and gallbladder stone visited the emergency department at our institution complaining of severe abdominal pain. Upon examination, she appeared slightly distressed; her temperature was 36.6 °C, blood pressure 153/101 mmHg, pulse 100 beats/min, and oxygen saturation 98% on room air. Epigastric tenderness without rebound or guarding tenderness, and pitting edema of all extremities were noted. The laboratory findings were remarkable for elevated white blood cell count (20650/ $\mu\text{L}$ ), C-reactive protein (8.62 mg/dL), and impaired renal function (BUN 70.2 mg/dL, creatinine 2.63 mg/dL). Urinalysis showed 1+ protein and 2+ occult blood. Although her platelet count had fallen to  $8.6 \times 10^4/\mu\text{L}$ , coagulation tests were normal. Serologies for hepatitis B virus, hepatitis C virus, anti-nuclear antibodies, cytoplasmic-Anti-Neutrophil Cytoplasmic Antibodies (ANCA), and perinuclear-ANCA were also negative. Abdominal computed tomography (CT) without contrast showed bowel wall thickening almost limited to jejunum, a stone at the neck of gallbladder, and a moderate amount of ascites surrounding the liver and the Douglas's pouch (Figure 1). Based on these findings, the patient was admitted to our institution with a diagnosis of acute abdomen, and intravenous sulbactam/cefoperazone was started.

Although her abdominal pain improved spontaneously after admission, her response to the antibiotic was minimal and her inflammatory reaction remained high. On day 6 following admission, the patient complained of severe abdominal pain. An emergent CT showed deterioration of the edema in the jejunum and the ascites (Figure 1). Although her antibiotic regimen was switched to imipenem/cilastatin, no improvement was observed. In light of these findings, an emergent laparotomy was carried out with tentative diagnoses including a serious intestinal infection refractory to antibiotics, a thrombosis or occlusion of the mesenteric vasculatures, and an intestinal lymphoma. Laparotomy findings included hemorrhagic ascites measuring more than 2000 mL, and a swollen, dark red jejunum. Twenty centimeters of the jejunum was resected, and an end-to-end anastomosis was conducted. The pathology was consistent with a diagnosis of polyarteritis nodosa (Figure 2). The pathological finding of a post-surgical skin lesion on her forearm was also consistent with the diagnosis.

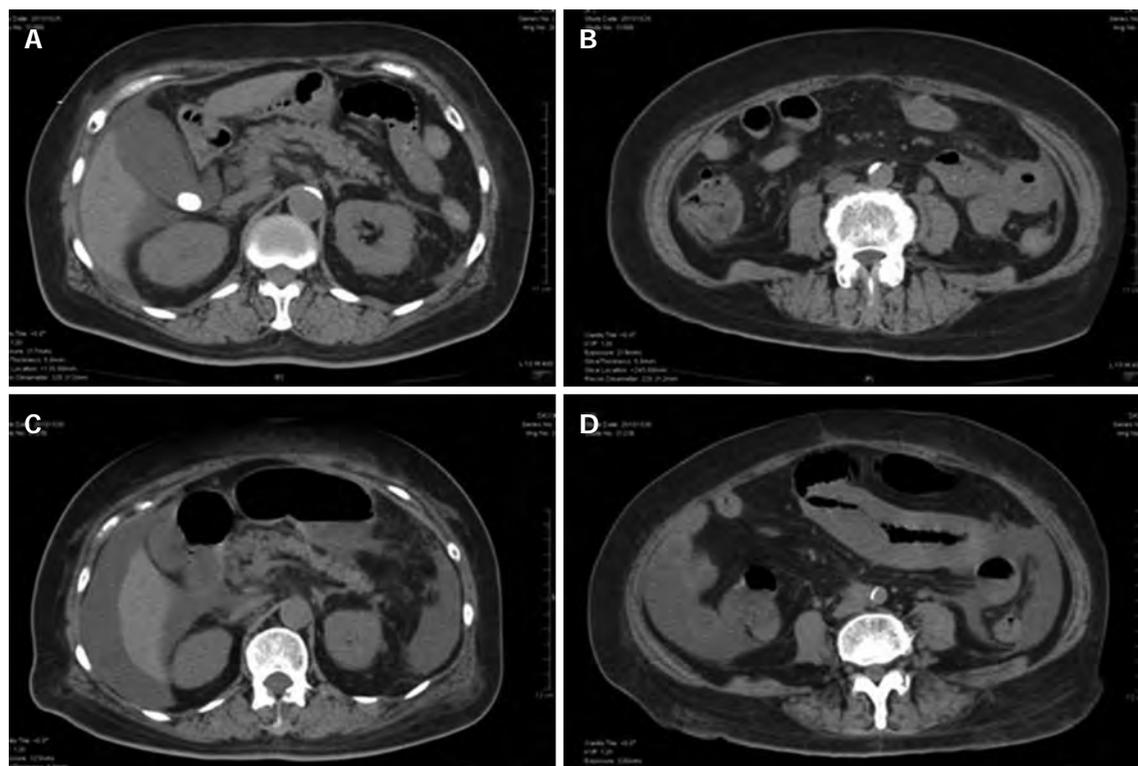

On day 17 following admission, steroid pulse therapy (methylprednisolone 1000 mg/d for 3 d) was prescribed, followed by a maintenance dose of steroids (60 mg/d for 8 d). Although her inflammatory reaction and renal function initially improved, the patient suffered a relapse of disease activity and her general status deteriorated despite

continuous hemodiafiltration and extensive use of antibiotics including ceftriaxone and ceftazidime. On day 32 following admission, an acute onset of left hemiparesis was observed, with normal head CT findings (Figure 3). At midnight of the same day, sudden respiratory arrest occurred. Although cardiopulmonary resuscitation was performed immediately after arrest, the patient died. An autopsy was not performed. The clinical course is summarized in Figure 4.

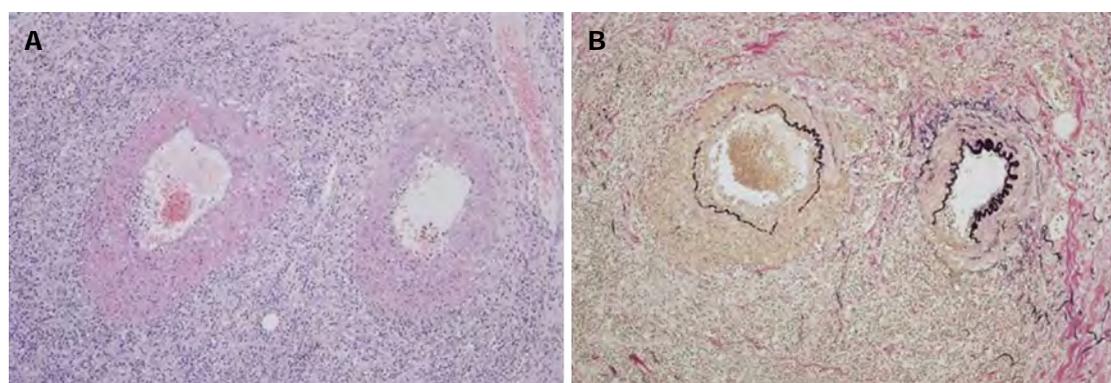

## DISCUSSION

Polyarteritis nodosa is a type of vasculitis affecting medium- and small-sized arteries. Epidemiologic studies of polyarteritis nodosa have generally been difficult to interpret because they have typically included patients with microscopic polyarteritis and other possible diseases as well. Recent studies, however, have estimated the prevalence per one million adults to be approximately 30 in France and Sweden<sup>[3,4]</sup>. Possible symptoms of polyarteritis nodosa include weight loss, livedo reticularis, testicular pain, myalgias or muscle weakness, mono- or polyneuropathy, hypertension, and renal dysfunction<sup>[1]</sup>. Unfortunately, no definitive diagnostic marker has ever been identified, and diagnosis is most often confirmed by biopsy. The prognosis of polyarteritis nodosa depends on the existence of serious organ involvement; in this regard, Guillevin *et al.*<sup>[5]</sup> have established 5 risk factors leading to higher rates of mortality. These include proteinuria > 1 g/d [relative risk (RR) for death was 3.6], renal insufficiency with serum creatinine > 1.58 mg/dL (RR = 1.86), gastrointestinal tract surgery (RR = 2.83), cardiomyopathy (RR = 2.18), and central nervous system involvement (RR = 1.76). When none of the 5 prognostic factors is present, the mortality rate at 5 years is 11.9%. However, when more than 3 factors are present, the mortality rate is as high as 45.95%.

Although polyarteritis nodosa is extremely rare in patients with an acute abdomen, acute abdomen is a relatively common manifestation of polyarteritis nodosa. Levine *et al.*<sup>[6]</sup> reported that 24 of the 54 cases (44%) they reviewed involved gastrointestinal lesions, and 13 required surgical intervention. Of the 24 cases presenting a gastrointestinal lesion, the mortality rate proved higher in the group requiring surgery (3/13, 23%) compared to the group that received more conservative treatment (1/11, 9%). The small intestine was reported to be involved in 3 of the 9 cases with polyarteritis nodosa that required abdominal surgery, 2 of the 3 patients died in such cases, while just 1 of the 6 patients died when the small intestine was spared<sup>[7]</sup>. According to an investigation of autopsy summaries in Japan, the small intestine is the most common site of gastrointestinal lesions and it is involved in 12 of the 15 cases (80%), while the large intestine is involved in 10 cases, liver and pancreas in 9 cases, gallbladder in 8 cases, stomach in 7 cases, tongue and esophagus in 6 cases, mesenterium in 3 cases, and appendix in 2 cases<sup>[8]</sup>. In summary, the small intestine is often involved in polyarteritis nodosa with acute

**Figure 1** Abdominal computed tomography findings. A, B: On day 1 showed ascites and bowel wall thickening; C, D: On day 6, both of the ascites and the bowel wall thickening, especially jejunum, had severely worsened.

abdomen and this situation suggests poor prognosis.

In the case of the 70-year-old female patient described here, we needed 6 d before a laparotomy was carried out and 16 d before a definitive diagnosis of polyarteritis nodosa could be made. Reviewing our case retrospectively, there were some findings inconsistent with a typical intestinal infection. First, the findings were remarkable for the presence of renal dysfunction with proteinuria and microscopic hematuria. Second, her abdominal pain and intestinal edema were so severe and resistant to antibiotics. Additionally, in our case, bowel wall thickening was limited to jejunum. We believe that such situation is very unlikely and there is no typical etiology that could explain the symptoms and findings. If we had considered these find-

**Figure 4 Clinical course of the patient.** Cefoperazone/sulbactam (CPZ/SBT) was started at day 1 and switched to imipenem/cilastatin (IPM/CS) at day 7. Ceftriaxone (CTRX) was started at day 26 and switched to ceftazidime (CAZ) at day 29. Steroid pulse therapy [methylprednisolone (mPSL) 1 g/d for 3 d] was started at day 16, and changed to maintenance dose of mPSL (60 mg/d) at day 19, then that was switched to oral steroid (PSL 60 mg/d) at day 22. According to deterioration of general status, steroid was again administered intravenously since day 31. Continuous hemodiafiltration (CHDF) was performed from day 13 to day 15, and intermittent blood transfusion was done at day 19, 21, 23 and 26. WBC: White blood cell; CRP: C-reactive protein.

ings more carefully, we might have suspected vasculitis, or other connective tissue diseases as a differential diagnosis. Nevertheless, since a biopsy remains indispensable for the diagnosis of polyarteritis nodosa and the patient's possible biopsy site was limited to the intestine at that time, we believe that a correct diagnosis was extremely difficult to ascertain in her situation.

Following diagnosis, we performed steroid pulse therapy (methylprednisolone 1000 mg/d for 3 d), followed by a maintenance dose of steroids (60 mg/d for 8 d). Although her inflammatory reaction and renal function initially improved after beginning pulse therapy, the patient subsequently worsened. Although repetitive steroid pulse therapy or another type of immunosuppressive therapy might have been effective in this case, as has been described in the literature<sup>[9]</sup>, we unfortunately did not have sufficient time to start such a treatment before the patient died.

Intestinal ischemia has generally been diagnosed by CT, and bowel wall thickening is one of the most reported findings in that situation<sup>[10]</sup>. Recently, magnetic resonance imaging (MRI) has begun to be regarded as an alternative modality to detect intestinal ischemia. *In vivo* study with animal model showed that bowel wall thickening was absent from arterial mesenteric ischemia, and bowel wall with reduced thickness resembling sheets of paper is rather observed 2-4 h after the onset, when evaluated by MRI<sup>[11]</sup>. CT findings in our case are possibly late findings after arterial occlusion, findings caused by reperfusion, or

that suggestive of venous infarction. Advances in imaging modality would further clarify the relationship between pathophysiology of intestinal ischemia and radiological findings.

At approximately 12 h before death, a left hemiparesis was observed in our patient, although a head CT revealed no obvious findings. It is difficult to state the cause of the patient's left hemiparesis since she died before a more thorough investigation could be conducted, but it is possible that it stemmed from complications of polyarteritis nodosa, including brain infarction and polyneuropathy<sup>[12-14]</sup>.

In conclusion, we have reported here a case of acute abdomen diagnosed as polyarteritis nodosa based on surgically resected jejunal necrosis. Vasculitis cannot be ruled out as a differential diagnosis in cases of acute abdomen, especially if the patient exhibits atypical findings, such as unexplained renal dysfunction or severe bowel wall thickening limited to small intestine. Additionally, it is worth noting that vasculitis cannot be ruled out even though serum markers, including ANCA, are negative, since there are no definitive diagnostic markers for polyarteritis nodosa.

**Key words:** Endoscopy; *Acinetobacter baumannii*; Bacteremia; Antibiotic prophylaxis

**Core tip:** After a literature review, we suggest that correct gastroendoscopy technique and skill in drainage procedures, as well as antibiotic prophylaxis, are of paramount importance in minimizing the risk of gastroendoscopy-associated bacteremia. Gastroenterologists should give more attention to gastroendoscopy-related infections, and increased clinical alertness may be the best way to reduce the impact from these types of infections.

### Abstract

Two cases of gastroendoscopy-associated *Acinetobacter baumannii* (*A. baumannii*) bacteremia were discovered at the study hospital. The first case was a 66-year-old woman who underwent endoscopic retrograde cholangiopancreatography and endoscopic retrograde papillotomy, and then *A. baumannii* bacteremia occurred. The second case was a 70-year-old female who underwent endoscopic retrograde biliary drainage due to obstruction of intra-hepatic ducts, and bacteremia occurred due to polymicrobes (*Escherichia coli*, *viridans streptococcus*, and *A. baumannii*). After a literature review, we suggest that correct gastroendoscopy technique and skill in drainage procedures, as well as antibiotic prophylaxis, are of paramount importance in minimizing the risk of gastroendoscopy-associated bacteremia.

### INTRODUCTION

Gastroendoscopy is a commonly used procedure for diagnosis and therapy, such as in endoscopic retrograde cholangiopancreatography (ERCP). Infection is one of the most common morbidity complications of gastroendoscopy. Septic complications of ERCP include ascending cholangitis, liver abscess, acute cholecystitis, infected pancreatic pseudocyst, infection following perforation of a viscus, and, less commonly, endocarditis and endovascularitis<sup>[1]</sup>. Bacteria can enter the biliary tract by hematogenous or, more frequently, by a retrograde route, and the most common organisms transmitted by ERCP are *Escherichia coli*, *Klebsiella* species, and *Enterobacter* species<sup>[2]</sup>. Here we report two interesting cases of gastroendoscopy-associated *Acinetobacter baumannii* (*A. baumannii*)(GEaAb) bacteremia.

## CASE REPORT

### Case 1

The patient was a 66-year-old woman who visited a gastroenterologist for complaints of right upper quadrant pain and hunger pain. The initial impression was of a gall bladder stone. An ERCP was performed, and it showed a common bile duct of 16.1 mm in diameter and several filling defects in the gall bladder; therefore, an endoscopic retrograde papillotomy (EPT) was executed over the proximal portion of the bile duct, after which a gallstone was removed. The course of the procedure went smoothly. She again began to feel right quadrant pain and fever the next day, so she was admitted for further evaluation and management. At admission, vital sign measurements were: blood pressure, 100/90 mmHg; temperature, 38 °C; pulse rate, 110 beats/min; and respiratory rate, 20 breaths/min. The patient appeared acutely ill. The abdomen was distended and ovoid. There was radiation pain and tenderness to her back, and abdominal fullness over the right quadrant area (positive Murphy's sign), but no rebounding pain. Admission laboratory results revealed the following: white blood cell count, 12700/mm<sup>3</sup>; blood creatinine level, 0.8 mg/dL; serum amylase, 815 IU/L; serum bilirubin, 0.88 mg/dL; aspartate transaminase, 55 U/L; and alanine transaminase, 140 U/L. Abdominal echography revealed peri-pancreatic fluid accumulation. On the first day of admission, the patient was treated with antibiotics (cefazolin 1 g every 8 h plus gentamicin 60 mg every 12 h) and adequate fluid hydration, after initially remaining nil per os (NPO). A blood culture revealed *A. baumannii* on the 4<sup>th</sup> admission day, and the antibiotic treatment was switched to imipenem-cilastatin 500 mg every 6 h according to the antibiotics susceptibility test. Clinically, the source of *A. baumannii* was from the biliary tract, and it could be related to the previous invasive procedure. Because of persistent fever, an abdominal computed tomography was performed and showed a pancreatic abscess; consequently, an echo-guided aspiration was performed on the 5<sup>th</sup> admission day. The fever gradually subsided and follow-up laboratory data showed improvement. The total duration of parenteral imipenem-cilastatin usage was 21 d, after which antibiotic therapy was switched to oral levofloxacin 500 mg per os daily. The patient was discharged on the 44<sup>th</sup> admission day and was followed in the out-patient department (OPD). She has recovered quite well.

### Case 2

This patient was a 70-year-old female with liver cirrhosis related to hepatitis C virus infection. At initial presentation, laboratory test results were as follows: serum bilirubin, 0.52 mg/dL; aspartate transaminase, 42 U/L; alpha-fetoprotein, < 20 ng/mL; and hepatitis C virus-antibody titer, positive. The abdominal computed tomography scan showed multiple nodular hypervascular tumor stains in both lobes of the liver, especially in the right lobe. Hepatocellular carcinoma was highly suspected. Transarterial

chemo-embolization (TACE) of both sides of the liver was performed, and she was regularly followed in the OPD while she received TACE 6 times over the course of 20 mo. Her follow-up laboratory tests showed a serum bilirubin of 8.6 mg/dL, an aspartate transaminase of 72 U/L, and an alkaline phosphatase of 371 U/L. An abdominal echography exam revealed focal dilated intra-hepatic ducts. Hence, an endoscopic retrograde biliary drainage (ERBD) procedure was performed accordingly, at which time a stent (11 Fr) was inserted into the intra-hepatic ducts through the common bile duct. She began to feel right quadrant pain and fever three days later, and she was admitted under the impression of cholangitis. At admission, vital signs included a blood pressure of 100/90 mmHg, a temperature of 38 °C, a pulse rate of 110 beats/min, and a respiratory rate of 20 breaths/min. Murphy's sign was positive. Admission laboratory results revealed the following: white blood cell, 5600/mm<sup>3</sup>; serum total bilirubin, 27.65 mg/dL; serum direct bilirubin, 19.2 mg/dL; aspartate transaminase, 60 U/L; and alanine transaminase, 140 U/L. The abdominal echography showed left intra-hepatic duct dilatation. On the first day of admission, the patient was treated with antibiotics (cefazolin 1 g every 8 h plus gentamicin 60 mg every 12 h) and adequate fluid hydration after initially being NPO. Echo-guided percutaneous transhepatic cholangial drainage was performed. Blood culture revealed polymicrobes (*Escherichia coli*, *viridans streptococcus*, and *A. baumannii*) on the 4<sup>th</sup> admission day, and treatment was changed to imipenem-cilastatin 500 mg every 6 h according to the antibiotics susceptibility test. The fever gradually subsided. Clinically, the source of *A. baumannii* was from the biliary tract, and it could be related to the previous invasive procedure. Follow-up laboratory data did not, however, seem much improved. This patient expired due to severe hepatic failure with multiple organ failure.

### Evidence-based literature review and epidemiological study

After noting those two GEaAb cases in our institute, we conducted an evidence-based literature review (Table 1)<sup>[3-7]</sup>. Norfleet's study showed that 6% of patients who received upper gastrointestinal endoscopic examinations developed bacteremia, but only one of 447 patients acquired *Acinetobacter* bacteremia<sup>[4]</sup>. Maulaz's study described that the bacteremia incidence in cirrhotic patients who received variceal ligation was 2.5%, and only one *Acinetobacter hwoffii* infection was disclosed<sup>[5]</sup>. Only two case reports described post-endoscopic retrograde cholangiopancreatography-associated *Acinetobacter* infection in the United States National Library of Medicine National Institutes of Health<sup>[6,7]</sup>. Additionally, we performed a retrospective cross-sectional epidemiological study in our institute to identify GEaAb bacteremia cases and elucidate the possible sources of infection for a further five years from the year of identifying these two patients. During this period of five years, we disclosed 45 *A. baumannii* bacteremia cases. Most of them resulted from hospital-

acquired pulmonary infection. We focused on biliary tract infections and gastroendoscopy-associated *A. baumannii*, but neither a case of biliary tract infection nor a case of GEaAb were disclosed among hospital-acquired infection patients. So, we excluded those hospital-acquired *A. baumannii* patients, and the results were 19 patients with documented non-hospital-acquired *A. baumannii* bacteremia. We focused on these 19 patients (the demographics and clinical presentations are listed in Table 2). We also performed a pulse-field gel electrophoresis (PFGE) analysis according to Seifert's method<sup>[8]</sup>, and the results are shown in Figure 1. Patients 1, 11 and 14 appeared to have had similar fingerprints according to a dendrogram and PFGE (Figure 1). In the analysis of 5 biliary sepsis cases, risk factors included one patient with common bile duct stone, one with diabetes mellitus, one with cholangiocarcinoma, one with liver cirrhosis, and one with hepatocellular carcinoma. In addition, 3 patients had received invasive diagnostic or therapeutic procedures: one had an EPT, one underwent percutaneous transhepatic cholangial drainage, and one had ERBD (Table 2). Two of 5 biliary sepsis cases developed *A. baumannii* bacteremia. All of those patients received prophylactic antibiotics before the invasive medical procedures.

## DISCUSSION

This is the first serial study and case reports of GEaAb bacteremia in Taiwan. In our study, this infection was seen in one patient after an EPT, and in one patient who underwent ERBD. Both diagnostic and therapeutic gastroendoscopy can lead to bacteremia, and gastroendoscopy-associated infection rates up to 27% have been associated with therapeutic procedures<sup>[9-11]</sup>.

## Mechanisms of gastroendoscopy-associated infections

Concerning the mechanisms of gastroendoscopy-associated infections, bacteria can enter the biliary tract by a hematogenous or, more frequently, a retrograde route. Estimates of

<sup>1</sup>This patient is case one, and she had received the endoscopic papillotomy one day before the episode of *Acinetobacter baumannii* (A. *baumannii*) bacteremia; <sup>2</sup>This patient had suspected hepatocellular carcinoma; <sup>3</sup>This patient had received the percutaneous transhepatic cholangial drainage three days before the episode of A. *baumannii* bacteremia, and the route of entry of A. *baumannii* could result from biliary tract. He was categorized to primary bacteremia due to lack of typical clinical symptoms and signs of biliary sepsis; <sup>4</sup>This patient is case two, and she had received the endoscopic retrograde biliary drainage one day before the episode of A. *baumannii* bacteremia. RUQ pain: Right upper quadrant pain; SOB: Shortness of breath; AMI: Acute myocardial infarction; TIA: Transient ischemic attack; CBD: Common bile duct; DM: Diabetes mellitus; DKA: Diabetic ketoacidosis; CHF: Congestive heart failure; HCC: Hepatocellular carcinoma; HBV: Hepatitis B virus; HCV: Hepatitis C virus; AF: Atrial fibrillation; CVA: Cerebrovascular attack; co-trimoxazole: Sulfamethoxazole-trimethoprim; S: Survived; E: Expired; P: Patient number; F: Female; M: Male; Y: Yes; N: No.

the incidence of clinically significant cholangitis have ranged from 0.4% to more than 10% (mean, 1.4%), depending upon the study population<sup>[12]</sup>. Entrance into the blood stream is presumably through minor trauma by the endoscope<sup>[13]</sup>. Another factor influencing the rate of cholangitis is the use of prophylactic antibiotics<sup>[14]</sup>. Results from these studies were similar to the results in our study.

### Organisms associated with gastroendoscopy-associated infections

The most frequent organisms responsible for cholangitis and biliary sepsis are enteric bacteria, such as *Escherichia coli*, *Klebsiella* species, and *Enterobacter* species<sup>[2]</sup>. *A. baumannii*, which was reported in this study, is rare, so we performed a molecular epidemiological study. Patients 1, 11 and 14 appeared to have had similar fingerprint patterns according to a dendrogram and PFGE (Figure 1), and those 3 patients had experienced invasive gastrointestinal endoscopic procedures. Although we suspect the relationship, we still cannot prove the causal association between the procedure and infection in this study. We lacked direct microbiological evidence as well as estimates of the infection rate in the gastroendoscopy room. Also, there was no significant evidence of endemic *A. baumannii* infection at Changhua County.

In conclusion, we believe that accurate gastroendoscopy techniques and skill in drainage procedures are of paramount importance for minimizing the risk of GEAb bacteremia. Antibiotic prophylaxis is also widely considered to be indicated in selected patients. Gastroenterologists should give more attention to gastroendoscopy-related infections,

**Figure 1** Dendrogram and pulse-field gel electrophoresis patterns of *SgrAI*-digested chromosome DNA of 24 *Acinetobacter baumannii* isolates. #1, #2: Nosocomial *Acinetobacter baumannii* (*A. baumannii*) strain isolated from the same period; @1: Environmental *A. baumannii* strain isolated from the endoscopic room; O1, O2: Outbreak *A. baumannii* strains; P: Clinical *A. baumannii* strains isolated from the numbered patient among 19 non-hospital-acquired *A. baumannii* bacteremia patients.

and increased clinical alertness may be the best way to reduce the impact from these types of infections.

## ACKNOWLEDGMENTS

The authors thank Changhua Christian Hospital for the kind gift of the clinical *A. baumannii* strains. The authors thank the Gastroendoscopy Room of Changhua Christian Hospital for surveillance cooperation. The authors thank Chou CS and Laiu JC of the Central Branch Office, Center for Disease Control, Taichung for the PFGE assistance.

Stricture; Leak; Endoscopic retrograde cholangiopancreatography

**Core tip:** Biliary complications continue to be a major cause of morbidity in liver transplant recipients. In this article, we review the etiology, as well as the main types of biliary complications according to the technique of biliary reconstruction and liver transplant procedure performed. Their management is also discussed with endoscopic techniques emerging as the preferred treatment option, obviating the need for surgery in majority of patients.

### Abstract

Biliary tract complications are the most common complications after liver transplantation. These complications are encountered more commonly as a result of increased number of liver transplantations and the prolonged survival of transplant patients. Biliary complications remain a major source of morbidity in liver transplant patients, with an incidence of 5%-32%. Post liver transplantation biliary complications include strictures (anastomotic and non-anastomotic), leaks, stones, sphincter of Oddi dysfunction, and recurrence of primary biliary disease such as primary sclerosing cholangitis and primary biliary cirrhosis. The risk of occurrence of a specific biliary complication is related to the type of biliary reconstruction performed at the time of liver transplantation. In this article we seek to review the major biliary complications and their relation to the type of biliary reconstruction performed at the time of liver transplantation.

**Key words:** Liver transplantation; Complication; Biliary;

### INTRODUCTION

Since the first experiences with liver transplantation in the 1960s, this procedure has become a standard treatment for end stage liver disease. Limited primarily by the donor liver supply, the number of orthotopic liver transplants (OLT) has continued to increase. In the United States alone, according to the American Liver Foundation, 6500 liver transplantations were performed in 2005. Although, because of constant improvements in surgical techniques, the rate of biliary complications following liver transplantation has been decreasing; they remain a major source of morbidity and mortality<sup>[1,2]</sup>. Post liver transplantation biliary complications include strictures, leaks, stones or debris, and sphincter of Oddi dysfunction (SOD). T-tube biliary reconstruction, Roux-en-Y anastomosis, ischemia, reperfusion injury, hepatic artery thrombosis (HAT), cytomegalovirus infection, and primary sclerosing cholangitis are some of the risk factors that have been implicated in biliary complications.

## TYPES OF BILIARY RECONSTRUCTION

The choice of biliary anastomosis is a major determinant of the risk of biliary complications after OLT<sup>[3,4]</sup>. The two most common forms of biliary reconstruction are choledochocholedochostomy (CC, duct-to-duct anastomosis) and choledochojejunostomy (CJ, connection of the bile duct to a portion of jejunum). The choice of biliary reconstruction is determined by multiple factors, including the underlying liver pathology, the size of donor and recipient bile ducts, prior transplant or previous biliary surgery, and the preference of the performing surgeon. There are no clear-cut guidelines on the optimal type of biliary reconstruction, and considerable variability exists between surgeons.

CC is the most common biliary reconstruction procedure performed during OLT. This type of reconstruction is usually preferred because the procedure is technically easier, it preserves the function of Sphincter of Oddi, and it also allows easy endoscopic access to the biliary system after the surgery<sup>[5]</sup>. Furthermore, the preservation of the sphincter of Oddi, theoretically decreases the risk of ascending cholangitis as it serves as a barrier against the reflux of enteric contents into the biliary tree. CC can be performed either with or without a T-tube. Routine use of a T-tube allows direct measurement of bile output and color in the early post-operative period, maintains easy access for radiological evaluation of the biliary system and allows rapid decompression of the biliary tree if needed. It also may reduce the risk of anastomotic stricture formation. On the other hand, the use of T-tubes has been associated with bile leak and cholangitis at the time of their removal. A recent retrospective study of 180 patients demonstrated an increased rate of overall complications (33% *vs* 15.5%) and an increased rate of cholangitis (10% *vs* 2.2%) in patients with a T-tube compared to those without. In that study patients without a T-tube had an increased survival rate compared to the T-tube population (80.1% *vs* 72.8%), an observation that was attributed to higher complication rates among those with a T-tube<sup>[5]</sup>. This observation is supported by a recent meta-analysis consisting of 1027 patients, in which those without a T tube had a decreased incidence of cholangitis and peritonitis with overall decreased rate of biliary complications. Interestingly, this meta-analysis did not show any significant differences between the T-tube and non T-tube groups in terms of other complications such as anastomotic bile leaks, fistulas, choledochojejunostomy revisions, stenting of the bile duct, hepatic artery thromboses, retransplantation, and mortality due to biliary complications<sup>[6]</sup>.

CJ is another type of biliary reconstruction usually recommended in patients with pre-existing biliary disease such as primary sclerosing cholangitis, or prior biliary surgery, and also when there is a size mismatch between donor and recipient ducts. Compared to CC, CJ takes longer to perform and adversely affects the ability to perform an endoscopic evaluation of the biliary system after the liver transplantation. Potential complications of

CJ include intestinal perforation, stricture, leakage, and bleeding at jejunostomy site.

## DIAGNOSIS OF BILIARY COMPLICATIONS

The presentation of biliary complications varies considerably. Some complications such as bile leaks may occur immediately in the post-operative period, while others may take weeks to develop. The clinical presentation can vary from asymptomatic patient with moderate liver enzyme elevations to a septic patient with fever and hypotension due to ascending cholangitis. Whenever a biliary complication is suspected, work-up usually begins with laboratory evaluation and an abdominal doppler ultrasound. Abdominal ultrasounds are relatively inexpensive, and are easy to perform. An abdominal ultrasound allows for the evaluation of the biliary tree and the corresponding hepatic vasculature. The positive predictive value of abdominal ultrasound is very high, especially in the presence of dilated bile ducts. In the absence of dilated bile ducts, the sensitivity of the ultrasound for detecting biliary obstruction ranges from 38%-68%<sup>[7]</sup>. In the event that the ultrasound does not reveal evidence of bile duct dilatation despite clinical suspicion, the next step can be magnetic resonance cholangiopancreatography (MRCP) or endoscopic retrograde cholangiopancreatography (ERCP), depending on their availability. MRCP has excellent sensitivity (93%-100%) in detecting biliary strictures; and can also offer a road map for the endoscopist in planning the necessary intervention<sup>[8]</sup>. Another advantage of MRCP is that it does not carry the invasive risk involved with ERCP or other interventions such as percutaneous transhepatic cholangiography (PTC). The upside of ERCP and PTC, on the other hand, is that they both offer a potential therapeutic advantage over MRCP. It should be noted, however, that ERCP is associated with a high failure rate in patients with Roux-en-Y reconstruction, except when double balloon enteroscopy is available to assess the biliary tree. PTC is usually reserved in cases where ERCP cannot be performed.

### *Bile leaks after OLT*

Bile leaks, along with strictures, account for the majority of complications post-OLT. Bile leaks occur in 2%-25% of cases after liver transplantation and can be classified in two categories: early bile leaks, which present within 4 wk of OLT; and late bile leaks, which present beyond this time<sup>[9-12]</sup>.

**Etiology:** Early bile leaks usually occur at the anastomotic site or at the T-tube insertion site. They can be caused by ischemia, relative downstream obstruction, sphincter of Oddi hypertension, or as a result of T-tube removal<sup>[13]</sup>. The majority of bile leaks after OLT are associated with either planned or inadvertent T-tube removal, and the leak often occurs at the T-tube insertion site. One factor that has been shown to predict development of bile leak after T-tube removal is the presence of mucosal duct irregularities on cholangiography.

**Presentation:** The presentation varies with extent of the leak. Bile leak should be suspected in any patient who develops abdominal pain, fever or any sign of peritonitis after liver transplant, especially after T-tube removal. Bile leaks not related to T-tube removal typically present within the first 30 d after OLT. Some patients, especially those on corticosteroids, may be asymptomatic, with no signs of pain or fever. In such cases, any unexplained elevations in serum bilirubin, fluctuation in cyclosporine levels, or bilious ascites should raise suspicion for a bile leak.

**Management:** Once the clinical suspicion of a bile leak following T-tube removal is raised, initial management usually involves pain control with analgesics, intravenous fluids, and supportive care. Biliary leaks due to ischemia are difficult to treat since the cause is usually not corrected by endoscopic or radiologic intervention. Leaks due to other causes usually respond to non-operative diversion of biliary flow, such as unclamping of the T tube, endoscopic sphincterotomy with or without endoscopic stenting at the time of ERCP, or placement of a PTC. ERCP with stenting of the bile duct, sphincterotomy, nasobiliary drainage, or a combination of these techniques has been shown to have high rates of success<sup>[9,14]</sup>. Most studies report resolution of symptoms in 85%-100% of the cases<sup>[15]</sup>. Although one study reported better results with nasobiliary drainage; most centers use an internal biliary stent to overcome the difference in pressure in the bile duct and the gut. The stent usually remains in place for several weeks. PTC is commonly used in cases where ERCP cannot be performed, or in patients with Roux-en-Y reconstruction where the biliary orifice cannot be reached with a regular sideview endoscope. In rare cases, surgical intervention may become necessary<sup>[9]</sup>.

### **Biliary strictures**

Post liver transplantation biliary strictures are usually classified as anastomotic or non-anastomotic. The incidence of biliary stricture ranges from 5%-15% after deceased donor liver transplantation and 28%-32% after living donor liver transplantation<sup>[7]</sup>. Strictures are commonly seen as late complications, occurring approximately 5-8 mo after transplantation.

### **Anastomotic strictures**

Anastomotic strictures (AS) at the site of biliary anastomosis are frequent after OLT and can occur in both CC and CJ type of reconstruction. AS are more common after CJ than CC due to the direct bilioenteric connection<sup>[1,12]</sup>.

**Etiology:** The pathogenesis of AS is believed to be from inadequate mucosa-to-mucosa anastomosis, surgical technique, local tissue ischemia, and the fibrotic nature of the healing process<sup>[16]</sup>. Early bile leak is also considered to be a risk factor for developing AS<sup>[9]</sup>. In those with a T-tube,

strictures at the CC anastomosis are often not typically evident until after removal of the T-tube. A slight and transient narrowing of the biliary lumen occurs frequently in biliary anastomosis shortly after the OLT due to post-operative edema. It is uncertain how many of these cases progress to clinically significant strictures.

**Presentation:** Biliary stricture should be suspected in any OLT patient who presents with jaundice, fever, abdominal pain, or even in patients with asymptomatic biochemical cholestasis. Dilatation of the bile ducts proximal to the biliary anastomosis may be observed on imaging studies in some patients but is not a pre-requisite for diagnosis. Histologic findings may be suggestive of biliary obstruction, such as pericholangitis or bile duct proliferation.

**Management:** When a clinically significant AS is found, treatment is warranted. In recent years, ERCP has seen an increase in popularity in the management of AS. Although results differ markedly, studies have demonstrated good response after endoscopic therapy in over 75% of the patients<sup>[17,18]</sup>. Endoscopic treatment is thus regarded as the treatment of choice for AS, especially in the CC group of patients. Stenting of the stricture during ERCP is performed with or without balloon dilatation of the stricture. The initial stent is then exchanged for a larger stent or multiple stents every 3 mo for an average of 1 year to dilate the stricture and prevent clogging and stone formation. In patients with CJ reconstruction, the initial treatment usually involves stenting by percutaneous approach. Some centers have reported that early strictures respond better to therapy than late strictures. If a stricture does not respond to endoscopic or percutaneous therapy, surgery may be indicated. Previous endoscopic or percutaneous treatment has not shown to influence the success rate of surgery in treating such complications.

### **Non anastomotic strictures**

Non anastomotic strictures (NAS), also known as ischemic type strictures, are well known and have been described since the beginning of liver transplantation. They are frequently hilar in location, but can also be diffusely intrahepatic. NAS tend to be longer and multiple on presentation. NAS incidence ranges from 5%-15% with mean time to presentation of 3.3-5.9 mo post-OLT<sup>[19,20]</sup>.

**Etiology:** A few theories have been proposed for the development of NAS. The blood supply to the supraduodenal bile duct is predominantly from vessels which are resected during OLT. The remaining blood supply to the donor bile duct then comes from the hepatic artery and its branches, which are tenuous and highly susceptible to ischemic injury. In patients with NAS, up to 50% have demonstrable HAT<sup>[21]</sup>. Prolonged cold ischemia time has also been shown to be responsible for the development of NAS. Besides ischemia, an immunological cause has also been proposed. This is mainly due to the observa-

tion of an increased incidence of NAS in cases with ABO-incompatible grafts, in patients with autoimmune hepatitis or primary sclerosing cholangitis, in patients suffering from chronic ductopenic rejection, and those with a CC chemokine receptor 5delta32 polymorphism. In many cases, NAS are probably multifactorial in origin with injury resulting from one or more of the above mechanisms<sup>[7,22]</sup>.

**Management:** The presentation of NAS is similar to that of AS. NAS are more difficult to manage than AS, as treatment in each case has to be individualized. It is therefore difficult to make generalized recommendations for management of NAS. In cases with early HAT, aggressive management with either revascularization or early re-transplantation has been recommended. In NAS not associated with HAT, endoscopic or percutaneous therapy are often attempted first. Repeated dilatation with stenting seems to be the most accepted treatment form<sup>[14]</sup>. Treatment success depends upon stricture severity, number, and location. Extra-hepatic strictures generally respond better to therapy. Different studies report variable treatment success rates, ranging from 50%-70%<sup>[10,23]</sup>. If radiological and endoscopic therapies fail, surgery may become necessary. Success rates are higher if surgery is done within 2 years of OLT and if the liver biopsy does not show any significant fibrosis. Re-transplantation may also be considered in patients with treatment failure, or in the presence of secondary biliary cirrhosis, recurrent cholangitis, or progressive cholestasis.

### SOD

Another common occurrence after OLT is a mild increase in the size of donor and recipient common bile ducts. In certain cases, significant dilatation of both recipient and donor bile duct in association with biochemical abnormalities occurs in the absence of cholangiographic evidence of obstruction. In these cases, SOD is suspected. The incidence of SOD is reported to be up to 70%<sup>[11,24]</sup>.

**Etiology:** The pathogenesis of SOD is attributed to denervation of the sphincter during OLT. This leads to an increase in basal pressure, thus causing increased pressures in the choledochal duct<sup>[24]</sup>. Very few studies have directly assessed the pressures in the sphincter of Oddi post-OLT. Two types of SOD have been proposed on the basis of pathogenic mechanisms: stenosis and dyskinesia<sup>[16,25,26]</sup>. Any process that leads to chronic inflammation and fibrosis, can lead to sphincter stenosis. Dyskinesia, on the other hand, is usually seen as a result of functional disturbance of the sphincter.

**Management:** There have been virtually no clinical trials that demonstrate the best treatment option for SOD. In recent years, endoscopic therapy with sphincterotomy with or without stenting has been the most acceptable treatment option for SOD.

### Biliary stones, sludge, and casts

On ERCP, stones, sludge and casts are usually seen as a defect in the contrast column and described as “filling defects”. Intrinsic bile duct obstruction, in the form of biliary stones and sludge, can virtually occur at any time following the OLT. Sludge is described as a thick collection of mucous, calcium bicarbonate and cholesterol crystals, which, when left untreated, can go on to form biliary stones. Sludge and casts usually occur within the first year of transplant, while stones tend to occur later on.

**Etiology:** Theoretically, anything that increases the viscosity of bile or reducing flow can predispose to the formation of sludge, and stones. Bile duct mucosal damage due to obstruction, ischemia, or infection is thought to play a role in the development of casts. Of patients presenting with biliary stones and sludge, most will have an underlying stricture. In addition, medications such as cyclosporine may play a role in bile lithogenicity by inhibiting bile secretion and promoting functional biliary stasis. Bile in transplant patients has been shown to be supersaturated with cholesterol, which is aggravated by T-tube drainage and depletion of the bile acid pool.

**Presentation:** Patients commonly present with abdominal pain, cholestatic liver tests, and uncommonly with cholangitis.

**Management:** A study demonstrated that cholangiography is the only reliable imaging method for sludge; ultrasonography and CT scans are of limited value. If sludge alone is present, then it would be reasonable to first attempt medical treatment with ursodeoxycholic acid. Endoscopic therapy with sphincterotomy, lithotripsy and stone extraction are successful in treating majority of filling defects, especially biliary stones<sup>[23]</sup>.

### Biloma

Bile rupture and spilling of bile within the liver and abdominal cavity may result in the formation of a biloma. Small bilomas, especially ones that communicate with the biliary tree, may resolve on their own. Although bilomas can generally be treated with antibiotics and percutaneous drainage, some may require placement of a biliary stent in the extrahepatic bile duct<sup>[9]</sup>. Surgical drainage of a biloma is viewed as a last resort option.

### Hemobilia

One of the rare complications seen after OLT is hemobilia. It is usually associated with percutaneous liver biopsy or PTC. The commonly described triad of right upper quadrant pain, jaundice, and gastrointestinal bleed is seen only in a minority of patients. Treatment of hemobilia requires both hemostasis and treatment of any associated biliary obstruction by clots. The bleeding stops spontaneously with supportive therapy and correction of coagulopathy in some cases. Embolization of the

bleeding vessel by interventional radiology is required if bleeding is persistent or severe<sup>[27]</sup>. Removal of clots from the biliary tree for relief of obstruction is usually done by ERCP.

### Ductopenia

Ductopenia (also referred to as bile duct paucity and vanishing bile duct syndrome) is a descriptive term for small intrahepatic bile duct loss from any cause. In post liver transplantation patients, acute and chronic rejection and ischemia are the most common culprits. The diagnosis is established by liver biopsy in the appropriate clinical setting. Treatment depends mainly on the underlying etiology of ductopenia.

## CONCLUSION

Biliary complications following liver transplantation are relatively common and continue to be a challenging aspect in the management of such patients. The development of these complications is heavily influenced by the type of anastomosis during surgery. The majority of biliary complications after liver transplantation are now a days being managed endoscopically rather than surgically. ERCP, in particular, has proven to be relatively safe and effective in the management of these complications.

### Abstract

The biological properties of tumor cells are known to be regulated by a multitude of cytokines and growth factors, which include epidermal growth factor receptor agonists and members of the transforming growth factor  $\beta$  family. Furthermore, the recent explosion of research in the field of chemokine function as mediators of tumor progression has led to the possibility that these small, immunomodulatory proteins also play key roles in carcinogenesis and may, therefore, be potential targets for novel therapeutic approaches. In this review, we will summarize recently reported findings in chemokine biology with a focus on the gastrointestinal tract.

**Key words:** Chemokine; Receptor; Signal transduction;

Tumor progression; Targeted therapeutics; Digestive system; Cancer

**Core tip:** The chemokine network makes an attractive target for therapeutic intervention in many tumor types, including those of the gastrointestinal tract. However, we need to define more selective and specific targets, to minimize systemic side effects during treatment.

### INTRODUCTION

#### *Cancer development and progression in the gastrointestinal tract*

Cancer is a disease in which normal cells acquire genetic and epigenetic abnormalities<sup>[1,2]</sup>, leading to disorientation of conventional processes for the maintenance of normal cell physiology. These aberrant genetic and epigenetic modifications to the normal cell induce abnormal cell motility, proliferation, and survival, eventually enabling these cells to invade into adjacent tissues and even to migrate to regional or distant organs where they may grow continuously as metastatic lesions<sup>[3]</sup>. For many cancer patients, metastasis is generally the major cause of disease-related death<sup>[4,5]</sup>. Therefore, it is indispensable to elucidate the basic molecular mechanisms of tumor development to identify effective therapeutic targets, which can possibly reduce the side-effects of treatment, and define useful molecular markers for early detection and prediction of disease course. Especially, the newly emerged concept of personalized medicine may require in-depth assessment of potential therapeutic molecular target(s) in each individual case through analysis of sig-

naling pathways and subsequent validation of treatment efficacy<sup>[6]</sup>.

Numerous reports have identified molecules that play key roles in development of gastrointestinal cancer. Amongst these, which include growth factors and their receptors<sup>[7-9]</sup>, signaling pathway components<sup>[10,11]</sup>, transcription factors<sup>[12,13]</sup>, matrix remodeling enzymes<sup>[14,15]</sup> and cytokines<sup>[16-18]</sup>, a milestone finding by Müller *et al*<sup>[19]</sup> made chemokines one of the most intensively studied molecular targets to understand the mechanisms of organ-specific metastasis. The chemotactic cytokines or chemokines contribute to the tumor microenvironment by establishing a chemokine gradient, which is important for the process of chemoattraction and subsequent cell motility and infiltration for metastasis<sup>[20,21]</sup>. In this review, we will summarize the current status of chemokine-related studies in digestive tract cancer.

Recent progress has made it clear that the non-tumor cells, such as stromal fibroblasts and inflammatory cells present in the microenvironment, also play critical roles in establishing the metastatic phenotype of tumor cells<sup>[22,23]</sup>. Indeed, a role for inflammation in cancer progression is well-recognized, with many different cancer types having an inflammatory component<sup>[24]</sup>. Tumor cell infiltration is aided by the presence of tumor-associated macrophages (TAMs), dendritic cells and lymphocytes<sup>[25-28]</sup>. While TAMs are able to kill tumor cells, they also play an important role in enhancing tumor development by secreting matrix metalloproteinases (MMPs)<sup>[29,30]</sup>, growth factors [interleukins (ILs), vascular endothelial growth factors (VEGFs)] and pro-angiogenic factors that support tumor cell growth, neovascularization, and tumor cell invasion through the stromal tissues<sup>[31]</sup>.

### Chemokines and signal transduction

**Chemokines and chemokine receptors:** In humans, the chemokine superfamily is comprised of more than 50 small secreted proteins. These molecules function as immune modulators, chemoattractants and as activators of lymphocytes. They are sub-divided into four major groups based on the relative position of conserved cysteine residues near to the N-terminus: CXC-, CC-, C-, and CX<sub>3</sub>C-chemokines<sup>[32-34]</sup>. The CXC-chemokines can be further subdivided according to the presence or absence of a three amino acid motif immediately N-terminal to the first cysteine. Therefore, a glutamic acid-leucine-arginine (ELR) sequence defines the ELR<sup>+</sup> CXC-chemokines, which generally function as activators and chemoattractants for neutrophils. In contrast, lymphocytes constitute the target cell type for most ELR<sup>-</sup> CXC chemokines. The CC-chemokines play both chemoattractant and immunomodulatory roles. CCL5 attracts monocytes, eosinophils and memory T-cells, and is one of the human immunodeficiency virus (HIV)-suppressive factors secreted by CD8<sup>+</sup> T-cells<sup>[35]</sup>. Similarly, CCL3 and the closely related CCL4 are also capable of inhibiting HIV infection of target cells, in addition to their pro-inflammatory and chemoattractant functions<sup>[35]</sup>. Furthermore, CC-chemokines are also reported to be involved

in lymphocyte recirculation and homing to secondary organs (CCL21), as well as T-cell trafficking within the thymus (CCL19)<sup>[36-38]</sup>.

While the major biological functions ascribed to chemokines regulate leukocyte trafficking and recruitment to inflammatory foci, chemokine receptors are also expressed on non-immune cells, and act as key modulators of the biological functions of other cell types. For example, CCL3 is a negative regulator of keratinocyte growth<sup>[39]</sup>, while the CXC-chemokine ligand (CXCL) 5<sup>[40]</sup>, CXCL8<sup>[41,42]</sup> and other ELR<sup>+</sup> chemokines stimulate endothelial cell migration during angiogenesis<sup>[43]</sup>.

To date, 19 chemokine receptors are known to be expressed in mammals<sup>[44]</sup>. Chemokines activate these specific G-protein-coupled receptors (GPCRs) on the surface of target cells. Chemokine receptors consist of an extracellular ligand binding domain, seven transmembrane spans, and an intracellular carboxyl terminus. The transmembrane domain consists of three intracellular domains and three hydrophobic extracellular domains. Variation of the amino-terminus sequence of these receptors defines the specificity for recognition of chemokine ligands, the binding of which results in phosphorylation of Ser/Thr residues in the intracellular domain and induction of f to the N-terminus of the receptor, specific signal transduction will be induced by the release of these heterotrimeric G-proteins (guanine nucleotide-binding proteins -G/G/G) that are bound to the intracellular carboxyl terminus. Each of these heterotrimeric G-proteins consists of several different subtypes<sup>[45]</sup>. Chemokine receptors are subdivided into four types in relation to the class of ligand to which they bind: CXC-chemokine receptors (CXCR), which bind CXC-chemokines; CC-receptors (CCR), for CC-chemokines; and XC-receptors and CX<sub>3</sub>C-receptors (CX<sub>3</sub>CR) for XC- and CX<sub>3</sub>C-chemokines, respectively. Among these receptors and ligands, there is promiscuous binding between several receptors and multiple chemokines (Table 1)<sup>[38]</sup>.

**Mechanisms of signal transduction:** Binding of chemokines to their innate receptors can activate a number of intracellular signaling pathways that lead to cell proliferation and migration. Downstream mediators identified to date include the small GTPase Ras; extracellular signal-regulated kinases (ERK)<sup>[46,47]</sup>; phosphatidylinositol-3-OH kinase (PI-3K)<sup>[47-49]</sup>, and the other small GTPases Rho, Rac and Cdc42<sup>[50,51]</sup>; and some of these are active in pathways that regulate the actin cytoskeleton. For example, it was shown that migration of Jurkat cells in response to CXCL12 through CXCR4 is mediated by both Rac- and Rho-dependent mechanisms. While Rac is activated by G<sub>i</sub> and G<sub>βγ</sub> subunits, activation of RhoA occurs *via* G<sub>α13</sub> and leads to phosphorylation of myosin light chains<sup>[52]</sup>. Furthermore, CXCL8 (IL-8) signaling through CXCR1 has been reported to mediate migration of leukocytes in a β1-integrin-dependent manner which requires downstream activation of p38 and c-Jun N-terminal kinases<sup>[53]</sup>. The quality and the quantity of chemokine signaling is not controlled only by the expression volume of chemokine ligand/receptor

but, also, by proteolytic processing of chemokine ligands. In this regard, MMPs are major modulators of chemokine signaling. For example, MMP9 can activate CXCL8 by processing its amino terminus, but it also abolishes the function of CXCL1 by cleaving it. Likewise, chemotactic activity of CCL7 is decreased by MMP2, and CXCL12 is decreased by multiple MMPs. However, numerous other proteases have also been documented to act upon chemokines and modulate their activity<sup>[54]</sup>. Furthermore, recent observations suggest more complexity in signal transduction mechanisms that are induced by heterodimerization of GPCRs<sup>[55]</sup>. As indicated above, chemokine and chemokine receptor interactions are complex and are connected to multiple combinations of effector proteins and divergent intracellular signaling pathways (Figure 1).

### Effects of chemokines on tumor cell proliferation

Many growth factors and cytokines act to control cell proliferation, either in a positive or a negative manner<sup>[56]</sup>. For example, epidermal growth factor (EGF) and related family members activate the EGF receptor (EGFR) and initiate divergent biochemical cascades that result in transcription of genes involved in cell cycle progression and other processes necessary for growth. In contrast, transforming growth factor-beta negatively regulates epithelial cell growth by inhibiting cell cycle transit. Signal transduction pathways regulated by these and other growth factors frequently become altered during tumorigenesis, resulting in deregulated cell growth. It has now become clear that deregulated function of multiple chemokines also contributes to enhanced tumor cell proliferation.

The ELR<sup>+</sup> CXC-chemokines play important roles in melanoma cell growth<sup>[57,58]</sup>. CXCL1 has also been implicated in non-melanoma skin cancers, including tumors of neural origin and squamous cell carcinomas. Zhou *et al*<sup>[59]</sup> demonstrated that CXCL1 is highly expressed in anaplastic astrocytomas *in vivo*, and reported that this enhanced cell growth, motility, adhesion to extracellular matrix, and invasion *in vitro*, as well as enhanced aggressiveness *in vivo*. Constitutive expression of CXCL1 in squamous cell carcinomas results in formation of an autocrine growth loop through the CXCR2 receptor, while overexpression of CXCL1, CXCL2 and CXCR2 in esophageal cancer also enhances proliferation<sup>[60]</sup>. Furthermore, it was found that CXCL2 activates signal transduction through an ERK dependent pathway<sup>[61]</sup>.

Transcriptional upregulation mediated through nuclear factor  $\kappa$ B (NF $\kappa$ B)-dependent pathways has been reported to be largely responsible for the enhanced levels of CXCL1 in tumor cells. The tumor promoter okadaic acid, which inhibits protein phosphatases and results in hyperphosphorylation of proteins at serine and threonine residues, activates transcription through two response elements in the CXCL1 promoter, utilizing three distinct NF $\kappa$ B subunits (p65, p52 and c-Rel)<sup>[62]</sup>. Upregulation of NF $\kappa$ B by the upstream NF $\kappa$ B-inducing kinase is also an important mechanism by which CXCL1 is upregulated<sup>[63]</sup>. NF $\kappa$ B-dependent induction of CXCL1 is further regulated by poly (ADP-ribose) polymerase-1 (PARP-1). In-

active PARP-1 binds to the CXCL1 promoter and blocks transcription by excluding NF $\kappa$ B. However, activation of PARP-1 causes its promoter binding ability to be lost leading to NF $\kappa$ B upregulation of CXCL1. In melanoma cells, PARP-1 is highly expressed and active<sup>[64]</sup>, and may be a major contributor to melanoma cell proliferation *via* chemokine-dependent mechanisms, together with constitutively expressed NF $\kappa$ B.

### Chemokines in tumor cell migration, invasion and homing

In terms of cancer metastasis, chemokine-dependent mechanisms for targeting to specific secondary sites is now widely recognized after studies showed upregulation of CXCR4 and CCR7 in breast cancer cells and that activation of these receptors could induce actin polymerization, migration and invasion<sup>[19]</sup>. Importantly, ligands for these receptors were shown to be expressed in organs that represent the primary sites for breast cancer metastasis, strongly suggesting that ligand-receptor "homing" functions *in vivo* to target tumor cells to sites of secondary growth. Organ-specific metastasis has been reported for different tumor types, including breast<sup>[65]</sup>, ovary<sup>[46]</sup> and epidermoid carcinomas<sup>[60]</sup>. Further, more than twenty tumor types have been documented to overexpress CXCR4<sup>[66]</sup>. Upregulation of CXCR4 expression in tumor cells through the action of VEGF also appears to be an important mechanism to further enhance invasiveness<sup>[67]</sup>.

CXCR4/CXCL12 overexpression is associated with metastasis to lung, liver, lymph nodes and bone marrow. Rearrangement of the actin cytoskeleton and alteration in cell polarity are fundamental processes required for cell motility, regulated at least in some cases by CXCL12-CXCR4 pathways<sup>[68]</sup>. CXCL12-CXCR4 signaling may also contribute to tumor progression by upregulating protease expression. In prostate cancer cells, various MMPs were shown to be modulated by CXCL12<sup>[69]</sup>. However, these effects were not consistent for all cell lines examined, suggesting that cell-specific factors may influence the response to CXCL12. In glioma cells, CXCL12 induced expression of MMP15 but not gelatinases. RNA interference studies proved that glioma cell invasiveness *in vitro*, and tumor aggressiveness *in vivo*, is due to the upregulation of MMP15 by CXCL12<sup>[70]</sup>. Chemokine-receptor interactions in skin, as a frequent metastatic site of malignant melanoma, may be another example: CCL27 is highly expressed in skin and the CCR10 receptor for this ligand is frequently upregulated in melanoma cells<sup>[71,72]</sup>.

Furthermore, mounting evidence points to cancer-associated stromal fibroblasts playing important roles in modulating tumor cell behaviour<sup>[73,74]</sup>. As p53 mutation or loss has been shown to occur in stromal cells<sup>[75,76]</sup>, this may upregulate CXCL12 and enhance proliferation and motility<sup>[77]</sup>.

### Chemokines and tumor cell survival

The majority of metastatic tumor cells fail to colonize secondary lesions successfully, most likely due to induction of programmed cell death<sup>[78]</sup>. For metastasized lesions to grow, enhancement of growth factors as well as

positive molecular interactions with surrounding cells in the lymph node or other organs are indispensable. For example, EGFR signaling can activate survival pathways regulated by protein kinase B (AKT)<sup>[79]</sup>. However, despite the presence of available growth factors, tumor growth at the secondary lesion may still be uncertain: it may also require other factors and/or pathways in order for cells to survive and proliferate. Studies have also shown that resistance to cell death induced by loss of attachment to the extracellular matrix (anoikis) is an important element at least for certain tumors<sup>[80]</sup>. Interestingly, some chemokine-receptor combinations, such as CXCL5-CXCR2<sup>[48]</sup> and CCL19/21-CCR7<sup>[81]</sup>, can activate PI-3K and AKT, key regulators of cell survival. Thus, interaction of chemokines with their receptors could play roles in multiple and complex biological processes that are important for successful survival in metastasized locations. For example, CCL2 is well known for regulating cell migration and is a key mediator of breast cancer cell migration<sup>[82]</sup>. Also using breast cancer cell lines, Fang *et al.*<sup>[83]</sup> demonstrated enhanced cell migration and survival along with increased phosphorylation of Smad3 and mitogen-activated protein kinases (MAPKs) in response to CCL2 and, moreover, they found that levels of the innate receptor CCR2 were elevated in breast cancers, accompanied with CCL2 expression. These investigators also suggested that MAPK and Smad3 signaling function as an independent/alternative mechanism for cell survival. Furthermore, they showed that CCL2-induced Smad3 signaling through MAPKs regulates expression and activity of Rho GTPase, thereby facilitating breast cancer cell motility and survival. Therefore, beyond well-described canonical chemokine ligand/receptor signaling, new molecules may need to be considered as critical players in chemokine signaling in cancer. The CXCL12-CXCR4 signaling pathway has been shown to be important for the survival of leukemic B cells in chronic lymphocytic leukemia (CLL) through activation of AKT and ERK1/2<sup>[84,85]</sup>. Moreover, O'Hayre *et al.*<sup>[86]</sup> recently identified additional molecular targets and novel phosphoproteins as possible mechanisms for cell survival in CLL. Amongst these is programmed cell death factor 4, found in all CLL cells examined, and also heat shock protein 27, which mediates anti-apoptotic signaling and has previously been linked to chemotherapeutic resistance, which was detected in a subpopulation of CLL patients. If the roles of these cell-survival-related proteins are supported by further future studies, it may be worth considering identifying these and other phosphoproteins whose functions are modified by certain chemokines in specific pathological conditions, such as cancer and/or inflammation in gastrointestinal disease.

### Chemokines and angiogenesis

Development of microvessels is another critical event that enables oxygen delivery and nurtures tumor cell survival at both primary and secondary sites<sup>[87]</sup>. Recently, intensive studies in normal angiogenic development using mouse model systems have revealed the importance of the angiogenic chemokine CXCL12 for the organized

development of vessel branching along with neural development (<https://intramural.nhlbi.nih.gov/labs/labsn/pages/publications.aspx>). Furthermore, Komatsu *et al.*<sup>[88]</sup> reported the importance of the small-G protein R-Ras for the development of abnormal collateral capillary systems which may play critical roles in the survival of localized tumors by supporting nutrient and oxygen delivery<sup>[89]</sup>. Nonetheless, it remains unclear how the tumor cells, which express chemokine receptors, respond to chemokines released from these pathological vessels, which are inherently "leaky". Several different chemokines are known to be pro-angiogenic, notably CXCL5 and CXCL8. Koch *et al.*<sup>[90]</sup> clearly demonstrated that CXCL8 could induce neovascularization in a rabbit corneal pocket assay. Furthermore, they also showed that the angiogenic activity present in conditioned media derived from macrophages or monocytes from rheumatoid synovial tissues was dependent upon CXCL8. Indeed, macrophages have been reported to induce malignant progression in a breast cancer model by initiating the angiogenic switch<sup>[91]</sup>. Additionally, CXCL8-CXCR2 signaling facilitates migration and proliferation of endothelial cells<sup>[92]</sup>, and the AKT pathway is important for GPCR-dependent angiogenesis<sup>[93]</sup> following CXCR1 and CXCR2 activation<sup>[49,81]</sup>. Also, the human herpesvirus-8, an etiological agent of the highly vascular Kaposi's sarcoma, induces expression of CXCL8<sup>[94]</sup>, providing further evidence for chemokine involvement in tumorigenesis<sup>[95]</sup>.

Notably, in contrast to the ELR<sup>+</sup> chemokines discussed above, most ELR<sup>-</sup> chemokines have anti-angiogenic or angiostatic activity<sup>[96]</sup>. Among these, CXCL9, CXCL10 and CXCL11 are inducible by other cytokines, including members of the IL family and interferons. The angiostatic response of these cytokine-inducible chemokines is mediated through the CXCR3 receptor, found on the surface of endothelial cells<sup>[97]</sup>. Specifically, an alternatively spliced variant of the receptor - CXCR3B - has been shown to mediate this activity<sup>[98]</sup>. In addition to inhibiting endothelial cell migration, these chemokines also block proliferation. A further critical review focused on the development of tumor angiogenesis is available<sup>[99]</sup>.

## CHEMOKINES IN DIGESTIVE SYSTEMS/ DEVELOPMENT AND PROGRESSION

Compared to normal cells, many cancer cells overexpress chemokine and chemokine receptors. Ligation of overexpressed chemokine receptors on tumor cells and the specific chemokines released from target organs seem to be critical regulators of metastasis<sup>[19,100]</sup>. As outlined above, chemokines and their receptors play various important roles in the regulation of invasion, metastasis and dissemination of cancer cells. Here we review chemokine/chemokine receptor interactions, specifically in digestive organs.

### Oral cavity

In the head and neck region, which includes oral cavity,

**Table 1** Ligand specificity of chemokine receptors implicated in gastrointestinal disease

| CC-chemokines |                    | CXC-chemokines |                 | CX <sub>3</sub> C-chemokine |                     |

pharynx, larynx, nasal cavity and paranasal sinuses, the head and neck squamous cell carcinoma (HNSCC) accounts for more than 90% of malignant neoplasms<sup>[101]</sup>. Despite intensive efforts, survival rates have shown limited improvement over the decades. When primary tumor location is taken into account, the outcome can be even worse, with advanced hypopharyngeal tumors having a 4% five-year survival<sup>[102]</sup>. Metastasis of HNSCC is generally *via* the lymphatic system to loco-regional sites. Recently, several different chemokines were shown to be highly expressed in HNSCC derived cell lines and patient tumor samples. For example, in a series of 94 HNSCCs, CXCL1 was found to be overexpressed in around 40% of lesions<sup>[103]</sup>. Measurement of microvessel density (MVD) in HNSCCs revealed a correlation between CXCL1 expression and angiogenic activity, as well as with nodal metastasis and infiltration of leukocytes. CXCL8 has long been recognized to participate in autocrine (and possibly paracrine) regulation of HNSCC proliferation<sup>[60]</sup>. Recent studies using global gene expression profiling of primary and synchronous metastatic HNSCC further support previous reports of CXCL8 upregulation<sup>[104]</sup>. Along with this observation, Chen *et al.*<sup>[105]</sup> reported that hydrogen sulfide produced by *Porphyromonas gingivalis* bacteria in the oral cavity induced expression of CXCL8 in gingival and oral epithelial cells. Potentially, this may provide a link between tumor development and the induction of inflammation in periodontal disease, which is associated with persistent bacterial infection, and similar results to this study have also been reported<sup>[106]</sup>.

In addition to CXCL8, another ELR<sup>+</sup> angiogenic chemokine, CXCL5, is highly expressed in some HNSCCs. Data suggest that CXCL5 enhances tumor development by stimulating proliferation, cell motility and invasion<sup>[107]</sup> as knockdown of CXCL5 by siRNA completely inhibited tumorigenicity in a mouse xenograft model.

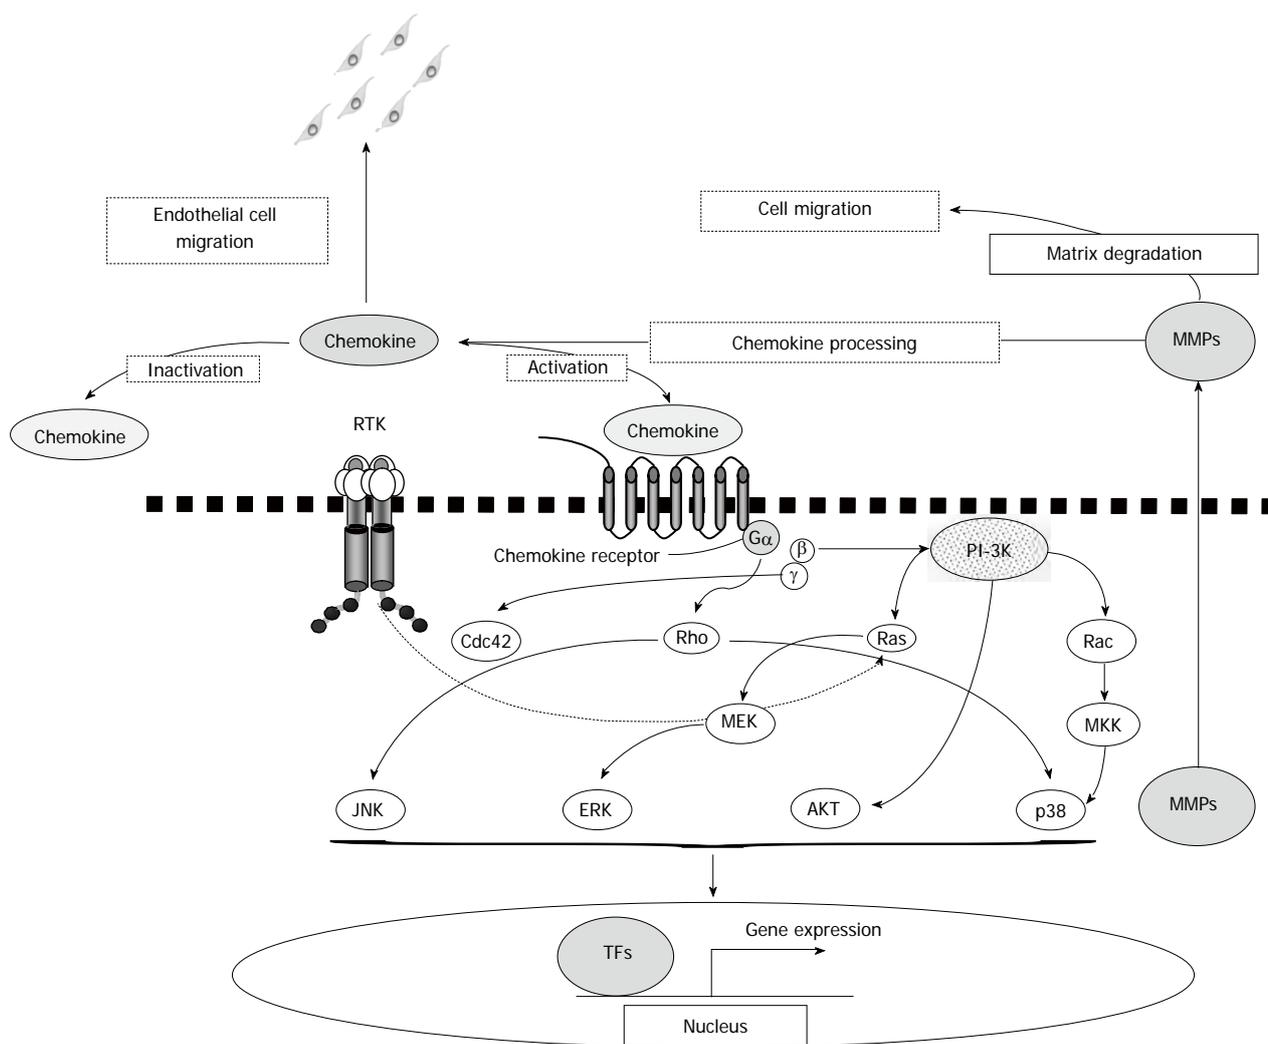

Furthermore, Delilbasi *et al.*<sup>[108]</sup> reported upregulated

CXCR4 expression in squamous carcinomas of the tongue by an immunohistochemical method. Of interest, their experiment exhibited no difference in expression between primary tumors of early and more advanced stage, although invading cells and those which had metastasized to lymph nodes exhibited higher CXCR4 expression, suggesting *in vivo* selection for this phenotype with malignant progression. Clatot *et al.*<sup>[109]</sup> also studied the possible correlation of CXCL12/CXCR4 expression and tumor recurrence and survival in HNSCC patients. They found no meaningful correlation between CXCR4 expression and either recurrence or survival, but a significant difference in CXCL12 expression. Further prospective studies are required to clarify this.

The loss of CCR6 expression in metastatic lesions with concomitant elevation of CCR7 in some HNSCCs was also documented<sup>[110]</sup>. CCL19 and CCL21, ligands for CCR7, induced migration of metastatic cells *in vitro*, whereas primary tumor cells responded to the CCR6 ligand, CCL20. Together, these data suggest that CCR7 upregulation might play a role in targeting tumor cells to sites of secondary growth *in vivo*, by facilitating entry into the lymphatic system and migration to regional lymph nodes. CCR7 signal transduction was also shown to activate cellular invasion and pro-survival pathways by PI-3K and PLC $\gamma$ -dependent, but EGFR-independent, mechanisms<sup>[111]</sup>.

### Esophagus

In the esophagus, several cytokines and chemokines are reported as possible mediators of gastroesophageal reflux, esophagitis, pre-cancerous change (typically Barrett's esophagus) and adenocarcinoma<sup>[112]</sup>. Amongst these, CXCL8 is reported as a molecular marker indicative of response to therapeutic procedures. For example, Oh *et al.*<sup>[113]</sup> compared the expression level of CXCL8 between pre- and post-operation of Nissen fundoplication in reflux esophagitis. They found that CXCL8 expression was significantly reduced postoperatively, as measured by quantitative real-time polymerase chain reaction (qRT-PCR). These authors also reported that CXCL8 expression was higher in patients with reflux compared to those without reflux. Furthermore, they found that patients with the highest CXCL8 expression were those with Barrett's dysplasia and adenocarcinoma. Chemokines and several other cytokines, such as ILs, CXCL8, and VEGFs were found to be upregulated in cancer-related cachexia, although the underlying mechanism is not understood<sup>[114]</sup>. Moreover, chemokine expression in tumors is complicated. Verbeke *et al.*<sup>[115]</sup> screened 51 patients operated on for colon adenocarcinoma, esophageal adenocarcinoma, or esophageal squamous cell carcinoma (SCC) by immunohistochemical staining to examine the expression of CXCL4L1, CXCL8, CXCL10, CXCL12, and VEGF. According to their study, the angiostatic chemokine CXCL4L1 was strongly expressed in colorectal cancer, while there was weaker expression in esophageal cancer. CXCL12 staining was almost negative in esophageal SCC, while stronger staining was observed in adenocarcinoma of the esophagus and colon. VEGF was moderately-to-strong-

**Figure 1 Chemokine-induced signal transduction pathways.** Schematic representation of signaling pathways activated by binding of chemokine ligands to their seven transmembrane G-protein coupled receptors. MMPs: Matrix metalloproteinases; TFs: Transcription factors; RTK: Receptor tyrosine kinase; ERK: Extracellular signal-regulated kinase; MEK: Mitogen-activated protein/extracellular signal-regulated kinase kinase; PI-3K: Phosphatidylinositol-3-OH kinase; MKK: Mitogen-activated protein kinase kinase; JNK: c-Jun N-terminal kinase; AKT: Protein kinase B.

ly positive in all 3 types of cancer, but relatively weaker in esophageal adenocarcinoma. Interestingly, not only was the expression of the angiogenic chemokines CXCL8 and CXCL12 heterogeneous in the samples, but so was the expression of the angiostatic chemokines CXCL10 and CXCL4L1. Based on these results, the roles of chemokines are likely complex in these tumors<sup>[115]</sup>. Recently, *in vitro* and *in vivo* studies using AMD3100, a pharmacological CXCR4 inhibitor, and the human HER2 inhibitor, trastuzumab, have indicated CXCR4 to be a positive regulator of human epidermal growth factor receptor 2 (HER2) expression in esophageal cancer. In this study, the authors also suggested a possible complex relationship between HER2 and CXCR4 in tumor development and metastasis<sup>[116]</sup>. These observations indicate further the involvement of multiple chemokines in molecular events that underpin different stages of cancer development.

### Stomach

In gastric cancer treatment, detection at an early stage of

tumor development is still the most effective curable approach. Amongst different types of gastric cancer, peritoneal dissemination is one of the most incurable conditions and no radical and effective treatment is available to date. Hashimoto *et al*<sup>[117]</sup> showed that the CXCL12/CXCR4 axis is important in peritoneal dissemination of gastric cancer cells. They found that CXCL12 ligation to CXCR4 on the cancer cell surface strongly and rapidly activates AKT-mammalian target of rapamycin signaling and co-activates production of other metastatic mediators, such as MMPs<sup>[117,118]</sup>. Graziosi *et al*<sup>[119]</sup> also suggested possible involvement of the p38 MAPK pathway in the development of peritoneal dissemination. Using an *in vivo* mouse system and administering p38 MAPK inhibitors ML3403 or SB203580, they observed decreased tumorigenesis. Microarray studies using these cancer cells identified several downregulated genes, such as CXCR4, fms-related tyrosine kinase 4, non-receptor spleen tyrosine kinase and collagen  $\alpha 2(IV)$ . Interestingly, p38 MAPK inhibitors induced significant downregulation of multidrug resistance-1 gene expression, a well-

defined marker of resistance to chemotherapy, which possibly induced susceptibility to the cisplatin treatment in this model<sup>[119]</sup>. In a separate study, Zhi *et al.*<sup>[120]</sup> examined the expression of CXCL12 in normal gastric tissue, gastric cancer cell lines, 35 primary gastric carcinomas and corresponding normal gastric tissues. They found that CXCL12 was downregulated in gastric cancer cell lines and patient samples of primary gastric carcinomas compared to normal samples. They provided evidence to show that CXCL12 expression was inversely associated with lymph node metastasis and histological grade. They concluded the possible cause of this downregulation of CXCL12 expression to be hypermethylation of the CXCL12 promoter, as treatment of highly metastatic cancer cell lines with a demethylating agent impaired its invasive phenotype<sup>[120]</sup>. One possible explanation for this reduction in CXCL12 might be to permit CXCR4-expressing gastric cancer cells to sense a CXCL12 gradient from target lymph nodes or other organs, which would otherwise be masked by CXCL12 expressed by the cancer cells. Together, these reports suggest that the peritoneal dissemination may be induced by the dissemination of CXCR4-expressing gastric cancer cells directed into the peritoneal area, which expresses high levels of CXCL12. Therefore, blocking molecular targets such as AKT and/or CXCR4 could be possible treatment strategies to prevent the activation of signaling events induced by CXCR4 ligation mediated by CXCL12 on the cancer cell surface. Moreover, preventing peritoneal dissemination itself might be possible by developing specific inhibitors that prevent binding between CXCR4 and its ligand. In this regard, Manu *et al.*<sup>[121]</sup> investigated plumbagin, which is a CXCR4 expression inhibitor, and it was widely effective in downregulating CXCR4 expression in cancer cell lines irrespective of the tissue of origin. The suggested mechanism of CXCR4 downregulation by plumbagin is through inhibition of NF $\kappa$ B. However, regulation of CXCR4 expression in cancer cells may not be so straightforward as initially expected. Bao *et al.*<sup>[122]</sup> found that HER2, which is frequently overexpressed in gastric cancer, interacts with CD44 and induces CXCR4 expression by blocking expression of microRNA-139. Additionally, EGF signaling may play an important synergistic role in concert with the CXCL12/CXCR4 axis in gastric cancer metastasis, as Yasumoto *et al.*<sup>[123]</sup> found that the EGFR ligands amphiregulin and heparin-binding EGF (HB-EGF)-like growth factor, as well as CXCL12, are highly expressed in malignant ascites. Their work showed that HB-EGF and CXCL12 together enhanced tumor necrosis factor  $\alpha$ -converting enzyme-dependent amphiregulin shedding from human gastric carcinoma (NUGC4) cells, which can promote proliferation of NUGC4 cells in animal models. These experiments strongly imply the possibility that several cancer signaling pathways besides the CXCL12/CXCR4 axis are important for development of gastric cancer metastasis.

When they screened 40 gastric cancer patient samples, Zhao *et al.*<sup>[124]</sup> found that CXCR4 mRNA levels were significantly higher in cases with lymph node metastasis than

those without; they also found that the CXCR4 protein level was correlated with poorly differentiated lesions, more advanced tumor stage and lymph node metastasis. Further, they reported higher CXCL12 mRNA in lymph nodes in patients with metastatic gastric cancer. Ingold *et al.*<sup>[125]</sup> used qRT-PCR to screen CXCL12/CXCR4 mRNA levels in 37 gastric carcinomas, and as well as screening protein levels in 347 gastric carcinomas and 61 matching lymph node metastases using tissue microarrays. They concluded that tumors expressing both CXCL12 in tumor cells and CXCR4 in adjacent microvessels showed a strong correlation with local tumor development and Union for International Cancer Control stages.

Another interesting study recently reported by Xu *et al.*<sup>[126]</sup> describes the possible activation of lymphangiogenesis pathways in gastric cancer by CXCL1 secretion. A technique was established in an animal model for recovery of lymphatic endothelial cells (LECs) from afferent lymph vessels of sentinel lymph nodes, and the gene expression profile between normal LECs and LECs with lymph node metastasis was compared using microarray analysis. They found that CXCL1 stimulated LEC migration and tube formation through FAK-ERK1/2-RhoA activation and reorganization of F-actin. Importantly, it is well known that CXCR2 expression, which is a CXCL1 receptor, is positively correlated with tumor, node, and metastasis (TNM) stage and lymphatic vessel density<sup>[127-130]</sup>. Thus, this study may strongly imply a role for CXCL1 in metastasis mediated through effects on LECs. CXCL8 has also been well studied in gastric cancer development. Using the gastric cancer cell line SCG-7901, Ju *et al.*<sup>[131]</sup> found that CXCL8 can enhance several tumor parameters, such as adhesion to endothelial cells, migration, and invasion. The expression of MMP9, intercellular adhesion molecule (ICAM)-1 and E-cadherin was upregulated in a dose-dependent manner. However, CXCL8 did not affect the proliferation of SCG-7901 cells under these conditions. Several groups have studied polymorphism of the CXCL8 251 allele. Wang *et al.*<sup>[132]</sup> reported the CXCL8 251 allele AA genotype as a risk factor for gastric cancer in Asian groups but not in Caucasian or Mexicans. Furthermore, statistical analysis revealed that the TA and AA polymorphism is significantly associated with the diffuse type of gastric cancer, and the AA genotype was found to be a risk factor for gastric cardia cancer. Song *et al.*<sup>[133]</sup> reported screening results of this allele in *Helicobacter pylori* (*H. pylori*)-infected Korean populations. They found a significant correlation between MMP9 and disease progression in the AA and AT genotype. Angiopoietin-1, which plays an important role in vascular development, showed upregulation, but not VEGF expression or disease progression in the AA genotype. They predicted that the CXCL8 251 AA genotype may be associated with angiogenesis in gastric carcinogenesis in the *H. pylori*-infected population. Vinagre *et al.*<sup>[134]</sup> reported that interaction between CXCL8 251 (AA and AT) allele mutation carriers and the infection of *H. pylori* strain [phosphoinositide PI4, 5P(2) binding protein (s1m1)

cytotoxin-associated gene A product (*cagA*) positive] may have higher risk for development of gastric adenocarcinoma. In addition, Schneider *et al.*<sup>[135]</sup> pointed out the complexity and difficulty in selecting *in vitro* epithelial study models to understand the molecular mechanisms of *H. pylori* infection. Moreover, a meta-analysis carried out by Liu *et al.*<sup>[135]</sup> indicated that the variable results reported by many different studies can be affected by differences of histological type, tumor location, *H. pylori* infection, ethnicity and geographic location<sup>[136]</sup>. Another CXC chemokine, CXCL5, was also reported recently to be a potential molecular marker for cancer development, especially for late stage gastric cancer<sup>[137]</sup>. However, it is not yet confirmed if this observation is a consequence of secondary change as a result of gastric cancer progression, or whether it is one of the primary molecular events leading to tumor development. As CXCL5 is linked to tumor development in other organs<sup>[77,107,138]</sup>, further confirmation is needed through the use of *in vitro* and *in vivo* model systems in the future. Yanagie *et al.*<sup>[139]</sup> performed a comparative analysis of differential gene expression related to chemokines/chemokine receptors and cytokines in established gastric cancer cell lines using a cDNA microarray approach. They found that CC-chemokines CCL2, 5, 21 and CXC-chemokines CXCL1, 7, 8, 12, 14 and chemokine receptor CCR6 were upregulated, while CCL3 and CCL25 were downregulated. These chemokines and their receptors may be potential candidates for cancer diagnosis and/or treatment.

Collectively, in gastric cancer development and metastasis, multiple chemokines likely play important roles. Further studies are required to elucidate the many functional roles of these chemokines, especially in synergistic regulation of the signaling pathways that control development of gastric cancers. Another detailed review on the role of chemokines in esophageal and gastric cancer is available<sup>[140]</sup>.

### Liver

The liver is one of the major metastatic targets of colon cancer and this attributes directly to patient mortality. Many molecules have been proposed as being responsible for the development of hepatic metastases, and accumulated data suggest there are several important signaling pathways involved in the development of both primary and metastatic liver cancer. Among them, the CXCL12-CXCR4, CX3CL1-CX<sub>3</sub>CR1, and the CCL20-CCR6 axes have received much attention<sup>[141]</sup>.

CXCR4 has been found to be a prognostic marker in various types of cancer as it plays an important role in normal stem cell homing. Cancer stem cells also express CXCR4, which implies that this axis may control the trafficking and metastasis of these cells to organs that express CXCL12, and the liver is one of these<sup>[142]</sup>. Recently, Li *et al.*<sup>[143]</sup> reported that the expression of CXCR4 was higher in portal vein tumor thrombus tissue than hepatocellular carcinoma (HCC), and lentivirus-mediated siRNA knockdown of CXCR4 was shown to impair the potential invasiveness of tumor thrombus cells significantly. By

screening tissues from 42 HCC patients, including tumor and adjacent regions, and comparing to tissues from cancer-free individuals, Liu *et al.*<sup>[128]</sup> found that CXCR2 mRNA was significantly higher in HCC than in adjacent or normal liver tissues. Interestingly, TNM staging was not correlated to the level of CXCR2 mRNA but the protein level was relevant to staging, as protein was markedly higher in lesions classified as Stage III/IV. CXCR2 mRNA and protein levels were correlated with intrahepatic metastasis, portal cancer embolus, and low differentiation. Other studies recently reported a possible therapeutic use of CCL2 for prevention of HCC metastasis. In a model of HCC, coupling adenovirus-based CCL2 and the thymidine kinase/ganciclovir expression was shown to prevent intrahepatic metastasis *in vivo*. This combination was also shown to induce an innate immune response involving monocytes/macrophages and NK cells, leading to prolongation of anti-metastatic effects<sup>[144-146]</sup>. CCL2 was also identified by Chen *et al.*<sup>[147]</sup> as a potential target for development of future HCC treatment. Using the recombinant foot-and-mouth disease virus capsid protein VP1 (rVP1), they were able to induce apoptosis of HCC cell lines through deactivation of the AKT pathway and stimulation of caspase cascades *via* Bax. Furthermore, rVP1 downregulated the expression of CCL2 in an AKT-dependent manner, which can support the survival and migration of HCC tumor cell lines<sup>[147]</sup>. CXCR7, a CXCL12 receptor, has also been reported to be upregulated in HCC<sup>[148]</sup>. In another study, shRNA knockdown of CXCR7 expression was found to inhibit many facets of tumor development, such as cell invasion, adhesion, VEGF secretion, endothelial tube formation and tumor growth, although it did not affect metastasis *in vivo*<sup>[149]</sup>. CXCR4, an alternative receptor to CXCR7 for CXCL12, is known to play important roles in liver metastasis. CXCL12 is expressed by endothelial cells and likely by Kupffer cells lining the liver sinusoids. The binding of CXCL12 to CXCR4 activates Rho, Rac and Cdc42, enabling tumor cell extravasation without affecting cell adhesion<sup>[150]</sup>.

In addition to direct roles in cancer development, chemokines make important contributions to chronic inflammatory diseases such as chronic hepatitis, which can be a possible precancerous condition. In chronic hepatitis, regulation of lymphocyte motility is controlled by several independent biochemical pathways. However, these signaling events are not well elucidated despite well-documented observations of lymphocyte recruitment to tissues *via* endothelium. Holt *et al.*<sup>[151]</sup> suggested that activated human liver myofibroblasts (aLMF) affect the migration and accumulation of lymphocytes within the inflamed liver. Also, when cultured *in vitro*, aLMF from inflamed human livers and hepatic stellate cells from non-inflamed livers secrete a distinct profile of cytokines and chemokines. The aLMF-conditioned media had chemotactic activity for lymphocytes, which was partially inhibited by pertussis toxin, implying a requirement for GPCR signaling. Additionally, contribution of GPCR-independent lymphocyte chemotaxis by IL-6, hepatocyte growth factor, and VEGF was also reported<sup>[151]</sup>.

## Pancreas

As a multitude of studies expand our knowledge of pancreatic disease, the important role of chemokines in the development of pancreatic cancer is becoming evident. CCL20 is well known for its expression in various human cancers<sup>[152-155]</sup>. In pancreatic adenocarcinoma (PAC) patients, CCL20 mRNA and protein expression was found to be significantly associated with advanced T-stage<sup>[154]</sup>. It is interesting that CCR6, a canonical CCL20 receptor, is upregulated in chronic pancreatitis, pancreatic cystadenoma and pancreatic carcinoma compared to controls<sup>[154]</sup>. It has also been reported that, in metastatic pancreatic carcinoma, expression of the angiogenic chemokines CXCL5 and CXCL8 is highly elevated compared to pancreatic cystadenoma or chronic pancreatitis<sup>[138]</sup>. This observation suggests a potential contribution of these chemokines to the development of metastatic pancreatic cancer. Furthermore, another report suggests that CXCL5 may be a possible prognostic biomarker for pancreatic cancer. Li *et al.*<sup>[156]</sup> reported that overexpression of CXCL5 is correlated with poorer tumor differentiation, advanced clinical stage, and shorter patient survival. These authors also performed xenograft assays in nude mice, in which they used shRNA downregulation of CXCL5 or antibody-mediated neutralization of CXCR2 and showed attenuation of pancreatic tumor cell growth. They also demonstrated that CXCL5 derived angiogenesis development was ERK, AKT and signal transducer and activator of transcription mediated signaling pathways<sup>[156]</sup>. Moreover, in a clinical study that analyzed 52 PACs and 52 pancreatic neuroendocrine tumors, Hussain *et al.*<sup>[157]</sup> found that expression of CXCL8 and its receptors CXCR1/2 were significantly upregulated compared to normal pancreatic tissues, a finding confirmed by immunohistochemistry and qRT-PCR. This may suggest the existence of autocrine and/or paracrine loops that contribute to the development of these tumors. As in other organs, many reports have suggested the importance of the CXCL12-CXCR4 axis in the development of pancreatic cancers. Cui *et al.*<sup>[158]</sup> compared expression of CXCL12 and CXCR4 between tumor and surrounding tissues. In tumor tissues, CXCL12 expression was significantly lower than that found in paracancerous tissues, normal pancreas, or lymph nodes. In contrast, CXCR4 expression in cancerous tissues was significantly higher than that in normal tissue. Furthermore, expression patterns of the CXCL12/CXCR4 and clinicopathological status showed a strong correlation, including lymph node metastasis. Additionally, CXCL12 expression was significantly associated with MVD but not with microlymphatic vessel density, while CXCR4 expression showed the opposite relationship<sup>[158]</sup>. These observations imply a significant role for CXCL12/CXCR4 signaling in the development and progression of metastatic pancreatic cancer. Also, in another study, samples from 249 PAC patients were screened by immunohistochemistry and tissue microarray for expression of innate CXCL12 receptors CXCR4 and CXCR7. Expression of CXCR7 was found to be associated with tumor grade, inversely associated

with tumor size, and possibly associated with tumor progression and differentiation<sup>[159]</sup>. Interestingly, though, no significant correlation was found between CXCR4 expression and clinicopathological parameters, which may seem to be inconsistent with previous reports<sup>[158]</sup>. However, this may be a manifestation of different mechanisms of pathogenesis. Together with these observations, data from many studies suggest CXCL12-CXCR4 signaling may be a rational therapeutic target to prevent the development and metastasis of pancreatic tumors<sup>[160,161]</sup>. For example, the activation of this axis can be attenuated by suppressing NF $\kappa$ B activity<sup>[162]</sup>. In pancreatic cancer, CX<sub>3</sub>CL1 and its cognate receptor CX<sub>3</sub>CR1, is another possible ligand-receptor combination associated with the pathogenesis of pancreatic cancer. Marchesi *et al.*<sup>[163,164]</sup> reported involvement of CX<sub>3</sub>CR1 in perineural invasion and dissemination of neoplastic cells along intra- and extra-pancreatic nerves. Use of CX<sub>3</sub>CR1 as a possible therapeutic candidate is discussed in detail elsewhere<sup>[165]</sup>. Pancreatic cancer is one of the most aggressive and intractable malignancies amongst all cancers<sup>[166]</sup>. Therefore, finding molecular markers to facilitate accurate diagnosis at early stages of disease is an urgent need. From the evidence available, several chemokine-receptor pairs may be good candidates. A combination of several markers, together with these chemokines, may be promising diagnostic tools, such as CXCL17-ICAM2<sup>[167]</sup> and a classical molecular marker for pancreatic cancer, carbohydrate antigen 19-9, together with CXCL7<sup>[168]</sup>.

## Small and large intestine

Inflammatory bowel disease (IBD) is a chronic inflammatory condition of the colon and small intestine. It is now considered that chemokine-mediated chronic inflammation is a direct cause of colitis-associated cancer (CAC). However, the underlying mechanism of CAC is complex and not well elucidated. CC-chemokines and their receptors have long been recognized as key players in tumor promotion and progression during the course of chronic colitis. In several reports, expression of CC-chemokines, including CCL2, is highly upregulated in the colonic mucosa of IBD patients, as well as in the azoxymethane and dextran sulfate sodium experimental colitis model system<sup>[169]</sup>. Observations in the D6 receptor knockout mouse provide another important example of the role of chemokines in IBD. D6 is a silent receptor known to bind to a wide array of pro-inflammatory chemokines promiscuously, including CCL2, 5, 8, 7, and 13 in humans. Compared to wild type mice, D6 knockout mice were found to be more susceptible to chemically-induced colitis and failed to recover from the colitis. This may be due to the lack of the D6 receptor, which usually sequesters overexpressed chemokines, failing to stop the development of symptoms<sup>[170]</sup>, and D6 plays a similar role in preventing liver injury<sup>[171]</sup>. Consistent with a suppressor role for D6, lymphatic vessels expressing D6 were demonstrated in epithelium and connective tissue of both small and large intestine<sup>[172]</sup>. Using a CCR2 knockout mouse or a CCL2 antagonist, Popivanova *et al.*<sup>[173]</sup> showed that

CCL2 is a crucial mediator of colon cancer development, as mice lacking CCL2 had reduced intracolonic macrophage infiltration and COX-2 expression, attenuated neovascularization, and reduced numbers and size of colon tumors.

B-lymphocytes collected from patients with Crohn's disease (CD) express toll-like receptor 2 (TLR2) at the cell surface and secrete high levels of CXCL8, and the clinical disease course is well correlated with CXCL8 expression<sup>[174]</sup>. In contrast, ulcerative colitis (UC) patients also express TLR2, but do not secrete CXCL8 in large amounts. However, CXCL8 is inducible in UC by stimulating TLR2 and its clinical activity correlates inversely with levels of circulating TLR2-positive B cells, converse to CD<sup>[174]</sup>. In a model of experimental colitis, it was shown that infection with *Bacillus polyfermenticus* (*B. polyfermenticus*) affects the biological responses of human intestinal microvascular endothelial cells, including cell migration, tube formation, and permeability through an NF $\kappa$ B/CXCL8 signaling axis<sup>[175]</sup>. Interestingly, this study also reported that *B. polyfermenticus* can accelerate the healing process of colitis by stimulating mucosal angiogenesis. Lopez *et al.*<sup>[176]</sup> found that *Lactobacillus rhamnosus* GG (LGG), a probiotic, can downregulate the flagellin-induced expression of CXCL8. Although the biological mechanisms of LGG in the maintenance of intestinal homeostasis are largely unknown, it is proposed that LGG may modulate induction of CXCL8 by tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) in the intestinal epithelium<sup>[176,177]</sup>. In colorectal adenocarcinoma cells HCT-116 and HCT-8, immunohistochemistry revealed that diverse stimuli can upregulate CXCL8 expression<sup>[115]</sup>, with upregulation of CXCL4L1 and synergistic CXCL8 and CXCL10 induction in carcinoma cells by IL-1 and TNF- $\alpha$  or immunoreactive fibronectin. In addition, full-length and N-terminally truncated (more active) CXCL8 was identified in HT-29 colorectal adenocarcinoma cells, as well as strong expression of CXCL4L1 and CXCL12 in patient samples<sup>[115]</sup>. Moreover, ERK2 and PI-3K/AKT have been identified as candidate pathways for induction of CXCL8 expression in HCT-15 colon cancer cells and MKN-45 gastric adenocarcinoma cells<sup>[178]</sup>.

Arijs *et al.*<sup>[179]</sup> reported that, in inflamed colonic IBD mucosa, many leukocyte/endothelial cell adhesion molecules (CAMs) and chemokines/chemokine receptors are upregulated, while E-cadherin gene expression was downregulated. Microarray analysis revealed that infliximab (an anti-TNF- $\alpha$  antibody) restores colonic gene expression of endothelial CAMs and most chemokines/chemokine receptors to normal levels of expression, with only CCL20 and CXCL1/2 expression remaining elevated after treatment. In addition to the previously identified 47 integrin-MADCAM1 axis, this study revealed a number of interesting targets for anti-adhesion therapy, including PECAM1, CXCL8, and CCL20, suggesting that anti-TNF- $\alpha$  therapy may work, at least in part, by downregulating certain CAMs<sup>[179]</sup>. Upregulation of CXCL1, CXCR1 and CXCR2 was reported by Oladipo *et al.*<sup>[180]</sup> in tumor epithelium compared to normal adjacent

tissue collected from patients with stage II and III CRC. In their analysis, no overall association between CXCL1, CXCR1 or CXCR2 expression and prognostic endpoints was found, although survival analysis demonstrated an inverse association between CXCL1 and recurrence-free survival in stage III patients. Interestingly, CXCL8 positivity in the tumor infiltrate correlated with earlier disease stage and improved relapse-free survival in multivariate Cox regression analysis<sup>[180]</sup>. Schroepf *et al.*<sup>[181]</sup> screened samples collected from 501 German patients with IBD (336 CD, 165 UC) including 258 children and 243 adults as well as 231 controls. They found CXCR3 pathway-related genes to be significantly overexpressed in inflamed colonic tissue of pediatric CD and UC patients. CXCL9, 10, and 11 are 3 innate ligands for CXCR3, and this study found a correlation between polymorphism in CXCL9 and pediatric CD, while carriers of the hetero- and homozygous genotype variants of CXCL11 rs6817952 were at increased risk for UC in all age groups. Thus, blockade of CXCR3 could be a possible therapeutic avenue in the future<sup>[181]</sup>. In a study using HT-29 colon cancer cells, Lee *et al.*<sup>[182]</sup> reported multiple regulatory roles of IL-17 on chemokine expression. Their results indicated a positive effect of IL-17 on chemokines that recruit neutrophils (CXCL8 and CXCL1) and Th17 cells (CCL20). Contrary to this, IL-17 represses expression of CXCL10, CXCL11, and CCL5, three chemokines that selectively recruit Th1 lymphocytes.

Collectively, these findings suggest that synergistic targeting of critical proteins such as chemokines and their receptors may lead to improved treatment outcomes for inflammatory bowel disease and cancer. Table 2 is attached as a summary of published studies related to chemokine/chemokine receptors and gastrointestinal diseases according to their description in this review.

## CHEMOKINE NETWORK AS A THERAPEUTIC TARGET

With the recent advances in understanding of the many and varied roles of chemokines and their receptors in tumor development and progression, together with the advent of targeted molecular therapies, excellent opportunities exist to develop novel approaches to treat cancer. This would appear to be of particular relevance for gastrointestinal malignancies, where radical improvements in clinical outcome have so far been elusive.

## CONCLUSION

It is clear that chemokine networks play critical roles in inflammatory diseases and cancer progression, and tumor cells may influence their own proliferation as well as affecting stromal and immune system cells, and *vice versa*. Therefore, the chemokine network makes an attractive target for therapeutic intervention in many tumor types, including those of the gastrointestinal tract. However, we need to define more selective and specific targets, to minimize systemic side effects during treatment.

**Table 2 Chemokines/chemokine receptors in this table appear sequentially according to their description in this review**

| Organ         | Chemokines and receptors | Possible role/observed phenomenon   |   |
|---------------|--------------------------|---|---|
| Oral cavity   | CXCL1                    | Angiogenic activity <sup>[103]</sup>  |   |
|               | CXCL8                    | Proliferation, metastasis, tumor development and the induction of inflammation in periodontal disease <sup>[60,104-106]</sup>   |   |
|               | CXCL5                    | Proliferation, cell motility and invasion <sup>[107]</sup>  |   |
|               | CXCR4                    | Enhancement of invasiveness <sup>[108]</sup>  |   |
|               | CXCL12                   | Upregulation in metastasis <sup>[109]</sup>   |   |
|               | CCR6, CCR7               | Involvement in metastatic activity <sup>[110]</sup>   |   |
|               | CCR7                     | Enhancement of invasion <sup>[111]</sup>  |   |
| Esophagus     | CCL20                    | Upregulated with bacterial infection in OSCC cell lines <sup>[152]</sup>  |   |
|               | CXCL8                    | Possible index of inflammation, upregulation in cancer-related cachexia <sup>[113,114]</sup>  |   |
|               | CXCR4                    | Positive regulator of HER <sup>[116]</sup>  |   |
| Stomach       | CXCL12, CXCR4            | Metastasis through activation of AKT-mTOR pathway and MMPs, upregulation in lymph node metastasis, strong correlation with tumor development <sup>[117,118,124]</sup>   |   |
|               | CXCR4                    | Enhancement of metastasis through p38 signaling pathway <sup>[119]</sup>  |   |
|               | CXCL12                   | Acquisition of invasive/metastatic phenotype, enhancement of proliferation when coexpressed with other molecules <sup>[120,123]</sup>   |   |
|               | CXCL1                    | Activation of lymphangiogenesis by stimulating LECs <sup>[126]</sup>  |   |
|               | CXCR2                    | Strong correlation with TNM staging and lymphatic vessel density <sup>[127-130]</sup>   |   |
|               | CXCL8                    | Enhancement of tumor development factors, and a possible risk factor as mutant, association with angiogenesis, development of gastric adenocarcinoma <sup>[132-134,183]</sup>   |   |
|               | CXCL5                    | Marker for late stage gastric cancer <sup>[137]</sup>   |   |
|               | Other candidates         | CC-chemokines (CCL2, 3, 5, 21, 25)/CXC-chemokines (1, 7, 8, 12, 14)/CCR6 <sup>[139]</sup>   |   |
|               | Liver                    | CXCR4   | Metastasis, upregulation in PVTT <sup>[142-143]</sup>   |
|               |                          | CXCR2   | Upregulation in HCC, especially in late stage <sup>[128]</sup>  |
| CCL2          |                          | Application to prevent metastasis, application to prevent HCC by deactivating AKT pathway <sup>[144-147]</sup>  |   |
| CXCR7         |                          | Upregulation in HCC, functional in tumor development and angiogenesis but not in metastasis <sup>[148-149]</sup>  |   |
| CXCL12, CXCR4 |                          | Enhancement of tumor cell extravasation through upregulation of Rho/Rac/Cdc42 <sup>[150]</sup>  |   |
| CCR6          |                          | Upregulation in metastasis <sup>[153]</sup>   |   |
| CCL20         |                          | Enhanced expression in HCC <sup>[155]</sup>   |   |
| D6 receptor   |                          | Prevention of liver injury <sup>[171]</sup>   |   |
| Pancreas      |                          | CCL20   | Associated with tumor staging <sup>[154]</sup>  |
|               |                          | CCR6  | Upregulated in chronic pancreatitis, pancreatic cystadenoma and pancreatic carcinoma <sup>[154]</sup> |
|               | CXCL5, CXCL8             | Upregulation in metastatic pancreatic carcinoma <sup>[140]</sup>  |   |
|               | CXCL5                    | Correlated with poorer tumor differentiation, advanced clinical stage, and shorter patient survival, and ERK, AKT and STAT mediated angiogenesis <sup>[156]</sup>   |   |
|               | CXCL8, CXCR1/2           | Upregulation in adenocarcinomas and neuroendocrine tumors <sup>[157]</sup>  |   |
|               | CXCL12, CXCR4            | Downregulation of CXCL12 and upregulation of CXCR4 in tumors. CXCL12 correlated with MVD but not with MLVD, while CXCR4 showed opposite pattern <sup>[158]</sup>  |   |
|               | CXCR4, CXCR7             | CXCR7 associated with tumor grade, inversely associated with tumor size, and possibly associated with tumor progression and differentiation but not with CXCR4 <sup>[159]</sup>   |   |
|               | CXsCL1, CX3CR1           | Perineural invasion and dissemination of neoplastic cells along intra- and extra-pancreatic nerves <sup>[163,164]</sup>   |   |
|               | CXCL17 (+ ICAM2)         | Diagnostic molecular marker <sup>[167]</sup>  |   |
|               | CXCL7 (+ CA19-9)         | Diagnostic molecular marker <sup>[168]</sup>  |   |
| Colon         | CXCL4L1                  | Upregulation in colorectal cancer <sup>[115]</sup>  |   |
|               | CCL2                     | upregulation in mucosa of IBD <sup>[169]</sup>  |   |
|               | D6 receptor              | Plays role of sequestering several chemokines (in mouse colitis model experiment), plays suppressive role in the development and growth of vascular tumors <sup>[170,172]</sup>   |   |
|               | CCL2, CCR2               | important mediator in colon tumor development <sup>[173]</sup>  |   |
|               | CXCL8                    | Upregulation along with the development of Crohn's disease, affecting biological responses of human intestinal microvascular endothelial cells in colitis model, positively correlated with earlier disease stage and improved relapse-free survival <sup>[164,175,180]</sup> |   |
|               | CXCL10, CXCL41           | Synergistic upregulation with CXCL8 by diverse stimuli, induction by ERK2 and PI-3K/AKT pathway <i>via</i> PAR2 <sup>[175,178]</sup>  |   |
|               | CCL20, CXCL1/2, CXCL8    | Remains high even after the treatment with anti-TNF antibody <sup>[179]</sup>   |   |
|               | CXCL1, CXCR1/2           | Upregulation in stage II and III CRC, upregulation in stage II and III CRC <sup>[180]</sup>   |   |
|               | CXCR3 pathway            | CXCL9-pediatric Crohn's disease, CXCL11-UC in all age groups <sup>[181]</sup>   |   |
|               | Other chemokines         | IL-17 affects CXCL8, CXCL1, CCL20, CXCL10, CXCL11 and CCR5 in colon cancer cells <sup>[182]</sup>   |   |

CXCL: CXC chemokine ligand; CXCR: CXC-chemokine receptor; CCR: CC-receptor; CXsCR: CXsC-receptor; CA19-9: Carbohydrate antigen 19-9; OSCC: Oral squamous cell carcinoma; HER: Human epidermal growth factor receptor; AKT: Protein kinase B; mTOR: Mammalian target of rapamycin; MMPs: Matrix metalloproteinases; LECs: Lymphatic endothelial cells; TNM: Tumor, node, and metastasis; PVTT: Portal vein tumor thrombus; HCC: Hepatocellular carcinoma; STAT: Signal transducer and activator of transcription; ERK: Extracellular signal-regulated kinase; MVD: Microvessel density; MLVD: Microlymphatic vessel density; IBD: Inflammatory bowel disease; PI-3K: Phosphatidylinositol-3-OH kinase; PAR2: Protease-activated receptor-2; CRC: Colorectal cancer; IL: Interleukin; TNF- $\alpha$ : Tumor necrosis factor- $\alpha$ .

toxicity cases, compared to numerous other causality assessment methods, which are inferior on various grounds. Among these disputed methods are the Maria and Victorino scale, an insufficiently qualified, shortened version of the CIOMS scale, as well as various liver un-specific methods such as the *ad hoc* causality approach, the Naranjo scale, the World Health Organization (WHO) method, and the Karch and Lasagna method. An expert panel is required for the Drug Induced Liver Injury Network method, the WHO method, and other approaches based on expert opinion, which provide retrospective analyses with a long delay and thereby prevent a timely assessment of the illness in question by the physician. In conclusion, HILI causality assessment is challenging and is best achieved by the liver specific CIOMS scale, avoiding pitfalls commonly observed with other approaches.

### Abstract

The diagnosis of herbal hepatotoxicity or herb induced liver injury (HILI) represents a particular clinical and regulatory challenge with major pitfalls for the causality evaluation. At the day HILI is suspected in a patient, physicians should start assessing the quality of the used herbal product, optimizing the clinical data for completeness, and applying the Council for International Organizations of Medical Sciences (CIOMS) scale for initial causality assessment. This scale is structured, quantitative, liver specific, and validated for hepatotoxicity cases. Its items provide individual scores, which together yield causality levels of highly probable, probable, possible, unlikely, and excluded. After completion by additional information including raw data, this scale with all items should be reported to regulatory agencies and manufacturers for further evaluation. The CIOMS scale is preferred as tool for assessing causality in hepa-

**Core tip:** This review focuses on diagnostic causality assessment algorithms that have been used so far in herb induced liver injury (HILI) cases. Detailed information of the various methods with their strengths and weaknesses is provided including their challenges and pitfalls that emerged during the assessing course. For the physician caring for a patient with suspected HILI, the Council for International Organizations of Medical Sciences (CIOMS) scale is the preferred tool for assessing causality compared to numerous other causality assessment methods, which are inferior on various grounds. CIOMS based assessment should start at the day HILI is suspected to ensure completeness of clinical data.

## INTRODUCTION

A total of 60 herbs, herbal drugs, and herbal dietary supplements have been reported to cause herb induced liver injury (HILI), though convincing causality assessment rarely was provided<sup>[1]</sup>. Presented as a tabular compilation, these 60 different herbal products were based on a recent analysis of 185 case reports, spontaneous reports, review articles, and comments. The consideration of possible hepatotoxicity in various reports has been discussed by the National Institutes of Health (NIH) in their recently released LiverTox database, covering a selected group of herbal and dietary supplement (HDS) products<sup>[2,3]</sup>. Among these are: Aloe vera, Black cohosh (BC), Cascara, Chaparral, Chinese and other Asian herbal medicines (*Ba Jiao Lian*, Chi R Yun, Ephedra, *Jin Bu Huan*, Sho Saiko To and Dai Saiko To, *Shou Wu Pian*), Comfrey, Fenugreek, Germander, Ginkgo, Ginseng, Glucosamine, Greater Celandine, Green Tea, Hoodia, Horse Chestnut, Hyssop, Kava, Margosa Oil, Milk Thistle, Noni, Pennyroyal, St John's Wort, Saw Palmetto, Senna, Skullcap, Usnic acid, Valerian, and Yohimbine<sup>[2,3]</sup>. However, causality confirmation was surprisingly rare for individual cases of suspected herbal hepatotoxicity, which often were published as narrative and anecdotal reports without valid and transparent data collection<sup>[1-3]</sup> that require stringent efforts for causality attribution<sup>[4]</sup>.

The focus of this review is on causality assessment methods for herbal hepatotoxicity with particular reference to liver specific evaluation methods. This approach gives insight into challenges and pitfalls of these methods with surprising clinical and regulatory issues. Valid causality assessment of assumed HILI cases is required for further case evaluations, otherwise speculations and fruitless discussions will emerge.

## DATA BASIS FOR CAUSALITY ASSESSMENT

### Herbal product essentials

Herbal product quality aspects are of primary concern, the respective evaluation should start at the day HILI is suspected. The products are destined for human use and must meet the highest possible quality based on specific standards (Table 1)<sup>[4-7]</sup>. Despite fulfilment of quality standards, batch and product variability is common<sup>[4,8-10]</sup>. Therefore, additional specific production quality standards have been described, for instance, as a proposal for a Kava Quality Standardization Code<sup>[8]</sup>. It details standardization of overall herbal quality and specifically addresses chemical, agricultural, manufacturing, nutritional, regulatory, and legislation standardizations. In addition, labelling and consumer leaflet of herbal drugs and herbal dietary supplements should mandatorily provide

a clear definition and identification of the plant family, subfamily, species, subspecies, and variety as classical botanical description for any herb used as an ingredient of a herbal product (Table 1)<sup>[4,8]</sup>.

As an example, several hundred kava varieties exist<sup>[8-11]</sup>, but specific information on kava variety identification was missing in all spontaneous reports and case report publications of suspected hepatotoxicity. This leaves open which kava variety had to be incriminated<sup>[9-17]</sup>. On the other hand, the regulatory recommendation for kava drugs was to use its peeled rhizome<sup>[8,11,15]</sup>. In various HILI cases, it remained unclear, whether unpeeled rhizomes, peeled and unpeeled roots, and/or stem peelings were also used<sup>[8,11,16,17]</sup>. This again hampered any evaluation of the causative agent of kava hepatotoxicity<sup>[16,17]</sup>. For both the United States Food and Drug Administration and the Australian Therapeutic Goods Administration, peeled kava rhizomes were recommended for kava supplements<sup>[18,19]</sup>.

Another point of interest focuses on solvents and solubilizers without regulatory advice<sup>[8,11,15,16]</sup>, as well as on adulterants, impurities, contaminants, or misidentified herbs<sup>[4,7,8,11]</sup>. These key issues of herbal product quality are rarely addressed in publications related to herbal hepatotoxicity<sup>[1,4,8-17,20-33]</sup>.

### Clinical data requirements

Other concerns focus on incomplete clinical evaluation. Beginning at the day HILI is suspected, the physician has to gather all necessary information for an accurate diagnosis and the exclusion of alternative causes under relevant clinical aspects (Tables 1 and 2)<sup>[1,4,13,14,17,20-26,34-59]</sup>. Hepatotoxicity requires strict criteria, best defined by alanine aminotransferase (ALT) and/or alkaline phosphatase (ALP) values<sup>[4]</sup>. Its increases are expressed in multiples of the upper limit of their normal range as  $N^{[60-62]}$ . For ALT, hepatotoxicity has been defined from  $> 2N^{[60,62]}$ ,  $> 3N^{[63]}$  or  $> 5N^{[64]}$ , while ALP values of  $> 2N$  are commonly considered diagnostic<sup>[60,62]</sup>. Restricting ALT increases to  $> 5N$  will eliminate false positive cases and substantiate causality at a higher level of probability<sup>[64]</sup>. Considering patients with  $ALT > 2N$  will include numerous cases with nonspecific increases, with higher requirements for thorough assessment and more stringent exclusion of causes unrelated to the herb(s) under discussion. Also for low threshold  $N$  values, the rate of alternative diagnoses must be higher<sup>[13,14,24-26,35-39]</sup>, and missing a hepatotoxicity definition results in false high case numbers due to overdiagnosing and overreporting<sup>[17,23-26,38,39]</sup>. Special care is required for reporting of confounding variables<sup>[4,13,14,18,24,39]</sup>. For clinicians, a checklist with all clinical details is available for most alternative diagnoses (Table 2)<sup>[62]</sup>.

### Checklist

For a pragmatic approach to assess causality, special attention by the physician is of utmost importance. Only this physician can arrange collection and assessment of all data, thereby providing good data quality. To achieve this, a checklist with all important product and clinical items (Tables 1 and 2) and a valid causality assessment

**Table 1 Essential steps of herbal hepatotoxicity assessments**

| Quality specifications  |
|---|
| Herbal product quality  |
| Good agricultural practices   |
| Good manufacturing practices  |
| Definition of plant family, subfamily, species, subspecies, and variety   |
| Definition of plant part  |
| Definition of solvents and solubilizers   |
| Lack of impurities, adulterants, and misidentifications   |
| Minimum of batch and product variability  |
| Lack of variety to variety variability  |
| Clinical assessment quality   |
| Brand name with details of ingredients, plant parts, batch number, and expiration date  |
| Identification as herbal drug or herbal supplement  |
| Herb as an ingredient of a polyherbal product or an undetermined herbal product   |
| Manufacturer with address   |
| Indication of herbal use with dates of symptoms leading to herbal treatment   |
| Daily dose with details of the application form   |
| Exact date of herb start and herb end   |
| Accurate dates of emerging new symptoms after herb start in chronological order   |
| Accurate date of initially increased liver values   |
| Timeframes of challenge, latency period, and dechallenge  |
| Verification or exclusion of a temporal association   |
| Provided temporal association is verified, evaluation of a causal relationship  |
| Gender, age, body weight, height, body mass index   |
| Ethnicity, profession   |
| Past medical history regarding general diseases and specifically liver diseases   |
| ALT value initially including normal range  |
| ALT values during dechallenge at least on days 8 and 30, as well as later on  |
| ALT values during dechallenge to exclude a second peak  |
| ALT normalization with exact date and actual value  |
| ALP value initially including normal range  |
| ALP values during dechallenge up to 180 d, as well as later on  |
| ALP values during dechallenge to exclude a second peak  |
| ALP normalization with exact date and actual value  |
| AST value initially including normal range  |
| Laboratory criteria for definition of hepatotoxicity and its pattern  |
| Definition of risk factors such as age and alcohol  |
| Alcohol and drug use  |
| Statement regarding actual treatment including steroids or ursodesoxycholic acid  |
| Assessment of preexisting and coexisting liver unrelated diseases   |
| Assessment of preexisting and coexisting liver diseases   |
| Consideration of the several hundreds of other possible liver diseases  |
| Providing details to exclude alternative diagnoses  |
| Assessment and exclusion of hepatitis A virus, hepatitis B virus, hepatitis C virus, hepatitis E virus, cytomegalovirus, Epstein-Barr virus, HSV, VZV |
| Liver and biliary tract imaging including color Doppler sonography of liver vessels   |
| Specific evaluation of alcoholic, cardiac, autoimmune, and genetic liver diseases   |
| Individual quantitative score of each alternative diagnosis   |
| Comedicated synthetic drugs, herbal drugs, herbal and other dietary supplements   |
| Definition of and search for accidental, unintended reexposure  |
| Assessing of unintended reexposure  |
| Search for evidence of prior known hepatotoxicity of the suspected herb   |
| Assessing of known hepatotoxicity caused by the herb  |
| Qualified data acquisition and documentation of complete data   |
| Transparent presentation of all data  |
| Causality assessment quality  |
| Prospective assessment by the physician suspecting herb induced liver injury  |
| Structured and quantitative method  |
| Liver specific causality assessment method validated for hepatotoxicity   |
| Use of the CIOMS scale  |
| Gathering of all data required for the CIOMS scale item by item   |
| Presentation of individual CIOMS items and of scores to regulatory agency   |
| Gathering all clinical data and presentation to regulatory agency   |
| Excluding all alternative causes and presentation to regulatory agency  |
| Regulatory case assessment by skilled hepatologist with clinical experience   |
| Regulatory assessment with assistance of external experts   |
| Transparent presentation of regulatory verified causality assessment results  |

Required quality specifications of herbal products refer to herbs, herbal drugs, and herbal supplements including herbal mixtures. ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; AST: Aspartate aminotransferase; CIOMS: Council for International Organizations of Medical Sciences; HSV: Herpes simplex virus; VZV: Varicella zoster virus.

**Table 2** Check list for herb induced liver injury diagnosis

| Items to be assessed   | Information obtained     |                          |                          |
|--|--------------------------|--------------------------|--------------------------|
|  | Yes                      | No                       | Partial                  |
| Brand name with batch number and expiration date   | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Indication of herbal use   | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Dates of symptoms leading to herbal treatment  | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Daily dose   | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Application form of herbal product   | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Exact date of herb start   | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Exact date of herb end   | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Accurate dates of emerging new symptoms after herb start in chronological order  | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Accurate date of initially increased liver values  | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Time frame of challenge  | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Time frame of latency period   | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Time frame of dechallenge  | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |

| Specific assessment of <i>M. Boeck</i> , amyloidosis, lymphoma, other malignant tumors, sepsis and others  | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |
| Other diseases   |                          |                          |                          |
| Clinical context   | <input type="checkbox"/> | <input type="checkbox"/> | <input type="checkbox"/> |

For each listed item, detailed results obtained for the individual patient are to be supplemented within the checklist. BMI: Body mass index; ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; AST: Aspartate aminotransferase; CT: Computer tomography; MRT: Magnetic resonance tomography; MRC: Magnetic resonance cholangiography; HAV: Hepatitis A virus; IgM: Immunoglobulin M; HBsAg: Hepatitis B antigen; HBe: Hepatitis B core; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HEV: Hepatitis E virus; IgG: Immunoglobulin G; HIV: Human immunodeficiency virus; CMV: Cytomegalovirus; PCR: Polymerase chain reaction; EBV: Epstein Barr virus; HSV: Herpes simplex virus; VZV: Varicella zoster virus; AIH: Autoimmune hepatitis; ANA: Antinuclear antibodies; SMA: Smooth muscle antibodies; AAA: Anti-actin antibodies; SLA: Soluble liver antigen; LP: Liver-pancreas antigen; LSP: Liver specific protein; ASGPR: Asialo-glycoprotein-receptor; LKM: Liver kidney microsomes; CYP: Cytochrome P450; PBC: Primary biliary cirrhosis; AMA: Antimitochondrial antibodies; PDH: Pyruvate dehydrogenase; PSC: Primary sclerosing cholangitis; p-ANCA: Perinuclear antineutrophil cytoplasmic antibodies; AIC: Autoimmune cholangitis; NASH: Non alcoholic steatohepatitis; ALD: Alcoholic liver disease; DILI: Drug induced liver injury; CIOMS: Council for International Organizations of Medical Sciences; TSH: Thyroid stimulating hormone.

algorithm (Tables 3-6) should be applied early in the unfolding disease, beginning at the day HILI is suspected. Unless this is done in a stringent way, poor data quality will be provided to the scientific community, regulatory

agencies, expert panels, and manufacturers, disabling reevaluation of the case. Initially poor data will produce poor results and is unacceptable. Complete and excellent case data including raw data provided by the physician

**Table 3** Methods of causality assessments for suspected herbal hepatotoxicity

| Methods of causality assessment | Specific criteria of various causality assessment methods |            |             |              |                |                 |

Compilation of details are derived from previous reports<sup>[2,3,60-62,76-79,81,89,102]</sup>. Council for International Organizations of Medical Sciences scale (CIOMS scale) refers to both the original scale<sup>[60]</sup> and its update (Tables 5 and 6)<sup>[62]</sup>. Liver-specific and liver-validated criteria reflect hepatotoxicity criteria. Expert based criterion refers to the requirement of several experts for the actual case under consideration. MV scale: Maria and Victorino scale; KL method: Karch and Lasagna method; DILIN method: Drug Induced Liver Injury Network method; WHO method: World Health Organization method.

**Table 4** Details of the various causality assessment methods for herb induced liver injury

| Assessed items with specific scores       | CIOMS | MV | Naranjo | KL | <i>Ad hoc</i> | DILIN | WHO | Expert opinion |
|---|-------|----|---------|----|---------------|-------|-----|----------------|
| Time frame of latency period (score)      | +     | +  | 0       | 0  | 0             | 0     | 0   | 0              |

Items lacking specific scores were not considered, with the exception of the last six features. The data of the Drug Induced Liver Injury Network method are derived from the report of Rockey *et al*<sup>[102]</sup>, references for the other methods are found in the text. Latency period indicates time from herb start to symptoms, alternatively to abnormal liver tests. The symbol + shows that this item is present and the symbol 0 indicates lack of this item. ALT: Alanine aminotransferase; ALP: Alkaline phosphatase; HAV: Hepatitis A virus; HBV: Hepatitis B virus; HCV: Hepatitis C virus; CMV: Cytomegalovirus; EBV: Epstein Barr virus; HSV: Herpes simplex virus; VZV: Varicella zoster virus; CIOMS: Council for International Organizations of Medical Sciences scale; MV: Maria and Victorino scale; KL: Karch and Lasagna method; DILIN: Drug-Induced Liver Injury Network method; WHO: World Health Organization method.

are necessary to circumvent later investigative efforts, subsequent discussions, and speculative conclusions.

At each step of the evaluation, full transparency of all data is mandatory. This includes a complete narrative medical history, a causality assessment based on an established algorithm, and presentation of all data as item by item and raw data, ready for reevaluation by other scientists. This is also relevant for case publications and case series analyses, which is indeed feasible as shown in the past<sup>[13,14,25,35-39,58]</sup>. The same transparency is needed for

statements and publications by regulatory agencies and expert panels. Neglecting full transparency will cause concern and uncertainty about the validity of the presented conclusions.

## GENERAL ASPECTS OF CAUSALITY EVALUATION

### Method categories

Some reservations exist about the best method for causal-

**Table 5 Updated Council for International Organizations of Medical Sciences scale for the hepatocellular type of injury with items required for causality assessment in herb induced liver injury cases**

| Items for hepatocellular injury   | Possible score | Patient's score |
|---|----------------|-----------------|
| Time to onset from the beginning of the herb  |                |                 |
| 5-90 d (rechallenge: 1-15 d)  | +2             |                 |
| < 5 or > 90 d (rechallenge: > 15 d)   | +1             |                 |
| Alternative: Time to onset from cessation of the herb   |                |                 |
| ≤ 15 d (except for slowly metabolized herbal chemicals: > 15 d)   | +1             |                 |
| Course of ALT after cessation of the herb   |                |                 |
| Percentage difference between ALT peak and N  |                |                 |
| Decrease ≥ 50% within 8 d   | +3             |                 |
| Decrease ≥ 50% within 30 d  | +2             |                 |
| No information or continued herbal use  | 0              |                 |
| Decrease ≥ 50% after the 30 <sup>th</sup> day   | 0              |                 |
| Decrease < 50% after the 30 <sup>th</sup> day or recurrent increase                                       | -2             |                 |
| Risk factors  |                |                 |
| Alcohol use (drinks/d: > 2 for women, > 3 for men)  | +1             |                 |
| No alcohol use (drinks/d: ≤ 2 for women, ≤ 3 for men)   | 0              |                 |
| Age ≥ 55 yr   | +1             |                 |
| Age < 55 yr   | 0              |                 |
| Concomitant herbs(s) and drug(s)  |                |                 |
| None or no information  | 0              |                 |
| Concomitant herb or drug with incompatible time to onset  | 0              |                 |
| Concomitant herb or drug with compatible or suggestive time to onset                                      | -1             |                 |
| Concomitant herb or drug known as hepatotoxin and with compatible or suggestive time to onset             | -2             |                 |
| Concomitant herb or drug with evidence for its role in this case (positive rechallenge or validated test) | -3             |                 |
| Search for non drug causes  |                |                 |
| Group I (6 causes)  |                |                 |
| Anti-HAV-IgM  |                |                 |
| HBsAg, anti-HBc-IgM, HBV-DNA  |                |                 |
| Anti-HCV, HCV-RNA   |                |                 |
| Hepatobiliary sonography/colour Doppler sonography of liver vessels/endsonography/CT/MRC                  |                |                 |
| Alcoholism (AST/ALT ≥ 2 IU/L)   |                |                 |
| Acute recent hypotension history (particularly if underlying heart disease)                               |                |                 |
| Group II (6 causes)   |                |                 |
| Complications of underlying disease(s)  |                |                 |
| Infection suggested by PCR and titre change for   |                |                 |
| CMV (anti-CMV-IgM, anti-CMV-IgG)  |                |                 |
| EBV (anti-EBV-IgM, anti-EBV-IgG)  |                |                 |
| HEV (anti-HEV-IgM, anti-HEV-IgG)  |                |                 |
| HSV (anti-HSV-IgM, anti-HSV-IgG)  |                |                 |
| VZV (anti-VZV-IgM, anti-VZV-IgG)  |                |                 |
| Evaluation of group I and II  |                |                 |
| All causes-groups I and II - reasonably ruled out   | +2             |                 |
| The 6 causes of group I ruled out   | +1             |                 |
| 5 or 4 causes of group I ruled out  | 0              |                 |
| Less than 4 causes of group I ruled out   | -2             |                 |
| Non herb cause highly probable  | -3             |                 |
| Previous information on hepatotoxicity of the herb  |                |                 |
| Reaction labelled in the product characteristics  | +2             |                 |
| Reaction published but unlabelled   | +1             |                 |
| Reaction unknown  | 0              |                 |
| Response to readministration  |                |                 |
| Doubling of ALT with the herb alone, provided ALT below 5N before reexposure                              | +3             |                 |
| Doubling of ALT with the herb(s) and drug(s) already given at the time of first reaction                  | +1             |                 |
| Increase of ALT but less than N in the same conditions as for the first administration                    | -2             |                 |
| Other situations  | 0              |                 |
| Total score for patient   |                |                 |

The compilation of the individual items is adapted from the updated version of the Council for International Organizations of Medical Sciences (CIOMS) scale<sup>[62]</sup> and the original CIOMS scale<sup>[60]</sup>. The above items refer to the hepatocellular type of injury, whereas items for the cholestatic (± hepatocellular) type are presented in Table 6. Regarding risk factor of alcohol use, 1 drink commonly contains about 10 g ethanol<sup>[2,3,90]</sup>. Total score and resulting causality grading: ≤ 0, excluded; 1-2, unlikely; 3-5, possible; 6-8, probable; ≥ 9, highly probable. HAV: Hepatitis A virus; IgM: Immunoglobulin M; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; CMV: Cytomegalovirus; CT: Computer tomography; EBV: Epstein Barr virus; HBc: Hepatitis B core; HBsAg: Hepatitis B antigen; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HEV: Hepatitis E; HILL: Herb induced liver injury; HSV: Herpes simplex virus; MRC: Magnetic resonance cholangiography; N: Upper limit of the normal range; VZV: Varicella zoster virus.

**Table 6 Updated Council for International Organizations of Medical Sciences scale for the cholestatic ( $\pm$  hepatocellular) type of injury with items required for causality assessment in herb induced liver injury cases**

| Items for cholestatic ( $\pm$ hepatocellular) injury  | Possible score | Patient's score |
|---|----------------|-----------------|
| Time to onset from the beginning of the herb  |                |                 |
| 5-90 d (rechallenge: 1-90 d)  | +2             |                 |
| < 5 or > 90 d (rechallenge: > 90 d)   | +1             |                 |
| Alternative: Time to onset from cessation of the herb   |                |                 |
| ≤ 30 d (except for slowly metabolized herbal chemicals: > 30 d)   | +1             |                 |
| Course of ALP after cessation of the herb   |                |                 |
| Percentage difference between ALP peak and N  |                |                 |
| Decrease ≥ 50% within 180 d   | +2             |                 |
| Decrease < 50% within 180 d   | +1             |                 |
| No information, persistence, increase, or continued herbal use  | 0              |                 |
| Risk factors  |                |                 |
| Alcohol use (drinks/d: > 2 for women, > 3 for men) and pregnancy  | +1             |                 |
| No alcohol use (drinks/d: ≤ 2 for women, ≤ 3 for men)   | 0              |                 |
| Age ≥ 55 yr   | +1             |                 |
| Age < 55 yr   | 0              |                 |
| Concomitant herbs(s) and drug(s)  |                |                 |
| None or no information  | 0              |                 |
| Concomitant herb or drug with incompatible time to onset  | 0              |                 |
| Concomitant herb or drug with compatible or suggestive time to onset                                      | -1             |                 |
| Concomitant herb or drug known as hepatotoxin and with compatible or suggestive time to onset             | -2             |                 |
| Concomitant herb or drug with evidence for its role in this case (positive rechallenge or validated test) | -3             |                 |
| Search for non drug causes  |                |                 |
| Group I (6 causes)  |                |                 |
| Anti-HAV-IgM  |                |                 |
| HBsAg, anti-HBc-IgM, HBV-DNA  |                |                 |
| Anti-HCV, HCV-RNA   |                |                 |
| Hepatobiliary sonography/colour Doppler sonography of liver vessels/endsonography/CT/MRC                  |                |                 |
| Alcoholism (AST/ALT ≥ 2 IU/L)   |                |                 |
| Acute recent hypotension history (particularly if underlying heart disease)                               |                |                 |
| Group II (6 causes)   |                |                 |
| Complications of underlying disease(s)  |                |                 |
| Infection suggested by PCR and titre change for   |                |                 |
| CMV (anti-CMV-IgM, anti-CMV-IgG)  |                |                 |
| EBV (anti-EBV-IgM, anti-EBV-IgG)  |                |                 |
| HEV (anti-HEV-IgM, anti-HEV-IgG)  |                |                 |
| HSV (anti-HSV-IgM, anti-HSV-IgG)  |                |                 |
| VZV (anti-VZV-IgM, anti-VZV-IgG)  |                |                 |
| Evaluation of group I and II  |                |                 |
| All causes-groups I and II - reasonably ruled out   | +2             |                 |
| The 6 causes of group I ruled out   | +1             |                 |
| 5 or 4 causes of group I ruled out  | 0              |                 |
| Less than 4 causes of group I ruled out   | -2             |                 |
| Non herb cause highly probable  | -3             |                 |
| Previous information on hepatotoxicity of the herb  |                |                 |
| Reaction labelled in the product characteristics  | +2             |                 |
| Reaction published but unlabelled   | +1             |                 |
| Reaction unknown  | 0              |                 |
| Response to readministration  |                |                 |
| Doubling of ALP with the herb alone, provided ALP below 5N before reexposure                              | +3             |                 |
| Doubling of ALP with the herb(s) and drug(s) already given at the time of first reaction                  | +1             |                 |
| Increase of ALP but less than N in the same conditions as for the first administration                    | -2             |                 |
| Other situations  | 0              |                 |
| Total score for patient   |                |                 |

The compilation of individual items is adapted from the updated version of the Council for International Organizations of Medical Sciences (CIOMS) scale<sup>[62]</sup> and the original CIOMS scale<sup>[60]</sup>. The above items refer to the cholestatic ( $\pm$  hepatocellular) type of injury, whereas items for the hepatocellular type are presented in Table 5. Regarding risk factor of alcohol use, 1 drink commonly contains about 10 g ethanol<sup>[2,3,90]</sup>. Total score and resulting causality grading: ≤ 0, excluded; 1-2, unlikely; 3-5, possible; 6-8, probable; ≥ 9, highly probable. ALP: Alkaline phosphatase; N: upper limit of the normal range; HAV: Hepatitis A virus; IgM: Immunoglobulin M; HBsAg: Hepatitis B antigen; HBc: Hepatitis B core; HBV: Hepatitis B virus; HCV: Hepatitis C virus; CT: Computer tomography; MRC: Magnetic resonance cholangiography; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; PCR: Polymerase chain reaction; CMV: Cytomegalovirus; EBV: Epstein Barr virus; HEV: Hepatitis E virus; HSV: Herpes simplex virus; IgG: Immunoglobulin G; VZV: Varicella zoster virus.

ity assessment in hepatotoxicity cases<sup>[1-4,13,14,17,21-26,34-39,59-64]</sup>. HILI case series reported in 23 publications with 573 HILI cases used various causality assessment meth-

ods<sup>[12-14,23,25,34-36,38,39,53,54,65-75]</sup>. These can be classified into prospective and retrospective analyses (Table 3).

The prospective evaluation focuses on the physician

caring for a patient with suspected liver injury. This setting requires a readily available and time efficient method to evaluate causation that can adapt to further clinical and causality approach necessities. Candidates are the Council for International Organizations of Medical Sciences (CIOMS) scale, also called Roussel Uclaf Causality Assessment Method scale<sup>[60-62]</sup>, the Maria and Victorino (MV) scale<sup>[76]</sup>, the Naranjo scale<sup>[77]</sup>, the Karch and Lasagna (KL) method<sup>[78]</sup>, and the *ad hoc* approach<sup>[79]</sup>.

Retrospective evaluations are based on an expert panel evaluating reported or published case data, sometimes going back for months or years. Examples are the Drug Induced Liver Injury Network (DILIN) method<sup>[73,80]</sup>, the World Health Organization global introspection method (WHO method) as defined by the WHO Collaborating Centre for International Drug Monitoring<sup>[81]</sup>, and the expert opinion<sup>[2,3]</sup>. Major differences exist (Table 3), especially when assessing items that require score attribution (Table 4).

### Usage frequency

Analyzing 23 publications of initially assumed causality but not necessarily confirmed later on<sup>[12-14,23,25,34-36,38,39,53,54,65-75]</sup> with HILI cases by BC, Greater Celandine, Green Tea extracts, some Herbalife products, Hydroxycut, kava, *Pelargonium sidoides*, and various herbs, the CIOMS scale was applied in 52.2%, the WHO method in 17.4%, the *ad hoc* approach in 13.1%, the Naranjo scale in 8.7%, and the KL and DILIN method each in 4.3% of these publications<sup>[82]</sup>. Similar results were obtained when analyzing the frequency for the 573 cases: the CIOMS scale was used in 275 cases (48.0%), the WHO method in 134 cases (23.4%), the Naranjo scale in 64 cases (11.2%), the *ad hoc* approach in 63 cases (11.0%), the KL method in 20 cases (3.5%), and the DILIN method in 20 cases (3.0%)<sup>[82]</sup>. For instance, the CIOMS scale was applied for Kava<sup>[13,14,67]</sup>, BC<sup>[25,34,71,72]</sup>, Greater Celandine<sup>[35,36]</sup>, *Pelargonium sidoides*<sup>[38,39]</sup>, and various herbs<sup>[75]</sup>, the WHO method for Kava<sup>[65,68]</sup> and Herbalife products<sup>[53,54]</sup>, the *ad hoc* approach for Kava<sup>[12,66]</sup> and Greater Celandine<sup>[69]</sup>, the Naranjo scale for BC<sup>[23]</sup> and Green Tea extracts<sup>[70]</sup>, the KL method for Herbalife products<sup>[74]</sup>, and the DILIN method for Hydroxycut<sup>[8]</sup><sup>[73]</sup>.

A systematic analysis of causality methods is also available for DILI cases<sup>[83]</sup>. In 2008, 61 DILI publications in the PubMed database over the last decade were reviewed. It revealed that in 38 publications (62.3%) no specific causality assessment method was mentioned; presumably, the evaluation was based on the *ad hoc* approach. The CIOMS scale, Naranjo scale, and WHO method were used in 10, 8, and 2 publications, respectively<sup>[83]</sup>. Therefore, in HILI and DILI publications the CIOMS scale was the preferred specific causality assessment method if the unstructured *ad hoc* approach is excluded. Physicians are well advised to use the CIOMS scale for HILI causality evaluation, to err on the side of caution.

### NIH PREFERENCE

The NIH LiverTox specifically addressed the item of

causality in hepatotoxicity cases<sup>[2,3]</sup>. It focuses primarily on using the CIOMS scale, which is discussed in detail. Moreover, the MV and Naranjo scales, the Bayesian, and expert opinion assessment are referred to; details of the DILIN causality assessment also are presented. Some strengths and weaknesses of these methods are compiled (Tables 3 and 4).

## PROSPECTIVE CAUSALITY ASSESSMENT METHODS

### CIOMS scale

The method of choice for the causality assessment of suspected HILI is the CIOMS scale in its original form<sup>[60,61]</sup> or preferably its update (Tables 5 and 6)<sup>[62]</sup>, with early starting of the evaluation at the day the physician assumes this diagnosis. The CIOMS scale is intended for prospective use at the time of manifestation; it does not require expert knowledge, is structured, quantitative, liver specific, and validated for hepatotoxicity (Table 3). Its items provide individual scores, which estimate causality levels for the agent(s) under consideration as highly probable, probable, possible, unlikely, and excluded (Tables 5 and 6). The CIOMS scale takes into account all core elements of hepatotoxicity and thereby has advantages over other algorithms (Table 4)<sup>[62]</sup>. Compared to the regulatory used *ad hoc* approach, assessment of HILI cases with the CIOMS scale leads to lower causality grades for the incriminated herb and/or for concomitant medications and to better reproducible results due to greater transparency<sup>[84]</sup>.

CIOMS was developed by an international expert panel and validated by cases with positive reexposure tests serving as a gold standard<sup>[60,61]</sup>. CIOMS based assessment has shown good sensitivity (86%), specificity (89%), positive predictive value (93%), and negative predictive value (78%)<sup>[61]</sup>. The scales differ slightly for the hepatocellular and the cholestatic ( $\pm$  hepatocellular) type of injury (Tables 5 and 6)<sup>[62]</sup>. Differentiation between these types is feasible by comparing the ratio of the serum activities of ALT and ALP at diagnosis of suspected herbal hepatotoxicity<sup>[60,62]</sup>. Enzyme activity is expressed as a multiple of the upper limit of the normal range (N), and the ratio (R) of ALT/ALP is calculated. Liver injury is classified as: (1) hepatocellular, if ALT > 2N alone or R  $\geq$  5; (2) cholestatic, when there is an increase of ALP > 2N alone or when R  $\leq$  2; and (3) mixed cholestatic-hepatocellular, if ALT > 2N, ALP is increased, and R between 2 and 5.

Strengths and weaknesses of the CIOMS scale have been discussed extensively<sup>[2,3,62,73,79,82,85-91]</sup>. This scale clearly compiles liver specific criteria for challenge, dechallenge, risk factors, exclusion of unrelated diseases, and comedication, but does not use liver histology data (Tables 5 and 6)<sup>[60,62]</sup>, agreed upon as less helpful criteria in most cases<sup>[90,91]</sup>. It considers unintentional reexposure results according to criteria as established by previous expert consensus meetings<sup>[92,93]</sup>. For reexposure results of the hepatocellular type of liver injury, ALT levels are as-

sessed before reexposure (designed as baseline ALT or ALTb), and at reexposure (designed as ALT<sub>r</sub>). The reexposure test is positive, if (1) ALT<sub>b</sub> is below 5N with N as the upper limit of the normal value, and (2) ALT<sub>r</sub>  $\geq$  2ALT<sub>b</sub><sup>[92]</sup>.

The test is negative, if only one or no criterion is fulfilled; it is uninterpretable, if ALT data are lacking for one or both times. For reexposure assessments of the cholestatic ( $\pm$  hepatocellular) type of liver injury, ALT has to be replaced by ALP. Criteria for positive reexposure tests are included in the updated CIOMS scale (Tables 5 and 6) and were not previously applied in cases with reported positive reexposure tests<sup>[40-57,59,91]</sup>. When these cases were submitted to retrospective analysis using the reexposure test criteria, a positive reexposure test could be confirmed in only 13/30 cases, the test was negative in 5/30 cases and uninterpretable in 12/30 cases<sup>[91]</sup>. In 8 cases of initially assumed Herbalife hepatotoxicity with a previously reported positive reexposure test result, retrospective evaluation applying the test criteria revealed that criteria for a positive reexposure were fulfilled in only 1/8 cases, whereas the reexposure test was classified as negative in another case or the data were considered as uninterpretable due to missing information to comply adequately with the criteria in the remaining six cases<sup>[94]</sup>.

The CIOMS scale was widely used for hepatotoxicity assessments in epidemiological studies, clinical trials, case reports, case series, regulatory analyses, and genotyping studies<sup>[13,14,24,25,35,36,38,39,58,59,61,64,72,79,84,86,87,90,95-98]</sup>. Proposals for refinement and strengthening of the CIOMS scale focused on the weight of individual parameters and risk factors such as alcohol and age, and other shortcomings were addressed<sup>[24,87,89,90]</sup>. However, there is lack of valid data to verify improvements based on reassessing and reevaluating of published approaches<sup>[87,89,90,98]</sup>, calling for new approaches.

Assessment of suspected HILI cases may be problematic in spontaneous reports with insufficient data. Evaluating these cases requires a sophisticated approach, as undertaken by EMA for 31 EU cases of suspected HILI by BC, using the CIOMS scale<sup>[34]</sup>. This series included 11/31 unassessable cases (35%) due to poor data quality, with causality assessment feasible in 20/31 cases (65%). Among these, EMA specified likely alternative causes in 8/20 cases with diagnoses such as autoimmune hepatitis, DILI, preexisting liver disease, alcoholic hepatitis, and preexisting liver cirrhosis with Stevens Johnson syndrome<sup>[34]</sup>. Causality for BC was unlikely or excluded in another 6/20 cases and 5/20 cases, respectively. In 1/20 cases, causality was judged as possible by EMA<sup>[34]</sup>, but upon further evaluation this particular case with insufficient data quality was attributed with an excluded causality<sup>[71]</sup>. Consequently, in this EMA study group of 31 EU cases there was little evidence of liver injury by BC based on the use of the CIOMS scale, which was most helpful in this particular analysis and provided robust results<sup>[34]</sup>. The approach of EMA to apply the CIOMS scale in hepatotoxicity cases<sup>[34]</sup> should be highly appreciated and is in line with the corresponding recom-

mendation by the NIH for their LiverTox database to prefer the CIOMS scale over other methods<sup>[2,3]</sup>.

At present, we are far away from valid data and strict management in suspected HILI cases, which impedes description of classic HILI by the majority of herbs. Possible or likely alternative diagnoses were evident in 278/573 cases (48.5%) of suspected HILI cases; causality assessment was impeded in 165/573 patients (29.0%) due to missing case data or lack of a temporal association, resulting in diagnostic problems in 77.5% of all cases<sup>[82]</sup>. Given these limitations, actual discussions of validity of reported HILI cases are understandable<sup>[82,90,91,94,98-100]</sup>, and uncertainty also extends to the validity of the type of liver injury reported for some cases lacking a probable or highly probable causality. Considering these restrictions, the hepatocellular type of injury was described for Indian Ayurvedic herbs<sup>[72,98]</sup>, Chaparral (*Larrea tridentata*)<sup>[40,98]</sup>, Dai Saiko To<sup>[47,98]</sup>, Germander<sup>[98]</sup>, Green Tea extract<sup>[98]</sup>, Greater Celandine<sup>[37]</sup>, Hydroxycut<sup>[6,98]</sup>, *Jin Bu Huan* (*Lycopodium serratum*)<sup>[45,98]</sup>, Kava<sup>[13]</sup>, the cholestatic or mixed type for Chaparral<sup>[98]</sup>, Germander<sup>[98]</sup>, Green Tea extract<sup>[98]</sup>, Greater Celandine<sup>[98]</sup>, Hydroxycut<sup>[6,98]</sup>; and the veno-occlusive disease for plants containing pyrrolizidine alkaloids such as *Senecio*, *Heliotropium*, *Crotalaria*, and *Symphytum* species<sup>[98]</sup>.

In clinical practice, the physician will start at the day HILI is suspected with the CIOMS scale to arrive at an initial estimation and to exclude the most frequent alternative causes, provided point by point in the CIOMS questionnaire (Tables 5 and 6). The practical application of the CIOMS scale was published in various case series<sup>[13,25,35,36,38,39,71,72,94]</sup> and is shown by two single cases as examples, one for a case of hepatotoxicity by Indian Ayurvedic herbs (Table 7)<sup>[58]</sup>, and another one for a case of liver injury by a dietary supplement<sup>[97]</sup>. For further refinement, specific information usually is necessary to rule out rare alternative causes (Table 2). This initial approach using the CIOMS scale ensures prospectively the collection of highly qualified case data and enables a sophisticated case evaluation currently and in the future. Information of individual CIOMS items (Tables 5 and 6), the checklist for HILI diagnosis (Table 2), all raw data, and a narrative case report should be presented to regulatory agencies, the scientific community, manufacturers, and expert panels to allow refined use of the CIOMS scale and all other case data, provided causality for the incriminated herb reached a probable or highly probable level.

### MV scale

The MV scale<sup>[76]</sup> was developed in an attempt to improve the CIOMS scale by adding other clinical elements and by simplifying and changing the relative weight of assessment parameters, in detail discussed by the NIH LiverTox<sup>[2,3]</sup> and others<sup>[62,87]</sup>, or briefly referenced<sup>[98]</sup>. As a shortened and modified version of the CIOMS scale<sup>[60]</sup>, the MV scale<sup>[76]</sup> has fewer specific criteria than the original CIOMS scale (Table 4); due to major differences in test cases, however, the equivalency to CIOMS has been debated<sup>[2,3,62,84,87,89,96]</sup>.

Specifically, the MV scale evaluates dechallenge as

**Table 7 Council for International Organizations of Medical Sciences scale as an example with items required for causality assessment in a patient with herb induced liver injury by four Indian Ayurvedic herbs**

| Items for hepatocellular injury   | Possible score | Psoralea corylifolia | Acacia catechu | Eclipta alba | Vetivexia zizanioidis |
|---|----------------|----------------------|----------------|--------------|-----------------------|
| Time to onset from the beginning of the herb  |                |                      |                |              |                       |
| 5-90 d (rechallenge: 1-15 d)  | +2             |                      |                |              |                       |
| < 5 d or > 90 d (rechallenge: > 15 d)   | +1             | +1                   | +1             | +1           | +1                    |
| Alternative: Time to onset from cessation of the herb   |                |                      |                |              |                       |
| ≤ 15 d (except for slowly metabolized herbal chemicals: > 15 d)   | +1             |                      |                |              |                       |
| Course of ALT after cessation of the herb   |                |                      |                |              |                       |
| Percentage difference between ALT peak and N  |                |                      |                |              |                       |
| Decrease ≥ 50% within 8 d   | +3             | +3                   | +3             | +3           | +3                    |
| Decrease ≥ 50% within 30 d  | +2             |                      |                |              |                       |
| No information or continued herbal use  | 0              |                      |                |              |                       |
| Decrease ≥ 50% after the 30 <sup>th</sup> day   | 0              |                      |                |              |                       |
| Decrease < 50% after the 30 <sup>th</sup> day or recurrent increase                                       | -2             |                      |                |              |                       |
| Risk factors  |                |                      |                |              |                       |
| Alcohol use (drinks/d: > 2 for women, > 3 for men)  | +1             |                      |                |              |                       |
| No alcohol use (drinks/d: ≤ 2 for women, ≤ 3 for men)   | 0              | 0                    | 0              | 0            | 0                     |
| Age ≥ 55 yr   | +1             | +1                   | +1             | +1           | +1                    |
| Age < 55 yr   | 0              |                      |                |              |                       |
| Concomitant herbs(s) and drug(s)  |                |                      |                |              |                       |
| None or no information  | 0              |                      |                |              |                       |
| Concomitant herb or drug with incompatible time to onset  | 0              |                      |                |              |                       |
| Concomitant herb or drug with compatible or suggestive time to onset                                      | -1             | -1                   |                |              |                       |
| Concomitant herb or drug known as hepatotoxin and with compatible or suggestive time to onset             | -2             |                      | -2             | -2           | -2                    |
| Concomitant herb or drug with evidence for its role in this case (positive rechallenge or validated test) | -3             |                      |                |              |                       |
| Search for non herb causes  |                |                      |                |              |                       |
| Group I (6 causes)  |                |                      |                |              |                       |
| Anti-HAV-IgM  |                | -                    | -              | -            | -                     |
| HBsAg, anti-HBc-IgM, HBV-DNA  |                | -                    | -              | -            | -                     |
| Anti-HCV, HCV-RNA   |                | -                    | -              | -            | -                     |
| Hepatobiliary sonography/colour Doppler sonography of liver vessels/endsonography/CT/MRC                  |                | -                    | -              | -            | -                     |
| Alcoholism (AST/ALT ≥ 2 IU/L)   |                | -                    | -              | -            | -                     |
| Acute recent hypotension history (particularly if underlying heart disease)                               |                | -                    | -              | -            | -                     |
| Group II (6 causes)   |                |                      |                |              |                       |
| Complications of underlying disease(s)  |                | -                    | -              | -            | -                     |
| Infection suggested by PCR and titre change for   |                |                      |                |              |                       |
| CMV (anti-CMV-IgM, anti-CMV-IgG)  |                | -                    | -              | -            | -                     |
| EBV (anti-EBV-IgM, anti-EBV-IgG)  |                | -                    | -              | -            | -                     |
| HEV (anti-HEV-IgM, anti-HEV-IgG)  |                | -                    | -              | -            | -                     |
| HSV (anti-HSV-IgM, anti-HSV-IgG)  |                | -                    | -              | -            | -                     |
| VZV (anti-VZV-IgM, anti-VZV-IgG)  |                | -                    | -              | -            | -                     |
| Evaluation of group I and II  |                |                      |                |              |                       |
| All causes-groups I and II-reasonably ruled out   | +2             | +2                   | +2             | +2           | +2                    |
| The 6 causes of group I ruled out   | +1             |                      |                |              |                       |
| 5 or 4 causes of group I ruled out  | 0              |                      |                |              |                       |
| Less than 4 causes of group I ruled out   | -2             |                      |                |              |                       |
| Non herb cause highly probable  | -3             |                      |                |              |                       |
| Previous information on hepatotoxicity of the herb  |                |                      |                |              |                       |
| Reaction labelled in the product characteristics  | +2             |                      |                |              |                       |
| Reaction published but unlabelled   | +1             | +1                   |                |              |                       |
| Reaction unknown  | 0              |                      | 0              | 0            | 0                     |
| Response to readministration  |                |                      |                |              |                       |
| Doubling of ALT with the herb alone, provided ALT below 5N before reexposure                              | +3             |                      |                |              |                       |
| Doubling of ALT with the herb(s) and drug(s) already given at the time of first reaction                  | +1             |                      |                |              |                       |
| Increase of ALT but less than N in the same conditions as for the first administration                    | -2             |                      |                |              |                       |

| Total score for each individual herb used by the patient  |                | +7                   | +5             | +5           | +5                    |

The data of the patient with severe hepatotoxicity by four different Indian Ayurvedic herbs are derived from a published report<sup>[58]</sup>, using the updated Council for International Organizations of Medical Sciences scale for the hepatocellular type of liver injury (Table 5). The symbol - signifies that this particular item has been evaluated and no abnormality was found. Regarding risk factor of alcohol use, 1 drink commonly contains about 10 g ethanol<sup>[2,3,90]</sup>. For the four herbs, the total score was either 5 (possible causality) or 7 (probable causality). ALT: Alanine aminotransferase; N: Upper limit of the normal range; HBsAg: Hepatitis B antigen; HBc: Hepatitis B core; HAV: Hepatitis A virus; IgM: Immunoglobulin M; HBV: Hepatitis B virus; HCV: Hepatitis C virus; CT: Computer tomography; MRC: Magnetic resonance cholangiography; AST: Aspartate aminotransferase; PCR: Polymerase chain reaction; CMV: Cytomegalovirus; EBV: Epstein Barr virus; HEV: Hepatitis E virus; HSV: Herpes simplex virus; VZV: Varicella zoster virus.

the time necessary for ALT or ALP to fall below 2N, considers a shorter latency period, asks for less accurate exclusion criteria of drug-independent causes, ignores concomitant drug use, emphasizes drugs with more than 5 years marketing without published hepatotoxicity, and overestimates extrahepatic manifestations like hypersensitivity reactions<sup>[76]</sup>. The validation used real and fictive cases and as gold standard the opinion of three external experts<sup>[76,87]</sup> and not cases with verified results of positive reexposure tests<sup>[76]</sup>; for initial validation of the CIOMS scale, both a panel of experts and positive reexposure tests were used<sup>[60,61]</sup>. Compared to the CIOMS scale<sup>[60]</sup>, the MV scale was equivalently accurate only in cases of hypersensitivity; otherwise, the CIOMS scale was superior to the MV scale<sup>[89,96]</sup>. A comparison of the two scales for hepatotoxicity cases demonstrated low consistency between the two systems, with agreement between the scales in only 18% of the cases; the CIOMS scale showed better discriminative power and produced assessments closer to those of specialists<sup>[87]</sup>. These limitations restrict the general use of the MV scale in hepatotoxicity cases<sup>[62]</sup>.

A recent HILI study confirmed poor concordance between the MV and CIOMS scales for both the herb and concomitant medication assessment. The CIOMS scale found higher causality levels for the herb and concomitant medications than the MV scale; this was associated with considerably lower causality levels provided by the MV scale compared to the *ad hoc* approach<sup>[84]</sup>. The low MV scores were attributed to various parameters such as prolonged latency and dechallenge periods, the presence of several alternative herb independent causes for the observed liver disease, only partial exclusion of herb unrelated causes due to missing essential case data, and lacking consideration of extrahepatic manifestations like rash, fever, arthralgia, peripheral eosinophilia, and cytopenia. It therefore appeared that various confounders precluded a high level of causality for the herb in a setting of HILI cases assessed by the MV scale.

The MV scale may be useful in some selected hepatotoxicity cases. Nonetheless, little evidence is provided that this scale has advantages over the CIOMS scale and should be the preferred tool<sup>[2,3,62,87,89,95,96]</sup>. It has been criticized by the NIH LiverTox that the elements used in the MV scale and their relative weights were based upon the authors' expert opinion and not by prospective evaluation of a variety of possible elements and different cutoff values and weights<sup>[2,3]</sup>. Additional concern was expressed that the MV scale focuses on hypersensitivity features that are comparatively infrequent in hepatotoxicity cases; it performs poorly in atypical cases, such as unusually long latency periods or residual chronic symptoms after cessation of the culprit<sup>[87]</sup>. Another issue raised was the low numbers of experts and the low degree of validation<sup>[2,3]</sup> of the MV scale<sup>[76]</sup>. Thus, the MV scale is not commonly recommended for assumed HILI cases and certainly is no substitute for the CIOMS scale<sup>[2,3,87,98]</sup>.

### Naranjo scale

The NIH LiverTox summarized the arguments for and against the Naranjo scale<sup>[2,3]</sup>. In detail, while this scale includes all general features important in assessing causality, most critical elements are not weighed in judging the likelihood of liver injury, for example specific time to onset, criteria for recovery time, and list of critical diagnoses to exclude, limiting the use of this scale for assessing hepatotoxicity. The Naranjo scale includes testing for drug levels, which is rarely helpful in idiosyncratic drug induced liver disease. Finally, the scale was designed for use in clinical trials, and points are subtracted if the reaction reappears with administration of placebo, which does not apply to the usual case of drug induced liver disease. Direct comparisons to the CIOMS scale have shown that the Naranjo scale is easier to apply, but has less sensitivity and specificity in assigning causality to cases of liver injury. These statements of the NIH LiverTox<sup>[2,3]</sup> supported other views<sup>[87]</sup>, confirming low sensitivity, and a lower prediction rate of the Naranjo scale in a careful comparison with the CIOMS scale for suspected hepatotoxicity cases<sup>[101]</sup>. These studies concluded that the Naranjo scale lacks validity and reproducibility when evaluating hepatotoxicity<sup>[86,93]</sup>; it was not recommended for hepatotoxicity assessment<sup>[87]</sup>.

The Naranjo scale was designed to assess causality of any adverse drug reaction (ADR), independent from the affected organ<sup>[77]</sup>. It substantially differs from other causality algorithms for hepatotoxicity (Tables 3 and 4)<sup>[2,3,24-26,63,79,87,88,101]</sup>. This scale relates toxic drug reactions to general pharmacological drug actions rather than possibly to idiosyncratic reactions like rare hepatotoxicity<sup>[77]</sup>. Its items include drug concentrations and monitoring, dose relations such as decreasing dose, placebo response, cross-reactivity, and confirmation of ADRs using unidentified objective evidence, which is relevant only for toxic reactions<sup>[77,79,88]</sup>. The general use of the Naranjo scale in hepatotoxicity cases<sup>[23,79]</sup> created concern<sup>[2,3,24-26,63,70,87,88,101]</sup>.

The use of the liver unspecific Naranjo scale<sup>[77]</sup> is unacceptable in suspected HILI cases<sup>[23,79]</sup>, its results are heavily disputed<sup>[24-26,63,70,79,88]</sup>; this pertains especially to the shortened version used by the United States Pharmacopeia (USP)<sup>[23,79]</sup> with only 5 of the original 10 items<sup>[88]</sup>. Lack of liver specificity associated with the Naranjo algorithm is evident by lack of a definition of liver injury as ADR; an unclear time frame and latency period; undefined time frames for dechallenge; no definition of risk factors; insufficient evaluation of alternative diagnoses; inappropriate assessment of comedication; and lacking definition of a positive rechallenge test (Table 4)<sup>[77,88]</sup>. This scale also was considered too insensitive, allowing a possible causality even in the absence of essential data, by virtue of the patient simply having taken the suspected agent<sup>[63,70]</sup>. Most importantly, the modified Naranjo scale as used by USP<sup>[23,70]</sup> did not exclude relevant alternative causes such as idiopathic autoimmune hepatitis, alcoholic or cardiac hepatopathy, other preexisting liver

diseases, DILI, and drug-induced rhabdomyolysis<sup>[24-26]</sup>. Use of this method has raised concern about judgement validity by the USP<sup>[63,88]</sup>. Considering all shortcomings along with the lack of liver specificity and validation for hepatotoxicity, the Naranjo scale should be excluded from use in hepatotoxicity cases. It certainly is no substitute for the CIOMS scale.

#### KL method

The KL method<sup>[78]</sup> is neither liver specific nor validated for hepatotoxicity (Table 3), it also lacks important items for hepatotoxicity assessment (Table 4). It was recently applied for causality assessment of suspected hepatotoxicity for some Herbalife products<sup>[74]</sup>. Subjective judgement is needed for many steps, making this method more prone to bias<sup>[87]</sup>. Though commonly applied by the Spanish Pharmacovigilance Centres<sup>[74]</sup>, the KL method is not used by the Spanish Group for the Study of Drug-induced Liver Disease<sup>[59,85,87,95]</sup>, which applies the CIOMS scale as the preferred assessment tool. The KL method should not be used for assessment of hepatotoxicity cases.

#### Ad hoc approach

Numerous published HILI reports lack any causality method description and presumably are based on the *ad hoc* assessment with its relevant shortcomings (Tables 3 and 4). When using this approach, the physician notes the coincidence of herbal product and chemical drug use, and will estimate the likelihood of a hepatotoxic reaction<sup>[89]</sup>.

After ruling out alternative causes, the *ad hoc* approach is often used to distinguish a probable, possible, or unlikely causality<sup>[89]</sup>. A probable causality is usually attributed when the manifestations of liver disease, temporal association, and dechallenge response seems to fit the typical signature pattern of the product in question. A possible attribution is assigned when one feature is not typical, the product not known to cause the reaction or so rarely that it is difficult to distinguish from background, or an alternative cause is less or equally plausible. An unlikely causality is assigned when most of the features are atypical or an alternative cause is more plausible<sup>[89]</sup>.

Though relevant items such as signature of symptoms, latency period, dechallenge, definitive exclusion of alternative causes, risk factors, alcohol use, and track record of the product are used<sup>[79,89]</sup>, no universally accepted description exists for either the method or its application<sup>[79]</sup>. Due to missing specific criteria (Tables 3 and 4), the *ad hoc* approach is obsolete to validly assess causality in HILI<sup>[79]</sup> or DILI cases<sup>[89]</sup>.

With the *ad hoc* assessment applied prior to the liver specific CIOMS scale, the physician inevitably will postpone an assessment by such a procedure and thereby delay the diagnosis. Since the parameters of the *ad hoc* approach are liver unspecific and not validated (Tables 3 and 4), this method should be replaced by better alterna-

tives. The NIH LiverTox does not even mention the *ad hoc* approach as a possible causality evaluation method for hepatotoxicity cases<sup>[2,3]</sup>.

## RETROSPECTIVE CAUSALITY ASSESSMENT METHODS

#### DILIN method

According to the NIH LiverTox, the DILIN method is based on a narrative summary and a compilation of clinical findings and sequential biochemical abnormalities<sup>[2,3]</sup>. These are extracted from clinical records and entered into a 65-page case report form, but a scoring system was lacking<sup>[102]</sup>, as opposed to the CIOMS scale (Table 4). The DILIN causality adjunction process is outlined in a 12 step flow diagram, using three independently assessing experts in hepatotoxicity who grade the likelihood of a causal relationship between the drug and liver injury in one of five scores<sup>[102]</sup>: (1) Definite (> 95% assurance): the evidence for the drug causing the injury is beyond a reasonable doubt; (2) Highly likely (75% to 95% assurance): the evidence for the drug causing the injury is clear and convincing but not definite; (3) Probable (50% to 74% assurance): the preponderance of the evidence supports the link between the drug and the liver injury; (4) Possible (25% to 49% assurance): the evidence for the drug causing the injury is equivocal but present; and (5) Unlikely (< 25% assurance): there is evidence that an etiological factor other than the drug caused the injury.

While these causality grades appear vague, attempts are made to provide an objective and critical evaluation of the likelihood that the liver injury is due to the suspected agent<sup>[2,3]</sup>. In particular, cases are not considered “probable” merely because there is no other explanation. Similarly, cases are not considered “definite” if another diagnosis is possible. If two or three drugs are implicated, only one can be considered probable, highly likely or definite, the others are assigned “possible” or “unlikely”, so that the total percent assurance does not exceed 100%<sup>[2,3]</sup>. The causality assessment is accepted as initially scored if the three expert reviewers completely agree; if there is disagreement, the reviewers meet to reconcile the differences and reach a final single score<sup>[2,3,102]</sup>. A complete summary of the definitions for each category is provided<sup>[102]</sup>.

The DILIN method requires experts and has shortcomings (Tables 3 and 4)<sup>[2,3,73,80,86,102]</sup>; it is therefore not suitable for the physician who needs assessment results during the early disease. The DILIN method was used for retrospective assessments of case series where time to conclusion is not a crucial issue<sup>[73,86,102]</sup>. In combination with the CIOMS scale, this method is the basis for future DILIN group studies of clinical, genetic, environmental, and immunological risk factors<sup>[80]</sup>. To exclude alternative causes in retrospective analyses by the DILIN method, screening was required for previous liver disease, alcohol use, hepatitis A, B, or C infection, autoantibodies, ceruloplasmin,  $\alpha_1$ -antitrypsin, ferritin, iron, and

imaging data; specific details or appropriate scores for each item were not provided (Table 4)<sup>[102]</sup>. Other possible causes were not considered (Table 2), including specific liver infections like hepatitis E or by cytomegalovirus (CMV), Epstein Barr virus (EBV), herpes simplex virus (HSV), and varicella zoster virus (VZV)<sup>[102]</sup>. At present, questions regarding the actual DILIN method validity remain, and transparent results of all diagnostic items from each individual patient would be preferred rather than a summarizing causality grade.

Another approach of the DILIN group targets a novel Causality Assessment Tool (CAT) specifically for HDS<sup>[103]</sup>. CAT was designed to retrospectively adjudicate multiple products as a single entity using structured causality assessment and expert opinion. The elements of the CAT considered the multiplicity of products consumed, implicated drugs, alternative diagnoses, and published DILI literature on the product or an ingredient<sup>[103]</sup>. In analogy to the scoring system, the DILIN method expresses causality levels as percentage assurance<sup>[102]</sup>; CAT also grades the likelihood of a causal relationship between HDS and liver injury from definitive to unlikely<sup>[103]</sup>. In this preliminary study, CAT was applied in 16 DILI cases, which were initially evaluated by the DILIN method and in which HDS are implicated as a potential cause. Overall agreement and reliability in this study of retrospective analysis requiring an expert panel was moderate<sup>[103]</sup>; this method needs further investigation and validation<sup>[98]</sup>.

### WHO method

In its recent statement, the NIH LiverTox does not mention the WHO method in connection with causality assessment methods for hepatotoxicity cases but rather discusses other methods<sup>[2,3]</sup>. Since the WHO method<sup>[81]</sup> was not developed for hepatotoxicity cases and therefore does not consider hepatotoxicity characteristics<sup>[79,104]</sup>, this omission appears warranted. The shortcomings of the unspecific features of the WHO method (Tables 3 and 4) have been a matter of major concern<sup>[38,39,104-106]</sup> and led to the conclusion that this scale is not appropriate for causality assessment in suspected HILI cases<sup>[79,104]</sup>.

The WHO method consists of two parts, one being the WHO scale to assess causality levels, the other one the global introspection by experts<sup>[81]</sup>. Though not validated for any ADR<sup>[103]</sup>, global introspection surprisingly represented a popular strategy in evaluating the likelihood of drug causality for general ADRs of all organs<sup>[107]</sup>. As early as 1986, however, global introspection by experts has been shown to be neither reproducible nor valid<sup>[107]</sup>. In detail, the assessor considers factors that might support a causal link of one or more drugs to an observed ADR, lists all factors, weighs their importance, and estimates the probability of drug causation; no specific checklist or level of strength is given<sup>[107]</sup>. It has been recognized that both the questions and the answers are ambiguous<sup>[79]</sup>. Though these shortcomings are described for general ADRs, they certainly also apply even more to hepatic ADRs.

The WHO scale has not been based on a gold standard, is not quantitative, not liver specific, and has not been validated for hepatotoxicity (Tables 3 and 4)<sup>[4,38,39,79,104-106]</sup>. In particular, reliability, sensitivity, specificity, positive and negative predictive values are unknown, but likely are low<sup>[79,81,104-106]</sup>. Its scope is also limited since it cannot discriminate between a positive and a negative correlation, thereby resulting in overdiagnosing and overreporting<sup>[104]</sup>.

The WHO method ignores relevant data like uncertainties in daily dose, temporal association, start, duration and end of herbal use, time to onset of ADR, and course of liver values after herbal discontinuation. Insufficiently considered or ignored are comedication, preexisting liver diseases, numerous alternative explanations, and exclusion of virus infections by hepatitis A, B, C and E, CMV, EBV, HSV, and VZV<sup>[38,39]</sup>. Since only a few raw data are evaluated, case duplications and retracted cases remain undetected by the WHO method to a higher degree than by other methods<sup>[38]</sup>. Despite these flaws, the WHO method was used for causality assessment<sup>[17,38,39,53,54]</sup>. Re-evaluation often could not confirm causality in cases of two assessed reports<sup>[38,39]</sup>; therefore, the use of the WHO method in HILI cases has major limitations.

Causality assessment by the WHO method requires a panel of experts rarely available at a hospital or a family physician office. Consequently, analyses based on this method are retrospective; their results are available long after the patient problems of assumed HILI.

### Expert opinion

Expert opinion as an assessment tool is poorly defined (Tables 3 and 4), except that a panel of specialists with clinical expertise in hepatology is available for causality assessment in HILI. For DILI, groups of skilled hepatologists exists without any doubt in most countries including Japan<sup>[108,109]</sup> and in expert projects like the international DILI Expert Working Group<sup>[90]</sup>, the United States DILIN group<sup>[73,80,86,102,103]</sup>, the Spanish Group for the Study of Drug-Induced Liver Disease<sup>[59,85,87,95,101]</sup>, and the Spanish-Latin American network on drug induced liver injury<sup>[110]</sup>. For HILI, the Hong Kong Herb-Induced Liver Injury Network is of importance<sup>[75]</sup>. However, the qualification of assessors is sometimes crucial and may be problematic as discussed in detail<sup>[88,105,106]</sup>. Even with specialists, individual opinion often results in judgement bias.

---

## RELEVANCE TO ACTUAL MEDICAL PRACTICE

---

For HILI case assessment, strategies need to be developed that are clinically useful and applicable in daily practice. These must meet the expectations of the scientific community, regulatory agencies, and manufacturers, provided the case is going to be reported. At the day when HILI is suspected and criteria of hepatotoxicity are fulfilled, the physician should explore through the internet and regulatory databases how frequently the suspected herb has been associated with hepatotoxic

adverse reactions both in the scientific literature and by regulatory notifications. Publication as an interesting case report should be encouraged, if there are few or even none hepatotoxicity reports of this particular herb. Consequently, the decision will depend on the physician's own interest and clinical experience, resulting in three different levels of assessment intensity. These include first a wait and see approach after cessation of the herbal product, second a strategy aimed at exclusion of the most frequent differential diagnoses, or third an exclusion of even rare alternative causes.

The first approach of wait and see requires little attention and few elements and is cost effective, at least initially but not necessarily in the further course. If for some reasons the correct diagnosis was missed, it will be costly and risky for the patient, the physician, or both. Submitting such an insufficiently documented case as suspected HILI case to scientific journals, regulatory agencies or manufacturers would be difficult to reconcile, leading to overreporting due to overdiagnosing<sup>[68,82,88,104,105,111]</sup>. In detail, diagnostic problems including alternative diagnoses as confounding variables were evident in 77.5% of 573 cases of initially suspected HILI, presented as spontaneous reports or as published case reports<sup>[82]</sup>.

For the second strategy, the elements of the updated CIOMS scale are sufficient, starting with the evaluation of time to onset to verify at least a temporal association between the herbal use and the liver disease (Tables 5 and 6). For instance, if clinical assessment, hepatobiliary sonography, or serology of hepatitis A-C provides an alternative cause as the correct and final diagnosis, the costs will remain low since further diagnostic measures are not warranted. If diagnostic exclusion is unsuccessful so far, parameters of CMV, EBV, HEV, HSV, and VZV are needed (Tables 5 and 6), though in reality these elements are rarely reported in suspected HILI cases<sup>[13,14,17,23-26,38,39,94]</sup>. With complete or even some missing CIOMS elements, the CIOMS scale provided causality for various herbs with levels of probable and highly probable<sup>[35-37]</sup>.

For the third level of evaluation, the physician will have to decide, which of the multiple other and rare differential diagnoses are worth of consideration. The checklist should be valued as a reminder of possible alternatives and as a suggestion for further approaches, depending on the clinical phenotype. Clearly, the number of criteria set for ruling out alternative causes is not required for all cases, the checklist therefore asks selectively whether the information was completely, partially or not obtained (Table 2). A sophisticated strategy is needed, however, if the case is reported to regulatory agencies and the scientific community, which are overflooded by poorly documented suspected and often misdiagnosed HILI cases<sup>[26,34-36,38,39,82]</sup>. For optimum case presentation, the individual items of the updated CIOMS scale should be provided for a single case (Table 7)<sup>[58,97]</sup> as well as for case series. This is feasible as shown in numerous

publications<sup>[13,25,35,36,38,39,71,72,94]</sup> for 26 cases<sup>[13]</sup>, 22 cases<sup>[25]</sup>, 22 cases<sup>[35]</sup>, 21 cases<sup>[36]</sup>, 15 cases<sup>[38]</sup>, 13 cases<sup>[39]</sup>, and 4-9 cases<sup>[71,72,94]</sup>. The presentation of the CIOMS items for the single case should be combined with a detailed report of all relevant case data<sup>[58,97]</sup> and a list of differential diagnoses that were excluded completely or partially, or were not considered<sup>[58]</sup>, similar to the checklist for HILI diagnosis (Table 2). For a case series, basis data for each individual case are to be provided in a single table, focusing on details required for causality assessment; examples are presented in various publications<sup>[14,25,35,36,38,39]</sup>. Presentation of excellent data will lead to valid causality results and appropriate conclusions. This is prerequisite for well founded assessments of further HILI cases, with benefit for patients, physicians, the scientific community, regulatory agencies, and manufacturers.

## FUTURE PERSPECTIVES

Future considerations will have to focus on improvements of causality assessment methods<sup>[90,98]</sup> to obtain prospectively valid HILI diagnoses at the time the patient experiences liver injury, corresponding efforts of retrospective causality assessments of HILI cases are promising and on the way with preliminary data<sup>[103]</sup>. Strategies are to be developed to characterize liver injury by various herbs with all facets. At the day HILI is suspected, causality assessment should be initiated in all cases using the CIOMS scale preferentially in its updated form (Tables 5 and 6). Supported by the checklist for HILI diagnosis (Table 2), this could provide HILI cases with a probable or highly probable causality for a special herb as basis for further evaluation. Overall, this will facilitate characterization of disease entities including phenotype standardization, retrospective reanalysis by expert panels, improvement of pharmacovigilance decisions, safety strategies of manufacturers, and studies directed to assess pathogenetic aspects of HILI.

Studies are needed in the future to assess factors leading to unpredictable HILI in few patients, who experience this disease with a probable or highly probable causality level. As for DILI, future issues for HILI cases with established causality are to define genetic, environmental, and immunological determinants of HILI susceptibility<sup>[80,90,112,113]</sup>. Overall, metabolomics, pharmacogenetics, proteomics, and transcriptomics are areas of potential interest in HILI, as detailed for DILI<sup>[112]</sup>. Since HILI is commonly an unpredictable disease<sup>[91]</sup>, experimental studies dealing with predictive cellular systems as used to identify potentially hepatotoxic synthetic drugs<sup>[114]</sup> will be of limited if any relevance for herbs. Similarly, applying well-defined primary cultures of human hepatocytes and measuring a panel of signals directly linked to key mechanisms of liver injury to predict drugs, which can cause liver injury<sup>[114]</sup>, will be restricted to drugs and not be applicable to herbs. Recent advances of the early pre-clinical assessment of the potential intrinsic hepatotoxicity of candidate drugs has been reviewed

in detail, focusing on cell-based models such as cell cultures with outcome and detection methods, on profiling technologies, and emerging technologies including stem cell technologies and 3D as compared to 2D culturing techniques<sup>[115]</sup>. However, it is unlikely that the results of these *in vitro* studies of intrinsic and predictable hepatotoxicity induced by synthetic drugs are transferable to a clinical setting of HILI that commonly represents the idiosyncratic and unpredictable form of liver injury by one or more herbs, each with multiple chemical constituents. More important seems the search for biomarkers in HILI patients with clearly established causality<sup>[116]</sup>.

## CONCLUSION

The rare liver injury by herbs, herbal drugs, and herbal supplements may present itself with numerous facets, providing challenging issues for causality assessment. The physician is responsible to make available all necessary data for a high quality judgement; otherwise, causality evaluation will be problematic. Timely causality assessment is mandatory when the disease is unfolding to base prospective diagnostic and therapeutic decisions. The most appropriate causality assessment method is the liver specific CIOMS scale, which should prospectively be applied by the physician. If used, other methods have pitfalls and cause ambiguous results debated on reasons of imprecision, liver unspecificity, and limitations to retrospective analyses, or they are unavailable due to requirements for expert panels.

(B220<sup>+</sup>), human lymphoma cell lines and mouse splenocytes stimulated with pokeweed mitogen (PWM) or lipopolysaccharide (LPS), and in dithiothreitol (DTT) and mitomycin-C treated Raji cells. DPP8 and DPP9 expression were measured in epidermal growth factor (EGF) treated Huh7 hepatoma cells, in fibrotic liver samples from mice treated with carbon tetrachloride (CCl<sub>4</sub>) and from multidrug resistance gene 2 (*Mdr2/Abcb4*) gene knockout (gko) mice with biliary fibrosis, and in human end stage primary biliary cirrhosis (PBC).

**RESULTS:** All three lymphocyte subsets expressed DPP8 and DPP9 mRNA. DPP8 and DPP9 expression were upregulated in both PWM and LPS stimulated mouse splenocytes and in both Jurkat T- and Raji B-cell lines. DPP8 and DPP9 were downregulated in DTT treated and upregulated in mitomycin-C treated Raji cells. DPP9-transfected Raji cells exhibited more annexin V<sup>+</sup> cells and associated apoptosis. DPP8 and DPP9 mRNA were upregulated in CCl<sub>4</sub> induced fibrotic livers but not in the lymphocytes isolated from such livers, while DPP9 was upregulated in EGF stimulated Huh7 cells. In contrast, intrahepatic DPP8 and DPP9 mRNA expression levels were low in the *Mdr2* gko mouse and in human PBC compared to non-diseased livers.

**CONCLUSION:** These expression patterns point to biological roles for DPP8 and DPP9 in lymphocyte activation and apoptosis and in hepatocytes during liver disease pathogenesis.

### Abstract

**AIM:** To investigate the expression of dipeptidyl peptidase (DPP) 8 and DPP9 in lymphocytes and various models of liver fibrosis.

**METHODS:** DPP8 and DPP9 expression were measured in mouse splenic CD4<sup>+</sup> T-cells, CD8<sup>+</sup> T-cells and B-cells

**Key words:** Dipeptidyl peptidase; CD26; Lymphocytes; Liver fibrosis; Biliary fibrosis

## INTRODUCTION

The four enzyme members of the dipeptidyl peptidase (*DPP*) 4 gene family, *DPP4*, fibroblast activation protein (*FAP*), *DPP8* and *DPP9*, have attracted considerable research interest in recent years since *DPP4* inhibitors became a successful therapy for type 2 diabetes<sup>[1,2]</sup>. *FAP* is a potential cancer therapeutic target<sup>[2,3]</sup>. *DPP4*, the most well characterized family member, has ubiquitous cell surface and extracellular expression<sup>[2,4-7]</sup>. *DPP8* and *DPP9* are the most recently discovered members of the *DPP4* gene family<sup>[8-11]</sup>. *DPP4*, *DPP8* and *DPP9* are ubiquitously expressed cytosolic enzymes with *DPP4*-like activity<sup>[8,11,12]</sup>. They are expressed by major epithelial organs including liver, colon, small intestine, stomach, lung, skin, tongue, kidney, testis and the lymphoid cells of lymph node, blood, thymus, and spleen<sup>[13]</sup>. The biological functions of *DPP8* and *DPP9* are largely uncharacterized.

*DPP4* is also known as *CD26* and has important roles in the immune system. It is a costimulatory molecule in T cell activation and proliferation and is critical in the development of T helper 1 responses to foreign antigens. It is expressed at detectable levels by some resting T cells but the cell surface expression increases 5-10 fold following stimulation with antigen or anti-CD3<sup>+</sup> interleukin-2 or with mitogens such as phytohaemagglutinin<sup>[14-19]</sup>. However, the costimulatory role of *DPP4/CD26* is mediated by extra-enzymatic activities<sup>[20-22]</sup>. Hence, some of the immunological effects observed in early *DPP4* inhibitor studies are now thought to be due to off-target non-selective inhibition of *DPP8* and *DPP9*<sup>[2,23,24]</sup>. In support of this viewpoint, there is some evidence that *DPP8* and *DPP9* are functionally significant in the immune system. Their mRNA levels are elevated in activated human leukocytes<sup>[25,26]</sup>. An inhibitor of *DPP8* and *DPP9* attenuates proliferation in *in vitro* models of human T-cell activation<sup>[23]</sup>. An inhibitor selective for *DPP8* and *DPP9* vs related proteases can suppress DNA synthesis in mitogen-stimulated splenocytes from both wildtype *DPP4*<sup>+/+</sup> and *DPP4*<sup>-/-</sup> gene knockout (gko) mice<sup>[27]</sup>. Moreover, *DPP8* and *DPP9* have been implicated in hematopoiesis and in inflammatory diseases including arthritis<sup>[2,28,29]</sup>. Most importantly, *DPP8* and *DPP9* are involved in processing and degradation of peptides involved in antigen presentation by Major histocompatibility complex class I<sup>[30]</sup>.

Inflammatory and immune responses are important in liver injury. Improved understanding of immune response, inflammation and fibrogenic progression is needed to advance the understanding of liver disorders. *DPP8* and *DPP9* are expressed in hepatocytes and lymphocytes of human cirrhotic liver<sup>[13]</sup>. Hepatocytes in the periportal area of regenerative nodules and lymphocytes in the portal tracts are strongly positive for *DPP8* and *DPP9* *in situ*

hybridization (ISH)<sup>[13]</sup>. Bile ducts and ductular reactions are ISH positive for *DPP9* but not for *DPP8*<sup>[13]</sup>. However, the role of *DPP8* and *DPP9* in liver is unknown. Other members of this protease family, *DPP4* and *FAP*, are altered in liver diseases and are potential disease markers and therapeutic targets<sup>[31-36]</sup>. Despite the pleiotropic roles of *DPP4* and *FAP* in various biological processes, *DPP4* and *FAP* gko mice exhibit no spontaneous defects, suggesting that *DPP4* and *FAP* are not essential for normal functions, and hence, targeting them is likely to lack adverse side effects<sup>[37,38]</sup>.

*DPP8* and *DPP9* have interesting properties in cell biological processes that may contribute to disease pathogenesis, such as apoptosis and cell migration<sup>[39,40]</sup>. Their biological functions, especially in the immune system, are important considerations for the selectivity of *DPP4* inhibitors over *DPP8* and *DPP9* in clinical development of *DPP* antagonists. Here we studied the expression of *DPP8* and *DPP9* in lymphocyte activation, proliferation and apoptosis and in liver injury to elucidate their potential biological roles in the immune system and in liver diseases.

## MATERIALS AND METHODS

### Materials

Antibodies are detailed in Table 1. Other materials were from Sigma-Aldrich (St Louis, MO, United States) unless stated.

### Animal studies

Mice were maintained in the Centenary Institute animal facility under specific pathogen-free conditions. The Animal Ethics Committee of the University of Sydney approved experimental procedures and housing arrangements. *FAP* gko<sup>[38]</sup> and *DPP4* gko mice<sup>[37]</sup> (C57BL/6J background) were bred at the Animal Resource Centre (Perth, Australia). Female multidrug resistance gene 2 (*Mdr2/Abcb4*) gko mice (FVB/N background) with targeted disruption of *Mdr2*, were obtained from Jackson Laboratory (Jackson Laboratory, Bar Harbor, ME, United States)<sup>[35]</sup>. Liver samples from the *Mdr2* gko and wild type (wt) mice were obtained at 4, 8 and 12 wk after birth, the time points that span the most active fibrosis progression<sup>[35]</sup>. RNA were obtained as previously described<sup>[41]</sup>. Lymphocytes from wt, *DPP4* gko and *FAP* gko mouse spleen, liver and lymph nodes were isolated as previously described<sup>[42]</sup>.

For the liver fibrosis mouse model, 8-wk-old female wt, *DPP4* gko and *FAP* gko mice were injected intraperitoneally with carbon tetrachloride (CCl<sub>4</sub>) twice weekly for 3 wk. Each dose comprised 5.36  $\mu$ L of 12% CCl<sub>4</sub> (in paraffin oil) per gram of initial weight of each mouse. Significantly elevated alanine aminotransferase (ALT) (68  $\pm$  11.1 U/L vs untreated controls 32  $\pm$  1.2 U/L) indicated liver injury. ALT was performed by an auto-analyzer at the Clinical Biochemistry Department of the Royal Prince Alfred Hospital. Organs were collected 3 d after the final CCl<sub>4</sub> treatment.

DPP: Dipeptidyl peptidase; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase; IgG: Immunoglobulin G; FITC: Fluorescein; PE: Phycoerythrin; APC: Allophycocyanin; HRP: Horse radish peroxidase; R-PE: R-phycoerythrin.

### Human liver samples

Human liver tissues were obtained from liver transplant recipients in accordance with National Health and Medical Research Council guidelines under Royal Prince Alfred Hospital Human Ethics Committee approvals. Non-diseased liver donors had an age range of 56-58 years and mixed genders. Cirrhotic livers were from primary biliary cirrhosis (PBC) patients of average age  $51.7 \pm 13.3$  years (range 27-67 years; 10 females, 2 males) and end stage alcoholic liver disease patients of average age  $49.3 \pm 8$  years (range 34-60 years, 9 males) as described previously.<sup>[40]</sup>

### In vitro stimulation assays

Human B lymphocyte Burkitt's lymphoma cell line (Raji) (ATCC, CCL-86) and human T cell leukemia cell line (Jurkat) (ATCC, TIB-153) were cultured in Roswell Park Memorial Institute (RPMI) Medium 1640 (Invitrogen, Carlsbad, CA, United States) supplemented with 10% fetal calf serum (FCS) and Penicillin-Streptomycin (100 units of penicillin and 100 µg/mL of streptomycin) (1 × P/S) and human liver hepatocellular carcinoma cell line Huh7 were grown in Dulbecco's Modified Eagle's Medium (Invitrogen) supplemented with 10% FCS and 1 × P/S.

Lymphocytes at  $1 \times 10^6$  cells/mL RPMI were treated with either 5 µg/mL pokeweed mitogen (PWM), 20 µg/mL lipopolysaccharide (LPS), 50 µg/mL Mitomycin C or 10 mmol/L dithiothreitol (DTT). Human liver hepatocellular carcinoma cell line, Huh7 cells were serum starved for 20 h before stimulation with 0, 1, 10, 100 ng/mL epidermal growth factor (EGF; R-D Systems, MN, United States) for 4 h.

### Apoptosis assay

To determine if DPP9 overexpression induces apoptosis, Raji cells were transiently transfected with wtDPP9-V5-His, mutDPP9-V5-His or vector control (pcDNA3.1/V5-HisA; Invitrogen, Carlsbad, CA, United States) as described previously,<sup>[39]</sup> then cultured. The lymphocytes

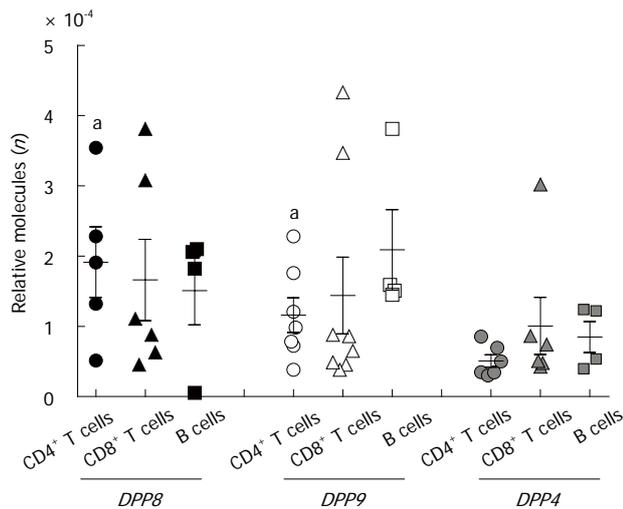

were transfected by electroporation using Amaxa® Cell Line Nucleofector® Kit V (Lonza, Basel, Switzerland) on a Lonza-amaxa Nucleofector device (Lonza). Forty hours post transfection, cells were washed with annexin binding buffer (10 mmol/L HEPES, 140 mmol/L NaCl, 2.5 mmol/L CaCl<sub>2</sub>, pH 7.4). Staining involved incubating cells with annexin V antibody (Table 1) for 30 min at room temperature in the dark followed by 4',6-diamidino-2-phenylindole (DAPI), Sigma Aldrich) at 100 ng/mL. Cells were enumerated using flow cytometry. Analysis was performed using FlowJo software (Tree Star Inc., Ashland, OH, United States).

### Fluorescence activated cell sorting

To isolate mouse lymphocyte subsets,  $3 \times 10^7$  splenocytes were resuspended in primary antibody diluted in phosphate buffered saline (PBS) containing 1% FCS and incubated in the dark, on ice for 30 min. The primary antibodies used are listed in Table 1. Following antibody staining, cells were washed with PBS containing 1% FCS. Cells underwent a final resuspension of  $2 \times 10^7$  cells/mL of PBS with 5% FCS and 2 mmol/L ethylene diamine tetraacetic acid (EDTA) to minimize clumping of cells. Twenty-five µL/mL of DAPI was added prior to cell sorting. Cell sorting was performed using the Fluorescence Activated Cell Sorting Vantage™ SE (BD Bioscience, NJ, United States). Cells were gated to exclude doublets and DAPI<sup>+</sup> (dead) cells. Three-way sort was performed to collect CD4<sup>+</sup> cells, CD8<sup>+</sup> cells and B220<sup>+</sup> cells into separate collection tubes.

### Real time quantitative polymerase chain reaction

RNA from cells was extracted using the RNAqueous-Micro™ kit (Ambion, TX, United States) following manufacturer's instructions. Total RNA (1 µg) was then reverse-transcribed to cDNA using 10 pmol of oligo(dT)<sub>12-18</sub> primer (Invitrogen, Carlsbad, CA, United States), 10 mmol/L deoxyribonucleotide triphosphates and SuperScript III reverse transcriptase (Invitrogen). Real time quantitative poly-

**Figure 1** Dipeptidyl peptidase mRNA expression in C57BL/6 mouse splenic lymphocyte subpopulations. Number of molecules relative to 18S RNA ( $n = 4-6$  mice). <sup>a</sup> $P < 0.05$  vs dipeptidyl peptidase (DPP) 4.

merase chain reaction (PCR) by Taqman<sup>®</sup> gene expression assays was performed using the Stratagene<sup>®</sup> Mx3000PTM System (La Jolla, CA, United States) according to manufacturer's recommendations. Taqman primers used for the assays were mouse *DPP4* (Mm00494548\_mL), *DPP8* (Mm00547049\_mL) and *DPP9* (Mm00841122\_mL). The samples were run in duplicates. The gene expression level was analyzed using a standard curve of serially diluted known numbers of molecules of the same gene and then normalized relative to 18S (Hs99999901\_s1). Quantitative PCR on human samples were performed using sequence detector (Prism, model 7700; Life Technologies, NY, United States) and were analyzed using sequence detector software (Prism, Version.1.6.3; Applied Biosystems Inc.). Primers used for human *DPP8* were forward: 5' CCAGATGGACCTCATTCAGACAG-3' and reverse: 5'GGTTGTTGCGTAAATCCTTGTGG-3' and for human *DPP9* were forward: 5'AGAAGCACCCACCGTCCTCTTTG-3' and reverse: 5'AGGACCAGCCATGGATGGCAACTC-3'. The number of molecules was normalized with human aldolase B (forward: 5'-CCTC-GCTATCCAGGAAAAC-3' and reverse: 5'TTGTAGA-CAGCAGCCAGGAC-3').

### Immunoblotting assay

Cells were washed with ice-cold PBS three times and then lysed with ice-cold lysis buffer (50 mmol/L Tris-HCl, 1 mmol/L EDTA, 1mmol/L MgCl<sub>2</sub>, 300  $\mu$ L of 150 mmol/L NaCl, 1% Triton-114, 10% glycerol and 1  $\times$  Roche complete protease inhibitor cocktail (Roche Applied Science, Mannheim, Germany) and stored at -80  $^{\circ}$ C. Protein concentration was determined using the micro BCA protein assay kit (Thermo Scientific, CA, United States) following the manufacturer's protocol. 50  $\mu$ g total of each cell lysate in LDS sample buffer (catalogue No. NP0007, Invitrogen) with reducing agent (catalogue No. NP0004, Invitrogen) in conditions that retain *DPP8* and *DPP9* dimerization<sup>[18,9,40]</sup> was resolved on 3%-8%

Tris-acetate sodium dodecyl sulfate-polyacrylamide gel electrophoresis (Invitrogen) followed by immunoblotting. Antibodies for immunoblotting are listed in Table 1. Relative band intensities were quantified using Image J and normalized against control proteins as indicated<sup>[40]</sup>.

### Statistical analysis

Results are expressed as individual replicates. Horizontal lines represent mean and error bars represent standard error. Differences among groups were analyzed using Mann-Whitney *t*-test by GraphPad Prism 5 software. *P* values  $< 0.05$  were considered significant.

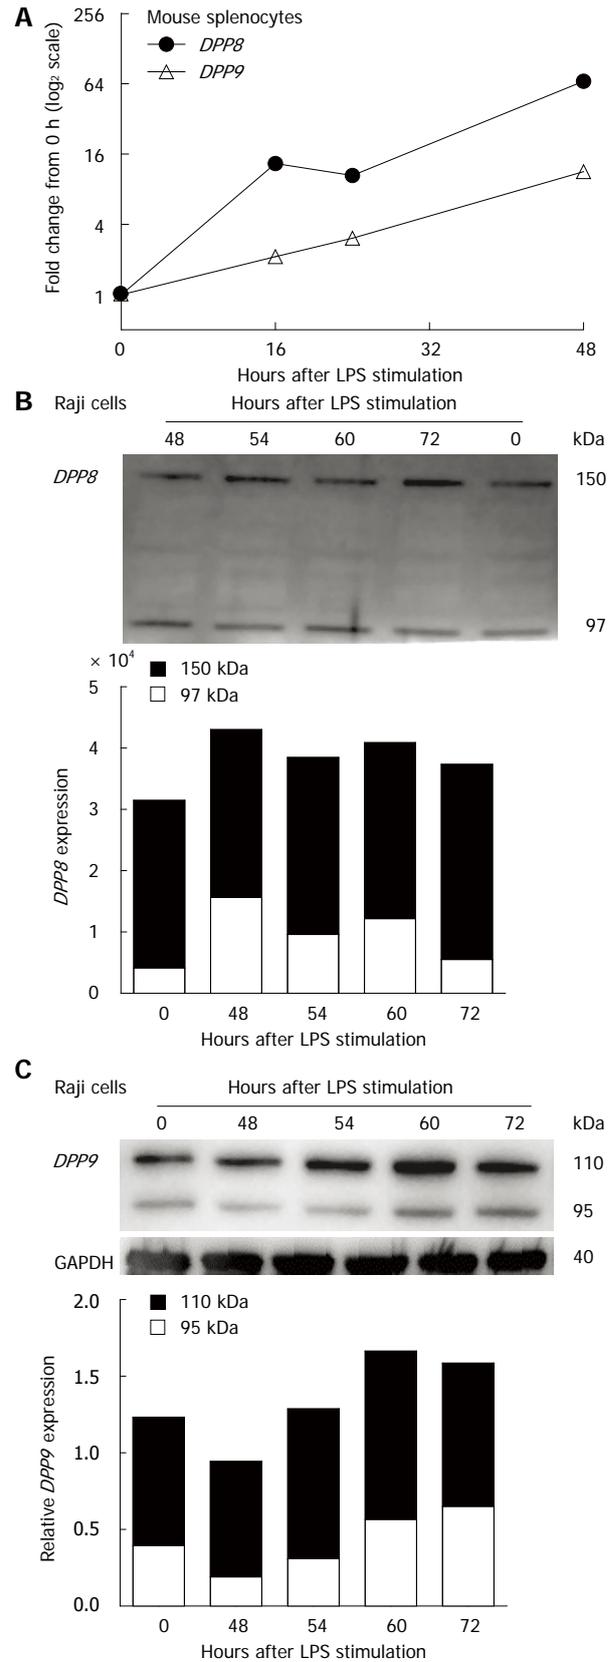

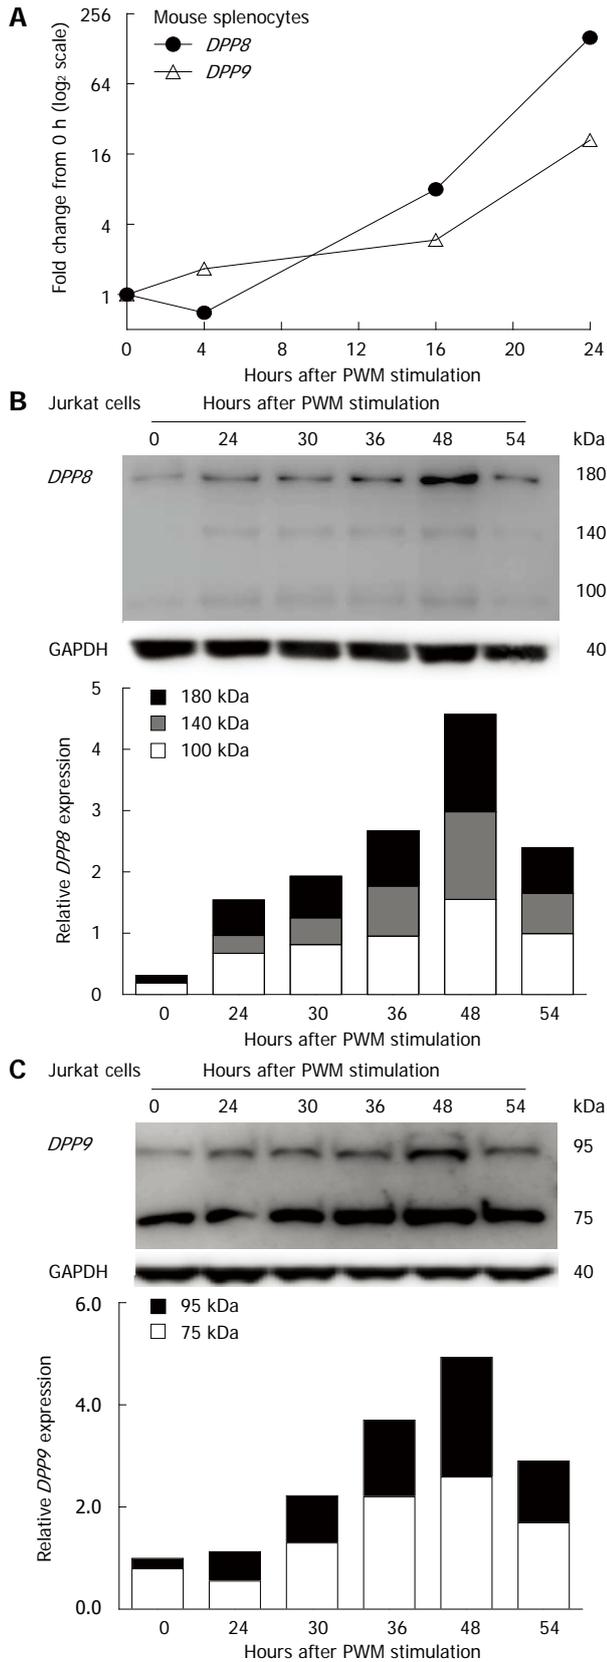

## RESULTS

To investigate which lymphocyte subsets express *DPP8* and *DPP9*, their transcript levels were quantified in the major lymphocyte subpopulations, CD4<sup>+</sup> (helper) and CD8<sup>+</sup> (cytotoxic) T cells and B220<sup>+</sup> (B cells) from normal C57BL/6 mouse splenocytes. All three lymphocyte subsets expressed *DPP8* and *DPP9* mRNA (Figure 1). *DPP8* and *DPP9* transcripts were expressed to significantly greater levels than *DPP4* transcripts in CD4<sup>+</sup> T cell subpopulation ( $P = 0.02$ ) and *DPP9* mRNA was significantly more abundant than *DPP4* mRNA in B cells ( $P = 0.03$ ).

To examine whether, like *DPP4*<sup>[7]</sup>, *DPP8* and *DPP9* are upregulated upon lymphocyte activation, mouse splenocytes were stimulated *in vitro* with PWM<sup>[43-45]</sup> and LPS<sup>[46,47]</sup>. *DPP8* and *DPP9* mRNA was markedly upregulated in PWM stimulated mouse splenocytes in a time dependent manner (Figure 2A). To examine whether the increased mRNA levels corresponded to protein expression, *DPP8* and *DPP9* proteins were measured in Jurkat (T cells) stimulated *in-vitro* with PWM. Both *DPP8* and *DPP9* were upregulated in a time dependent manner (Figure 2B and C).

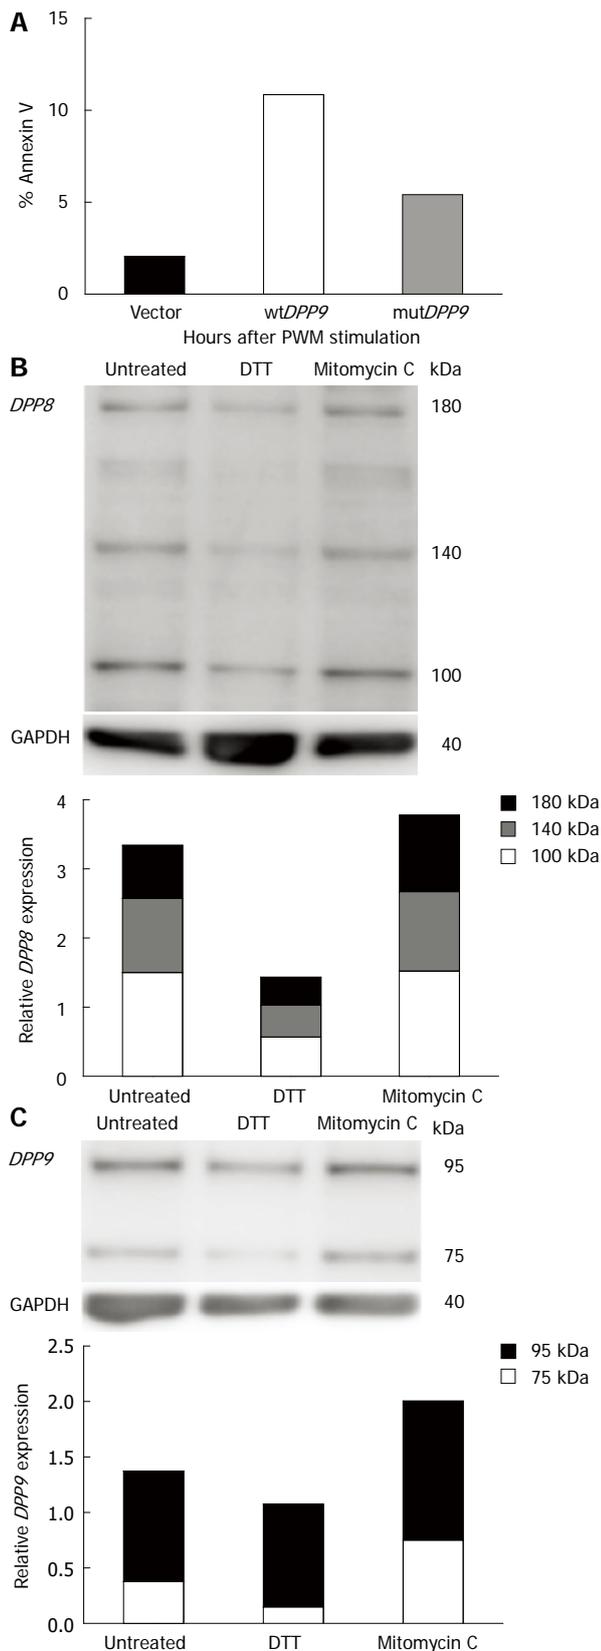

Similarly, mRNA levels of *DPP8* and *DPP9* were upregulated in LPS stimulated mouse splenocytes (Figure 3A). Also, LPS stimulated Raji (B cells) had upregulated *DPP8* and *DPP9* protein expression in a time dependent manner (Figure 3B and C).

Immunoblots of *DPP8* exhibited a slow mobility band at 150-180 kDa, which probably represents dimer or processed dimer, in addition to the faster mobility bands at 95-100 kDa that are likely to be monomer and truncated or trimmed monomer (Figure 2B and 3B). *DPP9* showed a slow mobility band of monomer at 110 kDa and faster mobility bands, which are possibly truncated or trimmed monomers at 75-95 kDa (Figure 2C and 3C)<sup>[18,9,40,48]</sup>. The intensity of all three *DPP8* bands increased in a time dependent manner with PWM stimulation in Jurkat cells (Figure 2B). However, in LPS stimulated Raji cells the intensity of only the 150 kDa band increased in a time dependent manner (Figure 3B). The intensity of all the *DPP9* bands increased with time in both PWM stimulated Jurkat cells and LPS stimulated Raji cells (Figure 2C and 3C). In PWM stimulated Jurkat cells, *DPP8* and *DPP9* expression both peaked at 48 h (Figure 2B and C). In Raji cells, increased expression of *DPP8* was observed at 72 h post LPS stimulation (the longest time point of the

study) (Figure 3B), and *DPP*9 expression peaked at 60 h (Figure 3C).

### *DPP*8 and *DPP*9 in lymphocyte apoptosis

We have previously shown that *DPP*9 overexpression induces intrinsic cell apoptosis in human hepatoma and embryonic kidney cell lines<sup>[39,40]</sup>. Similar to epithelial cells, *DPP*9 overexpression induced increased cell death in Raji cells (Figure 4A). This effect was less pronounced when Raji cells were transfected with mutant *DPP*9 lacking *DPP* activity (Figure 4A), suggesting that the enzyme activity of *DPP*9 influences lymphocyte apoptosis.

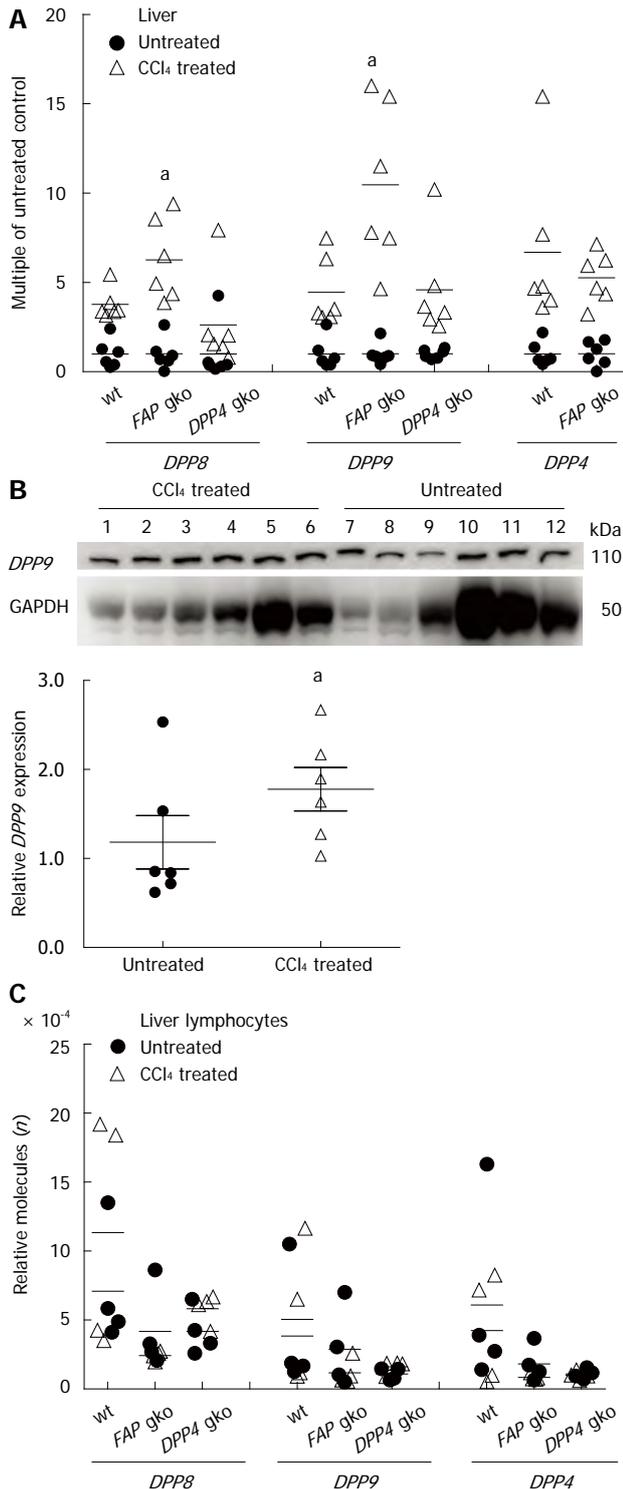

Interestingly, Raji cells treated with DTT, an antioxidant that impairs cell apoptosis, had less *DPP*8 and *DPP*9 expression compared to untreated cells (Figure 4B and C). Conversely, treatment of Raji cells with mitomycin C, a lectin that impairs cell proliferation, resulted in increased *DPP*8 and *DPP*9 expression in Raji cells (Figure 4B and C). Intensities of all *DPP*8 and *DPP*9 band sizes were less with DTT treatment and greater with Mitomycin C treatment compared to untreated cells (Figure 4B and C).

### *DPP*9 in EGF stimulated hepatocytes

EGF is a regulatory factor in cell survival, growth, proliferation and differentiation<sup>[49]</sup>. Previously, we have shown that *DPP*9 overexpression impairs EGF-stimulated cell proliferation in HepG2 and Huh7 human hepatoma cell lines<sup>[40]</sup>. *DPP*9 expression at 75 kDa was greater in Huh7 cells after EGF stimulation (Figure 5). This study expands the association of *DPP*9 with EGF in this hepatoma cell line.

### Intrahepatic *DPP*8 and *DPP*9 upregulation in CCl<sub>4</sub> induced liver injury

To examine *DPP*8 and *DPP*9 expression in liver injury,

**Figure 6** Dipeptidyl peptidase mRNA upregulation in carbon tetrachloride induced liver injury. **A:** Multiple of intrahepatic mRNA in carbon tetrachloride (CCl<sub>4</sub>) treated mice to mean of untreated control mice; <sup>a</sup>*P* < 0.05 in CCl<sub>4</sub> treated fibroblast activation protein (*FAP*) gene knockout (*gko*) vs wild type (*wt*); **B:** Dipeptidyl peptidase (*DPP*) 9 immunoblot of livers from CCl<sub>4</sub> treated (lanes 1-6) and untreated mice (lanes 7-12) (*n* = 6 per group). Densitometry of intrahepatic *DPP9* relative to glyceraldehyde 3-phosphate dehydrogenase (*GAPDH*). <sup>a</sup>*P* < 0.05 vs untreated controls; **C:** mRNA quantitation from isolated hepatic lymphocytes relative to 18S.

CCl<sub>4</sub> was used to induce liver fibrosis in *wt*, *DPP4 gko* and *FAP gko* mice. *DPP4*, *DPP8* and *DPP9* mRNA were

significantly more abundant in the livers from CCl<sub>4</sub> treated mice of all three genotypes compared to the untreated controls (Figure 6A). *DPP8* and *DPP9* mRNA expression in the CCl<sub>4</sub> treated livers were greater in the *FAP gko* mice compared to *wt* (*DPP8 P* = 0.02; *DPP9 P* = 0.02), suggesting that *DPP8* and *DPP9* might have compensatory roles in the absence of *FAP* (Figure 6A). The increase in *DPP9* mRNA in the fibrotic livers was consistent with protein expression in *wt* mice (*P* = 0.05) (Figure 6B). An appropriate antibody to mouse *DPP8* is not available.

Since *DPP8* and *DPP9* are expressed by human hepatic lymphocytes<sup>[13]</sup> and because there is an increase of infiltrating lymphocytes in liver fibrosis, we examined whether the mouse hepatic lymphocytes were likely to contribute to the observed upregulation of *DPP* expression. However, *DPP* mRNA in the mouse hepatic lymphocytes was similar in the fibrotic and normal livers (Figure 6C).

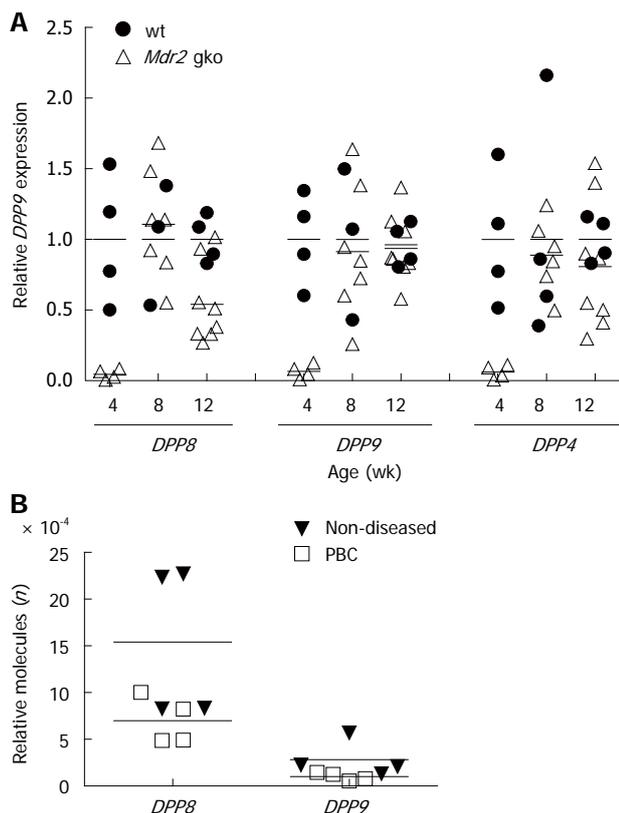

### Intrahepatic *DPP8* and *DPP9* downregulation in biliary liver disease

The *Mdr2 gko* mouse strain is deficient in the canalicular phospholipid flippase and is a model of periportal biliary fibrosis resembling primary sclerosing cholangitis<sup>[41]</sup>. These mice develop spontaneous hepatomegaly as early as 2 wk after birth and significant biliary fibrosis with a fivefold increased liver collagen content by 12 wk of age, when no further fibrosis progression occurs<sup>[41]</sup>. Measuring *DPPs* in these mice at 4, 8 and 12 wk of age showed that *DPP* mRNA expression was surprisingly very low at wk 4, significantly lower than in *wt* (*DPP8 P* = 0.03; *DPP9 P* = 0.03; *DPP4 P* = 0.03) (Figure 7A). At 8 and 12 wk of age, *DPP* expression levels were similar to *wt*.

In human end-stage PBC livers, *DPP9* mRNA expression was significantly less than in the non-diseased livers (*P* = 0.03) (Figure 7B). This finding is consistent with the results in the *Mdr2 gko* mice and with the human *DPP9* Western blot data<sup>[40]</sup>. *DPP8* mRNA expression levels in the non-diseased and PBC livers were not statistically different (*P* = 0.057).

## DISCUSSION

This study significantly promotes our understanding of the novel proteases *DPP8* and *DPP9* in lymphocytes, hepatocytes and liver injury. We showed that *DPP8* and *DPP9* are widely expressed in lymphocyte subpopulations and upregulated in mitogen activated lymphocytes in a time dependent manner. Besides lymphocyte activation, we demonstrated their potential involvement in lymphocyte apoptosis. In liver, we showed that *DPP8* and *DPP9* expression levels were altered in liver injury and confirmed their role in the regulation of EGF in hepatocytes, a mitogen that is considered crucial for hepatocyte proliferation and liver regeneration. The interestingly variable expression patterns of *DPP8* and *DPP9* in different conditions in lymphocytes and in liver injury suggest that these proteases may have important regulatory roles in the immune system and in liver disease pathogenesis.

**Figure 7** Dipeptidyl peptidase mRNA in mouse and human biliary liver diseases. **A:** Multiple of Intrahepatic dipeptidyl peptidase (*DPP*) mRNA in multidrug resistance gene 2 (*Mdr2*) gene knockout (gko) female mice to mean of wild type (wt) controls; **B:** Human end-stage primary biliary cirrhosis (PBC) and non-diseased control livers. Data from each individual is shown as the number of molecules relative to aldolase B (*n* = 4 per group).

*DPP8/9* activity and expression in lymphocytes have been reported previously<sup>[8,30,50]</sup>, but which lymphocyte subpopulations express *DPP8* and *DPP9* remained unknown. Here we show that all the lymphocyte subpopulations tested, CD4<sup>+</sup> T cells, CD8<sup>+</sup> T cells and B220<sup>+</sup> B cells express *DPP8* and *DPP9*. The wide expression of *DPP8* and *DPP9* in lymphocyte subpopulations suggests that these proteases have essential roles in the immune system. As it is now known that immune roles of *DPP4* are mainly extraenzymatic (such as protein-protein interaction), greater abundance of *DPP8* and *DPP9* compared to *DPP4/CD26* in the lymphocytes further supports the hypothesis that the immune effects with non-selective *DPP4* inhibitors in earlier studies were more likely due to *DPP8* and *DPP9* inhibition<sup>[2]</sup>.

We demonstrated a quantitative time-dependent up-regulation of *DPP8* and *DPP9* in mitogen-stimulated mouse splenocytes and human Jurkat CD4<sup>+</sup> T cells, as well as in polyclonally activated Raji B cells. Therefore, *DPP8* and *DPP9* might have roles in both T and B cell activation. *DPP8* and *DPP9* were upregulated in lymphocytes following acute mitogen stimulation, but with prolonged stimulation, they were downregulated. Hence, the role of *DPP8* and *DPP9* perhaps differ in recently activated lymphocytes compared to persistently activated lymphocytes.

*DPP9* enzyme activity induces intrinsic cell apoptosis in epithelial cells through the phosphatidylinositol-3-kinase/protein kinase B (Akt) signaling pathway<sup>[39,40]</sup>. Our data on Raji cells suggest that *DPP9* could similarly have a role in intrinsic lymphocyte apoptosis. Moreover the increase in *DPP8* and *DPP9* expression in mitomycin C treated cells is perhaps a hallmark of increased apoptosis in the absence of cell proliferation<sup>[51,52]</sup>. *DPP9* substrates and ligands involved in these processes have not been identified.

The modulation of *DPP8* and *DPP9* expression with varying lymphocyte activation, proliferation and apoptosis, implies that *DPP8* and *DPP9* have important regulatory roles in lymphocytes that deserve further investigation. Their role in lymphocyte activation is likely to differ from that of *DPP4*. While the role of cell surface *DPP4* in lymphocyte proliferation appears to be mainly extra-enzymatic<sup>[22]</sup>, enzyme inhibition of intracellular *DPP8* and *DPP9* affects lymphocyte proliferation<sup>[23]</sup>. The observation of less annexin V staining in Raji cells overexpressing *DPP9* enzyme mutant compared to wild type *DPP9* suggests that enzyme activity of *DPP9* is important for its role in apoptosis. *DPP9* modulates Akt phosphorylation in hepatoma cell lines<sup>[40]</sup>, so *DPP8* and *DPP9* might similarly modulate the activity of signaling molecules that are crucial in lymphocyte activation pathways. *DPP8* can cleave several chemokines, stromal cell-derived factor (SDF)-1 $\alpha$ , SDF-1 $\beta$ , inflammatory protein 10 and interferon-inducible T-cell alpha chemoattractant, *in vitro*<sup>[12]</sup>, however since *DPP8* is an intracellular protease, the biological relevance of this cleavage is unknown.

The association of *DPP4* and *FAP* with liver fibrosis is well documented<sup>[24,53]</sup>. Here we have demonstrated possible involvement of *DPP8* and *DPP9* in liver fibrosis, too. Treatment of mice with CCl<sub>4</sub> for 3 wk, which represents early fibrosis with mild hepatic injury, increased intrahepatic *DPP8* and *DPP9* expression. This association with early stage disease may suggest pro-fibrogenic roles of *DPP8* and *DPP9*. Though *DPPs* have been implicated in inflammation and inflammatory diseases<sup>[28,29,54]</sup>, no change in *DPP* expression was observed in hepatic lymphocytes in this early stage fibrosis, suggesting that hepatocytes, which constitute more than 80% of the liver cell population, are probably the major source of upregulated *DPP8* and *DPP9* in this liver fibrosis model.

Unlike the CCl<sub>4</sub> induced liver fibrosis model, *DPP8* and *DPP9* were downregulated in end stage human PBC and in the *Mdr2* gko mice. This suggests that *DPP8* and *DPP9* expression varies with the pathophysiology of liver diseases. The mouse CCl<sub>4</sub> model represents zone 3 fibrosis whereas *Mdr2* gko represents a zone 1 fibrosis model<sup>[41,55]</sup>. *DPP8* and *DPP9* show a zonal distribution pattern, with stronger staining in zone 3, the periportal hepatocytes and periportal lymphocytes<sup>[13]</sup>. Hence, the zonal injury pattern may be important for *DPP8* and *DPP9* expression. Another possibility could be that activated cholangiocytes downregulate *DPP8* and *DPP9* expression. In the *Mdr2* gko mice, *DPP8* and *DPP9* expression was least at week 4, when the cholangiocytes are

most active<sup>[41]</sup>. Hence, this could be the reason why *DPP8* and *DPP9* expression was downregulated in human PBC and *Mdr2* gko mice.

Alternatively, the differential expression of *DPP* in the different liver diseases could be due to acute *vs* chronic stimuli.  $\text{CCl}_4$  induces acute liver injury with hepatocyte damage followed by a repair phase that involves increased collagen deposition<sup>[55]</sup>. Administration of  $\text{CCl}_4$  twice per week for 3 wk leads to repeated cycles of injury and repair that results in fibrosis. We collected liver samples from the  $\text{CCl}_4$  treated mice at day 3 after the last  $\text{CCl}_4$  injection. At day 3, hepatocyte apoptosis is waning whereas fibrosis is developing<sup>[55]</sup>. In contrast, the *Mdr2* gko mice and human end stage PBC represent chronic liver injury, whereby there is persistent (mild) hepatocyte damage, a fibrogenic cholangiocyte/progenitor cell response and downregulation of collagenolytic activity resulting in continuing progression of biliary fibrosis until week 12 of age<sup>[41]</sup>. Thus, our data are consistent with the paradigm that *DPP8* and *DPP9* are upregulated in acute disease states then downregulated with progression to chronic disease states.

This distinctive *DPP* expression pattern in different liver diseases suggests that *DPP8* and *DPP9* have important regulatory roles in the pathogenesis of liver diseases, perhaps in modulating liver regeneration and apoptosis, which are important processes in liver disease progression. *DPP9* impairs EGF-stimulated hepatoma proliferation<sup>[40]</sup>. Our observation that *DPP9* is upregulated in the presence of EGF is perhaps part of a regulatory mechanism of *DPP9* in hepatocyte proliferation. *DPP9* can induce intrinsic apoptosis in hepatoma cell lines *via* the Akt signaling pathway<sup>[40]</sup>. Furthermore, *DPP8* and *DPP9* influence cell-extracellular matrix (ECM) interactions *in vitro*<sup>[39]</sup> and in liver fibrogenesis, cell-ECM interaction is responsible for disrupting wound healing and progressive scarring in liver disease<sup>[56]</sup>.

The upregulated expression of *DPP8* and *DPP9* in acute conditions and less expression in chronic or persistent conditions in the immune system and in liver injury suggests that *DPP8* and *DPP9* are crucial for early cellular responses to stimuli. The mechanisms of *DPP8* and *DPP9* are yet to be elucidated. One obstacle in *DPP8* and *DPP9* studies is the poor availability of appropriate tools, such as monoclonal antibodies and selective inhibitors<sup>[57]</sup>.

In conclusion, our study suggests that *DPP8* and *DPP9* have fundamental roles in the immune system, in lymphocyte activation and in apoptosis and they could be involved in liver fibrogenesis. A better understanding of the biological functions of *DPP8* and *DPP9* could help reveal their therapeutic potential for liver diseases, cancer, inflammatory and autoimmune diseases.

## COMMENTS

### Background

The four enzyme members of the dipeptidyl peptidase (*DPP*) 4 gene family, *DPP4*, fibroblast activation protein (*FAP*), *DPP8* and *DPP9* have attracted considerable research interest in recent years since *DPP4* inhibitors became a successful therapy for type 2 diabetes and *FAP* a potential cancer therapeutic target. *DPP8* and *DPP9* are the more recently discovered members of the *DPP4* gene family. They are ubiquitously expressed cytoplasmic enzymes with *DPP4* like enzyme activity. Many compounds intended to inhibit *DPP4* or *FAP* also inhibit *DPP8* and *DPP9*, but the compounds that became successful diabetes drugs are *DPP4*-selective.

### Research frontiers

*DPP4* is also known as CD26 T cell differentiation marker and has roles in T cell activation and proliferation. *DPP8* and *DPP9* are in lymphoid tissues and may have functional significance in the immune system. *DPP8* and *DPP9* are expressed in hepatocytes and expression is elevated in damaged hepatocytes near the septum of human cirrhotic liver. However, potential roles of *DPP8* and *DPP9* in liver disease are unknown. Here the authors studied the expression of *DPP8* and *DPP9* in lymphocyte activation, proliferation and apoptosis and in liver injury models to elucidate their potential biological roles in the immune system and in liver diseases. Models included hepatotoxicity from  $\text{CCl}_4$ , and the multidrug resistance gene 2 knockout mouse that spontaneously develops biliary fibrosis.

### Innovations and breakthroughs

This study significantly promotes our understanding of the novel proteases *DPP8* and *DPP9* in lymphocytes, hepatocytes and liver injury. The authors showed that *DPP8* and *DPP9* were widely expressed in lymphocyte subpopulations and were upregulated in activated lymphocytes in a time dependent manner. The authors also demonstrated potential involvement of *DPP8* and *DPP9* in lymphocyte apoptosis. In liver, the authors showed that *DPP8* and *DPP9* expression levels were altered in liver injury and confirmed their role in the regulation of epidermal growth factor in hepatocytes, a mitogen that is considered crucial for hepatocyte proliferation and liver regeneration.

### Applications

This study suggests that *DPP8* and *DPP9* have fundamental roles in the immune system, in lymphocyte activation and in apoptosis and they could be involved in chronic liver injury pathogenesis.

### Terminology

*DPP4* enzyme activity is a specialized proteolytic enzyme activity that cuts two amino acids from the N-terminus of each target peptide, usually cutting after a proline residue; Lymphocyte activation is a cellular process that leads to a radical shift in cell behavior to a more active and proliferative one. The activation of lymphocytes serves two purposes, augmenting the number of cells to respond to a particular antigen (clonal expression), and specializing to produce cytokines, and produce antibodies against a pathogen; cell apoptosis is the process of cell death mediated by an intracellular program. Apoptosis is important for normal cell turnover and organ remodeling.

### Peer review

The manuscript deals with regulation of *DPP8* and *DPP9* expression in activated lymphocytes and injured liver. Here the authors focus on the expression levels of *DPP8* and *DPP9* in lymphocyte subpopulations in a time dependent manner. The authors have confirmed the altered expression level of *DPP8* and *DPP9* in liver injury and also confirmed their role in the regulation of epidermal growth factor in hepatocytes. The work has been carefully conducted and the experiments are clearly described in the vast majority of the cases.

### Abstract

**AIM:** To investigate the effects of long term pretreatment with low-, medium- and high-dose aspirin (acetylsalicylic acid, ASA) on a model of acute pancreatitis (AP) induced in rats.

**METHODS:** Forty male Wistar rats were used. Three experimental groups, each consisting of eight animals,

received low- (5 mg/kg per day), medium- (150 mg/kg per day) and high-dose (350 mg/kg per day) ASA in supplemented pellet chow for 100 d. Eight animals, serving as the AP-control group, and another eight, serving as reference value (RV) group, were fed with standard pellet chow for the same period. After pretreatment, AP was induced in the experimental animals by intraperitoneal administration of cerulein ( $2 \times 50 \mu\text{g}/\text{kg}$ ), while the RV group received saline in the same way. Twelve hours after the second injection, the animals were sacrificed. Pancreatic tissue and plasma samples were collected. One part of the collected pancreatic tissues was used for histopathological evaluation, and the remaining portion was homogenized. Cytokine levels [tumor necrosis factor, interleukin (IL)-1 $\beta$ , IL-6], hemogram parameters, biochemical parameters (amylase and lipase), nuclear factor- $\kappa$ B, aspirin triggered lipoxins and parameters related to the antioxidant system (malondialdehyde, nitric oxide, hemeoxygenase-1, catalase and superoxide dismutase) were measured.

**RESULTS:** Cerulein administration induced mild pancreatitis, characterized by interstitial edema (total histopathological score of  $5.88 \pm 0.44$  vs  $0.25 \pm 0.16$ ,  $P < 0.001$ ). Subsequent pancreatic tissue damage resulted in an increase in amylase ( $2829.71 \pm 772.48$  vs  $984.57 \pm 49.22$  U/L,  $P = 0.001$ ) and lipase ( $110.14 \pm 75.84$  U/L vs  $4.71 \pm 0.78$  U/L,  $P < 0.001$ ) in plasma, and leucocytes ( $6.89 \pm 0.48$  vs  $4.36 \pm 0.23$ ,  $P = 0.001$ ) in peripheral blood. Cytokines, IL-1 $\beta$  ( $18.81 \pm 2.55$  pg/ $\mu\text{g}$  vs  $6.65 \pm 0.24$  pg/ $\mu\text{g}$ ,  $P = 0.002$ ) and IL-6 ( $14.62 \pm 1.98$  pg/ $\mu\text{g}$  vs  $9.09 \pm 1.36$  pg/ $\mu\text{g}$ ,  $P = 0.04$ ) in pancreatic tissue also increased. Aspirin pretreatment reduced the increase in the aforementioned parameters to a certain degree and partially improved the histopathological alterations caused by cerulein. No evidence of side effects related to chronic ASA administration (*e.g.*, inflammation or bleeding) was observed in the gastrointestinal tract in macroscopic and histopathological examination.

**CONCLUSION:** Long term ASA pretreatment could prevent and/or ameliorate certain hematological, serological and histological alterations caused by cerulein-induced AP.

**Key words:** Aspirin; Acute pancreatitis; Cerulein; Antioxidant; Cytokines

**Core tip:** Acute pancreatitis (AP) is an inflammatory and potentially life-threatening disease. An estimated 80000 cases of AP occur each year in the United States. There is no specific cure for AP; therefore, research interest has focused on prevention strategies. In the present study, the effects of a long-term pretreatment with different doses of aspirin, the oldest and most widely used non-steroidal anti-inflammatory drug, were investigated on a AP model in rats. Our results indicated that aspirin pretreatment dose-dependently prevents or ameliorates some hematological, serological and histological alterations caused by cerulein-induced AP.

## INTRODUCTION

Acute pancreatitis (AP) is an inflammatory disease with broad clinical variation, ranging from a mild and self-limiting condition to a severe, life-threatening necrotizing inflammation<sup>[1,2]</sup>. Furthermore, it can lead to the development of systemic inflammatory response syndrome (SIRS) and multisystem organ failure<sup>[3,4]</sup>.

AP may have numerous causes, such as bile duct obstructions, alcohol abuse, metabolic abnormalities, various toxins and infections<sup>[5]</sup>. One of the aforementioned incidents may trigger pancreatic acinar cell injury and premature activation of pancreatic zymogens<sup>[6]</sup>. The initial acinar cell damage is followed by local activation of the immune system and induction of transcription factors, such as nuclear factor- $\kappa$ B (NF- $\kappa$ B)<sup>[4,7]</sup>. Activation of inflammatory cells and transcription factors leads to elaboration of various proinflammatory mediators, such as tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ), interleukin (IL)-1 $\beta$  and IL-6<sup>[8]</sup>. If this proinflammatory response to acinar cell damage is balanced by an anti-inflammatory response, the pancreatitis and local inflammation resolve at this stage. However, in some cases, an overwhelming proinflammatory response upsets this balance and the proinflammatory mediators migrate into systemic circulation leading to a generalized inflammation and SIRS<sup>[4,8]</sup>.

In this context, proinflammatory mediators and NF- $\kappa$ B, which play a key role in expression of these mediators, emerge as potential therapeutic targets<sup>[6,8]</sup>.

Acetylsalicylic acid (ASA) exerts analgesic, antipyretic and antiplatelet effects, and is the oldest and most widely used nonsteroidal anti-inflammatory drug<sup>[9]</sup>. In addition to its conventional effects, ASA has a preventative effect on a wide range of diseases, including gastrointestinal cancer<sup>[10]</sup>, ischemic stroke<sup>[11]</sup>, myocardial infarction<sup>[12]</sup> and Alzheimer's disease<sup>[13]</sup>. The anti-inflammatory, analgesic and antipyretic efficacy of ASA is attributed mainly to its inhibitory impact on the enzymatic activity of cyclooxygenases (COX), which convert arachidonic acid to prostaglandins (PGs)<sup>[14]</sup>. On the other hand, it has been speculated that simple inhibition of PG production cannot fully account for the wide spectrum of effects of ASA<sup>[9,15]</sup>. Indeed, substantial data have been gathered, indicating that COX-independent mechanisms play a significant role in ASA's efficacy<sup>[15]</sup>. Kopp *et al.*<sup>[16]</sup> discovered that ASA inhibits NF- $\kappa$ B activation, which is a pivotal transcription factor in cytokine network. NF- $\kappa$ B regulates the expression of proinflammatory enzymes, cytokines, chemokines, immunoreceptors, acute phase proteins and cell adhesion molecules; therefore, it has often been termed a "central mediator of the immune system"<sup>[15,17,18]</sup>. In this regard, it has been stated that even partial inhibition of NF- $\kappa$ B by ASA could have a substantial effect on inflammation<sup>[16]</sup>. Another major finding was the discovery that acetylation of COX-2 by ASA can lead to transcellular biosynthesis of a new class of eicosanoids, the 15-epi-lipoxins or so-called aspirin-triggered lipoxins (ATL), which promote the resolution of inflammation<sup>[19,20]</sup>. Lipoxins have potent counter-regulatory effects *in vivo* and *in vitro* on proinflammatory mediators such as TNF- $\alpha$ , IL-1 $\beta$ , IL-6 and IL-4<sup>[19,21,22]</sup>. Furthermore it has been speculated that ASA's unique ability to trigger the synthesis of ATLs causes an increase in nitric oxide (NO) synthesis and this aspirin-elicited NO exerts anti-inflammatory effects<sup>[23]</sup>. Grosser *et al.*<sup>[24]</sup> found that ASA stimulates the expression and enzymatic activity of hemeoxygenase-1 (HO-1) protein in a COX-independent manner. HO-1 is a crucial mediator of the cellular antioxidant defense system and has anti-inflammatory, anti-apoptotic, and antiproliferative effects<sup>[25,26]</sup>. Recent data<sup>[27]</sup> elucidated the underlying mechanism of HO-1 expression stimulated by ASA: ATL is mainly responsible for the aforementioned stimulation.

Taken together, this wide spectrum of therapeutic effects of ASA is a consequence of its efficacy in regulating a network of biochemical and cellular events in a more complex manner than was initially thought<sup>[9,28]</sup>.

The significant role of proinflammatory mediators (*e.g.*, TNF- $\alpha$ , IL-1 $\beta$ , IL-6 and platelet activating factor) and transcription factors (*e.g.*, NF- $\kappa$ B and AP-1) in the pathogenesis and complications of AP are well documented in the literature<sup>[6,8]</sup>. Considering the inhibitory efficacy of ASA on these agents, it would be reasonable to suggest that ASA may be efficient in preventing or at-

**Table 1** Grouping and experimental design

| Group No. | <i>n</i> | Group name                 | ASA pretreatment (mg/kg) | AP induction |
|-----------|----------|----------------------------|--------------------------|--------------|
| 1         | 8        | Reference value            | No                       | No           |
| 2         | 8        | Acute pancreatitis control | No                       | Yes          |
| 3         | 8        | Low-dose ASA               | 5                        | Yes          |
| 4         | 8        | Medium-dose ASA            | 150                      | Yes          |
| 5         | 8        | High-dose ASA              | 350                      | Yes          |

tenuating AP and its subsequent complications. Furthermore, ASA's antioxidant efficacy exerted *via* the stimulation of HO-1 expression and the anti-inflammatory efficacy of ATL supports and strengthens the aforementioned hypothesis that ASA may be a therapeutic agent for the prevention and/or treatment of AP. However, to the best of our knowledge, there are no studies investigating the preventive and/or therapeutic effects of ASA on AP. Therefore, this study aimed to investigate the effects of ASA pretreatment on experimental AP in rats. By designing an experimental study with a long-term pretreatment, we focused on the preventive effects of ASA, rather than the curative ones, because the multiple and diverse mechanisms of action of ASA seem to be most effective on the initial proinflammatory progress in the pathogenesis of AP.

## MATERIALS AND METHODS

### Animals and grouping

Studies were performed on 40 male Wistar rats weighing 350-400 g. Animals were housed in polycarbonate cages (four rats/cage) with wood chip bedding and fed standard laboratory chow (supplemented with ASA for treatment groups) and tap water *ad libitum*. They were maintained in a climate-controlled animal room (temperature: 22 ± 3 °C; relative humidity: 60% ± 5%) with a 12 h/12 h light/dark cycle.

The Istanbul University's Local Ethics Committee approved all the experimental procedures. The animals were randomly allocated to five groups as shown in Table 1.

### ASA pretreatment and dosing

Low, medium and high doses of ASA pretreatment were performed as diet supplements for 100 d<sup>[29]</sup>. Doses of 80 mg/d, 2-4 and 6-8 g/d ASA have been regarded as low, medium and high doses for humans, respectively<sup>[30]</sup>. Based on average human body weight of 70 kg, these doses correspond to 1.1, 28-56 and 86-114 mg/kg per day, respectively<sup>[31]</sup>. These human doses were scaled to rats according to Kleiber's rule<sup>[32]</sup> using the following equation: dose (rat)/dose (human) = BW<sup>0.25</sup> (rat)/BW<sup>0.25</sup> (human) (BW = body weight)<sup>[33]</sup>. Based on the dose intervals derived from the above equation, the following doses were chosen for ASA pretreatment: 5 mg/kg (low-dose), 150 mg/kg (medium-dose) and 350 mg/kg (high-dose). Considering the daily food consumption of rats, stan-

dard rat chow material was supplemented with the corresponding amounts of ASA before pelleting to achieve the aforementioned low, medium and high doses. Groups 3-5 were fed these ASA supplemented pellets, while the other groups (Groups 1 and 2) received standard chow during the 100-d pretreatment.

### Induction of AP

After pretreatment, all the animals, except those in the reference value (RV) group (Group 1), received two intraperitoneal injections of cerulein in 0.9% NaCl at an hourly interval at a dose of 50 µg/kg to induce AP<sup>[34]</sup>. Animals in the RV group received injections of the same volume of sterile saline solution (0.9% NaCl) in the same way.

### Sample collection and preparation

Twelve hours after the induction of AP, all animals were anesthetized (xylazine/ketamine, 10/75 mg/kg) and exsanguinated *via* cardiac puncture. Blood samples were collected into ethylene diamine tetraacetic acid-coated tubes and plasma samples were separated *via* centrifugation after performing a complete blood count. The plasma samples were aliquoted and frozen at -80 °C. After sacrificing the animals, necropsies were performed and pancreatic tissues were removed. One part of the pancreas of each animal was used for homogenization, while the remaining portion was fixed in formol-saline (10%) for histopathological examination.

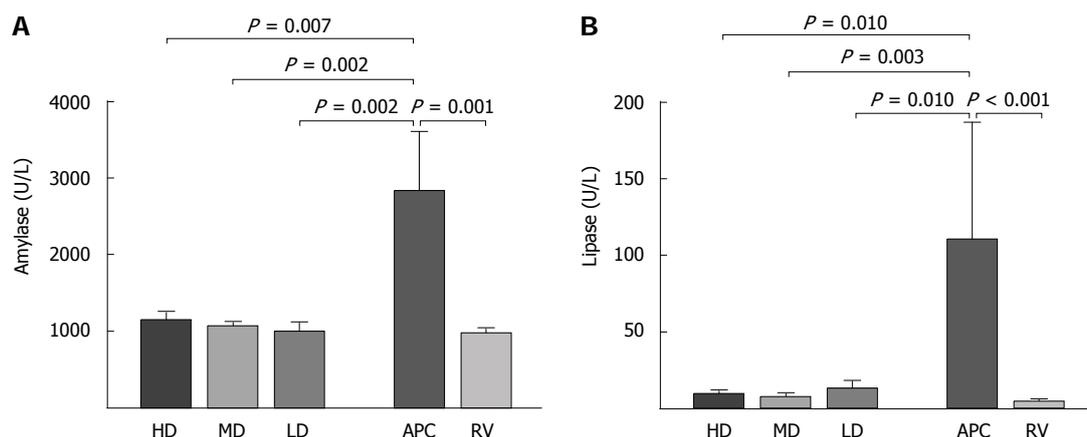

Pancreas samples were homogenized in a 20 mmol/L Tris-HCl buffer (pH 7.4) containing 0.5 mol/L sucrose, 25 mmol/L KCl and 5 mmol/L MgCl<sub>2</sub> using a rotor-stator homogenizer. The homogenates were centrifuged at 1000 *g* for 10 min at 4 °C, and the supernatants containing the cytosolic fraction were removed, aliquoted and frozen at -80 °C until assayed. Sedimented pellets containing the nuclear fraction were used to obtain nuclear protein extracts using a commercial protein extraction kit (Intron Biotechnology Inc., Sungnam, South Korea).

### Statistical analysis

TNF-α, IL-1β and IL-6 levels were determined in tissue homogenates containing the cytosolic fraction and in plasma samples using commercial enzyme-linked immunosorbent assay (ELISA) kits (Invitrogen, Camarillo, CA, United States). NF-κB levels were measured in nuclear protein extractions, using a commercial ELISA kit (USCN Life Science Inc., Wuhan, Hubei Province, China).

Catalase (CAT) activities (Cell Biolabs, San Diego, CA, United States), superoxide dismutase (SOD) activities (Assay Designs, Ann Arbor, MI, United States), and malondialdehyde (MDA) levels (Cell Biolabs) were measured in pancreas homogenates and in plasma using commercial test kits. HO-1 levels were determined in pancreas homogenates and plasma using commercial ELISA kits (Assay Designs).

Amylase and Lipase levels in plasma were measured using an automated analyzer (Architect 16200, Abbott,

**Figure 1 Plasma amylase (A) and lipase (B) activities.** Columns show the mean and the error bars represent SEM. All groups are compared with the acute pancreatitis control (APC) group and the statistical significance is expressed as a vertical  $P$  value over the column. IL, United States). Total NO levels were determined in plasma and pancreas homogenates using commercial test kits (Assay Designs). Plasma ATL levels were measured using commercial ELISA kits (Neogen, Lexington, KY, United States). Total protein contents of homogenates were determined using the method described by Lowry *et al.*<sup>[35]</sup> and all parameters measured in homogenates were proportioned to the total protein content of the homogenate in mg.

Tissue samples fixed in formol-saline were embedded in paraffin blocks, sectioned using a microtome and stained with hematoxylin-eosin. Histopathological scoring was performed as described by Gülçubuk *et al.*<sup>[36]</sup>, graded on a score of 0 to 3.

Statistical analysis of the obtained data was performed using the SPSS-software package (Version 11.5.2.1, SPSS Inc., Chicago, IL, United States). Results are expressed as mean  $\pm$  SEM. Data for all groups were first tested for normality using the Shapiro-Wilk test. Data of groups found to be normally distributed were then compared using one-way analysis of variance. If the normality assumption was found to be violated, data were analyzed using the non-parametric Kruskal-Wallis test. Planned (a priori) contrasts and Mann Whitney  $U$  tests were used for pairwise comparisons following parametric and non-parametric tests, respectively. The ordinal data of histopathological scoring were analyzed using aforementioned non-parametric tests.

## RESULTS

Intraperitoneal administration of cerulein ( $2 \times 50 \mu\text{g}/\text{kg}$ ) caused AP in all tested rats, as indicated by the marked increase in serum amylase and lipase levels (Figure 1) and histopathological changes (Figure 2).

Cerulein induced AP caused almost 3- and 23-fold increases in plasma amylase and lipase levels, respectively. ASA pretreatment significantly decreased these levels to close to those of the RV group (Figure 1). Cerulein-induced AP increased the peripheral white blood cell (WBC)

count significantly compared to the RV group ( $6.89 \pm 0.48$  and  $4.36 \pm 0.23$ , respectively,  $P = 0.001$ ). This increase was abolished by medium- and low-dose ASA.

### Cytokine levels, lipid peroxidation and WBCs

Columns show the mean and error bars represent SEM in all figures. All groups were compared with the APC group and statistical significance was expressed as a vertical  $P$  value over the column.

The histopathological scores are shown in Table 2. Marked interstitial edema was observed in the APC group, with a score of  $2.75 \pm 0.16$ . In contrast, the edema score of the RV group was  $0.25 \pm 0.16$  and the difference was significant ( $P < 0.001$ ). Concerning the total score (Figure 2), which indicates the overall level of pathological changes, a marked difference was found between the APC and RV group scores ( $5.88 \pm 0.44$  and  $0.25 \pm 0.160$ , respectively) with a high level of significance ( $P < 0.001$ ). Considering the histopathological scores, ASA pretreatment generally improved the histopathological changes. However, only the effect of the medium-dose was statistically significant ( $P < 0.001$  for the total score). No evidence of side effects related to chronic ASA administration (e.g., inflammation or bleeding) for any of the three doses was observed in the gastrointestinal tract by macroscopic and histopathological examinations.

### Histopathological scores

All groups were compared with the APC group and statistical significance was expressed as  $P$  values under the corresponding mean  $\pm$  SEM values.

As shown in Figure 3A, cerulein-induced AP caused a marked elevation of the IL-1 $\beta$  level in pancreatic tissue compared to that of the RV group ( $18.81 \pm 2.55 \text{ pg}/\mu\text{g}$  and  $6.65 \pm 0.24 \text{ pg}/\mu\text{g}$ , respectively,  $P = 0.002$ ). This elevation was suppressed significantly by ASA in all treatment groups. A similar increase was observed in the pancreatic IL-6 level ( $14.62 \pm 1.98 \text{ pg}/\mu\text{g}$  vs  $9.09 \pm 1.36 \text{ pg}/\mu\text{g}$ ,  $P = 0.04$ , Figure 3B); however, the low-dose could not prevent this increase, whereas the medium- and

ASA: Acetylsalicylic acid; RV: Reference values; APC: Acute pancreatitis control; LD: Low-dose; MD: Medium-dose; HD: High-dose.

high-dose ASA pretreatments could suppress the IL-6 elevation. There were no statistical differences between the groups regarding the TNF-α and NF-κB levels.

Cerulein-induced AP increased MDA levels in both plasma and pancreatic tissue compared to that of the RV group (Figure 3C and D). ASA pretreatment at all three

**Figure 3** Cytokine levels, lipid peroxidation and white blood cells. **A:** Cerulein induced acute pancreatitis (AP) caused a marked elevation of interleukin (IL)-1 $\beta$  level in pancreatic tissue compared to that of the reference values (RV) group ( $18.81 \pm 2.55$  and  $6.65 \pm 0.24$  pg/ $\mu$ g, respectively,  $P = 0.002$ ); **B:** This elevation was suppressed significantly by acetylsalicylic acid (ASA) in all treatment groups. A similar increase was observed in the pancreatic IL-6 level. However, this time, the low-dose seemed to be ineffective against it, while medium- and high-dose ASA pretreatments suppressed the IL-6 elevation. There was no statistical difference between the groups regarding the tumor necrosis factor- $\alpha$  and nuclear factor- $\kappa$ B levels; **C, D:** Cerulein induced AP increased malondialdehyde (MDA) levels in both pancreatic tissue and plasma compared to that of the RV group; **E:** Cerulein induced AP increased the peripheral white blood cell (WBC) count significantly compared to the RV group. HD: High-dose; MD: Medium-dose; LD: Low-dose; APC: Acute pancreatitis control.

doses inhibited this increase. Cerulein-induced AP increased the peripheral WBC count (Figure 3E). Other antioxidant system parameters, including NO, SOD, HO-1 and CAT, were not affected by cerulein-induced AP and ASA treatment; there were no significant differences between the treatment, APC and RV groups regarding these parameters.

## DISCUSSION

To the best of our knowledge, the present study is the first investigation of the effect of long-term ASA pretreatment on a cerulein-induced pancreatitis model. Our findings indicate that long term ASA pretreatment dose-dependently prevents or ameliorates certain hematologi-

cal, serological and histological alterations caused by cerulein-induced AP.

Cerulein-induced pancreatitis is the most preferred animal model of AP, because it is non-invasive, easily applicable and highly reproducible<sup>[37]</sup>. The similarity of the cerulein-induced histopathology to human AP, especially in the early phase, has substantially increased the preference for this model<sup>[38]</sup>. Administration of cerulein, a cholecystokinin (CCK) analog, stimulates the pancreatic acinar cells *via* CCK receptors, which leads to prematuration of proteolytic enzymes<sup>[39]</sup>. The activation of proteases triggers an autodigestion of pancreatic tissue, causing vascular damage, edema, fibrosis and necrosis, which constitute the histopathological profile of AP<sup>[6]</sup>. The markedly higher edema, hemorrhage, necrosis and the total histopathological scores of the APC group compared to the RV group, observed in our present study, are the expected results of the cerulein-induced AP model and are consistent with the literature.

The serum amylase level has been the most widely used parameter for the diagnosis of AP<sup>[40]</sup>, since 1929, when its diagnostic value was demonstrated for the first time<sup>[41]</sup>. The serum lipase level, another widely accepted marker of AP, rises after the onset of AP in parallel with the amylase level, although its rise starts slightly later and lasts longer than that of amylase<sup>[42]</sup>. The plasma levels of both enzymes have substantial sensitivity and specificity for the diagnosis of AP<sup>[43]</sup>. As expected, in the present study, both the amylase and lipase levels rose markedly in the AP group. In the pretreatment groups, ASA prevented the elevation of both enzyme levels. This observation constitutes additional evidence supporting the preventive effect of ASA against cerulein-induced AP.

There is a positive correlation between the severity of AP and the increase in the peripheral WBCs<sup>[44]</sup> and the WBC count is one of the parameters included in most of the scoring systems used for the assessment of the severity of AP<sup>[45]</sup>. The increased WBC in the AP group is an expected result of the inflammation induced by cerulein. Our observation that the WBC count of medium- and low-dose groups was significantly lower than that of the AP group and close to that of the RV animals, suggests that ASA pretreatment ameliorates the inflammation induced in the pancreas.

Cytokines are a group of low-molecular weight proteins that play a crucial role in induction and progression of inflammatory processes, including AP. Thus, they have been subjected to a wide range of studies in this context<sup>[18,46,47]</sup>. Consequently there is no doubt about the constitutive role of many cytokines in progression of local tissue damage and distant complications in AP<sup>[46]</sup>.

Cytokines can be functionally divided into two groups: pro- and anti-inflammatory cytokines<sup>[46]</sup>. In the proinflammatory group TNF- $\alpha$  and IL-1 $\beta$  are especially prominent and are regarded as "first-line" cytokines<sup>[48]</sup>. IL-1 $\beta$  levels are elevated in the cerulein-induced models of AP<sup>[4,8,49]</sup>. Furthermore, a strong, positive correlation was found between the increase in IL-1 $\beta$  level and the severity of

inflammation<sup>[46,50]</sup>. In the present study, the IL-1 $\beta$  level in pancreatic tissue increased nearly threefold in the AP group compared with the RV group, whereas the difference between plasma levels showed no statistical significance. This rise in the IL-1 $\beta$  level in the AP group is an expected result of cerulein-induced AP. In addition, the contrast observed between the tissue and plasma levels of IL-1 $\beta$  is consistent with previous reports<sup>[50,51]</sup>. Considering the tissue levels of IL-1 $\beta$  in the pretreatment groups, ASA pretreatment had a significant diminishing effect. This finding is consistent with the amylase, lipase and MDA levels. Thus, this represents further evidence of the protective effect of ASA pretreatment against AP. IL-6 is another proinflammatory cytokine that increases in cerulein-induced pancreatitis<sup>[52]</sup>. IL-6 levels correlate with the clinical scenario and severity of AP; therefore, IL-6 has been attributed as a marker of the disease<sup>[4,53]</sup>. Thus, the increase in the IL-6 level in the APC group in the present study is an expected result of cerulein-induced AP. ASA pretreatment in the medium- and high-dose groups decreased the pancreatic IL-6 level significantly. This effect is consistent with the other findings of our study. The numerical decrease in the low-dose group was not statistically significant.

Sanfey *et al.*<sup>[54]</sup> suggested a possible involvement of reactive oxygen species (ROS) in the pathogenesis of AP and since then, observations from increasing numbers of experimental studies have supported this suggestion<sup>[55,56]</sup>. Consequently, there is currently no doubt about the detrimental role of oxidative stress in the pathogenesis of AP and this makes it a therapeutic target. Yu *et al.*<sup>[52]</sup> reported that, in the cerulein-induced AP model, administration of cerulein increased ROS formation and oxidative stress, and caused an increase in IL-1 $\beta$  expression. In the present study, the MDA level, an indicator of oxidative stress, was elevated in the cerulein administered AP group, both in plasma and in pancreatic tissue. This high level of MDA in the AP group, taken together with increased pancreatic IL-1 $\beta$  expression, is a consequence of cerulein-induced AP and these data are consistent with the findings of Yu *et al.*<sup>[52]</sup>. ASA reduces oxidative stress by exerting free radical scavenging activity and antioxidant efficacy<sup>[57-60]</sup>. The findings of Shi *et al.*<sup>[61]</sup> support ASA's free radicals scavenging efficacy and also suggest that it is more potent than several well established antioxidants, such as ascorbate, glutathione and cysteine, with respect to the reaction rate. In the present study, oxidative stress, indicated by the MDA levels, decreased in all the ASA treated groups compared with the AP-induced groups, in both the plasma and pancreatic tissue homogenates. Moreover, considering the plasma, these levels were even below the levels of the reference group, which was fed with commercial diet without ASA supplementation. These findings can be explained by potent antioxidant effect of ASA and are in accordance with the other results presented in this study. Nevertheless, parameters related to the enzymatic antioxidant system, including NO, SOD, HO-1 and CAT, showed no significant changes. Thus,

the reduced oxidative stress induced by ASA in the treatment groups seems not to involve the classic enzymatic antioxidant system and could be attributed to alternative mechanisms<sup>[60]</sup>.

When examining the histopathological scores numerically, the ASA pretreatment generally attenuated the alterations caused by AP. Nevertheless, these numerical changes could not be confirmed statistically for all treatment doses or for all histopathological parameters. Only the reducing effect of the medium dose (150 mg/kg) on edema, necrosis and total score values was found to be statistically significant ( $P = 0.002$ ,  $P = 0.007$  and  $P < 0.001$ , respectively). These histopathological scoring results seem to be inconsistent with the previously discussed data for amylase, lipase, MDA and IL-1 $\beta$ , which were reduced significantly by ASA pretreatment at all three doses. Although there is evidence showing that serum amylase and lipase levels do not correlate with the histopathological alterations and severity of AP<sup>[62-64]</sup>, we believe the aforementioned inconsistency resulted from the high variance of our data set and the small sample size and should be considered as a limitation of our study.

The analgesic, antipyretic, antiplatelet and antiinflammatory effects of ASA have been known for a long time, and most of these effects have been attributed to its COX-inhibitory activity<sup>[14]</sup>. However, it has been speculated that the therapeutic potential of ASA cannot be completely explained by COX inhibition<sup>[15,65]</sup>. Previous results from a wide variety of studies revealed different mechanisms of action of ASA, including inhibition of proinflammatory cytokines, such as IL-1 $\beta$ <sup>[65]</sup>, scavenging of ROS<sup>[59]</sup>, triggering the production of antiinflammatory mediators, such as ATL<sup>[21,22]</sup>, and inhibition of transcription factors, such as NF- $\kappa$ B<sup>[66]</sup>.

In conclusion, our findings indicate that the ASA pretreatment exerted preventive and/or ameliorating effects against AP by normalizing some of the hematological and biochemical indicators of the disease to close to those of the reference value group. These beneficial effects of the pretreatment were confirmed partially by the histopathological findings.

Our findings suggest that these beneficial effects of ASA can be explained by its free radical scavenging efficacy and the inhibitory effect on proinflammatory cytokines IL-1 $\beta$  and IL-6. The ATL pathway, involving the stimulation of NO and HO-1 expression, seemed not to play a role in this preventive effect, as there was no difference between groups with respect to the ATL levels.

Beside its conventional use as an analgesic, antiinflammatory and antipyretic agent, daily intake of ASA is recommended by a large group of physicians as a preventive therapy against cardiovascular diseases<sup>[67,68]</sup>. Furthermore, several studies have indicated the efficacy of long-term ASA use in prevention of colorectal cancer<sup>[69]</sup>, and the long-term use of ASA as a chemopreventive agent against other cancer types has attracted substantial research interest<sup>[70]</sup>. Our results may provide another perspective on the effects of long-term ASA pretreatment.

## COMMENTS

### Background

Acute pancreatitis (AP) is an inflammatory disease with broad clinical variation, ranging from a mild and self-limiting condition to a severe, life-threatening necrotizing inflammation. Aspirin (acetylsalicylic acid, ASA) is the oldest and most widely used non-steroidal anti-inflammatory drug. In addition to its conventional effects, ASA is effective in the prevention of a wide range of diseases, including gastrointestinal cancer, ischemic stroke, myocardial infarction and Alzheimer's disease. This broad range of effectiveness has led to the daily intake of aspirin being recommended by a wide group of physicians as a preventive therapy for the aforementioned diseases. Considering the early events in pathophysiology of AP and the broad variety of aspirin's mechanisms of action, it is reasonable to hypothesize that long term aspirin pretreatment can effectively prevent AP.

### Research frontiers

An estimated 80000 cases of AP occur each year in the United States. Much research interest has focused on prevention strategies because there is no specific cure for AP.

### Innovations and breakthroughs

In the present study, the effects of ASA pretreatment on a pancreatitis model were investigated for the first time. The findings indicate that long term ASA pretreatment dose-dependently prevents or ameliorates some hematological, serological and histological alterations caused by cerulein-induced AP.

### Applications

The experimental data obtained in the present study point out another aspect of aspirin's preventive effectiveness and could be used in further studies of preventive strategies against AP.

### Peer review

This is a very interesting, well-structured and original study, being the first reported study on this topic. It is methodologically well planned and performed with well-designed cohorts. The paper is well written and clear.

### Abstract

**AIM:** To investigate the role of growth hormone (GH), hyperbaric oxygen therapy (HBOT) and combined therapy on the intestinal neomucosa formation of the gastric serosa.

**METHODS:** Forty-eight male Wistar-albino rats, weighing 250-280 g, were used in this study. The rats were divided into four groups ( $n = 12$ ): Group 1, control, gastric serosal patch; Group 2, gastric serosal patch +

GH; Group 3, gastric serosal patch + HBOT; and Group 4, gastric serosal patch + GH + HBOT. Abdominal access was achieved through a midline incision, and after the 1-cm-long defect was created in the jejunum, a 1 cm × 1 cm patch of the gastric corpus was anastomosed to the jejunal defect. Venous blood samples were taken to determine the insulin-like growth factor 1 (IGF-1) and insulin-like growth factor binding protein 3 (IGFBP-3) basal levels. HBOT was performed in Groups 3 and 4. In Groups 2 and 4, human GH was given subcutaneously at a dose of 2 mg per kg/d for 28 d, beginning on the operation day. All animals were sacrificed 60 d after surgery. The jejunal segment and the gastric anastomotic area were excised for histological examination. The inflammatory process, granulation, collagen deposition and fibroblast activity at the neomucosa formation were studied and scored. Additionally, the villus density, villus height, and crypt depth were counted and recorded. The measurements of villus height and crypt depth were calculated with an ocular micrometer. New vessel growth was determined by calculating each new vessel in a 1 mm<sup>2</sup> area.

**RESULTS:** In the histological comparison of groups, no significant differences were observed between the control group and Groups 2 and 3 with respect to epithelialization, granulation, fibroblastic activity and the inflammatory process, but significant differences were present between the control group and all others groups (Groups 2-4) with respect to angiogenesis ( $P < 0.01$ ) and collagen deposition ( $P < 0.05$ ,  $P < 0.01$ ). Significant differences between the control group and Group 4 were also observed with respect to epithelialization and fibroblastic activity ( $P < 0.01$  and  $P < 0.05$ , respectively). There were significant differences in villus density in all of groups compared with the control group ( $P < 0.05$ ). Crypt depth was significantly greater in Group 4 than in the control group ( $P < 0.05$ ), but no other groups had deeper crypts. However, villus height was significantly longer in Groups 2 and 4 than in

the control group ( $P < 0.05$ ). The comparison of groups revealed, significant difference between control group and Groups 2 and 4) with respect to the levels of IGF-1 and IGFBP-3 ( $P < 0.01$ ) 3 wk after the operation.

**CONCLUSION:** HBOT or GH and combined therapy augmented on neomucosal formation. The use of combined therapy produced a synergistic effect on the histological, morphological and functional parameters.

Effect of growth hormone, hyperbaric oxygen and combined therapy on the gastric serosa. *World J Gastroenterol* 2013; 19(19): 2904-2912 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i19/2904.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i19.2904>

## INTRODUCTION

Short bowel syndrome (SBS) is a significant problem in clinical medicine that emerged at the beginning of the last century, when the first resections of the gastrointestinal tract were performed<sup>[1]</sup>. SBS a malabsorptive disorder characterized by the loss of intestinal length, occurs when patients have  $< 200$  cm of the post-duodenal small intestine, resulting in inadequate digestion and/or nutrient absorption<sup>[2-5]</sup>. Depending on the extent, degree, and location of the intestinal resection, patients may experience severe malabsorption of fluids, electrolytes, and other nutrients. Many become dependent on long-term parenteral nutrition, which has been a life maintenance therapy<sup>[6]</sup>. Even in the best hands, this treatment can be associated with nutritional deficiencies, septic complications and life-threatening organ failure<sup>[7-9]</sup>. Another important factor is the time allowed for post-enterectomy or in utero bowel loss adaptation, which is the compensatory process in the remnant small intestine that includes mucosal regeneration, villous hypertrophy, bowel dilatation and lengthening, and delayed motility<sup>[10]</sup>. Growth hormone (GH), glutamine, and dietary modification have been proposed as a regimen to enhance bowel adaptation<sup>[3,6,7]</sup>. GH administration produced a positive nitrogen balance at all levels of energy intake<sup>[4,5,11,12]</sup>. Evidence supporting the use of GH in the SBS includes the observation that exogenous GH stimulates structural and functional intestinal adaptation<sup>[13,14]</sup>.

The treatment consists of surgery to slow intestinal transit or increase the area of absorption. Reconstructive procedures on the remnant bowel and intestinal transplantation are areas of special interest to surgeons working in this field<sup>[4,10,15]</sup>. Another potential technique for increasing the intestinal surface area is the growth of new intestinal mucosa, which takes advantage of the regenera-

tive capability of the intestine<sup>[10]</sup>. Some researchers made gastric anastomosis and, colonic and abdominal wall flaps between intestinal defects in experimental SBS to expand the mucosal surface. The regenerated intestine develops by lateral ingrowth from the surrounding mucosa and becomes functionally normal intestinal mucosa<sup>[16-19]</sup>.

In gastrointestinal surgery, if the degree of hypoxia is sufficient to interfere with tissue viability, the tissues become necrosed, resulting in delayed wound healing<sup>[20]</sup>. Ischemic wounds heal poorly and become infected. Tissue hypoxia can be reversed using hyperbaric oxygen therapy (HBOT). The effects of HBOT result from increased pressure and hyperoxia. Several studies have shown that increased oxygen tension with HBOT not only prevents the adverse effects of ischemia but also accelerates healing in different types of wounds<sup>[21]</sup>.

The serosal patch technique is one of the most popular methods. However, in many cases, only short segments of the small intestine can be patched because of the limited serosal surface and anatomical factors. In this experimental study, we used a gastric serosal patch to form neomucosa in ileum defects. Our aim in the present work was to investigate the role of GH, HBOT and combined therapy on the intestinal neomucosa formation of the gastric serosa.

## MATERIALS AND METHODS

### Animals

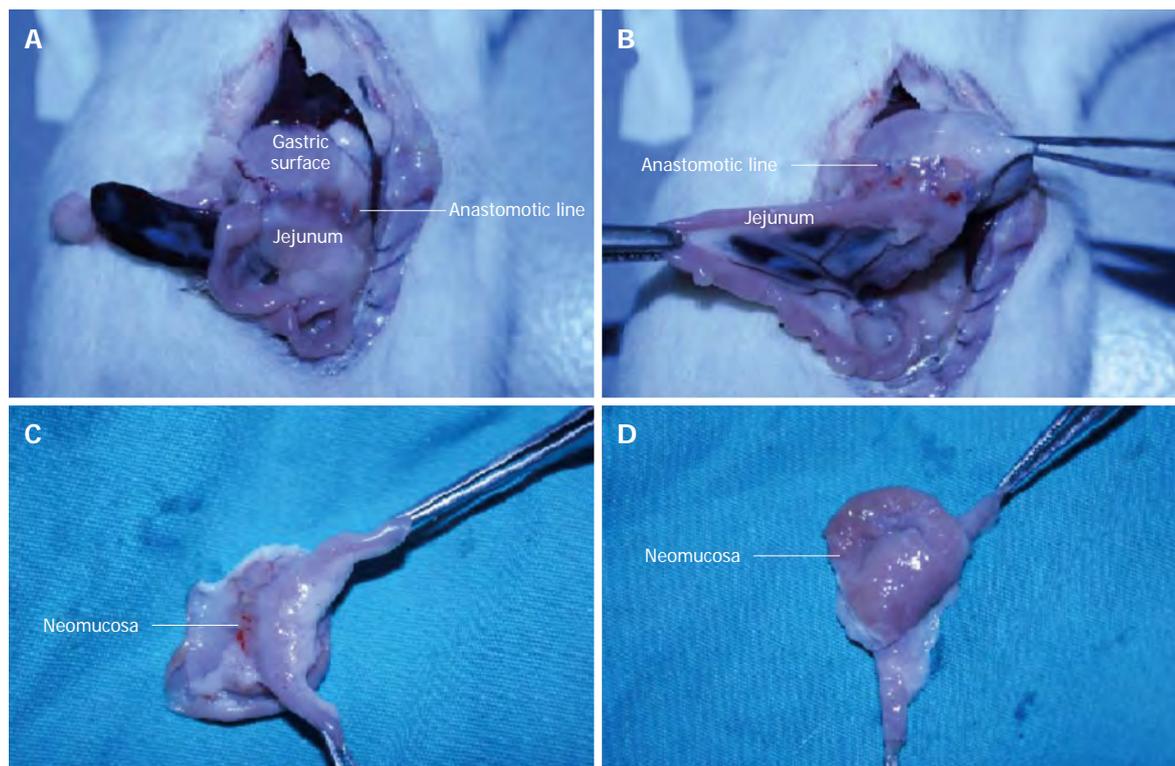

Forty-eight male Wistar-albino rats (Istanbul University, Institute of Experimental Medicine and Research, Turkey), weighing 250-280 g, were used in the study. The study was approved by the ethics committee of Istanbul University, Istanbul Medical School. All animals were housed in cages in a room at a constant temperature of  $22 \pm 2$  °C. The rats were fed a standard chow diet and tap water.

### Study design

The rats were divided into four groups ( $n = 12$ ): Group 1, control, gastric serosal patch; Group 2, gastric serosal-patch + GH; Group 3, gastric serosal patch + HBOT; Group 4, gastric serosal patch + GH + HBOT.

### Surgical procedure

After one night of fasting, the animals were anaesthetized with an intramuscular injection of ketamine hydrochloride (50-100 mg per kg of body weight). Abdominal access was achieved through a midline incision, and the jejunum was incised at 1 cm longitudinally. After the 1-cm-long defect was created in the jejunum, a 1 cm  $\times$  1 cm patch of the gastric corpus was anastomosed to the jejunal defect with interrupted 6/0 polypropylene sutures (Figure 1A and B). During the operation, venous blood samples (portal vein) were taken to determine the insulin-like growth factor 1 (IGF-1) and insulin like growth factor binding protein 3 (IGFBP-3) basal levels. After the bleeding control had been performed, 2 cc of 0.9% NaCl was injected into the intraperitoneal area, and the abdo-

**Figure 1** Surgical procedure and histopathological assessment. A, B: Anastomotic line is shown between the gastric surface and jejunum, C: Outer surface of the neomucosa formation is shown with the jejunal segment; D: Inner surface of the neomucosa is shown, and the neomucosa has a typical small intestinal phenotype.

men was closed with 3/0 continuous silk sutures. Twelve hours after the surgery, water was given; twenty-four hours after the surgery, food was given.

### Treatment

HBOT was started 12 h after the surgery and completed after 12 d. The HBOT was performed 3 times per day for the first 4 d, 2 times per day for the following 4 d and then once per day for the remaining 4 d. This therapy was applied in the Istanbul Faculty of Medicine, Department of Underwater and Hyperbaric Medicine. The total number of HBOT sessions was 24. The treatments were conducted in a small research chamber (0.4 m<sup>3</sup>). The chamber was flushed with oxygen for 10 min to vent the air inside before compression, and thus the animals could be pressurized with 100% oxygen. The HBOT sessions consisted of 10 min of compression to 2.5 atmosphere absolute (ATA), 60 min at 2.5 ATA and 10 min of decompression to the surface pressure.

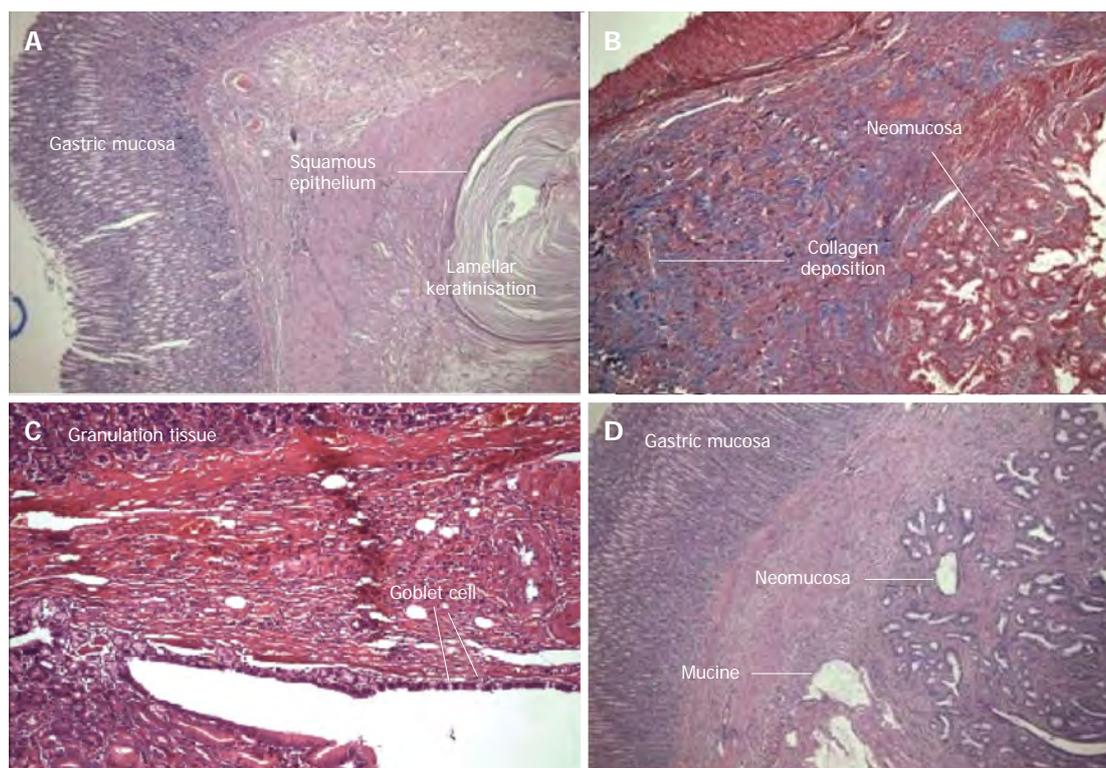

In Groups 2 and 4, human GH was given [Norditropin 4 IU (1.3 mg), Novo Nordisk-Denmark] subcutaneously at a dose of 2 mg per kg/d<sup>[22-25]</sup> for 28 d, beginning on the operation day.

### Histopathological assessment

All of the rats were sacrificed 60 d after the operation. The anastomosis, including the jejunal segment and the gastric anastomotic area, was excised (Figure 1C and D). To clean the fat tissues, the anastomotic area was washed with distilled water. The edges of the anastomotic area

were determined by following the subject line of the non-absorbable suture. Then, the area was fixed in 10% formalin for approximately 24 h and embedded in a paraffin block. Transverse sections of the embedded tissue, 4 μm in thickness, were stained with hematoxylin and eosin, and the histological assessment was performed in a blinded manner. The intestinal neomucosa, inflammatory process, granulation and fibroblast activity at the neomucosa formation were studied and scored (from 0 to 3; 0, none; 1, slight; 2, moderate; 3, dense). Masson's trichrome staining was performed to distinguish the cells from the surrounding connective tissue. Three dyes were employed, and solution C was used to stain for collagen. Collagen deposition in the neomucosa was scored according to the density in the tissue (from 0 to 3; 0, none; 1, slight; 2, moderate; 3, dense). Small intestinal epithelial cell lineages (goblet cells and enteroendocrine cells) were identified within the regenerated intestinal mucosa. The goblet cells were stained by the periodic acid-Schiff stain, and mucin was identified with alcian blue staining, pH 2.5. The alcian blue staining at pH 2.5 was used because the acid mucins of the small intestine are primarily sialo mucins<sup>[26]</sup>. The enteroendocrine cells were identified by immune histochemical staining.

Additionally, the villus density, villus height, and crypt depth were determined and recorded. The villus density was scored (from 0 to 3). The measurements of villus height and crypt depth were calculated with an ocular micrometer. New vessel growth was determined by calculating each new vessel in a 1 mm<sup>2</sup> area.

**Figure 2 Histological and morphologic evaluation.** A: Unexpected neomucosal formation. The gastric corpus mucosa can be seen. The squamous epithelium and lamellar keratinization formed from the anastomosis [Hematoxylin and eosin (HE)  $\times$  100] (Group 3); B: Granulation tissue and newly formed neomucosa. The blue area is connective tissue (Masson Trichrome  $\times$  100) (Group 4); C: In the gastric mucosa of the large granulation tissue, newly formed goblet cells can be seen (HE  $\times$  100) (Group 4); D: The left side shows the gastric mucosa, and the right side shows newly formed neomucosa that contains mucin. The granulation tissue is reduced (HE  $\times$  100) (Group 4).

### ***GH assessment***

To determine the GH efficacy, we assessed the venous IGF-1 and IGFBP-3 levels at the beginning of treatment and on postoperative day 21. Blood samples were taken from the tail vein of the rats. The analyses were performed in a biochemistry laboratory, at the Cerrahpasa Medical Faculty, University of Istanbul. The levels of IGF-1 and IGFBP-3 were measured by double-antibody, immune-radiometric assays. The IGF-1 antibody was from Immunotech France, and the IGFBP-3 antibody was from Diagnostic Systems Laboratories. The mean intra batch coefficients of variation calculated from the quality-control samples in this study were 5.6% and 2.7% for IGF-1 and IGFBP-3, respectively.

### ***Statistical analysis***

The statistical analysis was performed using SPSS 16.0 for Windows. Spearman's test was used for the intergroup correlations. Differences in the histological parameters between the treatment and control groups were analyzed non-parametrically with the Student-*t* test. All data were expressed as the mean  $\pm$  SD, and  $P < 0.05$  was accepted as significant.

## **RESULTS**

### ***Mortality analysis***

Seven rats died in the early phase (in the first week) of

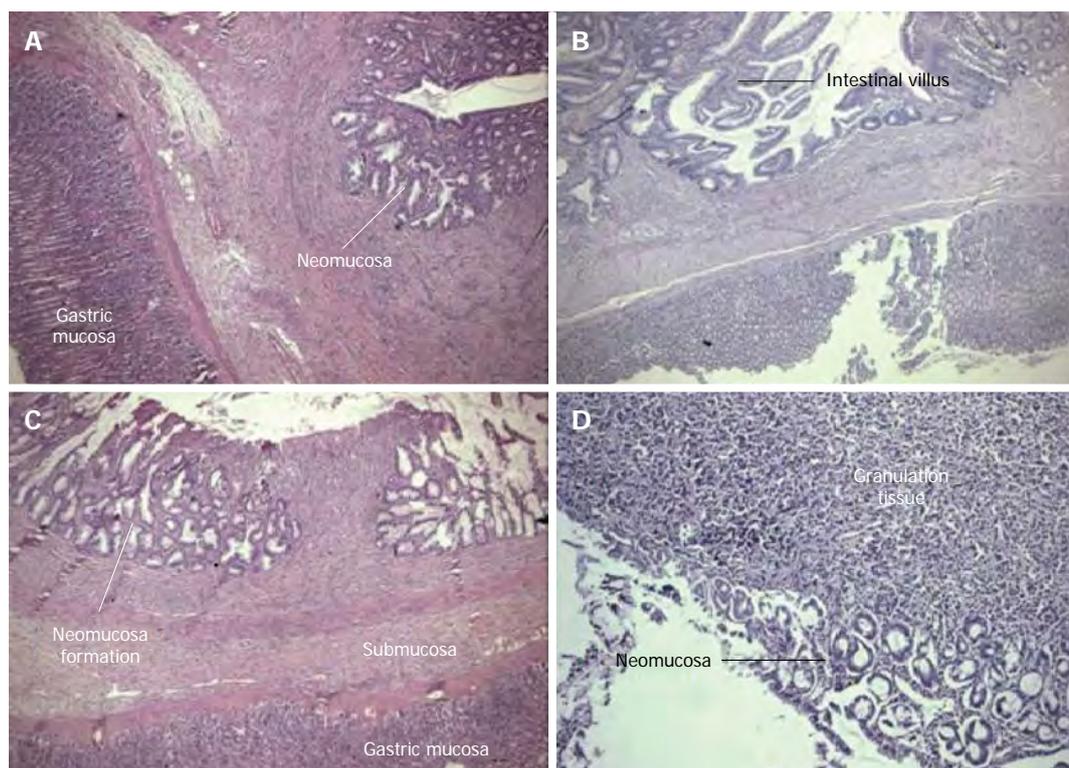

the study. Upon post-mortem examination, we discovered that two had anastomotic leakage and sepsis, two had ileus, and three had pneumothorax.

### ***Histological evaluation***

In the histological comparison of the groups, no significant differences were observed between the control group and Groups 2 and 3 with respect to epithelialization, granulation, fibroblastic activity and the inflammatory process ( $P > 0.05$ ), but significant differences were observed between the control group and all other groups (Groups 2-4) with respect to angiogenesis ( $P < 0.01$ ) and collagen deposition ( $P < 0.05$ ,  $P < 0.01$ ) (Figure 2). We also found significant differences between the control group and Group 4 with respect to epithelialization and fibroblastic activity ( $P < 0.01$  and  $P < 0.05$ , respectively). Two histological parameters were significantly different in Groups 2 and 3, and four histological parameters were significantly different in Group 4. These parameters in Group 4 were epithelialization, fibroblastic activity, angiogenesis and collagen deposition. The histological features and results are given in Table 1.

### ***Morphologic evaluation***

For the morphologic evaluation, we measured the villus density ( $\text{mm}^2$ ), villus height and crypt depth in the neomucosa. By 60 d, the luminal surface of the neomucosa tissue was nearly covered by mucosal epithelium. The

**Figure 3** There were significant differences in the villus density in all of the groups compared with the control group. A: Gastric corpus mucosa on the left, newly formed thin neomucosa on the right. The muscularispropria has not yet formed. The granulation tissue regressed [Hematoxylin and eosin (HE) × 100] (Group 3); B: Neomucosa formation is observed at the bottom of the gastric mucosa (HE × 125) (Group 4); C: The granulation tissue is in the middle, with newly formed neomucosa on either side. At the bottom, the stomach tissue is visible (HE × 100) (Group 2); D: The early development of the mucosal layer and granulation tissue (HE × 125) (Group 1).

All parameters scored from 0 to 3, angiogenesis counted within 1 mm<sup>2</sup>, villus density, goblet cells, mucin secretion and collagen deposition, scored from 0 to 3. The P<sup>1</sup> value compares Groups 1 and 2, P<sup>2</sup> value compares Groups 1 and 3, and P<sup>3</sup> value compares Groups 1 and 4. All values are expressed as the mean ± SD. GH: Growth hormone; HBOT: Hyperbaric oxygen therapy.

neomucosa had a typical small intestinal phenotype (Figure 1C and D). There were significant differences in the villus density in all of the groups compared with the control group ( $P < 0.05$ ). The crypt depth was significantly greater in group 4 than in the control group ( $P < 0.05$ ), but no other groups had deeper crypts. However, the villus height was significantly longer in Groups 2 and 4 than in the control group ( $P < 0.05$ ) (Figure 3). The comparison of the morphological characteristics and activation of the

neomucosa between the groups revealed significant differences between the control group and Groups 2-4, with respect to the number of goblet cells and mucin secretion, respectively (both  $P < 0.01$ ) (Figure 2C and D). When we analyzed all of the groups, we obtained the highest significant differences in Group 4. The morphological and functional features in all groups are given in Table 1. We could not make any comparisons between in groups, because the immunohistochemical staining was too weak.

**Table 2** The per-operative and 3-wk post-operative venous levels of like growth factor and insulin like growth factor binding protein 3 (nmol/L)

The *P* value compares the per- and post-operative levels within the same group, *P*<sup>1</sup> value compares the levels between Groups 1 and 2, and *P*<sup>2</sup> value compares the levels between Groups 1 and 4. All values are expressed as the mean ± SD. NS: Non-significant; GH: Growth hormone; HBO: Hyperbaric oxygen therapy; IGF-1: Like growth factor; IGFBP-3: Insulin like growth factor binding protein 3.

### GH determination

To determine the effect of the GH, we measured the IGF-1 and IGFBP-3 blood levels in the rats. The comparisons revealed no significant differences between the control group and Groups 2 and 4 in the blood levels of IGF-1 and IGFBP-3 (*P* > 0.05) per-operatively but significant differences between the control group and the other groups (Groups 2 and 4) in the levels of IGF-1 and IGFBP-3 (*P* < 0.01) 3 wk after the operation (Table 2). We also compared the per- and post-operative results within each group. There were significant differences in Groups 2 and 4 (*P* < 0.05, Table 2).

## DISCUSSION

The use of serosal patching to grow new intestinal mucosa is a technique for enlarging the intestinal surface. In the literature, different animal models have been utilized to study the growth of intestinal neomucosa in full thickness defects patched with a variety of surfaces, including colonic serosa, abdominal wall, pedicle flaps, and prosthetic material. The serosal patch technique is one of the most popular methods. However, in many cases, only short segments of small intestine can be patched because of the limited serosal surface and anatomical factors<sup>[10,27]</sup>. The peritoneal surface has also been utilized to develop epithelial cells. In a rat model, researchers folded the colon to form a seromuscular tunnel and sutured the two ends to the transected ileum. After 6-12 wk, a pouch in which a single layer of cylindrical epithelium had developed showed evidence of disaccharidase activity<sup>[10]</sup>. Erez *et al*<sup>[28]</sup> showed that using pigs and rats, one could successfully enlarge the small bowel surface by growing new mucosa on the parietal peritoneum following entero-peritoneal anastomosis. Some important advantages of this technique include the absorption of fluids and electrolytes through the peritoneum, and slowing of the bowel transit time. Bragg *et al*<sup>[29]</sup> used colonic serosa for patching, and by 8 wk, the defects were completely covered by neomucosa. In this study, we used the gastric serosal surface as a patch. An extensive literature search did not reveal a previous report of the use of the gastric serosal surface for this technique. We selected the gastric serosal-

surface because the gastric serosa constitutes a large area and because it is anatomically close to the small intestine. Furthermore, the stomach tissue is thick and has a wide network of collateral blood vessels. The fitness for surgery is also influenced by the interaction of the main vein with the easily protected neomucosa structure, the ability of the serosal flap of the small bowel to easily move to the surface, and the quick self-renewal and large surface area of the gastric surface, enabling the surgical operation to be repeated multiple times. In our study, we demonstrated that neomucosal formation occurred two months after the operation. To prevent SBS, it is important that the surface area of the bowel increases rapidly after the surgery to allow the absorption of nutrients to occur. To increase the rate of neomucosal formation, we used GH and HBO together. To our knowledge, this study is the first to report the use of both these techniques together to encourage neomucosal formation.

There are a number of peptide growth factors, such as IGF-1, or general growth factors, such as GH, that are used as promoting factors for intestinal hyperplasia and adaptation<sup>[1,2,6,14,30,31]</sup>. GH is expressed throughout the intestinal epithelium and in the lamina propria, muscularis mucosa, submucosa, and muscularispropria, indicating the potential for direct GH action within the intestine. GH has been shown to directly promote wound healing and growth of the intestine by increasing cell proliferation and collagen deposition<sup>[14]</sup>. In neomucosa formation, Thompson investigated the effect of epidermal growth factor (EGF), and octreotide-induced enterocyte apoptosis. Compared with the controls, the EGF group had decreased apoptosis in the crypt and villus<sup>[32]</sup>. Circulating GH binds to the GH receptor in the target cells and stimulates the production of IGF-1 in the liver and other target tissues, including the intestine<sup>[14]</sup>. Clinical trials of GH treatment have reported significantly increased levels of IGF-1 and IGF-binding protein-3<sup>[14,33-35]</sup>. In the GH treatment group, to control the efficacy of the GH, we assessed the level of the IGF-1 and IGF-binding protein at the end of 3 wk. Groups 2 and 4 had significantly higher levels of these hormones at the end of week three compared with the control group (*P* < 0.01).

Oxygen is an essential material for cell metabolism,

and reparative processes, such as cell proliferation and collagen synthesis<sup>[21,36,37]</sup>, have an especially increased demand for oxygen. Evidence from animal and cell line studies has shown that HBOT, the administration of pure oxygen at pressures greater than 1 ATA, results in increased growth factor production, such as platelet-related growth factor, transforming growth factor- $\beta$ 1 and vascular endothelial growth factor, and improved wound healing<sup>[38,39]</sup>. Hyperoxygenation can also increase collagen production, enabling these rapidly migrating fibroblasts to lay down larger, stronger beds of collagen for the advancing capillary beds, leading to increased granulation tissue formation and enhanced overall healing<sup>[40]</sup>. A search of the literature did not reveal any data on HBOT regarding neomucosa formation. In plastic surgery, hyperbaric oxygen has also been used for the management of wounds requiring skin grafting and for the treatment of ischemic flaps<sup>[39]</sup>. Additionally, HBOT has been reported to improve the healing of foot ulcers and glucose metabolism in patients with diabetes mellitus<sup>[56]</sup>. Angiogenesis is a process in which new blood vessels originate by budding or spouting from pre-existing vessels. HBOT increases angiogenesis, which is an important step in wound healing<sup>[21]</sup>. Huddy *et al*<sup>[41]</sup> published the results of giving HBOT to a patient who had suffered from SBS with stomal complications. After the therapy, the patient rapidly made natural adaptations. Neovascularization has been suggested as the mechanism by which HBOT acts. In our study, angiogenesis was significantly different in Group 3, which was given HBOT, compared with the control group ( $P < 0.01$ ). Moreover, collagen (Masson trichrome) was significantly different in Group 3 compared with the control group ( $P < 0.05$ ). This situation is consistent with other data reported in the literature in which HBOT increased the formation of collagen and angiogenesis. The exact mechanism by which HBOT enhances neomucosal formation is not known. There is no direct evidence regarding the mechanism by which HBOT improved neomucosa formation in our study. We thought our use of HBOT directly increased angiogenesis and collagen formation. Furthermore, HBOT may have increased the levels of some growth factors. To further examine the role of HBOT in wound healing, a more in-depth analysis of growth factors is warranted. In our study, we found some adverse side effects of HBOT. Three animals died of pneumo-thorax with the use of HBOT at the beginning. We believe that during the HBOT therapy, the tension pneumo-thorax complication can occur rarely in experimental animals; this condition was a cause of animal deaths in our study. The pneumo-thorax, could be caused directly by the high pressure of the HBOT. Murphy *et al*<sup>[42]</sup> showed that tension pneumo-thorax occurred in 3 patients who underwent HBOT. The GH and HBOT combined treatment had positive effects in all 4 groups.

Studies on the management of SBS have continued worldwide. Early attempts at increasing the surface area by serosal patching with regeneration from the margins of the wound were limited by the marked contraction of

the defects created, and thus only a modest gain in the surface area was achieved. The use of stem cells isolated from the intestine should lead to further progression of intestinal regeneration<sup>[43]</sup>. The current techniques for experimental intestinal tissue engineering employ artificial biodegradable scaffolds in a 3-dimensional structure in which organoid units are seeded<sup>[43,44]</sup>. Although these results have been reported as experimental studies, they have not been tested in clinical studies yet. Our study is a pilot study and also an experimental study model. We suggest that using this method in appropriate cases is easy. These adaptations will be increased with the combined use of GH and HBOT.

In conclusion, this study demonstrated that intestinal neomucosa can be successfully produced on a gastric serosal surface. In addition, HBOT, GH and their combined therapy augmented neomucosal formation. The combination therapy appears to be more effective. The simultaneous use of both therapies produced a synergistic effect on the histological, morphologic and functional parameters.

## COMMENTS

### Background

Short bowel syndrome (SBS) is a malabsorptive disorder characterized by loss of intestinal length and occurs when patients have < 200 cm post-duodenal small intestine, resulting in inadequate digestion and/or nutrient. Treatment consists of surgery to slow intestinal transit or to increase the area of absorption. Reconstructive procedures on the remnant bowel and intestinal transplantation are areas of special interest to surgeons working in this field. Another potential technique for increasing the intestinal surface area is the growth of new intestinal mucosa, which takes advantage of the regenerative capability of the intestine. The regenerated intestine develops by lateral in growth from the surrounding mucosa and is functionally to normal intestinal mucosa.

### Research frontiers

The serosal patch technique is one of the most popular technique to treat SBS. In this experimental study, authors used gastric serosal patch to form neomucosa in ileum defects. In literature search did not reveal a previous report of the use of the gastric serosal surface for this technique. Moreover in the present work is to investigate the role of growth hormone, hyperbaric oxygen therapy (HBOT) and combined therapy on intestinal neomucosa formation of the gastric serosa. Evidence supporting the use of growth hormone (GH) in the SBS includes the fact that exogenous GH stimulates structural and functional intestinal adaptation. Several studies have shown that increased oxygen tension with HBOT not only prevents adverse effects of ischemia but also accelerates healing in different types of wounds.

### Innovations and breakthroughs

In this experimental study, 1 cm-long defect was created in the jejunum, after that a 1 cm  $\times$  1 cm patch of the gastric corpus was anastomosed to the jejunal defect with interrupted 6/0 polypropylene sutures. HBOT was started 12 h after the surgery and completed to 12 d. GH were given subcutaneously at a dose of 2 mg per kg/d for 28 d beginning on the operation day. In order to increase the rate of neomucosal formation, we used the GH and HBOT together. This is the first study to report using these two techniques together to encourage neomucosal formation.

### Applications

Their study is a surface expander research and also is an experimental study model. Authors suggest that it is easy to use of this method in the appropriate cases. These adaptation will be increased with the togetherness use of GH and HBOT.

### Terminology

SBS, also short gut syndrome or simply short gut, is a malabsorption disorder caused by the surgical removal of the small intestine, or rarely due to the complete dysfunction of a large segment of bowel.

**Peer review**

This study demonstrated that intestinal neomucosa can be successfully raised on a gastric serosal surface. In addition, HBOT or GH and combined therapy augmented on neomucosal formation. Combination therapies seem to be more effective. Simultaneous use of combined therapy produced synergistic effect on histological, morphologic and functional parameters.

### Abstract

**AIM:** To investigate the association of p42.3 expression with clinicopathological characteristics and the biological function of p42.3 in human hepatocellular carcinoma (HCC).

**METHODS:** We used reverse transcription-polymerase chain reaction (RT-PCR), quantitative real-time RT-PCR and western blotting to detect p42.3 mRNA and protein expression in hepatic cell lines. We examined primary HCC samples and matched adjacent normal tissue by

immunohistochemistry to investigate the correlation between p42.3 expression and clinicopathological features. HepG2 cells were transfected with a pIRES2-EGFP-p42.3 expression vector to examine the function of the *p42.3* gene. Transfected cells were analyzed for their viability and malignant transformation abilities by 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay, colony formation assay, and tumorigenicity assay in nude mice.

**RESULTS:** p42.3 is differentially expressed in primary HCC tumors and cell lines. Approximately 69.6% (96/138) of cells were p42.3-positive in hepatic tumor tissues, while 30.7% (35/114) were p42.3-positive in tumor-adjacent normal tissues. Clinicopathological characteristics of the HCC specimens revealed a significant correlation between p42.3 expression and tumor differentiation ( $P = 0.031$ ). However, p42.3 positivity was not related to tumor tumor-node-metastasis classification, hepatitis B virus status, or hepatoma type. Regarding p42.3 overexpression in stably transfected HepG2 cells, we discovered significant enhancement of cancer cell growth and colony formation *in vitro*, and significantly enhanced tumorigenicity in nude mice. Western blot analysis of cell cycle proteins revealed that enhanced p42.3 levels promote upregulation of proliferating cell nuclear antigen, cyclin B1 and mitotic arrest deficient 2.

**CONCLUSION:** p42.3 promotes tumorigenicity and tumor growth in HCC and may be a potential target for future clinical cancer therapeutics.

**Key words:** p42.3; Hepatocellular carcinoma; HepG2; Overexpression; Tumorigenicity

**Core tip:** p42.3 is a novel tumor-specific and mitosis phase-dependent expression gene. It is believed to be involved in tumorigenesis in gastric and colorectal can-

cer. To the best of our knowledge, this is the first study to investigate the expression and function of p42.3 in hepatocellular carcinoma (HCC). We found that p42.3 promotes tumorigenicity and tumor growth in HepG2 cells and is overexpressed in HCC. These results suggest that p42.3 may act as a novel tumor biomarker and aid in the development of improved therapeutic strategies.

Overexpression of p42.3 promotes cell growth and tumorigenicity in hepatocellular carcinoma. *World J Gastroenterol* 2013; 19(19): 2913-2920 Available from: URL: <http://www.wjnet.com/1007-9327/full/v19/i19/2913.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i19.2913>

## INTRODUCTION

Hepatocellular carcinoma (HCC) is a major world health problem due to its high incidence and fatality rate. The annual number of new HCC cases worldwide is over one million, making it the 5<sup>th</sup> most common cancer and the 3<sup>rd</sup> leading cause of cancer-related deaths<sup>[1]</sup>, accounting for more than 1 million deaths annually<sup>[2]</sup>. Despite improvements in monitoring and clinical treatment strategies, HCC prognosis remains poor<sup>[3,4]</sup>. Discovering novel biomarkers that correlate with HCC development or progression may present opportunities to reduce the severity of this disease through early and novel therapeutic interventions.

In our previous research, we cloned the full-length cDNA of the *p42.3* gene by using mRNA differential display in a synchronized gastric cancer (GC) cell lines. We found that p42.3 expression is frequently upregulated in primary tumors and embryonic tissues but not in normal tissues from adult organs. Moreover, stable silencing of p42.3 in BGC823 cells suppresses tumorigenicity and cell proliferation with accumulation of cells at G2/M stage of the cell cycle<sup>[5]</sup>. In addition, Jung *et al*<sup>[6]</sup> reported that the expression of p42.3 mRNA was significantly elevated in colorectal cancer (CRC) tissues compared to normal tissues. All these data indicate that p42.3 plays an important role in tumorigenesis, suggesting that it may be a potential tumor biomarker. In order to elucidate the role of p42.3 in tumorigenesis, we characterized p42.3 expression and validated its biologic significance in HCC.

## MATERIALS AND METHODS

### Patients and tissues

HCC specimens ( $n = 138$ ) were collected from 98 men and 40 women (age, 31-74 years; mean  $\pm$  SD, 52.6  $\pm$  8.7 years) who were inpatients at Beijing Cancer Hospital, Beijing, China, from January 2006 to September 2009. Patient data are shown in Table 1. All patients underwent a radical resection with curative intent and had sufficient clinical information available. No patients had received

TNM: Tumor-node-metastasis; NS: Not significant; HBV: Hepatitis B virus.

chemotherapy or radiation therapy. Moreover, 114 adjacent normal hepatic tissues (at least 5 cm distant from the tumor edge) were also collected from HCC patients. Tumor stage was classified according to the American Joint Committee on Cancer tumor-node-metastasis (TNM) classification. The investigation project and its informed consent have been examined and certified by the Ethics Committee of Beijing Cancer Hospital.

### Tissue microarray immunohistochemistry

The hepatic tissue microarray was constructed using a tissue array instrument as previously described<sup>[7]</sup>. For immunohistochemistry studies, sections were deparaffinized and rehydrated. Endogenous peroxidase activity was blocked by incubation in 3% H<sub>2</sub>O<sub>2</sub> solution for 10 min at room temperature. After blocking with 5% skim milk, sections were incubated with specific murine p42.3 mAb (1:1000, our lab) at 4 °C overnight, followed by the incubation with the peroxidase-based EnVision TM kit (Dako Cytomation, Cambridgeshire, United Kingdom) for 30 min at room temperature. The reaction product was visualized with diaminobenzidine (DAB, Dako, Glostrup, Denmark) for 5 min at room temperature. Sections were counterstained with hematoxylin.

Purified IgG from normal mouse sera was used as a negative control. The number of tumor cells or normal hepatic cells was evaluated by two independent pathologists. A specimen with more than 20% immunostained cells was classified as a positive case.

### Cell lines and cell culture

The 6 human HCC cell lines MHCC97L, MHCC97M3,

BEL7402, Huh7, HepG2, and SMMC7721 and the immortal human hepatocyte line HL7702 were routinely maintained as previously described<sup>[8]</sup>. HL7702 was cultured in Roswell Park Memorial Institute medium (RPMI 1640; Gibco, Grand Island, NY, United States), supplemented with 20% fetal bovine serum (FBS; Gibco). BEL7402 and SMMC7721 cell lines were cultured in RPMI 1640 medium supplemented with 10% FBS. The remaining cell lines were cultured in Dulbecco's modified Eagle's medium (DMEM; Gibco) supplemented with 10% FBS. All media contained 100 units/mL penicillin and 100 µg/mL streptomycin. All cell lines were maintained at 37 °C in 5% CO<sub>2</sub>.

#### Reverse transcription-polymerase chain reaction and quantitative real-time reverse transcription-polymerase chain reaction

Total RNA was extracted from cell lines using TRIzol (Qiagen, United States). The prepared RNA (5 µg) was mixed with oligo-dT primers and reverse-transcribed with moloney murine leukemia virus reverse transcriptase (Promega, United States) for 60 min at 37 °C, followed by polymerase chain reaction (PCR) amplification with specific primers for p42.3 (forward: 5'-TGGACTGCG-GCCTGCTGAA-3'; reverse: 5'-ACTCCATCGCTGT-GTTTCAAT-3'). PCR amplification was performed in 20 µL using a thermocycler (Biometra, Germany) with the following PCR program: pre-denaturation for 5 min at 94 °C, denaturation for 45 s at 94 °C, annealing for 45 s at 61 °C, extension for 45 s at 72 °C, and a final elongation at 72 °C for 10 min. β-Actin served as an internal positive control (forward: 5'-TCACCCACACTGTGCCCATC-TACGA-3'; reverse: 5'-CAGCGGAACCGCTCATTTGC-CAATGG-3'). PCR was performed for 24 or 32 cycles (β-actin 24 cycles; p42.3 32 cycles). PCR products were separated by electrophoresis on a 1.5% agarose gel. Quantitative real-time reverse transcription-PCR (Q-RT-PCR) using SYBR-Green Master PCR mix (Applied Biosystems, Carlsbad, CA) was performed in triplicate (p42.3 forward: 5'-CCTGGCATCTTTACTGGACTGGA-3'; p42.3 reverse: 5'-GTGCCAGCCTGTCTCACATTTTC-3'). Quantification was normalized to the endogenous control β-actin (forward: 5'-TTAGTTGCGTTACACCCTTTC-3'; reverse: 5'-ACCTTCACCGTTCCAGTTT-3').

#### Western blotting

Cell lysates were prepared by incubating cells at 4 °C for 1 h in a buffer containing 50 mmol/L Tris-HCl, pH 8.0, 0.5% Nonidet P-40, 2 mmol/L dithiothreitol, 5 mmol/L ethylene diamine tetraacetic acid, 100 mmol/L NaCl, and 2 mmol/L phenylmethylsulfonyl fluoride. Equal amounts of protein were electrophoresed on a 12% sodium dodecylsulfate polyacrylamide gel and transferred to a polyvinylidene difluoride membrane using standard techniques. We used four specific antibodies obtained from Santa Cruz Biotechnology: proliferating cell nuclear antigen (PCNA) (diluted 1:300; F-2), cyclin B1 (diluted 1:500; H-433), cell division cycle 25 A (Cdc25A) (diluted 1:500; DCS-122), and cell division cycle 25 homolog

C (Cdc25C) (diluted 1:500; C-20). The following specific antibodies were also used: mitotic arrest deficient 2 (MAD2) (diluted 1:1000; Ab70383; Abcam, United Kingdom), actin (diluted 1:10000, AC-15; Sigma, United States), and p42.3 (diluted 1:1000; our lab). Nonspecific binding was blocked using a 5% fat-free milk solution. Signals were detected using an enhanced chemiluminescence system (Amersham Pharmacia Biotech).

#### Plasmid construction and cell transfection

The whole coding region of p42.3 was cloned into the pIRES2-EGFP vector at the *Bam*HI and *Hind*III sites. Nucleotide sequences of the subcloned cDNAs were verified by sequencing. HepG2 were selected and cultured at 60%-70% confluence in 35 mm plates. Cells were transfected with recombinant p42.3 plasmids or an empty vector using Lipofectamine 2000 (Invitrogen, Carlsbad, United States). At 48 h post-transfection, cells were seeded for 21 d in selection medium containing 400 µg/mL G418 to screen for stable clones. To confirm the transfection efficiency, RT-PCR and Western blot analysis were performed.

#### 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay and soft agar colony formation assay

Stably transfected cells were seeded ( $2 \times 10^3$ ) in duplicates into each well of a 96-well culture plate and grown in 200 µL DMEM with 5% FBS; 10 µL 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT; Genview, Florida, United States) (5 mg/mL) was added at 0, 24, 48, 72, 96 and 120 h. The MTT was removed after 4 h incubation; 100 µL of dimethylsulfoxide (Amresco, Cochran, United States) was added to each well, then incubated for 30 min. Absorbency was measured at 570 nm using an iMark Microplate Reader (Bio-Rad, CA, United States).

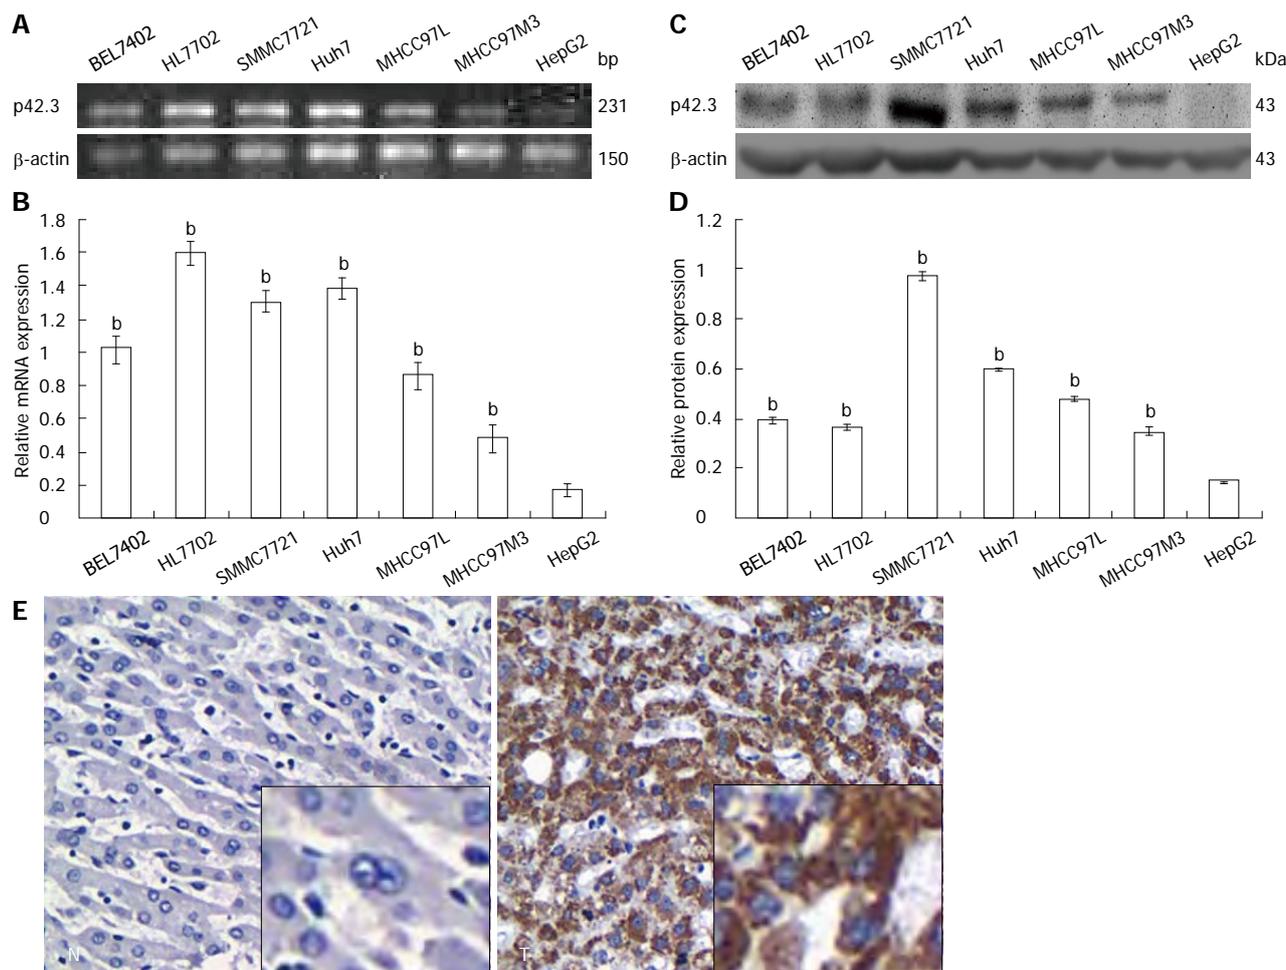

For the soft agar assay, cells ( $2 \times 10^3$ ) were trypsinized and resuspended in 4 mL of 0.3% agar in DMEM containing 10% FBS, and overlaid with 0.6% agar in 60-mm culture dishes. The dishes were incubated routinely for 21 d. Colonies were stained with 0.2% *p*-iodonitrotetrazolium violet, then photographed and counted.

#### Tumorigenicity assay in nude mice

Stably transfected cells were washed twice and resuspended in 1 × Hank's buffer at a concentration of  $1 \times 10^6$  cells/mL. A 100-µL cell suspension of HepG2-p42.3 was then injected subcutaneously into the left dorsal flank of 10, 4-wk-old female nude mice. As a control, the right side was inoculated with HepG2-vector. Tumor diameters were checked every 3 d, and tumor volume was calculated according to  $ab^2/2$  ( $a > b$ ). Tumor specimens were collected at 15 d after injections and split. Immunohistochemistry (IHC) analysis was used to detect p42.3 protein expression. Three independent experiments were performed and yielded similar results.

#### Statistical analysis

To evaluate the possible differences of p42.3 expression in different hepatic specimens, we performed Pearson's

**Figure 1** Detection of p42.3 in hepatic cell lines and hepatocellular carcinoma tissues. A: Reverse transcription-polymerase chain reaction (RT-PCR) analysis showed that p42.3 was detectable in all 7 cell lines, and the lowest expression was in HepG2 cells; B: Relative expression of p42.3 mRNA in seven hepatic cell lines using quantitative real-time RT-PCR. Data are shown as the mean  $\pm$  SD, endogenous references was  $\beta$ -actin ( $^*P < 0.01$  vs HepG2); C and D: Expression of p42.3 protein in hepatic cell lines analyzed by Western blotting (C) and shown as mean  $\pm$  SD (D) ( $^*P < 0.01$  vs HepG2); E: Negative staining of p42.3 in hepatocellular carcinoma-adjacent normal tissue (left), positive staining of p42.3 in tumor (right). Original magnification,  $\times 100$ ; the inset boxes are at original magnification  $\times 200$ .

$\chi^2$  test. The Student's two-sided *t*-test was used to compare test and control sample values in MTT assay, soft agar colony formation assay and tumorigenicity assay. All statistical analyses were carried out using the SPSS statistical software package 16.0 (SPSS Inc., United States). *P* values  $< 0.05$  were considered statistically significant.

## RESULTS

### p42.3 protein expression in human tumor cell lines

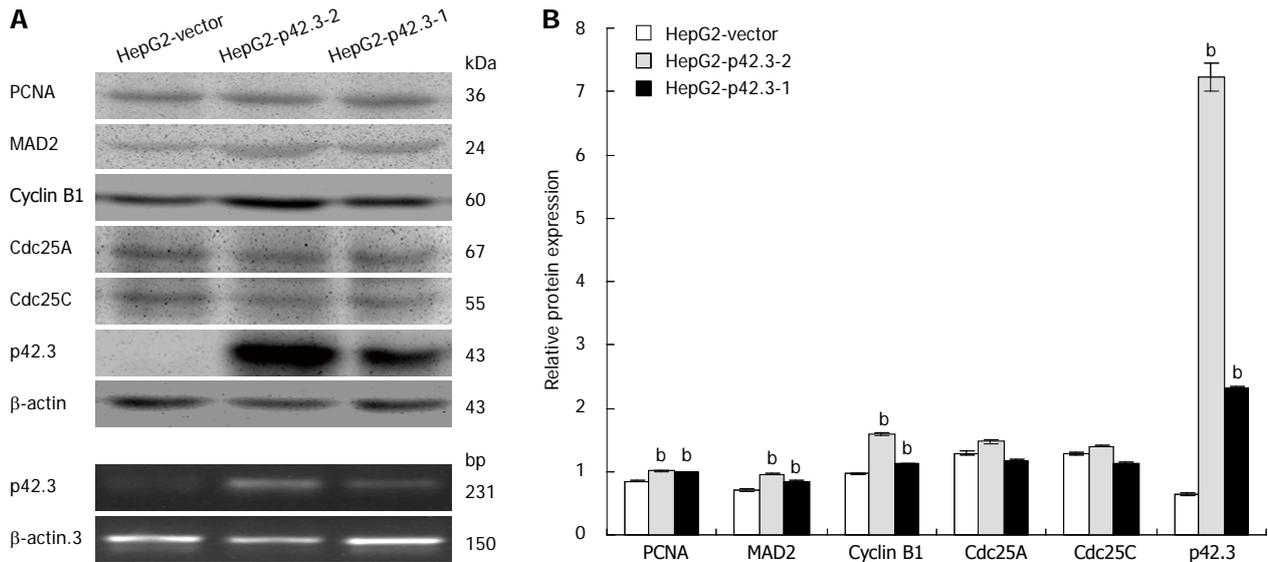

p42.3 mRNA and protein expression were examined in 6 human HCC cell lines and the immortal human hepatocyte HL7702. RT-PCR and Q-RT-PCR showed that p42.3 mRNA was expressed in all of 7 cell lines (7/7, 100%), and the lowest expression was found in HepG2 cells (Figure 1A and B). Consistent with mRNA expression levels, p42.3 protein was expressed at high levels in all cell lines except HepG2 cells (6/7, 85.7%) (Figure 1C and D). Thus, we confirmed that the HepG2 cell line is a p42.3-deficient line and could therefore be used as a model to investigate p42.3 protein function.

### p42.3 protein levels in human primary tumors

To characterize p42.3 expression in HCC specimens, IHC was performed on tumor tissues and tumor-adjacent normal tissues. We found p42.3 protein was detected in 69.6% (96/138) of hepatic tumor tissues. However, p42.3 expression was less apparent, with significantly less positive cells (30.7%, 35/114) in tumor-adjacent normal tissues ( $P < 0.001$ , Table 1 and Figure 1E). The results indicate that p42.3 protein is highly expressed in primary HCC tissues rather than tumor-adjacent normal tissues. Analysis of the clinicopathological characteristics of the 138 HCC specimens revealed a significant correlation between p42.3 expression and tumor differentiation ( $P = 0.031$ , Table 1). However, we found no relationship between p42.3 positivity and tumor TNM classification, hepatitis B virus status, or type of hepatoma.

### Overexpression of p42.3 induces PCNA, cyclin B1 and MAD2 expression in HepG2 p42.3-deficient cells

To examine the gene function of p42.3 overexpression on HCC cells, we stably transfected the pIRES2-EGFP-

**Figure 2** The effect on molecular by overexpression of p42.3 in HepG2 cells. A: Reverse transcription-polymerase chain reaction and Western blotting were performed to confirm p42.3 overexpression in a stable single colony of HepG2-p42.3-1 and HepG2-p42.3-2 cells. p42.3 expression was deficient in the HepG2-vector control cells.  $\beta$ -actin served as an internal control; B: Expression of proteins shown as mean  $\pm$  SD. Consistent with p42.3 protein expression, proliferating cell nuclear antigen (PCNA), mitotic arrest deficient 2 (MAD2) and cyclin B1 expression were significantly upregulated. The protein levels of cell division cycle 25 A (Cdc25A) and cell division cycle 25 homolog C (Cdc25C) hardly changed following p42.3 expression ( $^bP < 0.01$  vs HepG2-vector).

p42.3 expression vector into HepG2 cells. A cell line that stably expresses p42.3 (HepG2-p42.3) was generated and analyzed by western blotting. As shown in Figure 2, p42.3 protein was not detected in cells stably transfected with the empty vector. However, p42.3 protein was significantly increased in the p42.3 overexpressing cells, HepG2-p42.3-1 and HepG2-p42.3-2. These results indicated that the eukaryotic vector for p42.3 used in this study sufficiently upregulates p42.3 expression in HepG2 cells.

Since p42.3 is a novel cell cycle-dependent protein, we investigated cyclin B1 and other M phase-related proteins in p42.3-expressing HepG2 cells and control cells (HepG2-vector). We found that p42.3 expression resulted in a significant upregulation in PCNA, cyclin B1 and MAD2 protein levels. However, Cdc25A and Cdc25C protein levels only slightly changed with p42.3 expression (Figure 2).

#### Overexpression of p42.3 promotes growth and colony formation in HepG2 cells

The effects of p42.3 overexpression on the viability of HepG2 cells were measured using an MTT colorimetric assay. We found that transfection with pIRES2-EGFP-p42.3 promotes HepG2 cell growth. A stable single clone of HepG2-p42.3-1 and HepG2-p42.3-2 cells grew much faster over a 6-day period when compared to parental HepG2-vector cells, indicating that p42.3 may confer a strong growth capability in HepG2 cells ( $P < 0.01$ , Figure 3A).

The colony formation assay was used to evaluate the ability for anchorage-independent growth of cells in soft agar medium. Our data showed a significant increase in HepG2-p42.3-1 and HepG2-p42.3-2 colony formation in both number and size; however, the HepG2-vector

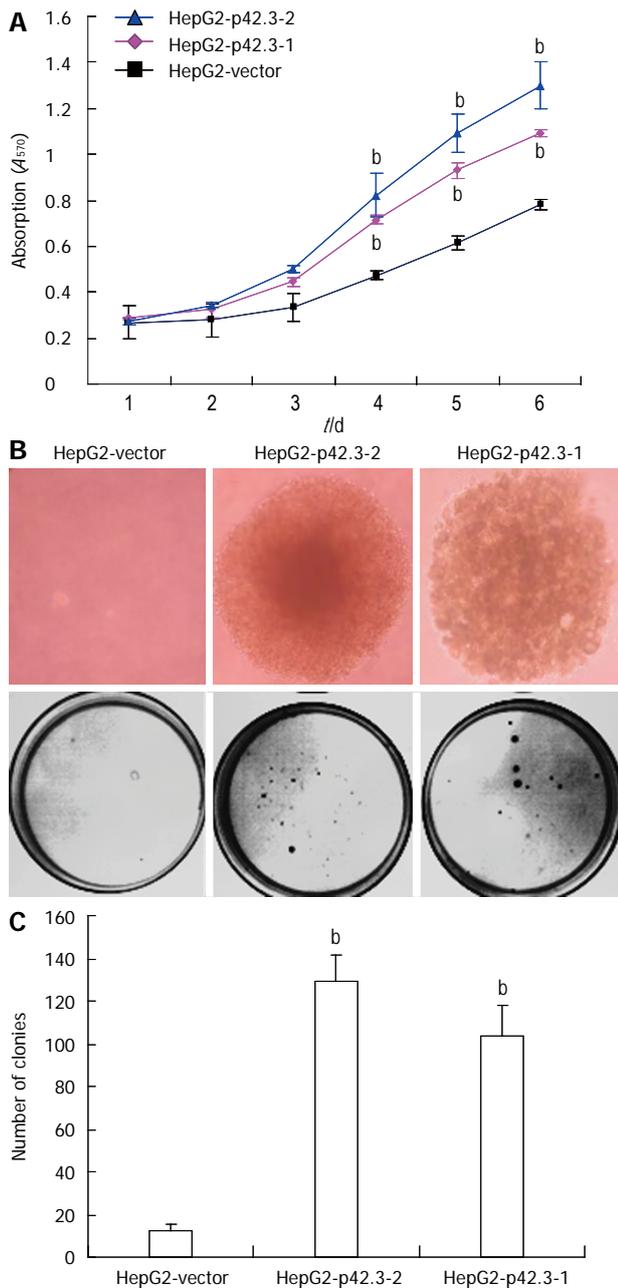

cells only formed a few small colonies ( $P < 0.01$ , Figure 3B and C). This suggests that p42.3 confers anchorage-independent growth to cells.

#### Overexpression of p42.3 promotes HepG2 cell tumorigenicity

We tested p42.3 tumorigenicity in nude mice. HepG2-p42.3 cells were injected subcutaneously into the left dorsal flank of female nude mice (BALB/c), the right side was injected with HepG2-vector cells as a control. Of the 5 animals injected with HepG2-p42.3-1 or HepG2-p42.3-2 cells, tumors appeared faster and were larger than in the controls (HepG2-vector) ( $P < 0.01$ , Figure 4A and B). After the animals were sacrificed, the xenografts were removed and collected for immunohistochemistry analysis. The results showed that p42.3 protein was found in all HepG2-p42.3 xenografts, but that p42.3 protein was not found in HepG2-vector xenografts (Figure 4C). These results further confirmed that the p42.3 overexpression promotes tumorigenicity of HepG2 cells.

## DISCUSSION

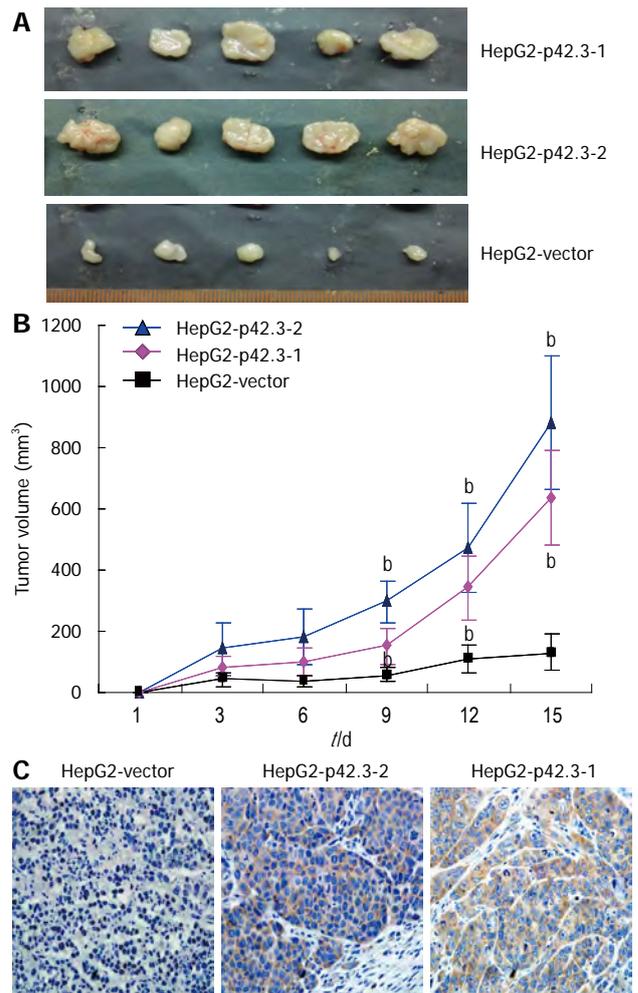

p42.3 is a highly conserved mammalian gene and strong G2 induction<sup>[5,9-11]</sup>. Moreover, p42.3 is involved in Chromosome segregation<sup>[12]</sup>, it may play a key role in tumorigenicity. Our previous studies have shown that p42.3 was overexpressed in GC tissue and its expression is cell cycle dependent in the BGC823 cell line, expression peaked at early G1 phase<sup>[5,13]</sup>. Additionally, reduced proliferation and tumorigenic properties were detected in the BGC823 cell line that lacked p42.3<sup>[5]</sup>, suggesting that p42.3 is involved in gastric carcinogenesis. While most studies have focused on the roles of p42.3 in GC development<sup>[5,11,14]</sup>,

**Figure 3** Promotion of cell growth and colony formation with p42.3 overexpression in HepG2 cells. A: Promotion of cell growth after overexpression of p42.3 in HepG2. Growth curve comparing HepG2-p42.3-1, HepG2-p42.3-2, and HepG2-vector cells over a 6-d time course. Data are shown as the mean  $\pm$  SD of three independent experiments ( $^*P < 0.01$  vs HepG2-p42.3-1); B: The colonies of HepG2-p42.3-1, HepG2-p42.3-2, and HepG2-vector formed on soft agar. The colonies grew faster and were larger in HepG2 cells that overexpressed p42.3-2 than in the HepG2-vector control cells; C: Raw value indicating colony number. Data revealed that the colony-forming activities of HepG2-p42.3-1 and HepG2-p42.3-2 were significantly promoted on soft agar. The data represent the mean  $\pm$  SD of three independent experiments ( $^*P < 0.01$  vs HepG2-vector).

the roles of p42.3 in other cancer remain to be elucidated. Therefore, we characterized p42.3 expression in HCC tissues from patients. Moreover, we investigated p42.3 functions and potential mechanisms of action in HepG2 cells.

In 7 human HCC cell lines, consistent with the mRNA

**Figure 4** Promotion of tumorigenesis by overexpression of p42.3 shows statistical significance compared with the control in HepG2 cells. A: The tumor induced by HepG2-p42.3-1 and HepG2-p42.3-2 was much larger than that in the control; B: Over the course of 15 d, the tumor growth curve comparing HepG2-p42.3-1, HepG2-p42.3-2, and HepG2-vector cells revealed that p42.3-overexpressing cells grew faster ( $^*P < 0.01$  vs HepG2-p42.3-1); C: Immunohistochemistry staining was performed in xenograft tissues from tumors. p42.3 protein was detectable in xenografts that were formed by injection of p42.3-overexpressing cells, but not in the tumors developed from HepG2-vector cells.

expression, p42.3 protein was highly expressed with the exception of the HepG2 line. In concert with our previous study in GC cells, we found that the p42.3 gene was highly expressed in the majority of the tested tumor cell lines. This suggests that the p42.3 gene is overexpressed in tumor cells. In previous research, data showed that the p42.3 gene is closely related to GC and CRC<sup>[5,6]</sup>. Similarly, our current data revealed that the p42.3 protein was expressed in 64.7% of hepatic tumor tissues compared to only 35.3% in tumor-adjacent normal tissues. The clinical p42.3 data in GC, CRC and HCC tissues suggest that upregulation of p42.3 may be a common feature in a variety of tumors.

Our results further support the hypothesis that p42.3 might stimulate cellular viability and malignant transformation since overexpression of p42.3, by stable transfection of the pIRES2-EGFP-p42.3 into HepG2 cells, significantly promotes cancer cell growth by MTT colo-

rimetry and colony formation *in vitro*, and significantly induced tumorigenicity in nude mice. Thus, these findings provide evidence that p42.3 plays an important role in tumorigenesis. Therefore, we investigated the molecular mechanism responsible for stimulating cell growth and malignant transformation. Since the expression of p42.3 is cell cycle dependent and G2/M checkpoint abrogated<sup>[5,11,13,15]</sup>, we analyzed the effects of elevated p42.3 levels on a series of cell cycle proteins. Our results indicate that p42.3 expression significantly upregulates PCNA, cyclin B1 and MAD2 protein levels. However, Cdc25A and Cdc25C protein levels hardly change with p42.3 expression. Cyclin B1 is one of the key genes involved in M-phase regulation<sup>[16-20]</sup>. Together with Cdc2, cyclin B1 forms a complex that controls M-phase entry and exit<sup>[17,21]</sup>. Cyclin B1 can promote the G2-M transition, and even leads to a loss cell proliferation control, thus leading to malignant transformation<sup>[22,23]</sup>. The alteration of cyclin B1 protein levels shown here is consistent with our previous study<sup>[5]</sup>, it shows p42.3 may a regulator of cyclin B1. Furthermore, MAD2 is a component of the mitotic spindle assembly checkpoint that prevents the onset of anaphase until all chromosomes are properly aligned at the metaphase plate<sup>[24,29]</sup>, and MAD2 is involved in mediating the upregulation of cyclin B1 proteins<sup>[30,31]</sup>. Our results showed that the significant increase in expression of cyclin B1 and Mad2 may correlation with G2/M checkpoint abrogation. On the other hand, though Cdc25 phosphatases involved in cell cycle checkpoints as key regulators of normal cell division and the cell's response to DNA damage<sup>[32-35]</sup>, our data did not reveal any obvious change in total Cdc25A and Cdc25C levels with p42.3 overexpression, Cdc25 phosphatases may have no role in the cell's response to induced p42.3 expression.

In summary, the data obtained in this study demonstrate that p42.3 protein is upregulated in primary HCC tissues but not tumor-adjacent normal tissues, and that cyclin B1 might be responsible for the cellular proliferation and malignant transformation induced by p42.3. These insights may help to identify p42.3 as a potential target for improved cancer therapies or as a diagnostic marker in clinical cancer treatment.

## COMMENTS

### Background

Hepatocellular carcinoma (HCC) is a major world health problem due to its high incidence and fatality rate. Discovering novel biomarkers that correlate with HCC may present opportunities to reduce the severity of this disease. As a novel tumor-specific and mitosis phase-dependent expression gene, p42.3 is involved in cell proliferation and tumorigenesis in gastric cancer (GC). Previous data also indicate that p42.3 expression is significantly elevated in GC and colorectal cancer (CRC), thus raising the possibility that it may act as a potential tumor biomarker.

### Research frontiers

p42.3 is a novel tumor-specific and mitosis phase-dependent expression gene. It is involved in tumorigenesis in GC and CRC. However, the research concerning p42.3 in HCC is lacking. In this study, the authors investigate p42.3 expression and function in primary HCC. These results suggest that p42.3 may act as a novel disease biomarker and aid in the development of improved therapy strategies.

### Innovations and breakthroughs

Recent reports have highlighted that p42.3 is involved in GC and CRC. This is the first study to investigate the expression and function of p42.3 in HCC. The authors found that p42.3 promotes tumorigenicity and tumor growth in HepG2 cells and is overexpressed in HCC.

### Applications

In understanding the expression and function of p42.3 in HCC, this study may represent a future strategy as a therapeutic target and/or improve clinical cancer HCC treatment.

### Peer review

The authors examined the expression of p42.3 and its function in HCC. These data revealed that p42.3 was increased in HCC and in all HCC cells with the exception of HepG2 cells. Moreover, p42.3 expression was correlated with tumor differentiation. p42.3 promotes tumorigenicity and tumor growth in HCC; therefore, it may be used as a potential target to improve the clinical treatment of HCC.

### Abstract

**AIM:** To investigate the effects of the heme oxygenase (HO)-1/carbon monoxide system on iron deposition and portal pressure in rats with hepatic fibrosis induced by bile duct ligation (BDL).

**METHODS:** Male Sprague-Dawley rats were divided randomly into a Sham group, BDL group, Fe group, deferoxamine (DFX) group, zinc protoporphyrin (ZnPP) group and cobalt protoporphyrin (CoPP) group. The levels of HO-1 were detected using different methods. The serum carboxyhemoglobin (COHb), iron, and portal vein pressure (PVP) were also quantified. The plasma and mRNA levels of hepcidin were measured. Hepatic fibrosis and its main pathway were assessed using Van

Gieson's stain, hydroxyproline, transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1), nuclear factor-E2-related factor 2 (Nrf2), matrix metalloproteinase-2 (MMP-2) and tissue inhibitor of metalloproteinase-1 (TIMP-1).

**RESULTS:** Serum COHb and protein and mRNA expression levels of HO-1 and Nrf2 were increased in the BDL group compared with the Sham group and were much higher in the CoPP group. The ZnPP group showed lower expression of HO-1 and Nrf2 and lower COHb. The levels of iron and PVP were enhanced in the BDL group but were lower in the ZnPP and DFX groups and were higher in the CoPP and Fe groups. Hepcidin levels were higher, whereas superoxide dismutase levels were increased and malonaldehyde levels were decreased in the ZnPP and DFX groups. The ZnPP group also showed inhibited TGF- $\beta$ 1 expression and regulated TIMP-1/MMP-2 expression, as well as obviously attenuated liver fibrosis.

**CONCLUSION:** Reducing hepatic iron deposition and CO levels by inhibiting HO-1 activity through the Nrf2/Keap pathway could be helpful in improving hepatic fibrosis and regulating PVP.

**Key words:** Heme oxygenase-1; Hepcidin; Iron accumulation; Oxidative stress; Portal vein pressure; Carboxyhemoglobin; Bile duct ligation

**Core tip:** In this study, inhibiting heme oxygenase-1 (HO-1)/carbon monoxide (CO) system by zinc protoporphyrin in rat liver fibrosis induced by bile duct ligation, the author aimed to affect the HO-1/CO system by iron deposition and portal pressure. Reducing hepatic iron deposition and CO levels by inhibiting HO-1 activity through the nuclear factor-E2-related factor 2/Keap pathway could be helpful in improving hepatic fibrosis and maintaining portal vein pressure.

## INTRODUCTION

Iron is an essential nutrient for growth and survival, but excessive iron accumulation in cells can result in cell injury<sup>[1,2]</sup>. Iron overload is not uncommon in many patients with end-stage liver cirrhosis, and it can also occur in patients with a history of multiple blood transfusions<sup>[3,4]</sup>.

Research has shown that in cultured hepatocytes, iron activates hepatic stellate cells and increases the secretion of latent transforming growth factor- $\beta$  (TGF- $\beta$ ) due to hepatocytes being injured by iron in the pathogenesis of iron-induced liver fibrosis<sup>[5]</sup>. In mice, iron overload enhanced the development of carbon tetrachloride-induced hepatic fibrosis<sup>[6]</sup>. In clinical studies, approximately half of patients with hereditary iron accumulation (hemochromatosis) developed liver fibrosis<sup>[7]</sup>. Moreover, a significant reduction of fibrosis in the liver was demonstrated in a number of thalassemia patients treated with deferasirox<sup>[8]</sup>.

Clinically, repeated large-volume blood transfusions are sometimes necessary for cirrhotic patients with massive upper gastrointestinal bleeding; in most cases, patients are transfused with packed red blood cells (RBCs), which results in iron overload as the human body cannot excrete iron. Each unit of RBCs contains approximately 250 mg of iron, and after 10-15 RBC transfusions, iron typically accumulates in the liver, heart, skin, and endocrine organs<sup>[9]</sup>. However, how iron overload affects the pathogenesis and treatment of patients with hepatic fibrosis is not yet well understood.

Heme oxygenase-1 (HO-1) is the primary rate-limiting enzyme in heme catabolism. It catalyzes the oxidative degradation of heme into free iron, carbon monoxide (CO), and biliverdin<sup>[10,11]</sup>.

Previous reports have recently shown HO-1 to be protective in liver cells in various liver diseases such as acute liver injury, alcoholic liver disease, liver fibrosis and ischemia/reperfusion injury through multiple pathways<sup>[12-15]</sup>. Other reports have indicated that this protection might be restricted to a narrow threshold of HO-1 over-expression<sup>[13,16]</sup>. Our previous studies showed that over-expression of HO-1 could be harmful to the liver functioning of rats with cirrhosis induced by bile duct ligation (BDL)<sup>[17,18]</sup>, which was also reported by Froh *et al*<sup>[19]</sup>, but whether this effect was related to iron accumulation and CO release was not clear.

In normal Sprague-Dawley (SD) rats, increased HO activity as a pro-oxidant mechanism resulted in iron accumulation in the liver; in contrast, decreased HO activity reduced intracellular iron levels and oxidative stress<sup>[20]</sup>.

In this study, we investigated the effect of HO-1 on iron accumulation and CO release by inhibiting or inducing HO-1 expression with zinc protoporphyrin (ZnPP) or cobalt protoporphyrin (CoPP) in fibrotic rat models induced by BDL, and we further studied whether regulating HO-1 expression could improve liver fibrosis by reducing hepatic iron accumulation and portal vein pressure (PVP).

## MATERIALS AND METHODS

### Animal care

The experimental protocols were approved by the Animal Care and Use Committee of Dalian Medical University (Liaoning Province, China), in accordance with the guidelines established by the Canadian Council on Animal Care.

### BDL and treatment in rat

Fifty-three healthy male SD rats, weighing 200-220 g, were obtained from the Laboratory Animal Center of Dalian Medical University and were randomly divided into six groups: a Sham group ( $n = 6$ ), BDL group ( $n = 10$ ), CoPP treatment group ( $n = 12$ ), ZnPP treatment group ( $n = 8$ ), Fe treatment group ( $n = 9$ ) and DFX treatment group ( $n = 8$ ). The rats were housed in a specific pathogen-free (SPF) center, at room temperature of 24-26 °C and relative humidity of 60%-65%. Water was provided ad libitum.

The rats were well fed and housed for 3 d before any experimental protocols. Biliary cirrhosis was induced by BDL<sup>[21,22]</sup>. Five groups underwent BDL together with Sham-operated animals as a healthy control. The surgical procedures were approved by the Animal Care and Use Committee of Dalian Medical University. Laparotomy was performed under anesthesia with ether. The bile duct was isolated and double-ligated with a 3-0 silk suture. The abdominal wall and skin were closed with 4-0 silk sutures, and the antibiotic gentamicin (0.3 mL) was injected intramuscularly. Rats in the Sham group underwent laparotomy with the bile duct isolated but not ligated. After surgery, the Sham and BDL groups received an intraperitoneal injection of saline. Other groups received an intraperitoneal injection consisting of CoPP, ZnPP, iron-dextran (ID) and deferoxamine (DFX) (5, 5, 50, 100 mg/kg body weight) three times per week, respectively. After the establishment of the rat models, the number of rats was reduced to 6 in each group because of deaths during the study process.

ZnPP and CoPP (Sigma, St Louis, MO, United States) were dissolved in 0.2 mol/L of NaOH, adjusted to a pH of 7.4, were diluted in 0.85% NaCl, with a final concentration of 1 mg/mL as previously described, and were used for inhibiting and inducing HO-1 expression, respectively<sup>[23]</sup>. DFX mesylate salt and ID (Sigma, St Louis, MO, United States) were diluted in 0.85% NaCl with final concentrations of 40 and 20 mg/mL, respectively. Histostain™ - Plus Kits (SP9001) (Zhongshan Goldenbridge

Biological Technology, Beijing, China); hydroxyproline (HYP), malonaldehyde (MDA) and superoxide dismutase (SOD) (Key GEN Biotech Nanjing, China); a hepcidin enzyme-linked immunosorbent assay (ELISA) Kit (EIAab Science, Wuhan, China); and a TaKaRa RNA polymerase chain reaction (PCR) kit (avian myeloblastosis virus), version 3.0 (TaKaRa Biotechnology, Dalian, China), were used in this study.

### Sample collection and examination

Four weeks after surgery, a catheter connected to a pressure transducer (BL-420F biological experimental system, Chengdu Technology and Market Co. Ltd., China), was placed in the portal vein to measure PVP. Subsequently, 1 mL of arterial blood was withdrawn to measure carboxy-hemoglobin (COHb), using a Rapid Lab 1245 Blood Gas Analyzer (Siemens, New York, NY, United States). Then, blood samples were collected from the abdominal aorta to measure serum levels of alanine aminotransferase (ALT), aspartate aminotransferase (AST), total bilirubin (TBIL), and serum iron, using a Hitachi 7600-110 automatic biochemical analyzer (Hitachi Co, Tokyo, Japan). The levels of liver SOD and MDA were determined with a UV-2100 spectrophotometer (Chemito Instruments Pvt. Ltd.).

### Liver iron content measurement

Liver iron content was determined by atomic absorption spectrometry with acetylene-air flame atomization. The analysis was performed with a Varian atomic absorption spectrometer (Mulgrave) with deuterium background correction. Measurements were obtained with a 248.3 nm analytical line in the spectral interval of 0.2 nm. Iron concentration was determined by the standard addition method. Sample digestion was accomplished with the MDS 2000 microwave sample preparation system (CEM) in Teflon cartridges, using a mixture of nitric acid (5 mL) and hydrogen peroxide (2 mL) (both from Merck, ultrapure grade) for 20 min at a pressure of 120 psi. The resulting product was analyzed directly in the Teflon cartridges.

### Histology and immunohistochemistry

Part of liver lobe was excised, and the tissue was fixed in 10% neutral formalin solution and embedded in paraffin. Hematoxylin and eosin staining and Van Gieson's (VG) staining were performed according to standard procedures. The severity and degree of lesions were graded according to methods previously described<sup>[24,25]</sup>. Briefly, tissue sections (4  $\mu$ m thick) were treated with HCl (5%) to liberate ferric ions. The samples were then treated with 5% potassium ferrocyanide to produce insoluble ferric ferrocyanide. The slides were counterstained with Neutral red. For immunohistochemical examination, deparaffinized sections were incubated with HO-1 antibodies (1:1000 dilution) and appropriate biotinylated secondary antibodies, followed by the avidin-biotin-peroxidase complex. The immunoreactive signal was developed by color

deposition, using diaminobenzidine as a substrate. Yellow material in the cytoplasm was considered to indicate positive cells. Cell staining was assigned 4 scores, as previously described<sup>[26]</sup>. The final score was defined as staining intensity  $\times$  percentage of positive cells. The mean score of five fields was used to compare the six groups.

### Hepatic HYP content

Liver tissue (100 mg) was prepared for HYP determination, according to a modification of the method previously described<sup>[27]</sup>. The HYP content of the liver, as an indirect measurement of tissue collagen content, was expressed in microgram per gram of wet weight ( $\mu$ g/g).

### Measurement of plasma hepcidin

Plasma hepcidin was measured by ELISA and was determined using 96-well microtiter plates coated with the recombinant peptide and a polyclonal antibody (Santa Cruz Biotechnology, INC, 1:3000 dilution). Assay procedures were performed according to the manufacturer's instructions, and absorbance of each well was determined at a 450 nm wavelength. The process was performed as described previously<sup>[28]</sup>.

### Western blot analysis

The resected hepatic tissues were extracted with lysis buffer (1% Triton X-100; 50 mmol/L Tris-HCl, pH 7.6; 150 mmol/L NaCl; and 1% protease inhibitor cocktail). The protocols for western blot analyses have been described previously<sup>[29]</sup>. Western blot analyses were performed with liver homogenates (30  $\mu$ g protein) using anti-nuclear factor-E2-related factor 2 (Nrf2) antibody (Boster Biological Technology, Wuhan, China, 1: 100 dilution), anti-TGF- $\beta$ 1 antibody (Boster Biological Technology, Wuhan, China, 1:100 dilution), anti-HO-1 antibody (Abcam, Cambridge, MA, United States, 1:2000 dilution), anti- $\beta$ -actin antibody (Zhongshan Goldenbridge Biological Technology, Beijing, China, 1:500 dilution), and secondary antibody anti-rabbit and anti-mouse immunoglobulin G (Biosynthesis Biotechnology, Beijing, China, 1:500 dilution). The intensity of each signal was corrected using the values obtained from the immunodetection of  $\beta$ -actin, and the relative protein intensity was expressed as multiples of the content in the normal group.

### RNA isolation and gene expression analysis

Total RNA was extracted from the livers following a standard guanidinium phenol-chloroform extraction protocol. The quantity of RNA was determined by measuring the optical density at 260 nm ( $A_{260} = 1$  for 40  $\mu$ g/mL RNA), and the purity of RNA was assessed by determining the ratio of the optical density obtained at 260 and 280 nm (pure RNA:  $A_{260}/A_{280} = 2.0$ ) using a UV-1206 spectrophotometer (Shimadzu, Japan). An aliquot of each mixture was used for reverse-transcription (RT)-PCR amplification, using reagents purchased from Takara Bio Inc. (Dalian, China). PCR products were separated by 2.5% agarose gel electrophoresis. The product bands were

**Table 1** Primers used for the reverse transcription-polymerase chain reaction and polymerase chain reaction analysis

| Gene           | Gene ID  | Forward/reverse | Sequences 5'-3'      | Product size (bp) |

photographed, and the density of each product band was quantified. The results are expressed as the ratios of the band density for target mRNA to that of  $\beta$ -actin mRNA. The primers utilized for PCR and RT-PCR are listed in Table 1.

### Statistical analysis

All of the data are presented as the mean  $\pm$  SD. Statistical testing was performed with SPSS software, version 16.0. The groups were compared using one-way analysis of variance with Dunnett's multiple comparison test (where applicable). Correlative comparison of two non-hierarchical variances with normal distribution was evaluated by Pearson's test, whereas Spearman's test was used for non-normally distributed data.  $P < 0.05$  was considered statistically significant.

## RESULTS

### Measurement of biochemical indicators in liver fibrosis induced by BDL

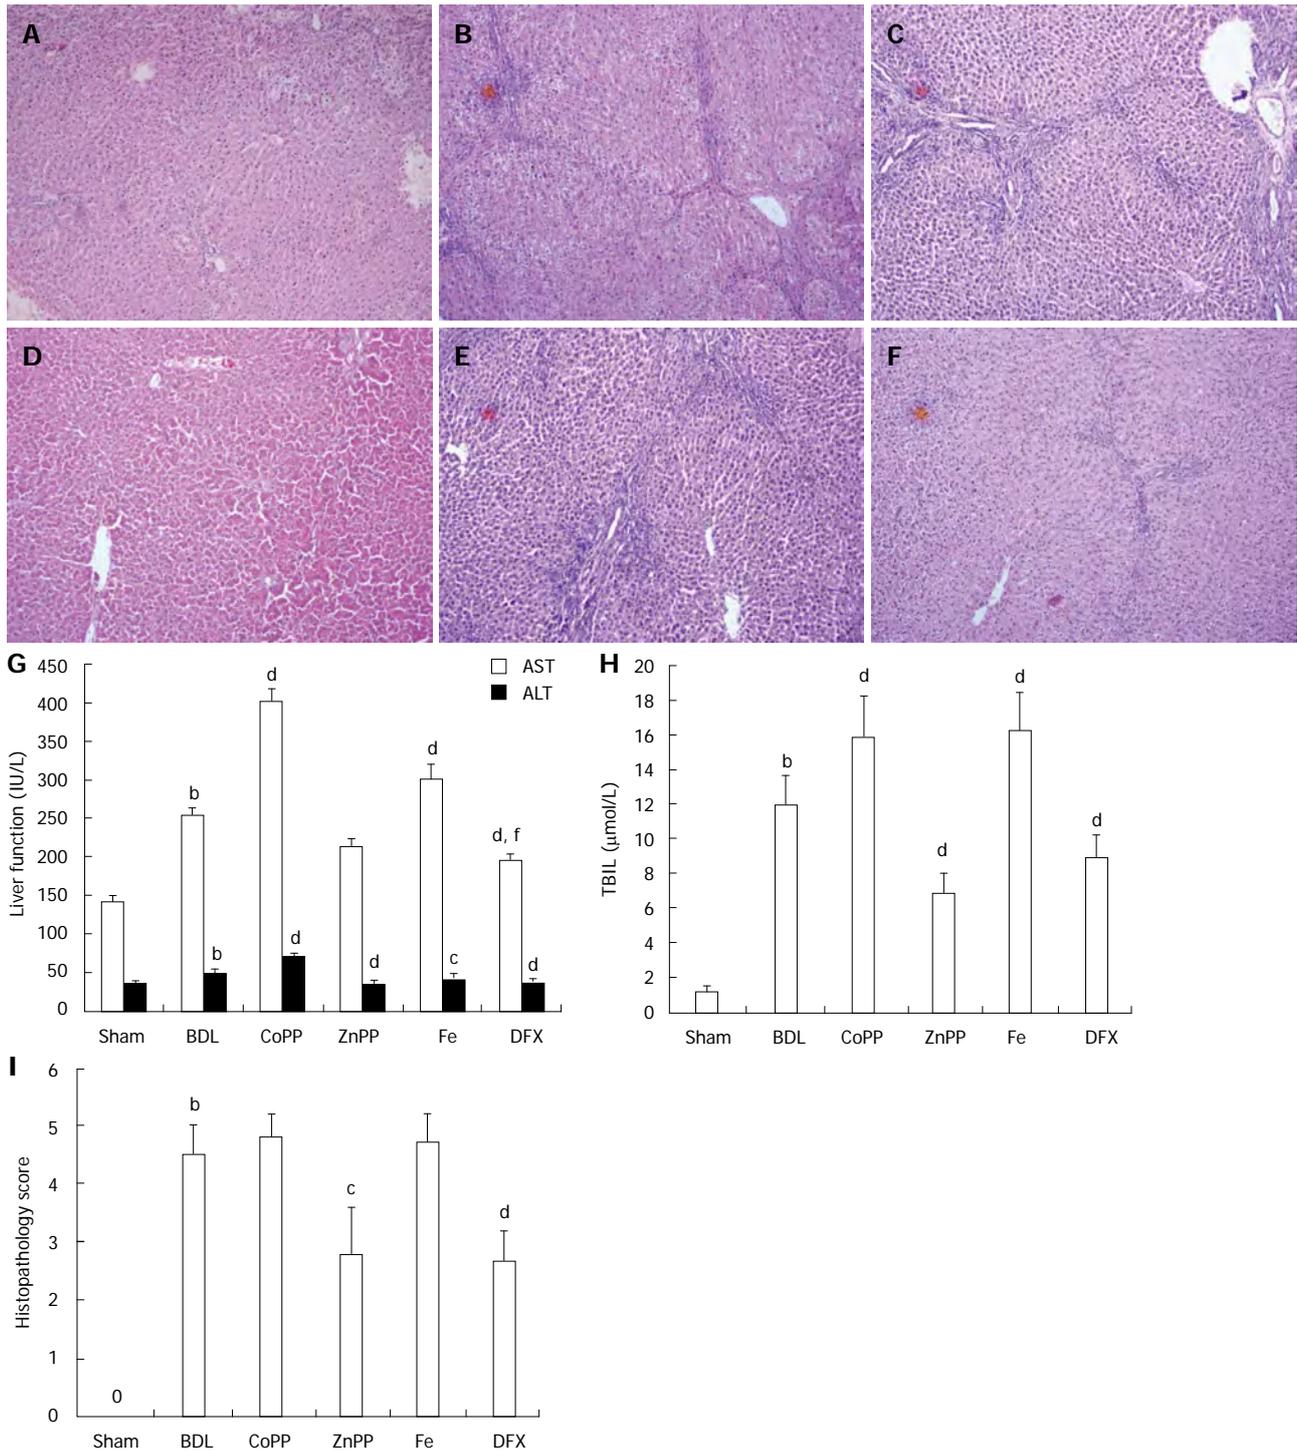

Four weeks postoperatively, common bile duct dilatation was observed in the BDL group, and ascites and jaundice also developed in the BDL group, suggesting that the BDL model was successfully established in our experiments.

The serum levels of AST, ALT and TBIL in the BDL group were much higher than those in the Sham group ( $P < 0.01$ ). These levels were much lower in the ZnPP group and DFX group, but the levels in the CoPP group and Fe group were significantly higher than those in the BDL group ( $P < 0.01$ ) (Figure 1G and H). The serum levels of AST were decreased in the DFX group compared with those in the ZnPP group ( $P < 0.05$ ) (Figure 1G). These data indicated that inhibiting HO-1 expression and further reducing iron accumulation could improve liver function; in contrast, inducing HO-1 expression aggravated liver injury.

### Inhibiting HO-1 expression reduced liver fibrosis and PVP induced by BDL

Liver damage was analyzed by hematoxylin and eosin staining. The livers in the Sham group showed normal lobular architecture with central veins and radiating hepatic cords (Figure 1A). Obvious fibrous hyperplasia and fibrosis extension with fibroblast proliferation were found in the interlobular and central venous regions in the livers in the BDL and CoPP groups (Figure 1B and C). Compared with the BDL group, fibrous hyperplasia was significantly reduced around the central veins in the ZnPP group (Figure 1D). The histopathological scores for fibrosis in the livers of BDL rats were improved in the ZnPP group (Figure 1E). Collagen type I was observed with VG staining (Figure 2A-F). In the BDL group, collagen type I in the portal area and bile duct wall was much thicker than in the Sham group ( $P < 0.01$ ) (Figure 2A and B). Compared with the BDL group, there was a decrease in type I collagen in the ZnPP group. The extent of fibrosis was much higher in the CoPP group than in the BDL group ( $P < 0.01$ ) (Figure 2G). The change in HYP content in liver tissue was in accordance with type I collagen. It was observed that HYP was significantly decreased in the ZnPP group compared with the BDL group (Figure 2H). These data showed that inhibiting HO-1 expression reduced collagen deposition in liver fibrosis.

The COHb levels in arterial blood were significantly higher in the BDL group compared with the Sham group ( $P < 0.01$ ), and they were much lower following ZnPP and DFX treatment, while they were higher in the CoPP- and Fe-treated groups than in the BDL group ( $P < 0.01$ ) (Figure 3A). PVP was significantly higher in the BDL group compared with the Sham group ( $P < 0.01$ ). Compared with the BDL group, PVP decreased in the ZnPP and DFX groups ( $P < 0.01$ ) and was enhanced in CoPP and Fe rats ( $P < 0.01$ ). Moreover, PVP decreased following ZnPP treatment relative to DFX treatment ( $P < 0.05$ ) (Figure 3B).

**Figure 1** Pathological features of rat liver tissue detected by hematoxylin and eosin staining and serum index. A: Normal lobular architecture in the Sham group; B, C, E: Obvious fibrous hyperplasia and fibrosis extension with fibroblast proliferation in the bile duct ligation (BDL) group, cobalt protoporphyrin (CoPP) group and Fe group; D and F: Less fibrous hyperplasia and fibrosis in the zinc protoporphyrin (ZnPP) group and deferoxamine (DFX) group; G, H: Levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT) and total bilirubin (TBIL); I: Histopathological scores for fibrosis (magnification  $\times 100$ ). Values are expressed as mean  $\pm$  SE ( $n = 6$ ). <sup>b</sup> $P < 0.01$  vs Sham group; <sup>c</sup> $P < 0.05$ ; <sup>d</sup> $P < 0.01$  vs BDL group; <sup>f</sup> $P < 0.01$  vs ZnPP group.

Levels of TGF- $\beta 1$  were significantly enhanced in the BDL group compared with the Sham group ( $P < 0.01$ ). These levels were lower in the ZnPP group and higher in the CoPP group compared with the BDL group (Figure 4A and B). The mRNA expression levels of MMP-2 and TIMP-1 were much higher in the BDL group than in the

Sham group ( $P < 0.01$ ). These levels were significantly lower in the ZnPP group and higher in the CoPP group than in the BDL group ( $P < 0.01$ ) (Figure 4C). These results showed that down-regulated HO-1 expression reduced extracellular matrix (ECM) deposition and fibrosis.

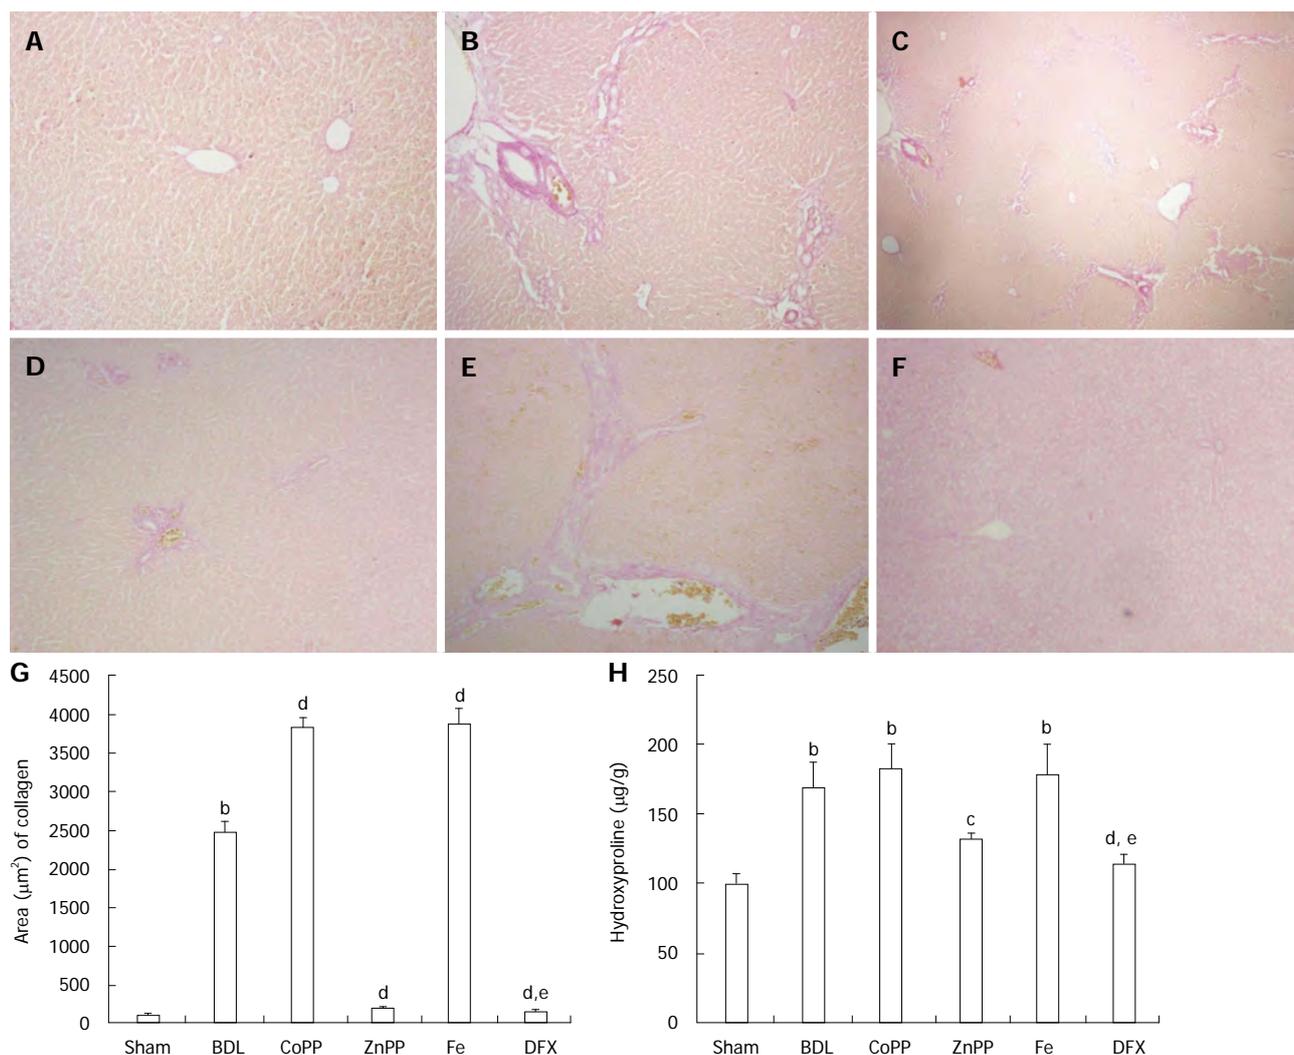

Figure 2 Van Gieson's staining of collagen I for liver sections and liver hydroxyproline content. A-F: Collagen type I was deposited in the bile duct ligation (BDL) group, cobalt protoporphyrin (CoPP) group and Fe group (B, C and E) and was rarely found in the Sham group, zinc protoporphyrin (ZnPP) group and deferoxamine (DFX) group (A, D and F); G: The area of collagen type I; H: Hydroxyproline content of liver tissue (magnification,  $\times 100$ ). Values are expressed as mean  $\pm$  SE ( $n = 6$ ). <sup>b</sup> $P < 0.01$  vs Sham group; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs BDL group; <sup>e</sup> $P < 0.05$  vs ZnPP group.

### HO-1 mediated iron accumulation and oxidative stress in liver

The mRNA and protein expression levels of HO-1 were significantly higher in the BDL group than in the Sham group ( $P < 0.01$ ). These levels were obviously lower in the ZnPP group and higher in the CoPP group than in the BDL group ( $P < 0.01$ ) (Figure 4A and B). Hepatic immunostaining showed that HO-1 was mainly expressed in the liver cells and partly in the mesenchymal cells and Kupffer cells. Localization of HO-1 occurred mainly around the centrilobular veins (Figure 5A-F). The values of HO-1 expression were consistent with the above data (Figure 5G).

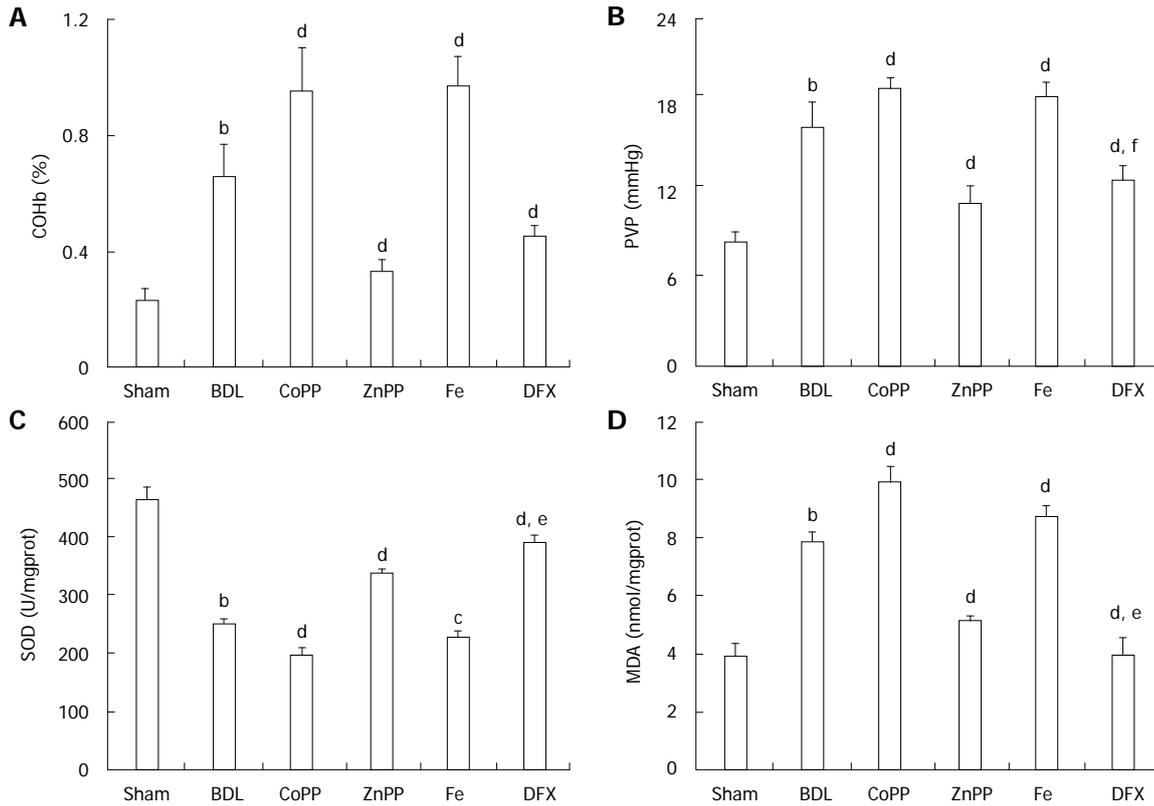

The serum levels of iron in the BDL group were significantly higher than in the Sham group ( $P < 0.01$ ). These levels were greatly lower in the ZnPP group than in the BDL group ( $P < 0.01$ ) (Figure 6G). The change in liver iron content was in accordance with serum iron levels (Figure 6H).

The mRNA and plasma levels of hepcidin were signi-

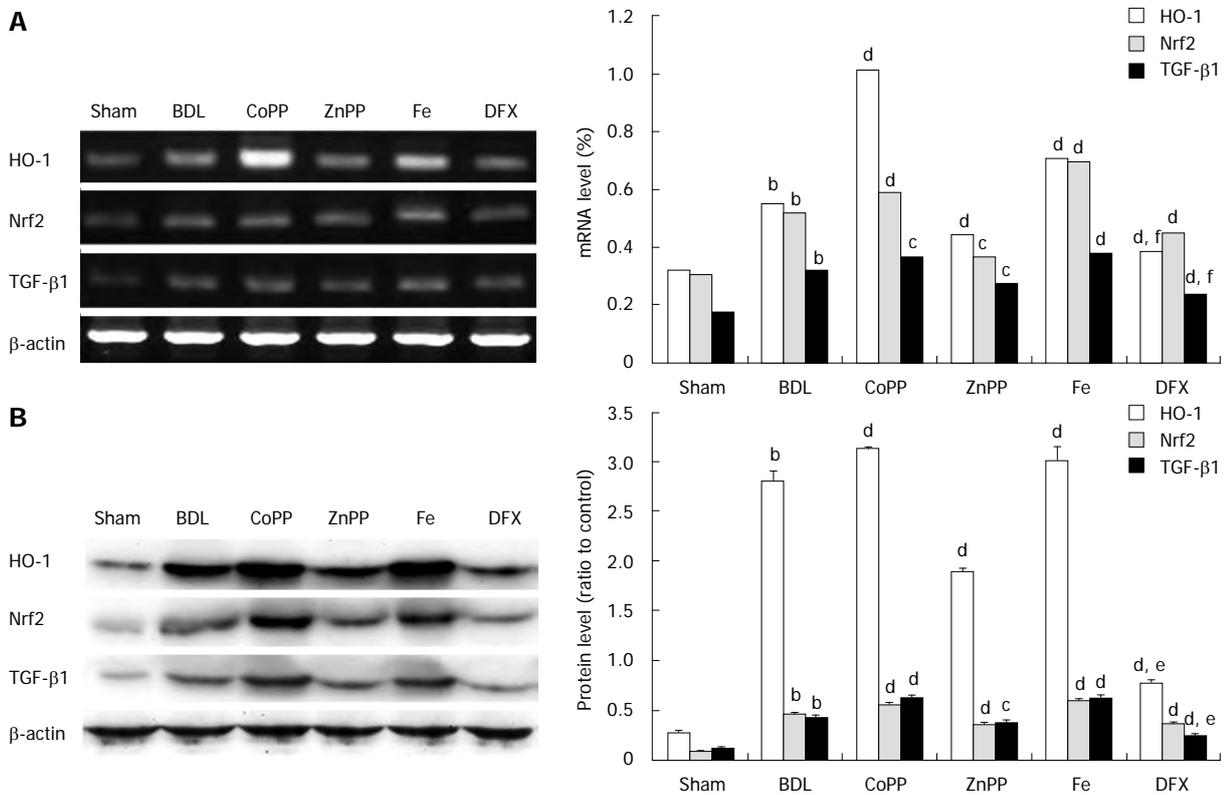

ficantly lower in the BDL group than in the Sham group ( $P < 0.01$ ). These levels were higher in the ZnPP group and lower in the CoPP group compared with the BDL group, and they were higher in the DFX group than in the ZnPP group (Figure 4C and 6I).

We used Prussian blue staining to localize iron accumulation in liver tissue and found that iron obviously accumulated in the BDL and CoPP groups. Iron was strongly stained mainly in Kupffer cells in these groups (Figure 6B and C). However, iron staining was rarely found in the Sham and ZnPP groups (Figure 6A and D). These results indicate that inhibiting HO-1 expression could reduce iron production, resulting in decreased iron accumulation in the liver. In contrast, enhanced HO-1 expression led to increased hepatic accumulation of iron.

Levels of SOD were obviously lower in the BDL group than in the Sham group ( $P < 0.01$ ), and they were significantly higher in the ZnPP group and lower in the CoPP group than in the BDL group ( $P < 0.01$ ) (Figure 3C). The MDA change tendency was opposite that of

**Figure 3** The levels of carboxyhemoglobin, portal vein pressure malonaldehyde and superoxide dismutase. A, B: The levels of carboxyhemoglobin (COHb) were accordance with heme oxygenase-1 expression, and portal vein pressure (PVP) levels were measured; C, D: The levels of superoxide dismutase (SOD) and malonaldehyde (MDA) was detected. Values are expressed as mean  $\pm$  SE ( $n = 6$ ). <sup>b</sup> $P < 0.01$  vs Sham group; <sup>c</sup> $P < 0.01$  vs BDL group; <sup>d</sup> $P < 0.05$ , <sup>e</sup> $P < 0.01$  vs zinc protoporphyrin (ZnPP) group. BDL: Bile duct ligation; CoPP: Cobalt protoporphyrin; DFX: Deferoxamine.

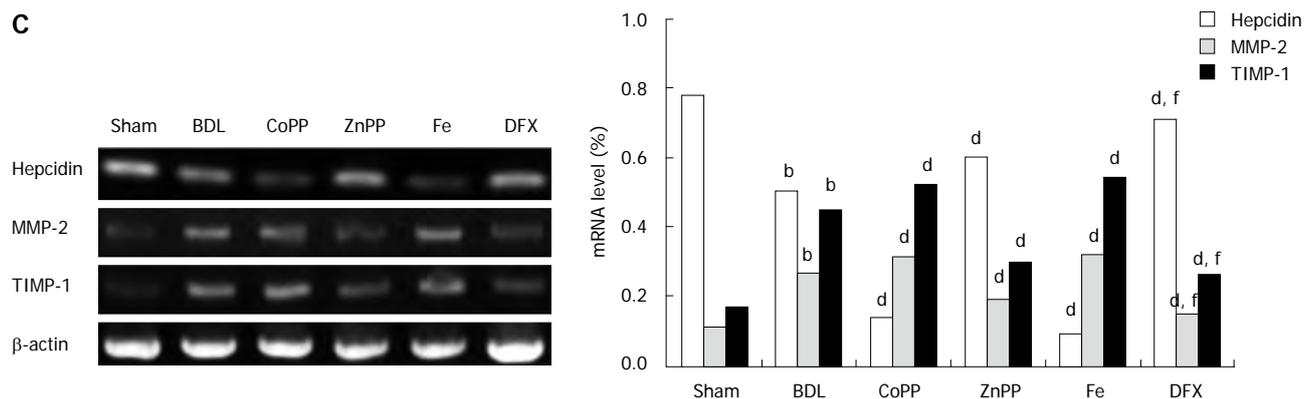

Figure 4 The heme oxygenase-1, transforming growth factor- $\beta$ 1, nuclear factor-E2-related factor 2, hepcidin, matrix metalloproteinase-2 and tissue inhibitor of metalloproteinase-1 expression were detected by Western blot and reverse transcription-polymerase chain reaction. A, B: The mRNA and protein levels of heme oxygenase-1 (HO-1), transforming growth factor- $\beta$ 1 (TGF- $\beta$ 1) and nuclear factor-E2-related factor 2 (Nrf2); C: The mRNA levels of hepcidin, matrix metalloproteinase-2 (MMP-2) and tissue inhibitor of metalloproteinase-1 (TIMP-1). Values are expressed as mean  $\pm$  SE. <sup>b</sup> $P < 0.01$  vs Sham group; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs bile duct ligation (BDL) group; <sup>e</sup> $P < 0.05$ , <sup>f</sup> $P < 0.01$  vs zinc protoporphyrin (ZnPP) group. CoPP: Cobalt protoporphyrin; DFX: Deferoxamine.

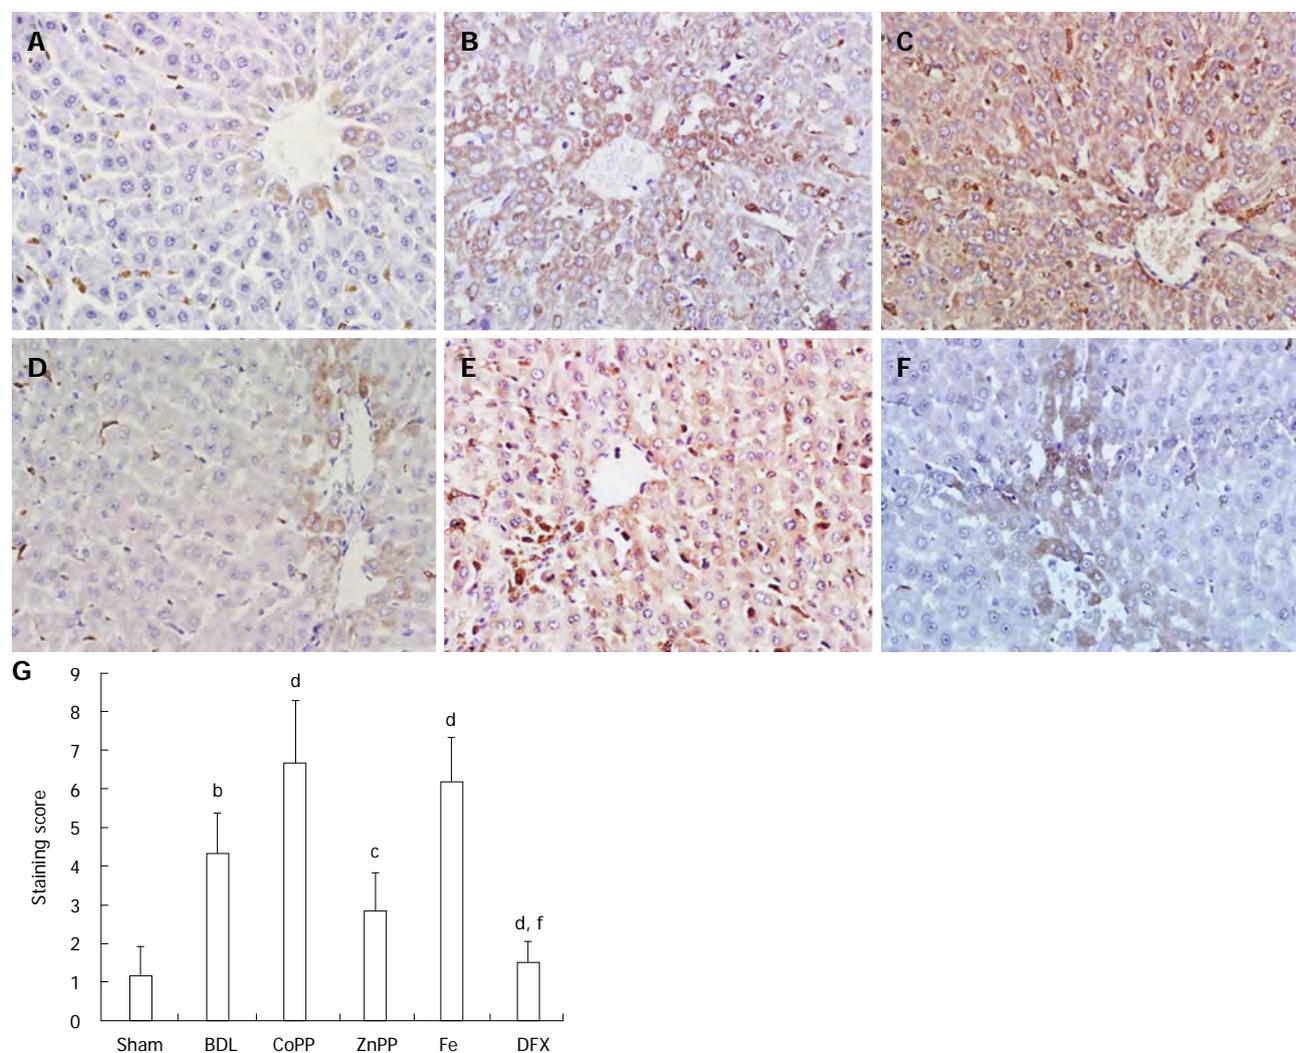

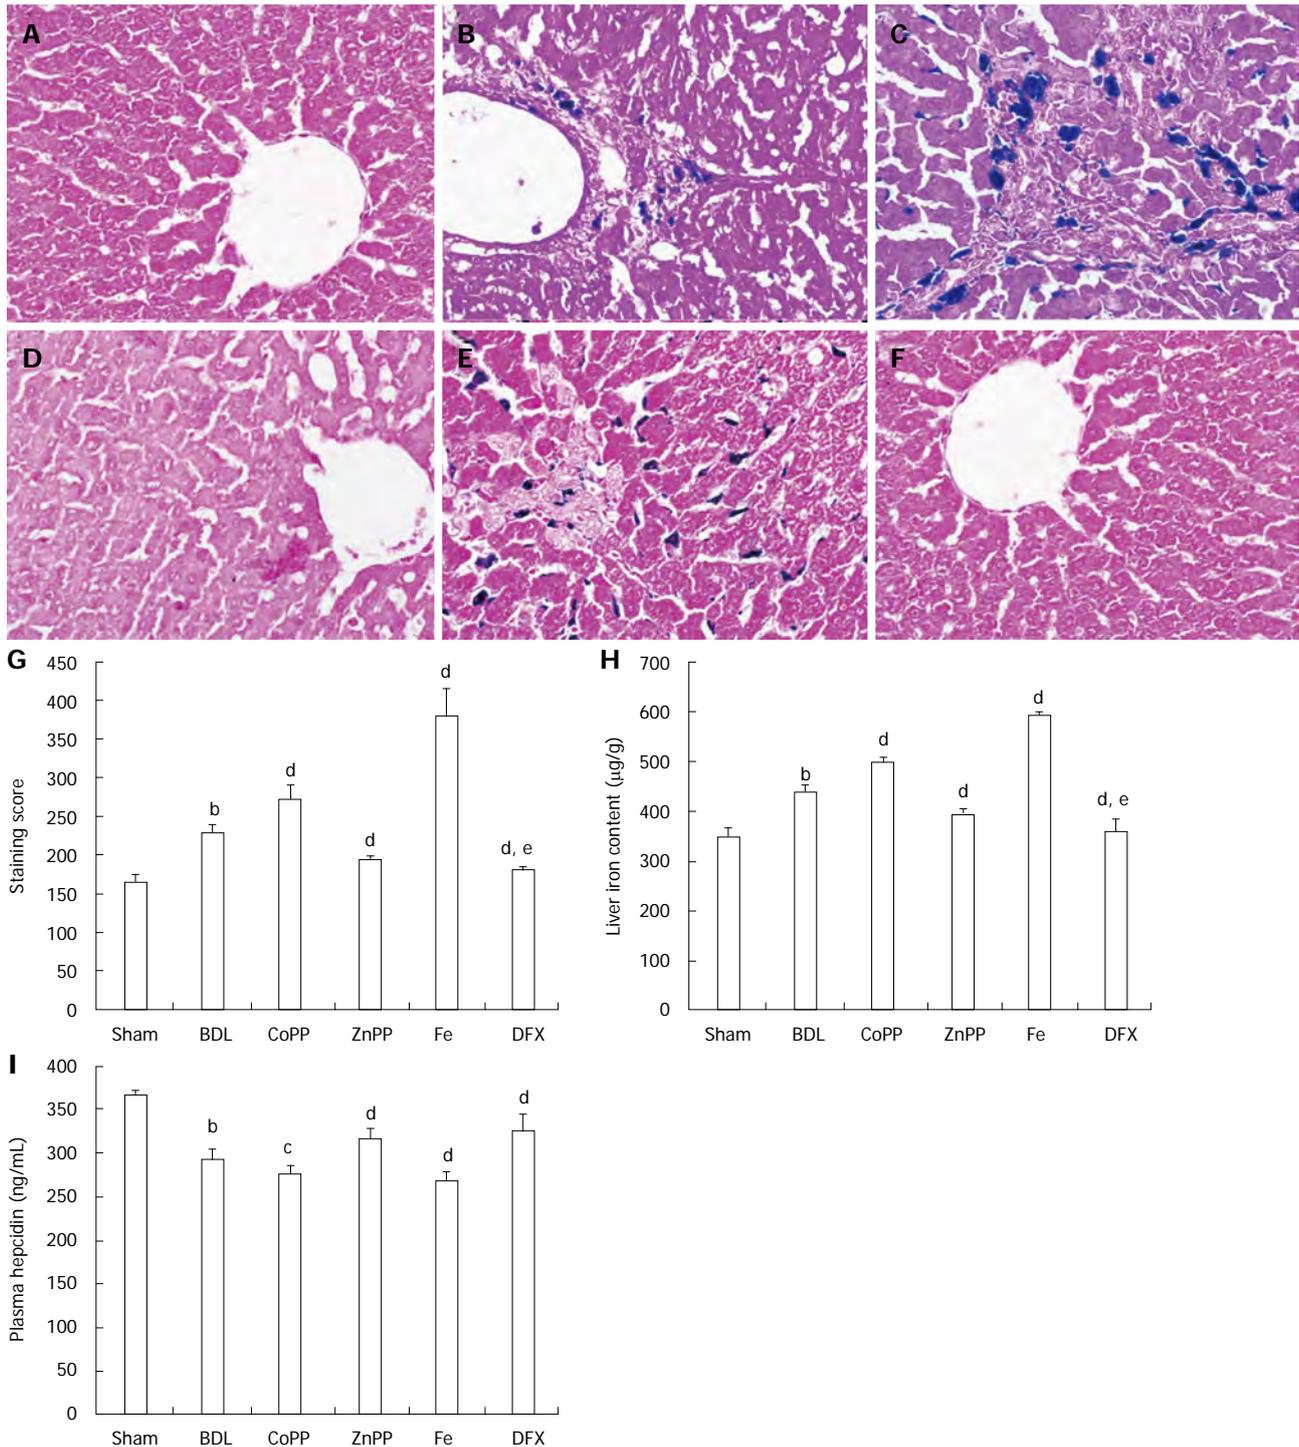

Figure 5 Liver sections were stained with heme oxygenase-1 antibody. A: Heme oxygenase-1 (HO-1) expression was less around the central veins in the Sham group; B, C, E: Much more HO-1 expression was found around the central veins in the bile duct ligation (BDL) group, cobalt protoporphyrin (CoPP) group and Fe group; D, F: Less staining was observed in the zinc protoporphyrin (ZnPP) group and deferoxamine (DFX) group; H: Immunohistochemical staining scores (magnification  $\times 400$ ). Values are expressed as mean  $\pm$  SE ( $n = 6$ ). <sup>b</sup> $P < 0.01$  vs Sham group; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs BDL group; <sup>f</sup> $P < 0.01$  vs ZnPP group.

**Figure 6** Perl's Prussian blue staining, levels of hepcidin, serum and liver iron. A: No iron accumulated in the Sham group; B: A small amount of iron mainly accumulated on Kupffer cells in the bile duct ligation (BDL) group; C: Much more iron accumulation was found in interlobular and macrophagocytes in the cobalt protoporphyrin (CoPP) group; D, F: Almost no iron accumulation was detected in the zinc protoporphyrin (ZnPP) group and deferoxamine (DFX) group; E: Massive iron accumulation was observed in the Fe group; G, H: There were no differences in the hepatic and serum iron content of these six groups; I: Plasma hepcidin also was measured by enzyme-linked immunosorbent assay (magnification  $\times 400$ ). Values are expressed as mean  $\pm$  SE ( $n = 6$ ). <sup>b</sup> $P < 0.01$  vs Sham group; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs BDL group; <sup>e</sup> $P < 0.05$  vs ZnPP group.

SOD (Figure 3D). In the BDL model, inhibiting HO-1 expression reduced oxidative stress.

#### Iron induced oxidative stress and *Nrf2* expression

Both the serum iron and liver iron content were higher in the Fe group but lower in the DFX group compared

with the BDL group (Figure 6G and H). Prussian blue staining showed more iron accumulation in the Fe group and less in the DFX group (Figure 6E and F). The ZnPP group showed low iron levels (Figure 6D and F-H). The levels of plasma hepcidin were obviously lower in the Fe group but higher in the DFX group compared with the

BDL group (Figure 6I). The expression of HO-1 was significantly higher in the Fe group but was lower in the DFX group compared with the BDL group ( $P < 0.01$ ). It was also lower in the DFX group than in the ZnPP group (Figure 4A and B).

The mRNA and protein expression levels of Nrf2 were enhanced in the BDL group compared with the Sham group. Additionally, these levels were significantly higher in the CoPP and Fe groups than in the BDL group, and they were lower in the ZnPP and DFX groups ( $P < 0.01$ ) (Figure 4A and B). We found the levels of SOD in the Fe group to be slightly lower than in the BDL group ( $P < 0.05$ ); however, they were much higher than in the DFX group ( $P < 0.01$ ) (Figure 3C). The levels of MDA were significantly increased in the Fe group but were reduced in the DFX group compared with the BDL group ( $P < 0.01$ ) (Figure 3D). The levels of SOD were much higher, and MDA was lower in the DFX group compared with the ZnPP group ( $P < 0.01$ ) (Figure 6C and D). These data indicate that iron accumulation in the liver increased the oxidative stress reaction and caused further damage to the liver.

Hematoxylin and eosin staining showed more fibrous hyperplasia in the Fe group and less in the DFX group compared with the BDL group (Figure 1E and F). The content of HYP was significantly higher in the Fe group than in the Sham group ( $P < 0.01$ ), and it was lower in the DFX group than in the BDL group ( $P < 0.01$ ) (Figure 2H). Compared with the BDL group, collagen I was increased in the Fe group and decreased in the DFX group (Figure 2E-G). The mRNA and protein expression levels of  $\alpha$ -smooth muscle actin and TGF- $\beta$ 1 were significantly enhanced in the Fe group and decreased in the DFX group compared with the BDL group (Figure 4A and B). The levels of MMP-2 and TIMP-1 mRNA were much higher in the Fe group and were lower in the DFX group compared with the BDL group ( $P < 0.01$ ). Compared with the ZnPP group, TGF- $\beta$ 1 expression and ECM were lower in the DFX group (Figure 4C).

### Correlation between oxidative stress and liver fibrosis

Correlation analysis revealed that both SOD and MDA were significantly correlated with HYP levels ( $R = -0.912, 0.887$ , respectively,  $P < 0.01$ ). These data also showed that oxidative stress could result in ECM deposition in the liver and could further aggravate liver fibrosis.

## DISCUSSION

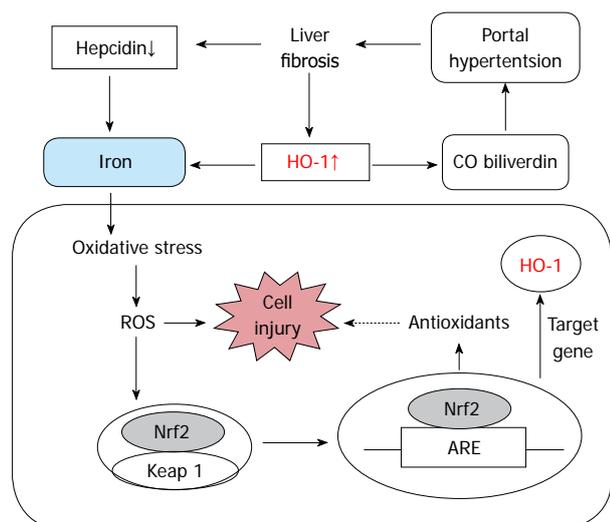

Many chronic liver diseases progress to hepatic fibrosis<sup>[30]</sup>. Iron overload in the liver increased the risk of developing fibrosis, as well as subsequent morbidity and mortality<sup>[31]</sup>. HO-1 catalyzes heme into iron, and it plays an important role in iron homeostasis. A previous study showed that HO-1 was associated with hepatocellular damage and had multiple mechanisms to influence liver fibrosis progression. In this study, we aimed to investigate how iron and CO, the product affected by HO-1 activity, affected hepatic fibrosis and PVP. We found that

lower HO-1 expression could reduce iron accumulation and PVP and improve fibrosis.

In several chronic liver diseases, HO-1 plays a protective effect in the liver against oxidative stress-dependent damage<sup>[32-34]</sup>. However, its protective effects in inflammation and fibrosis have been disputed. Some studies have shown that HO-1 over-expression increases liver injury in rats under conditions of experimental chronic cholestasis<sup>[19]</sup>. Low HO-1 induction was shown to be cytoprotective, and high levels of HO-1 could result in the accumulation of free divalent iron, thus increasing oxidative injury in fibroblast cell cultures<sup>[35]</sup>. We found that lower HO-1 expression could benefit end-stage liver cirrhosis by reducing iron accumulation, which is accordance with the findings of the above studies. Surprisingly, induction of HO-1 interfered with chronic inflammation and prevented progression of liver fibrosis in Mdr2-knockout mice, and it further might delay progression to hepatocellular carcinoma<sup>[33]</sup>. Our previous study indicated that induction of HO-1 could ameliorate immune liver fibrosis<sup>[36]</sup>. The reason why the above studies are different from this study could be that HO-1 plays a diverse role in different stages during the progression of liver fibrosis. In early stages of liver fibrosis, inducing HO-1 could have a protective effect, but it could increase liver injury in end stages *via* liver hypertension. Moreover, the different animal models for inducing fibrosis could constitute another explanation of these results.

The majority of endogenous CO is catalyzed by inducible expression of HO-1. CO can modulate blood flow and maintain the integrity of the vessel wall<sup>[37]</sup>. COHb levels can be used to estimate HO activity in experimental animals. Interestingly, we observed that up-regulated COHb resulted from increased HO-1, which aggravated PVP in BDL rats. Moreover, lower levels of COHb can decrease the PVP found in the ZnPP and DFX treatment groups. HO/CO plays a role in the pathophysiology of portal hypertension, and CO can regulate the intrahepatic vascular resistance of cirrhotic rats<sup>[38]</sup>. Tarquini *et al*<sup>[39]</sup> indicated that the HO/CO system is activated in patients with liver cirrhosis, and CO contributes to the hyperdynamic circulatory syndrome. CO might improve intrahepatic microcirculation in early stage hepatic fibrosis, and excessive CO could be harmful, leading to an unbalanced nitric oxide/CO system in end-stage hepatic fibrosis. It therefore seems best to reduce PVP by decreasing CO.

Normally, HO-1 is only slightly expressed in hepatocytes and Kupffer cells. In hepatic cirrhosis, the expression of HO-1 is increased. Khan *et al*<sup>[20]</sup> reported that an increase in HO-1 expression is associated with iron accumulation. The study of Kartikasari *et al*<sup>[40]</sup> showed that iron is derived from intracellular heme degradation, and HO-1 activity contributes to increased levels of intracellular labile iron. Other research has shown that non-heme iron increases are associated with the induction of HO-1 in neurons, microglia and capillary endothelial cells, whereas HO-2 levels remain unchanged, implying that the non-heme iron increases might be the result

**Figure 7** Iron is involved in the heme oxygenase-1 cycle *via* the nuclear factor-E2-related factor 2/Keap1 pathway, and heme oxygenase-1 regulates portal pressure in liver cirrhosis. Low hepcidin and heme oxygenase-1 (HO-1) over-expression could mediate iron accumulation, which accelerates oxidative stress, leading to cell injury, and it also increases HO-1 expression through the nuclear factor-E2-related factor 2 (Nrf2)/Keap1 pathway. Nrf2 protects cells against oxidative stress, but this effect is limited, and Nrf2 contributes to induction of HO-1 expression, which can produce iron. HO-1 can increase carbon monoxide (CO) production, and an unbalanced CO/nitric oxide system could play a role in portal pressure. ROS: Reactive oxygen species. ARE: Antioxidant response element.

of HO-1-mediated heme degradation<sup>[41]</sup>. These results showed that HO-1 played a central role in maintaining iron homeostasis *in vivo*. In this study, we found that serum iron and liver iron contents all increased in the CoPP group, and inhibiting HO-1 activity with ZnPP reduced iron accumulation in the liver and further attenuated liver fibrosis in liver fibrosis induced by BDL.

Hepcidin is expressed mainly in the liver, and it functions as a negative regulator of iron absorption from the duodenum. It was also noted that hepcidin was abnormally low in alcoholic patients with associated iron overload<sup>[42]</sup>. Iron was accumulated in the liver and pancreas of hepcidin-deficient mice<sup>[43]</sup>. It also was found that serum pro-hepcidin concentrations were lowered in liver cirrhosis, which could be the result of impaired liver functioning<sup>[44]</sup>. Hepcidin is down-regulated during progressive cholestasis in biliary atresia<sup>[45-47]</sup>. Furthermore, Huang *et al.*<sup>[48]</sup> showed that iron loading down-regulates hepcidin by inhibiting both inflammatory and iron-sensing pathways and inhibiting transducers and activators of transcription 3 and SMAD4 signaling *in vivo*. These findings are consistent with the results of our experiment. Under physiological conditions, hepcidin expression is stimulated by iron overload and inflammation and is suppressed by anemia and tissue hypoxia<sup>[49,50]</sup>. However, levels of hepcidin were decreased in the iron accumulation group and were increased in the ZnPP and DFX groups in our study. The reason for this finding might have been the various signals affecting hepcidin production. Up-regulation of hepcidin by inhibiting HO-1 expression could be benefi-

cial for cholestasis in cirrhosis.

It is now commonly accepted that HO-1 plays an important role in the control of inflammation and oxidative stress<sup>[51]</sup>. HO-1 protected primary human hepatocytes from ethanol-derived oxidative stress *via* the MAPK/Nrf2 pathway<sup>[52]</sup>. Surprisingly, however, in this study, we found that inducing HO-1 expression increased MDA and decreased SOD. Further, these results indicate that HO-1 could not reduce the oxidative stress reaction. Other studies have shown the pro-oxidant nature of the released cellular low-molecular-mass iron and the antioxidant effect of the released bilirubin<sup>[53]</sup>. In this study, we demonstrated that the pro-oxidant activities of iron accumulation were much stronger than the antioxidant effects of bilirubin.

Iron primarily accumulates in the reticuloendothelial cells. Previously, it was shown that increased deposition of iron in the liver often triggered oxidative stress and inflammation and induced liver cell damage<sup>[54]</sup>. It can participate in Fenton and Haber-Weiss chemistry, and excessive redox-active iron might lead to oxidative stress, with damage to membranes, proteins and DNA<sup>[55]</sup>. It was also shown that increased deposition of iron in the liver induced liver cell damage and cirrhosis by triggering oxidative stress and inflammation<sup>[56]</sup>. In fact, signs of iron-catalyzed lipid peroxidation and oxidative stress have been found by many investigators during chronic iron overload in rodents<sup>[57,58]</sup>. In this study, iron intoxication dramatically enhanced MDA adducts, decreased antioxidant enzyme SOD and aggravated liver injury in the BDL, CoPP and Fe groups. Our results revealed that iron accumulation exacerbated the oxidative stress reaction, leading to the aggravation of liver cirrhosis.

Previous reports have shown that elevated hepatic iron can activate Nrf2 in 3,5,5-trimethyl-hexanoyl-ferrocene-treated mouse models<sup>[59]</sup>. In our study, Nrf2 was up-regulated in the BDL, CoPP and Fe groups, in which iron accumulation in the liver was found. Nuclear translocation of activated Nrf2 is an important upstream contributor to the induction of HO-1 expression<sup>[60]</sup>. Up-regulation of Nrf2 increased HO-1 gene transcription in the CoPP and Fe groups. The pathway of iron-dependent HO-1 induction involves Nrf2/Keap. Nrf2 also plays a key role in the protection of cells against oxidative stress<sup>[61]</sup>. However, in our study, Nrf2's protective effect was limited, and HO-1, which is its target gene, increased iron production, resulted in oxidative stress.

Previous studies have demonstrated that oxidative stress significantly contributes to hepatic fibrogenesis from various liver injuries<sup>[62]</sup>. Reactive oxygen species (ROS) can stimulate the production of type I collagen and could act as intracellular signaling mediators of TGF- $\beta$ <sup>[63,64]</sup>. Our study showed that preventing oxidative stress by inhibiting HO-1 expression could attenuate liver fibrosis through regulation of the TGF- $\beta$ 1 pathway and reducing collagen deposition.

In conclusion, HO-1 played a pivotal role in iron accumulation and portal pressure in the livers in our study

(Figure 7). In the clinic, many end-stage cirrhosis patients with upper gastrointestinal bleeding treated with multiple massive transfusions run the risk of iron overload and further liver injury. Today, iron chelation therapy is often utilized to remove excess stored iron in some diseases<sup>[65,66]</sup>. In our study, iron accumulation induced hepatic fibrogenesis, indicating that cirrhotic patients with massive stored RBC transfusions would benefit from iron removal therapy. Our research provided a new way to reduce liver iron and portal pressure by inhibiting HO-1 expression. However, we must find a proper model for the simulation of upper gastrointestinal bleeding and transfusion. In clinical experiments, we will attempt to include cirrhotic patients with bleeding complications, who would eventually receive transfusions, to investigate the effects of iron transfusions on liver cirrhosis.

Removing iron and reducing portal pressure by inhibition of HO-1 improves liver fibrosis in bile duct-ligated rats. In addition, iron is also closely related to another complication of cirrhosis: hepatocellular carcinoma<sup>[67]</sup>. Regulation of iron homeostasis, by interfering with HO-1, could effectively treat hepatic cirrhosis and also prevent hepatocellular carcinoma.

## COMMENTS

### Background

Iron overload in the liver is a very common phenomenon in many chronic liver diseases. Heme oxygenase-1 (HO-1) and its by-products, iron and carbon monoxide (CO), play crucial roles in hepatic fibrosis. The underlying molecular mechanisms of HO-1, regarding iron deposition and portal vein pressure (PVP) in hepatic fibrosis, remain unknown.

### Research frontiers

HO-1 and degradation products are important to cytoprotection in many types of liver injury, but protection can be restricted to a narrow threshold. Iron overload often triggers oxidative stress and inflammation and induces liver cell damage, and the CO/nitric oxide system could be harmful to portal pressure. Iron can activate nuclear factor-E2-related factor 2 (Nrf2) and increase HO-1 expression. Inhibiting HO-1 activity is necessary for reducing iron and PVP.

### Innovations and breakthroughs

In this study, by inhibiting HO-1 expression by zinc protoporphyrin in rat liver fibrosis induced by bile duct ligation (BDL), the author aimed to affect the HO-1/CO system by iron deposition and portal pressure. Reducing hepatic iron deposition and CO levels by inhibiting HO-1 activity through the Nrf2/Keap pathway could be helpful in improving hepatic fibrosis and maintaining PVP.

### Applications

Removing iron and reducing CO by inhibiting HO-1 activity provides a new strategy for treating liver fibrosis, and further, it could help prevent liver carcinoma.

### Terminology

HO-1 is a primary rate-limiting enzyme in heme catabolism. It catalyzes the oxidative degradation of heme to free iron, CO, and biliverdin. Nrf2 is an important upstream contributor to the induction of HO-1 expression, and it has a protective effect on cells against oxidative stress. Hepcidin is expressed mainly in the liver, and it functions as a negative regulator of iron absorption from the duodenum.

## Peer review

This study analyzed the role of HO-1 inhibition in rat liver fibrosis using an experimental model of BDL. The results are interesting, and they suggest that regulation of iron homeostasis and CO production could effectively treat liver cirrhosis and PVP and even prevent hepatocellular carcinoma.

### Abstract

**AIM:** To evaluate the long-term natural history of the gastroduodenal lesions secondary to extrahepatic embolization with Yttrium 90 ( $^{90}\text{Y}$ ) spheres.

**METHODS:** From September 2003 to January 2012, 379 procedures of liver radioembolization (RE) using resin microspheres loaded with  $^{90}\text{Y}$  were performed in

our center. We have retrospectively compiled the data from 379 RE procedures performed in our center. We report a comprehensive clinical, analytical, endoscopic and histologic long-term follow-up of a series of patients who developed gastroduodenal lesions after the treatment.

**RESULTS:** Six patients (1.5%) developed gastrointestinal symptoms and had gastrointestinal lesions as shown by upper endoscopy in the next 12 wk after RE. The mean time between RE and the appearance of symptoms was 5 wk. Only one patient required endoscopic and surgical treatment. The incidence of gastrointestinal ulcerations was 3.75% (3/80) when only planar images were used for the pre-treatment evaluation. It was reduced to 1% (3/299) when single-photon emission computed tomography (SPECT) images were also performed. The symptoms that lasted for a longer time were nausea and vomiting, until 25 mo after the treatment.

**CONCLUSION:** All patients were free from severe symptoms at the end of follow-up. The routine use of SPECT has decreased the incidence of gastrointestinal lesions due to unintended deployment of  $^{90}\text{Y}$  particles.

## INTRODUCTION

Radioembolization (RE) with microspheres embedded with Yttrium 90 ( $^{90}\text{Y}$ ) is a therapeutic option for primary and secondary liver tumors. Prior to treatment, an angiography is performed to identify the hepatic vasculature and to mimic the actual procedure by injecting  $^{99}\text{Tc}$ -radiolabeled macroaggregated albumin ( $^{99}\text{Tcm}$ -MAA)<sup>[1]</sup>. During this procedure, guidelines recommend the embolization of the gastroduodenal artery, right gastric, and other extrahepatic arteries to isolate the hepatic circulation<sup>[2]</sup>. Unintended extrahepatic deployment of particles is a rare but well known complication of this procedure, that may result in cholecystitis<sup>[3]</sup>, pancreatitis<sup>[4]</sup>, radiation pneumonitis<sup>[5]</sup> and gastrointestinal ulcerations<sup>[6,7]</sup>. Radiation injury is likely to be the main pathogenical factor of these lesions<sup>[6]</sup>. However, although the small diameter of the particles (20–30  $\mu\text{m}$ ) does not induce a significant macroembolic effect, it has been shown in animal models that microspheres may sometimes aggregate and occlude small size vessels<sup>[8]</sup>.

Radiation-induced gastrointestinal ulcerations may have a significant negative impact in quality of life due to decreased oral intake, pain or anemia, and the even need to perform gastric surgery has been described<sup>[9]</sup>. However, most case reports or series only describe the appearance and immediate consequences and very little is known about the long-term outcome of this complication. We describe for the first time a case series of six patients with gastrointestinal lesions secondary to RE and their clinical, endoscopic and histologic long-term follow-up.

## MATERIALS AND METHODS

From September 2003 to January 2012, 379 procedures of liver RE using resin microspheres loaded with  $^{90}\text{Y}$  (SIR-Spheres, Sirtex Medical, Sidney, Australia) were performed in our center. Six patients (1.5%) developed gastrointestinal symptoms and had an upper endoscopy performed in the next 12 wk after the procedure that showed gastrointestinal lesions. Findings in the initial and the subsequent gastroduodenoscopies and their histopathologic studies were compiled retrospectively. Although the follow-up was not structured, at least two endoscopies were available from all but one patient. The maximum endoscopic follow-up time was 78 mo. We have gathered from the medical reports and thoroughly analyzed all clinical, analytical, endoscopic and histopathological findings.

## RESULTS

### *Patient characteristics*

The characteristics of the six patients included in the study are shown in Table 1. Mean age was 53.1 years and a range of primary tumors were treated including cholangiocarcinoma and liver metastases from different primary tumors. None of the patients had any significant gastrointestinal disease before RE and only two patients were

receiving concomitant anticancer treatments, namely the combination of 5-fluorouracil, leucovorin and oxaliplatin (FOLFOX, patient 1), and the combination of gemcitabine and oxaliplatin (GEMOX, patient 4).

### *RE procedure*

From the day of RE and for the following 2 mo, all patients received pantoprazole (40 mg daily) and a tapered regimen of corticosteroids.

A selective embolization of any extrahepatic vessel that could be included in the treated volume was performed prior to microsphere injection. Regarding variant anatomies, patient 2 presented a complete occlusion of the celiac axis and reversed blood flow of the pancreatoduodenal artery and in patient 4 the right hepatic artery originated from the superior mesenteric artery. The mean activity of  $^{90}\text{Y}$  administered was 1.02 GBq. In 4 patients (66%) the spheres were infused in the common or proper hepatic artery. In one case a bilobar treatment was performed by injecting the microspheres into the left and right branches of the hepatic artery (patient 4). In this patient only half the prescribed dose could be injected into the left hepatic artery due to spasm, while the entire prescribed dose was injected into the right hepatic artery uneventfully. This was the only case in which premature occlusion of the vessel occurred. In the remaining case the site of injection was the left hepatic artery (lobar infusion, patient 2).

$^{99}\text{Tcm}$ -MAA scans obtained prior to the procedures consisted in planar scintigraphic images in 3 patients and planar plus single-photon emission computed tomography (SPECT) images in the 3 other patients. When considered relative to the number of RE procedures, the incidence of gastrointestinal ulcerations was 3.75% (3 out of 80 patients) in the early period when planar images were used, and only 1% (3 out of 299 patients) in the late period when SPECT was also performed. We have retrospectively reviewed the  $^{99}\text{Tcm}$ -MAA scans of these 6 patients and no activity was observed in the gastrointestinal area prior to RE.

### *Endoscopic and histological findings*

Patients had their first upper endoscopy performed 1 to 12 wk after RE (Table 2) but none of them required an urgent procedure. At diagnosis, all of them showed ulcers and erosions in the stomach and/or duodenum (Figure 1). Gastrointestinal lesions were found only in the stomach in 3 cases, while the duodenum and the pyloric channel were also affected in 1 and 2 patients, respectively. Mucositis (gastritis or duodenitis) was present in 5 patients (83%) and a friable mucosa was described in 2 patients (33%). The mean endoscopic follow-up was 29.6 mo and the end of follow-up was usually due to clinical improvement (5 patients, 83%). One patient (case 6) died 2.5 mo after the procedure due to tumor progression. No patient showed neoangiogenesis, scars or antral deformities at diagnosis but these findings were lately seen in 4 patients (67%) after a mean period of 7.5 mo.

Table 1 Patient and treatment characteristics

| Patient | Age (yr) | Primary tumor      | Concomitant treatment | Gastroduodenal artery embolization | Site of injection             | Gastrointestinal activity on <sup>99m</sup> Tc-MAA scan | Dose administrated | Pain during infusion |
|---------|----------|--------------------|-----------------------|------------------------------------|-------------------------------|---|--------------------|----------------------|
| 1       | 60       | Colorectal         | FOLFOX                | Yes                                | Common hepatic artery         | No  | 75%                | Yes                  |
| 2       | 39       | Pancreatic NET     | No                    | No                                 | Left hepatic artery           | No  | 100%               | No                   |

<sup>1</sup>A gastroenteroanastomosis was later performed (25 mo after the diagnosis of gastrointestinal ulcers). RE: Radioembolization; CTCAE: Common Terminology Criteria for Adverse Events.

Microspheres were detected in all the biopsy specimens, mainly located in the vessels of the *lamina propria*. Granulation tissue was frequently present next to the ulcers, along with a variable grade of lymphoplasmocytic and eosinophilic inflammatory infiltrate. In some samples, focal atypia (patient 1) or anaplasia (patient 3) were present. None of the samples from the gastric mucosa showed bacilli suggestive of *Helicobacter pylori* (*H. pylori*) infection and none of the patients had a previous documented *H. pylori* infection.

### Treatment

Only one patient (patient 3) required endoscopic treatment because of late anemia and duodenal stenosis. Thirteen mo after RE, argon plasma coagulation was successfully used to treat the antral and duodenal mucosa. He required this endoscopic treatment because of significant and progressive anemia (hemoglobin dropped from 13.7 g/dL at baseline to 8 g/dL prior to endoscopic treatment and the patient had already received transfusion of 6 units of packed red blood cells) and weight loss. Anemia resolved but his nutritional status worsened over the next mo due to a duodenal stenosis. Finally a gastroentero-

anastomosis to the first jejunal loop was performed 25 mo after the diagnosis of gastrointestinal ulcers with antropyloric deformity.

All patients referred abdominal pain as the initial symptom, mainly located in the epigastric region (Table 3). Other symptoms were nausea and vomiting (5 patients, 83%) and anorexia (3 patients, 50%). The mean time between RE and the appearance of symptoms was 5 wk (range 2 to 12 wk). Patients were treated with multiple combinations of proton pump inhibitors, Sucralfate, Almagate, Domperidone, Misoprostole, Pentoxifylline, Cinitapride and Metoclopramide. A slow but progressive improvement was seen in all but one of the patients described above (83%). The majority of these symptoms were mild and graded 1 or 2 in the Common Terminology Criteria for Adverse Events grading scale. Abdominal pain had a maximum grade of 1 or 2, which means a mild pain that only in some patients limited activities of daily living. Nausea and vomiting was graded with a maximum of 1 in all but one patient. This correlates with one or two episodes of emesis a day in the worst period with symptoms during the follow-up.

Table 3 Clinical follow-up and treatment

| Patient | Time from RE to symptoms (wk) | Clinical follow-up time (mo) | Symptoms (CTCAE v4.02 grading scale) |                     |          | Treatment  |                        |                   | Weight loss <sup>1</sup> (kg) | Hemoglobin <sup>2</sup> (g/dL) | Reason for end of endoscopic follow up |
|---------|-------------------------------|------------------------------|--------------------------------------|---------------------|----------|--|------------------------|-------------------|-------------------------------|--------------------------------|--|
|         |                               |                              | Pain                                 | Nausea and vomiting | Anorexia | Treatment used   | Time on treatment (mo) | Clinical response |                               |                                |  |
| 1       | 4                             | 6                            | Epigastric pain (1)                  | No                  | No       | Pantoprazole, domperidone and almagate                   | 4                      | Yes               | 6                             | -1.5                           | Improvement                            |

<sup>1</sup>Maximal loss of weight over 4 mo; <sup>2</sup>Maximal change in hemoglobin over 4 mo. CTCAE: Common Terminology Criteria for Adverse Events; RE: Radioembolization.

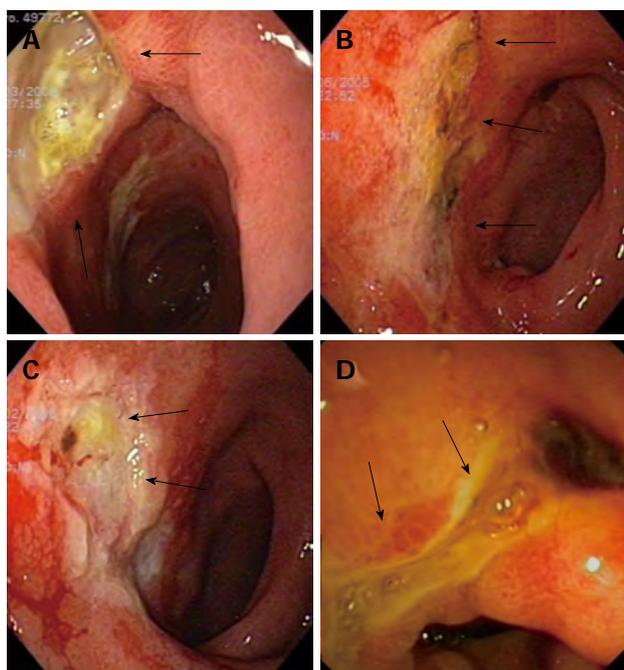

Figure 1 Figures of patient 5. A: A big and deep ulcer was seen in the pyloric channel and duodenal bulb at diagnosis (arrows); B: The same ulcer as in (A) in the same location seen 3 mo later, partially healed (arrows); C: Ulcer located in the duodenal bulb (arrows) with an irregular and friable mucosa after 11 mo; D: Endoscopic view of antral, pyloric and duodenal bulb deformity (arrows) seen with endoscopic ultrasound scope 78 mo after diagnosis.

## DISCUSSION

RE is an accepted therapeutic technique for advanced

primary and secondary liver tumors. It seems to be better tolerated than transarterial chemoembolization in terms of abdominal pain<sup>[10]</sup>, length of hospital stay<sup>[11]</sup> and post-embolization symptoms<sup>[12]</sup>. Main complications do not result from the microembolic effect of the spheres, even in patients with portal vein occlusion, but rather from an excessive irradiation of non-target tissues, including the liver<sup>[13]</sup>.

We describe in this case series an incidence of symptomatic gastroduodenal lesions after RE of 1.5% (6 out of 379 patients). Other authors have reported an incidence between 0% and 28%, with an average 4.8% calculated from the data previously published in 23 studies<sup>[7]</sup>. The two largest series of patients with secondary liver tumors from colorectal cancer or other malignancies reported rates of grade 3 gastrointestinal ulceration of 1% to 2%<sup>[14,15]</sup>. A higher incidence of 3.7% was found among 325 patients with hepatocellular carcinoma treated in 8 different European institutions<sup>[16]</sup>.

A decrease in the incidence of gastroduodenal lesions was observed when SPECT images were used for evaluation the RE procedures compared with planar images. These data suggest that SPECT imaging is an important tool to minimize the risk of gastrointestinal adverse events secondary to RE treatment. Our results arise from a retrospective single center study. If they are further confirmed by other series, a possible change in the current guidelines could be considered in favor of the use of SPECT imaging.

In most patients (4 out of 6 patients, 66%) the spheres were injected from the common or proper hepatic artery.

This site of injection leads to a greater chance of non-target embolization of the spheres in extrahepatic vessels. However, we have retrospectively reviewed all the angiographies and none of them showed collaterals or had extrahepatic deposits of MAA in the subsequent scans. In one of the patients treated by bilobar injection, a spasm in the left hepatic artery could have contributed to this complication.

In our case series, two patients were receiving combined concomitant treatment with the combination of oxaliplatin and 5-fluorouracil (FOLFOX) or gemcitabine (GEMOX). None of these drugs produce gastrointestinal lesions that could act as a confounding factor. In a literature search, we have found only one case of gastroduodenal ulceration with FOLFOX therapy and the patient was concurrently treated with Bevacizumab<sup>[17]</sup>. Saif *et al*<sup>[18]</sup> described a case of a patient treated with gemcitabine and warfarine who presented with gastrointestinal haemorrhage secondary to gastric and duodenal ulcers (with an international normalized ratio of 8.0). The lesions in our series are not likely to have been caused by these drugs, but we can not exclude a certain contribution.

The most common presenting symptoms in our series were abdominal pain, nausea/vomiting and anorexia. The intensity was usually mild and did not limit daily activities. Many drugs have been used, alone or in combination, demonstrating a slow but effective relieve of symptoms of this complication. However, more studies are needed to determine the best medical treatment. Only one patient required elective surgical treatment due to a late (> 1 year) duodenal stenosis. No urgent endoscopic or surgical treatment was performed. All but one patient are free of symptoms at the end of follow-up. All these data suggest that unintended gastrointestinal deployment of particles should be considered as a potential but transient cause of abdominal pain after the procedure. As shown in our series, the largest so far reported, a conservative approach must be considered as the primary treatment option. Nevertheless, the long-standing duration of symptoms (maximum 25 mo) in association with other factors (anemia, tumor progression and other comorbidities) certainly impacts the quality of life of affected patients. A common approach between oncologists, hepatologists and endoscopists would help improving the management and prognosis of the RE procedure and its complications.

## COMMENTS

### Background

Primary and secondary liver neoplasms are an important cause of morbidity and mortality worldwide. Radioembolization is a treatment indicated in those patients not eligible for curative resection or liver transplantation but still have their disease confined to the liver. It is considered a liver-directed therapy in which implanted radioactive microspheres are delivered into the arteries that feed the tumors. Secondary to this procedure some of the spheres can get into the arteries that feed some extrahepatic territories as the gastrointestinal tract.

### Research frontiers

As the unintended extrahepatic deployment of Yttrium 90 spheres is a rare complication of radioembolization little is known about its management and long-term prognosis. The authors have reviewed the clinical, endoscopic, analytical

and histologic long-term follow-up of patients treated with this liver-directed therapy. They also describe how the introduction of new image techniques has decreased the incidence of this complication.

### Innovations and breakthroughs

In this retrospective single-center study, the authors have found an incidence of 1.5% of gastrointestinal lesions secondary to the inadvertent deployment of radioactive microspheres. The incidence of this complication decreased from 3.75% to 1% when single photon emission computed tomography images were included in the routine planification of the treatment. The most frequent symptoms referred at diagnosis were abdominal pain and nausea and vomiting.

### Applications

The authors have shown the good long-term prognosis of this rare complication. It should be considered as a potential but transient cause of abdominal pain after the procedure. As it may be associated with long-standing symptoms the authors should take into account this complication to increase the patients' quality of life. It seems like the inclusion of new image techniques have decreased the incidence of this complication, but more research is needed to confirm these promising results.

### Terminology

Radioembolization: Treatment procedure in which radioactive microspheres loaded with Yttrium 90 are delivered into the hepatic artery.

### Peer review

This paper is well written and adds to understanding of outcomes of patients with ulcers following radioembolization.

### Abstract

**AIM:** To study gastric mucosal interleukine-8 (*IL-8*) mRNA expression, the cytotoxin-associated gene A (*cagA*) mutation, and serum pepsinogen (PG) I / II ratio related risk in Thai gastric cancer.

**METHODS:** There were consent 134 Thai non-cancer volunteers who underwent endoscopic narrow band imaging examination, and 86 Thais advance gastric cancer patients who underwent endoscopic mucosal biopsies and gastric surgery. Tissue samples were taken by endoscopy with 3 points biopsies. The serum PG I, II, and *Helicobacter pylori* (*H. pylori*) immunoglobulin G (IgG) antibody for *H. pylori* were tested by enzyme-linked immunosorbent assay technique. The histopathology description of gastric cancer and non-cancer with *H. pylori* detection was defined with modified Sydney Score System. Gastric mucosal tissue *H. pylori* DNA was extracted and genotyped for *cagA* mutation. Tissue *IL-8* and cyclooxygenase-2 (COX-2) mRNA expression were conducted by real time relative quantitation polymerase chain reaction. From 17 Japanese advance gastric cancer and 12 benign gastric tissue samples, all were tested for genetic expression with same methods as well as Thai gastric mucosal tissue samples. The multivariate analysis was used for the risk study. Correlation and standardized *t*-test were done for quantitative data, *P* value < 0.05 was considered as a statistically significant.

**RESULTS:** There is a high non *cagA* gene of 86.8 per cent in Thai gastric cancer although there are high yields of the East Asian type in the positive *cagA*. The *H. pylori* infection prevalence in this study is reported by combined histopathology and *H. pylori* IgG antibody test with 77.1% and 97.4% of sensitivity and specificity, respectively. The serum PG I / II ratio in gastric cancer is significantly lower than in the non-cancer group, *P* = 0.045. The serum PG I / II ratio of less

than 3.0 and *IL-8* mRNA expression  $\geq 100$  or  $\log_{10} \geq 2$  are significant cut off risk differences between Thai cancer and non-cancer,  $P = 0.03$  and  $P < 0.001$ , respectively. There is a significantly lower PGI/II ratio in Japanese than that in Thai gastric cancer,  $P = 0.026$ . Serum PG I / II ratio at cut off less than 3.0 and *IL-8* mRNA expression Raw RQ  $> 100$  or  $\log_{10} > 2$  are significantly difference between Thai cancer group when compared to non-cancer group,  $P = 0.013$  and  $P < 0.001$ , respectively. In the correlation study, low PG I / II ratio does not associate with chronic atrophic gastritis severity score in Thais non-cancer cases. However, there is a trend, but not significant convert correlation between *IL-8* mRNA expression level and low PG I / II ratio in Thai positive *H. pylori* infection. The high expression of *IL-8* gene demonstrates a poorer prognosis by stage and histology.

**CONCLUSION:** Predominant gastric mucosal *IL-8* mRNA expression level, *H. pylori* infection, and low PG I / II ratio are relative risks for Thai gastric cancer without correlation with *cagA* mutation.

**Key words:** Gastric cancer; *CagA* mutation; Interleukine-8 mRNA expression; *Helicobacter pylori*; Pepsinogen I / II ratio

**Core tip:** A high level of interleukine-8 (*IL-8*) mRNA expression was detected in more than eighty percent of Thai gastric cancer patients and nearly two fold in the normal Thai population. The majority of northern Thai gastric cancer patients who had negative *cagA* gene *Helicobacter pylori* infection even with or without its mutation, still have a high *IL-8* mRNA expression level. The pathogenesis of Thai gastric cancer may primarily involve another gate-way besides the bacterial factor. The results show that there is a predominantly cancer inflammation state regulated by *IL-8* mRNA expression level that can be detected in Thai gastric cancer patients.

Predominant mucosal *IL-8* mRNA expression in non-*cagA* Thais is risk for gastric cancer. *World J Gastroenterol* 2013; 19(19): 2941-2949 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i19/2941.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i19.2941>

## INTRODUCTION

Gastric cancer pathogenesis is a well-known worldwide multifactorial condition. The gastric cancer incidence rate in Thailand ranks ninth by 4.1:100000 in males and 2.1:100000 in females. Despite being a low incidence country, northern Thailand has a higher gastric cancer in-

cidence rate with 6.6:100000 in males that ranks fifth of overall cancer in the northern Thai region, and 4.5:100000 in females<sup>[1]</sup>. The author was interested in the carcinogenesis of gastric cancer in Thais, and why the incidence in Thais is much different from other East Asian countries. The interleukin-8 (*IL-8*) gene is one of the principal mediators for the inflammatory response gate way that was first reported in 1970s, and it is one of factors that are possible to affect gastric cancer carcinogenesis<sup>[2]</sup>. A recent case-controlled surveillance study in northern Thailand on cytokine gene *IL-1b-511* mutations in three East Asian populations showed no predominantly correlated specific causative factor responsible for differences among ethnics and histologic types<sup>[3,4]</sup>. Therefore, the author proposed the study on other gate-ways of cytokine expression in the human gastric mucosal cell.

Recently, an *in vitro* study showed the association of the mucosal tissue *IL-8* mRNA expression related to the *Helicobacter pylori* (*H. pylori*), positivity cytotoxin-associated gene A (*cagA*) gene. The East Asian genotype was reported in Japanese gastric cancer in about 85% of the cases. Many *in vitro* studies showed this toxicity gene related to gastric mucosal cell injury, inflammation, and oncogenic potential<sup>[5-7]</sup>. The *cagA*, East Asian genotype is commonly detected in chronic gastritis and gastric cancer of the Japanese<sup>[8,9]</sup>. There is reported data that a low serum pepsinogen (PG) I / II ratio of less than 3.0 with a PG I level of less than 70 ng/dL was considered as a high risk factor for Japanese gastric cancer<sup>[10,11]</sup>. There is no recent *in vivo* study reporting a correlation among these above factors, especially *IL-8* and cyclooxygenase-2 (COX-2) mRNA expression level in Thais.

The author hypothesized that gastric mucosal tissue *IL-8* mRNA expression may be different among ethnicities, and it may correlate to other reference pathogenesis factors. This study aimed to look for the risk and correlation of these factors in Thai gastric cancer. The level of *IL-8*, COX-2 mRNA expression, and *cagA* gene mutation distribution were also to be the first report in Thai gastric cancer.

## MATERIALS AND METHODS

Research methodology was considered and permitted by Thai and Japanese local ethical committees, the NRCT and Japan Society for the Promotion of Science code ID-NRCT 10726.

### Patient characteristics and volunteer selection

An experimental based cross-sectional study was conducted in the Gastrointestinal Surgery and Endoscopy Unit, Chiang Mai University Hospital from 2007 through 2010. Informed consents were obtained from 86 Thai gastric cancer patients who underwent narrow band imaging (NBI) endoscopy and gastric surgery during year 2007-2010, and 134 Thai non-cancer volunteers who underwent NBI endoscopic examination from 2006 to 2008. All gastric cancer patients in this study had locally

advanced gastric cancer, and underwent examinations by endoscopy before curative gastric resection. Seventeen advanced stage Japanese gastric cancer and 12 non-cancer surveillance patients were recruited. Peptic ulcer disease was excluded in this study. Gastric mucosal tissue samples were taken by endoscopy with three biopsy sites for pathology and bimolecular genetic tests before surgical treatment. In cancer cases, biopsy points were specified from non-necrotic areas of the tumor. The histopathology description of the tumor and histologic type were defined. For pathological examination in both groups, chronic gastritis and metaplasia with *H. pylori* detection were classified with a modified Sydney Score System.

### Serum PG I and II level, and *H. pylori* immunoglobulin G antibody test

A 5 cc sample of venous blood was collected from each study participant. The red blood cell and serum separation was done, and preserved at -20 °C. The serum PG I, II, and immunoglobulin G (IgG) antibody for *H. pylori* were tested by the standard enzyme-linked immunosorbent assay technique. The standard cut off value used was a PG I level of more than 70 ng/mL or PG I / II ratio more than 3.0 for no atrophy or positive Grade 1, PG I < 70 ng/mL and PG I / II ratio < 3.0 excluding severe atrophy for moderate atrophy or positive Grade 2, and PG I < 30 ng/mL and PG I / II ratio < 2.0 for severe atrophy or positive Grade 3, respectively<sup>[10,11]</sup>. All samples were tested twice for reliability confirmation (Toyobo, co, Ltd., Japan)

### Tissue *H. pylori* DNA extraction and *cagA* genotyping method

The tissue *H. pylori* DNA extracted from the lower antral position in the stomach was examined by the polymerase chain reaction method, and genotyped for *cagA* mutation in all samples by the author (Samples were also examined by double blinded test by Toyobo, co, Ltd). The *H. pylori* positive control of *cagA* positive strain number 11638 (Western), 26695 (Western), and F57 (East Asian) were provided by the collaborative institute. The bacterial tissue DNA and genotyping method with primers used in this study were conducted as recently described. The specific oligonucleotide primers forward (5'-AAAAGC-GACCTTGAAAATTC-3'; nucleotides 2299-2319), reverse-1 (5'-CTTCATTTTTTGAGCTTGTTGAGC-3'; nucleotides 2488-2463) and reverse-2 (5'-ATTAAT-GCGTATGTGGCTGTTAGTAGC-3'; nucleotides 3222-3195, were originally described by Azuma *et al.*<sup>[12]</sup>.

### Cell line culture and gastric mucosal total mRNA extraction with reverse transcriptase reaction for cDNA synthesis

The AGS cell line was grown before cell collection for mRNA extraction at a cell count of  $2 \times 10^6$ - $4 \times 10^6$ . They underwent a total mRNA extraction protocol. The technique followed was a reverse transcriptase reaction using a commercial high capacity RNA-to-cDNA kit (Applied Biosystems)<sup>[13]</sup>.

### Gastric mucosal *IL-8* and *COX-2* mRNA expression by relative quantification real time reverse transcription-polymerase chain reaction

We conducted the experiment from three positions of gastric mucosal biopsies in all Thai and Japanese study participants. All of gastric mucosal tissue samples were transformed to cDNA after total mRNA extraction. The analysis was substantially correctable by analysis both in raw relative quantitation (RQ) and log<sub>10</sub> value for adjusted normal distribution curve. All Human TaqMan probe primer express that was used in this study had 81-base pairs (bp) *IL-8* specific human primer assay ID number Hs99999034\_m1, 111- base pairs (bp) *COX-2* assay ID number Hs01573471\_m1, and 121- base pairs (bp) specific human glyceraldehyde-3-phosphate dehydrogenase (GAPDH) Hs99999905\_m1 those designed and supplied by Applied Biosystems, United States. The internal control was performed by GAPDH of a matched number template. The real-time relative quantitation value was measured by comparing to the base line value of AGS cell line subject control before making the analysis.

### Statistical analysis

A student *t*-test was used for quantitative data, *IL-8* and *COX-2* mRNA expression level, and PG level. The  $\chi^2$  test was used for qualitative data. The correlation study for pair factors was done in subgroup analysis for defined groups of ethnic, cancer and non-cancer populations. The multivariate analysis was used for risk study for both non-normal distribution and normal distribution curve data bases. STATA 11.0, United States and SPSS 16, United States were used for statistical analysis, and the *P* value of less than 0.05 was considered statistically significant.

## RESULTS

There were 86 cases of advanced gastric cancer and 45 (33.8%) normal control cases, 46 (34.6%) non-peptic disease benign lesions without recent history of any treatment, and 42 (31.6%) chronic gastritis cases among 134 non-cancer control cases who were included in the genetic expression experiment. Thai male and female cancer incidences are 60.5% (52/86) and 34.0% (39/86), respectively. Males are also the predominant gender in Japanese. Both nations have significantly high incidence of gastric cancer at age 40 years old or above.

The *H. pylori* infection prevalence is reported by combined histopathology, *H. pylori* IgG antibody level, and 23S rDNA results that have 77.1% and 97.4% of sensitivity and specificity, respectively. Among Thai cancer patients and non-cancer volunteers, *H. pylori* prevalence was 72.1% and 71.6%, respectively. Meanwhile, Thai gastric cancer cases had a *cagA* genotype demonstrated in only 7/62 (12.3%) in positive *H. pylori* infection cases by 23S rDNA that yields six cases of East Asian type and one case of Western type. In non-cancer volunteers, there were 62/98 (63.9%) of positive *cagA* and 34/98 (36.1%) of negative *cagA* genotyping in positive *H. pylori* infec-
