The enzyme PG results, showed a significantly lower PG I / II ratio with a mean of 3.3 ± 1.7 in gastric cancer patients than one in non-cancer volunteers, *P* = 0.045, and of other CAG, *P* = 0.002. There is a significantly lower PG I / II ratio in Japanese gastric cancer than in Thai gastric cancer, *P* = 0.026.

For *IL-8* and *COX-2* mRNA expression results, 86 Thai gastric cancers were tested successfully in comparison with 134 Thai non-cancer volunteers. The detection rates of *IL-8* mRNA expression were 77/86 (89.5%) in Thai gastric cancer and 102/134 (74.6%) in Thai non-cancer volunteers. Thai population characteristic data that was examined for *IL-8* mRNA expression is demonstrated in Table 1. Serum enzyme PG I, II level, and *H. pylori* infection status are demonstrated in the cancer population and non-cancer volunteers in Thais is demonstrated in Table 2. We found a remarkable number of Thai gastric cancers with a negative *cagA*; therefore, *IL-8* mRNA expression was examined and the cut-off point of expression value difference is demonstrated in Table 3. Serum PG I / II ratio at cut-off point of less than 3.0 and raw RQ ≥ 100 or log<sub>10</sub> ≥ 2 of *IL-8* mRNA expression level showed the significantly different between the Thai gastric cancer group and the non-cancer group, *P* = 0.045 and *P* < 0.001, respectively. In the multivariate analysis application, the four co-factors related to gastric cancer risk including *IL-8* mRNA expression in Thais are shown in Table 4.

At the same stage of advanced gastric cancer, the mean levels of *IL-8* mRNA expression in Thai cancer

**Figure 1** Mean interleukine-8 mRNA expression level measurement of relative quantitation by real-time reverse transcription-polymerase chain reaction study in gastric cancer comparing with non-cancer population both Japanese and Thais. In Japanese and Thais, gastric mucosal interleukine-8 (*IL-8*) mRNA expression in cancer is higher than in non-cancer with *P* = 0.05. The mean level of *IL-8* mRNA expressions in Thai cancer and Japanese cancer were 9615.65 (log<sub>10</sub> = 2.62) and 1509.11 (log<sub>10</sub> = 2.17), respectively, *P* = 0.014. The mean level of *IL-8* mRNA expression in non-cancer Thais is 2262 (log<sub>10</sub> = 1.49) while that in non-cancer Japanese is 10.79 (log<sub>10</sub> = 0.69), *P* < 0.001.

and Japanese cancer were 9615.65 (log<sub>10</sub> = 2.62) and 1509.11 (log<sub>10</sub> = 2.17), respectively, *P* = 0.014. For gastric cancer risk at cut-off *IL-8* expression level by log<sub>10</sub> greater than two in Thais and Japanese, odds ratio (OR) = 7.97 (95%CI: 3.75-16.97, *P* < 0.001) and OR = 4 (95%CI: 1.29-12.40), respectively. In the non-cancer group, we found that the *IL-8* mRNA expression level was lower than cancer population with a significant difference, *P* < 0.001. The total mean *IL-8* mRNA expression in non-cancer Thais was 2262 (log<sub>10</sub> = 1.49) while that in Japanese non-cancer was 10.79 (log<sub>10</sub> = 0.69), *P* < 0.001. In comparison within the same ethnic group, the mean levels of *IL-8* mRNA expression in Thai and Japanese cancer were higher than those in non-cancer, *P* = 0.05 as showed in Figure 1.

The *COX-2* mRNA expression did not indicate significant rising level with detection rate of 65% in Thai and Japanese gastric cancer. In comparison with *IL-8* mRNA expression, although the level of *COX-2* mRNA expression was slightly higher in gastric cancer than normal gastric mucosal tissue, there were much lower levels than those of *IL-8* mRNA expression.

In the correlation study, low PG I / II ratio was not associated with the CAG severity score in Thai non-cancer cases because of a few number of CAG in both Thai gastric cancer and non-cancer populations in this study. There was no significant difference for the *IL-8* mRNA expression level in cancer between positive and negative *H. pylori* infection. There was no direct correlation of *IL-8* mRNA expression level and serum *IgG* levels. In subgroup analysis, there was a significant difference of higher levels in groups of poorly differentiated histopathology in comparing both nations. For the diffuse histologic type, the *IL-8* mRNA expression level is about 1.5 times higher than that of intestinal histologic type with a statistically significant difference in Japanese.

**Table 2** Serum enzyme pepsinogen I, II level and *Helicobacter pylori* infection detection results in Thais *n* (%)

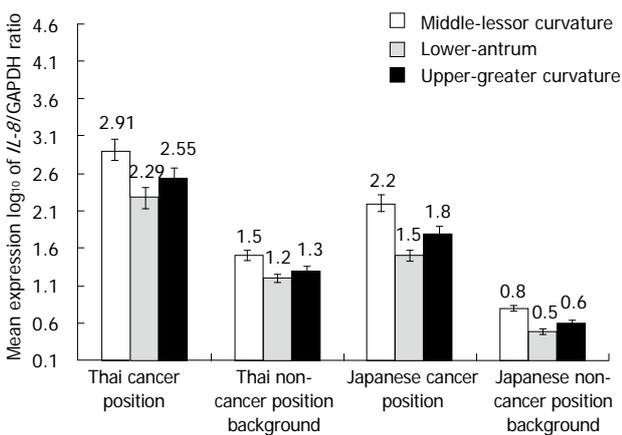

| Variable                             | Cancer<br>( <i>n</i> = 86) | Benign<br>( <i>n</i> = 134) | <i>P</i> value       |

**Table 5** Comparative means interleukine-8 mRNA expression level detection between Thai and Japanese Cancer populations divided by histopathology *n* (%)

| Histopathology  | Thai<br>( <i>n</i> = 77) | Japanese<br>( <i>n</i> = 17) | <i>P</i> value |
|-----------------|--------------------------|------------------------------|----------------|
| Diffuse type    | 55 (71.4)                | 4 (23.5)                     | 0.01           |
| mean ± SD       | 2.85 ± 1.10              | 2.55 ± 0.52                  | 0.95           |
| Intestinal type | 22 (28.6)                | 13 (76.5)                    |                |
| mean ± SD       | 2.52 ± 1.11              | 1.56 ± 1.06                  | 0.01           |

Statistical difference between groups (*P* = 0.04). *IL-8*: Interleukin-8.

and positive *cagA* by  $\log_{10} = 3.29 (\pm 1.68)$  in the Thai gastric cancer group. However, there were few numbers of Thai gastric cancers with positive *cagA*. In other subgroup analysis of 18 Thais who had high grade CAG, some level of *IL-8* mRNA expression in the 12 Japanese non-cancer patients appeared which an equivalently lower level.

Gastric cancer mucosal tissue *IL-8* mRNA expression in the cancer position had a significantly higher mean level than its level at the non-cancer background position in both Thai and Japanese shown in Figure 2. There was significantly different *IL-8* mRNA expression level between intestinal (favorable) and diffuse (unfavorable) histologic cell types. In Thai gastric cancer, the poorly differentiated gastric adenocarcinoma and signet ring cell were predominantly found in this study. The  $\log_{10}$  *IL-8* mRNA mean expressions in unfavorable cell type were 2.55 and 2.85 in Japanese and Thais, respectively, as shown in Table 5. There is a significantly higher level of *IL-8* mRNA expression in diffuse cell type than that in a differentiated histologic cell type, *P* = 0.04. The differentiated histologic cell type in Thais has higher expression level than that in Japanese with a statistically significant difference, *P* = 0.013. The RT-PCR results of gastric mucosal tissue and AGS

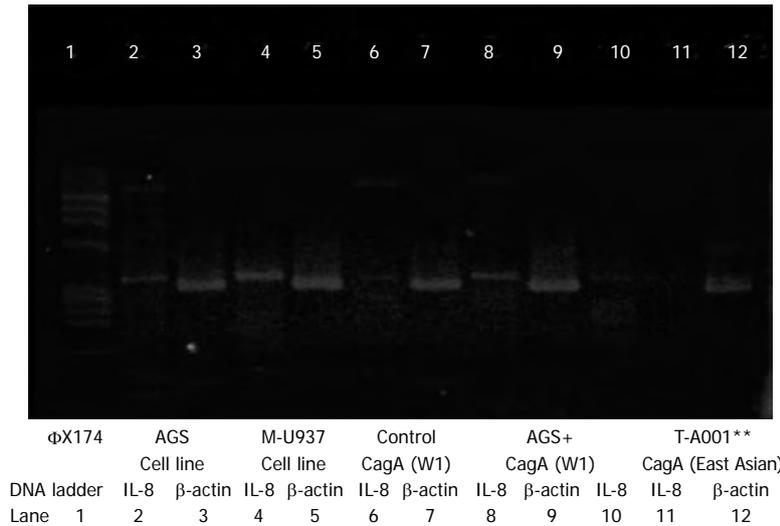

Figure 3 Basic experiment result on real-time reverse transcription-polymerase chain reaction of interleukine-8 mRNA expression with AGS, macrophage cell line, normal gastric mucosal cell, AGS cancer cell line co-culture with two strains of *cagA Helicobacter pylori*, and positive *cagA*, Thai non-cancer samples sequences showed on 12 lanes. M: Marker.

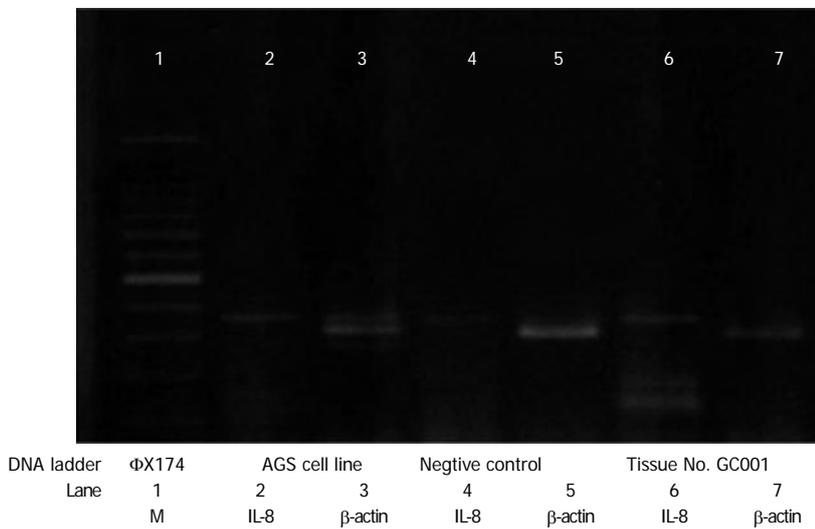

Figure 4 Real-time reverse transcription-polymerase chain reaction result of interleukine-8 mRNA expression from AGS, negative control, and Thai gastric cancer mucosal tissues. The positive results of interleukine-8 (*IL-8*) mRNA expression appeared at 320 bp band comparing with 300 bp band of marker (M) in lane 1.

cell line *IL-8* mRNA expression were demonstrated in Figure 3. and Figure 4. However, there was no significant difference of *IL-8* mRNA expression level between positive and negative *H. pylori* infection in subgroup analysis of non-cancer background positions.

In summary, *IL-8* mRNA expression level is predominantly found, and trend toward an inverted correlation to PG I / II low ratio in Thai gastric cancer patients. There is no direct correlation of *IL-8* mRNA expression level with the *cagA* gene mutation in Thai gastric cancer.

## DISCUSSION

In the present *in vivo* study, there is a significant risk of *IL-8* mRNA expression level predominantly found rising up more than 80% of northern-Thai gastric cancer. There is significantly higher level of *IL-8* mRNA expression in poorly differentiated than in well differentiated carcinoma in both Thailand and Japan. There is a trend of converted independent correlation with the very low PG I / II ratio in gastric cancer as well as a few numbers of Thai severe CAG, but no direct correlation with positive *H. pylori* infection or *cagA* genotypes.

Higher level *IL-8* mRNA expression in non-cancer Thais comparing with non-cancer Japanese demonstrated the difference of gastric mucosal defense and genetic expression between the two nations. Thai gastric cancer has less background of CAG. In this study, there is no evidence that showed a direct correlation of *IL-8* mRNA expression with *cagA* mutation genotype in *H. pylori* positive cases. Predominant *IL-8* mRNA expression level resulted in non-atrophic mucosa of both gastric cancer and non-cancer Thais. The result is different from previous *in vitro* or some *in vivo* studies in high incidence gastric cancer countries, such as Japan, China, and South Korea.

In Thai gastric cancer patients, *IL-8* mRNA expression level at the lesser curvature is the most represented location. Its predominantly high level may represent relatively vascular invasion as well as major gastric mucosal inflammation. However, the area of gastric antrum in Thai gastric cancer patients has less activity than the lesser curvature because atrophy occurs more frequently.

Also, a high level of *IL-8* mRNA expression is matched with the poor prognosis by histopathology cell type and tumor stage. Long-term bacterial infection has less effect to change the gastric mucosa into CAG. In our

recent six year followed up study in non-cancer cases controlled with positive *H. pylori* infection and without eradication of 500 new non-cancer cases, a few people developed severe gastritis and still have a high PG I / II ratio. In this study, the number of high PG I / II ratio in Thai cancer is still about 45% which is nearly the same percentage in our recently published study<sup>[4]</sup>.

A few gastric cancer preventive models on natural Thai products were reported<sup>[14]</sup>. There is one study on diet consumption in Thais showing a linkage of gastric cancer risk. The factors which were found to be a higher risk but not statistically significant were low intake of vegetables and fruits (OR = 1.2, 95%CI: 0.74-1.96) and Jeaw prik (mainly chilly with Plara broth or pickled fish), a kind of preserved food in North and North-eastern regions of Thailand (OR = 1.2, 95%CI: 0.76-2.01)<sup>[15]</sup>. The consensus of the Asian Pacific guideline on gastric cancer prevention is still debated in some experts' opinions<sup>[16]</sup>. *H. pylori* infection screening in a low risk gastric cancer population is not recommended, but serum PG may be helpful to screen the high risk population in northern Thailand. We reported its different characteristics that rely on *H. pylori* IgG antibody and PG I / II ratio in our cancer populations comparing to the data in a Japanese report<sup>[17]</sup>.

The Japanese study primarily reported the relation of *cagA* genotype and a low PG I / II ratio. Nevertheless, approximately half of the Thai cancer population demonstrates a low ratio of PG I / II similar to the Japanese. There are still a small number of Thais who had a severe atrophy score related to *H. pylori* infection though in the positive *cagA* Thai population.

In this study, the negative *cagA* gene is found in the majority of Thai gastric cancer unlike the Japanese. In Thais, the poorly differentiated cell type gastric adenocarcinoma occurred mainly in the negative *cagA* gene *H. pylori* infection, not in Western type *cagA*.

There is a small number of the Thai population who had a severe atrophy score of gastric mucosa found in our recent and present collaborative study<sup>[18]</sup>. Reduction of the fundic gland in chronic gastritis was also related to the low level of PG I / II ratio in Japanese<sup>[19,20]</sup>. In our recent study of subgroup analysis on the PG I / II ratios, there was no significant difference between CAG and gastric cancer group,  $P = 0.12$ . However, the low PG I / II ratio was significantly related to gastric cancer when compared to normal population in a recent match-case control study by OR of 2.3 (95%CI: 1.10-4.80),  $P = 0.025$ <sup>[4]</sup>. The tumor location demonstrated locations mainly at the upper portion and corpus in both of our studies. In the present study, the author found risk for cancer by OR 2.06 (95%CI: 0.94-4.47),  $P = 0.059$  that seems to be close to the result of our recent study. The low PG I / II ratio was not found to be a high percentage in Thais unlike in Japanese gastric cancer<sup>[9]</sup>.

For other genetic host factors, in one interesting study, two of the four gastric carcinoma cell lines expressed vascular endothelial growth factor (VEGFR-3) mRNA. In 17 of 36 gastric carcinoma specimens, VEGFR-3-specific

immune activity was detected in tumor cells. These angiogenesis and lymphangiogenesis were also detected in VEGF-C-transfected tumors than in control tumors<sup>[21]</sup>. *IL-8* mRNA expression is found to be the gate way mechanism of the vascular epithelial growth factor. For *IL-1* gene, it is a pro-inflammatory cytokine, and the T/T genotype of *IL-1β-511* is suspected as the risk factor of both hypochlorhydria related *H. pylori* infection and gastric cancer in a case-control population in the United States<sup>[22]</sup>. The author reported that *c/c* genotype was a risk in Japanese, and a lower number of *c/c* genotype was found as a minor risk related to Thai gastric cancer<sup>[4]</sup>.

Recent *in vivo* animal models studies showed the expressions of *IL-8* and COX-2 had linkage to the epithelial cell which was co-infected with *H. pylori*. However, our preliminary study reported that there was no difference of *IL-8* mRNA expression level between a cell line which was co-infected with *H. pylori* and the Thai gastric mucosa tissues which had positive or negative *H. pylori*<sup>[23,24]</sup>. The toleration, remarkable host response to cancer inflammatory process, healing of stomach mucosal turnover rate, and re-healing process of ulcer in Thais may be different and caused by host susceptible differences to the virulence bacteria.

The theory regarding inflammatory cytokine's influence on cancer development was first contributed by Rudolph Virchow around 150 years ago<sup>[25]</sup>. Many studies regarding *IL-8* gene expression remarkably found significant relation with *H. pylori* infection and many *cag* pathogenicity island both *in vitro*<sup>[26,27]</sup> and in some number in *in vivo* study of Japanese cancer<sup>[28,29]</sup>. However, no study has demonstrated differences of expression level in the individualized host<sup>[30]</sup>.

In this study, Japanese gastric cancer has a lower *IL-8* mRNA expression on average than that in Thai gastric cancer patients at the same stage of disease and *H. pylori* infection status. However, Japanese gastric adenocarcinoma cases are mostly an intestinal type and infected by positive *cagA* strain *H. pylori*. In contrast with northern Thai gastric adenocarcinoma cases, they are mostly diffuse histologic cell type, and infected by negative *cagA* strain *H. pylori*. Therefore, the authors speculate that the predominant level of *IL-8* mRNA expression found in non-*cagA* gene *H. pylori* infection is not directly related to atrophic gastritis mucosa in Thai gastric cancer.

Some results in this study are unexpected outcomes and different from our recent knowledge of *in vitro* and *in vivo* study in Japanese atrophic gastric mucosa which almost easily infected by positive *cagA H. pylori* infection. The *cagA* was also the suspected cause of the *IL-8* gene expression rising.

This result in Thais showed that gastric mucosal tissue *IL-8* mRNA expression has a higher level in the advanced stage and poorer differentiated cell type than in favorable histology or differentiated cell type. The author was suspicious that the less atrophic background of Thai stomach cancer and non-cancer gastric mucosa may be caused by non-*cagA H. pylori* infection. However, the high level of mRNA *IL-8* gene expression in Thai gastric can-

cer cases may be explained by the cancer inflammation carcinogenesis that may not be directly related to only *H. pylori* infection in Thais.

The level of *IL-8* mRNA expression in Thai gastric cancer or poorly differentiated gastric carcinoma may be regulated by other factors besides of *H. pylori* infection. Also, unknowns remain regarding how long *IL-8* mRNA expression has been high before the occurrence of gastric cancer or after becoming a more advanced stage. Although the author analyzed the level of *IL-8* and *COX-2* mRNA expression level in normal mucosa and of advanced gastric cancer, this occurrence could not be shown in early gastric cancer. The environmental factors and bacterial virulence effect cannot be excluded.

In this study, the signet ring cell type is predominantly found in Thai gastric cancer population. The poor prognostic histological cell type may have different disease carcinogenesis related to gastric mucosal tissue *IL-8* mRNA high expression level and severity of the disease. The *COX-2* mRNA expression level is directly correlated with only the *H. pylori* infection, and tended to be suppressed unlike *IL-8* mRNA expression. The author supposed that extremely high gastric mucosal *IL-8* expression level may relate to other factors, such as VEGF that could not be demonstrated in this study and should be explored further.

In conclusion, this present *in vivo* study shows results of new factual data on predominant gastric mucosal *IL-8* mRNA expression level in Thai gastric mucosal biopsy tissues in both non-cancer and gastric cancer volunteers. In the present study, the northern Thai gastric cancer population has a high incidence of signet ring cell by the nature of histologic type. The positive *H. pylori* may be one of the co-factors, though the host is infected with non-*cagA* gene and still has an extremely high *IL-8* mRNA expression level. This cytokine expression may represent the individual host defense in both high and low incidence gastric cancer ethnics. The factual results in an experimental based study demonstrated how prevalence of the northern Thai gastric cancer host had active co-infection or had been recently infected by non-*cagA* gene *H. pylori* infection. The *IL-8* mRNA expression level does not directly correlate to non-*cagA* *H. pylori* infection in Thai gastric cancer. However, there is a trend of converted correlation between *IL-8* mRNA expression and low ratio PG I / II without statistical significance, and it seems to be an independent correlation. By these preliminary results, the author expected to do further study on *IL-8* mRNA expression that may act as one of prognostic genetic biomarkers in clinical practice and for chemotherapy application in the nearby future. A study on the current cancer chemotherapy with northern Thai gastric cancer population is on-going.

## ACKNOWLEDGMENTS

This study with preliminary results was presented in a free oral paper symposium session of Oncology and Stomach session, International Surgical Week 2011, in Yokohama during August 28-September 1.

## COMMENTS

### Background

The incidence of gastric carcinoma is very low although the incidence of *Helicobacter pylori* (*H. pylori*) seemed not to be low in Thais. However, the northern Thai population still has the highest gastric cancer incidence in Thailand. Currently, the disease incidence is rising faster than in the past and still the second cause of cancer death worldwide. The cause and risk factors for gastric cancer carcinogenesis in Thais is unclear especially the risk related with *H. pylori* infection or other cofactors.

### Research frontiers

Interleukine-8 (*IL-8*) mRNA expression is a common event found in some epithelial malignancies and in gastric adenocarcinoma either due to *H. pylori* caused chronic inflammation or other causes by unrelated carcinogens. It is not clear how the level of this expression related to gastric adenocarcinoma. The authors demonstrated that the predominant overexpression of *IL-8* mRNA could be a potential relative risk for gastric adenocarcinoma in Thais and demonstrated the difference of its level in relationship with the histologic type of gastric cancer.

### Innovations and breakthroughs

Recent reports have highlighted the importance of cytotoxin-associated gene A (*cagA*) *H. pylori* infection and its mutation type that is shown predominantly in Japanese gastric cancer carcinogenesis. Particularly in the well differentiated histologic type, the *IL-8* mRNA expression level in the Japanese seems to be much lower than in Thais. However, its level in poorly differentiated cell type of Thai gastric adenocarcinoma has less atrophic background and a higher level of expression than in well differentiated gastric adenocarcinoma. This is the first study to report how measurement of *IL-8* mRNA expression level demonstrates risk in non-*cagA* *H. pylori* infection of Thai gastric cancer and the trend of differences in carcinogenesis related to *H. pylori* infection between high and low incidence ethnics. Furthermore, their *in vivo* studies would suggest that the *IL-8* mRNA expression level yields high prevalence detection in gastric adenocarcinoma and may be a useful tool for gastric cancer prognostic or therapeutic study.

### Applications

By understanding different *IL-8* mRNA expression levels, this study may represent a future study with a tissue molecular biomarker for gastric cancer.

### Terminology

*IL-8* mRNA expression is pro-inflammatory cytokines that is detected in gastric epithelial mucosa and gastric cancer cell lines, such as Kato III and AGS cells.

### Peer review

The authors examined the expression of *IL-8* and cyclooxygenase-2 in AGS cell line, normal gastric mucosa, gastritis, and gastric adenocarcinoma tissues. It revealed that *IL-8* mRNA expression predominantly increased in poorly differentiated or signet ring cell gastric adenocarcinoma that showed the trend of a poorer prognosis. The expression was not directly correlated to *cagA* *H. pylori* infection and its mutation type. The results are interesting and may represent a different carcinogenesis of Thai gastric cancer in comparison to recent Japanese studies.

### Abstract

**AIM:** To study the current application situation of gastrointestinal (GI) endoscopy in mainland China.

**METHODS:** From 12 August, 2011 to 15 February, 2012, draft questionnaires were sent by e-mail to 289 hospital-based GI endoscopy units, including units with three levels (provincial, prefecture and county level) in mainland China. All the surveyed GI endoscopy units were state-owned and hospital-based. Proportions were compared using  $\chi^2$  tests. Comparisons between groups were performed using the Mann-Whitney *U* test. A probability of  $P < 0.05$  was considered to represent a statistically significant difference.

**RESULTS:** Based on satisfactory replies, 169/279 (60.6%) of units were enrolled in the survey, which covered 28 provinces (90.3%, 28/31) in mainland China. Compared with published survey data, the number of GI endoscopes per unit has increased by nearly three times (from 2.9 to 9.3) in the past decade. About

33 of 169 (19.5%) endoscopy units possessed an X-ray machine, which was mainly owned by provincial endoscopy units (43.2%, 19/44). Video capsule endoscopes, which were almost unavailable ten years ago, were owned by 20.7% (35/169) of GI endoscopy units. Endoscopic submucosal dissection could be performed by 36.4% (19/44) of the provincial units, which was significantly higher than the prefecture level (9.9%,  $P < 0.01$ ) and county level (0.0%,  $P < 0.01$ ) units, respectively.

**CONCLUSION:** Rapid development in GI endoscopy has been made in mainland China, and major diagnostic endoscopes and therapeutic endoscopy procedures are predominantly used in large endoscopy units.

© 2013 Baishideng. All rights reserved.

**Key words:** Application situation; Gastrointestinal endoscopy; Video capsule endoscopy; Endoscopic submucosal dissection

**Core tip:** Rapid developments in gastrointestinal (GI) endoscopy have taken place in China in the past decade. Major diagnostic endoscopes and therapeutic endoscopy procedures are predominantly confined to large endoscopy units, whereas small and medium units, often perform fewer endoscopic procedures and have less equipment, and are mostly restricted to diagnostic endoscopy. In addition to improvement in GI endoscopy equipment, standard procedures including the standard reprocessing for endoscopy will be the focus in the future in China.

## INTRODUCTION

Endoscopy is a universally popular, minimally invasive intervention for gastrointestinal (GI) and pancreato-biliary disorders<sup>[1]</sup>. It is reported that > 10 million GI endoscopies are performed every year in the United States<sup>[2]</sup>, and the number of procedures worldwide, although there are no exact figures, is believed to be increasing yearly due to the rapid increase in popularity of GI endoscopy. Although GI endoscopy services have become a routine procedure in western countries<sup>[3]</sup>, in most developing countries GI endoscopy services are sometimes available in so-called centres of excellence<sup>[4]</sup>.

In the past decade, the emergence and application of a variety of novel endoscopic techniques and equipment, *e.g.*, video capsule endoscopy (VCE) and double/single balloon enteroscopy (DBE/SBE) have substantially promoted the diagnostic value for GI tract lesions<sup>[5-7]</sup>. Additionally, also in the past decade, GI endoscopy has experienced rapid evolution from a diagnostic medical procedure to a minimally invasive therapeutic procedure, *e.g.*, endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD) for removal of mucosal lesions<sup>[8-10]</sup>. All these advances in GI endoscopy have ushered in a new era in digestive medicine. However, the systemic data concerning the current status and development of GI endoscopy in China is still lacking. Here, we conducted a survey of GI endoscopy procedures and equipment in hospital-based GI endoscopy units, in order to demonstrate the rapid development of GI endoscopy in mainland China in the past decade.

## MATERIALS AND METHODS

### Survey design

According to the scale (bed number) and location, hospitals in mainland China are traditionally divided into three levels: provincial (bed numbers > 1000/hospital, usually located in the provincial capital city), prefecture (bed numbers 500-1000/hospital, usually located in the prefecture capital city) and county (bed numbers < 500/hospital, usually located in county city) level; or large scale (*i.e.*, provincial) and small-to-medium scale (*i.e.*, prefecture and county level). The endoscopy units from three levels of hospitals are regarded as provincial, prefecture and county level endoscopy units, respectively.

From 12 August, 2011 to 15 February, 2012, 289 GI endoscopy units, which are official members of the Chinese Society of Digestive Endoscopy, were included in the present study. All the surveyed GI endoscopy units were state-owned and hospital-based. They were required to fill in a questionnaire. The questionnaires were sent by e-mail to the physician in charge of the unit, and if an e-mail address was unavailable or invalid, a phone call was made to complete the questionnaire. The draft comprised 21 questions about the endoscopy equipment and procedures performed in the units. The queries pertained to: the number of GI endoscopy procedures performed per year; the number and brands of all kinds of GI endo-

scopes; the number of separate purpose-designed rooms for endoscopy procedures; the number of the full-time GI endoscopy physicians and nurses; the major auxiliary endoscopy equipment (*e.g.*, X-ray machine); which endoscopy procedure they could perform [*e.g.*, endoscopic retrograde cholangiopancreatography (ERCP), EMR and ESD].

### Ethical considerations

The study was approved by the Ethics Committee of Chinese PLA General Hospital.

### Statistical analysis

Proportions were compared using  $\chi^2$  tests. Comparisons between groups were performed using the Mann-Whitney *U* test. A probability of  $P < 0.05$  was considered to represent a statistically significant difference. Statistical analysis was performed using SPSS version 13.0 (Chicago, IL, United States).

## RESULTS

### Responding GI endoscopy units and their locations

Based on provision of a satisfactory reply, 169/289 (58.5%) GI endoscopy units from three levels of hospital were enrolled in our study, which covered 28 provinces (90.3%, 28/31) in mainland China. Of these, 44 (26.0%, 44/169) units were from provincial hospitals, 91 (53.8%, 91/169) from prefecture level hospitals, and 34 (20.1%, 34/169) from county level hospitals.

### Number of endoscopy procedures per year

All 44 provincial endoscopy units performed  $\geq 5000$  procedures, which was significantly higher than the prefecture-level (16.5%,  $P < 0.05$ ) and county-level (0.0%,  $P < 0.05$ ) endoscopy units (Table 1).

### Number of endoscopes per unit

The average number of gastrointestinal endoscopes (including all types of GI endoscope) for the 169 endoscopy units was 9.3/unit (1568/169). The average number of endoscopes in the provincial endoscopy units was  $22.4 \pm 5.5$ , which was significantly higher than that in the prefecture level ( $5.4 \pm 1.4$ ,  $P < 0.05$ ) and county level ( $2.7 \pm 1.2$ ,  $P < 0.05$ ) units. Moreover, 59.1% (26/44) of the provincial endoscopy units had at least 10 endoscopes, which was also significantly higher than that of the prefecture level (6.6%,  $P < 0.05$ ) and county level (0.0%,  $P < 0.05$ ) units (Table 1).

All of the 169 endoscopy units possessed gastroscopies. The possession rate of colonoscopies in provincial and prefecture level units was 100% and 97.8%, respectively, which was significantly higher than that of county level units (88.2%,  $P < 0.05$ ). Enteroscopies (DBE/SBE) were available only in provincial units (40.9%, 18/44) and a VCE was possessed by 20.7% (35/169) of all GI units (Table 1).

### Endoscope manufacturers

The most frequently used GI endoscopes were manufac-

<sup>a</sup>*P* < 0.05 vs prefecture-level or county-level endoscopy units; <sup>c</sup>*P* < 0.05 vs county-level endoscopy units. EUS: Endoscopic ultrasonography; VCE: Video capsule endoscope; DBE/SBE: Double balloon/single balloon enteroscopy; ERCP: Endoscopic retrograde cholangiopancreatography; EMR: Endoscopic mucosal resection; ESD: Endoscopic submucosal dissection; EVS: Endoscopic variceal sclerotherapy; EVL: Endoscopic variceal ligation.

tured by Olympus (140/169, 82.8%), followed by Fujinon (52/169, 30.8%) and Pentax (28/169, 16.6%).

#### Number of full-time staff in GI endoscopy units

The average number of full-time physicians in each provincial endoscopy unit was 3.0  $\pm$  1.3, which was significantly higher than that in prefecture level (1.6  $\pm$  1.2, *P* < 0.05) and county level (1.2  $\pm$  0.9, *P* < 0.05) endoscopy units. A similar trend was found for the numbers of full-time nurses in these three levels of endoscopy units (Table 1).

#### Possession of X-ray machine in GI endoscopy units

Thirty three of the 169 (19.5%, 33/169) endoscopy units possessed an X-ray machine. Furthermore, 43.2% of the provincial endoscopy units owned an X-ray machine, which was significantly higher than that of prefecture level (15.4%, *P* < 0.01) and county level (0.0%, *P* < 0.01) endoscopy units (Table 1).

#### Endoscopy procedures performed

Polypectomy could be performed by all the provincial units (100%), 78.0% of the prefecture level units and 41.2% of county level units. ERCP could be performed by 77.3% of the provincial units, which was significantly higher than

**Table 2 Comparison of main endoscopy items in three independent surveys**

EUS: Endoscopic ultrasonography; VCE: Video capsule endoscope; ERCP: Endoscopic retrograde cholangiopancreatography; EVS: Endoscopic variceal sclerotherapy; EVL: Endoscopic variceal ligation.

in the prefecture level (42.9%, *P* < 0.05) and county level (11.7%, *P* < 0.01) units. A similar trend was also found for EMR, ESD and endoscopic variceal sclerotherapy (EVS)/endoscopic variceal ligation (EVL) (Table 1).

#### Comparisons of gastrointestinal endoscopy between current survey and previously published data

From January 2000 to November 2010, only two regional endoscopy surveys (*i.e.*, Shanghai survey in 2001 and Qinghai provincial survey in 2003) in mainland China were available by searching the Chinese national (Wanfang bases) and international databases (Medline), and they were both published in Chinese<sup>[11,12]</sup>. The major GI endoscopy items mentioned by these two regional surveys were compared with the current survey results, and a rapid development of GI endoscopy items, including the average number of GI endoscopes per unit, was shown in Table 2.

## DISCUSSION

In 1973, GI endoscopy was first introduced from Japan into China. Since then, much progress in GI endoscopy has been made by Chinese endoscopists, and the efforts and achievements of Chinese endoscopists in GI endoscopy have gradually gained international recognition<sup>[13-16]</sup>. For example, with regard to the latest endoscopy techniques, EUS, ERCP, VCE and DBE have been the focus for Chinese endoscopists, and they have accounted for 66% of all the international publications<sup>[17]</sup>.

Although the Shanghai survey in 2001 and the Qinghai provincial survey in 2003 were from single and different areas in China, which means lower comparability with the present survey here we use them to demonstrate the progress of GI endoscopy facilities in the past decade in mainland China because these are the only journal publications available<sup>[11,12]</sup>.

The total number of GI endoscopes per unit is an important and determinant factor for what kinds of and how many endoscopy procedures they can perform. In the present survey, the average number of GI endoscopes per unit increased nearly threefold (9.3/unit) compared with that of previously published data ten years ago (the average number for Shanghai and Qinghai surveys was 2.9/unit). This is major progress in mainland China in the past decade.

VCE was first reported in 2000 by an Israeli company, Given Imaging<sup>[5]</sup>, and it is predicted that major developments in endoscopy over the next 10-20 years will centre on this technique<sup>[18]</sup>. In the past eight years, the possession rate of VCE has markedly increased from 2.7% (Qinghai survey, 2003) to 20.7% in the present survey.

EUS and small-intestine enteroscopy have been used in clinical practice for many years<sup>[19,20]</sup>, but in the past decade, these two types of endoscopy have developed rapidly. For example, DBE, which has evolved from conventional push enteroscopy, was first introduced into clinical practice in 2001 by Yamamoto *et al*<sup>[21]</sup>. DBE is a completely new technique that allows complete visualization, biopsy and treatment of small-bowel diseases. In the Shanghai survey, the rates for EUS and push-type enteroscopy were 4.3% and 7.2%, respectively, but in the present survey, the possession rates had increased to 10.6% and 22.4%, respectively. However, these two types of endoscope were still mainly owned by provincial hospitals in mainland China, which was largely due to their high cost and fewer indications for such procedures in small-to-medium endoscopy units (*i.e.*, prefecture and county level units).

Another important piece of endoscopy equipment, especially for large scale units, is a dedicated X-ray machine, which is necessary for a variety of GI interventions, including ERCP, percutaneous trans-hepatic catheter drainage, luminal stent placements and dilation<sup>[22]</sup>. In the Shanghai survey, the rate of possession of a dedicated X-ray machine (not mentioned in the Qinghai survey) was 5.7% (8/138), and the rate has increased to 19.5% in the present survey. Our data also demonstrated that Olympus was the leading manufacturer of GI endoscopes in mainland China, which is in accordance with the fact that Tokyo-based Olympus is the world's largest manufacturer and provider of conventional endoscopes<sup>[23]</sup>.

Staffing requirements for GI procedures should be based on what is needed to ensure safe and proficient performance of the individual procedure<sup>[24]</sup>. As the number of procedures carried out and the complexity of the procedures and equipment have increased, the need for specialised staff has become apparent. Our survey indicated that most full-time endoscopy staff were found in provincial hospitals in mainland China.

Compared with the Shanghai survey in 2001, easily performed therapeutic procedures, such as polypectomy, have become more popular in the past 10 years; even in small-to-medium endoscopy units in China. Another conventional procedure is ERCP, which was first performed

in 1968 and is usually regarded as the representative endoscopic intervention in pancreaticobiliary disorders<sup>[25]</sup>. In 1973, ERCP was introduced to China, and since then it has been extensively used. It is estimated that Chinese physicians perform nearly 60000 ERCP procedures annually, including therapeutic ERCP<sup>[17]</sup>. Our survey showed that, in China, ERCP (diagnostic and/or therapeutic) was a frequently performed procedure not only in provincial hospitals (77.3%), but also in prefecture level hospitals (42.9%). In the Shanghai survey in 2001, the overall rate of capability of performing ERCP was 38.4%, but now the nationwide rate has increased to 45.6%.

EVS or EVL is an effective endoscopic procedure for treatment of oesophageal varices<sup>[26]</sup>, and it has been frequently performed in China because of the large number of patients with oesophagogastric variceal bleeding<sup>[27]</sup>. The Shanghai survey showed that 40.2% of the surveyed endoscopy units can perform an EVS procedure. According to the present survey, EVS/EVL is now frequently carried out in provincial (75.0%) and prefecture level (40.7%) units (Table 2); but in county level units (9.0%), there is still room to increase the popularity of this procedure, with regard to its simple operation without special devices. EMR and ESD were developed in the past decade as a novel therapeutic endoscopic procedure to remove the mucosal lesions, including early malignant lesion<sup>[8,9]</sup>. Our survey demonstrated that EMR or ESD is also predominantly confined to the large units (provincial level) in mainland China, which may be due to the shortage of special devices in small-to-medium endoscopy units, and the procedure itself is technically demanding.

In conclusion, rapid developments have taken place in GI endoscopy in China in the past decade. Major diagnostic endoscopes and therapeutic endoscopy procedures are predominantly confined to large endoscopy units (*i.e.*, provincial hospitals), whereas small-to-medium units, often perform fewer endoscopic procedures and have less equipment, and are mostly restricted to diagnostic endoscopy. In addition to improvements in GI endoscopy equipment, standard procedures including the standard reprocessing for endoscopy will be the focus in the future in China<sup>[28]</sup>. Therefore, there is still much room for improvement in GI endoscopy in China, and our results may provide crucial information needed for the national level GI endoscopy planning.

## ACKNOWLEDGMENTS

We thank Professor Yan-Qing Li (Department of Gastroenterology, Qilu Hospital, Shandong University, Jinan, Shandong Province), Professor Ming-Jun Sun (Department of Gastrointestinal Endoscopy, the First Affiliated Hospital, China Medical University, Shenyang, Liaoning Province), Professor Xiao-Ping Wu (Department of Gastroenterology, the Second Hospital, Central South University, Changsha, Hunan Province), Professor Xue-Hong Wang (Department of Gastroenterology, the Affiliated Hospital, Qinghai University, Xining, Qinghai

Province), Hai Xing Jiang (Department of Gastroenterology, the First Affiliated Hospital of Guangxi Medical University, Nanning, Guangxi Zhuang Autonomous Region), Yu-Xiu Yang (Department of Gastroenterology, the People's Hospital of Henan Province, Zhengzhou, Henan Province) and Professor Yang Li (Department of Gastroenterology, Ningxia Medical University, Yinchuan, Ningxia Hui Autonomous Region) for their commitment to the survey, and we are indebted to all our colleagues who have taken the time to answer this survey.

## COMMENTS

### Background

Endoscopy is a universally popular, minimally invasive intervention for gastrointestinal (GI) and pancreatico-biliary disorders. Although GI endoscopy services have become a routine procedure in western countries, in most developing countries GI endoscopy services are sometimes available in so-called centres of excellence.

### Research frontiers

In the past decade, the emergence of a variety of novel endoscopic equipment and techniques, *e.g.*, video capsule endoscopy (VCE), double/single balloon enteroscopy, endoscopic mucosal resection and endoscopic submucosal dissection (ESD) have substantially promoted the application value for GI tract lesions worldwide. GI endoscopy is experiencing rapid evolution from a diagnostic medical procedure to a minimally invasive therapeutic procedure.

### Innovations and breakthroughs

The authors conducted a survey of GI endoscopy procedures and equipment in hospital-based GI endoscopy units, in order to demonstrate the current status of GI endoscopy in mainland China in the past decade. Based on provision of a satisfactory reply, 169/289 (58.5%) GI endoscopy units from three levels of hospital were enrolled in their study, which covered 28 provinces (90.3%, 28/31) in mainland China.

### Applications

The authors found that the number of GI endoscopes per unit increased by nearly three times (from 2.9 to 9.3) in the past decade. The VCE, which was almost completely unavailable ten years ago, was possessed by 20.7% (35/169) of GI endoscopy units. ESD could be performed by 36.4% (19/44) of the provincial units, which was significantly higher than the prefecture level (9.9%) and county level (0.0%) units, respectively.

### Terminology

The survey of GI endoscopy included equipment and procedures performed in each GI endoscopy unit. The questionnaires comprised 21 questions which were sent by e-mail to the physician in charge of the unit.

### Peer review

This is a very important survey reflecting the development of GI endoscopy in mainland China in the past decade.

### Abstract

**AIM:** To study the effect and tolerance of intraperitoneal perfusion of cytokine-induced killer (CIK) cells in combination with local radio frequency (RF) hyperthermia in patients with advanced primary hepatocellular carcinoma (HCC).

**METHODS:** Patients with advanced primary HCC were included in this study. CIK cells were perfused intraperitoneal twice a week, using  $3.2 \times 10^9$  to  $3.6 \times 10^9$  cells each session. Local RF hyperthermia was performed 2 h after intraperitoneal perfusion. Following an interval of one month, the next course of treatment was administered. Patients received treatment until disease progression. Tumor size, immune indices (CD3<sup>+</sup>, CD4<sup>+</sup>,

CD3<sup>+</sup>CD8<sup>+</sup>, CD3<sup>+</sup>CD56<sup>+</sup>), alpha-fetoprotein (AFP) level, abdominal circumference and adverse events were recorded. Time to progression and overall survival (OS) were calculated.

**RESULTS:** From June 2010 to July 2011, 31 patients diagnosed with advanced primary HCC received intraperitoneal perfusion of CIK cells in combination with local RF hyperthermia in our study. Patients received an average of  $4.2 \pm 0.6$  treatment courses (range, 1-8 courses). Patients were followed up for  $8.3 \pm 0.7$  mo (range, 2-12 mo). Following combination treatment, CD4<sup>+</sup>, CD3<sup>+</sup>CD8<sup>+</sup> and CD3<sup>+</sup>CD56<sup>+</sup> cells increased from  $35.78\% \pm 3.51\%$ ,  $24.61\% \pm 4.19\%$  and  $5.94\% \pm 0.87\%$  to  $45.83\% \pm 2.48\%$  ( $P = 0.016$ ),  $39.67\% \pm 3.38\%$  ( $P = 0.008$ ) and  $10.72\% \pm 0.67\%$  ( $P = 0.001$ ), respectively. AFP decreased from  $167.67 \pm 22.44$  to  $99.89 \pm 22.05$  ng/mL ( $P = 0.001$ ) and abdominal circumference decreased from  $97.50 \pm 3.45$  cm to  $87.17 \pm 4.40$  cm ( $P = 0.002$ ). The disease control rate was 67.7%. The most common adverse events were low fever and slight abdominal erubescence, which resolved without treatment. The median time to progression was 6.1 mo. The 3-, 6- and 9-mo and 1-year survival rates were 93.5%, 77.4%, 41.9% and 17.4%, respectively. The median OS was 8.5 mo.

**CONCLUSION:** Intraperitoneal perfusion of CIK cells in combination with local RF hyperthermia is safe, can efficiently improve immunological status, and may prolong survival in HCC patients.

**Key words:** Cytokine-induced killer cell; Radio frequency hyperthermia; Primary hepatocellular carcinoma; Intraperitoneal perfusion; Clinical observation

**Core tip:** Intraperitoneal perfusion of cytokine-induced killer (CIK) cells in combination with local radio frequency hyperthermia can result in a high concentration of

CIK cells. This treatment can efficiently improve immunological status, and attack small lesions in the abdominal wall, which can reduce ascites and relieve abdominal distention. This comprehensive treatment may prolong survival time and improve quality of life in patients with advanced hepatocellular carcinoma.

Intraperitoneal perfusion of cytokine-induced killer cells with local hyperthermia for advanced hepatocellular carcinoma. *World J Gastroenterol* 2013; 19(19): 2956-2962 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i19/2956.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i19.2956>

## INTRODUCTION

Primary hepatocellular carcinoma (HCC) is one of the most common malignant tumors worldwide and has a poor prognosis. Surgical resection at an early stage is still the best remedy<sup>[1]</sup>. As the onset of HCC is occult, it is typically diagnosed in stage III-IV when patients present with clinical symptoms. However, the surgical resection rate is only 10%-30%. Currently, there is still no standard treatment for advanced HCC, but minimally invasive therapy and targeted therapy are favored. Patients with HCC may have poor therapeutic outcomes due to multiple local lesions or excessive tumor load. Consequently, integrative therapy is now a useful treatment for patients with advanced HCC<sup>[2]</sup>.

Adoptive cellular immunotherapy has been applied in the clinical treatment of advanced HCC due to the close relationship between the pathogenesis of HCC and the autoimmune system, and the persistence of pathogenic factors such as hepatitis and cirrhosis<sup>[3-5]</sup>. Cellular immunotherapy includes several types of immunological cells, such as lymphokine-activated killer cells, tumor infiltrating lymphocytes and cytokine-induced killer (CIK) cells. CIK cells have been confirmed to have potential for immunotherapy against residual tumor cells. In recent years, several authors have reported that CIK cells were a heterogeneous population, and the major population to express both T cell marker monoclonal antibody and natural killer cell marker monoclonal antibody<sup>[6]</sup>. Cells with this phenotype are rare (1%-5%) in natural peripheral blood mononuclear cells. CIK cells are able to expand nearly 1000-fold when cultured in a cytokine cocktail, comprising interleukin (IL)-1 $\alpha$ , interferon- $\gamma$  (IFN- $\gamma$ ), IL-2 and mAbs against CD3, and have characteristics which are more effective in the treatment of tumors with a non-major histocompatibility complex (MHC)-restricted mechanism<sup>[7]</sup>. Thus, CIK cells may have some benefit in potential immunotherapeutic treatments in patients with HCC.

Hyperthermia treatment of tumors refers to tumor tissue which is treated with a continuous direct current through two or more electrodes placed outside the tumor. Some researchers have suggested that hyperthermia can

normalize cell growth, and accelerate cell division after inhibiting cell division when it becomes abnormally accelerated<sup>[8,9]</sup>. Hyperthermia is an alternative treatment for HCC patients and has a positive effect on tumors. This study aimed to evaluate the safety and efficacy of the combination of CIK cell therapy and local radio frequency (RF) hyperthermia in patients with advanced HCC.

## MATERIALS AND METHODS

### General information

From June 2010 to July 2011, 31 patients with advanced HCC in the Oncology Center of Clifford Hospital were included in this study. Seven patients were identified by pathological diagnosis and the remaining patients all met the clinical diagnostic criteria<sup>[10]</sup>. Staging of disease was by tumor-node-metastasis staging according to the American Joint Committee on Cancer staging criteria<sup>[11]</sup>. All patients were stage III-IV without metastases outside the abdomen. Reasons for being unable to undergo surgery and transcatheter arterial chemoembolization (TACE) were as follows: multiple tumors with obscure boundaries, extremely small remnant liver, lesions close to or involving great vessels, extreme damage to the cardiovascular system or other organs, liver functional lesion and rejection of surgery or TACE. Written informed consent was obtained before treatment.

### Instrument and reagents

The instrument used was the FACS Calibur Flow cytometer (manufactured by BD Biosciences, United States). The reagents required for incubation of CIK cells were as follows: IL-1 $\alpha$  (10  $\mu$ g/vial, PeproTech Inc., Rocky Hill, NJ, United States), monoclonal mouse anti-human CD3 (500  $\mu$ g/vial, PeproTech Inc.), IFN- $\gamma$  (1000000 U/vial, PeproTech Inc.), IL-2 (PeproTech Inc.), complete Roswell Park Memorial Institute (RPMI) 1640 medium (GIBCO, RPMI 1640 + gentamicin + 5% human type AB serum), lymphocyte separation medium (Tianjin Biological Products Company, Tianjin, China), human type AB serum (Tianjin Biological Products Company) and normal saline.

### Preparation of CIK cells

CIK cells were prepared by the Cell Laboratory as follows: mononuclear cells were isolated from 50 mL peripheral blood from each patient using a blood cell separator, and then incubated in medium containing 1000 U/mL IFN- $\gamma$  at 37 °C; 24 h later 100 ng/mL monoclonal mouse anti-human CD3, 1000 U/mL IL-2 and 1000 U/mL IL-1 $\alpha$  were added; the culture medium was renewed every 3 d and rhIL-2 was replenished. After 7-10 d, CIK cells were collected when the cell count reached  $3.2 \times 10^9$  to  $3.6 \times 10^9$ , centrifuged, washed with normal saline, dispersed in 100 mL normal saline (containing 5 mL 20% human serum albumin) and retained as a sample.

### Abdominocentesis

Routine abdominocentesis was performed before intraperitoneal perfusion of CIK cells and a tube was left

**Table 1** Clinical characteristics of the patients included in this study (*n* = 31)

| Characteristics               | <i>n</i> (%)       |

in the abdomen for perfusion. After abdominocentesis, 100-200 mL physiologic saline was perfused into the abdomen and observations on defecation sensation, discomfort, and whether the tube was smooth and in the correct position for the preparation of intraperitoneal perfusion of CIK cells were carried out. Patients with a recent history of surgery or suspicious ankyloenteron required ultrasonic guidance during abdominocentesis.

### Local RF hyperthermia

The machine used was an EHY-2000 local RF Hyperthermia Machine, made in Hungary. Health education and psychological preparation were carried out prior to treatment. Patients were evaluated for dysmetabolism and disturbed perception of temperature. Patients were asked to lie on the treatment water bed in the correct body position according to treatment requirements. An appropriate electrode plate size was chosen to cover the body surface projection area of the tumor. Treatment time was 60 min per session and power was 100-150 W (according to the tolerance level of patients).

### Intraperitoneal perfusion of CIK cells in combination with local RF hyperthermia

Intraperitoneal perfusion of CIK cells was performed twice a week (Monday and Thursday), with  $3.2 \times 10^9$  to  $3.6 \times 10^9$  cells each session. Local RF hyperthermia was carried out 2 h after intraperitoneal perfusion. In one treatment course consisting of 4 sessions,  $1.2 \times 10^{10}$  to  $1.5 \times 10^{10}$  cells were perfused. After an interval of one month, the next treatment course was administered, resulting in a time period of 1.5 mo for one cycle. Patients received

treatment until disease progression or intolerant adverse effects.

### Follow-up

Patients were followed up for 1 year. The treatment process, adverse reactions, and lost cases were recorded. A computed tomography (CT) or magnetic resonance imaging scan of the liver was performed every 2 mos. The size and number of tumors before and after treatment were compared. The therapeutic effect was evaluated and recorded. Levels of peripheral blood T lymphocyte subgroups ( $CD3^+$ ,  $CD4^+$ ,  $CD3^+CD8^+$  and  $CD3^+CD56^+$ ), abdominal circumference (patients with seroperitoneum) and AFP level were determined every 2 wk. Time to progression (TTP) and overall survival (OS) were calculated.

### Statistical analysis

Results were analyzed using SPSS 17.0 software. The data were expressed as mean ± SD. The survival curves were calculated using the Kaplan-Meier method. *P* < 0.05 was considered statistically significant.

## RESULTS

### Patient profile

From June 2010 to July 2011, a total of 31 patients aged 28-61 years (mean  $47.6 \pm 8.8$  years) were included in this study. The characteristics of the patients are shown in Table 1.

### Efficacy evaluation

According to the Response Evaluation Criteria In Solid Tumors, none (0%) of the patients had a complete response, 10 (32.25%) patients had a partial response (PR), 11 (35.48%) patients had no change (SD), and 10 (32.25%) patients had progressive disease. After treatment, AFP level decreased from  $167.67 \pm 22.44$  to  $99.89 \pm 22.05$  ng/mL (*P* = 0.001) and seroperitoneum in 14 patients significantly decreased, with abdominal circumference decreasing from  $97.50 \pm 3.45$  to  $87.17 \pm 4.40$  cm (*P* = 0.002).

### Changes in cell immunity indices

The immunologic markers examined included the serum levels of  $CD3^+$ ,  $CD4^+$ ,  $CD3^+CD8^+$  and  $CD3^+CD56^+$  T cells. After CIK cells were transfused back into the patients, all of these immune parameters increased, but not all of them increased significantly (Table 2).

### Adverse events

No serious adverse events were observed in this study. Several mild adverse events were observed, which rapidly resolved without treatment (Table 3).

### TTP and OS

TTP and OS were assessed in all 31 eligible patients. The median follow-up was  $8.3 \pm 0.7$  mo (range, 2-12 mo). At the time of the analysis, 25 patients were dead and 6 patients were alive. The median TTP was 6.1 mo (95%CI:

**Table 2** Immunity indices before and after treatment

| Group                              | Pre-treatment  | Post-treatment | P value |
|------------------------------------|----------------|----------------|---------|
| CD3 <sup>+</sup>                   | 70.44% ± 6.68% | 72.67% ± 6.22% | 0.55    |
| CD4 <sup>+</sup>                   | 35.78% ± 3.51% | 45.83% ± 2.48% | 0.016   |
| CD3 <sup>+</sup> CD8 <sup>+</sup>  | 24.61% ± 4.19% | 39.67% ± 3.38% | 0.008   |
| CD3 <sup>+</sup> CD56 <sup>+</sup> | 5.94% ± 0.87%  | 10.72% ± 0.67% | 0.001   |

**Table 3** Treatment-related adverse events (*n* = 31)

| Side effects              | <i>n</i> (%) |
|---------------------------|--------------|
| Abdominal side effects    |              |
| Abdominal pain            | 3 (9.67)     |
| Abdominal erubescence     | 5 (16.12)    |
| Abdominal lesser tubercle | 1 (3.22)     |
| Systemic side effects     |              |
| Slight fever              | 4 (12.90)    |
| Dizziness                 | 3 (9.67)     |
| Debilitation              | 6 (19.35)    |
| Nausea or vomiting        | 1 (3.22)     |
| Diarrhea                  | 2 (6.44)     |
| Tachycardia               | 1 (3.22)     |

4.8-7.2). The 3-, 6- and 9-mo and 1-year survival rates were 93.5%, 77.4%, 41.9% and 17.4%, respectively. The median OS was 8.5 mo (Figure 1).

### Typical case 1

A 57-year-old male was diagnosed with primary HCC by CT-guided aspiration biopsy of the liver in July 2010. Diffuse lesions in the liver with portal vein encroachment were observed on the CT scan. The patient also had complications of abdominal distention, debilitation, lack of appetite and emaciation. Eastern Cooperative Oncology Group (ECOG) was 2. AFP level was 201 ng/mL, alanine aminotransferase (ALT) 70 U/L, and aspartate aminotransferase (AST) 120 U/L. T lymphocyte subgroups were CD3<sup>+</sup> 76%, CD4<sup>+</sup> 22%, CD3<sup>+</sup>CD8<sup>+</sup> 17%, and CD3<sup>+</sup>CD56<sup>+</sup> 5.6%, respectively. The patient received 3 cycles of intraperitoneal CIK cells in combination with local RF hyperthermia. The patient achieved a PR. AFP fell to 98 ng/mL and ECOG increased to 1. ALT and AST fell to normal levels. T lymphocyte subgroups were CD3<sup>+</sup> 77%, CD4<sup>+</sup> 34%, CD3<sup>+</sup>CD8<sup>+</sup> 27% and CD3<sup>+</sup>CD56<sup>+</sup> 9.1%, respectively (Figure 2A and B).

### Typical case 2

A 51-year-old male was admitted to hospital due to abdominal distention and pain. The patient was diagnosed with primary hepatic carcinoma in December 2012, and underwent surgery in a local hospital with postoperative Sorafenib therapy. The patient had been experiencing obvious abdominal distention with abdominal pain, poor appetite, nausea, and emesis for 1 mo. Enhanced CT scanning showed multiple metastases in the liver, metastases in the portal lymph nodes and significant seroperitoneum. Due to the advanced stage of hepatic carcinoma, further surgical treatment and interventional therapies were inappropriate. Considering the failure

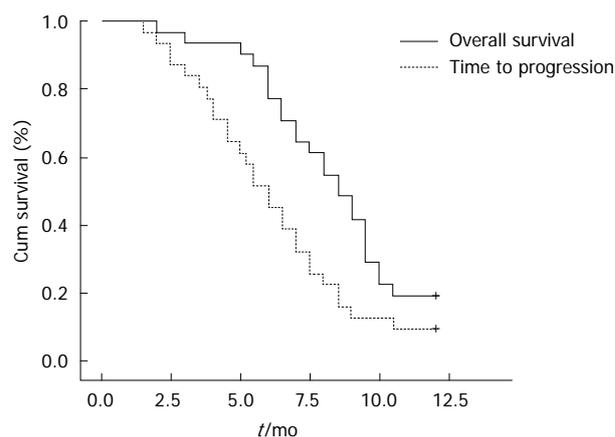

Figure 1 Time to progression and overall survival after treatment.

of targeted drug treatment, intraperitoneal perfusion of CIK cells in combination with local RF hyperthermia was administered to the patient. Before treatment, abdominal circumference was 97.5 cm. Ultrasound examination showed that the deepest portion of seroperitoneum was 8.16 cm. After 1 cycle of treatment with intraperitoneal perfusion of CIK cells in combination with local RF hyperthermia, the patient noted that abdominal distention was significantly reduced, with a decrease in abdominal circumference to 93.0 cm and seroperitoneum decreased to 5.03 cm under ultrasound examination (Figure 2C and D).

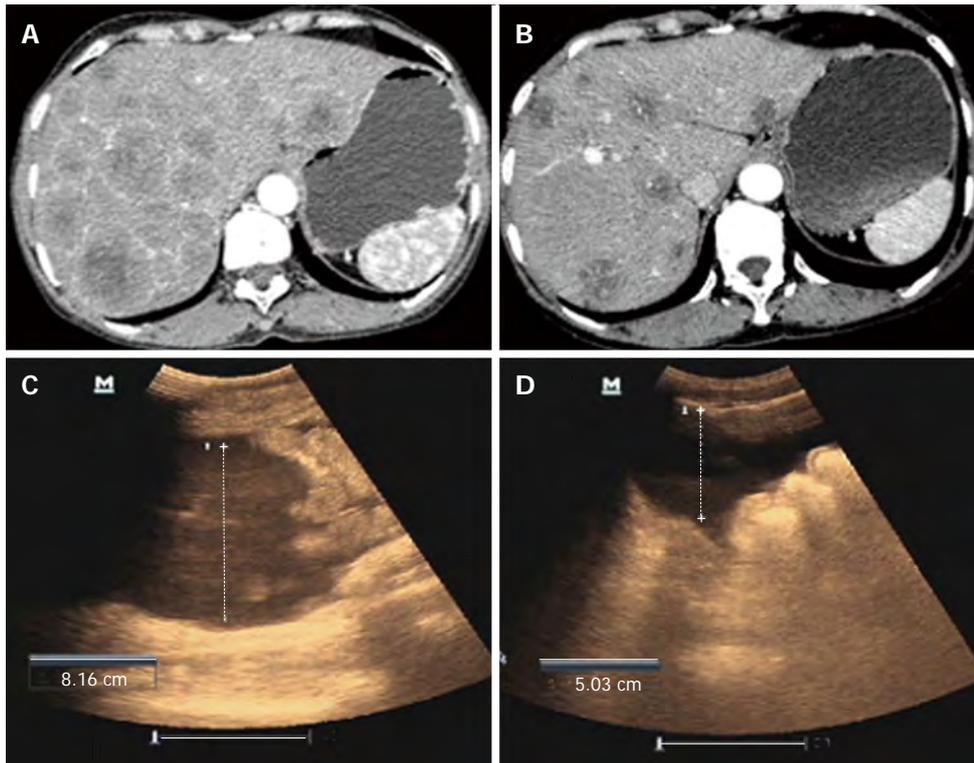

## DISCUSSION

Recently, targeted therapy and palliative chemotherapy have been the main treatment approaches for patients with advanced HCC. New targeted drugs such as sorafenib and sunitinib have improved clinical efficacy. However, the serious side effects and high costs of these drugs make it impossible for many patients to complete the entire treatment course<sup>[12,13]</sup>. Thus, it is necessary to investigate alternative therapies for patients with advanced HCC.

### Tumor killing ability of CIK cells

The special biological behavior of primary HCC, such as multiple lesions, existing hepatitis and cirrhosis, continuously suppresses cellular immunity and results in immune dysfunction. Autoimmune disorders in patients with HCC is manifested by lower levels of CD4<sup>+</sup> and CD3<sup>+</sup>CD56<sup>+</sup> cells and significantly higher levels of CD8<sup>+</sup> cells<sup>[14,15]</sup>. The ability to efficiently kill tumor cells is the ultimate requirement in immune effector candidates for adoptive immunotherapy. CIK cells have a MHC-independent tumor killing capacity in both solid and hematologic malignancies. The antitumor activity is mainly associated with a high percentage of the CD3<sup>+</sup>CD56<sup>+</sup> subset<sup>[16,17]</sup>. The exact mechanism involved in tumor recognition and killing is not completely known, but mainly involves the secretion of a cytokine to inhibit the growth of tumor cells<sup>[18-20]</sup>.

It has been demonstrated that CIK cells are effective against some solid malignancies including lung, gastro-

**Figure 2** Computed tomography scan. A: Typical case 1 with hepatocellular carcinoma before treatment; B: Typical case 1 with hepatocellular carcinoma after treatment; C: Typical case 2 with hepatocellular carcinoma before treatment; D: Typical case 2 with hepatocellular carcinoma after treatment.

intestinal and mesenchymal tumors both *in vitro* and *in vivo*<sup>[21,22]</sup>. Oliosio *et al*<sup>[23]</sup> reported 12 patients (6 advanced lymphomas, 5 metastatic kidney carcinomas and 1 HCC) who were intravenously transfused with  $28 \times 10^9$  (range,  $6 \times 10^9$  to  $61 \times 10^9$ ) CIK cells per patient during one cycle. The treatment schedule consisted of three cycles of CIK cell infusions at an interval of 3 wk. After treatment, the absolute median number of lymphocytes, CD3<sup>+</sup>, CD8<sup>+</sup> and CD3<sup>+</sup>CD56<sup>+</sup> cells significantly increased in peripheral blood. In our study, CD4<sup>+</sup>, CD3<sup>+</sup>CD8<sup>+</sup> and CD3<sup>+</sup>CD56<sup>+</sup> cells increased after treatment from  $35.78\% \pm 3.51\%$ ,  $24.61\% \pm 4.19\%$  and  $5.94\% \pm 0.87\%$  to  $45.83\% \pm 2.48\%$  ( $P = 0.016$ ),  $39.67\% \pm 3.38\%$  ( $P = 0.008$ ) and  $10.72\% \pm 0.67\%$  ( $P = 0.001$ ), respectively. Our results were similar to those of Oliosio *et al*<sup>[23]</sup>.

#### **Intraperitoneal perfusion with local hyperthermia**

The most common causes of death in patients with advanced HCC are liver failure, ascites and obstruction. Control of the abdominal tumor is the principal goal of treatment, which can prolong survival and improve quality of life. Recently, intravenous infusion of CIK cells has been widely used in the treatment of HCC. However, the concentration of CIK cells is low in tumor tissues following intravenous infusion, and the anti-tumor effect is low. In this study, in order to achieve a high concentration of CIK cells in the abdomen, CIK cells were perfused intraperitoneally instead of intravenously. Intraperitoneal perfusion of CIK cells in combination with local RF hyperthermia can improve efficacy in clinical practice. The primary reason for this may be that hyperthermia

accelerates the conjugation of CIK cells and tumor cells, which improves the reaction rate of CIK cells. Local RF hyperthermia after high-capacity perfusion of CIK cells improves the sensitivity of tumor cells, allowing CIK cells to permeate into tumor cells more effectively.

Local RF hyperthermia kills tumor cells by heating using physical energy and the temperature of tumor tissue rises to an effective treatment temperature. Studies have shown that high temperature can damage the membranes of mitochondria, lysosomes and endoplasmic reticulum and triggers the massive release of acid hydrolase from lysosomes, resulting in membranolysis, outflow of cytoplasm and death of cancer cells<sup>[24,25]</sup>. In addition, some studies have reported that hyperthermia improves immune function by stimulating the development of the anti-tumor immune effect and resolving the inhibition of blocking factors in the immune system<sup>[26]</sup>. The core points behind this treatment were to administer intraperitoneal perfusion of CIK cells to improve immune function to kill the tumor, and local hyperthermia to enhance the concentration of CIK cells which directly affect liver tumor tissues and small lesions on the abdominal wall, which can damage cancer cells and effectively reduce abdominal dropsy. Local hyperthermia plays an important role in enhancing the concentration of CIK cells which directly affect these parameters.

#### **Adverse events**

The most common adverse events in our study were low fever and slight abdominal erubescence, which resolved without treatment. No serious side effects were observed.

During the treatment process, 4 patients experienced low fever ranging from 37.5-38 °C, which resolved without treatment. This fever might have been caused by the application of IL-2. Some other symptoms, including erythema and lesser tubercle of abdominal subcutaneous fat, were observed, which were caused by high temperature and were relieved by simple symptomatic treatment. Intraperitoneal perfusion of autologous CIK cells can avoid immune rejection triggered by foreign cell infusion.

In conclusion, intraperitoneal perfusion of CIK cells in combination with local RF hyperthermia is safe and effective for advanced HCC. More clinical trials with a large sample size are warranted to provide evidence for further applications. The addition of palliative chemotherapy or targeted therapy is worthy of further investigation.

## COMMENTS

### Background

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors worldwide. Recently, integrative therapy has become a useful treatment for patients with advanced HCC. Due to the close relationship between the pathogenesis of HCC and the autoimmune system, cellular immunotherapy has been used in the clinical treatment of advanced HCC. In addition, local hyperthermia increases the role of cytokine-induced killer (CIK) cells in killing tumor tissues.

### Research frontiers

Intraperitoneal perfusion of CIK cells in combination with local radio frequency (RF) hyperthermia can improve immune function in HCC patients, shrink the tumor, and relieve discomfort such as debilitation and abdominal distention.

### Innovations and breakthroughs

Recently, intravenous infusion of CIK cells has been widely used in the treatment of HCC. However, the concentration of CIK cells is low in tumor tissues following intravenous infusion, and the anti-tumor effect is low. In their research, intraperitoneal perfusion of CIK cells in combination with local RF hyperthermia resulted in a high concentration of CIK cells in the abdominal cavity and effective killing of tumor tissues.

### Applications

The authors have been using this treatment strategy for more than 1 year. Forty-two patients accepted this treatment, of whom 31 were selected for this study. There were no serious adverse events following this treatment. A few patients showed low-grade fever or slight chest distress which resolved after symptomatic treatment. Following intraperitoneal perfusion of CIK cells in combination with local RF hyperthermia, abdominal distention resolved, tumor size diminished, and survival time was prolonged in some patients. This treatment strategy is worthy of further investigation.

### Terminology

CIK cells are alloplasmic cells with non-major histocompatibility complex (MHC) restriction anti-tumor activity which is acquired by multiple-cell factor-cultivation *in vitro* from human peripheral blood mononuclear cells. CD3<sup>+</sup>CD56<sup>+</sup> T is the main effector cell of the CIK cell group, and is also called nature killer cell-like T lympholeukocyte. These cells have powerful anti-tumor activity and MHC restriction of T lympholeukocytes. Local RF hyperthermia is used in the non-invasive treatment of malignant tissues. The difference between the complex dielectric constant (complex impedance) of malignant and healthy tissues makes it possible to select malignant tissues.

### Peer review

In this study, 31 patients with advanced HCC who could not be treated by surgical treatments or interventional therapies, were treated by CIK cell intraperitoneal perfusion in combination with RF local hyperthermia. The result showed that this treatment is safe and reliable, and worthy of further clinical studies of a larger sample. It is a new option of treatment for patients with advanced HCC.

### Abstract

**AIM:** To investigate the effect of Danzhi Jiangtang capsule (DJC) on monocyte chemoattractant protein-1 (MCP-1) mRNA expression in newly diagnosed type 2 diabetes mellitus (T2DM) subclinical vascular lesions.

**METHODS:** Sixty-two patients with newly diagnosed T2DM subclinical vascular lesions were randomly divided into a control group and treatment group of 31 cases each. Oral antidiabetic therapy with routine western medicine was conducted in both groups, and the treatment group was additionally treated with DJCs. The treatment course for both groups was 12 wk. Before and after treatment, the total efficiency and traditional Chinese medicine (TCM) syndrome score were calculated. The fasting plasma glucose (FPG), 2-h plasma glucose (2hPG), fasting insulin (FINS), insulin resis-

tance index (IRI), hemoglobin (Hb)A1c, blood lipids, and hemorheology indices were determined. In addition, the levels of vascular endothelial growth factors including thrombomodulin (TM), von Willebrand factor (vWF), P-selectin and MCP-1 mRNA were determined.

**RESULTS:** After 12 wk of treatment, the TCM syndrome score was significantly decreased compared to before treatment in both groups. After treatment, FPG, 2hPG, HbA1c, FINS, IRI, total cholesterol, triglycerides, low-density lipoprotein, high-density lipoprotein, whole blood low shear specific viscosity, plasma specific viscosity, TM, vWF, P-selectin and MCP-1 mRNA were significantly improved compared to before treatment in both groups. After treatment, the total efficiency and TCM syndrome score in the treatment group were better than in the control group. FINS, IRI, whole blood high shear specific viscosity, plasma specific viscosity, TM, vWF, P-selectin and MCP-1 mRNA level in the treatment group were significantly reduced after treatment compared with control group.

**CONCLUSION:** DJCs are efficacious in supplementing qi, nourishing yin and invigorating blood circulation, and upregulate MCP-1 mRNA expression in patients with T2DM subclinical vascular lesions.

**Key words:** Danzhi Jiangtang capsule; Type 2 diabetes mellitus; Subclinical vascular lesions; Monocyte chemoattractant protein-1

**Core tip:** The occurrence and development of type 2 diabetes mellitus (T2DM) is accompanied by an inflammatory response. Monocyte chemoattractant protein (MCP)-1 is a member of the CC chemokine subfamily, and is a key mediator of inflammation. MCP-1 also belongs to the chemokine superfamily. T2DM subclinical vascular lesions are a type of mild inflammation. En-

endothelial cell MCP-1 can be increased markedly. Danzhi Jiangtang capsule is a traditional Chinese medicine compound preparation. The technique can restrain mononuclear cell chemotactic activity by supplementing qi, nourishing yin and invigorating blood circulation, thereby preventing and treating subclinical vascular lesions.

Fang ZH, Liu Y, Bao TT, Ni YQ, Liu J, Shi GB, Wu JP, Yang JP, Zhang H. Effect of Danzhi Jiangtang capsule on monocyte chemoattractant protein-1 mRNA expression in newly diagnosed diabetes subclinical vascular lesions. *World J Gastroenterol* 2013; 19(19): 2963-2968 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i19/2963.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i19.2963>

## INTRODUCTION

The occurrence and development of type 2 diabetes mellitus (T2DM) is accompanied by an inflammatory response, which then promotes the process of T2DM. Monocyte chemoattractant protein (MCP)-1 is a member of the CC chemokine subfamily, and is a key cytokine mediator of the inflammatory response. MCP-1 also belongs to the chemokine superfamily<sup>[1]</sup>. As shown in a large number of experimental studies, MCP-1 is a risk factor for the occurrence and development of insulin resistance (IR), T2DM and related vascular complications<sup>[2]</sup>.

Danzhi Jiangtang capsule (DJC) is a traditional Chinese medicine (TCM) compound preparation, and is efficacious in supplementing qi, nourishing yin and invigorating blood circulation. In this study, we investigated the effects of DJCs on general indexes, including fasting plasma glucose (FPG), 2-h postprandial plasma glucose (2hPG), fasting insulin (FINS), insulin resistance index (IRI), hemoglobin (Hb)A1c, blood lipids, and hemorheology indicators in newly diagnosed T2DM subclinical vascular lesions, and the effects on expression of vascular endothelial growth factors including thrombomodulin (TM), von Willebrand factor (vWF), P-selectin and MCP-1 mRNA. The objective was to investigate preliminarily the mechanism of TCM on delaying vascular lesions. This study has importance for achieving a comprehensive understanding of the efficacy of DJCs and illuminating the multichannel and multitarget regulating effects of TCM on newly diagnosed T2DM subclinical vascular lesions.

## MATERIALS AND METHODS

### General data

A total of 62 outpatients and inpatients with T2DM in the Department of Metabolism and Endocrinology, First Affiliated Hospital of Anhui College of Traditional Chinese Medicine were enrolled in this study from 2009 to 2011. All patients conformed to the diagnostic criteria of diabetes according to World Health Organization (1999),

without clinical manifestations of heart, brain or kidney vascular lesions. Color Doppler ultrasound showed that the intima-media thickness of the common carotid, femoral and iliac arteries was > 0.6 cm. The exclusion criteria were as follows: patients with diabetes duration > 1 year; pregnant or lactating women; patients with metabolic disorders (*e.g.*, ketoacidosis) and complicated severe infection in the preceding month; patients complicated with a vascular lesion of the heart, brain, kidney or other region, or other severe primary diseases; patients taking anticoagulant, antiplatelet or antifibrinolytic drugs during the preceding month.

Patients were randomly divided into a control group (31 cases, 7 male and 14 female, mean age  $53.67 \pm 9.32$  years) and treatment group (31 cases, 16 male and 15 female, mean age  $51.90 \pm 10.13$  years). There was no significant differences in age, sex, FPG, 2hPG, HbA1c, FINS, body mass index and IRI between the two groups ( $P > 0.05$ ).

### Experimental methods

Basic treatments including diabetes education, alimentary control, and regular exercise were conducted in both groups. According to actual conditions, patients were treated with one or more antidiabetic drugs, with uniform administration in both groups. The antidiabetic drugs were as follows: metformin hydrochloride tablets (Glucophage; 0.5 g; Shanghai Squibb Pharmaceutical Co. Ltd., China), Acarbose (Glucoba; 50 mg; Bayer Pharmaceutical Co. Ltd., Leverkusen, Germany), pioglitazone hydrochloride (Kasiping; 15 mg; East China Pharmaceutical Group, Zhejiang, China), gliclazide sustained release tablets (Gliclazide tablets; 30 mg; Servier Pharmaceutical Company, Paris, France), and repaglinide tablets (NovoNorm; 1 mg; Novo Nordisk Pharmaceutical Industries, Bagsvaerd, Denmark). In the treatment group, in addition to the oral administration with the above western medicines, the patients were treated with DJCs (provided by the Pharmaceutical Formulations Centre, First Affiliated Hospital of Anhui College of Traditional Chinese Medicine; 1.8 g of effective extract in each capsule) at a dose of five capsules, three times daily (a total daily dose of 15 capsules).

### Observational indexes

**Blood glucose and blood lipid:** Blood glucose was determined by the glucose hexokinase method. Total cholesterol (TC), triglycerides (TG), low-density lipoprotein (LDL) and high-density lipoprotein (HDL) with fasting for > 12 h were determined using a Hitachi-7600 fully automatic biochemical analyzer.

**Hemorheology indices:** High shear specific viscosity and low shear specific viscosity of whole blood, plasma specific viscosity, hematocrit and fibrinogen were determined using a rotary whole blood viscometer and plasma viscometer in the Experimental Centre, First Affiliated Hospital of Anhui College of Traditional Chinese Medicine.

**Vascular endothelial growth factors:** Fasting venous

**Table 1 Comparison of fasting plasma glucose, 2-h plasma glucose, haemoglobin A1c, fasting insulin, insulin resistance index, total cholesterol, triglycerides, low density lipoprotein, high density lipoprotein, haemorheology indices, thrombomodulin, von Willebrand factor, P-selectin levels and monocyte chemoattractant protein-1 mRNA levels**

<sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs before treatment; <sup>c</sup> $P < 0.05$  vs control group. FPG: Fasting plasma glucose; 2hPG: 2-h plasma glucose; HbA1c: Haemoglobin A1c; FINS: Fasting insulin; IRI: Insulin resistance index; TC: Total cholesterol; TG: Triglycerides; LDL: Low density lipoprotein; HDL: High density lipoprotein; TM: Thrombomodulin; vWF: von Willebrand factor; MCP-1: Monocyte chemoattractant protein-1.

blood was obtained during the early morning. After anticoagulation with ethylenediaminetetraacetic acid and centrifugation (4 °C, 3000 g, 10 min), the plasma was separated and stored at -70 °C. TM was quantitatively determined using an enzyme-linked immunosorbent assay (ELISA) kit (ADL Company, CA, United States). vWF was quantitatively determined by the double antibody sandwich ELISA method (Shanghai Sun Biotechnology). P-selectin was quantitatively determined by the ABC-ELISA double antibody sandwich method (R and D Systems, Minneapolis, MN, United States).

**MCP-1 mRNA:** Expression of serum MCP-1 mRNA was determined using the reverse transcriptase polymerase chain reaction (Promega, Madison, WI, United States) according to the manufacturer's instructions.

### Statistical analysis

Statistical analysis was performed using SPSS 17.0 statistical software. Non-normally distributed data were logarithmically transformed to normally distributed data. Normally distributed measurement data are expressed as mean ± SD. Analysis of variance was performed for comparisons of multiple means. Student's *t* tests were used to analyze the differences between two samples.  $\chi^2$  tests were conducted to compare the enumerated data.  $P < 0.05$  or  $P < 0.01$  was considered to be statistically significant.

## RESULTS

### Comparison of blood glucose and blood lipid levels

Before treatment, there was no significant difference in FPG, 2hPG, HbA1c, FINS, IRI, TC, TG, LDL and HDL

level between the two groups ( $P > 0.05$  for all comparisons). After treatment with western medicines, the above indexes were significantly improved in both groups ( $P < 0.05$  or  $P < 0.01$ ). In addition, after treatment, FINS and IRI levels in the treatment group were significantly lower than in the control group ( $P < 0.05$ ), and HDL in the treatment group was significantly higher than in the control group ( $P < 0.05$ ) (Table 1).

### Comparison of hemorheology indices

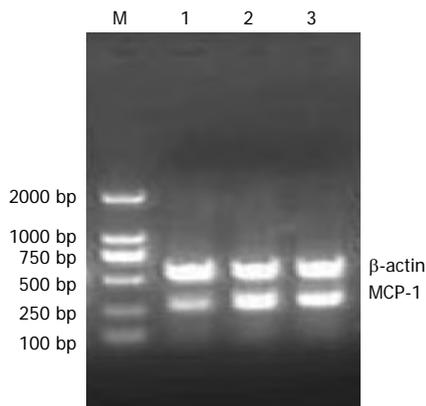

Before treatment, there was no significant difference in high shear specific viscosity and low shear specific viscosity of whole blood, plasma specific viscosity, hematocrit, and fibrinogen level between the two groups ( $P > 0.05$  for all comparisons). After treatment, the whole blood high shear specific viscosity, plasma specific viscosity and hematocrit in the treatment group were significantly lower than in the control group ( $P < 0.05$ ) (Table 1).

### Comparison of TM, vWF and P-selectin levels

In the control group, after treatment, TM, vWF and P-selectin levels decreased, but the differences compared with baseline values before treatment were not significant ( $P > 0.05$ ). In the treatment group, the above indexes were significantly reduced after treatment ( $P < 0.05$  or  $P < 0.01$ ) and compared with the control group ( $P < 0.05$  or  $P < 0.01$ ) (Table 1).

### Comparison of MCP-1 mRNA levels

Before treatment, there was no significant difference in MCP-1 mRNA levels between the two groups ( $P > 0.05$ ). After treatment, the MCP-1 mRNA level in the treatment group was significantly lower than before ( $P < 0.01$ ) and

**Figure 1** Electropherogram of monocyte chemoattractant protein-1 mRNA obtained by reverse transcription-polymerase chain reaction. MCP-1: Monocyte chemoattractant protein-1; M: Marker; 1: Normal group; 2: Control group; 3: Treatment group.

compared with control group ( $P < 0.05$ ) (Figure 1 and Table 1).

## DISCUSSION

The disease course of newly diagnosed T2DM is  $< 1$  year. There are different degrees of vascular lesions in 50% of patients with newly diagnosed T2DM. Subclinical vascular lesions exist in some patients with newly diagnosed T2DM, but the clinical symptoms are atypical<sup>[3-5]</sup>. They are the pathological basis of diabetic complications, with an extensive scope. Once the subclinical vascular lesions occur, they develop rapidly and both large and small vessels, arteries, capillaries and veins may be involved, with complicated lesions in many organs, such as angiopathy, brain, kidney, eyeground, nerve and skin. T2DM subclinical vascular lesions are caused by many factors including abnormal glucose metabolism, IR, lipid metabolism disorders, inflammatory factors, and oxidative stress<sup>[6,7]</sup>. Vascular endothelial injury is the initiating step of T2DM subclinical vascular lesions, and the anatomical endothelial layer is also the first involved site. During T2DM, continued hyperglycemia and high capillary pressure can cause vascular endothelial cell injury and dysfunction, changing angiostasis and hemodynamics, activate the coagulation system and platelets, and increase the vascular permeability, thus leading to a series of pathological changes<sup>[8]</sup>. Therefore, studying the change in endothelial cell function is beneficial for further preventing the occurrence and development of T2DM subclinical vascular lesions.

In recent years, TM has been confirmed as a molecular marker of endothelial cell injury<sup>[9,10]</sup>. In addition, it can be used as a marker for judging the severity of atherosclerosis of peripheral arteries and coronaries, and a sensitive detection index for the occurrence of vascular complications<sup>[11]</sup>. As found in prospective studies, vWF is involved in blood coagulation, and can promote platelet adhesion<sup>[12]</sup>. It is an important marker for predicting early subclinical endothelial cell injury in T2DM and develop-

ment of urinary albumin excretion rate<sup>[13]</sup>. In addition, it is an important risk factor for new microvascular lesions. P-selectin has been a research hotspot for vascular lesions in recent years. It is an important marker of endothelial cell injury and platelet activation, and is considered to be an important factor in the initial pathological process of atherosclerosis<sup>[14]</sup>.

MCP-1 is one member of the CC chemokine subfamily, and is a key cytokine mediator of the inflammatory response<sup>[15]</sup>. In T2DM, high-level blood glucose, non-enzymatic glycosylated protein, angiotensin, oxidative stress, interleukin-1, and tumor necrosis factor- $\alpha$  can all up-regulate MCP-1 expression<sup>[16-19]</sup>. MCP-1 can specifically induce blood monocytes to enter the endothelium of the lesion. This is an important mechanism in the occurrence and development of T2DM vascular lesions<sup>[20]</sup>. MCP-1 mainly attracts monocytes and T lymphocytes, and induces monocytes and endothelial cells to express adhesion molecules. It can promote various inflammatory cells, especially monocytes, to aggregate in the lesion sites, and respond to stimulation of the inflammatory cytokines<sup>[21]</sup>. In addition, MCP-1 can promote peripheral blood mononuclear cells to adhere, chemoattract and migrate to the intima, and then phagocytose lipids and transform into foam cells<sup>[22]</sup>. The activated leukocytes and vascular wall cells can release a variety of growth factors, which promote vascular smooth muscle cell proliferation, stimulate inflammation<sup>[23]</sup>, and participate in the occurrence and development of atherosclerosis. It has been found that MCP-1 plays an important role in atherosclerosis in diabetes, and can be used as a useful index for predicting T2DM subclinical atherosclerosis<sup>[24]</sup>. At the same time, MCP-1 is considered to be a potential biochemical marker for reflecting early atherosclerotic changes and prognosis<sup>[25]</sup>.

Therefore, MCP-1 is closely related to the occurrence and development of T2DM vascular lesions. Further study of MCP-1 will enrich the theoretical basis for pathogenesis of T2DM vascular lesions. Analysis of the chemokine dynamic change, regulatory mechanism and interactions, and treatment aimed at chemokines and receptors is a new method for therapy of T2DM vascular complications. The deepening awareness of the complexity of the chemokine network has provided new methods and means for prevention and treatment of T2DM vascular lesions.

TCM believes that the prethrombotic status of T2DM is similar to the blood stasis syndrome of emaciation-thirst disease. The pathogenesis of emaciation-thirst disease is that the dryness-heat, impairment of yin, and body fluid scorching will cause blood viscosity and blood stagnation. The long-term yin deficiency injures the healthy qi, leading to qi and yin deficiency and weakness, which aggravate the blood stasis. Deficiency of yin affects yang, and insufficiency of yang brings about cold syndrome. The cold coagulation causes blood stasis. The blood stasis is present throughout the disease course, and is a common pathological product and pathogenic factor of emaciation-thirst disease. In the treatment of this dis-

ease, supplementing qi, nourishing yin, invigorating blood circulation and dissolving stagnant blood should be carried out, and the treatment emphasis should be focused on regulating qi-blood circulation and improving blood circulation. DJCs are composed of Radix Pseudostellariae, Radix Rehmanniae, Cortex Moutan, Dodder, Alisma, leech and others. Radix Pseudostellariae can invigorate the qi of the spleen and kidney. Radix Rehmanniae can nourish the yin of the spleen and kidney. Dodder can tonify the kidney to arrest spontaneous emission. Cortex Moutan and leech can promote qi circulation, invigorate blood circulation, dissolve stagnant blood, and resolve kidney collateral obstruction. Alisma can clear heat and purge phlegm. The whole prescription can supplement qi and nourish yin, invigorate blood circulation and dissolve stagnant blood, thus achieving the efficacy of balancing yin and yang, dispelling blood stasis, and making the kidney pulse unobstructed. Modern pharmacological research shows that Radix Pseudostellariae, Radix Rehmanniae and Alisma have certain antidiabetic and antihypertensive effects. Moutan bark can inhibit a cyclooxygenase reaction, thus inhibiting platelet aggregation. The hirudin contained in leech can inhibit the effect of thrombin on fibrinogen, impede blood coagulation, and prevent thrombus formation. In addition, Leech also secretes a histamine-like substance, which can directly expand the blood vessels, activate plasmin, and inhibit collagen synthesis, thus reducing the blood viscosity and improving the hemorheology.

Results of this study have shown that, after treatment with DJCs, FINS and IRI levels are significantly lower than those obtained from basic treatment, with an increase in HDL level. In addition, after treatment with DJCs, the whole blood high shear specific viscosity, plasma specific viscosity and hematocrit, as well as TM, vWF and P-selectin expression levels are significantly reduced, with downregulated peripheral blood MCP-1 mRNA expression. This indicates that DJCs can alleviate lipid metabolism disorders, downregulate expression of TM, vWF, P-selectin and MCP-1 mRNA, lower whole blood viscosity and plasma specific viscosity, reduce hematocrit, antagonize platelet activation, inhibit platelet aggregation, and protect vascular endothelial cells, thus intervening in the newly diagnosed T2DM subclinical vascular lesions. It is believed that this therapy, by supplementing qi, nourishing yin and invigorating blood circulation, can enhance the anticoagulant and fibrinolytic activity, intervene in the hypercoagulable state, and improve the function of impaired endothelial cells. This has important significance in delaying vascular complications associated with T2DM.

## COMMENTS

### Background

The occurrence and development of type 2 diabetes mellitus (T2DM) is accompanied by an inflammatory response, which in turn promotes the process of T2DM. Monocyte chemoattractant protein (MCP)-1 is a member of the CC chemokine subfamily, and is a key cytokine mediator of the inflammatory response. MCP-1 also belongs to the chemokine superfamily. As shown in a large

number of experimental studies, MCP-1 is a risk factor for the occurrence and development of insulin resistance, T2DM and related vascular complications.

### Research frontiers

The disease course of newly diagnosed T2DM is < 1 year. There are different degrees of vascular lesions in 50% of patients with newly diagnosed T2DM. Subclinical vascular lesions exist in some patients with newly diagnosed T2DM, but the clinical symptoms are atypical. They are the pathological basis of diabetic complications, with an extensive scope.

### Innovations and breakthroughs

This study has important significance for comprehensive understanding of the efficacy of Danzhijiangtang capsules (DJCs) and illuminating the multichannel and multitarget regulating effects of traditional Chinese medicine on newly diagnosed T2DM subclinical vascular lesions.

### Applications

DJCs are efficacious in supplementing qi, nourishing yin and invigorating blood circulation, and can upregulate MCP-1 mRNA expression in patients with T2DM subclinical vascular lesions.

### Terminology

In recent years, thrombomodulin has been confirmed as a molecular marker of endothelial cell injury. In addition, it can be used as a marker for judging the atherosclerosis severity of peripheral arteries and coronaries, and a sensitive detection index for the occurrence of vascular complications.

### Peer review

This manuscript describes a traditional Chinese medicine DJCs for treatment of T2DM subclinical vascular lesions, and it has significant research interest.

### Abstract

**AIM:** To characterize the two components of theory of mind (ToM) in patients with esophageal cancer combined with depression.

**METHODS:** Sixty-five patients with esophageal cancer combined with depression (depressed group) and 62 normal controls (control group) were assessed using reading the mind in the eyes test, faux pas task, verbal fluency test, digit span test and WAIS IQ test. The depressed group was divided into two subgroups including psychotic depressed (PD) group (32 cases) and nonpsychotic depressed (NPD) group (33 cases).

The clinical symptoms of patients were assessed using Beck depression inventory version II and brief psychiatric reacting scale (BPRS).

**RESULTS:** There was a significant difference between the depressed group and the control group on tasks involving ToM social perceptual components (mind reading:  $t = 7.39, P < 0.01$ ) and tests involving ToM social cognitive components (faux pas questions:  $t = 13.75, P < 0.01$ ), respectively. A significant difference was also found among the PD group, the NPD group and the control group on mind reading ( $F = 32.98, P < 0.01$ ) and faux pas questions ( $\chi^2 = 78.15, P < 0.01$ ), respectively. The PD group and NPD group performed worse than normal group controls both on mind reading and faux pas questions ( $P < 0.05$ ). The PD group performed significantly worse than the NPD group on tasks involving ToM (mind reading:  $F = 18.99, P < 0.01$ ; faux pas questions:  $F = 36.01, P < 0.01$ ). In the depressed group, there was a negative correlation between ToM performances and BPRS total score (mind reading:  $r = -0.35, P < 0.01$ ; faux pas questions:  $r = -0.51, P < 0.01$ ), and between ToM performances and hostile suspiciousness factor score (mind reading:  $r = -0.75, P < 0.01$ ; faux pas questions:  $r = -0.73, P < 0.01$ ), respectively.

**CONCLUSION:** The two components of ToM are both impaired in patients with esophageal cancer combined with depression. This indicates that there may be an association between ToM deficits and psychotic symptoms in clinical depression.

Theory of mind deficits in patients with esophageal cancer combined with depression. *World J Gastroenterol* 2013; 19(19): 2969-2973 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i19/2969.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i19.2969>

## INTRODUCTION

Depression exists in about 24% of patients with esophageal cancer<sup>[1]</sup>. It is found that there are theory of mind (ToM) deficits in patients with depression<sup>[2-4]</sup>. In cognitive neuropsychiatry, the ToM is divided into a social perceptual component and a social cognitive component<sup>[5,6]</sup>, in terms of information processing theories. In recent years, the social cognitive impairment caused by depression and its potential cognitive neuropsychological mechanisms have become a research hotspot<sup>[2-4]</sup>.

It is reported that the occurrence of esophageal cancer combined with depression is closely related with cognition in disease<sup>[7-9]</sup>. Whether the cognitive biases include ToM deficits or not is not clear. In this study, the ToM deficits in patients with esophageal cancer combined with depression were investigated, and the relation between ToM deficits and psychotic symptoms was discussed.

## MATERIALS AND METHODS

### Research objects

Sixty-five patients with esophageal cancer combined with depression in Changzhou Second People's Hospital Affiliated to Nanjing Medical University (Changzhou, China) were studied from January to December in 2011. Their beck depression inventory version II (BDI-II)<sup>[10]</sup> scores were not less than 5. All patients had an education background of junior middle school and above. They were right-handed and had normal eyesight and hearing. There was no patient with a medical history of head trauma, central nervous system disease, metastatic brain tumor, mental illness or substance dependence. No patient had been treated with chemotherapy.

The patients were divided into a psychotic depressed (PD) group (32 cases) and a nonpsychotic depressed (NPD) group (33 cases), according to whether or not patients had psychotic symptoms [the brief psychiatric reacting scale (BPRS)<sup>[11]</sup> total score was > 35]. Psychotic symptoms were distinguished from schizophrenia. The ages of patients were 28-60 years, with an average age of  $48.50 \pm 4.53$  years. They had obtained 9-16 years of education, with an average education duration of  $12.57 \pm 1.64$  years. The average age of the NPD group and the PD group was  $45.00 \pm 5.02$  and  $46.28 \pm 4.19$  years, respectively. The average duration of education in the NPD

group and the PD group was  $12.18 \pm 1.06$  and  $11.37 \pm 1.25$  years, respectively.

The control group consisted of 62 cases of college students, physicians and people with normal physique. They had no medical history of neurological disease, mental illness, substance abuse, or family psychiatry. They had an education background of junior middle school and above. They were right-handed and had normal eyesight and hearing. Their ages were 27-62 years, with an average age of  $47.65 \pm 4.64$  years. The duration of education was 9-16 years, with an average education duration of  $11.59 \pm 2.01$  years.

All research participants had signed informed consent before enrolling in this study. The patients had obtained the agreement of guardians. There was no significant difference in gender, age, or duration of education between the depressed group and the control group ( $P > 0.05$ ) or between the PD group, the NPD group and the control group ( $P > 0.05$ ). The difference in disease course between the NPD group and the PD group was not statistically significant ( $t = 0.69$ ,  $P > 0.05$ ).

### Reading the mind in the eyes test

The reading the mind in the eyes test reflected the social perceptual component of ToM. It required the participants to conduct a perceptual processing of the mental activity status of the character in the eye area, and select one word from four alternatives which could most accurately reflect the character's mental activity status. The gender recognition task was used as a control task, which required the participant to recognize the gender of the character in the eye area. It reflected the perceptual processing of general social cues. Five min of learning of alternative vocabulary annotations was performed before test. One score was obtained for each correct answer. For a total of 34 questions (17 male and 17 female), there was a total score of 34 for reading the mind in the eyes test and the gender recognition task, respectively<sup>[12-14]</sup>.

### Faux pas task

The faux pas task (faux pas questions) belonged to the social cognitive component of ToM. It required the research object to plot the mental activity status of the character in the story and judge whether or not the character had said the words which should not be said or the embarrassing words, according to the storyline. The understanding of general text content in story was used as a control question. It reflected the understanding of the story content, and comprised 20 little stories (10 faux pas stories and 10 stories without faux pas). There were 2 faux pas questions and 2 control questions for each story. One score was obtained for each correct answer. The total score for faux pas questions and control questions was 20 and 40, respectively<sup>[13-15]</sup>.

### Clinical evaluation and neuropsychological test

The clinical symptoms of patients were assessed using BDI-II and BPRS ( $K = 0.83$ ). The WAIS-IQ test<sup>[16]</sup>, digit

<sup>1</sup>*t* test,  $P < 0.01$  vs NPD group; <sup>2</sup>Bonferroni test or Mann-Whitney *U* test,  $P < 0.05$  vs control group; <sup>3</sup>*t* test,  $P < 0.01$  or  $0.05$  vs NPD group. VFT: Verbal fluency test; DST: Digit span test; PD: Psychotic depressed; NPD: Nonpsychotic depressed.

span test (DST)<sup>[17]</sup> and verbal fluency test (VFT)<sup>[18]</sup> were conducted on all research objects. The DST included the recitation and inverted recitation of digits. The total score was expressed as the sum of two recitation scores. The VFT required the participant to say as many names as possible of vegetables, fruits and animals. One score was obtained for each correct answer. There was no score for duplicated names.

### Statistical analysis

Statistical analysis was performed using SPSS 13.0 statistical software. The  $\chi^2$  test, independent samples *t* test, single factor analysis of variance (using Bonferroni correction for multiple comparisons) and Kruskal-Wallis test (using Mann-Whitney *U* test for multiple comparisons) were used to compare data according to the different types of variables. In the depressed group, the analysis of covariance was conducted on ToM performance using the BDI-II score as a covariant, and the partial correlation analysis was conducted between ToM performance and BPRS total score, and between ToM performance and other factor scores, respectively.

## RESULTS

### Comparisons of general data

There was no significant difference in IQ score between the depressed group and the control group ( $t = 0.52$ ,  $P > 0.05$ ). It was the same with IQ score among the NPD group, PD group and control group ( $F = 0.12$ ,  $P > 0.05$ ). The BDI-II score ( $t = 6.77$ ,  $P < 0.01$ ), BPRS score ( $t = 6.78$ ,  $P < 0.01$ ), anxiety-depression factor score ( $t = 3.56$ ,  $P < 0.01$ ) and hostile suspicion factor score ( $t = 10.95$ ,  $P < 0.01$ ) in the PD group were significantly higher than those in the NPD group. The differences in other factors scores were not significant between the two groups ( $P > 0.05$ ). Results were shown in Table 1.

### Comparisons of neuropsychological test performance

As shown in Table 2, the VFT score in the depressed group was significantly lower than that in the control group ( $t = 4.34$ ,  $P < 0.01$ ), but there was no significant difference in DST score between the two groups ( $t = 0.75$ ,  $P > 0.05$ ). The differences in VFT score among the NPD group, PD group and control group were statistically significant ( $F = 15.56$ ,  $P < 0.01$ ). The VFT score in the PD group was significantly lower than that in the control group and the NPD group ( $P < 0.05$ ), respectively, and there was no significant difference between the NPD group and the control group ( $P > 0.05$ ).

### Comparisons of ToM test performances

There was a significant difference between the depressed group and control group on tasks involving a ToM social perceptual component (mind reading:  $t = 7.39$ ,  $P < 0.01$ ) and tests involving a ToM social cognitive component (faux pas questions:  $t = 13.75$ ,  $P < 0.01$ ), respectively. But there was no significant difference for the gender recognition score and control questions score ( $t = 0.47$ ,  $P > 0.05$ ;  $t = 0.52$ ,  $P > 0.05$ ), respectively. A significant difference was also found among PD group, NPD group and control group on mind reading ( $F = 32.98$ ,  $P < 0.01$ ) and faux pas questions ( $\chi^2 = 78.15$ ,  $P < 0.01$ ). Results of multiple comparisons showed that the PD group was worse than the NPD group and the NPD group was worse than the control group on mind reading ( $P < 0.05$  for both). In addition, on faux pas questions, the PD group performed worse than the control group and the NPD group, respectively, (Mann-Whitney *U* = 153.08,  $Z = -7.38$ ,  $P < 0.05$ ; Mann-Whitney *U* = 127.95,  $Z = -4.26$ ,  $P < 0.05$ ), and the NPD group performed worse than the control group (Mann-Whitney *U* = 153.13,  $Z = -6.81$ ,  $P < 0.05$ ). In addition, the PD group performed significantly worse than the NPD group on tasks involving ToM (mind reading:  $F = 18.99$ ,  $P < 0.01$ ; faux pas questions:  $F = 36.01$ ,  $P < 0.01$ ).

### Partial correlation analysis between ToM performance and BPRS score

In the depressed group, the faux pas questions score was positively correlated with the mind reading score ( $r = 0.56$ ,  $P < 0.01$ ). There was a negative correlation between ToM performances and BPRS total score (mind reading:  $r = -0.35$ ,  $P < 0.01$ ; faux pas questions:  $r = -0.51$ ,  $P < 0.01$ ), and between ToM performances and hostile suspiciousness factor scores (mind reading:  $r = -0.75$ ,  $P < 0.01$ ; faux pas questions:  $r = -0.73$ ,  $P < 0.01$ ), respectively. There was no correlation between ToM performances and other factors score related to BPRS ( $P > 0.05$ ).

## DISCUSSION

This study aims to investigate the components of ToM in patients with esophageal cancer combined with depression. Results show that the depressed group performed worse than the control group on tasks involving ToM social perceptual components and test involving ToM social cognitive components, respectively. This suggests that the ToM deficits exist in patients with esophageal cancer combined with depression. These results are in accordance with the studies of Inoue *et al.*<sup>3,41</sup> and Lee *et al.*<sup>191</sup>, in which ToM deficits are found in patients with depression in ToM tests.

In this study, there are impairments in the social perceptual component and social cognitive component of ToM. The social perceptual component of ToM occurs mainly in the right cerebral hemisphere, and the left cerebral hemisphere is mainly responsible for the social cognitive component<sup>16,121</sup>. This indicates that there are bilateral brain impairments in patients with esophageal cancer combined with depression. These results are similar to those of the study by Rotenberg<sup>201</sup> which suggests that depression is related not only to right hemisphere dysfunction, but also to left hemisphere prefrontal hypo-function. This indicates that there is a cognitive neuropsychology mechanism of bilateral brain impairments for depression.

In this study, the ToM performances in the PD group are significantly worse than those in the NPD group. Results of partial correlation analysis show that there was a negative correlation between ToM performances and BPRS total score, and between ToM performances and hostile suspiciousness factor score, respectively. This indicates that there is a positive correlation between ToM deficits and psychiatric symptoms in clinical depression. Therefore, early detection and intervention of ToM deficits and psychiatric symptoms in patients with esophageal cancer combined with depression is helpful for reducing the perniciousness of disease.

There is no metastatic brain tumor or chemotherapy in these patients, which has purified the samples to a certain extent. But the remote effects of tumors on neuropsychiatric function can not be excluded. Therefore, the follow up is very important for enriching and improving the final results.

## COMMENTS

### Background

Twenty-four percent of esophageal cancer patients also have depression, which may aggravate the disease condition and affect the treatment and rehabilitation. Previous studies suggest that there are a variety of cognitive disorders including theory of mind (ToM) deficits in patients with depression. The occurrence of esophageal cancer complicated with depression is closely related to cognition on disease. Whether cognitive biases include ToM deficits is not clear.

### Research frontiers

ToM deficits are social cognitive disorders. In this study, ToM deficits in esophageal cancer patients complicated with depression are observed using "Reading the Mind in the Eyes" test and Faux pas Task.

### Innovations and breakthroughs

Previous studies on cognitive impairment in esophageal cancer patients complicated with depression mainly focus on episodic memory impairment, executive function decline, psychomotor slowing and attention deficits, except ToM deficits. In this study, ToM deficits in esophageal cancer patients complicated with depression have been investigated. This contributes to prevention and treatment of esophageal cancer with depression, and improvement of patient's social adaptability.

### Applications

Results of this study can be applied to preventing and treating esophageal cancer with depression, and improving the rehabilitation level and social adaptability of patients.

### Terminology

ToM refers to the knowledge system on speculation of psychological state, namely the cognitive system on judgment of psychological state such as belief, intention, wish, need, motive and emotion. It is one of the most basic abilities of an individual for adapting into society. In cognitive neuropsychiatry, ToM is divided into a social perceptual component and social cognitive component, in terms of information processing theory.

### Peer review

This is good research. It finds ToM deficits in esophagus cancer patients complicated with depression, and has analyzed the damage characteristics of two subcomponents. This study is helpful for clinical assessment of cognitive disorders in esophageal cancer patients complicated with depression, and prevention and treatment of disease. In addition, it can provide new approaches for improving the social adaptabilities of patients.

### Abstract

Hepatic hemangiomas are the most common benign tumor of the liver. Most hepatic hemangiomas remain asymptomatic and require no treatment. Giant hepatic hemangiomas with established complications, diagnostic uncertainty and incapacitating symptoms, however, are generally considered an absolute indication for surgical resection. We present a case of a giant hemangioma with intestinal obstruction following transcatheter arterial embolization, by which the volume of the hemangioma was significantly reduced, and it was completely resected by a left hepatectomy. A 21-year-old Asian man visited our hospital for left upper quadrant pain. Examinations at the first visit revealed a left liver hemangioma occupying the abdominal cavity, with a maximum diameter of 31.5 cm. Embolization of the left hepatic artery was performed and confirmed a decrease in its size. However, the patient was readmitted to our hospital one month after embolization for intestinal obstruction. A left hepatectomy was completed through a herringbone incision, and safely removed a giant hemangioma of 26.5 cm × 19.5 cm × 12.0 cm in

size and 3690 g in weight. Pre-operative arterial embolization is effective for reducing tumor size, but a close follow-up to decide the time for hepatectomy is important.

### INTRODUCTION

Liver hemangiomas are the most common benign tumors of the liver, with an estimated prevalence of 3%-20%<sup>[1-3]</sup>. Most of them are small in size (< 4 cm in diameter) and asymptomatic and are discovered incidentally during

screening tests by modern diagnostic procedures. Giant hemangiomas are defined as tumors with a diameter > 4 cm, and symptoms rarely appear unless the tumor size exceeds 4 cm<sup>[4-6]</sup>. Although the majority of hepatic hemangiomas remain asymptomatic, symptomatic hepatic hemangiomas can present with abdominal pain, hemorrhage, biliary compression, or a consumptive coagulopathy.

A range of treatment options exists for liver hemangiomas, from observation to various radiological and surgical procedures. When treatment is needed, surgical excision of the hemangioma is most effective, and associated with low morbidity and mortality<sup>[7,8]</sup>. Other treatments, including transcatheter arterial embolization (TAE)<sup>[9]</sup>, arterial ligation<sup>[10]</sup>, radiotherapy<sup>[11]</sup>, radiofrequency ablation<sup>[12]</sup>, corticosteroid therapy<sup>[13]</sup>, and liver transplantation<sup>[14,15]</sup>, have been employed for large unresectable lesions. Apart from liver transplantation, however, the long-term effect of these methods usually cannot be anticipated.

Here, we report a case of a giant hemangioma with intestinal obstruction following TAE treatment, by which the volume of the hemangioma was significantly reduced, and it was completely resected by a left hepatectomy.

## CASE REPORT

A 21-year-old Asian man visited a local hospital for left upper quadrant pain as the chief complaints. Ultrasonography, performed during the visit, detected huge hypoechoic lesions, and under the diagnosis of a giant hemangioma, he was recommended for surgery and transferred to our hospital. The patient's past or family medical history was unremarkable. Physical examination revealed a grossly distended abdomen without a fluid wave, and tenderness and bounce pain in the left upper quadrant.

On admission, the patient's laboratory values were notable for an international normalized ratio of 1.16, a decreased fibrinogen level of 1.99 g/L (normal range, 2.0-4.0) and D-dimer levels of 8.12 mg/L fibrinogen equivalent unit (normal range, < 0.55 mg/L). The results of blood routine and liver function tests were normal, including a total bilirubin level of 0.99 mg/dL, an albumin level of 40.2 g/L, and an indocyanine green retention rate at 15 min of 5.6%. Serum tumor markers were all within normal range.

Multi-detector computed tomography (MDCT) on admission revealed a huge hemangioma, 31.5 cm × 24.8 cm × 11.1 cm, located on the left liver, and replacing the parenchyma of the left liver. His abdomen was distended by the huge hemangioma extending to the pelvis. The non-contrast phase showed a homogenous hypodense lesion contrasted with the surrounding liver parenchyma. On arterial phase images, the lesion remained hypodense relative to normal liver, but early central enhancement was detected. On delayed phase images, the lesion showed progressive fill-in. These findings indicated a giant hemangioma. The left hepatic artery and its branches were extremely stretched, and the left portal vein was compressed and occluded by the tumor. The left hepatic

duct was slightly dilated as a result of compression by the hemangioma. The left hepatic vein was completely occluded, while the hepatic vena cava and the middle and right hepatic veins remained patent (Figure 1A-C). The gastrointestinal tract was compressed with no sign of intestinal obstruction. Volumetric analysis revealed a tumor volume of 6503 mL and a right hemiliver volume of 1140 mL. The findings of MDCT were further confirmed by magnetic resonance imaging (Figure 2).

TAE of the left hepatic artery was performed with lipiodol. Thereafter, we planned to calculate and investigate the tumor volume, anatomical positions, and recanalizations by dynamic MDCT once a month, not to misjudge the timing of operation. However, the patient was readmitted to our emergency department one month after TAE, with abdominal pain for two days and clinical characteristics of intestinal obstruction. MDCT on admission revealed the thickening and swelling of the small bowel, dilatation and multiple liquid gas level of the lower part of esophagus, stomach and small bowel, and the colon collapsed. Volumetric analysis revealed that the tumor volume had decreased to 3988 mL (Figure 1D-F). The patient was initially managed conservatively by gastrointestinal decompression and intravenous therapy. Close observation and timely treatment were conducted. The patient's condition improved in 7 d.

The remarkable volume reduction of the tumor allowed for a safe approach to the portal vein and hepatic artery. Through a herringbone incision, a left hepatectomy was safely conducted after the ligation of left hepatic artery, middle hepatic artery and left branch of portal vein. There were extensive adhesions formed between the hemangioma and the jejunum, ileum, sigmoid colon, peritoneum and omentum. No dilated intestinal loops were found. The duration of operation was 280 min and intraoperative blood loss was 400 mL. The resected tumor was 26.5 cm × 19.5 cm × 12.0 cm in size and 3690 g in weight (Figure 3). Histologically, it was diagnosed as a cavernous hemangioma with local subcapsular necrosis, calcification and fibrous tissue proliferation.

The patient's post-operative course was uneventful and he was discharged from the hospital 16 d after surgery. At 6 mo following surgery, he enjoys an improved quality of life with normal liver function.

## DISCUSSION

Cavernous hemangiomas of the liver are benign, and usually small (< 4 cm) in size, but when they are larger than 4 cm in diameter, they are classified as giant cavernous hemangiomas<sup>[16]</sup>. They arise from the mesoderm and are composed of blood-filled cavernous spaces of varying size lined with a single layer of flat endothelial cells, which may be separated by fibrous septa of variable thickness<sup>[16,17]</sup>. Hemangiomas show specific features in imaging diagnosis; therefore most cases can be diagnosed preoperatively. As a hemangioma increases in size, it can cause congestion, bleeding, thrombosis and infarc-

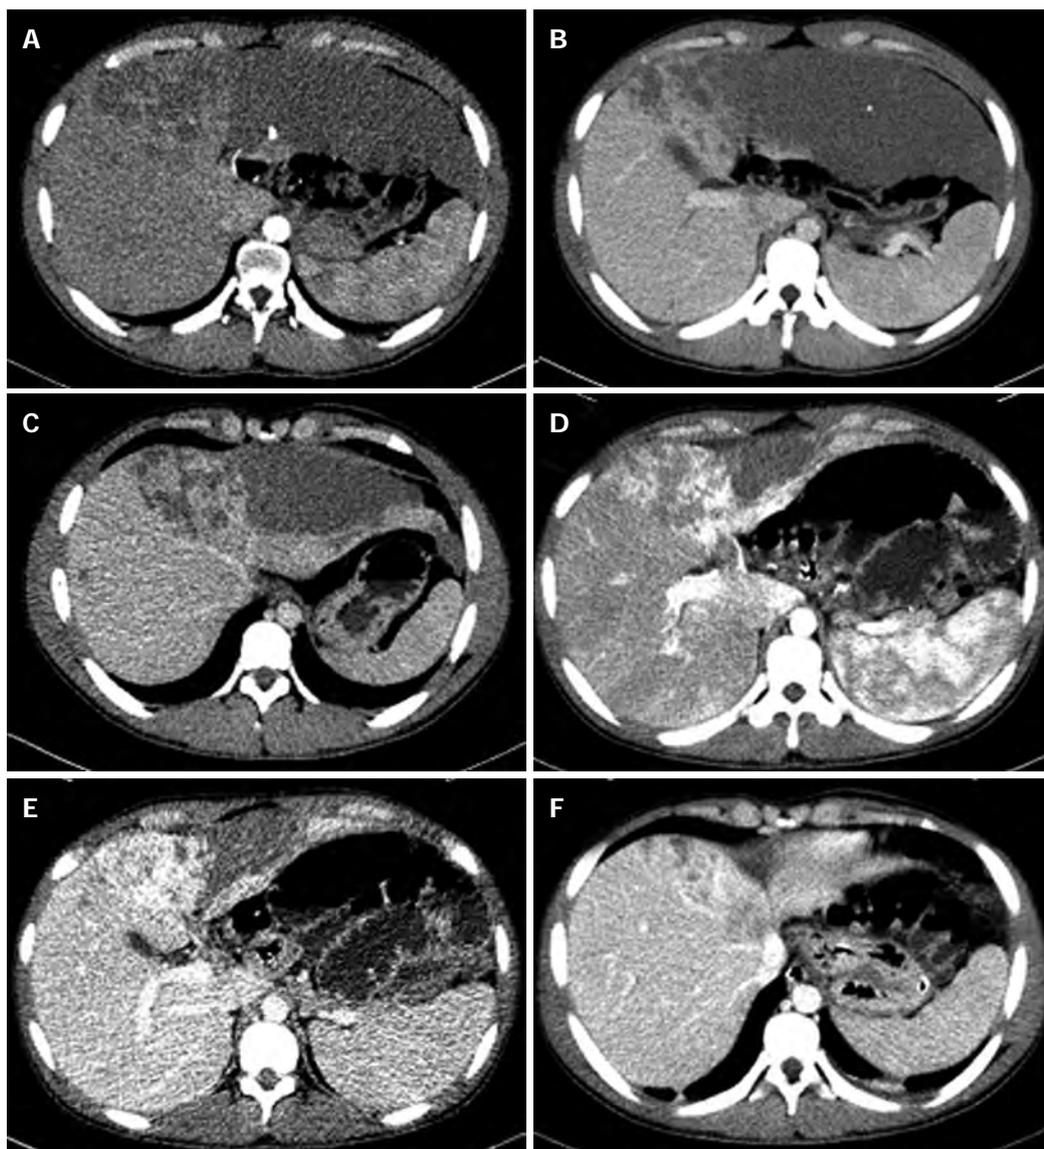

Figure 1 Axial images of multi-detector computed tomography. Multi-detector computed tomography (MDCT) images at the first visit (A-C), and corresponding MDCT slices just before the operation (*i.e.*, one month after transcatheter arterial embolization) (E-G).

tion (and consequent stomachache), Kasabach-Merritt syndrome, and spontaneous rupture. Out of the mass effect, it might produce symptoms such as obstructive

jaundice, biliary colic, and gastric outlet obstruction<sup>[18]</sup>.

A recent major argument in the treatment of liver hemangiomas is the indications of operation. Considering the benign and non-progressive nature of the dis-

ease, it is currently accepted that a giant hemangioma is not necessarily an indication for surgery just because of its size, and continued observation in asymptomatic patients or patients with minimal abdominal symptoms seems to be justified<sup>[19,20]</sup>. Surgery remains the only consistently effective curative treatment for giant hemangiomas and should be considered for patients with established complications, diagnostic uncertainty and incapacitating symptoms, where operative risk is acceptable, or where the diagnosis remains uncertain despite appropriate specialist investigation<sup>[21]</sup>. Various other treatment methods have been reported but their long-term results have been poor<sup>[20]</sup>.

In our case, the patient complained of abdominal pain. For the treatment of a giant hemangioma accompanied with symptoms, surgical resection is primarily recommended. Based on the liver function tests and remnant liver volume, urgent primary tumor resection seemed possible. But we considered that an urgent resection at the first admission would be dangerous because it seemed difficult to approach the bifurcation of hepatic artery and portal vein behind the tumor. Liver transplantation was also considered an option, but the patient strongly refused because of donor shortage and high expenses for transplantation. Although some authors reported that symptomatic giant liver hemangiomas can be managed successfully and non-invasively by TAE with a satisfactory decrease in symptoms and tumor volume<sup>[22]</sup>, the effect of TAE generally seems to be variable and sometimes even results in a volume increase<sup>[14,15]</sup>. However, there were reports that TAE for giant hemangiomas, performed prior to surgical resection, facilitated the mobilization of the liver by shrinking the hemangioma and, consequently, decreased intraoperative hemorrhage<sup>[9,23]</sup>. We also performed TAE before surgery to ensure the safety of the future radical resection of the tumor, which resulted in a decrease in the size of hemangioma, as shown in the previous report.

Considering the various complications and vascular recanalization after TAE which might postpone the operation and result in the loss of an opportunity for the radical resection, some authors recommend urgent operation after TAE<sup>[9,24]</sup>. In the present case, the patient was readmitted to our hospital one month after TAE with intestinal obstruction. To our knowledge, intestinal obstruction after embolization of a giant hepatic hemangioma has not previously been reported in the English literature, we speculated that it might be related to the tumor shrinkage, and inflammatory adhesions formed between the tumor and small bowel. Based on this speculation and the remarkable volume reduction of the tumor, we decided to perform a left hepatectomy. Fortunately, the operation was safely conducted without any complication, and our speculation was confirmed by the laparotomy and histological examination. However, when to operate should be decided on a case-by-case basis, with close follow-up and meticulous assessment by skillful surgeons and radiologists, not to misjudge the appropriate timing for the radical surgery.

We report a case of a single huge hemangioma with intestinal obstruction following TAE treatment, by which the volume of the hemangioma was significantly reduced, and it was completely resected by a left hepatectomy. The outcome in our case indicates the importance of pre-operative management to reduce tumor size before surgery, and surgeons should pay attention to the complications of TAE.

### Abstract

Arbitrarily, modern day treatment of inflammatory bowel disease begins with the introduction of immunosuppressives for ulcerative colitis. Clinical improvement with sulfasalazine had been meaningful but modest. Treatment with adrenocorticotrophic hormone and corticosteroids led to clinical responses never before realized but it took much too long to recognize that they were not capable of maintaining remission, that adverse reactions were subtle but potentially devastating and that some other agent would be necessary to capitalize on their transient advantage. This of course was true in the treatment of Crohn's disease as well. Not much was ever made of the role of sulfasalazine for Crohn's disease, but with the severing of the diazobond and the elimination of the sulphur component, the 5-aminosalicylic acid (5-ASA) products clearly led to clinical improvement, especially in cases of Crohn's colitis and those with ileitis where the 5-ASA product was released in the terminal ileum and more proximal in the small bowel as well as in ulcerative colitis. The induction of remission was first demonstrated by 6-mercaptopurine (6-MP) with case reports and uncontrolled trials in patients with ulcerative colitis, but its placebo controlled trial for Crohn's disease firmly established its role in inducing remission. No subsequent trial has confirmed

its similar role for ulcerative colitis, but nevertheless clinicians know well that 6-MP works at least as well and probably more effectively for ulcerative colitis than for Crohn's disease. What changes have taken place utilizing 6-MP in the management of inflammatory bowel disease since its introduction in the 1960's and 1970's and its trial for Crohn's disease published in the *New England Journal of Medicine* in 1980?

**Key words:** 6-Mercaptopurine; Crohn's disease; Ulcerative colitis

**Core tip:** Calculation of dose, utilization of serological tests, maintenance therapy, desensitization to 6-mercaptopurine (6-MP), toxicity to 6-MP, post-operative prevention, extraintestinal manifestations, perirectal fistulas and other fistulas, pregnancy, role of biologicals in management, brand name *vs* generic 6-MP and azathioprine.

Korelitz BI. Expert opinion: Experience with 6-mercaptopurine in the treatment of inflammatory bowel disease. *World J Gastroenterol* 2013; 19(20): 2979-2984 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i20/2979.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i20.2979>

### CALCULATION OF DOSE

In the original controlled study, the dose of 6-mercaptopurine (6-MP) chosen by Present and myself was based on weight at 1 ½ mg per kilogram. This precedent has subsequently been used in almost all other studies around the world when the immunosuppressive of choice was 6-MP rather than Azathioprine. Despite this and due to my own experience based on the wide range of leukopenia as influenced by dose, I changed my preference from dose by weight and started all patients at 50 mg/d. Since

in both cases my policy was to have blood drawn for a complete blood count (CBC), at one, two and three weeks, a rapid fall in the white blood cell count (WBC) would be recognized early and the drug could be reduced or stopped accordingly. On the contrary should there be no fall in the WBC and there also be no clinical improvement in the inflammatory bowel disease (IBD), ulcerative colitis (UC) and Crohn's disease (CD), I would have the opportunity to increase the dose within the 3 wk period<sup>[1-5]</sup>.

If the patient were still on steroids when the 6-MP was started and there was clinical improvement, I have reduced the steroid dose early to minimize its duration, also keeping in mind that the WBC was elevated because of the steroids and their reduction might accelerate the leukopenia. Reintroduction of 6-MP after stabilization on recovery from the leukopenia would be by 25-50 mg less than before. Some patients tolerate only as little as 1/2 tablet or 25 mg/wk while others require an increase up to 300 mg/d, the low and the high doses being equally effective for the individual case.

This exercise has been modified by the availability of biologicals since the severity of disease and lack of response to early doses of 6-MP will serve to accelerate the decision to add the biological to the therapy<sup>[6-8]</sup>.

---

## UTILIZATION OF SEROLOGICAL TESTS TO INFLUENCE THE DOSE OF 6-MP

---

Since these tests were not available in the 1960's and 1970's, we were permitted a prolonged period of experience without them and then later learned that I never had to utilize them. By the time I would decide to start 6-MP the first CBC was drawn and interpreted before there was even time to receive a report on thiopurine methyltransferase, TGN or TPPT. Furthermore, a favorable clinical response was documented as early as possible since the blood counts were entered on a monitor sheet followed by directions by me when the patient called as told to do so. If the patient did not call on time, it was the practice of my office to call them should a change in dose be warranted. With increased experience, I would also get liver function tests including a GGTP early on and then periodically to recognize mild abnormalities consistent with an acceptable "transaminitis" versus a progressive abnormality of true liver damage. One monitor sheet included a column for WBC, Hb, Hct, and platelets and another for bilirubin, serum glutamic oxaloacetic transaminase, serum glutamic pyruvate transaminase, alkaline phosphatase, GGTP and Amylase<sup>[9-12]</sup>.

---

## MAINTENANCE THERAPY WITH 6-MP FOLLOWING SUCCESSFUL INDUCTION

---

As an outcome of the original controlled trial, we learned that the mean time to induction of remission was three months. Even then, however, it was clear that some patients responded faster, even as little as three weeks, and

others might take up to a year and still be successful. The differences were modified by recognizing the success of a small dose of 6-MP leading to that dose becoming the maintenance dose, and the failure of the initial dose leading to a relatively rapid increase until the maintenance dose was found without requiring a whole year or even six months. Again, should the patient be on steroids when the 6-MP was started, tapering and elimination of the steroids was part of the goal, always mindful that any reduction of steroids increased the risk for leukopenia.

The role of immunosuppressives in top down vs bottom up straddles these two approaches to therapy. This is because 6-MP has maintenance as well as induction value as opposed to steroids which work quickly but have no maintenance value and infliximab which also works quickly and does have maintenance value. The 6-MP, however, is slower in its action than both of the above in most cases. Therefore 6-MP will be more appropriate as a Step Up drug unless used from the outset as a Top Down in conjunction with infliximab as done in the Sonic Trial.

At the other end of the spectrum, after prolonged remission on 6-MP [ $\pm$  a 5-aminosalicylic acid (5-ASA) product but no biological as yet], some patients wanted to stop the drug, others refused to stop it remembering the severity of their disease before its introduction, and others accepted my recommendation based on clinical judgment. The time between CBC's and LFT's was already extended due to persistence of normality, so that some patients reached an interval of three months. I have chosen not to extend the interval beyond this period. If I then chose to reduce the dose on clinical grounds (usually because of patients' persistent fear of toxicity), I would deduct 25-50 mg. from the daily dose and keep that level for a trial of one year before considering a further reduction. This means that some patients would be maintained on one tablet/day (reduced from 2/d or 1 1/2/d) and others on 1/2 every other day reduced from 1/2/d or 1/2 on two out of three days.

At this time I will add that in a few cases I eventually stopped the 6-MP entirely. I have not yet analyzed the results but have witnessed many examples of recurrence on both stopping and reducing the dose of the 6-MP<sup>[13-16]</sup>.

---

## DESENSITIZATION TO 6-MP IN THE COURSE OF TREATMENT OF IBD

---

Next to leukopenia, allergic reactions to 6-MP are the next most common adverse effects. Whether nausea and malaise are also on an allergic basis has not been clear. In my own experience, the most common allergic reactions are fever, skin rash, joint pains and back pain. Unfortunately, the 6-MP has often been terminated on this basis and both CD and UC have frequently progressed in severity thereafter, leading to surgical resections which might not have been necessary. Just as we have found earlier that desensitization to sulfasalazine not only is frequently successful, and treatment with that drug resulted in remissions of IBD, particularly UC, desensitization has been fruitful for 6-MP. This has been done by starting

with as little as 1/8 tablet and increasing the dose every few days or switching to Azathioprine at either full dose or the same fractions. In my experience the only allergic reaction to which desensitization has rarely been successful has been pancreatitis. Once desensitization to 6-MP has been accomplished, remission has been maintained on this drug for many years<sup>[17,18]</sup>.

## TOXICITY TO 6-MP IN THE COURSE OF TREATMENT OF IBD

Other than leukopenia and allergic reactions to 6-MP, concern about neoplasm has prevailed. After many years of experience, I am convinced that malignant tumors such as breast, lung, liver, pancreas, kidney, prostate and brain are not more common in those treated with 6-MP than in the entire IBD population or the general population. The problem of lymphoma has warranted intense observation and it is statistically significantly increased but still rare. I accept the conclusion that a lymphoma occurs in somewhere between 1:2000 and 1:4000 cases. If it occurs its prognosis is no different than lymphomas in IBD patients not treated with 6-MP or Azathioprine or no IBD. The exception to this rule is the hepato-splenic lymphoma which carries the worst prognosis of the lymphomas and it occurs in children, particularly male children who have the most virulent IBD, so that even in this group of patients it is challenging not to use 6-MP as well as to using it. Most patients with this type of lymphoma have been on combination therapy (6-MP or Azathioprine plus IV infliximab) but the onus is on the immunosuppressive since the lymphoma rarely occurs with infliximab alone. The one neoplasm which theoretically might be increased with immunosuppressive therapy is colon cancer superimposed on ulcerative or Crohn's colitis. My own studies and those of others have shown that this is not the case. If anything, treatment with immunosuppressives has reduced the risk of colon cancer, probably as a result of eliminating inflammation due to successful therapy.

Unfortunately, skin cancers are common in IBD patients treated with immunosuppressives. While basal cells can be successfully resected and don't often lead to terminating 6-MP, this is not so true of squamous cell carcinomas which I see fairly commonly in patients who have received the drug for many years. I have rarely seen a melanoma in patients on 6-MP.

Opportunistic infections are rare. When they occur they correlate best with situations when the disease is not controlled by the immunosuppressive drug and usually when the patient is still being treated with steroids.

Pancreatitis usually occurs within three weeks of onset of treatment with 6-MP. In our original studies, we encountered pancreatitis in 3% of patients. I rarely see it anymore.

Thrombocytopenia is fairly common in patients on 6-MP and if it occurs it is usually in conjunction with leukopenia. Anemia due to 6-MP is rare and if it occurs is most likely accompanied by a pancytopenia and requires

stopping the immunosuppressive therapy<sup>[19-26]</sup>.

## POST OPERATIVE PREVENTION WITH 6-MP

Trials of available drugs for prevention of recurrent ileitis after ileo-colic resection have been disappointing. My own study of 6-MP for this indication showed statistically significant but not impressive results. Nevertheless, I have had many patients who started 6-MP following surgery who have remained without clinical recurrence for many years. It is my impression that endoscopic recurrence may occur despite taking the 6-MP, but its progress to a point of clinical recurrence is extremely retarded. I have also reassessed the results of my own study and learned that when the 6-MP is started in the immediate peri-operative period, protection against the recurrence is far more effective. This is an area where infliximab is proving to be more effective than immunosuppressives, again best when started immediately postoperatively. More studies in the area of which drug, both, and when are needed to resolve this question<sup>[27-29]</sup>.

## THE ROLE OF IMMUNOSUPPRESSIVES FOR EXTRAINTestinal MANIFESTATIONS

Before the advent of biologicals, treatment of pyoderma gangrenosum, erythema nodosum, arthritic manifestations and uveitis were often successful with the introduction of 6-MP. If however, the extraintestinal manifestation occurs while the patient is already taking an immunosuppressive, the need to introduce a biological is clear.

## PERIRECTAL FISTULAS AND OTHER FISTULAS

Many of my own studies have demonstrated the favorable effect on all fistulas with 6-MP treatment. Perirectal fistulas and abscesses often require incision and drainage in conjunction with 6-MP but are more likely to be recurrent without immunosuppressive therapy at the same time. Infliximab also has been very effective in closing fistulas. Nevertheless, it is fairly common to see persistent drainage from fistulas despite treatment with either drug alone and even with the combination. Fortunately, the severity of the residual fistula is not great and if the primary CD has been brought into remission, the patient tolerates the drainage well<sup>[30,31]</sup>.

## PREGNANCY AND IMMUNOSUPPRESSIVES

The issue of 6-MP and AZA before and during pregnancy prevails since the most common years of onset

of Crohn's disease and ulcerative colitis are during the ages of greatest fertility and Crohn's disease occurs more often in females than males. Furthermore, consideration of continuing immunosuppressives during pregnancy is markedly diluted as an issue since pregnancy usually takes emotional priority over treatment of the disease in female IBD patients who want to stop all medications and so often the obstetrician is encouraging them to do so.

The evidence favoring continuing 6-MP/AZA during the pregnancy is based on the following: (1) The largest reported study on pregnancy and adverse outcomes possibly attributed to 6-MP from Mount Sinai has concluded that these drugs are safe; (2) Most adverse reactions to 6-MP/AZA occur early, soon after the drug is started. Therefore, the coincidence of any other toxicity to 6-MP in pregnancy most likely must be attributed to active disease; and (3) If the most virulent factor with toxic complications during pregnancy is active Crohn's disease and if the patient is in a remission just achieved by the drug, it should not be stopped. On the other hand, in a study from Lenox Hill Hospital there was a 23% incidence of spontaneous abortions (*vs* 13% in IBD controls), a 3% incidence of ectopic pregnancies (compared with none in IBD controls) and finally an abnormal amniocentesis in 2 patients (and none in the IBD controls).

Statistically speaking, no one is yet certain of the risk or the safety of immunosuppressives taken before or during pregnancy and therefore no conclusion should yet be drawn. Logically there must be a compromise solution: (1) Given that the most important issue is active Crohn's disease at conception, if the patient has already been started on the immunosuppressive drug it should be continued and the dose even increased if the clinical severity of the disease warrants it; (2) If the IBD is in remission and has been for months or for years, I find no contraindication to stopping the drug at or before the diagnosis of pregnancy since our experience has shown that any exacerbation is not likely to occur immediately or for that matter even for months, by which time the pregnancy may be ended or at least the fetus is protected through the first trimester when theoretically it would be most susceptible to any danger. Should an exacerbation occur earlier in the pregnancy, the choice may be made to reintroduce the drug; (3) The risk of toxicity to the pregnancy when the father is the one who has the IBD and is taking 6-MP/AZA raises a special consideration. If the male has been in remission, it might be prudent to stop the drug for 1 to 3 mo before conception. Since the timing of the pregnancy is so infrequently controlled, this opportunity does not occur often; and (4) Decisions whether to continue 6-MP/AZA in pregnant women and their husbands who are taking the drug for IBD require rigorous clinical judgement. For example, if the woman has been in remission for a long time, it seems reasonable to stop the drug until delivery since recurrence is very unlikely. If recurrence does develop, then the drug can be restarted at that time. If either the pregnant female patient or the husband with IBD have active Crohn's

disease or have been in remission only briefly following a severe attack, I recommend continuing the drug. This is an area where rules should not be rigid<sup>[32-36]</sup>.

---

## THE ROLE OF 6-MP SINCE THE AVAILABILITY OF BIOLOGICALS; WHEN TO ADD ONE TO THE OTHER, WHEN TO TERMINATE ONE OR THE OTHER AND WHICH ONE

---

Some of the most challenging therapeutic decisions have been raised since the publication of articles suggesting that once a patient with Crohn's disease is in clinical remission while being treated with both infliximab and 6-MP/AZA, there is no advantage to continuing the immunosuppressive drug. These studies do not adequately allow for the duration of treatment with the 6-MP, when it was started in reference to infliximab, or the duration and dose of infliximab required to bring the patient into remission. Furthermore, it does not allow for the conclusions of the Study of Immunomodulator Naïve Patients in Crohn's Disease which demonstrated that the therapeutic efficacy of the combination of infliximab and 6-MP/AZA is greater than either drug alone.

The following are the my suggested options for changing therapy for Crohn's disease and ulcerative colitis in regard to either 6-MP or AZA alone, infliximab or other biological alone, and 6-MP/AZA and a biological together.

### *No response or beginning failure with 6-MP/AZA alone*

Increase the dose if WBC or platelets permit; add a biological; add a 5-ASA product (this is a particularly good opportunity to add a once daily dose product for compliance reasons.); surgery, usually the last resort, but influenced by location and specific complication of Crohn's disease.

### *No response or failure with a biological*

Increase the dose, decrease the interval between infusions or injections; add 6-MP or AZA; add a 5-ASA product; change the biological; Measure serum infliximab and antibody levels for guidance; brief rescue therapy with intravenous corticosteroids; Surgery, usually the last resort, but influenced too by location and specific complication of the Crohn's disease.

### *Failure with combined therapy of immunosuppressive and biological*

Increase the dose of the immunosuppressive if WBC or platelet counts permit; decrease the interval between infusions or injections; add a 5-ASA product; brief rescue therapy with intravenous corticosteroids; measure serum infliximab and antibody levels for guidance; stop biological if degree of immunogenicity is high and accompanied by allergic symptoms such as joint pains; stop 6-MP or

AZA if complications suspected of being attributed to these drugs are evident, such as nausea, malaise, fever, and worsening liver or pancreatic function tests; surgery.

### **Eliminating 6-MP/AZA after remission with combined therapy of immunosuppressives and biologicals**

Complications of drug or disease; reduce the dose - especially for persistent leukopenia; patients' fear of late complications; in some cases of pregnancy or anticipated pregnancy; continuation influenced by earlier severity of the disease.

### **Eliminating biologicals (when used alone) after remission**

Fear of complications of the drug; lack of compliance; now substitute 6-MP/AZA; first extend interval for infusion or injection; first reduce the dose; add a 5-ASA product if not already done.

### **Eliminating the biological or immunosuppressive after remission with both**

To be considered preferably only after 1 full year of maintenance therapy and full dose of both after remission achieved; first reduce dose of the immunosuppressives; eventually eliminate the 6-MP/AZA or the biological; the author's preference is to eliminate the 6-MP/AZA and continue the biological; later reduce the dose of the biological as well.

Once remission of the IBD has been maintained for at least a year, there are many considerations. While some patients do not wish to change the therapeutic program because of its success, others are fearful of complications of either or both drugs and are anxious to eliminate or reduce. In some cases the specific indication for starting the program remains tolerable but not eliminated, in which case I encourage the patient to persist. In other cases where the indication for starting one or both drugs is gone and indeed mucosal healing has been accomplished as well (mucosal healing to me requires histological healing), I undertake a dose reduction.

Despite the efforts made in rationalizing the reduction of 6-MP vs infliximab, the subsequent management is currently influenced by the subsequent course of the primary disease rather than patient hardships or drug complications. I have witnessed exacerbations of Crohn's disease and ulcerative colitis following elimination or reduction of both drugs. The course of management is then clear by reinstating the appropriate drug, preferably to the dose of 6-MP at which the longest remission was maintained or the infliximab at the dose and frequency of infusions in which remission was achieved.

One other option for failure or intolerance to 6-MP or lack of response to Remicade is the substitution of a different biological. My experience is biased by the long period of time with the availability of only the Remicade. With the subsequent introduction of Adalimumab and Certolizumab pegol, I had already learned how to use the infliximab well and had no need to change, or if the infliximab had failed so then did the other biological that I

then tried. Furthermore, I don't consider self administration of the biological an advantage since the patient has been known to alter the dose or the frequency for whatever the rationale whenever the guidance of the managing gastroenterologist is reduced or otherwise modified. Rapport between patient and doctor remains an influential factor in successful therapy even though the scientific evidence for this might be lacking<sup>[37-39]</sup>.

## **BRAND NAME VS GENERIC 6-MP AND AZATHIOPRINE**

While there are no controlled trials to resolve this issue, I have seen more recurrences of IBD after switching to the generic than when continuing with the brand (Purinethol or Imuran). Therefore, I continue using the brand name when feasible.

### Abstract

MicroRNAs, a key class of gene expression regulators, have emerged as crucial players in various biological processes such as cellular proliferation and differentiation, development and apoptosis. In addition, microRNAs are coming to light as crucial regulators of innate and adaptive immune responses, and their abnormal expression and/or function in the immune system have been linked to multiple human diseases including inflammatory disorders, such as inflammatory bowel disease, and cancers. In this review, we discuss our current understanding of microRNAs with a focus on their role and mode of action in regulating the immune system during inflammation and carcinogenesis.

### INTRODUCTION

MicroRNAs (miRNAs, miR) are small (approximately 20-22 nucleotides), non-coding RNAs that post-transcriptionally regulate gene expression by binding to the 3'-untranslated region of target mRNAs, leading to mRNA degradation or translational inhibition<sup>[1]</sup>.

Since the identification of the first miRNA, *lin-4*, in *Caenorhabditis elegans* in 1993<sup>[2,3]</sup>, thousands of miRNA genes have been identified in animal and plant genomes<sup>[4]</sup>. As a class, miRNAs account for about 1%-2% of genes in worms, flies, and mammals<sup>[5]</sup>. Each miRNA can target hundreds of mRNAs within a given cell type, and a single mRNA is often the target of multiple miRNAs, and thus over half of the human transcriptome is predicted to be under miRNA regulation, embedding this post-transcriptional control pathway within nearly every biological process<sup>[5]</sup>.

Given its fundamental biological roles, it is not sur-

prising that miRNA expression is tightly controlled and that its deregulation can lead to various diseases. In this review, we summarize our current knowledge about the physiological role of miRNAs in mammalian biology and the manner in which miRNA activities contribute to diseases including inflammatory disorders and cancer.

## MIRNA BIOSYNTHESIS AND REGULATION

### Biosynthesis

Our knowledge of miRNA biogenesis and regulation has been greatly expanded in recent years<sup>[1]</sup>. The canonical miRNA biogenesis takes place in a multi-step process and involves two RNase III endonucleases, Dicer and Drosha. MiRNAs are encoded by genomic DNA and are most commonly transcribed by RNA polymerase II, which generates a primary miRNA (pri-miRNA) transcript. Within the primary transcripts, miRNAs form stem-loop structures, which contain the mature miRNA as part of an imperfectly paired double-stranded stem connected by a short terminal loop. Pri-miRNAs are then processed by a microprocessor complex, a multiprotein complex with the two core components, Drosha and DiGeorge Syndrome critical region 8 (DGCR8)<sup>[6-8]</sup>. This results in the formation of a hairpin-shaped RNA molecule of 70-100 bp called miRNA precursor or pre-miRNA, which is then exported into the cytoplasm in a process involving the nucleocytoplasmic shuttle Exportin-5 and in a Ran-GTP-dependent manner<sup>[9-11]</sup>. In cytoplasm, the pre-miRNA hairpin is cleaved by the endonuclease DICER into an imperfect miRNA:miRNA\* duplex of 21-23 nucleotides in length<sup>[12]</sup>. After separation of the two strands of the duplex, one of the strands (the mature miRNA) is transferred into an Argonaute (Ago) protein located in the RNA-induced silencing complex (RISC or miRISC), which is involved in the repression of gene expression by leading miRNAs to specific target mRNAs, whereas the other strand (the star-strand) is degraded. It has been shown that strand selection and RISC assembly in mammals are accomplished by a complex that contains Dicer, Ago and the double-stranded RNA binding protein TRBP<sup>[13-15]</sup>. MiRNAs target mRNAs by interacting with sites of imperfect complementarity. Short “seed” sequences at the 5'-ends of miRNAs (nucleotides 2-8) are critical, and in some cases fully sufficient, for target selection<sup>[16,17]</sup>.

### Regulation

Although there have been recent advances in our knowledge of the biogenesis of the miRNA pathway, relatively little is known about the mechanisms regulating the activity of the pathway's components. Several recent studies indicate that the regulation of miRNA expression and function occurs at three levels: transcription, processing and subcellular localization<sup>[17,18]</sup>.

The first, and one of the most important, mechanisms controlling miRNA abundance is the regulation of pri-

miRNA transcription, which could be positively or negatively regulated by different factors such as transcription factors, enhancers, silencers and epigenetic modification in miRNA promoters<sup>[16]</sup>. For example, the oncogene c-myc can bind to the promoter of the miR-17-5p cluster, thereby up-regulating expression of the miRNAs encoded by the cluster<sup>[19,20]</sup>. Similarly, the tumour suppressor p53 has been shown to upregulate the transcription of miR-34 family members, inhibiting important factors of cell proliferation and survival, such as Bcl2 and Cdk4 and 6<sup>[21-24]</sup>. A region of miRNA genes is located within CpG islands involving the epigenetic control of miRNA transcription. It is estimated from recent works that 5%-10% of mammalian miRNAs are epigenetically regulated<sup>[19,25-27]</sup>.

Several post-transcriptional regulatory mechanisms that affect miRNA processing at different stages, from the pri-miRNA transcripts to the delivery of mature miRNAs to their target mRNAs, have recently been investigated<sup>[18]</sup>. For example, p53 can form a complex with Drosha, which increases the processing of pri-miRNAs to pre-miRNAs<sup>[28]</sup>. Histone deacetylase I can enhance pri-miRNA processing by deacetylating the protein DGCR8 of the microprocessor complex<sup>[29]</sup>. Cytokines such as interferons have been shown to inhibit Dicer expression, decreasing the processing of pre-miRNAs<sup>[30]</sup>.

## MICRORNAS AND IMMUNE SYSTEM

The immune system has evolved to maintain self-tolerance and to recognize efficiently specific pathogens. The innate immune system acts as a first protector providing an immediate response to pathogens, and propagation of the innate response activates the adaptive immune system. Both innate and adaptive immune responses are highly regulated, and recent studies have shed light on the role of miRNAs in this intricate system<sup>[31,32]</sup>. The role of miRNAs in immune responses will be discussed in this section.

### MicroRNAs and innate immune response

The innate immune system is activated *via* recognition of pathogen-associated molecular patterns by toll-like receptors (TLRs)<sup>[33]</sup>, which will recruit adaptor proteins to the receptor, followed by activation of downstream signalling pathways such as the nuclear factor kappa-light-chain-enhancer of activated B cells (NF- $\kappa$ B) pathway<sup>[34]</sup>. This signal transduction ultimately leads to induction of immune gene expression.

The first study examining the effect of lipopolysaccharide (LPS)-mediated activation of TLR signalling on miRNA production identified miR-155, miR-146a and miR-132, which are induced in human macrophages by LPS<sup>[35]</sup>. Further analysis showed that miR-155 is induced by LPS, cytokine IFN- $\beta$  and various TLR ligands in murine macrophages<sup>[36,37]</sup>. MiR-155, once induced, is involved in the activation of tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) and interleukin-6 (IL-6), enzyme linked immunosorbent assay pathway *via* targeting the Fas-associated

death domain protein, I B kinase  $\epsilon$ , and receptor (TNF receptor superfamily)-interacting serine-threonine kinase 1<sup>[37]</sup>. MiR-155 plays a role in the innate immune response by regulating suppressor of cytokine signalling (SOCS)-1, a negative regulator of dendritic cell antigen-presenting capacity<sup>[37-39]</sup>. Likewise, miR-155-deficient dendritic cells exhibit impaired antigen presentation and therefore are unable to activate T cells to promote inflammation<sup>[39]</sup>. One study demonstrated that in human myeloid-derived DCs, knockdown of miR-155 expression significantly increased protein expression of the pro-inflammatory cytokine IL-1<sup>[40]</sup>. The same study also showed that miR-155 directly inhibited expression of the pro-inflammatory signalling protein TAK1-binding protein 2 (TAB2, also known as MAP3K7IP2), which could be a mechanism underlying its anti-inflammatory property<sup>[40]</sup>. In contrast, other studies have shown that miR-155 can enhance inflammatory responses. Overexpression of miR-155 in mouse bone marrow leads to a myeloproliferative phenotype that is similar to that observed transiently after LPS stimulation<sup>[41]</sup>. MiR-155 can negatively regulate SHIP1, an important negative regulator of phosphoinositide 3-kinase (PI3K) and the downstream AKT pathway<sup>[42,43]</sup>. SHIP1, which is similar to SOCS1, is a negative regulator of TLR4 signaling<sup>[44]</sup>, and hence repression of SHIP1 by miR-155 may counter this negative regulation and increase downstream AKT signalling.

Like miR-155, miR-146a is induced by LPS, TNF- $\alpha$  and IL-1 $\beta$  in a NF- $\kappa$ B-dependent manner. MiR-146a in turn inhibits expression of two components of the TLR4 signaling pathway, IL-1 receptor associated kinase and TNF receptor-associated factor-6<sup>[35]</sup>. Thus, miR-146a functions as a negative feedback regulator of the TLR/NF- $\kappa$ B pathway. MiR-155 and miR-146 expression is increased in macrophages in response to LPS stimulation, while miR-125b expression is decreased. MiR-125b can target TNF- $\alpha$  mRNA, and a decrease in its expression leads to elevated TNF- $\alpha$  production and consequently increased inflammatory response<sup>[37]</sup>.

Macrophage inflammatory response to infection involves the upregulation of several miRNAs, such as miR-21, miR-9 and miR-147<sup>[45-47]</sup>. These miRNAs can also be induced by TLR signaling, and can negatively regulate activation of inflammatory pathways in myeloid cells. MiR-9 represses NF- $\kappa$ B subunit 1 (NFKB1/p50 unit) and helps to maintain a constant level of NF- $\kappa$ B1 protein expression during TLR4-mediated activation of monocytes and neutrophils<sup>[46]</sup>. MiR-147 has been shown to attenuate TLR2, TLR3 and TLR4-mediated production of inflammatory proteins such as TNF- $\alpha$  and IL-6<sup>[47]</sup>. Induction of miR-21 inhibits PDCD4, an IL-10 inhibitor, thereby derepressing IL-10. IL-10 in turn inhibits miR-155, allowing SHIP1 to be derepressed and inhibit TLR signaling<sup>[45,48]</sup>. Hence, immune responses are highly regulated by TLRs-mediated upregulation of different miRNAs.

In addition to miRNA induction by TLR signaling, recent studies have also reported inflammatory repres-

sion, such as miR-155 repression, in response to anti-inflammatory cytokine IL-10<sup>[49]</sup>.

### MicroRNAs and adaptive immune response

In addition to their role in regulating the innate immune system, miRNAs have been implicated in adaptive immunity by controlling the development and activation of T and B cells.

#### T cells

Specific miRNA expression profiles have been reported in different T cell subsets and stages of development<sup>[50-52]</sup>, suggesting that miRNA-mediated regulation of signalling networks in T cells, and probably other immune cells, is dynamic and highly regulated. Interestingly, miRNA profiling in naive, effector and memory CD8<sup>+</sup> T cells has revealed that a few highly expressed miRNAs are dynamically regulated during antigen-specific T-cell differentiation<sup>[52]</sup>. Mice exhibiting T-cell specific deletion of Dicer had lower numbers of mature T cells with abnormally developed T-cell subsets than wild-type mice, indicating that miRNAs are required for T cell development<sup>[53,54]</sup>. Two specific miRNAs have been implicated in T cell development, and probably account for some of the phenotype of Dicer-deficient T cells. The miR-17-92 cluster suppresses expression of pro-apoptotic proteins, including BCL-2-interacting mediators of cell death (BIM or BCL2L11) and phosphatase and tensin homologue. This miRNA cluster is thought to increase T cell survival during development and is expressed during the double negative 2 stage of thymopoiesis<sup>[55]</sup>.

The role of miRNAs in the differentiation of T cells into distinct effector T helper cell subsets has been recently reported. It was demonstrated that miR-326 regulates differentiation of Th17 cells both *in vitro* and *in vivo*<sup>[56]</sup>. MiR-155 is implicated in regulatory T (T<sub>reg</sub>) cell formation and function, since forkhead box P3 (FOXP3), a transcription factor that is required for the development and function of T<sub>reg</sub> cells, may directly regulate the expression of this miRNA<sup>[57]</sup>. Furthermore, miRNA-155-deficient mice are immunodeficient, indicating the implication of miR-155 in homeostasis and the immune system<sup>[39]</sup>. Similarly, using genetic deletion and transgenic approaches, Thai and colleagues showed the important role of miR-155 in the mammalian immune system, specifically in regulating T helper cell differentiation and the germinal center reaction to produce an optimal T cell-dependent antibody response<sup>[58]</sup>. Certain miRNAs, such as the miR-17-92 cluster, might be involved in the development and function of T follicular helper cells (specialized T cells that provide selective signals to supporting germinal center B cells), which are essential for long-lived antibody responses<sup>[59,60]</sup>. In addition, miR-181a, which is increased during early T cell development and down-regulated in mature CD4 T cells such as Th1 and Th2 effector cells, can enhance TCR signaling strength by inhibiting multiple phosphatases that negatively regulate the TCR signaling cascade<sup>[61]</sup>. Finally, conditional deletion

of *Dicer* or *Drosha* in T<sub>reg</sub> cells led to lethal autoimmune inflammatory disease, accompanied by impaired development or function of T<sub>reg</sub> cells, indicating the role of miRNAs in T<sub>reg</sub> cell biology<sup>[62-64]</sup>.

### B cells

Distinct miRNA profiles in naive, germinal central and post-germinal central B cells have been reported<sup>[65-67]</sup>, suggesting the implication of miRNAs in B cell development and maturation. A pioneer study showed that miR-181 is highly expressed in B cells of mouse bone marrow, and its ectopic expression in hematopoietic stem and progenitor cells resulted in an increase in the percentage of B-lineage cells but not in T cells or myeloid cells<sup>[68]</sup>, indicating the role of lineage-specific miRNAs in regulating lymphocyte development. Conditional deletion of *Dicer* in B cells completely arrested B cell development in mice, which is thought to be due to dysregulated expression of the pro-apoptotic protein BIM, probably during the selection of effective antigen receptors<sup>[69]</sup>. Notably, B cells lacking miR-17-92 family and *Dicer*-deficient B cells exhibited similar gene expression profiles<sup>[70]</sup>, suggesting that this miRNA cluster could play a determining role in the regulation of B cell development.

Recent studies have explored the role of miR-150, a miRNA specifically expressed by mature lymphocytes, in B cell differentiation<sup>[51,71,72]</sup>. MiR-150 expression increases during B-cell maturation in bone marrow, and its constitutive expression blocked B cell development at the transition from the pro-B-cell to pre-B-cell developmental stage, leading to severe defects in the production of mature B cells<sup>[71]</sup>. MiR-150-deficient mice exhibited a 2-fold increase in splenic B-1 cell numbers, with a relative decrease in those of B-2 cells, but had no apparent defect in the development of other lymphoid-derived T- and B-cell types<sup>[72]</sup>. Mice expressing a miR-150 transgene early in life also had dramatically impaired B cell development with normal T cell levels. These defects in miR-150 gain- and loss-of-function were further shown to be due to dysregulation of c-Myb, a target of miR-150 and a transcription factor that controls multiple steps of lymphocyte development<sup>[72]</sup>. MiR-155-deficient B cells showed defects in antibody class switching and differentiation into plasma cells, resulting in an impaired humoral response to T cell-dependent antigenic stimulation<sup>[39,58,73]</sup>. The constitutive expression of miR-34a blocked B cell development at the pro-B to pre-B cell transition, leading to a reduction in mature B cells<sup>[74]</sup>. This block appeared to be mediated by miR-34a-inhibited expression of the transcription factor Foxp1<sup>[74]</sup>, which is an essential regulator of B cell development<sup>[75]</sup>. Together, these studies show the important role of miRNAs in normal B cell development.

## MICRORNAS AND INFLAMMATORY BOWEL DISEASE

As miRNAs play a critical role in the regulation of the immune system, failure of miRNA regulation is associ-

**Table 1 MicroRNAs dysregulated in ulcerative colitis and/or Crohn's disease**

<sup>1</sup>miRNAs upregulated specifically in non-inflamed colonic mucosa; <sup>2</sup>miRNAs downregulated specifically in non-inflamed tissue colonic mucosa. UC: Ulcerative colitis; CD: Crohn's disease.

ated with several human disorders such as inflammatory bowel disease (IBD) (Table 1), which is a chronic inflammatory gastrointestinal disorder. Although the etiology of IBD remains largely unknown, extensive studies in the last decades have suggested that it involves environmental and genetic factors that lead to dysfunction of the epithelial barrier with consequent deregulation of the mucosal immune system and responses to gut microbiota<sup>[76]</sup>.

Distinguished miRNA expression profiles have been recently described in tissues of patients with active and inactive UC, CD, irritable bowel syndrome (IBS), infectious colitis (IC), and microscopic colitis (MC)<sup>[77]</sup>. Wu and colleagues demonstrated that active UC was associated

with the differential expression of 11 miRNAs (3 significantly decreased and 8 significantly increased in UC tissues). MiR-192, the expression of which is decreased in active UC, was predominantly localized to colonic epithelial cells, and targeted macrophage inflammatory peptide (MIP)-2 $\alpha$ , a chemokine expressed by epithelial cells<sup>[77]</sup>. In colonic epithelial cells, TNF- $\alpha$ -induced MIP-2 $\alpha$  expression was inhibited by a miR-192 mimic. In contrast, miR-21 is significantly increased in patients with active UC compared to healthy subjects. In inactive UC patients, miR-375 and miR-422 expression was increased, while that of miR-192 was unaltered compared to healthy subjects<sup>[77]</sup>. Inactive UC showed similar expression levels of miR-375, miR-422b, and miR-23a to IBS and IC tissues. The miRNAs differently expressed in active UC were not dysregulated in MC and CD. This study highlights the specific miRNA expression patterns in active and inactive IBD tissues, and suggests that miRNAs could regulate expression of proteins implicated in the pathogenesis.

Another study showed the upregulated expression of several miRNAs in active UC compared to healthy colonic biopsies, suggesting that upregulation of miRNAs may be responsible for the development of intestinal inflammation in UC<sup>[78]</sup>. MiR-21 was found among the upregulated miRNAs, which is consistent with the findings of Takagi *et al.*<sup>[78]</sup>.

Of interest, Fasseu and colleagues identified restricted subsets of miRNAs abnormally expressed in inactive colonic mucosa of IBD patients<sup>[79]</sup>. This elegant study identified 14 (in UC) and 23 (in CD) miRNAs with significantly altered expression (> 5-fold increase or < 0.05-fold decrease) in quiescent colonic mucosa compared to healthy control tissues. Eight of the miRNAs (miR-26a, -29a, -29b, -30c, -126\*, -127-3p, -196a, -324-3p) were commonly dysregulated in non-inflamed UC and CD. Six miRNAs (miR-196b, -199a-3p, -199b-5p, -320a, -150, -223) displayed significantly distinct dysregulation of expression between non-inflamed UC and CD colonic biopsies. Interestingly, several miRNA genes with dysregulated expression mapped within acknowledged IBD-susceptibility loci. In addition, significant dysregulated expression of four and five miRNAs specific to inflamed UC or CD tissues, respectively, compared to healthy controls was observed<sup>[79]</sup>. This study sheds light on the role of miRNAs as contributors to IBD susceptibility, in particular their implication in the onset and/or relapse of inflammation from quiescent mucosa of IBD patients.

There have been recent reports of differential miRNA expression profiles in the peripheral blood of IBD patients<sup>[80]</sup>. Four miRNAs (miR-199a5p, -362-3p, -532-3p and miRplus-E1271) were upregulated and one miRNA (miRplus-F1065) was downregulated in the peripheral blood of patients with active CD, but not inactive CD, compared to healthy controls<sup>[80]</sup>. Both active and inactive CD patients had increased expression of miR-340 and decreased expression of miR-149 in the blood. Expression of three miRNAs (miR-103-2, 262-3p, 532-3p) was increased in the blood of both active and inactive UC

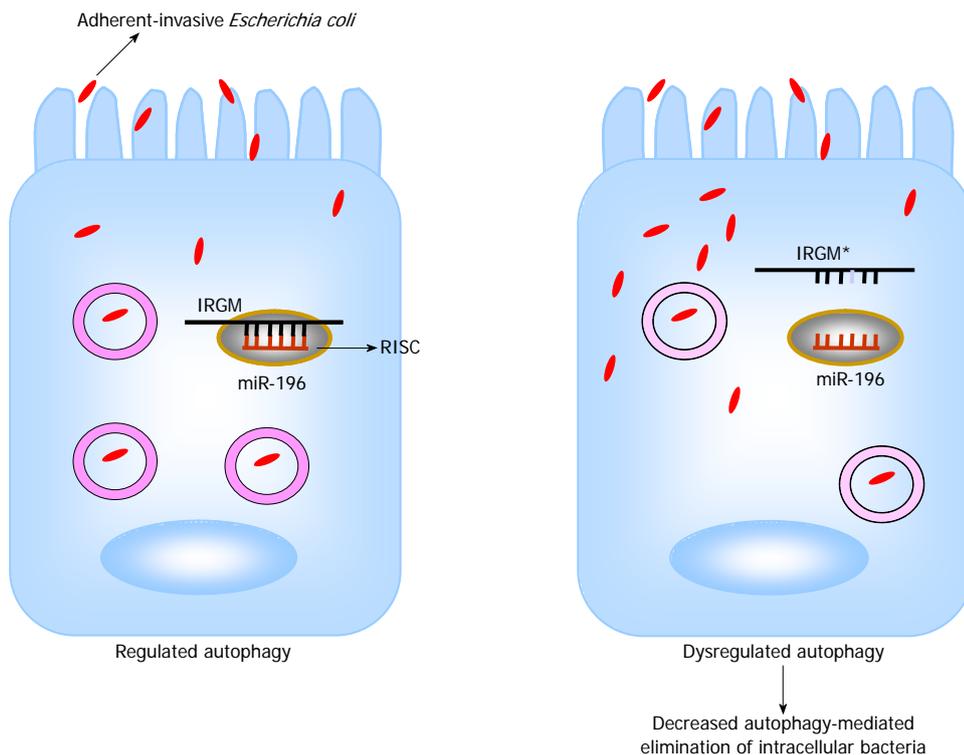

patients. In addition, a subset of 11 miRNAs can distinguish active CD from active UC<sup>[80]</sup>. This study importantly supports the evidence that distinct peripheral blood miRNA profiles in different circulating immune cell types are associated with IBD.

Efforts have been made to understand the mechanisms underlying the implication of miRNAs in the pathogenesis of IBD. The potential association between single nucleotide polymorphisms (SNPs) in pre-miRNA coding regions and IBD susceptibility has been analyzed. A study in a Japanese cohort of 170 UC patients and 403 healthy controls revealed the association of three SNPs (rs11614913, rs2910164, and rs3746444) in coding regions of pre-miR-196a2, pre-miR-146a and pre-miR-499<sup>[81]</sup>. Of particular interest, the CD-associated SNP C313T in immunity-related GTPase family, M (*IRGM*) gene caused a loss in binding of miR-196<sup>[82]</sup> (Figure 1). *IRGM* plays an important role in the immune system by its involvement in the autophagy process. In addition, miR-196 is overexpressed in the inflamed epithelium of CD patients and downregulates the *IRGM* protective variant (c.313C) but not the risk-associated allele (c.313T)<sup>[82]</sup>. Loss of tight regulation of *IRGM* expression by miR-196 resulted in defects in autophagy-mediated control of intracellular replication of adherent-invasive *Escherichia coli* (AIEC), leading to abnormal persistence of AIEC in host cells (Figure 1). This suggests that the association of *IRGM* with CD could arise from abnormal miRNA-mediated *IRGM* regulation, which affects the efficacy of autophagy, thereby contributing a synonymous polymorphism as a likely causal variant.

Intestinal microbiota is increasingly recognized as a risk for, and a causal factor of, IBD. Our recent studies showed that miRNAs are involved in the regulation of host gene expression by gut microbiota<sup>[83]</sup>. In another study, we showed that miRNAs play a role in determining the unique physiological characteristics of intestinal epithelial cells, such as their differentiation during migration along the crypt/villus axis<sup>[84]</sup>. In particular, expression of CD98, a transmembrane glycoprotein that regulates integrin signalling, cellular homeostasis and innate immune response in the gut<sup>[85]</sup>, and its function are directly under the control of miRNAs during the differentiation of intestinal epithelial cells<sup>[86]</sup>. MiRNAs could also be involved in the upregulation of CD98 during intestinal inflammation and IBD<sup>[86]</sup>. The biological importance of miRNAs in the pathogenesis of IBD is becoming clearer, and targeting miRNAs in the gastrointestinal tract may be a promising approach for future therapeutic opportunities.

## MICRORNAS AND COLORECTAL CANCERS

The transformation of a normal epithelium into a cancerous state involves modifications in several genes that are involved in different stages of carcinogenesis such as apoptosis, proliferation, limitless replicative potential of tumor cells, angiogenesis, migration and invasion<sup>[87]</sup>.

**Figure 1** Hypothetical model for the involvement of miR-196 in the pathogenesis of Crohn's disease. MicroRNAs (miRNAs, miR) 196 normally targets immunity-related GTPase family, M (IRGM) mRNA within RNA-induced silencing complex (RISC) for a negative regulation (left panel). The IRGM risk allele (IRGM\*) mRNA lacks the binding site for miR-196 and therefore is not regulated by this miRNA (right panel). During Crohn's disease, loss of tight regulation of IRGM\* expression by miR-196 may lead to defects in autophagy with most intracellular bacteria replication occurring in dysfunctional vacuoles<sup>[82]</sup> (dotted cycle). This consequently results in abnormal persistence of pathogens in host cells, which could further worsen disease status<sup>[82]</sup>.

Colorectal cancer (CRC) is one of the most common cancers worldwide. Its incidence is greater in industrial countries than in developing countries<sup>[88]</sup>. MiRNAs have been shown to play an important role in oncogenesis by regulating the expression of genes involved in cancer initiation, promotion and development<sup>[89]</sup>. Hundreds of miRNAs mapped to the human genome regions that are known to be altered in cancer, and a similar number of miRNAs are aberrantly expressed in cancerous tissues<sup>[90,91]</sup>. By analyzing miRNA expression profile (miRNome) of prostate, stomach, pancreas, lung, breast and colon tumors, Volinia and colleagues identified a solid cancer miRNA signature including those with well-characterized cancer association, such as miR-17-5p, miR-20a, miR-21, miR-92, miR-106a, and miR-155<sup>[92]</sup>. In particular, 21 miRNAs are up-regulated and 1 is down-regulated in colon tumors compared to normal tissue<sup>[92]</sup>. MiRNA profiles can identify different tissue and tumor types better than mRNA expression patterns, making them attractive targets for development as cancer biomarkers<sup>[93]</sup>. Distinguished miRNA profiles can even be found in the serum of patients with cancers. The functions of such circulating miRNAs have not been identified, but profiling of serum miRNAs might be a powerful approach for early cancer diagnosis. The cancer-associated miRNAs may function as oncogenes or tumor suppressors depending on their role in carcinogenesis. Some of the best examples of such miRNAs will be discussed in this section

(Figure 2).

### Oncogenic miRNAs

MiR-21 is one of the most up-regulated miRNAs in various cancers, including CRC<sup>[92,94]</sup>, and was identified as an independent predictor of overall survival in the validation set containing tumor samples from 113 patients with CRC<sup>[95]</sup>. It has been shown that miR-21 is involved in invasion, intravasation and metastasis processes by targeting the tumor suppressor PDCD4<sup>[96]</sup>, and in CRC tissues expression of miR-21 is inversely correlated with that of PDCD4 compared to normal tissue<sup>[97]</sup>. Shibuya and colleagues suggested that miR-21 expression may predict poor prognosis in CRC<sup>[98]</sup>. Likewise, these authors also examined the prognostic value of miR-155 in CRC since its expression is up-regulated in tumor tissues compared to normal adjacent tissues from CRC patients<sup>[98]</sup>. MiR-155 was previously shown to target the tumor protein 53-induced nuclear protein 1 (TP53INP1), a pro-apoptotic stress-induced p53 target, and significant reduction or loss of TP53INP1 expression was detected during adenocarcinoma progression<sup>[99]</sup>.

MiR-17-92 and miR-106b-25 clusters are known to be up-regulated in CRC stromal tissues compared with normal stroma<sup>[100]</sup>. They include, respectively, multiple mature miRNAs, miR-17, miR-18a, miR-19a, miR-20a, miR-19b1, miR-92-1<sup>[101]</sup>, and miR-106b, miR-93 and miR-25<sup>[102]</sup>. These miRNA clusters play an important role

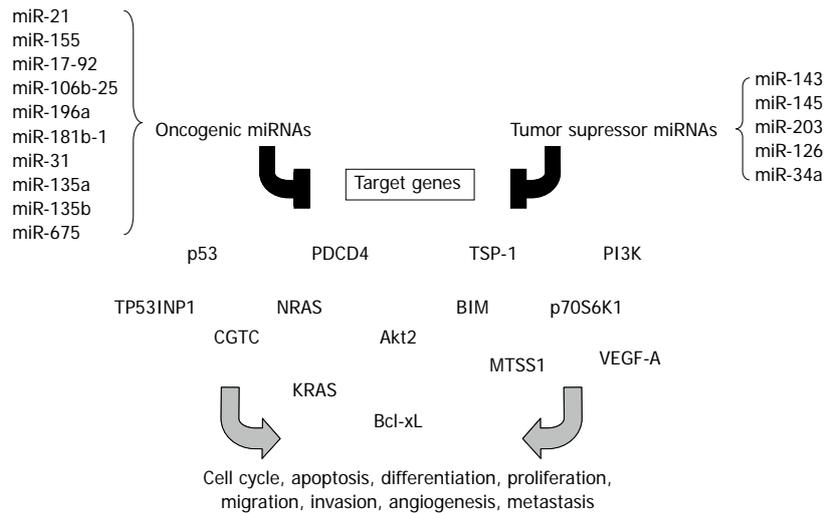

Figure 2 Overview of “oncogenic” and “tumor suppressor” microRNAs related to colorectal cancer described in this review, their targets and different carcinogenesis pathways in which they have been implicated.

during carcinogenesis<sup>[92,100,103,104]</sup>. An anti-apoptotic effect of miR-17-92 appears to be one of the mechanisms underlying its procarcinogenic role in CRC development and progression<sup>[105]</sup>. Abrogation of miR-92a leads to cell apoptosis, and there is a correlation between the miR-17-92 overexpression in tumors of CRC patients and the downregulated expression of BIM, a member of the Bcl-2 family that promotes apoptosis<sup>[105]</sup>. Some works have reported that there is an interconnection between the expression of miR-17-92 cluster and angiogenesis, which occurs later in tumor development and is one of the most important stages in carcinogenesis. Dews and colleagues demonstrated that the anti-angiogenic factors thrombospondin-1 (tsp-1) and connective tissue growth factor (CTGF) are down-regulated by this cluster in intestinal epithelial cells expressing constitutively the oncogene c-myc<sup>[106]</sup>, which was shown to be involved in regulation of miR-17-92 expression<sup>[20]</sup>. MiR-18 targets tsp-1 and miR-19 modulates the expression of CTGF<sup>[107]</sup>.

Other miRNAs have also been identified as causal factors in colon carcinogenesis. For example, miR-196a had higher expression level in CRC tissues than in normal epithelial tissues<sup>[108]</sup>. MiR-196a exerts a pro-oncogenic influence in CRC as a high level of its expression promotes the oncogenic phenotype of colorectal cancer cells such as increased cell detachment, migration and invasion<sup>[109]</sup>. MiR-31 is often up-regulated in CRC and its high expression associated with advanced tumor stage but the clinical significance is unclear<sup>[110]</sup>. MiR-181b-1, miR-135a, miR-135b, miR-675 are also known to be up-regulated in CRC tumors<sup>[111]</sup>. MiR-135a is able to promote the growth and invasion of CRC cells by targeting the metastasis suppressor 1<sup>[112]</sup>.

### Tumor suppressor miRNAs

Mir-143 and miR-145 are among the best examples of tumor suppressor miRNAs. The expression of these miRNAs is down-regulated in CRC tumors, and in other

cancers such as breast, prostate, cervical and lymphoid cancer<sup>[113-115]</sup>. Many studies have reported that down-regulation of miR-143 and miR-145 correlates with poor prognosis<sup>[110,115,116]</sup>. The expression and post-transcriptional maturation of these miRNAs were recently shown to be enhanced by the tumor suppressor p53 in response to DNA damages in CRC cell lines<sup>[28,117]</sup>. In particular, miR-143 is involved in inhibition of oncogene KRAS expression<sup>[118]</sup>. MiR-145 is reported to inhibit tumor growth and angiogenesis by directly targeting p70S6K1<sup>[117]</sup>, which is activated by mTOR, and its overexpression in cancer cells induces tumor angiogenesis<sup>[119-121]</sup>. Another study reported that this miRNA is able to inhibit tumor growth and angiogenesis in breast cancer by targeting N-RAS and VEGF-A, which are key players in carcinogenesis<sup>[122]</sup>.

It was recently demonstrated that miR-34a is down-regulated in colon tumors and also in circulating blood<sup>[123]</sup>. Furthermore, ectopic expression of miR-34a in CRC cell line reduces cell proliferation, demonstrating that this miRNA has a tumor suppressive function in colon carcinogenesis<sup>[124]</sup>. Several studies conducted in 2007 revealed that miR-34a can target p53, leading to apoptosis and cell cycle arrest<sup>[21-24,125]</sup>. MiR-203 is identified as another tumor suppressor miRNA. Its low expression was found *in vitro* in CRC cell lines and was correlated with tumor size in CRC. MiR-203 can inhibit proliferation of cancer cell lines<sup>[126]</sup>. Li *et al.*<sup>[127]</sup> showed that miR-203 overexpression significantly decreased cell proliferation and survival and induced cell apoptosis in the p53-mutated CRC cells. The tumor suppressive role of miR-203 was mediated by negatively regulating Akt2 expression *via* mRNA degradation. In addition, overexpression of miR-203 decreased expression of the anti-apoptotic gene Bcl-xL, leading to a resistance to apoptosis<sup>[127]</sup>. MiR-126 is specifically expressed in endothelial cells and is known to be down-regulated in CRC compared to normal tissue *via* an unknown mechanism<sup>[128]</sup>. *In vitro* studies suggested that a loss in negative regulation of p85 subunit of PI3K

by miR-126 could lead to a selective growth advantage during colon carcinogenesis<sup>[129]</sup>.

## CONCLUSION

MiRNAs are a class of gene regulators that have recently emerged as key players in the innate and adaptive immune system. Changes in miRNA expression are observed in many human diseases such as inflammatory bowel disease and cancers. Dysregulated miRNA expression profiles in IBD have been reported and could be used as diagnostic biomarkers but further studies are needed to examine the mechanism of their action in the etiopathogenesis of this disease and their clinical utility. Emerging evidence suggests that miRNAs play important roles in the pathogenesis of a limited range of human cancers. Some miRNAs may be directly involved in cancer development by controlling cell differentiation and apoptosis, while others may be involved in cancers by targeting cancer oncogenes and/or tumor suppressors. Given the critical role of miRNAs, current studies are focusing on their association with CRC incidence and prognosis and on the possibility of using circulating miRNAs or fecal miRNA expression as noninvasive early detection biomarkers. These data suggest that miRNAs may be potential molecular classifiers, early detection biomarkers, and therapeutic targets for CRC. Finally, miRNA-based cancer therapy has been limited to targeting a single miRNA<sup>[130,131]</sup>. However, it has been recently shown that the small molecule enoxacin, a fluoroquinolone used as an antibacterial compound, enhances the miRNA-processing machinery by binding to TRBP<sup>[132]</sup>. Thus, if most cancers are characterized by a dysregulation of global mature miRNA expression, restoration of the global miRNome may be an attractive approach in cancer therapy. In conclusion, a better understanding of the function of miRNAs is providing new insights into the molecular basis of human pathologies, and new biomarkers for disease diagnosis and therapy.

### Abstract

Tumors have long been viewed as a population in which all cells have the equal propensity to form new tumors, the so called conventional stochastic model. The cutting-edge theory on tumor origin and progression, tends to consider cancer as a stem cell disease. Stem cells are actively involved in the onset and maintenance of colon cancer. This review is intended to examine the state of the art on colon cancer stem cells (CSCs), with regard to the recent achievements of basic research and to the corresponding translational consequences. Specific prominence is given to the hypothesized origin of CSCs and to the methods for their identification. The growing understanding of CSC biology is driving the optimization of novel anti-cancer targeted drugs.

**Key words:** Colon cancer stem cells; Colorectal cancer; CD133; Therapy; Chemoresistance

**Core tip:** According to the “cancer stem cell” (CSC) theory, tumor growth and spread are driven by a minority of cancer cells which exhibit characteristics similar to normal stem cells. Although CSCs have been implicated in colon carcinogenesis, due to the complexity of their biology and unsolved technical issues, an unequivocally approved identification and isolation strategy is still a matter of debate. Several markers have been used to identify colon CSCs but the function of these proteins in CSC biology has not yet been clarified. Moreover, the possibility that CSCs might contribute to the failure of existing chemotherapies to eradicate malignant tumors, indicate that targeting of CSCs may represent a promising strategy to eradicate chemoresistant cancers. Aim of this review was to acquire more information on the biology of human colon CSCs and shed light on the role of this cells in the onset and the maintenance of colon cancer.

### INTRODUCTION

The intestine epithelium is subjected to a rapid and continuous regeneration, supported by crypt intestinal stem cells (ISCs). This feature severely increases the risk for malignant conversion<sup>[1]</sup>. Indeed, colorectal cancer (CRC) is one of the most common type of neoplasm worldwide, representing the second leading cause of morbidity and mortality from cancer in both Europe and the United States. This means that CRC can also be considered one of the main national emergencies, both in terms of morbidity and in terms of social and economic costs<sup>[2]</sup>.

Studies on CRC pathogenesis have been originally focusing on the clonal selection process, a model of carcinogenesis postulated in 1975<sup>[3]</sup>. The characterization

of the genetic mechanisms underlying this process has been performed, for the first time, in the early 90s by Bert Vogelstein, who developed the molecular model of CRC progression known as “Vogelstein model”. According to it, the CRC develops from epithelial cells lining the gastrointestinal tract, which undergo sequential mutations in specific DNA sequences that disrupt normal mechanisms of proliferation and self-renewal<sup>[3,4]</sup>. This pathogenic model still represents a paradigm of tumor growth and provides a standard rationale to dissect the molecular mechanisms responsible for CRC. Though, current anticancer treatments are often unable, even those based on molecular targeted strategies, to eradicate the disease. Otherwise, the cellular origin of human cancers is still controversial and the mechanisms responsible for the complexity and heterogeneity of tumors remain to be defined<sup>[3,4]</sup>. In recent years, converging evidence has suggested that human cancer can be considered as a stem cell disease. Therefore, the “stochastic” theory for the cellular origin of cancer, based upon the assumption that all cancer cells are equally malignant and able to give rise to tumors, has been abandoned in favor of the “hierarchical” theory. The latter assumes that: (1) tumors are hierarchically organized; and (2) only a rare subpopulation of undifferentiated cells at the apex of this hierarchy have the unique biological properties necessary for tumor initiation, maintenance and spreading. Given the similarities between tumor-initiating cells and normal stem cells (SC), the tumor-initiating cells have been termed “cancer stem cells” (CSCs)<sup>[5]</sup>. In its simplicity, this hypothesis suggests that tumorigenesis is an “aberrant organogenesis”, supported by a minority of cancer cells, that by consecutive genetic changes, can differentiate to give rise to different phenotypes in the neoplastic population<sup>[6]</sup>.

The hierarchical model implies that within tumors there are cells with different tumorigenic potential: cells that have lost the ability to propagate the tumor and cells that retain their clonogenic ability. Indeed, biologically distinct populations of CSCs have been identified within hematological malignancies<sup>[7]</sup> and in most solid tumors, including colon cancer<sup>[8,9]</sup>. The origin of CSCs is still unclear but the discovery of stem cells in the majority of normal tissues, including colon crypts, support the hypothesis that normal SC might represent a possible target for tumorigenic mutations, due to both their long life and their capacity of self-renewal<sup>[10]</sup>.

Cancer stem cells theory has profound translational implications. Current treatments are hardly able to completely eradicate cancer cells, being often complicated by the occurrence of tumor recurrence and/or metastasis and are burdened by toxicity issues. The failure of chemotherapy may at least in part lie in its capacity of targeting the bulk of cancer without affecting stem cells. These can on turn replicate after treatment and, eventually, develop selective features responsible for the occurrence of drug-resistance, which usually characterize and complicate the course of the disease<sup>[11-13]</sup>.

Several studies have suggested that the CSC fraction

may be identified within a variety of human cancers, including CRC, by the expression of the CD133 surface marker<sup>[8,9,14,15]</sup>. CD133 (also known as prominin-1 in rodents or AC133 in humans), a 120 kDa transmembrane and cell surface protein, has been shown to characterize normal and cancer stem cells in several human tissues, including the colonic mucosa. Hence, CD133 has been used to identify and isolate tumor initiating cells from human colon cancers. CD133+ cells are able to maintain themselves as well as to differentiate and re-establish tumor heterogeneity upon serial transplantation *in vivo*<sup>[8,9]</sup>. However, despite constant research efforts, the molecular mechanisms and signaling pathways that regulate the behavior of CD133-expressing cells remain unknown. Aim of this review was to acquire more information on the biology of human colon CSCs and shed light on the role of CD133+ tumor-initiating cells in the onset and the maintenance of colon cancer.

## CANCER STEM CELLS: PROPERTIES

It is widely accepted the concept that tumor is an heterogeneous entity derived from a small subpopulation of undifferentiated cancer cells, the CSCs. CSCs are defined as cells having three unique properties: the capacity of self-renew indefinitely, the ability to recreate the full repertoire of cancer cells of the parent tumor and the expression of a distinctive set of surface biomarkers<sup>[16]</sup>. It must be emphasized that self-renewal is not synonymous with proliferation. Self-renewal involves the ability of SC populations to precisely maintain their numbers through a combination of symmetric and asymmetric SC division, giving rise to one or both daughter cells identical to the mother and retaining SC properties<sup>[17]</sup>. In the case of CSCs, mechanisms involved in self-renewal are deregulated and seem to lead to CSC overpopulation. The underlying mechanisms for generating excess of CSC numbers are believed to relate to increases in symmetric CSC division (which produces two CSC daughters) relative to asymmetric CSC division (which produces one CSC daughter and one non-CSC daughter). Many authors have documented this concept quantitatively, using mathematical modeling<sup>[17]</sup> or fluorescent dye assay<sup>[18]</sup>. These authors have showed that only increased symmetric division of CSCs could account both for the biologic observation that there is an exponential increase in CSC populations in tumoral tissues and for the known long lag phase, which is typical in the development of many cancers, including colorectal cancer<sup>[17]</sup>. Although CSCs have the capacity for self-renewal, they are relatively quiescent; that is, they have proliferative capacity but are often not cycling. Indeed, they have been shown to have significantly longer cell cycle times than proliferating non-SCs. This is presumably due to the arrest of SCs at a G0-like cell cycle phase or checkpoint<sup>[19]</sup>.

Another property of CSCs is their potential for multilineage differentiation. This is consistent with the concept that CSCs, like normal SCs, give rise to a hierarchical

organization of cell populations that underlie organogenesis<sup>[20]</sup>.

CSCs also display alterations of DNA repair, due to the presence of cytoprotective properties (including telomerase activation and high expression of anti-apoptotic factors), and a relatively low proliferative potential. In addition, they express high levels of proteins belonging to the ABC membrane transporters family, involved in chemotherapeutic resistance (*i.e.*, to paclitaxel, cisplatin, 5-fluorouracil, mitoxantrone, methotrexate, anthracyclines, etoposide, vinca alkaloids, camptothecins, topotecan, imatinib)<sup>[20]</sup>. These unique properties of CSCs would explain the failure of many antitumor therapies, which affect rapidly dividing cells, determining only a reduction of tumor cells number, while CSCs divide slowly and are not sensitive to the cytotoxic drugs. New insight in the molecular mechanisms that underlie these processes were obtained by studying the intracellular regulator of gene expression<sup>[21]</sup>.

On this regard, Bitarte and colleagues showed that the micro RNA miR-451 was downregulated in colonospheres, obtained from different colon carcinoma cells, versus parental cells. The expression of miR-451 caused a decrease in self-renewal, tumorigenicity, and chemoresistance to irinotecan of colonospheres. Authors demonstrated that miR-451 downregulation allows the expression of the target gene macrophage migration inhibitory factor, which induces cyclooxygenase-2 (COX-2) expression. In turn, COX-2 allows Wnt activation, which is essential for CSC growth. Furthermore, miR-451 restoration decreased expression of the ATP-binding cassette drug transporter ABCB1 and resulted in irinotecan sensitization. These findings correlated well with the lower expression of miR-451 observed in patients who did not respond to irinotecan-based first-line therapy compared with patients who did<sup>[22]</sup>. Moreover, various signaling pathways have already been identified and described in CSCs. It is known that standard pathways for self-renewal of normal stem cells, such as Wnt, Notch and Hedgehog signaling, are also present in CSCs and have an important role in their function. Targeting critical steps in those pathways, however, will be complicated by intense crosstalks as well as main safety issues related to the pleiotropic effects of these signaling molecules<sup>[23]</sup>. Nevertheless, there are already several reports indicating that CSCs can be selectively targeted without damaging normal stem cells<sup>[24]</sup>. These and other findings could reasonably pave the way to the development of novel, more efficient and less toxic anti-cancer medications.

## CANCER STEM CELLS: DEFINITION

In operational terms, CSCs can only be defined experimentally on the basis of their ability to regenerate continuously the tumor. The implementation of this approach, explains the use of alternative terms in the literature. For example, the term “tumor-initiating cells” is frequently used to describe putative CSCs. However, both

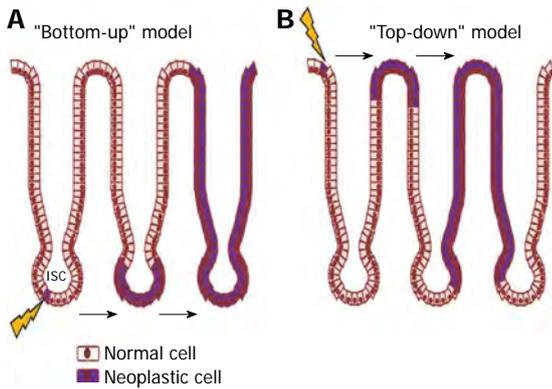

these terms (cancer stem cell and tumor-initiating cells) can cause confusion about the cell type to which they relate<sup>[16]</sup>. In fact, the term CSCs might suggest that these cells arise from normal stem cells, which have acquired a number of genetic mutations sufficient to induce malignant transformation. This assumption is probably true in many cancers, but may not be the case of all tumors. It is plausible, indeed, that in some tumors, a number of differentiated cells can acquire the capacity for self-renewal, through multiple mutagenic events, and thus “reacquire” stem-like properties<sup>[25]</sup>.

On the other hand, the term “tumor-initiating cells”, according to experimental evidence, refers to the ability of these cells to initiate tumors when transplanted in a xenograft model. In this case, it could be incorrectly inferred that the cell that gives rise to the xenograft tumor is the same cell in which the first oncogenic mutation occurred. This is unlikely, since it is clear that the cells that drive aberrant growth at one precise moment may differ from those acting during different stages in tumor evolution or during metastasis. Furthermore, both genetic and epigenetic instability can induce cellular heterogeneity within the stem and non-stem cell populations of the tumor<sup>[26]</sup>. It has been argued that species differences alone might account for the selective growth of subpopulations of cells in xenotransplantations. Indeed, the great majority of cells in a mouse lymphoma were shown recently to possess tumor initiating capacity when allografted into syngenic mice<sup>[27]</sup>.

## WHICH IS THE ORIGIN OF COLON CANCER STEM CELLS?

Although, as mentioned earlier, the sequence of events in CRC has been intensively studied, the cell of origin for cancer formation is still poorly known. Two possible hypotheses have been suggested: the so called “bottom-up” and the “top-down” theories. The first proposes that an ISC, either a progenitor or a differentiated cell, is the first transformed cell, as a consequence of anomalous differentiation, giving rise directly to cancer cells or reprogramming itself, acquiring SC behavior before inducing cancer<sup>[28-30]</sup> (Figure 1).

ISCs represents the ideal target for neoplastic transformation, due to their extended life span that alter their behavior as a result of genetic and epigenetic changes. Also, similar signalling pathways may regulate self-renewal in stem cells and cancer cell, so that the transformation of an SC would require fewer mutations compared to a progenitor cell<sup>[31,32]</sup>. Conversely, histological evidence suggested that colon cancer might arise from late progenitors or even an early differentiated cell<sup>[33]</sup>, sustaining the “top-down model” of CRC development. By contrast, genetic observation recently support strongly the bottom-up theory. Indeed, the identification of specific genes expressed in the stem cells of the intestine has recently allowed to show that the cell of origin of adenomas, induced by a constitutively active Wnt signaling, is the stem

**Figure 1** Schematic presentation of two possible ways of colon adenocarcinoma formation. A: “Bottom-up” theory: intestinal stem cells (ISCs, arrow) at the base of the crypt, within the stem cell zone, are the cell of origin of neoplasia as a consequence of anomalous differentiation; B: “Top-down” theory: a progenitor or differentiated cell is the first transformed cell that can acquire stem cells (arrow) behavior before inducing cancer.

cell of the small intestine<sup>[30,34,35]</sup>. These studies have demonstrated that ISC-specific deletion of both functional adenomatous polyposis coli (APC) alleles using *Bmi1*-, *CD133*- and (leucine-rich-repeat containing G-protein-coupled receptor 5) *Lgr5*- CRE recombinase mice leads to efficient tumor formation. Interestingly, Barker and colleagues also showed that tumor formation does not occur when APC is deleted in progenitors or differentiated cells<sup>[30]</sup>. These results show that the cell giving rise to adenomas in the small intestine is the stem cell. It is still pending, though, whether *BMI*-, *LGR5*-expressing cells or *CD133*-expressing cells of the tumor, are able alone to induce tumor progression and therefore are markers of the intestinal CSC.

Recently, Schwitalla *et al.*<sup>[36]</sup> have suggested that these models do not exclude each other and that tumor-initiating mutations can occur in both *Lgr5*+ crypt stem cells or in more differentiated *Lgr5*-cells, as long as these initially negative cells dedifferentiate and re-express *Lgr5*. Indeed, the authors have demonstrated, in a genetic model of intestinal tumor initiation, that epithelial non-stem cells can re-express stem cell markers and be converted into tumor-initiating cells. This phenomenon is strictly dependent on the degree of Wnt activation and can only be observed when Wnt signaling is markedly elevated<sup>[37]</sup>.

It has also been discussed that even cells from outside the tumor, for example, bone marrow-derived cells, might also serve as CSC’s ancestors. This phenomenon has been firstly demonstrated in a murine model of gastric cancer induced by *Helicobacter pylori*, in which SC derived from bone marrow were able to generate the tumor<sup>[37,38]</sup>.

Emerging evidence suggests that bone-marrow-derived mesenchymal stem cells (BM-MSCs) contribute to tissue regeneration in the colon partly by promoting neovascularization or arteriogenesis<sup>[39,40]</sup>. Although tumor stromal fibroblasts are mainly recruited from local tissue fibroblasts, it has been proposed that BM-MSCs are recruited into the stroma of developing tumors<sup>[41-43]</sup>. Several studies have demonstrated that BM-MSCs can se-

lectively migrate to sites of mucosal damage and wound healing including colorectal cancers, where a number of tumor-related inflammatory reactions and abnormal tissue regeneration phenomena take place actively. It also has been shown that cancer cells release specific factors that induce BM-MSC mobilization and recruitment to the tumor stroma where they eventually contribute to the formation of a tumor-supportive microenvironment<sup>[44]</sup> (Table 1).

## IDENTIFICATION OF COLON CANCER STEM CELLS: LIMITS AND CONTROVERSIES

The correct identification and isolation of the cells responsible for tumor formation is always challenging in cancer research. Although CSCs have been implicated in colon carcinogenesis, due to the complexity of their biology and unsolved technical issues, an unequivocally approved identification and isolation strategy is still a matter of debate<sup>[32]</sup>. The gold standard for identifying a CSC is the capacity to propagate tumors as xenografts in immunocompromised mice. However, it has been argued that species differences alone might account for the selective growth of subpopulations of cells in these assays. Indeed, the great majority of cells in a mouse lymphoma were shown recently to possess tumor initiating capacity when allografted into syngenic mice<sup>[27]</sup>. Moreover, serial transplantation experiments with animal models are laborious and time-consuming, hence the need to develop reliable surrogate assays.

Several *in vitro* assays have been used to identify CSCs can derive, including sphere assays, surface cell markers and the Hoechst dye efflux properties, which identify the

so-called Side-Population (SP). Studies have also been performed to define putative CSC genetic signatures. However, each of these methods has potential pitfalls that complicate the interpretation of results<sup>[25]</sup>.

It is clearly not sufficient to define a stem cell based only on surface markers. Moreover, none of the markers used to isolate stem cells in various normal and cancerous tissues is expressed exclusively by the stem cell fraction. Indeed most markers used for colon CSC isolation are chosen either because they are expressed in normal stem cells or as they were found to identify CSCs in other malignancies, either hematological or solid. The disadvantage of choosing markers in this fashion is that the functional effect of expression of the marker in CSCs is usually unknown.

For instance, focusing on CRC, several studies have suggested that the CSC fraction within colon cancer might be identified by the expression of the cell surface marker CD133<sup>[8,9]</sup>. CD133 is a trans-membrane glycoprotein, expressed by normal progenitors belonging to neuronal, hematopoietic, epithelial and endothelial lineages. In the last years, CD133 has become the “molecule of the moment”, being recognized as a putative CSC marker for many human solid tumors, including liver, pancreas and colon neoplasms<sup>[14,45]</sup>. However, despite constant research efforts, the molecular mechanisms and signaling pathways that regulate the behavior of CD133-expressing CSC, remain unknown.

In particular, we demonstrated the existence of a population of self renewing cells expressing CD133 within primary and metastatic human CRC<sup>[5]</sup>. This antigen was expressed in significantly higher percentage in CRC samples, compared to the respective normal tissues. CD133-positive cells were also found in liver metastases (up to 10%), while they were hardly detectable in the healthy liver tissue<sup>[5]</sup>. In addition, CD133+ cells, isolated from different human colonic adenocarcinoma lines (CaCo-2, HT29, LoVo), were highly clonogenic *in vitro* and gave rise to tumors following transplantation in mice. Conversely, the CD133-negative fraction of all cell lines had a lower clonogenic potential in soft agar assays and did not generate tumors in secondary recipients<sup>[45]</sup>, confirming the tumor initiating properties of CD133+ CSC. Interestingly, we also provided the original demonstration that modulation of CD133 expression in the CaCo-2 colon cancer cell line was associated with corresponding variations in the expression levels of both Endothelin-1 and nuclear receptor subfamily 4, group A, member 2<sup>[46]</sup>, both known to play an important role in the proliferation and metastasis processes. This modulation was associated with a significant inhibition of the cells' clonogenic and migration ability, thus further confirming a role of the CD133 molecule in the definition of the CSC phenotype<sup>[46]</sup>.

There are though still some controversies on the role of CD133 as a CSC marker in CRC; the opposing theories emerge from the evidence that most CD133 antibodies target glycosylation-dependent epitopes<sup>[35]</sup>, whose

presence is related to the differentiation stage of the cell. Experimental data from colon and glioblastoma cells suggested that the differential glycosylation of specific epitopes may mask the presence of CD133 on cells previously characterized as negative<sup>[47,48]</sup>. Moreover, CD133 has been found to be expressed by the full spectrum of undifferentiated and differentiated colonic epithelial cells, both in humans and in mice<sup>[49]</sup>. Shmelkov *et al.*<sup>[49]</sup> have demonstrated that primary and metastatic colon cancers contain CD133+ and CD133- parenchymal tumor cells, and both types of cells are capable of tumor initiation, as observed in a xenotransplantation model. A similar lack of specificity has been also observed for other potential CSC markers of CRC, such as CD44, CD166, CD29, CD24, Lgr5, and nuclear beta-catenin<sup>[50]</sup>. In fact, the vast majority of cells that express these markers are not stem cells<sup>[51]</sup>.

Another approach to identify CSCs is their presence within the so-called “Side Population”. SP cells have been first described within the hematopoietic system. In particular, bone marrow stem cells contain a subpopulation that extrude the DNA-binding dye, Hoechst 33342, out of the cell membrane. Comparing the fluorescence intensity on the wavelength of blue against the red, the SP appears as a tail of cells with low fluorescence. This phenotype is attributed to the activity of the ABC membrane transporter proteins that can confer drug resistance to stem cells. These proteins can be blocked by inhibitors of efflux pumps, such as verapamil<sup>[52-54]</sup>. The SP fractions have been identified in various human tissues<sup>[55,56]</sup>, cancer specimens<sup>[57,58]</sup> and tumor cell lines<sup>[59,60]</sup> and it has been suggested that they may represent the true stem cell population. However, as with cell surface markers, the SP phenotype is not synonymous with stemness. Indeed, a recent article claimed that both SP and non-SP cells, isolated from gastrointestinal cancer cell lines, displayed similar clonogenic and tumorigenic potential *in vitro* and *in vivo*, and showed identical expression of putative stem cell markers. Therefore, the Authors concluded that the SP does not enrich for stem cells in gastrointestinal cell lines<sup>[61]</sup>. Also, possible toxicity of the dye, in cells not capable of extrusion, should also be considered as a caveat to interpreting functional assays of SP cells.

Without a better understanding of normal tissue stem cells and their susceptibility to neoplastic transformation, it will be difficult to conduct conclusive studies of the existence and origins of CSCs (Table 1).

## WHICH STRATEGY TO TARGET COLON CSCS?

According to the CSC model, the few self-renewing CSCs that mediate tumor growth are difficult to kill and their persistence might explain tumor recurrence after therapy<sup>[62]</sup>. Indeed, chemotherapeutics interfere with the ability of rapidly growing cells to divide, so CSCs may be spared, leading to tumor recurrence and metastasis<sup>[11-13]</sup>. Therefore, to assess the efficacy of therapeutics, it is

necessary to accurately distinguish tumorigenic from non-tumorigenic cancer cells and to understand which progression model occurs in the tumor. Unfortunately, the complex network of mechanisms that regulate SC renewal and carcinogenesis is not clear.

Chemotherapeutic resistance is exerted either through a shift from active state to quiescence or through a wide spectrum of protective mechanisms that characterize CSC biology; these include altered DNA damage repair, altered cell-cycle checkpoint control, malfunction of apoptosis, expression of drug transporters and detoxifying enzymes, and a high expression of proteins belonging to the ABC membrane transporters family<sup>[63,64]</sup>.

Moreover, the plasticity of CSCs and the epithelial-to-mesenchymal transition (EMT) complicate therapeutic approaches because participate in the acquisition of both *de novo* and acquired drug resistance<sup>[65]</sup>. Indeed, EMT can trigger reversion to a CSC-like phenotype, providing an association between EMT, CSCs and drug resistance<sup>[66]</sup>. Several key signaling pathways contribute to this process, such as transforming growth factor  $\beta$  and Wnt, that are well known to induce EMT and promote stem cell maintenance<sup>[67,68]</sup>. Recent studies have implicated microRNA functionality in these processes; indeed the dysregulation of microRNA expression is likely to be a major contributing factor in the etiology of some cancers<sup>[69,70]</sup>.

It is therefore essential to renovate the therapeutic repertoire by designing new treatments that specifically target CSCs and, at the same time, also eliminate the non-CSC population, intervening in the process of EMT<sup>[65,71]</sup>. Novel therapeutic strategy based on targeting EMT pathways and CSC maintenance might be a promising tool for CRC defeat.

Moreover, CSCs can be functionally antagonized by inducing their differentiation. Differentiation therapy forces cells to shift into a mature phenotype, lose their self-renewal abilities, and therefore become vulnerable to conventional treatment. For instance, salinomycin, a highly selective potassium ionophore, was recently described as the first compound that can selectively eradicate the tumor through induction of terminal epithelial differentiation of CSCs<sup>[72]</sup>. Gupta *et al.*<sup>[72]</sup> revealed that salinomycin decreases the proportion of CD44<sup>high</sup>/CD24<sup>low</sup> breast cancer cells, whereas paclitaxel has opposing effects. Importantly, cells exposed to salinomycin were less capable of inducing tumors following injection into mice; salinomycin also slowed the growth of the animals' tumors through unknown mechanisms<sup>[71]</sup>. Salinomycin is thought to inhibit potassium-positive channel-regulated migration and interfere with EMT and metastasis<sup>[72]</sup>. Also induction of differentiation in colon CSCs by exposing these cells to Bone Morphogenetic Protein 4 (BMP4), which can initiate a differentiation program as well as mediate apoptosis, sensitizes CRC cells to the effects of 5-Fluorouracil (5-FU) or oxaliplatin *in vivo*, resulting in complete and long term regression of colon xenografts<sup>[73]</sup>.

The potential toxic effect, that might occur from the impact on normal SCs, can be minimized by target-

ing molecules or pathways that are preferentially active in CSCs<sup>[73]</sup>. Monoclonal antibodies could be directed against cell surface molecules, such as CD133, CD44, or even drug transporters, resulting in reduction of tumor size, metastatic potential, and resistance to chemoradiotherapy<sup>[74,75]</sup>.

Advances in high-throughput technologies and bioinformatics will allow developing additional compounds targeting CSC signaling pathways. Currently there are two established targets for such therapies: epidermal growth factor receptor (EGFR), which belongs to the ErbB family of tyrosine kinase receptors and is abnormally activated in many tumors<sup>[76]</sup>, and vascular endothelial growth factor (VEGF), which is known to promote formation of new vessels by inducing growth and differentiation of endothelial cells<sup>[77,78]</sup>. Several clinical trials have demonstrated that introduction of targeted therapies with monoclonal antibodies against EGFR (cetuximab) and VEGF (bevacizumab) in addition to 5-FU, resulted in a significant survival increase in patients with advanced disease<sup>[79]</sup>.

Another rational target includes blockage of various self-renewal pathways, including Wnt, Notch, PTEN, and Hedgehog<sup>[80]</sup>. Small-molecules that inhibit the Wnt pathway and  $\gamma$ -secretases that inhibit the Notch pathway have been recently identified as novel approaches to CRC<sup>[73]</sup>. The Wnt/ $\beta$ -catenin pathway has been implicated in the maintenance of the intestinal crypt stem cell phenotype and Wnt signaling dysregulation through either loss of APC function or oncogenic  $\beta$ -catenin mutations has been shown to cause the majority of sporadic cancer cases<sup>[81]</sup>. Disruption of Tcf/ $\beta$ -catenin complexes by selected small-molecule antagonists has been shown to antagonize cellular effects of  $\beta$ -catenin and to result in inhibition of cellular proliferation in colon cancer cells<sup>[82]</sup>. Similarly, the Notch signaling pathway has been reported to be overexpressed in colon CSCs, where it was found to play a role in colon CSC viability, tumorigenicity, and self-renewal<sup>[83-87]</sup>. Van Es *et al.*<sup>[87]</sup> have demonstrated that blocking the Notch cascade with a gamma-secretase inhibitor induced goblet cell differentiation in adenomas in mice carrying a mutation of the APC tumor suppressor gene and subsequent tumor growth arrest. Moreover, Hoey *et al.*<sup>[88]</sup> have demonstrated that by inhibiting delta-like 4 ligand (DLL4), an important component of the Notch pathway, with human monoclonal antibody 21M18 in colon carcinoma xenografts, the tumor growth as well as the CSC frequency, was decreased compared to control. Interestingly, even though treatment of the xenografts with irinotecan, a chemotherapeutic often used in colon cancer, slowed down tumor growth, and the clonogenicity was increased. Combination treatment of irinotecan with anti-hDLL4 reduced again the tumor growth and stem cell frequency, at even higher levels than the anti-DLL4 treatment alone. This indicates that inhibiting Notch signaling reduces CSC frequencies and sensitizes tumor cells for irinotecan treatment.

It has recently been observed that the inhibition of

the interleukin (IL)-4 pathway with an anti-IL-4 antibody or an IL-4 receptor antagonist in CD133+ colorectal CSCs augmented the antitumor effects of conventional chemotherapeutics<sup>[89-90]</sup>. Indeed, colon carcinomas produce IL-4 that functions in an autocrine manner, promoting antiapoptotic pathways in these tumors. Inhibiting IL-4 by blocking antibodies sensitizes the cells for killing by 5-FU and oxaliplatin IL-4<sup>[89-90]</sup>.

Reversing chemoresistance and radioresistance represents a promising proposal. This can be achieved through interference with a plethora of cellular components, including inactivation of drug transporters and DNA checkpoint kinases, depletion of reactive oxygen species scavengers, and inhibition of signal transduction pathways.

Interestingly, little is as of yet known with regard to the metabolism of CSC population, leaving an exciting avenue unstudied in the dawn of the emerging field of metabolomics. The Warburg effect, the premise of which is that cancer cells restrict use of fatty-acid oxidation in favor of glycolysis as an ATP energy source, can also be harnessed to create novel broad-spectrum anticancer agents<sup>[91-94]</sup>. A recent study by Akao *et al.*<sup>[95]</sup> provided initial evidence of metabolic changes in therapy-resistant cell populations by demonstrating significant overexpression of a metabolic “master-regulator” Sirt1 in DLD-1 5-FU-resistant cells.

Altogether, these data illustrate the therapeutic utility of the cancer stem cell concept, which, by enabling specific examination of more aggressive cancer-initiating and cancer propagating subpopulations, provides the tools for discovery of novel mechanisms of cancer therapeutic resistance (Table 1).

## CONCLUSION

Understanding the details of CSCs' biology is a primary goal in basic oncology research but would also pave the way for a better clarification of CRC progression. The translation implication of such information is clearly deducible. In particular, the combination of previously known and new markers defining CSC specificity, could lead to the development of a better oriented anticancer therapy, possibly targeting CSCs.

### Abstract

**AIM:** To investigate the effectiveness of antioxidant compounds in modulating mitochondrial oxidative alterations and lipids accumulation in fatty hepatocytes.

**METHODS:** Silybin-phospholipid complex containing

vitamin E (Realsil®) was daily administered by gavage (one pouch diluted in 3 mL of water and containing 15 mg vitamin E and 47 mg silybin complexed with phospholipids) to rats fed a choline-deprived (CD) or a high fat diet [20% fat, containing 71% total calories as fat, 11% as carbohydrate, and 18% as protein, high fat diet (HFD)] for 30 d and 60 d, respectively. The control group was fed a normal semi-purified diet containing adequate levels of choline (35% total calories as fat, 47% as carbohydrate, and 18% as protein). Circulating and hepatic redox active and nitrogen regulating molecules (thioredoxin, glutathione, glutathione peroxidase), NO metabolites (nitrosothiols, nitrotyrosine), lipid peroxides [malondialdehyde-thiobarbituric (MDA-TBA)], and pro-inflammatory keratins (K-18) were measured on days 0, 7, 14, 30, and 60. Mitochondrial respiratory chain proteins and the extent of hepatic fatty infiltration were evaluated.

**RESULTS:** Both diet regimens produced liver steatosis (50% and 25% of liver slices with CD and HFD, respectively) with no signs of necro-inflammation: fat infiltration ranged from large droplets at day 14 to disseminated and confluent vacuoles resulting in microvesicular steatosis at day 30 (CD) and day 60 (HFD). In plasma, thioredoxin and nitrosothiols were not significantly changed, while MDA-TBA, nitrotyrosine (from  $6 \pm 1$  nmol/L to  $14 \pm 3$  nmol/L day 30 CD,  $P < 0.001$ , and  $12 \pm 2$  nmol/L day 60 HFD,  $P < 0.001$ ), and K-18 (from  $198 \pm 20$  to  $289 \pm 21$  U/L day 30 CD,  $P < 0.001$ , and  $242 \pm 23$  U/L day 60 HFD,  $P < 0.001$ ) levels increased significantly with ongoing steatosis. In the liver, glutathione was decreased (from  $34.0 \pm 1.3$  to  $25.3 \pm 1.2$  nmol/mg prot day 30 CD,  $P < 0.001$ , and  $22.4 \pm 2.4$  nmol/mg prot day 60 HFD,  $P < 0.001$ ), while thioredoxin and glutathione peroxidase were initially increased and then decreased. Nitrosothiols were constantly increased. MDA-TBA levels were five-fold increased from  $9.1 \pm 1.2$  nmol/g to  $75.6 \pm 5.4$  nmol/g on day 30,  $P < 0.001$  (CD) and doubled with HFD on day 60. Realsil

administration significantly lowered the extent of fat infiltration, maintained liver glutathione levels during the first half period, and halved its decrease during the second half. Also, Realsil modulated thioredoxin changes and the production of NO derivatives and significantly lowered MDA-TBA levels both in liver (from  $73.6 \pm 5.4$  to  $57.2 \pm 6.3$  nmol/g day 30 CD,  $P < 0.01$  and from  $27.3 \pm 2.1$  nmol/g to  $20.5 \pm 2.2$  nmol/g day 60 HFD,  $P < 0.01$ ) and in plasma. Changes in mitochondrial respiratory complexes were also attenuated by Realsil in HFD rats with a major protective effect on Complex II subunit CII-30.

**CONCLUSION:** Realsil administration effectively contrasts hepatocyte fat deposition, NO derivatives formation, and mitochondrial alterations, allowing the liver to maintain a better glutathione and thioredoxin antioxidant activity.

## INTRODUCTION

Simple steatosis of the liver without inflammation is considered a rather benign condition, although it represents a favoring substrate for the potentially damaging effects of a second hit (*i.e.*, ischemia-reperfusion, starvation)<sup>[1]</sup>. However, severe fatty degeneration represents a leading factor of hepatocyte dysfunction (mitochondrial respiration, microsomal metabolism, biliary secretion)<sup>[2]</sup> and is associated with excess delivery of nitrosative and oxidative stress molecules<sup>[3]</sup>, thus potentially rendering the liver a major source of systemic alterations in patients with metabolic syndrome<sup>[4]</sup>. Also, while several adaptive metabolic mechanisms have been described during the early phase of fatty infiltration<sup>[1,5]</sup> including expression of intracellular sensors and signaling molecules for lipid metabolism and oxidative stress pathways<sup>[6,7]</sup>, the threshold above which fat infiltration becomes dangerous is not clear, so far. Indeed, it has been observed that transient hepatocellular triglycerides accumulation is essential for normal liver regeneration<sup>[8]</sup> and represents a mechanism of liver protection from lipotoxicity. Buffering free fatty acids might, therefore, prevent the formation of liver steatosis<sup>[9]</sup>. By contrast, several observations suggest that ongoing fatty degeneration indeed exposes hepatocytes to higher risk of oxidative damages<sup>[10]</sup>.

Experimental rat models of liver steatosis are characterized by accumulation of triglycerides, decreased mitochondrial function, and increased activity of microsomal enzymes<sup>[2]</sup>. The altered functions of these subcellular organelles favor the enhanced production of reactive oxygen species (ROS) and NO derivatives with consequent morphological and functional modifications of crucial structures, thus rendering fatty hepatocytes particularly susceptible to additional injuring factors<sup>[3]</sup>.

A number of natural or chemical compounds are able to counteract the damages induced by oxidative and nitrosative stress and therefore are claimed to have antioxidant properties. Vitamin E efforts a remarkable protection against lipid oxidation<sup>[11]</sup> and, if vehiculated within a phospholipid complex together with silybin, a *silybum marianum* extract, protects against pro-fibrotic oxidative injury<sup>[12]</sup>. Less is known about the effectiveness of such a compound to block or modulate ROS/NO production and their pro-oxidant effects. Also, it would be of interest to know if the administration of such an antioxidant complex may contribute to break off the intracellular mechanisms leading to a progressive accumulation of neutral lipids in fatty hepatocytes and in particular, mitochondrial dysfunction.

Therefore, this study aimed to evaluate the effect of a silybin-phospholipid complex containing vitamin E (Realsil<sup>®</sup>) on hepatocyte fatty degeneration and nitrosative/oxidative stress in two different rat dietary models [choline deficiency (CD) and high fat diet (HFD)] of fatty liver. Both diets induce fatty degeneration without major inflammation and fibrosis, representing therefore ideal models for assessing changes associated with simple steatosis without the metabolic consequences depending on inflammation. The results of this study contribute to clarify both pathophysiologic mechanisms of damage in fatty hepatocytes and of pharmacological protection.

## MATERIALS AND METHODS

Male Wistar rats (b.w. 250-270 g, Harlan, S. Pietro al Natissone, Italy) were kept under controlled conditions of temperature and humidity and on a 12 h dark/light cycle. Animals were divided into five groups: rats fed a CD diet (Dyets, Bethlem, PA); rats fed a CD diet plus daily administration of Realsil by gavage (one pouch diluted in 3 mL of water and containing 15 mg vitamin E and 47 mg silybin complexed with phospholipids); rats fed a HFD (20% fat content), containing 71% total calories as fat, 11% as carbohydrate, and 18% as protein (Altromin Rieper, Vandoies, Italy); rats fed a HFD supplemented by daily administration of Realsil by gavage; control group fed a normal semi-purified diet containing adequate levels of choline, 35% total calories as fat, 47% as carbohydrate, and 18% as protein. The control diet, CD, and HFD were nutritionally adequate, calorically equivalent (1 kcal/mL), and contained equal amounts of fat as olive and safflower oil with excess corn oil added to the HFD.

Following an overnight fast, five rats per group were

**Table 1** Characteristics and fat infiltration of rats fed a choline-deficient diet or a high fat diet with or without Realsil or a normal choline-supplemented diet (controls)

ALT: Alanine transaminase.

anesthetized with xylazine/ketamine (5.45 mg/36.4 mg/kg *im*) and then sacrificed by decapitation on days 0, 7, 14, and 30 for the CD and 0, 14, 30 and 60 for the HFD groups. Blood was collected into heparinized tubes and centrifuged at 4000 × *g* for 5 min to obtain serum. Livers were removed immediately and homogenized in an ice-cold potassium-phosphate buffer containing 5 mmol/L EDTA (pH 7.4). General and liver parameters are reported in Table 1.

The protocol was conducted according to the Guide Principles for the care and use of laboratory animals and was approved by the local committee for animal experimentation.

### Biochemical determinations

Total glutathione (GSH) determination was performed by precipitating tissue homogenates with 15% sulfosalicylic acid and processing the supernatant by the oxidized glutathione recycling procedure<sup>[13]</sup>. Protein thiols were measured with an Elmann's procedure modification<sup>[14]</sup>. The hepatic and serum levels of thiobarbituric acid malondialdehyde complex (MDA-TBA) were first separated by high-performance liquid chromatography using an analytical column Spherisorb ODS 5 μmol/L (250 mm × 4.6 mm) eluted with 60% (v/v) potassium phosphate buffer 50 mmol/L, pH 6.8 and 40% (v/v) methanol at a flow rate of 1 mL/min. Next, spectrophotometric detection of the MDA-TBA adducts occurred at 532 nm<sup>[15]</sup>. Glutathione Peroxidase (GPx) activity was assessed by use of the method described by Flohè *et al.*<sup>[16]</sup>. Calculations were made with 1 unit enzyme considered as the amount consuming 1.15 μmol of nicotinamide adenine dinucleotide phosphate reduced (NADPH) in 1 min at 37 °C (pH 7.0). Thioredoxin levels were quantitated by a standardized ELISA method in serum and liver homogenates. Procedure followed the manufacturer's instructions (Histo-line Laboratories S.r.l., Milan, Italy); samples were located in micro-wells previously coated with a polyclonal antibody (LF-PA0002) and successively with a primary (LF-MA0077) and a secondary HRP-conjugated anti-mouse antibody (81-6720). After the addition of a chromogenic system, the reaction was stopped and absorbance read at 492 nm. Nitrosothiols were measured according to the method of Cook *et al.*<sup>[17]</sup> using a mixture of sulfa-

nilamide/N-1-naphtyl-ethylendiamine dihydrochloride, neutral Griess as reagents. Nitrotyrosine in the serum was quantified using an ELISA Kit containing Streptavidin-peroxidase conjugate which reacts with the substrate tetramethylbenzidine as per manufacturer's instructions (HyCult Biotechnology b.v., UDEN, The Netherlands) with absorbance read at 450 nm. Keratin 18 fragments (K-18) level was quantified in serum using the ELISA Kit as per manufacturer's instructions (Cusabio Biotech Co., Ltd): samples were located in microwells previously coated with a human-specific antibody and successively with one substrate and a chromogenic system. The reaction was stopped and absorbance read at 450 nm. Protein concentration was measured by using a Bio-Rad kit for the assay of proteins (Bio-Rad GmbH, Munich, Germany).

### Western blotting analysis

The expression of mitochondrial oxidative phosphorylation (OXPHOS) system components was assessed by using an antibody cocktail targeting specific subunits from complexes I (NADH-ubiquinone oxidoreductase), II (succinate dehydrogenase), III [ubiquinone-cytochrome c oxidoreductase (COX)], IV (cytochrome c oxidase), and V (ATP synthase). β-actin was used as a loading control. Frozen tissues were homogenized in a cold Ripa buffer (50 mmol/L Tris-HCl, pH 8.8; 150 mmol/L NaCl; 1% Igepal; 0.5% sodium deoxycholate; 0.1% SDS) supplemented with a protease inhibitor cocktail (Sigma) and ruptured by 30 passages through a needle. Homogenized tissues were centrifuged at 14000 rpm (4 °C, 10 min). The supernatant was collected and kept at -80 °C until used. Protein concentration of each sample was measured using BCA Protein Assay kit according to the manufacturer's protocol. After denaturation at 100 °C during 5 min in Laemmli buffer (BioRad), proteins (30 μg) were separated by electrophoresis on 10% SDS-polyacrylamide gels (SDS-PAGE) and transferred to a polyvinylidene difluoride (PVDF) membrane. After blocking with 2% of milk in TBST (50 mmol/L Tris-HCl, pH 8; 154 mmol/L NaCl, and 0.1% Tween 20) for 1 h at room temperature, membranes were incubated overnight at 4 °C with antibodies against OXPHOS components (1:2000) and β-actin (1:2500). Membranes were incubated with secondary alkaline phosphatase-

conjugated antibodies: goat anti-mouse IgG (1:5000) for 1 h at room temperature. Membranes were incubated with ECF detection system (Amersham, GE Health-Care, Piscataway, NJ) and read with the Versa Doc imaging system (Bio-Rad, Barcelona, Spain).

### Histology

Liver specimens were fixed in 10% neutral buffered formalin and paraffin embedded. Five sections of 4  $\mu\text{m}$  thickness from each sample were cut and stained with toluidin blue-periodic acid-schiff stain. Histologic features were examined on five low-power fields per specimen, and a semi-quantitative estimation of the empty vacuoles (fat) was performed by measuring the fat percentage distribution on the surface areas.

### Chemicals

Total OXPHOS Rodent Antibody Cocktail was purchased from Mitosciences Inc. (Cambridge, MA). Secondary alkaline phosphatase-conjugated antibodies were purchased from Jackson ImmunoResearch Laboratories, Inc. (Cambridgeshire, United Kingdom). All other chemicals used were of the highest purity available and were purchased from Sigma-Aldrich Chemical Co. (Barcelona, Spain or Milan, Italy).

### Statistical analysis

All data are expressed as mean  $\pm$  SD. The Mann-Whitney rank sum test was used to compare groups. For multiple comparisons, the ANOVA on ranks analysis of variance followed by Dunn's method was used. The nonparametric Spearman rank order correlation was used to relate biochemical parameters.  $P < 0.05$  defined significance.

## RESULTS

### Effect of CD and HFD on general parameters and liver histology

Feeding CD or HFD was associated with a progressive and significant increase of liver weight but not of body weight at days 30 and 60, respectively, as compared with control rats (Table 1). In rats with fatty liver, ALT levels increased progressively. At days 30 and 60, both CD and HFD rats showed a two-to-threefold increase.

Rats on CD and HFD showed remarkable liver steatosis (Figure 1 and Table 1). There was a progressive hepatic fat infiltration ranging from large droplets at day 14 to disseminated and confluent vacuoles resulting in microvesicular steatosis at day 30 (CD) and day 60 (HFD). Single cell necrosis was rarely noted. No evidence for inflammation and/or fibrosis was present.

### Effect of CD on oxidative and nitrosative stress parameters

In the liver, CD was associated with a higher content of GSH, thioredoxin, and nitrosothiols, while GPx activity was higher at day 7 and then lower at day 30 (Table 2). MDA-TBA levels were five-fold higher from  $9.1 \pm 1.2$

nmol/g to  $75.6 \pm 5.4$  nmol/g at day 30 (Figure 2). Serum MDA-TBA and nitrosothiols levels as well as nitrotyrosine and K-18 (Table 2) were higher in CD rats.

### Effect of HFD on oxidative and nitrosative stress parameters

In the liver, HFD determined a progressive decrease in the content of GSH, thioredoxin and nitrosothiols (Table 3). GPx activity was initially unchanged, then increased and next decreased (Table 3); MDA-TBA were doubled at day 60 (Figure 2). Serum levels of MDA-TBA, K-18, nitrotyrosine and nitrosothiols were significantly higher in HFD rats (Figure 3).

### Effect of HFD on mitochondrial oxidative phosphorylation complexes

Samples from liver, heart and skeletal muscle were compared regarding the content in subunits of the mitochondrial respiratory chain. Western blotting yielded bands to all OXPHOS subunits studied, although the band corresponding to complex III was very difficult to detect in the three tissues and hence was not quantified by densitometry. Band density for each protein was normalized for the corresponding  $\beta$ -actin band.

In the liver (Figure 4), the HFD caused an increase in the amount of the Complex I subunit NDUF8 (at day 60) and Complex IV subunit I, COX I (at day 30) and a decrease of Complex II subunit 30kDa, CII-30 (days 14 and 60) and ATP synthase subunit  $\alpha$ , CV- $\alpha$  (day 14). Minor changes in the heart and skeletal muscle proteins were observed (data not shown).

### Effect of Realsil on general parameters, liver histology, stress markers, and mitochondrial proteins

Realsil administration was associated with a lower increase of liver weight and a less pronounced increase of serum transaminase levels in rats (Table 1). As shown (Figure 1 and Table 2), Realsil resulted in a lower extent of fat infiltration in both CD and HFD rats. In CD rats, Realsil determined an improvement in the number and diameter of fat droplets. In HFD rats, Realsil was associated with a lower diameter of fat droplets; the number of droplets per histological section was lower at day 30 but higher at day 60, as a likely consequence of a less confluent phenomenon.

Realsil was protective against CD and HFD induced oxidative and nitrosative changes both in the liver and in plasma. The improvement in such parameters was more evident for CD rats. In particular, the decrease of liver GSH and nitrosothiols was kept to 50% compared with untreated rats, while the changes in MDA-TBA, thioredoxin, and GPx were less marked although significant (Table 2). The same parameters were less affected by Realsil in HFD rats (Table 3 and Figure 3). In fact, the hepatic concentrations of GSH, MDA-TBA, GPx, and nitrosothiols did not differ significantly compared to untreated HFD rats. Only thioredoxin levels were maintained to a higher level by Realsil administration. In these

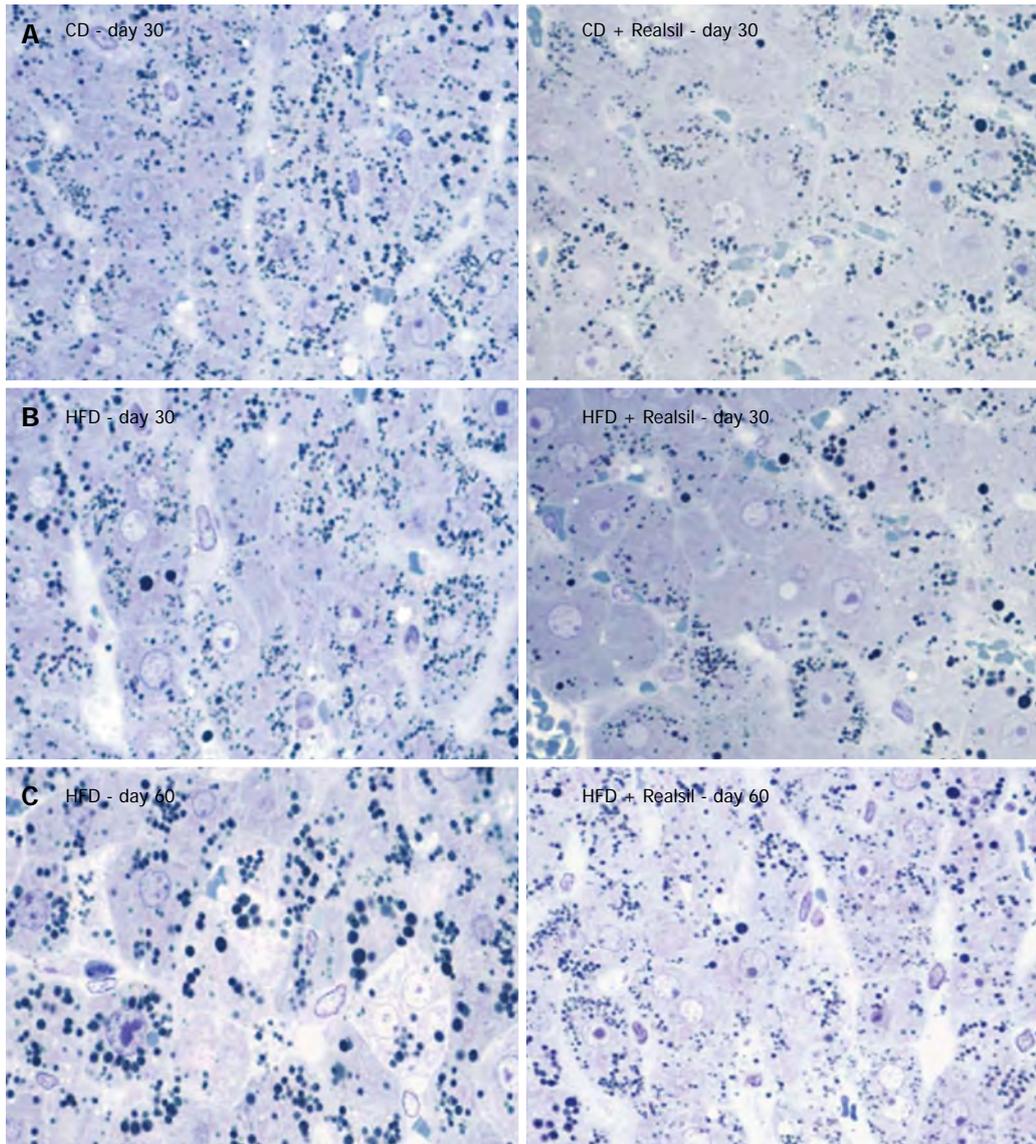

Figure 1 Light micrographs of rat liver stained with toluidin blue-periodic acid-schiff stain. A: Liver from rat fed a choline deficient diet (day 30); B: Liver from rat fed a high fat diet (day 30); C: Liver from rat fed a high fat diet (day 60). Right column without and left column with administration of Realsil (Magnification: 200 ×). CD: Choline deficiency; HFD: High fat diet.

rats, Realsil halved the variations of serum MDA-TBA and nitrotyrosine levels, while it was less effective on K-18 ( $222 \pm 15$  IU/L *vs*  $242 \pm 23$  IU/L at day 60 in treated and untreated HFD rats, respectively) and nitrosothiols ( $72 \pm 10$  nmol/L *vs*  $81 \pm 9$  nmol/L at day 60 in treated and untreated HFD rats, respectively) levels.

In HFD animals receiving also Realsil, several changes occurred in liver mitochondria (Figure 4). At day 14, administration of Realsil resulted in a significant increase in the protein levels of NDUFB8 subunit, which were slightly decreased (although not statistically significant) by the diet alone. On the other hand, Realsil in HFD animals further decreased the amount of CII-30 (day 14), NDUFB8 (day 30), and COX I (day 60). At day 60, Realsil had protective effect on the Complex II subunit CII-30 by increasing the amount of the protein that was decreased by the diet alone. Interestingly, in the muscle,

at day 60 Realsil reversed the effect induced by HFD in CII-30 subunit and in COX I subunit and, at day 30, decreased CV- $\alpha$  subunit protein amount.

## DISCUSSION

Obesity is a health problem in developed countries<sup>[18-21]</sup> and is related to insulin resistance, dyslipidemia, type 2 diabetes, hypertension, and liver steatosis (NAFLD)<sup>[22]</sup>. Simple steatosis is considered a benign condition with low risk of evolution, while its inflammatory form (NASH) is considered a risk factor for liver cirrhosis.

Mechanisms governing hepatocellular fat deposition involve metabolic pathways partly depending on the up-regulation of peroxisome proliferator-activated receptor and on the consequent activation of adipocyte differentiation programs<sup>[23]</sup>. The relationship between

The liver of rats fed a choline-deficient (CD) diet without (S)/with (R) Realsil or a normal choline-supplemented diet (controls). Values from controls are reported in the first column under the parameter. Data are mean ± SD of  $n = 5$  rats per group at each time point. <sup>a</sup> $P < 0.05$  vs control rats; <sup>c</sup> $P < 0.05$  vs rats on CD diet without Realsil at the same time point. GPx: Glutathione peroxidase; MDA-TBA: Malondialdehyde-thiobarbituric acid reactive substances; K-18: Keratin-18; prt: Protein.

intracellular metabolic processes and systemic changes occurring in patients with fatty liver are still under debate. Also, the effect of modulating compounds and antioxidant molecules on such lipid effectors and on NO metabolic changes has been poorly investigated. Mitochondria, coordinators of energy metabolism, are actively involved in such processes<sup>[18,21]</sup>. In NASH patients, mitochondria show morphological alterations and functional impairment<sup>[7,24]</sup>. Ultrastructural modifications were also observed in rats fed a steatogenic diet (HFD)<sup>[25]</sup>. Mitochondria are the most relevant source of ROS in most cells and especially in fatty hepatocytes<sup>[26,27]</sup>. ROS alter the activity of JNK enzymes, disturb insulin signaling, and enhance potassium transport across the inner mitochondrial membrane<sup>[28]</sup> leading to mitochondrial uncoupling and triggering as well adaptive response<sup>[29-31]</sup>.

In a recent study<sup>[3]</sup>, we observed that hepatocytes react to fat deposition by a very early increase of GSH and thioredoxin both in the cytosol and in the mitochondria to likely prevent lipid and protein oxidation. Prolongation of steatogenic diet, however, led to major mitochondrial redox changes, *i.e.*, increased MDA-TBA, progressive decrease of GSH and thioredoxin, and increase of mixed disulfides, nitrates, and nitrosothiols, all consistent with both oxidative damage and increased NO synthesis. In fatty livers, NO synthase (iNOS) is induced by enhanced inflow of gut-derived toxins<sup>[32]</sup> and tumor necrosis factor- $\alpha$  expression<sup>[33]</sup> and generates hyper reactive species such as NO with accumulation of nitrotyrosine<sup>[33]</sup>. This likely reflects an increased peroxynitrite formation

**Figure 2** Concentrations of malondialdehyde-thiobarbituric acid reactive substances. A: Liver of rat fed a choline-deficient diet; B: Liver of rat fed a high fat diet. Closed square: Without; open square: With Realsil administration; open circle: Control rats fed a standard chow-diet with adequate content of choline. Data are mean ± SD of  $n = 5$  rats per group at each time point. <sup>a</sup> $P < 0.05$  vs control rats; <sup>c</sup> $P < 0.05$  vs untreated rats at the same time points. MDA-TBA: Malondialdehyde-thiobarbituric.

and suggests potential NO participation to liver injury<sup>[34]</sup>. Thioredoxin, a redox-active protein induced by oxidative stress<sup>[35]</sup>, is actively involved in NO regulation through nitrosothiols cleavage<sup>[36,37]</sup>. Nitrosothiols, formed by conjugation of NO with free thiols, oppose peroxynitrite formation and act as intracellular messenger controlling cellular and mitochondrial functions<sup>[38,39]</sup>.

In the fatty liver, intracellular redox changes and protein nitrosation may represent a major factor stimulating the progression from simple steatosis to NASH<sup>[40]</sup>. Also, a critical role for such hepatic variations in the pathogenesis of systemic chronic inflammatory conditions has been recently proposed<sup>[41,42]</sup>. In our study, we show that liver steatosis is associated with high levels of circulating NO derivatives (nitrosothiols and nitrotyrosine) and with high levels of K-18, the major keratin expressed in the liver and one of the most prominent substrates of caspases during hepatocytes apoptotic death<sup>[43]</sup>. These alterations were closely dependent on the changes occurring in the liver in which GSH content and thioredoxin activity declined with ongoing steatosis. Also, the close

The liver of rats fed a high fat diet (HFD) diet without (S)/with (R) Realsil or a standard control diet (controls). Values from controls are reported in the first column under the parameter. Data are mean  $\pm$  SD of  $n = 5$  rats per group at each time point. <sup>a</sup> $P < 0.05$  vs control rats; <sup>c</sup> $P < 0.05$  vs rats on HFD diet without Realsil at the same time point. GPx: Glutathione peroxidase; NADH: Nicotinamide adenine dinucleotide; prt: Protein.

relation observed between the circulatory NO derivatives and K-18 levels clearly links NO with the hepatic inflammatory processes occurring under marked liver steatosis.

Previous studies have demonstrated elevation of these molecules in NAFLD<sup>[44]</sup> as a consequence of the increased apoptotic rate due to hepatic inflammation<sup>[45]</sup>.

In the present work, the HFD promoted alterations in mitochondrial complexes, although not deep enough to result in bioenergetic changes, as reported for other diet models including CD<sup>[46,47]</sup>. Interestingly, the limited array of alterations observed in the heart and skeletal muscle points to the conclusion that this model selectively affects the liver.

In this scenario, the administration of antioxidant molecules able to contrast oxidative and nitrosative phenomena improved most of the investigated stress parameters both in the liver and in serum. In fact, in our study the administration of Realsil was effective in reducing the extent of fatty infiltration of the liver and in modulating the changes in mitochondrial function and oxidative and nitrosative stress both in the liver and in the systemic circulation. This would suggest that Realsil is effective in contrasting the metabolic alterations resulting in excess fat deposition and at the same time in counteracting the increased formation of ROS and NO species.

**Figure 4** Western blotting analysis of the components of liver mitochondrial oxidative phosphorylation system in rats receiving high fat diet with (grey bar) or without (black bar) Realsil and in control (white bar) rats fed a standard chow-diet. Band density for the target protein normalized for the corresponding  $\beta$ -actin for A: Respiratory complex I; B: Respiratory complex II; C: Respiratory complex IV; D: Respiratory complex V; E: Picture representative of Western blotting analysis. Data are means  $\pm$  SE of  $n = 3-4$  independent experiments. <sup>a</sup> $P < 0.05$  vs control rats; <sup>c</sup> $P < 0.05$  vs untreated rats at the same time points.

Silybin, the major constituent of milk thistle extract, affords hepatoprotection *in vitro* and *in vivo*<sup>[48,49]</sup> by inhibiting the production of pro-inflammatory and pro-fibrogenic factors<sup>[12,50]</sup>. The conjugation with phospholipids greatly increases its intestinal absorption and the systemic bioavailability<sup>[51]</sup>. However, the mechanisms of the hepatocyte protection have not been completely defined. Some hypotheses point to a potential antioxidant cytoprotective effect of Realsil by including the modulation of protein oxidation/denitrosation and the maintenance of membrane lipid composition and function<sup>[52]</sup>. To demonstrate these effects, we investigated the protective ef-

fects of Realsil on oxidative/nitrosative changes both in the liver and in circulation.

Indeed, although the subtle mechanisms regulating the protein nitrosation/denitrosation process have not been completely identified, it has been shown that thioredoxin-deficient cells denitrosate nitrosothiols less efficiently<sup>[37]</sup> and that nitrosative stress is critically important in promoting S-nitrosylation and nitration of various mitochondrial proteins, leading to mitochondrial dysfunction, decreased energy supply, and increased hepatic injury<sup>[53]</sup>. With ongoing steatosis, the decrement in hepatic thioredoxin and GSH levels we observed may be due

also to a down-regulation process associated with excess deposition of fat and toxic molecules and may indirectly contribute to the progressive appearance of other oxidative changes.

In our study, Realsil was able to counteract most of the oxidative biochemical alterations during the early phases of steatosis while it resulted less effective later (30 and 60 d) when the extent of fat infiltration was massive. The protection promoted by Realsil is certainly exerted at different levels and particularly at mitochondrial level<sup>[54]</sup>. The changes (both morphological and biochemical) observed in the liver of rats receiving Realsil were also evident at systemic level and this more explicitly relates systemic with hepatic changes in animals with fatty liver.

## COMMENTS

### Background

Fatty degeneration represents a leading factor of hepatocyte dysfunction and is associated with excess delivery of stress molecules thus rendering the liver a major source of systemic alterations in patients with metabolic syndrome. Adaptive metabolic mechanisms have been described during the early phase of fatty infiltration including expression of intracellular sensors and signaling molecules for lipid metabolism and oxidative stress pathways. Vitamin E efforts a remarkable protection against lipid oxidation and, if vehicled within a phospholipids complex together with silybin, a *silybum marianum* extract, protects against pro-fibrotic oxidative injury.

### Research frontiers

The threshold above which fat infiltration becomes dangerous is not clear, so far. Several observations suggest that ongoing fatty degeneration indeed exposes hepatocytes to higher risk of oxidative damages.

### Innovations and breakthroughs

Little is known about the effectiveness of vitamin E-silybin-phospholipid complex in blocking or modulating reactive oxygen species/NO production and their oxidant effects. This study also gives answer to the question whether administration of an antioxidant complex is able to break off the intracellular mechanisms leading to a progressive accumulation of neutral lipids in fatty hepatocytes and mitochondrial dysfunction.

### Applications

Realsil was able to counteract most of the oxidative hepatic changes during the early phases of steatosis while it resulted less effective later when the extent of fat infiltration was massive. The changes observed in the rat fatty liver were also evident at systemic level pointing to a relationship between systemic and hepatic alterations.

### Terminology

Liver steatosis occurs when the amount of neutral fat exceeds 5% of organ weight. Realsil is a compound constituted by vitamin E and silybin complexed with phospholipids. Silybin is a *silybum marianum* extract; it is known to protect against pro-fibrotic oxidative injury.

### Peer review

In this descriptive study, the authors show that Realsil is able to reduce liver injury in two different animal models of steatosis. Realsil seems to protect by decreasing toxic free radicals species as highly delivered by fatty hepatocytes.

### Abstract

**AIM:** To analyze trends in incidence and mortality of acute pancreatitis (AP) and chronic pancreatitis (CP) in the Netherlands and for international standard populations.

**METHODS:** A nationwide cohort is identified through record linkage of hospital data for AP and CP, accumulated from three nationwide Dutch registries: the hospital discharge register, the population register, and the death certificate register. Sex- and age-group specific incidence rates of AP and CP are defined for the period 2000-2005 and mortality rates of AP and CP for the period 1995-2005. Additionally, incidence and mortality rates over time are reported for Dutch and international (European and World Health Organization) standard populations.

**RESULTS:** Incidence of AP per 100000 persons per year increased between 2000 and 2005 from 13.2 (95%CI:

12.6-13.8) to 14.7 (95%CI: 14.1-15.3). Incidence of AP for males increased from 13.8 (95%CI: 12.9-14.7) to 15.2 (95%CI: 14.3-16.1), for females from 12.7 (95%CI: 11.9-13.5) to 14.2 (95%CI: 13.4-15.1). Irregular patterns over time emerged for CP. Overall mean incidence per 100000 persons per year was 1.77, for males 2.16, and for females 1.4. Mortality for AP fluctuated during 1995-2005 between 6.9 and 11.7 per million persons per year and was almost similar for males and females. Concerning CP, mortality for males fluctuated between 1.1 (95%CI: 0.6-2.3) and 4.0 (95%CI: 2.8-5.8), for females between 0.7 (95%CI: 0.3-1.6) and 2.0 (95%CI: 1.2-3.2). Incidence and mortality of AP and CP increased markedly with age. Standardized rates were lowest for World Health Organization standard population.

**CONCLUSION:** Incidence of AP steadily increased while incidence of CP fluctuated. Mortality for both AP and CP remained fairly stable. Patient burden and health care costs probably will increase because of an ageing Dutch population.

© 2013 Baishideng. All rights reserved.

**Key words:** Acute pancreatitis; Chronic pancreatitis; Epidemiology; Incidence; Mortality

**Core tip:** Large scale epidemiological studies reporting time trends of incidence and mortality of chronic pancreatitis (CP) are strikingly scarce compared to the also limited epidemiological studies on acute pancreatitis (AP). Reported are the Dutch incidence rates of AP and CP for the period 2000-2005, and mortality rates of AP and CP for the period 1995-2005. The incidence rates of AP steadily increased while the incidence of CP fluctuated. Population mortality for both AP and CP remained fairly stable. Both incidence and mortality rates increased markedly by age. So, especially in ageing populations, it is to be expected that patient burden and health care costs will increase.

Spanier BWM, Bruno MJ, Dijkgraaf MGW. Incidence and mortality of acute and chronic pancreatitis in the Netherlands: A nationwide record-linked cohort study for the years 1995-2005. *World J Gastroenterol* 2013; 19(20): 3018-3026 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i20/3018.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i20.3018>

## INTRODUCTION

Over the last decades, the incidence and number of hospital admissions of both acute pancreatitis (AP)<sup>[1-10]</sup> and chronic pancreatitis (CP) have consistently increased in the Western countries<sup>[11-14]</sup>. Increasing alcohol intake, more gallstone-related pancreatitis, increased pancreatic enzyme testing and improvements of diagnostic tests and interventional techniques have all been suggested as possible explanations<sup>[4,5,6,8,15-17]</sup>.

The disease spectrum of AP ranges from mild and self-limiting (approximately 85%) to a life-threatening illness resulting in significant morbidity and mortality<sup>[18-21]</sup>. At onset, AP regularly results in hospitalization<sup>[22,23]</sup>. Generally, in the Western countries the case fatality proportion of AP decreased over time, but the overall population mortality did not change<sup>[2,16]</sup>.

CP is characterized by ongoing or recurrent episodes of abdominal pain accompanied by progressive pancreatic exocrine and endocrine insufficiency. Hospitalization is required in case of an exacerbation to control pain (*e.g.*, opioid medication, endoscopic duct drainage, pancreaticojejunostomy and/or resection) and for the treatment of complications such as pseudocysts<sup>[15,16,24,25]</sup>. The overall survival for CP patients is reduced compared with the general population. Most notably because of the impact of non-pancreatic effects of excess alcohol consumption and/or smoking, independent of CP itself<sup>[15,16]</sup>.

Epidemiological studies from the Netherlands for AP are scarce and this is even more the case for CP<sup>[2,11,22]</sup>. Eland *et al*<sup>[2]</sup> reported the latest incidence rates and mortality of AP from 1985 to 1995, both based on hospital discharge data. Our group reported about the trend in hospital admissions in the Netherlands for AP and CP<sup>[11]</sup>. For both groups, the hospital admissions have increased substantially from 1992 to 2004.

In this study we report the incidence rates of AP and CP for the period 2000-2005 and mortality rates of AP and CP for the period 1995-2005 following linkage of three distinct nation-wide Dutch registries. Additionally, data on incidence and mortality rates over time are reported for Dutch and international standard populations.

## MATERIALS AND METHODS

### Case finding

Cases of AP and CP were identified by linkage of three distinct nation-wide Dutch registries: the hospital discharge register [HDR: formerly also known as the National Information System on Hospital Care (NISHC)],

the population register (PR), and the death certificate register (DCR). The HDR contains discharge data from academic and general hospitals in the Netherlands (<http://www.dutchhospitaldata.nl/>). Since 1992 almost all (> 97%) Dutch hospitals are linked to the HDR with 99% coverage of all hospital admissions. For each hospital discharge the dates of admission and discharge, type of admission, and diagnoses at discharge (primary and secondary) are recorded along with anonymous patient characteristics like: sex, date of birth, postal code of the living address, and country of origin. Hospital discharge diagnoses in the HDR are coded according to the International Classification of Diseases, 9<sup>th</sup> revision, Clinical Modification (ICD-9CM). We retrospectively retrieved all hospital admissions (> 1 d of hospital stay) for the period 1 January 1995-31 December 2005 from the HDR with acute (code 577.0) or chronic (code 577.1) pancreatitis as the primary discharge diagnoses.

A single patient with multiple admissions will have several records in the HDR. Because of its anonymous nature however, only partially identifiable information is provided at the record level. For the accurate count of pancreatitis cases, it is necessary to identify different admissions, potentially in different hospitals, by the same patient. To identify these unique cases in the HDR the records were linked to the PR which is maintained by Statistics Netherlands of the Dutch Ministry of Economy Affairs. The PR contains continuously updated demographic data on all citizens residing in the Netherlands like name, date of birth, sex, nationality, living address, dates of immigration and/or emigration, and date of death.

HDR records can be linked to the PR by a combination of three identifiers: sex, date of birth, and (the numeric part of) the postal code at the time of admission. Linkage fails if several citizens are of the same sex, are born on the same date, and live in the same postal code area at the time at least one of them is admitted (“administrative siblings”). Also, linkage fails if any key data are lacking in the HDR or in the PR.

Statistics Netherlands enables the unique linkage of about 86% of all yearly hospital admissions to the PR, suggesting that counts at the person level should be multiplied by 100/86 to derive national estimates. However, the probability of unique linkage is not equal across subgroups in the general population and over time. For instance, persons in high-density population areas, persons born in countries with inaccurate birth dates, and moving persons have a lower probability of unique linkage. To compensate for linkage failure, stratum-specific multipliers were calculated for sex, 5-yearly age cohorts, and country of origin (available from the corresponding author upon request). While doing so, we took into account that our aim was to estimate the incidence rather than the prevalence of AP and CP.

### From case finding to incident cases

We defined an incident case during any specific year as

a person with an admission for AP or CP during that year which is not preceded by another admission of the same person with the same discharge diagnosis during at least five years prior to the specified year. To identify incident cases, it is mandatory that all admissions during the observation period have been identified for each person. Hence, a person known in the PR should be always uniquely identifiable during the observation period 1995-2005 based on the linkage keys sex, age, and the postal code.

### **Incidence rates and standardized incidence rates**

Sex- and age- specific incidence rates for the years 2000-2005 were defined as the yearly number of new pancreatitis cases per 100000 members of the Dutch reference population alive during the year, excluding immigrated or emigrated citizens and after adjustment for stratum-specific linkage failure between the HDR and the PR<sup>[26]</sup>. The yearly incidence rates were standardized with reference to the age and sex distribution of the Dutch reference population in 2000 to identify the possible impact of a Dutch ageing population on the observed trends in incidence rates over time. Standardizations were also performed with reference to the age distribution (assuming evenly distributed male and females) of the European and World Health Organization (WHO) standard populations to enable direct comparisons among trends in incidence and mortality rates across countries that differ by age (and sex) distributions of their respective populations<sup>[27]</sup>.

### **Mortality rates and standardized mortality rates**

Deaths associated with AP and CP were identified by linkage of the PR and the DCR which is also maintained by Statistics Netherlands.

General practitioners and hospitals are obliged to complete a death certificate for each deceased person, and notify the primary and up to three secondary causes of death. Causes of death are coded according to the International Classification of Diseases coding system with acute and chronic pancreatic related death coded as 577.0 and 577.1 respectively for the year 1995 (ICD-9CM) or K850 and K860/K861 respectively for the years 1996 and later (ICD-10CM). The register is nearly complete (99.7%) with regard to persons deceased in the Netherlands, meaning that deaths after emigration are lacking. For their completeness and reliability, only the primary causes of death were analyzed. The mortality rate was expressed per 1000000 general population members excluding the ones that emigrated any time between 1995 and 2005. Again, yearly mortality rates were recalculated with reference to the age and sex distribution of the Dutch reference population in 2000 as well as with reference to the age distribution of the European and WHO standard populations.

### **Statistical analysis**

We assumed the AP and CP incidence and mortality rates to follow Poisson distributions when calculating 95%CI. The Statistical Package for the Social Sciences versions

14.0 and 18.0 (SPSS, Chicago, IL, United States) were used for statistical analysis.

## **RESULTS**

In 1995-2005, 18819221 citizens were known in the population register with 49.75% being male. Slightly under 10.4 percent immigrated or emigrated, leaving 16866819 patients in the Dutch reference population for the incidence estimates, 12163581 of whom were always uniquely identifiable during 1995-2005. Hence, the average multiplier for the incidence estimates amounted to 1.387.

### **Incidence rates acute pancreatitis per 100000 persons per year**

The overall incidence rate of AP increased during the 2000-2005 period from 13.2 (95%CI: 12.6-13.8) in 2000 to 14.7 (95%CI: 14.1-15.3) in 2005. The incidence rate for males rose from 13.8 (95%CI: 12.9-14.7) to 15.2 (95%CI: 14.3-16.1), for females from 12.7 (95%CI: 11.9-13.5) to 14.2 (95%CI: 13.4-15.1), reflecting yearly increases of 1.6% and 1.9% respectively (Figure 1A).

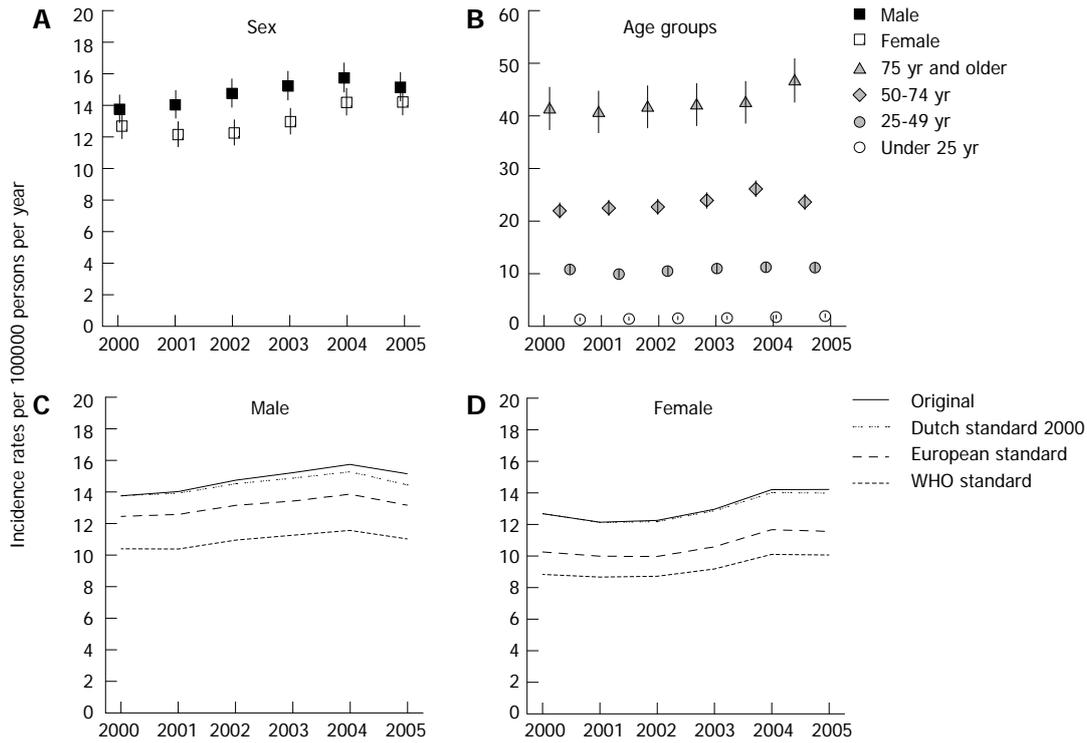

Incidence rates ranged from below 1 in the younger age groups (< age 15 years) to as high as 50.7 in 2005 for the patients of 85 years and above. Figure 1B shows the incidence rates for four major age groups (< 25, 25-49, 50-74 and > 74 years). The incidence rate in the 50-74 age group was highest in 2004 (26.1; 95%CI: 24.6-27.7); in the eldest age group the incidence rate was increased in 2005 (46.5; 95%CI: 42.5-50.9) compared to the preceding years.

The mean yearly incidence rates of AP by 5-yearly age groups and by sex peaked at the ages of 80-84 for both, males (55.4; 95%CI: 42.8-71.6) and females (41.9; 95%CI: 33.8-52.0). The mean yearly incidence rate was higher for females (7.1; 95%CI: 4.7-10.7) than males (3.4; 95%CI: 1.9-6.0) for persons in their early twenties. However, between the ages of 44 and 84, the opposite was observed with 30%-63% higher mean yearly incidence rates for males than for females.

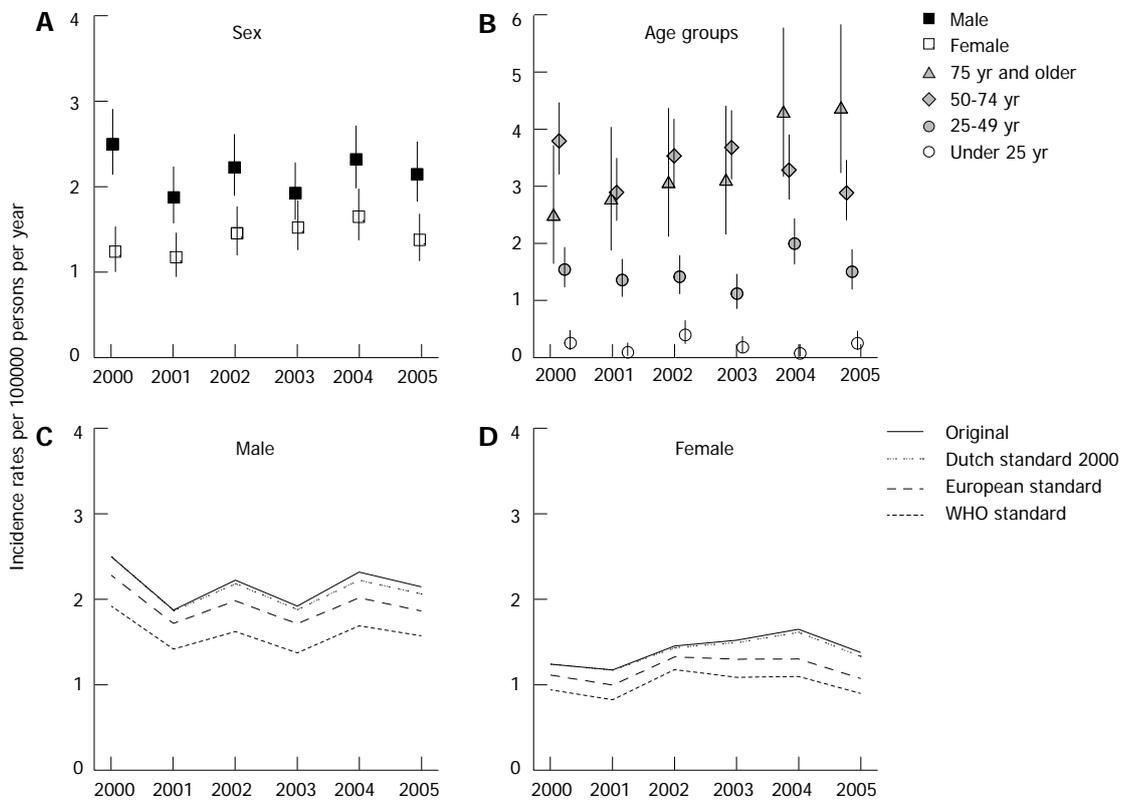

Figure 1C and D (males and females) show the original as well as the Dutch 2000, the European and the WHO standardized incidence rates of AP. Both figures show lowest incidence rates for the WHO standard population (range males: 10.4-11.6; range females: 8.6-10.1), followed by the European standard population (range males: 12.5-13.9; range females: 10.0-11.7), and the Dutch standard population (range males: 13.8-15.3; range females: 12.1-14.0). The figures show that the discrepancy between the original incidence rate and the standardized rates increases over time for males, indicating a small effect of an ageing Dutch population.

### **Incidence rates chronic pancreatitis per 100000 persons per year**

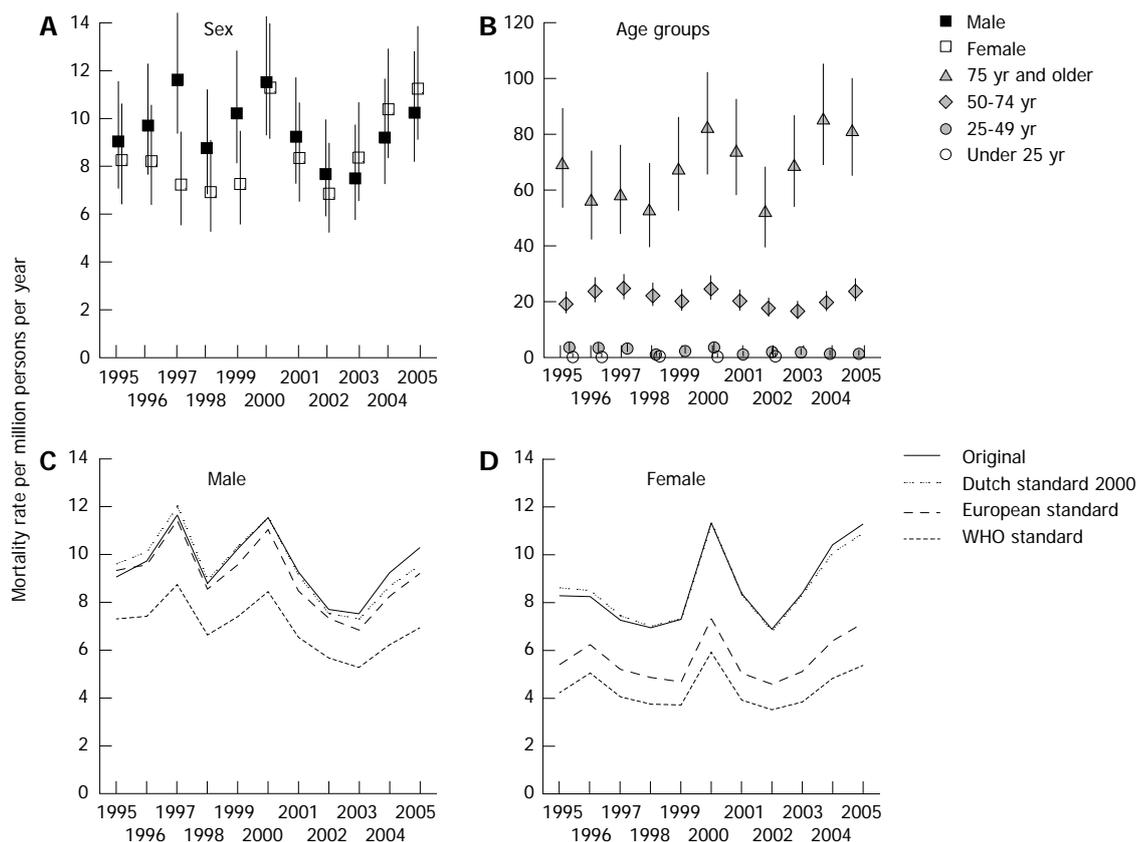

The overall incidence rate of CP during the 2000-2005 period averaged 1.77, fluctuating between 1.52 (95%CI: 1.32-1.74) in 2001 and 1.98 (95%CI: 1.76-2.22) in 2004. Figure 2A shows the incidence rates of male and female

**Figure 1** Incidence rates acute pancreatitis per 100000 persons per year. A: The incidence rates of male and female acute pancreatitis (AP) cases; B: The incidence rates for four major age groups (< 25, 25-49, 50-74 and > 74 years); C (males) and D (females): The original as well as the Dutch 2000, the European and the World Health Organization (WHO) standardized incidence rates of AP.

**Figure 2** Incidence rates chronic pancreatitis per 100000 persons per year. A: The incidence rates of male and female chronic pancreatitis (CP) cases; B: The incidence rates for four major age groups (< 25, 25-49, 50-74 and > 74 years); C (males) and D (females): The original as well as the Dutch 2000, the European and the World Health Organization (WHO) standardized incidence rates of CP.

**Figure 3** Mortality rates acute pancreatitis per million persons per year. A: The male and female mortality rates of acute pancreatitis (AP) for 1995-2005; B: The mortality rates for four major age groups (< 25, 25-49, 50-74 and > 74 years); C (males) and D (females): The original as well as the Dutch 2000, the European and the World Health Organization (WHO) standardized mortality rates of AP.

CP cases. The incidence rates for males averaged 2.16, 50% higher than the incidence rates for females (mean of 1.4). The incidence rates for males fluctuated over time with lower rates in the years 2001 and 2003 (both 1.9; 95%CI: 1.6-2.3) compared with the year 2000 (2.5; 95%CI: 2.1-2.9). Among females, the incidence rates during the years 2003 (1.5; 95%CI: 1.3-1.8) and 2004 (1.6; 95%CI: 1.4-2.0) were higher than during the year 2001 (1.2; 95%CI: 0.9-1.5).

Incidence rates ranged from below 0.5 in the younger age groups (< age 20 years) to as high as 5.2 (95%CI: 3.5-7.8) in 2005 for the patients between 75 and 79 years of age. Figure 2B shows the incidence rates for four major age groups (< 25, 25-49, 50-74 and > 74 years). While the incidence rate fluctuated in the 50-74 years age group between 3.8 (95%CI: 3.2-4.5) in 2000 and 2.9 (95%CI: 2.4-3.5) in 2001 and 2005, the incidence rate in the age group of 75 and older increased steadily by 75%, from 2.5 (95%CI: 1.7-3.7) in 2000 to 4.4 (95%CI: 3.2-5.8) in 2005.

The mean yearly incidence rates of CP for males between 65 and 74 years (65-69 years: 6.2, 95%CI: 3.9-9.8; 70-74 years: 5.1, 95%CI: 3.0-8.9) more than doubled the rates for females (65-69 years: 2.3, 95%CI: 1.2-4.7; 70-74 years: 2.4, 95%CI: 1.2-5.0).

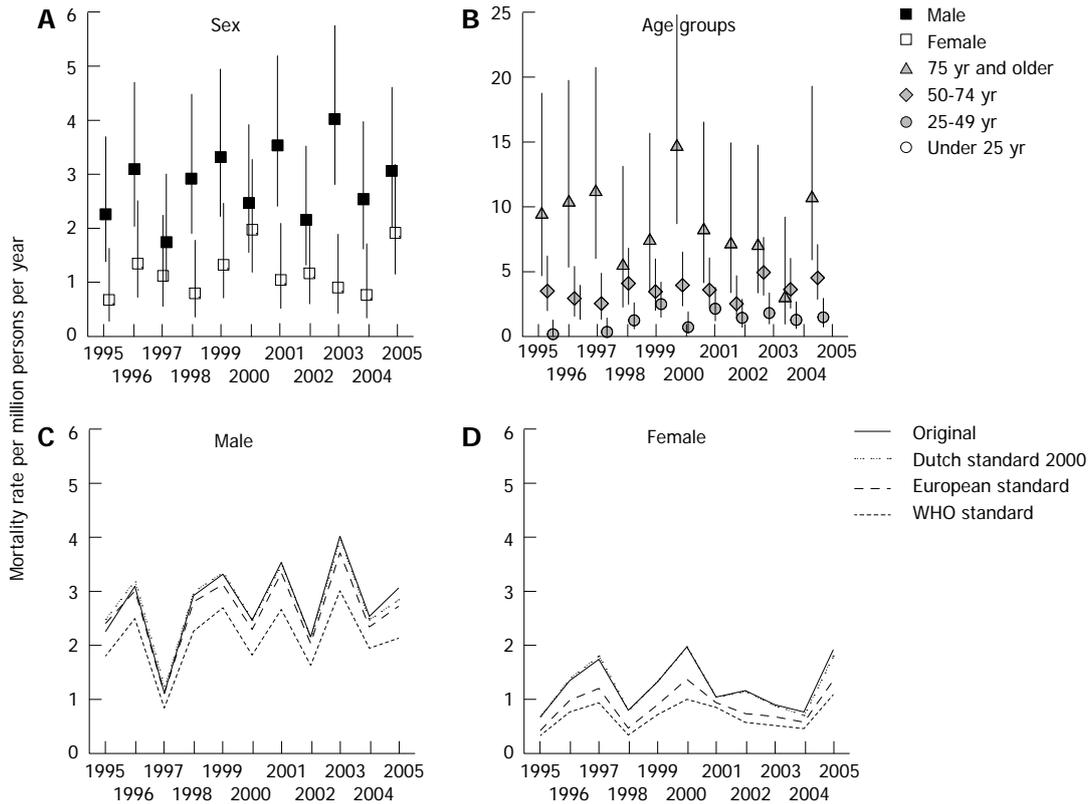

Figure 2C and D (males and females) show the original as well as the Dutch 2000, the European and the WHO standardized incidence rates of CP. The incidence

rates for the WHO standard population ranged from 1.4 to 1.9 for males and from 0.8 to 1.2 for females. For the European standard population, the ranges were 1.7-2.3 and 1.0-1.3 for males and females respectively. The ranges for the Dutch standard population in 2000 (range males: 1.9-2.5; range females: 1.2-1.6) were nearly identical to the non-standardized data.

#### **Mortality rates acute pancreatitis per million persons per year**

Between 1995 and 2005, 1524492 persons died in the Netherlands. In 2264 cases AP was notified as a cause of death. Of these, 65.6% or 1484 cases (0.97 pro mille of all deceased persons) died with AP as the primary cause of death, including 764 males and 720 females.

Figure 3A shows the male and female mortality rates of AP for 1995-2005. The mortality rates fluctuated between 6.9 and 11.7 were similar for males and females except for the years 1997 and 1999 when more males than females died (1997: 11.7; 95%CI: 9.4-14.5 *vs* 7.26; 95%CI: 5.56-9.48); 1999: 10.3; 95%CI: 8.2-12.9 *vs* 7.3; 95%CI 5.61-9.51). Figure 3B shows the mortality rates for four major age groups (< 25, 25-49, 50-74 and > 74 years). The mortality rate for patients younger than 50 years of age stayed below 3.6 (95%CI: 2.3-5.6) and for the 50-74 years age group below 18.6 (95%CI: 14.8-23.5), whereas the mortality rate more than tripled up to 85.3 (95%CI:

**Figure 4** Mortality rates chronic pancreatitis per million persons per year. A: The male and female mortality rates of chronic pancreatitis (CP) for 1995-2005; B: The mortality rates for four major age groups (< 25, 25-49, 50-74 and > 74 years); C (males) and D (females): The original as well as the Dutch 2000, the European and the World Health Organization (WHO) standardized mortality rates of CP for 1995-2005.

69.1-105.4) for the oldest age group.

Figure 3C and D (males and females) show the original as well as the Dutch 2000, the European, and the WHO standardized mortality rates of acute pancreatitis. An ageing effect for males is present with in 1995 a 6.1% higher and in 2005 a 7.1% lower Dutch standardized rate compared to the original rate. On average, the mortality rates for the European and Dutch standard populations are 31.6%, respectively 36.8% higher than the WHO standard. Although the overall pattern is irregular, a gradual decline over time in mortality rates for males can be noted.

Among the females a smaller ageing effects emerges with in 1995 a 4% higher and in 2005 a 3.4% lower Dutch standardized rate compared to the non-standardized rate. On average, the mortality rates for the European and WHO standard populations are 52.7%, respectively 96.8% below the Dutch standard.

#### **Mortality rates chronic pancreatitis per million persons per year**

Between 1995 and 2005 745 patients died in the Netherlands with CP notified as a cause of death. Of these, 43.9% or 327 cases (0.21 pro mille of all deceased Dutch patients in the same period) died with CP as the primary cause of death, including 223 males and 104 females.

Figure 4A shows the male and female mortality rates of CP for 1995-2005. The mortality rates for males fluctuated between 1.1 (95%CI: 0.6-2.3) in 1997 and 4.0

(95%CI: 2.8-5.8) in 2003, for females between 0.7 (95%CI: 0.3-1.6) in 1995 and 2.0 (95%CI: 1.2-3.2) in 2000. Except for 1997, 2000, 2002 and 2005 the male mortality rate exceeded the female mortality rate.

Figure 4B shows the mortality rates for four major age groups (< 25, 25-49, 50-74 and > 74 years). The mortality rate for patients younger than 50 years of age stayed below 2.3 (95%CI: 1.3-4.0) and for the 50-74 age group below 4.5 (95%CI: 2.9-7.1), whereas for the oldest age group the mortality rate went up to as high as 14.7 (95%CI: 8.7-24.9).

Figure 4C and D (males and females) show the original as well as the Dutch 2000, the European, and the WHO standardized mortality rates of CP for 1995-2005. Again, an ageing effect for males is present with in 1995 a 9.7% higher and in 2005 a 7.1% lower Dutch standardized rate compared to the original rate. On average, the European and WHO standardized rates are 5.9% and 32.4% lower than the Dutch rate. No clear ageing effect is observed for females. On average, the European and WHO standardized rates are 42% and 83.5% lower than the Dutch rate.

## **DISCUSSION**

We performed a nationwide record-linked study to analyze the time trends of the incidence and mortality rates of AP and of CP in the Netherlands. We show that

between 2000-2005 the incidence of AP per 100000 persons per year increased over time for both, males (from 13.8 to 15.2) and females (from 12.7 to 14.2). Relatively stable patterns over time emerged for the incidence rate of AP per 100000 persons per year by different age groups. The steady increase of the incidence of AP over time corresponds to the results of a former retrospective study performed in the Netherlands between 1985-1995<sup>[2]</sup>. However, the similar growth pattern in our study was observed at a lower level. Eland *et al*<sup>[2]</sup> observed incidence rates for the year 1995 of 17.0 males and 14.8 females per 100000 person-years. If we take for granted that no decrease in incidence rates took place during the unobserved years 1996-1999, then several decisions concerning study design may have contributed to the difference in incidence rate level. Eland *et al*<sup>[2]</sup> retrieved primary as well as secondary discharge diagnoses from the HDR, whereas we only included AP as a primary discharge diagnosis in order to reduce the risk of misclassification of cases. Further, we excluded single-day admissions for AP. This seems reasonable, because patients with a first attack of AP usually get admitted for several days<sup>[2,9]</sup>. Moreover, by identifying unique cases following the linkage of two nationwide registries, double counting of cases is a circumvented issue in our study. Considering these reasons for differences in level despite a similar growth pattern, the former reported incidence rates in the Netherlands may be somewhat overestimated.

Other recent population-based studies in Western countries too report increasing incidence rates of AP<sup>[3,4,6,7,10,28-31]</sup>. The studies - although somewhat heterogeneous by design - indicate that the reported incidence rates of AP in the Netherlands are low and even far lower compared to reported rates from several Scandinavian countries and the United States<sup>[16]</sup>. The observed differences in incidence rates between these geographical locations are not clearly understood and presumably reflects differences in risk factor prevalence. It has been suggested that the increase of the incidence of AP in the Western countries could be explained by an increase in alcohol intake<sup>[16]</sup>. According to the registry data of Statistics Netherlands the general self-reported alcohol consumption slightly decreased in the period 2000-2005 ([www.cbs.nl](http://www.cbs.nl)). Therefore, the incidence increase of acute pancreatitis seems not to be explained by a change in alcohol consumption, at least not in the Netherlands. We observed that the incidence rates of AP increased considerably with age. This is in accordance with observations elsewhere<sup>[2-4,7,29]</sup>.

The incidence rates of CP in the Netherlands have now been reported for the first time. In contrast to AP, irregular patterns over time emerged for the incidence rates of CP per 100000 persons per year for males (mean: 2.16) and females (mean: 1.4). The incidence rate increased with age, with a top in 2005 at 4.4 in the age group of 75 or older. Recent large scale epidemiological studies reporting the time trends of incidence of CP are strikingly scarce<sup>[15,16]</sup>. The latest reported incidence rates of CP vary between 5.9 and 7.9 per 100000 per-

sons<sup>[11,31,32]</sup>. In comparison to those studies, our observed incidence rates of CP are somewhat lower. This may in part be explained by our study limitations (see below). In accordance to other studies, we show that CP is predominantly a disease of males<sup>[11-13,15,16,31]</sup>. The average incidence rate for males is 50% higher than for females. This is even more pronounced in the older age groups.

The mortality rate for AP per million persons per year fluctuated between 6.9 to 11.7 during the 1995-2005 period. Others too reported fairly stable overall annual population mortality rates<sup>[2,10,13]</sup>. The mortality rate increased rapidly for patients of 50 years of age and above, which too is in accordance with observations elsewhere<sup>[2,4,10,29]</sup>. Advanced age may be an independent risk factor for severe AP<sup>[33]</sup>. Mortality rates were almost similar for males and females.

Concerning CP, the mortality rate per million persons per year for both males and females fluctuated within a stable bandwidth. Tinto *et al*<sup>[13]</sup> also reported that between 1979 and 1999 the age-standardized mortality rate broadly remained unchanged in England. Merely, the mortality rate for males exceeded the female rate. The mortality rate for persons of 75 years of age and older increased most promptly. Generally, the survival rate for patients with CP is poor<sup>[15,16,34,35]</sup>. CP patients tend to die of other causes such as smoking related cancers, cardiovascular disease and alcoholic liver cirrhosis.

Both incidence and mortality rates over time are reported for Dutch and international standard populations. On average, the reported rates are the lowest for the WHO standard population, followed by the European and the Dutch standard populations, which clearly reflects their different age distributions. In addition, an ageing effect was observed during the study period, particularly for male incidence rates. The ageing of the Dutch population will most likely continue for another decade, for which reason an increase in patient burden and a rise in health care costs can be anticipated.

Our study has several potential limitations. We defined an incident case during any specific year as a person with an admission that was not preceded by another admission of the same person with the same discharge diagnosis during at least five years prior to the specified year. So, an admitted, incident case in 2000 had no previous admission during 1995-1999 (five years). Further, an admitted, incident case in 2002 had no previous admission in 1995-2001 (seven years). It would have been a contradiction to allow a person to be classified as an incident case in 2002, if he had already been admitted once before in 1996 for the same reason. This analytical approach however may have led to a downward pressure on the incidence rates in later years (near 2005) compared to the earlier years (near 2000). Hence, growth patterns may be slightly underestimated.

Another limitation is that we did not identify incident CP cases among the persons already identified as incident AP cases. Presumably, this resulted in only a minimal underestimation of the incidence rate of CP. A recent study showed that CP developed in alcoholic AP cases with a

cumulative incidence of just 13% in 10 years<sup>[36]</sup>. Only, in patients with a recurrent alcoholic AP, the incidence of CP at 2 years after initial relapse was 38%. Unfortunately, we do not have sufficient data about the etiology of AP and CP in our study population.

Another issue concerns the reliability of the reported incidence rates which depends heavily on the HDR as a reliable source for hospital discharge data concerning AP and CP.

Eland *et al*<sup>[2]</sup> performed, as a part of a retrospective study in which incidence rates of AP in the Netherlands were assessed, a restricted validation analysis. They concluded that the overreporting due to miscoding and the underreporting due to non-coding were comparable and that observed incidence rates seem to reflect true rates.

Previously, we retrospectively analyzed the reliability of hospital discharge data of in total 483 admissions for both AP and CP collected in the HDR. We observed a substantial miscoding and non-coding of discharge diagnoses of AP and CP on the level of individual hospital admissions, ultimately leading to a limited underestimation at group level of the total number of AP and CP diagnoses of 15.8% and 6% respectively<sup>[37]</sup>.

Furthermore, there is a potential underestimation of the incidence rates due to non-referral of AP and CP patients. For the present study, we retrieved the AP and CP hospital admissions (> 1 d of hospital stay) from the HDR. Underestimation due to non-referral is probably limited for AP, because in the Netherlands almost all AP patients are admitted to a hospital for more than one day<sup>[22]</sup>. Whether or not this also holds for CP patients in the Netherlands is unknown. Generally, some CP patients, especially in the early stage of the disease, are only treated in an outpatient clinic setting and treated in a single-day hospital admission. So, by excluding the single-day admissions in our study, the underestimation will be of greater importance for CP compared to the AP. Historical volume data from the forerunner of the HDR (the earlier mentioned NISHC) on the use of hospital resources by CP patients suggest that approximately 6% of all admissions are single-day admissions. Considering that individual CP patients frequently need multiple single-day admissions, once under such treatment, it is likely that at the person count level, the degree of underestimation is even less than 6%.

In conclusion, we observed an increase in the incidence rate of AP and a fluctuating incidence rate of CP between 2000 and 2005 in the Netherlands. On average, the mortality rate for both AP and CP remained fairly stable between 1995-2005. Both incidence and mortality rates increase markedly by age and are lower for international standard populations. Therefore, in light of the continuing ageing of the Dutch population, patient burden and health care costs will most probably increase.

## COMMENTS

### Background

Over the last decades, the incidence and number of hospital admissions of

both acute pancreatitis (AP) and chronic pancreatitis (CP) have consistently increased in the Western countries. AP and CP are associated with significant morbidity and mortality and a substantial use of health care resources.

### Research frontiers

Large scale epidemiological studies reporting time trends of incidence and mortality of CP are strikingly scarce compared to the also limited epidemiological studies on AP. Mostly, national registries are used in isolation for epidemiological studies on AP and CP. Joint application of these registries by record linkage at the level of the individual patients provides a unique opportunity for improving the accuracy of epidemiological data.

### Innovations and breakthroughs

By following linkage of three distinct nationwide Dutch registries, the authors report in a more valid way the incidence and mortality rates of AP and CP (now for the first time) in the Netherlands. Standardizations were performed with reference to age distribution of the European and World Health Organization standard populations to enable direct comparisons among trends in incidence and mortality rates across countries that differ by age and sex distributions of their respective populations.

### Applications

The incidence rates of AP steadily increased while the incidence of CP fluctuated. Population mortality for both AP and CP remained fairly stable. Both, incidence and mortality rates increased markedly with age. In ageing populations, it is to be expected that patient burden and health care costs will increase.

### Terminology

The disease spectrum of AP ranges from mild and self-limiting to a life-threatening illness. CP is characterized by ongoing or recurrent episodes of abdominal pain accompanied by progressive pancreatic exocrine and endocrine insufficiency. Main etiological factors are gallstones and alcohol abuse.

### Peer review

This is a descriptive study of the trends in incidence and mortality of AP and CP from three linked nationwide Dutch registries for the years 1995-2005. The databases included the hospital discharge registry, the population registry, and the death certificate registry. The authors discuss the limitations of each database and the methods to link them. Given these limitations, major findings included the observation that the incidence of AP increased in both males and females, but the mortality rates remained stable. The incidence and mortality of AP and CP increased with age, which has implications for future incidence in an aging population.

### Abstract

**AIM:** To investigate the role of matrix metalloproteinase (MMP)-9 in the pathogenesis of postoperative liver failure (PLF) after extended hepatectomy (EH).

**METHODS:** An insufficient volume of the remnant

liver (RL) results in higher morbidity and mortality, and a murine model with 80%-hepatectomy was used. All investigations were performed 6 h after EH. Mice were first divided into two groups based on the postoperative course (*i.e.*, the PLF caused or did not), and MMP-9 expression was measured by Western blotting. The source of MMP-9 was then determined by immunohistological stainings. Tissue inhibitor of metalloproteinase (TIMP)-1 is the endogenous inhibitor of MMP-9, and MMP-9 behavior was assessed by the experiments in wild-type, MMP-9(-/-) and TIMP-1(-/-) mice by Western blotting and gelatin zymography. The behavior of neutrophils was also assessed by immunohistological stainings. An anti-MMP-9 monoclonal antibody and a broad-spectrum MMP inhibitor were used to examine the role of MMP-9.

**RESULTS:** Symptomatic mice showed more severe PLF (histopathological assessments:  $2.97 \pm 0.92$  vs  $0.11 \pm 0.08$ ,  $P < 0.05$ ) and a higher expression of MMP-9 ( $71085 \pm 18274$  vs  $192856 \pm 22263$ ,  $P < 0.01$ ). Non-native leukocytes appeared to be the main source of MMP-9, because MMP-9 expression corresponding with CD11b positive-cell was observed in the findings of immunohistological stainings. In the histopathological findings, the PLF was improved in MMP-9(-/-) mice ( $1.65\% \pm 0.23\%$  vs  $0.65\% \pm 0.19\%$ ,  $P < 0.01$ ) and it was worse in TIMP-1(-/-) mice ( $1.65\% \pm 0.23\%$  vs  $1.78\% \pm 0.31\%$ ,  $P < 0.01$ ). Moreover, neutrophil migration was disturbed in MMP-9(-/-) mice in the immunohistological stainings. Two methods of MMP-9 inhibition revealed reduced PLF, and neutrophil migration was strongly disturbed in MMP-9-blocked mice in the histopathological assessments ( $9.6 \pm 1.9$  vs  $4.2 \pm 1.2$ ,  $P < 0.05$ , and  $9.9 \pm 1.5$  vs  $5.7 \pm 1.1$ ,  $P < 0.05$ ).

**CONCLUSION:** MMP-9 is important for the process of PLF. The initial injury is associated with MMP-9 derived from neutrophils, and MMP-9 blockade reduces PLF. MMP-9 may be a potential target to prevent PLF after

EH and to overcome an insufficient RL.

Matrix metalloproteinase-9 in the initial injury after hepatectomy in mice. *World J Gastroenterol* 2013; 19(20): 3027-3042 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i20/3027.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i20.3027>

## INTRODUCTION

Liver resection is considered the standard treatment for primary malignant tumors and liver metastases. Currently, advanced surgical techniques for hepatectomy, development of preoperative evaluation and improvements in intensive postoperative care have resulted in a decline in perioperative morbidity and mortality. However, postoperative liver failure (PLF) still occurs despite these developments. Extended hepatectomy (EH) has the advantage of high curability, but increases morbidity and mortality compared with more limited resections<sup>[1]</sup>. The volume of the remnant liver (RL) is correlated with perioperative morbidity and mortality<sup>[1]</sup>. PLF is also related to the patient's condition<sup>[2]</sup>. The rationale for PLF is the overall recovery course after EH. Prognosis of PLF in insufficient RL after EH is poor<sup>[1,2]</sup>.

The mechanism of progressive PLF after EH is not fully understood. The main pathway of failure of liver regeneration is still controversial, and it is unclear how excessive apoptosis or progressive necrosis is attributable to insufficient RL after EH. Matrix metalloproteinases (MMPs) are a family of zinc-containing neutral proteases that are capable of degrading the extracellular matrix and basement membrane. Among MMPs, MMP-9, also known as gelatinase B, is well characterized<sup>[3-5]</sup>. Expression of MMP-9 is reported to be associated with several pathophysiological conditions, such as rheumatoid arthritis<sup>[6]</sup>, atherosclerosis<sup>[6]</sup>, encephalopathy<sup>[7]</sup> and tumor invasion<sup>[8,9]</sup>. Recent studies have demonstrated that MMP-9 plays a pivotal role in ischemia/reperfusion injury in the liver transplantation field<sup>[4,10]</sup>. We hypothesized that MMP-9 plays a role in the pathogenesis of PLF after EH accompanied by postoperative shear stress due to portal hypertension and insufficient RL, and we previously reported the results of our preliminary study<sup>[11]</sup>. In this study, we examined the initial pathway of necrosis in the PLF process and MMP-9 expression in the early phase after EH by using an experimental mice model. In addition, we evaluated the efficacy of MMP-9 blockade on initial injury in the liver by deleting MMP-9 in the mouse, using a monoclonal antibody and a broad spectrum MMP inhibitor.

## MATERIALS AND METHODS

### Animals

Male C57BL/6 mice [wild-type (WT), 10-14 wk old] purchased from Jackson Laboratory (Bar Harbor, ME), were housed in a conventional mouse room with a 12-h light/dark cycle, food, and water. MMP-9(-/-) mice, which were a gift from Dr. Roberts Senior (Washington University, St. Louis, MO), and tissue inhibitor of metalloproteinase (TIMP)-1(-/-) mice, which were purchased from Jackson Laboratory were used. Both knock-out strains had the background of C57/BL/6, and all mice were bred in our secure animal facility. All experimental protocols were approved by the ethical committee of the Mayo Clinic (Protocol No. IACUC 24907) in accordance with the National Institutes of Health Guide for the Care and Use of Laboratory Animals.

### Eighty percent-partial hepatectomy in mice

Surgical procedures for the murine hepatectomy model are well established, and our method has been described in detail elsewhere<sup>[12]</sup>. For 80%-partial hepatectomy (PH), the left posterior, left and right anterior, and right posterior lobes were resected. In brief, under general anesthesia using isoflurane, liver lobes were mobilized after laparotomy. A hemostatic clip (Teleflex Medical, Triangle Park, NC) was applied across the pedicle at the base of the liver lobes instead of ligation, and liver lobes were cut distal to the applied clip. Only laparotomy was performed as the sham control group. Before abdominal closure, 2 mL of warm saline was administered intraperitoneally. Cephalexin (30 mg/kg) and buprenorphine (0.1 mg/kg) were given subcutaneously. To preserve the same quality throughout the series, all procedures for presented data were performed only by Ohashi N. To confirm the presented data, Hori T repeated this study including 90%-PH. Postoperatively, mice were housed under a controlled temperature, humidity, and light with free access to food and water.

First, we performed 90%-PH in 50 WT mice, and all mice died at the early postoperative period. In this study, we employed 80%-PH as the relevant clinical model. Ninety-percent-PH showed greater damage in the preliminary study, but we considered that 10%-RL was clinically irrelevant. Paradoxically, some survivors without any symptoms were observed after 80%-PH.

We then performed 80%-PH in 38 WT mice and sham surgery in 12 WT mice, to evaluate the postoperative course. In the following experiments, 80%-PH was performed with 20 age-matched WT mice, 19 MMP-9(-/-) mice and 20 TIMP-1(-/-) mice.

Focal and/or patchy necrosis is an important finding after PH<sup>[13-16]</sup>, and progressive necrosis is found from the early postoperative period after EH<sup>[13,14,16]</sup>. In this study, all of the mice were sacrificed at 6 h after 80%-PH. The RL was harvested and divided for histological analysis (formalin and frozen fixation) and protein analysis (snap frozen at -80 °C). Serum samples were collected and sep-

arated by using Microtainer tubes (BD, Franklin Lakes, NJ).

### **MMP-9 inhibition experiment using anti-MMP-9 monoclonal antibody and the broad-spectrum MMP inhibitor GM6001**

The WT mice were treated with 3 mg/kg of anti-MMP-9 neutralizing monoclonal antibody (clone 6-6B, EMD, Gibbstown, NJ) by intravenous injection 1 h before 80%-PH (MMP-9 mAb group,  $n = 6$ ). In the control mice, the same volume of non-immunized murine IgG of the same isotype (EMD, Gibbstown, NJ) was injected in the same manner (control IgG group,  $n = 6$ ). In another experiment, a broad spectrum MMP-inhibitor, GM6001 (Millipore, Billerica, MA) (100 mg/kg), diluted in 10% dimethyl sulfoxide (DMSO) was administrated intraperitoneally 2 h before 80%-PH (GM6001 group,  $n = 10$ ). Ten percent DMSO was injected in the control mice in the same manner as for GM6001 (vehicle group,  $n = 10$ ).

### **Biochemical analysis**

Serum levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were determined by a commercially available kinetic detection kit (Pointe Scientific, INC, Canton, MI), and total bilirubin (T-Bil) levels were determined by the QuantiChrom™ Bilirubin Assay Kit (BioAssay Systems, Hayward, CA).

### **Western blotting analysis**

Liver samples were homogenized in a buffer containing 10 mmol/L Tris-HCl (pH 7.4), 150 mmol/L NaCl, 1% Triton-X, 0.1% sodium dodecyl sulfate (SDS), 1 mmol/L ethylene diamine tetra-acetic acid (EDTA), 1 mmol/L ethylene glycol tetra-acetic acid, 1 mmol/L phenylmethylsulfonyl fluoride, and protease and phosphatase inhibitors. Homogenates were centrifuged at 105000  $g$  for 1 h at 4 °C. Supernatants were collected and protein concentration was determined by BCA assay (Pierce, Rockford, IL). Forty micrograms of protein was separated *via* SDS-polyacrylamide gel electrophoresis (SDS-PAGE) and transferred to a polyvinylidene difluoride (PVDF) membrane (Millipore, Bedford, MA). Membranes were blocked with 5% nonfat milk in TBS-T [20 mmol/L Tris (pH 7.4), 500 mmol/L NaCl, and 0.05% Tween-20] and probed using an antibody for MMP-9 (R and D, Minneapolis, MN), and then they were incubated with peroxidase-conjugated secondary antibodies (Santa Cruz Biotechnology, Santa Cruz, CA) followed by enhanced chemi-luminescence (ECL) or ECL-plus reagent (Amersham Biosciences, Piscataway, NJ). Equal loading was confirmed by immunoblotting using glyceraldehyde-3-phosphate dehydrogenase (GAPDH) monoclonal antibody (IMGENEX, San Diego, CA) on the same membrane. Signals were quantified using the ImageQuant program (Molecular Dynamics, Sunnyvale, CA).

### **Gelatin zymography**

The RL extracts were analyzed by gelatin zymography

with affinity chromatography to characterize gelatinase activity. In brief, 400  $\mu$ g of extract samples were incubated with 100  $\mu$ L of Gelatin-Sepharose 4B (GE Healthcare) and equilibrated buffer containing 50 mmol/L Tris-HCl pH 7.5, 150 mmol/L NaCl, 5 mmol/L CaCl<sub>2</sub>, 0.02% Tween-20, and 10 mmol/L EDTA for 2 h at 4 °C. After multiple washing, gelatin-Sepharose beads were resuspended in the same volume of 2X zymography sample buffer (Bio-Rad Laboratories, Hercules, CA) and loaded on 10% SDS-PAGE gels containing 1 mg/mL of gelatin (Bio-Rad Laboratories). After electrophoresis, the gel was washed with 2.5% Triton X-100 for renaturing twice for 30 min, and it was then incubated in development buffer (Bio-Rad Laboratories) for 20 h at 37 °C. After incubation, the gel was fixed and stained with 0.5% Coomassie Blue R-250 (Bio-Rad Laboratories) for 1 h and destained with 10% acetic acid in 40%-methanol solution. Gelatinase zymography standards (Millipore, Billerica, MA) were used for the positive control.

### **Histology and immunohistochemical staining**

Formalin-fixed liver specimens were embedded in paraffin, and 5- $\mu$ m sections were stained with hematoxylin and eosin (HE). Immunohistochemical (IHC) staining for CD11b (MAC-1) and CD68 was performed on frozen sections (5  $\mu$ m), while paraffin sections were used for desmin, myeloperoxidase (MPO) and MMP-9 single staining. Antigen retrieval heating with citric acid (pH 6.0) was performed after deparaffinization with paraffin sections. For horseradish peroxidase based staining with 3,3' diaminobenzidine tetrahydrochloride (DAB) (DAKO, Carpinteria, CA), 0.3% H<sub>2</sub>O<sub>2</sub> was added to quench endogenous peroxidase activity, and an ABC kit (Vector Laboratories Inc, Burlingame, CA) was used during the staining procedure according to the manufacturer's instructions. For dual staining, sections were blocked with 5% bovine serum albumin (BSA) in PBS. The antibodies for MMP-9 (AF909), intercellular adhesion molecule 1 (ICAM-1) (AF796), CD11b (clone M1/70) (R and D, Minneapolis, MN), CD68 (clone FA-11), desmin (Abcam, Cambridge, MA), and MPO (Ab-1) (Thermo scientific, Fremont, CA) were incubated for the primary reaction. Alexa Fluor 568 donkey anti-goat IgG (H + L), Alexa Fluor 488 donkey anti-rabbit IgG and Alexa Fluor 488 donkey anti-rat antibody (Invitrogen, Carlsbad, CA) were incubated for the secondary reaction. In each experiment, BSA solutions without antibodies were applied for a negative control.

### **Histological analysis**

The HE sections were digitally scanned with the Scanscope XT system and analyzed with Aperio Imagescope software (Aperio Technologies, Inc., Vista, CA). Histological areas were blindly counted and measured with three randomly selected fields approximately 3 mm<sup>2</sup> in each section. The positivity of DAB staining for MMP-9 was automatically calculated using the positive pixel count function with Imagescope software with 10 ran-

domly selected fields with the reference to the presence of necrosis, respectively. The value was indicated by the percentage of positive pixels out of the total pixels. The number of infiltrated granulocytes was evaluated in five randomly-captured 40 high power fields in each section with an Olympus BX50 fluorescence microscope (Olympus Optical, Tokyo, Japan).

### *In situ* zymography

*In situ* gelatinolytic activity was performed on cryostat sections (20- $\mu$ m thickness) using the EnzChek Gelatinase assay kit (Molecular Probes, Eugene, Oregon, United States). Sections were incubated with 20  $\mu$ g/mL fluorescent conjugated gelatin (DQ gelatin) in reaction buffer (50 mmol/L Tris-HCl, 150 mmol/L NaCl, 5 mmol/L CaCl<sub>2</sub>, and 0.2 mmol/L sodium azide) for 2 h at 37 °C. After being washed with PBS three times, they were fixed in 4% paraformaldehyde in PBS. We incubated sections with GM6001 (100  $\mu$ mol/L) prior to DQ gelatin incubation as a negative control in each experiment. Sections were mounted with Vectashield (Vector Laboratories Inc, Burlingame, CA). Gelatinase activity was visualized using fluorescent microscopy (Olympus BX50, Japan).

### Statistical analysis

Data are presented as the mean  $\pm$  SE. Statistical comparisons were performed using ANOVA followed by the two-sample *t*-test with Bonferroni adjustment. A *P* value  $<$  0.05 was considered statistically significant.

## RESULTS

### *Necrosis is a pivotal event for PLF in the RL after 80%-PH*

Murine behavior in hepatic failure has been well described<sup>[17,18]</sup>. Mice with intrahepatic-hemorrhage and necrosis were observed to be sick and inactive, whereas mice without such injury were asymptomatic and active. We classified these mice into groups based on these findings as follows below. Mice were divided into two groups; asymptomatic (Group I) and symptomatic (Group II).

We performed 80%-PH in 38 WT mice and sham surgery in 12 WT mice to compare the difference in the RL with or without PLF at several time points after 80%-PH. Among these mice, we randomly selected five asymptomatic mice which were active, nimble and reactive to stimulation, and six symptomatic mice which were sick and inactive, slow-moving and sluggish 6 h after 80%-PH. As shown in Figure 1A and B, multiple necrotic foci with microhemorrhage in the middle zone were observed in the symptomatic mice, while a small amount of necrosis was observed in the asymptomatic mice. These HE findings are consistent with a previous report<sup>[19]</sup>. We measured the area of necrosis as an objective marker of liver injury. The area of necrosis ( $2.97\% \pm 0.92\%$  vs  $0.11\% \pm 0.08\%$ ,  $P < 0.05$ ) (Figure 1C) and the number of necrotic foci ( $3.60 \pm 0.87/\text{mm}^2$  vs  $0.26 \pm 0.17/\text{mm}^2$ ,  $P < 0.01$ ) in the RL were significantly larger in symptomatic mice than those in asymptomatic mice (Figure 1D). Serum levels of AST

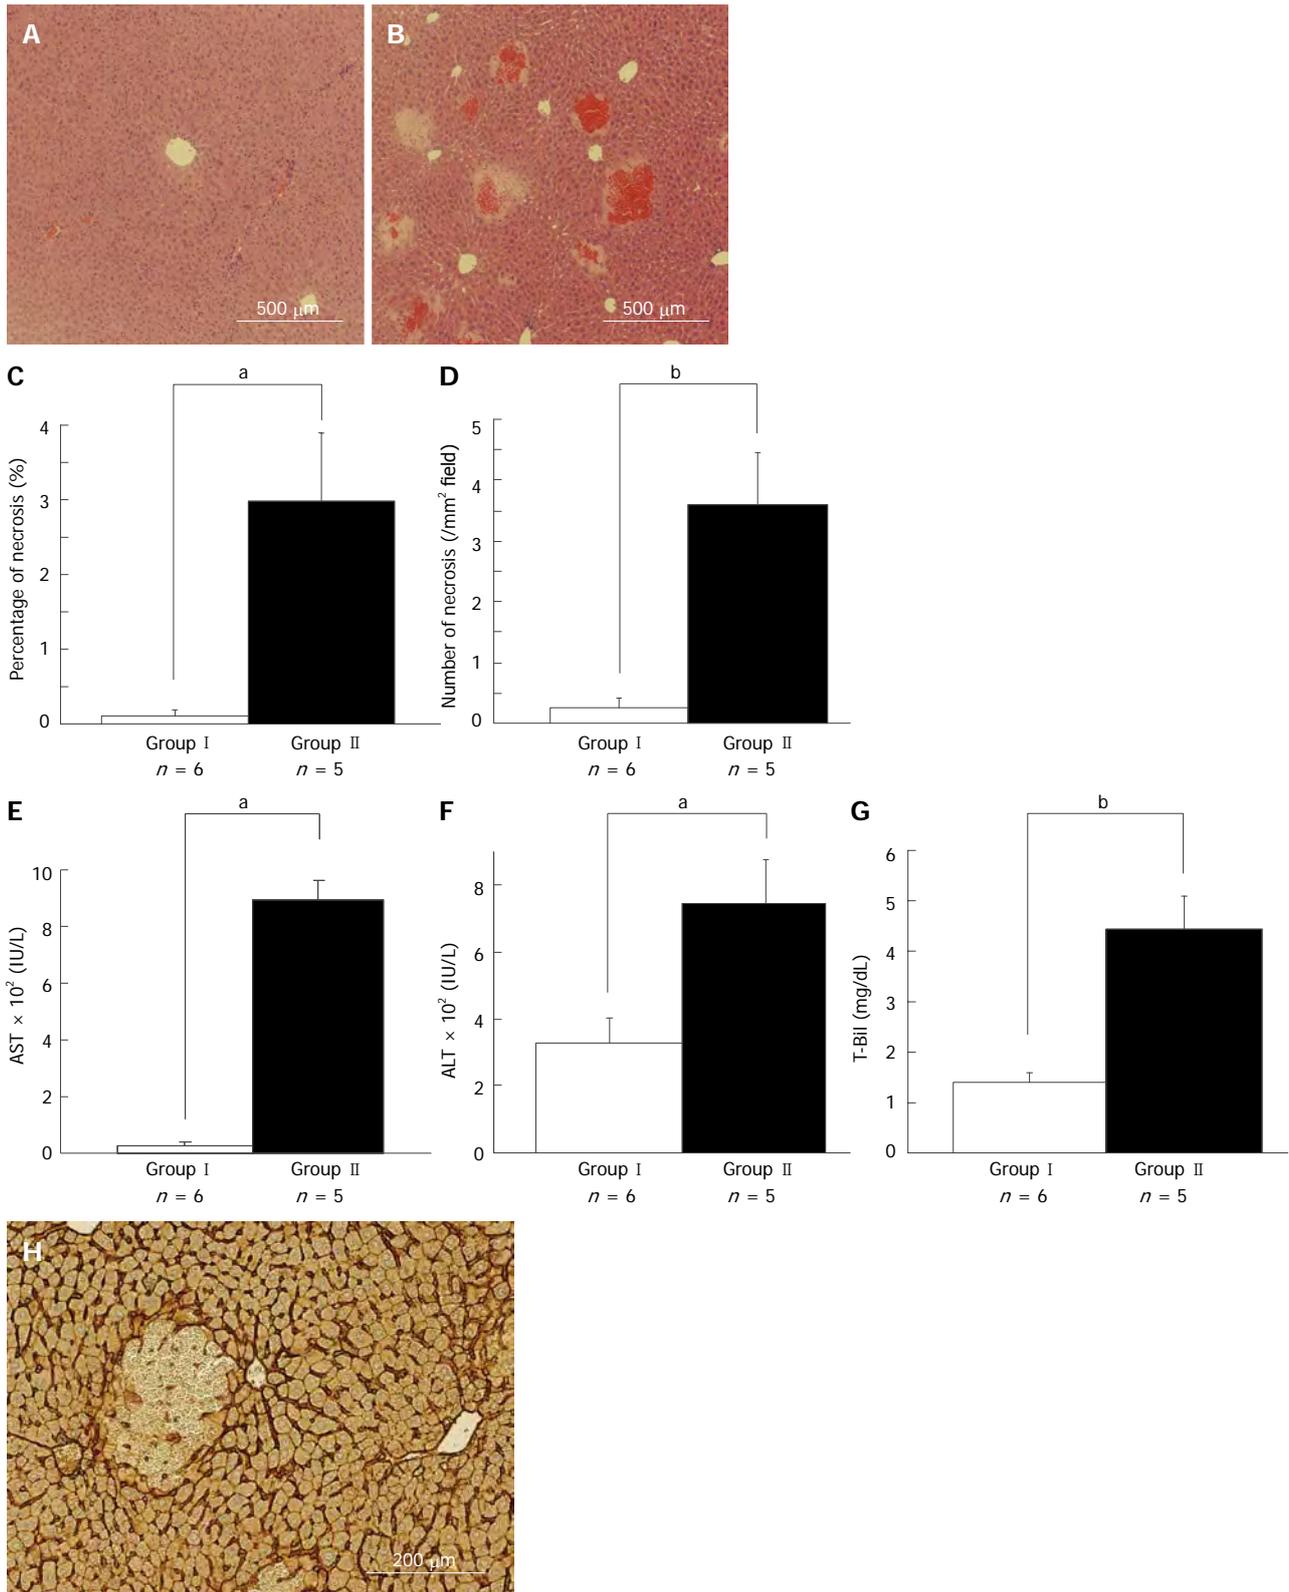

( $785 \pm 15$  IU/L vs  $452 \pm 39$  IU/L,  $P < 0.01$ ) (Figure 1E), ALT ( $744 \pm 135$  IU/L vs  $328 \pm 77$  IU/L,  $P < 0.05$ ) (Figure 1F), and T-Bil ( $4.45 \pm 0.63$  mg/dL vs  $1.41 \pm 0.19$  mg/dL,  $P < 0.01$ ) (Figure 1G) were significantly higher in symptomatic mice than those in asymptomatic mice. These results clearly indicated that symptomatic mice were in the process of PLF as shown by the increase in AST and ALT levels and hyperbilirubinemia. In some mice, which failed to recover even 6 h after 80%-PH, multiple necroses might have been responsible for the process of PSL in this model. Enhanced necrosis was observed in the RL at the late phase (12 h or later, data not shown), and these preliminary data confirmed that the necrotic pathway is progressive. In addition, intrahepatic-hemorrhage was observed in most of the necrotic lesions, which suggested the possibility that the initial sinusoid endothelial cell injury leading to sinusoidal breakdown is attributable to necrosis in the RL. In our model, dehiscence of sinusoids and loss of continuity of endothelial cells were observed in ICAM-1 immunostaining, which was strongly positive in endothelial cells (Figure 1H).

We performed retrospective analysis of perioperative factors including the resected liver weight/body weight and surgery time with 11 mice whose prognosis was predictable. Perioperative factors were not different between asymptomatic and symptomatic mice, but the resected liver weight/body weight ratio in the symptomatic mice tended to be larger than that in the asymptomatic mice ( $3.8\% \pm 0.1\%$  vs  $3.5\% \pm 0.1\%$ ,  $P = 0.06$ ). It is possible that the extent of hepatectomy is an important factor for postoperative liver injury after EH.

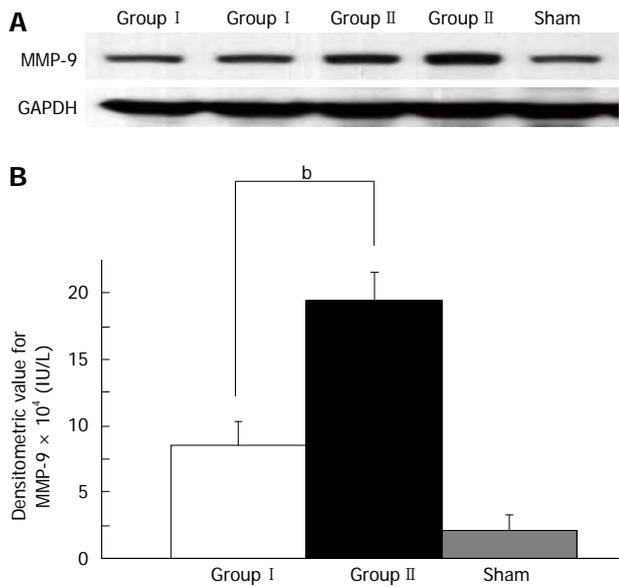

Macro- and microscopically, we confirmed the preservation of vascularization in the RL, immediately after 80%-PH by sodium fluorescent perfusion via the portal vein and abdominal aorta, to exclude model specific effects including surgical issues. In addition, we observed similar histological findings after 80%-PH with the traditional suture ligation method<sup>[13]</sup> (data not shown). These results demonstrated that the process of PSL after EH was widely and histologically characterized by RL necrosis, and was probably initialized as early onset sinusoid breakdown following progressive necrosis of hepatocytes.

### *MMP-9 expression is enhanced in RL dysfunction 6 h after 80%-PH and is associated with liver necrosis*

We compared MMP-9 expression in the RL between asymptomatic mice and symptomatic mice at 6 h. Enhanced MMP-9 expression was confirmed in symptomatic mice after EH compared with that in the asymptomatic mice after EH and sham surgery mice as shown by Western blotting analysis ( $P < 0.01$ ) (Figure 2). IHC showed that MMP-9 expression was mainly observed in round-shaped cells in the liver parenchyma and necrotic areas, and was less common in stellate-shaped cells. A small amount of MMP-9 expression was observed in hepatocytes compared with the above-mentioned cells (Figure 3A and B). To evaluate the association of necrosis and MMP-9 in liver tissue, we compared the expression level of MMP-9 between 10 randomly selected fields (3 mm<sup>2</sup>)

**Figure 1** Necrosis is a pivotal event for postoperative liver failure in the remnant liver after 80%-partial hepatectomy. There were histological and hematochemical differences between asymptomatic and symptomatic mice suspected as having postoperative liver failure 6 h after 80%-partial hepatectomy (PH) (A, B). Representative images of the remnant liver (RL) 6 h after 80%-PH in asymptomatic mice (A) and symptomatic mice (B) are shown. Significant multiple necroses with microhemorrhage were observed in the middle zone in symptomatic mice (B), while no obvious liver damage was observed in asymptomatic mice (A). The percentage area of necrosis (C) and the number of necrosis in each mm<sup>2</sup> (D) in the RL were confirmed. Necrotic areas were significantly larger and more prevalent in symptomatic mice liver compared with asymptomatic mice. Serum levels of aspartate aminotransferase (AST) (E), alanine aminotransferase (ALT) (F) and total bilirubin (T-Bil) (G) 6 h after 80%-PH are shown. AST, ALT and T-Bil levels were significantly elevated in symptomatic mice compared with those in asymptomatic mice. Representative image of immunohistochemistry of intercellular adhesion molecule-1 (ICAM-1) in the RL 6 h after 80%-PH is shown (H). ICAM-1 expression was clearly observed, particularly in the sinusoid lining in areas without necrosis. We observed a breakdown in sinusoid structure with hemorrhage in necrotic areas after 80%-PH in mice, <sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 vs asymptomatic mice.

**Figure 2** Western blotting analyses for matrix metalloproteinase-9 were performed in the remnant liver in asymptomatic mice and symptomatic mice after 80%-partial hepatectomy. Representative image (A) and histograms (B) of Western blotting analyses for matrix metalloproteinase-9 (MMP-9) are shown. MMP-9 protein expression in the liver was enhanced in symptomatic mice in the process of postoperative liver failure compared with that in asymptomatic mice after extended hepatectomy and sham-treated mice (<sup>b</sup>*P* < 0.01 between Groups I and II).

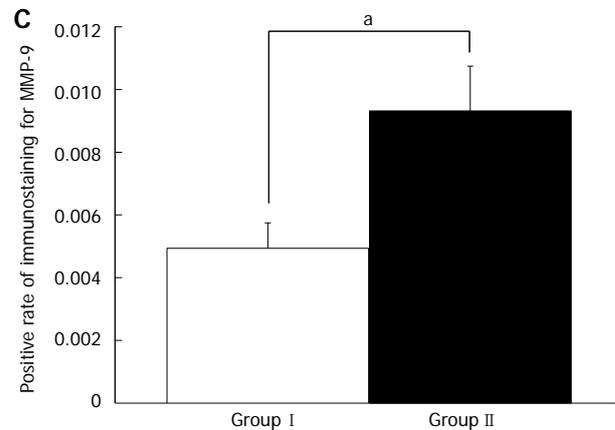

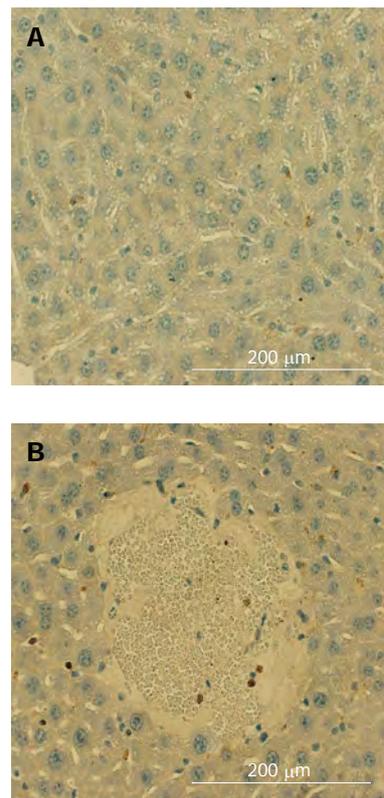

of areas with necrosis and those without necrosis in IHC sections. Enhanced MMP-9 expression was observed in the areas including necrosis compared with those without necrosis (*P* < 0.05, Figure 3C). This result suggested that MMP-9 expression is associated with necrosis in the RL after EH.

**Main source of MMP-9 is CD11b-positive nonnative leukocytes in the RL 6 h after 80%-PH**

To determine the source of MMP-9, we performed dual immunofluorescent analysis with MMP-9 and various cell marker antibodies in the liver. CD68 and desmin were used as specific markers for Kupffer cells and hepatic stellate cells in immunostaining, respectively. MMP-9 expression was not observed in CD68-positive Kupffer cells, while MMP-9 expression was partially confirmed in desmin-positive hepatic stellate cells (Figure 4A-F). In addition, we clearly detected MMP-9 expression corresponding with CD11b positive-cells, which are generally expressed in nonnative leukocytes in the liver including monocytes, granulocytes and macrophages (Figure 4G-I). These results suggested that MMP-9 was expressed in the RL 6 h after 80%-PH, and it appeared to be mainly produced by leukocytes that had migrated from the outside of the liver, similar to that described in a liver ischemia/reperfusion injury model<sup>[20]</sup>.

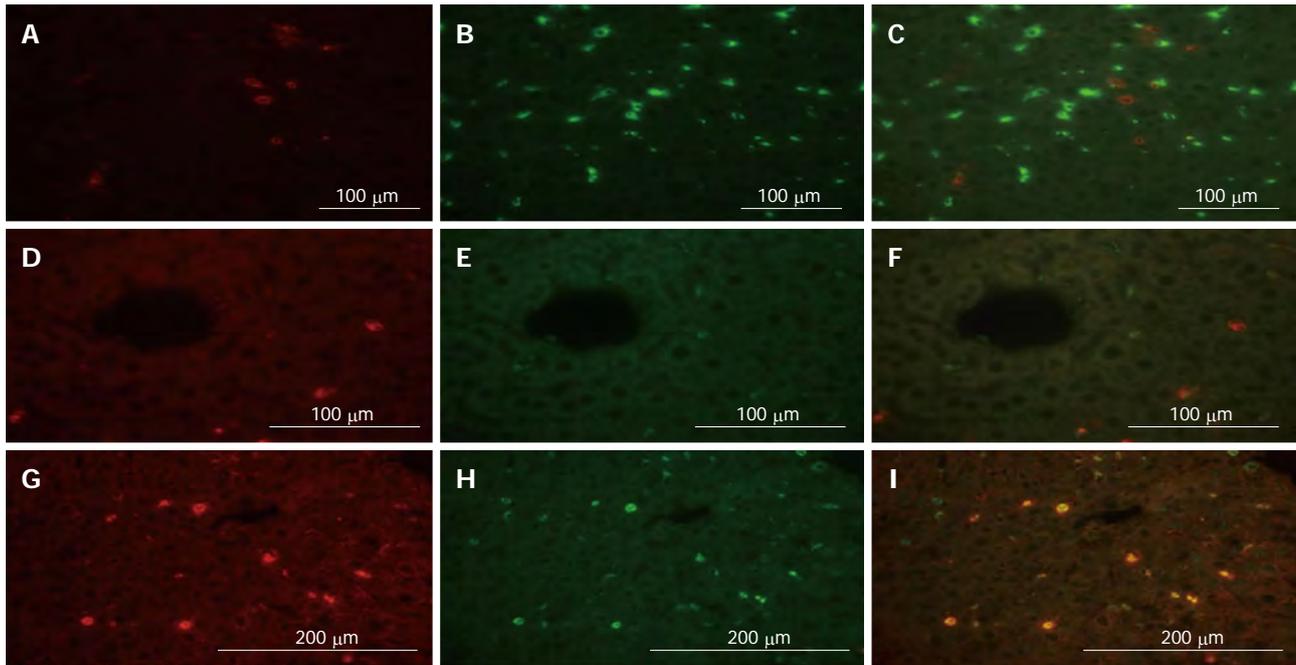

**MMP-9 deletion ameliorates initial injury in the RL 6 h after 80%-PH**

TIMP-1 is an endogenous inhibitor of MMP-9. We performed 80%-PH in 20 WT, 19 MMP-9(-/-) and 20

**Figure 3** Immunohistochemical analysis for matrix metalloproteinase-9 in the remnant liver in symptomatic mice after 80%-partial hepatectomy was performed. A: Representative images of matrix metalloproteinase-9 (MMP-9) staining in an area without necrosis; B: A necrotic area in the same sample are shown. Histograms of the results of distribution analysis show MMP-9 expression; C: Enhanced expression was observed in the areas close to necrosis compared with areas without necrosis in damaged RL (<sup>a</sup>*P* < 0.05 between Groups I and II).

TIMP-1(-/-) mice to compare the difference in the RL 6 h after 80%-PH. Among these mice, we randomly selected samples from 15 WT, 15 MMP-9(-/-) and 14 TIMP-1(-/-) mice. To evaluate the effects of MMP-9 on the initial injury in the RL, we compared the area (percentage) of necrosis and the number of necrotic foci in the RL among these samples. There were significantly fewer and smaller necrotic lesions in MMP-9(-/-) mice compared with WT mice and TIMP-1(-/-) mice (area, WT: 1.65% ± 0.23%; MMP-9(-/-): 0.65% ± 0.19%;

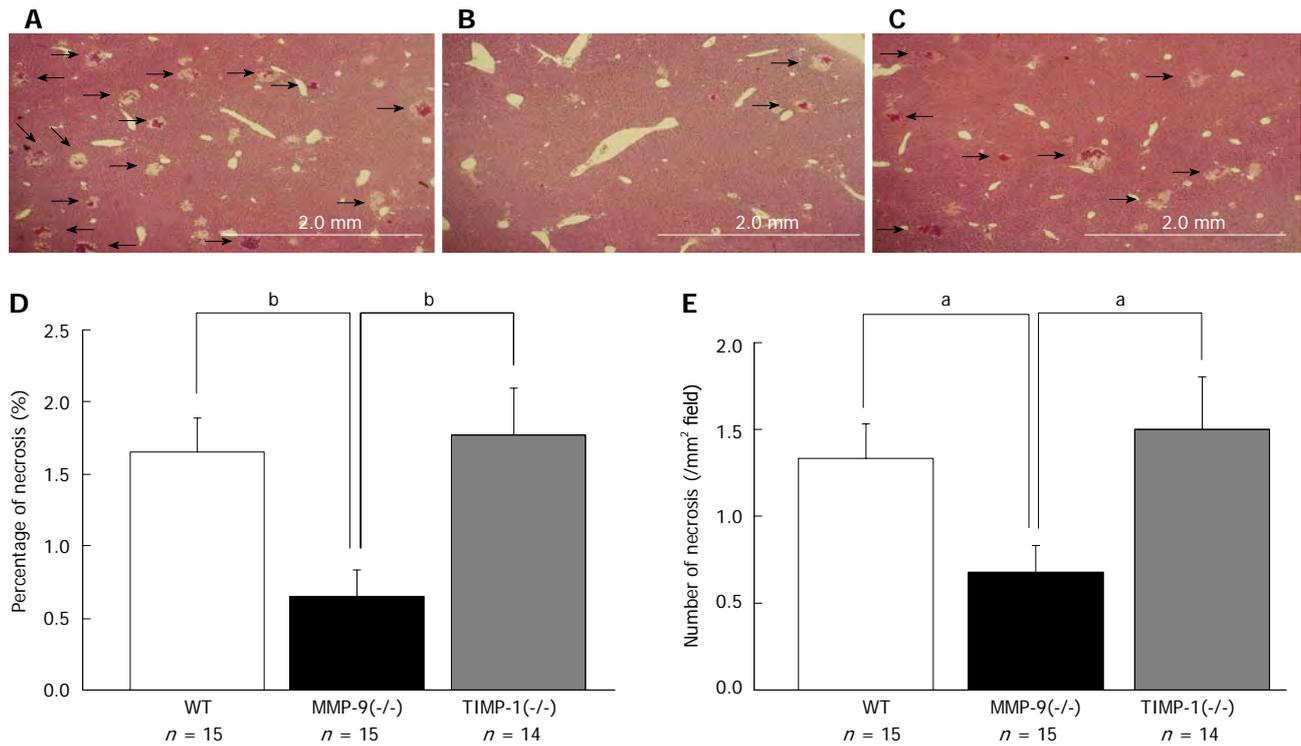

**Figure 4** Localization analysis of matrix metalloproteinase-9 by dual immune-fluorescence in the remnant liver after 80%-partial hepatectomy is shown. A: Fluorescent microscopy images of matrix metalloproteinase-9 (MMP-9) labeled in red (Alexa Fluor 568); B: CD68 labeled in green (Alexa Fluor 488); C: A merged image of MMP-9 and CD68 staining are shown; D: MMP-9 labeled in red (Alexa Fluor 568); E: Desmin labeled in green (Alexa Fluor 488); and F: A merged image of MMP-9 and desmin are shown; G: MMP-9 labeled in red (Alexa Fluor 568); H: CD11b labeled in green (Alexa Fluor 488); I: A merged image of MMP-9 and CD11b are shown. Protein expression of MMP-9 was mainly localized in CD11b-positive cells and desmin-positive cells to some degree.

TIMP-1(-/-):  $1.78\% \pm 0.31\%$ ; MMP-9(-/-) *vs* WT:  $P < 0.01$ ; MMP-9(-/-) *vs* TIMP-1(-/-):  $P < 0.01$ , (number of necrotic foci, WT:  $1.34 \pm 0.20/\text{mm}^2$ ; MMP-9(-/-):  $0.68 \pm 0.16/\text{mm}^2$ ; TIMP-1(-/-):  $1.50 \pm 0.30/\text{mm}^2$ ; MMP-9(-/-) *vs* WT:  $P < 0.05$ ; MMP-9(-/-) *vs* TIMP-1(-/-):  $P < 0.05$ ) (Figure 5). There was no significant difference in necrosis between WT and TIMP-1(-/-) mice. The levels of AST (WT:  $520 \pm 69$  IU/L; MMP-9(-/-):  $482 \pm 76$  IU/L; TIMP-1(-/-):  $636 \pm 58$  IU/L) and ALT (WT:  $544 \pm 73$  IU/L; MMP-9(-/-):  $466 \pm 92$  IU/L; TIMP-1(-/-):  $566 \pm 54$  IU/L) were lowest in MMP-9(-/-) mice, but this was not statistically significant among the groups. Additionally, T-Bil levels showed a similar tendency (WT:  $2.72 \pm 0.36$  mg/dL; MMP-9(-/-):  $2.23 \pm 0.27$  mg/dL; TIMP-1(-/-):  $2.76 \pm 0.28$  mg/dL). In Western blotting and gelatin zymography analysis, MMP-9 deletion of protein expression and activity in MMP-9(-/-) mice were confirmed. Protein expression of MMP-9 in WT mice was similar to that in TIMP-1(-/-) mice (Figure 6A). In gelatin zymography analysis, a distinct pro-form of MMP-9 and a slightly active form of MMP-9 were detected in WT and TIMP-1(-/-) mice (Figure 6B). No difference in MMP-9 activity was detected in the genotypes. Since there was no change in MMP bands among the groups because of the principle of protein separation by SDS-PAGE in zymography, we performed *in situ* gelatin zymography to examine the gelatinolytic activity *in situ*. We observed reduced gelatinolytic activity in MMP-9(-/-) mice and enhanced activity in TIMP-1(-/-) mice compared with that in WT mice (Figure 6C-E). MMP-9 deletion, which suppresses gelatinolytic activity, was associated with the amelioration

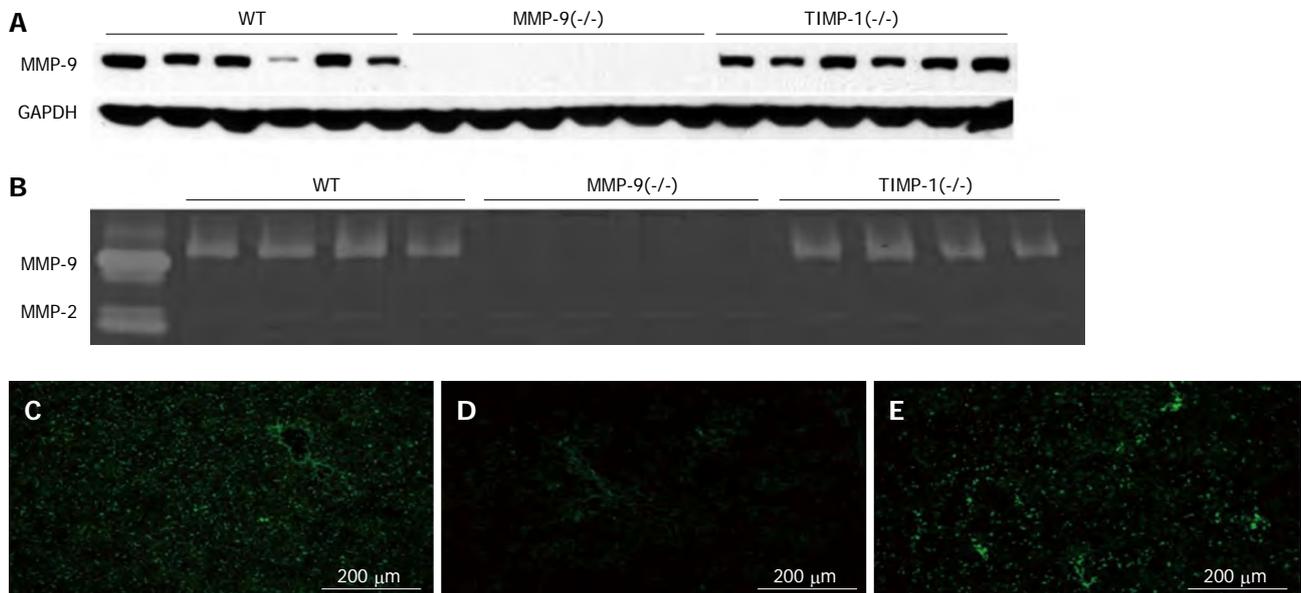

of formation of necrosis and necrotic progression in the RL after 80%-PH. However, TIMP-1 deletion, which induces the enhancement of gelatinolytic activity, did not exacerbate initial injury of the RL after EH. These results suggested that the involvement of TIMP-1 in inhibition of MMP activity appeared to be limited to PLF 6 h after EH. We investigated survival after 80%-PH was performed in WT, MMP-9(-/-) and TIMP-1(-/-) mice, but a significant survival benefit was not observed by MMP-9 deletion ( $P \geq 0.05$ ).

#### **MMP-9 deletion inhibits the accumulation of neutrophils in the RL 6 h after 80%-PH**

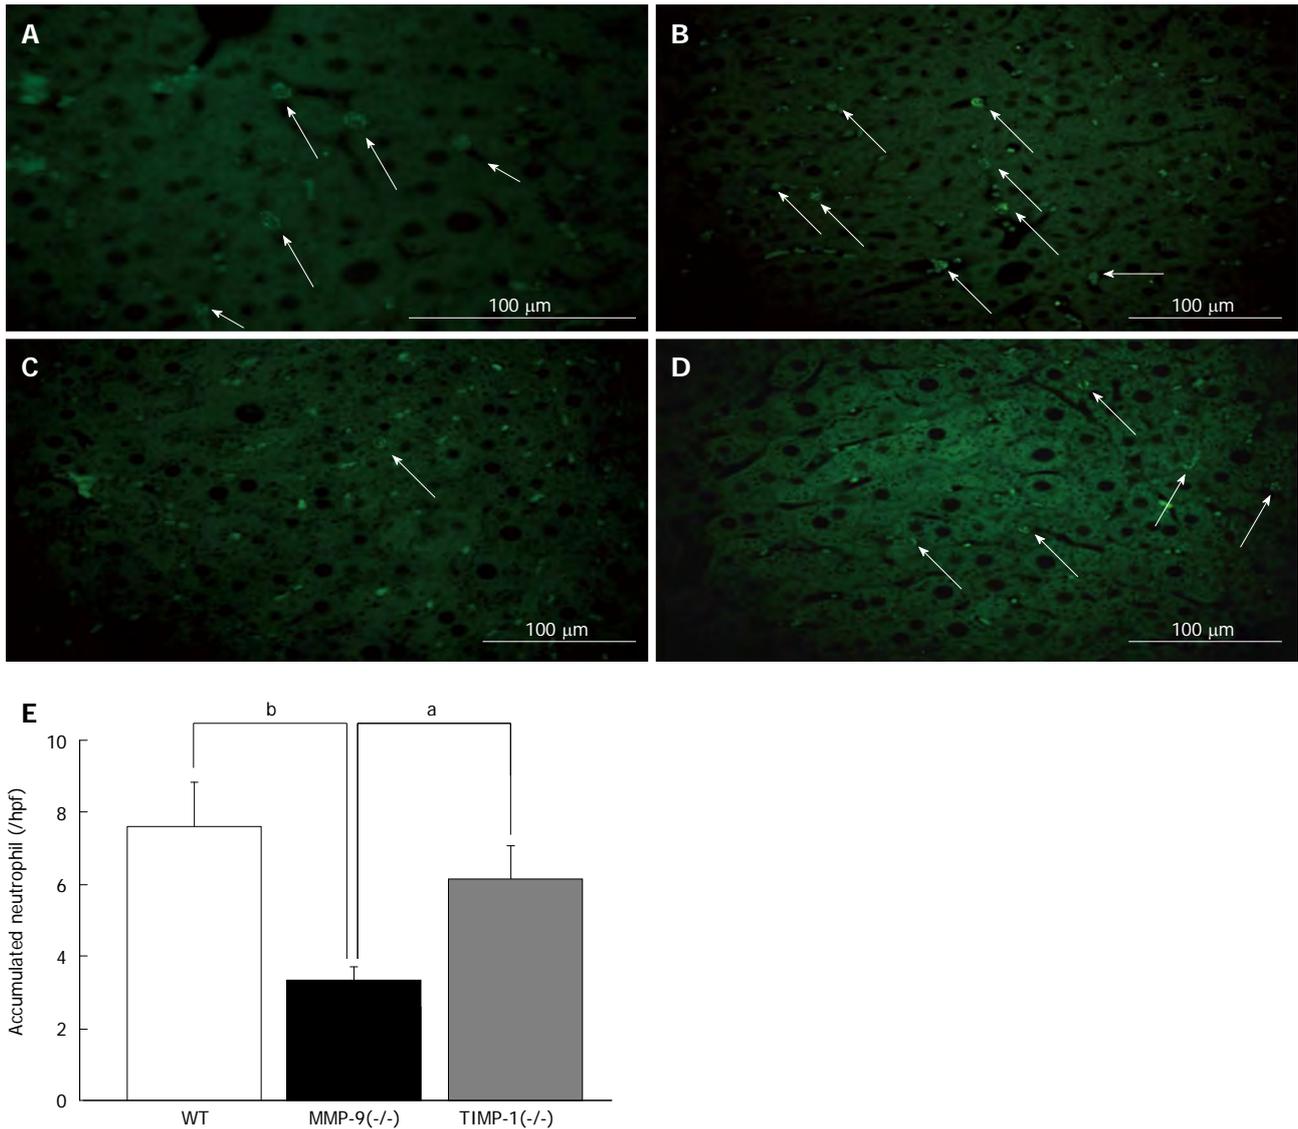

To evaluate the effect of MMP-9 deletion on cell kinetics, we investigated whether neutrophil migration after 80%-PH has an effect on the RL in WT, MMP-9(-/-) and TIMP-1(-/-) mice. We performed immunofluorescence staining for myeloperoxidase (MPO) to investigate this issue. As shown in Figure 7A, MPO-positive neutrophils could be easily recognized by characteristic staining patterns in cytoplasmic azurophilic granules, and MPO was also positive in liver tissue macrophages (Kupffer cells)<sup>[21]</sup>. Because of the difficulty in distinguishing between infiltrated neutrophils in the liver parenchyma and those that were adhered to the sinusoidal wall, accumulated neutrophils were counted in liver tissue. We observed significantly fewer neutrophils in MMP-9(-/-) mice ( $3.3 \pm 0.4$ ) than in WT ( $7.6 \pm 1.3$ ) and TIMP-1(-/-) mice ( $6.1 \pm 1.0$ ; each value per 40 high-power field; WT *vs* MMP-9(-/-),  $P < 0.01$ ; MMP-9(-/-) *vs* TIMP-1(-/-),  $P < 0.05$ ) (Figure 7B-E). There were no differences in ICAM-1 expression

**Figure 5** Histological analysis between wild-type, matrix metalloproteinase-9(-/-), and tissue inhibitor of metalloproteinase-1(-/-) mice 6 h after 80%-partial hepatectomy were performed. Representative images of the remnant liver (RL) 6 h after 80%-PH in wild-type (WT) (A), matrix metalloproteinase-9 (MMP-9)(-/-) (B), and tissue inhibitor of metalloproteinase-1 (TIMP-1)(-/-) mice (C) are shown. Samples that included necrosis were selected for this figure. The percentage (D) and the number of necrotic foci per mm<sup>2</sup> (E) of the necrotic area in the RL are shown. We observed significantly smaller and less necrotic foci in MMP-9(-/-) mice compared with WT and TIMP-1(-/-) mice (<sup>a</sup>*P* < 0.05, <sup>b</sup>*P* < 0.01 vs WT and TIMP-1).

**Figure 6** Matrix metalloproteinase-9 activity in the remnant liver with wild-type, matrix metalloproteinase-9(-/-), and tissue inhibitor of metalloproteinase-1(-/-) mice 6 h after 80%-partial hepatectomy is shown. A: Western blotting analysis for matrix metalloproteinase-9 (MMP-9) and glyceraldehyde 3-phosphate dehydrogenase (GAPDH) for a loading control was performed. The expression of MMP-9 in wild-type (WT) and tissue inhibitor of metalloproteinase-1 (TIMP-1)(-/-) mice and deletion in MMP-9(-/-) mice were observed at the protein level; B: Gelatin zymography analysis is shown; C-E: Pro-form MMP-9 activity and a slightly active form of MMP-9 were detected in WT and TIMP-1(-/-) mice. The activity of MMP-2 was the same depending on its genotype. *In situ* gelatin zymography analysis using DQ gelatin for gelatinolytic activity in the liver tissue is shown. A reduction in gelatinolytic activity in MMP-9(-/-) mice and enhancement in TIMP-1(-/-) mice are observed.

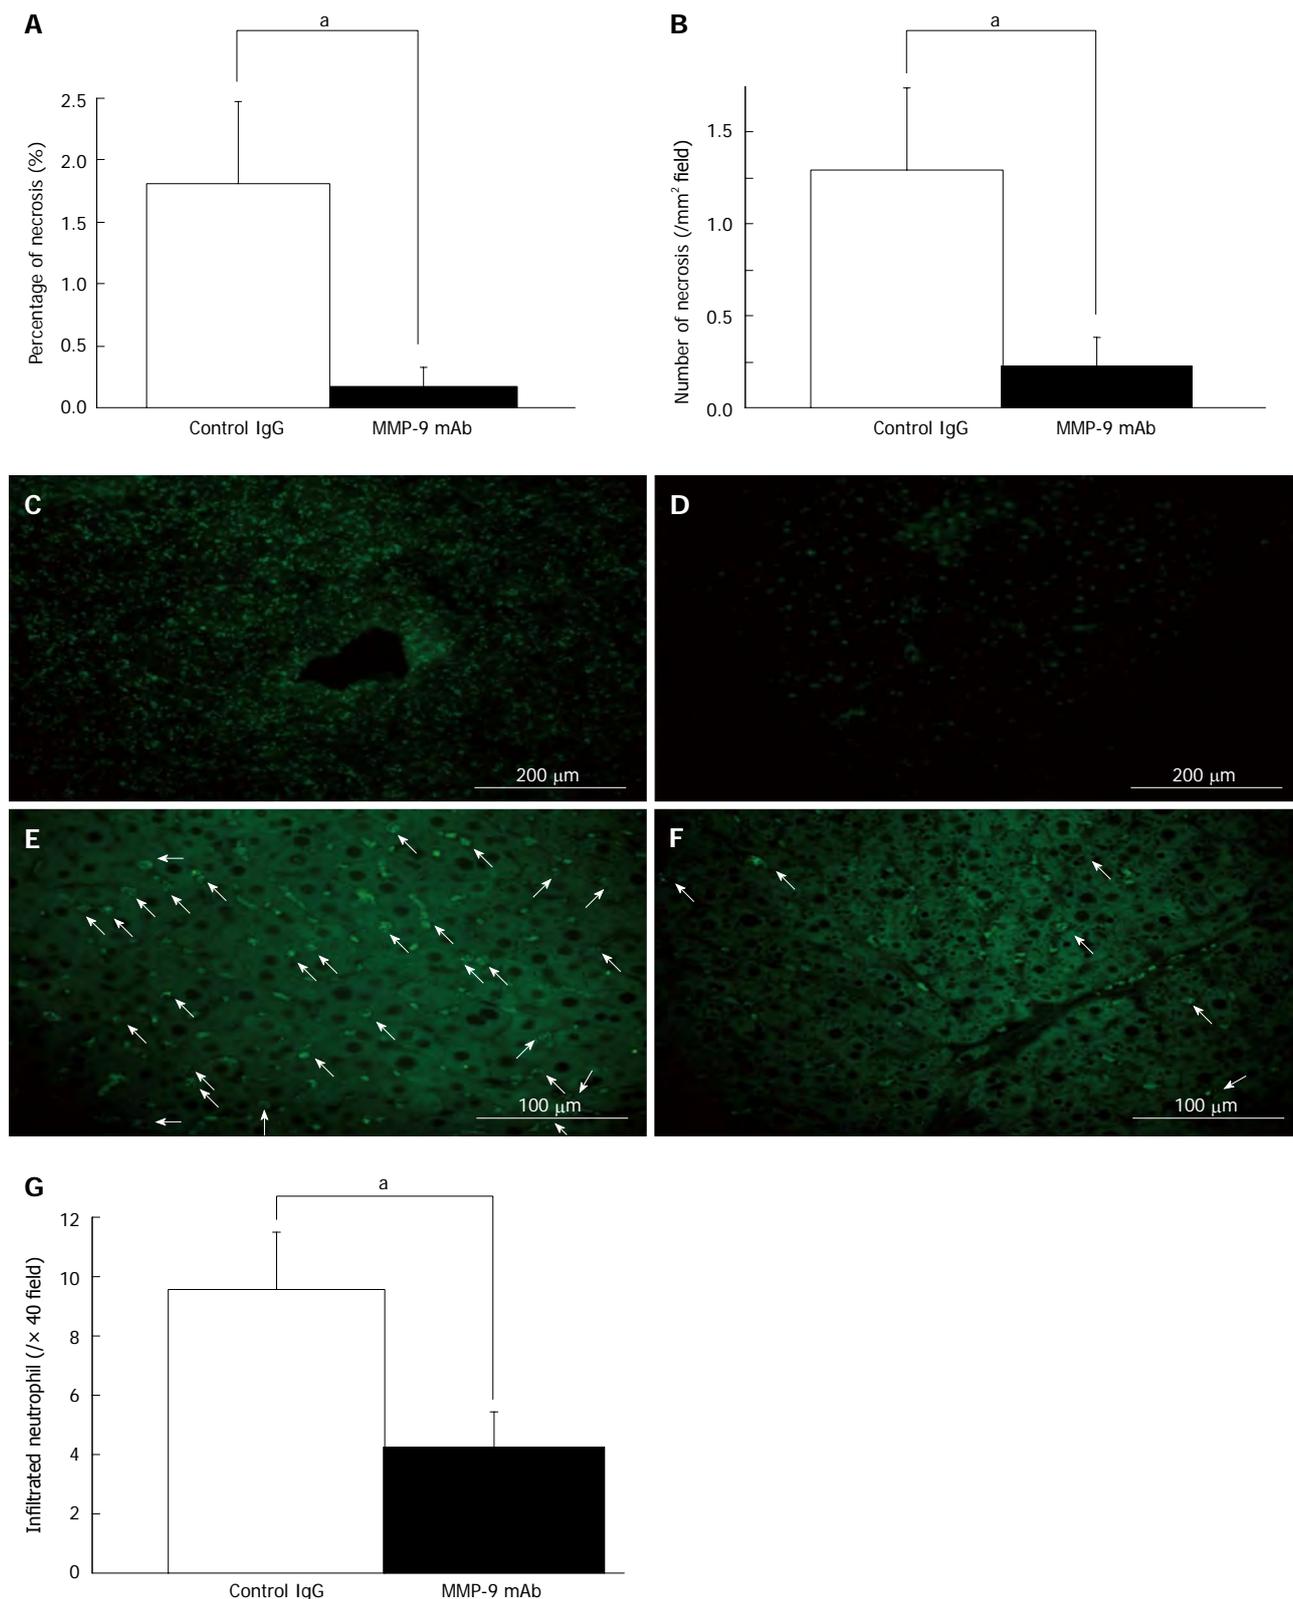

**Figure 7** Immunohistochemistry analysis for accumulated neutrophils with myeloperoxidase staining between wild-type, matrix metalloproteinase-9(-/-) and tissue inhibitor of metalloproteinase-1(-/-) mice 6 h after 80%-partial hepatectomy was performed. Myeloperoxidase (MPO) staining labeled in green (Alexa Fluor 488) is shown (A). Cytoplasmic azurophilic granules were characteristically stained in neutrophils. Representative images of MPO staining on a remnant liver (RL) section in green in wild-type (WT) (B), matrix metalloproteinase-9 (MMP-9)(-/-) (C), tissue inhibitor of metalloproteinase-1 (TIMP-1)(-/-) mice (D) are shown. A histogram of the number of accumulated neutrophils in the liver is shown. We observed significantly fewer neutrophils in the RL in MMP-9(-/-) mice than in WT and TIMP-1(-/-) mice (<sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs WT and TIMP-1(-/-) (E).

among WT, MMP-9(-/-) and TIMP-1(-/-) mice in Western blotting and IHC analysis (data not shown). These results suggested that MMP-9 deletion was associated with a decrease in migrated neutrophils in the liver, which was related to an amelioration of the initial injury in the RL after EH, and probably an infiltrating process seemed to be influenced. Therefore, MMP-9 might play a supportive role for infiltration of neutrophils into the RL at the early phase after EH.

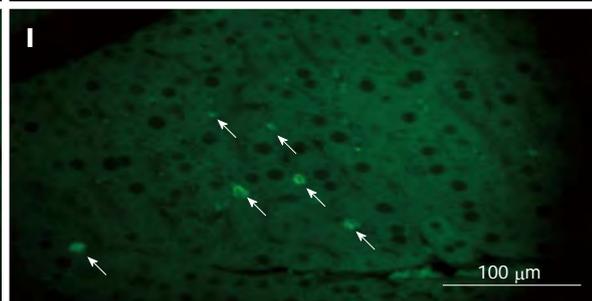

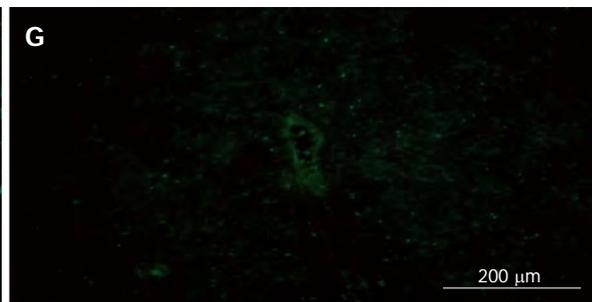

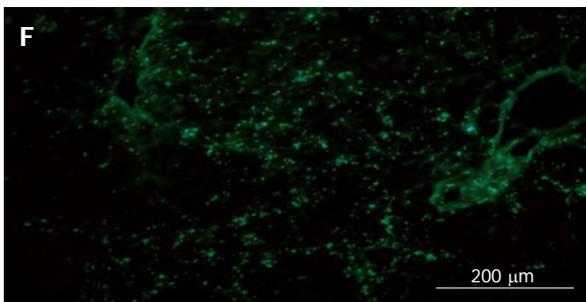

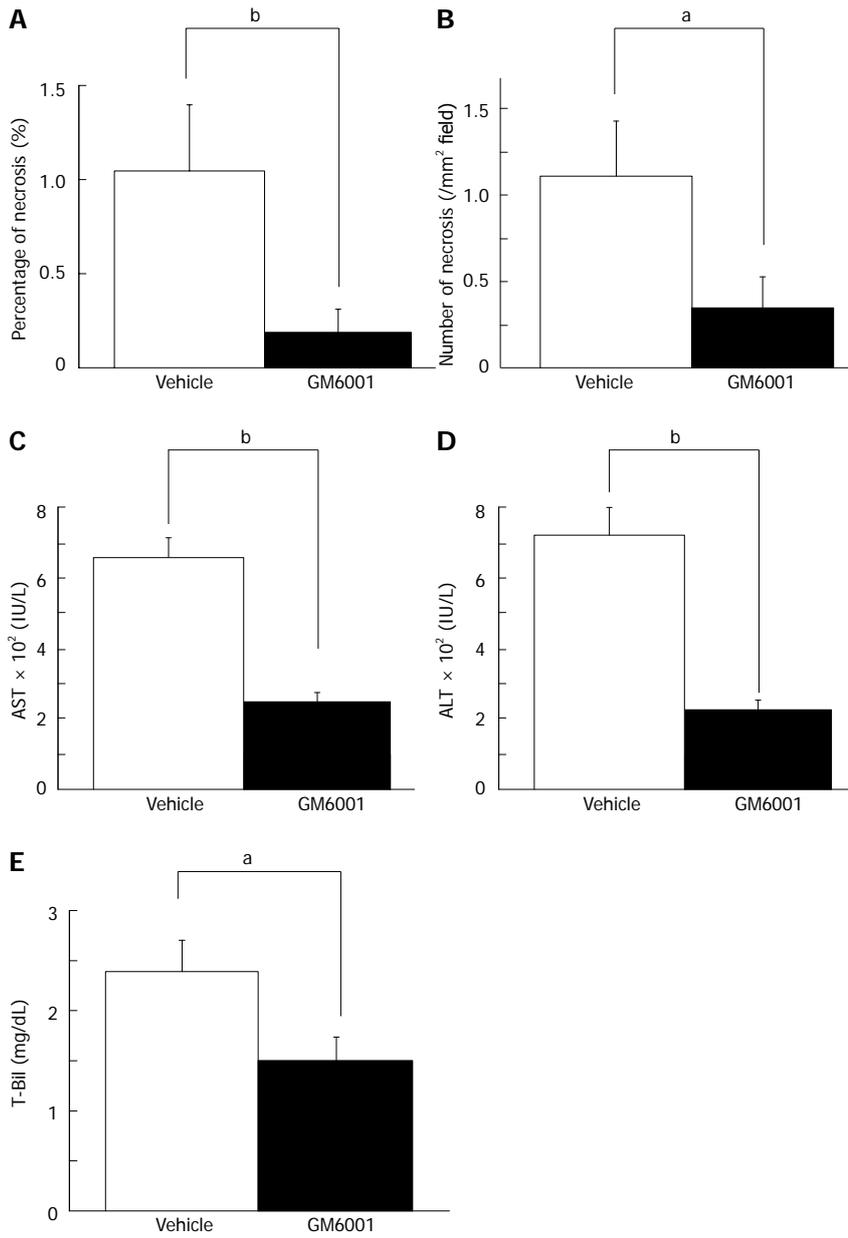

**Inhibition of MMP-9 by a monoclonal antibody of MMP-9 and the broad-spectrum MMP inhibitor GM6001 ameliorate initial injury of the liver 6 h after 80%-PH**

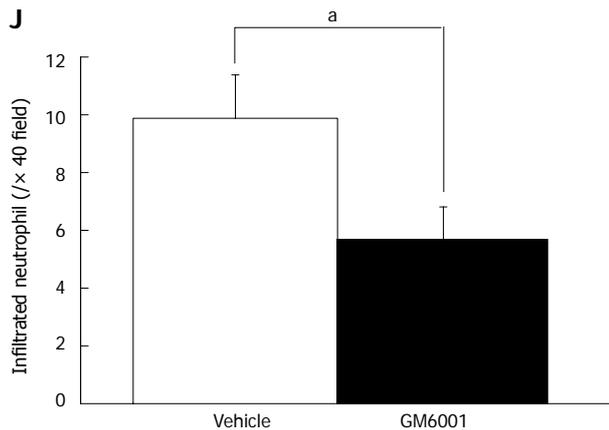

Investigation of inhibition of MMP-9 *in vivo* was performed by two different methods using a blocking

monoclonal antibody and a broad-spectrum MMP inhibitor (GM6001). Each treatment clearly improved survival curves after 80%-PH ( $P < 0.01$ ). In the RL, there were significantly smaller and fewer necrotic lesions in the monoclonal antibody-injected mice (mAb group) than in the control IgG-injected mice (control IgG group) (area:  $0.17\% \pm 0.15\%$  vs  $1.81\% \pm 0.66\%$ ,  $P < 0.05$ , Figure 8A; number of foci:  $0.23 \pm 0.16/\text{mm}^2$  vs  $1.23 \pm 0.44/\text{mm}^2$ ,  $P < 0.05$ , Figure 8B). Serum levels of AST, ALT and T-Bil were lower in the monoclonal antibody-injected mice than those in the control IgG-injected mice, but this not statistically significant ( $P \geq 0.05$ ). We confirmed suppression of gelatinolytic activity in the mAb group by *in situ* gelatin zymography compared with that in the control IgG group (Figure 8C and D). There were significantly

**Figure 8** Inhibition of matrix metalloproteinase-9 by a monoclonal antibody of matrix metalloproteinase-9. We investigated the outcome of inhibition of matrix metalloproteinase-9 (MMP-9) by monoclonal antibody (mAb) in 80%-partial hepatectomy (PH) in mice, and performed histological analysis of liver necrosis 6 h after 80%-PH (A, B). Liver damage was significantly reduced in the group with mAb compared with that in the control IgG group. Serum levels of aspartate aminotransferase, alanine aminotransferase and total bilirubin were lower in the mAb-treated mice, but this was not significant. Representative images of *in situ* gelatin zymography analysis with DQ gelatin revealed that gelatinolytic activity was suppressed in the mAb-treated mice (D) compared with that in control IgG-treated mice (C). Representative images of myeloperoxidase staining on remnant liver (RL) sections in control IgG-treated mice (E) and mAb-treated mice (F) are shown. A histogram of the number of accumulated neutrophils in the RL 6 h after 80%-PH shows that there are significantly fewer neutrophils in mAb-treated mice than in IgG-treated controls (G) ( $^*P < 0.05$  vs IgG group).

**Figure 9** Broad-spectrum matrix metalloproteinase-9 inhibitor GM6001 ameliorate initial injury of the liver 6 h after 80%-partial hepatectomy. We inhibited matrix metalloproteinase-9 by GM6001 in 80%-partial hepatectomy (PH) mice, and determined liver necrosis 6 h after 80%-PH. Liver damage was significantly reduced in the GM6001-treated mice compared with that in the vehicle-treated group (A, B). Serum levels of aspartate aminotransferase (AST) (C), alanine aminotransferase (ALT) (D) and total bilirubin (T-Bil) (E) were significantly lower in the GM6001-treated mice than those in the vehicle-treated mice. Representative images of *in situ* gelatin zymography analysis with DQ gelatin are shown. Gelatinolytic activity was suppressed in the GM6001-treated mice (G) compared with that in the vehicle-treated mice (F). Representative images of myeloperoxidase staining on remnant liver (RL) sections in vehicle-treated mice (H) and GM6001-treated mice (I) are shown. A histogram of the number of accumulated neutrophils in the RL after extended hepatectomy shows that there are significantly fewer neutrophils in the GM6001-treated mice than in the vehicle-treated mice (J) (<sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs vehicle-treated mice).

fewer accumulated neutrophils in the mAb group than in the control IgG group (mAb:  $4.2 \pm 1.2$  vs control IgG:  $9.6 \pm 1.9$ , each per 40 high-power field,  $P < 0.05$ ) (Figure 8E-G).

Similarly, the inhibition study by GM6001 showed a significant suppression in the area of liver necrosis ( $1.04\% \pm 0.36\%$  vs  $0.19\% \pm 0.13\%$ ,  $P < 0.01$ , Figure 9A) and the number of foci compared with the vehicle group ( $1.12 \pm 0.31/\text{mm}^2$  vs  $0.35 \pm 0.19/\text{mm}^2$ ,  $P < 0.05$ , Figure 9B). The levels of AST ( $660 \pm 66$  IU/L vs  $243 \pm 28$  IU/L,  $P < 0.01$ , Figure 9C), ALT ( $702 \pm 88$  IU/L vs  $212 \pm 33$  IU/L,  $P < 0.01$ , Figure 9D) and T-Bil ( $1.49 \pm 0.25$  mg/dL vs  $2.39 \pm 0.30$  mg/dL,  $P < 0.05$ , Figure 9E) were significantly lower in the GM6001 group than those in the vehicle group. *In situ* gelatin zymography analysis indicated inhibition of gelatinolytic activity in the GM6001 group (Figure 9F-I). Additionally, the accumulation of neutrophils was significantly suppressed in the GM6001 group compared with the vehicle group ( $9.9 \pm 1.5$  per 40 high-power field vs  $5.7 \pm 1.1$  per 40 high-power field,  $P < 0.05$ ) (Figure 9J). These results suggested that therapy with exogenous MMP-9 inhibition has the potential to reduce the initial injury of RL after EH.

## DISCUSSION

The mechanism of PLF is not fully understood, because of the involvement of various clinical perioperative factors, such as pre-existing liver disease, infection, transfusion, and insufficient volume of the RL. Murine and rat models have been used to determine the mechanisms for many years. Jin *et al*<sup>[15]</sup> showed necrosis of hepatocytes by oxidative injury after 87%-PH in mice. Catardegirmen *et al*<sup>[22]</sup> reported that blockage of the receptor for advanced glycation end products (RAGE) improves survival after 85%-PH and preserves liver parenchyma

with the absence of necrosis in 85%-PH. Yoshida *et al*<sup>[23]</sup> reported the efficiency of a caspase inhibitor for survival after 95%-PH in rats by attenuating apoptosis of hepatocytes. Both necrosis and apoptosis pathways appear to be involved in PLF process after EH. We previously performed marginal hepatectomy to evaluate the difference between predictive liver failure and normal recovery at the early phase. Use of hemoclips and a surgical microscope enabled us to complete the surgical procedure within 10 min and to stabilize the outcomes after surgery in our model<sup>[12]</sup>. In this previous study, a quick procedure appeared to reduce the opportunity for an infection or any complications<sup>[12]</sup>. In our preliminary study, histological changes from 80%-PH<sup>[12]</sup> were slightly improved compared with a conventional model by Higgins *et al*<sup>[24]</sup>. Our marginal PH model could be helpful for evaluation of the direct effects of insufficient volume of the RL after EH, from the viewpoint of the deletions of irrelevant factors.

With regard to the mechanism of liver failure, only a few studies have focused on the initial changes in the RL after EH. Panis *et al*<sup>[16]</sup> reported the presence of centrilobular necrosis, which varied in the severity in different areas of sections as well as a fatty change and microvascular steatosis 24 h after 85%-PH in the rat. Jin *et al*<sup>[15]</sup> reported severe sinusoidal narrowing as early as 6 h, and swelling, fatty degeneration and nuclear condensation of hepatocytes by 48 h after 87%-PH in asymptomatic mice<sup>[15]</sup>. In small-for-size grafts used in transplantation, a vacuolar cytoplasm or considerable mitochondrial swelling in hepatocytes, irregular large gaps between sinusoidal lining cells and collapse of the space of Disse have been observed<sup>[25]</sup>. Our study clearly showed multiple necroses with intrahepatic-hemorrhage in the RL, and biochemical results also revealed PLF at the early phase after 80%-PH in symptomatic mice. In-

terestingly, these histological changes were similar to the findings of a lipopolysaccharide/galactosamine-induced acute liver failure model<sup>[26]</sup>. Initial extravasation of red blood cells, sinusoidal congestion, destruction of parenchymal architecture and subsequent total destruction of micro-architecture with hemorrhage were reported 4 to 8 h after a challenge of galactosamine and lipopolysaccharide<sup>[26]</sup>. We also observed dehiscence of sinusoids 6 h after 80%-PH. The mechanism of sinusoidal cell injury is not fully understood. Many efforts after PH, such as hyperperfusion and shear stress due to portal hypertension, appear to have the potential to physically damage sinusoidal endothelial cells (SECs), and intensive decompression of the portal vein has recently been proposed as an intra-operative strategy for liver transplantation with small-for-size grafts<sup>[27]</sup>. We observed distention of the portal vein during 80%-PH. An increase in portal flow indicates an increased exposure of bacterial products or toxic agents from the gut for an insufficient RL after EH, and this condition may affect SECs. The development of SEC injury followed by parenchymal cell injury is considered as an important mechanism in monocrotaline-induced veno-occlusive disease or acetaminophen hepatotoxicity<sup>[28-30]</sup>, because SEC injury leads to hepatic microcirculatory dysfunction and hemorrhage<sup>[28,29]</sup>. SEC gap formation after treatment with galactosamine/endotoxin in mice has been reported to affect neutrophil extravasation and hemorrhage of liver parenchyma, and activated MMP is involved in SEC gap formation<sup>[31]</sup>. MMPs have been shown to be involved in several liver injury mechanisms including the fulminant liver failure model<sup>[32]</sup>, sinusoidal obstruction syndrome model<sup>[33]</sup> and hepatic ischemia/reperfusion injury model<sup>[20]</sup>. Olle *et al.*<sup>[34]</sup> have reported the importance of MMP-9 associated with tumor necrosis factor, hepatocyte growth factor, vascular endothelial growth factor and the apoptosis pathway for liver regeneration. Mohammed *et al.*<sup>[35]</sup> showed that TIMP-1 affects the hepatocyte cell cycle in the liver regeneration process. These findings indicate MMPs' negative and positive potential in liver disease. A RL with considerable damage requires emergent regeneration for survival after EH. The role of MMPs appears to be more complex.

We demonstrated that MMP-9 expression was enhanced in the damaged liver associated with necrosis, and the main source of MMP-9 was CD11b-positive nonnative leukocytes and hepatic stellate cells 6 h after 80%-PH. Our results appear to be consistent with the ischemia/reperfusion injury model and acute liver failure model<sup>[26]</sup>. Kim *et al.*<sup>[36]</sup> showed initial MMP-9 expression at 3 h in only periportal hepatocytes after 70%-PH in the rat, and positive staining gradually spread for up to 48 h. In our 80%-PH model, there was little expression of MMP-9 in hepatocytes 6 h after surgery, and our results suggested that a severe situation after 80%-PH impairs the regular process for normal regeneration observed after 70%-PH<sup>[13,36]</sup>. Yan *et al.*<sup>[26]</sup> showed bimodal alteration of MMP-9 mRNA in the acute liver failure model. We observed a change in bimodal activity (the second peak

was after 12 h) by zymography after 80%-PH (data not shown). Taken together, these results suggest that there are two different modalities for MMP-9 production. Although we previously reported that MMP-9 plays an important role in the development of parenchymal hemorrhage and necrosis in the small remnant liver after massive hepatectomy and that successful MMP-9 inhibition attenuates the formation of hemorrhage and necrosis and might be a potential therapy to ameliorate liver injury<sup>[11]</sup>, the origin of MMP-9 production was unclear. We speculate that it is necessary to separately consider the roles of MMP-9 produced from leukocytes at the early phase and from hepatocytes at the late phase of EH.

In the current study, we focused on the initial MMP-9 expression and hypothesized that it plays a role in liver injury in the RL after EH. To examine the involvement of MMP-9 in initial liver injury after EH, we evaluated the effect of inhibition of MMP-9 using three different methods *in vivo* including MMP-9-deficient mice, an inhibitory monoclonal antibody and a broad spectrum inhibitor. In all of the MMP-9 inhibitory experiments, suppression of the initial injury was clearly observed with the inhibition of MMP-9. Our results suggested that MMP-9 plays a pivotal role in liver injury, especially in the formation of necrosis, likely sinusoidal injury after 80%-PH. Perioperative factors in each experiment were not different between each experimental group such as the resected volume, the surgical time and intra-operative blood loss. In the experiments with genetic deficient mice, we examined whether TIMP-1 deficiency had any effects on the theoretical enhancement of MMP-9 activity on liver injury simultaneously. We observed the reverse effects in TIMP-1 deficient mice compared with MMP-9-deficient mice with an increased gelatinolytic activity. No exacerbation of liver injury in the TIMP-1-deleted condition suggested insufficiency of TIMP-1 to regulate MMP-9 activity after EH. Mohammed *et al.*<sup>[35]</sup> showed that TIMP-1 was slightly increased 6 to 18 h after 70%-PH in the rat. We did not assess TIMP-1 expression in the current study. However, it is possible that TIMP-1 could be used as a therapeutic target to reduce MMP-9 levels related to liver injury.

In the current study, we did not observe any survival benefits of MMP-9 inhibition in MMP-9(-/-) mice, although the other two methods of inhibition of MMP-9 showed improvement of survival. MMP-9 was shown to be important in liver regeneration in PH by Olle *et al.*<sup>[34]</sup>. Additionally, the possibility of impairment of the host defense by MMP-9 deficiency was reported in a sepsis model by Renckens *et al.*<sup>[37]</sup>. Excessive MMP-9 activity induced by shear stress after PH may have the potential to induce initial liver injury. Application of MMP-9 blockade should be precisely controlled.

In this study, we evaluated the accumulation of neutrophils in the RL after 80%-PH. Areas of necrosis were correlated with the number of accumulated neutrophils. The infiltration of polymorphonuclear neutrophils (PMNs) has been reported in several liver diseases<sup>[38-41]</sup> and even after EH<sup>[42]</sup>. We could not identify infiltrated

neutrophils as a central effector on liver injury after 80%-PH, but a possible explanation may be provided by an association between neutrophils and SEC destruction. In addition, recent studies have shown that MMP-9 derived from neutrophils affects several pathophysiological conditions such as blood brain barrier breakdown after an ischemic stroke and gut barrier dysfunction in an acute pancreatitis model<sup>[43,44]</sup>. Keck *et al.*<sup>[45]</sup> showed that PMN-derived MMP-9 contributes to the accumulation of PMNs in the inflammation site and it initiates damage to the basement membrane. Although our results are consistent with the previous work described above, the mechanism of liver damage or regeneration is complicated. Periportal infiltration of inflammatory cells will increase the liver damage, but this infiltration is paradoxically necessary to trigger the liver regeneration<sup>[46-48]</sup>. Though the balance of damage and regeneration is still unclear, we speculated that the MMP-9 produced from neutrophil may be important factor for a successful liver regeneration after EH. Further study is needed to elucidate the involvement of MMP-9 associated with neutrophils in liver injury after EH with an insufficient RL.

In summary, our data showed that the pathway of liver necrosis related to initial sinusoidal endothelial cell injury is responsible for the PLF process after EH with an insufficient RL. The initial injury is associated with MMP-9 derived from neutrophils, and blockade of MMP-9 reduces initial liver injury in an *in vivo* model. Our results suggest that MMP-9 may be a potential target for preventive care or further challenging for EH.

## ACKNOWLEDGMENTS

We are grateful to Dennis W Dickson, Monica Castanedes-Casey, Virginia R Phillips, Linda G Rousseau and Melissa E Murray (Department of Neuroscience, Mayo Clinic in Florida, Jacksonville, FL 32224, United States) for their technical support with histopathological assessment.

## COMMENTS

### Background

Postoperative liver failure (PLF) after extended hepatectomy (EH) can cause an insufficient volume of the remnant liver (RL), resulting in higher morbidity and mortality.

### Research frontiers

The mechanism of liver damage or regeneration is complicated. Periportal infiltration of inflammatory cells will increase the liver damage, but this infiltration is paradoxically necessary to trigger the liver regeneration. This PLF is progressive from the early postoperative period, but the mechanism is unknown. Authors hypothesized that matrix metalloproteinase (MMP)-9 plays a role in PLF pathogenesis.

### Innovations and breakthroughs

Though the balance of damage and regeneration is still unclear in the RL after EH, the MMP-9 produced from neutrophil may be important factor for a successful liver regeneration after EH.

### Applications

Their data showed that the pathway of liver necrosis related to initial sinusoidal endothelial cell injury is responsible for the PLF process after EH. The initial injury is associated with MMP-9 derived from neutrophils, and blockade of

MMP-9 reduces initial liver injury.

### Terminology

Their results suggest that MMP-9 may be a potential target for preventive care or further challenging for EH.

### Peer review

In this manuscript, authors attempt to investigate that the effect of MMP9 in the initial injury after hepatectomy in mice. The work is of potential interest to the readership of the *World Journal of Gastroenterology*.

### Abstract

**AIM:** To evaluate the association between *Helicobacter pylori* (*H. pylori*) infection and *MLH1* and *MGMT* methylation and its relationship with microsatellite instability (MSI).

**METHODS:** The methylation status of the *MLH1* and

*MGMT* promoter region was analysed by methylation specific methylation-polymerase chain reaction (MSP-PCR) in gastric biopsy samples from uninfected or *H. pylori*-infected children ( $n = 50$ ), from adults with chronic gastritis ( $n = 97$ ) and from adults with gastric cancer ( $n = 92$ ). *MLH1* and *MGMT* mRNA expression were measured by real-time PCR and normalised to a constitutive gene ( $\beta$  actin). MSI analysis was performed by screening MSI markers at 4 loci (Bat-25, Bat-26, D17S250 and D2S123) with PCR; PCR products were analysed by single strand conformation polymorphism followed by silver staining. Statistical analyses were performed with either the  $\chi^2$  test with Yates continuity correction or Fisher's exact test, and statistical significance for expression analysis was assessed using an unpaired Student's *t*-test.

**RESULTS:** Methylation was not detected in the promoter regions of *MLH1* and *MGMT* in gastric biopsy samples from children, regardless of *H. pylori* infection status. The *MGMT* promoter was methylated in 51% of chronic gastritis adult patients and was associated with *H. pylori* infection ( $P < 0.05$ ); this region was methylated in 66% of gastric cancer patients, and the difference in the percentage of methylated samples between these patients and those from *H. pylori*-infected chronic gastritis patients was statistically significant ( $P < 0.05$ ). *MLH1* methylation frequencies among *H. pylori*-infected and non-infected chronic gastritis adult patients were 13% and 7%, respectively. We observed methylation of the *MLH1* promoter (39%) and increased MSI levels (68%) in samples from gastric cancer patients in comparison to samples from *H. pylori*-infected adult chronic gastritis patients ( $P < 0.001$  and  $P < 0.01$ , respectively). The frequency of promoter methylation for both genes was higher in gastric cancer samples than in *H. pylori*-positive chronic gastritis samples ( $P < 0.05$ ). The levels of *MLH1* and *MGMT* mRNA were significantly reduced in chronic gastritis samples that were also hypermethylated ( $P < 0.01$ ).

**CONCLUSION:** In summary, *MGMT* and *MLH1* methylation did not occur in earlier-stage *H. pylori* infections and thus might depend on the duration of infection.

**Key words:** *Helicobacter pylori*; Microsatellite instability; Promoter methylation; *MLH1*; *MGMT*; Gastric cancer

**Core tip:** Gastric carcinogenesis is a multistep process that is triggered by *Helicobacter pylori* (*H. pylori*) infection and characterised by multiple genetic and epigenetic alterations, including the DNA repair genes. To date, few advances have been made to determine the time duration required for to *H. pylori* infection to induce such epigenetics alteration and thus potentially induce gastric carcinogenesis. The results presented in this study indicate that the methylation of the *MGMT* and *MLH1* promoter regions might depend on the duration of infection because these methylation events were not observed in children.

## INTRODUCTION

*Helicobacter pylori* (*H. pylori*) is an important pathogen in the human stomach. The natural acquisition of *H. pylori* infection occurs mainly during childhood. Once established within the gastric mucosa, the infection persists for life if left untreated. The epidemiological evidence and the rare occurrence of peptic ulcers or gastric atrophy in children<sup>[1,2]</sup> suggest that *H. pylori*-related gastric mucosal damage might be progressive through childhood into adulthood. *H. pylori* infection elicits a host inflammatory response, including mucosal infiltration by polymorphonuclear leukocytes, macrophages, and T and B lymphocytes. The inflammatory response has a slow onset and becomes chronic after a long period of infection. Although the symptoms of chronic infection are not as severe as those of acute inflammation, the condition is persistent<sup>[3]</sup>. The activated inflammatory cells release reactive oxygen and nitrogen species that can induce DNA injury and cellular apoptosis<sup>[4]</sup>. The chronic colonisation of the stomach with *H. pylori* causes inflammation within the gastric mucosa and activates multiple oncogenic pathways<sup>[5]</sup>.

The interaction of *H. pylori* with the surface mucosa results in the increased release of pro-inflammatory cytokines<sup>[6]</sup> that exacerbate the inflammatory response. The persistence of this immune response leads to chronic inflammation, one of the factors associated with DNA

methylation. DNA methylation is one of the most important epigenetic modifications and primarily occurs on the cytosine residues of CpG dinucleotides, which are frequently clustered into CpG islands within the promoter regions of certain genes<sup>[7]</sup>. DNA methylation of these promoter regions inhibits transcription through chromatin structural changes that are mediated by the interactions of the methyl-cytosines with the protein complexes that recruit histone-modifying enzymes<sup>[8,9]</sup>.

Globally, gastric cancer is the fourth most common type of cancer and the second leading cause of cancer death, and 930000 new cases of gastric cancer are projected per year. South Korea, Japan and Eastern Asia have the highest incidences of gastric cancer, followed by Eastern Europe and Latin America<sup>[10]</sup>. Since the discovery of *H. pylori* by Warren *et al* in 1982<sup>[11]</sup>, many studies have demonstrated a strong association between *H. pylori* infection and the development of gastric cancer<sup>[12,13]</sup>. Moreover, in 1994, the International Agency for Research on Cancer recognised *H. pylori* as a definitive carcinogenic agent based on several epidemiological reports<sup>[14]</sup>. The primary mechanism by which *H. pylori* induces gastric cancer is thought to include the upregulation of several genes, including cytokines, oncogenes and growth factors, as well as the downregulation of tumour suppressor genes. These alterations in gene expression are believed to result from mutations and microsatellite instability<sup>[15]</sup>. Additionally, several studies have demonstrated a close association between *H. pylori* infection and aberrant CpG island methylation<sup>[16-18]</sup>.

Many critical genes are silenced by DNA methylation during cancer development. Recent studies have shown that the silencing of certain DNA repair genes by DNA methylation might be related to the occurrence of tumorigenic mutations. The expression levels of *MLH1*, a mismatch repair gene, are frequently altered in gastric cancers, and changes in *MLH1* expression can promote tumour development<sup>[19]</sup>. Additionally, O<sup>6</sup>-methylguanine DNA methyltransferase (*MGMT*) is a protein required for the repair of alkylated guanines in DNA that arise from exposures to environmental alkylation mutagens or through endogenous mechanisms. It has been reported that the loss of *MGMT* expression might increase the occurrence of genetic mutations and thus lead to gastric cancer development<sup>[20]</sup>. Additionally, Kitajima *et al*<sup>[21]</sup> reported that the loss of *MGMT* along with mismatch repair (MMR) proteins in gastric cancer patients is an important event in tumour progression.

Microsatellite instability (MSI) is one hallmark of DNA MMR deficiency that is observed in gastric carcinogenesis. Microsatellites are short DNA sequence repeats that are scattered throughout the human genome. Errors in the DNA MMR mechanisms of tumour cells can result in the expansion or contraction of these repeated sequences and thus MSI<sup>[22]</sup>. MSI occurs in nearly every case of gastric cancer that is associated with germline mutations of the MMR genes.

The inactivation of the MMR genes *MSH2* and

*MLH1*, either through a mutation or an epigenetic mechanism, is responsible for the development of MSI in gastric cancer. The aberrant loss of expression of either the *MLH1* or *MSH2* proteins has been observed in patients exhibiting gastric cancer with MSI. In particular, altered *MLH1* expression is associated with self-gene inactivation through the hypermethylation of its promoter regions<sup>[23,24]</sup>.

It is well established that *H. pylori* infection leads to chronic inflammation in the gastric mucosa, which is a condition associated with DNA methylation. Because such epigenetic alterations play an important role in the regulation of gene expression and the maintenance of DNA integrity and stability, the aim of this study was to analyse the effects of *H. pylori* infection on the methylation statuses of *MLH1* and *MGMT* and the relationship between the methylation of these promoters and microsatellite instability in *H. pylori*-infected or uninfected children as well as infected or uninfected adults with chronic gastritis or gastric cancer.

## MATERIALS AND METHODS

### Patients

This study was approved by the following institutions: the Ethical Committee of the Paulista Medical School, State University (UNESP), Botucatu, SP, Brazil; the Sao Francisco University, Braganca Paulista, SP, Brazil; the School of Medicine of the São Paulo University, SP, Brazil; and by the National Committee of Ethics in Research, Brasília, DF, Brazil. Informed consent to participate in the study was obtained from all patients.

This study included 239 patients, of which 50 were children between the ages of 2 and 18 years old (average age =  $8 \pm 4$  years; 47% male, 53% female) who suffered from dyspepsia. Of the remaining patients, 97 suffered from chronic gastritis (average age =  $35 \pm 13$  years; 33% male, 67% female), and 92 suffered from gastric cancer (average age =  $60 \pm 12$  years; 82% male, 18% female). All of the patients were non-smokers, did not abuse alcohol and were not using prescription or recreational drugs.

### Biopsy collection

Biopsies from patients with gastric complaints were obtained from the lesser curvature of the antrum (the distal region of the stomach) within 2 cm of the pyloric ring during endoscopies. For patients with gastric cancer, biopsies were obtained during gastric surgeries (to remove gastric carcinoma). One biopsy was used for a rapid urease test<sup>[25]</sup>, 2 were used for histopathological evaluations, and 1 was used for bacterial genotyping by polymerase chain reaction (PCR). *H. pylori* infection was considered present when positive results were obtained from all of the following tests: rapid urease test, histological analysis and gastric biopsy PCR. The patients were considered uninfected when negative results were obtained for all tests.

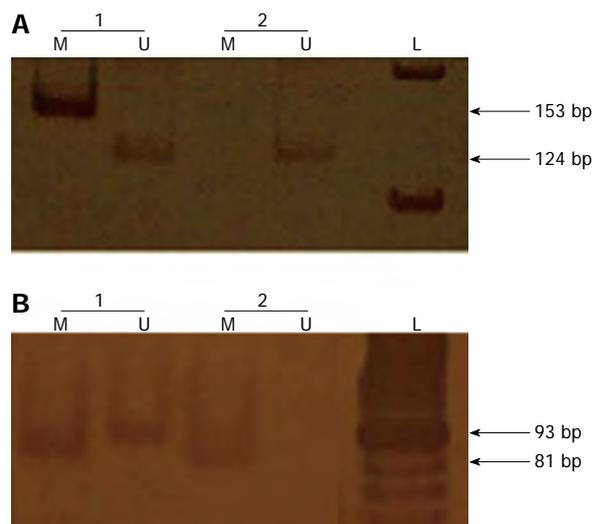

Figure 1 Example of the results from methylation-specific polymerase chain reaction analysis. A: *MLH1*; B: *MGMT*. Lane U: Amplified product with primers for unmethylated sequences; Lane M: Amplified product with primers for methylated sequences; L: Ladder.

### Histopathology

Gastric mucosal samples were fixed in 10% formalin for 24 h, dehydrated in alcohol and xylene, and embedded in paraffin. Sequential 3-5- $\mu$ m sections were cut and stained with haematoxylin-eosin for routine histology. Gastritis was classified according to Sydney's system<sup>[26]</sup>, and the presence of *H. pylori* was determined by carbolfuchsin staining of the sections.

### Bisulphite treatment and methylation-specific PCR

Bisulphite treatment was performed on 1  $\mu$ g of DNA with the EpiTect Bisulfite kit (Qiagen, Valencia, CA, United States). Methylation-specific PCR (MSP-PCR) was performed with a primer set specific to the methylated or unmethylated sequences (M or U sets, respectively)<sup>[27]</sup>. The PCR reactions were performed in a final volume of 25  $\mu$ L with approximately 200 ng of sodium bisulphite-treated DNA and 25 pmol of each primer. The PCR amplifications were performed for 40 cycles that each consisted of a denaturation step at 95  $^{\circ}$ C for 5 min, a primer-annealing step at 58  $^{\circ}$ C for 35 s and an extension step at 72  $^{\circ}$ C for 40 s, with a single final extension step at 72  $^{\circ}$ C for 7 min. The reaction products were separated by electrophoresis on 8% polyacrylamide gels and visualised by silver staining (Figure 1).

### RNA extraction and real-time PCR

The gastric biopsies were collected, snap frozen, and stored at -80  $^{\circ}$ C in RNAlater<sup>®</sup> (Qiagen, Valencia, CA, United States). Total RNA was isolated with the RNeasy tissue kit<sup>®</sup> (Qiagen). The gastric cancer biopsies were microdissected prior to RNA extraction. The PixCell<sup>®</sup> IIe Laser Capture Microdissection (LCM) System (Arc-turus Engineering, Mountain View, CA, United States)

**Table 1 Primers used for real-time polymerase chain reaction**

| Gene           | Primer    | Sequence (5'-3')        |
|----------------|-----------|-------------------------|
| <i>β-actin</i> | Sense     | ACACTGGCTCGTGTGACAAGG   |
|                | Antisense | CGGCTAATACACACTCCAAGGC  |
| <i>MGMT</i>    | Sense     | CACCACACTGGACAGCCCTTT   |
|                | Antisense | CGAACTTGCCAGGAGCTTTATTT |
| <i>MLH1</i>    | Sense     | CGGTAACTACCAATGCCTCAAC  |
|                | Antisense | TTCTCGACTAACAGCATTTC    |

was used to obtain laser captures using an amplitude of 50 mW, a duration of 800 ms and a 7.5-mm beam. RNA from the capture lids (Arcturus) that contained the microdissected tissue was extracted with the PicoPure RNA isolation kit (Arcturus). Single-stranded cDNA was synthesised from the RNA using the high capacity cDNA archive kit<sup>®</sup> (Applied Biosystems, Foster City, CA, United States) according to the manufacturer's protocol.

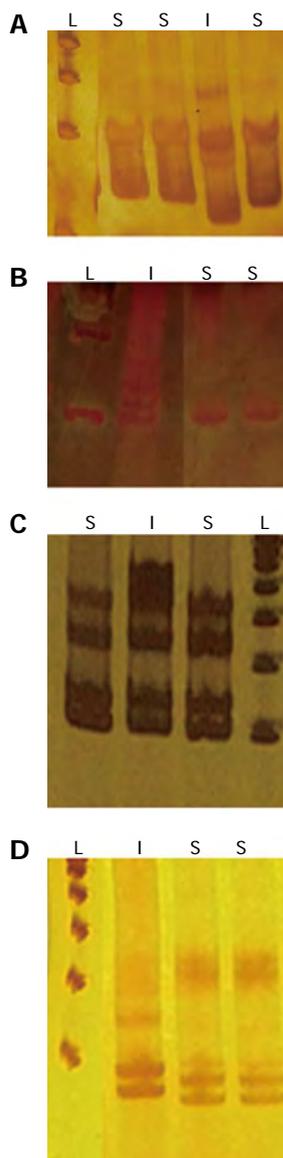

Quantitative PCR was performed on a 7300 real-time PCR system (Applied Biosystems) and the threshold cycle numbers were determined with the RQ Study software (Applied Biosystems). The reactions were run in triplicate and the threshold cycle numbers were averaged. The 50-μL reaction mixture was prepared as follows: 25 μL of Sybr Green<sup>®</sup> Quantitative PCR SuperMix-UDG (Invitrogen Life Technologies, Alameda, CA, United States), 10 mmol/L of each primer (Table 1) and 10 μL of cDNA (100 ng). The reactions were performed with a preliminary UDG treatment for 2 min at 50 °C and denaturation for 2 min at 95 °C, followed by 45 cycles of denaturation at 95 °C for 15 s, annealing at 60 °C for 15 s, and primer extension at 72 °C for 15 s. This treatment was followed by a melting-point analysis of the double-stranded amplicons that consisted of 40 cycles of 1 °C decrement (15 s each), beginning at 95 °C. The first derivative of this plot, dF/dT, is the rate of change of fluorescence in the reaction. A significant change in fluorescence occurs at the melting point of the double-stranded PCR products. A plot of dF/dT versus temperature displays these changes as distinct peaks.

*MLH1* and *MGMT* gene expression was measured and normalised to a constitutive gene (*β-actin*). The relative expression was calculated according to the formula  $2^{-(\Delta\Delta C_t)[28]}$ , and the results are expressed as the average gene expression ± SD.

**MSI analysis**

All samples were analysed for 4 markers (BAT-25, BAT-26, D17S250 and D2S123) as recommended by the American National Cancer Institute (NCI) workshop on MSI<sup>[29]</sup>.

PCR was performed in a final volume of 25 μL with approximately 200 ng of template genomic DNA and 25 pmol of each primer. PCR amplifications were performed for 35 cycles that consisted of a denaturation step at 95 °C for 30 s, a primer-annealing step at 55-58 °C for 30 s and an extension step at 72 °C for 30 min, followed by a final single extension step at 72 °C for 10 min.

**Figure 2** Example of the results from polymerase chain reaction-single strand conformation polymorphism analysis. A: BAT25; B: BAT26; C: D2S123; D: D17S250. Lane S: Stable; Lane I: Instable; L: Ladder 10 bp.

Single strand conformation polymorphism (SSCP) analysis was performed on each sample. Briefly, 12 μL of each PCR product were mixed with 12 μL of denaturing buffer (95% Formamide, 0.05% Bromophenol blue, and 0.05% xlenocianol), denatured at 95 °C for 5 min and separated by electrophoresis on a non-denaturing 7% polyacrylamide gel for 3 h at room temperature. The single strands of the PCR products were visualised as bands by silver staining.

MSI was defined as a shift in the mobility of the DNA band from either allele or by the appearance of a new band (Figure 2). The MSI status was also confirmed by direct sequencing (data not shown). High-level instability (MSI-H) was defined by the presence of more than one instability marker. Low-level instability (MSI-L) was defined as the presence of a single instability marker. Finally, if no instability markers were present, the sample

was classified as displaying microsatellite stability (MSS)<sup>[29]</sup>.

### Statistical analysis

The association between microsatellite instability and the methylation pattern was evaluated with either the  $\chi^2$  test with Yates continuity correction or Fisher's exact test. Statistical significance for expression analysis was assessed by an unpaired Student's *t*-test. A *P* value of < 0.05 was considered statistically significant.

## RESULTS

The presence of *H. pylori* infection was analysed in biopsy specimens from 50 paediatric patients and 189 adult patients who underwent endoscopies. Infections were detected in 22 of the 50 (44%) children, 83 of the 97 (86%) adults with chronic gastritis and all (100%) of the 92 adult gastric cancer patients.

Methylation was not detected in the promoter regions of *MLH1* and *MGMT* in the paediatric samples. The samples from the chronic gastritis patients showed hypermethylation in the *MHL1* gene promoter region in 11 of the 83 (13%) samples from the *H. pylori*-infected subjects and in 1 of the 14 (7%) samples from the uninfected subjects (*P* > 0.05; Table 2). Methylation of the *MHL1* promoter region was observed in the samples from 36 of the 92 (39%) gastric cancer patients. The differences observed in the percentages of methylated samples are statistically significant when the patients with gastric cancer are compared to those with chronic gastritis, regardless of *H. pylori* infection status (*P* < 0.001; *P* < 0.05, respectively; Table 2).

In patients with chronic gastritis, *MGMT* promoter region methylation was observed in the biopsies from 42 of the 83 (51%) *H. pylori*-positive patients and 3 of the 14 (21%) *H. pylori*-negative patients (Table 2); this difference was statistically significant (*P* < 0.05). In the gastric cancer patients, *MGMT* promoter region methylation

| Child <i>H. pylori</i> negative  | -                        | 0.25 ± 0.03  | -                        | 0.13 ± 0.08  |
| Child <i>H. pylori</i> positive  | -                        | 0.27 ± 0.02  | -                        | 0.12 ± 0.01  |
| Adults <i>H. pylori</i> negative | 0.35 ± 0.01 <sup>b</sup> | 0.85 ± 0.07  | 0.40 ± 0.16 <sup>b</sup> | 0.99 ± 0.21  |
| Adults <i>H. pylori</i> positive | 0.88 ± 0.10 <sup>b</sup> | 1.29 ± 0.27  | 0.79 ± 0.19 <sup>b</sup> | 1.78 ± 0.47  |
| Gastric cancer                   | 0.27 ± 0.07              | 0.25 ± 0.08  | 0.49 ± 0.10              | 0.46 ± 0.10  |

*MLH1* and *MGMT* mRNA values are expressed as the mean ± SD. <sup>b</sup>*P* < 0.01 vs unmethylated samples in the same subject category. *H. pylori*: *Helicobacter pylori*.

was observed in the biopsies from 61 of the 92 (66%) patients. The difference in the percentages of samples with *MGMT* promoter region methylation between the gastric cancer patients and the non-infected chronic gastritis patients was statistically significant (*P* < 0.01). Additionally, there was a statistically significant difference between the percentages of methylated samples from the gastric cancer patients and the *H. pylori*-infected chronic gastritis patients (*P* < 0.05). Furthermore, the frequency of promoter methylation for both genes was higher in the gastric cancer samples than in the *H. pylori*-positive chronic gastritis samples; this difference was statistically significant (*P* < 0.05).

The *MLH1* and *MGMT* gene expression levels were measured and evaluated in the context of promoter methylation. The levels of both *MLH1* and *MGMT* mRNA were significantly reduced in the methylated samples compared to the unmethylated samples in both the *H. pylori*-positive and uninfected adult chronic gastritis samples (Table 3). Overall, gastric cancer patients and paediatric patients had low levels of *MLH1* and *MGMT* mRNA expression.

Biopsy samples from children with chronic gastritis were relatively stable for the tested microsatellite markers. Only 2 samples (both *H. pylori*-negative) were scored as MSI-H, and the remaining paediatric samples were scored as MSS (stable; Table 4). MSI was present in 51 of the 83 (61%) *H. pylori*-positive chronic gastritis samples from adults. Of these, 37 (73%) samples were scored as MSI-L and 14 (27%) samples as MSI-H. MSI was observed in 9 of the 14 (64%) uninfected patients with gastritis; 6 (67%) samples were scored as MSI-L and 3 (33%) as MSI-H. MSI was observed in 63 of the 92 (68%) gastric cancer patients; 38 (60%) were scored as MSI-L and 25 (40%) as MSI-H. No significant association was found between *H. pylori* infection and MSI in the samples from chronic gastritis adult patients. However, there was a significant difference (*P* = 0.03) in the percentages of samples with MSI for between the gastric cancer patients and the *H. pylori*-infected chronic gastritis patients.

Various authors have postulated that the methyla-

MSI-H, the presence of more than one instability marker. MSI-L, the presence of a single instability marker. MSS, no instability markers were present. <sup>a</sup>*P* < 0.05 vs *Helicobacter pylori* (*H. pylori*)-positive chronic gastritis samples.

tion of the *MHL1* promoter region leads to the down-regulated expression of the *MHL1* gene, an effect that is strongly associated with MSI<sup>[23,24,30]</sup>. Therefore, we evaluated whether there was any association between the *MLH1* methylation status and MSI in our study population. The data presented in this study show a strong association between the *MLH1* methylation status and MSI in patients with gastric cancer (*P* < 0.01). However, we did not find any significant association between the *MLH1* methylation status and MSI in the samples from chronic gastritis adult patients, regardless of *H. pylori* infection status. Additionally, a multivariate analysis did not show that the *H. pylori* infection was associated with gene promoter methylation and MSI.

## DISCUSSION

Genomic DNA methylation is one of the most important epigenetic modifications in eukaryotes. DNA methylation is essential for life, and alterations of the methylation process are often associated with carcinogenesis related to chronic inflammation or persistent infections of viruses or other pathogenic microorganisms. In this setting, we evaluated the effects of *H. pylori* infection on the methylation patterns of the *MLH1* and *MGMT* promoter regions as well as the MSI statuses of paediatric and adult patients.

Children are an interesting natural model for *H. pylori* infection studies not only because they are not usually exposed to gastric mucosal irritants such as alcohol, tobacco, and anti-inflammatory medications but also because the gastric mucosal changes in children might represent an earlier stage of the inflammatory response when compared to those in adult hosts, due to the shorter duration of *H. pylori* infections in children. To our knowledge, this is the first study to evaluate the methylation patterns of DNA repair genes in paediatric samples. Our data showed an absence of the methylation in the *MLH1* and *MGMT* promoter regions and that the mRNA levels of both genes were similar in infected and uninfected children. Although our data did not indicate an effect of *H. pylori* infection on the methylation patterns of two DNA repair genes, a recent study reported an association

between *H. pylori* infection and the methylation patterns of 7 genes in paediatric samples; however, none of these genes were involved with DNA repair<sup>[31]</sup>. The methylation levels in these susceptible loci were increased in the adult samples when compared to the paediatric samples, suggesting that the altered methylation patterns might be related to the duration exposure to of *H. pylori*<sup>[31]</sup>. Accordingly, our data showed that the methylation rates were significantly higher in the samples from adults with chronic gastritis than in the samples from children with chronic gastritis.

Recently, it has been shown that prolonged bacterial infections lead to saturation of the repair capabilities of the host cells and thus to an ineffective and mutagenic DNA repair system<sup>[32]</sup>. Accordingly, it is believed that *H. pylori*-associated gastric mucosal damage might be progressive through childhood and into adulthood<sup>[1,2]</sup>. Taking this into account, our data suggest that *H. pylori* infection-mediated DNA methylation in adults may depend not only on the level of the inflammatory response but also on the persistence and duration of the infection.

Our data showed high levels of *MGMT* promoter region methylation in patients with *H. pylori*-positive chronic gastritis when compared to those with *H. pylori*-negative chronic gastritis, indicating that *MGMT* promoter methylation is significantly associated with *H. pylori* infection in chronic gastritis cases. Previous studies reported that *MGMT* CpG methylation is more frequent and extensive in *H. pylori*-infected versus uninfected patients<sup>[33]</sup>. Additionally, it has been suggested that the *MGMT* promoter methylation in *H. pylori*-infected patients is related to tumour progression<sup>[34,35]</sup>.

Our data showed no differences in *MLH1* promoter region methylation between patients with *H. pylori*-positive chronic gastritis and those with *H. pylori*-negative chronic gastritis. However, the methylation levels were higher in patients with gastric cancer than in patients with chronic gastritis. Similarly, it has been reported that *MLH1* promoter methylation occurs late in intestinal metaplasia development<sup>[36]</sup>. Taken together, our data suggest that *MLH1* methylation occurs late in the progression of gastric carcinoma and that methylation depends partly on the persistence of the *H. pylori* infection.

The data presented herein also showed that the methylation of the promoter regions significantly reduced the mRNA levels of both *MGMT* and *MLH1* in patients with chronic gastritis, regardless of *H. pylori* infection status. Conversely, no differences in mRNA levels were observed in gastric cancer samples, regardless of methylation status; this is likely consequent to other epigenetic and genetic mechanisms. Recently, it was reported that *H. pylori* infections in patients with gastritis were associated with *MGMT* hypermethylation and reduced levels of *MGMT* mRNA in the gastric epithelium<sup>[33]</sup>. Similar results were reported for *MLH1* in gastric carcinoma samples<sup>[19]</sup>. Therefore, it is possible that the hypermethylation of the *MLH1* promoter region leads to the reduced expression of its protein product. This phenomenon could permit

the accumulation of mutations due to the lack of surveillance and repair that are consequent to this deficiency in the DNA repair system. Ultimately, the deficient DNA repair process can be detected by the appearance of microsatellite instability<sup>[37]</sup>.

In this study, we screened a group of *H. pylori*-infected and uninfected paediatric patients as well as a group of adult patients who were divided as follows: *H. pylori*-infected chronic gastritis patients, uninfected chronic gastritis patients and gastric cancer patients (all of whom were infected with *H. pylori*). MSI instability was found to be a very rare event in the paediatric population. Our data showed that *H. pylori* infection was not associated with MSI among patients with chronic gastritis. The incidence of MSI in gastric cancer patients was 64%, which was consistent with results reported previously by others (incidences ranging from 58% to 76%)<sup>[38,39]</sup>. Additionally, several studies have reported the presence of MSI in patients with intestinal metaplasia and gastric cancer, suggesting that the development of MSI may be an early event in the multi-step progression of gastric carcinogenesis<sup>[40,41]</sup>.

The presence of MSI-H in sporadic carcinomas has been significantly associated with the loss of *MLH1* expression<sup>[42,43]</sup>. This phenomenon was associated with the hypermethylation of the *MLH1* promoter, which is the underlying mechanism that causes MSI in gastric adenomas and early gastric cancers<sup>[24,44]</sup>. It is well known that *H. pylori* infection causes an increased rate of cell turnover in the gastric mucosa and thus overwhelms the DNA repair system. This process might allow for the accumulation of mutations that are consequent to *H. pylori* infection and other environmental risk factors<sup>[45]</sup>.

Previously, we reported that *H. pylori* infection leads to decreased *MLH1* expression in patients with gastric cancer<sup>[46]</sup>. This result correlated with the high levels of MSI that were detected in these samples because the downregulation of *MLH1* can lead to DNA repair system failures. Moreover, when the methylation patterns were compared with the *MLH1* expression levels and the MSI levels in gastric cancer samples, we found higher methylation levels and a consequent downregulation of *MLH1* in samples that were characterised as MSI-H versus those characterised as MSI-L samples ( $P < 0.03$ ). Similarly, Mizoshita *et al.*<sup>[47]</sup> identified a strong association between the MSI phenotype and the loss of *MLH1* expression in advanced gastric cancers.

We did not find an association between *MGMT* promoter region methylation and MSI status. Furthermore, it was observed that the methylation of both the *MLH1* and *MGMT* promoter regions is a frequent event in gastric cancers. Similarly, Zou *et al.*<sup>[44]</sup> reported an increase in *MGMT* methylation during the progression from intestinal metaplasia to early gastric carcinoma.

*H. pylori* infections are generally acquired during childhood and, if left untreated, will persist indefinitely. These infections lead to chronic inflammation, one of the factors associated with epigenetic alterations and

possibly with the development of gastric cancer. The results presented in this study indicate that the methylation of the *MGMT* and *MLH1* promoter regions might be considered to be dependent on the duration of infection because similar methylation patterns had not been observed in children. Moreover, in gastric cancer patients it was shown that the *MLH1* expression levels, the hypermethylation pattern of the *MLH1* promoter region and the consequent increase in MSI frequency are all related events. The results of this study are in accordance with the results presented in previous studies; taken together, these findings provide a better understanding of gastric carcinogenesis in the Brazilian population. Although other authors had previously studied these genes in gastric cancers or in chronic gastritis samples from adult patients, this is the first study that included samples from children with chronic gastritis to represent the earlier stages of the inflammatory response, which supported the idea that the methylation of these genes might depend on the duration of the *H. pylori* infection, among other factors.

Another interesting point of this study is that it addresses a new concept described by Ogino *et al.*<sup>[48]</sup>, termed “Molecular Pathological Epidemiology”, a new field of epidemiology based on the molecular classification of cancer, in which a known or suspected etiologic factor is examined in relation to a specific molecular change to gain insights into the carcinogenic mechanisms. It is well known that gastric carcinogenesis is a multifactorial process that results from the interactions of factors related to diet, environment, individual genetic susceptibility and *H. pylori* infection. In this manner, this study provides insights into the carcinogenic mechanisms that are induced by *H. pylori* infection, one of the etiologic factors involved in gastric carcinogenesis, and the induction of epigenetic alterations in the early stages of this process. The chronic gastric mucosal inflammation induced by *H. pylori* infection, which is characterised by mucosal infiltration by polymorphonuclear leukocytes, macrophages and T and B lymphocytes, leads to the release of reactive oxygen species (ROS) from activated inflammatory cells. ROS can induce DNA damage and the lack of a proper MMR repair system, which is partly due to the persistence of the organisms and the associated inflammation, and thus can lead to the accumulation of DNA mutations in gastric epithelial cells that contribute to gastric carcinogenesis. Additionally, recent studies have shown that specific types of inflammation that are characterised by the expression of specific inflammation-related genes, as well as increased cell proliferation, are necessary for methylation induction. In a previous study, the authors showed that *H. pylori*-induced inflammation was able to induce methylation, unlike alcohol or saturated NaCl-induced inflammation<sup>[49]</sup>. Despite all of the evidence for *H. pylori* infection-induced methylation, we cannot exclude the presence of potential confounding factors such as differences in individual host genetics, different bacterial strains and the local microenvironment, all of which might

affect an association study. Further studies of *H. pylori*-induced molecular pathogenesis will be useful to our understanding of gastric carcinogenesis.

## COMMENTS

### Background

Gastric carcinogenesis is a multistep process that is triggered by *Helicobacter pylori* (*H. pylori*) infection and characterised by multiple genetic and epigenetic alterations, including the DNA repair genes. The action of *H. pylori* through inflammatory mediators might play a key role in the epigenetic silencing of these genes.

### Research frontiers

Impairment of the DNA MMR system is a known mechanism of carcinogenesis and tumour progression. *H. pylori* infection leads to chronic inflammation in the gastric mucosa, which is associated with DNA methylation; this epigenetic alteration plays an important role in the regulation of gene expression and the maintenance of DNA integrity and stability. To date, few advances have been made to determine the time duration required for to *H. pylori* infection to induce such epigenetics alteration and thus potentially induce gastric carcinogenesis.

### Innovations and breakthroughs

To the knowledge, this is the first study to evaluate the methylation patterns of DNA repair genes in paediatric samples. Children can be considered interesting natural models for the study of *H. pylori* infection not only because they are not usually submitted to gastric mucosal irritants such as alcohol, tobacco, and anti-inflammatory medications but also because the gastric mucosal changes in children might represent an earlier stage of the inflammatory response compared to those in adult hosts, due to the shorter duration of *H. pylori* infections in children. The results presented in this study indicate that the methylation of the *MGMT* and *MLH1* promoter regions might depend on the duration of infection because these methylation events were not observed in children.

### Applications

This study indicates that the impairment of the DNA MMR system through DNA promoter methylation is an infrequent event in the early stages of *H. pylori*-induced inflammation.

### Peer review

This is overall an interesting study that analyses the relationship between *H. pylori* infection and molecular changes in the gastric mucosa, diseases, and cancers. In this respect, this is a very unique study in the field of MPE research in non-neoplastic diseases (gastritis).

### Abstract

**AIM:** To investigate whether neoadjuvant-intensified radiochemotherapy improved overall and disease-free survival in patients with locally advanced rectal cancer.

**METHODS:** Between January 2007 and December 2011, 80 patients with histologically confirmed rectal adenocarcinoma were enrolled. Tumors were clinically classified as either T3 or T4 and by the N stage based on the presence or absence of positive regional lymph nodes. Patients received intensified combined modality treatment, consisting of neoadjuvant radiation therapy (50.4-54.0 Gy) and infusional chemotherapy (oxaliplatin 50 mg/m<sup>2</sup>) on the first day of each week, plus five daily continuous infusions of fluorouracil (200 mg/m<sup>2</sup> per die) from the first day of radiation therapy until radiotherapy completion. Patients received five or six cycles of oxaliplatin based on performance status, clinical lymph node involvement, and potential risk of a non-sphincter-

conserving surgical procedure. Surgery was planned 7 to 9 wk after the end of radiochemotherapy treatment; adjuvant chemotherapy treatment was left to the oncologist's discretion and was recommended in patients with positive lymph nodes. After treatment, all patients were monitored every three months for the first year and every six months for the subsequent years.

**RESULTS:** Of the 80 patients enrolled, 75 patients completed the programmed neoadjuvant radiochemotherapy treatment. All patients received the radiotherapy prescribed total dose; five patients suspended chemotherapy indefinitely because of chemotherapy-related toxicity. At least five cycles of oxaliplatin were administered to 73 patients. Treatment was well tolerated with high compliance and a good level of toxicity. Most of the acute toxic effects observed were classified as grades 1-2. Proctitis grade 2 was the most common symptom (63.75%) and the earliest manifestation of acute toxicity. Acute toxicity grades 3-4 was reported in 30% of patients and grade 3 or 4 diarrhoea reported in just three patients (3.75%). Seventy-seven patients underwent surgery; low anterior resection was performed in 52 patients, Miles' surgery in 11 patients and total mesorectal excision in nine patients. Fifty patients showed tumor downsizing  $\geq$  50% pathological downstaging in 88.00% of tumors. Out of 75 patients surviving surgery, 67 patients (89.33%) had some form of downstaging after preoperative treatment. A pathological complete response was achieved in 23.75% of patients and a nearly pathologic complete response (stage ypT1ypN0) in six patients. An involvement of the radial margin was never present. During surgery, intra-abdominal metastases were found in only one patient (1.25%). Initially, 45 patients required an abdominoperineal resection due to a tumor distal margin  $\leq$  5 cm from the anal verge. Of these patients, only seven of them underwent Miles' surgery and sphincter preservation was guaranteed in 84.50% of patients in this subgroup. Fourteen patients received postoperative

chemotherapy. In the full analysis of enrolled cohort, eight of the 80 patients died, with seven deaths related to rectal cancer and one to unrelated causes. Local recurrences were observed in seven patients (8.75%) and distant metastases in 17 cases (21.25%). The five-year rate of overall survival rate was 90.91%. Using a median follow-up time of 28.5 mo, the cumulative incidence of local recurrences was 8.75%, and the overall survival and disease-free survival rates were 90.00% and 70.00%, respectively.

**CONCLUSION:** The results of this study suggest oxaliplatin chemotherapy has a beneficial effect on overall survival, likely due to an increase in local tumor control.

**Key words:** Rectal cancer; Neoadjuvant treatment; Intensified radiochemotherapy; Oxaliplatin; Fluorouracil

**Core tip:** Management of rectal cancer requires a multimodality treatment approach. The objective of this study was to determine whether neoadjuvant-intensified radiochemotherapy, using traditional radiation therapy in combination with oxaliplatin and 5-fluorouracil (5-FU), could improve the overall and disease-free survival rates in patients with locally advanced rectal cancer. Conventional chemotherapeutic strategies typically only use 5-FU infusion. The results from this study indicate that the addition of oxaliplatin to the chemotherapeutic regime enhances the 5-year overall survival rate, facilitates a high rate of sphincter preservation, and reduces the local recurrence rate relative to the traditional strategies previously reported in the literature. Furthermore, oxaliplatin addition was well tolerated by patients, demonstrating an acceptable level of toxicity.

Neoadjuvant-intensified treatment for rectal cancer: Time to change? *World J Gastroenterol* 2013; 19(20): 3052-3061 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i20/3052.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i20.3052>

## INTRODUCTION

Management of rectal cancer requires a multimodality treatment approach. Significant progress has been made in the conventional modalities of surgery, radiotherapy and chemotherapy, typically used to treat this type of cancer. The frequent spread of neoplastic cells to mesorectal nodes and the consequent increase in local recurrence has led to surgical standardization using total mesorectal excision (TME). With standard TME surgery, the incidence of local recurrence in lymph node metastasis-negative, pN0, tumors is reduced. However, the local recurrence rate is still higher than 20% in patients with lymph node

positive, pN+, disease and chemotherapy has remained the standard adjuvant care. Technical progress in radiation techniques, identified in major accuracy planning, and further analysis of accurate timing in sequential multimodality therapy has created improvements in local control, toxicity (acute and chronic), and sphincter preservation<sup>[1-3]</sup>.

Previous work by Sauer *et al*<sup>[4]</sup> from the German Rectal Cancer Study Group identified preoperative radiochemotherapy as the standard treatment for patients with stage cT3-4 and/or N+ tumors. Based on empiric data and on the efficacy demonstrated in stage III colon cancer patients<sup>[5,6]</sup>, the addition of a second chemotherapeutic agent in a neoadjuvant setting confirmed oxaliplatin (OXP) radiosensitizing properties both *in vitro* and *in vivo*<sup>[7]</sup>.

The goal of this work was to determine whether neoadjuvant-intensified radiochemotherapy improved the overall and disease-free survival, which is typically only achieved with 5-fluorouracil (5-FU) treatment, in patients with locally advanced rectal cancer. In this study, tumor downstaging, pathological complete response (pCR), and negative radial (circumferential) margins of tumors were assessed as well as the overall and disease-free survival rates in a cohort of 80 patients, 51 of whom had already been evaluated as previously described<sup>[8]</sup>. The results indicate that oxaliplatin therapy, in addition to traditional radiation and 5-FU therapies, enhances the overall survival rate and reduces local recurrence in patients with rectal cancer.

## MATERIALS AND METHODS

### Eligibility criteria

Patients enrolled were positively diagnosed with rectal adenocarcinoma as shown by histological analysis. Tumors were within 12 cm from the anal margin and clinically classified as described below. The performance status (PS), age, normal blood parameters and normal renal function were also assessed. Patient exclusion criteria consisted of the presence of synchronous tumors, cardiovascular disease, history of neurological or psychiatric disorders, and previous pelvic radiotherapy. All patients were enrolled after providing informed consent.

### Staging

The pre-treatment staging included obtaining the complete history and careful physical examination of the patient, digital rectal examination, rectocolonoscopy, trans-rectal ultrasound and total body computerized tomography. Patient tumors were evaluated by ultrasound exam and tumor stage (T) was classified according to the American Joint Committee on Cancer tumor, nodes, metastasis (TNM) Staging System<sup>[9]</sup>. With the exception of one sample, all tumors were classified as either T3 or T4 and N+ if positive regional lymph nodes were detected without any distant metastases. In the case of an uncertain diagnosis, patients underwent abdominal-pelvic

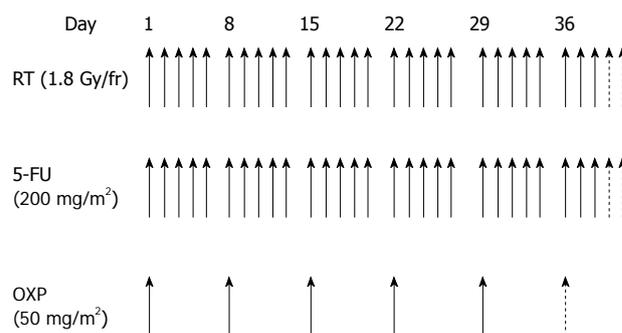

magnetic resonance imaging. The evaluation of clinically positive lymph nodes (N) was performed by trans-rectal ultrasound and TC; lymph nodes  $\geq 1$  cm were considered pathological.

### Treatment

**Radiotherapy:** As the physical positioning of a patient must remain identical for both the initial localization of the tumor by computerised tomography (CT) scanning and during subsequent treatment, a planning CT scan was performed in the treatment position. Patients were treated in the prone position using a belly-board device to displace the small bowels out of the treatment field. A radio-opaque marker was placed on the anal verge. CT images were acquired from the level of L1 to 3 cm below the anal marker with 5 mm slice spacing. CT data were analyzed using Treatment Planning Software (Pinnacle<sup>®</sup>) for target volume definition and dose solutions. The planning target volume 1 (PTV1) encompassed the primary tumor, the mesorectal and posterior pelvic sub-regions, and the regional node. The presacral, obturator and internal iliac lymph nodes were monitored in all patients. The external iliac lymph nodes were monitored if clinically positive or in the case of T4 tumor. The inguinal lymph nodes were irradiated if there was major tumor extension to the internal and external anal sphincter. The superior field border was located at the bifurcation of the common iliac vessels (L5/S1 interspace); the inferior margin was 5 cm below the inferior edge of the tumor. The lateral extension was 2 cm outside of the pelvic bones. The posterior border was placed 1 cm behind the sacrum to include sacral hollows. The anterior limit was placed at the posterior margin (cT3) or anterior margin (cT4) of the symphysis.

The PTV2 included the tumor mass with a 2 cm 3-D margin. The organs at risk were bowel (Dmax < 55 Gy), bladder (V50 60%; V60 50%), femoral heads (V50 60%), and anal canal (Dmax < 55 Gy). Patients were set up daily, using sagittal and lateral tattoos and a laser to prevent lateral rotation. Electronic portal imaging was used to check treatment organization once a week from the start to the end of treatment; portal images were compared with digitally-reconstructed radiographs from the planning CT scan. Radiation therapy was delivered with a 3-D-conformational multiple field technique at a dose of 45 Gy (in 25 daily fractions of 1.8 Gy given in 5 wk) to the whole pelvis for PTV1 and 5.4-9.0 Gy (in 3-5 daily fractions of 1.8 Gy) to the tumor volume for PTV2 with 6-15 MV energy photons.

**Chemotherapy:** All patients received a central venous access (port-a-cath) for delivering chemotherapy. Chemotherapy consisted of a 2-h oxaliplatin infusion (50 mg/m<sup>2</sup>) on the first day of each week of radiotherapy, and five daily continuous infusions of 5-FU (200 mg/m<sup>2</sup> per die). Patients received five or six cycles of oxaliplatin, dependent on PS, clinical lymph node involvement, and potential risk of a non-sphincter-conserving surgical pro-

**Figure 1 Neoadjuvant-intensified treatment protocol.** Patients received 50.4 Gy (solid arrows) or 54.0 Gy (dashed arrows) of radiation therapy (RT), 28 d (solid arrows) or 30 d [dashed arrows of fluorouracil (5-FU) and five (solid arrows) or six (dashed arrow)] weekly cycles of oxaliplatin dependent on performance status, clinical lymph node involvement, and potential risk of a non-sphincter-conserving surgical procedure. Radiation therapy was delivered with a 3-D-conformational multiple field technique at a daily dose of 1.8 Gy/fraction. All patients received a central venous access (port-a-cath) for delivering chemotherapy. Chemotherapy consisted of a 2-h oxaliplatin infusion (50 mg/m<sup>2</sup>) on the first day of each week of radiotherapy, and five daily continuous infusions of 5-FU (200 mg/m<sup>2</sup>).

cedure. Desamethasone (8 mg) and ondansetron (8 mg) were administered before the oxaliplatin infusion. Figure 1 shows the neoadjuvant treatment protocol.

Toxicity was evaluated using National Cancer Institute's Common Terminology Criteria for Adverse Events version 3.0<sup>[10]</sup>. Oxaliplatin and 5-FU dose reductions were not planned. For occurrence of hematological toxicity grade 3 or neurological toxicity grade 2, the oxaliplatin administration was interrupted; both chemotherapeutic agents were stopped if grade 3 toxicity was reached. If severe toxicity persisted, did not return to grade 1, or was classified as grade 4, chemotherapy was cancelled but radiotherapy was completed.

**Surgery:** Five weeks from the end of neoadjuvant treatment, each patient underwent digital rectal examination, total body TC, colonoscopy and trans-rectal ecography to evaluate clinical response. Surgery was planned seven to nine weeks after the end of radiochemotherapy treatment. The surgeon chose the type of surgery to perform.

**Adjuvant chemotherapy:** Adjuvant chemotherapy treatment was left to the oncologist's discretion and was recommended in patients with lymph node metastases.

### Pathologic examination of the operative specimen

Pathological staging was designated as pTNM and depended on the data acquired clinically in addition to surgical and pathologic findings. Radial margins were considered positive if there was evidence of microscopic invasion. Downstaging was defined as a reduction of at least one level in T or N staging between the baseline ultrasound exam and histopathological staging. Downsizing was defined as a reduction of lesion diameter between pre-treatment ultrasound evaluation and histopathological results. pCR was defined as the absence of any residual

**Table 1** Characteristics of patients *n* (%)

| Characteristics               | Patients   |
|-------------------------------|------------|
| Performance status            |            |
| 0                             | 52 (65.00) |
| 1                             | 27 (33.75) |
| 2                             | 1 (1.25)   |
| Localization                  |            |
| ≤ 5 cm from anal verge        | 45 (56.25) |
| > 5 to ≤ 8 cm from anal verge | 19 (23.75) |
| > 8 cm from anal verge        | 16 (20.00) |
| Stage                         |            |
| II A                          | 19 (23.75) |
| III A                         | 1 (1.25)   |
| III B                         | 30 (37.50) |
| III C                         | 30 (37.50) |

tumor cells detected in the operative specimen.

### Patient recruitment

This study was an extension of a previous study of 51 patients<sup>[8]</sup>. Between January 2007 and December 2011, 29 new patients were enrolled for a total of 80 participants: 25 females (31.25%) and 55 males (68.75%). The patients' ages ranged between 36-76 years (average = 63.55 years). Patients presented clinically with rectal bleeding (39/80, 48.75%) that may have been accompanied by a change in bowel habits, such as unexplained constipation and diarrhea (10/80, 12.50%). At a pre-treatment evaluation, 75.00% of patients showed pathological tumor-positive lymph nodes; 37.5% of patients were clinically staged as III B and 37.5% as III C. The distance of the inferior margin of the tumor lesion was located in the lower rectum at ≤ 5 cm from the anal verge in 56.25% of patients. The characteristics of patients are listed in Table 1.

### Follow-up

After surgery, all patients were monitored at three-month intervals for the first year and at six-month intervals for the subsequent years. All patients were stratified into five cohorts according to the year of the last treatment. We defined "absolute permanence" as the greatest number of months of permanence in each cohort. Absolute permanence, overall survival (OS) and disease-free survival (DFS) were measured in months from the end of the neoadjuvant treatment.

### Statistical analysis

Statistical analysis was performed using the following factors: 1 - sex, 2 - age, 3 - PS, 4 - TNM clinical staging, 5 - cranio-caudal extension of tumor lesion, 6 - tumor location, 7 - total radiotherapy dose, 8 - cycles of associated chemotherapy, 9 - interval between neoadjuvant treatment and surgery, 10 - type of surgery, 11 - toxicity, 12 - OS, 13 - DFS, 14 - pathologic downstaging, and 15 - pCR. Factors from 1 to 11 were considered "causal" or "predictive"; factors from 12 to 15 characterized the "considerable" results of therapy. Standard descriptive statistics were used to evaluate the distribution of each

factor. OS and DFS were evaluated in each cohort. To determine the association between downstaging or pCR and predictive factors, the univariate analysis was performed using the non-parametric Bernard test. Statistical tests were one-sided. Changes of OS and DFS according to predictive factors were assessed using a logistic model in multivariate analysis. Statistical analysis was performed using MATLAB software, version 7.5.0.342 (R2007b), and SAS software, version 9.1.

## RESULTS

### Compliance

Seventy-five patients completed the programmed radio-chemotherapy treatment. All patients received the radiotherapy prescribed total dose of 50.4 Gy in 75 patients (93.75%) and 54 Gy in five patients (6.25%). Five patients suspended chemotherapy indefinitely because of chemo-related toxicity after the second cycle (one patient), third cycle (two patients), or fourth cycle (two patients). Twelve patients stopped the planned neoadjuvant treatment because of acute toxicity: five patients interrupted radiation therapy only and seven patients interrupted both treatments. In these patients, radiotherapy was stopped for an average period of 10.58 d (range 2-22 d).

### Surgery

Seventy-seven out of 80 patients underwent surgery. A "wait and see" approach was recommended to only one patient; he was unfit for surgery because of type II diabetes mellitus and pericarditis co-morbidities. After neoadjuvant treatment, he underwent pelvic RM that indicated a complete clinical regression of the tumor. One patient did not undergo surgery because of liver metastases. One patient had a myocardial infarction two weeks after the end of radiochemotherapy and died.

For those patients who were eligible, surgery was planned an average of 9.30 wk (range 5-24 wk) after the end of neoadjuvant treatment. Low anterior resection was performed in 52 patients, Miles' surgery in 11 patients, and transanal endoscopic microsurgery in nine patients. Three patients had a different surgical approach. Two patients died of intra-operative complications. None had positive radial margins. At the beginning, 45 patients required an abdominoperineal resection due to a distal tumor margin distance of ≤ 5 cm from the anal verge. Only seven patients underwent Miles' surgery, and sphincter preservation was guaranteed in 84.50% of this subgroup of patients. Post-operative complications were recorded in nine patients; the most common type was perianastomotic fistula (six patients) and other post-operative complications included fever (one patient), intestinal obstruction (one patient), and adhesion (one patient).

### Pathologic complete response and downstaging

Downsizing and downstaging was evaluated by comparing clinical staging to pathological staging. Fifty patients showed tumor downsizing of ≥ 50% and associated

**Table 2** Evaluation of overall survival and disease-free survival

| Cohort | $\alpha$ | $\Omega$ | AP, mo | OS, mo | DFS, mo | OS/AP % | DFS/OS % |
|--------|----------|----------|--------|--------|---------|---------|----------|
| 2007   | 16       | 3        | 54.00  | 50.90  | 46.90   | 94.28   | 92.14    |
| 2008   | 22       | 3        | 42.90  | 39.30  | 34.90   | 91.40   | 89.01    |
| 2009   | 18       | 2        | 30.80  | 29.40  | 22.60   | 95.53   | 76.97    |
| 2010   | 13       | 0        | 17.40  | 17.40  | 15.30   | 100.00  | 87.93    |
| 2011   | 11       | 0        | 6.30   | 6.30   | 5.60    | 100.00  | 88.79    |
| Total  | 80       | 8        | 29.80  | 27.90  | 23.90   | 93.45   | 85.88    |

$\alpha$ : Survived;  $\Omega$ : Died; AP: Absolute permanence; OS: Overall survival; DFS: Disease-free survival.

downstaging in 88.00% of tumors. Out of 75 patients surviving surgery, 67 patients (89.33%) had some form of downstaging from preoperative treatment. After surgery, 25 patients (33.33%) harbored tumors that were classified as Stage I. Of these, 18 patients (72.00%) had clinical positive nodes at diagnosis. Pathologic complete response, defined as the absence of tumor cells in the operative specimen, was observed in 18 patients (22.50%); only six of them had clinical negative lymph nodes at diagnosis. Six patients had a nearly pathologic complete response (stage ypT1ypN0). During surgery, intra-abdominal metastases were found in one patient only (1.25%).

### Adjuvant chemotherapy

Fourteen patients received postoperative chemotherapy. Twelve patients had lymph node-positive tumors previously identified by trans-anal ultrasound (eight patients with cN2 and four patients with cN1). One patient had positive lymph nodes identified by histopathological examination and distant metastases were detected intraoperatively in one patient. Of 16 patients with ypT3ypN0 disease, only four were assigned to adjuvant chemotherapy.

### Overall survival and disease-free survival

Until January 2012, surviving patients were monitored with a follow-up program; the average follow-up time was 27.28 mo and the median follow-up time was 28.50 mo (range 2-58 mo). Twenty-four patients were followed for 25-36 mo, 18 patients followed for 37-48 mo, and 11 patients were followed for at least 49 mo.

In the full analysis of study cohort, eight of the 80 patients died. Seven deaths were related to rectal cancer and one death was caused by unrelated causes. Of these, one patient died before surgery, two died during surgery, and four deaths occurred during the follow-up program. Of the latter, two patients had local recurrence 6 and 9 mo, respectively, after the end of neoadjuvant treatment and two patients had distant metastases 13 and 15 mo, respectively, after the end of preoperative radiochemotherapy. Three out of the four patients had stage III B disease at diagnosis.

The absolute permanence (AP), OS, and DFS times were evaluated for each cohort (Table 2 and Figure 2), as well as the permanence/OS and permanence/DFS ratios and the total number of patients surviving ( $\alpha$ ) or

deceased ( $\Omega$ ) at the time of analysis (Table 2). It is important to note that OS times were nearly equivalent to absolute permanence times; the permanence/OS ratios were greater than 90% in all years evaluated. Remarkably, comparisons between OS and DFS demonstrated that the DFS/OS ratio was always higher than 88%, except in the 2009 cohort.

Of 19 patients with a complete response (18 pathological and one clinical), 18 patients are still disease-free survivors. One patient had local recurrence 19 mo after the end of neoadjuvant treatment. In the full analysis of the study participants, locoregional recurrence was observed in seven patients (8.75%) an average of 21.29 mo (range 6-39 mo) after the end of preoperative radiochemotherapy, six patients showed downstaging, and one patient had no benefit from neoadjuvant treatment. Local recurrence was located in the perianastomotic region (six cases) or pre-sacral region (one case). Distant metastases were recorded in 17 cases (21.25%) where eight patients presented pulmonary metastases after an average of 22.75 mo (range 7-38 mo) after the end of neoadjuvant treatment and six patients had liver metastases after an average of 6.83 mo (range 1-16 mo) after the end of radiochemotherapy. Individual cases of brain and ovarian metastases were recorded 6 and 12 mo, respectively, after the end of preoperative treatment. One patient presented distant metastases in multiple locations. Of these 17 patients, only five showed negative lymph nodes at diagnosis.

### Toxicity

**Acute toxicity:** Table 3 summarizes the incidence of acute toxicity. Proctitis, grade G2, was the most common symptom (63.75%) and the earliest manifestation of acute toxicity. On average, proctitis symptoms appeared during the ninth day of radiation therapy (range 2-25 d). Grade G1-2 diarrhea was noted in 31.00% of patients. Grades 3-4 toxicity was seen only in nine patients, with symptoms of diarrhea (three patients), proctitis (four patients), and abdominal pain (two patients). Genitourinary toxicity was observed in 32.50% of patients. Symptoms included an increase in frequency and dysuria, usually during the end of third week of radiation therapy (range 3-26 d). Of the 23 patients with dysuria, 47.83% (11 patients) were classified as G2. Radiation dermatitis was reported in 30 patients; ten patients' symptoms were graded as G1, 17 patients as G2, and three patients as G3. There was a significant correlation between radiation dermatitis and tumors located within 5 cm of the anal verge ( $P$  value, 0.0076). No hematological toxicity was observed. Hypersensitivity reactions were recorded in six patients. One patient stopped chemotherapy after the second cycle. One patient completed all five prescribed cycles of intensified chemotherapy, but during the last two cycles was administered 5-FU only. Four patients completed the prescribed treatment after taking a one-week break.

Sixteen patients presented neurologic toxicity due to oxaliplatin. Neuropathy was classified as G3 in only one patient, who had sensory loss and paresthesia during the

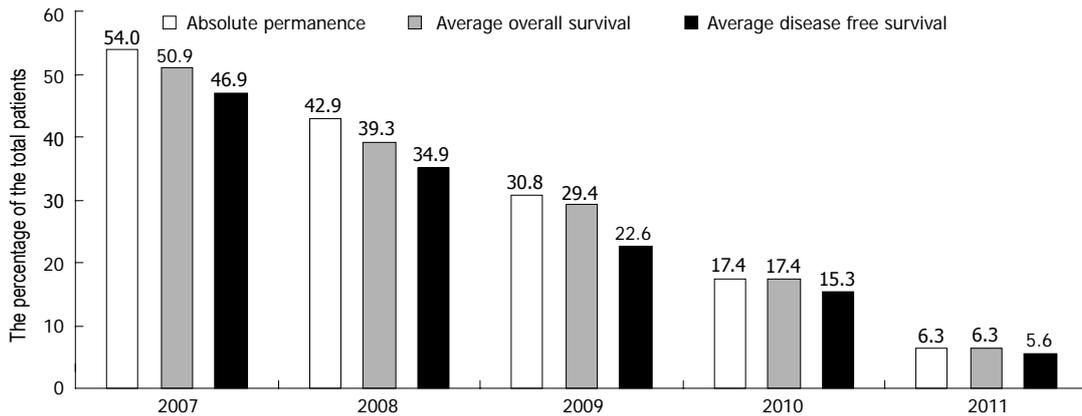

Figure 2 Absolute permanence (white column), overall survival (grey column), and disease-free survival (black column) comparisons. Patient data was stratified by year and is represented as a percentage of the total cohort of patients.

Table 3 Incidence of acute toxicity *n* (%)

end of the fifth cycle of chemotherapeutic treatment. In total, 11 patients (13.75%) had adverse cardiovascular events. Two patients experienced acute myocardial infarction (IMA), two patients experienced pulmonary embolism, and seven patients experienced deep vein thrombosis requiring anticoagulant therapy. Embolic events G3-4 arose after the end of neoadjuvant-intensified radiochemotherapy by an average of 4.42 mo (range 1-8 mo). One patient died 2 wk after the end of treatment; it was considered an IMA-related death. One patient died dur-

ing surgery of cardiac infarction.

**Late toxicity:** Late toxicity was defined as long-term toxic effects occurring at least 6 mo after the end of radiochemotherapy treatment. Considering all enrolled patients, gastrointestinal toxicity was the most evident late side effect and was recorded in 37 patients (46.25%). Fecal incontinence was reported in 32.43% of patients and proctitis in 32.43% of patients. Four patients had diarrhea and five patients had an increase in stool frequency. Seven patients reported sexual dysfunction. Urinary incontinence was observed in three patients with colostomy. In 11 out of 60 patients with acute proctitis, the symptoms continually persisted as G1-2 grade. No correlation was observed between acute toxicity and late toxicity. Neuropathy with loss of deep tendon reflexes and paresthesia that did not interfere with activities of daily living was documented in five patients and acute neuropathic toxicity was reported in 16 patients.

### Correlation analysis

We evaluated 11 “predictive” factors: (1): sex; (2): age; (3): PS; (4): TNM clinical staging; (5): cranio-caudal extension of the tumor lesion; (6): tumor location; (7): total radiotherapy dose; (8): cycles of associated chemotherapy; (9): interval between neoadjuvant treatment and surgery; (10): type of surgery; and (11): toxicity. Univariate analysis did not show any significant correlation between “predictive” factors and downstaging or pCR. There was no causal significant correlation between “predictive” factors and OS or DFS in the multivariate analysis.

Two additional statistical analyses were of interest and enhanced the evaluation of the data. First, the linear relationship between the infusion of six cycles of chemotherapy and tumor sizes smaller than 5 cm was statistically significant (*P* value, 0.0334). Second, a causal correlation was found between surgery performed seven weeks before the end of neoadjuvant treatment and OS or DFS, although the data was not stratified by the surgery characteristics.

## DISCUSSION

### *Multimodality treatment in rectal cancer*

In the past two decades, several clinical trials have been performed to determine the role of a multimodal approach in treating rectal cancer. These clinical trials faced three problems: (1) determination of temporal sequencing of treatment modalities; (2) integration of radiotherapy and chemotherapy; and (3) radiation dose fractionation. Testing and analysis of new approaches should be aimed at defining therapeutic strategies to improve local tumor control and overall survival benefit<sup>[11]</sup>.

Year after year, local recurrence has represented the prevailing method of treatment failure. Now, with improvement in surgical and radiotherapeutic techniques, local tumor control rates have improved. Neoadjuvant radiotherapy and concurrent 5-FU based chemotherapy, as compared with the same protocol delivered after surgery, has improved local control<sup>[4]</sup>. The addition of 5-FU to radiation therapy also has been shown to significantly reduce the incidence of local recurrences<sup>[4,11,12]</sup>. Likewise, survival has improved with standardization of total mesorectal excision surgery<sup>[13-16]</sup>. The decrease in local recurrence rates emphasizes the need to investigate the risk of distant metastases and requires new treatment strategies to improve distant tumor control.

Although most patients achieve tumor downstaging after preoperative radiochemotherapy, the debate over monochemotherapy *vs* polichemotherapy still remains. Specifically, whether 5-FU infusion, the standard of care in rectal cancer, is better than multichemotherapeutic agents for reducing the risk of distant metastases. The prevalence of distant metastases (24%-30%) stresses the importance of a more effective systemic treatment<sup>[11]</sup>.

### *Evaluation*

In this study, the effects of a multimodal therapy approach for rectal cancer were evaluated. Disease-free survival was considered the most efficient indicator of the absence of disease and is the most robust indicator of effective treatment. In our previously reported study<sup>[8]</sup>, we evaluated the toxicity and efficacy of preoperative-intensified radiochemotherapy, and the subsequent pathologic complete response, downstaging, and sphincter preservation rates. In the current study, the patient cohort from the previous study was expanded with 29 new cases and the overall survival and disease-free survival rates were evaluated and stratified per year.

The aim of this study was to verify efficacy of neoadjuvant-intensified treatment. Oxaliplatin (50 mg/m<sup>2</sup> per week) was added to the standard 5-FU chemotherapy, normally given in continuous infusion of 200 mg/m<sup>2</sup> per die during each day of radiation therapy. Weekly administration of oxaliplatin, with the cumulative dose of 300 mg/m<sup>2</sup>, was chosen so that its toxic effects were reduced and to optimize its radiosensitizing properties. This intensified radiochemotherapy regime was used to test the hypothesis that it could produce greater OS and

DFS within tolerable toxicity. An empirical analysis of the study results confirms our hypothesis; the treatment was well tolerated, with high compliance and a relatively good level of toxicity. All patients had received the total prescribed radiotherapy dosage and at least five cycles of oxaliplatin were administered to 91.25% of patients.

The compliance rate (93.75%) was slightly higher than rates registered in studies in which intensified radiochemotherapy regimes were adopted (range 64%-85%)<sup>[17-21]</sup>. Most of the acute toxic side effects observed in this study were classified as grade 1-2. Grade 3-4 acute toxicity was reported in 30% of patients and was only slightly higher than data from the STAR-01 trial (24%) and the ACCORD study (25%)<sup>[17,18]</sup>. Of note, cardiovascular toxicity represented 45.83% of grade 3-4 acute toxic effects.

### *Thromboembolic risk*

Thromboembolic risk could be ascribed to the type of chemotherapy administered or to surgery. In the literature, there is not enough available data describing this risk, although chemotherapy is recognized as an independent risk factor for a thromboembolic event<sup>[22]</sup>. Ng *et al*<sup>[23]</sup> examined the frequency and pattern of cardiotoxicity in 153 patients treated with capecitabine used in addition with oxaliplatin for advanced colorectal cancer and found that 6.7% of patients developed thromboembolic events. Randomized studies, aimed to assess the efficacy of neoadjuvant radiochemotherapy treatment in locally advanced rectal cancer, with or without oxaliplatin, did not analyze cardiovascular toxicity. Chua *et al*<sup>[24,25]</sup> reported that during induction chemotherapy using capecitabine and oxaliplatin, 10 patients (8.5%) had cardiac or thromboembolic events and four patients died in a phase II trial. The incidence rate of that study was slightly lower than the rate reported here (13.75%). The high rate of thromboembolic risk may be associated with properties of oxaliplatin that boost the 5-FU thrombogenic effect<sup>[26]</sup>. Certainly, the rise in cardiovascular, chemo-related toxicity must be monitored carefully and kept under control. Because of the risk, neoadjuvant-intensified radiochemotherapy must be interrupted if cardiac symptoms appear.

### *Toxicity*

Excluding cardiovascular toxicity, grade 3 or 4 acute toxic effects occurred only in 13 patients (16.25%) with diarrhea occurring just in three patients (3.75%). In both STAR-01 and ACCORD trials, addition of oxaliplatin to 5-FU based radiochemotherapy increased toxicity rates. In those studies, grade 3-4 diarrhea was recorded in 15% and 13% of patients given oxaliplatin *vs* 4% and 3% of those in the control group, respectively<sup>[17,18]</sup>. The lowest rates of acute gastrointestinal toxicity in this study were observed in the oxaliplatin regimen, given as 2-h infusion at a dose of 50 mg/m<sup>2</sup> per week. Grade 3-4 long-term toxic effects were not recorded.

**Neoadjuvant-intensified radiochemotherapy efficacy**

It was difficult to determine if the cause of fecal incontinence and sexual function was due to radiation therapy, surgery, or both treatments. Sixty-four patients, or 80% of the enrolled patients, underwent conservative surgery. Of these patients, 10.45% reported sexual dysfunction and 17.91% fecal incontinence.

The sphincter preservation rate, evaluated in the total patient cohort and in a subgroup of 45 patients with a tumor localization  $\leq 15$  cm from the anal verge, was 80% and 84.50%, respectively. These results are slightly better than the ACCORD trial, in which conservative surgery was performed in 77.20% of patients, and similar to the STAR-01 study, in which 82% of patients had sphincter preservation. In the literature, the incidence of pCR and negative radial margins, in patients who received preoperative radiochemotherapy with 5-FU and oxaliplatin, ranged from 10% to 24% and from 80.95% to 100%, respectively<sup>[18-20,24,25,27,28]</sup>. Randomized trials confirmed an improvement in the local tumor control rate. Neoadjuvant treatment has been associated with a reduction of local recurrence of 6%-15%, although the incidence of distant metastases was still 30%<sup>[29-32]</sup>. A retrospective study showed that pathologic downstaging and pCR were essential for an accurate prediction of disease-free survival and overall survival<sup>[33]</sup>.

In 22.5% of patients, no residual cancer cells were identified and the tumor was staged as pT0N0. Pathological complete response rates reached 23.75% and were evaluated by post-treatment RM. One patient is still a disease-free survivor 21 mo after the end of radiochemotherapy. The majority of patients, 83.75%, had some form of tumor downstaging after preoperative treatment; involvement of the radial margin was never present.

The 5-year overall survival rate (90.91%) in this study was better than results observed in randomized trials of locally advanced rectal cancer, which only observed survival rates of 65%-68%<sup>[12,13,26]</sup>. The results of this study indicate that intensification of radiochemotherapy using oxaliplatin is effective in preoperative treatment and showed that a strong response to neoadjuvant treatment increased the overall patient survival.

Considering a median follow-up of 28.5 mo (range 2-58 mo) in the total cohort, the cumulative incidence of local recurrences was 8.75% and the incidence of OS and DFS was 90% and 70%, respectively. The most common type of first recurrence was pulmonary metastases, which arose in eight patients. This observation confirmed the need to include CT thorax controls during the follow-up program. Although some questions remain, such as the need for adjuvant chemotherapy and whether oxaliplatin boosts the 5-FU trombogenic effect, the radiochemotherapy regime used (OXP 50 mg/m<sup>2</sup> and 5-FU 200 mg/m<sup>2</sup>) seems to be appropriate to produce good clinical results and to maintain toxicity at tolerable levels.

In conclusion, the results of this study indicate that neoadjuvant-intensified radiochemotherapy in patients with rectal cancer carcinoma improved pathological

complete response, negative radial margins, and sphincter preservation. The chemotherapy regime of OXP 50 mg/m<sup>2</sup> and 5-FU 200 mg/m<sup>2</sup> was well tolerated, with few severe toxic effects. Despite the small number of patients enrolled, this study suggests that the addition of oxaliplatin has a beneficial effect on overall survival, likely due to an increase in local control, although there was not a clear increase in distant metastases control. On the basis of these results, the importance and validity of intensified radiochemotherapy to reduce local recurrence should be emphasized. Currently, we are waiting for longer follow-up data from the randomized phase III trials. Future studies will address the treatment and management of recurrent distant metastases in rectal cancer.

**COMMENTS****Background**

Management of rectal cancer needs a multimodality treatment approach. Significant progress has been made in the conventional modalities of surgery, radiotherapy and chemotherapy used to treat this type of cancer. The decrease in local recurrence rates emphasizes the need to investigate the risk of distant metastases and indicates that new treatment strategies are necessary to improve distant control.

**Research frontiers**

Although most patients achieve a tumor downstaging after preoperative radiochemotherapy, the question of monochemotherapy versus polichemotherapy still remains. Infusion of 5-fluorouracil (5-FU), the standard of care in rectal cancer, is better than multi-chemotherapeutic agents for reducing the risk of distant metastases. The incidence of distant metastases (24%-30%) stresses the importance of a more effective systemic treatment.

**Applications**

The objective of this study was to determine whether neoadjuvant-intensified radiochemotherapy improved the overall and disease-free survival rates in patients with locally advanced rectal cancer. Typically, improved survival rates have only been achieved with 5-FU treatment.

**Terminology**

Oxaliplatin is a chemotherapeutic agent. Studies *in vitro* and *in vivo* confirm its radiosensitizing properties.

**Peer review**

This is a retrospective review in a significant number of patients with favourable results and worth publication.

### Abstract

**AIM:** To assess the efficacy of glucmannan (GNN) as the sole treatment for abdominal pain-related functional gastrointestinal disorders (FGIDs).

**METHODS:** We conducted a double-blind, placebo-controlled, randomized trial. Patients were recruited among children referred to the Department of Paediatrics, Medical University of Warsaw. Included in the study were children aged 7-17 years with abdominal pain-related FGIDs classified according to the Rome III diagnostic criteria. The children were randomly assigned to receive GNN, a polysaccharide of 1,4-D-glucose and D-mannose, a soluble fiber from the Japanese Konjac plant, at a dosage of 2.52 g/d (1 sachet of 1.26 g 2 times a day), or a comparable placebo (maltodextrin) at the same dosage. The content of each sachet was dissolved in approximately 125 mL of fluid and was consumed twice daily for 4 wk.

**RESULTS:** Of the 89 eligible children, 84 (94%) completed the study. "No pain" and "treatment success" (defined as no pain or a decrease  $\geq$  2/6 points on the

FACES Pain Scale Revised) were similar in the GNN ( $n = 41$ ) and placebo ( $n = 43$ ) groups [no pain (12/41 vs 6/43, respectively; RR = 2.1, 95%CI: 0.87-5.07) as well as treatment success (23/41 vs 20/43; RR = 1.2, 95%CI: 0.79-1.83)]. No significant differences between the groups were observed in the secondary outcomes, such as abdominal cramps, abdominal bloating/gasiness, episodes of nausea or vomiting, or a changed in stool consistency. GNN demonstrated no significant influence on the number of children requiring rescue therapy, school absenteeism, or daily activities.

**CONCLUSION:** In our setting, GNN, as dosed in this study, was no more effective than the placebo in achieving therapeutic success in the management of FGIDs in children.

**Key words:** Functional abdominal pain; Abdominal pain-related functional gastrointestinal disorders; Children

**Core tip:** This study focused on abdominal pain-related functional gastrointestinal disorders (FGIDs) which are a common problem in children. The aim of the study was to assess the effectiveness of glucmannan (GNN), a soluble fiber of the Japanese Konjac plant, in alleviating the frequency and the severity of pain in children with FGIDs. We have demonstrated through our prospective, double-blind, placebo-controlled, randomized study that GNN in this setting for 4 wk was not effective in treatment of the FGIDs. The obtained results led us to the conclusion that further studies are needed to explore the role of GNN in the pathophysiology of functional disorders.

## INTRODUCTION

Functional abdominal pain (FAP) is one of the most common reasons for a referral to a physician<sup>[1]</sup>. According to various estimates of the prevalence of FAP, approximately 13% to 38% of children and adolescents report functional abdominal problems<sup>[2]</sup>.

The diagnosis of FAP is symptom-based. The Rome III criteria for abdominal pain-related functional gastrointestinal disorders (FGIDs) have been validated and assist clinicians make diagnoses<sup>[2]</sup>. The vast majority of children with FGIDs are subsequently diagnosed with functional dyspepsia (FD), irritable bowel syndrome (IBS), and childhood abdominal pain (AP)<sup>[3,4]</sup>. The symptoms associated with these diagnoses have a great impact on the patients' quality of life, daily activities, and school absenteeism, which in turn can result in long-term psychological implications<sup>[2]</sup>. Therefore, patients as well as caregivers and physicians are interested in safe and reliable treatments to relieve troublesome symptoms. Unfortunately, the medical cause for these symptoms remains unclear, thus limiting currently available therapies. FGIDs continue to represent a significant challenge in approaches to patient management.

For most children with FGIDs, no organic causes for their pain are found on physical examination or during investigations<sup>[5]</sup>. One of the recent hypotheses regarding the pathophysiology of FGIDs proposes that the biological and environmental factors that alter the enteric flora and visceral perception cause the development of functional disturbances<sup>[2,6]</sup>. The associations between the enteric microbiota, immune activation, and the role of lumen-mucosa interaction have been explored recently<sup>[2,7,8]</sup>. However, a precise explanation of the etiology of FGIDs remains to be expounded.

Regardless of the lack of a biophysiological model for FGIDs, a variety of therapeutic options have been tried. Unfortunately, studies have proven that most options do not exert any significant influence on the natural history of FGID development<sup>[2]</sup>. Two recent Cochrane systematic reviews have revealed weak evidence for the benefits of medication or dietary manipulation in children with functional abdominal pain<sup>[9,10]</sup>. Only 2 small, randomized clinical trials (Christensen 1982, Feldman 1985) have been conducted in children with FGIDs, and they compared the effects of added dietary fiber with placebo<sup>[9,11,12]</sup>. The results and conclusions of these trials were not consistent. Nevertheless, many clinicians routinely recommend the use of bulking agents or dietary fiber to stimulate regular bowel movements and to improve the symptoms associated with FGIDs<sup>[2]</sup>.

The goal of our study was to assess the efficacy of glucomannan (GNN) as the sole treatment for FGIDs in children. GNN, a polysaccharide of 1,4-D-glucose and

D-mannose, is a soluble fiber from the Japanese Konjac plant. GNN exhibits properties that are typical of dietary fiber. Thus, it may provide a positive effect on many aspects of gut physiology and the appropriate functioning of enteric microbiota in patients with FGIDs<sup>[8,13]</sup>.

## MATERIALS AND METHODS

### *Trial design*

We conducted a double-blind, placebo-controlled, randomized trial (RCT) from January 2009 to October 2011. The recommendations of the CONSORT 2010 Statement for reporting parallel group randomized trials were followed<sup>[14]</sup>.

### *Participants*

Patients were recruited among children referred to the Department of Paediatrics, the Medical University of Warsaw, from January 2009 to October 2011. The RCT included children aged 7-17 years with abdominal pain-related FGIDs classified according to the Rome III diagnostic criteria (Table 1)<sup>[5]</sup>. Patients with organic gastrointestinal diseases (as established by the medical history, complete blood count, urinalysis, stool examination for occult blood, ova and parasites, blood chemistries, abdominal ultrasound, breath hydrogen testing, and endoscopy, if needed), other chronic disease, or growth failure were excluded from the study. Additionally, during the time of the study, subjects were instructed not to take any medications that could influence the enteric flora, including antibiotics and commercially available probiotic or prebiotic preparations.

### *Interventions*

At the randomization visit, the inclusion criteria were checked. Potentially eligible patients were evaluated using a full review of their clinical histories and the results of a physical examination. The included subjects were randomized into a group receiving either GNN (Dicoman Junior, Vitis Pharma, Poland) at a dosage of 2.52 g/d, *i.e.*, 1 sachet of 1.26 g 2 times a day, or a group receiving a comparable placebo (maltodextrin) at the same dosage. The content of each sachet was dissolved in approximately 125 mL of fluid and was consumed twice daily for 4 wk. The manufacturer had no role in the conception, design, or conduct of the study or in the data analysis.

Subjects were instructed to ingest the preparation twice a day, in the morning and in the evening, for 4 wk and to record any symptoms in a questionnaire at the end of the study. At randomization, parents received 28 sachets for the first 2 wk of the study. After this period, the parents were contacted to examine the children's compliance with the treatment, provide them with the next 28 sachets, and schedule the exact timing of a final visit. The assessment of all outcome measures was based on the patients' questionnaires collected at the final visit. Additionally, the subjects and/or caregivers were asked to report the following information in their diaries: compli-

**Table 1 Study population baseline characteristics *n* (%)**

|  | Placebo    | Glucomannan |

| Number of subjects who required rescue therapy | 20         | 25          |

<sup>1</sup>Wilcoxon's test.

ance with consumption of the product and information on any other treatment given to the child during the study. The diary was constructed in a simple, understandable mode. The FACES Pain Scale Revised was used to assess the severity of pain<sup>[15]</sup>. The scale consists of 6 faces that reflect different levels of pain, ranging from a relaxed face on the left (no pain, indicating a score of 1 points - “face 0”) to a face showing intense pain on the right (highest pain possible, indicating a score of 6 points - “face 5”).

### Outcomes

The primary outcome measures included the proportion of patients with self-reported no pain and that of patients with treatment success, which was defined as no pain or a decrease of  $\geq 2/6$  points on the FACES Pain Scale Revised<sup>[15]</sup>. The subjective assessment of pain frequency, abdominal cramps, abdominal bloating/gasiness, the number of episodes of nausea or vomiting; changes in stool consistency (loose or constipated stools) during the study were the secondary outcome measures. Furthermore, the frequencies of school absenteeism and changes in daily activities were assessed, as was the percentage of children requiring rescue therapy. Finally, all adverse effects were recorded, and their possible relation to the study product consumption was evaluated. Compliance was assessed by direct questioning of the subjects or their caregivers during clinic visits.

### Randomization

Block randomization, with a block size of 6, was performed using a computer-generated random number list prepared by an investigator with no clinical involvement in the trial. The sequence was concealed until all data were analyzed.

### Blinding

Both the participants and the researchers conducting the study were blinded. The study intervention product was prepared centrally by the hospital pharmacy at the Medical University of Warsaw with the assistance of independent personnel who were not involved in the conduct of the trial. The active product and the placebo were packaged in identical sachets and labeled with one of two codes, each allocated to the experimental product or placebo. This procedure was performed by an independent pharmacist, who was the only person aware of the codes' meanings. The randomization numbers had been previously generated, and every patient eligible for inclusion received a consecutive number from the list. The appearance and texture of the dry placebo product were identical to those of the active product. When mixed with water, GNN turned into a substance of jelly-like consistency; however, this only occurred if the solution was not consumed within a few minutes, which was the recommended time limit for consumption.

### Statistical analysis

The sample size was based on the treatment success outcome (*i.e.*, the proportion of participants with no pain or a decrease of  $\geq 2/6$  points on the FACES Pain Scale Revised). It was estimated that an initial sample size of 80 patients would be sufficient to reveal a difference in the treatment effect of 30% (70% of the participants receiving GNN compared with 40% of the participants receiving placebo) considering that  $\alpha = 0.05$  and a power (beta) of 80%. The number of 80 for the children accounted for approximately 10% withdrawals or losses.

The computer software “R” [version 2.13.1 (2011-07-08)] was used for the analysis. Analyses of continuous data were performed with a parametric analysis (Student's *t*-test) in the case of a normal distribution of variables. The Mann-Whitney test was implemented for non-normally distributed variables. The  $\chi^2$  or Fisher's exact test were used, as appropriate, for the analysis of dichotomous outcomes. The RR or the mean difference (MD) with a 95%CI was calculated using the computer software StatsDirect [version 2.7.8b (2011-11-09)]. The differences between the study groups were considered to be statistically significant when the *P* value was  $< 0.05$  or when the 95%CI: for the RR did not exceed 1.0 or, for the MD, did not exceed 0. The results were analyzed using an Available Case Analysis (ACA).

### Ethical considerations

Parents and children were fully informed about the schedule and the aims of the study. Informed consent was obtained from at least one caregiver of each child included in the study and from all children older than 12 years of age.

The Ethics Committee of The Warsaw Medical University approved the study. The trial was registered at ClinicalTrials.gov (<http://clinicaltrials.gov>), number NCT 01495806.

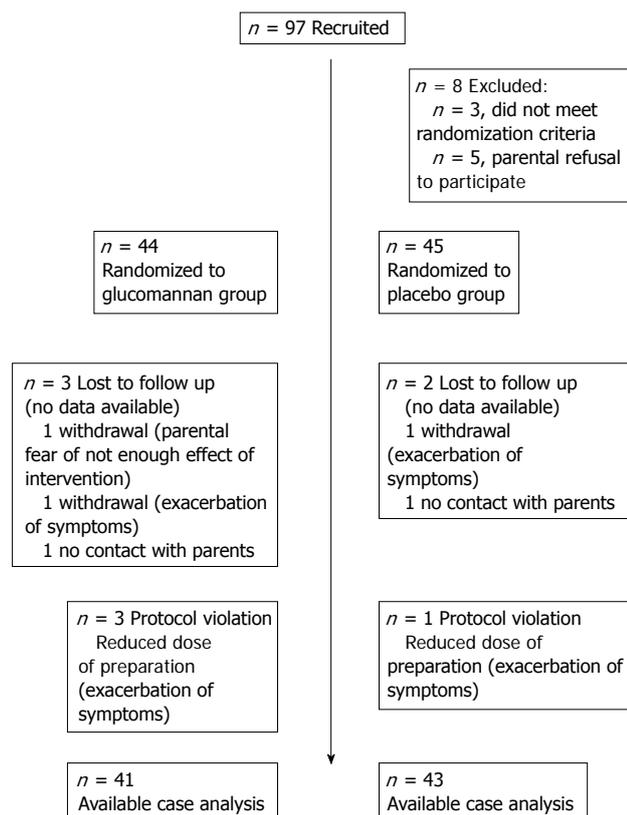

Figure 1 Flowchart of patients participating in the study. Declaration of funding interests: This study was funded in full by the Medical University of Warsaw.

## RESULTS

### Patients' characteristics and compliance

Figure 1 shows a flowchart of the subjects' progression through the study. Of the 97 eligible children, 89 underwent randomization. Among them, 44 children were assigned to the experimental GNN group, and 45 children were assigned to the placebo group. Of the 89 randomized children, 84 (94%) completed the study. There was no significant difference in the drop-out rate between the 2 groups. The baseline demographic and clinical characteristics were similar between the experimental and placebo groups (Table 1).

### Primary outcomes

Overall, 18 of the 84 (21%) subjects reported the primary outcome measure of 'no pain'. The subjects in the GNN group were more likely to experience "no pain" (29%) than the subjects in the placebo group (14%); however, the difference was not statistically significant (RR = 2.1, 95%CI: 0.87-5.07).

"Treatment success" (defined as no pain or a decrease  $\geq 2/6$  points on the FACES Pain Scale Revised) was similar between the study groups. Of the 41 children in the GNN group, 23 (56%) experienced treatment success, compared with 20 of the 43 (47%) in the placebo group (RR = 1.21, 95%CI: 0.79-1.83).

Originally, we had also planned to conduct a subgroup analysis (*e.g.*, FD, FAP, IBS). However, due to the small number of patients included in the subgroups and the overlap of symptoms between the patients with various types of functional disorders, we decided against conducting this analysis.

### Secondary outcomes

No significant differences between the GNN and placebo groups were observed in the secondary outcome measures, such as the subjective assessment of gastrointestinal symptoms: (1) Abdominal cramps (32% *vs* 49%, respectively;  $P = 0.12$ ); (2) Abdominal bloating/gassiness (44% *vs* 51%, respectively;  $P = 0.39$ ); (3) Number of episodes of nausea or vomiting (7% *vs* 2%, respectively;  $P = 0.34/24\%$  *vs* 33%, respectively;  $P = 0.31$ ); or (4) Change in stool consistency (loose stools: 29% *vs* 39%, respectively;  $P = 0.33$ ; constipated stools: 27% *vs* 21%, respectively;  $P = 0.53$ ).

### Rescue therapy

The percentage of patients requiring rescue therapy was similar in both groups (GNN 19% *vs* placebo 14%, respectively;  $P = 0.53$ ).

### Subjects' activities

The GNN supplementation showed no significant influence on the frequency of school absenteeism (10% *vs* 14%, respectively;  $P = 0.56$ ) or on changes in daily activities (27% *vs* 19%, respectively;  $P = 0.37$ ) during the study.

### Adverse effects

The GNN was well tolerated, and no adverse effects were recorded in any of the patients. However, 4 patients in the GNN group complained of an exacerbation of symptoms (1 discontinued the therapy; 3 required a dose reduction) compared with 2 patients in the placebo group (1 discontinued therapy; 1 required a dose reduction). Nonetheless, it was difficult to establish causality in these cases because the course of FGIDs was defined by exacerbations and periods of recovery.

## DISCUSSION

This prospective, double-blind, placebo-controlled, randomized study showed that GNN, a soluble fiber of the Japanese Konjac plant, as used in this study and setting for 4 wk, was not effective in reducing the frequency or severity of pain in children with abdominal pain-related FGIDs. Although "no pain" was more likely to occur in the GNN group, the difference was of borderline statistical significance.

The study groups did not differ with regard to any of the secondary outcomes, such as the proportion of patients with gastrointestinal symptoms during the study period, the need for rescue therapy, and the occurrence of adverse effects.

### Fiber as a treatment option for FGIDs

The optimal management strategy for abdominal pain-related FGIDs in children is a matter of ongoing debate. Because of their obscure pathophysiology, the management of FGIDs remains challenging. This difficulty has prompted interest in new and safe treatment options, among them dietary interventions.

Given their safety profiles, prebiotics (especially soluble fiber) appear to be attractive therapeutic options for FGIDs<sup>[16]</sup>. Dietary fiber is not digested by human enzymes but is instead fermented by the flora of the large intestine<sup>[17,18]</sup>. There are several reasons why these agents might, in theory, prove to be beneficial in the management of functional disorders. First, some studies have demonstrated the positive effects of prebiotics on changes in the intestinal microbiota through the selective stimulation of the growth of potentially protective bacteria (bifidobacteria and, in part, lactobacilli) and the simultaneous inhibition of potentially pathogenic microorganisms<sup>[8,19-23]</sup>. Second, fiber increases biomass, feces weight and defecation frequency, which can alter the volume and composition of the stool and gas<sup>[8,13,18,24]</sup>. These changes in intestinal contents can affect the gastrointestinal symptoms associated with functional disturbances<sup>[2,8,18]</sup>. Additionally, a reduction in the pH and the release of short-chain organic acids stabilize the intestinal environment<sup>[8,16,19,25]</sup>. Finally, prebiotic-induced changes could indirectly modulate various parameters of the immune system, such as the NK-cell activity, the secretion of Il-10 and interferon, and the lymphocyte proliferation that may establish intestinal regularity<sup>[8,18,26]</sup>.

Dietary fiber consumption has remained low in many populations, especially in children. The American Academy of Pediatrics recommends a daily dietary fiber intake for children of 0.5 g/kg body weight, up to 35 g/d<sup>[27]</sup>. Williams *et al.*<sup>[28]</sup> proposed a minimum daily fiber intake equivalent to the age in years plus 5 g/d for children older than 2 years of age.

Few studies have evaluated the response of functional abdominal disorders to prebiotics. Furthermore, most data on the possible use of prebiotics in the management of functional disorders and the rationale for their use are derived from the studies of adults with IBS<sup>[16,19,26]</sup>. Until now, there have been only 3 published papers (Christensen 1982, Christensen 1986, Feldman 1985), which described 2 trials and assessed the effect of fiber supplementation on FGIDs in children<sup>[9]</sup>. These 2 trials, which met the inclusion criteria for the Cochrane systematic review, concerned the dietary interventions for recurrent abdominal pain (RAP) and irritable bowel syndrome (IBS) in children<sup>[9]</sup>. Both studies involved a total of 92 children with recurrent abdominal pain, and they evaluated the effect of fiber supplementation on the improvement in gastrointestinal complaints<sup>[11,12]</sup>. According to this meta-analysis, the pooled odds ratio for improvement in the frequency of abdominal pain was 1.26 (95%CI: 0.25-6.29)<sup>[9]</sup>. Feldman *et al.*<sup>[12]</sup> (52 children recruited) described changes in the intensity of pain; however, the differences between

the fiber and placebo groups were not statistically significant. Christensen *et al.*<sup>[11]</sup> (40 children recruited) reported the mean number of episodes of pain during the study period, but the differences in the results between groups were also not statistically significant. The lack of recent findings concerning the potential application of fiber in the management of children with FGIDs instigated our decision to examine the effectiveness of GNN, which is composed of a dietary fiber, *i.e.*, water-soluble polysaccharide.

### Dose and duration of treatment

The optimal dose and treatment duration of GNN therapy have not yet been clearly established. Recently, we used GNN to treat functional constipation in children, where it proved to be relatively safe<sup>[13]</sup>. In the present study, regardless of the dietary recommendations for daily fiber intake, we used only one standard dose of fiber for all participants to provide a relatively easy administration regimen for the clinicians and parents. We applied a daily intake of 2.52 g/d, which exceeded the minimum dose of fiber suggested in the literature for therapeutic purposes<sup>[13]</sup>.

Considering the chronic nature of functional disorders, the chosen duration of treatment (4 wk) appears to be optimal for evaluating GNN's potential therapeutic influence on gastrointestinal complaints. The administration of GNN, a soluble fiber preparation, was the sole intervention implemented, allowing one to draw conclusions regarding its effectiveness without any confounding influence from other treatments.

### Participants

Evaluating children as study participants is a complicated issue because they complain of nonspecific chronic abdominal pain and constitute a heterogeneous group of patients. To minimize the heterogeneity of our study's population, the diagnosis was based on the well-recognized Rome III criteria<sup>[5]</sup>.

The trial was conducted in a pediatric department oriented towards the diagnosis and treatment of children with functional abdominal pain. Nevertheless, the possibility that only less affected patients were included in the study could not be entirely eliminated. The pattern of the response to treatment may differ from that in patients with more severe courses of functional disturbances.

### Strengths and limitations of the study

We used the appropriate methods to generate the allocation sequence and allocation concealment. We then strived to maintain the blinding of the selection, treatment, monitoring, data management, and data analyses throughout the study. In addition, the follow-up was appropriate. Data were obtained from more than the 94% of the participants. All of these features minimize the risk of systematic bias.

The lack of an apparent effect of GNN compared with the placebo may be explained by an inadequate dose

and an overly brief treatment period. Although the optimal dose and duration of treatment for GNN have not yet been established, a tentative conclusion can be drawn: subjects with abdominal pain-related FGIDs require a modification of the GNN dose and an extension of the period of supplementation to improve their gastrointestinal symptoms. Additionally, nutritional habits can modify the natural course of abdominal complaints. We realized that precise data on the daily fiber intake would be useful. However, collecting that type of information would have required the use of a food diary. We abstained from this process for 2 major reasons. First, our study population of children aged 7-17 years included children who attended school. Collecting reliable information from children in this age group represents a particularly challenging task. Second, the use of a food diary, especially in this group of patients, provides only an approximate evaluation of dietary intake. Moreover, the validity of paper diary records is sometimes questionable. Well-known problems with paper diaries include poor adherence and retrospective recording<sup>[29]</sup>. As there were no differences between the groups in terms of the baseline characteristics, we may expect that the randomization was implemented properly and that the daily fiber intake was similar in both groups.

It is known that success in treating patients with abdominal pain-related FGIDs depends on the relationship established between a patient and a physician. An “active listening approach” and an enthusiastic, positive, and encouraging attitude towards treatment help improve subjects’ responses to both the therapeutic attempts and the placebo<sup>[30]</sup>. The placebo effect in adults ranges from 10%-70% for FD and from 0%-84% for IBS<sup>[6]</sup>. We used a placebo control group, which is considered an essential requirement for interventional studies<sup>[31]</sup>. According to our previous experiences based on earlier studies conducted in children with functional abdominal pain and functional constipation, we were able to predict the high proportion of children who were responsive to the placebo<sup>[3,13]</sup>. Considering our positive patient-physician relationship, we expected a drop-out rate of approximately 10% (6% at the end of the trial), in contrast to the 20% drop-out rate estimated for most trials. Thus, paradoxically, these positive relationships can be a potential weakness of our investigation.

Finally, another potential limitation of this trial is that although the overall number of patients was adequate, the study did not allow the analysis of the data for a specific diagnosis of abdominal pain-related FGIDs, *e.g.*, FD, IBS or FAP.

Consequently, an obvious next step in future research should be to identify the characteristics of children with specific abdominal pain-related FGIDs who respond to GNN treatment. Identifying this group of patients will allow for the selection of the optimal GNN dose to improve long-term gastrointestinal symptoms. Further studies are also needed to explore the role of GNN in the pathophysiology of functional disorders.

In our setting, GNN as dosed in this study was no more effective than the placebo in achieving therapeutic success in the management of abdominal pain-related FGIDs in children.

## COMMENTS

### Background

Abdominal pain-related functional gastrointestinal disorders (FGIDs) are widespread complaints in the pediatric population, affecting from 13% to 38% of children and adolescents. The symptoms associated with FGIDs have a great impact on patients’ quality of life and their daily activities, which in turn can result in long-term psychological implications. Therefore a variety of therapeutic options have been considered to date.

### Research frontiers

Many clinicians routinely recommend the use of bulking agents or dietary fiber to stimulate regular bowel movements and to improve symptoms associated with FGIDs. However, only two small, randomized clinical trials (Christensen 1982, Feldman 1985) conducted in children with FGIDs, which compared the effects of added dietary fiber with placebo, were identified. The results and conclusions of these trials were not consistent.

### Innovations and breakthroughs

Development of the optimal management strategy for abdominal pain-related FGIDs in children is difficult. Soluble fiber seems to be an attractive therapeutic option for FGIDs. Only a small number of studies that have evaluated the response of functional abdominal disorders to fiber are available. Additionally, the optimal dose and treatment duration have not been clearly established yet. In the present study, the standard daily dose (2.52 g/d) of glucomannan was used for all participants in order to provide a relatively easy administration regimen for clinicians and parents. The dose was equal to the minimum dose of fiber suggested in the literature for therapeutic purposes. Because of the chronic nature of functional disorders, the 4 wk duration of treatment was chosen to evaluate glucomannan’s potential therapeutic influence on gastrointestinal complaints. The most important contribution of this study and its strength is its methodology. The adequate methods for generation of the allocation sequence, allocation concealment and blinding of selection, treatment, monitoring, data management, and data analyses were used throughout the study. Data were obtained from more than the 94% of the participants. All of these features minimize the risk of systematic bias.

### Applications

The study results suggest that, glucomannan was no more effective than placebo in achieving therapeutic success in the management of abdominal pain-related FGIDs in children.

### Terminology

Glucomannan, a polysaccharide of 1,4-D-glucose and D-mannose, is a soluble fiber from the Japanese Konjac plant. Glucomannan exhibits properties that are typical of dietary fiber. There are several reasons why these agents might, in theory, prove to be beneficial in the management of functional disorders. Some studies have demonstrated positive effects of fiber on changes in the intestinal microbiota by selective stimulation of the growth of potentially protective bacteria with simultaneous inhibition of potentially pathogenic microorganisms. Fiber increases biomass, feces weight and defecation frequency, which can in turn alter the volume and composition of stool and gas. These changes in intestinal contents can affect the gastrointestinal symptoms associated with functional disturbances.

### Peer review

This study employs a simple, methodologically sound model. The main conclusion of the study is the lack of influence of glucomannan supplementation on the level and duration of pain in children with FGIDs.

### Abstract

**AIM:** To evaluate the efficacy and safety of sodium hyaluronate solution (SH) in endoscopic submucosal dissection (ESD) of gastric neoplasms.

**METHODS:** A prospective multicenter randomized, double blind, controlled trial was designed and utilized in this study. A total of 76 patients with 5-20 mm sized gastric neoplasms were enrolled at three academic hospitals in South Korea from June 2011 to October 2011. Patients were randomly assigned to the 0.4% sodium

hyaluronate or control groups. All lesions underwent endoscopic ESD. ESD was performed with 0.4%SH and normal saline (NS) solution for submucosal injection. Efficacy was assessed using *en bloc* resection and the number of additional injections. Secondary evaluation variables were the volume of injection material, steepness of mucosal elevation, bleeding rate, procedural time and operator satisfaction. Finally, the safety was assessed by analyzing adverse events during the study.

**RESULTS:** The usefulness rate in the 0.4%SH group and the controlled group had statistically significant difference under intention to treat (ITT) analysis (90.91% vs 61.11%  $P = 0.0041$ ). Under per protocol (PP), the usefulness rate is statistically significant different (93.10% vs 61.76%,  $P = 0.0036$ ). The difference in volume of the solution injected between 0.4%SH group and the controlled group and NS group was also statistically significant under intention to treat and per protocol analysis (ITT:  $0.03 \pm 0.02$  mL vs  $0.06 \pm 0.03$  mL,  $P = 0.0003$ , PP:  $0.03 \pm 0.02$  mL vs  $0.06 \pm 0.03$  mL,  $P = 0.0004$ ). Satisfaction above the grade good was significantly higher in the SH group under intention to treat and per protocol analysis (ITT: 90.91% vs 61.11%,  $P = 0.0041$ , PP = 93.11% vs 61.77%,  $P = 0.0022$ ). Adverse events above grade 3 were not noticed in either group. All adverse events were treated and were judged as not associated with the submucosal injection solutions.

**CONCLUSION:** 0.4%SH solution is a safe and effective agent that doesn't cause any significant adverse events and is useful for submucosal injection during ESD.

**Key words:** Sodium hyaluronate; Endoscopic submucosal dissection; Gastric neoplasm; Endoscopic mucosal resection

**Core tip:** Saline-assisted endoscopic mucosal resection is an established method for excision of nonpolypoid early neoplastic lesions of the gastrointestinal tract. However, it is sometimes difficult to maintain a desired level of tissue elevation after injection of saline, especially when using a one-channeled endoscope. Adequate elevation of the mucosa and sufficient elevation time is achieved more effectively when a material more viscous than normal saline (NS) is used. The 0.4% sodium hyaluronate solution (SH) used in this study provides a more effective and prolonged cushion effect for large lesions without serious adverse events compared to NS. Therefore, endoscopic submucosal dissection (ESD) with SH is more useful than ESD with NS.

Kim YD, Lee J, Cho JY, Kim SW, Kim SH, Cho YK, Jang JS, Han JS, Cho JY. Efficacy and safety of 0.4 percent sodium hyaluronate for endoscopic submucosal dissection of gastric neoplasms. *World J Gastroenterol* 2013; 19(20): 3069-3076 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i20/3069.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i20.3069>

## INTRODUCTION

Endoscopic mucosal resection (EMR) using submucosal saline injection is an established method for excision of nonpolypoid early neoplastic lesions of the gastrointestinal tract<sup>[1,2]</sup>. Numerous resection methods have been developed using the submucosal injection technique. In 1998, Hosokawa developed an IT knife (insulated tipped electro-surgical knife) useful for endoscopic submucosal dissection (ESD)<sup>[3]</sup>, which has made *en bloc* resection of not only elevated lesions but depressive lesions without ulcers and flat lesions possible, compared to EMR. The procedure has minimal limitations regarding location and size of the lesions. The technical advancement of ESD combined with development of many endoscopic accessories has made ESD a standard treatment of early gastric cancer in selected cases.

The submucosa is a thin connective tissue layer with a lax structure compared to the mucosa or the muscularis propria. The injection of solutions to this layer forms a bulla and lifts the lesion above. Submucosal injection during ESD facilitates the removal of the lesions, provides a safety cushion during resection, and prevents perforations during the procedure. The most commonly used material is normal saline (NS). However, it is sometimes difficult to maintain a desired level of tissue elevation after an injection of saline, especially when using a one-channeled endoscope<sup>[4]</sup>.

An ideal submucosal injection solution would have a prolonged cushion effect, and be easily available and inexpensive, nontoxic, and easy to inject<sup>[5]</sup>. Sodium hyaluronate solution (SH) is a macromolecular polysaccharide composed of *D*-glucuronate and *N*-acetyl-*D*-

glucosamine. The high viscosity, elasticity, and lack of antigenicity or toxicity<sup>[6-8]</sup> have led to its extensive use in ophthalmologic surgical procedures and intra-articular injections. Since Yamamoto *et al*<sup>[9]</sup> reported the use of SH in porcine stomach yielding a more distinct and prolonged submucosal elevation compared to NS, numerous studies have used SH for difficult cases.

The authors aimed to compare the usefulness rate and safety of 0.4%SH in ESD as compared to NS in a multicenter prospective randomized double-blind control study.

## MATERIALS AND METHODS

### Patient selection

From June 2011 to October 2011, 76 patients with less than 20 mm sized early gastric cancer or gastric adenoma were enrolled in 3 independent academic hospitals in South Korea. Experienced endoscopists with more than 300 cases of ESD experience performed the ESD. Criteria for inclusion in the study were: (1) patients between the ages of 20 and 80; (2) patients with 5- to 20-mm early gastric cancer or gastric adenoma; and (3) patients who gave written informed consent. The limitation of the lesion size to less than 20 mm was based on the absolute indication criteria of ESD. Exclusion criteria of the study were: (1) residual or recurrent lesion; (2) lesions accompanied by ulcers; (3) undifferentiated cancer; (4) advanced malignant neoplasm; (5) patient with pacemakers; (6) history of hypersensitivity to hyaluronic acid; (7) serum creatinine  $\geq$  1.5 mg/dL or creatine clearance  $\leq$  50 mL/min; (8) patients with severe liver disease; (9) severe cardiovascular disease; (10) patient taking immunosuppressants including prednisolone or anti-cancer agents; (11) alcohol- or drug-addicts; (12) pregnant or lactating patients; and (13) patients judged by a physician as inappropriate for inclusion.

### Study design

The clinical trial was approved by the Korean Food and Drug Administration (KFDA) and the study protocol was approved by the Institutional Review Board of each center. Written informed consent was obtained from all the patients.

The study was double-blinded by having an independent investigational device manager that supplied the solutions used for the study. The endoscopist was blind to the material used. During the procedure, an experienced assistant did the injection of fluids to the submucosa. Although the endoscopist could visualize the elevation effect, the difference in pressure during injection of the material was known only to the injecting assistant. The injecting assistant did not take any part in evaluating the satisfaction grade of the materials. All lesions were resected through ESD. The margin of the lesion was marked through electrocautery and submucosal injection was done at the normal mucosa adjacent to the lesion. ESD was initiated after an adequate amount of solution was injected to lift the lesion. The maximum amount of

0.4%SH solution (Endo-Mucoup, BMI Korea, Co., Ltd) for the procedure was limited to 40 mL, which is 1/10 the nontoxic level administered into the peritoneum. The amount of SH solution supplied for the procedure was limited to 40 mL and any additional amount of injection needed used NS. Necessary medication or procedure for the treatment of coexisting disorders of the patients was allowed. Except for the use of epinephrine and indigo carmine, any other material for submucosal injection solution was prohibited.

The study was designed as a multicenter, randomized, double blind, and placebo-controlled trial. The primary outcome of the study was *en bloc* complete resection and additional injections of the solution used. *En bloc* complete resection was defined as *en bloc* resection with negative resection margins confirmed histopathologically. Additional resection was defined as the number of additional injects required to maintain the mucosal lifting for the procedure. The usefulness rate was defined as the percentage of *en bloc* complete resection with 1 or less additional injection during the procedure (Table 1). The 40 mL of SH was decided for the efficacy evaluation as it is 1/10 the nontoxic level administered into the peritoneum.

Secondary outcomes of the study included: (1) volume of the solution injected; (2) the steepness of the lift; (3) presence or absence of bleeding; (4) procedure time; and (5) satisfaction of the solution. The volume of the solution used for evaluation was the total amount of the solution divided by the area of the lesion (long diameter  $\times$  short diameter). The steepness of the lift was graded as steep, mild, or non lifted. The percentage of each grade was used for evaluation. Bleeding was defined as the need for electrocauterization before the incision and after injecting the submucosal solution. The procedure time was defined as the period from the marking of the margins to the completion of the excision. Satisfaction rate of the solution was comprehensively assessed by evaluating the *en bloc* complete resection rate and the number of additional injections (Table 1).

The safety of the solution was assessed through 5 grades of symptoms and signs unwarranted during the study. Grade 1 adverse event was defined as symptoms or signs that do not require treatment and do not inhibit daily activities. Grade 2 adverse events were defined as symptoms or signs that required treatment but did not inhibit daily activities. Grade 3 adverse events were when the patient experienced substantial discomfort leading to limitation of daily activities and requiring admission. Life-threatening adverse events were defined as grade 4. Death was defined as grade 5. For each adverse event, the clinician assessed the association of the response to the submucosal injection solution as definitely related, probably related, possibly related, probably not related, definitely not related, or unknown.

### Sample size

This multi center randomized, double-blind, placebo-controlled study was designed with a level of significance

$\alpha = 0.05$  and detection power  $1 - \beta = 0.8$  to test the superiority of the 0.4%SH solution compared to NS for the lift and maintenance of the submucosa during ESD. The calculated sample size was 76 patients. Thirty-four patients were analyzed in each group assuming a 10% rate of non-comparability in the two groups.

### Statistical analysis

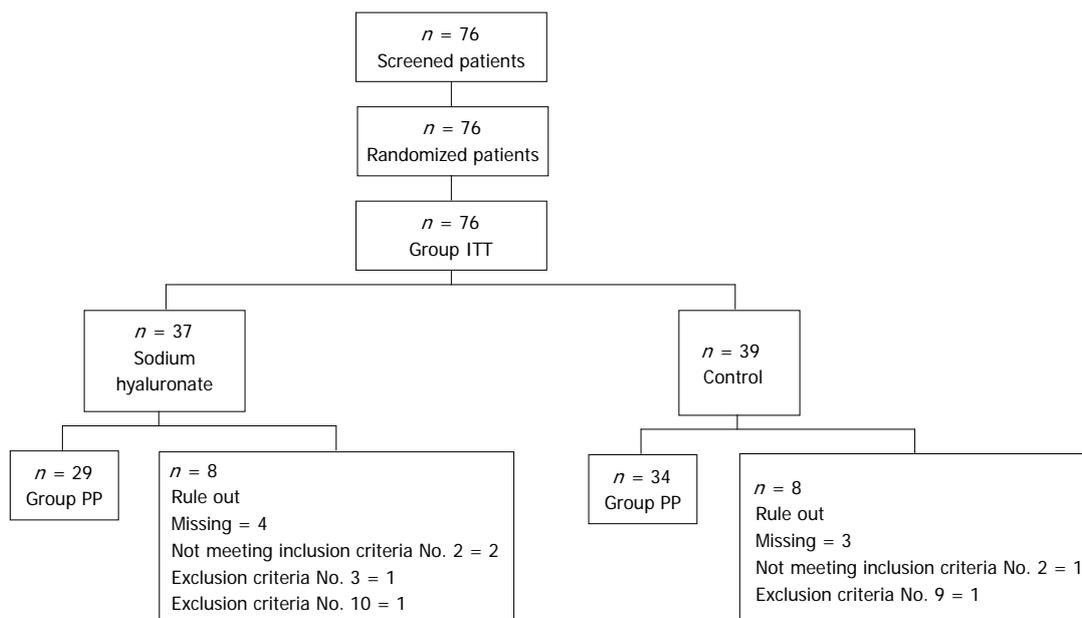

Statistical analysis was done using SAS software 9.1 version (SAS Institute, Cary, NC). Intention to treat analysis and per protocol analysis was used in the study. The clinical usefulness was assessed using both methods, with intention to treat as the primary method. Per protocol analysis was used for demographic data and adverse effects. Continuous variables for the two groups were compared using *t*-test and  $\chi^2$  test or the Fisher's exact test, which was used for categorical variables. The primary outcome, the usefulness rate, was analyzed using the  $\chi^2$  test and 95% CIs are given. The secondary outcomes, volume of the solution used and procedure time were analyzed using *t*-test. Presence or absence of bleeding and satisfaction of the solution was assessed using  $\chi^2$  test. Safety evaluation using the total number of the adverse effects and the rate of patients with more than 1 adverse effect was done using the  $\chi^2$  test. Null hypotheses of no difference were rejected if *P*-values were less than 0.05.

## RESULTS

Seventy-six patients who underwent screening examination and who gave informed written consent were included in this study. Using randomization, 37 patients were assigned to the 0.4%SH group and 39 patients were assigned to the control group that used NS for submucosal injection. All these patients were included in the intention to treat analysis. Eight patients from the 0.4%SH group and 5 patients from the control group were either lost to follow up or had a clinical trial protocol violation; the remaining 63 patients were included in the per protocol analysis (Figure 1). There were no statistically significant differences in the patients' age, sex, percentage of gastric cancer, or location of the lesion between the two groups (Table 2).

### Clinical usefulness

Usefulness, the primary outcome of the study, was assessed using both intention to treat analysis and per protocol analysis, with intention to treat as the primary method. Under intention to treat analysis, the usefulness rate of the 0.4%SH group (90.91%, 30/33) was found to be significantly greater than the control group (61.11%, 22/36) ( $P = 0.0041$ ). Using the per protocol analysis, the usefulness rate of the 0.4%SH group and the control were 93.10% (27/29) and 61.76% (21/34), respectively. The difference of the usefulness rate using per protocol analysis was also statistically significant ( $P = 0.0036$ ). The usefulness according to the site of the gastric neoplasm,

**Figure 1 Trial profile.** Inclusion criteria No. 2, 5 mm ≤ adenoma or adenocarcinoma ≤ 20 mm; exclusion criteria No. 3, undifferentiated adenocarcinoma; exclusion criteria No. 9, severe functional abnormalities of cardiovascular system; exclusion criteria No. 10, concomitant medication with systemic prednisolone, anticancer agents or immunosuppressive agents. ITT: Intention to treat; PP: Per protocol.

**Table 1 Measurement of usefulness and satisfaction**

| Complete <i>en bloc</i> resection | Additional injection | Usefulness | Satisfaction |
|-----------------------------------|----------------------|------------|--------------|
| Complete                          | 0                    | Usefulness | Excellent    |
| Complete                          | 1                    | Usefulness | Good         |
| Complete                          | ≥ 2                  | Useless    | Moderate     |
| Incomplete or not evaluated       | -                    | Useless    | Poor         |

using the intention to treat (ITT) analysis revealed that 0.4%SH was statistically significantly useful when used during procedures for gastric neoplasms at the body and angle. However, there was no statistically significant difference in procedures done at the antrum. Using a per-protocol analysis, 0.4%SH showed statistically significant usefulness in all the sites of the stomach.

Secondary outcomes of the study were analyzed including volume of the solution injected, the steepness of the lift, presence or absence of bleeding, procedure time, and satisfaction of the solution (Table 3).

The volume of the solution used for evaluation was the total amount of the solution divided by the area of the lesion (long diameter × short diameter). The volume of the solution injected for the 0.4%SH group (0.03 ± 0.02 mL) was significantly less compared to the control group (0.06 ± 0.03 mL) (P = 0.0003). The difference in volume of the solution injected between the 0.4%SH group and NS group using per protocol analysis was also statistically significant (P = 0.0004).

The procedure time was defined as the period from the marking of the margins to the completion of the excision. The procedure time analyzed by intention to treat showed 23.42 ± 16.76 min in the 0.4%SH group

and 21.64 ± 16.52 min in the control group. Using the per protocol analysis the procedure times were 23.79 ± 17.51 min in the 0.4%SH group and 19.71 ± 12.65 min in the control group. Although the procedure time for the 0.4%SH group was shorter compared to the control group, the difference was not statistically significant.

The steepness of the lift was graded as steep, mild, or non lifted in the two study groups and showed no statistically significant differences.

The absence of bleeding during injection of the submucosal solution was higher in the 0.4%SH group (96.97%, 32/33) compared to the control group (88.89%, 32/36) using the intention to treat analysis. Using the per protocol analysis, the absence of bleeding was 100% (29/29) in the 0.4%SH group and 88.24% (30/34) in the control group. However, the difference was not statistically significant in both analyses.

Satisfaction with the solution was comprehensively assessed by evaluating the *en bloc* complete resection rate and the number of additional injections. ESD with *en bloc* complete resection and no additional submucosal injection was defined as excellent. *En bloc* complete resection with 1 additional submucosal injection was defined as good. Satisfaction above the grade good was significantly higher in the 0.4%SH group (90.91%, 30/33) compared to the control group (61.11%, 22/36) using intention to treat analysis (P = 0.0175). Using per protocol analysis showed statistically significant difference in the satisfaction above the grade good in 93.11% (27/29) and 61.77% (21/34) in the 0.4%SH group and control group, respectively (P = 0.0022).

The ESD that had additional submucosal injections was analyzed by the site of the lesion using the usefulness rate, volume of solution injection and procedure time (Table 4).

**Table 2** Demographic characteristics of the patients at base line

ITT: Intention to treat; PP: Per protocol.

The sites of the lesion were divided into the antrum group and body/angle group. Under intention to treat analysis on antrum, there is no significant difference of the usefulness rate in the 0.4%SH group (90.00%, 18/20) compared to the control group (66.67%, 18/27) ( $P = 0.086$ ). But using per protocol analysis, the antrum had a significantly higher usefulness rate in the 0.4%SH group (93.75%, 15/16) compared to the control group (65.38%, 3/8) ( $P = 0.036$ ). The usefulness rate analyzed in the lesions located at the body/angle using intention to treat analysis was 92.30% (12/13) in the 0.4%SH group compared to the 66.67% (6/9) in the control group. The difference was statistically significant ( $P = 0.007$ ). Per protocol analysis also revealed a statistically significant higher usefulness rate of 92.30% (12/13) in the 0.4%SH group compared to 37.50% (3/8) in the control group ( $P = 0.007$ ).

The amount of volume injected at the antrum using intention to treat analysis was  $0.03 \pm 0.02$  mL in the 0.4%SH group and  $0.06 \pm 0.04$  mL in the control group.

**Table 4** Summary of results on location

ITT: Intention to treat; PP: Per protocol.

The smaller amount used in the 0.4%SH group was statistically significant ( $P = 0.003$ ). Using per protocol analysis, the difference in the amount of volume injected 0.4%SH group ( $0.03 \pm 0.02$  mL) and control group ( $0.06 \pm 0.04$  mL) was statistically significant ( $P = 0.011$ ).

The amount of volume injected at the body/angle using intention to treat analysis was  $0.03 \pm 0.02$  mL in the 0.4%SH group and  $0.05 \pm 0.02$  mL in the control group. The smaller amount used in the 0.4%SH group was statistically significant ( $P = 0.047$ ). Using per protocol analysis, the difference in the amount of volume injected 0.4%SH group ( $0.03 \pm 0.02$  mL) and control group ( $0.05 \pm 0.03$  mL) was statistically significant ( $P = 0.039$ ).

The procedure time using both intention to treat analysis and per protocol analysis based on the site of the lesion showed no statistically significant differences.

### Adverse events

Adverse events were seen in 8 out of the 76 patients, with 13 incidents in the intention to treat analysis. Grade 1 adverse events were noticed in 12.50% (5/37) of the SH group and 2.44% (1/39) of the control group. Grade 2 adverse events were seen in 7.50% (3/37) and 9.76% (4/39) of the 0.4%SH group and control group, respectively. Adverse events above grade 3 were not noticed in both groups. Gastrointestinal symptoms were the most common adverse events with 10 out of the 13 incidents. Five cases of nausea, 3 cases of vomiting, and each 1 case of dyspepsia and hematemesis were noticed. All adverse events were treated and were judged as not associated with the submucosal injection solutions.

## DISCUSSION

ESD is now a standard treatment for early gastric neo-

plasms in the gastrointestinal tract. The EMR used currently are strip-biopsy method or lift and cut EMR<sup>[10]</sup>, endoscopic resection after local injection of a solution of hypertonic saline and epinephrine<sup>[11]</sup>, endoscopic double-snare polypectomy<sup>[12]</sup>, EMR using an over-tube<sup>[13]</sup>, strip-biopsy using two small diameter endoscopes<sup>[14]</sup>, EMR with a cap-fitted panendoscope<sup>[15]</sup>, an EMR using a ligation device<sup>[16,17]</sup>. The submucosal injection of solutions during the resection of gastrointestinal neoplasm is an essential part of the resection procedure<sup>[18-21]</sup>. Tanabe *et al.*<sup>[10]</sup> introduced strip biopsy with submucosal injection using NS as a safety cushion. Since Ikeda *et al.*<sup>[22]</sup> injected a mixture of hypertonic saline and epinephrine to lift the lesion in 1986, lifting the lesion with a safety cushion underneath the lesion has become an essential procedure in EMR. ESD can resect a larger lesion without regard to the location of the lesion compared to EMR. To achieve an *en bloc* resection of a large lesion, adequate lift of the lesion is needed for a prolonged period. Numerous solutions are under research and have been used for mucosal resection. These agents include NS, mixture of NS and epinephrine, hypertonic saline (3.8%), hypertonic glucose solution (20%, 50%), 10% glycerin + 5% fructose + 0.9% NS, SH, hydroxypropyl methylcellulose, and a fibrinogen mixture. NS is easily available, cheap, and causes minimal tissue injury due to its isotonic property. However, NS is easily absorbed to the tissue and multiple injections are needed. The mixture of NS and epinephrine (1:10000) is most widely used. The steepness and maintenance of the cushion is not significantly different from NS, but the mixture of epinephrine causes vasoconstriction of the vessels leading to hemostasis. The addition of indigo carmine to the mixture assists in identifying the submucosa and muscularis propria during resection of the deep margins. However, during ESD, the cushion is easily dissipated and multiple injections are needed. This leads to a prolonged procedure time and the risk of perforation is high when resecting the lesion without adequate cushion. Therefore, an ideal agent would have a higher viscosity to maintain the cushion longer and require fewer additional injections during the procedure. Although hypertonic saline and hypertonic glucose solution had a steeper elevation compared to NS, this was not statistically significant. The hypertonic solution has a propensity to cause tissue injury and may delay healing of the artificial ulcer after the procedure.

SH has a prolonged cushion-effect and causes minimal tissue injury. However, the solution is expensive and has special requirements for storage. Hydroxypropyl methylcellulose has a similar viscosity and tensile strength compared to SH and has an adequate cushion-effect, is inexpensive, and is easy to store. However, the synthetic material can cause cross-antigen reaction in the body. Fibrinogen mixture is a 340 kDa high molecular glycoprotein separated from blood. The viscosity is high and has a microvascular hemostatic effect. However, the high viscosity requires a large diameter injection tip. Lee *et al.*<sup>[23]</sup> report that the fibrinogen mixture is superior to NS in

the procedure time, total volume of solution injection, and additional injection rates in ESD.

SH is considered the best solution for submucosal dissection. However, its use is limited due to the high cost of the solution. The molecular weight and dilution rate of SH is continuously researched to decrease the cost and find the dilution rate for effective lifting. Fujishiro *et al.*<sup>[24,25]</sup> report that the optimal viscosity and tensile strength was 1% 1900-kDa solution. However, 1% 800-kDa, 0.5% 1900-kDa, 0.5% z800-kDa, and 0.25% 1900-kDa solutions all showed similar results. Concentration of the solution below 1% still maintained adequate viscoelasticity while not increasing osmolarity or causing tissue injury. Despite the fact that it is an ideal substance for submucosal injection, the high cost and special requirements for storage led to a mixture of it with other hypertonic solutions.

This study evaluated the clinical usefulness and safety of 0.4%SH compared to NS. All procedures for the resection of the lesions were ESD. The size of the lesion was limited to 2cm due to the absolute indication of ESD for early gastric cancers without lymph node metastasis<sup>[14]</sup>. This led to the limitation of gastric adenoma size to less than 2cm. The primary outcome, usefulness rate, analyzed using intention to treat and per protocol analysis revealed higher and statistically significant rates in the 0.4%SH group. Secondary outcome of the study including volume of the solution injected, the steepness of the lift, presence or absence of bleeding, procedure time, and satisfaction with the solution were analyzed. The volume of the solution injected was statistically significantly decreased and satisfaction of the solution was significantly superior in the 0.4%SH group. The limitation of the size in the inclusion criteria may have limited the analysis of the resection rate in the two groups. The usefulness rate may have showed a more significant difference in the two groups as the size of the lesion is increased. The procedure time of the two groups in this study showed no statistically significant difference. This may have been due to the fact that the size of the lesion was limited to less than 2 cm. The experienced clinicians participating in this study may have decreased the difference in time required for the 2 groups. However, if larger lesions with scars were included in the study, even experienced clinicians may show a difference in the procedure time for the 2 groups due to the multiple injections that may be required to maintain the cushion-effect during the procedure. Therefore, a prospective study including gastric adenoma that has no limitation of size in *en bloc* resection using ESD may show a difference in the usefulness rate, volume of solution injected and satisfaction with the solution. The procedure time may show a significant difference because 0.4%SH had a prolonged cushion-effect and requires less additional injections compared to NS. There were grade 1 and grade 2 adverse events observed in this study. However, there was no statistically significant difference in the two groups and clinicians judged that the adverse events were not related to the solution

injected. Therefore, the use of 0.4%SH for submucosal injections during ESD is considered safe.

This study has a size limitation of 2 cm. Gotoda *et al.*<sup>26]</sup> reported that due to the lack of lymph node metastasis, mucosal gastric cancer less than 3 cm accompanied by an ulcer and submucosal gastric cancer invading the SM1 layer less than 3 cm are also indications of endoscopic therapy. This has formed the basis of the expanded criteria for endoscopic therapy in early gastric cancer. However, the current study was approved by the KFDA for absolute indications of ESD for early gastric cancer. The size of the gastric adenomas was also limited for evaluation of the two materials without bias.

The recent development of endoscopic accessories with more skilled clinicians has led to *en bloc* resection of lesions without regard to the location and size. This has led to a more extended indication of ESD and a solution with a long lasting cushion-effect is needed. Using NS for lesions that are easily approachable and small is cost-effective. However, for lesions that are large and difficult to approach, the procedure time could be prolonged with more frequent complications. In these cases, using 0.4%SH for the submucosal injection would be more cost-effective.

In conclusion, the ideal agent would have a prolonged cushion effect, be easily available, nontoxic, easy to inject, and inexpensive. SH has a long-lasting cushion effect compared to the widely used NS and leads to a safe and effective procedure. SH has no significant adverse events compared to NS and is safe. With the recent advances in the indication of ESD in early gastric cancer, development of endoscopic accessories, and more trained clinicians, the resection of large lesions without concern regarding the location of the lesion is possible. Therefore, with appropriate measures taken regarding price and storage issues, 0.4%SH may further enhance the ease and safety of ESD.

## COMMENTS

### Background

Endoscopic submucosal dissection (ESD) has made *en bloc* resection of early gastric neoplasms possible. A sufficient amount of submucosal fluid cushion is one of the important requisites for ESD. The ideal injection agent should provide a long-lasting submucosal cushion.

### Research frontiers

The submucosal injection during ESD is a requisite for safety during and after ESD. An ideal submucosal injection solution would have a prolonged cushion effect, be easily available, nontoxic, easy to inject, and inexpensive. Numerous solutions are being studied to determine if they are safe and effective in the procedure.

### Innovations and breakthroughs

There are no studies evaluating the efficacy and safety of sodium hyaluronate solution (SH) solution in ESD for gastric neoplasm in a Korean population.

### Applications

0.4%SH solution gives gastric mucosa long lasting lifting compared to normal saline (NS), thereby ESD using it is more effective compared to the control group. The solution is safe when comparing adverse events to the NS group. Therefore, 0.4%SH is a useful agent for submucosal injection during ESD.

### Peer review

This is a randomized controlled trial on efficacy and safety of 0.4% sodium hyaluronate for gastric ESD. It is worthy publishing.

### Abstract

**AIM:** To introduce robotic cholecystectomy (RC) using new port sites on the low abdominal area.

**METHODS:** From June 2010 to June 2011, a total of 178 RCs were performed at Ajou University Medical Center. We prospectively collected the set-up time (working time and docking time) and console time in all robotic procedures.

**RESULTS:** Eighty-three patients were male and 95 female; the age ranged from 18 to 72 years of age (mean  $54.6 \pm 15.0$  years). All robotic procedures were successfully completed. The mean operation time was  $52.4 \pm 17.1$  min. The set-up time and console time were  $11.9 \pm 5.4$  min (5-43 min) and  $15.1 \pm 8.0$  min (4-50 min), respectively. The conversion rate to laparoscopic or open procedures was zero. The complication rate was 0.6% ( $n = 1$ , bleeding). There was no bile duct injury or mortality. The mean hospital stay was  $1.4 \pm 1.1$  d. There was a significant correlation between the

console time and white blood cell count ( $r = 0.033$ ,  $P = 0.015$ ). In addition, the higher the white blood cell count (more than 10000), the longer the console time.

**CONCLUSION:** Robotic cholecystectomy using new port sites on the low abdominal area can be safely and efficiently performed, with sufficient patient satisfaction.

**Key words:** Robotic cholecystectomy; Port sites; Operation time; Abdominal area; Gallbladder disease

**Core tip:** The robotic procedure is safe; however, it is not acceptable as a standard operation for gallbladder disease because of its lack of benefits for patients as a result of the high cost and prolonged operating time. In the previous studies, port sites of robotic cholecystectomy were located on the supraumbilical area, similar to laparoscopic surgery. In this study, we changed the port placements from the upper abdominal area to the lower abdominal area.

### INTRODUCTION

Laparoscopic cholecystectomy is a standard technique for treatment of gallbladder diseases<sup>[1]</sup>. However, there are some disadvantages to using laparoscopic techniques<sup>[2]</sup>, and laparoscopic surgery can have a steep learning curve<sup>[3]</sup>. To overcome these limitations of laparoscopic techniques, the robotic-assisted procedure de-

veloped, the 3-dimensional view, magnification, tremor suppression, and flexibility of the instruments<sup>[4,5]</sup> have allowed precise operating techniques in general surgery<sup>[6-8]</sup>. Since the first robotic-assisted cholecystectomy was performed in 1997, many reports have been published, including comparative<sup>[8-10]</sup> and non-comparative studies<sup>[6,11-15]</sup>. All authors agreed on the safety and feasibility of the robotic procedure. However, most of them concluded that this procedure is not acceptable as a standard operation because of the lack of benefits for patients due to the high cost and prolonged operating time. In this regard, the benefits of the robotic procedure in gallbladder diseases have not yet been established.

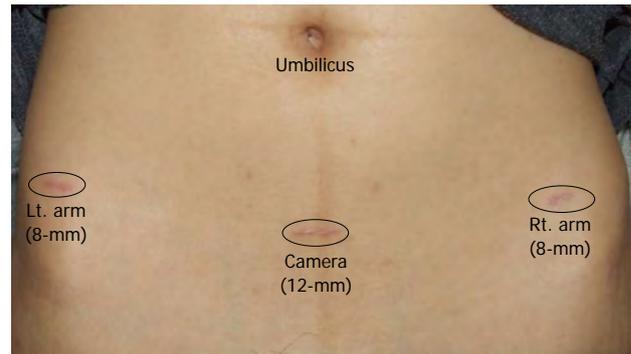

Based on the above reports, port sites of robotic cholecystectomy were located on the supraumbilical area, similar to laparoscopic surgery. As a result, we performed robotic cholecystectomy, changing the port placements from the upper abdominal area to the lower abdominal area. In this study, we examined robotic cholecystectomy using port sites located on the low abdominal area and evaluated its surgical outcomes.

## MATERIALS AND METHODS

From June 2010 to June 2011, a total of 178 robotic cholecystectomies were performed at Ajou University Medical Center. We prospectively collected the set-up time (working time and docking time) and console time in all robotic procedures. The initial indications of surgery included gallbladder polyp or symptomatic gallstones. Exclusion criteria were the presence of acute cholecystitis and previous history of extensive upper abdominal surgery. Informed consent was obtained for the robotic cholecystectomy. We retrospectively reviewed the medical records of all patients and analyzed data, including demographic information, clinical presentation, results of laboratory studies, operative records, postoperative complications, and postoperative hospital stay.

In this study, the operating time was defined as the time from skin incision to wound closure. The working time extended from the first skin incision until the decision to bring the da Vinci into place was made. The docking time spanned the setup of the robot onto the surgical field. The set-up time was defined as the time from skin incision until the start the dissection. The console time was defined as the time from the start of dissection until the moment the gallbladder was completely freed from the liver.

The robotic-assisted operations were performed with the 4-arm da Vinci robot system (Intuitive Surgical, CA, United States). The operating team consisted of one operating surgeon and one assisting resident. The assisting resident replaced instruments and paced clips during cholecystectomy. Robotic cholecystectomy was performed using a three or four port technique. A total of three trocars were utilized as shown in Figure 1. First, a 12-mm trocar was inserted through a vertical incision

**Figure 1** Port sites of robotic cholecystectomy. A 12-mm trocar was inserted through a vertical incision below the umbilicus using an open method. The 8-mm ports were placed 7 to 10 cm distant from the endoscope.

below the umbilicus using an open method. CO<sub>2</sub> gas was introduced through this trocar to obtain an intraperitoneal pressure of 12 mm Hg. All other ports were placed under direct visualization. The 8-mm ports were placed 7 to 10 cm distant from the endoscope. An additional fourth trocar (3 or 5 mm) was placed in the right anterior axillary line in the upper quadrant in cases of severe inflammation of gallbladder and thickening of the gallbladder wall and used for retraction and clip/loop placement.

The patient was then placed in reverse Trendelenburg position with the right side up. The da Vinci surgical robot was then brought into position and docked. The Maryland forceps was inserted into the right robotic positioner, and a cadere grasper was placed into the left positioner. The dissection was performed according to the critical view method as described by Strasberg *et al.*<sup>[16]</sup>. After clear identification of the cystic duct and cystic artery, only the cystic duct was ligated manually with clips. In contrast, the cystic artery was coagulated just around the gallbladder and not ligated. The gallbladder was dissected from the fossa and placed in an endoscopic retrieval bag. Once fully dissected, the gallbladder was removed through the umbilical port in an endopouch. The robot was then withdrawn, and the 12-mm port site was closed with absorbable sutures.

Patients were discharged 1 d after surgery if sufficiently recovered and if pain and nausea had receded. All patients were seen for examination and reassessment at the outpatient clinics 1 wk after surgery. Laboratory tests were performed only if indicated.

### Statistical analysis

Statistical analysis was performed with independent *t*-test, and Spearman's correlation. *P*-value < 0.05 was considered statistically significant.

## RESULTS

### Clinical findings

Eighty-three patients were male and 95 female; the age

Table 1 Clinical characteristics

|   | RC (n = 178)    |
|---|-----------------|
| Age (yr)                                  | 40.1 ± 9.8      |
| Gender (male/female)                      | 83/95           |
| Laboratory findings                       |                 |
| White blood cell count (/m <sup>3</sup> ) | 7483.4 ± 2670.8 |
| AST (IU/L)                                | 62.9 ± 124.0    |
| ALT (IU/L)                                | 68.9 ± 134.4    |
| Total bilirubin (mg/dL)                   | 1.0 ± 0.9       |
| Combined diseases                         |                 |
| Diabetes mellitus                         | 5               |
| Hypertension                              | 29              |

| COPD                                      | 0               |

RC: Robotic cholecystectomy; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; COPD: Chronic obstructive pulmonary disease.

Table 2 Operation time of robotic cholecystectomy

|                      | RC (n = 178) |
|----------------------|--------------|
| Operation time (min) | 52.4 ± 17.1  |
| Set-up time (min)    | 11.9 ± 5.4   |
| Working time (min)   | 7.6 ± 4.2    |
| Docking time (min)   | 4.3 ± 2.5    |
| Console time (min)   | 15.1 ± 8.0   |

RC: Robotic cholecystectomy.

ranged from 18 to 72 years of age (mean  $54.6 \pm 15.0$  years). Table 1 shows the clinical characteristics of patients who underwent robotic cholecystectomy. The associated diseases were hypertension ( $n = 29$ ), diabetes mellitus ( $n = 5$ ), hypothyroidism ( $n = 2$ ), and hepatitis ( $n = 2$ ). The previous operations were appendectomy ( $n = 10$ ), C-section ( $n = 10$ ), and hysterectomy ( $n = 1$ ). Endoscopic retrograde cholangiopancreatogram was performed in 18 patients. After surgery, two patients in robotic cholecystectomy (RC) group were diagnosed with gallbladder (GB) cancer. A 53-year-old man who was diagnosed with a gallbladder mass underwent cholecystectomy with lymph node dissection. Unfortunately, tumor penetrated the serosa layer of the gallbladder (T3N0). We recommended re-operation; however, he refused the surgery in our hospital and did not follow up. The other patient was a 60-year-old man who had undergone surgery for gallbladder polyp and was diagnosed with T1a gallbladder cancer. There was no recurrence for 8 mo after surgery.

### Surgical outcomes

All robotic procedures were successfully completed. The mean operation time was  $52.4 \pm 17.1$  min. The set-up time and console time were  $11.9 \pm 5.4$  min (5-43 min) and  $15.1 \pm 8.0$  min (4-50 min), respectively (Table 2). The conversion rate to laparoscopic or open procedures was zero. The complication rates was 0.6% ( $n = 1$ , bleeding) (Table 3). The patient who had complications was a

Table 3 Surgical outcomes of robotic cholecystectomy

|                                 | RC (n = 178)  |
|---------------------------------|---------------|
| Complications                   |               |
| Bleeding                        | 1             |
| Bile duct injury                | 0             |
| Open conversion                 | 0             |
| Total hospital stay (d)         | $2.9 \pm 1.8$ |
| Postoperative hospital stay (d) | $1.4 \pm 1.1$ |

RC: Robotic cholecystectomy.

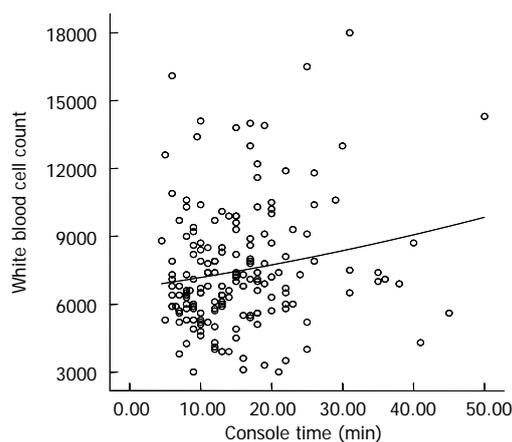

Figure 2 Correlation between console time and white blood cell count. There was a significant correlation between console time and white blood cell count ( $r = 0.182$ ,  $P = 0.015$ ).

34-year-old female who underwent re-operation on postoperative day 1; previous incisions on the low abdominal area were employed during the surgery. We identified the focus of bleeding on the gallbladder bed and coagulated the bleeder. She was finally discharged from the hospital without any symptoms. There was no bleeding associated with the cystic artery. There was no bile duct injury and mortality. The mean postoperative hospital stay was  $1.43 \pm 1.16$  d.

We analyzed the relationship between console time and other factors. The results showed that the only significant correlation was between console time and white blood cell count ( $r = 0.182$ ,  $P = 0.015$ ) (Figure 2). In addition, the higher the white blood cell count (more than 10000), the longer the console time (Table 4).

## DISCUSSION

Since 2005, when the robotic system was first introduced in South Korea, other investigators have also reported experience with surgical robotics in a variety of surgical procedures, including cholecystectomy, gastrectomy, and thyroidectomy<sup>[17-19]</sup>. However, hepato-biliary surgeons in South Korea stopped performing robotic-assisted cholecystectomy because of the lack of advantages for patients compared to its high cost<sup>[8,9,20]</sup>. In our hospital, we experienced the first fully robotic procedure in a pa-

**Table 4 Relationship between console time and inflammation of gallbladder**

|                    | WBC (< 10000)<br>(n = 151) | WBC (≥ 10000)<br>(n = 27) | P value |
|--------------------|----------------------------|---------------------------|---------|
| Console time (min) | 14.6 ± 7.5                 | 18.3 ± 9.9                | 0.025   |

WBC: White blood cell.

tient who was diagnosed with choledochal cyst; the patient underwent resection of the cyst and intracorporeal hepaticojejunostomy. After that, we decided to change the trocar placements when using the robotic system in gallbladder diseases. Before beginning robotic surgery, Professor Kim (Kim WH) also enrolled in the Intuitive Surgical da Vinci training course.

In the present study, we used only three of four arms of the da Vinci system to reduce the instrument-related costs. Most importantly, port sites were also much lower than the umbilical line. The 12-mm camera port site was located almost 10 cm from the umbilicus. The other two 8-mm port sites were located around the right and left anterior superior iliac spine. This line can be called the “Panty line” or “Bikini line”. All patients were satisfied with both the degree of postoperative pain and scarring. However, we experienced a problem in that the length of the robotic arms were too short to dissect the gallbladder, especially in big or obese patients. Indeed, Cadière *et al*<sup>[21]</sup>. Previously suggested that the robotic approach requires new operative strategies and a change in the pattern of trocar placement. Most surgeons will likely agree that, although Nio *et al*<sup>[9]</sup>. Reported on altered positioning of trocars in robot-assisted laparoscopic cholecystectomy, their locations were not different from the laparoscopic technique. In the early period of the study, we included patients who were diagnosed with gallbladder polyp or minimal symptomatic gallstones. As the number of cases increased, we attempted robotic procedures in cases of inflamed gallbladder, such as acute cholecystitis, empyematous cholecystitis, and gangrenous cholecystitis. According to previous reports, some authors did not perform robotic procedures in acute cholecystitis<sup>[11,22,23]</sup>. In study by Ruurda *et al*<sup>[14]</sup>, the rates of acute cholecystitis were 17%, and there was one conversion to an open procedure, caused by the surgeons’ inability to expose the gallbladder sufficiently because of severe cholecystitis. In the present study, there was no conversion to laparoscopic or open procedures after including cases of acute cholecystitis.

Thus far, most authors have reported that the operation time of robotic procedures was much longer than cases that used laparoscopic technique. The operation time varied, with a range of 55-152 min<sup>[13,14,21,23-28]</sup>. The reason for the various results in those studies was that the definition of the operation time was heterogeneous; the operation time was defined as the time from skin incision to skin closure, or it included anesthesia or time

in the robotic room. In the present study, the operation time was 81.3 ± 19.0, similar to other results<sup>[14,21,24-28]</sup>. Marescaux *et al*<sup>[24]</sup> reported that the median time for dissection was 25 min (range 14-109 min) and the overall operative time was 108 min, similar to times of conventional laparoscopy. In this study, the console time was 15.1 ± 8.0 min, similar to another report<sup>[24]</sup>. The console time in cases of inflamed gallbladder was longer than that of cases of non-inflamed gallbladder.

The conversion rates of robotic procedures in other studies have been almost zero<sup>[9,13,21,22,25,27]</sup>; our data showed similar results. However, Miller *et al*<sup>[28]</sup> reported that conversion to conventional laparoscopic techniques was necessary due to malfunction of graspers in three consecutive procedures. The other reasons for conversion were in cases of acute cholecystitis<sup>[24]</sup>, presence of severe adhesions, and poor visualization<sup>[26]</sup>. In this study, we found that the fourth 5-mm instrument was effective in grasping and retracting the edematous gallbladder. Until now, we have experienced no conversion after the indications were expanded to include severe acute cholecystitis. There are two published reports of 8-mm port-site hernias, so it should be recommended that any port greater than 5 mm in diameter should be routinely sutured closed<sup>[22,29]</sup>. We did not experience an 8-mm port-site hernia, likely due to the short follow-up period after surgery.

To our knowledge, this study is the first large series of robotic cholecystectomy in South Korea. Some advantages of robotic cholecystectomy from this study are as follows. First, patient satisfaction regarding a lower lying wound was very high because of the absence of a scar on the upper abdominal area. Second, the subjective perception of the surgeons is that the robotic system makes dissection easier at Callot’s triangle. Furthermore, the use of the robotics allowed the surgeon to remain in an ergonomic position throughout the procedure. This could reduce the fatigue experienced during prolonged or difficult operations, especially in cases of severe acute cholecystitis. Third, the robotic procedure is safely performed in patients who underwent upper abdominal surgery, because an adhesiolysis can be easily performed throughout the lower lying port sites.

In summary, robotic cholecystectomy using the new port sites on the low abdominal area can be safely and efficiently performed, with sufficient patient satisfaction. However, we recommend that the more difficult cases (due to acute inflammation) were likely excluded from participation in an early period.

## COMMENTS

### Background

To overcome the limitations of laparoscopic techniques, the robotic-assisted procedure developed, the 3-dimensional view, magnification, tremor suppression, and flexibility of the instruments have allowed precise operating techniques in general surgery. The robotic procedure is safe; however, it is not acceptable as a standard operation for gallbladder disease because of the lack

of advantages for patients compared to its high cost.

### Research frontiers

Since the first robotic-assisted cholecystectomy was performed in 1997, the benefits of the robotic procedure in gallbladder diseases have not yet been established. In the previous studies, port sites of robotic cholecystectomy were located on the supraumbilical area, similar to laparoscopic surgery. As a result, we performed robotic cholecystectomy, changing the port placements.

### Innovations and breakthroughs

Recent reports have highlighted the importance of changing the port placements from the upper abdominal area to the lower abdominal area. This is the first study to report that robotic cholecystectomy with lower lying ports can be safely and efficiently performed.

### Applications

This study may represent a new strategy for surgical intervention in the treatment of patients with gallbladder diseases.

### Terminology

Da Vinci robot system (Intuitive Surgical, CA, United States) is composed of the surgeon's viewing and control console and a movable cart with four articulated robot arms.

### Peer review

This study is a feasibility study that demonstrates that robotically assisted cholecystectomy may be performed. The technical details of port placement by the authors will make it helpful to the general surgeon who wishes to use the robot to assist with cholecystectomy.

### Abstract

**AIM:** To analyze whether high-intensity focused ultrasound (HIFU) ablation is an effective bridging therapy for patients with hepatocellular carcinoma (HCC).

**METHODS:** From January 2007 to December 2010, 49 consecutive HCC patients were listed for liver transplantation (UCSF criteria). The median waiting time

for transplantation was 9.5 mo. Twenty-nine patients received transarterial chemoembolization (TACE) as a bridging therapy and 16 patients received no treatment before transplantation. Five patients received HIFU ablation as a bridging therapy. Another five patients with the same tumor staging (within the UCSF criteria) who received HIFU ablation but not on the transplant list were included for comparison. Patients were comparable in terms of Child-Pugh and model for end-stage liver disease scores, tumor size and number, and cause of cirrhosis.

**RESULTS:** The HIFU group and TACE group showed no difference in terms of tumor size and tumor number. One patient in the HIFU group and no patient in the TACE group had gross ascites. The median hospital stay was 1 d (range, 1-21 d) in the TACE group and two days (range, 1-9 d) in the HIFU group ( $P < 0.000$ ). No HIFU-related complication occurred. In the HIFU group, nine patients (90%) had complete response and one patient (10%) had partial response to the treatment. In the TACE group, only one patient (3%) had response to the treatment while 14 patients (48%) had stable disease and 14 patients (48%) had progressive disease ( $P = 0.00$ ). Seven patients in the TACE group and no patient in the HIFU group dropped out from the transplant waiting list ( $P = 0.559$ ).

**CONCLUSION:** HIFU ablation is safe and effective in the treatment of HCC for patients with advanced cirrhosis. It may reduce the drop-out rate of liver transplant candidate.

## INTRODUCTION

Deceased donor liver transplantation provides one of the best treatments to patients with hepatocellular carcinoma (HCC) and cirrhosis. The numbers of donations and cases performed are on a rising trend. However, the scarcity of liver grafts in many parts of the world, especially Asia, leads to a significant dropout rate of patients from liver transplant waiting lists, particularly patients with HCC and a low model for end-stage liver disease (MELD) score<sup>[1]</sup>. In order to reduce the dropout rate, different bridging therapies have been proposed. Among them, transarterial chemoembolization (TACE) and radiofrequency ablation (RFA) are most popular. Despite of treatment applied before liver transplantation, the dropout rate for TACE ranged from 15% to 35% in different studies<sup>[1,2]</sup>. RFA seems to have produced better results but the dropout rate also ranged from 5.8% to 14% in various studies<sup>[3,4]</sup>.

High-intensity focused ultrasound (HIFU) ablation is one of the latest treatments. It provides a totally non-invasive therapy to HCC and is viable even in patients with severe cirrhosis. In one of our previous studies, it achieved a complete ablation rate of 82.4% for HCCs smaller than 3 cm in with just one treatment session. It is well tolerated even in patients with advanced cirrhosis and age<sup>[5]</sup>. The current study is the first study that investigates whether HIFU therapy can be safely performed in HCC patients with cirrhosis and whether it can reduce the dropout rate of liver transplant candidates.

## MATERIALS AND METHODS

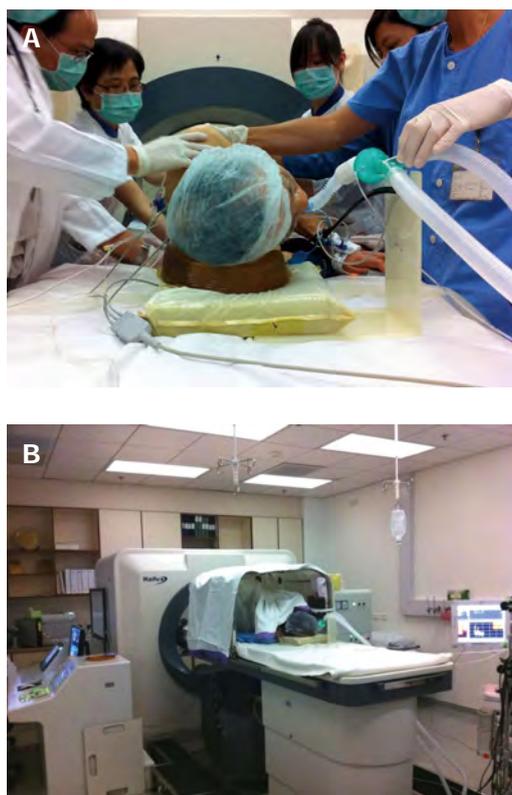

From January 2007 to December 2010, 49 consecutive HCC patients were listed for deceased donor liver transplantation (UCSF criteria). The diagnosis of HCC was confirmed by histology, elevated level of serum alpha-fetoprotein (> 400 ng/mL), or typical radiological appearance of lesion shown by contrast computed tomography or contrast magnetic resonance imaging. The median waiting time for transplantation was 9.5 mo. Patients who were listed for transplantation received TACE as a bridging therapy before transplantation. HIFU ablation has been used as a standard local ablative therapy since 2006 for HCC patients who have poor liver function and cannot tolerate hepatectomy<sup>[5]</sup>. This is a retrospective study performed with prospectively collected data. Informed consent to treatment and to the use of data for research was obtained beforehand.

Five patients received HIFU ablation and 29 patients received TACE as a bridging therapy. Fifteen patients received no treatment before transplantation. Another five patients with the same tumor staging (within the UCSF criteria) who were not on the transplant waiting list but received HIFU ablation were included for comparison. All patients were comparable in terms of Child-Pugh and MELD scores, tumor size and number, and cause of cirrhosis.

Contraindications to TACE included main portal vein thrombosis, arteriovenous shunting, Child-Pugh C cirrhosis, and extrahepatic metastasis. Cisplatin was used as the chemotherapeutic agent and was delivered with Lipiodol, followed by Gelfoam particle embolization. Selective cannulation and embolization of the feeding arteries of the tumors were performed whenever possible. During the procedure, 10 mL of Lipiodol was mixed with 10 mg of cisplatin into a 20 mL emulsion. Depending on the tumor size and number, 4-60 mL of the Lipiodol emulsion was injected into the catheter placed in the artery supplying the tumor, or into the hepatic artery proper beyond the gastroduodenal artery for bilobar disease. Light embolization of the feeding artery was then performed with pellets sized 1 mm × 2 mm mixed with 40 mg of gentamycin. Gelfoam injection was stopped when the blood flow in the artery supplying the tumor slowed down but before occlusion occurred. TACE was repeated every 2 to 3 mo. Patients were monitored every month for hepatic and renal functions and alpha-fetoprotein level. TACE was terminated if there was evidence of further derangement of liver function (bilirubin > 50 μmol/L, ascites not controlled by diuretics, or hepatic encephalopathy), progression of disease, extrahepatic metastasis, or any other major complication.

HIFU ablation was offered to patients with poor liver function or decompensated cirrhosis as documented by (1) presence of gross ascites; (2) disease at Child-Pugh B or above; and (3) tumor located at site considered difficult for percutaneous RFA. The treatment probe can target lesions as deep as 10 cm beneath the skin; any lesion within this range can be ablated. Contraindications to HIFU ablation included serum bilirubin level above 100 μmol/L and subcutaneous tissue thicker than 3.5 cm as adipose tissue would absorb a substantial amount of energy from the energy pathway.

All HIFU treatments were carried out by experienced hepatobiliary surgeons and radiologists. The JC HIFU system (Chongqing Haifu Technology, Chongqing, China) was used. The system comprises a real-time diagnostic imaging unit, a therapeutic unit, a degassed water circulation unit, and a computer system. The real-time diagnostic imaging unit provides direct visualization of the tumor. The therapeutic unit consists of an ultrasound energy transducer which focuses the ultrasound energy at a 12-cm focal point. The degassed water circulation unit provides a medium for ultrasound transmission outside the body. The computer system controls these three units.

**Figure 1** Locations of patient and control panel to the treatment console. A: The patient was placed in a right lateral position on the treatment console; B: The control panel is located next to the treatment console.

Before operation, the skin of the patient was cleaned by 70% alcohol followed by degassed water to remove all the grease from the skin. A dose of antibiotics (1.2 g of amoxicillin/clavulanic acid) was given on induction. A dose of proton pump inhibitor was also given on induction. Every patient was subjected to general anesthesia to aid comfort as the whole procedure could last for 3 h and the patient had to lie still and endure long periods of breath-holding. In addition, general anesthesia allowed manipulation of tumor location by the Valsalva maneuver during the procedure. If the tumor was at the dome of the liver, artificial right pleural effusion was induced before treatment. If the tumor was located at the right lobe of the liver, the patient was put in a right lateral position (Figure 1A). For better ultrasound conduction, the patient was put in a water bath. The surgeon and the radiologist controlled the operation from the control panel next to the treatment unit (Figure 1B). The treatment was performed under real-time ultrasound image guidance. The lesion was localized by a 3.6-MHz diagnostic ultrasound probe (Philips) incorporated at the center of the transducer. Parallel slices of the target tumor with 5-mm separations were planned and then ablated slice by slice with focused ultrasound energy produced by the transducer operating at 0.8 MHz. Grey-scale changes of the ablated sites were observed during the ablation procedure, indicating the temperature change inside the target lesion.

After the procedure, the patient was usually sent to the general ward and was closely monitored for vital signs, particularly body temperature. Transient hypothermia could occur as the patient had been immersed in a water bath. For patients who had received artificial pleural effusion, radiograph of the chest was taken to check for pneumothorax.

Tumor response was categorized according to the RECIST criteria: (1) complete response was denoted by disappearance of all target lesions; (2) partial response was denoted by at least a 30% decrease in the sum of the largest diameters of the target lesions; (3) progressive disease was denoted by at least a 20% increase in the sum of the largest diameters of the target lesions or appearance of one or more new lesions; and (4) stable disease was denoted by the absence of sufficient shrinkage of tumor qualified as partial response and the absence of sufficient increase of tumor qualified as progressive disease<sup>[6]</sup>. Contrast computed tomography or contrast magnetic resonance imaging was performed one month after the HIFU treatment and then every three month to evaluate tumor response before transplantation.

### Statistical analysis

The baseline characteristics of patients were expressed as medians with range. The Mann-Whitney *U* test was used to compare continuous variables and a  $\chi^2$  test was used to compare discrete variables. Statistical significance was denoted by  $P < 0.05$ . All statistical calculations were made with the SPSS/PC + computer software (SPSS, Chicago, IL, United States).

## RESULTS

The TACE group and the HIFU group had no difference in age, hepatitis B virus infection, or hepatitis C virus infection. The two groups of patients had similar liver function in terms of serum levels of albumin, aspartate aminotransferase and alanine aminotransferase, prothrombin time, indocyanine green retention rate, and international normalized ratio. One patient in the HIFU group had gross ascites before treatment. No patient in the TACE group had gross ascites. The two groups showed no difference in terms of tumor size and tumor number (Table 1). Table 2 shows the Child-Pugh and MELD scores of the patients. The median number of sessions of TACE was 3 (range, 1-7).

The median hospital stay was 1 d (range, 1-21 d) in the TACE group and two days (range, 1-9 d) in the HIFU group ( $P < 0.000$ ). Seven patients in the TACE group dropped out from liver transplant waiting list. One of them developed extrahepatic metastasis and six of them had local progression of disease rendering them unqualified for transplantation. No patient in the HIFU group dropped out during the study period ( $P = 0.559$ ).

According to the RECIST criteria, nine patients (90%) had complete response and one patient (10%) had partial response in the HIFU group. In the TACE group, only

Data are expressed as absolute *n* (%) or median (range). HIFU: High-intensity focused ultrasound; TACE: Transarterial chemoembolization.

one patient (3%) had response to the treatment while 14 patients (48%) had stable disease and 14 patients (48%) had progressive disease (*P* = 0.00).

Three out of the five patients in the HIFU group subsequently received transplantation. The median waiting time was nine months (range, 3-36 mo). Histopathological examination showed coagulation necrosis with no active tumor cells in two of the excised livers. One patient had 90% necrosis of the HCC. None of the patients who had received HIFU ablation as a bridging therapy developed complication due to intolerance of the procedure. The other two patients who were still waiting for transplantation had stable disease during the study period.

## DISCUSSION

The incidence of HCC is increasing throughout the world. The annual incidence of HCC in hepatitis B carriers is around 0.5%. The incidence in patients with liver cirrhosis is even higher at around 2.5% annually<sup>[7,8]</sup>. Hepatitis-B-related cirrhosis is common in Asia, where HCC is endemic. Other risk factors for the development of HCC include hepatitis C infection, alcoholic cirrhosis, genetic hemochromatosis, and primary biliary cirrhosis. These patients should be offered regular surveillance in order to identify small tumors that may be potentially treatable. However, most patients with small HCCs have no symptoms. Resection is the main hope of cure for HCC but is only possible in 25% of the patients because the disease is usually so advanced at presentation and is frequently associated with cirrhosis<sup>[9,10]</sup>. For patients with unresectable HCC, liver transplantation appears to be the only viable option. The chance of receiving a liver graft varies worldwide. Liver donation rate is highest in Spain where there are 33.7 donations per one million of the population. In contrast, the donation rates in Asia range from only 0.05 to 4.3 donations per one million of the popula-

MELD: Model for end-stage liver disease; HIFU: High-intensity focused ultrasound; TACE: Transarterial chemoembolization.

tion. The general lack of suitable deceased donors makes successful liver transplantation for HCC difficult<sup>[11,12]</sup>. In order to maximize the benefit of utilizing this scarce resource, different liver graft allocation systems are adopted worldwide. The principle of allocation is to prioritize the sickest and yet maintain the highest survival rate possible. As a corollary, patients with very high MELD scores have priority. In most countries, patients with unresectable HCC and yet lower MELD scores have a low priority.

The results of liver transplantations in the early period of development were not satisfactory, with a 5-year survival rate below 40%. This urged recognition of poor prognostic factors in liver transplantation in patients with HCC<sup>[13]</sup>. Mazzaferro *et al.*<sup>[14,15]</sup> showed that a subgroup of patients with radiological evidence of a single tumor smaller than 5 cm in diameter or two to three tumors each smaller than 3 cm in diameter had better survival outcome. The Milan criteria were established in 1996 and have led to the improvement of the 5-year survival rate to 83%. At many transplant centers, patients with tumor status beyond the Milan criteria are not accepted for transplantation and those on transplant waiting lists are delisted if their tumors enlarge to beyond the criteria, ensuring that liver grafts are allocated to patients predicted to have longer survival<sup>[16]</sup>.

In order to make sure patients receive appropriate treatment before transplantation so as to remain listed, different bridging therapies have been tried. This is particularly important for patients whose treatment options are limited by poor liver reserve and portal hypertension. TACE and RFA are the most popular bridging therapies.

TACE is a standard bridging therapy at some centers, achieving a rate of down-staging of tumors of around 40%. However, about 20% of patients develop tumor progression after TACE, rendering them delisted<sup>[1,2,17,18]</sup>. RFA is an effective thermal ablative treatment modality and is widely practiced to treat small HCCs. RFA is

**Figure 2** The tumor nodule shows coagulative necrosis. The necrotic tumor tissue shows a barely preserved architectural pattern and loss of cellular details. Hematoxylin and eosin stain,  $\times 200$ .

also used as a bridging therapy. Successful tumor downstaging is observed in 70%-85% of patients. However, the dropout rate after RFA is around 14%<sup>[3,19-21]</sup>. TACE and RFA seem to be effective bridging therapies, but only for selected patients. They are not safe for patients with liver decompensation such as gross ascites and thrombocytopenia.

The concept of using ultrasound energy as a penetrating force to destroy something remote originated in last century and was summarized by Kremkau<sup>[22]</sup>. In the 1950's, researchers brought the phenomenon of piezoelectricity to the clinical setting, treating Parkinson's disease and other neurological conditions with focused ultrasound energy<sup>[23-26]</sup>.

Nowadays clinical HIFU ablation for liver tumors utilizes a unique frequency of ultrasound wave, 0.8-3.5 MHz, which can be focused at a distance from the therapeutic transducer. The accumulated energy at the focused region induces necrosis of the target lesion by elevating the tissue temperature to above 60 °C<sup>[27,28]</sup>. Temperature outside the focus point remains static as particle oscillation remains minimal. This is an advantage of HIFU over RFA in which inadvertent collateral damage is unavoidable. Patients with derangement of liver function and thrombocytopenia usually show intolerance of RFA<sup>[29]</sup>. A bridging therapy must not cause further liver decompensation. The slow process of heating by HIFU energy propagation followed by resting leads to little tissue destruction beyond the focused point.

The presence of gross ascites facilitates HIFU treatment. As ultrasound energy travels much better in water than in air, ascites encourages energy propagation to the target lesion. In addition, the presence of ascites acts as a cushion of coolant inside the peritoneal cavity and prevents the muscle wall and skin absorbing too much energy from the beam pathway where subcutaneous tissue burn could happen.

HIFU ablation is a totally extracorporeal non-invasive treatment modality using focused ultrasound energy that is capable of causing coagulative necrosis of the target lesion via intact skin without the need of surgical incision.

The unique needleless design of the HIFU system makes HIFU ablation superior to RFA, as percutaneous needle penetration may induce hemorrhage from a hypervascular tumor in a patient with coagulopathy and a low platelet count. Furthermore, without needle puncture, there is no risk of direct tumor seeding to the surrounding major vessels<sup>[30]</sup>. For tumors located at the dome of the liver, open RFA would be required if HIFU ablation is not used.

Figure 2 demonstrates the effect of HIFU ablation on the HCC in one of the excised liver in the series in the present study. Coagulative necrosis of the tumor was observed microscopically on almost the whole cut surface. Although histological examination showed the presence of viable tumor cells at a few focuses, there was no gross tumor progression. HIFU ablation was a successful bridging therapy in this case in which TACE and RFA were not considered acceptable treatment due to the poor liver reserve.

Repeated sessions of HIFU or adjuvant TACE should be performed to enhance the effect of tumor necrosis when liver function allows and the waiting time is prolonged.

Wu *et al.*<sup>[31]</sup> reported the results of HIFU treatment for 68 patients with liver tumors. Thirty patients subsequently received liver resection. In histological examination, all the lesions showed complete coagulation necrosis.

We recently published the results of HIFU treatment for 49 patients with HCC. The complete ablation rate was comparable to that of RFA, ranging from 79.5% to 82.4%. The complication rate was around 8.2%. The complications were mainly mild skin edema and injury due to energy accumulation at the ultrasound beam pathway. The treatment was well tolerated in most of the patients. The median hospital stay was 4 d<sup>[5]</sup>.

In conclusion, to the best of our knowledge, we are the first liver transplant center investigating HIFU ablation as a bridging therapy before liver transplantation. In this study, HIFU ablation was shown to be an effective thermal ablation method. The treatment stopped gross tumor progression in a patient with severe cirrhosis when TACE and RFA were contraindicated. HIFU treatment can potentially reduce the dropout rate of patients from the transplant waiting list. In a broader sense, HIFU may prolong the survival of selected patients with decompensated cirrhosis for which liver transplantation is not an option.

## COMMENTS

### Background

The lack of liver grafts in many places, particularly Asia, is the major obstacle to liver transplantation for patients with hepatocellular carcinoma (HCC). An effective bridging therapy which is well tolerated by patients with decompensated liver cirrhosis is important and much needed.

### Research frontiers

High-intensity focused ultrasound (HIFU) ablation is a relatively new technique which provides a non-invasive treatment for HCC. However, its efficacy and safety in candidates of liver transplantation have not been known. In this study, the authors demonstrated that it is an effective treatment modality for liver

transplant candidates who have decompensated cirrhosis.

### Innovations and breakthroughs

This is the first original study on the effect of HIFU ablation as a bridging therapy for liver transplantation. Unlike radiofrequency ablation, HIFU ablation does not require any needle puncture and so eliminates the risk of disease dissemination. It can even be performed in patients with gross ascites without the risk of precipitating liver decompensation. In the study, the ablation caused no adhesion. The absence of adhesion renders the subsequent liver transplantation easier.

### Applications

With its advantages, safety and efficacy as demonstrated in this study, HIFU ablation should be considered as a treatment option for HCC. This study already proved that it is a safe and effective bridging therapy before liver transplantation for HCC.

### Terminology

HIFU ablation utilizes a unique frequency of ultrasound wave of 0.8 to 3.5 MHz, causing a cavitation effect in the target lesion.

### Peer review

The authors studied the effect of HIFU ablation on HCC performed before liver transplantation. The study demonstrated that HIFU ablation is an effective ablation modality which is totally non-invasive. It can effectively reduce the drop-out rate of liver transplant candidates by giving effective control on their tumors. The histological examination of the excised livers provided evidence that necrosis is effective in an *in vivo* model, which makes this article unique of its kind.

### Abstract

**AIM:** To develop a real-time polymerase chain reaction (PCR) method to detect and quantify *Campylobacter jejuni* (*C. jejuni*) from stool specimens.

**METHODS:** Primers and a probe for real-time PCR were designed based on the specific DNA sequence of the *hipO* gene in *C. jejuni*. The specificity of the primers and probe were tested against a set of *Campylobacter spp.* and other enteric pathogens. The optimal PCR conditions were determined by testing a series of conditions with standard *C. jejuni* template. The detection limits were obtained using purified DNA from bacterial culture and extracted DNA from the stool specimen. Two hundred and forty-two specimens were analyzed for the presence of *C. jejuni* by direct bacterial culture and real-time PCR.

**RESULTS:** The optimal PCR system was determined using reference DNA templates, 1 × uracil-DNA glycosylase, 3.5 mmol/L MgCl<sub>2</sub>, 1.25 U platinum *Taq* polymerase, 0.4 mmol/L PCR nucleotide mix, 0.48 μmol/L of each primer, 0.2 μmol/L of probe and 2 μL of DNA template in a final volume of 25 μL. The PCR reaction was carried as follows: 95 °C for 4 min, followed by 45 cycles of 10 s at 95 °C and 30 s at 59 °C. The detection limit was 4.3 CFU/mL using purified DNA from bacterial culture and 10<sup>3</sup> CFU/g using DNA from stool specimens. Twenty (8.3%, 20/242) *C. jejuni* strains were isolated from bacterial culture, while 41 (16.9%, 41/242) samples were found to be positive by real-time PCR. DNA sequencing of the PCR product indicated the presence of *C. jejuni* in the specimen. One mixed infection of *C. jejuni* and *Salmonella* was detected in one specimen and the PCR test for this specimen was positive.

**CONCLUSION:** The sensitivity of detection of *C. jejuni* from stool specimens was much higher using this PCR assay than using the direct culture method.

**Key words:** *Campylobacter jejuni*; Real time polymerase chain reaction; Application

**Core tip:** In the present study, we developed an effective real-time polymerase chain reaction method based on the specific DNA sequence of the *hipO* gene in *Campylobacter jejuni* (*C. jejuni*). The detection limit of this assay is 4.3 CFU/mL. A study of 242 clinical stool specimens from diarrheal patients indicated that this method is more sensitive than direct bacterial culture for the identification of *C. jejuni* from stool specimens.

## INTRODUCTION

*Campylobacter* spp., *Salmonella* spp., *Yersinia* spp., *Shigella* spp., and *Escherichia coli* (*E. coli*) O157 are the leading causes of human bacterial gastroenteritis worldwide<sup>[1]</sup>. *Campylobacter jejuni* (*C. jejuni*) is the main species of *Campylobacter* that affects humans<sup>[2,3]</sup>. *Campylobacter* infections have been investigated and followed with considerable interest since the early 1980s in China, and there have been numerous reports on *C. jejuni* infection in patients with diarrhea. However, reports and the frequency of isolation of *C. jejuni* from diarrheal patients have decreased since the late 1990s. Improvement in sanitary conditions may explain this decline in numbers; however, the difficulty in detecting this fastidious pathogen might be another contributor to the decreased number of reports and frequency of isolation. Our recent pilot study revealed that the ratio of isolation of this pathogen from stool specimens of diarrheal patients was considerably different among surveillance spots in different laboratories (2%-15%, unpublished). Sensitive and accurate detection of this pathogen is important, both for the treatment of patients and for prompt epidemiological investigation.

With the development of genomic DNA sequencing, online databases, and bioinformatic analyses, nucleic acid-based methods, particularly polymerase chain reaction (PCR) methods, have become promising tools for the rapid, reliable, and sensitive detection and diagnosis of pathogenic infection<sup>[4-8]</sup>. In this study, we developed a real-time PCR assay to detect *C. jejuni*. We then combined this PCR assay with DNA sequence analysis and compared this method with the direct culture method to detect *C. jejuni* in stool specimens obtained from patients with diarrhea. The results obtained in this study provide a proof of concept for PCR-based detection of *C. jejuni* infection in patients with diarrhea, may lead to the development of a pre-screening approach for isolating *C. jejuni*.

## MATERIALS AND METHODS

### Sample collection and culture-based detection

Two hundred and forty-two stool specimens were collected from diarrheal patients (with ages ranging from 6 to 72 years) in the outpatient facilities of 11 hospitals. The specimens were transferred to a laboratory within 4 h for bacterial culture. The remainder of the samples was frozen at -80 °C for DNA extraction. A sterile cotton swab was twisted in each stool sample and streaked directly on selective Skirrow agar plates consisting of Columbia agar base (CM331, Oxoid, Basingstoke, United Kingdom), selective supplement (SR0069, Oxoid), and 5% defibrinated sheep blood. The plates were incubated in a microaerobic atmosphere (5% O<sub>2</sub>, 10% CO<sub>2</sub> and 85% N<sub>2</sub>) at 42 °C for

48 h. Suspected colonies were picked and identified by gram staining, oxidase and catalase tests, and hippurate hydrolysis analysis, according to our previous report<sup>[9]</sup>. All specimens were also examined for the presence of *Shigella* spp., *Salmonella* spp., *Yersinia* spp. and *E. coli* O157 by culture on xylose lysine deoxycholate agar, deoxycholate hydrogen sulfide lactose agar, cefsulodin-irgasan-novobiocin agar, and sorbitol MacConkey agar, respectively. Suspected colonies were identified biochemically using API 20E strips, and the cultures were confirmed up to the species level by further serotype or PCR analysis, as previously described<sup>[10,11]</sup>.

### DNA preparation from bacterial culture

Reference genomic DNA was extracted from the *Campylobacter* isolates cultured in this study by using a QIAamp DNA mini kit (Qiagen, Düsseldorf, Germany). DNA templates from other reference pathogens were gifts from Drs. Huaiqi Jing and Biao Kan. The reference DNA templates are shown in Table 1.

### Primers and probe design

Specific DNA fragments of the *hipO* gene were compared using BLASTn and Vector NTI suite 6.0 software. The primers and probe sets were designed and synthesized by Shanghai Huirui Biotechnology Co., Ltd. The sequences of the primers and probe used in this study were: *hipO*-F, 5'-CGGATAGTTATAGTATTGAAGT-TATTGG-3', *hipO*-R, 5'-GAAGCAGCATAAATAG-GATCTTTT-3', and *hipO*-P, 5'-FAM-TTCTGGAG-CACTTCCATGACCACC-BHQ1-3'.

### Optimization for real-time PCR

The optimal PCR conditions were determined by testing a series of conditions with standard *C. jejuni* template. The standard PCR curve was constructed using genomic DNA from *C. jejuni* strain NCTC11168. The detection limits of this assay from pure culture and stool specimens were determined using 10-fold dilutions of quantified reference *C. jejuni* genomic DNA templates (1 × 10<sup>0</sup> to 1 × 10<sup>6</sup> CFU/mL) and the same amount of bacteria inoculated into stool specimens that were previously confirmed to contain no *Campylobacter*. The specificity of this assay was verified using genomic DNA from other enteric pathogens. The *C. jejuni*-inoculated samples were also cultured to compare the detection limits.

### Evaluation of repeatability

To evaluate the reproducibility of the assay, five serial dilutions with three replicates per concentration were performed for two separate *C. jejuni* genomic DNA templates (NCTC11168 and ATCC33560). The serial dilutions were also performed on three different *C. jejuni* strains (81116, ATCC49349 and ICDCCJ07001) simultaneously. The curves were constructed on the basis of the log pg/mL of the genomic DNA and threshold cycle (Ct). Reproducibility was assessed using the SD of the Ct value and the SD of the slope of each dilution curve, respectively.

### PCR detection of *C. jejuni* from stool specimens and DNA sequencing of PCR products

After direct culture, the stool specimens were stored at -80 °C until DNA extraction using a QIAamp DNA stool mini kit (Qiagen), which was performed in accordance with the manufacturer's instructions. Conventional PCR with the universal primers targeting conserved bacterial 16s rRNA gene sequences was carried out to evaluate the validity of the template used in this study. Real-time PCR was performed in a 25- $\mu$ L volume with 2  $\mu$ L of purified DNA obtained directly from stool specimens. All the samples with Ct < 35 were considered positive. Each of the positive PCR products, except for the ones from the culture-positive specimens, was confirmed with conventional PCR using the same primers, and the PCR products were purified and sequenced. Online sequence BLAST was performed using the NCBI BLASTN suite ([http://blast.ncbi.nlm.nih.gov/Blast.cgi?PROGRAM=blastn&BLAST\\_PROGRAMS=megaBlast&PAGE\\_TYPE=BlastSearch&SHOW\\_DEFAULTS=on&LINK\\_LOC=blasthome](http://blast.ncbi.nlm.nih.gov/Blast.cgi?PROGRAM=blastn&BLAST_PROGRAMS=megaBlast&PAGE_TYPE=BlastSearch&SHOW_DEFAULTS=on&LINK_LOC=blasthome)).

## RESULTS

### Bacterial culture

Twenty *C. jejuni* (8.3%, 20/242) isolates, 34 (14%, 34/242) *Salmonella* isolates, and one (0.4%, 1/242) *Shigella* isolate were obtained by direct plating of the 242 stool specimens. *Salmonella* was the most frequently isolated pathogenic genus from the stool specimens and *C. jejuni* was the second most frequently isolated. No *Yersinia* or *E. coli* O157 isolates were found. In another laboratory, serotyping methods were used to further identify *Salmonella* and *Shigella* colonies.

### Optimized PCR assay

The optimal PCR system was determined using reference DNA templates, 1  $\times$  uracil-DNA glycosylase, 3.5 mmol/L MgCl<sub>2</sub>, 1.25 U platinum *Taq* polymerase, 0.4 mmol/L PCR nucleotide mix, 0.48  $\mu$ mol/L of each primer, 0.2  $\mu$ mol/L of probe, and 2  $\mu$ L of DNA template in a final volume of 25  $\mu$ L run with the following parameters: 95 °C for 4 min, followed by 45 cycles of 10 s at 95 °C and 30 s at 59 °C. Fluorescence signals were measured at the end of the annealing step of every cycle. PCR products were verified using DNA electrophoresis through 2% agarose gels. The size of the PCR product was consistent with the expected size (85 bp) in each case. The specificity of the primers and probe were tested against *Campylobacter spp.* and other enteric pathogens. Only *C. jejuni* showed positive reactions. All the other templates gave negative results, including other *Campylobacter spp.*

### Detection limit and stability of the PCR assay

Serial dilutions from 10<sup>0</sup> to 10<sup>6</sup> CFU/ml of the target template were subjected to the real-time PCR assay (Figure 1A). The standard curve based on the dilutions of genomic DNA showed a linear relationship between Log

CFU/mL and threshold cycles (Ct; Figure 1B). Copy numbers could be obtained by the following equation using the standard curve:  $Y(Ct) = -3.993X (\log \text{CFU/mL}) + 37.51$  ( $R^2 = 0.998$ ). When Ct = 35, the detection limit of the PCR assay for pure culture was approximately 4.3 CFU/mL. However, when Ct = 35, the detection limit for *C. jejuni* in the stool specimens was 10<sup>3</sup> CFU/g, and we could not obtain a linear relationship between log CFU/g and Ct using serial bacterial inoculation in different stool specimens. The curves constructed from the serial dilution replicates of the individual *C. jejuni* templates and those generated from the three different *C. jejuni* templates are shown in Figure 2. The variation of the Ct value and the slopes of the curves indicated that this assay could be stably reproduced.

### PCR detection from stool specimens

The detection limit from both bacterial culture and real-time PCR (with Ct < 35) for the inoculated stool samples was 10<sup>3</sup> CFU/g; therefore, a Ct value of  $\leq 35$  was considered positive for the real-time PCR assay in this study. Forty-one (16.9%, 41/242) samples were found to be positive by the real-time PCR method. All culture-positive specimens showed positive PCR results (Ct < 34). DNA sequencing of the positive PCR products for the culture-negative samples indicated the presence of *C. jejuni*. The samples containing *Salmonella* and *Shigella* isolates tested negative by real-time PCR (Ct > 40), except for one sample that contained both *C. jejuni* and *Salmonella* (Ct = 27).

## DISCUSSION

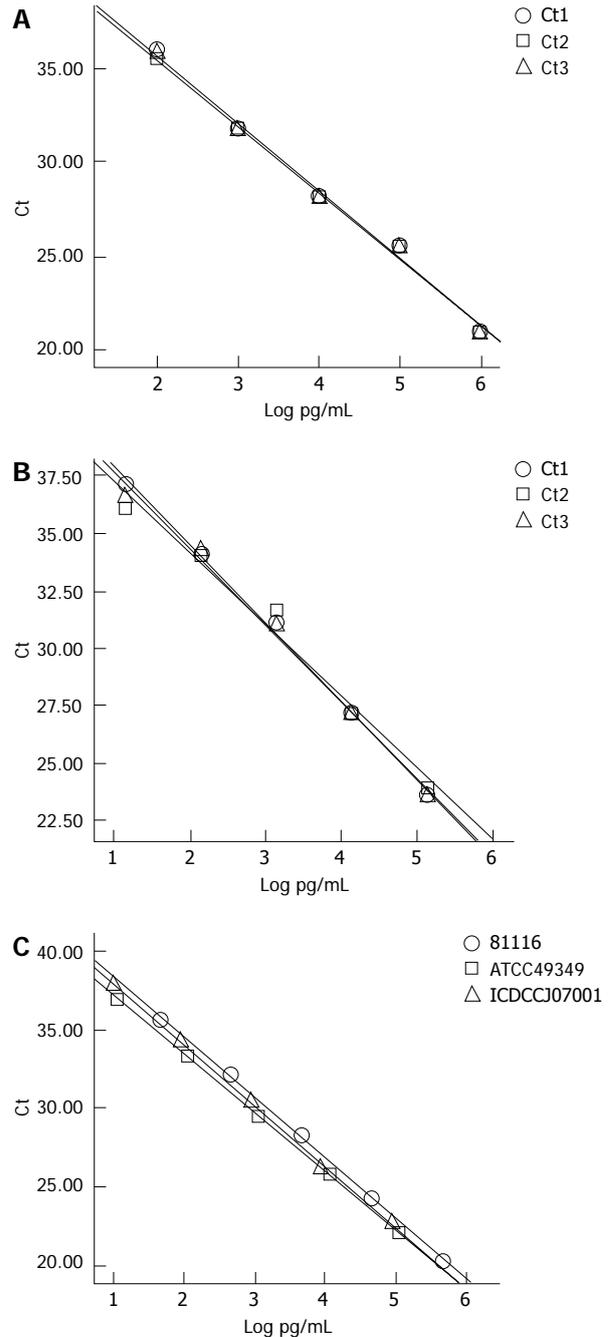

*C. jejuni* is one of the major causes of food borne disease

worldwide<sup>[12]</sup>. It is an important pathogen of acute bacterial diarrhea in humans and has been associated with the development of Guillain-Barré syndrome, a post-infectious polyneuropathy<sup>[13,14]</sup>. Routine detection of *Campylobacter* species in the clinical setting is currently based on culture-based detection and subsequent phenotypic identification. Its detection is difficult because of its special growth requirements, low infectious doses, and potential for entering a viable, but not cultivable, state<sup>[15,16]</sup>. The traditional “gold standard” diagnostic methods for *Campylobacter* infection include bacterial culture and culture-based biochemical tests. These methods are both time-consuming and laborious. In addition to the fastidious culture requirements, the discrimination and differentiation of *Campylobacter spp.* are complicated and error prone. For example, distinguishing *C. jejuni* from *C. coli* is usually done on the basis of the biochemistry test for hippurate hydrolysis. Only *C. jejuni* gives a positive reaction, but previous studies have found that 10% of *C. jejuni* isolates failed to hydrolyze hippurate under laboratory conditions<sup>[17,18]</sup>. The accurate identification of *Campylobacter* up to species level is an essential prerequisite for many epidemiological studies.

In the present study, we developed a real-time PCR assay based on the specific DNA fragment of the *hipO* gene from *C. jejuni*, which could identify *C. jejuni* directly and differentiate it from other pathogens, especially from other *Campylobacter spp.*, in stool specimens from diarrheal patients. The specificity of the PCR system was

**Figure 2** Stability tests. A: Curves constructed based dilutions of the genomic DNA of *Campylobacter jejuni* (C. jejuni) NCTC11168; B: Curves constructed based on the dilution of the genomic DNA of *C. jejuni* ATCC33560; C: Curves generated from the serial dilution of the genomic DNA of *C. jejuni* 81116, ATCC49349 and ICDCCJ07001. Ct: Threshold cycle.

verified with 27 reference enteric pathogens (Table 1). The detection limit of this PCR assay is less effective for stool samples than for pure culture. Loss of template during DNA extraction or inhibitors present in the stool specimens could reduce the efficiency<sup>[19]</sup>. Two hundred and forty-two stool specimens from patients with diarrhea were tested by the direct culture and by the PCR assay. All the culture-positive samples gave positive PCR results and samples containing other pathogens tested negative by PCR (Ct > 40). The DNA sequence of the

positive PCR products indicated the presence of *C. jejuni* in the specimens. The sensitivity of this PCR assay (100%, 41/41) was much higher than that of direct bacterial culture (49%, 20/41). The result from the mixed infection sample indicated that this PCR assay is considerably accurate. The results presented in this study contrast with those reported by certain previous studies, in which PCR results were found to have the same or less sensitivity compared with the direct culture method for the detection of *C. jejuni* from stool specimens<sup>[20,21]</sup>. However, Maher *et al*<sup>[22]</sup> used a DNA probe-based PCR assay and were able to identify 94% (17/18) and 32% (35/109) of *Campylobacter* infections from culture-positive and culture-negative stool specimens, respectively. Furthermore, Bessède *et al*<sup>[23]</sup> proved the weakness of the culture methods compared with PCR and immunoenzymatic methods of detection of *Campylobacter*. Notably, many aspects of the culture-based method, such as the choice of the selective media used for culture, need to be improved<sup>[24]</sup>. Although the sensitivity of the PCR system was high in this study, false-negative PCR results may still occur because of the presence of inherent inhibitors or because of very low numbers of organisms.

Interestingly, when *C. jejuni* were inoculated into stool specimens, the detection limit by the PCR assay was 10<sup>3</sup> CFU/g. The PCR detection limit from stool samples was similar to that reported in a previous study, but the detection limit of the direct culture methods mostly depended on the culture methods used, particularly the choice of plating medium, which may influence the efficiency of *C. jejuni* isolation during direct plating of fecal samples<sup>[25,26]</sup>. Instant plating of the inoculated samples in this study might increase the laboratory isolation capacity. Meanwhile, the non-uniformity of the clinical stool specimens in terms of physical matter, target organisms, the associated fecal flora and transportation status would result in variability of the culture results. In this study, although we used selective medium under specific microaerobic atmosphere conditions, some samples were contaminated with *Proteus* bacilli, and the suspected colonies could not be picked because of the rapid spread of the contaminants. *Proteus* bacilli may be one of the agents that reduced culture sensitivity, and the use of cotton swabs rather than inoculating loops for streaking on plates might have increased this contamination. In this study, we used QIAamp DNA stool mini kits to extract the DNA; the QIAamp kit has the highest sensitivity and requires the least manipulation of template DNA prior to PCR. More research is required to develop an in-house procedure for DNA extraction from different specimens and for optimizing the extraction process to increase the desired yield.

In conclusion, the real-time PCR assay developed in this study is sufficiently sensitive and accurate for *C. jejuni* detection from stool specimens. Although the PCR results do not permit its use as the standard method of diagnosing *C. jejuni* infection in the clinical setting, this newly developed method will benefit large-scale epidemiology

investigations and pre-screening for bacterial isolation.

## COMMENTS

### Background

*Campylobacter jejuni* (*C. jejuni*) is a major food-borne pathogen. In addition to enteritis, *C. jejuni* infection can also cause Guillain-Barré syndrome, an autoimmune neuropathy in humans. The "gold standard" diagnostic methods for *C. jejuni* infection include bacterial culture and culture-based biochemical tests. Primary *in vitro* culture of *C. jejuni* is difficult because of its special growth requirements, low infectious doses, and potential for entering a viable, but not cultivable, state. In addition to its fastidious culture conditions, current methods for discrimination and differentiation of *Campylobacter* spp. are complicated and fallible. Specific DNA detection, particularly real-time polymerase chain reaction (PCR), is a promising tool for the rapid, reliable, and more sensitive detection and diagnosis of *C. jejuni* infection. In this study, the authors developed and validated a real-time PCR assay method for the detection of *C. jejuni* from stool specimens.

### Research frontiers

*C. jejuni* is a fastidious organism and requires microaerophilic conditions for *in vitro* culture. Nucleic acid-based methods for the detection of *C. jejuni* infection are research hotspots, particularly PCR methods, which are promising tools for the rapid, reliable, and more sensitive detection of *C. jejuni* for laboratory-based diagnosis.

### Innovations and breakthroughs

In the present study, the authors developed a sensitive and specific real-time PCR assay using a DNA fragment of the *hipO* gene in *C. jejuni*, which can directly differentiate *C. jejuni* from other pathogens and other *Campylobacter* spp. from stool specimens obtained from diarrheal patients.

### Applications

The real-time PCR assay developed in this study is sensitive and accurate for the detection of *C. jejuni* from stool specimens. This method will benefit both large-scale epidemiology investigations and the clinical diagnosis of *C. jejuni* infection in humans.

### Peer review

This is an excellent and well-written manuscript. The authors are to be congratulated on developing and validating their own in-house PCR-based technique to detect *C. jejuni* in stool specimens. The *hipO* gene is specific to *C. jejuni*; therefore, by definition, this is a highly specific test.

### Abstract

**AIM:** To explore risk factors for lymph node metastases in early gastric cancer (EGC) and to confirm the appropriate range of lymph node dissection.

**METHODS:** A total of 202 patients with EGC who underwent curative gastrectomy with lymphadenectomy in the Department of Surgery, Xinhua Hospital and Ruijin Hospital of Shanghai Jiaotong University Medical School between November 2003 and July 2009, were retrospectively reviewed. Both the surgical procedure and the extent of lymph node dissection were based on the recommendations of the Japanese gastric cancer treatment guidelines. The macroscopic type was

classified as elevated (type I or II a), flat (II b), or depressed (II c or III). Histopathologically, papillary and tubular adenocarcinomas were grouped together as differentiated adenocarcinomas, and poorly differentiated and signet-ring cell adenocarcinomas were regarded as undifferentiated adenocarcinomas. Univariate and multivariate analyses of lymph node metastases and patient and tumor characteristics were undertaken.

**RESULTS:** The lymph node metastases rate in patients with EGC was 14.4%. Among these, the rate for mucosal cancer was 5.4%, and 8.9% for submucosal cancer. Univariate analysis showed an obvious correlation between lymph node metastases and tumor location, depth of invasion, morphological classification and venous invasion ( $\chi^2 = 122.901, P = 0.001; \chi^2 = 7.14, P = 0.008; \chi^2 = 79.523, P = 0.001; \chi^2 = 8.687, P = 0.003$ , respectively). In patients with submucosal cancers, the lymph node metastases rate in patients with venous invasion (60%, 3/5) was higher than in those without invasion (20%, 15/75) ( $\chi^2 = 4.301, P = 0.038$ ). Multivariate logistic regression analysis revealed that the depth of invasion was the only independent risk factor for lymph node metastases in EGC [ $P = 0.018, \text{Exp (B)} = 2.744$ ]. Among the patients with lymph node metastases, 29 cases (14.4%) were at N1, seven cases were at N2 (3.5%), and two cases were at N3 (1.0%). Univariate analysis of variance revealed a close relationship between the depth of invasion and lymph node metastases at pN<sub>1</sub> ( $P = 0.008$ ).

**CONCLUSION:** The depth of invasion was the only independent risk factor for lymph node metastases. Risk factors for metastases should be considered when choosing surgery for EGC.

**Key words:** Gastric neoplasm; Lymph node metastasis; Risk factors; Gastrectomy; Lymphadenectomy

**Core tip:** Early gastric cancer (EGC) is defined as a lesion confined to the mucosa or the submucosa, irrespective of the presence of regional lymph node metastases. In this study, we retrospectively evaluated the distribution of metastatic nodes in a two-center cohort of 202 patients with EGC. To assess nodal status in EGC, we applied an index calculated by the multiplication of the incidence of metastases in the respective node stations. Univariate and multivariate analyses were applied to confirm the clinicopathological factors associated with lymph node metastases, and to provide a basis for choosing the optimal surgical treatment and for determining the appropriate range of lymph node dissection.

## INTRODUCTION

Early gastric cancer (EGC) is defined as a lesion confined to the mucosa or the submucosa, irrespective of the presence of regional lymph node metastases<sup>[1]</sup>. Five-year survival rates in EGC tend to be greater than 90%, with lymph node status being the most important prognostic factor<sup>[2,3]</sup>. In patients with EGC and lymph node metastases, a 5-year survival rate of 87.3% has been reported, compared to 94.2% in those without nodal involvement<sup>[4]</sup>. Considering the low rate of lymph node metastasis in EGC<sup>[5,6]</sup>, the Japanese guidelines recommend endoscopic mucosal resection, reduction surgery D1 plus No. 7 and 8a and D1 plus No. 7, and 8a and 9 lymph node resection, for the treatment of patients with phase T1 disease. However, this approach is controversial outside Japan. At present, the general consensus is that endoscopic mucosal resection (EMR) or distal gastrectomy plus limited lymph node resection can be undertaken in most patients with mucosal cancer, and a distal gastrectomy plus D2 lymph node resection should be performed in most patients with submucosal cancer<sup>[2,3]</sup>.

Recently, in order to reduce operative and post-operative complications, and to improve quality of life, less invasive surgical alternatives, such as EMR, endoscopic submucosal dissection, laparoscopy-assisted gastrectomy and limited surgery, are used for the treatment of EGC. Although there has been substantial research on the prediction of risk factors for lymph node metastases in EGC, no definitive criteria are available. In addition, controversy surrounds the indications for local treatment in EGC, and limited surgery and the appropriate extent of lymphadenectomy.

In this study, we retrospectively evaluated the distribution of metastatic nodes in a two-center cohort of 202

patients with EGC. To assess nodal status in EGC, we applied an index calculated by the multiplication of the incidence of metastases in the respective node stations. Univariate and multivariate analyses were performed to confirm the clinicopathological factors associated with lymph node metastases, and to provide a basis for choosing the optimal surgical treatment and for determining the appropriate range of lymph node dissection.

## MATERIALS AND METHODS

### Ethics

This work has been carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. This study was approved ethically by the Institutional Review Board of Shanghai Jiaotong University. All patients provided written informed consent.

### Patients

A total of 202 patients with EGC, as defined by the Japanese Classification of Gastric Carcinoma<sup>[7]</sup>, who underwent curative gastrectomy with lymphadenectomy in the Department of Surgery, Xinhua Hospital and Ruijin Hospital of Shanghai Jiaotong University Medical School between November 2003 and July 2009, were retrospectively reviewed. Of these, there were 132 men and 70 women, ranging in age from 25 to 87 years (mean 58.1 ± 12.9 years). Mucosal tumors were found in 122 patients (60.4%) and submucosal tumors in 80 (39.6%). Lymph node involvement was detected in 29 patients (Table 1).

### Surgery

All operations were performed with curative intent. Curative surgery was defined as the removal of all gross tumors and the demonstration of tumor-negative surgical margins by microscopic examination of the entire circumference. Surgical procedures comprised 171 distal gastrectomies, 24 proximal gastrectomies and seven total gastrectomies. Proximal gastrectomy involved resection of the proximal half of the stomach via an abdominal approach, with an intraabdominal esophago-gastric anastomosis. Following a total gastrectomy with D2 lymph node dissection, an esophagojejunostomy was used routinely for Roux-en-Y reconstruction. Proximal and distal resection margins were evaluated intraoperatively to confirm freedom from disease. Both the surgical procedure and the extent of lymph node dissection were based on the recommendations of the Japanese gastric cancer treatment guidelines<sup>[7]</sup>. A total of 2926 lymph nodes (LNs), with a median of 14.5 LNs per patient, were removed. No patient received neoadjuvant therapy before surgery.

### Pathological examination

In both hospitals, the surgical team immediately examined the lymph nodes macroscopically, which were then divided and classified into lymph node stations, as defined by the Japanese Classification of Gastric Carcinoma. No

CEA: Carcinoembryonic antigen.

size limitation was imposed for lymph node harvesting. Specimens were fixed in formalin, stained with hematoxylin and eosin, and sent for histopathological evaluation, following which the number of histologically confirmed lymph nodes was recorded for each lymph node station. Each lymph node was embedded in paraffin and at least two sections were performed. Immunohistochemistry for micrometastasis was not performed.

Tumor size was recorded as the maximum diameter. The depth of infiltration was measured at the deepest point of penetration of the cancer cells. The macroscopic type was classified as elevated (type I or II a), flat (II b), or depressed (II c or III), according to the Japanese Classification of Gastric Carcinoma<sup>[7]</sup>. Of the 202 patients, 26 (12.9%), 21 (10.4%) and 155 (76.7%) were elevated, flat or depressed, respectively. Histopathologically, papillary and tubular adenocarcinomas were grouped together as differentiated adenocarcinomas, and poorly differentiated and signet-ring cell adenocarcinomas were regarded as undifferentiated adenocarcinomas. Overall, tumors were

differentiated in 121 patients and undifferentiated in 81.

The relationship between various clinicopathological factors and the presence or absence of lymph node metastases was then examined. Clinicopathological parameters included patient age (< 60 years or ≥ 60 years), sex, tumor location (U = upper third, M = middle third, or L = lower third of the stomach), tumor size (maximum dimension ≤ 20 mm or > 20 mm), macroscopic type (elevated, flat, or depressed), depth of invasion (mucosal or submucosal), histological type (differentiated or undifferentiated), carcinoembryonic antigen levels (CEA, < 5 ng/mL or ≥ 5 ng/mL), lymphatic invasion (present or absent) and venous invasion (present or absent). Evaluation of these factors was undertaken according to the Japanese Classification of Gastric Carcinoma established by the Japanese Research Society for Gastric Cancer.

### Statistical analysis

Descriptive data are presented as the mean ± SD. For between group comparisons, continuous variables were analyzed using the Student's *t* test, and categorical variables with the  $\chi^2$  test. Factors found to be significant ( $P < 0.05$ ) in univariate analysis were included in subsequent multivariate logistic regression analysis, in order to identify independent variables associated with lymph node metastases. All statistical analyses were undertaken using the Statistical Package for the Social Sciences (SPSS) for Windows, Version 17.0 (SPSS Inc., Chicago, IL, United States).

## RESULTS

### Univariate analysis of lymph node metastases in EGC and clinicopathological factors

Univariate analysis was performed on the relationship between lymph node metastases and clinicopathological factors. The findings revealed a close relationship between tumor location, depth of invasion, morphological classification, venous invasion and lymph node metastases ( $\chi^2 = 122.901$ ,  $P = 0.001$ ;  $\chi^2 = 7.14$ ,  $P = 0.008$ ;  $\chi^2 = 79.523$ ,  $P = 0.001$ ;  $\chi^2 = 8.687$ ,  $P = 0.003$ , respectively). There was no correlation between lymph node metastases and sex, age, tumor size, number of retrieved lymph nodes, histological type, lymphatic invasion, nervous invasion, and serum levels of carcinoembryonic antigen (CEA) (Table 2).

In patients with mucosal cancers, no significant differences in the occurrence of lymph node metastases were found in relation to sex, age, tumor location, tumor size, number of retrieved lymph nodes, morphological classification, histological type, lymphatic invasion, venous invasion, nervous invasion and CEA levels (Table 2).

In patients with submucosal cancers, there was no significant difference in the occurrence of lymph node metastases in relation to sex, age, tumor location, tumor size, number of retrieved lymph nodes, morphological classification, histological type, lymphatic invasion, nervous invasion and CEA levels. However, the lymph node

<sup>1</sup>Statistically significant. Tumor site: middle and lower *vs* upper; Tumor depth: submucosa *vs* mucosa; Macroscopic type: flat and depressed *vs* elevated; Vessel ambolus: + (present) *vs* - (absent), <sup>a</sup>*P* < 0.05. In patients with mucosal cancers, no significant differences in the occurrence of lymph node metastases were found in relation to the clinicopathological factors. CEA: Carcinoembryonic antigen.

metastases rate in patients with venous invasion (60%, 3/5) was higher than in those without invasion (20%, 15/75), and the difference was significant ( $\chi^2 = 4.301$ , *P* = 0.038) (Table 2). Venous invasion, as a source variable, was therefore used in the logistic regression model. This revealed that it was not an independent risk factor for lymph node metastases in submucosal cancer [B = 1.792, SE = 0.957, Wals = 3.502, *P* = 0.061, Exp (B) = 6.000] (Table 2).

#### Multivariate analysis of lymph node metastases in EGC

Multivariate analysis revealed that the depth of invasion was an independent risk factor for lymph node metastases [*P* = 0.018, Exp (B) = 2.744]. Venous invasion was

also an important influencing factor [ $P = 0.116$ , Exp (B) = 4.147, Table 3]. Tumor location, depth of invasion, morphological classification, and venous invasion had no significant impact on nodal involvement rates.

#### Relationship between depth of invasion and number of metastatic lymph nodes

There was no significant difference between mucosal and submucosal tumors in terms of number of retrieved lymph nodes, using the independent sample  $t$  test ( $t = 0.350$ ,  $df = 200$ ,  $P = 0.727$ , mean difference = 0.534). The number of metastatic lymph nodes in those with mucosal tumors was slightly higher than in those with submucosal tumors. The results of dissected nodes were as follows: mucosa ( $n = 122$ ),  $14.70 \pm 9.894$ ; submucosa ( $n = 80$ ),  $14.16 \pm 11.656$ ,  $P = 0.727$ ; for the metastasis nodes, mucosa ( $n = 122$ ),  $3.91 \pm 5.576$ ; submucosa ( $n = 80$ ),  $3.72 \pm 3.102$ ,  $P = 0.908$ . The difference was not significant.

#### Number of retrieved lymph nodes and lymph node metastasis ratios for involved lymph nodes at each nodal station in EGC

The metastatic ratio is the ratio of metastatic nodes to the total number of dissected nodes and was recorded for each nodal station for all regional lymph nodes. There were 110 metastatic lymph nodes, an incidence of 3.8%. Among them, more lymph nodes were retrieved in stations No. 3, 4, 6, 7, 1, 9, 8 and 12. The number of retrieved lymph nodes in above stations was between 108 and 861, and the metastatic ratio was between 0% and 5.9%. Fewer lymph nodes were retrieved in stations No. 5, 13, 2, 11, 14, 10 and 15. The retrieved number was between 13 and 78, and the metastatic ratio was between 0% and 34.8%. Only one patient received station No. 16 lymph node dissection, and no metastasis was found. According to the Japanese Classification of Gastric Carcinoma<sup>[7]</sup>, 29 cases (14.4%) were at N1, seven cases were at N2 (3.5%), and two cases were at N3 (1.0%). A direct skip to N2, without moving through N1, occurred in two cases (1.0%). There were no skips to N3 without going through N2. The incidence of lymph node metastases in each station, from high to low, was as follows: station No. 14 (34.8%), No. 2 (11.1%), No. 6 (5.9%), No. 3 (4.8%), No. 11 (3.7%), No. 4 (3.4%), No. 5 (2.6%), No. 8 (2.5%), No. 9 (2.2%), No. 7 (1.5%), and No. 1 (0.6%). There were no station No. 10 and No. 11 lymph node metastases in two patients who had undergone a total gastrectomy combined with a splenectomy (Table 4).

#### Lymph node metastasis ratios and incidence at each station in upper third, middle third and lower third gastric cancers

The extent of metastases in 25 cases with upper third gastric cancer was as follows: four cases were at N1 (2.0%), an incidence of 3.4%, and a metastatic rate of 16.0%; one case was at N2 (0.5%), an incidence of 4.5%, and a metastatic rate of 4.0%; and no metastases was

**Table 3** Multivariate analysis of lymph node metastases in early gastric cancer for the entire study population

|                  | RR    | 95%CI       | P <sup>1</sup>     |

found at N3. At N1, lymph node metastases occurred in stations No. 2, 3, and 4, but not in station No. 1. The incidence of metastases was 5.3%, 5.5%, and 1.6% in stations No. 2, 3, and 4, respectively, and the metastatic rate was 4.0%, 8.0%, and 4.0%, respectively. At N2, lymph node metastases occurred only in station No. 8, and the incidence of metastases was 16.7%, and the metastatic rate was 4.0% (Table 5).

The extent of metastases in middle third gastric cancers was as follows: 18 cases (8.9%) occurred at N1, an incidence of 3.5% and a rate of 18.4%; five cases occurred at N2 (2.5%), an incidence of 1.4%, and a rate of 5.1%; and two cases occurred at N3 (1.0%), an incidence of 14.3%, and a rate of 2.0%. At N1, station No. 1, 3, 4, 5, and 6 had lymph node metastases, a rate of 1.0%, 9.2%, 5.1%, 1.0% and 2.0%, respectively. At N2, station No. 8, 9 and 11 had lymph node metastases, a rate of 1.0%, 3.1%, and 1.0%, respectively. At N3, only station No. 2 and 14 had lymph node metastases, a rate of 1.0%. No distal lymph node metastasis was identified (Table 5).

The extent of metastases in lower third gastric cancers was: 20 cases (9.9%) had metastases at N1: an incidence of 5.7%, and a rate of 25.3%; two cases (1.0%) had metastases at N2: an incidence of 1.8%, and a rate of 2.5%; there were no cases of metastases at N3 or at

distal lymph nodes. In N1, the metastatic rate, from high to low, was 8.9%, 8.9%, 6.3% and 1.3% respectively, and incidence was 5.9%, 11.0%, 2.7%, and 2.9%, respectively in stations No. 3, 6, 4, and 5. In N2, lymph nodes in stations No. 7 and 14 were most frequently involved, while no metastases occurred in stations No. 1, 8, 9, 11, and 12. At N2, lymph node metastases occurred in station No. 7, in a depressed type and differentiated submucosal tumor with a diameter 3.0 cm. Lymph node metastases occurred in a mucosal tumor in station No. 14 with a diameter 6.0 cm. It was a type 0-III differentiated cancer (Table 5).

#### Correlation between lymph node metastases at pN1 and pN2 and clinicopathological factors

Univariate analysis of variance revealed a close relationship between the depth of invasion and lymph node metastases at pN1 ( $P = 0.008$ ). There was no obvious rela-

tionship between the depth of invasion and lymph node metastases at pN2 ( $P = 0.334$ ). There was no significant correlation between tumor size, morphological classification, differentiation, lymphatic invasion and the presence of lymph node metastases at pN1 and pN2 (Table 6).

## DISCUSSION

Five-year survival rates in EGC tend to be greater than 90%, with lymph node status the most important prognostic factor. In those with lymph node metastases, a 10-year survival rate of 72% has been reported, compared to 92% for those without nodal involvement<sup>[2]</sup>. Although research has explored the issue of predicting risk factors for lymph node metastases in EGC, as yet there are no definitive criteria. In addition, controversy surrounds indications for local treatment and a limited surgical approach, and the range of lymph node dissection. Hence, in this study, we aimed to explore the risk factors for the development of lymph node metastases in EGC, to confirm the optimal range of lymph node dissection, and to provide a basis for a rational approach to surgical management.

Reported rates of lymph node metastases in EGC range from 5.7% to 20%<sup>[8-16]</sup>. However, Hayes *et al*<sup>[17]</sup> reported a rate over 40% during surgery. Depending on the depth of invasion, EGC can be classified as mucosal or submucosal, with a rate of lymph node involvement of 0%-21%<sup>[11,18,19]</sup> for mucosal tumors, and 16.5%-30%<sup>[2,3,19-22]</sup> for submucosal tumors. Based on anatomical and histological characteristics, there is a close relationship between the depth of tumor invasion and lymph node metastases in EGC. Once the tumor has invaded the submucosal layer, the rate of lymph node metastases increases significantly. In our group of 202 patients with EGC, lymph node metastases occurred in 29. Among these, there were 11 cases of mucosal and 18 cases of submucosal cancer. The rate of involved lymph nodes was higher in those with submucosal cancer than

in mucosal cancer (22.5% *vs* 9.0%,  $\chi^2 = 7.14$ ,  $P = 0.008$ ).

In our group, male patients predominated, accounting for 65.3%, while was similar to other reports<sup>[18,23-26]</sup>. Studies to date suggest that EGC frequently occurs in the lower third of the stomach<sup>[18,22,26]</sup>. In our study, 48.5% of cases originated in the middle third, which was similar to the report from Fujimoto *et al*<sup>[14]</sup>. Also in our group, 52.0% of patients had tumors greater than 2 cm. Larger tumors have higher rates of lymph node metastases. Of the 29 cases with lymph node metastases, the tumor size in 18 was greater than 2 cm, accounting for 62.1% of all metastases. Morphological classification was mainly of the depressed type (77.2%). Among these, type 0-IIc and type 0-III accounted for approximately 50%. Histologically, most tumors were differentiated, accounting for 59.9%, which was similar to that reported by Abe *et al*<sup>[27]</sup>.

Although the lymph node metastatic rate in EGC is relatively low, it has been shown that the presence of lymph node metastases predicts a poor prognosis<sup>[28-32]</sup>. Thus, many researchers have attempted to investigate the relationship between nodal involvement and clinicopathological factors. The size of the primary tumor, undifferentiated histopathological characteristics, lymphatic or venous invasion, and a cancerous ulcer are associated with nodal metastases in EGC<sup>[8,9,12,14,32-42]</sup>. Univariate analysis confirmed a correlation between tumor location, depth of invasion, morphological classification, venous invasion and lymph node metastases in EGC in our study ( $\chi^2 = 122.901$ ,  $P = 0.001$ ;  $\chi^2 = 7.14$ ,  $P = 0.008$ ;  $\chi^2 = 79.523$ ,  $P = 0.001$ ;  $\chi^2 = 8.687$ ,  $P = 0.003$ , respectively), while nodal metastases were not associated with sex, age, tumor size, number of retrieved lymph nodes, histological type, lymphatic invasion, nervous invasion, and CEA levels. Boku *et al*<sup>[12]</sup> reported an association between lymph node metastases and the tumors arising from the distal third of the stomach, indicating that cancers arising from this section have a worse prognosis. In our study, tumors originating in the upper third of the stomach had a nodal metastatic rate of 8%, compared to 15.3% for the middle third and 15.2% for the lower third, which was similar to that reported by Boku *et al*<sup>[12]</sup>. Reports have suggested both a lack of association between the occurrence of lymph node metastases and mucosal tumors of the upper and middle third of the stomach<sup>[19]</sup>, and a marked increase in nodal involvement with distal gastric cancers<sup>[43]</sup>. Data from our study revealed a lymph node metastases rate in mucosal and submucosal tumors of 9.0% and 22.5%, respectively, which was similar to other reports<sup>[19,44]</sup>. At present, endoscopic submucosal resection is often used for patients with mucosal cancer, while data from Hölscher contradicts this approach<sup>[19]</sup>. Our data indicates that, prior to surgery, determination of the depth of invasion is important for predicting lymph node metastases. Preoperative staging technology, particularly endoscopic ultrasonography, can determine the depth of invasion, but there can be errors of judgment<sup>[11,16,45,46]</sup>. In Japan, the morphological classification of EGC is summarized as elevated, flat and depressed type. The rate of

lymph node metastases in the elevated subtype was relatively high, being 16% in our study. The rate of lymph node metastases tends to be markedly higher in patients with venous or lymphatic invasion<sup>[46]</sup>. However, our results did not concur with this, which might be explained by the fact that the number of specimens varied, and the quantity of venous or lymphatic invasion that we included was low.

It is generally acknowledged that tumor size is closely related to lymph node metastases. Hölscher<sup>[19]</sup> found no evidence of lymph node metastases in mucosal cancers less than 1 cm, and in submucosal cancers. Moreover, lymph node metastases have not been identified in patients with mucosal cancers less than 2 cm<sup>[19]</sup>. Tumors greater than 2 cm appear to be independent risk factors for lymph node metastases<sup>[19,22,47,48]</sup>. In our group, although the rate of lymph node metastases in patients with tumors greater than 2 cm (17.1%) was clearly greater than that observed with smaller tumors (11.3%), the difference was not significant, which is similar to the results from Lee *et al*<sup>[18]</sup>.

Histological type is also closely related to nodal status<sup>[9,18,35,41,42]</sup>. In our group, the rate of lymph node metastases in non-differentiated tumors was higher than in differentiated cancer, 17.3% and 12.4%, respectively. However, a non-differentiated tumor was not an independent risk factor for lymph node metastases. Abe *et al*<sup>[49]</sup> suggest that, apart from tumor size, submucosal invasion and lymphatic invasion, a correlation also exists between females and the occurrence of lymph node metastases. In females, the biological behavior of gastric cancer tends to be more invasive. Moreover, it has also been shown that the extent of the invasiveness of gastric cancer cannot be fully explained by tumor size, depth of invasion or lymphatic invasion<sup>[49]</sup>. A possible explanation for the fact that gastric cancer tends to be more invasive in females could be related to endogenous estrogen levels, which might promote tumor growth.

In recent years, endoscopic surgery has become one of the standard procedures, and is indicated for patients with mucosal tumors, tumors less than 2 cm in size, and those without lymph node metastases. Our results suggest that the rate of lymph node metastases is markedly higher in those with cancers of the middle and lower third of the stomach, and those with submucosal tumors, who are therefore not suitable for endoscopic surgery.

Multivariate analysis found that only depth of invasion was an independent risk factor for lymph node metastases in EGC [ $P = 0.018$ , Exp (B) = 2.744], which is consistent with previous studies<sup>[18,26,31,32,35,37,50-55]</sup>. Multivariate analysis by Kim *et al*<sup>[3]</sup> on 748 cases of EGC, indicated that tumor size, poorly differentiated tumors and submucosal cancers were all independent risk factors for lymph node metastases. Hyung *et al*<sup>[56]</sup> suggest that poorly differentiated tumors, submucosal cancer, tumor size, and venous or lymphatic invasion are independent risk factors for nodal metastases. Many other studies have reached similar conclusions, namely that tumor

size, depth of invasion, histological type, morphological classification, venous or lymphatic invasion, are all independent risk factors for lymph node metastases in EGC<sup>[3,14,22,26,27,47,48,50,56-62]</sup>.

A consideration of the number of lymph node is related to the extent of surgical intervention, which is also related to the depth of tumor invasion. Thus the depth of tumor invasion is also associated with the number of lymph nodes: as the depth increases, the number of lymph nodes also increases. In our group, all 202 cases of EGC had a radical gastrectomy. Post-operatively, 2892 regional lymph nodes were located. In 122 cases, where tumor invasion was limited to the mucosal layer, 1790 lymph nodes were found, with an average of 14.67 per case. In 80 cases with tumor invading the submucosa, 1102 lymph nodes were detected, with an average of 13.77 per case. The difference between the number of lymph nodes in mucosal and in submucosal cancer was not significantly different ( $P = 0.727$ ). Five hundred and sixty lymph nodes were found in 29 cases with lymph node metastases, an average of 19.31 per case. In our study, there was a relationship between the number of lymph nodes and the presence of lymph node metastases. In 29 patients with metastases, the number of involved nodes with tumor depth limited to the mucosa was similar to that observed for submucosal tumors, with no significant difference between the two groups.

Our results showed that there was no obvious correlation between lymph node metastases in mucosal cancer, and sex, age, tumor location, tumor size, the number of retrieved lymph nodes, morphological classification, histological type, lymphatic invasion, nervous invasion and CEA levels. Currently, there is much interest in the optimal management approach for patients with submucosal tumors and involved lymph nodes<sup>[36-40]</sup>. In a univariate analysis, An *et al*<sup>[22]</sup> demonstrated that tumor size, histological type, the Lauren classification, the depth of tumor invasion, lymphatic invasion and nervous invasion, were all relevant in terms of the risk of lymph node metastases in submucosal cancer. Of these factors, tumor size and lymphatic invasion are independent risk factors for nodal involvement<sup>[22,36-39]</sup>. In our study, there was no obvious correlation between the presence of lymph node metastases in patients with submucosal cancer, and sex, age, tumor location, tumor size, the number of retrieved lymph nodes, morphological classification, histological type, lymphatic invasion, nervous invasion, and CEA levels. Nonetheless, the lymph node metastases rate (60%, 3/5) in those with venous invasion was higher than that observed in patients without invasion (20%, 15/75), and the difference was significant. However, an analysis of venous invasion, as a source variable, in the logistic regression model, did not confirm it as an independent risk factor for lymph node metastases. An *et al*<sup>[22]</sup> considered that, for 19.4% of patients with submucosal cancer and lymph node metastases, laparoscopic subtotal distal gastrectomy plus lymph node dissection improved both the resection rate and quality of life. Controversy continues

as to which surgical approach is the optimal for the management of patients with submucosal cancer<sup>[40]</sup>.

Most lymph node metastases in EGC are limited to N1 and/or N2. In line with previous reports<sup>[34,63]</sup>, and our own experience, approximately 80%-90% of nodal metastases in EGC are limited to the N1. The proportion of involved N2 and N3 lymph nodes is lower at 10%-19% and 0%-1%, respectively<sup>[22,34,63,64]</sup>. This appears to support R2 resection<sup>[65]</sup>. In our group, of 29 patients with lymph node metastases, all were N1, seven were N2 (24.1%), and two were N3 (6.9%). These results are all higher than those reported by An *et al*<sup>[22]</sup>. Among them, the two N3 patients had the following clinicopathological features: both were mucosal cancers; the tumor size was relatively large, at 6 cm and 2.5 cm, respectively; and both tumors were depressed subtypes. Both patients underwent a radical gastrectomy plus a D2 lymph node dissection. Even in EGC, extensive lymph node metastases can occur. Surgeons should avoid conventional limited surgery, and assess the range of possible surgical resections<sup>[22]</sup>. Kuni-saki *et al*<sup>[55]</sup> believe that, for most cases of mucosal cancer, the routine D2 lymph node dissection might also be too invasive. Therefore, the method and range of lymph node dissection should be based on clinicopathological features before and after surgery. However, Yoshikawa *et al*<sup>[44]</sup> suggest that, during surgical treatment of mucosal cancers, apart from perigastric lymph node dissection, it is necessary to perform lymph node dissection at the coeliac trunk and beside the common hepatic artery. Our results support this recommendation. In our group, there was one case of mucosal cancer with a station No. 8 lymph node metastasis.

Since the mid 1900s, D2 lymph node dissection has been the standard procedure worldwide for the management of EGC, particularly for submucosal tumors. Studies have shown that the rate of lymph node metastases for N1 is 9%-16%, 4%-6% for N2, and 0.3%-1% for N3<sup>[49,56,59,66]</sup>. Accordingly, if D2 surgery is performed in all patients with EGC, 70%-80% would undergo unnecessary lymph node evacuation, and analysis suggests that these patients do not necessarily benefit as a result<sup>[40]</sup>. Consequently, indications for standard D2 lymph node dissection should be reconsidered. Our study revealed that, for cancers originating in the middle third of the stomach, the lymph node metastasis rate at N2 was 5.1%, mainly station No. 9, whereas there were no metastases in stations No. 7 and No. 12. Similarly, the metastasis rate in lower third tumors was 2.5%, mainly station No. 7 and No. 14. There was one case of metastasis (1.3%) in each of these. In upper third cancers, the rate was 4.0%, predominately station No. 8, with one case of metastasis (4.0%). Thus, when performing D2 surgery, patients with station No. 7 and No. 12 lymph nodes in tumors from the middle third of the stomach, stations No. 1, 8, 9, 11, and 12 lymph nodes in those from the lower third, and stations No. 7, 9-11 lymph nodes in the upper third should not be referred for routine dissection. In tumors of the middle third of the stomach, there was only one

case of N3 lymph node metastasis in both stations No. 2 and No. 14, and the metastasis rate was 1.0%. There were no N3 and distal lymph node metastases in tumors from both the upper and the lower third of the stomach. The benefit of performing D3 dissection in EGC is extremely low, with a long operative time and relatively more complications, which adversely affect quality of life. Therefore, D3 dissection should be avoided in EGC. There were no distal lymph node metastases in our study, and thus expanded lymph node dissection was not required.

Investigating the correlation between pN1 and pN2 lymph node metastases and clinicopathological factors, we found no significant associations between nodal status at pN1 and pN2 and tumor diameter, morphological classification, tumor differentiation and lymphatic invasion. The lymph node metastasis rate (22.5%, 18/80) at N1 in patients with submucosal cancers was higher than in those with mucosal cancers (9.0%, 11/122), and the difference was significant ( $\chi^2 = 7.144$ ,  $P = 0.008$ ). A histological study performed by Asao *et al.*<sup>[67]</sup> on 417 patients with gastric cancer who had routine gastrectomy plus D2 lymph node dissection, reported a rate of lymph node metastases in submucosal cancer of 1.3% (2/154), and in mucosal cancer distal to the perigastric part of 18% (17/96). These nodal metastases were mainly concentrated around the common hepatic artery and the coeliac trunk. In submucosal cancer, there was no nodal metastases elsewhere<sup>[67]</sup>. However, our study highlighted that tumors with N2 lymph node metastases were usually submucosal, with a diameter greater than 2.0 cm and were of the depressed subtype. Thus, we suggest that submucosal cancers, with a diameter greater than 2.0 cm, and of the depressed subtype are risk factors lymph node metastases. Patients with these factors should be identified during surgery.

There are limitations to this study. Firstly, it was retrospective, based on the examination of morphological samples after surgery. Prospective studies are needed to confirm whether our approach could be applied to endoscopic surgery based on biopsies. It is essential to define the acute T stage before surgery, in order to safely implement limited lymph node dissection. Although the accuracy of endoscopic ultrasonography is relatively high, overestimation or underestimation occurs<sup>[46]</sup>. Secondly, according to a previous Japanese study based on different depths of tumor invasion, mucosal cancer can be further subdivided into m1, m2, and m3 cancer, and submucosal cancer into sm1, sm2 and sm3 cancer. Moreover, there were obvious differences between the subgroups, with m1 and m2 cancers not usually associated with lymph node metastases, and the rate of nodal metastases in m3 cancers varies from 0% to 12.8%. At present, most endoscopic specialists agreed that all patients with mucosal cancers are suitable for EMR, while Hölischer *et al.*<sup>[19]</sup> oppose this view. Unfortunately, our two hospitals do not routinely perform sub-classifications for mucosal and submucosal cancers, which we plan to redress in future studies. Thirdly, the number of patients in our study was

lower than in the Japanese study. In a seminal study by Gotoda<sup>[46]</sup>, 5000 patients with EGC were enrolled. Results from our study need to be confirmed in larger studies.

In summary, our research revealed a lymph node metastasis rate of 14.4% in patients with EGC, with a rate of 5.4% for mucosal tumors and 8.9% for submucosal tumors. The occurrence of lymph node metastasis in EGC is related to tumor location, depth of invasion, morphological classification and venous invasion, with depth of invasion identified as the only independent risk factor for nodal involvement. Lymph node metastases should be considered when deciding on the surgical management of EGC.

## COMMENTS

### Background

Five-year survival rates in early gastric cancer (EGC) tend to be greater than 90%, with lymph node status the most important prognostic factor. Recently, in order to reduce operative and post-operative complications, and to improve quality of life, less invasive surgical alternatives, such as endoscopic mucosal resection (EMR), endoscopic submucosal dissection (ESD), laparoscopy-assisted gastrectomy and limited surgery, are used for the treatment of EGC. Although there has been substantial research on the prediction of risk factors for lymph node metastases in EGC, no definitive criteria exist.

### Research frontiers

The presence of lymph node metastases in EGC predicts a poor prognosis. In the area of the appropriate extent of lymphadenectomy in EGC, the research hotspot is to investigate the relationship between nodal involvement and clinicopathological factors, predict risk factors for lymph node metastases in EGC and determine the indications for local treatment in EGC, and limited surgery and the appropriate extent of lymphadenectomy.

### Innovations and breakthroughs

The presence of lymph node metastases predicts a poor prognosis, univariate analysis confirmed a correlation between tumor location, depth of invasion, morphological classification, venous invasion and lymph node metastases in EGC in this study. The results suggest that the rate of lymph node metastases is markedly higher in those with cancers of the middle and lower third of the stomach, and those with submucosal tumors, who are therefore not suitable for endoscopic surgery. When performing D2 surgery, patients with station No. 7 and No. 12 lymph nodes in tumors from the middle third of the stomach, stations No. 1, 8, 9, 11, and 12 lymph nodes in those from the lower third, and stations No. 7, 9, 10, and 11 lymph nodes in the upper third should not be referred for routine dissection. D3 dissection should be avoided in EGC. There were no distal lymph node metastases in this study, and thus expanded lymph node dissection was not required. The authors suggest that submucosal cancers, with a diameter greater than 2.0 cm, and of the depressed subtype, are risk factors for lymph node metastases. Patients with these factors should be identified during surgery.

### Applications

The depth of invasion is the only independent risk factor for lymph node metastases. Risk factors for metastases should be considered when choosing surgery for EGC.

### Terminology

EGC: A lesion confined to the mucosa or the submucosa, irrespective of the presence of regional lymph node metastases; EMR: A technique used for providing accurate histological staging of superficial gastrointestinal neoplasms and providing a minimally invasive technique for removal of superficial malignancies; ESD: A technique for the resection of early gastrointestinal neoplasia, whose main advantage is that lesions can be resected without almost any size limit.

### Peer review

The paper is good and complex. The authors thoroughly explained the problem of prediction of risk factors for lymph node metastasis in early gastric cancer.

They have described, in detail, the research results, as well as, the discussion. The conclusion was a logical consequence of the research results.

### Abstract

**AIM:** To investigate computed tomography (CT) and magnetic resonance imaging (MRI) manifestations of rectal gastrointestinal stromal tumors (GISTs) in order to enhance the recognition of these rare tumors.

**METHODS:** Fourteen patients with pathologically proven rectal GISTs were retrospectively reviewed. Patient histories were retrospectively reviewed for patient age, gender, presenting symptoms, endoscopic investigations, operation notes and pathologic slides. All tumors were evaluated for CD117, CD34 expression, and the tumors were stratified according to current criteria of the National Institutes of Health (NIH). In all cases the first pre-operation imaging findings (CT and MRI,  $n = 3$ ; MRI only,  $n = 8$ ; CT only,  $n = 3$ ) were analyzed by two experienced radiologists by consensus, which include:

tumor size, shape, CT density (hypodense, isodense and hyperdense), MRI signal intensity (hypointense, isointense and hyperintense), epicenter (intraluminal or extraluminal), margin (well-defined or ill-defined), internal component (presence of calcifications, necrosis, hemorrhage or ulceration), pattern and degree of enhancement, invasion into adjacent structures. After review of the radiologic studies, clinical and pathological findings were correlated with radiological findings.

**RESULTS:** The patients, 13 men and 1 woman, were aged 31-62 years (mean =  $51.5 \pm 10.7$  years). The most common initial presentation was hematochezia ( $n = 6$ ). The mean tumor diameter was  $5.68 \pm 2.64$  cm (range 1.5-11.2 cm). Eight lesions were round or oval, and 6 lesions were irregular. Eleven lesions were well-defined and 3 had ill-defined margins. Ten tumors were extraluminal and 4 were intraluminal. The density and MR signal intensity of the solid component of the lesions were similar to that of muscle on unenhanced CT ( $n = 6$ ) and T1-weighted images ( $n = 11$ ), and hyperintense on T2-weighted MR images. Calcification was detected in 2 tumors. Following intravenous injection of contrast media, 3 lesions had mild enhancement and 11 lesions had moderate enhancement. Enhancement was homogenous in 3 lesions and heterogeneous in 11. In 1 of 11 patients who underwent both CT and MRI, the tumor was homogenous on CT scan and heterogeneous on MRI. Eight patients were classified as high risk according to the modified recurrent risk classification system of NIH.

**CONCLUSION:** Rectal GISTs usually manifest as large, well-circumscribed, exophytic masses with moderate and heterogeneous enhancement on CT and MRI. The invasion of adjacent organs, bowel obstruction and local adenopathy are uncommon.

**Key words:** Gastrointestinal stromal tumors; Rectum;

## Computed tomography; Magnetic resonance imaging

**Core tip:** Rectal gastrointestinal stromal tumors (GISTs) are so rare that little information has been reported on their radiological features. This study describes the computed tomography (CT) and magnetic resonance imaging (MRI) features of rectal GISTs with clinical and pathological correlation, in order to better understand this rare disease. Rectal GISTs usually manifest as large, well-circumscribed, exophytic masses with moderate and heterogeneous enhancement on CT and MRI. The presence of invasion of adjacent organs, bowel obstruction and local adenopathy is uncommon.

Rectal gastrointestinal stromal tumors: Imaging features with clinical and pathological correlation. *World J Gastroenterol* 2013; 19(20): 3108-3116 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i20/3108.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i20.3108>

## INTRODUCTION

Gastrointestinal stromal tumors (GISTs), which arise from the interstitial cell of Cajal or its precursor, the intestinal mesenchymal precursor cell, are the most common mesenchymal neoplasms of the gastrointestinal tract. They are defined by their expression of CD117 (KIT), a tyrosine kinase growth factor receptor, which distinguishes them from other mesenchymal neoplasms such as leiomyomas, leiomyosarcomas, schwannomas, and neurofibromas and which determines the appropriateness of CD117-inhibitor therapy. Throughout the length of the gastrointestinal tract, GISTs arise most commonly in the stomach (60%-70%) followed by the small bowel (20%-25%), however, GISTs in the rectum are extremely rare (5%)<sup>[1]</sup>. It was reported that GISTs account for 0.6% of all malignant rectal tumors<sup>[2]</sup>. The imaging features of rectal GISTs are unclear due to their rarity and have only been described in small series<sup>[3-6]</sup>. Surgical resection remains the initial treatment for localized rectal GISTs<sup>[7]</sup>, familiarity of these imaging features may permit preoperative diagnosis and improve the surgical management of patients. The purpose of our study was to describe the computed tomography (CT) and magnetic resonance imaging (MRI) features of rectal GISTs with clinical and pathological correlation, in order to enhance the understanding of this rare disease.

## MATERIALS AND METHODS

The database of the Department of Surgery at our hospital was reviewed in order to identify patients presenting between January 2000 and June 2012 with histologically and immunohistochemically confirmed GISTs arising in the rectum. Fourteen patients were identified during this

period. Patient histories were retrospectively reviewed for patient age, gender, presenting symptoms, endoscopic investigations, and surgical notes. Pathologic slides of the specimens and mitotic activity (number of mitoses per 50 consecutive high-power fields) were reviewed by an experienced pathologist, and the tumors were stratified according to the current criteria of the National Institutes of Health (NIH)<sup>[8]</sup>. All tumors were evaluated for CD117 and CD34 expression.

In all cases, the first pre-operative CT or MRI was reviewed. Of the 14 patients, 3 underwent both CT and MRI examinations, 8 underwent only MRI examinations and 3 underwent only CT examinations. The CT and MRI technique varied somewhat due to the different imaging equipment and the retrospective nature of the study. However, intravenous contrast-enhanced images had been obtained for studies in all patients. A retrospective review of CT and MR images was implemented by two radiologists by consensus. The following imaging features of each mass were assessed: tumor size, shape, CT density (hypodense, isodense and hyperdense), MRI signal intensity (hypointense, isointense and hyperintense), epicenter (intraluminal or extraluminal), margin (well-defined or ill-defined), internal component (presence of calcifications, necrosis, hemorrhage or ulceration), pattern of enhancement (homogeneous or heterogeneous), and invasion into adjacent structures. The degree of enhancement of the lesion was assessed subjectively and categorized as follows: mild, when the enhancement was similar to that of adjacent muscle; moderate, when the enhancement was higher than that of muscle, but lower than that of blood vessels; and marked, when the enhancement was approaching that of blood vessels. High signal intensity in the necrosis on T1WI was defined as hemorrhage. The adjacent structures were also assessed for the presence of invasion. Findings on CT and MRI for abdominal adenopathy and hepatic metastasis were also evaluated. After review of the radiologic studies, surgical notes and excised specimens were correlated with radiological findings.

## RESULTS

### Clinical findings

Our patient cohort included 13 men and 1 woman with a mean age of  $51.5 \pm 10.7$  years (range, 31-62 years), and the clinical findings are summarized in Table 1. Digital colorectal examination was performed in 7 patients. Colonoscopy showed a mass protruding from the rectal wall with intact overlying mucosa in 6 patients (Figure 1), while a central mucosal ulceration was revealed in 1 patient. Two of these 7 patients underwent additional endoscopic ultrasonography, which showed hypoechoic masses that were contiguous with the muscularis propria of the rectal wall (Figure 1). All masses were found in the lower part of the rectum, with a distance from the anal verge ranging from 2.0 to 5.5 cm. Twelve patients

**Table 1 Summary of the presenting complaints of 14 patients with rectal gastrointestinal stromal tumors**

| Presenting symptoms or signs           | <i>n</i> |
|--|----------|
| Incidental finding on an imaging study | 2        |
| Change of defecation habit             | 2        |
| Hematochezia                           | 6        |
| Pelvic pain                            | 1        |
| Narrow stools                          | 1        |
| Difficult defecation                   | 1        |
| Sense of anal falling inflation        | 1        |

underwent radical resection, including abdominoperineal resection (*n* = 9) and low anterior resection (*n* = 3) depending on the extent and localization of the tumors. The other 2 patients underwent transanal excision. At the time of surgical exploration, none of the patients had evidence of remote metastasis. Tumor rupture was not found during surgery. No lymph node metastases were identified pathologically in all 12 patients who underwent lymphadenectomy.

### Pathological findings

Immunohistochemical staining showed that all tumors were positive for CD117 (14/14) (Figure 2), while 13 patients were positive for CD34 (13/14). The masses were solid and grayish-white or dark-red with areas of hemorrhage or necrosis on the cut sections (Figure 3), and showed a spindle cell pattern under light microscope (Figure 2). According to the current NIH classification scheme, 8 tumors (8/14) had high risk, 3 (3/14) had intermediate risk, 3 (3/14) had low risk for aggressive behavior.

### Imaging findings

The diameter of the tumors ranged from 1.5 to 11.2 cm (mean, 5.68 ± 2.64 cm). The tumor was smaller than 5 cm in 4 patients and larger than 5 cm in 10 patients. Eight masses were either round (*n* = 2) or oval (*n* = 6), and 6 were irregular. The tumors showed definite intraluminal tumor growth in 4 patients, whereas extraluminal tumor growth was seen in the majority of our patients (10/14) (Figures 1-8). Eleven tumors showed a well-defined margin, and 3 tumors showed contour irregularity or blurring.

On unenhanced CT images, the density of the 6 tumors was 33-45 HU (mean, 38 HU) which was similar to that of muscle. Flecks of calcification were detected in 2 extraluminal tumors (Figures 4, 5). Following intravenous administration of contrast media, the majority (4/6) of rectal GISTs were moderately enhanced masses with areas of unenhanced low attenuation on CT scan. A homogeneous pattern of enhancement was less common and was present in 2 of the patients who underwent CT studies (Figure 6); in 1 patient who underwent both CT and MRI, the tumor was homogenous on CT scan, but demonstrated heterogeneous enhancement with foci of fluid signal on MR images. All the heterogeneous tumors

showed areas of fluid density in keeping with cystic changes on cut sections.

In the 11 cases examined with MRI, the solid component of all the tumors was isointense to skeletal muscle on T1-weighted images and hyperintense on T2-weighted images. There were some intratumoral high-intensity foci on T1WI representing hemorrhage (*n* = 1) (Figure 3) and hyperintensity on T2WI corresponding to necrosis (*n* = 8) (Figure 7). Nine of these 11 tumors were heterogeneous, with non-enhancing components showing fluid signal. After intravenous administration of gadolinium, 7 lesions had moderate enhancement and 4 lesions had mild enhancement on fat-suppressed T1WI. Ulceration to the rectal lumen was seen in 1 patient (Figure 8). Bowel obstruction, abdominal adenopathy and remote metastasis were not seen in any of our patients.

## DISCUSSION

Although an increasing amount of literature concerning GISTs has been published, there is little information reported on the radiological features of rectal GISTs due to their rarity. To our knowledge, this article is the largest study of rectal GISTs in the radiological literature.

### Clinical characteristics

It was reported that rectal GISTs occur in adults between the fifth and sixth decades with a significant male predominance (71%)<sup>[9]</sup>. In this study, there was a marked male predominance with a male: female ratio of 13:1, and the mean age at onset was 51.5 years, in line with the pathological literature. The clinical manifestations of rectal GISTs depend on the location and size of the tumors and are often nonspecific<sup>[10-12]</sup>. A GIST can remain clinically silent and present late when the tumor is large. Two of our patients were asymptomatic and the tumors were incidental findings, perhaps due to their small size (less than 3.0 cm in maximum diameter) and tendency to grow exophytically. The exophytic growth pattern may also explain why rectal GISTs rarely cause intestinal obstruction even when they are large. Miettinen *et al*<sup>[9]</sup> reported that rectal bleeding was the most common symptom in patients with a large rectal GIST more than 5 cm. In this study, the most frequent symptom was also hematochezia.

### Imaging features

Rectal GISTs generally manifest as large eccentric masses growing beyond the rectal wall<sup>[3-6]</sup>. Our series showed a similar growth pattern. Although larger tumors have a higher rate of malignancy, size does not predict benignity, and small GISTs have been known to behave in a malignant fashion<sup>[13-16]</sup>. Since most rectal GISTs arise within the muscularis propria of the intestinal wall, they most commonly have an exophytic growth pattern with the epicenter located well outside the rectum<sup>[17,18]</sup>. GISTs arising from the anterior rectal wall in male patients can even mimic tumors of prostatic origin on CT<sup>[19,20]</sup>. Thus,

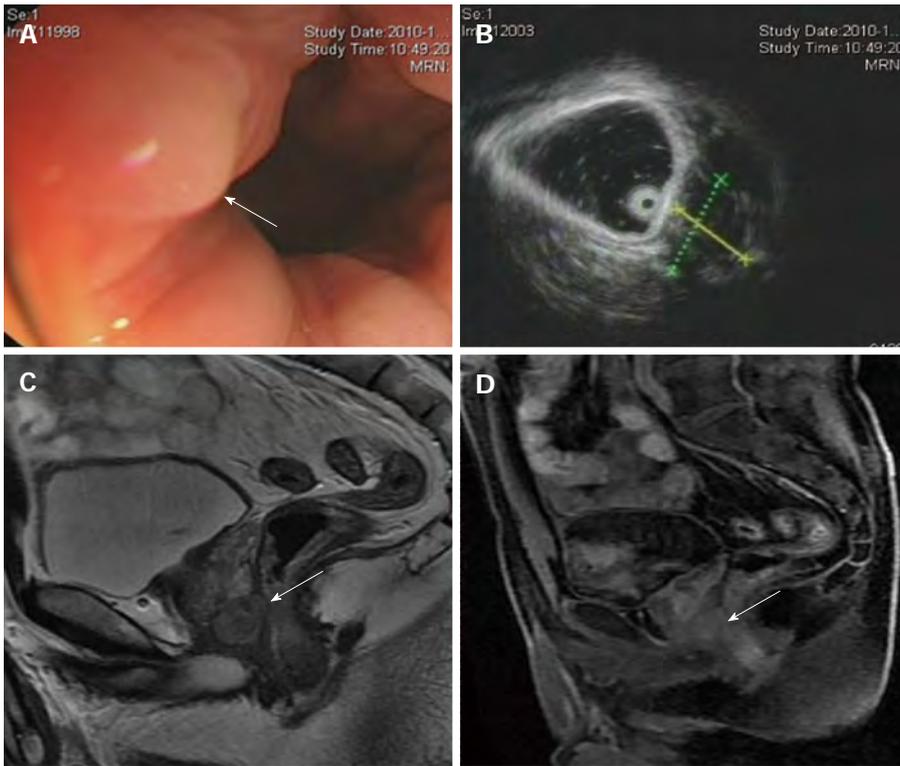

Figure 1 A 40-year-old man with a rectal gastrointestinal stromal tumor. A: Colonoscopy shows a mass protruding from the rectal wall with intact overlying mucosa (arrow); B: Endoscopic ultrasonography shows a well-defined hypoechoic mass located along the right anterior aspect of the rectal wall; C: Sagittal T2-weighted magnetic resonance imaging shows an oval, homogenous, hyperintense mass with a sharp margin bordering the anterior rectal wall. A small area of anatomical continuity between the tumor and the anterior rectal wall is observed (arrow); D: Postcontrast T1-weighted image shows a slightly homogeneously enhancing mass (arrow).

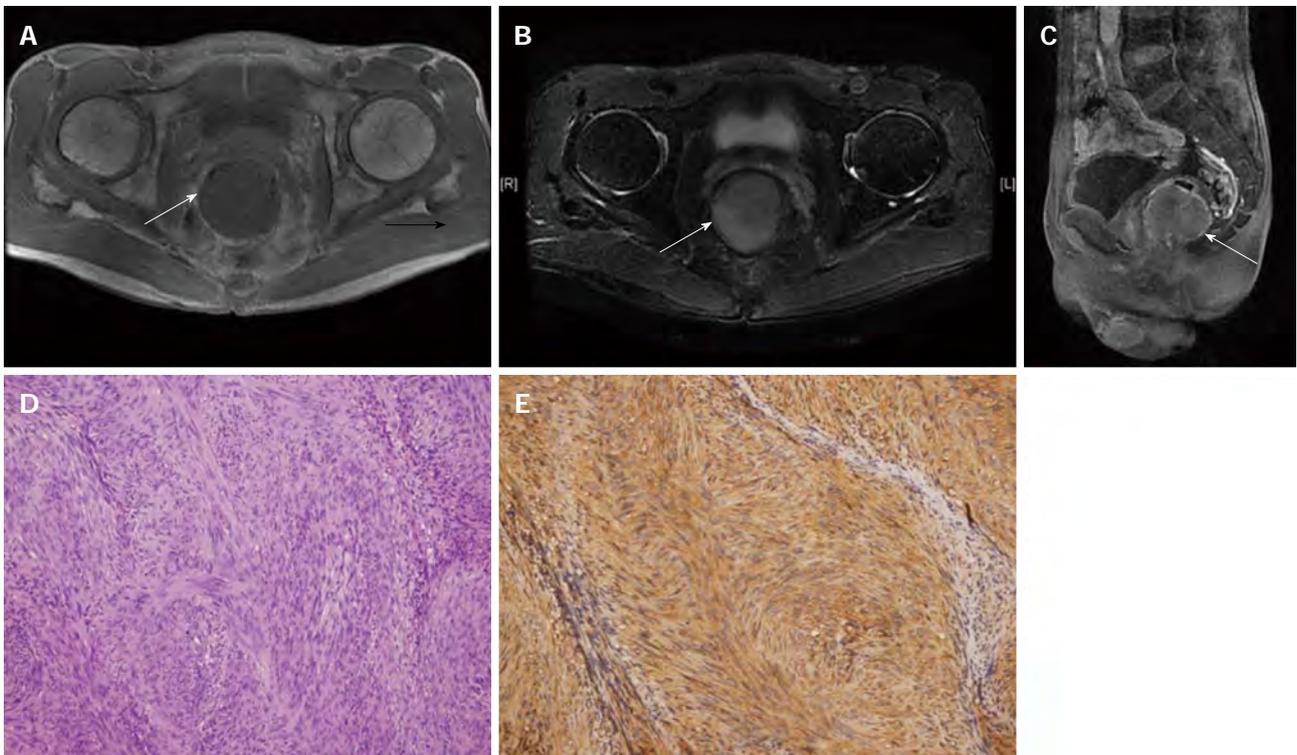

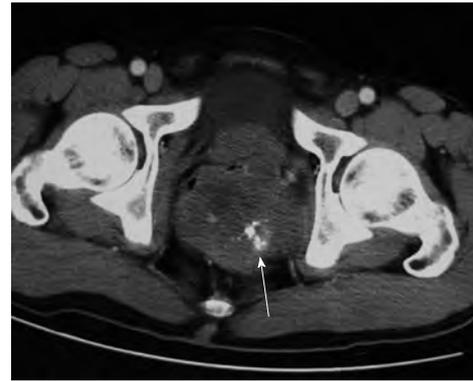

Figure 2 A 56-year-old man with a rectal gastrointestinal stromal tumor. A: Axial T1WI shows the lesion as a round, intraluminal, homogenous, hypointense mass with a sharp margin (arrow); B: It shows homogenous hyperintense on T2WI (arrow); C: Sagittal enhanced T1WI shows homogenous moderate enhancement (arrow); D: Photomicrograph shows fascicular proliferation of spindle-shaped tumor cells (hematoxylin and eosin,  $\times 200$ ); E: The tumor cells were strongly and diffusely positive for CD117 staining (immune-histochemistry,  $\times 200$ ).

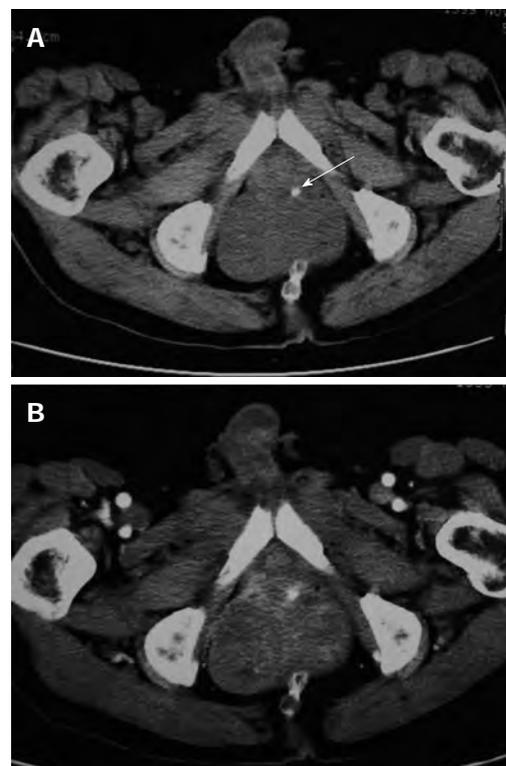

**Figure 3** A 62-year-old man with a rectal gastrointestinal stromal tumor. A: The mass is located between the prostate and the anterior rectal wall and its epicenter is well outside the rectum. Axial T1-weighted MR image shows a high signal (arrow) within the mass, in keeping with hemorrhage; B: Sagittal T2WI shows a heterogenous mixed-intense mass with blurring contour (arrow); C: Postcontrast T1WI shows the solid component of the mass enhanced heterogeneously (arrow); D: Macroscopic cross section shows a pale yellow, tan and solid mass with hemorrhage (arrow).

the classic rule regarding determination of the organ of origin based on the location of the epicenter of a

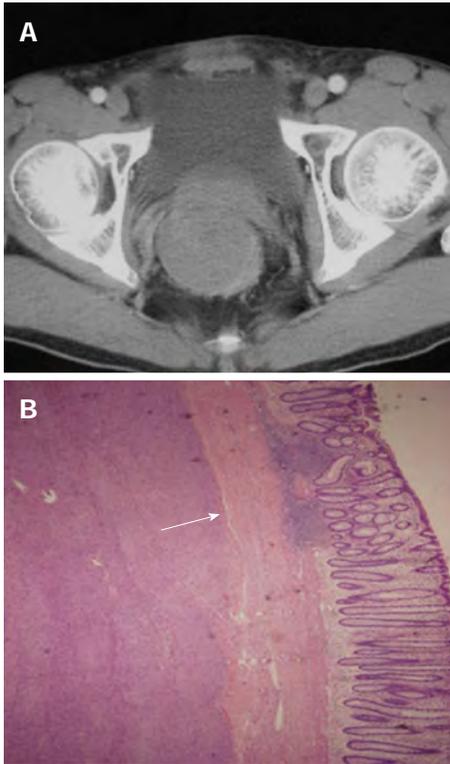

**Figure 4** A 52-year-old man with a rectal gastrointestinal stromal tumor. The mass is located in the left posterior wall of the rectum with scattered calcification (arrow).

**Figure 5** A 61-year-old man with a rectal gastrointestinal stromal tumor. A: The mass located in the left wall of the rectum with fleck of calcification at the tumor margin (arrow); B: The mass enhanced heterogeneously following intravenous administration of contrast media.

tumor is often not applicable. In such cases, enhanced MRI should be performed. MRI with direct multiplanar capability is definitely more useful in determining the exact tumor origin, delineating the spatial relation to adjacent structures, and outlining the pelvic floor surgical anatomy. In our study, tumor-rectal wall continuity was revealed in the sagittal plane, which suggested the diagnosis of a rectal mass. On the other hand, invasion of adjacent organs was better seen on MRI compared with CT examination.

In this study, most of the tumors were round or oval and smooth with well-defined margins. On unenhanced CT, rectal GISTs appear as isodense with normal muscle

**Figure 6** A 53-year-old man with a rectal gastrointestinal stromal tumor. A: Computed tomography scan shows a round intraluminal mass with a sharp margin; B: Photomicrograph shows the tumor originating from the muscularis propria (arrow) of the rectum (hematoxylin and eosin,  $\times 20$ ).

as the standard for comparison. On unenhanced MRI, rectal GISTs appear as isointense to skeletal muscle on T1-weighted images and hyperintense on T2-weighted images, and moderately or mildly enhanced on CT and/or MR studies. A heterogeneous pattern of enhancement is more common on CT and/or MR studies, and was present in 11 of our cases. Heterogeneity corresponds to intralesional necrosis or hemorrhage, which was confirmed on cut sections. It is likely that MRI may be superior to CT in detecting the internal component. Only one of our patients underwent both CT and MRI, and the tumor was homogenous on CT scan, but was heterogeneous with fluid signal on MR images.

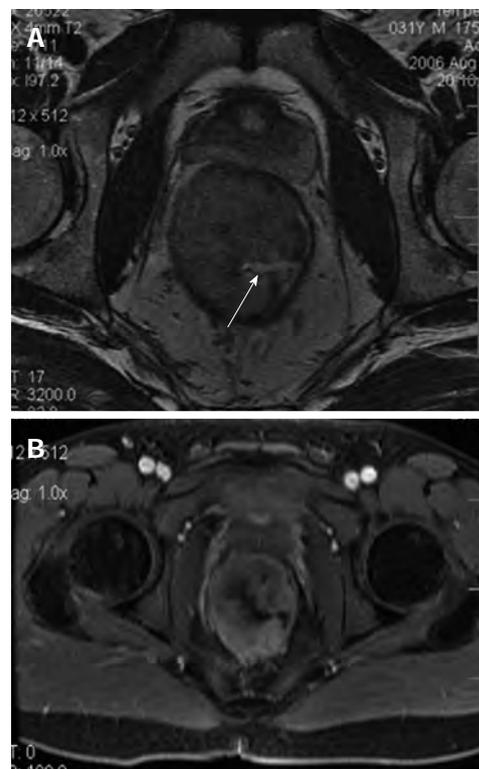

Although calcification is not a usual clinicopathologic feature of GISTs, it has been reported in previous studies<sup>[21-23]</sup>. Most calcifications within GISTs are circumscribed and patchy. In our study, one of the two calcified tumors showed focal calcification and the other was mottled. Previous episodes of bleeding or tumor necrosis with cystic degeneration may cause calcification<sup>[24,25]</sup>. Because these tumors are submucosal, the overlying mucosa can be intact. However, overlying mucosal ulcerations are often present and cause bleeding, and are more common in high risk GISTs<sup>[26-28]</sup>.

### Differential diagnosis

Unfortunately, there is significant overlap between the imaging appearances of rectal GISTs and other rectal diseases, such as epithelial neoplasms, lymphoma or

**Figure 7** A 59-year-old woman with a rectal gastrointestinal stromal tumor. The mass is located between the uterus and the anterior rectal wall with focal fluid signal on T2WI corresponding to necrosis (arrow).

**Figure 8** A 31-year-old man with a rectal gastrointestinal stromal tumor. A: Axial T2WI shows the lesion as an intraluminal mass with ulceration (arrow) of the rectal lumen; B: The mass is enhanced moderately heterogeneously following intravenous administration of gadolinium.

carcinoids. Most of these tumors may be differentiated from rectal GISTs by the presence of the following features: well-demarcated margins, prominent extraluminal location and no surrounding adenopathy, and the lack of bowel lumen constriction despite the large size of the rectal GIST. This behavior is unlike most cases of adenocarcinoma which has a propensity for luminal obstruction. The appearance of a smooth regular border is a feature that allows these tumors to be differentiated from malignant epithelial neoplasms. Signs of intratumoral degeneration, such as cystic change, hemorrhage, and calcification, should exclude lymphoma from the

differential diagnosis.

Due to the submucosal origin of the tumors, endoscopy is only of use when the tumor infiltrates the mucosa and can be detected<sup>[29]</sup>. In addition to endoscopy, endoscopic ultrasonography is a valuable technique in the diagnosis of these tumors because it can reliably distinguish intramural lesions from extrinsic compression. Enhanced MRI with an endoluminal coil has been performed to determine the tumor origin in some reported cases<sup>[30-32]</sup>, but these procedures are invasive, and are rarely used in routine examinations.

### Pathological features

CD117 is the most specific and important diagnostic molecular marker of GISTs. Most GISTs (more than 95%) express CD117, which can be detected immunohistochemically<sup>[9,33]</sup>. Although CD117-positive expression is very common in GISTs and a major defining characteristic of GISTs, it is not absolutely necessary for the diagnosis of GISTs. CD34 is also commonly expressed in GISTs, which is less specific compared with CD117 and is not considered a requirement for the diagnosis of GISTs either<sup>[34-36]</sup>. The review of pathology in our patients showed that the tumors were strongly positive for CD117 and in most cases also CD34, consistent with previous reports.

The pathologic differentiation and biologic behavior of GISTs have been continuing topics of controversy for many years. A small number of GISTs recur or metastasize despite a histologically benign appearance. Therefore, some authors support stratifying GISTs into very low-, low-, intermediate-, and high-risk categories rather than classifying them as benign or malignant. The NIH risk classification system, which consists of tumor size, mitotic count (number of mitoses per 50 consecutive high-power fields), anatomic location, and tumor rupture, is recommended as a valuable tool for estimating the clinical behavior of GISTs<sup>[8]</sup>. Rectal GISTs have a high-risk tendency<sup>[23]</sup> which was observed in the majority of our patients.

Attempts to predict the potential high-risk behavior of GISTs from their imaging features is difficult. It was reported that GISTs with irregular margins, size larger than 10 cm, central necrosis, ulceration, and heterogeneous contrast enhancement are normally regarded as denoting aggression<sup>[37,38]</sup>. These signs are mainly derived from a study population of stomach and small intestine GISTs and seldom from rectal GISTs. However, our series is small and no correlation between radiologic appearance and risk levels could be established with regard to the degree of necrosis, hemorrhage, ulceration, or contrast material enhancement.

There are several limitations in this study. The study was retrospective and the reviewers of the imaging studies knew that all patients had a pathologically confirmed rectal GIST, which may have increased the sensitivity for detecting each imaging sign. In addition, different CT and MRI equipment and techniques were used. How-

ever, these problems are simply unavoidable due to the rarity of this type of tumor, and this should not have significantly affected the imaging features studied.

In summary, we present the largest series of radiological studies of rectal GISTs to date. These tumors often present with hematochezia. They are normally seen as large, bulky, exophytic rectal masses with heterogeneous enhancement on CT and MRI. Cross-sectional imaging, which allows better visualization of the origin of the mass, its internal components, and other organ involvement, is indicated for surgical planning.

## COMMENTS

### Background

Rectal gastrointestinal stromal tumors (GISTs) are very rare, which accounts for 0.6% of all rectal malignant tumors. Only a few reports concerning the radiological features of rectal GIST has been published due to its rarity. Surgical resection remains the mainstay of therapy for localized rectal GISTs, familiarity of their radiological features may permit preoperative diagnosis and improves surgical management of patients. Thus, it is very important to enhance the understanding of the imaging features of this rare tumor.

### Research frontiers

The current imaging knowledge of rectal GISTs is based on a few case reports. Grassi *et al* reported a 4-cm mass in a 70-year-old man that showed marked, irregular, eccentric thickening of the lateral left wall of the lower third of the rectum. Hama *et al* reported a 9.8-cm mass in a 50-year-old man that was contiguous with the prostate and enhanced on both computed tomography (CT) and magnetic resonance imaging (MRI). Levy *et al* reported six anorectal gastrointestinal stromal tumors, and found that anorectal GISTs were typically large, well-demarcated anorectal masses containing hemorrhage.

### Innovations and breakthroughs

This study contained a relative large cohort of cases of rectal GISTs confirmed by histology and immunochemistry. All the patients had a complete medical records including age, gender, presenting symptoms, endoscopic examinations, surgical notes and pre-operative cross-sectional imaging studies. The authors focused on the correlation of imaging features of this rare tumor with clinical and pathological characteristics.

### Applications

Rectal GISTs are normally seen as large, bulky, exophytic rectal masses with heterogeneous enhancement on CT and MRI. Cross-sectional imaging, which allows better visualization of the origin of the mass, its internal components, and other organ involvement, is indicated for surgical planning.

### Terminology

GIST is the most common mesenchymal neoplasm of the gastrointestinal tract, which arises from the interstitial cell of Cajal or its precursor. The rectum is the rare primary site involving about 5% cases. Due to the submucosal origin of the rectal GISTs, the presence of the following features allows these tumors to be differentiated from malignant epithelial neoplasms: well-demarcated margins, prominent extraluminal location and no surrounding adenopathy, and the lack of bowel lumen constriction despite the large size of the tumor.

### Peer review

The authors reported imaging features of rectal gastrointestinal stromal tumors with clinical and pathological correlation. The main strength of this study is the relatively large number ( $n = 14$ ) of patients and broader spectrum of imaging findings in this rare tumor. The findings are instructive to both radiologists and physicians.

### Abstract

**AIM:** To review the clinicopathological characteristics of concurrent gastrointestinal stromal tumors (GISTs) and gastric adenocarcinoma.

**METHODS:** We retrospectively analyzed eight cases of synchronous adenocarcinoma and GIST in the stomach that had been surgically resected with curative intent between March 2003 and December 2008 in Xinhua hospital and Ruijin hospital. The adenocarcinoma was determined to be the primary tumor based on the histological features. The GIST cells were diffusely and strongly positive for CD34 and CD117.

**RESULTS:** The patients were six men and two women aged 47-80 years (average, 68.6 years). GIST was pre-operatively detected in only one patient. The average sizes of the gastric adenocarcinomas and GISTs were

6.000 ± 2.6186 cm and 1.825 ± 1.4370 cm, respectively. All GISTs were very low- or low-risk lesions that were detected during evaluation, staging, operation or follow-up for gastric adenocarcinoma.

**CONCLUSION:** We hypothesized that the stomach was influenced by the same unknown carcinogen, resulting in a simultaneous proliferation of different cell lines (epithelial and stromal cell).

### INTRODUCTION

Gastrointestinal stromal tumors (GISTs) are mesen-

chymal tumors of the digestive tract and have various clinical and biological characteristics. The expression of c-Kit distinguishes GISTs from true leiomyomas, leiomyosarcomas and other mesenchymal tumors of the gastrointestinal tract<sup>[1-3]</sup>. The stomach (60%-70%) and small intestine (20%-30%) are the most common sites of GISTs<sup>[1,2]</sup>. GISTs are composed of spindle (70%) or epithelioid (30%) cells and are positive for c-Kit (CD117), CD34 and occasionally for actin, but almost always negative for desmin and S-100 protein<sup>[4]</sup>, in contrast to other mesenchymal tumors. Benign GISTs are far more common than malignant ones (10%-30%)<sup>[1]</sup>, and all GISTs are often found incidentally at surgery and excised in the same session<sup>[5]</sup>.

Collision tumors of the stomach are uncommon; however, several cases have been reported. Most collision tumors of the stomach are composed of an adenocarcinoma intermixed with a gastric lymphoma<sup>[6-9]</sup>. Some are composed of an adenocarcinoma intermixed with a carcinoid tumor<sup>[8,10,11]</sup>. However, gastric collision tumors composed of a GIST and an adenocarcinoma are exceedingly rare. Ruka *et al.*<sup>[12]</sup> found that 10% of their GIST patients had an associated non-GIST neoplasm, usually, a carcinoma. Furthermore, Maiorana *et al.*<sup>[15]</sup> found that of 52 patients with gastric GISTs, six patients (11.5%) had an associated, second gastric tumor (five adenocarcinomas and one carcinoid tumor).

Most of these publications were reports of single cases. Here, we present a series of eight patients with synchronously occurring GISTs and gastric adenocarcinomas. The aim of this study was to evaluate the clinicopathological characteristics of GISTs occurring concomitantly with gastric adenocarcinomas and to provide an English literature review<sup>[14,15]</sup>.

## MATERIALS AND METHODS

### Patients

We analyzed the clinicopathological findings in eight patients with CD117-immunopositive GISTs (six men and two women) who underwent surgery with a curative intent for a primary, resectable tumor without detectable metastases, between March 2003 and December 2008. Their clinicopathological data were supplemented by a review of all available medical and histopathological records from Xinhua hospital and Ruijin hospital. Selected were the patients with postoperative pathological diagnosis of primary gastric GIST, and patients who didn't receive chemotherapy and Imatinib as adjuvant treatment. Excluded were patients who had synchronous gastrointestinal stromal tumors in stomach and extra-stomach neoplasms, patients with initial surgery performed in other hospital, and patients with the pathology diagnostic data insufficiency. None of the patients had a family history of gastrointestinal carcinoma or GIST. Prior to the commencement of the present study, our ethics committee deemed that approval of the committee and informed consent were not required for the retrospective analysis

of clinical data.

### Methods

GISTs were defined as primary spindle cell and/or epithelioid neoplasms of the tubular gastrointestinal tract with CD117 overexpression, with or without CD34 expression according to well-established criteria for the diagnosis of GISTs<sup>[16,17]</sup>. The risk of aggressive GISTs was assessed using criteria derived from the 2002 Fletcher classification. For each patient with a primary tumor and no metastatic disease at the time of diagnosis, a TGM system<sup>[18]</sup> was used for staging: T: T1, localized and < 5 cm; T2, localized and  $\geq$  5 cm; T3, contiguous organ invasion or peritoneal implants; T4, tumor rupture. G: G1, low grade; G2, high grade. M: M0, no metastases; M1, metastases present. The final staging system was determined as follows: Stages I (< 5 cm) and II ( $\geq$  5 cm) are localized lesions with low histologic grade. Stage III lesions are either high-grade tumors of any size or tumors with regional involvement (contiguous organ invasion or peritoneal implants). Stage IVA refers to patients with systemic metastases or unresectable tumor. Stage IVB is designated when tumor rupture has occurred despite resection of all macroscopic disease. The gastric adenocarcinomas were staged according to the TNM system devised by the International Union Against Cancer<sup>[19]</sup>.

Representative hematoxylin and eosin-stained slides of archival tumor specimens were prepared from formalin-fixed, paraffin-embedded tissue blocks. To confirm the histogenesis of GISTs, immunohistochemistry (IHC) panels were obtained with the following markers: CD117, CD34, smooth muscle actin (SMA) and S-100. The IHC studies were performed using formalin-fixed, paraffin-embedded blocks and primary antibodies to the above markers, on a standard, automated, streptavidin-biotin peroxidase-detection system (EnVision™ Autostainer Visualization System; DakoCytomation, Glostrup, Denmark) equipped with a microwave antigen-retrieval step. Parallel positive controls were run for each antibody. A rabbit or mouse, universal, negative-control monoclonal antibody was used for each specific antibody.

### Ethics committee approval

This study was approved by the Bioethics Committees at each hospital.

### Statistical analysis

Statistical analyses were performed using the Statistical Package for the Social Sciences, version 11.0 (SPSS Inc., Chicago, IL). Descriptive data are presented as the mean  $\pm$  SD.

## RESULTS

The study consisted of eight patients, including six men (75%) and two women (25%). The median age of the patients at the time of presentation was 68.6 years (range, 47-80 years). The most common presenting features were

**Table 1** Size and histological characteristics of gastrointestinal stromal tumors in eight patients

abdominal discomfort ( $n = 3$ ), gastrointestinal bleeding ( $n = 2$ ), difficulty eating ( $n = 1$ ), nausea and vomiting ( $n = 1$ ) and weight loss ( $n = 1$ ). Some patients had more than one of these symptoms. The median duration of disease was 1.5 mo (range, 0.5-6 mo). Total ( $n = 1$ ) or subtotal gastrectomies ( $n = 7$ ) were performed in the patients with gastric malignancy.

All patients underwent preoperative gastroscopy, which revealed an ulcerative lesion in four patients, a diffuse infiltrative lesion in two patients and an infiltrative ulcerative lesion in two patients. All lesions were diagnosed as adenocarcinomas on biopsy examination. Body computer tomography (CT) scans and chest images were available for review in all eight patients. In one patient, preoperative CT revealed a soft tissue lesion with a diameter of 5.0 cm in the lesser curvature, this lesion was considered a GIST.

All patients underwent simultaneous, radical resection of the gastric adenocarcinoma and GIST. In most cases, the stromal tumors were an incidental finding during operation. Detailed clinicopathological data for all GISTs are shown in Tables 1 and 2. According to the American Joint Committee on Cancer staging, 87.5% of patients had stage I tumors, and 12.5% of patients had stage II tumors. The mean GIST size was  $1.825 \pm 1.4370$  cm (range, 0.6-5.0 cm). Seven GISTs were located in the serosal layer, and one was present in the muscular layer. All GISTs were of the spindle type, and were strongly and diffusely positive for CD117 and CD34. Six GISTs were also positive for vimentin (VIM) (75.0%), four for S-100 (50.0%), three for desmin (37.5%) and two for SMA

(25.0%).

The synchronous gastric adenocarcinomas were located in different parts of the stomach (Table 3). The mean sizes of the primary adenocarcinomas were  $6.000 \pm 2.6186$  cm (range, 2.0-8.0 cm). No patients had distant metastases at the time of diagnosis. Half of the tumors were poorly differentiated; in the case of the other half, differentiation was not recorded because there is no standard for pathological recording. One of the patients had early gastric cancer, and the other seven had advanced gastric cancers; two patients each had stage I and II disease, three had stage III disease and one had stage IV disease.

## DISCUSSION

The term gastric stromal tumor was originally coined by Mazur *et al*<sup>[20]</sup>. Most gastric stromal tumors exhibit variable differentiation; these tumors tend to originate from primitive mesenchymal cells<sup>[21]</sup>, rather than from smooth muscle cells. GISTs are rare neoplasms that are most commonly located in the stomach (39%-60%), small bowel (30%-42%), colon-rectum (5%-10%) and esophagus (5%)<sup>[22]</sup>. The most common symptoms of the patients in the current study were abdominal masses, pain and bleeding<sup>[23,24]</sup>. The symptoms of these tumors depend on their size and location<sup>[24]</sup>. GISTs are generally found within the deeper stroma and the submucosa, and therefore, in most of the reported cases of synchronous gastric adenocarcinoma and GIST, the preoperative biopsy specimens have shown only adenocarcinoma. GISTs are often incidentally detected during imaging studies, operation or examination of the resected specimens<sup>[25]</sup>.

In this report, only one case of GIST was detected preoperatively, on a CT scan; the others were found incidentally during or after operation, upon general pathological examination. Owing to the variability and specific characteristics of GISTs, the coexistence of these tumors with other gastric tumors should be considered in the treatment of gastric cancer. To avoid missed diagnosis or misdiagnosis of GISTs, imaging studies such as ultrasonography, CT and magnetic resonance imaging should be performed in patients in whom gastric cancer is detected on gastroscopy. Moreover, surgical exploration in these patients should be careful and comprehensive. If suspi-

**Table 3** Clinical characteristics, treatments and outcomes of gastric adenocarcinoma in eight patients

| Patient No. | Primary site         | Size (cm) | TNM status    | Surgical resection     | Gross appearance             | Histology                              | Clinical presentation    |
|-------------|----------------------|-----------|---------------|------------------------|------------------------------|--|--------------------------|
| 1           | Cardia               | 8         | T3N1M0, III B | Radical operation      | Ulcerative infiltrative type | The low differentiation adenocarcinoma | Difficulty in swallowing |

TNM: Tumor, nodes, metastasis-classification.

cious lesions are found, these should not be assumed to be metastases of gastric cancer. Physicians should consider the possibility of other types of tumors, radically resect the suspicious lesion, obtain frozen sections for pathological examination, determine the histological origin of the lesion and apply appropriate surgical techniques. In addition, any nodule on the walls of the digestive tract should be carefully assessed so that no small GIST is overlooked during the postoperative pathological examination.

Liszka *et al*<sup>[26]</sup> retrospectively analyzed the clinicopathological characteristics of 22 cases of concurrent GISTs and other tumors, including two cases of GISTs accompanied by gastric cancers, and 60 cases of only GISTs. They found that the risk of invasion was much lower and the tumor diameter was smaller in patients with concurrent GISTs and other tumors than in patients with only GISTs ( $P < 0.05$ ), which is consistent with our results. These findings may be attributable to the following factors: the risk of malignant invasion of GISTs is relatively low, and the biological behavior of GISTs might have been inhibited by the gastric cancer. However, definitive evidence for this theory is lacking at present.

The morphology of GIST cells is usually spindle shaped (70%), epithelioid (20%) or mixed. GISTs are immunohistochemically positive for Kit expression (90%-95%) and often for Bcl-2 (80%), CD34 (70%), SMA (35%), S-100 (10%) and desmin (5%) expression. In this study, all the GISTs were strongly and diffusely positive for CD117 and CD34. Six GISTs were also positive for VIM (75.0%), four for S-100 (50.0%), three for desmin (37.5%) and two for SMA (25.0%). Fletcher *et al*<sup>[17]</sup> proposed a classification for malignancies that was based on tumor size and the number of mitotic divisions. According to this classification, all the tumors in our study were classified as low risk or very low risk; nevertheless, careful follow-up is mandatory.

Collision tumors rarely develop in the stomach. The frequency of secondary malignancies in GIST patients has been reported to be 4.5%-35% in different series<sup>[15,27-33]</sup>. The most common GIST-associated malig-

nancies were gastrointestinal carcinomas (47%), prostate cancer (9%), lymphoma/leukemia (7%) and breast cancer (7%)<sup>[27]</sup>. Single case reports have described the occurrence of adenocarcinoma admixed with gastric lymphoma, carcinoid tumor, leiomyosarcoma<sup>[13,34-37]</sup> or rhabdomyosarcoma<sup>[35,36]</sup>, as well as adenoma admixed with a sarcomatous stromal component<sup>[38]</sup>. Thus far, only a few case reports of gastric collision tumors consisting of adenocarcinoma and leiomyoma have been documented<sup>[39,40]</sup>. Rare cases of concurrent presentation of gastric adenocarcinoma and GIST have been reported in the literature<sup>[13,15,24,37,41-46]</sup>. Maiorana *et al*<sup>[13]</sup> found that 6 of 52 (11.5%) patients with gastric GISTs had an associated second gastric tumor (five adenocarcinomas and one carcinoid tumor), which considering the restriction of both tumor types to the stomach, indicates a high incidence. In 2000, Maiorana *et al*<sup>[13]</sup> found that GISTs were the most common non-epithelial tumor that could simultaneously occur with epithelial tumors (carcinomas and carcinoid tumors); they also reported five cases of GIST combined with gastric cancer.

The admixture of gastric epithelial and stromal tumors raises the question of whether such an occurrence is a simple incidental association or whether the two lesions are connected by a causal relationship. Some researchers claim that this simultaneous presentation is coincidental; however, others hypothesize that some unknown carcinogens induce the simultaneous proliferation and oncogenesis of epithelial and stromal cells<sup>[13-15,24,41,42,44,45]</sup>. Theoretically, genetic mutations could play an important role in the pathogenesis of gastric synchronous tumors; however, no available evidence supports a common genetic mutation underlying gastric adenocarcinoma and GIST<sup>[27,47,48]</sup>. Another hypothesis suggested in experimental models is that the same unknown carcinogenic agent may interact with two adjacent tissues, causing the simultaneous development of tumors of different histological types<sup>[13,41,49-52]</sup>. Cohen *et al*<sup>[51]</sup> reported that exposure to both acetylsalicylic acid and nitrosoguanidine causes synchronous development of both gastric cancer and leiomyosarcoma. An interesting hypothesis is that a single

carcinogenic agent may interact with two neighboring tissues, inducing the development of tumors of different histological types in the same organ<sup>[51]</sup>. *Helicobacter pylori* has been found to be related to the pathogenesis of gastric carcinoma and mucosa-associated lymphoid tumor<sup>[53,54]</sup> or GIST<sup>[24]</sup>. Liu *et al.*<sup>[42]</sup> hypothesized that the stomach was influenced by the same unknown carcinogen, resulting in the simultaneous proliferation of different cell lines (epithelial and stromal cells).

Our study has some limitations: it was retrospective and the number of patients was small. This limited the validity of significant statistical evidence that can be extrapolated from our study. In addition, our study does not answer the question of whether a causal relationship exists between gastric adenocarcinoma and GIST, since we did not perform genetic and molecular ancillary tests. This study, however, highlights an interesting observation of a possible association between gastric adenocarcinoma and GIST that should encourage further statistically validated and genetically based studies.

In conclusion, the synchronous occurrence of GISTs and other gastrointestinal malignancies is more common than it has been considered. The concomitant GIST is usually discovered incidentally during endoscopy, imaging study or operation performed because of the other malignancy. We have reported eight cases of GIST combined with gastric cancer. All the GISTs were positive for CD117 and CD34. The cause of the association between GISTs and adenocarcinoma is difficult to determine. In the majority of cases, this association is most likely coincidental. Surgical excision is the mainstay of therapy, and further research is required for explaining this simultaneous tumor development.

## COMMENTS

### Background

Gastrointestinal stromal tumors (GISTs) are mesenchymal tumors of the digestive tract and have various clinical and biological characteristics. The expression of c-Kit distinguishes GISTs from true leiomyomas, leiomyosarcomas and other mesenchymal tumors of the gastrointestinal tract.

### Research frontiers

GISTs are generally found within the deeper stroma and the submucosa, and therefore, in most of the reported cases of synchronous gastric adenocarcinoma and GIST, the preoperative biopsy specimens have shown only adenocarcinoma. GISTs are often incidentally detected during imaging studies, operation or examination of the resected specimens.

### Innovations and breakthroughs

The authors hypothesized that the stomach was influenced by the same unknown carcinogen, resulting in a simultaneous proliferation of different cell lines (epithelial and stromal cell).

### Applications

In the majority of cases, this association is most likely coincidental. Surgical excision is the mainstay of therapy, and further research is required for explaining this simultaneous tumor development.

### Peer review

Synchronous gastric adenocarcinoma and GIST were not common but can be found sometimes in practice. Usually, intraoperatively serendipitous GISTs are of very low risk and with their max diameters less than 1 cm. Carefully preoperative imaging evaluation might be helpful to find the > 1 cm GIST. This topic is interesting and lack of relevant literatures, especially the data of the epidemiological incidence. If possible, the author should report the data of its proportion

in the consecutive series.

### Abstract

**AIM:** To analyze risk factors for refractoriness to proton pump inhibitors (PPIs) in patients with non-erosive reflux disease (NERD).

**METHODS:** A total of 256 NERD patients treated with the PPI esomeprazole were enrolled. They were classified into symptom-free and residual symptoms groups according to Quality of Life in Reflux and Dyspepsia (QoLRad) scale. All subjects completed questionnaires on psychological status (self-rating anxiety scale; self-rating depression scale) and quality of life scale (Short Form 36). Multivariate analysis was used to determine the predictive factors for PPI responses.

**RESULTS:** According to QoLRad, 97 patients were confirmed to have residual reflux symptoms, and the remaining 159 patients were considered symptom free. There were no significant differences between the two groups in lifestyle factors (smoking and alcohol consumption), age, *Helicobacter pylori* infection, and hiatal hernia. There were significant differences between the two groups in relation to sex, psychological distress including anxiety and depression, body mass index (BMI), and irritable bowel syndrome (IBS) ( $P < 0.05$ ). Logistic regression analysis found that BMI  $< 23$ , comorbid IBS, anxiety, and depression were major risk factors for PPI resistance. Symptomatic patients had a lower quality of life compared with symptom-free patients.

**CONCLUSION:** Some NERD patients are refractory to PPIs and have lower quality of life. Residual symptoms are associated with psychological distress, intestinal disorders, and low BMI.

© 2013 Baishideng. All rights reserved.

**Key words:** Risk factors; Refractoriness; Proton pump inhibitors; Non-erosive reflux disease

**Core tip:** Non-erosive reflux disease (NERD) is significantly more refractory to proton pump inhibitor (PPI) treatment than erosive esophagitis is, although the reason is unclear at present. Here, we investigated the risk factors for refractoriness to PPI treatment in patients with NERD. Our results demonstrate that some NERD patients are refractory to standard doses of PPIs and have a lower quality of life. Residual symptoms are associated with psychological distress, intestinal disorders, and low body mass index. Recognition of this might hold the key to improving long-term management of NERD.

## INTRODUCTION

Gastroesophageal reflux disease (GERD) is caused by abnormal reflux of gastric contents into the esophagus and is characterized by specific symptoms such as heartburn and acid regurgitation. An epidemiological survey has found that GERD is a common condition with a prevalence of 10%-20% in Western Europe and North America<sup>[1]</sup>. The prevalence of GERD in China is lower than that in Western countries, but appears to be increasing<sup>[2,3]</sup>. However, only about one-third to one-half of patients with GERD has endoscopically positive findings such as erosions and ulcers, whereas others with GERD symptoms have no obvious mucosal breaks during endoscopic examination. Therefore, GERD includes erosive esophagitis (EE) and endoscopy-negative reflux disease, which is also known as non-erosive reflux disease (NERD)<sup>[4,5]</sup>. At present, the most effective drug therapy for GERD is proton-pump inhibitors (PPIs)<sup>[6]</sup>. PPI treatment results in sustained acid reduction for symptom control in the majority of patients. However, 17%-32% of patients with GERD in primary care trials have experienced persistent, troublesome heartburn or regurgitation despite standard-dose PPI treatment, and the majority of them have even experienced refractory symptoms at higher doses<sup>[7-10]</sup>. Studies have shown that EE and NERD have different responses to PPIs because their pathogenesis is distinct<sup>[11-13]</sup>. In addition, NERD is significantly more refractory than EE to PPI treatment<sup>[14,15]</sup>. However, a recent meta-analysis has reported that NERD has the same response rate to PPIs as EE has, and the previously reported low response rate in patients with NERD was likely the result of inclusion of patients with upper gastrointestinal symptoms who did not have reflux disease<sup>[16,17]</sup>.

PPI failure has become a common clinical dilemma in gastrointestinal clinics and has been increasingly encountered at the primary care level as well. It is likely to be an expensive clinical problem because patients tend to utilize health care resources repeatedly, such as clinic visits, diagnostic studies, and prescription medication. A previous observation has shown that non-acid reflux contributes to poor effectiveness of PPIs in both NERD and EE patients<sup>[18]</sup>. However, most previous studies regarding PPI responses and the natural course of EE and NERD were based on Western countries; there have been few reports from Eastern Asian countries, including China<sup>[14,19]</sup>. In addition, the risk factors that affect the response of patients with NERD to PPIs are unclear at present<sup>[20,21]</sup>. To the best of our knowledge, there has been no report on the risk factors for response to PPIs in patients with NERD

in China. Here, we investigated the risk factors for refractoriness to PPI treatment in patients with NERD and propose a potential treatment strategy for them.

## MATERIALS AND METHODS

### Patient selection

Patients with NERD receiving PPI (esomeprazole) maintenance treatment were consecutively enrolled from May 2008 to August 2010. We enrolled 256 patients with reflux symptoms who were assessed by a locally validated GERD questionnaire, the Chinese GerdQ<sup>[22]</sup>. All patients were positive for ambulatory 24-h esophageal pH monitoring (DeMeester score > 14.27). All patients had undergone endoscopy at his/her first visit to exclude erosive reflux disease. All patients with NERD recruited for our study were using standard-dose esomeprazole for at least 6 mo.

### Exclusion criteria

According to the recent Rome III Criteria, patients with functional heartburn whose typical symptoms were associated with neither abnormal pH testing nor a positive symptom index were excluded<sup>[23,24]</sup>. Patients were excluded if there was a history of gastrointestinal surgery, Barrett's esophagus, peptic ulcer, or gastroduodenal cancer, and if they could not accurately express their condition or were unwilling to accept the scale survey.

### Assessments

The patients' medical records were screened for gastrointestinal morbidity, years since the first episode, and comorbidity (unclear what to deliver). Information was obtained regarding age, sex, smoking, alcohol use, *Helicobacter pylori* (*H. pylori*) infection, body mass index (BMI), comorbid irritable bowel syndrome (IBS), and hiatal hernia. The BMI was categorized using 23 and 25 kg/m<sup>2</sup> as a cut-off point in accordance with the WHO recommendation for Asia. IBS was diagnosed using a questionnaire based on the Rome III Criteria. All patients were asked to complete the following questionnaires.

### Quality of life in reflux and dyspepsia

The reflux version of quality of life in reflux and dyspepsia (QoLRad) is a disease-specific instrument, including 25 items combined into five dimensions: emotional distress, sleep disturbance, vitality, food/drink problems, and physical/social functioning. The recall period refers to the last week. QoLRad outcome has been shown to reflect treatment response and impact of symptoms<sup>[25]</sup>. A 7-point scale was used to assess item severity or frequency (1 = a great deal/all of the time; 2 = a lot/most; 3 = a moderate amount/quite a lot; 4 = some; 5 = a little; 6 = hardly any; 7 = none). The lower the scores were, the more severe the impact on daily functioning. Patients scoring  $\geq 6$  on all dimensions were considered symptom free, and those scoring < 6 on at least one dimension as having residual symptoms.

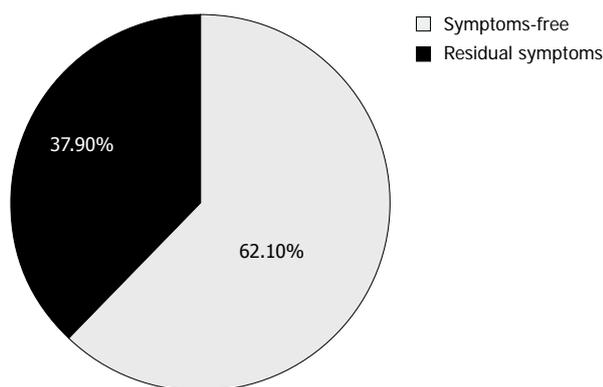

Figure 1 Effectiveness of proton pump inhibitor in 256 patients with non-erosive reflux disease.

**Table 1 Self-rating anxiety scale and self-rating depression scale scores in the two groups of patients**

| Group             | n   | SAS score    | SDS score    | SAS%            | SDS%           |
|-------------------|-----|--------------|--------------|-----------------|----------------|
| Residual symptoms | 97  | 42.68 ± 6.21 | 52.36 ± 6.93 | 46.39% (45/97)  | 50.52% (49/97) |
| Symptom-free      | 159 | 31.17 ± 6.15 | 43.13 ± 5.27 | 10.06% (16/159) | 8.18% (13/159) |
| Control           | 52  | 30.74 ± 8.18 | 35.32 ± 6.71 | 0.00% (0/20)    | 1.90% (1/52)   |

Self-rating anxiety scale (SAS) grades:  $F = 104.54$ ,  $P < 0.001$ ; Self-rating depression scale (SDS) grades:  $F = 143.91$ ,  $P < 0.001$ ; SAS%:  $\chi^2 = 52.30$ ,  $P < 0.001$ ; SDS%:  $\chi^2 = 79.58$ ,  $P < 0.001$ .

### Zung self-rating anxiety scale and Zung self-rating depression scale

The scores of the 20 items in the self-rating depression scale (SDS) and self-rating anxiety scale (SAS) were added and multiplied by 1.25. The nearest integer was taken as the standard score. An SDS standard score  $\geq 53$  indicated the presence of depression. An SAS standard score  $\geq 50$  indicated the presence of anxiety<sup>[26]</sup>.

### Quality of life scale (Short Form 36, SF-36)

This 36-question survey measured generic quality of life in eight dimensions<sup>[27]</sup>: physical functioning (PF), role limitations-physical (RP), bodily pain (BP), general health (GH), vitality (VT), social functioning (SF), role limitations-emotional (RE), and mental health (MH). Summary physical component score (PCS) and mental component score (MCS) were also calculated from patient responses. Raw scores were converted to a scale of 0 to 100, with higher scores indicating higher levels of health or wellbeing.

### Data analysis

The ages of the patients were categorized into deciles. Descriptive statistics (mean and SD) and additional analyses were calculated using SPSS version 14.0. Mean values were compared using Student's *t* test and analysis of variance, and two-sided *P* values of 0.05 were considered statistically significant. Ninety-five percent confidence intervals and two-tailed *P* values were calculated for the

| <i>Helicobacter pylori</i> positive | 59%                        | 62%                    | 11.52       | < 0.001 |
| BMI (kg/m <sup>2</sup> )            |                            |                        | 6.19        | 0.045   |
| $\geq 25$                           | 37                         | 86                     |             |         |
| 23–24.9                             | 30                         | 38                     |             |         |
| < 23                                | 30                         | 35                     |             |         |
| Comorbid IBS                        | 37%                        | 12%                    | 36.44       | < 0.001 |
| Hiatal hernia                       | 9%                         | 8%                     | 1.75        | 0.186   |

BMI: Body mass index; IBS: Irritable bowel syndrome.

ORs. Multivariate logistic regression analysis was carried out using determinants with *P* values  $\leq 0.1$ .

## RESULTS

A total of 256 patients with NERD on PPI treatment were included in the study (mean age 58 years, 53% male). Residual reflux symptoms were investigated by analyzing their impact on QOLRad score. They were divided into the residual symptoms ( $n = 97$ ) and symptom-free ( $n = 159$ ) groups according to QOLRad scores (Figure 1). Scores for SAS and SDS were significantly higher in the residual symptoms than symptom-free group (Table 1).

Demographics, clinical and laboratory findings is summarized in Table 2. We found that there was no significant difference between the two groups with regard to age, smoking, alcohol consumption, *H. pylori* infection, and hiatal hernia. A significant sex difference was observed in the residual symptoms and symptom-free groups. There were more women than men in the residual symptoms than symptom-free group ( $P < 0.05$ ). There were significantly more patients in the residual symptoms group with BMI < 23 and comorbid IBS than in the symptom-free group (Table 2). Multivariate analysis of patient characteristics indicated that the risk factors for residual symptoms were: BMI < 23, comorbid IBS, and mental health problems (anxiety or depression) (Table 3). The SF-36 scores indicated that symptomatic patients had a lower quality of life than those who were symptom free (Table 4).

## DISCUSSION

Patients with NERD experience typical GERD symptoms caused by acid and non-acid reflux, but they do not have visible esophageal injury<sup>[28,29]</sup>. NERD is a more common type of GERD in Asian than in Western populations<sup>[30]</sup>. Patients with NERD are a heterogeneous group including various subpopulations with different mechanisms for their main symptoms: reflux of acidic and non-acidic

**Table 3** Multivariate logistic regression of patient characteristics (*n* = 256)

| Variables    | $\beta$ | SE   | Z     | P value | B     | OR   | 95%CI     |
|--------------|---------|------|-------|---------|-------|------|-----------|
| Women        | -0.14   | 0.10 | 6.25  | < 0.001 | -0.19 | 0.66 | 0.31-0.89 |

gastric contents, mucosal hypersensitivity, intraesophageal distension by gas, intraduodenal infusion of fat, muscle contractions, and psychological abnormalities. Some studies have reported that the proportion of patients with NERD that responds to a standard dose of PPI is 20%-30%, which is lower than the proportion of patients with EE<sup>[15,17]</sup>. Some NERD patients even use high doses of PPI but cannot completely control the symptoms. For a long time, ineffective drug maintenance treatment has become a common problem in primary care<sup>[31,32]</sup>. These patients tend to utilize repeatedly healthcare resources, such as frequent consultations, referrals, diagnostic tests, and repeat prescriptions, which consume a large amount of medical resources. These patients also bear physical suffering and economic pressure, which seriously affect their quality of life<sup>[33]</sup>. Several studies have demonstrated that the proportion of patients with NERD that respond to a standard dose of PPI is 60%-70%, which is lower than that of patients with EE<sup>[34]</sup>. A recent study has suggested that, in well-defined NERD patients, the estimated complete symptom response rate after PPI therapy is comparable to the response rate in patients with EE. The previously reported low response rate in studies with patients classified as NERD was probably the result of inclusion of patients with upper gastrointestinal symptoms who did not have reflux disease. In the present study, we found that only 62.1% of patients with NERD treated with PPI were symptom free, and 37.9% of patients had residual symptoms and had a significantly lower quality of life.

The reason why NERD is more refractory than EE to PPIs is unclear at present. Previous observations have shown that the pathogenesis of NERD is associated with age, sex, lifestyle, *H. pylori* infection, BMI, comorbid IBS, and hiatal hernia<sup>[31]</sup>. It has also been shown that patients with NERD often have more psychological problems than those with EE<sup>[35,36]</sup>. A large number of epidemiological investigations have found that anxiety, depression, and chronic stress can lead to NERD<sup>[37]</sup>. Conventional treatment for NERD depends on PPI applications, but it cannot resolve the underlying psychological problems. Patients with NERD are often not satisfied with the treatment. Zerbib *et al.*<sup>[38]</sup> have reported that a no-reflux pattern demonstrated by 24-h pH-impedance monitoring is associated with response to PPIs in patients with

**Table 4** Social functioning-36 scores in residual symptoms and symptom-free groups

GERD symptoms. In contrast, absence of esophagitis, presence of functional digestive disorders, and BMI ≤ 25 kg/m<sup>2</sup> are strongly associated with PPI failure.

To date, there has been no report on the risk factors that affect the response of NERD patients to PPI therapy in China. In the present study, we found that there was no significant difference between the symptom-free and residual symptoms groups with regard to age, smoking, alcohol consumption, *H. pylori* infection, and hiatal hernia. However, symptomatic patients differed from symptom-free patients in relation to sex, BMI, comorbid IBS, and psychological distress. These variables were analyzed by multivariate analysis and we found that anxiety, depression, comorbid IBS, and BMI < 23 were independent risk factors associated with residual symptoms, but sex was not a risk factor for residual symptoms. We used the modified BMI criteria as proposed by the WPRO, which considers the smaller body frame of Asians and provides a more accurate reflection of body fat stores, thus avoiding a false perception of not being overweight<sup>[39]</sup>.

In conclusion, our results demonstrate that some NERD patients are refractory to standard doses of PPIs and have a lower quality of life. Residual symptoms are associated with psychological distress, intestinal disorders, and low BMI. Recognition of this might hold the key to improving long-term management of NERD.

## COMMENTS

### Background

Non-erosive reflux disease (NERD) is significantly more refractory than erosive esophagitis to proton pump inhibitor (PPI) treatment, although the reason is unclear at present.

### Research frontiers

Here, the authors report a study of the risk factors for PPI refractoriness in Chinese patients with NERD. The majority of studied cases were sporadic.

### Innovations and breakthroughs

Although a previous observation has shown that non-acid reflux contributes to poor effectiveness of PPIs in NERD patients, there has been no report on the risk factors for response to PPIs in patients with NERD in China. Here, the authors investigated the risk factors for refractoriness to PPI treatment in patients

with NERD and propose a potential treatment strategy for them.

### Applications

The authors found that some NERD patients were refractory to standard doses of PPIs and had a lower quality of life. Residual symptoms were associated with psychological distress, intestinal disorders, and low body mass index. Recognition of this might hold the key to improving long-term management of NERD.

### Terminology

There is no specific, unique terminology that will not be familiar to the majority of readers.

### Peer review

This was a qualitative study with an original approach to establishing the risk factors for refractoriness to PPIs in patients with NERD. This is an important problem in the treatment of these patients. The study was well designed and the results are clearly described.

### Abstract

**AIM:** To detect the expression of huCdc7 in colorectal cancer.

**METHODS:** The mRNA and protein expression of huCdc7 in 39 colorectal cancer tissue specimens and matched tumor-adjacent normal colorectal tissue specimens was detected by reverse transcription-polymerase chain reaction and immunohistochemistry, respectively.

**RESULTS:** The relative expression level of huCdc7 mRNA in colorectal cancer was significantly higher than that in tumor-adjacent normal colorectal tissues ( $0.03675 \pm 1.00$  vs  $0.01199 \pm 0.44$ ,  $P < 0.05$ ). huCdc7-positive cells displayed brown granules in the nucleus. Tumor tissues contained many huCdc7-positive cells, whereas normal colorectal tissues contained very few positive cells.

**CONCLUSION:** huCdc7 may play an important role in the development and progression of colorectal cancer.

### INTRODUCTION

huCdc7 is ubiquitously expressed in human tissues and can regulate DNA replication initiation. Abnormal expression or excessive activation of huCdc7 can promote excessive cell proliferation and cause tumorigenesis. Colorectal cancer is a common digestive tract tumor with a gradually increasing incidence. This study aimed to detect the expression of huCdc7 in colorectal cancer to provide a basis for the diagnosis and treatment of this malignancy.

### MATERIALS AND METHODS

#### Specimen collection

Tissue specimens were collected from 39 patients with colorectal cancer who were surgically treated at our hospital. Colorectal cancer tissue specimens and matched

tumor-adjacent normal colorectal tissue specimens (5 cm away from tumor tissue) were placed in liquid nitrogen immediately after surgical specimens were removed. The final diagnosis of colorectal cancer and tumor-adjacent normal colorectal tissues was made pathologically.

### Main reagents

M-MLV reverse transcriptase (Promega, United States), Taq DNA polymerase (Takara, Japan), and dNTPs (Takara, Japan) were obtained commercially. The primers for the amplification of a 525-bp CDC7 gene fragment were: forward, 5'-GCT CAG CAG GAA AGG TGT TC-3' and reverse, 5'-AGT TTG ATT GGG GCA CTT TG-3'. The primers for amplification of a 420-bp glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) gene fragment were: forward, 5'-GTC AGT GGT GGA CCT GAC CT-3' and reverse, 5'-AGG GGT CTA CAT GGC AAC TG-3'.

### Reverse transcription-polymerase chain reaction

**Preparation of total RNA:** Total RNA was extracted using TRIzol reagent (GIBCO/BRL, United States). All centrifuge tubes, plastic and glasswares and water used for RNA extraction were treated to create an RNase-free environment. A homogenizer was baked at 200 °C for 4 h to remove RNase and then cooled. Tissue samples were frozen in liquid nitrogen, pulverized into powder, and placed in the homogenizer containing TRIzol reagent. After homogenization for several minutes, the homogenized sample was transferred to an RNase-free centrifuge tube. Following the addition of chloroform, the tube was centrifuged at 4 °C. The upper aqueous phase was transferred to an RNase-free centrifuge tube, and isopropanol was added to precipitate the RNA. The tube was centrifuged at 4 °C, and the pellet was washed twice with 75% ethanol and dissolved in RNase-free deionized water. The purity of extracted RNA was assessed by measuring the *A*<sub>260</sub>/*A*<sub>280</sub> ratio (1.7-2.0) using an ultraviolet spectrophotometer. 3-morpholinopropanesulfonic acid-formaldehyde denaturing agarose gel electrophoresis was performed to check if the extracted RNA was degraded. To remove the contamination of genomic DNA, RNA sample was treated with RNase-free DNA enzyme I (Ambion, United States).

**cDNA synthesis:** Two micrograms of total RNA were mixed with 1 μL of random primers (50 pmol/L, 1 μL) and 15 μL of diethylpyrocarbonate-treated water, placed at 70 °C for 3 min and then immediately placed on ice for 5 min. The following components were then added: 5 μL of 5 × buffer, 1 μL of 10 mmol/L dNTP, 1 μL of M-MLV reverse transcriptase (200 U/μL), and 0.75 μL of RNase inhibitor (40 U/μL, TaKaRa). The mixture was incubated at 42 °C for 2 h.

**Semiquantitative reverse transcription-polymerase chain reaction:** The *huCdc7* gene was amplified using cDNA as the template. *GAPDH* was used as a control.

Polymerase chain reaction (PCR) conditions were as follows: denaturation at 94 °C for 3 min; 35 cycles (25 cycles for *GAPDH*) of denaturation at 94 °C for 30 s, annealing at 58.5 °C for 30 s, and extension at 72 °C for 40 s; and a final extension at 72 °C for 5 min. PCR products were resolved by 2% agarose gel electrophoresis. Band densities were analyzed using the FR-980 bio-electrophoresis image analysis system.

**Real-time PCR:** The CFX96 real-time PCR detection system (BIO-RAD, United States) was used to detect the expression of genes of interest in tumor tissues and matched tumor-adjacent normal tissues. PCR reaction was performed in a 20-μL system consisting of 10 μL of SYBR Premix EX Taq, 0.4 μL of each primer (10 μM), 2 μL of DNA, and 7.2 μL of ddH<sub>2</sub>O. *GAPDH* was used as an internal control. The experiment was repeated three times to ensure the reliability of the results. The expression level of the *huCdc7* gene was calculated using the following formulas:  $Cdc7 \Delta Ct = \text{mean } Cdc7Ct - \text{mean } GAPDHCt$ , and  $Cdc7 \Delta \Delta Ct = Cdc7 \Delta Ct \text{ cancer tissue} - Cdc7 \Delta Ct \text{ tumor-adjacent tissue}$ . Relative expression level of the *huCdc7* gene was calculated using the  $2^{-Cdc7 \Delta \Delta Ct}$  method.

### Immunohistochemistry

Streptavidin-peroxidase immunohistochemical staining was performed using a commercial kit according to the manufacturer's instructions.

### Statistical analysis

Statistical analysis were performed using SPSS 10.0 software. Means between two groups were compared using the *t* test. *P* values < 0.05 were considered statistically significant.

## RESULTS

### huCdc7 mRNA expression

The relative expression levels of huCdc7 mRNA in colorectal cancer and tumor-adjacent normal colorectal tissues were  $0.03675 \pm 1.00$  and  $0.01199 \pm 0.44$ , respectively. Statistical analysis indicated that the expression level of huCdc7 mRNA was significantly higher in colorectal cancer than in tumor-adjacent normal colorectal tissues (*P* < 0.05) (Figure 1).

### huCdc7 protein expression

huCdc7-positive cells displayed brown granules in the nucleus. Tumor tissues contained many huCdc7-positive cells, whereas normal colorectal tissues contained very few positive cells (Figure 2).

## DISCUSSION

*Cdc7* is a serine/threonine kinase, and huCdc7 is expressed in all human tissues<sup>[1]</sup>. By forming complex with other molecules in the nucleus, huCdc7 can phosphorylate and activate chromosome-binding minichromosome

Figure 1 Semiquantitative reverse transcription-polymerase chain reaction determination of huCdc7 and glyceraldehyde-3-phosphate dehydrogenase mRNA expression in colorectal cancer (1, 3, 5, 7, 9 and 11) and tumor-adjacent normal colorectal tissues (2, 4, 6, 8, 10 and 12). GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

maintenance complex (MCM) proteins. The MCM family has multiple members, including MCM2, MCM4 and MCM6. huCdc7 has the strongest ability to phosphorylate MCM2<sup>[2]</sup>. On one hand, MCMs function as helicase, a component of cell cycle initiation complex<sup>[3]</sup>. On the other hand, MCMs can act as important regulatory factors for S phase checkpoints to control cell cycle progression.

It is still unclear how huCdc7 mediates these processes. The expression of huCdc7 is tightly controlled by some factors and auxiliary proteins in normal cell cycle and maintained in a dynamic equilibrium state. In tumor cells, huCdc7 is abnormally expressed and excessively activated due to cell cycle disturbances. Hess *et al*<sup>[4]</sup> found that huCdc7 was overexpressed in tumor cells and excessive expression of huCdc7 promoted excessive MCM2 activation and abnormal proliferation of tumor cells. In addition, they found that huCdc7 was overexpressed in metastatic tumor cells, suggesting that tumor metastasis may be closely related to abnormal high huCdc7 expression. A previous study has revealed that CDC7 kinase is a predictor of survival and a novel therapeutic target in epithelial ovarian carcinoma<sup>[5]</sup>. Similar findings have also been reported in some studies on lymphoma<sup>[6]</sup>.

In this study, we utilized semi-quantitative reverse transcription-PCR and immunohistochemistry to determine the expression of huCdc7 in colorectal cancer and tumor-adjacent normal colorectal tissues. We found that huCdc7 mRNA expression was significantly higher in colorectal cancer than in normal colorectal tissues. huCdc7 is a conservative serine/threonine kinase that is indispensable for DNA replication initiation. Abnormal high expression of huCdc7 will promote DNA replication, cause abnormal cell proliferation, and thereby lead to the occurrence of tumors.

To investigate the relationship between huCdc7 and tumor development and progression, Montagnoli *et al*<sup>[7]</sup> used the siRNA interference technology to suppress high huCdc7 expression in tumor cells. They found that the phosphorylation levels of MCM2 activation sites were greatly decreased, DNA replication initiation in tumor cells was restrained, and tumor cell growth slowed down. In addition, some researchers believe that high huCdc7 expression in tumor cells is related to p53 inactivation<sup>[8]</sup>.

A study on ovarian cancer revealed that CDC7 kinase can predict survival and serve as a target for cancer treatment. Kim *et al*<sup>[9]</sup> found that siRNA-mediated inhibition

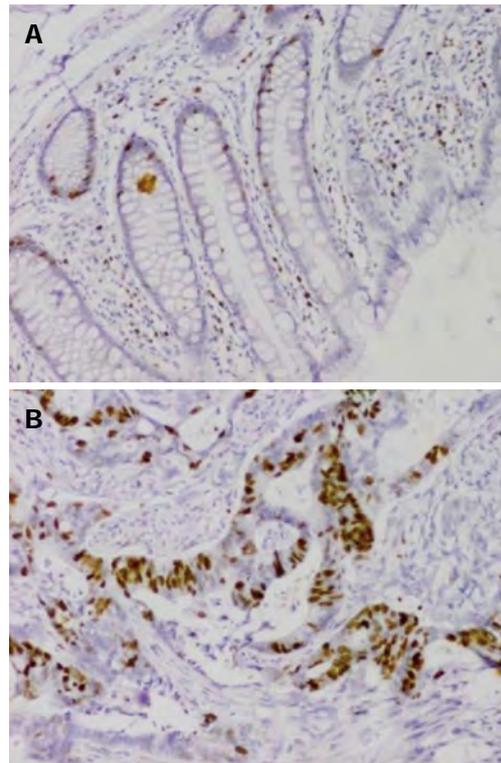

Figure 2 Immunohistochemical staining of huCdc7 in normal colorectal tissues (A) and colorectal cancer (B) (magnification,  $\times 100$ ).

of huCdc7 reduced the phosphorylation level of the N-terminus of MCM4. As a result, Cdc 45 could not be positioned to the chromosome and replication initiation complex could not form. This inhibited, to a certain extent, tumor cell proliferation. Thus, inhibition of huCdc7 activity can effectively inhibit tumor cell growth and promote tumor cell apoptosis, without damage to normal cells. A recent study has identified PHA-767491 as an inhibitor of huCdc7<sup>[10]</sup>, which may be used to down-regulate abnormal huCdc7 expression to inhibit abnormal DNA replication and cell cycle progression in tumors.

Small molecule compounds that can interfere with the activity of CDC7 have been developed and proved to be effective in inhibiting tumor growth in animal models. Unprecedented attention has been paid to the inhibition of CDC7 kinase activity for suppressing DNA replication in tumor cells and inducing tumor cell apoptosis. Further elucidation of the role of huCdc7 in colorectal cancer may improve the treatment of this malignancy.

## COMMENTS

### Background

huCdc7 is ubiquitously expressed in human tissues and can regulate DNA replication initiation. Abnormal expression or excessive activation of huCdc7 can promote excessive cell proliferation and cause tumorigenesis. Colorectal cancer is a common digestive tract tumor and has a gradually increasing incidence.

### Research frontiers

In this study, tissue specimens were collected from 39 surgically treated patients with colorectal cancer. Colorectal cancer tissue specimens and matched tumor-adjacent normal colorectal tissue specimens (5 cm away from tumor tis-

sue) were placed in liquid nitrogen immediately after surgical specimens were removed. The final diagnosis of colorectal cancer and tumor-adjacent normal colorectal tissues was made pathologically.

### Innovations and breakthroughs

The relative expression level of huCdc7 mRNA in colorectal cancer was significantly higher than that in tumor-adjacent normal colorectal tissue. huCdc7-positive cells displayed brown granules in the nucleus. Tumor tissue contained many huCdc7-positive cells, whereas normal colorectal tissue contained very few positive cells.

### Applications

The authors found that huCdc7 may play an important role in the development and progression of colorectal cancer.

### Peer review

In the manuscript, the authors detected the expression of huCdc7 in colorectal cancer. The data is interesting. The manuscript is short, but informative.

### Abstract

**AIM:** To evaluate the correlation between nonalcoholic fatty liver disease (NAFLD) and microvascular complications in type 2 diabetes mellitus (T2DM).

**METHODS:** Data were obtained from 1217 inpatients with T2DM (757 females, 460 males; aged  $63.39 \pm 12.28$  years). NAFLD was diagnosed by hepatic ultrasonography. Diabetic nephropathy (DN), diabetic peripheral neuropathy (DPN), and diabetic retinopathy (DR) were diagnosed according to their respective criteria. The prevalence of NAFLD and the independent correlations of clinical characteristics with NAFLD were determined by cross-tabulation and logistic regression, respectively.

**RESULTS:** Approximately 61% of inpatients with T2DM in Qingdao, China had NAFLD, which decreased significantly with increase in age and prolonged course of diabetes. The prevalence of NAFLD in patients presenting with DN, DPN and DR was 49.4%, 57.2% and 54.9%, respectively. These rates were significantly lower than those of patients without DN, DPN and DR (65.9%, 65.6% and 66.1%, respectively,  $P < 0.05$ ). Participants with NAFLD had greater body weight, waist circumference (WC), body mass index (BMI), fasting blood glucose (FBG), hemoglobin A1c, alanine aminotransferase, aspartate aminotransferase,  $\gamma$ -glutamyltransferase, blood pressure, as well as triglyceride (TG) levels and lower high-density lipoprotein (HDL) concentration than those without NAFLD ( $P < 0.05$ ). NAFLD was positively correlated with BMI, WC, TG, FBG, diastolic blood pressure, and systolic blood pressure but negatively correlated with the duration of diabetes, DR, DPN, DN, and HDL.

**CONCLUSION:** Despite the benign nature of NAFLD, efforts should be directed toward early diagnosis, intensive blood glucose and blood pressure control, and effective dyslipidemia correction.

**Key words:** Nonalcoholic fatty liver disease; Type 2 diabetes mellitus; Diabetic nephropathy; Diabetic retinopathy; Diabetic neuropathy

**Core tip:** Nonalcoholic fatty liver disease (NAFLD) and diabetic microangiopathy complications represent important burdens for patients with type 2 diabetes mellitus (T2DM). However based on the finding that the prevalence of NAFLD was negatively correlated with age and duration of T2DM, we suggest that NAFLD is benign process and efforts should be directed at strengthening early diagnosis, intensive blood glucose

and pressure control, and effective dyslipidemia correction to prevent and minimize occurrence of NAFLD.

## INTRODUCTION

Diabetes is an independent risk factor for the development of nonalcoholic fatty liver disease (NAFLD) and progression to advanced liver disease, including fibrosis, cirrhosis, and hepatocellular carcinoma<sup>[1]</sup>. Cross-sectional studies have reported that the prevalence of NAFLD in patients with type 2 diabetes mellitus (T2DM) ranges from 42.1% to 75.2% in China<sup>[2,3]</sup>. With the rising incidence and prevalence of T2DM in China<sup>[4]</sup>, a close estimate of the prevalence of NAFLD, as well as its clinical risk factors, is important for predicting the number of patients that require monitoring for more advanced liver diseases, or those who may benefit from future disease-modifying agents.

Targher *et al*<sup>[5]</sup> have reported that most individuals with NAFLD are older, more likely to be male, and have a longer duration of diabetes than those without NAFLD. By contrast, Williamson *et al*<sup>[6]</sup> have reported that participants with definite steatosis (grade 3) are significantly younger and have shorter duration of diabetes than the combined normal/probably normal groups (grades 0-2). Zhou *et al*<sup>[3]</sup> have indicated that the prevalence of NAFLD in men aged < 50 years is higher than that in women. However, this finding is contrary for patients > 50 years; that is, the prevalence of NAFLD is higher in women<sup>[3]</sup>. Thus, further studies must be conducted to ascertain the differences in the prevalence of NAFLD between the sexes and the relationship between age, duration of diabetes, and prevalence of NAFLD.

The present cross-sectional study determined the prevalence and some risk factors for NAFLD and evaluated its correlations with microvascular complications in a large cohort of inpatients with T2DM in Qingdao, China. Differences in the prevalence of NAFLD between men and women, as well as the clinical and biochemical characteristics of the condition, are discussed.

## MATERIALS AND METHODS

A total of 1217 T2DM patients (757 women and 460 men) participated in this study. All patients were hospitalized between January 2008 and January 2012 at the Department of Internal Medicine, Affiliated Hospital of Medical College, Qingdao University, China. Most participants abstained from alcohol consumption ( $n = 1107$ ;

91%) or drank minimally (alcohol consumption < 20 g/d;  $n = 110$ ; 9%). Patient information such as sex, birth date, duration of diabetes, daily alcohol consumption, smoking status, and medications (including hepatotoxic drugs such as glucocorticoids, amiodarone, methotrexate, or antineoplastic drugs) were obtained by the questionnaire method. The heights and body weights (BWs) of the patients were measured (*i.e.*, without wearing a heavy coat and shoes). Body mass index (BMI) was calculated by dividing the BW (kg) by the square of the height (m). Waist circumference (WC) was measured in a standing position at the level of the umbilicus. Fasting plasma glucose (FPG), hemoglobin A1c (HbA1c), alanine aminotransferase (ALT), aspartate aminotransferase (AST),  $\gamma$ -glutamyltransferase (GGT), fasting serum triglyceride (TG), high-density lipoprotein (HDL) cholesterol, and low-density lipoprotein (LDL) cholesterol were determined using standardized methods in our laboratory. Serology for viral hepatitis B and C was also assessed in all participants. Hepatic ultrasonography scanning was performed on patients after an overnight fast by assigned and experienced radiologists, who were blinded to the health conditions of the patients. The liver was graded for markers of hepatic steatosis by using established criteria: a bright hepatic echo pattern (compared with the echo response of the right kidney); increased attenuation of the echo beam; and presence of focal fatty sparing<sup>[6]</sup>. Participants manifesting symptoms of hepatic steatosis or showing abnormal blood tests of liver function tests were further investigated for other parameters such as antinuclear antibody, antismooth muscle antibody, anti-mitochondrial antibody, and ferritin.

This study was approved by the Ethics Committee of the Affiliated Hospital Medical College, Qingdao University, and all participants provided written informed consent.

### Definition of NAFLD

NAFLD was defined as the presence of definite hepatic steatosis on ultrasound scan (*i.e.*, grade 3) in the absence of a secondary cause for hepatic steatosis. Secondary causes were defined as: alcohol consumption  $\geq 14$  U/wk or participant report of alcohol excess; use of hepatotoxic medication (glucocorticoids, isoniazid, methotrexate, amiodarone, and tamoxifen) within 6 mo prior to the study; positive hepatitis B or C serology; ferritin concentration  $\geq 1000$  mg/L (milder hyperferritinemia can be associated with obesity, insulin resistance, and NAFLD); clinically significant positive immunology titers (antismooth muscle antibody titer  $\geq 1:160$  or antimitochondrial antibody titer  $\geq 1:40$ ); or previous diagnosis of a persistent secondary cause for chronic liver disease according to their medical records. Patients were excluded from calculations on the prevalence of NAFLD if their data on the above-mentioned measures were missing, such that a secondary cause could not be excluded.

Diabetic microvascular complications included dia-

**Table 1** Baseline characteristics of the study participants, according to nonalcoholic fatty liver disease status

| Variables                | Without NAFLD  | With NAFLD     | <i>P</i> value |
|--------------------------|----------------|----------------|----------------|
| <i>n</i>                 | 475            | 742            |                |
| Sex (female/male)        | 287/188        | 470/272        | > 0.05         |
| Age (yr)                 | 65.11 ± 11.70  | 62.29 ± 12.52  | < 0.05         |
| Diabetes duration (yr)   | 11.31 ± 7.10   | 8.47 ± 6.87    | < 0.05         |
| Height (cm)              | 163.99 ± 8.49  | 164.20 ± 8.24  | > 0.05         |
| BW (kg)                  | 65.54 ± 9.76   | 74.32 ± 11.64  | < 0.05         |
| WC (cm)                  | 88.75 ± 8.72   | 96.76 ± 10.32  | < 0.05         |
| BMI (kg/m <sup>2</sup> ) | 24.33 ± 2.87   | 27.49 ± 3.37   | < 0.05         |
| Current smokers (%)      | 17.7           | 14.3           | > 0.05         |
| SBP (mmHg)               | 131.43 ± 17.93 | 141.56 ± 16.15 | < 0.05         |
| DBP (mmHg)               | 76.94 ± 8.87   | 83.61 ± 9.57   | < 0.05         |
| FBG (mmol/L)             | 7.72 ± 3.18    | 8.97 ± 3.20    | < 0.05         |
| HbA1c (%)                | 8.45 ± 2.44    | 8.91 ± 2.47    | < 0.05         |
| ALT (mmol/L)             | 17.16 ± 8.19   | 25.72 ± 13.01  | < 0.05         |
| AST (mmol/L)             | 18.23 ± 6.74   | 22.34 ± 9.00   | < 0.05         |
| GGT (mmol/L)             | 19.47 ± 16.32  | 25.05 ± 17.94  | < 0.05         |
| TG (mmol/L)              | 1.45 ± 1.06    | 2.12 ± 1.43    | < 0.05         |
| TC (mmol/L)              | 4.99 ± 1.41    | 5.04 ± 1.22    | > 0.05         |
| LDL (mmol/L)             | 2.95 ± 0.92    | 2.95 ± 0.82    | > 0.05         |
| HDL (mmol/L)             | 1.24 ± 0.29    | 1.17 ± 0.28    | < 0.05         |

Data are expressed as mean ± SD or proportions of the entire cohort of participants. BW: Body weight; WC: Waist circumference; BMI: Body mass index; SBP: Systolic blood pressure; DBP: Diastolic blood pressure; FBG: Fasting blood glucose; HbA1c: Hemoglobin A1c; ALT: Alanine aminotransferase; AST: Aspartate aminotransferase; GGT:  $\gamma$ -glutamyltransferase; TG: Triglyceride; TC: Total cholesterol; LDL: Low-density lipoprotein; HDL: High-density lipoprotein.

betic nephropathy (DN), diabetic peripheral neuropathy (DPN), and diabetic retinopathy (DR). DN was diagnosed by a positive persistent proteinuria for at least three consecutive readings per year, serum creatinine > 130  $\mu$ mol/L, and/or glomerular filtration rate < 60 mL/min. DPN was diagnosed in the presence of persistent numbness, paresthesia, loss of hearing of the tuning fork and sense of vibration, and failure to elicit a knee and/or ankle jerk. DR was diagnosed in the presence of retinal hemorrhage, exudates, and macular edema<sup>[7]</sup>.

### Statistical analysis

Analyses were conducted using SPSS version 17.0. Data are presented as means ± SD or proportions, where appropriate. Skewed variables (*e.g.*, TG and HDL) were logarithmically transformed, and genomic means are presented. Independent *t* and  $\chi^2$  tests were used to compare the differences in means or proportions between different subgroups. The independent associations of variables with NAFLD were determined by a binary logistic regression. A value of *P* < 0.05 was considered statistically significant.

## RESULTS

### Clinical and biological characteristics of study population

The mean demographic and clinical characteristics of the patients were as follows: age, 63.39 ± 12.28 years;

duration of diabetes, 9.58 ± 7.09 years; BW, 70.9 ± 11.75 kg; WC, 93.63 ± 10.48 cm; BMI, 26.26 ± 3.54 kg/m<sup>2</sup>; FBG, 8.48 ± 3.25 mmol/L; HbA1c, 8.73% ± 2.47%; TG, 1.85 ± 1.33 mmol/L; total cholesterol (TC), 5.0 ± 1.29 mmol/L; HDL, 1.20 ± 0.29 mmol/L; and LDL, 2.95 ± 0.86 mmol/L.

The baseline characteristics of the study participants according to their NAFLD status are presented in Table 1. The prevalence of NAFLD in patients with T2DM was 61%, and no statistical difference was indicated between men and women (59.1% *vs* 62.1%, *P* > 0.05). Participants with NAFLD had higher BW, WC, BMI, FBG, HbA1c, ALT, AST, GGT, blood pressure and TG levels, and lower HDL concentration than those without NAFLD (*P* < 0.05). Meanwhile, no statistical difference was observed in the smoking history, height, plasma TC, and LDL levels between the groups. However, participants diagnosed with NAFLD were younger and had shorter duration of diabetes than those without NAFLD (*P* < 0.05).

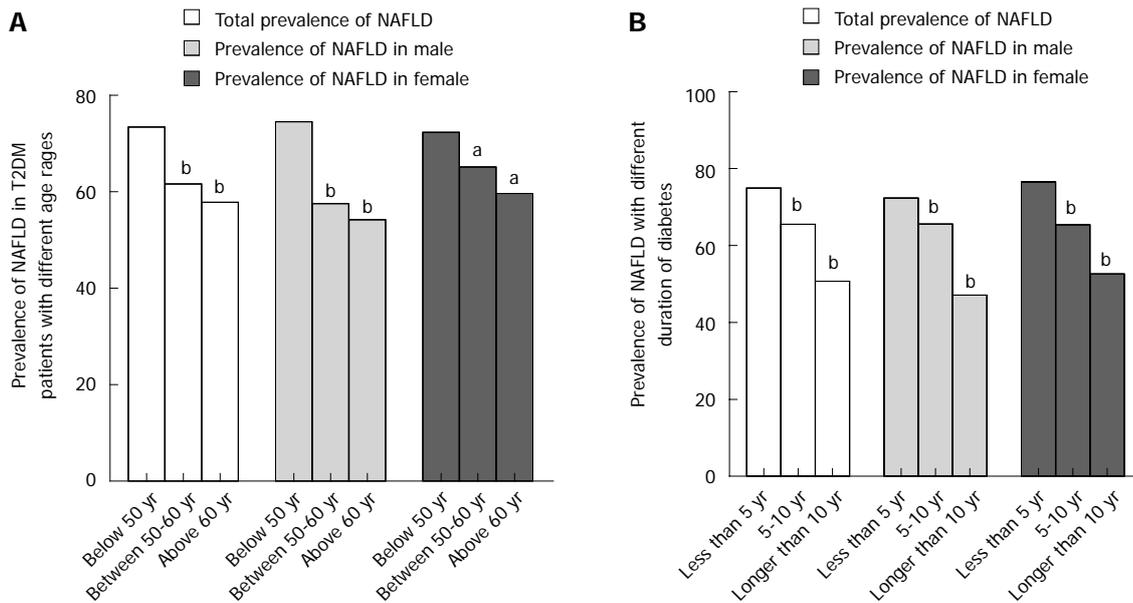

### Prevalence of NAFLD in T2DM patients by age range and duration of diabetes

Patients were divided into three groups according to age: < 50, 50-60, and > 60 years. The prevalence rates of NAFLD for the three age groups were 73.4%, 61.6%, and 57.8%, respectively, indicating that the prevalence of NAFLD decreased significantly as age increased (Figure 1A, *P* < 0.05). This trend persisted even when patients were classified by sex (74.5%, 57.5%, and 54.2% in men and 72.3%, 65.1%, and 59.6% in women, *P* < 0.05). Although the prevalence of NAFLD in women was higher than that in men < 50 years and the reverse was evident at > 50 years, no significant difference was found in the prevalence of NAFLD between men and women at different ages (Figure 1A, *P* > 0.05).

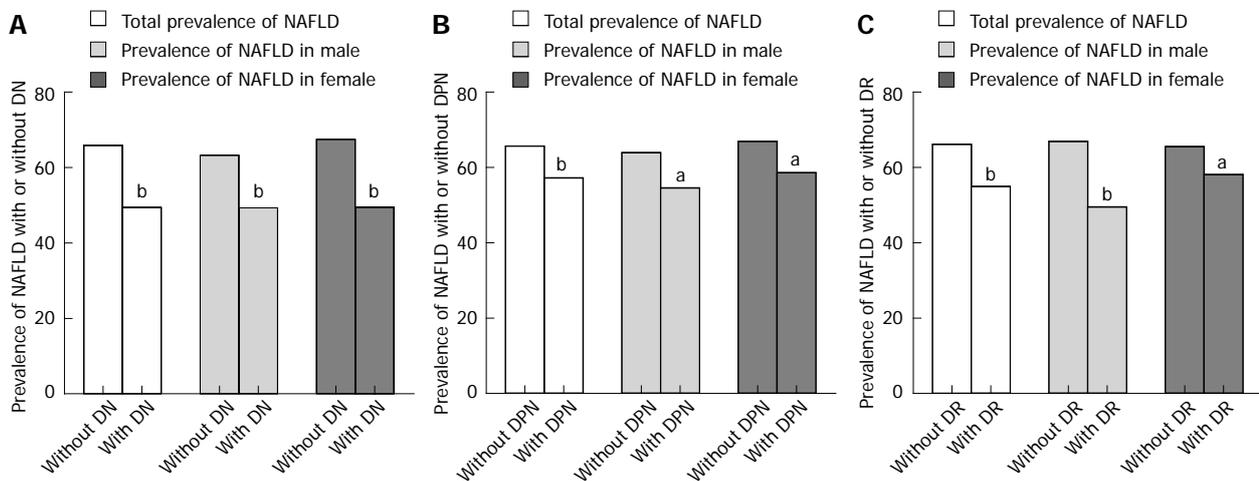

When patients were divided into three groups according to duration of diabetes, that is, < 5 years, 5-10 years, and > 10 years, the prevalence rates of NAFLD were 74.9%, 65.5%, and 50.7%, respectively. This indicates that the prevalence of NAFLD decreased significantly as diabetes was prolonged (Figure 1B, *P* < 0.05). This trend persisted even when patients were classified by sex (72.3%, 65.6%, and 47.1% in men and 76.5%, 65.4%, and 52.6% in females, respectively, *P* < 0.05). No significant difference was indicated in the prevalence rate of NAFLD between men and women with different durations of diabetes (Figure 1B, *P* > 0.05).

### Prevalence of NAFLD in T2DM with or without microangiopathic complications

The incidence of NAFLD was found to correlate negatively with DN, as shown in Figure 2A (*r* = -0.154, *P* < 0.05). The general prevalence of NAFLD in T2DM with and without DN was 49.4% and 65.9%, respectively (*P* < 0.05). This trend persisted even when patients were stratified by sex (*r* = -0.13 in men, *r* = -0.17 in women,

**Figure 1** Prevalence of nonalcoholic fatty liver disease in type 2 diabetes mellitus patients according to different age ranges and durations of diabetes. **A:** Prevalence of nonalcoholic fatty liver disease (NAFLD) in patients aged < 50, 50-60, and > 60 years was 73.4%, 61.6%, and 57.8%, respectively, indicating that the prevalence of NAFLD decreased significantly with increasing age (<sup>b</sup> $P < 0.01$  vs group below 50 years). In men (74.5%, 57.5%, and 54.2%, respectively, <sup>b</sup> $P < 0.01$  vs group below 50 years) and women (72.3%, 65.1%, and 59.6%, respectively, <sup>a</sup> $P < 0.05$  vs group below 50 years), the prevalence of NAFLD decreased significantly with increasing age. The prevalence of NAFLD in men was higher than in women (74.5% and 72.3%, respectively,  $P > 0.05$ ) in the < 50 years age group; however, the reverse was evident in the > 50 years age group (57.5% and 65.1%, respectively, in the 50-60 years age group, and 54.2% and 59.6%, in the > 60 years age group, both  $P > 0.05$ ); **B:** Prevalence of NAFLD, according to duration of diabetes, was 74.9%, 65.5%, and 50.7% for < 5, 5-10, and > 10 years, respectively. Prevalence of NAFLD decreased significantly with prolonged course of diabetes (<sup>b</sup> $P < 0.01$  vs group less than 5 years). This trend persisted even when patients were stratified by sex (72.3%, 65.6%, and 47.1%, respectively, in men, and 76.5%, 65.4%, and 52.6% in women, <sup>b</sup> $P < 0.01$  vs group less than 5 years). There were no significant differences in the prevalence of NAFLD between men and women with different durations of diabetes ( $P > 0.05$ ). T2DM: Type 2 diabetes mellitus.

**Figure 2** Prevalence of nonalcoholic fatty liver disease in T2DM with or without microangiopathy complications. **A:** Incidence of nonalcoholic fatty liver disease (NAFLD) negatively correlated with DN ( $r = -0.154$ ,  $P < 0.05$ ). This trend persisted even when patients were stratified by sex ( $r = -0.13$  in men,  $r = -0.17$  in women, both  $P < 0.05$ ). Prevalence of NAFLD in T2DM with and without DN was 49.4% and 65.9%, respectively (<sup>b</sup> $P < 0.01$  vs group without DN). Prevalence of NAFLD in men without DN was significantly higher than in patients with DN (63.3% and 49.3%, respectively, <sup>b</sup> $P < 0.01$  vs the group without DN). Prevalence of NAFLD in women without DN was significantly higher than in patients with DN (67.5% and 49.5%, respectively, <sup>b</sup> $P < 0.01$  vs the group without DN); **B:** Incidence of NAFLD negatively correlated with DPN ( $r = -0.086$ ,  $P < 0.05$ ). This trend persisted even when patients were stratified by sex ( $r = -0.095$  in men,  $r = -0.084$  in women, both  $P < 0.05$ ). The general prevalence of NAFLD in T2DM with and without DPN was 57.2% and 65.6%, respectively (<sup>b</sup> $P < 0.01$  vs the group without DPN). Prevalence of NAFLD in men without DPN was significantly higher than in patients with DPN (63.9% and 54.5%, respectively, <sup>a</sup> $P < 0.05$  vs the group without DPN). Prevalence of NAFLD in women without DPN was also significantly higher than that in patients with DPN (66.9% and 58.6%, respectively, <sup>a</sup> $P < 0.05$  vs the group without DPN); **C:** Incidence of NAFLD negatively correlated with DR ( $r = -0.114$ ,  $P < 0.05$ ). This trend persisted even when patients were stratified by sex ( $r = -0.176$  in men,  $r = -0.076$  in women, both  $P < 0.05$ ). Prevalence of NAFLD in T2DM with and without DR was 54.9% and 66.1%, respectively (<sup>b</sup> $P < 0.01$  vs the group without DR). Furthermore, the Prevalence of NAFLD in men without DR was significantly higher than that in patients with DR (66.9% and 49.5%, respectively, <sup>b</sup> $P < 0.01$  vs the group without DR). Prevalence of NAFLD in women without DR was also significantly higher than that in patients with DR (65.5% and 58.1%, respectively, <sup>a</sup> $P < 0.05$  vs the group without DR).

T2DM: Type 2 diabetes mellitus; WC: Waist circumference; TG: Triglyceride; BMI: Body mass index; FBG: Fasting blood glucose; SBP: Systolic blood pressure; DBP: Diastolic blood pressure; HDL: High-density lipoprotein; DR: Diabetic retinopathy; DPN: Diabetic peripheral neuropathy; DN: Diabetic nephropathy.

both  $P < 0.05$ ). The prevalence of NAFLD in men without DN was significantly higher than that of patients with DN (63.3% and 49.3%, respectively,  $P < 0.05$ ). Similarly, the prevalence of NAFLD in women without DN is significantly higher than that of patients with DN (67.5% and 49.5%, respectively,  $P < 0.05$ ).

The incidence of NAFLD was found to correlate negatively with DPN, as shown in Figure 2B ( $r = -0.086$ ,  $P < 0.05$ ). The general prevalence of NAFLD in T2DM with and without DPN was 57.2% and 65.6%, respectively ( $P < 0.05$ ). This trend also persisted when patients were stratified by sex ( $r = -0.095$  in men,  $r = -0.084$  in women, both  $P < 0.05$ ). The prevalence of NAFLD in men without DPN was significantly higher than that of patients with DPN (63.9% and 54.5%, respectively,  $P < 0.05$ ). Similar results were found in women (66.9% and 58.6%, respectively,  $P < 0.05$ ).

The incidence of NAFLD was negatively correlated with DR, as shown in Figure 2C ( $r = -0.114$ ,  $P < 0.05$ ). The general prevalence of NAFLD in T2DM with and without DR was 54.9% and 66.1%, respectively ( $P < 0.05$ ). This trend persisted even when patients

were stratified by sex ( $r = -0.176$  in men,  $r = -0.076$  in women, both  $P < 0.05$ ). The prevalence of NAFLD in men without DR was significantly higher than that of patients with DR (66.9% and 49.5%, respectively,  $P < 0.05$ ). Similar results were determined in women (65.5% and 58.1%, respectively,  $P < 0.05$ ).

### Risk factors for the development of NAFLD in patients with T2DM

With NAFLD as the dependent variable, the variables that were independently associated with NAFLD in T2DM patients were identified by binary stepwise logistic regression. Independent predictors of NAFLD were BMI (OR for log BMI:  $1.238 \times 10^7$ ; 95%CI:  $154915.06-9.897 \times 10^7$ ), WC (OR for log WC: 261.44; 95%CI: 1.691-4.422.03), TG (OR for log TG: 7.79; 95%CI: 3.99-15.19), FBG (OR = 1.08; 95%CI: 1.02-1.15), diastolic blood pressure (DBP) (OR = 1.03; 95%CI: 1.01-1.05), systolic blood pressure (SBP) (OR = 1.03; 95%CI: 1.021-1.04), duration of diabetes (OR = 0.96; 95%CI: 0.93-0.98), DR (OR = 0.71; 95%CI: 0.51-0.99), DPN (OR = 0.69; 95%CI: 0.50-0.95), DN (OR = 0.32; 95%CI: 0.22-0.46), and HDL (OR for log HDL: 0.17; 95%CI: 0.03-0.89) (Table 2).

However, the risk factors for NAFLD in men and women were not identical. Independent predictors of NAFLD in men were BMI (OR for log BMI:  $4.52 \times 10^{10}$ ; 95%CI:  $6.12 \times 10^7-3.33 \times 10^{13}$ ), TG (OR for log TG: 37.88; 95%CI: 11.34-126.61), DBP (OR = 1.09; 95%CI: 1.05-1.12), duration of diabetes (OR = 0.94; 95%CI: 0.90-0.98), and HDL (OR: for log HDL: 0.01; 95%CI: 0-0.21) (Table 2). Independent predictors of NAFLD in women were BMI (OR for log BMI:  $2.21 \times 10^7$ ; 95%CI:  $395927.04-1.23 \times 10^9$ ), TG (OR for log TG: 3.48; 95%CI: 1.54-7.90), FBG (OR = 1.22; 95%CI: 1.13-1.31), SBP (OR = 1.04; 95%CI: 1.03-1.05), duration of diabetes (OR = 0.96; 95%CI: 0.93-0.98), DPN (OR = 0.65; 95%CI: 0.43-0.98), DR (OR = 0.61; 95%CI: 0.41-0.93), and DN (OR = 0.29; 95%CI: 0.19-0.46) (Table 2).

## DISCUSSION

NAFLD represents an important burden of disease for patients with T2DM; however, the magnitude of the problem is currently unknown. In this study, the prevalence of NAFLD in hospitalized Chinese T2DM patients was calculated at 61%. This prevalence is lower than that reported by Lu *et al*<sup>[2]</sup> in 2009 (75.18%) but markedly higher compared with that reported by Zhou *et al*<sup>[3]</sup> conducted 5 years ago (42.1%).

A limitation of this study was that the diagnosis of NAFLD was based on ultrasound imaging. The patients did not undergo liver biopsy and histological examination, which is the gold standard technique for identifying steatosis. The sensitivity of ultrasonography in detecting

steatosis varies between 60% and 94% and is dependent on the degree of steatosis. In particular, sensitivity is significantly low when the degree of steatosis is < 30%<sup>[5,8]</sup>. Furthermore, some participants with normal ultrasound scans may have undiagnosed hepatic fibrosis and thus be considered a severe case of NAFLD<sup>[6]</sup>. Therefore, the cases that were potentially misclassified by ultrasonography might have resulted in an underestimated prevalence of NAFLD. This limitation might have attenuated the magnitude of our effect measures to null. The findings of this study may then be considered conservative estimates of the prevalence of NAFLD in hospitalized Chinese T2DM patients.

This study revealed that the prevalence of NAFLD in male hospitalized T2DM patients was 59.1%, which was slightly lower than that in female patients (62.1%), but without statistical significance. When patients were divided into three groups according to their age (*i.e.*, < 50, 50-60, and > 60 years), the prevalence of NAFLD in women was higher than in men aged < 50 years, whereas the reverse was evident when age was > 50 years. However, no significant difference was indicated in the prevalence of NAFLD between male and female patients at different ages. This finding differs from that of Zhou *et al.*<sup>[3]</sup>, who reported that the prevalence of fatty liver in patients < 50 years old was significantly higher in men than women; however, the reverse was evident when participants were older than 50 years. In the present study, several male patients with NAFLD, especially those aged < 50 years, were excluded for overdrinking. With this factor considered, the prevalence of NAFLD in male hospitalized T2DM patients may be significantly higher than that of female patients.

In our study, patients were assessed according to three age groups. The prevalence rates of NAFLD significantly decreased as age increased. This trend persisted even when the patients were stratified by sex. These observations are inconsistent with those of Targher *et al.*<sup>[5]</sup>, who reported that the prevalence of NAFLD increased with age (*i.e.*, 65.4% among participants aged 40-59 years and 74.6% among those aged  $\geq$  60 years;  $P < 0.001$ ). By contrast, Lu *et al.*<sup>[2]</sup> found that the prevalence of NAFLD in Chinese T2DM patients did not increase with age. In particular, T2DM patients in China aged 40-59 years are more prone to NAFLD. These findings are consistent with those published in a review by Duvnjak *et al.*<sup>[9]</sup>, which reports that the highest prevalence of NAFLD occurs in those aged 40-60 years. A potential explanation for these observations is that middle-aged persons are often too busy to participate in physical exercise and are more likely to dine outside of the home, whereas older and retired persons may have more time for physical exercise and devote more attention to their lifestyle. These behaviors among middle-aged persons may be one reason why Chinese patients with T2DM are more vulnerable to NAFLD, considering that the prevalence

of NAFLD does not increase with age<sup>[2]</sup>.

Patients were also assessed according to the duration of diabetes (*i.e.*, < 5, 5-10, and > 10 years). The prevalence rates of NAFLD decreased significantly with the prolonged course of diabetes. This trend persisted even when patients were stratified by sex. No significant difference was observed in the prevalence of NAFLD between male and female patients with different durations of diabetes. These findings contradict those of Banerjee *et al.*<sup>[10]</sup>, who found that a longer duration of T2DM was significantly associated with NAFLD. The association of a shorter duration of diabetes with liver disease has been previously described. A possible explanation for this association may be that a greater degree of hyperinsulinemia in early T2DM increases the uptake of free fatty acids (FFAs) by hepatocytes<sup>[6]</sup>. Popović *et al.*<sup>[11]</sup> presented a significant negative correlation between the duration of diabetes and fasting insulinemia as well as insulin resistance assessed by homeostatic model assessment-insulin resistance index. Increased fasting insulinemia and hepatic insulin resistance may trigger a reduced catabolism of lipoproteins rich in TGs and an increased hepatic very LDL production via changes in the rate of apolipoprotein B synthesis and degradation, as well as *de novo* lipogenesis or increased FFA flux from adipose tissue into the liver<sup>[12]</sup>.

In this study, we demonstrated that the general prevalence of diabetic microangiopathy complications (*i.e.*, DN, DPN and DR) increased significantly with age increased (data not shown). This trend persisted even when the patients were stratified by sex. When the patients were stratified by duration of T2DM, the prevalence rates of diabetic microangiopathy complications increased significantly with prolonged duration of T2DM (data not shown). In previous reports, the age and duration of diabetes were common risk factors for the three microvascular complications of T2DM<sup>[13-17]</sup>. Thus, chronic microvascular diabetic complications increase gradually with prolonged duration of T2DM, and the clinical symptoms tend to worsen progressively. Consequently, these patients need to pay more attention to their lifestyle and drug therapy. Therefore, the incidence of NAFLD does not increase with a prolonged duration of T2DM.

The development of NAFLD is a multifaceted cascade of physiological and biochemical events, including genetic, environmental, metabolic, and stress-related factors; the exact risk factors for NAFLD have not been clearly identified<sup>[18]</sup>. On the basis of the univariate analysis results, patients diagnosed with NAFLD were significantly younger and had a shorter duration of diabetes than those without NAFLD. The BW, WC, BMI, SBP, DBP, FBG, HbA1c, and TG were significantly higher, and HDL cholesterol was significantly lower in patients with NAFLD (Table 1,  $P < 0.05$ ). Multivariate analysis identified the following as independent pre-

dictors of NAFLD: BMI, WC, TG, FBG, DBP, SBP, duration of diabetes, DR, DPN, DN, and HDL. This observation is consistent with the findings reported in literature that the prevalence of NAFLD is closely associated with obesity, dyslipidemia, hypertension, and glucose intolerance, a cluster of metabolic disorders that is now recognized as metabolic syndrome<sup>[10,18,19]</sup>. However, the negative correlations between the prevalence of NAFLD and the duration of diabetes, DR, DPN, and DN identified in this study are inconsistent with the data reported in previous studies<sup>[10]</sup>. Given the negative correlations between the prevalence of NAFLD as well as the duration of diabetes and diabetic chronic microvascular complications, more attention should be given to lifestyle and drug therapy, particularly in patients presenting an aggravation in any of the clinical symptoms mentioned above.

Despite the difference in the independent risk factors for NAFLD between men (Table 2) and women (Table 2), both positively correlated with BMI, TG, and hypertension and a negative correlation with the duration of diabetes. In men, the prevalence of NAFLD positively correlated with DBP but negatively with HDL (Table 2). In women, the prevalence of NAFLD positively correlated with FBG and SBP but negatively with DPN, DR and DN (Table 2). According to a previous study, SBP represents the most prevalent type in obese women, being a stronger predictor of cardiovascular disease than DBP<sup>[20]</sup>. Therefore, the regulation of SBP is more critical for women.

Although most patients with NAFLD presented with non-progressive bland steatosis, few others developed a histological subtype of nonalcoholic steatohepatitis (NASH), which can develop to cirrhosis, hepatocellular carcinoma, and liver-cancer-related death<sup>[9,21,22]</sup>, especially for NASH patients with T2DM<sup>[21,23,24]</sup>. Thus, specialists have considered that NAFLD may not be a completely benign disorder<sup>[9,25]</sup>. On the contrary, we consider NAFLD a benign condition because of the negative relationship between the prevalence of NAFLD with age and duration of T2DM. No treatment to alleviate NAFLD or prevent its progression has been scientifically proven. However, various therapeutic alternatives aimed at interfering with the risk factors involved in the pathogenesis of this disorder have been applied to prevent the progression of NAFLD to end-stage liver disease. The most important therapeutic measure is to increase insulin sensitivity by motivating patients to change their lifestyle habits, particularly by diet modification and participation in physical activities to lose weight<sup>[26,27]</sup>.

Tushuizen *et al.*<sup>[28]</sup> reported that after 44 wk of exenatide therapy, patients experienced a 73% reduction in hepatic fat content (*i.e.*, from a baseline of 15.8% to 4.3%), as evaluated by proton magnetic resonance spectroscopy. This finding is consistent with that reported by Ding *et al.*<sup>[29]</sup> on the reduced hepatic lipid content in exenatide-treated ob/ob or obese mice compared with

placebo-treated mice. Lazo *et al.*<sup>[30]</sup> reported that a 12-mo intensive lifestyle intervention in patients with T2DM significantly reduced steatosis and NAFLD. In addition, Lo *et al.*<sup>[24]</sup> have reported that diet-induced NASH fibrosis is exacerbated by diabetes and attenuated by insulin therapy. On the basis of these findings, we believe that NAFLD is reversible, and patients may benefit from its early diagnosis and treatment<sup>[31]</sup>.

In conclusion, the results of this study suggest that NAFLD is extremely common in people with T2DM, positively correlates with BMI, WC, TG, FBG, DBP, and SBP, and negatively correlates with the duration of diabetes, DR, DPN, DN, and HDL. Given that hepatic fat content can be reversed with lifestyle changes and drugs, NAFLD should be included in future preventive public health initiatives, and the affected individuals should be motivated to adopt a healthier lifestyle<sup>[27]</sup>. Patients with T2DM should be always assessed for NAFLD to ensure early diagnosis and entry into proper and thorough medical care. Future efforts should be directed toward strengthening early diagnosis, intensive blood glucose and blood pressure control, and effective dyslipidemia correction to prevent and minimize the occurrence of NAFLD.

## COMMENTS

### Background

Diabetes is an independent risk factor for the development of nonalcoholic fatty liver disease (NAFLD) and its progression to more advanced liver diseases, including fibrosis, cirrhosis, and hepatocellular carcinoma. NAFLD and diabetic microangiopathy complications represent important burdens of disease for patients with type 2 diabetes mellitus (T2DM). Previous studies have shown that the prevalence of NAFLD and microangiopathy complications in patients with T2DM significantly correlate with age and duration of T2DM. However, few studies have focused on the relationship between NAFLD and diabetic microangiopathy complications.

### Research frontiers

Many studies have reported that individuals with NAFLD are older, more likely to be male, and have a longer duration of diabetes than those without NAFLD. However, recently, conflicting results have shown that participants with definite steatosis are significantly younger and have shorter durations of diabetes than the combined normal/probably normal groups. Further studies are required to ascertain the differences in the prevalence of NAFLD between the sexes, and the relationships between age, duration of diabetes, and prevalence of NAFLD.

### Innovations and breakthroughs

The relatively larger cross-sectional study of inpatients with T2DM in Qingdao, China showed that the prevalence of NAFLD was 61%. However, based on the finding that the prevalence of NAFLD was negatively correlated with age and duration of T2DM, the authors believe that NAFLD is a benign process.

### Applications

Our results suggest that patients with T2DM should be always assessed for NAFLD to ensure early diagnosis and entry into proper and thorough medical care. Future efforts should be directed at strengthening early diagnosis, intensive blood glucose and pressure control, and effective dyslipidemia correction to prevent and minimize the occurrence of NAFLD.

### Terminology

NAFLD is defined as the presence of definite hepatic steatosis on ultrasound scan in the absence of a secondary cause for hepatic steatosis. Diabetic microvascular complications included diabetic nephropathy (DN), diabetic peripheral neuropathy (DPN), and diabetic retinopathy (DR). DN is defined by increased urinary albumin excretion in the absence of urinary tract infection or other renal abnormalities. DPN is diagnosed in the presence of persistent numbness, par-

esthesia, loss of hearing of the tuning fork and sense of vibration, and failure to elicit a knee and/or ankle jerk. DR is diagnosed in the presence of retinal hemorrhages, exudates, and macular edema.

### Peer review

This was a good descriptive study in which the authors evaluated the correlation between NAFLD and microvascular complications in Chinese T2DM patients. The results are interesting and suggest that NAFLD is likely a benign process and efforts should be directed at early diagnosis, intensive blood glucose and blood pressure control, and effective dyslipidemia correction, which is of clinical interest.

### Abstract

**AIM:** To investigate the value of combined detection of circulating cell-free DNA (cfDNA),  $\alpha$ -fetal protein (AFP) and  $\alpha$  L-fucosidase (AFU) for diagnosis of hepatocellular carcinoma (HCC).

**METHODS:** Serum samples from 39 HCC patients and 45 normal controls were collected. Branched DNA (bDNA) was used to detect the level of cfDNA, and a receiver operating characteristic curve was employed to evaluate the diagnostic sensitivity, specificity, accuracy, positive predictive value, negative predictive value, positive likelihood ratio, negative likelihood ratio and Youden index, and to assess the diagnostic efficiency and their correlations with the clinicopathological features. AFP and AFU were detected by chemilumines-

cence and colorimetry, respectively. The significance of combined detection of the three biomarkers was discussed.

**RESULTS:** cfDNA level was increased in 22 of the 39 HCC samples and in 2 of the 45 normal controls. cfDNA level in HCC samples was significantly higher than that in normal controls ( $P < 0.05$ ). There were significant differences in sex and extra- and intrahepatic metastasis ( $P < 0.05$ ). There was no significant correlation between cfDNA, AFP and AFU in the detection of HCC. The sensitivity of combined detection of cfDNA with one marker (AFP or AFU) and cfDNA with two markers (AFP and AFU) was 71.8%, 87.2% and 89.7% vs 56.4%, 53.8% and 66.7% for cfDNA, AFP and AFU used alone, respectively, the difference being statistically significant ( $P < 0.05$ ).

**CONCLUSION:** Quantitative analysis of cfDNA is sensitive and feasible, and the combined detection of cfDNA with AFP or AFU or both could improve the diagnostic sensitivity for HCC.

**Key words:** Alu; Branched DNA; Circulating cell free DNA; Diagnosis; Hepatocellular carcinoma

**Core tip:** Various techniques are available to quantify serum circulating free cell DNA (cfDNA), some of these techniques require abstraction and purification as there is only a very small amount of cfDNA in the serum. This study investigates the value of combined detection of cfDNA,  $\alpha$ -fetal protein (AFP) and  $\alpha$  L-fucosidase (AFU) for diagnosis of hepatocellular carcinoma. Quantitative analysis of cfDNA is sensitive and feasible, and the combined detection of cfDNA with AFP or AFU or both could improve the diagnostic sensitivity for hepatocellular carcinoma.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors worldwide, with an incidence which ranks third and mortality which ranks second in all malignant tumors. The one-year survival in patients with HCC without surgical ablation is less than 30%, and the 5-year recurrence rate is about 80%, even in patients who undergo radical resection. Therefore, the key to HCC treatment is early detection and diagnosis<sup>[1,2]</sup>. Existing biomarkers for the diagnosis of HCC are alpha-fetal protein (AFP),  $\gamma$ -glutamyltranspeptidase isoenzymes II (GGT-II),  $\alpha$  L-fucosidase (AFU) and acidic isoferritin<sup>[3]</sup>, of which AFP remains the most specific marker due to its recognized effect in the diagnosis of HCC and assessment of the curative effect, prognosis and recurrence. However, not all HCC patients are diagnosed by AFP alone as the false negative rate of AFP is about 30%. Markers like AFU and GGT-II have assisted in diagnosing patients with HCC whose AFP levels are negative, but they can not replace AFP in the diagnosis of HCC. Therefore, there is an urgent need to find a new biomarker which is superior or at least equivalent to AFP for the diagnosis of HCC.

Cell-free fetal DNA (cfDNA) has been extensively studied over the past few decades. Supported by theory and observation, two major sources of cfDNA have been postulated: first, fragmented DNA released as a consequence of cell death (apoptotic/necrotic) and, second, active metabolic secretion of DNA from cells. Considerable research effort has been made on the use of cfDNA as a biomarker in cancer diagnosis. cfDNA from malignancies exhibits characteristic changes such as mutations, deletions, methylations and microsatellite aberrations which are distinct from those in benign conditions, and thus may be useful in the diagnosis of cancer<sup>[4]</sup>.

This study was designed to validate a bDNA-based Alu assay for quantifying human cfDNA in blood, and explore the feasibility of Alu quantification for HCC screening.

## MATERIALS AND METHODS

### Patients and samples

Included in this study were 39 patients randomly selected from those who had been diagnosed with HCC by clinical and radiographic evaluations at the Affiliated Hospital of Nantong University (Nantong, China) between May and October 2011. They included 32 males and 7 females ranging in age from 40 to 85 years. Forty-

five healthy volunteers (36 males and 9 females; age range 28-83 years) who were negative for physical indices following health examination and documented to have normal liver biochemistry served as controls. Fresh blood was collected in serum separator tubes (Vacuette, Austria) coated with a clot activator and barrier gel, and EDTA tubes (Kangshi, China) for plasma, were centrifuged at  $1600 \times g$  for 10 min, and then microcentrifuged at  $16000 \times g$ . The separated serum was immediately stored at  $-80^\circ\text{C}$ . The samples tested were diluted using the standard human genomic DNA qualification kit according to the manufacturer's instructions, with an initial concentration of  $2.73 \times 10^5$ .

### Methods

**Quantitation of cfDNA:** Ten  $\mu\text{L}$  diluted serum was added to lysis solution to a final volume of 100  $\mu\text{L}$  containing 50% Lysis Mixture (Panomics) and 1 g/L proteinase K. Target gene probe sets containing 250, 250 and 250 fmol of capture extender probe (CE), blocking probe and label extender probe (LE) were added to the blood lysate. The lysate was then transferred to an assay well in a 96-well plate (Panomics, Redwood City, CA, United States) covalently coated with capture probe (CP) oligo, incubated at  $55^\circ\text{C}$  for 1 h, washed 3 times with 200  $\mu\text{L}$  wash buffer ( $0.1 \times$  standard 4 saline citrate containing 0.3 g/L lithium lauryl sulfate), sequentially hybridized with 100  $\mu\text{L}$  1:1000 dilution of bDNA preamplifier (amplifier) (Panomics) at  $55^\circ\text{C}$  for 30 min and then with 100  $\mu\text{L}$  (50 fmol) 3'-alkaline phosphatase-conjugated Label Probe oligo (Panomics) at  $50^\circ\text{C}$  for 30 min, and then washed three times. After the final wash, the alkaline phosphatase substrate dioxetane (Panomics) was added to the wells and incubated at room temperature for 5-10 min to detect luminescent signals using an Lmax microtiter plate luminometer (a molecular device). The reagent for the QuantiGene 2.0 DNA Assay was provided by Professor Zhang Lurong from Florida State University, United States.

In the same 96-well-plate, samples with a known amount of Human Genomic DNA were added as follows: 0, 50, 100, 200 and 400 ng/mL, respectively. A standard curve was mapped out by the computer. The standard Human Genomic DNA solution was obtained from Promega, Madison, United States.

**Quantitation of AFP:** The concentration of AFP in the serum samples from HCC patients was measured manually with the ARCHITECT AFP Reagent Kit (Abbott, Chicago, IL, United States) according to the calibrator dose response curve by the chemiluminescence method using an Abbott 2000 immunoassay instrument.

**Quantitation of AFU:** The activity of AFU in the serum samples from HCC patients was measured manually with a Shanghai Institute of Naval Medicine Biotechnology Center Kit (Shanghai, China) by a colorimetric method using a BA-88 semi-automatic biochemical analyzer.

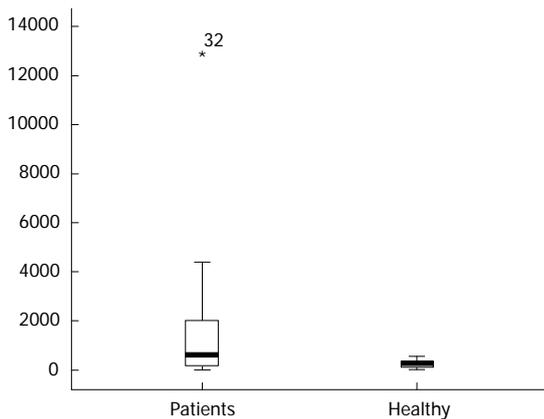

Figure 1 Circulating cell-free DNA levels in 39 hepatocellular carcinoma patients and 45 normal controls.

### Interpretation of the results

**Reference value of cfDNA:** The content of cfDNA in each sample was calculated according to the standard curve. A receiver operating characteristic (ROC) curve was drawn to select the Youden's index<sup>[5]</sup>, and the highest sensitivity and specificity (Youden's index = sensitivity + specificity-1) were selected as the cut-off values. A value greater than or equal to the cut-off value was regarded as positive, and smaller values were regarded as negative.

**Reference value of AFP:** According to the clinical diagnosis and staging criteria of HCC of the Chinese Anti-Cancer Association, a content of AFP greater than or equal to 400 ng/mL is considered positive, and a content smaller than this value is negative, excluding cases of pregnancy, embryonic tumors of the reproductive system, active liver disease and metastatic liver cancer.

**Reference value of AFU:** According to the reagent kit manual, the activity of serum AFU = (A determination tube-A control tube)/average A standard tube × 400, a value greater than 650 μmol/L per hour is considered positive, 550-650 μmol/L per hour is suspicious, and less than 550 μmol/L per hour is negative.

### Statistical analysis

Statistical analysis of the data was performed using the SPSS 13.0 software package. As the results of the concentrations of cfDNA, AFP and AFU in each group were normally distributed, they were presented as the median (range of detection). Measurement data were based on mean ± SD. Correlations between the three indices were evaluated with Pearson's correlation coefficient. The rates of interclass were determined using the  $\chi^2$  test. A *P* value less than 0.05 was considered statistically significant.

## RESULTS

### Results of quantitative detection of cfDNA

The content of serum cfDNA in the 39 HCC samples

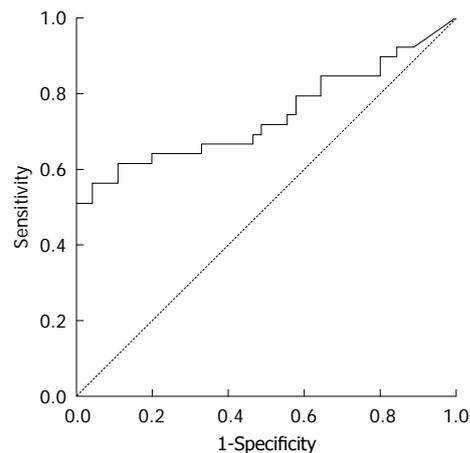

Figure 2 Receiver operating characteristic curve of serum circulating cell-free DNA in 39 hepatocellular carcinoma patients and 45 normal controls.

ranged from 12866.8 ng/mL to 0 ng/mL, with a median of 557.59 ng/mL compared with 569.2963 ng/mL, 0 ng/mL and 240.07 ng/mL in the 45 normal control samples, and a significant difference was observed between them (*P* < 0.05) (Figure 1). According to the ROC curve (Figure 2), the Youden index was maximal when the concentration of cfDNA was 509.9774 ng/mL, therefore 509.9774 ng/mL was defined as the positive value.

The ROC area under the curve (AUC) was  $0.742 \pm 0.058$ , therefore a sum score of the classifier at 509.9774 ng/mL was chosen as the optimal cut-off, as it had the highest Youden's index of 0.520. At this cut-off value, the sensitivity was 56.4%, the specificity was 95.6%, the accuracy was 77.4%, the positive predictive value was 91.7%, the negative predictive value was 71.7%, the positive likelihood ratio was 12.692 and the negative likelihood ratio was 0.048.

### Correlations between clinicopathological features and cfDNA expression

Correlations between clinicopathological features and serum cfDNA level were observed, suggesting that serum cfDNA level in HCC patients was correlated with intrahepatic and extrahepatic metastasis and gender (Table 1).

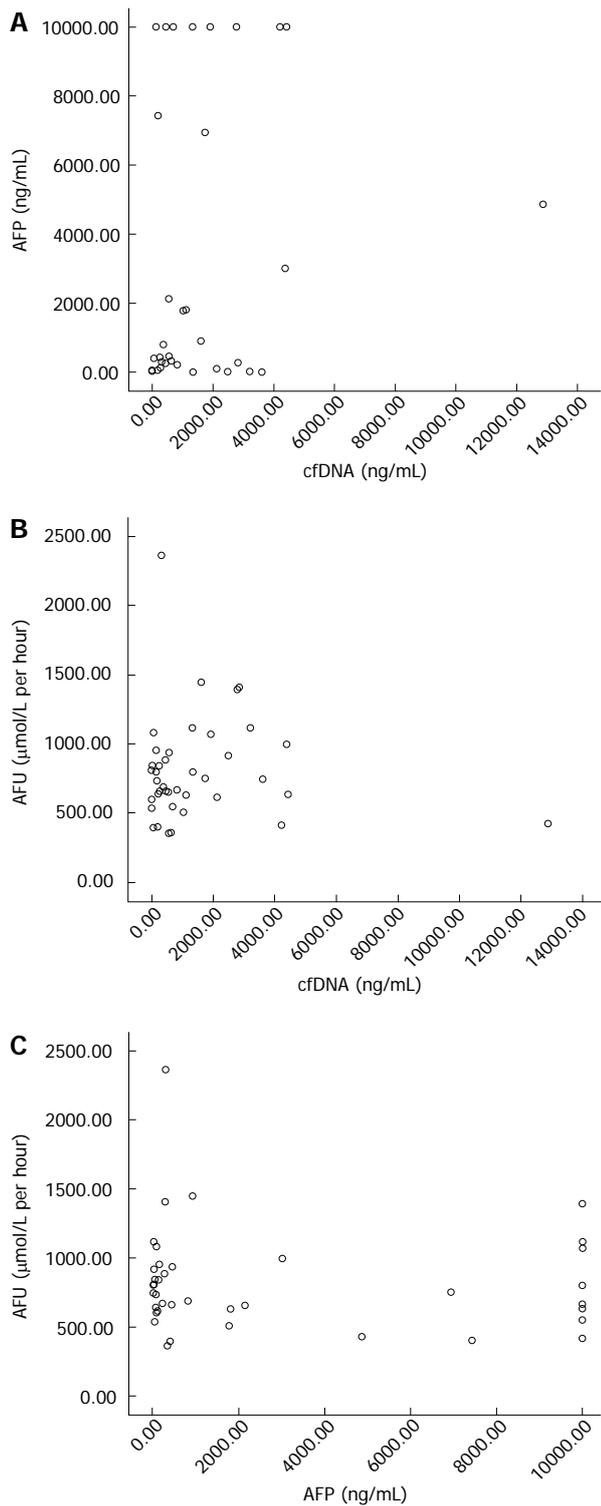

### Results of quantitative detection of AFP and AFU

The content of serum AFP in HCC samples ranged from > 10000 ng/mL to 3.92 ng/mL, with a median of 392.07 ng/mL, compared with 526.10 ng/mL, 1.31 ng/mL and 6.02 ng/mL in the normal control samples, and a significant difference was observed between them (*P* < 0.05).

The content of serum AFU in HCC samples ranged from 2366 ng/mL to 362 ng/mL, with a median of 744 ng/mL compared with 792 ng/mL, 121 ng/mL and 431 ng/mL in the normal control samples, and a significant difference was observed between them (*P* < 0.05).

### Correlation analysis between cfDNA, AFP and AFU

Scatter point diagrams were mapped out to analyze correla-

**Figure 3** Correlation coefficient. A:  $r = 0.243$  showing no significant correlation between circulating cell-free DNA and  $\alpha$ -fetoprotein; B:  $r = -0.0735$  showing no significant correlation between circulating cell-free DNA and  $\alpha$  L-fucosidase; C:  $r = -0.085$  showing no significant correlation between  $\alpha$ -fetoprotein and  $\alpha$  L-fucosidase.

tions between the three indices using SPSS13.0 (Figure 3).

**Detection of cfDNA in combination with AFP and AFU**

Compared with the diagnostic efficiency of cfDNA, AFP or AFU alone, combined detection improved the diag-

cfDNA: Circulating cell-free DNA.

nostic efficiency of HCC to some extent (Table 2).

**DISCUSSION**

Circulating free cell DNA is the fragmentation of nucleic acids in body fluids, and has been described in the serum of healthy persons and patients with a variety of diseases, including systemic lupus erythematosus (SLE), diabetes, cerebral stroke, rheumatoid arthritis, myocardial infarction, pulmonary embolism, preeclampsia, Whipple’s disease and malignant tumors<sup>[6-10]</sup>. Investigations have detected increased cfDNA in the plasma of patients with severe injuries, organ failure and multiple organ dysfunction syndromes. Elevated levels of cfDNA were also found in patients who had undergone organ transplantation<sup>[11]</sup>. Fetal cfDNA has been detected in maternal plasma and has been used for the prenatal diagnosis of fetal abnormalities<sup>[12]</sup>. Blunt traumatic injury and burn injury can also cause cfDNA release into the blood circulation<sup>[13]</sup>. Many studies have reported the detection of cfDNA in the serum of patients with various malignant and benign tumors. It is hypothesized that cfDNA may originate from lymphocytes and other nucleated cells in healthy individuals, however, the origin of cfDNA in malignant tumors is not fully understood<sup>[14]</sup>.

Previous studies have suggested the use of serum cfDNA in the diagnosis of HCC. One study showed that cfDNA level was significantly higher in HBV carriers than in normal controls<sup>[15]</sup>. Ren *et al*<sup>[16]</sup> suggested that cfDNA level correlated inversely with HCC prognosis, and was attributable to HBV infection in most cases, suggesting that cfDNA may be a predictive marker for the prognosis of HBV-related HCC. In HCV-related HCC patients, serum cfDNA levels were positively correlated with the increased expression of several inflammatory cytokine genes, suggesting that serum cfDNA is associated with local inflammation. cfDNA is a potential non-inva-

<sup>a</sup>*P* < 0.05 vs group circulating cell-free DNA (cfDNA) +  $\alpha$ -fetal protein (AFP); <sup>c</sup>*P* < 0.05 vs group cfDNA +  $\alpha$  L-fucosidase (AFU); <sup>e</sup>*P* < 0.05 vs group cfDNA + AFP + AFU.

sive cancer biomarker as it is easily isolated from the circulation<sup>[17]</sup>. Positive correlations were observed between cfDNA level, aspartate aminotransferase (AST) level and the number of leukocytes and neutrophils in HCV-related HCC patients, but not in HCV carriers<sup>[18]</sup>. The level of cfDNA in serum can function as a predictor of overall survival in distant organs after curative hepatectomy in patients with HCV-related HCC<sup>[19]</sup>. In our study, serum cfDNA level was significantly higher in HCC patients than in normal controls; patients with intrahepatic and extrahepatic metastasis had a significantly higher cfDNA level; and male patients had higher cfDNA levels as compared with female patients. Therefore, it is clear that serum cfDNA level is associated with intrahepatic and extrahepatic metastasis and gender in HCC patients, but is not closely associated with age, HbsAg or liver cirrhosis. The significance of serum cfDNA in the clinical diagnosis of HCC is as follows: First, serum cfDNA level is positively correlated with the degree of differentiation and metastasis and negatively correlated with the prognosis of HCC patients, suggesting that cfDNA may be useful in monitoring the pathogenic condition of HCC. Second, serum cfDNA level is relevant to the survival of HCC patients after hepatectomy, suggesting that cfDNA may be a useful marker for surgical or non-surgical treatment decision making.

Various techniques are available to quantify serum cfDNA, some of these techniques require abstraction and purification as there is only a very small amount of cfDNA in the serum, and these technologies have failed to reach expectations. The bDNA amplification-based Alu assay is a new technology to quantify serum cfDNA directly and does not require extraction of cfDNA from the serum. The Alu family is the largest of the short interspersed elements (SINEs). Each Alu sequence is approximately 300 bp with a high homology of 70%-98%<sup>[20,21]</sup>. The sequence AGCT at the 170 degree position can be recognized and cut by the restriction enzyme Alu. Recent studies<sup>[22,23]</sup> on the Alu sequence showed that it had a unique structure and physiological function, and was associated with a variety of malignant

tumors and other human diseases such as gene deletion or duplication of homologous recombination, gene rearrangement of chromosome translocation, and change in transcriptional level. The results of our study suggest that the bDNA technique may be a useful approach in the diagnosis of HCC, as amplification of the hybridization signal is needed instead of amplification of the target sequence. In addition, it is simple, economical, time saving and reproducible.

AFP is the most commonly used biomarker for HCC screening, and a continuous elevation in AFP is considered a risk factor for HCC. AFP has been widely used in HCC survey, diagnosis, evaluation of treatment effects and prediction of recurrence<sup>[24,25]</sup>. AFP can also be used to monitor treatment and prognosis. Vigilance is required when AFP is higher than 400  $\mu$ g/L or rises continuously. The survival period is very short in patients with an AFP value > 500  $\mu$ g/L and bilirubin > 2 mg/L. A rapid increase in AFP often suggests the occurrence of HCC metastasis. Postoperative elevation of AFP > 200  $\mu$ g/L often indicates incomplete resection of HCC tissue, or the occurrence of metastasis. AFP can also be used in other cancers, such as testicular cancer, teratoma, gastric carcinoma, and pancreatic carcinoma. However, not all HCC cases are diagnosed by AFP alone, as the false negative rate is approximately 30%. False positive AFP results are also seen in some patients with non malignant conditions such as viral hepatitis and cirrhosis. The level of AFP can also increase continuously in the blood or urine of pregnant women, but usually does not exceed 300  $\mu$ g/L.

AFU is a lysosomal acid hydrolase found extensively in human tissues, with higher activity in the liver and kidney. Some researchers<sup>[26]</sup> believe that increased serum AFU in HCC patients is associated with an increase in its synthesis, while others reported that hepatoma cells can produce a type of inhibitor to reduce substrate hydrolysis, resulting in substrate accumulation and a compensatory increase in AFU, which is an effective marker of HCC<sup>[27,28]</sup>. In the present study, the sensitivity of AFU, cfDNA and AFP was 66.7% 56.4% and 53.8%, respec-

tively; the specificity of AFU was only 75.6% compared with 95.6% for cfDNA and AFP, and 91.1% for AFP; the accuracy of cfDNA, AFP and AFU was 77.4%, 73.8% and 71.4%, respectively, with no significant differences between them. Although the sensitivity of AFU was the highest of the three, its specificity was very low. In contrast, the sensitivity of cfDNA and AFP was lower than that of AFU, and their specificity was relatively high. There were no significant correlations between cfDNA, AFP and AFU. The specificity of detection of cfDNA combined with AFP or AFU was lower. However, the sensitivity improved significantly, and the accuracy was similar. The sensitivity of combined detection with the three items was slightly improved, while the specificity was decreased. Taking into account the economic burden of HCC treatment, we believe that combined detection of any two of the three biomarkers is better than combined detection of all three biomarkers in the diagnosis of HCC. In our opinion, cfDNA in combination with AFP or AFU may effectively improve the clinical detection of HCC.

In conclusion, cfDNA for HCC detection has a high sensitivity and specificity, and the clinical significance is similar to AFP, and cfDNA is not correlated with AFP and AFU. The combined detection of cfDNA with one or two markers can significantly improve the diagnostic rate of HCC.

## COMMENTS

### Background

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors worldwide. Existing biomarkers for the diagnosis of HCC are  $\alpha$ -fetoprotein (AFP),  $\gamma$ -glutamyltranspeptidase isoenzymes II (GGT-II),  $\alpha$ -L-fucosidase (AFU) and acidic isoferritin, of which AFP remains the most specific marker for the diagnosis of HCC. However, not all HCC patients are diagnosed using AFP alone. Circulating free cell DNA (cfDNA) has been extensively studied over the past few decades, and has a high sensitivity and specificity in the detection of HCC.

### Research frontiers

cfDNA results from the fragmentation of nucleic acids in body fluids, and has been described in the serum of healthy persons and patients with a variety of diseases. This research was designed to investigate the value of cfDNA in the diagnosis of HCC, determine correlations between cfDNA and clinicopathological features, and explore the value of combined detection of cfDNA, AFP and AFU in the clinical diagnosis of HCC.

### Innovations and breakthroughs

Various techniques are available to quantify serum cfDNA, some of these techniques require abstraction and purification as there is only a very small amount of cfDNA in the serum, and these technologies have failed to reach expectations. The bDNA amplification-based Alu assay is a new technology to quantify serum cfDNA directly and does not require the extraction of cfDNA from serum.

### Applications

The results of this study suggest that the quantitative analysis of cfDNA is sensitive and feasible, and the combined detection of cfDNA with AFP or AFU or both could improve the diagnostic sensitivity for HCC.

### Terminology

cfDNA: cfDNA results from the fragmentation of nucleic acids in body fluids, and has been described in the serum of healthy persons and patients with a variety of diseases. Alu: The Alu family of short (~300 bp) interspersed elements is one of the most successful mobile genetic elements, having increased to a copy number in excess of one million in primate genomes in the last 65 million years.

### Peer review

The study provides some new information. However, a brief mention regarding

the importance of studying circulating DNA and its pathophysiological relevance in cancer needs to be highlighted. The authors should be encouraged to present the observed levels of DNA in healthy controls and patients. This will facilitate the readers to understand the significance of the observed differences in both groups studied. The clinical translational potential of cfDNA as a diagnostic/prognostic biomarker for HCC is not addressed in detail, and needs to be elaborated.

### Abstract

**AIM:** To investigate the effects of *Lactobacillus plantarum* (*L. plantarum*) CA16 and *L. plantarum* SC4 on hyperlipidemic mice.

**METHODS:** Male Kunming mice were fed a high-cholesterol diet for 28 d to construct hyperlipidemic models. Hyperlipidemic mice and normal mice were assigned to 3 groups which were separately treated with *L. plantarum* CA16, *L. plantarum* SC4, and physiological saline through oral gavage for 28 d. Total cholesterol (TC), triglycerides (TG), high-density lipoprotein cholesterol (HDL-C), and low-density lipoprotein cholesterol (LDL-C) levels were measured by commercially available enzyme kits. FACS Calibur flow cytometry was used

to examine hepatic and renal nuclear factor-erythroid 2-related factor 2 (Nrf2) expression. The morphology of livers was checked by hematoxylin and eosin staining and optical microscope observation.

**RESULTS:** Compared with normal mice, hyperlipidemic mice possessed significantly higher TC ( $3.50 \pm 0.43$  vs  $2.89 \pm 0.36$ ,  $P < 0.01$ ), TG ( $1.76 \pm 0.07$  vs  $1.10 \pm 0.16$ ,  $P < 0.01$ ), and LDL-C ( $1.72 \pm 0.20$  vs  $0.82 \pm 0.10$ ,  $P < 0.01$ ) levels, resulting in an increase of atherogenic index (AI) ( $2.34 \pm 1.60$  vs  $0.93 \pm 0.55$ ,  $P < 0.05$ ) and LDL-C/HDL-C ratio ( $1.43 \pm 0.12$  vs  $0.51 \pm 0.16$ ,  $P < 0.05$ ). After treatment with *L. plantarum* CA16/*L. plantarum* SC4, TG ( $1.43 \pm 0.27/1.54 \pm 0.10$  vs  $1.76 \pm 0.07$ ,  $P < 0.01/P < 0.05$ ) and LDL-C ( $1.42 \pm 0.07/1.47 \pm 0.12$  vs  $1.72 \pm 0.20$ ,  $P < 0.01/P < 0.01$ ) in hyperlipidemic mice significantly decreased. In addition, TC, HDL-C, AI, and LDL-C/HDL-C ratio were all positively changed. Meanwhile, the treatment markedly alleviated hepatic steatosis and significantly stimulated Nrf2 expression ( $73.79 \pm 0.80/72.96 \pm 1.22$  vs  $54.94 \pm 1.84$ ,  $P < 0.01/P < 0.01$ ) in hepatocytes of hyperlipidemic mice.

**CONCLUSION:** *L. plantarum* CA16 and *L. plantarum* SC4 may protect against cardiovascular disease by lipid metabolism regulation and Nrf2-induced antioxidative defense in hyperlipidemic mice.

© 2013 Baishideng. All rights reserved.

**Key words:** *Lactobacillus plantarum*; Hypolipidemic; Nuclear factor erythroid 2-related factor 2; Metabolic syndrome; Hepatic steatosis; Cardiovascular disease

**Core tip:** Protective effects of *Lactobacillus plantarum* (*L. plantarum*) CA16 and *L. plantarum* SC4 strains on hyperlipidemic mice were found, including regulating lipid metabolism, alleviating hepatic steatosis and reducing cardiovascular disease (CVD) risk. The mechanism of intracorporal antioxidation of *Lactobacillus* strains may be related to stimulation of nuclear factor-

erythroid 2-related factor 2 (Nrf2) expression. Hypolipidemic effect and Nrf2-induced antioxidative defense may contribute to the reduction of CVD risk. We suggest that food fermented by the strains be used as part of the diet to relieve lipid metabolism related metabolic syndrome and to reduce the risk of CVD.

## INTRODUCTION

Metabolic syndrome is a cluster of cardiovascular and type 2 diabetic risk factors<sup>[1]</sup>. The International Diabetes Federation defines metabolic syndrome as central obesity plus any two of raised triglycerides (TG), reduced high-density lipoprotein cholesterol (HDL-C), raised blood pressure, and raised fasting plasma glucose<sup>[2]</sup>. Disturbances of lipid homeostasis lead to metabolic syndrome and increase the risk of cardiovascular disease. A 1% increase in plasma cholesterol levels can increase the risk of coronary events up to 3%<sup>[3]</sup>. Elevated low-density lipoprotein cholesterol (LDL-C) accompanied with insufficient HDL-C is a risk predictor of atherosclerosis<sup>[4]</sup>. Hypercholesterolemia stimulates formation of free radicals, decreases activity of antioxidant enzymes, and eventually leads to elevated lipid peroxides including oxidized low density lipoprotein (Ox-LDL), which is an independent atherogenic factor<sup>[5]</sup>.

Nuclear factor-erythroid 2-related factor 2 (Nrf2) is a transcription factor that binds to antioxidant response elements (ARE) in the promoter regions of many antioxidative enzymes and phase II detoxifying enzymes<sup>[6]</sup>. Oxidative stress results in accumulation of Nrf2 in the cytoplasm and initiation of transcription of target genes after translocating into the nucleus<sup>[7]</sup>. Inhibition of LDL oxidation can protect against oxidative stress linked atherosclerosis. Belghitha found that bacterial levan was beneficial for antiarteriosclerosis hypolipidemic and antioxidant effects<sup>[8]</sup>. We suppose that both exogenous antioxidants and endogenous antioxidant enzymes can strengthen antioxidative defense. Therefore, antioxidant defense triggered by improving Nrf2 expression can be envisaged as a promising strategy in reducing the incidence of atherosclerosis.

Some strains of *Lactobacillus* have been studied as probiotics. They may protect against mutagens and carcinogen exposure, gastrointestinal disease, skin disorders, yeast infections, urinary tract infection, diabetes<sup>[9]</sup>, and immune dysfunction<sup>[10]</sup>. Hypolipidemic effects of LAB were shown in mice<sup>[11,12]</sup> and rabbits<sup>[13]</sup>. Antioxidative activity of LAB, a potential application valued in prevention of atherosclerosis, was also reported *in vitro*<sup>[14]</sup> and *in vivo*<sup>[15]</sup>.

Extracorporeal antioxidative activity of *Lactobacillus casei* KCTC 3260 may be caused by chelating metal ions<sup>[14]</sup>. However, an intracorporeal antioxidative mechanism of LAB has not been defined. In the present study, we investigated the change in Nrf2 expression in mice after the application of *Lactobacillus plantarum* (*L. plantarum*) CAI6 or *L. plantarum* SC4 to discuss the possible mechanism.

Probiotic strains may have acid or bile salt tolerance to colonize the gastrointestinal tract of the host. Several tests have been taken to screen strains tolerating low pH and high concentration of cholate<sup>[16]</sup>. Cells have been coated with sodium alginate to increase viscosity and stability of strains<sup>[17]</sup>.

The primary aim of this study was to investigate the effects of *L. plantarum* CAI6 and *L. plantarum* CS4 on alleviation of metabolic syndrome and prevention of cardiovascular disease (CVD) in high-cholesterol fed mice.

## MATERIALS AND METHODS

### Microbial cultures

*L. plantarum* CAI6 (GenBank accession number: KC470704) and *L. plantarum* SC4 (GenBank accession number: KC470705) were isolated from Chinese pickled cabbage and raw milk, respectively. The two strains could survive in MRS medium (pH 3.0) supplemented with 0.3% sodium taurocholate (date not shown). The strains were cultured in MRS broth and incubated at 37 °C for 24 h. Each activated culture was centrifuged and diluted with 0.9% saline water to obtain a preparation of  $2.0 \times 10^9$  cfu/mL. 0.1% (w/v) sodium alginate was added to make the strains have better acid resistance, bile resistance, and stability in digestive tract.

### Animals

Thirty-Six adult male Kunming mice with a weight of  $20 \pm 2$  g were obtained from the Academy of Military Medical Sciences (Beijing, China). The mice were housed in a controlled animal room at  $20 \pm 2$  °C and 60% relative humidity with 12 h light/dark photoperiod. Diet and water could be accessed freely. The care and handling of the animals were in compliance with the internationally accepted standard guidelines for use of animals, and was approved by Science and Technology Committee of Yanshan University on Animal Care and Use.

### Experimental protocol

Half of the mice were fed a high-cholesterol diet (75% basic diet, 10% lard, 10% soybean meal, 5% egg yolk) for a period of up to 28 d to construct a hyperlipidemic model (HM). For comparison, the other mice were maintained on standard laboratory diet for 28 d to develop a normal model (NM). Then the mice of HM and NM were randomly assigned to three groups ( $n = 6$ ), respectively.

Group I (NM): normal mice fed a standard laboratory diet and physiological saline (10 mL/kg); Group II (NM/CAI6): normal mice fed a standard laboratory diet and *L. plantarum* CAI6 (10 mL/kg); Group III (NM/SC4): normal mice fed a standard laboratory diet and *L. plan-*

*tarum* SC4 (10 mL/kg); Group IV (HM): hyperlipidemic mice fed a high-cholesterol diet and physiological saline (10 mL/kg); Group V (HM/CAI6): hyperlipidemic mice fed a high-cholesterol diet and *L. plantarum* CAI6 (10 mL/kg); and Group VI (HM/SC4): hyperlipidemic mice fed a high-cholesterol diet and *L. plantarum* SC4 (10 mL/kg).

The mice were treated by intragastric administration for 28 d before being anesthetized with chloral hydrate and sacrificed. Food and water consumption and body weight were recorded daily. Blood samples were drawn from the ophthalmic venous plexus. After centrifugation (2000 rpm, 10 min, 4 °C), the serum samples were collected and stored at -20 °C. The liver and kidney were excised, rinsed in ice-cold physiological saline, weighed, and then stored at -20 °C.

### Serum lipids analysis

Serum TC, TG, HDL-C, and LDL-C levels were measured using commercially available enzyme kits (Beihuangtai clinical reagent Ltd, Beijing, CHN). The TC level was measured with an enzymatic method based on the conversion to a chromogen with maximum absorption at 500 nm by cholesterol ester hydrolase, cholesterol oxidase, and peroxidase<sup>[18]</sup>. The determination of TG was based on an enzymatic method coupled with lipase, glycerokinase, glycerol oxidase and peroxidase<sup>[19]</sup>. The HDL-C level was assayed by the same enzymatic method based on specific precipitation of VLDL-C and LDL-C in the presence of phosphotungstic acid. The LDL-C value was calculated by following formula:  $LDL-C = TC - HDL-C - TG/5$ <sup>[20]</sup>.

### Morphology of liver

Fresh livers of mice were fixed with 4% paraformaldehyde for 24 h, dehydrated gradually in a graded series of ethanol, clarified in xylene, and embedded in paraffin wax. Hematoxylin and eosin stained liver was observed by an optical microscope (X5Z-G, Chongqing Optical and Electrical Instrument Co., Ltd, CHN).

### Determination of Nrf2 expression in liver and kidney

Liver and kidney tissues suspensions were prepared in ice-cold 0.1 mol/L PBS. Antibodies were diluted in 0.1 mol/L PBS containing 0.1%NaN<sub>3</sub>. 10<sup>6</sup> cells/mL were incubated with primary anti-Nrf2 antibodies for 30 min on ice, mixed with 200 μL of 4 % paraformaldehyde, and incubated for 30 min at 4 °C. After washing twice with 0.1 mol/L PBS containing 0.1%NaN<sub>3</sub>, the supernatant was discarded by centrifugation. 3%BSA, 0.1%NaN<sub>3</sub> and 10% saponin (Sigma Co., United States) were added to cell pellets and blended for 15 min, then mixed with 500 μL PBS (pH 7.4). After removal of the supernatant, 0.5 μg of secondary FITC-conjugated rabbit anti-mouse antibody were added and incubated on ice for 60 min. Finally, the cells were resuspended in 1 mL of 0.1 mol/L PBS. The hepatocytes and nephrocytes were scanned using a FACSCalibur (Becton-Dickinson, United States) respectively, and fluorescence of Nrf2 positive cells were quantified. Nonspecific binding of secondary antibody was excluded by incubating the cells only with the FITC-labelled secondary antibody. For reproducibility, the experiment was repeated three times. The software BD CellQuest Pro (Becton Dickinson Biosciences, United States) was used and the data were calculated by fluorescence intensity formula [ $I = \text{Log}(x\text{-mode}) \times 340$ ].

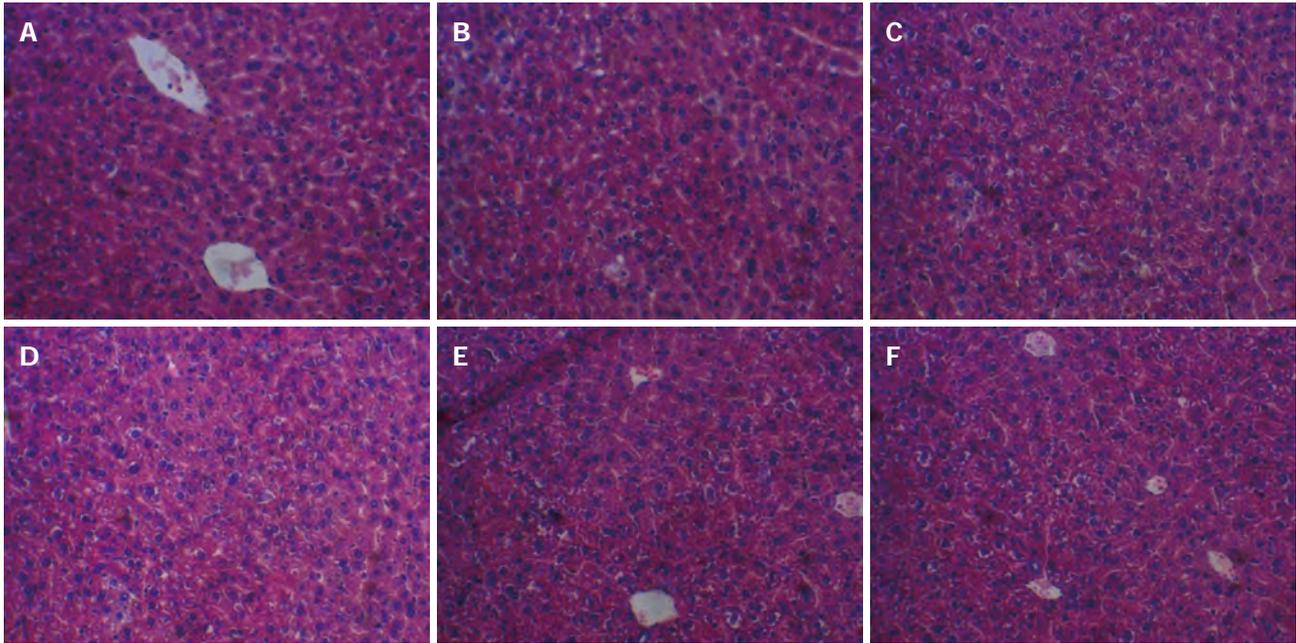

### Statistical analysis

All data were expressed as mean ± SD. Statistical analysis was performed using SPSS 13.0 software. Differences between the groups were analyzed by One-Way ANOVA followed by Duncan's multiple range tests. Statistical significance was considered at the  $P < 0.05$  level.

## RESULTS

### Effects on body weight, diet intake, and liver index

As shown in Table 1, the mice subjected to a high cholesterol diet had a significant increase in body weight (BW)

**Figure 1** Effects of *Lactobacillus plantarum* SC4 or *Lactobacillus plantarum* CAI6 on liver morphology in mice fed high-cholesterol diet. Tissues were stained with hematoxylin and eosin (20 × 10). A: High-cholesterol diet group; B: Normal diet group; C: Normal diet with *Lactobacillus plantarum* (*L. plantarum*) CAI6 group; D: Normal diet with *L. plantarum* SC4 group; E: High-cholesterol diet with *L. plantarum* CAI6 group; F: High-cholesterol diet with *L. plantarum* SC4 group.

compared with mice on a normal diet ( $P < 0.01$ ). In HM mice, oral administration of CAI6 or SC4 daily did not have any significant effect on BW, while CAI6-treated mice and SC4-treated mice had a significant ( $P < 0.01$  and  $P < 0.05$ , respectively) increase *vs* the NM group. In NM mice, CAI6 or SC4 had no significant effect on BW compared with NM mice receiving neither CAI6 or SC4. None of the groups showed a significant difference in total dietary intake or liver index. However, an increase in liver index in the HM group compared to the NM group was found, and CAI6 and SC4 decreased this.

#### Effect on plasma lipid profiles

Effect of the treatment on serum lipid levels was shown in Table 1. The TC, TG and LDL-C levels of mice in the HM group showed a significant increase ( $P < 0.01$ ) compared with the NM group. Meanwhile, HDL-C in the HM group decreased by 26% compared to the NM group. Moreover, a significantly increased ( $P < 0.05$ ) atherogenic index (AI) accompanied with a significantly reduced ( $P < 0.05$ ) LDL-C/HDL-C ratio was observed in the HM group. The HM mice orally administrated with strains (CAI6/SC4) showed different degrees of decline in serum TG (-19%,  $P < 0.01$ /-13%,  $P < 0.05$ ), TC (-10%/-7%), LDL-C (-17%,  $P < 0.01$ /-15%,  $P < 0.01$ ) levels, and an increase in HDL-C (+13%/+9%) level as compared to the HM group that did not receive CAI6 or SC4. As a result, those mice had a lower AI (-29%/-17%) and a higher LDL-C/HDL-C ratio (+23%/+11%) than the HM group receiving no treatment. As for the NM mice, the administration had no significant effect on serum TC, TG, HDL-C and LDL-C levels, but could reduce AI (-39%/-24%) and increase LDL-C/HDL-C ratio (+21%/+5%).

#### Hepatic morphology

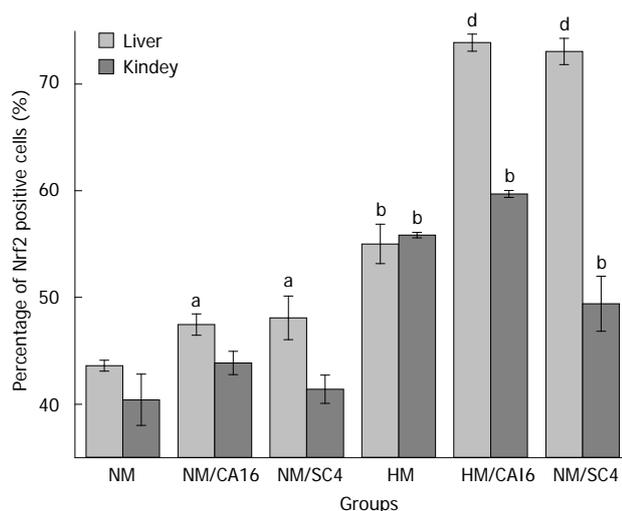

The livers of the HM group were larger compared with those in the NM group and became beige. The hepatic cells with clear cytoplasm, nucleus, nucleolus and central vein (A) in the NM, NM/CAI6 and NM/SC4 group, showed normal histology in Figure 1A-C<sup>[21]</sup>. The liver sections of the HM mice exhibited massive fatty changes and severe steatosis with cytoplasmic vacuoles confirmed by histopathological examination in Figure 1D. In addition, the size of lipid droplets in the HM/CAI6 and NM/SC4 groups were remarkably smaller than those of the HM group (Figure 1E, F), suggesting that the *L. plantarum* strains could reduce the build-up of lipid droplets and keep hepatocytes normal.

#### Effect on Nrf2 levels

Nrf2 expression in liver and kidney tissues was shown in Figure 2. Liver/kidney Nrf2 levels were significantly higher (+26%,  $P < 0.01$ /+38%,  $P < 0.01$ ) in the HM group than the NM group. Liver Nrf2 increased significantly in the HM/CAI6 (+34%,  $P < 0.01$ ) and HM/SC4 (+33%,  $P < 0.01$ ) groups respectively, compared with the HM group. A significant increase in liver Nrf2 level was also found in the NM/CAI6 (+9%,  $P < 0.05$ ) and NM/SC4 (+10%,  $P < 0.05$ ) groups as compared to the NM group. Contrary to the situation in the liver, the HM/CAI6 or HM/SC4 groups showed no significant increase in kidney Nrf2 level.

## DISCUSSION

The mice in the HM group possessed raised TG, reduced HDL-C, and elevated BW resulting in a high risk of developing metabolic syndrome. Accumulation of TG and

**Figure 2** Effect of *Lactobacillus plantarum* SC4 or *Lactobacillus plantarum* CA16 on liver and kidney nuclear factor-erythroid 2-related factor 2 expression in mice fed high-cholesterol diet. Results were expressed as mean  $\pm$  SD ( $n = 6$ ). <sup>a</sup> $P < 0.05$  vs normal diet (NM) group, <sup>b</sup> $P < 0.01$  vs NM group, <sup>d</sup> $P < 0.01$  vs high-cholesterol diet (HM) group. NM/CA16: Normal diet with *Lactobacillus plantarum* (*L. plantarum*) CA16 group; NM/SC4: Normal diet with *L. plantarum* SC4 group; HM/CA16: High-cholesterol diet with *L. plantarum* CA16 group; HM/SC4: High-cholesterol diet with *L. plantarum* SC4 group; NM: Normal diet group; HM: High-cholesterol diet group.

TC in the bloodstream has been proven related to atherosclerosis, and by extension, the risk of coronary heart disease and stroke. Elevated concentrations of oxidized LDL-C are associated with atherosclerotic plaque formation on the walls of arteries, but increased HDL-C levels may reduce the risk due to the ability of HDL transporting cholesterol back to the liver for excretion or to other tissues<sup>[22]</sup>. Therefore, the HM mice had an increased risk of CVD. The results showed that both AI, an indicator for severity of atherosclerosis<sup>[23]</sup>, and LDL-C/HDL-C, a valuable tool to evaluate coronary heart disease (CHD) risk<sup>[24]</sup>, were increased in HM mice, which is in agreement with the above view.

Serum TG, TC and LDL-C levels decreased in the HM/CA16 and HM/SC4 groups when compared with the HM group while serum HDL-C level increased revealing that *L. plantarum* CA16 and *L. plantarum* SC4 exerted a hypolipidemic effect and could relieve lipid related metabolic syndrome. AI and LDL-C/HDL-C ratios were also lower in the HM/CA16 and HM/SC4 groups, suggesting that *L. plantarum* CA16 and *L. plantarum* SC4 reduced the risk of CVD. Non-HDL-C, representing the total amount of cholesterol in the potentially atherogenic lipoproteins, was regarded as a risk predictor of cardiovascular outcomes on drug treatment<sup>[25]</sup>. After strains (CA16/SC4) treatment, non-HDL-C decreased by 22% (1.80 vs 2.30) and 15% (1.96 vs 2.30) respectively. Additionally, NM mice treated with strains (CA16/SC4) had positive changes in AI (-39%/-24%) and LDL-C/HDL-C ratio (-16%/-4%). So, we suppose that the strains have preventive and therapeutic effects for CVD.

The liver is the hub of fat synthesis and transporta-

tion. The liver can use fatty acids hydrolyzed from fat in food to synthesize cholesterol and TG. High fat intake of HM mice disequibrated lipid metabolism, resulting in accumulation of TG in liver and an increased increment of the liver index, and hepatic steatosis occurred<sup>[26]</sup>. The result of liver tectology proved that the *L. plantarum* strains had important potential in alleviating hepatic steatosis attributed to mediation of lipid metabolism and had protective effects on hepatic structure.

Oxidative stress is thought to be linked to atherogenesis<sup>[27]</sup>. Therefore, much attention has been paid to the antioxidant hypothesis in prevention and treatment of CVD<sup>[28,29]</sup>. In recent times, antioxidant activity of many hypolipidemic substances has been detected and the activities of SOD, CAT and GSH-Px are usually used as test standards<sup>[15,30]</sup>. To suffer ROS-mediated injury, cells initiate the Nrf2/ARE signaling pathway stimulated by Nrf2. Giovanni. E reported that the pathway plays an important role in vascular homeostasis and the defense of endothelial and smooth muscle cells against sustained oxidative stress associated with diseases such as atherosclerosis and preeclampsia<sup>[31]</sup>. Our results showed that liver and kidney Nrf2 expression was significantly ( $P < 0.01$ ) increased in the HM group compared with the NM group, revealing that a cholesterol-rich diet may bring about remarkable modifications in antioxidant defense mechanisms *in vivo*. Furthermore, oral administration of *L. plantarum* CA16 and *L. plantarum* SC4 both could significantly ( $P < 0.01$ ) increase liver Nrf2 levels compared with the HM group. So we envisage that spontaneous and strain-stimulated complex mechanisms conjointly promote Nrf2 expression in the liver. Accumulation of Nrf2 in the liver may initiate anti-oxidative stress and result in inhibition of Ox-LDL production, reducing the risk of atherosclerosis. Combining all the analyses above, the anti-CVD mechanism of the strains may be a regulation of lipid metabolism to alleviate metabolic syndrome and a stimulation of Nrf2 expression to initiate antioxidant defense. The actual mechanisms which account for strain-stimulated Nrf2 expression and the transcription and expression of antioxidase genes in Nrf2/ARE pathway need further study.

Dietary management has been shown to be an effective way to alleviate metabolic syndrome<sup>[32,33]</sup>. Some LAB-fermented probiotic products are commercially available<sup>[34]</sup>. Jeun *et al*<sup>[11]</sup> found that live *L. plantarum* was more effective than dead *L. plantarum* in reduction of plasma lipid levels and supposed that the active compounds may be derived from metabolic activity of live *L. plantarum*. Adding fermented foods seems like a good way to increase the number of live bacteria in a diet. LAB-fermented food, including both live LAB and active metabolin, seems the best form to apply LAB in our daily lives. The strains *L. plantarum* CA16 and *L. plantarum* SC4, which can be regarded as probiotics for their beneficial impacts, were isolated from milk and pickle, respectively. Therefore, *L. plantarum* CA16-fermented milk or *L. plantarum* SC4-fermented pickle may also exert those effects.

We suppose that the strains-fermented food may be used as a dietary approach to alleviate metabolic syndrome and prevent CVD.

## COMMENTS

### Background

Hyperlipidemia, an integral part of metabolic syndrome, is a major risk factor for cardiovascular diseases (CVD). Oxidation of low-density lipoprotein (LDL) cholesterol is linked to atherogenesis, and antioxidant drugs become a therapeutic approach. *Lactobacillus* regarded as probiotics have been proven to possess hypolipidemic and antioxidant effects. A probiotic diet, a kind of dietary management, for example fermented food, is a promising way to prevent and treat CVD.

### Research frontiers

CVD remains a major public health problem. The relationship between cardiovascular risk and serum lipid and related factors has been extensively studied to find valuable predictors of cardiovascular risk. Oxidative modification of LDL plays an important role in the genesis of arteriosclerosis. Based on the antioxidant hypothesis that suboptimal levels of principal antioxidant micronutrients are hitherto underrated risk factors for CVD, much research has focussed on the effects of antioxidant substances on CVD. Some *Lactobacillus* strains are probiotics, so novel *Lactobacillus* strains potentially used as probiotics have been continuously selected, and their applications have been investigated. Dietary approaches to alleviate metabolic syndrome have been shown in many studies.

### Innovations and breakthroughs

Recent research has highlighted the antioxidant hypothesis in prevention and treatment of CVD and demonstrated the antioxidant ability of *Lactobacillus* strains. However, the antioxidative mechanism of *Lactobacillus in vivo* has not been known. In the study, the authors investigated the effects of *Lactobacillus plantarum* (*L. plantarum*) CA16 and *L. plantarum* SC4 on nuclear factor-erythroid 2-related factor 2 (Nrf2) expression in hyperlipidemic mice. This is the first study to report the mechanism of intracorporal antioxidation of *Lactobacillus* strains may be the stimulation of Nrf2 expression. Furthermore, these studies suggest that *L. plantarum* CA16 and *L. plantarum* SC4 could reduce the risk of CVD by a hypolipidemic effect and Nrf2-induced antioxidative defense.

### Applications

As *L. plantarum* CA16 and *L. plantarum* SC4 have shown obviously protective effects on hyperlipidemic mice, food fermented by the strains may be used as dietary management to alleviate disorders of lipid metabolism related metabolic syndrome and to reduce the risk of CVD.

### Terminology

Metabolic syndrome is a combination of medical disorders, such as disturbances of glucose and lipid homeostasis, which increase the risk of developing CVD. Coronary heart disease, a type of CVD, is a narrowing or blockage of the coronary arteries, usually caused by atherosclerosis in a condition where an artery wall thickens as a result of the accumulation of fatty materials. Nrf2 is a transcription factor that regulates the expression of anti-oxidative stress enzyme genes. Stimulating the Nrf2 related signal pathway has been studied for treating diseases caused by oxidative stress.

### Abstract

It has been reported recently that small undifferentiated intramucosal early gastric cancer (EGC) < 20 mm in size without any lymphovascular involvement or ulcerative findings had virtually no risk of lymph-node (LN) metastasis. Consequently, the indications for endoscopic resection were expanded to include such undifferentiated EGC lesions. We describe herein a case of a small undifferentiated intramucosal EGC < 20 mm in size without lymphovascular involvement or ulcerative findings that involved lymph-node metastasis. A 57-year-old female underwent pylorus preserving gastrectomy as standard treatment for an undifferentiated EGC 15 mm in size without any ulcerative finding. The surgical specimen revealed a signet-ring cell carcinoma with a moderately to poorly differentiated adenocarcinoma limited to the mucosa that was 15 mm in size with no lymphovascular involvement or ulcerative findings. This case involved LN

metastasis, however, and the lesion was diagnosed as pathological stage II A (T1N2M0) according to the Japanese Classification of Gastric Carcinoma.

### INTRODUCTION

Endoscopic resection (ER) is generally indicated for early gastric cancer (EGC) with no risk of lymph-node (LN) metastasis. Hirasawa *et al*<sup>[1]</sup> reported there was virtually no risk of LN metastasis in undifferentiated EGCs < 20 mm

**Figure 1** Pre-treatment endoscopic examination. Esophagogastroduodenoscopy revealed pale depressed mucosal lesion on anterior wall of middle gastric body approximately 15 mm in size with no ulcerative finding and non-atrophic background mucosa. A: Conventional white light endoscopy; B: With indigo-carmine dye staining.

**Figure 2** Surgically resected specimen. A: Formalin-fixed specimen from pylorus preserving gastrectomy; B: Panoramic view of lesion with hematoxylin and eosin staining. Mucosal lesion 15 mm × 12 mm in size with no ulcer finding and pink lines corresponding to lesion depression (hematoxylin and eosin staining, × 1).

in size without lymphovascular involvement or ulcerative findings and such lesions could satisfy the indications for ER. We encountered, however, a case of a small undifferentiated intramucosal EGC meeting all of the above-mentioned criteria that actually involved LN metastasis and decided to report this seemingly rare occurrence.

## CASE REPORT

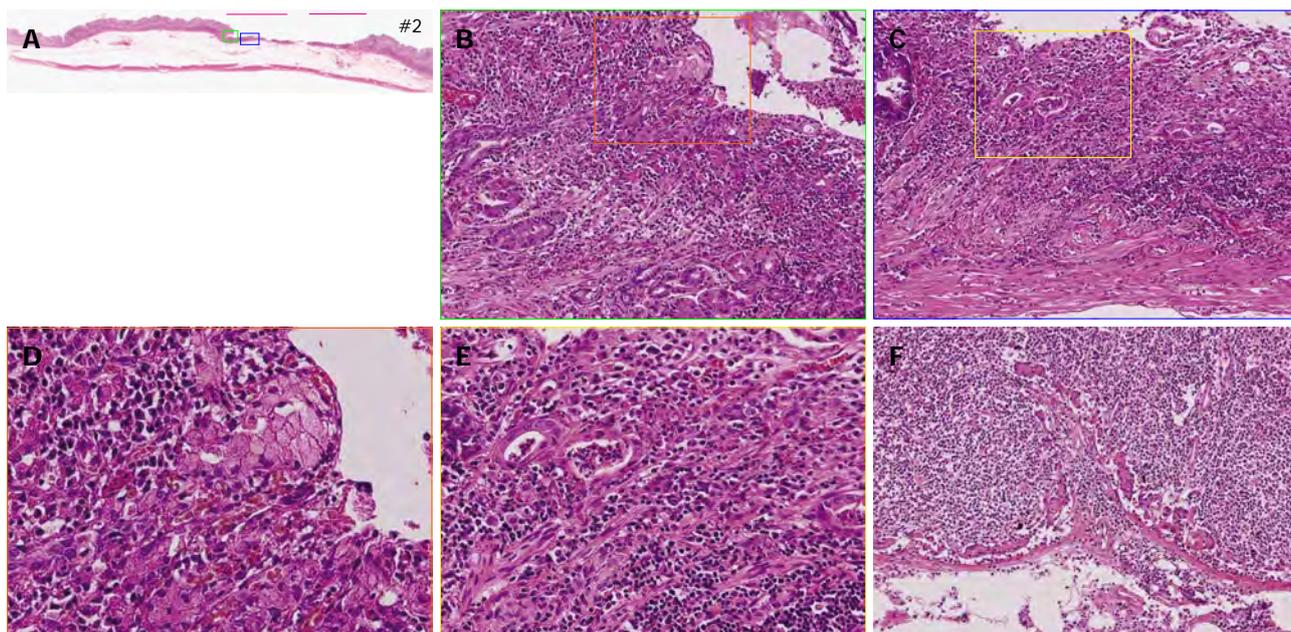

A 57-year-old female underwent an esophagogastroduodenoscopy (EGD) for a medical check-up in December 2008. The results indicated gastric cancer, and she was referred to our hospital for treatment. The EGD revealed a pale depressed mucosal lesion that was Type 0-IIc in accordance with the Japanese Classification of Gastric Carcinoma (JCGC)<sup>[2]</sup> located on the anterior wall of the middle gastric body (Figure 1). The size of the lesion was approximately 15 mm, and there was no ulcerative finding. The biopsy specimen revealed a signet-ring cell carcinoma. Computed tomography (CT) indicated no distinct regional LN or distant metastasis. Laboratory results were within normal limits and the serum carcinoembryonic antigen level was normal. We diagnosed this lesion as clinical (c) T1(M), cN0, cM0, cStage I A according to the JCGC; therefore, pylorus preserving gastrectomy was performed as the standard treatment. The surgical specimen revealed a signet-ring cell carcinoma with a moderately to poorly differentiated adenocarcinoma limited to the mucosa without lymphovascular involvement or ulcerative findings (Figures 2 and 3A-E). The lesion was 15 mm × 12 mm in size, and the resection margin was free of tumor cells. In addition, tumor cells were posi-

tive for mucin (MUC)5AC and negative for MUC6 with an MUC5AC/MUC6 double layer and Ki-67 localization both absent (Figure 4). Some portions of the resected regional LNs (lesser curvature LNs; LN station 3), however, included metastatic cancer cells (3/32) that were also identified as a signet-ring cell carcinoma (Figure 3F). This lesion was then diagnosed as pathological (p)T1(M), ly0, v0, pN2, pM0, pStage II A according to the JCGC. Four years after surgery, the patient was in good condition and disease free without any signs of tumor recurrence based on the latest follow-up EGD and CT examinations.

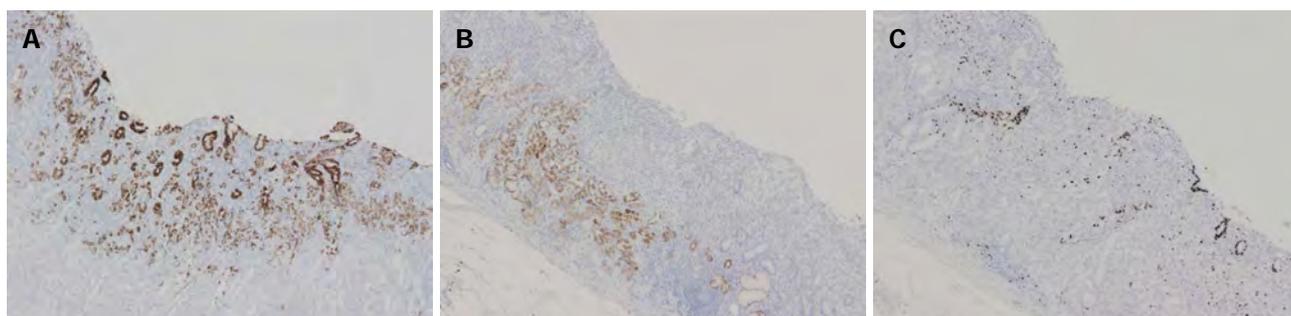

## DISCUSSION

ER is widely accepted as a minimally invasive treatment for intramucosal EGC with virtually no risk of LN metastasis<sup>[2-6]</sup>. An earlier report, however, demonstrated undifferentiated intramucosal EGC had a higher probability of LN metastasis (4.2%)<sup>[3]</sup>, and gastrectomy with regional lymphadenectomy has been considered essential treatment for such lesions. More recently, Hirasawa *et al*<sup>[1]</sup> reported small undifferentiated intramucosal EGCs < 20 mm in size without lymphovascular involvement or ulcerative findings had virtually no risk of LN metastasis (95%CI, up to 0.96%). Therefore, such small undifferentiated EGCs have become candidates for ER. It was within this context we experienced the present case involving a small undifferentiated intramucosal EGC < 20 mm in size without any lymphovascular involvement or ulcerative findings that evidenced LN metastasis.

Both Nasu *et al*<sup>[7]</sup> and Park *et al*<sup>[8]</sup> previously reported similar cases of a small undifferentiated intramucosal

**Figure 3 Histopathological findings.** A: Panoramic view with hematoxylin and eosin staining ( $\times 1$ ); B: Signet-ring cell carcinoma identified at lesion edge (green frame in A,  $\times 40$ ); C: Moderately to poorly differentiated adenocarcinoma limited to mucosa visible in lesion center. Low magnification view (blue frame in A,  $\times 40$ ); D: High magnification view of red frame in B ( $\times 200$ ); E: High magnification view of yellow frame in C ( $\times 200$ ); F: Image showing signet-ring cell carcinoma invasion of station 3 lymph node (N2) ( $\times 40$ ).

**Figure 4 Immunohistochemical staining.** Tumor cells positive for mucin (MUC)5AC (A,  $\times 10$ ) and negative for MUC6 with an MUC5AC/MUC6 double layer (B,  $\times 4$ ) and Ki-67 (C,  $\times 4$ ) localization both absent.

EGC  $< 20$  mm in size (13 and 17mm, respectively) without lymphovascular involvement or findings of ulceration that involved LN metastasis. In addition, Abe *et al*<sup>[9]</sup> reported three cases involving LN metastasis of small undifferentiated intramucosal EGCs  $< 20$  mm in size (10, 12 and 20 mm, respectively) without any ulcerative findings and concluded ER should not be indicated for undifferentiated EGCs  $> 10$  mm in size. There was no reference in those three cases, however, regarding the existence of lymphovascular involvement. Hirasawa *et al*<sup>[10]</sup> also reported a case with LN metastasis of a small undifferentiated intramucosal EGC that was 13 mm in size and without an ulcerative finding. According to their case report, routine histological examination of the endoscopic submucosal dissection specimen sectioned at intervals of 2 mm indicated an intramucosal tumor without lymphovascular involvement or ulceration. Hematoxylin and eosin staining of one of the 60 additional deep-cut sections of the original resected specimen, however, revealed lymphatic

involvement in the mucosa. The authors then suggested practical limitations in determining lymphovascular involvement through routine histological examinations may not always facilitate the detection of LN metastasis.

Based on the various published reports supportive of the findings in our particular case, the possibility of LN metastasis developing from a small undifferentiated intramucosal EGC  $< 20$  mm in size without ulceration exists even if there is no apparent lymphovascular involvement<sup>[7,8]</sup>. It is highly desirable, therefore, to clarify the predictive factors for the development of LN metastasis with such small undifferentiated intramucosal EGCs. Takizawa *et al*<sup>[11]</sup> evaluated the conditions in which LN metastasis was unlikely and ER of undifferentiated EGCs had a greater probability of being effective. Such conditions included intramucosal cancers without lymphovascular involvement or ulcerative findings and: (1) lesions  $< 10$  mm in size; (2) the presence of Ki-67 localization; (3) the presence of a double layer (MUC5AC/

MUC6); and/or (4) the presence of only a signet-ring cell carcinoma. The conditions in our case included a lesion > 10 mm in size, the absence of Ki-67 localization, the absence of a double layer (MUC5AC/MUC6), and the presence of not only a signet-ring cell carcinoma but also a moderately and poorly differentiated adenocarcinoma. In addition, more recently, Takizawa *et al.*<sup>[12]</sup> reported that LN metastasis was significantly more common in mixed predominantly undifferentiated (MU)-type intramucosal cancer than in pure undifferentiated (PU)-type intramucosal cancer and concluded MU-type tumors might have greater malignant potential than PU-type tumors. Actually, the present case was MU-type intramucosal cancer with lymph-node metastasis.

If it were possible to evaluate the pathology of all resected specimens in detail using deep-cut sections and immunohistochemical staining as indicated in the above-mentioned reports<sup>[10-12]</sup>, we might be able to predict those cases in which LN metastasis of small undifferentiated intramucosal EGCs would most likely occur, but it is not always feasible to perform such extensive pathological evaluations in clinical practice. We need to recognize the distinct possibility, therefore, of LN metastasis developing from small undifferentiated intramucosal EGCs < 20 mm in size without lymphovascular involvement or ulcerative findings because of the practical limitations related to such histological examinations<sup>[10]</sup>. It is, therefore, imperative that physicians thoroughly explain the possibility of LN metastasis to patients before performing ER for small undifferentiated intramucosal EGCs so as to obtain their informed consent and then conduct more careful follow-up surveillance examinations including CT scans, ultrasonography and/or EUS in addition to EGDs subsequent to ER treatment.

In order to satisfactorily demonstrate the validity of treating small undifferentiated intramucosal EGCs with ER, a large prospective study analyzing therapeutic outcomes will need to be conducted in the near future before the recently expanded indications for treating such lesions with ER should be accepted for general clinical use.

per gastrointestinal endoscopy revealed mucus production from the papilla of Vater, characterized by its protruding and dilated orifice. Endoscopic ultrasonography visualized the polypoid tumor in the distal bile duct, but no invasive region was suggested by diagnostic imaging. Therefore, the initial diagnosis was IPNB. After endoscopic nasobiliary drainage, a pylorus-preserving pancreaticoduodenectomy was performed. Pathological examination of the resected bile duct revealed papillary proliferation of biliary-type cells with nuclear atypia, indicating pancreaticobiliary-type IPNB. In addition, solid portions comprised of tumor cells with characteristic salt-and-pepper nuclei were evident. Immunohistochemistry revealed expression of the neuroendocrine marker synaptophysin in this solid component, diagnosing it as a neuroendocrine tumor (NET). Furthermore, the MIB-1 proliferation index of NET was higher than that of IPNB, and microinvasion of the NET component was found, indicating neuroendocrine carcinoma (NET G3). This unique case of MANEC, comprising IPNB and NET, provides insight into the pathogenesis of biliary NET.

### Abstract

We present the first case of an intraductal papillary neoplasm of the bile duct (IPNB) accompanying a mixed adenoneuroendocrine carcinoma (MANEC). A 74-year-old woman presented with fever of unknown cause. Laboratory data revealed jaundice and liver injury. Contrast-enhanced computed tomography revealed a 20 mm polypoid tumor in the dilated distal bile duct, which exhibited early enhancement and papillary growth. Up-

**Core tip:** A 74-year-old woman presented with fever and jaundice. Computed tomography revealed a polypoid tumor in the dilated distal bile duct. Pylorus-preserving pancreaticoduodenectomy was performed. A solid portion comprised of tumor cells with

characteristic salt-and-pepper nuclei was found. Immunohistochemistry revealed synaptophysin expression in the solid portion, diagnosing it as a neuroendocrine tumor (NET). This case provides insight into the pathogenesis of biliary NET.

Intraductal papillary neoplasm of the bile duct accompanying biliary mixed adenoneuroendocrine carcinoma. *World J Gastroenterol* 2013; 19(20): 3161-3164 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i20/3161.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i20.3161>

## INTRODUCTION

Intraductal papillary neoplasm of the bile duct (IPNB) is a new entity, defined as biliary neoplasms showing papillary or villous proliferation within the dilated lumens of intrahepatic and extrahepatic bile ducts by the 2010 World Health Organization (WHO) Classification of Tumors of the Digestive System<sup>[1]</sup>. IPNB encompasses several lesions, which were previously categorized as biliary papilloma, papillomatosis, papillary adenocarcinoma of the bile duct, and intraductal growth-type cholangiocarcinoma. The following three key pathologic features are characteristically evident in IPNB in varying combinations: (1) exophytic and papillary proliferation of neoplastic biliary epithelial cells, with delicate fibrovascular stalks within bile duct lumens; (2) mucin hypersecretion (macroscopic mucin is evident in some cases); and (3) variable dilatation or multilocular cystic changes of affected bile ducts.

Neuroendocrine tumors (NETs), including carcinoid tumors, are commonly found in several organs, including the pancreas and gastrointestinal tract. Most biliary NETs exist as a component of mixed adenoneuroendocrine carcinomas (MANECs)<sup>[2]</sup>. MANECs are found in hepatic hilar cholangiocarcinomas with hepatolithiasis, gallbladder cancers, and extrahepatic cholangiocarcinomas, and show a characteristic histology<sup>[3]</sup>. Moreover, since the NET components of biliary MANECs define prognosis, it is important to identify them and consider indications for adjunctive therapy, such as somatostatin analogues.

We encountered a patient with IPNB accompanying a NET in the extrahepatic bile ducts. This case is unique, has a different histology from most biliary MANECs, and provides insight into the histogenesis of NETs in biliary tumors.

## CASE REPORT

### Clinical course

A 74-year-old woman consulted a family physician for fever of unknown cause. Laboratory data revealed jaundice

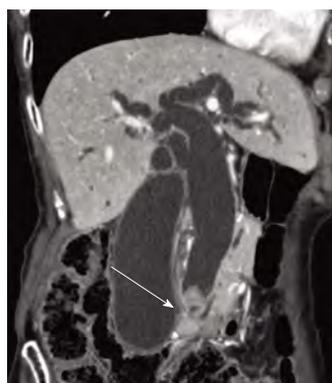

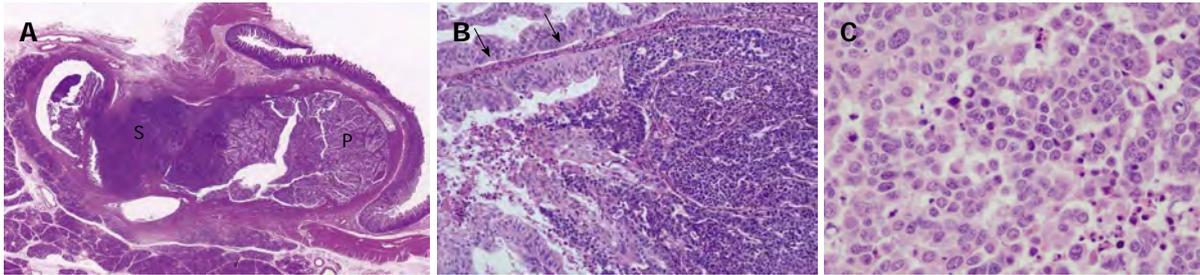

Figure 1 Computed tomography of the bile duct. Computed tomography revealed dilatation of the bile duct and an elevated lesion (arrow) at the bottom of the lower bile duct.

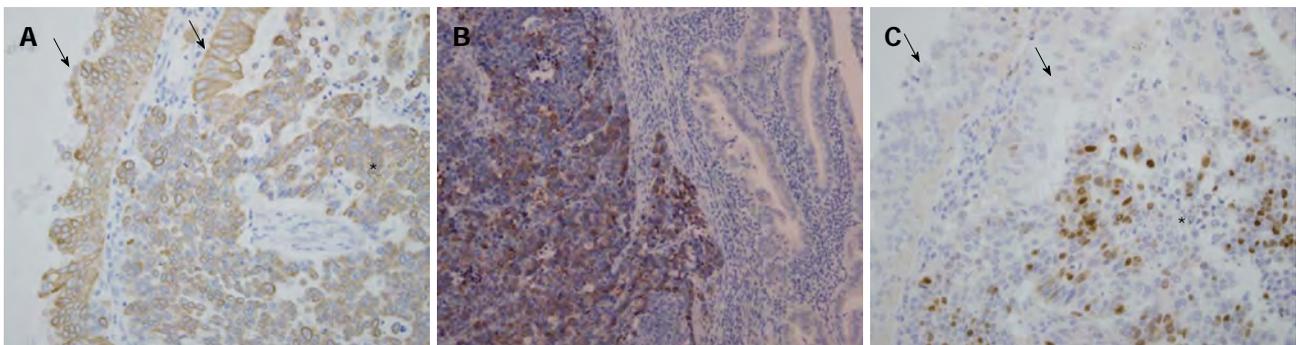

and liver injury. Computed tomography (CT) revealed an elevated lesion in the distal bile duct. She was admitted to our hospital for further examination and treatment. Enhanced CT revealed a 20 mm polypoid tumor, which exhibited early enhancement and papillary growth (Figure 1). Magnetic resonance image (MRI) and magnetic resonance cholangiopancreatography (MRCP) confirmed these findings. Mucus production was evident from the papilla of Vater, characterized by its protruding and dilated orifice. Endoscopic ultrasonography revealed a polypoid tumor in the distal bile duct. No invasive tumor regions were detected using these imaging techniques. Therefore, the initial diagnosis was IPNB. After endoscopic nasobiliary drainage (ENBD), a pylorus-preserving pancreaticoduodenectomy was performed. The postoperative course was uneventful, except for slight pneumonia.

### Pathology of the resected bile ducts

A whitish tumor occupying the dilated lumen of the distal bile duct was found, and the proximal portion of the bile duct was also dilated. As shown in Figure 2A, the tumor was comprised of two different areas: papillary and solid. The papillary proliferating area consisted of cholangiocyte-like columnar epithelial cells covering fine fibrovascular cores, and showed moderate-to high-grade intraepithelial neoplasia, indicating pancreaticobiliary-type IPNB (high-grade intraepithelial neoplasia) according to the WHO classification<sup>[1]</sup> (Figure 2B). Immunohistochemistry revealed expression of the biliary-type cytokeratin (CK): CK19 (Figure 3A) in these cells, but not CK20, confirming biliary-type IPNB. Conversely, the solid area lacking acinar/glandular structure (Figure 2A and B) was comprised of tumor cells with salt-and-pepper nuclei, a high nucleus-to-cytoplasm ratio, and increased nuclear chromatin (Figure 2C). Immunohistochemistry for neuroendocrine markers revealed synaptophysin expression (Figure 3B), but not chromogranin A and CD56 expression, indicating a NET component of MANEC. Furthermore, NET, as well as IPNB components, expressed CK19 (Figure 3A). The MIB-1 proliferation index of the NET component was significantly higher than that of the IPNB component (Figure 3C). Focal invasion of NET and IPNB components into the ductal wall was evident, but no pancreatic or lymph node metastasis was observed.

**Figure 2** Pathological findings from the resected bile duct (hematoxylin eosin staining). A: A semi macro cross-sectional image of the resected extrahepatic bile duct. In the dilated bile duct, the tumor was comprised of two distinct parts: papillary (P) and solid (S); B: The boundary between the papillary (right) and solid (left) areas. The papillary area consisted of a papillary proliferation of cholangiocyte-like columnar epithelial cells covering fine fibrovascular cores (arrows). In the solid area, a lacunar tumor was evident, but lacked distinct acinar/glandular structures. Magnification:  $\times 100$ ; C: The solid tumor at higher magnification. Tumor cells exhibited characteristic salt-and-pepper nuclei, a high nucleus-to-cytoplasm ratio, and increased nuclear chromatin. Magnification:  $\times 400$ .

**Figure 3** Immunohistochemistry for cytokeratin 19, synaptophysin, and Ki-67. A: Both the solid (asterisk) and papillary (arrows) components were positive for CK19. Magnification:  $\times 200$ ; B: Synaptophysin expression was evident in the solid component (left), indicating a neuroendocrine tumor, but not in the papillary component (right). Magnification:  $\times 100$ ; C: Although Ki-67-positive cells were scarce in the papillary component (arrows), many Ki-67-positive cells were identified in the solid component (asterisk). Magnification:  $\times 200$ .

## DISCUSSION

IPNB is characterized by a grossly visible, exophytic proliferation of neoplastic cholangiocytes with delicate fibrovascular cores. The WHO classification of digestive tumors<sup>[1]</sup> recognizes IPNB as a precancerous entity of cholangiocarcinoma. Surgical resection is the most optimal treatment for IPNB because mucin production by these tumors causes recurrent cholangitis and obstructive jaundice, even if these tumors are considered benign. Incomplete surgical resection often causes tumor recurrence; furthermore, recurrence in the remaining bile ducts can develop after apparently complete resection of even noninvasive tumors because of tumor multifocality<sup>[4,5]</sup>.

Radiographic imaging modalities, including CT, MRI, and MRCP, are recommended noninvasive techniques for detecting masses and evaluating the tumor extent. Although cholangiography and cholangioscopy carry risks of complications, these diagnostic techniques are useful for evaluating tumor extent, operative planning, and biliary intervention<sup>[6,7]</sup>. In this case, it was not difficult to evaluate the degree of tumor invasion using noninvasive radiographic techniques. However, pathological confirmation could not be obtained via biopsies or cytology. Peroral cholangioscopy and intraductal ultrasonography

may be necessary for pathological diagnosis. Unfortunately, we were unable to perform these invasive radiographies due to a lack of consent from the patient, who was suffering from pancreatitis after ENBD.

The degree of malignancy and histological atypia of IPNB ranges from borderline or low to moderate in the intraluminal papillary portions, to highly malignant and atypical in the invasive portions. IPNBs without invasive components are comprised of two subgroups: low-grade intraepithelial neoplasia and high-grade intraepithelial neoplasia. Moreover, the neoplastic cells of IPNB are cytologically classifiable into four phenotypes: pancreaticobiliary, intestinal, gastric (clear cell type), and oncocytic types<sup>[1]</sup>. This case was IPNB with associated pancreaticobiliary-type invasive carcinoma.

NETs in the digestive system, including in the gallbladder and extrahepatic bile ducts, are classified as: NET G1 [carcinoid; mitotic count:  $< 2$  per 10 high-power fields (HPF); and/or  $\leq 2\%$  Ki-67 index]; NET G2 (mitotic count: 2-20 per 10 HPF; and/or 3%-20% Ki-67 index); neuroendocrine carcinoma (large- or small-cell type); and MANEC, according to the 2010 WHO classification<sup>[2,8]</sup>. In biliary MANEC, the adenocarcinomatous component is located on the surface of the main tumor, and the majority of stromal invasion, including vascular invasion and lymph node metastasis, involves the NET

component<sup>[3]</sup>. Therefore, the NET component of biliary MANEC is considered to define prognosis<sup>[3]</sup>. In this case, contrary to typical biliary MANEC, the adenocarcinomatous component of MANEC was identified as IPNB. NET adjacent to the IPNB component resulted in both being intermingled in one mass (Figure 2B). Moreover, both NET and IPNB were immunophenotypically positive for CK19, suggesting that NET originated from the transformation of biliary tumor cells constituting IPNB. However, the NET component exhibited extensive proliferation and broad stromal invasion of the bile duct wall compared with IPNB, suggesting that the NET component defined the prognosis in this case.

In the pancreas, concomitant intraductal papillary mucinous neoplasm (IPMN; a pancreatic counterpart of IPNB) and pancreatic neuroendocrine tumor (pNET) are frequent, and the prevalence of pNET with IPMN was 2.8%-4.6% according to previous reports<sup>[9,10]</sup>. However, IPNB accompanying NET has not been previously reported. This case provides important insight into the histogenesis of biliary NET.

In summary, IPNB accompanying biliary MANEC in this patient provided important information for the elucidation of the histogenesis of NET in biliary tumors.

### Abstract

Aseptic abscesses are an emergent entity and have been described in inflammatory bowel disease, especially in Crohn's disease, and in other diseases. However, aseptic abscesses associated with Behçet's disease are extremely rare. We report a Japanese male diagnosed with an incomplete type of Behçet's disease who developed multiple aseptic abscesses of the spleen and liver. In 2002, the spleen abscesses were accompanied by paroxysmal oral aphthous ulcers and erythema nodosum. As the patient's response to antibiotic treatment was inadequate, a splenectomy was performed. Severe inflammatory cell infiltration, largely of polymorphonuclear neutrophils, was observed without evidence of bacterial or fungal growth. Although the patient had no history of ocular symptoms or genital ulcers, a diagnosis of incomplete Behçet's disease was made according to the Japanese diagnostic criteria because of the presence of paroxysmal arthritis and epididymitis since 2002. In 2005, multiple liver abscesses developed with right hypochondrial pain and seemed to be attributed to Behçet's disease because the abscesses yielded negative results during a microbiologic investigation

and failed to go into remission under antibiotic therapy. Oral prednisone (15 mg/d) was started in May 2006, and the abscesses dramatically disappeared 4 wk after treatment. Although the patient had a relapse of the liver abscesses in association with the tapering of prednisone, the augmentation of prednisone dosage yielded a response. The abscesses of the liver and spleen were strongly suggested to be attributed to Behçet's disease. Clinician should be aware of the existence of aseptic abscesses as uncommon manifestations of Behçet's disease.

## INTRODUCTION

Behçet's disease (BD) is a systemic inflammatory disease commonly characterized by oral and genital ulcerations, with involvement of the skin and eye. The manifestations of BD are protean, and all symptoms and signs tend to recur either alone or in combination. Aseptic abscesses (AAs) are characterized by deep, sterile, round lesions consisting of neutrophil infiltration that do not respond to antibiotic therapy but improve with corticosteroid and immunosuppressive drugs. Clinical reports and case series concerning AAs in patients with inflammatory bowel disease, neutrophilic dermatoses, and other diseases have been published<sup>[1-5]</sup>. Although BD belongs to a group of neutrophilic dermatoses, AAs associated with BD are extremely rare. Here, we describe a patient with BD complicated by AAs of the liver and spleen, which were successfully treated with corticosteroid therapy.

## CASE REPORT

In February 2006, a 20-year-old Japanese male suffering from multiple liver abscesses associated with sporadic fever, right hypochondrial pain, and elevated inflammatory markers was admitted to our hospital. In 2002, at the age of 16, he developed oral aphthous ulcers, erythema nodosum, pericardial effusion, and multiple spleen abscesses (Figure 1A). As for the aphthous ulcers and erythema nodosum, resolution occurred spontaneously. Pericardiocentesis was performed. Effusive pericarditis was thought to be the cause of the pericardial fluid; however, it did not reaccumulate after pericardiocentesis. Because empirical antibiotic therapy had the least effect and symptoms such as fever and left hypochondrial pain persisted, an open splenectomy was performed in October 2002. Upon macroscopic examination, sections of the resected spleen showed multiple yellow nodular lesions (10-20 mm in diameter) (Figure 1B). Pathological examination confirmed the presence of severe inflammatory cell infiltration, largely of polymorphonuclear neutrophils, without evidence of bacterial or fungal growth. In addition to oral aphthosis and erythema nodosum, the primary symptoms of BD, paroxysmal arthritis and epididymitis have occurred since 2002. Although the patient had no history of ocular symptoms or genital ulcers, a diagnosis of incomplete BD was made according to the criteria of the BD Research Committee of Japan<sup>[6]</sup>. Spleen abscesses were suspected to be attributed to BD, but the association was difficult to prove. Paroxysmal oral aphthosis and arthritis persisted after splenectomy, and at the age of 19 in March 2005, multiple abscesses with an aggressive inflammatory response developed in the liver. Antibiotics were unable to demonstrate any benefit, and the liver abscesses seemed to be attributed to BD. Colchicine (with a 1.5 mg maximum daily dose) was started in July 2005. However, the patient had elevated inflammatory markers, fever, and right hypochondrial pain.

Upon physical examination, the patient did not present with fever, oral aphthosis, erythema nodosum, articular swelling, or abdominal tenderness at the time. The

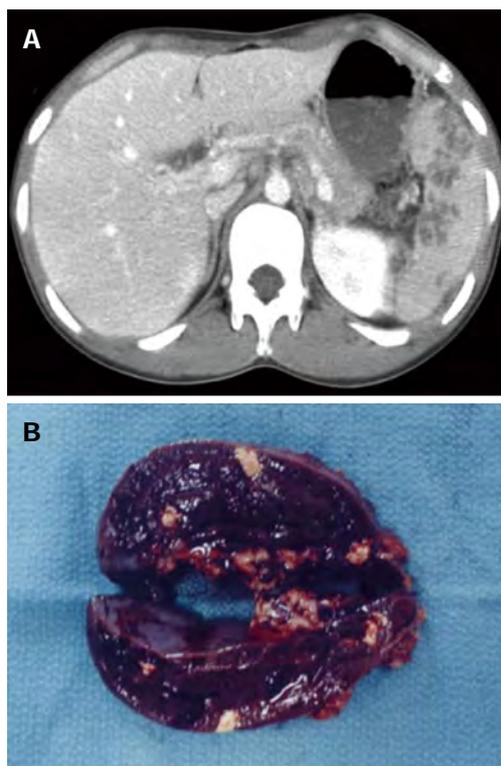

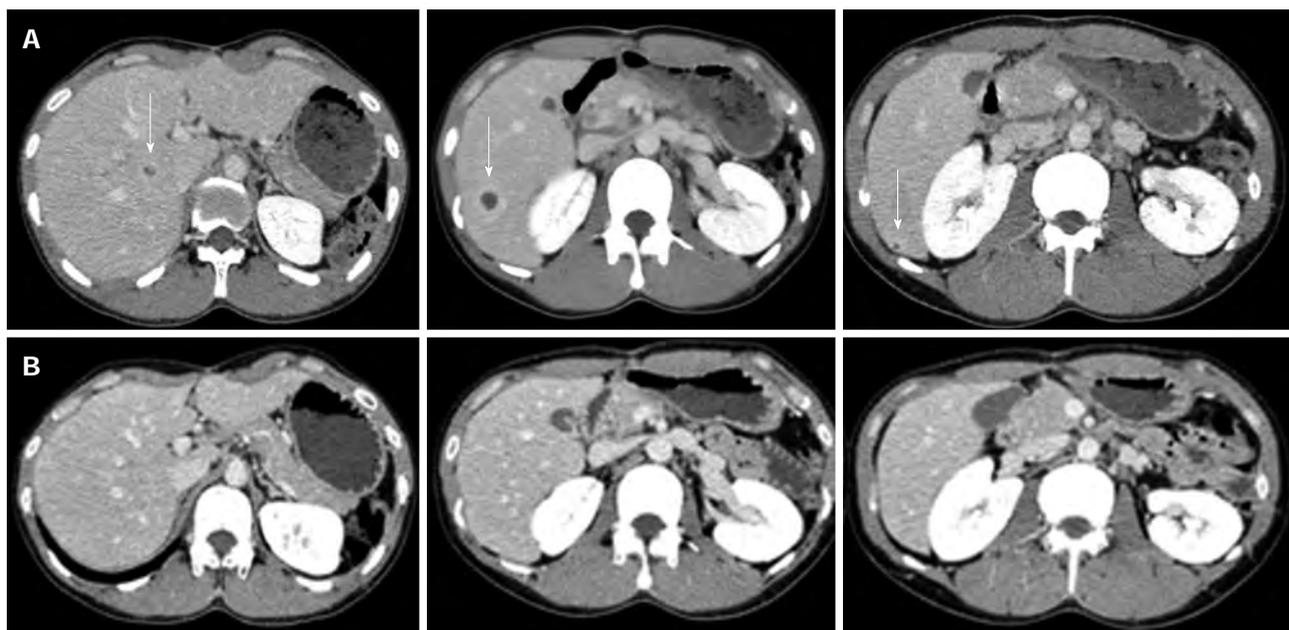

Figure 1 Contrast-enhanced abdominal computed tomography scan showing multiple spleen abscesses (A), and macroscopic findings of the cut surface of the resected spleen (B).

findings from the laboratory examinations are summarized as follows: white blood cell count, 13400/L (normal: 4000-9000/L) with 69% neutrophils; hemoglobin, 14.8 g/dL (normal: 12.0-16.0 g/dL); platelets,  $57.1 \times 10^4$ /L (normal:  $14.0-40.0 \times 10^4$ /L); aspartate aminotransferase, 21 U/L (normal: 10-40 U/L); alanine aminotransferase, 30 U/L (normal: 5-40 U/L); lactate dehydrogenase, 137 U/L (normal: 115-245 U/L); total bilirubin, 0.4 mg/dL (normal: 0.3-1.2 mg/dL); alkaline phosphatase, 583 U/L (normal: 115-359 U/L); gamma-glutamyl transferase, 123 U/L (normal:  $\leq 70$  U/L); and C-reactive protein (CRP), 11.0 mg/dL (normal:  $< 0.3$  mg/dL). The results of the kidney function tests were within the normal limits. Antinuclear antibodies (speckled staining pattern) showed a 40-fold positive result (normal:  $< 40$ -fold). Rheumatoid factor, antineutrophil cytoplasmic antibodies, and HLA-B51 antigen were negative (HLA-A24, B52, and B60 antigens were positive). Colonoscopy showed only a small aphthous ulcer in the terminal ileum; pathological examination showed non-specific chronic inflammation without any evidence of Crohn's disease (CD), such as noncaseating granuloma. Blood and urine cultures were negative. An abdominal ultrasound scan was performed, which showed multiple round lesions in the liver. Contrast-enhanced abdominal computed tomography scan demonstrated multiple areas of low-attenuation with ring enhancement in the liver (Figure 2A). Despite empirical antibiotic therapy, no clinical improvement was achieved. Ultrasound-guided percutaneous aspiration of the abscess yielded pus containing numerous neutrophils; no

**Figure 2** Contrast-enhanced abdominal computed tomography scan showing multiple liver abscesses (arrow) before (A) and 4 wk after corticosteroid therapy (B). Multiple areas of low-attenuation with ring enhancement were seen in the liver as indicated by the arrows (A). However, the areas vanished after treatment (B).

microbes were found in the culture. A fine needle biopsy of the liver lesions was performed, and a pathological examination revealed necrotic tissue containing inflammatory cells. Based on this evidence, these lesions were interpreted as aseptic liver abscesses associated with BD, and oral low-dose prednisone (15 mg/d), in addition to colchicine, was initiated in May 2006. A rapid improvement in the patient's symptoms occurred; the levels of CRP and liver enzymes reached normal range, and the liver abscesses disappeared within 4 wk of the initiation of corticosteroid therapy (Figure 2B). The dose of prednisone was gradually tapered; at 7.5 mg/d prednisone, however, the CRP level increased again, requiring a higher dose of prednisone. Therefore, the patient was maintained on low-dose prednisone therapy (10-12.5 mg/d) to restrain the inflammatory response. Elevated CRP was observed without obvious abnormality in August 2010, and the recurrence of AAs in the liver was detected by abdominal CT without abdominal symptoms in August 2011. After escalating the dose of prednisone to 20 mg/d, the liver abscesses vanished once again. The dose of prednisone was gradually tapered to 15 mg/d, and complete clearance of the liver lesions was achieved in February 2012.

## DISCUSSION

We present a patient with BD who developed AAs in the spleen and liver. AAs are an emergent entity. This condition has been described in inflammatory bowel disease (IBD), especially in CD, as well as in other diseases such as Sweet's syndrome and pyoderma gangrenosum<sup>[1-5]</sup>. Most patients with AAs have some underlying disease, and it has been proposed that AAs belong to the spectrum of

autoinflammatory multifactorial disorders<sup>[1]</sup>. The diagnosis of AAs is of exclusion on the basis of the following criteria suggested by André *et al*<sup>[1]</sup>: (1) deep abscess(es) upon radiologic examination, with neutrophilic features proven by surgical pathology or aspiration when performed; (2) negative blood cultures, negative serologic tests for bacteria, and, when surgical procedure or aspiration are performed, sterile standard, acid-fast bacillus and fungal cultures of pus; (3) failure of antibiotic therapy; and (4) rapid improvement by corticosteroids, sometimes in combination with immunosuppressive drugs. The main clinical manifestations of AAs are fever, abdominal pain, and weight loss. A rare case of BD complicated by multiple intrahepatic abscesses, which was dramatically resolved by antibiotic therapy, was reported<sup>[7]</sup>. There is also a case report of BD that was suspected to be complicated by sterile cerebral abscesses, although the clinical state of the patient gradually improved without immunosuppressive therapy<sup>[8]</sup>. In our patient, the liver and spleen abscesses were negative upon microbiologic investigation, and remission was not achieved under antibiotic therapy. Furthermore, the rapid resolution of the abscesses with corticosteroid therapy, even at the time of disease relapse in association with the tapering of prednisone, also favored a diagnosis of BD-associated AAs. Based on a PubMed search of the literature, our patient is the first unfulfilling case of sterile visceral abscesses associated with BD.

A differential diagnosis of CD *vs* BD can be difficult. Although ulcerative lesions at the ileocecal area are common in both diseases, we diagnosed the patient as having intestinal BD because of a lack of factors suggestive of CD: there was only one ulcerative lesion, its shape was not longitudinal, and histopathological examination showed no granulomatous lesions. It is also often difficult to dif-

ferentiate incomplete types of BD from Sweet's syndrome because some overlapping manifestations exist between BD and Sweet's disease. Unfortunately, a skin biopsy was not performed. However, we are convinced of the diagnosis of incomplete BD in this case because our patient had a chronic course with remissions and relapses, as well as a history of epididymitis and pericarditis, found in relatively rare manifestations of BD<sup>[9]</sup>.

Neutrophilic dermatoses are well-recognized cutaneous manifestations of systemic diseases such as IBD, and the wide spectrum of the disease includes Sweet's syndrome and pyoderma gangrenosum. These diseases may share common features such as sterile infiltration of polymorphonuclear leukocytes; BD is analogous to this condition<sup>[10]</sup>. Extracutaneous neutrophilic infiltrates are observed in all forms of neutrophilic dermatoses, but they predominate in Sweet's syndrome<sup>[11]</sup>. Sweet's syndrome associated with BD has been reported, and there may be similarities in the pathogenesis of BD and Sweet's disease<sup>[12]</sup>. Therefore, it seems reasonable that BD was complicated by AAs, although the mechanism remains unclear. Classically, Th1 immune response polarization has been known to be the main characteristic of BD immunopathogenesis<sup>[13]</sup>. The interleukin 17 (IL-17)-mediated (Th17) immune response may also contribute to immunological aberrations of BD<sup>[14]</sup>. IL-8-producing T cells were suggested to orchestrate neutrophil-rich pathologies of BD<sup>[15]</sup>. It was proposed that liver disease occurring in IBD is mediated by an aberrant homing of gut-derived T cells to the liver, with subsequent extensive lymphocyte infiltration of the liver<sup>[16]</sup>. Therefore, the mechanism by which AAs of the liver and spleen occurred in our case might be explained by an aberrant T cell-mediated immune response.

A patient with CD and associated AAs who underwent successful splenectomy was reported<sup>[17]</sup>. However, in our study, the patient developed AAs in the liver after splenectomy and finally needed immunosuppressive therapy. The risks of postoperative infection and thrombosis after splenectomy are now widely accepted. Accordingly, splenectomy as a treatment option might not be advisable in cases of AAs associated with BD.

In conclusion, we present a case of aseptic liver and spleen abscesses as the presenting picture of incomplete BD, in which complete remission was only obtained by corticosteroid therapy. The current case illustrates the possibility of the existence of AAs as uncommon manifestations of BD. Thus, physicians should be aware of this possibility to avoid a delay in diagnosis and unnecessarily aggressive therapies such as splenectomy.

### Abstract

The number of patients developing esophageal cancer after gastrectomy has increased. However, gastric remnant is very rarely used for reconstruction in esophageal cancer surgery because of the risk of anastomotic leakage resulting from insufficient blood flow. We present a case of esophageal cancer using gastric remnant for esophageal substitution after distal gastrectomy in a 57-year-old man who presented with a 1-month history of mild dysphagia and a background history of alcohol abuse. Gastroscopy showed a 1.2 cm × 1.0 cm bulge tumor of the lower third esophagus with the upper margin located 39 cm from the dental arcade. Computed tomography of the chest showed lower third esophageal wall thickening. The patient underwent en bloc radical esophagectomy with a two-field lymph node dissection of the upper abdomen and mediastinum *via* a left-sided posterolateral thoracotomy through the seventh intercostal space. The upper end of the esophagus was resected 5 cm above the tumor. The gastric remnant was used for reconstruction of the esophago-gastrostomy and placed in the left thoracic cavity. The patient started a liquid diet on postopera-

tive day 8 and was discharged on the 10<sup>th</sup> postoperative day without complications. In this report, we demonstrate that the gastric remnant may be used for reconstruction in patients with esophageal cancer as a substitute organ after distal gastrectomy.

Esophageal reconstruction with remnant stomach: A case report and review of literature. *World J Gastroenterol* 2013; 19(20): 3169-3172 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i20/3169.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i20.3169>

### INTRODUCTION

The number of patients developing esophageal cancer after gastrectomy has increased. Reconstruction is a challenge in esophageal cancer surgery when a previous subtotal gastric resection has been performed. In general, there has been a tendency to select the colon or jejunum

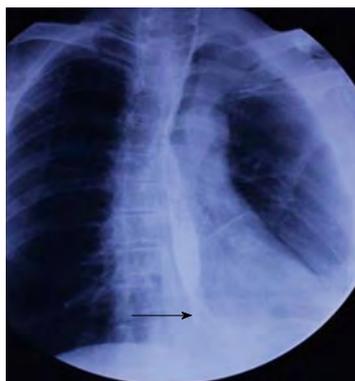

Figure 1 Barium esophagography. Esophagography shows a type 1 tumor, 1.5 cm in length, in the lower thoracic esophagus (arrow).

Figure 3 Upper gastrointestinal endoscopy shows a tumor 39 cm from the incisor, the anterior wall of the esophagus has a lip bulge about 1.2 cm × 1.0 cm.

Figure 2 Thoracic computed tomography shows a tumor 1 cm in diameter (arrow).

for substitution of the gastric tube, in order to avoid anastomotic leakage resulting from insufficient blood flow, which requires complicated operative procedures and leads to higher operative morbidity and mortality<sup>[1,2]</sup>. Herein, we report a patient with esophageal cancer and previous distal gastrectomy, who was successfully treated with esophagectomy and remnant stomach reconstruction without micro-vascular anastomosis.

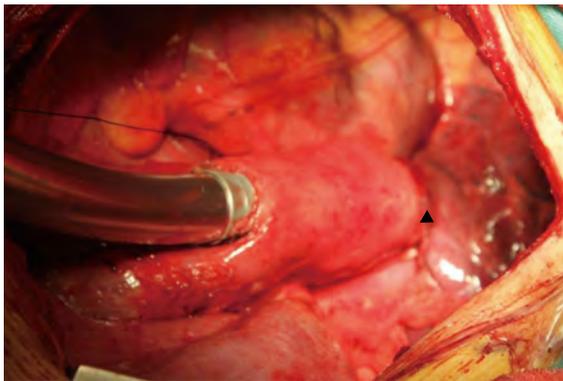

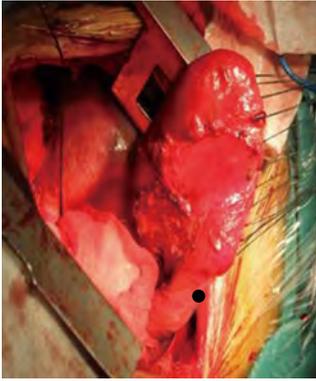

## CASE REPORT

A 57-year-old man had undergone distal gastrectomy with lymph node dissection 7 years previously for gastric cancer with a Billroth II anastomosis, pathologically diagnosed as highly differentiated adenocarcinoma, pT2N0M0; stage I b, according to the 7<sup>th</sup> edition of the UICC-TNM Classification of Malignant Tumors<sup>[3]</sup>. He was admitted to our hospital with a history of mild dysphagia with solids only for one month. His medical history was notable for alcohol abuse. Physical examination of the chest and abdomen revealed no abnormal findings. Barium esophagography revealed an approximately 1 cm arc filling defect in 1/3 of the lower esophagus with local mucosal damage and wall stiffness. The size of the gastric remnant was measured before surgery with contrast barium esophagography X-ray and was found to be 10 cm in length at the lesser curvature (Figure 1). Computed

tomography of the chest showed thickening of the lower third of the esophageal wall (Figure 2). Gastroscopy confirmed a 1.2 cm × 1.0 cm bulge tumor in the lower third of the esophagus with the upper margin located 39 cm from the dental arcade (Figure 3). The lesion did not stain with Lugol's solution. Pathological examination of the biopsy specimen revealed squamous cell carcinoma. Exclusion of cerebral, abdominal, skeletal, lymph node and other distal metastases (M0) was accomplished using [<sup>18</sup>F]-fluoro-2-deoxy-D-glucose positron emission tomography, and distant metastases to other organs were not found.

Prior to surgery, the complete colon was examined by endoscopy, and the bowel was prepared by mechanical cleansing. The patient underwent en bloc radical esophagectomy *via* a left-sided posterolateral thoracotomy through the 7<sup>th</sup> intercostal space, with a two-field lymph node dissection in the upper abdomen and mediastinum. The upper end of the esophagus was resected 5 cm above the tumor, and the left gastric artery and short gastric artery were then divided. The remnant stomach was freed up to the gastro-esophageal junction, and appeared rosy with adequate bloody supply probably due to the efferent jejunal flap with its wide gastrojejunal anastomosis (Figure 4). We decided to preserve the remnant stomach for reconstruction. The jejunum was freed from surrounding tissues. A gastric tube was extended far enough to reach the proximal esophagus. An esophagogastric anastomosis was performed mechanically under the level of the left inferior pulmonary vein using a circular stapler by an anterior gastrotomy to the high point of the fundus of the gastric remnant. The gastric remnant was placed in the left thoracic cavity. A micro-vascular anastomosis was not performed. Enteral nutrition therapy was *via* a jejunal stoma. The operative time was 266 min and the estimated blood loss was 435 mL.

Histologically, the tumor was diagnosed as a highly differentiated squamous cell carcinoma with tumor-free margins (Figure 5), and metastases in the abdomen and mediastinum lymph node were not found. The pathological stage was pT2N0M0; stage I b, according to the 7<sup>th</sup> edition of the UICC-TNM Classification of Malignant Tumors<sup>[3]</sup>.

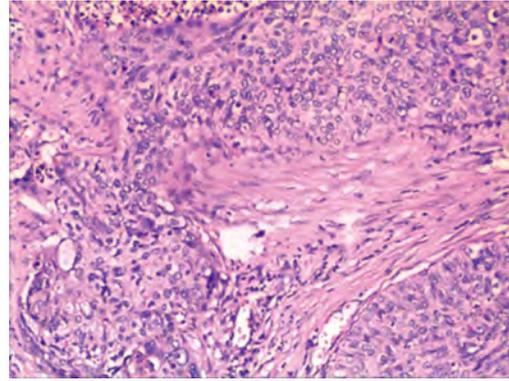

**Figure 4** Esophagus is anastomosed to the remnant stomach. During surgery, after cutting the left, right and short gastric vessels, the remnant stomach relies on the blood supply of the anastomotic stoma alone and is still rosy. Circle: Jejunum-stomach anastomotic stoma; Triangle: Esophagus-remnant stomach anastomotic stoma.

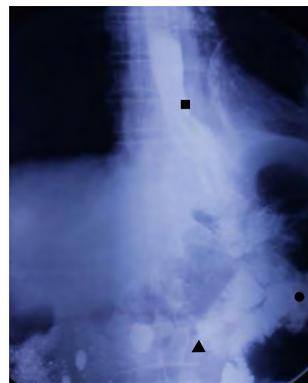

The postoperative course was uneventful, with no complications resulting from insufficient blood supply. The integrity of the anastomosis of the esophago-gastrostomy was confirmed by water soluble contrast radiography on postoperative day 7, with no signs of leakage or stricture (Figure 6). The patient started a liquid diet the following day and was discharged on the 10<sup>th</sup> postoperative day without complications. On follow-up at 6 mo after surgery, the patient was alive with no evidence of recurrence. He had improved food intake; mainly managing a solid diet with an average intake per meal of approximately 450 mL. Barium esophagography confirmed the absence of stricture, with efficient emptying of the remnant stomach.

## DISCUSSION

It was first reported in 1970 that a high incidence of gastrectomy (8.7%) was found in patients with esophageal cancer. Although surgical resection is the standard treatment for esophageal cancer after subtotal gastrectomy, the optimal management of this disease, including the surgical approach and the conduit for reconstruction, remains controversial. For patients with esophageal cancer and a history of gastrectomy, the esophagus is frequently reconstructed using colon interposition with a vascular pedicle<sup>[4]</sup>. The disadvantages of colon interposition include a long operative time for colon mobilization, highly

**Figure 5** The tumor was diagnosed as highly differentiated squamous cell carcinoma.

**Figure 6** Barium esophagography on the 7<sup>th</sup> postoperative day. Esophagography shows that barium passes smoothly through the anastomotic stoma, without leakage. Square: Anastomotic stoma; Triangle: Afferent loop of jejunum; Circle: Efferent loop of jejunum.

invasive procedures and additional anastomosis, which increase the incidence of postoperative complications<sup>[5]</sup>. Increased blood loss was observed when resolving adhesions in the upper abdominal cavity caused by gastrectomy. When using the remnant stomach, the procedure is easier, and the aims are to minimize surgical insults and to maximize the patient's quality of life. A reduction in the number of surgical maneuvers below the transverse colon and fewer bowel anastomoses represent real advantages<sup>[6]</sup>. In addition, use of the gastric remnant for reconstruction may offer substantial advantages to the elderly population in terms of fewer cardiac and pulmonary complications, rapid recovery of bowel function, shorter hospital stay, and a faster return to physical activities.

A remnant stomach can last for more than five years before the diagnosis of esophageal cancer. Establishment of the collateral circulation is important for healing of the anastomotic stoma. The blood supply of the remnant stomach may be maintained by the reconstituted microvascular supply from the widely anastomosed jejunal loop or vascular adaptation of the stomach and anastomotic site<sup>[6]</sup>, which may enhance perfusion of the gastric tube at the time of anastomosis and thus decrease anastomotic complications after esophagogastrectomy. Reavis demonstrated that gastrointestinal anastomoses were associated

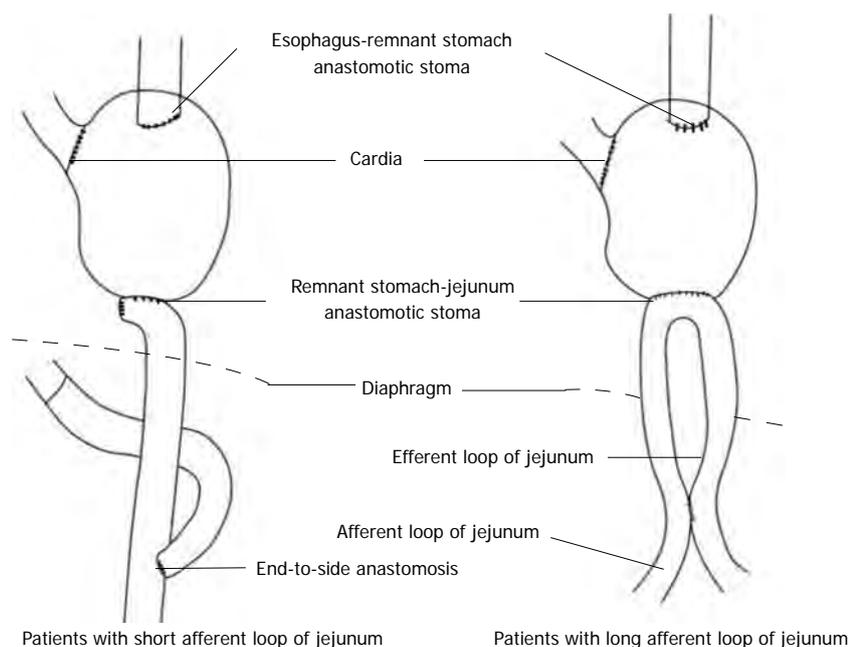

Figure 7 Scheme of the resection area of the gastric remnant and the esophagus (pre-operative), and reconstruction of the organs (post-operative).

with both vasodilation and angiogenesis and resulted in increased blood flow to the gastric fundus prior to esophago-gastric anastomosis in animals, which translated into a decrease in anastomotic dehiscence<sup>[7]</sup>. In our case, wide gastrojejunal anastomosis was seen in this operation. During surgery, 30 min after the left, right and short gastric vessels were cut, the remnant stomach was still rosy (Figure 5). We think that this wide anastomosis maintained the blood supply in the remnant stomach by reconstituting the intramural network. No complications occurred during the postoperative period, and barium esophagography on the 7<sup>th</sup> postoperative day showed that barium passed smoothly through the anastomotic stoma, without leakage. Preoperative bowel preparation should be conducted in such patients. If a poor blood supply in the remnant stomach is seen during surgery, then colon interposition should be used to replace esophageal surgery.

If the remnant stomach can not be lifted to the thorax to perform tension-free anastomosis with the esophagus during esophagectomy, the length of the afferent loop of the jejunum should be observed, if the afferent loop is short, it should be cut at the anastomotic stoma and an end-to-side anastomosis with the efferent loop of the distal jejunum should be performed; if the afferent loop is long, a side-to-side anastomosis should be performed 10-15 cm from the afferent and efferent loops, thus increasing the lifting height of the remnant stomach and jejunal loop (Figure 7).

We report a patient with esophageal cancer and previous distal gastrectomy who was successfully treated with esophagectomy and remnant stomach reconstruction without micro-vascular anastomosis. It is important to select an appropriate operative method for patients with esophageal cancer after distal gastrectomy, and its loca-

tion and stage must be determined. The remainder of the stomach can be used as an esophageal substitute depending on the curability of the esophageal cancer and the blood supply, which allows rapid recovery of bowel function and shorter hospital stay.

### Abstract

The fortuitously discovered liver lesion is a common problem. Consensus might be expected in terms of its work-up, and yet there is none. This stems in part from the fact that there is no preventive campaign involving the early detection of liver tumors other than for patients with known liver cirrhosis and oncological patients. The work-up (detection and differential diagnosis) of liver tumors comprises theoretical considerations, history, physical examination, laboratory tests, standard ultrasound, Doppler ultrasound techniques, contrast-

enhanced ultrasound (CEUS), computed tomography and magnetic resonance imaging, as well as image-guided biopsy. CEUS techniques have proved to be the most pertinent method; these techniques became part of the clinical routine about 10 years ago in Europe and Asia and are used for a variety of indications in daily clinical practice. CEUS is in many cases the first and also decisive technical intervention for detecting and characterizing liver tumors. This development is reflected in many CEUS guidelines, *e.g.*, in the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB) guidelines 2004, 2008 and 2012 as well as the recently published World Federation for Ultrasound in Medicine and Biology-EFSUMB guidelines 2012. This article sets out considerations for making a structured work-up of incidental liver tumors feasible.

**Key words:** Contrast-enhanced ultrasound; Hepatocellular carcinoma; Hemangioma; Focal nodular hyperplasia; Metastasis; Ultrasonography; Recommendations; Guidelines

**Core tip:** The presented paper is intended to discuss, comment and illustrate the recently published international guidelines on hepatic applications of contrast-enhanced ultrasound. Recommendations are based on a prospective multicenter study with more than 1000 histologically confirmed tumors and on national and international guidelines. The focus is on the important clinical work-up of the fortuitously discovered liver lesion. In contrast to most other published papers dealing with imaging methods, these recommendations also give advice for the clinician from a clinical point of view, including laboratory data. The described work-up includes different scenarios, *e.g.*, the asymptomatic (healthy) patient *vs* the oncological patient. Limitations of techniques and sources of error are also explained.

ol 2013; 19(21): 3173-3188 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i21/3173.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i21.3173>

## INTRODUCTORY CONSIDERATIONS

Guidelines for contrast-enhanced ultrasound were first published by the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB) in 2004<sup>[1]</sup>. Further EFSUMB guidelines were published in 2008<sup>[2]</sup> and 2011<sup>[3]</sup>, and updated EFSUMB-World Federation for Ultrasound in Medicine and Biology liver guidelines have been concurrently published in the *European Journal of Ultrasound* (Ultraschall in der Medizin)<sup>[4]</sup> and *Ultrasound in Medicine and Biology*<sup>[5]</sup>. The presented paper is intended to discuss, comment and illustrate the recently published liver guidelines. The focus is on the important clinical work-up of the fortuitously discovered liver lesion<sup>[6]</sup>. The topic has been recently introduced by a German CME-article<sup>[6]</sup> which will be described in more detail.

### Frequency of incidental focal liver lesions

There are only few available data on the frequency of incidental focal liver lesions (FLL); this is true also for standard values in the abdomen<sup>[7-9]</sup>. In a forensic medicine autopsy series there were focal liver or gallbladder lesions ranging in size from 0.3 to 30 mm in 52% of 95 men (35-69 years old). The incidence rose with age<sup>[10]</sup>. Liver incidentalomas are found in 7.2%-33% of all patients investigated by computed tomography (CT) scan<sup>[11,12]</sup>. Liver tumors (5%) or focal fatty lesions (12%) were detected ultrasonically in 19% of a cohort of patients with Crohn's disease<sup>[13]</sup>. Reports on ultrasound screening at a population level in Asiatic countries suggest a prevalence for incidental focal liver lesions of 2.3%-6.2%<sup>[14,15]</sup>.

**Focal liver lesions in an asymptomatic and healthy population:** Fortuitously discovered liver tumors in asymptomatic and healthy persons without any previous history of malignant disease tend in most cases to be benign<sup>[13,16]</sup>. The core duty with regard to these patients is to document the benignity of the lesion or to exclude a malignant or inflammatory infiltration requiring treatment. In the case of a benign lesion further differential diagnostic characterization (diagnostic category) is desirable, although in most cases not absolutely necessary. In a well population of 64 patients referred for opinion about incidental solid liver lesions, Little *et al.*<sup>[17]</sup> found approximately 50% had hemangiomas, 7/64 had focal nodular hyperplasia (FNH) and 5/64 had adenomas. Approximately 25% had a neoplasm and 17% (11/64) had a malignant tumor. None of the lesions < 3 cm were malignant.

**Focal liver lesions in oncological patients:** Should there be signs of a malignant lesion, therapeutic options are generally dependent on knowing the correct diagnostic category. The procedure in patients with incidental

liver space-occupying lesions differs quite considerably from that which applies to patients with pathognomonic clinical symptoms, risk factors or a previous history of malignancy, who will also be briefly discussed in this review article in order to distinguish them. In patients with a tumor history, the probability that a focal liver lesion will be a metastasis is significantly higher. However, it must also be recalled that only 51%-88.8% of liver lesions detected by CT with a maximal size of 10-15 mm are actual metastases<sup>[18-20]</sup>. In this group at least 65% of single lesions < 15 mm are benign<sup>[19]</sup>.

In summary, focal liver space-occupying lesions are common opportunistic findings. A rational work-up strategy which is as noninvasive as possible must allow for the fact that the vast majority of these findings in asymptomatic persons are benign.

### What are the common focal liver lesions?

Common benign FLL include cysts, calcifications, FNH, nodular regenerative hyperplasia, biliary hamartoma (von Meyenburg complex), as well as regional hyper- and hyposteatoses on the one hand and true neoplasias on the other, *viz.* hemangioma and the significantly less common but prognostically important hepatocellular adenoma (HCA). Combined occurrence of FNH and hemangioma has been observed in one-third of cases<sup>[21]</sup>.

Inflammatory infiltrates, inflammatory pseudotumors<sup>[22]</sup>, abscesses and extramedullary hematopoietic lesions are more unusual<sup>[23]</sup>. Angiomyolipoma and other benign mesenchymal tumors, and benign (infantile) hemangioendothelioma, are true rarities<sup>[24,25]</sup>.

Common malignant FLL encompass primary [hepatocellular carcinoma (HCC) and cholangiocellular carcinoma (CCC)] and secondary neoplasias (metastases). Lymphomas can infiltrate the liver as primary or secondary tumors, but they and the extremely rare malignant mesenchymal neoplasias will not be further discussed here<sup>[26]</sup>. The prevalence of infective lesions such as hydatid disease is very region dependent but in most Western communities is uncommon<sup>[27]</sup>.

### Which imaging techniques are available?

The most commonly used imaging techniques are conventional B-mode ultrasound and color Doppler techniques. Compared to native ultrasound, contrast-enhanced (boosted echosignal) ultrasound (CEUS) improves the detection rate of FLL and makes it possible in nearly all cases to assess the malignant/benign status of hepatic space-occupying lesions in healthy liver parenchyma<sup>[28]</sup>. In large multicenter studies, CEUS revealed a diagnostic precision of over 90% in differentiating benign from malignant FLL<sup>[29,30]</sup>. Specific vascular patterns additionally allow, with a high level of reliability, FLL to be categorized into benign and malignant forms<sup>[31]</sup>. For assessment of the chest and abdomen in tumor patients (detection, staging), a CT scan is the method of choice, but it is considerably less useful than CEUS and magnetic resonance imaging (MRI) for the differential diagnosis of liver tumors<sup>[32,33]</sup>.

In the differential diagnosis of FLL, CEUS is better than the CT scan and at least equivalent to MRI<sup>[28,34-36]</sup>. A decisive advantage of CEUS in comparison to other cross-sectional methods is the real time representation of tumor vascularization along with much higher spatial and temporal resolution. Accordingly, FLL < 20 mm and even < 10 mm can be classified with a diagnostic reliability of over 80%<sup>[37]</sup>. Disadvantages of CEUS are the somewhat greater dependency on patient-specific factors, the lack of a complete field display and, with multiple lesions, the need to focus on a single lesion in the arterial phase. MRI, as well as contrast-enhanced imaging, is superior to CT for liver lesion detection and characterization. Commonly used MRI contrast agents fall into two main groups. The first group is extracellular gadolinium-based contrast agents, which provide similar contrast enhancement patterns to that seen with conventional CT contrast enhancement, although the signal enhancement is much stronger with MR. The second group is hepatobiliary agents, which have the properties of the first group but add another dimension to contrast enhancement as they are taken up by functioning hepatocytes and excreted into bile, resulting in further improvement to lesion detection and characterization<sup>[33]</sup>.

Elastographic imaging, especially transient elastography and acoustic radiation force impulse, has been shown to be of value to assess the severity of liver fibrosis in patients with chronic viral hepatitis to distinguish patients with mild fibrosis from those with significant fibrosis and liver cirrhosis. Strain elastography, shear wave elastography using acoustic radiation force impulse, and real time elastography are promising techniques for liver tumor characterization. Elastography has been studied recently to characterize focal liver lesions, and to differentiate between benign and malignant masses in a few studies, but so far cannot be recommended in daily routine<sup>[38-40]</sup>. The EFSUMB will soon be publishing guidelines and recommendations on the use of elastography and related methods.

#### **Which laboratory tests are available?**

Tumor markers are of low utility in the differential diagnosis of FLL. That also applies to alpha-fetoprotein, which is not raised in up to 40% of all cases of HCC, whereas nonspecific increases are, in contrast, common in active viral hepatitis and liver cirrhosis<sup>[41,42]</sup>. A rise in gamma-glutamyltransferase was observed in 76% of a group of 424 patients with FNH<sup>[21]</sup>. Laboratory test parameters are, however, very useful in the context of an FLL for diagnosing a hitherto undetected diffuse liver parenchymal pathology<sup>[42]</sup>.

#### **Appraisal of malignancy/benignity and prognosis**

The detection of a liver space-occupying lesion is followed by the question of whether it is malignant or benign. On the basis of the dual blood supply to the liver with arterial and its organ-specific portal venous sinusoidal circulation, analysis of the portal venous phase has shown that it is possible to classify malignant tumors reliably through use of ultrasound contrast media<sup>[29,31,35-37]</sup>.

The outcome is equally good with SonoVue<sup>®</sup> and Levovist<sup>®</sup><sup>[43-45]</sup>, and with Definity<sup>®</sup><sup>[46]</sup>.

A liver tumor can then be categorized (after excluding cysts and calcifications by B-mode imaging) as benign when enhancement or hypercontrast is demonstrated after 2 min, which is similar to normal liver parenchyma. In individual cases (particularly neuroendocrine tumors<sup>[47,48]</sup>) evaluation should also take place after > 2 min (up to 5 min)<sup>[27,49]</sup>.

**Limitations, source of error:** Erroneous diagnoses with contrast medium in ultrasound stem in particular from the inexperience of the investigator and incorrect instrument setting, as well as from concluding the investigation too early before the late phase.

The key source of error is bubble destruction due to an excessively high mechanical index or permanent sonication of the lesion. Premature destruction of the contrast medium can simulate faulty late-phase contrasting compared to non-sounded liver tissue. A FNH which is hyper-enhanced in the portal venous phase can therefore appear falsely hypo-enhanced due to the destroyed bubbles<sup>[50]</sup>.

Before every contrast medium ultrasound investigation, cysts and calcifications must be excluded by conventional ultrasound, since these structures do not exhibit contrast medium enhancement and could therefore be erroneously interpreted as a malignant infiltration.

The arterial phase is also of particular relevance for the correct appraisal of degenerative changes, *e.g.*, necrotic plaques and abscesses show no contrast onset either in the arterial phase or portal venous phase. It is of further significance, especially with benign liver tumors, that degenerative and shrinking processes can lead to changes in perfusion and thus in imaging correlates. Typical tumor features are therefore to be expected only with tumors of up to approximately 50 mm in diameter. Larger tumors, independent of their etiology, often show degenerative changes (calcifications, fibrosis, necroses, cystic areas and many other features).

Distinctive features have been reported with benign cholangiocellular adenoma<sup>[51]</sup>, benign cholangiofibroma<sup>[45]</sup>, rare bile duct tumors<sup>[52]</sup>, inflammatory pseudotumor<sup>[22]</sup>, sarcoma<sup>[26]</sup> and other rare tumor entities<sup>[27,49]</sup>. Allowance must also be made for artifacts<sup>[50]</sup>.

#### **What importance has histology?**

Due to the increasing quality of modern imaging techniques, particularly CEUS, the utility of ultrasound- or CT-guided biopsy for diagnostic categorization of focal liver lesions has fallen off considerably in the last few years<sup>[53]</sup>.

In the German Society for Ultrasound in Medicine (DEGUM) multicenter study, CEUS was evaluated as non-diagnostic in only 92 of 1349 cases of FLL (6.9%)<sup>[29,31,34-37,54]</sup>. Biopsy is therefore now only seldom required to establish whether a lesion is malignant or benign. Biopsy is still pertinent, however, in the differential diagnosis of malignant liver lesions, particularly before a planned palliative chemotherapy, *e.g.*, if several primary tumors are involved.

Because of a significant risk of puncture channel metastases, biopsy confirmation of HCC or metastases which are potentially resectable or likely to undergo liver transplantation should always be avoided if the imaging diagnosis appears to be clinically reliable<sup>[42]</sup>. Overall, imaging-guided biopsy of focal liver space-occupying lesions is a safe method with a clinically significant complication rate of approximately 0.5%<sup>[53]</sup>. As a rule, ultrasound-guided biopsy with a 20-18 gauge Trucut™ or aspiration cannula is the method of choice<sup>[53,55,56]</sup>. The diagnostic accuracy of ultrasound-guided biopsy is dependent on many factors and attains only about 90% even under optimal conditions<sup>[53,57,58]</sup>. There is a significant risk, especially with benign lesions, of overestimation (false-positive malignant diagnoses)<sup>[59]</sup>. Yield and sensitivity can be improved through CEUS-guided biopsy, in particular with small lesions which are not well demarcated on B-mode ultrasound, as well as tumors with necrotic components<sup>[60-62]</sup>. Highly promising new options for improving biopsy yield, particularly with lesions which are difficult to display ultrasonographically or are poorly accessible, include image fusion of radiological tomography procedures and CEUS, as well as three-dimensional electromagnetic or GPS-guided needle guidance<sup>[6,53,63,64]</sup>.

It is possible to characterize liver incidentalomas in over 90% of cases noninvasively. In terms of diagnostic reliability and cost-effectiveness, contrast-enhanced ultrasonography is the imaging method of choice. Magnetic resonance imaging is an equivalent diagnostic alternative.

#### ***What is the evidence base for the recommendations?***

Recommendations are based on national and international guidelines, on the prospective multicenter DEGUM study with more than 1000 histologically confirmed tumors<sup>[29]</sup>, as well as another prospective multicenter study from France<sup>[30]</sup>, and on published accounts of liver tumors, especially those histologically confirmed<sup>[26,45,65,66]</sup>. In the intervening period, there have also been two meta-analyses which validate the equivalence of CEUS, contrast-enhanced CT and contrast-enhanced MRI in the diagnosis of FLL<sup>[67,68]</sup>. The cost-effectiveness rules of the German Social Charter Sozialgesetzbuch V should also be observed in the work-up of liver tumors<sup>[69]</sup>; this applies to unnecessary secondary imaging as well as to biopsies which are not properly indicated.

## **INTRODUCTION: THE ASYMPTOMATIC PATIENT**

In an otherwise healthy patient, the accidental discovery of a focal liver lesion has an estimated probability > 95% of being benign, without the need for recourse to other imaging techniques<sup>[17]</sup>. Successive use of additional diagnostic procedures and measures is unable to improve the high general prediction rate for the malignant/benign nature of FLL, since the sensitivity, specificity and exactitude of all available procedures (with the exception of histology) are lower than the high clinical pretest prob-

ability. All diagnostic procedures are thus of service only to the individual affected patient in the context of recognition of prognostically relevant differential diagnoses. This diagnostic starting point of a fortuitously discovered focal liver lesion in the situation of a check-up in a completely healthy, asymptomatic person with a “blank-slate” medical history is, however, likely to be seldom encountered in such a straightforwardly exclusive way, in spite of a general trend towards “routine” and prophylactic investigations. More commonly, indications for investigation emerge which do not primarily suggest the existence of an FLL (*e.g.*, investigation of acute abdominal pains or during hospital admission for a cardiovascular condition), and in which the discovery of an FLL in spite of symptoms is still regarded as a major surprise. Moreover, the complete history is not always available in a patient referred for investigation. Accordingly, the first step following the discovery of a liver incidentaloma should always be to obtain a more detailed history. Further factors which should enter the initial evaluation are FLL number, size and (sonographic) morphology, as well as ultrasound criteria for the existence of a liver parenchymal pathology.

## **INTRODUCTION: THE SYMPTOMATIC PATIENT**

In a symptomatic patient, FLL is identified on the basis of the imaging process indication (symptomatology or previous history).

#### ***Patients with underlying malignant disease***

In a patient with underlying malignant disease and FLL, the probability of a malignant infiltration is thought to be about 50%, although this estimate is fettered by a high level of imprecision, especially since it is dependent on the underlying tumor entity. While a high percentage of very small solitary lesions are benign even in tumor patients, the probability of a metastasis increases depending on the following factors: size of the lesion(s), multifocal nature, presence of specific B-mode criteria (hypoechoic, halo) and, of course, existence of general symptoms, which are typical for a generalized tumor pathology. In the DEGUM multicenter study, a previous history of tumor in patients without liver cirrhosis increased the probability of malignancy for a given FLL by a factor of 1.8<sup>[35]</sup>. In the differential diagnosis of patients with hematological systemic diseases, it should be borne in mind that, along with infiltrations of the primary disease or extramedullary hematopoietic tissue foci, small hypoechoic liver lesions can correspond to multiple mycotic abscesses in both immune competent and suppressed patients. The indication for obtaining a histology specimen by biopsy for diagnostic confirmation is more often raised in this clinical situation, given that it has (diagnostic and prognostic) implications for treatment.

#### ***Patients with underlying inflammatory disease***

In patients with underlying inflammatory disease, confir-

mation or exclusion of an abscess is fundamental. CEUS has proved to be particularly helpful in this respect, since abscesses can be reliably identified due to their avascularity and immediately drained under ultrasonographic guidance. Extravascular administration of ultrasound contrast medium is of use in testing for successful drainage and, for instance, for reliably detecting (or excluding) a biliary communication<sup>[53]</sup>. Many other, but rarer, inflammatory infiltrations should be considered, *e.g.*, granuloma, inflammatory pseudotumor<sup>[22]</sup>, Bartonellosis<sup>[70]</sup>, *etc.*, which can ultimately only be reliably diagnosed histologically. In patients with rheumatological systemic diseases, nodular regenerative hyperplasias are a typical finding<sup>[71]</sup>. A study showed that patients with systemic lupus erythematosus are five-fold more likely to have liver hemangiomas than a control group<sup>[72]</sup>.

### **Patients with underlying chronic liver disease**

Existing chronic liver disease, particularly cirrhosis of the liver, raises the suspicion that every focal liver lesion is in fact a HCC, although benign FLL and other malignant liver tumors should of course be excluded. More than 80% of all detected FLL in a cirrhotic liver with a diameter  $\geq 20$  mm are HCC<sup>[42,73]</sup>. For FLL  $< 20$  mm the proportion of HCC is smaller, although it still lies well above 50%<sup>[42]</sup>. In the DEGUM multicenter study, 76.6% of FLL in hepatic cirrhosis patients were HCC, as opposed to a figure of only 6.1% in patients without hepatic cirrhosis<sup>[35]</sup>. Regeneration nodes (7.8%), metastases (4.3%), hemangioma (2.8%) and cholangiocellular carcinoma (2.5%) were considerably more infrequent than HCC<sup>[35]</sup>. Primary sclerosing cholangitis, but also chronic cholangitis in Caroli syndrome, fasciola hepatica fluke infestation ([www.efsumb.org](http://www.efsumb.org)) or hepaticolithiasis, as well as chronic hepatitis B and C and hepatic cirrhosis, are predisposing factors for the development of a CCC<sup>[74-77]</sup>.

**HCC:** HCC shows increased enhancement in the arterial phase compared to the surrounding liver parenchyma; however, less vascularized hepatocellular carcinomas are observed in up to 10% of patients<sup>[78]</sup>. Angioinvasion is typical of HCC and demonstration of a portal venous thrombosis indicative. Color duplex ultrasound is important and CEUS decisive for differentiating between banal portal venous thromboses and tumor thromboses. It is possible to demonstrate (arterial) blood flow signals in a tumor thrombus, but not in a purely coagulative thrombus. On use of echosignal boosters, the HCC typically shows an arterial hyperenhancement of the tumor compared to the circumferential liver tissue, while no contrast is yet apparent in the surrounding liver. A chaotic vessel pattern typically stands out in HCC as a sign of neovascularization<sup>[78]</sup>. Diagnostic criteria for HCC in patients with hepatic cirrhosis will not be more extensively dealt with in this article on the grounds of its specific terms of reference, and readers are directed to the current guidelines and the accompanying commentaries<sup>[21,79-83]</sup>. Only passing reference can also be made to the important and

much discussed differential diagnosis of cholangiocellular carcinomas in the cirrhotic liver<sup>[80,84]</sup>.

**Special case of HCC in the non-cirrhotic liver:** HCC is observed in up to 15%-20% of cases in the non-cirrhotic liver<sup>[85]</sup>. The majority of these HCC (“nearly all”) already appear hypervascularized in native color Doppler ultrasounds. In such cases it is possible that they may be confused with other hypervascularized liver tumors (FNH, HCA or hypervascularized metastasis). CEUS facilitates the correct procedure in nearly all these HCC (biopsy); all HCC cases observed by us showed hypoenhancement in the healthy liver parenchyma in the portal venous phase.

**HCC, intrahepatic cholangiocarcinoma, extrahepatic cholangiocarcinoma and guidelines:** Guidelines for clinical practice have become an integral part of the diagnosis and treatment of patients around the world. They provide an invaluable source of diagnostic algorithms, recommended treatments, safety information and training procedures. A discussion of currently published guidelines has been recently introduced<sup>[21,80-84,86]</sup> and will be summarized.

The American Association for the Study of Liver Diseases (AASLD) updated their 2005 Practice Guidelines<sup>[41]</sup> in July 2010, eliminating CEUS from the diagnostic algorithm for HCC, regardless of lesion size<sup>[42]</sup>. The reasons for this were two-fold: CEUS may cause false-positive HCC diagnosis in patients with cholangiocarcinoma, and CEUS is not available in the United States. The revised guidelines are not in agreement with the guidelines and recommendations of the EFSUMB, which includes CEUS in the characterization algorithm for FLL in non-cirrhotic patients as well as in cirrhotic patients with lesions  $> 2$  cm in size that emerge during a surveillance regimen<sup>[2]</sup>. The AASLD guidelines suggest only enhanced 4-phase multi-detector CT or dynamic contrast-enhanced MRI for the characterization of nodules  $> 1$  cm in size. The Asian Pacific Association for the Study of the Liver recommendations on hepatocellular carcinoma states that CEUS is as sensitive as dynamic CT or MRI in the diagnosis of HCC<sup>[87]</sup>. This dichotomy of clinical opinion presents difficulties for the physician attempting to optimize diagnostic potential for patients based upon imaging expertise on a case-by-case basis.

The rationale for the current AASLD guideline change was based on a single retrospective 21 patient case study from the Barcelona Hepatologist Group, which reported that intrahepatic cholangiocarcinoma (ICC) may occasionally (10 of 21 patients in mainly small nodules) display a vascular pattern similar to the vascular pattern considered indicative of hepatocellular carcinoma in CEUS, possibly leading to incorrect diagnoses<sup>[73]</sup>. There is no dispute that CEUS can, and perhaps should be, combined with other imaging modalities to make a definitive diagnosis in difficult cases. However, legitimate concerns have been raised over whether CEUS should be entirely removed from

important guidelines based upon a single, relatively small-scale study<sup>[88]</sup>. In contrast, recent studies from multiple investigators have produced extensive quantitative and qualitative data that suggest that CEUS is indeed valid as a primary diagnostic imaging modality in the characterization of HCC: These data are clearly supportive of the reinstatement of CEUS in the AASLD guidelines. The purpose of this review is to summarize these studies in order to validate the need for the continued use of CEUS as a pivotal diagnostic imaging tool in FLL diagnosis.

Importantly, ICC can also present variable enhancement patterns that relate to tumor size and cellular content. Chen *et al*<sup>[89,90]</sup> confirmed that whereas smaller ICC can present with homogeneous enhancement patterns similar to HCC, larger tumors may show diverse patterns due to compression-induced central hypovascularity and necrosis. Unfortunately, Vilana *et al*<sup>[73]</sup> did not address the developmental stage or cellular morphology of the ICC lesions evaluated by CEUS in their study. Even benign lesions can occasionally be misdiagnosed because of late-phase hypoenhancement; this can occur in lesions that contain scar tissue or pronounced fibrosis<sup>[54]</sup>. Knowledge of these pathomorphological enhancement and vascular patterns in FLL, and in HCC/ICC in particular, can be a critical factor in differential diagnosis. The use of a blood pool ultrasound contrast agent like SonoVue<sup>®</sup> is highly beneficial, in that it can aid demonstration of the hemodynamics and microvascular morphology of the liver and lesion in continuous real-time.

Several studies have suggested that CEUS is at least equal to CT and MRI for the diagnosis of FLL, including the differential diagnosis of HCC/ICC. Chen *et al*<sup>[90]</sup> compared enhancement patterns of pathologically proven ICC from 40 patients undergoing CEUS with SonoVue<sup>®</sup> with those generated in contrast-enhanced CT (CECT). They found that the correct diagnosis was made in 80% of the lesions at CEUS but in only 67.5% of the lesions at CECT. The arterial phase (AP) enhancement was consistent for both modalities, but the portal venous (PV) wash-out at CEUS was more pronounced than that at CECT. Visualization of the four enhancement patterns was equivalent in both modalities, indicating that it is pathophysiology, not the technology, which determines the enhancement pattern. Their conclusion was that CEUS is at least equivalent to CECT for the characterization of ICC.

Another study to assess the concordance of enhancement patterns at CEUS, CECT, and contrast-enhanced MRT (CEMRI) looked at 144 confirmed FLL including 49 HCCs<sup>[91]</sup>. Randomized image sets from each modality were evaluated by three blinded readers who answered identical questions regarding enhancement patterns and temporal changes in AP and PV enhancement. AP enhancement showed a mean concordance of > 76% across modalities. Concordance in the PV phase was lower at 61%. The majority of discordances were malignancies where sustained PV phase enhancement was seen at CECT and CEMRI but not at CEUS; included in this group were 18 HCCs, 6 metastases, and 3 ICCs. The

authors concluded that this result was due to the aforementioned tendency of CT and MRI contrast agents to diffuse into the interstitium from the leaky vessels of malignant lesions. Benign lesions showed sustained PV enhancement in all imaging modes. A further illustration of the importance of timing issues in comparing imaging modes for FLL was demonstrated in the examination of hemangiomas<sup>[65]</sup>; some smaller, rapidly enhancing hemangiomas showed trademark centripetal progression only with real-time CEUS.

The conclusions from numerous studies, including the DEGUM multicenter trial<sup>[34,36]</sup>, are that CEUS is an appropriate rapid first diagnostic procedure following initial identification of liver lesions by non-enhanced ultrasound in clinical routine, and that it is diagnostically non-inferior to CECT/CEMRI.

**Benign liver tumors in a cirrhotic liver:** Benign liver tumors should theoretically occur just as frequently in a cirrhotic liver as in patients with healthy livers<sup>[21,78,81,83]</sup>. Most studies report the opposite<sup>[35,36]</sup>. Before resection of hepatocellular carcinomas which may be susceptible to curative treatment, otherwise benign and in particular hypervascularized liver tumors (FNH, hepatocellular adenoma, shunt hemangioma, metastases especially of neuroendocrine tumors<sup>[47,48]</sup>) should be excluded in order to avoid incorrectly indicated operations.

#### ***Patients with otherwise predisposing diseases***

There are many kinds of patients with otherwise predisposing diseases. Examples here include hyperechoic adenomas in glycogen storage diseases, hemangiomas related to genetic syndromes with angiomatous malformations, focal biliary cirrhotic nodes in cystic fibrosis<sup>[92]</sup>. Readers are directed to specialist textbooks<sup>[27,49]</sup>.

The work-up of fortuitously discovered focal liver lesions is guided by contextual information from the clinical history, from which can be inferred the relative probability of malignant and clinically relevant benign lesions, the differential diagnostic spectrum and the utility of histological confirmation.

---

## **HYPERECHOIC LIVER LESION**

---

### ***Asymptomatic patient***

The most common hyperechoic (or better: more strongly echogenic) focal liver lesion is hemangioma, which is observed three times more often in women than in men (> 95%). Most hemangiomas (approximately 70%) are “typical” (Table 1) and can be correctly identified by conventional B-mode and color Doppler sonography; further measures are not necessary. In about 30% of patients there will be an atypical criterion, and in such cases contrast-enhanced imaging procedures can be used (CEUS, MRI)<sup>[65,91,93-100]</sup>. It should also be mentioned that hemangiomas in patients with fatty livers (hepatic steatosis) can appear to be isoechoic or hypoechoic compared to hyperechoic parenchyma. Lesions suspected of being

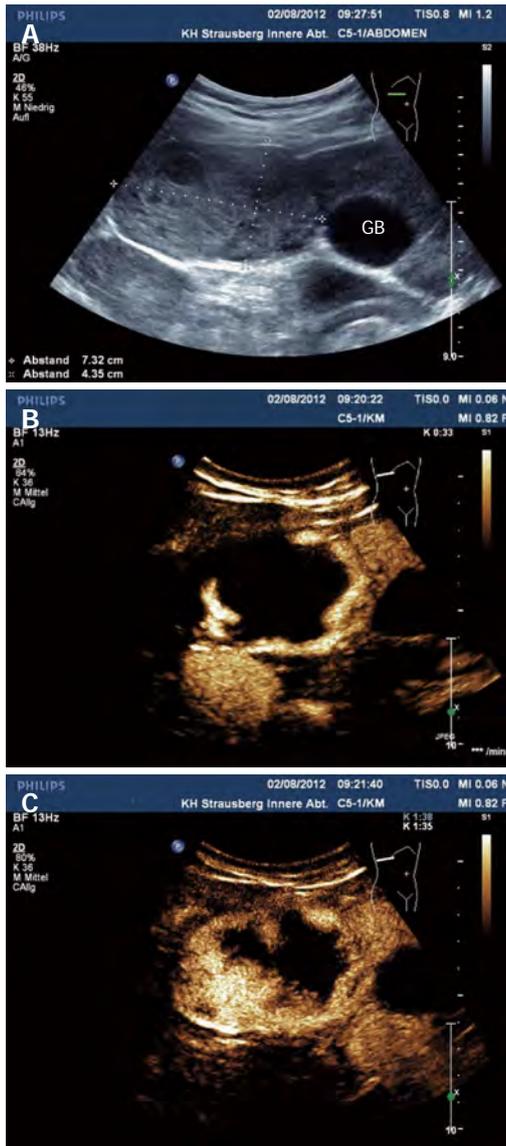

Figure 1 Hemangioma. Large hemangioma in B-mode (A), with typical peripheral nodular contrast enhancement (B) and centripetal fill-in (C). GB: Gallbladder.

hemangiomas which hypoattenuate in the portal venous phase after contrast medium administration should be biopsied and histologically confirmed<sup>[65]</sup>.

**Special features of hemangiomas:** Two signs typical of hemangiomas are peripheral nodular contrast medium enhancement and the iris-diaphragm phenomenon. The peripheral globular contrast medium enhancement is complemented by the centripetally progressive (partial) fill-in of the hemangioma (Figure 1).

Unfortunately, this typical contrast medium representation overlaps with the pattern in liver metastases arising from gastrointestinal carcinomas, and it is possible to confuse them<sup>[47]</sup>. Unlike metastases, which in the late phase progressively show less strongly echogenic contrast compared to normal liver tissue, hemangiomas are on a sustained basis more strongly enhanced than their surroundings.

The expression “high-flow hemangioma” (10% of hemangiomas), which is used in computer tomography, was marked by early onset and offset of contrast medium and can in our opinion be better described by the expression “shunt hemangioma”, since this hemangioma is characterized by arterial-portal venous shunts. Shunt hemangiomas are characteristically rather small (< 20 mm) and are typically found in areas of variable fatty degeneration compared to enveloping liver tissue. Normal liver tissue is predominantly (80%) perfused with lipid- and hormone-containing portal venous blood, whereas arterially perfused shunt hemangiomas show a lower lipid and insulin concentration than portal venous blood, which also leads to a lesser degree of fat deposition in surrounding hepatocytes. It is also known through angiographic and magnetic resonance tomographic studies that arteriovenous and/or portal venous shunts can lead to earlier contrast medium fill-in of the hemangioma<sup>[65]</sup> (Figure 2).

Liver hemangiomas can be solitary, but may also be multifocal and in very rare cases (in childhood) diffuse. An association with FNH is also not uncommon<sup>[24,101,102]</sup>. Readers are directed to the literature regarding special features of biopsy in hemangiomas<sup>[53,55,56]</sup> and rare hemangioma subtypes<sup>[65]</sup>. Ultrasound findings in 400 patients with hemangioma examined by CEUS have been recently published (Table 2)<sup>[81]</sup>.

#### Symptomatic patient

Very large hemangiomas can through extrusion, compression and very seldom hemorrhage themselves give rise to symptoms. Fundamentally, the criteria described for asymptomatic patients apply to symptomatic patients too. The indication for biopsy and histological confirmation may perhaps be more permissively made in daily routine if a multiplicity of confusing additional findings is present.

#### Differential diagnosis

In the differential diagnosis, consideration must be given to regional fat degeneration zones (which can often be unequivocally characterized based on their localization<sup>[103-106]</sup>), hyperechoic hepatocellular adenoma (particularly in storage diseases, which are extremely rare)<sup>[45,66,107]</sup> and neuroendocrine tumor metastases<sup>[47,48]</sup>, which in their early form

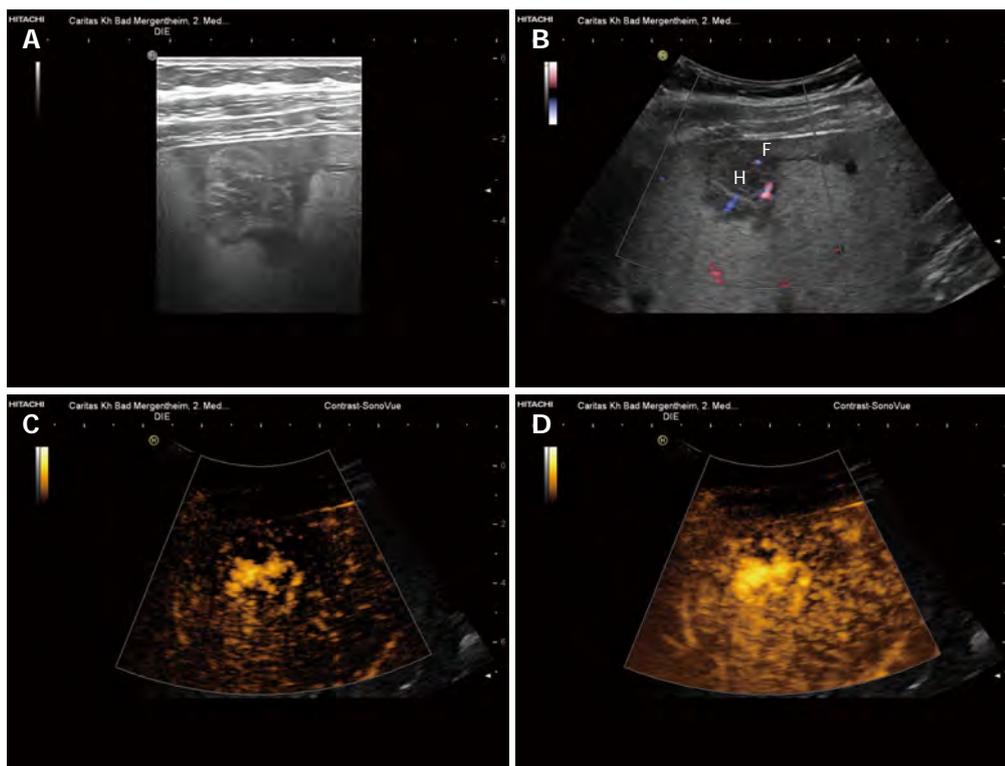

Figure 2 Shunt hemangioma. Shunt hemangiomas are typically small (often < 20 mm) with abundant arterio(porto)-venous shunts (functionally described as high flow hemangiomas). They are often surrounded by less fat-containing hypoechoic liver parenchyma (A, B) due to the dominant arterial blood flow in comparison to the reduced portal venous perfusion. Arterial contrast enhancement of the shunt-hemangioma is also shown (C, D). H: Hemangioma; F: Less fat-containing hypoechoic area. Reproduced with permission from Dietrich *et al*<sup>[65]</sup>.

can look remarkably like hemangiomas. Many rare causes of hyperechoic tumors have been described<sup>[49]</sup> and are only relevant insofar as indeterminate findings must be biopsied and histologically confirmed if a therapeutic decision is to emerge. Old abscesses and echinococcoses<sup>[53,108]</sup> and a miscellany of other disease syndromes should be borne in mind in the individual case.

### ISOECHOGENIC LIVER LESION

The most commonly isoechogenic liver lesions are focal nodular hyperplasia, hepatocellular adenoma, hepatocellular carcinoma and isoechogenic metastases. All these entities should be considered in symptomatic and asymptomatic patients equally, although the incidence profile is different. All isoechogenic lesions should be investigated using a contrast-enhanced imaging technique. Late-phase contrast medium hypoenhancement is a decisive indication for biopsy.

#### Asymptomatic patient

In asymptomatic patients, the differential diagnosis of FNH and HCA is the main objective. Both entities are far more commonly found in female patients. About 20% of FNHs occur multifocally, and co-association with hemangiomas is not uncommon<sup>[24,101,102,109]</sup>. It is important to exclude malignant differential diagnoses with a high degree of certainty, which is only possible with recourse

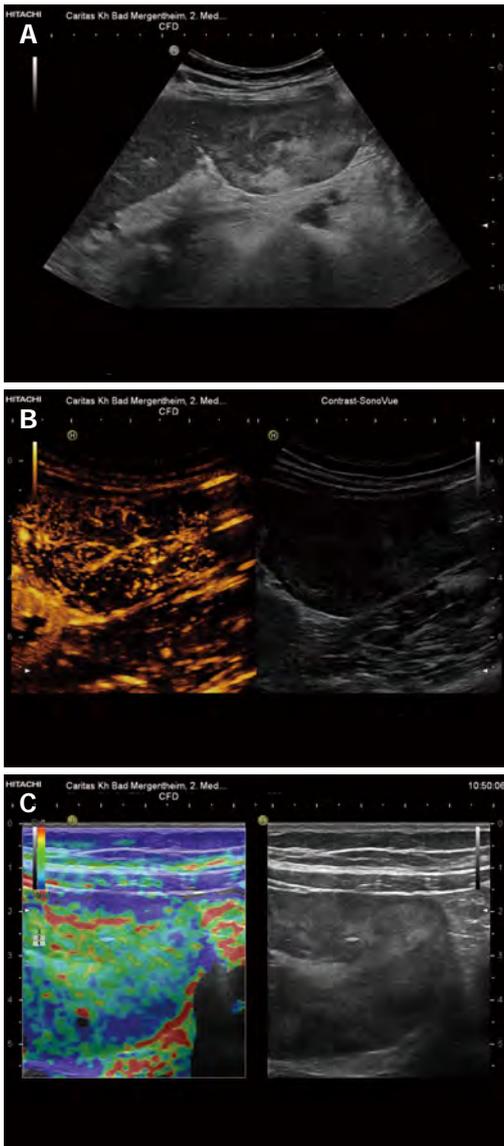

**Table 2** Ultrasound findings in 400 patients with hemangioma *n* (%)

| Characteristics   | <i>n</i> = 400 |
|---|----------------|
| Size, cm (mean ± SD)  | 2.6 ± 3.1      |
| B-mode, echogenicity  |                |
| Echo-rich   | 363 (91)       |
| Isoechoic or echopoor   | 37 (9)         |
| Vascularity assessed by colour Doppler imaging  |                |
| No intra-lesional vessels   | 379 (95)       |
| Intra-lesional vessels (hypervascular)  | 21 (5)         |
| Peripheral nodular enhancement  | 328 (82)       |
| Strong homogenous arterial enhancement  | 31 (8)         |
| No specific enhancement pattern or not determinable (e.g., due to size of the lesion, solitary fibrotic nodule) | 41 (10)        |
| Complete iris diaphragm phenomenon  | 320 (80)       |
| Incomplete iris diaphragm phenomenon  | 80 (20)        |

to a contrast-enhanced technique.

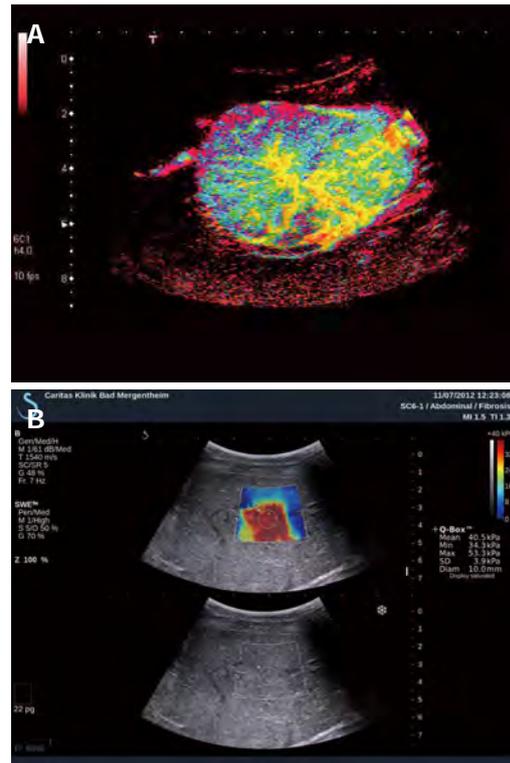

**Focal nodular hyperplasia and hepatocellular adenoma:** It has become possible to differentiate focal nodular hyperplasia from hepatocellular adenoma through echo-signal-boostered ultrasonography<sup>[66,81,110]</sup>. Unlike in FNH, portal veins and bile ducts are not present in hepatocellular adenoma. The two can therefore be differentiated through analysis of the portal venous phase<sup>[45,66]</sup>, which shows a typical hypoenhancement with HCA.

**Figure 3** Teleangiectatic focal nodular hyperplasia. Pedunculated liver tumor, histologically teleangiectatic focal nodular hyperplasia with signs of peliosis. A: B-mode imaging shows heterogenous echogenicity; B: Contrast-enhanced ultrasound reveals central arterial blood supply; C: Real-time elastography shows harder periphery and softer central portions of the lesion.

FNH typically exhibits arterial increased enhancement, which tends to be very marked in the first few seconds. Centrifugal (70%) or eccentric (30%) enhancement through one (or, in larger tumors, several) afferent correspondingly situated arteries is a diagnostic pointer. Further tumor enhancement takes place through a vessel architecture radiating out from this artery. FNH shows, in the portal venous and later phases, at least low-grade increased enhancement in about 95% of cases provided that bubble destruction does not lead to an error of interpretation<sup>[50]</sup> (Figures 3 and 4).

In the arterial phase, hepatocellular adenoma is hypervascularized, without however the characteristic vessel architecture described for FNH. Compared to the surrounding liver parenchyma, there is slightly poorer contrast medium enhancement in the portal venous and

**Figure 4** Focal nodular hyperplasia. A: In addition to conventional contrast-enhanced ultrasound (CEUS), parametric CEUS displays also the timeline of contrast enhancement (early enhancement in yellow, later enhancement in blue); B: Histologically proven. B-mode revealed isoechoic lesion, very difficult to identify. Shear wave elastography reveals very hard tissue of the lesion, shown in red in comparison to the surrounding soft liver parenchyma.

at least in the late phases (> 20 min), making it possible in most cases to differentiate it from FNH. Contrast medium hypoenhancement in the late phase is a decisive indication for liver biopsy. Ultrasound findings in 424 patients with FNH and 36 patients with HCA examined by CEUS are summarized in Table 3<sup>[21]</sup>.

**Possibilities of error:** Differentiating hepatocellular adenoma from highly differentiated hepatocellular carcinoma<sup>[111]</sup> is not possible by means of an imaging procedure, making it necessary to proceed to histological investigation of the tissue. It should be borne in mind here that error is inherent even in histological evaluation. Erroneous histological evaluations based on non-representative tissue samples and mixed forms of both tumors have been observed, with the result that in the individual case only resection and tissue preparation are unequivocal. Hepatocellular adenoma is frequently observed in patients with storage diseases<sup>[107]</sup>. Reliable tumor characterization of hepatocellular adenomas using imaging procedures is then only possible provided secondary regressive changes are not present, a phenomenon which is observed particularly with large (> 50 mm) adenomas.

**Symptomatic patient**

In symptomatic patients, the differential diagnosis of metastases and HCC is clinically of prime importance. Me-

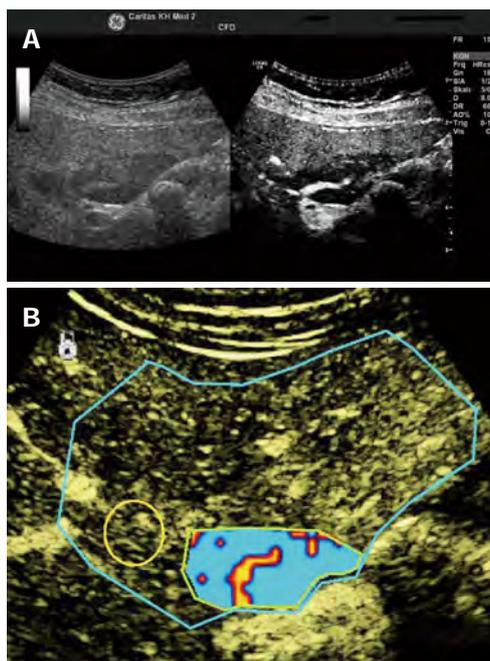

Figure 5 Focal fatty sparing. A: Focal fatty changes may simulate masses on conventional B-mode ultrasound; B: In the arterial, portal venous and late phases, focal fatty changes show similar enhancement patterns to that of the adjacent liver parenchyma. Contrast-enhanced ultrasound is helpful for the identification of the centrally located arteries. Typically centrally located arteries (and often also portal venous branches and hepatic veins) can be identified. Dynamic vascular pattern improves contrast imaging. Reproduced with permission from Cui *et al*<sup>[120]</sup>.

tastases can be identified with a high degree of reliability with CEUS in the portal venous and late phases due to their hypoenhancement. Biopsy and histological confirmation follow to determine the clinical course of action. Abscesses are diagnosed, contingent to severity, due to their avascularity. Hepatocellular adenomas should be included in the differential diagnosis in spite of their rarity, since they present in up to 30% of cases with nonspecific upper abdominal complaints, although they may also (if very rarely) manifest as acute abdominal pain (hemorrhage)<sup>[24,45,66]</sup>.

**Differential diagnoses**

It is important to note the variety of miscellaneous liver tumors. As a rule, where findings are unclear it is advisable to obtain histological confirmation or, if warranted by the clinical outcome, to proceed to surgery (*q.v.*, also “differential diagnoses of hypoechoic liver lesions”).

**HYPOECHOIC LIVER LESION**

The origin of hypoechoic lesions is considerably more varied and confusing. All hypoechogenic lesions (with the exception of those which can safely be categorized as regionally distinct fat degeneration zones) should be investigated using a contrast-enhanced imaging technique. Evaluation with CEUS in the portal venous and late phase is determinant in this context, and contrast

**Table 3** Ultrasound findings in 424 patients with focal nodular hyperplasia and 36 patients with hepatocellular adenoma

|   | Focal nodular hyperplasia (n = 424) | Hepatocellular adenoma (n = 36) |
|---|-------------------------------------|---------------------------------|

medium hypo-enhancement in the late phase is a decisive indication for liver biopsy.

**Asymptomatic patient**

In asymptomatic patients with fatty liver syndrome, the differential diagnosis of FNH and HCA is of prime importance. Malignant differential diagnoses must be excluded with a high degree of certainty, and this is only possible using a contrast-enhanced technique.

**Special features of focal fat sparing:** Regional areas of focal fat sparing are found in almost all patients with fatty liver<sup>[21,103-105]</sup> and are only seldom a diagnostic challenge. In terms of color duplex ultrasound, both focal fat deposition and focal sparing are in themselves inconspicuous; neither increased nor decreased blood perfusion is recognizable, since the liver tissue is in principle still normal tissue. The centrally situated afferent arterial and efferent venous vessels are typical, and can be recognized in many cases with the use of good instrument technology and a corresponding investigative technique (www.efsumb.org, case of the month). Even in the echosignal-boosted sequence, regionally distinct fat infiltration zones are apparent in contrast medium dynamics with centrally afferent artery and later as normal liver tissue.

In the arterial phase, afferent vessels can be displayed; in the portal venous phase they do not differ from their surroundings and can therefore be differentiated from true neoplastic entities. In this problem area CEUS is better than all other procedures (Figure 5).

**Symptomatic patient**

In symptomatic patients, the differential diagnosis of metastases (Figure 6) and HCC (Figure 7) is clinically of prime importance, the former being identifiable with a high degree of certainty using CEUS in the portal venous and late phase on account of their hypoenhancement.

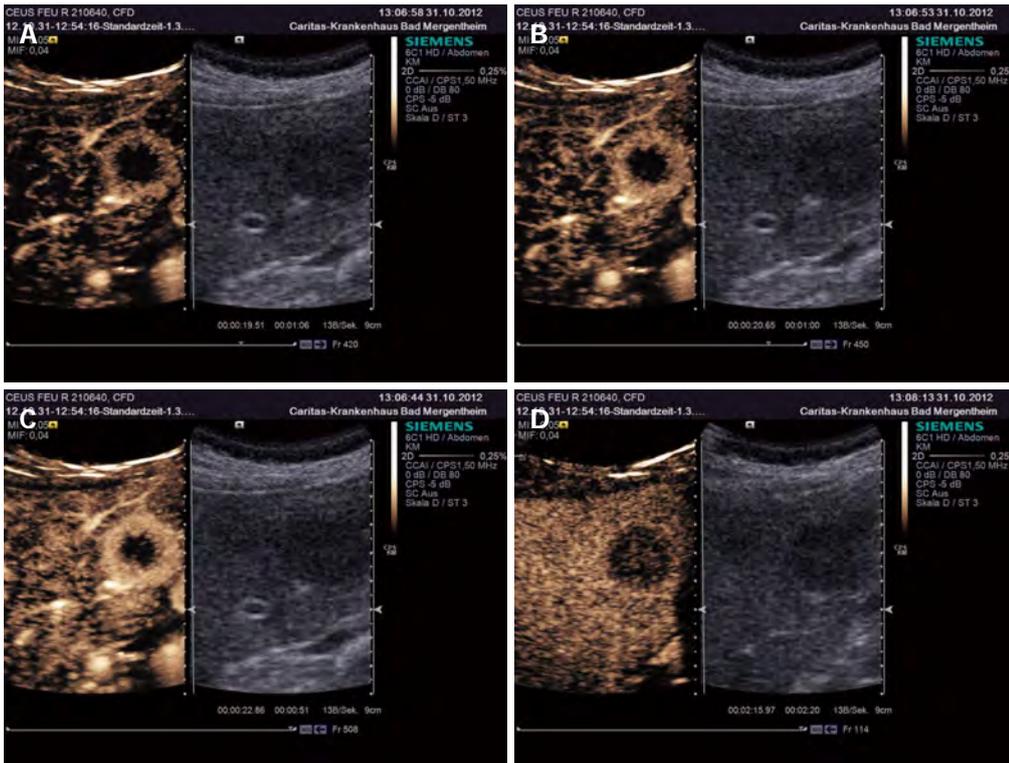

Figure 6 Liver metastasis. In contrast to the variably enhancing arterial phase (A-C), liver metastases are typically hypoechoic during the portal venous (sinusoidal) phase (D) which facilitates their reliable diagnosis.

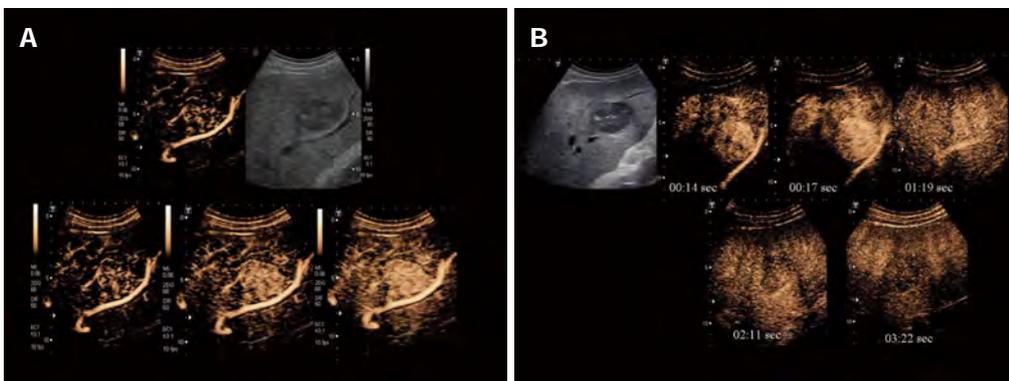

Figure 7 Hepatocellular carcinoma with arterial hyperenhancement (A) and hypoechoic enhancement in the portal venous phase (B).

Biopsy and histological confirmation follow to determine the clinical course of action. Inflammatory processes are diagnosed depending on the severity of the condition through their uneven enhancement (inflammation) or avascularity (abscess).

**Differential diagnoses**

Attention should be given to the wide range of miscellaneous liver tumors which are set out in the current literature and in textbooks<sup>[27,49]</sup>. As a rule, where findings are unclear it is advisable to obtain histological confirmation or, if warranted by the clinical outcome, to proceed to surgery. The main features of hepatic abscess have been published<sup>[2,112,113]</sup>. Typical enhancement patterns are summarized in Table 4. The evidence from the German

DEGUM study illustrates the key role that CEUS plays in diagnostic imaging of FLL; therefore, we discuss the study in more detail and refer to explanatory references<sup>[21,81]</sup>.

**Discussion of the DEGUM multicenter trial:** In total, 1349 patients (677 men and 672 women; mean age 59.8 years; range 12-91 years) were prospectively recruited at fourteen ultrasound centers<sup>[29]</sup>. In the majority of patients ( $n = 841$ ; 62.3%), the FLL was an incidental finding. Underlying liver cirrhosis was present in 234 patients (17.3%) while 364 patients (27.0%) were known to have an extrahepatic malignancy. Patients with liver lesions that could be diagnosed by B-mode ultrasound, such as cysts or distinctive hemangiomas, were not included in the study. These patients would not proceed for further examina-

**Table 4** Typical enhancement pattern for the characterization of focal liver lesions

| Lesion                                      | Arterial phase   | Portal venous and late phase                                   |
|---|--|--|
| Hemangioma (Figures 1 and 2)                | Circular vascular enhancement without central intratumoral vessels                 | Nodular enhancement and "fill-in" pattern                      |
| Focal nodular hyperplasia (Figures 3 and 4) | Radial centrifugal or "spoke wheel" pattern, then rapid, complete hyperenhancement | Iso- or hyperenhancement                                       |
| Focal fatty sparing (Figure 5)              | Central arterial blood supply  | Isoenhancement   |
| Metastasis (Figure 6)                       | Asymmetrical, chaotic enhancement configuration                                    | Hypoenhancement  |
| Hepatocellular carcinoma (Figure 7)         | Hyperenhancement and disorganized vascularity                                      | Iso- or hyperenhancement, depending upon tumor differentiation |

Reproduced with permission from reference Dietrich *et al*<sup>[81]</sup>.

tion in routine practice. Also excluded from the study were patients with malignant liver tumors that showed infiltration into the hepatic vasculature.

CEUS can be considered at least equal to, and in some ways superior to, CECT and CEMRI as a diagnostic tool. The reasons for differences between the modalities in lesion assessment may be method-related; the volume of microbubbles injected as a bolus (1.2-4.8 mL) administered over a period of a few seconds is more temporally sensitive than the larger volume of CT contrast agent (usually 100-150 mL) injected with a flow rate of 3-6 mL/min over 20-40 s. Diffusion of CECT contrast agent into the interstitium and the subsequent slow wash-out can result in erroneous diagnoses based upon PV enhancement patterns, whereas PV wash-out evident in CEUS may not be apparent in CECT. The pre-determined scan delay in CECT can miss the rapid initial wash-in and AP hypervascular response seen in CEUS. Extensive analyses have been carried out on the reasons for discordance between CEUS and CECT/CEMRI imaging in FLL, examining the effects of timing, diffusion, and fat content of the liver/lesion<sup>[114]</sup>.

Liver tumor characterization and other CEUS applications are described in more detail in currently published issues of *Ultraschall in der Medizin (European Journal of Ultrasound)*<sup>[21,80,81,83,84]</sup>.

Along with clinical context and medical history, echogenicity and ultrasound morphology set limits to the many-sided differential diagnostic spectrum of focal liver lesions. In determining whether a lesion is malignant or benign, the late phase of contrast-enhanced ultrasound is decisive, whereas diagnostic typing and characterization are particularly dependent on the evaluation of specific vascularization patterns in the arterial onset phase.

## ADDITIONAL CEUS IMAGING TECHNIQUES

Contrast-enhanced endoscopic ultrasound techniques<sup>[115,116]</sup>, real-time 3D reconstructions<sup>[86,117,118]</sup>, CEUS-guided cholangiodrainage<sup>[51]</sup> and other techniques have also been used to analyze liver tumor morphology, but the mentioned techniques are not part of this manuscript. EFSUMB is currently preparing recommendations and guidelines on the use of elastography (strain imaging methods), also dealing with liver pathology, and these will be published

soon (see also [www.efsumb.org](http://www.efsumb.org)).

## SUMMARY AND PERSPECTIVES

Computer tomography has only a limited pertinence in the characterization of liver tumors and is used essentially for staging. With CEUS, it is possible to determine whether almost all liver tumors are malignant or benign by analysis of the portal venous and late phases. Based on oncological considerations, this is followed by biopsy in patients with hypoenhancement in the portal venous and later phases, depending on whether knowledge of the histology will have a clinically applicable outcome. The predictive power of CEUS and other imaging procedures is limited in the cirrhotic liver. Attention must be paid to the special features of HCC and CCC in hepatic cirrhosis<sup>[80,84]</sup>. Dynamic ultrasound techniques<sup>[119-121]</sup> for the objectification of findings and treatment outcomes, as well as new indication ranges, are undergoing evaluation. Transient elastography for the evaluation of liver tumors is very promising<sup>[39,122-126]</sup> but has yet to establish itself as a routine method in this type of problem.

### Abstract

E2F family of transcription factors regulates various cellular functions related to cell cycle and apoptosis. Its individual members have traditionally been classified into activators and repressors, based on *in vitro* studies. However their contribution in human cancer is more complicated and difficult to predict. We review current knowledge on the expression of E2Fs in digestive system malignancies and its clinical implications for patient prognosis and treatment. E2F1, the most extensively studied member and the only one with prognostic value, exhibits a tumor-suppressing activity in esophageal, gastric and colorectal adenocarcinoma, and in hepatocellular carcinoma (HCC), whereas in pancreatic ductal adenocarcinoma and esophageal squamous cell carcinoma may function as a tumor-promoter. In the latter malignancies, E2F1 immunohis-

tochemical expression has been correlated with higher tumor grade and worse patient survival, whereas in esophageal, gastric and colorectal adenocarcinomas is a marker of increased patient survival. E2F2 has only been studied in colorectal cancer, where its role is not considered significant. E2F4's role in colorectal, gastric and hepatic carcinogenesis is tumor-promoting. E2F8 is strongly upregulated in human HCC, thus possibly contributing to hepatocarcinogenesis. Adenoviral transfer of E2F as gene therapy to sensitize pancreatic cancer cells for chemotherapeutic agents has been used in experimental studies. Other therapeutic strategies are yet to be developed, but it appears that targeted approaches using E2F-agonists or antagonists should take into account the tissue-dependent function of each E2F member. Further understanding of E2Fs' contribution in cellular functions *in vivo* would help clarify their role in carcinogenesis.

**Key words:** E2F; Colorectal cancer; Gastric cancer; Esophageal cancer; Pancreatic cancer; Hepatocellular carcinoma; Digestive system malignancies

**Core tip:** The E2F family of transcription factors has been in the focus of cancer research because its members regulate significant cellular functions related to cell cycle and apoptosis. E2Fs may act either as tumor-promoters or as tumor-suppressors, depending on the tissue. This review highlights the role of E2Fs in digestive system malignancies and their possible implication in diagnosis, treatment and prognosis.

## INTRODUCTION

The E2F family of transcription factors is involved in a vast number of cellular functions related to cell cycle and apoptosis. The study of E2F began in the mid 1980s when it was identified as a transcription activator of the adenoviral *E2* gene promoter<sup>[1,2]</sup>. The role of the prototype member, E2F1, in cancer was identified in the early 1990s through its ability to bind to and regulate the retinoblastoma protein pRb<sup>[3-7]</sup> with several members to follow either through their homology to E2F1 or through their association with pRb-related proteins (pocket proteins)<sup>[8-16]</sup>.

Early *in vitro* studies rose expectations that, through the traditional classification of the E2F family members into activators and repressors, accurate predictions about their contribution in human carcinogenesis could be possible, with oncogenic behavior expected for the former and tumor-suppressing function for the latter group. Nevertheless, *in vivo* studies have sunk the initial enthusiasm as their role appears to be by far more complicated<sup>[17]</sup>.

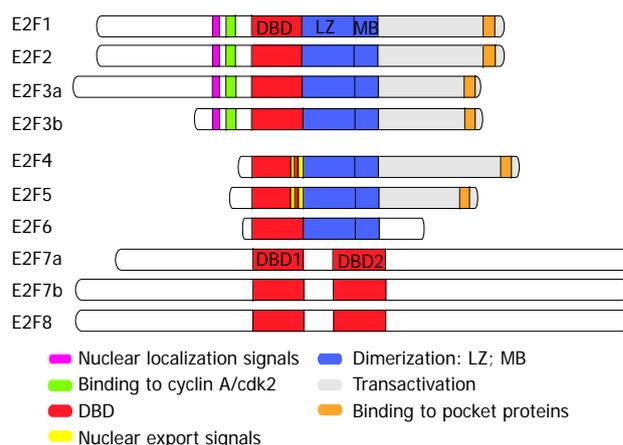

E2F1 is the most thoroughly investigated member of the E2F family in human malignancies. Other members have also been studied but in lesser extent. In non-small cell lung carcinoma, increased E2F1 and E2F3 expression has been associated with worse patient prognosis<sup>[18-21]</sup>. In breast cancer, enhanced E2F1 or E2F4 expression have been proposed as poor prognostic indicators, whereas increased E2F5 expression has been reported in certain histological subtypes<sup>[22-26]</sup>. In ovarian cancer, E2F1-5, E2F7 and E2F8 expression is reportedly increased. In addition, increased E2F4 and E2F7 expression has been related to better overall or disease-free survival, respectively, whereas that of E2F8 was linked to worse overall survival<sup>[27-30]</sup>. In prostate cancer, E2F2 and E2F3 expression increases, while E2F1 is absent<sup>[25,31]</sup>. In urothelial carcinomas of the bladder, E2F3 expression is enhanced, while that of E2F1 depends on the presence of invasion<sup>[25,32-37]</sup>. Increased E2F1 expression has also been observed in thyroid cancer, small cell lung carcinoma, glioblastoma and lymph node metastases from malignant melanoma<sup>[38-42]</sup>.

The aim of the current review is to summarize the collective knowledge on the role of various E2F family members in digestive system malignancies and to identify possible clinical implications for patients' diagnosis and prognosis and for future treatment strategy design.

## E2F STRUCTURE AND REGULATION

To date, eight members of the mammalian E2F family have been recognized and characterized<sup>[36,43]</sup>, though the most recently identified, namely E2F7<sup>[44,45]</sup> and E2F8<sup>[46,47]</sup>, bear little homology to their traditional counterparts (Figure 1). Two E2F3 proteins, E2F3a and E2F3b, have been identified, which are produced from the same gene through the use of alternate promoters<sup>[48,49]</sup>. E2F7 also has two isoforms, E2F7a and E2F7b, which are produced through by alternative splicing of the primary transcript<sup>[50]</sup>.

The greatest homology among the different members

**Figure 1 Mammalian E2F family of transcription factors.** In the context of digestive system malignancies, E2F1 may exhibit a tumor-suppressing role in colorectal, gastric and esophageal adenocarcinoma, as well as in hepatocellular carcinoma. On the contrary, in pancreatic ductal adenocarcinoma and esophageal squamous carcinoma a tumor-promoting role has been shown. A tumor-promoting role is demonstrated for E2F4 in colorectal, gastric and liver carcinogenesis. E2F8 may contribute to hepatocarcinogenesis, as it has been shown to be strongly upregulated in human hepatocellular carcinoma. DBD: DNA binding domain; LZ: Leucine zipper; MB: Marked box.

of this family is observed in the DNA binding domain. The older members E2F1-6 possess N-terminal DNA binding domain, followed by leucine zipper and marked box domains that mediate heterodimerization. With the exception of *E2F6*, the established members of the family possess a C-terminal transactivation domain containing the pocket protein binding region<sup>[36]</sup>. E2F1-3 have nuclear localization signals adjacent to their cyclin A-binding domain. This ensures their movement to the nucleus, thereby modulating E2F activity in a cell cycle-dependent manner<sup>[51-53]</sup>. E2F1-6 require heterodimerization with one of the dimerization partner (DP) proteins, DP1, DP2 or DP3 in order to form functional transcription factors which can bind DNA with high affinity<sup>[54-59]</sup>. E2F4 and E2F5 have bipartite nuclear export signals, which mediate their export to the cytoplasmic compartment and they rely on heterodimerization with one of DP proteins for their translocation to the cell nucleus<sup>[60,61]</sup>. The proteins DP2 and DP3 are thought to be alternatively spliced products of a single gene. The role of DP subunits is not completely elucidated and it appears that the function of E2F-DP heterodimer is dictated by the E2F subunit<sup>[56,57]</sup>.

The transcriptional activity of E2F1-5 is regulated through their binding with the pRb protein or the related pocket proteins p107 and p130<sup>[62-64]</sup>. E2F1-3 bind to pRb when the latter is found in its hypophosphorylated form<sup>[13]</sup>, E2F4 can bind to any of the pocket proteins, whereas E2F5 associates predominantly with p130<sup>[65,66]</sup>. Generally, when a pocket protein is hypophosphorylated can associate and block the transcriptional activity of E2F-DP heterodimers by masking the transcription activation domain of E2Fs, rendering them inactive (passive repression)<sup>[43]</sup>. Furthermore, the pocket protein/E2F-DP complex is guided to E2F binding sites where it can

recruit histone deacetylases that suppress transcription by remodelling the nucleosome (active repression)<sup>[67-70]</sup>. E2F6-8 are presumed to repress E2F-responsive genes independently of pocket proteins<sup>[10,11,50,71]</sup>.

## ROLE AND FUNCTION OF E2F TRANSCRIPTION FACTORS

E2F family members have been traditionally classified as activators and repressors. E2F1-3a are often referred to as activators because they transcriptionally activate certain target genes, for example cyclin E. This E2F subclass is expressed in a cell cycle-regulated manner exhibiting highest levels in the late G1 and S phase. In other words, they induce the entrance of quiescent cells in the S phase of cell cycle and overcome arrest mediated by the p16<sup>INK4a</sup> cyclin-dependent kinase inhibitor<sup>[43,72]</sup>. E2F3b-5 comprise the repressor subclass because their main function seems to be the repression of transcription of some E2F target genes when they associate with pocket proteins. This subgroup is expressed constitutively, but transcriptional repression by these factors takes place predominantly in cells which are in quiescence and early G1 phase<sup>[43]</sup>. E2F6-8 are also considered as repressors but they do so, as previously stated, by a manner independent of pocket protein family members<sup>[10,11,16,44-46,71]</sup>. The abovementioned classification, which is based on results of *in vitro* studies, is probably oversimplified and does not accurately reflect the dynamics of E2F-dependent transcriptional control<sup>[17,43]</sup>. The study of E2Fs' role *in vivo* has been challenging because of three main obstacles impending complete understanding of their functions. Firstly, there is a high degree of functional redundancy among activators and repressors. Secondly, there is a functional antagonism between E2F-mediated activation and repression in the regulation of normal cell proliferation. Thirdly, the members of this family have the ability to regulate each others expression, forming complex feedback loops to ensure a balance between activators and repressors in each phase of the cell cycle<sup>[17]</sup>.

## E2FS IN DIGESTIVE SYSTEM MALIGNANCIES

### Esophageal cancer

Amplification of E2F1 is often found in esophageal squamous cell carcinomas and the survival of patients with such aberration is significantly lower than that of patients without it<sup>[73]</sup>. Furthermore, positive E2F1 immunostaining correlates with histological grade and tumor stage with the overall survival being worse for patients with E2F1-positive tumors<sup>[74,75]</sup>. E2F1 expression is also shown to be positively associated with cell proliferation but not apoptosis<sup>[76]</sup>. Interestingly, the sequential transfer of the wild-type *p53* and *E2F1* genes into esophageal cancer cell lines induces tumor cell apoptosis *via* E2F1/ARF/MDM2/p53 pathway<sup>[77]</sup>. It is possible that reduced

apoptosis *in vivo* can be explained by a model suggested in non-small cell lung carcinoma, whereby tumors with deregulated E2F1/pRb network cannot promote p53-dependent apoptosis under conditions of *p53* mutation or MDM2 overexpression<sup>[19]</sup>. The situation is quite the opposite in esophageal adenocarcinomas arising in the background of Barrett esophagus. In such cases, E2F1 immunohistochemical expression exhibits a positive correlation with apoptosis and an inverse relationship with cell proliferation, implying that apoptosis is probably the tumor-suppressive mechanism activated by E2F1. The tumor-suppressing activity of E2F1 in adenocarcinomas of Barrett esophagus could be explained by the intestinal-type nature of the metaplastic mucosa and it may also be dictated by the embryological origin of the lower third of esophagus from the foregut<sup>[78]</sup>.

### Gastric adenocarcinoma

E2F1 is found to be overexpressed in about 40% of gastric adenocarcinomas, whereas gene amplification of E2F1 rarely occurs<sup>[79-81]</sup>. Experimental studies have provided evidence that adenovirus-mediated E2F1 overexpression in gastric carcinoma cells induces widespread apoptosis, probably through direct or indirect upregulation of phosphatase and tensin homolog (PTEN) expression, activation of caspase-3 and -9 and decrease in nuclear factor kappa-light-chain-enhancer of activated B cells expression *via* PI3K/PTEN/Akt signalling pathway, especially when combined with cyclin-dependent kinase inhibitors, such as roscovitine. This points to a tumor-suppressing role of E2F1 in this type of cancer<sup>[82-86]</sup>. Interestingly, at least one study has demonstrated the opposite effect, *i.e.*, downregulation of E2F1 significantly inhibited the infiltration and proliferation abilities of human gastric cancer cells. This inconsistency was attributed to the difference in activation of E2F1 at different points of the cell cycle to keep a dynamic balance<sup>[87]</sup>. E2F1 immunoreactivity was shown to independently predict favorable overall survival in gastric adenocarcinoma patients who received adjuvant chemoradiation therapy with 5-fluorouracil and leucovorin after gastrectomy and correlated with localized tumor, intestinal histological subtype and thymidylate synthase expression, supporting its role as a potential biological marker, predictive of clinical outcome in this particular setting<sup>[88]</sup>. Similar to colorectal adenocarcinomas, microsatellite unstable gastric adenocarcinomas frequently exhibit mutation of the adenosine-guanine-cytosine (AGC) repeat of the *E2F4* gene, that probably represents an early event in this context, allowing for additional gene anomalies to accumulate during tumor progression<sup>[89-94]</sup>.

### Colorectal adenocarcinoma

There are a number of studies that investigated the role of E2F family members, especially E2F1, in the context of colorectal cancer. E2F1 expression was indeed found increased in some early studies<sup>[81,95]</sup>. Later on, increased E2F1 expression was found directly related to increased

apoptotic levels and inversely related to cell proliferation, particularly when serial or semiserial sections were analyzed<sup>[25,96,97]</sup>, suggesting a tumor-suppressing role. E2F1 expression is higher in lung metastasis of colon adenocarcinoma and also correlates closely with the expression of thymidylate synthase in both the primary tumor and metastases, indicating worse response to 5-fluorouracil due to resistance<sup>[98,99]</sup>.

On the other hand, E2F4 has been directly associated with cell proliferation in colorectal cancer, suggesting a tumor-promoting role<sup>[97,100]</sup>. This finding is in agreement with experimental observations in cell line and animal models demonstrating increased nuclear expression of E2F4 in the replicating colon epithelium<sup>[101-104]</sup>. Of interest, the immunohistochemical expression of E2F1 was inversely correlated with that of E2F4 when studied in serial histological sections, suggesting a possible mechanistic interlink between the two family members that has yet to be identified<sup>[97]</sup>. An other interesting observation is that *E2F4* contains a stretch of 13 serine residues in its trans-activation domain encoded by a microsatellite trinucleotide AGC repeat within the *E2F4* gene. This repeat is often found mutated in various gastrointestinal tumors, including human colorectal cancer with microsatellite instability and it is believed to be one of the targets of DNA mismatch repair deficiency<sup>[93,105-107]</sup>.

E2F2 has only recently been investigated in colorectal adenocarcinoma. Its expression at the tissue level was found to be very low without any relationship to kinetic parameters, leading to the hypothesis that E2F2 expression does not contribute in colorectal carcinogenesis but rather reflects the functional redundancy between E2F members of the same subgroup<sup>[97]</sup>.

### Hepatocellular carcinoma

In a recent study, nuclear immunohistochemical expression for E2F1 was positively related to tumor apoptotic index in a series of human hepatocellular carcinomas, supporting a pro-apoptotic role of E2F1 in this type of cancer<sup>[108]</sup>. Interestingly, studies investigating HCC-cell lines or mouse models have provided evidence pointing towards a tumor-promoting role of E2F1 by demonstrating that its overexpression led to increased expression of upstream cell proliferation or anti-apoptotic genes<sup>[109-112]</sup>. Other investigators have demonstrated that, in a transgenic mouse model, endogenous c-myc was upregulated in the early stages of hepatocarcinogenesis, whereas p53 was overexpressed in the tumors, suggesting that both E2F1-mediated proliferation and apoptosis are operative but at different stages of hepatocarcinogenesis<sup>[113]</sup>.

E2F3 and E2F4 are also shown to be upregulated in HCC<sup>[114-116]</sup>. Of note, HCCs exhibiting microsatellite instability has shown deletions in AGC triplet repeats in the coding region of the *E2F4* gene in a similar manner as demonstrated for microsatellite unstable colorectal cancer<sup>[93,105-107,117]</sup>. These results suggest that both microsatellite instability and mutations of *E2F4* commonly occur in HCC and may play an important role in hepatocarcinogenesis<sup>[117]</sup>.

Lastly, it has been demonstrated that E2F8 is strongly upregulated in human HCC and it could thus contribute to oncogenesis and progression in this type of cancer. Mechanistic analyses indicated that E2F8 could bind to regulatory elements of cyclin D1, regulating its transcription and promoting accumulation of S-phase cells<sup>[118]</sup>.

### Pancreatic cancer

E2F1 may have a tumor-promoting role in pancreatic ductal adenocarcinoma. A direct correlation has been found between E2F1 immunohistochemical expression and cell proliferation index, as well as an inverse relationship between E2F1 immunopositivity and histological grade and disease-associated survival<sup>[119]</sup>. Interestingly, stable overexpression of E2F1 and decreased pRb expression resulting in the liberation of E2F in pancreatic cancer cell lines may be responsible for the demonstrated increase in chemotherapy-induced apoptosis<sup>[120]</sup>. Moreover, infection of pancreatic cancer cells lines by E2F1-expressing adenoviral vector has been shown to increase gemcitabine-induced apoptosis as well as etoposide- or roscovitine-induced apoptosis<sup>[121,122]</sup>.

## ISSUES IN E2F BIOLOGY

Deregulated expression of E2F family of transcription factors is a common phenomenon in human cancer. Little is known though about the magnitude and the nature of their contribution. The prevailing view is that E2F activators and repressors operate in a coordinated manner to achieve proper cell cycle progression and/or apoptosis and that disturbance of this well orchestrated interaction can contribute to carcinogenesis. According to the traditional classification of the different E2F members into activators and repressors, it would be expected that clear predictions about their function in cancer could be made. Unfortunately, this is not the case and this classical approach stemming from *in vitro* studies is openly challenged in practice<sup>[17,43]</sup>. To complicate things further, numerous E2F target genes have been identified reflecting the fact that E2Fs participate in cellular processes beyond the cell cycle<sup>[123-127]</sup>.

Regarding digestive system malignancies, E2F1 may exhibit a tumor-suppressing role in colorectal, gastric and esophageal adenocarcinoma, as well as in hepatocellular carcinoma, probably through pro-apoptotic activity<sup>[25,78,82-86,96,97,108]</sup>. On the contrary, a tumor-promoting role has been attributed to E2F1 in the context of pancreatic ductal adenocarcinoma and esophageal squamous carcinoma<sup>[73-76,119]</sup>. It is very interesting though that in experimental models involving adenoviral transfer of E2F1 in esophageal squamous and pancreatic cancer cell lines apoptosis was evoked<sup>[77,121,122]</sup>. The possible role, correlations and prognostic significance of E2F1 expression in digestive system malignancies is summarized in Table 1.

E2F4, a classical “repressor”, seems to play a tumor-promoting role in colorectal, gastric and liver carcinogenesis<sup>[90,92,93,97,117]</sup>. It is also well documented that AGC

**Table 1** Possible role, correlations and prognostic significance of increased E2F1 expression in digestive system malignancies

| Tumor                            | Role              | Clinicopathological relationships                                   | Prognostic significance | Ref.    |
|----------------------------------|-------------------|---|-------------------------|---------|
| Esophageal                       |                   |   |                         |         |
| Squamous cell carcinoma          | Tumor-promoting   | ↑ tumor stage, ↑ histological grade, ↓ overall survival             | Yes                     | [74,75] |
| Adenocarcinoma                   | Tumor-suppressing | ↑ survival  | Yes                     | [78]    |
| Gastric adenocarcinoma           | Tumor-suppressing | Localized disease, intestinal histological type, ↑ overall survival | Yes                     | [88]    |
| Colorectal adenocarcinoma        | Tumor-suppressing | ↑ survival  | Yes                     | [25,96] |
| Hepatocellular carcinoma         | Tumor-suppressing |   | No                      | [108]   |
| Pancreatic ductal adenocarcinoma | Tumor-promoting   | ↑ histological grade, ↓ disease-free survival                       | Yes                     | [119]   |

↑: Increased; ↓: Decreased.

repeats in the *E2F4* gene are commonly found mutated in various gastrointestinal malignant neoplasms exhibiting microsatellite instability and they are thought to represent one of the targets of DNA mismatch repair deficiency<sup>[89-94,105-107,117]</sup>. Of note, in colorectal cancer, an inverse relationship between the immunohistochemical expression of E2F1 and E2F4 has been demonstrated when examined in serial histological sections<sup>[97]</sup>. It would be interesting to investigate if such a relationship can be confirmed in other gastrointestinal cancers as well and, if so, whether there is a common “switch” connecting mechanistically these two opposing transcription factors.

## CONCLUSIONS AND PERSPECTIVES

E2F family of transcription factors serves key roles in cell cycle progression, apoptosis, cell differentiation and stress responses. Following their traditional classification into activators and repressors, it has been tempting to assign to them oncogenic or tumor-suppressing functions, thus predicting their role in carcinogenesis. A number of investigators have focused into showing a prognostic value of E2F expression in different kind of digestive tract malignancies<sup>[25,74-76,78,88,96,119]</sup>. Others have gone a step further and, based on their experimental work, suggest therapeutic strategies involving adenoviral transfer of *E2F* in a gene therapy context to sensitize cancer cells for conventional chemotherapeutic agents<sup>[82,121,122]</sup>.

However, clinical and experimental studies in mice openly challenge this traditional view, which does not appear to reflect the complexity of E2F function in tumorigenesis. It appears, though, that this function is exerted in a tissue-dependent manner. It is appealing to consider the development of treatment strategies involving E2F-antagonists, that would suppress cell proliferation, and E2F-agonists, that would promote apoptosis<sup>[128]</sup>. Nevertheless, targeted therapeutic approaches against E2F family members should take into account the tissue-dependent function of each member.

It is quite obvious that, although our knowledge on this intriguing family of transcription factors is seemingly increasing, little is known about their function *in vivo*. The introduction and use of modern molecular techniques and experimental models have identified numerous targets for these factors, helping us unravel the mystery of

their contribution in normal tissues. This can be the necessary step in order to clarify to which extent they exert pivotal roles in cancer development<sup>[17]</sup>.

## ACKNOWLEDGMENTS

The authors would like to thank Mrs. Maria Chatzopoulou for her kind contribution in creating Figure 1.

### Abstract

Combination therapy with peginterferon (pegIFN)- $\alpha$  and ribavirin (RBV) has been the standard of care (SOC) for chronic hepatitis C. Unfortunately, not all patients can achieve a sustained virologic response (SVR) with this regimen. SVR rates are approximately 80% in patients with hepatitis C virus (HCV) genotype 2, 3, 5 and 6 and 40%-50% in patients with genotype 1 and 4. Therefore, strategies to improve SVR rates have been an important issue for clinical physicians. Several direct acting antiviral agents (DAAs) have significantly higher SVR rates when combined with pegIFN- $\alpha$  and RBV than pegIFN- $\alpha$  and RBV alone. Treatments containing DAAs have several advantages over the previous SOC, including higher specificity and efficacy, shorter treatment durations, fewer side effects, and oral adminis-

tration. Based on these advantages, treatment with pegIFN- $\alpha$  and RBV plus telaprevir or boceprevir has become the current SOC for patients with genotype 1 HCV infection. However, many patients are either not eligible for therapy or decline treatment due to coexisting relative or absolute contraindications as well as an inability to tolerate the hematological side effects and adverse events caused by the new SOC. These factors have contributed to the advent of pegIFN- $\alpha$ -free regimens. The newest therapeutic regimens containing sofosbuvir and ABT-450 have shown promising results. In this review, we summarize the development of anti-HCV agents and the clinical efficacy of sofosbuvir and ABT-450-based therapies as well as the potential for future HCV studies.

**Key words:** Sofosbuvir; ABT-450; Hepatitis C virus; Antiviral therapy; Sustained virologic response

**Core tip:** We are entering an era in which the development of antiviral agents and successful treatment of chronic hepatitis C is rapidly escalating. In this review, we have summarized the history of anti-hepatitis C virus (HCV) agents from interferon- $\alpha$  (IFN- $\alpha$ ) to the latest sofosbuvir- and ABT-450-based therapies. Although a new generation of direct acting anti-HCV agents has largely improved the sustained virologic response rates of patients, many unmet needs and questions remain, such as IFN-free regimens for difficult to treat patients, avoidance of cross-resistance, the role of interleukin-28B status as well as the management of some advanced and co-infected patients.

## INTRODUCTION

Chronic hepatitis C virus (HCV) infection is currently a major global health problem that affects 160 million people worldwide and is one of the main causes of chronic liver cirrhosis and hepatocellular carcinoma<sup>[1,2]</sup>. Compared with the former standard of care (SOC), the current SOC, consisting of peginterferon (pegIFN)- $\alpha$  and ribavirin (RBV) plus telaprevir or boceprevir, achieves higher rates of sustained virologic response (SVR), which is defined as undetectable HCV RNA in the serum for 24 wk after the end of treatment. SVR is associated with a better outcome for chronic hepatitis C (CHC) patients<sup>[3,4]</sup>. However, not all patients can achieve SVR<sup>[5,6]</sup>. In addition, triple therapy has many side effects and contraindications that result in a number of eligible patients refusing therapy<sup>[7,8]</sup>.

Based on these complications, pegIFN- $\alpha$ -free regimens could be an alternative for some patients. Several pegIFN- $\alpha$ -free regimens containing sofosbuvir and ABT-450 have shown high SVR rates with only 12 wk of treatment and mild adverse events. These regimens have the potential to be the newest SOC for CHC in the near future. Here, we summarize the clinical development history of anti-HCV agents as well as recent studies of the efficacy and adverse event profile of sofosbuvir and ABT-450 regimens. We also discuss the future focus for HCV studies.

## BRIEF DEVELOPMENT HISTORY OF ANTI-HCV AGENTS

### IFN era

Anti-HCV therapy is the backbone for the treatment of CHC. Since the late 1980s, IFN- $\alpha$  has gradually become the core of antiviral treatment<sup>[9-13]</sup>. However, IFN- $\alpha$  monotherapy achieved suboptimal efficacy until combined with RBV<sup>[14-22]</sup> (Figure 1). PegIFN- $\alpha$  has a higher plasma concentration and half-life than interferon, which results in an improved SVR rate as well as improved patient compliance as the pegylated form can be injected once weekly<sup>[23-25]</sup>. Higher SVR rates were achieved with combination therapy of pegIFN plus RBV than with pegIFN monotherapy, which has become the SOC during the past decade<sup>[26,27]</sup>. Meanwhile, the true meaning of SVR was unclear until a large cohort study demonstrated that patients who achieved SVR could be considered cured<sup>[28]</sup>. Unfortunately, not all patients, especially those infected with genotype 1 and 4 HCV could achieve SVR with the SOC. Furthermore, side effects, long-term treatment, contraindications and poor compliance all spurred the development of new agents with shorter treatment durations, fewer contraindications, oral administration, higher specificity, and fewer side effects.

### Era of direct acting antiviral agents

HCV is classified in the genus hepacivirus of the family flaviviridae. Once the virus is released into the cell, the

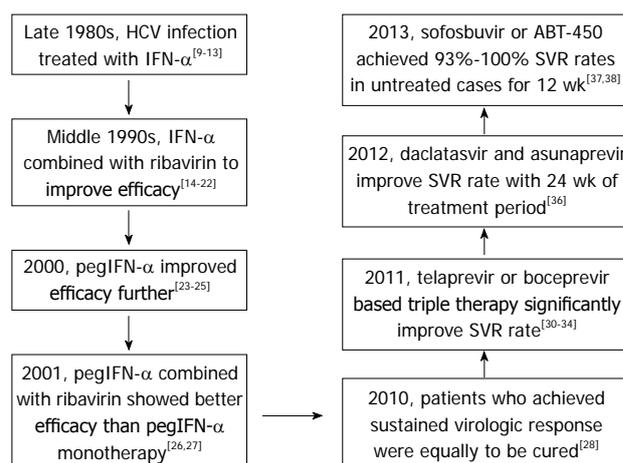

Figure 1 Brief development history of the anti-hepatitis C virus agents. HCV: Hepatitis C virus; IFN- $\alpha$ : Interferon- $\alpha$ ; SVR: Sustained virologic response; pegIFN- $\alpha$ : Peginterferon- $\alpha$ .

viral polyprotein is translated and cleaved by host proteases and the viral NS3-4A protease into ten mature proteins. Next, viral RNA is replicated into progeny RNA by the viral NS5B polymerase. Another viral protein, HCV NS5A, is indispensable for viral replication and assembly and could be a nonenzymatic target for therapeutics. With the structures of NS3/4A protease and NS5B polymerase solved and the rapid development of different cell culture models and biotechnology<sup>[29]</sup>, HCV research has been flourishing both on the bench and in industry. In particular, intensive efforts have focused on developing direct acting antiviral agents (DAAs) that can block the activity of viral enzymes.

The serine protease inhibitors telaprevir and boceprevir, approved by the United States Food and Drug Administration in 2011, were the first and currently only DAA to make it to the clinic. Telaprevir is a linear peptidomimetic HCV NS3/4A serine protease inhibitor, and boceprevir is a protease inhibitor that binds to the HCV NS3 active site. Treatment regimens consisting of telaprevir or boceprevir plus pegIFN- $\alpha$  and RBV had significantly higher SVR rates in genotype 1 patients and became the SOC thereafter<sup>[30-34]</sup>. However, this new SOC has more adverse events and a similar treatment duration when compared with the former SOC<sup>[35]</sup>, and monotherapy with telaprevir or boceprevir was shown to be impractical due to the rapid selection of resistant variants. In 2012, preliminary clinical data showed that combination therapy with the NS5A replication complex inhibitor daclatasvir and the NS3 protease inhibitor asunaprevir could also achieve high efficacy rates after 24 wk of treatment<sup>[36]</sup>, especially in prior null responders. These results showed the potential of a pegIFN-free regimen for 24 wk treatment duration. However, some patients in this study experienced viral breakthrough due to resistant variants, which ultimately resulted in treatment failure.

In January 2013, Gane *et al.*<sup>[37]</sup> and Poordad *et al.*<sup>[38]</sup> published clinical data on the efficacy of sofosbuvir- (also known as GS-7977) and ABT-450-based oral

| 8     | 25       | 1a/1b (22/3)          | Untreated                    | Sofosbuvir + RBV 12 wk                              | 84%      |

The dose of sofosbuvir is 400 mg (*qd*), peginterferon- $\alpha$  (pegIFN- $\alpha$ )-2a is 180  $\mu$ g (*qw*), ribavirin (RBV) is 500 mg (*bid*) for patients with body weight < 75 kg, and RBV is 600 mg (*bid*) for patients with body weight > 75 kg. *qd*: Once daily; *bid*: Twice daily; *qw*: Once weekly; SVR: Sustained virologic response.

treatment regimens for 12 wk treatment duration. The results showed that 100% of genotype 2/3 patients and 93%-95% of genotype 1 patients achieved SVR. The sofosbuvir and ABT-450 studies were open-label clinical studies that assessed various combination and dosages of agents in previously treated and previously untreated patients. Sofosbuvir exhibits a higher barrier to resistance than ABT-450 because its target, the NS5B polymerase is highly conserved, and viral fitness is crippled if variants occur in the polymerase active site. Sofosbuvir also exhibits pan-genotypic antiviral activity compared to genotype-specific agents, such as ABT-450, asunaprevir, telaprevir and boceprevir. Although some mild adverse events were observed, these studies validated the feasibility of achieving extremely high SVR rates with a pegIFN-free regimen and a short treatment duration of 12 wk.

### General characteristics of representative DAAs

We summarize representative DAAs from 2011 to January 2013 in Table 1. There have been several treatment evolutions during this timeframe. First, most of these agents were designed for genotype 1 patients, with genotypes 2 and 3 only being considered recently. Second, the treatment period has gradually decreased to 12 wk. Third, dosing frequency has generally improved from three times daily to once daily, which will undoubtedly contribute to better patient compliance. Fourth, combination therapy has gradually shifted away from exclusive combinations with pegIFN- $\alpha$  to trials with and without pegIFN- $\alpha$  to finally pegIFN- $\alpha$ -free regimens. Finally, we found that at least two representative agents were developed from bench to bedside every year. Compared with other DAAs,

the sofosbuvir and ABT-450 regimens not only achieve extremely high SVR rates with 12 wk of treatment in treatment-naïve patients but are also efficacious in genotype 2 and 3 patients without the need for pegIFN- $\alpha$ .

## CLINICAL EFFICACY OF SOFOSBUVIR AND ABT-450

Sofosbuvir is a direct acting nucleotide polymerase inhibitor<sup>[39]</sup>, and ABT-450 is a potent macrocyclic HCV NS3 protease inhibitor. Both have been developed as oral therapies for the treatment of chronic HCV infection. Phosphorylated nucleotide analogues, such as sofosbuvir, are converted within the host hepatocyte to the active nucleoside triphosphate, which competes with natural nucleotides, thereby terminating RNA replication in the nascent viral genome. Sofosbuvir acts as a nonobligate chain terminator, targeting the highly conserved active site of the HCV-specific NS5B polymerase<sup>[38]</sup>. The mechanism of action of NS3 protease inhibitors has been thoroughly reviewed elsewhere<sup>[35]</sup>. As a potent inhibitor of CYP3A4 (the primary enzyme involved in first-pass metabolism of most protease inhibitors), ritonavir can increase the plasma concentration and half-life of ABT-450, decrease the emergence of resistance mutations in the NS3 gene, and permit once-daily dosing of ABT-450<sup>[38,40,41]</sup>.

### Clinical efficacy of sofosbuvir-based therapy

Gane *et al.*<sup>[37]</sup> published an open-label clinical trial of 95 previously untreated HCV genotype 1/2/3 patients and genotype 1 null responders (Table 2). The patients were

**Table 3 Overview of 50 hepatitis C patients under ABT-450 regimen**

| Pyrexia                           | 0%-18%             | No data                      |

<sup>1</sup>Adverse events during ABT-450 regimen were only listed those that occurred in more than 20% of patients.

divided into 8 groups: sofosbuvir monotherapy and sofosbuvir plus RBV therapy with or without pegIFN- $\alpha$  for 8 or 12 wk. The results showed that 100% of previously untreated genotype 2/3 patients achieved SVR based on sofosbuvir plus RBV. For previously untreated genotype 1 patients, the SVR rate was 84%. Unfortunately, the SVR rate was only 10% for genotype 1 patients who had no response to previous therapy. These results indicate that genotype 2/3 untreated patients can be completely cured with 12 wk of sofosbuvir plus RBV therapy alone.

#### Clinical efficacy of ABT-450-based therapy

Poordad *et al.*<sup>[38]</sup> published an open-label, phase 2a clinical trial of 50 genotype 1 patients, including untreated patients and patients with no or partial response to prior therapy (Table 3). The patients were divided into 3 groups. Patients received a combination of ABT-333 (a nonnucleoside NS5B polymerase inhibitor), RBV and ritonavir plus two different dosages of ABT-450 for 12 wk. The results showed that 93% and 95% of previously untreated genotype 1 patients achieved SVR. Further-

more, 47% prior null and partial responders achieved SVR. These results indicate that almost all untreated patients with genotype 1 can achieve SVR with ABT-450-based regimens, and null and partial responders can achieve higher SVR rates than previously possible.

#### ADVERSE EVENTS OF SOFOSBUVIR AND ABT-450 REGIMENS

Both sofosbuvir and ABT-450 regimens have various adverse events (Table 4). The most frequent adverse events observed with sofosbuvir-based therapies were headache, fatigue, insomnia, nausea, rash, and anemia<sup>[37,42]</sup>. For ABT-450-based therapies, the most frequent adverse events were fatigue, nausea, headache, dizziness, insomnia, pruritus, rash, and vomiting. Some laboratory abnormalities were also observed during the treatment period, including anemia for sofosbuvir-based treatment and hyperbilirubinemia for ABT-450-based therapy. Some laboratory abnormalities were more common among patients receiving pegIFN- $\alpha$ -2a. Most adverse events and abnormalities were mild, and none led to treatment interruption.

#### INTERLEUKIN-28B POLYMORPHISM IN THE SOFOSBUVIR AND ABT-450 ERA

Genome-wide association studies have demonstrated that single nucleotide polymorphisms near the interleukin-28B (*IL-28B*) gene that encodes IFN- $\lambda$ 3 are closely associated with spontaneous and treatment-induced HCV clearance<sup>[43-46]</sup>. The rs12979860 CC genotype is associated with a two-fold greater SVR rate than the TT genotype in European-American individuals. Similar ratios have been observed in both African-American and Hispanic populations of genotype 1 chronic hepatitis C patients. The presence of the C-allele is always accompanied by higher SVR rates, indicating that this allele may favor the clearance of HCV. In studies of sofosbuvir and ABT-450, five groups achieved SVR rates of 100%, independent of IL-28B status (Table 5). Therefore, lower SVR rates may not be primarily due to *IL-28B* genotypes. Instead, these patients may have acquired resistant variants during treatment. However, it should be noted that the sample size

**Table 5 Interleukin-28B polymorphism in sofosbuvir and ABT-450 era**

| Group      | Status before treatment                 | IL-28B CC (n) | IL-28B CT (n) | IL-28B TT (n) | SVR rate |
|------------|---|---------------|---------------|---------------|----------|

pegIFN- $\alpha$ : Peginterferon- $\alpha$ ; SVR: Sustained virologic response; RBV: Ribavirin.

of these studies too small to reach a definitive conclusion on the role of IL-28B. Whether *IL-28B* genotype will be a predictive marker for treatment response with the new drug regimens requires further investigation with large sample sizes.

## PERSPECTIVES

### **Genotype 1 patients with no or partial response to prior therapy will be the focus of future studies**

Currently, the highest SVR rate observed in genotype 1 patients who have no response to prior therapy is 90%, which was achieved with daclatasvir and asunaprevir-based therapy (Table 6). SVR rates in this patient population treated with telaprevir and boceprevir regimens were only 33% and 52%, respectively, which was significantly inferior to the rates in treatment-naïve patients. Sofosbuvir plus RBV has achieved an excellent SVR rate in untreated genotype 1 patients compared with genotype 1 patients who had no response to previous treatment. While the ABT-450 regimen achieved high efficacy in genotype 1 patients with no or partial response to prior treatment, the SVR rate was still less than 50%. All of the above-mentioned results suggest that genotype 1 patients with no or partial response should be the focus of further investigation. Furthermore, genotype 1a patients have more opportunities to develop resistance to the DAAs combination from Poordad *et al*<sup>[38]</sup>. Genotype 1a accounts for 89%, 8 out of 9 patients with virologic failure

in group 3 who have been analyzed for the presence of resistance-associated variants. The genetic barrier to resistance of protease inhibitors is relatively lower for subtype 1a because this subtype only requires one nucleotide substitution to generate resistance, whereas the 1b virus requires two. Accordingly, genotype 1a patients may be more difficult to treat in new DAAs era.

### **DAA combinations with less cross-resistance may be the solution for genotype 1 patients with no or partial response to prior therapy**

Although it has not been investigated in a head-to-head study, genotype 1 patients with no or partial response to prior therapy have different SVR rates (10% vs 90%) with different DAA combinations (Table 6)<sup>[37,38]</sup>, indicating that different DAA combinations might be important to successfully treating these types of patients. Various combinations of DAAs are now under investigation<sup>[47,48]</sup>. However, why a particular combination may lead to an improved SVR rate in these patients remains unclear. It is possible that adding another DAA could complement the mechanisms of action of other agents in the regimen as well as decrease the appearance of cross-resistant variants. As Table 6 shows, 90% of genotype 1 patients with no response to prior therapy can achieve SVR<sup>[33]</sup>, suggesting that a potent DAA combined with pegIFN- $\alpha$  and RBV may be one choice for those patients who can endure the adverse events and long period of treatment.

### Combinations with less cross-resistance are the goal for the future

Various DAA combinations have now been investigated, such as asunaprevir plus daclatasvir; sofosbuvir plus RBV; sofosbuvir plus daclatasvir; faldaprevir plus BI207127; ABT-450/ritonavir plus ABT-333; ABT-450, ritonavir plus ABT-072; miracitabine, danoprevir plus ritonavir; and alisporivir plus RBV<sup>[47]</sup>. DAA combinations not only have the potential to increase antiviral efficacy but also to reduce the risk of viral breakthrough. When combining DAAs, it is important to consider combinations that have a low propensity for cross-resistance. The genetic barriers to resistance of DAAs appear to be an important factor during the development of resistance. When two agents with a low genetic barrier to resistance are combined, breakthrough occurs more quickly<sup>[49]</sup>. Adding on pegIFN- $\alpha$  or RBV<sup>[36]</sup> as well as nucleoside analogues with a higher genetic barrier might be better tactics for overcoming resistance<sup>[37,50]</sup>. For example, 90% of difficult-to-treat patients can achieve SVR with a combination of daclatasvir, asunaprevir, pegIFN- $\alpha$ 2a and RBV for 24 wk of treatment<sup>[36]</sup>. Furthermore, 84%-100% of patients can achieve SVR with a combination of sofosbuvir plus RBV for 12 wk of therapy<sup>[37]</sup>.

### PegIFN- $\alpha$ : To be with or not to be with

Whether or not to include pegIFN- $\alpha$  is a key issue in the DAA era. Several years ago, many hepatologists believed that HCV treatment would be IFN free. Now, however, the ability to do away with IFN is not so clear, especially in some difficult-to-treat patients. Although not compared in a head-to-head study, the SVR rate was relatively lower in refractory patients treated with a pegIFN-free regimen, as shown in Table 6. This information indicates that IFN-free regimens may be available for easy-to-treat patients in the near future, whereas IFN might be necessary for difficult-to-treat patients.

### Role of IL-28B in reducing treatment duration

In Tables 2 and 5, groups 4 and 6 differ with respect to treatment duration (12 and 8 wk, respectively). In group 4, 81% (9/11) of patients were genotype CC or CT. In group 6, 90% (9/10) of patients were genotype CC or CT. It will be interesting to investigate whether IL-28B polymorphisms could predict treatment duration in the DAA era, especially in patients with the potential to reduce the treatment course.

### Other aspects

In addition to above-mentioned situations, results from group 5 patients who received sofosbuvir monotherapy suggested the crucial role of RBV in maintaining an antiviral response (Table 2). However, the exact mechanism by which RBV contributes to SVR in the DAA era remains uncertain. Another area of important research in the future will likely be treatment of patients with cirrhosis, and hepatitis B virus and human immunodeficiency virus co-infected patients. Although the sofosbuvir- and ABT-450-

based therapies were well tolerated, the safety profile of other combination treatments remains to be seen.

## CONCLUSION

A series of clinical trials have demonstrated that we are currently experiencing a “watershed moment” for the treatment of hepatitis C<sup>[51,52]</sup>. Despite some unresolved questions, the recent achievements demonstrating DAAs as potent new HCV clearing agents with improved SVR rates appear to be encouraging, and it may be possible to cure nearly all HCV-infected patients in the near future. The progress of new anti-HCV agents might indicate that agents with specificity, sensitivity and a high barrier to resistance are the mainstay for conquering pathogen-related disease. Future studies may focus on the improvement of SVR rates in genotype 1 patients who have no or partial response to prior therapy as well as special patient populations, such as those with cirrhosis or co-infected patients. Furthermore, determining an optimal combination therapy with little cross-resistance and few adverse events as well as better understanding the status of IL-28B polymorphism and the potential mechanism of how RBV may synergize with DAAs are also areas of future study.

### Abstract

**AIM:** To analyze the epidemiology, clinical characteristics, treatment patterns and outcome in hepatocellular carcinoma (HCC) patients.

**METHODS:** We analyzed clinical, pathological and therapeutic data from 256 consecutive patients, examined at S. Croce Hospital in Cuneo-Piedmont, with a diagnosis of HCC between 30<sup>th</sup> June 2000 and 1<sup>st</sup> July 2010. We analyzed the hospital imaging database and examined all medical records, including the diagnosis code for HCC (155.0 according to the ICD-9M classification system), both for inpatients and outpatients, and discovered 576 relevant clinical records. After the exclusion of reports relating to multiple admissions for the same patient, we identified 282 HCC patients. Moreover, from this HCC series, we excluded 26 patients: 1 patient because of an alternative final diagnosis, 8 patients be-

cause of a lack of complete clinical data in the medical record and 17 patients because they were admitted to different health care facilities, leaving 256 HCC patients. To highlight possible changes in HCC patterns over the ten-year period, we split the population into two five-year groups, according to the diagnosis period: 30<sup>th</sup> June 2000-30<sup>th</sup> June 2005 and 1<sup>st</sup> July 2005-1<sup>st</sup> July 2010. Patients underwent a 6-mo follow up.

**RESULTS:** Two hundred and fifty-six HCC patients were included (male/female 182/74; mean age 70 years), 133 in the first period and 123 in the second. Hepatitis C virus (HCV) infection was the most common HCC risk factor (54.1% in the first period, 50.4% in the second;  $P = 0.63$ ); in the first period, 21.8% of patients were alcoholics and 15.5% were alcoholics in the second period ( $P > 0.05$ ); the non-viral/non-alcoholic etiology rate was 3.7% in the first period and 20.3% in the second period ( $P < 0.001$ ). Child class A patients increased significantly in the second period ( $P < 0.001$ ). Adjusting for age, gender and etiology, there was a significant increase in HCC surveillance during the second period ( $P = 0.01$ ). Differences between the two periods were seen in tumor parameters: there was an increase in the number of unifocal HCC patients, from 53 to 69 ( $P = 0.01$ ), as well as an increase in the number of cases where the HCC was  $< 3$  cm [from 22 to 37 ( $P = 0.01$ )]. The combined incidence of stage Barcelona Clinic Liver Cancer 0 (very-early) and A (early) HCC was 46 (34.6%) between 2000-2005, increasing to 62 (50.4%) between 2005-2010 ( $P = 0.01$ ). Of the patients, 62.4% underwent specific treatment in the first group, which increased to 90.2% in the second group ( $P < 0.001$ ). Diagnosis period ( $P < 0.01$ ), Barcelona-Clinic Liver Cancer stage ( $P < 0.01$ ) and treatment *per se* ( $P < 0.05$ ) were predictors of better prognosis; surveillance was not related to survival ( $P = 0.20$ ).

**CONCLUSION:** This study showed that, between 2000-2005 and 2005-2010, the number of HCV-related

HCC decreased, non-viral/non alcoholic etiologies increased and of surveillance programs were more frequently applied.

## INTRODUCTION

Hepatocellular carcinoma (HCC) is the 5<sup>th</sup> most common cancer and the 3<sup>rd</sup> leading cause of cancer mortality worldwide<sup>[1]</sup>. In recent decades, the incidence of HCC has risen in Europe and the United States; this trend may be explained to several factors, such as increased surveillance programs for HCC-high risk patients, improved management of chronic liver disease, and an epidemic of hepatitis C virus (HCV) infection in the late 1970s<sup>[2]</sup>. HCC related to HCV infection is a preventable disease whose incidence can be decreased by controlling HCV transmission; in Japan, the incidence of HCC began to decrease by 2000, mainly because of decreased HCV-related cases<sup>[3]</sup>. Considering the current provision of HCV prevention programs in Europe, can a similar decrease of HCV-related HCC be expected in the future?

HCC occurs two to four times more often among men than women, and within an established background of chronic liver disease (fibrosis or cirrhosis). Hepatitis B virus (HBV) and HCV infections are known independent risk factors for HCC, as well as alcohol consumption<sup>[4]</sup>. Nevertheless, 5%-30% of patients with HCC lack a defined, identifiable risk factor. Recently, it was suggested that non-alcoholic steatohepatitis (NASH) might account for a substantial portion of cryptogenic cirrhosis and HCC cases<sup>[5]</sup>. NASH is a more severe form of non-alcoholic fatty liver disease (NAFLD) that is associated with obesity, diabetes, dyslipidemia and insulin resistance<sup>[5]</sup>. International guidelines recommend surveillance for patients at high risk for HCC<sup>[6,7]</sup>, yet surveillance is not recommended in patients at risk for NASH.

Non-randomized trials and observational studies reported a survival benefit in small HCC recognized within surveillance programs, but these studies had unavoidable biases<sup>[8]</sup> and the evidence supporting surveillance efficacy in term of improving survival is limited. However, surveillance using 6-mo ultrasound (US) best identifies liver nodules less than 1 cm, and small HCC could benefit from more effective treatment<sup>[9]</sup>. Certain HCC treatments are potentially curative depending on cancer stage, liver function and performance status, as well as on resources and level of practitioner expertise<sup>[10]</sup>. The Barcelona Clinic Liver Cancer (BCLC) staging system is widely accepted in clinical practice and was adopted as the reference system by the American Association for the Study of Liver Disease (AASLD) in 2010<sup>[7,11]</sup>. The BCLC system includes data on patient's performance status, the number and size of nodules, cancer symptoms and liver function. The BCLC stratifies patients into separate prognostic categories and suggests treatment options according to the stage<sup>[11,12]</sup>. Patients with localized stage HCC could benefit from curative therapies, such as resection, percutaneous ablation or liver transplantation, whereas patients with intermediate or advanced stages may benefit from non-curative treatments, such as chemoembolization. Recent studies demonstrating that chemoembolization improves survival in well-selected patients with unresectable HCC<sup>[13]</sup> have led to a greater propensity for chemoembolization treatment, as well as a modification of indication to treatment, such as inclusion of more patients with well-compensated disease and advanced tumors<sup>[14]</sup>.

We created a database of consecutive HCC patients diagnosed in S. Croce General Hospital (Cuneo, Italy) from June 2000 to July 2010. Using this database, we designed the present study to assess clinical characteristics, treatment patterns and outcomes in patients with HCC.

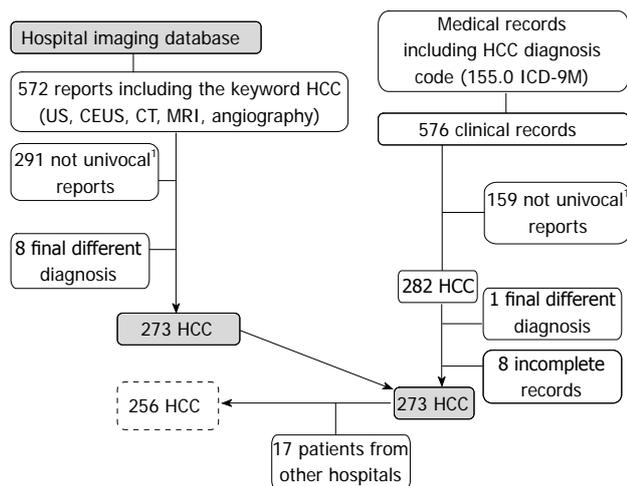

## MATERIALS AND METHODS

### Patients

Our population was a consecutive series of patients, examined at S. Croce Hospital in Cuneo, Piedmont, with a diagnosis of HCC between 30<sup>th</sup> June 2000 to 1<sup>st</sup> July 2010. All cases with initial HCC diagnosis were considered eligible; incident diagnosis as well as diagnosis was carried out during surveillance.

We analyzed the hospital imaging database and found 572 reports that included the keyword HCC. After exclusion of reports performed for the same patient and reports presenting a different final diagnosis (despite the presence of the keyword), we identified 273 actual HCC patients.

To better identify all the HCC patients referred to our hospital, we examined all medical records that included the diagnosis code for HCC (155.0 according to the ICD-9M classification system), both for inpatients and outpatients; we discovered 576 clinical records, and after exclusion of records presenting the same name (multiple admissions for the same patient), we identified 282 actual

**Figure 1** Selection of hepatocellular carcinoma patients. <sup>1</sup>Not-univocal: Reports/records repeated/belonging for/to patients already recruited. US: Ultrasound; CEUS: Contrast enhanced ultrasound; CT: Computed tomography; MRI: Magnetic resonance imaging; HCC: Hepatocellular carcinoma.

HCC patients. Nine patients were excluded from this series: one patient because of an alternative final diagnosis and eight patients because of lack of complete clinical data in the medical record (Figure 1).

To highlight possible changes in HCC patterns over the ten-year period, we split the population into two five-years groups, according to the diagnosis period: 30<sup>th</sup> June 2000-30<sup>th</sup> June 2005 and 1<sup>st</sup> July 2005-1<sup>st</sup> July 2010.

Patients were classified according to the cause of liver disease as follows: (1) HBV, if patients were hepatitis B surface antigen-positive; (2) HCV, if patients were serum antibody anti-HCV positive; (3) alcoholic, if the daily ethanol intake was > 60 g for women and > 80 g for men for more than 10 years; (4) multi-etiology, if there was a combination of these causative factors; and (5) others, when the cause was different from those cited above (as primary biliary cirrhosis, autoimmune hepatitis, hemochromatosis, *etc.*).

On admission, clinical (general conditions, presence of ascites, jaundice, *etc.*), biochemical (routine biochemical tests, liver function tests, alpha-fetoprotein, *etc.*) and imaging (US, computed tomography, magnetic resonance imaging, hepatic arterial angiography) parameters were assessed.

The HCC database included personal data, etiology of hepatic liver disease, biochemical tests, imaging features (number of nodules, size, presence of ascites, presence of hepatic thrombosis, and presence of metastasis), surveillance application (defined by two US examinations over the last 12 mo)<sup>[7]</sup> and Child Pugh score<sup>[15]</sup>.

We collected the following data regarding HCC treatment: type, number of procedures, number of admissions, days of hospitalization, treatment complications, presence of post-embolization syndrome (defined by the onset of fever, abdominal pain, moderate degree of ileus, moderate cholestasis and transaminase elevation, self-limited in less than 48 h)<sup>[7]</sup>.

### Diagnosis and severity of chronic liver disease

Diagnosis of cirrhosis was made by clinical (endoscopic and/or US signs of portal hypertension, and/or a nodular margin of the liver at US examination) and laboratory features; when possible and/or indicated, cirrhosis was confirmed by histology. The severity of liver dysfunction was scored according to the Child-Pugh classification<sup>[15]</sup>.

### Diagnosis and staging of HCC

Diagnoses of HCC were carried out according to internationally accepted criteria<sup>[6,7]</sup> and, if required, confirmed by cytology and/or histology.

HCC was classified as unifocal, paucifocal ( $\leq 3$  nodules), multifocal ( $> 3$  nodules), infiltrative and/or massive (infiltrating pattern of growth and/or a huge mass with a diameter  $> 10$  cm and an undefined boundary)<sup>[16]</sup>. The tumor size of expanding nodules was also measured (in cases of multinodular tumors, the largest one was measured).

HCC stage was scored according to the BCLC staging system<sup>[11]</sup>, recently validated by the AASLD<sup>[7]</sup>.

### Statistical analysis

Univariate associations were tested using the Pearson  $\chi^2$  test for proportions. Multivariate logistic regression models were fitted. All tests were two-sided with a significance level of  $P < 0.05$ .

Survival was calculated from the time of cancer diagnosis to death, with values censored at the date of the last follow up. The Kaplan-Meier method was used to estimate the cumulative probability of survival according to surveillance (yes *vs* no), BCLC stage (very-early and early *vs* others) and treatment (yes *vs* no). Difference between survival curves was assessed using the Log-Rank test; a  $P$  value  $< 0.05$  was considered significant.

A Cox proportional hazard model was fitted to test the role of prognostic factors associated with probability of death in the univariate analysis. All statistical analyses were performed using the SAS statistical package (SAS Institute, Cary, NC, United States).

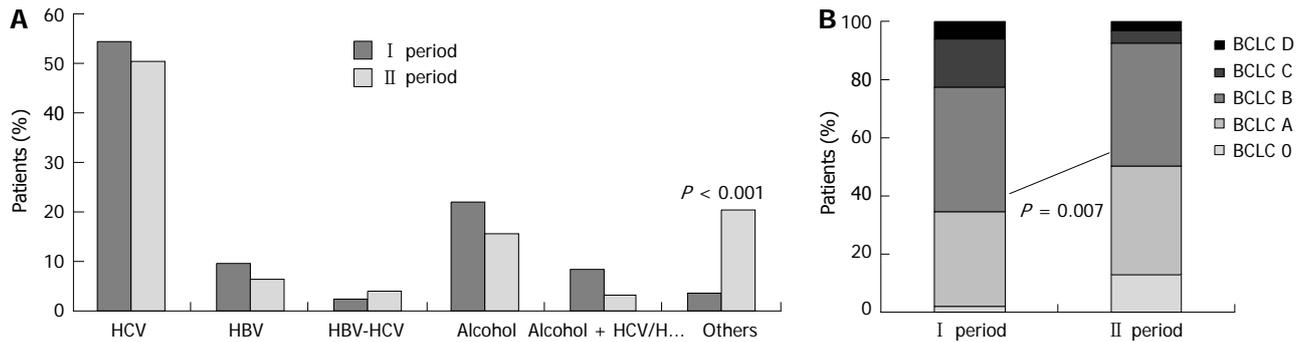

## RESULTS

Two hundred and seventy-three consecutive HCC patients was identified over the study period, but 17 patients were admitted to different health care facilities and were excluded because of difficulty in accessing to medical records and clinical data (Figure 1).

Ultimately, 256 HCC patients were included, 133 in the first group (2000-2005) and 123 in the second group (2005-2010).

### Clinicopathological features

The median age was 70-year-old (range 32-92 years), with no difference between the two groups. The male/female ratio was 182/74. Chronic liver disease was present in 252 cases (98.4%); cirrhosis in 234 (91.4%) and chronic hepatitis in 18 cases (7%). Four patients presented histologically normal livers.

**Figure 2** Different liver disease etiologies and distribution of Barcelona Clinic Liver Cancer stages in the first (I) period (2000-2005) and in the second (II) period (2005-2010). A: Different liver disease etiologies; B: Distribution of Barcelona Clinic Liver Cancer (BCLC) stages. HCV: Hepatitis C virus; HBV: Hepatitis B virus.

According to the Child-Pugh score, 159 cirrhotic patients (62.1%) were class A, 83 patients (32.4%) were class B and 14 patients (5.5%) were class C. Comparing the two groups, there were more class A patients in the second period (67 cases *vs* 92 cases,  $P < 0.001$ ). The distribution of different Child classes was not related to gender ( $P = 0.41$ ) or to age ( $P = 0.37$ ), but Child class B was more represented among alcoholic patients ( $P = 0.007$ ).

The most common cause of liver disease was HCV infection (134 cases, 52.3%), with a higher incidence in women than in men ( $P < 0.001$ ). The second most common HCC risk factor was alcoholic liver disease (48 cases, 18.7%), more frequently in men than in women ( $P = 0.01$ ). HBV infection was identified in 21 cases (8.2%), and an HBV-HCV infection was present in only eight patients (3.1%). Moreover, 15 patients presented a virus infection (6 patients with HBV infection and 9 patients with HCV infection) associated with alcohol consumption. Finally, in 30 cases, the cause of liver disease was different: 4 cases presented a diagnosis of primary biliary cirrhosis (1.6%), 2 cases of autoimmune hepatitis (0.8%), 3 cases of hereditary hemochromatosis (1.2%). Twenty-one cases (8.2%) presented only type 2 diabetes mellitus as potential risk factor for liver disease; however, none of these patients underwent a liver biopsy to confirm the presence of NAFLD-NASH. Comparing the two time periods by etiology (Figure 2A), we noticed a decreasing trend of HCV-related HCCs (72 cases *vs* 62 cases,  $P = 0.63$ ) in the second period, with a parallel increase of HCCs not related to viral infection nor to alcohol (5 cases *vs* 25 cases,  $P < 0.001$ ); in particular, there were significantly more patients with diabetes and HCC in the second period (3 cases *vs* 18 cases,  $P < 0.001$ ).

The diagnosis of HCC was made by histology and/or cytology in 55 patients and by imaging in 201 cases.

Alpha-fetoprotein (AFP) was  $> 100$  ng/dL in 59 cases (23%) and  $> 200$  ng/dL in 74 cases (28.9%), while in the remaining patients, the AFP value was not available.

Sixty-one cases (23.8%) were diagnosed in patients undergoing semiannual US surveillance, while the remaining 195 cases (76.2%) were diagnosed in patients occasionally submitted to US or during an US follow-up at an interval longer than 6 mo. Adjusting for age, gender, etiology and

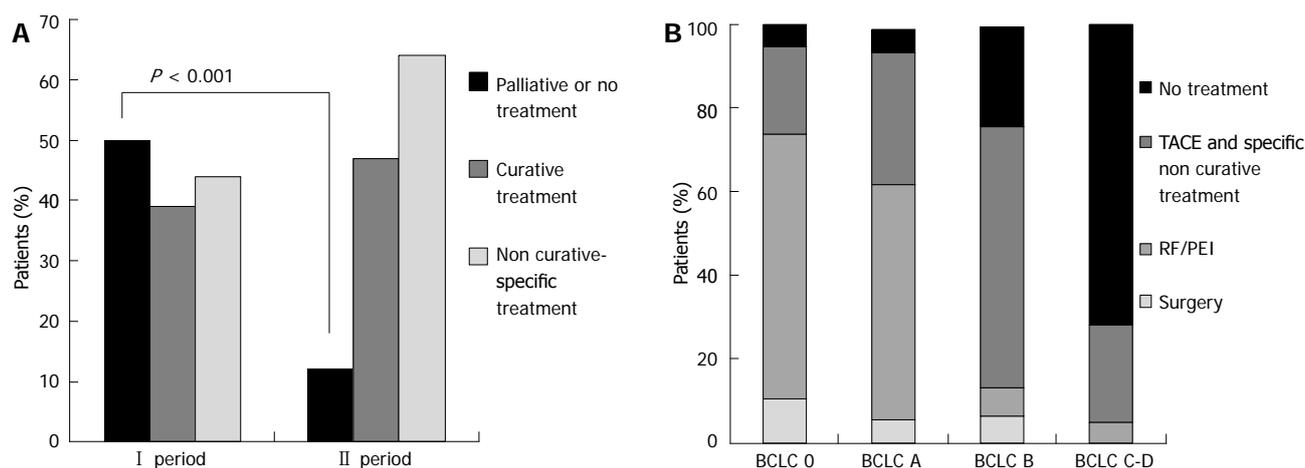

Child-Pugh class, the probability to undergo surveillance was inferior among alcoholic patients ( $P = 0.002$ ) and patients with “other causes” of liver disease ( $P < 0.001$ ). Comparing the two groups and after adjusting for age, gender, etiology, surveillance was more relevant in the second period than in the first ( $P = 0.01$ ).

At the time of diagnosis, most HCCs were unifocal (122 cases, 47.7%), 55 HCCs were paucifocal (21.4%), 62 HCCs were multifocal (24.3%) and 17 HCCs were massive (6.6%). The most common pattern of presentation of HCC over the whole study period was a single nodule more than 3 cm, but less than 5 cm, in diameter (128 cases, 50%). In the multivariate analysis, the probability of discovering a unifocal HCC and an HCC  $< 3$  cm in diameter was higher in patients undergoing surveillance ( $P = 0.001$  and  $P = 0.01$ , respectively) as well as in the second group ( $P = 0.02$  and  $P = 0.001$ , respectively). Portal thrombosis was detected in 29 patients (11.3%), more commonly in young patients ( $< 65$  years,  $P = 0.045$ ), in Child class B and C patients ( $P = 0.017$ ) and in multifocal HCCs ( $P = 0.02$ ). Extra-hepatic metastases were present in 19 patients (7.4%), whereas ascites were detected in 68 cases (26.6%).

Patients were grouped into five different stages according to the BCLC system (Figure 2B). Nineteen patients (7.4%) belonged to stage BCLC 0 (very-early), 89 (34.7%) to stage BCLC A (early), 109 (42.6%) to stage BCLC B (intermediate), 27 (10.6%) to stage BCLC C (advanced) and 12 (4.7%) to stage BCLC D (terminal). In the multivariate analysis, the probability of discovering a very early/early HCC (BCLC 0 or A) was higher in patients undergoing regular 6-mo surveillance ( $P = 0.003$ ) and in the second period ( $P = 0.007$ ).

### Treatment

Sixty-two patients (24.2%) received palliative care or no therapy. The untreated patient cohort presented with more advanced HCC (BCLC B  $P = 0.003$ ; BCLC C-D  $P < 0.001$ ) and a more elevated bilirubin value ( $P = 0.05$ ). There was a slight, but non-significant, trend to treat fewer women than men ( $P = 0.079$ ), and patients aged  $> 65$  years ( $P = 0.053$ ). Treatment distribution was not related to etiology.

**Figure 3** Treatment distribution in the two different periods and different Barcelona Clinic Liver Cancer stages. A: Treatment distribution comparing the two 5-year periods (2000-2005 vs 2005-2010); B: Distribution of treatments in different Barcelona Clinic Liver Cancer (BCLC) stages. TACE: Trans-arterial chemoembolization; RF/PEI: Radiofrequency/percutaneous ethanol injection.

Comparing the two 5-year periods, in the first period 50 patients (37.6%) did not receive any specific treatment for HCC, whereas in the second period, only 12 patients received no specific treatment (9.8%,  $P < 0.001$ ) (Figure 3A). This decrease was accounted for mainly by HCCs in the intermediate-advanced stage (BCLC B,  $P = 0.007$ ; BCLC C-D,  $P = 0.01$ ).

One hundred and ninety-four patients (75.8%) received HCC-specific treatment. During 2000-2005, 83 patients (62.4%) received a specific treatment, compared to 111 patients (90.2%) during 2005-2010. When adjusting for gender, age, etiology, BCLC stage and surveillance, the probability to receive specific treatment was higher in the later time period ( $P < 0.001$ ).

Among treated patients, 86 (44.3%) underwent curative procedures: surgical resection in 14 cases, percutaneous ablation in 70 cases [percutaneous ethanol injection in five cases, radiofrequency (RF) in 65 cases], and orthotopic liver transplantation (OLT) only in two cases. In three cases it was impossible to perform RF despite the initial indication because of the onset of pain during the procedure (two cases) or HCC location. These three patients underwent trans-arterial chemoembolization (TACE). In 2000-2005, 39 of 83 treated patients (47%) underwent a curative treatment; in the second period it was 47 of 111 treated patients (42.3%,  $P = 0.61$ ). Interestingly, over the entire study period, only 86 of 108 patients (79.6%) suitable for curative treatment according to BCLC stage effectively underwent it, whereas 15 patients (14%) underwent TACE and seven patients (6.5%) did not receive any specific treatment. In multivariate analysis, curative treatments were less probable in the intermediate-advanced stage (BCLC B,  $P = 0.01$ ; BCLC C-D,  $P = 0.007$ ), but there was no difference in curative treatment distribution according to gender, age, etiology and surveillance. In 2000-2005, 69.6% of potentially curable cases underwent a curative treatment, while 21.7% received only TACE and the remaining 8.7% did not receive any specific treatment. In 2005-2010, the

proportion of treated patients decreased to 61.3% ( $P = 0.04$ ), with 32.3% of potentially curable patients receiving TACE and 6.4% not receiving any treatment.

Over the entire study period, among treated patients, 108 (55.6%) underwent non-curative specific treatment: TACE (conventional or Drug-Eluting-Beds TACE) was performed in 90 cases, selective internal radiotherapy (SIRT) in four cases, chemotherapy and/or hormone-therapy in 14 cases. Interestingly, 44 patients who underwent TACE (48.8%) were in BCLC 0-A, *i.e.*, in curable stages (Figure 3B).

At multivariate analysis, TACE application was more common in patients aged  $< 65$  years ( $P = 0.04$ ), while it was less common in advanced-terminal stage (BCLC C-D  $P = 0.03$ ) and in patients with bilirubin  $> 2$  mg/dL ( $P = 0.02$ ); there was no difference in TACE application according to gender, etiology or surveillance.

Thirty-four patients received TACE (77.4% of a total of 44 patients receiving specific non-curative treatment; seven patients underwent chemotherapy and three patients underwent hormone-therapy) in the first period and 56 (87.5% of a total of 64 patients receiving specific non-curative treatment; four patients underwent chemotherapy and four patients underwent SIRT) in the second period ( $P = 0.25$ ). However, after adjusting for gender, age, etiology, BCLC stage and surveillance, the probability to receive TACE was higher in the second period ( $P = 0.01$ ). TACE application during the second period increased mainly for BCLC B ( $P = 0.001$ ), but also in BCLC 0-A ( $P = 0.04$ ).

Only 6 patients were treated with Sorafenib, all of them during the second period.

The prevalence of post-embolization syndrome was 20.4% (50 cases over 245 loco-regional procedures), with no significant differences between the two groups ( $P = 0.07$ ). Interestingly, in the first period, an antibiotic therapy (without any clinical and/or laboratory suspicion of infectious complication) was started in only six cases (31.6% of all cases), while in the second period, antibiot-

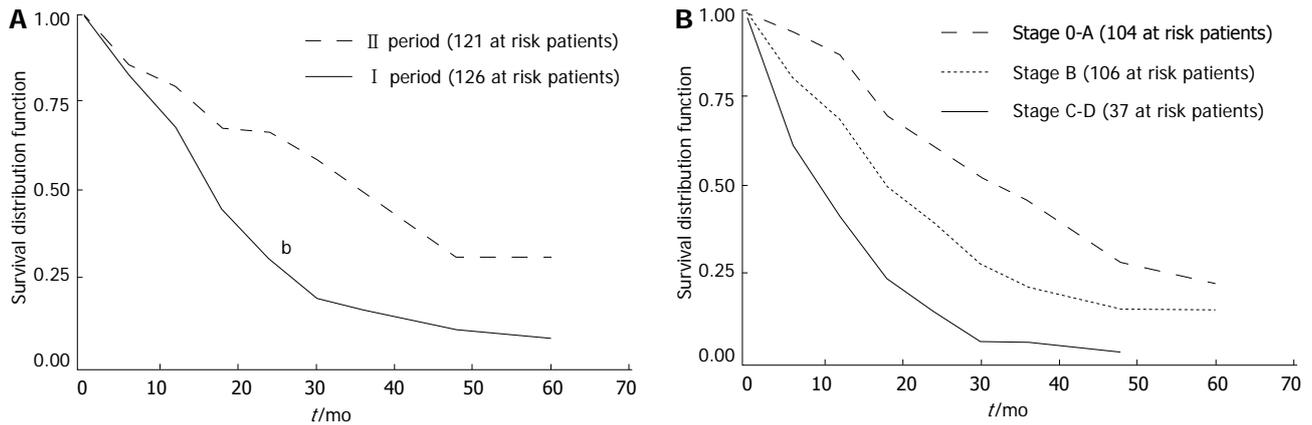

Figure 4 Survival in the two different periods, different Barcelona Clinic Liver Cancer stages. A: Survival in the two different periods, I = (2000-2005) vs II (2005-2010), <sup>b</sup>*P* < 0.01 vs II period; B: Survival in different Barcelona Clinic Liver Cancer stages.

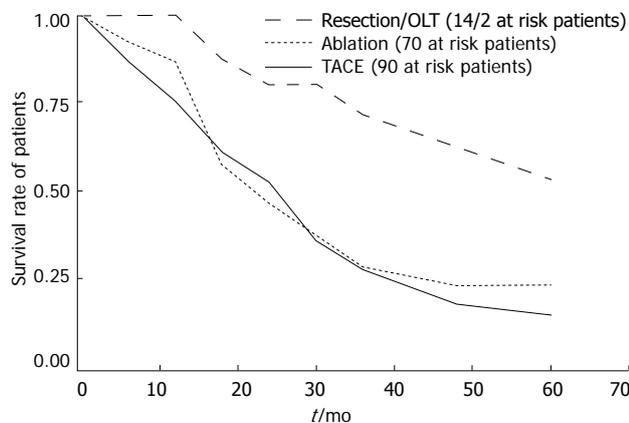

Figure 5 Survival according to treatment. OLT: Orthotopic liver transplantation; TACE: Trans-arterial chemoembolization.

ics treatment was administered to 14 patients (45.2% of all cases) (*P* = 0.5).

**Survival**

During follow up, nine patients (3.5%; seven patients from the first group and two from the second group) dropped out of the study. By December 31<sup>st</sup>, 2010, 172 patients (67.2%) had died and 75 patients (29.3%) were still alive.

The overall median survival from diagnosis was 22.4 mo (range 0-125 mo). Factors associated with better survival in HCC patients were diagnosis in the second period (*P* < 0.01) (Figure 4A), early BCLC stage (*P* < 0.01) (Figure 4B), and treatment (both curative treatments and TACE, *P* < 0.05) (Figure 5).

On the other hand, age (*P* = 0.17) and surveillance (*P* = 0.20) were not significantly associated with a better outcome (Table 1).

In the multivariate analysis (Table 2) only treatment (both curative treatments and TACE: HR = 0.37; 95%CI: 0.24-0.57) and BCLC stage (B *vs* A: HR = 1.50; 95%CI: 1.03-2.19; C-D *vs* A: HR = 1.75; 95%CI: 1.01-3.03) emerged as significant predictors of survival, while age,

gender and surveillance were not significantly associated with a better outcome; patients with a history of alcohol-related liver disease showed a trend toward an increased mortality, but this did not reach the level of statistical significance (alcohol *vs* viral infection HR = 1.43; 95%CI: 0.96-2.12).

Elevated bilirubin and alpha-fetoprotein levels were strongly associated with mortality in the univariate analysis (Table 1). However, they were also highly correlated with BCLC stage and the information was not available for about 20% of the patients. Therefore, they were not included in the multivariate model.

**DISCUSSION**

*Epidemiology*

This long-term retrospective study was carried out in a large series of consecutive HCCs recruited over ten years at Cuneo Hospital, which is the local referral center for the diagnosis and the treatment of HCC.

We believe that our findings closely represent the “real world” of HCC in Northern Italy. The number of cases identified reflects the current incidence of HCC in Italy, as reported in the latest epidemiological studies<sup>[17]</sup>. In Italy, HCC incidence is supposed to have started to decrease steadily by 2007<sup>[18]</sup>, as a consequence of reduced HCV infection related cirrhosis. We noticed this trend in our study, with an initial decrease of HCCs in more recent years (133 in the first period *vs* 123 in the second period), which may be related to a reduction in HCV-related HCCs. This phenomenon could be confirmed in the coming years through continuous monitoring of our population.

Our data confirmed that HCC occurs in a setting of chronic liver disease in 98% of cases<sup>[13]</sup>. The main risk factor for HCC was HCV infection, as reported in previous Italian series<sup>[19-21]</sup>, followed by alcohol, as in other developed countries<sup>[22]</sup>. Our data showed only a slight decrease in HCV-related HCC over the study period, although this figure probably would have been more relevant taking into account only the two-year extremes. Furthermore, in the second period there was a significant

BCLC: Barcelona Clinic Liver Cancer.

increase in HCCs unrelated to either viral infection or to alcohol. These cases were mainly patients with type 2 diabetes mellitus. This figure might reflect an increased attention to HCC in this specific population as a consequence of recent studies that reported diabetes and obesity as possible independent risk factors for HCC through the development of NAFLD and NASH<sup>[5,23]</sup>. To date, there are no evidence-based recommendations as to whether this group should be screened for HCC, as in other HCC high-risk groups<sup>[7]</sup>. Nonetheless, future data may change this recommendation, and there is increasing interest in this issue in the international literature.

### Clinical features and treatment

Surveillance programs in HCC high-risk populations have led to the early detection of small tumors eligible for curative therapies<sup>[19,24-26]</sup>, which may lead to improved outcomes<sup>[13]</sup>. Surveillance with US every 6 mo for detection of early HCC is therefore applied extensively in clinical practice and is recommended by the guidelines for HCC management<sup>[6,7]</sup>.

However, in our study, less than one-third of HCCs (23.8%) were discovered under surveillance, in agreement with other Italian studies<sup>[27-29]</sup>. On the other hand, surveillance has increased significantly in recent years, probably as a result of increased dissemination of international evidence demonstrating the benefit of surveillance in HCC risk groups. Moreover, in our population, surveillance was inferior in alcoholic patients and in patients with "non-viral/non-alcoholic" cirrhosis. This may be related to poor compliance to strict follow up in the former group, and to a current lack of specific recommendations in the later.

The prognosis in HCC patients is determined by tumor stage, underlying liver function reserve and general

BCLC: Barcelona Clinic Liver Cancer.

health status<sup>[6,7,9]</sup>. The BCLC staging system<sup>[11]</sup> takes into account all these factors, and, to date, it is recommended as the reference staging system for HCC<sup>[7,12]</sup>.

As far as tumor stage is concerned, over the entire study period, the most common HCC presentation pattern was a single nodule with a diameter between 3 and 5 cm; notably, in the 2005-2010 period, there was a significant increase in unifocal HCC and in small HCC (< 3 cm of diameter), as a result of the increased use of surveillance programs. In a previous Italian study<sup>[30]</sup>, multifocal HCCs were more common among multi-etiology cirrhotic patients, while unifocal HCCs were more common among HCV-related cirrhosis and among younger patients (< 65 years). In our study, the morphological pattern at the time of diagnosis was not associated with etiology or age, but multifocal HCC was moderately more prevalent among Child B and C class patients than among Child A class patients. With regard to liver function, the majority of our population was in Child class A, in keeping with other Italian studies<sup>[19,31]</sup>. Moreover, there was an increase in the number of Child class A patients during the second period, which could also be related to the increased use of surveillance.

Finally, as far as HCC staging is concerned, almost half of the population was in BCLC stage B (intermediate stage) at the time of diagnosis. As expected, very-early/early HCCs (BCLC stage 0 and A) were more common in patients who underwent surveillance and, consequently, were present in the 2005-2010 cohort. To date, this is the first Italian study to apply the BCLC staging system; other Italian groups have used the CLIP score<sup>[19-21]</sup>. Given the complexity of HCC management in clinical practice, we strongly emphasize the need to use a common staging system that can easily define patient groups for different therapies and that can stratify them into separate prognosis categories<sup>[7]</sup>. The BCLC staging system meets all these characteristics. We stress that the use of guidelines is very important for providing

patients with the best treatment options.

In our population, the proportion of HCC patients who underwent specific treatment grew significantly during the last period; however, this growth was not associated with an increased use of curative treatments, as we could expect given the higher number of BCLC 0-A patients in the second period, but may be caused by the increased use of non-curative treatments, such as TACE, in intermediate stage HCCs (BCLC B) in recent years. In fact, in our population, potentially curative therapies were underutilized, even among very early/early HCCs. Similar findings have been obtained in previous studies<sup>[21,30,32]</sup>. This may have two possible explanations: firstly, the lack of application of BCLC staging system leading to an incorrect allocation of early HCCs to the proper therapeutic approach; and, secondly, the BCLC staging system does not take into account patients' age, leading to the possibility that, in elderly patients, non-curative treatments were preferred over curative therapies, given the slow HCC growth and the survival benefit provided by non-curative therapies<sup>[33]</sup>.

On the other hand, there was a proportion of patients in our population with intermediate-advanced HCC who underwent curative treatments, namely "overtreated patients", as reported in another Italian series<sup>[30]</sup>.

Among curative therapies, the most common choice was percutaneous ablation with radiofrequency. This switch from resection to the less invasive and less expensive percutaneous ablation therapy is a current practice supported by the good results achieved in terms of survival. In addition, this preference may be related to the relative high median age of our population (70 years, range 32-92 years); indeed, ablation permits a shorter hospital admission with less severe post-operative complications.

Overall, a large proportion of our population received TACE over the ten-year study period. The use of TACE increased significantly during the last years, mainly in intermediate stage HCCs, as a result of current evidence that TACE improves survival in patients who cannot benefit from curative treatment and who do not have severe impairment in liver function, vascular invasion and extra-hepatic diffusion<sup>[13,34,35]</sup>. However, our data shows an increased use of TACE in very-early/early HCC stages, and this trend may be explained by the older median age of this patients' group during the second period, leading to a preference of TACE over curative therapies.

The prevalence of post-embolization syndrome was similar to other series, but in the last years we noticed an increment in antibiotic consumption, despite the absence of signs of infection; this finding underlines the widespread and increasingly frequent inappropriate use of antibiotic treatment in clinical practice.

Liver transplant had a very limited role in the therapy of HCC in our population. Despite a relatively large number of potentially OLT-eligible patients (38 patients, 63% Child-A), only five subjects were submitted to OLT evaluation and two (1%) were definitively transplanted.

This low rate of OLT is hard to explain considering that in Piedmont, three liver transplant centers were available at that time. Consequently, at least in our region, OLT should be regarded as a virtual rather than a real therapeutic option.

Notably, almost one-third of HCC patients did not receive any specific treatment; obviously, untreated patients presented more commonly an intermediate-advanced HCC, and there was a non-significant trend in treating fewer patients aged more than 65 years and women. Nonetheless, the rate of untreated patients decreased during the last period, as a result of the parallel increase in treating intermediate-advanced HCCs with non-curative therapies.

### Survival

As expected, the prognosis of our patients was dictated by liver function, BCLC stage, and diagnosis period.

As far as surveillance is concerned, it was effective in detecting HCCs at an early stage, where curative treatment may be more effective. This fact explains the previously reported survival benefit for patients in surveillance programs<sup>[36]</sup>. Therefore, the effect of surveillance on survival was usually not significant in multivariate analysis after adjusting for these factors in most studies<sup>[37-39]</sup>. In addition, at multivariate analysis, surveillance has not proved to be an independent prognostic factor.

Chen *et al*<sup>[40]</sup> reported that HCC surveillance resulted in early diagnosis of liver cancer, but not in mortality reduction, because therapy was ineffective. We observed a similar scenario, with an increased rate of HCCs diagnosed at an early stage in the last period, but without a parallel increase in application of curative therapies. Therefore, the surveillance program must be accompanied with appropriate treatment options for patients with newly diagnosed HCC, to improve their survival and justify the expense.

With regard to the therapeutic impact on survival, there was an obvious survival benefit in patients that underwent surgery (OLT plus resection) over the TACE group. Ablation was the most extensively applied curative therapy, but there was only a small survival benefit over the TACE group. This fact may be explained by an inappropriate selection of patients for loco-regional therapy (ablation or TACE). Moreover, as reported by Tseng *et al*<sup>[20]</sup>, it is possible that in early HCC the two therapies did not differ in terms of survival, but only in terms of recurrence.

Therapy "*per se*" resulted as an independent favorable prognostic variable in our patients, suggesting that the amenability to treatment identifies a subset of patients with expected better survival.

In conclusion, our cohort study (being in between a population-based and a referral center-based investigation) offers a picture close to what actually occurs in clinical practice. As reported in previous series<sup>[19-21,27,28,30]</sup>, in the real clinical practice, the approach to HCC is far from being adequate, and this tumor remains an undertreated or inappropriately treated complication, despite positive

changes that have occurred during recent years. We stress that this state of affairs should be a stimulus for further implementation of surveillance and improved employment of the various therapeutic opportunities available.

## COMMENTS

### Background

Hepatocellular carcinoma (HCC) is the 5<sup>th</sup> most common cancer and the 3<sup>rd</sup> leading cause of cancer mortality worldwide. In recent decades, a rising incidence has been reported in Europe and United States. Hepatitis B virus and hepatitis C virus infections are known independent risk factors for HCC, as well as alcohol consumption.

### Research frontiers

Approaches to HCC treatment are potentially curative depending on cancer stage, liver function and performance status, as well as on resources and the level of practitioner expertise. The Barcelona Clinic Liver Cancer (BCLC) staging system has come to be widely accepted in clinical practice as the reference system to stratify patients into separate prognostic categories and to suggest the treatment options according to the stage.

### Innovations and breakthroughs

Data showed a significant increase in HCCs related to neither viral infection nor alcohol; these cases were mainly patients with type 2 diabetes mellitus. This figure might reflect an increased attention in research HCC in this specific population, as a consequence of recent evidence reporting diabetes and obesity as possible independent risk factors for HCC through the development of non-alcoholic steatohepatitis and non-alcoholic fatty liver disease.

### Applications

The study identified the increased use of surveillance in the latest years, probably as a result of increasing diffusion and knowledge of international evidence about related benefits. However, at multivariate analysis, surveillance has not proved to be an independent prognostic factor. In this population study, potentially curative therapies were underutilized, and this should be a stimulus to a more adequate employment of different therapeutic opportunities.

### Peer review

The authors present an interesting series of patients with HCC treated over 10 years in a single institution. Changes in epidemiology and a lack of strict adherence to the BCLC treatment recommendations follow other recently published series.

### Abstract

**AIM:** To evaluate the functional differences between the 2 liver lobes in non-cirrhotic patients by using computed tomography/<sup>99m</sup>Tc-galactosyl human serum albumin (CT/<sup>99m</sup>Tc-GSA) single-photon emission computed tomography (SPECT) fusion images.

**METHODS:** Between December 2008 and March 2012, 264 non-cirrhotic patients underwent preoperative liver function assessment using CT/<sup>99m</sup>Tc-GSA SPECT fusion images. Of these, 30 patients, in whom the influence of a tumor on the liver parenchyma was estimated to be negligible, were selected. Specifically, the selected patients were required to meet either of the following criteria: (1) the presence of an extrahepatic tumor; or (2) presence of a single small intrahepatic tumor. These 30 patients were retrospectively analyzed to calculate the percentage volume (%Volume) and the percentage function (%Function) of each lobe. The ra-

tio between the %Function and %Volume (function-to-volume ratio) of each lobe was also calculated, and the ratios were compared between the 2 lobes. Furthermore, the correlations between the function-to-volume ratio and each of 2 liver parameters [lobe volume and diameter ratio of the left portal vein to the right portal vein (LPV-to-RPV diameter ratio)] were investigated.

**RESULTS:** The median values of %Volume and %Function were 62.6% and 67.1% in the right lobe, with %Function being significantly higher than %Volume ( $P < 0.01$ ). The median values of %Volume and %Function were 31.0% and 28.7% in the left lobe, with %Function being significantly lower than %Volume ( $P < 0.01$ ). The function-to-volume ratios of the right lobe (1.04-1.14) were significantly higher than those of the left lobe (0.74-0.99) ( $P < 0.01$ ). The function-to-volume ratio showed no significant correlation between the lobe volume in either lobe. In contrast, the function-to-volume ratio showed significant correlations with the LPV-to-RPV diameter ratio in both lobes (right lobe: negative correlation,  $r_s = -0.37$ ,  $P = 0.048$ ; left lobe: positive correlation,  $r_s = 0.71$ ,  $P < 0.001$ ). The function-to-volume ratio in the left lobe tended to be higher, and that in the right lobe tended to be lower, in accordance with the increase in the LPV-to-RPV diameter ratio.

**CONCLUSION:** CT/<sup>99m</sup>Tc-GSA SPECT fusion images demonstrated that the function of the left lobe was significantly decreased compared with that of the right lobe in non-cirrhotic livers.

CT/<sup>99m</sup>Tc-GSA SPECT fusion images demonstrate functional differences between the liver lobes. *World J Gastroenterol* 2013; 19(21): 3217-3225 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i21/3217.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i21.3217>

## INTRODUCTION

Preoperative evaluation of future remnant liver function is critical for patients undergoing hepatic surgery<sup>[1]</sup>. Overestimation of the remnant liver function can lead to life-threatening postoperative hepatic failure, and its underestimation can lead to a lost opportunity for potentially curative surgery. Conventionally, post-hepatectomy remnant liver function has been estimated preoperatively using computed tomography (CT) volumetry<sup>[1-4]</sup>. CT can provide precise anatomical information, and the remnant liver volume, measured by CT volumetry, has been reported to be an effective predictor of hepatic dysfunction after hepatectomy<sup>[1,5-8]</sup>. However, the indirect estimation of liver function by CT volumetry is reliable only when the function is assumed to be homogenous over the whole liver<sup>[6,7]</sup>. Recent reports on liver scintigraphy showed that regional hepatic function could be significantly decreased under various conditions, such as unilateral portal flow decrease or biliary stenosis<sup>[9-15]</sup>, although regional liver volume was maintained. Such observations indicate the difficulty associated with assuming strict homogeneity of the whole liver function. Therefore, accurate estimation of residual liver function, rather than estimation of residual liver volume, is more important for predicting the postoperative hepatic functional reserve<sup>[16,17]</sup>.

<sup>99m</sup>Tc-galactosyl human serum albumin (<sup>99m</sup>Tc-GSA) single-photon emission CT (SPECT) was developed to facilitate investigations of regional hepatic function. Several reports have proved that <sup>99m</sup>Tc-GSA SPECT is more suitable for evaluating remnant liver function than CT volumetry<sup>[14,18-20]</sup>. Further improvements have resulted in the recent development of a new SPECT examination method, CT/<sup>99m</sup>Tc-GSA SPECT fusion examination. A disadvantage of conventional <sup>99m</sup>Tc-GSA SPECT was poor anatomical resolution, and this newly developed SPECT has a tremendously improved anatomical resolution owing to the fusion of CT and <sup>99m</sup>Tc-GSA SPECT. Recent reports have indicated that accurate regional function, based on precise anatomical information, could be evaluated using this technique<sup>[11,6,21,22]</sup>.

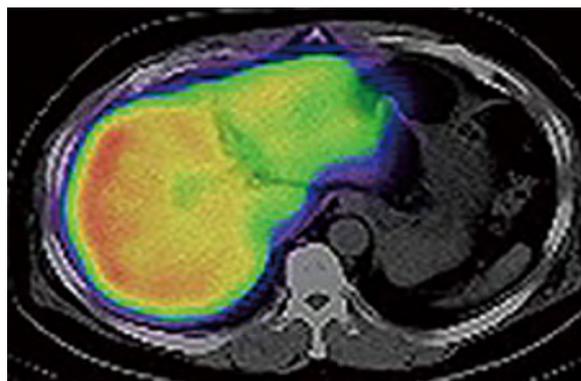

Figure 1 Computed tomography/<sup>99m</sup>Tc-galactosyl human serum albumin single-photon emission computed tomography fusion image in a 58-year-old male with early gallbladder cancer. The uptake of <sup>99m</sup>Tc-galactosyl human serum albumin was markedly decreased in the interior portion of the left lobe. This computed tomography image was at the level of the center of the left lobe, and was neither the cranial edge nor the caudal edge of that lobe.

In our department, remnant liver volume and function have been routinely estimated preoperatively by using CT/<sup>99m</sup>Tc-GSA SPECT fusion images since December 2008, resulting in the realization that the function of the interior portion of the left lobe was diminished compared with that of the right lobe, despite the absence of anatomical conditions suggestive of liver function heterogeneity (Figure 1). This study aimed to evaluate the functional differences between the 2 main lobes in non-cirrhotic livers. The percentage volume (%Volume) and percentage function (%Function) of each lobe were calculated using fusion images, and these data were compared between lobes.

## MATERIALS AND METHODS

### Patients

Between December 2008 and March 2012, 264 non-cirrhotic patients underwent preoperative liver function assessment by using CT/<sup>99m</sup>Tc-GSA SPECT fusion imaging. Cirrhotic patients were not included in this study because it is well known that the hemodynamics of bilateral portal flow and the bilateral lobe volumes are clearly different between non-cirrhotic and cirrhotic livers<sup>[23,24]</sup>. These differences might greatly influence the function of each lobe, and therefore, we investigated only non-cirrhotic livers in the current study. Each patient provided informed consent and our local ethics review committee approved the study. Of these patients, those in whom the influence of a lesion on the liver parenchyma was estimated to be negligible were selected for further study. Specifically, the selected patients were required to meet either of the following criteria: (1) presence of an extrahepatic tumor, where the tumor was close to the liver surface and had been preoperatively estimated to require hepatectomy, but both intraoperative and pathological findings showed the absence of direct tumor invasion into the liver; or (2) presence of small, intrahepatic tumors; those with large tumors were eliminated because

such tumors might compress the surrounding liver parenchyma, resulting in a significant decrease in function. Eligible patients who met criterion 2 were limited to those with a single, small (< 3 cm diameter) tumor. Furthermore, the tumor had to be located on the liver surface and not in contact with a major branch of portal vein or hepatic vein. Thirty-six patients met either of these 2 criteria. Three patients treated by transcatheter arterial embolization and another 3 patients in whom the diagnosis could not be confirmed histopathologically because of the absence of surgery were excluded; thus, a total of 30 patients were included in this retrospective study. All these 30 patients underwent 4-phase multidetector-row CT (1 unenhanced image and 3 contrast-enhanced images) preoperatively, which confirmed that none had anatomical abnormalities, such as portal venous occlusion, hepatic artery stenosis, or intrahepatic biliary stenosis. Furthermore, it was also confirmed that there was no heterogeneous hepatic parenchymal enhancement in 3 contrast-enhanced images from each patient. The clinical characteristics of the 30 patients are shown in Table 1. Fifteen patients met criterion 1 [11 with early gall bladder cancer without liver invasion (Figure 2A), 1 with a gastric gastrointestinal stromal tumor (Figure 2B), 1 with peritoneal dissemination of ovarian cancer (Figure 2C), 1 with intra-abdominal recurrence of gastric cancer, and 1 with extrahepatic bile duct cancer, without jaundice]. Fifteen

patients met criterion 2 [4 with hepatocellular carcinoma, 9 with liver metastasis (Figure 2D), and 2 with intrahepatic cholangiocarcinoma]. Each tumor was confirmed to meet the inclusion criteria, on the basis of the examination of surgically resected specimens.

### CT/<sup>99m</sup>Tc-GSA SPECT fusion examination

All patients underwent CT/<sup>99m</sup>Tc-GSA SPECT fusion examination with a Symbia T6 scanner (Siemens, Munich, Germany) (Figure 3). This instrument combines variable angle dual detector SPECT with 6-slice CT for rapid, accurate attenuation correction and precise localization. The instrument also enables the seamless transition from a SPECT examination to a CT examination, and both SPECT and CT images could be obtained in a single examination without the need for a position change.

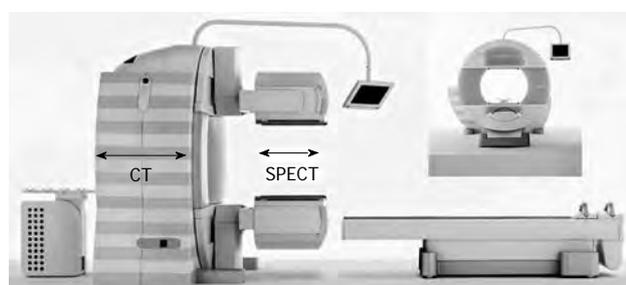

After overnight fasting, the patient was placed in a supine position. Cardiac and respiratory synchronization were not used in this modality. Instead, to minimize the possibility of artifacts due to cardiac pulsation and respiratory motion, the patients were encouraged to rest and take a small, slow breath before image acquisition. <sup>99m</sup>Tc-diethylenetriaminepentaacetic acid-GSA (Nihon Medi-Physics, Tokyo, Japan) (185 MBq/3 mg) was injected into an antecubital vein. SPECT data acquisition (60 steps of 20 s/step, 360°, 128 × 128 matrix) was started 20 min after the injection with a low-energy, high-resolution collimator; the entire study duration was approximately 30 min. The reconstruction algorithm for SPECT was a 3-dimensional ordered subset expectation maximization, with attenuation and scatter corrections. Following SPECT examination, non-enhanced CT images were obtained under standard conditions of 130 kV, 345 mA, 12 mm table feed per rotation, 0.6-s gantry rotation time, 0.6-mm collimation, and 1-mm reconstruction. CT images were reconstructed using a standard reconstruction algorithm with a 166-cm field-of-view of the target sites. The SPECT and CT images were fused automatically using the embedded Siemens common platform software Syngo MI workplace. SPECT slice data were retrieved through Digital Imaging and Communications in Medicine (DICOM), and SPECT slices were converted to a CT-like data volume for the fusion of the SPECT and CT images.

### Image analysis

All fusion images were evaluated retrospectively by hepatobiliary pancreatic surgeons with 13 and 24 years of experience. The extent of each lobe was manually circled on the non-enhanced CT image, with consensus between the evaluators, and 3 radiologists in our institution checked the accuracy in each case (Figure 4A and B). The extent of the left and right lobes was determined using anatomical landmarks, such as the middle hepatic vein and gallbladder bed, and by confirming the portal branch of segments 4, 5 and 8. The caudate lobe was excluded from the range of each lobe. The boundary between the right lobe and the caudate lobe was defined by the line connecting the bifurcation of the right portal vein (RPV)

**Figure 2** Computed tomography images of patients meeting criterion 1 or 2. A: An 82-year-old man with early gallbladder cancer, in whom the preoperative computed tomography (CT) scan showed a tumor localized in the gallbladder (white arrow); B: A 59-year-old man with gastric gastrointestinal stromal tumor, in whom a preoperative CT scan showed that the tumor had invaded the left lateral segment of the liver. However, no invasion into the liver was detected intraoperatively (circle); C: A 64-year-old woman with peritoneal dissemination of ovarian cancer, in whom a preoperative CT scan showed an implanted small tumor on the surface of the left caudate lobe (black arrow); D: A 62-year-old woman with liver metastasis, in whom a preoperative magnetic resonance image showed a small (5 mm) tumor on the liver surface (circle).

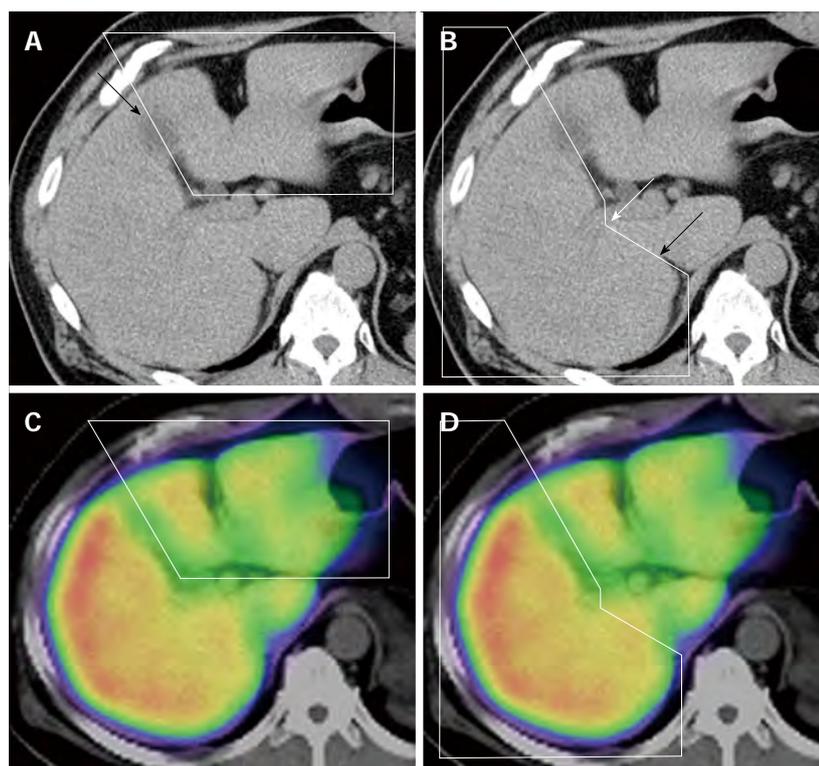

**Figure 3** Integrated computed tomography and single-photon emission computed tomography system, consisting of variable angle dual-detector single-photon emission computed tomography and 6-slice computed tomography. The system allows the seamless transition from a single-photon emission computed tomography (SPECT) examination to a computed tomography (CT) examination.

and the right wall of the inferior vena cava<sup>[25]</sup> (Figure 4B). The extent of each lobe, determined from the CT image, was automatically projected on the SPECT/CT fusion image (Figure 4C and D). The volume of each lobe was automatically determined using the Syngo software. The %Volume of each lobe was also automatically determined by dividing the volume of each lobe by the total liver volume. In the case of intrahepatic small tumors (criterion 2), tumor volumes were subtracted from the liver volumes. The %Function of each lobe was also automatically calculated by dividing the scintillation counts

in each lobe by the total scintillation counts in the whole liver. The ratio between the %Function and %Volume (function-to-volume ratio) of each lobe was calculated, and the ratios were compared between the 2 lobes.

#### Clinical liver function parameter

Serum liver function tests, including albumin level, bilirubin level, platelet count, prothrombin time, and the presence or absence of hepatitis virus were investigated in all patients. Two other parameters that might influence <sup>99m</sup>Tc-GSA accumulation in the liver were also measured on CT images. The first parameter was the degree of fat deposition, which was assessed by measuring the CT attenuation values [in Hounsfield units (HU)] on unenhanced CT images<sup>[26,27]</sup>. We delineated 12 regions of interest (ROIs) of 1 cm diameter within the liver. One ROI was defined in 4 sectors (right posterior, right anterior, left medial, and left lateral) at 3 representative levels. The levels consisted of the confluence of the right hepatic vein, the umbilical portion, and the right posterior portal vein. While defining ROIs, special attention was placed on excluding cystic areas and the vessels. The mean attenuation value of 6 ROIs in the right posterior and right anterior sectors was defined as the attenuation value of the right lobe, and that of the 6 ROIs in the left medial and lateral sector was defined as the attenuation value of the left lobe. The second parameter was the left portal vein (LPV)-to-RPV diameter ratio. The diameters of the portal veins were measured on

**Figure 4** Range of each lobe on the computed tomography and computed tomography/single-photon emission computed tomography fusion image. A: The extent of the left lobe is manually circled on the non-enhanced computed tomography (CT) image. The arrow shows the gallbladder bed; B: The extent of the right lobe on the non-enhanced CT image. The boundary between the right lobe and the caudate lobe was defined by the line connecting the bifurcation of the right portal vein (white arrow) and the right wall of the inferior vena cava (black arrow); C and D: The extent of each lobe determined from the CT image was automatically projected on the single-photon emission computed tomography/CT fusion image (C: Left lobe; D: Right lobe).

the contrast-enhanced CT images, and the LPV-to-RPV diameter ratio was calculated.

### Statistical analysis

The Wilcoxon signed-rank test was used for the following comparisons: (1) comparison of 2 liver parameters (the attenuation value on an unenhanced CT image and the diameter of the portal veins on an enhanced CT image) between the 2 lobes; (2) comparison of the diameters of the LPV and the RPV; (3) comparison of the %Volume and %Function values in each lobe; and (4) comparison of the function-to-volume ratio between the 2 lobes. The correlations between the function-to-volume ratio and the 2 liver parameters (lobe volume and LPV-to-RPV diameter ratio) were assessed using Spearman's correlation coefficient. Data were analyzed using SPSS Statistics 19 (IBM, Armonk, NY, United States), and  $P < 0.05$  was considered statistically significant.

## RESULTS

### Serum liver function test

All values of the serum liver function tests were within the reference ranges for all patients (Table 1). Hepatitis B virus antigen and hepatitis C virus antibody were positive in 1 and 5 patients, respectively. However, none of them were associated with active hepatitis, and none of them showed clinical symptoms of hepatitis. There were no cases of non-B, non-C hepatitis.

### Degree of fat deposition in each lobe

The attenuation value of the right lobe ranged from 35.0 to 70.5 HU (median, 56.3 HU), and that of the left lobe ranged from 39.5 to 73.0 HU (median, 57.5 HU). Only 2

of 30 patients showed severe fatty change with an attenuation value of  $< 40$  HU. There were no significant differences between the attenuation values of the 2 lobes.

### Diameter of the LPV and the RPV

The diameter of the RPV ranged from 6.6 to 13.6 mm (median, 10.2 mm), and that of the LPV ranged from 4.5 to 10.8 mm (median, 8.4 mm). The diameters of the RPV were significantly larger than those of the LPV ( $P < 0.001$ ). The LPV-to-RPV diameter ratios ranged from 0.5 to 1.26.

### Comparison of the %Volume and %Function in each lobe

The extent of each lobe could be clearly defined on the CT image, and both %Volume and %Function in each lobe could be calculated for all patients. The %Volume and %Function of the right lobe ranged from 51.5% to 77.8% (median, 62.6%) and from 55.6% to 83.8% (median, 67.1%), respectively (Figure 5); the %Function was significantly higher than the %Volume in the right lobe ( $P < 0.01$ ). The %Volume and %Function in the left lobe ranged from 20.2% to 44.2% (median, 31.0%) and from 17.4% to 42.0% (median, 28.7%), respectively (Figure 5); the %Function was significantly lower than the %Volume in the left lobe ( $P < 0.01$ ).

### Comparison of the function-to-volume ratio between lobes

The function-to-volume ratio of the right lobe ranged from 1.04 to 1.14 (median, 1.08), and this ratio was  $> 1.0$  in all patients (Figure 6). The function-to-volume ratio of the left lobe ranged from 0.74 to 0.99 (median, 0.92), and this ratio was  $< 1.0$  in all patients. The function-to-volume ratios of the right lobe were significantly higher than those of the left lobe ( $P < 0.01$ ).

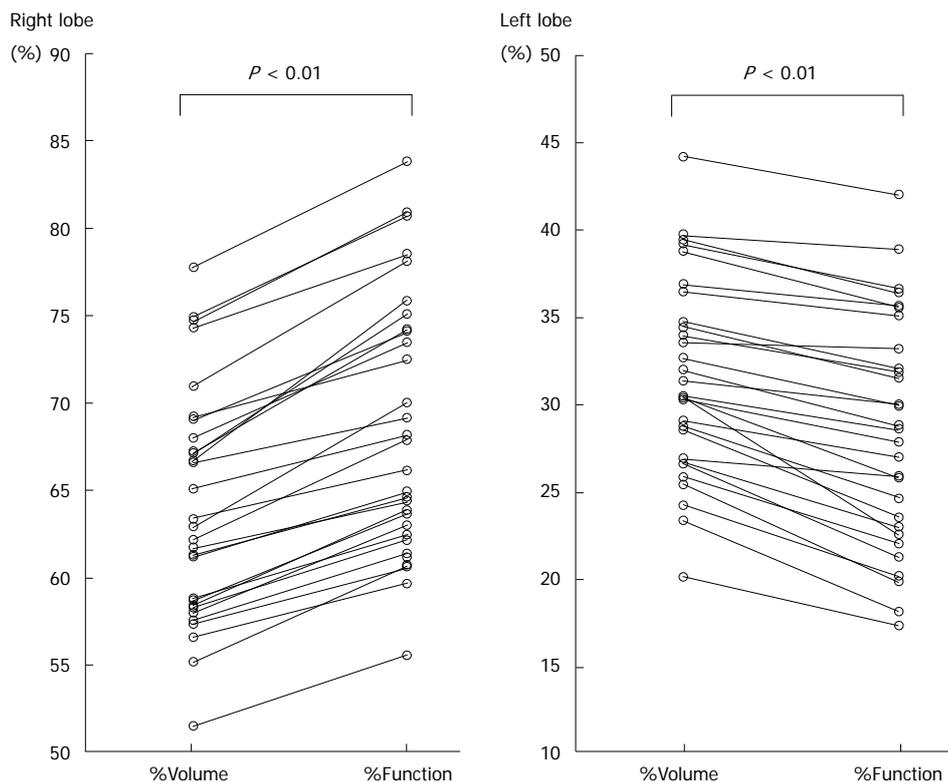

Figure 5 Percentage volume and percentage function of each lobe. The %Function was significantly higher than the %Volume in the right lobe ( $P < 0.01$ ). The %Function was significantly lower than the %Volume in the left lobe ( $P < 0.01$ ).

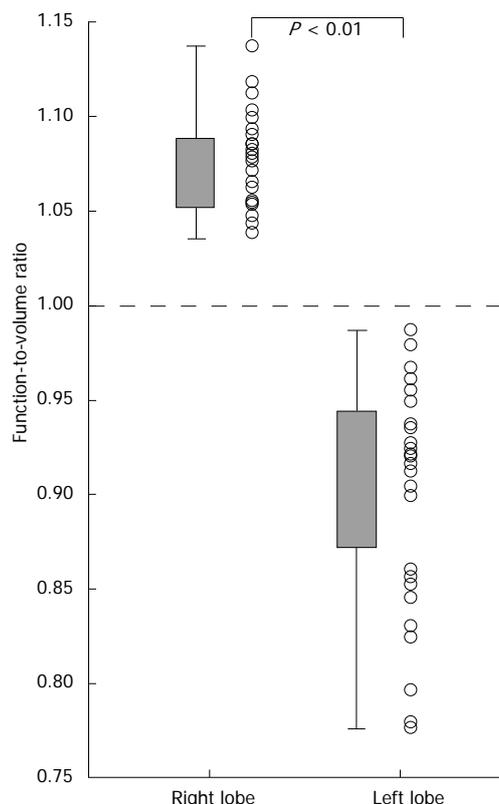

Figure 6 Comparison of the function-to-volume ratio between the right and left lobes. The function-to-volume ratios of the right lobe were significantly higher than those of the left lobe ( $P < 0.01$ ).

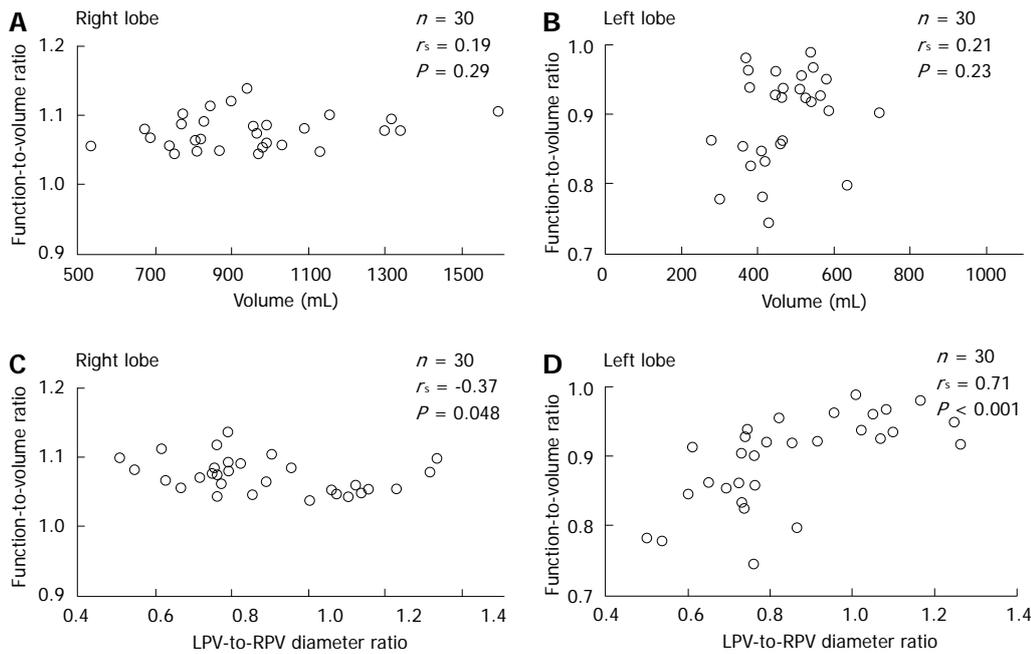

**Correlation between the function-to-volume ratio and 2 liver parameters (lobe volume and LPV-to-RPV diameter ratio)**

The function-to-volume ratio showed no significant cor-

relation with lobe volume in either lobe (right lobe;  $r_s = 0.19$ ,  $P = 0.29$ , left lobe;  $r_s = 0.21$ ,  $P = 0.23$ ). In contrast, the function-to-volume ratio showed a significant correlation with LPV-to-RPV diameter ratio in both lobes (right lobe; negative correlation,  $r_s = -0.37$ ,  $P = 0.048$ , left lobe; positive correlation,  $r_s = 0.71$ ,  $P < 0.001$ ) (Figure 7).

**DISCUSSION**

Conventionally, future remnant liver function after hepatectomy has been estimated using CT volumetry. Simulation by CT volumetry is satisfactory because it has better resolution and can provide precise anatomical information, if the function of the whole liver can be assumed to be homogeneous<sup>[1,5-8]</sup>. However, recent reports on the use of <sup>99m</sup>Tc-GSA scintigraphy have shown that regional hepatic function is significantly decreased when conditions such as biliary stenosis or unilaterally decreased portal flow exist<sup>[9-15]</sup>. The liver parenchyma, the area surrounding the tumor, has also been reported to be damaged by mechanical compression caused by intrahepatic tumors<sup>[5]</sup>. Therefore, accurate estimation of residual liver function, rather than estimation of residual liver volume, is more important for predicting postoperative hepatic functional reserve, and this has led to the development of <sup>99m</sup>Tc-GSA SPECT<sup>[1,6,16,20,28]</sup>. Several studies have shown that preoperative estimates of remnant liver function from <sup>99m</sup>Tc-GSA scintigraphy show better correlation than those from CT volumetry with postoperative liver function tests; therefore, <sup>99m</sup>Tc-GSA scintigraphy provides a better prediction of postoperative liver function<sup>[14,18-20]</sup>. Although this scintigraphic examination is not yet widely used worldwide, it is recognized as a useful modality for

**Figure 7** Correlation between the function-to-volume ratio and 2 liver parameters in each lobe. A and B: The function-to-volume ratio showed no significant correlation with lobe volume in either lobe; C and D: The function-to-volume ratio showed a significant correlation with the ratio of the diameter of the LPV to that of the RPV in both lobes (C: Right lobe, negative correlation; D: Left lobe, positive correlation). LPV: Left portal vein; RPV: Right portal vein.

preoperative liver function assessment in Japan, and we have decided the surgical indication on the basis of the estimated remnant liver function ratio measured by this modality. The plasma clearance rate of indocyanine green (ICGK) was measured preoperatively in each patient, and a patient with a future liver remnant ICGK value (ICGK  $\times$  remnant liver function ratio) of  $> 0.05$  was considered a candidate for hepatectomy<sup>[29]</sup>.

In this study, the volume ratio and the functional ratio of the 2 lobes were accurately measured using the newly developed CT/<sup>99m</sup>Tc-GSA SPECT fusion imaging technique. Although contrast-enhanced CT has usually been employed for volumetry, the anatomical landmarks could be confirmed in all cases in this non-enhanced CT. Therefore, setting the boundary between the 2 lobes was not complicated, and it could be performed reliably with confirmation by radiologists. The functional ratio was approximately 8% higher than the volume ratio in the right lobe and approximately 8% lower than the volume ratio in the left lobe. Furthermore, there were significant correlations between the function-to-volume ratio and the LPV-to-RPV diameter ratio in both lobes. The function-to-volume ratio in the left lobe tended to be higher, and that in the right lobe tended to be lower, in accordance with the increase of the diameter ratio.

This appears to be the first report to describe the functional differences between the 2 hepatic lobes using <sup>99m</sup>Tc-GSA scintigraphy. A few reports on liver scintigraphy with other agents, such as <sup>99m</sup>Tc-dimethyliminodiacetic acid for biliary scintigraphy and radiolabeled colloids for depiction of the reticuloendothelial system, have also shown lower uptake in the left liver lobe than in the right lobe<sup>[30,31]</sup>. The results of this study indicate that postsurgical remnant liver function and the tolerable extent of hepatectomy might change depending on the region of the hepatectomy. Residual liver function might be less after right-sided hepatectomy than after left-sided hepatec-

tomy, even if the hepatectomy volumes were equivalent.

Four possible causative factors for the functional discrepancy between the 2 lobes were estimated. First, the partial volume effect (PVE) of the peripheral part of the liver: the scintillation counts in the left lobe might have been underestimated owing to it being relatively thinner than the right lobe. However, we originally began this research because we realized there was decreased function in the interior portion of the left lobe on the fusion images. Furthermore, if PVE is the main cause of the functional decrease in the left lobe, the function-to-volume ratio should become higher in accordance with the increase in the lobe volume. However, there was no correlation between the lobe volume and the function-to-volume ratio. Second, the effect of tracer accumulation in the heart: to confirm the presence or absence of artifacts from tracer accumulation in the heart, we checked all SPECT images of all 30 patients, and no apparent artifact could be confirmed. Third, heterogeneous fat deposition: we investigated the mean CT attenuation values of the 2 lobes on non-enhanced CT images because the degree of fat deposition might influence the tracer accumulation. However, there were no differences in the degree of fat deposition between the 2 lobes. We concluded that the influences of these 3 factors were not significant, even if they could not be completely excluded from contributing to the functional discrepancy between the 2 lobes. Fourth, the portal flow difference: it is speculated that the difference in the bilateral portal flow might be the cause of the functional discrepancy. It is well known that the bilateral portal veins are developmentally distinct<sup>[32]</sup> and that the blood flow of the LPV is decreased compared with that of the RPV in non-cirrhotic livers<sup>[23,24]</sup>. During the early fetal period, the right and left hepatic lobes are not connected<sup>[32]</sup>. The main portal vein, which flows into the RPV, supplies blood only to the right lobe. The LPV, which is not connected to the portal vein, receives blood

from the left umbilical vein. Subsequently, the LPV joins the RPV through an almost 90° right turn. Within a week of birth, the infant's umbilical vein is completely obliterated, and the placental blood supply to the left lobe is cut off with the main circulation to the liver being taken over by the portal vein that was previously supplying only the right lobe. The left lobe is then supplied with blood only from the LPV, and blood flow in the LPV is less than that of the RPV<sup>[23]</sup>. Although the liver receives a dual blood supply from the portal vein and the hepatic artery, a decrease in portal flow without an arterial flow change can cause significant decreases in regional function<sup>[14,15,22]</sup>. Previous studies showed that a reduction in unilateral portal flow induced a decrease in both the function and the volume of the ipsilateral lobe, and the degree of the functional decrease was significantly higher than the degree of the volume decrease<sup>[14,15,22]</sup>. The decreased function observed in the left lobe in this study was also thought to be attributed to the lower flow volume in the LPV compared with that in the RPV. Although the measurement of the portal flow volume by Doppler ultrasound would be most appropriate to prove this speculation, we had no such data. Instead, we measured the diameter of the bilateral portal veins on CT images. Although the diameter of the portal vein could not directly indicate the portal flow volume, it is one of 2 factors that define the blood flow volume<sup>[23,24]</sup>. In this study, the LPV-to-RPV diameter ratio showed a significant correlation with the function-to-volume ratio in both lobes, indicating that portal flow significantly influenced the function of the 2 lobes.

Despite the novel findings of this study, it does have some limitations. First, although intrahepatic tumors in the surgical cases were limited to small tumors and the influence of the tumor on the surrounding parenchyma was estimated to be negligible, we cannot be certain that these tumors had no effect. However, the number of cases of right-sided tumors was higher than the number of cases of left-sided tumors (8 tumors in the right lobe and 4 tumors in the left lobe). Thus, although these tumors might have caused some degree of functional decrease, the decrease would more often have been associated with the right lobe. Second, although the lower function in the left lobe can be explained by decreased left portal flow, the mechanism of the functional discrepancy between the 2 lobes has not been sufficiently elucidated, and further investigation is necessary.

In conclusion, the results of this study on the use of CT/<sup>99m</sup>Tc-GSA SPECT fusion images indicated that the function of the left lobe was significantly decreased compared with that of the right lobe in non-cirrhotic livers. The function-to-volume ratio of each lobe showed a significant correlation with the LPV-to-RPV diameter ratio.

## COMMENTS

### Background

Preoperative evaluation of future remnant liver function is critical for patients undergoing hepatic surgery. In authors' department, remnant liver volume and function have been routinely estimated preoperatively using computed tomography/<sup>99m</sup>Tc-galactosyl human serum albumin (CT/<sup>99m</sup>Tc-GSA) single-photon emission computed tomography (SPECT) fusion imaging since December 2008, resulting in the

realization that the function of the interior portion of the left lobe was diminished compared with that of the right lobe, despite the absence of anatomical conditions suggestive of liver function heterogeneity. This study aimed to evaluate the functional differences between the 2 main lobes in non-cirrhotic livers.

### Research frontiers

Although recent reports have indicated the effectiveness of this newly developed CT/<sup>99m</sup>Tc-GSA SPECT fusion imaging technique for estimating the future remnant liver function, there have been no reports on the heterogeneous GSA accumulation between the 2 lobes.

### Innovations and breakthroughs

The results of this study on the use of CT/<sup>99m</sup>Tc-GSA SPECT fusion imaging indicated that the function of the left lobe was significantly decreased compared with that of the right lobe in non-cirrhotic livers. Furthermore, the function-to-volume ratio of each lobe showed a significant correlation with the left portal vein-to-right portal vein diameter ratio.

### Applications

The results of this study indicate that postsurgical remnant liver function and the tolerable extent of hepatectomy might change depending on the region of the hepatectomy. The residual liver function might be less after right-sided hepatectomy than after left-sided hepatectomy, even if the hepatectomy volumes were equivalent.

### Terminology

CT/<sup>99m</sup>Tc-GSA SPECT fusion examination is a newly developed SPECT examination method. Conventional <sup>99m</sup>Tc-GSA SPECT has the disadvantage of poor anatomical resolution, and this newly developed SPECT has a tremendously improved anatomical resolution owing to the fusion of CT and <sup>99m</sup>Tc-GSA SPECT.

### Peer review

This study describes that lobular differences in tracer accumulation can be observed even in patients with an apparently homogeneous liver on <sup>99m</sup>Tc-GSA SPECT. This finding is potentially important in the preoperative evaluation of future remnant liver function.

### Abstract

**AIM:** To explore the effect of lysine acetylation in related proteins on regulation of the proliferation of gastric cancer cells, and determine the lysine-acetylated proteins and the acetylated modified sites in AGS gastric cancer cells.

**METHODS:** The CCK-8 experiment and flow cytometry were used to observe the changes in proliferation and cycle of AGS cells treated with trichostatin A (TSA). Real time polymerase chain reaction and Western blotting were used to observe expression changes in p21, p53, Bax, Bcl-2, CDK2, and CyclinD1 in gastric cancer cells exposed to TSA. Cytoplasmic proteins in gastric cancer cells before and after TSA treatment were immunoprecipitated with anti-acetylated lysine antibodies, separated using sodium dodecyl sulfate polyacrylamide

gel electrophoresis gel and silver-stained to detect the proteins by mass spectrometry after removal of the gel. The acetylated proteins in AGS cells were enriched with lysine-acetylated antibodies, and a high-resolution mass spectrometer was used to detect the acetylated proteins and modified sites.

**RESULTS:** TSA significantly inhibited AGS cell proliferation, and promoted cell apoptosis, leading to AGS cell cycle arrest in G0/G1 and G2/M phases, especially G0/G1 phase. p21, p53 and Bax gene expression levels in AGS cells were increased with TSA treatment duration; Bcl-2, CDK2, and CyclinD1 gene expression levels were decreased with TSA treatment duration. Two unknown protein bands, 72 kDa (before exposure to TSA) and 28 kDa (after exposure to TSA), were identified by silver-staining after immunoprecipitation of AGS cells with the lysine-acetylated monoclonal antibodies. Mass spectrometry showed that the 72 kDa protein band may be PKM2 and the 28 kDa protein band may be ATP50. The acetylated proteins and modified sites in AGS cells were determined.

**CONCLUSION:** TSA can inhibit gastric cancer cell proliferation, which possibly activated signaling pathways in a variety of tumor-associated factors. ATP50 was obviously acetylated in AGS cells following TSA treatment.

**Key words:** Trichostatin A; Acetylation modification; Gastric cancer; Mass spectrometry; ATP50; PKM2

**Core tip:** Previous research has shown that deacetyltransferase inhibitors not only induce cell cycle arrest, differentiation and apoptosis of many tumor cells *in vitro*, but also inhibit tumor growth in tumor-bearing animals. They are through the acetylation modification of deacetyltransferase inhibitor on histone. Only a few studies have focused on the acetylation modification by deacetyltransferase on non-histone. This is the first study to identify acetylated proteins in gastric cancer

cells before and after exposure to trichostatin A to explore the effect of lysine acetylation of related proteins on the regulation of gastric cancer cell proliferation. Moreover, the lysine-acetylated proteins and the modified sites in AGS cells were assessed. We explored whether ATP5O was obviously acetylated after trichostatin A treatment in AGS cells.

Mechanisms of trichostatin A inhibiting AGS proliferation and identification of lysine-acetylated proteins. *World J Gastroenterol* 2013; 19(21): 3226-3240 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i21/3226.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i21.3226>

## INTRODUCTION

Gastric cancer has a high incidence and mortality worldwide, especially in East Asia<sup>[1,2]</sup>. More than 400000 new patients with gastric cancer are diagnosed in China every year. The prevalence and mortality of this disease in China are higher than the world average values<sup>[3]</sup>. In the absence of targets, traditional chemotherapy has severe side effects. Therefore, cancer treatment and research are now focusing on molecular targeted therapy due to its high selectivity, good efficacy and reduced side effects.

Histone acetylation/deacetylation modification, one of the essential mechanisms of gene transcriptional regulation, occurs mainly in conservative lysine residues on histone H3 and H4 tails, which are regulated by histone acetyltransferases and histone deacetylases (HDACs). Significantly increased activity of HDACs leads to an expression imbalance of some molecules affecting cell proliferation, apoptosis and cell cycle, thus causing cancer<sup>[4]</sup>. A large number of studies have shown that deacetyltransferase inhibitors not only induce cell cycle arrest, differentiation and apoptosis of many tumor cells *in vitro*, but also inhibit tumor growth in tumor-bearing animals<sup>[5,6]</sup>. There have been numerous studies on the acetylation modification by deacetyltransferase inhibitors on histone, however, studies focusing on the acetylation modification by deacetyltransferase on non-histones are rare. Further studies are needed to investigate the acetylated non-histones involved in tumor growth and metabolism, and the signaling pathways through which these proteins induce tumor apoptosis. We treated AGS gastric cancer cells with the histone deacetyltransferase inhibitor, trichostatin A (TSA), to identify differentially acetylated non-histones before and after TSA treatment. We also explored the apoptosis and proliferation mechanisms of gastric cancer cells.

## MATERIALS AND METHODS

### Materials

AGS cells were purchased from the Cell Resource Center of Shanghai Institutes for Biological Sciences, Chinese Academy of Sciences; Ham's F12 medium was from

HyClone; trypsin-EDTA solution and fetal bovine serum from Invitrogen; the cell counting kit-8 (CCK-8) from Dojindo Company; TSA from Sigma (batch number T1952); the Annexin V-FITC Apoptosis Detection Kit, FACS Calibur and LSR™ II Flow Cytometer from BD Pharmingen; the primer was designed by Shanghai Sangon Biotech Co., Ltd.; Agarose I™ was from Amresco, the RNeasy Mini Kit from Qiagen; the Reverse Transcription System from Promega; SYBR® Premix Ex Taq™ from TaKaRa; ABI prism 7300 polymerase chain reaction (PCR) from ABI; Amersham ECL plus the Western blotting Detection System and CNBr Activated Sepharose 4B from GE; Pierce BCA Protein Assay Kit from Thermo; Acetyl- $\alpha$ -Tubulin (Lys40) (D20G3) XP® Rabbit mAb from CST; Goat anti-rabbit IgG-HRP from Sigma; LTQ VELOS from Thermo Finnigan, and anti-ATP5O and anti-PKM2 antibodies from Sigma.

### CCK-8 experiment

AGS cell strains were cultured in Ham's F12 medium + 10% FBS for 24 h and divided into 8 groups (3 holes in each group). The media in the holes were added to complete media containing TSA at final concentrations of 0, 0.015, 0.03, 0.06, 0.1, 0.25, 0.5 and 1  $\mu\text{mol/L}$ , respectively. The complete media were incubated with 5% CO<sub>2</sub> at 37 °C for 72 h, and then added to CCK-8 solution in the proportion of 100  $\mu\text{L}/10 \mu\text{L}$ , and left to stand at 37 °C for 1 h. Absorbance was then read at a wavelength of 450 nm using a microplate reader.

### Detection of cell apoptosis and cycle by flow cytometry

Two dishes of AGS cells cultured for 24 h were added to complete medium containing TSA at a final concentration of 0.25  $\mu\text{mol/L}$ , and a further two dishes of cultured cells were added to new medium as a control. The media were incubated with 5% CO<sub>2</sub> at 37 °C for 24 h, centrifuged, transferred to a 5 mL culture tube and the supernatant was removed. The cells were re-suspended, and 5  $\mu\text{L}$  Annexin V-FITC and propidium iodide (PI) were added, incubated in the dark at 20-25 °C for 15 min and then 400  $\mu\text{L}$  Annexin V binding solution was added for flow cytometry. Annexin V-FITC had green fluorescence and PI had red fluorescence. The wavelength of light excited by flow cytometry was adjusted to 488 nm. FITC fluorescence was detected with a band-pass filter of 515 nm and PI fluorescence was detected with a filter of more than 560 nm. In addition, the cell sediments were added to 1 mL of 70% ethanol, fixed, washed, centrifuged twice, re-suspended in 0.5 mL PBS containing 50  $\mu\text{g}/\text{mL}$  PI and 100  $\mu\text{g}/\text{mL}$  RNase A, and incubated in the dark at 37 °C for 30 min to determine the cell cycle using a flow cytometer according to standard procedures. The results were analyzed using a cycle meter and the software FlowJo6.3<sup>[7]</sup>.

### Real-time polymerase chain reaction

AGS cells cultured for 24 h were added to complete medium containing TSA at final concentrations of 0 and 0.25  $\mu\text{mol/L}$ , respectively (the former for the control).

Bcl-2: B cell lymphoma-2; CDK2: Cyclin-dependent kinase 2; Bax: Bcl-associated X protein.

The total RNA in all samples was extracted, quantified and reversely transcribed according to the Qiagen kit instructions. Fluorescence quantitative PCR was carried out on p21, p53, Bax, Bcl-2, CDK2 and CyclinD1, followed by data collection and analysis. The PCR primer sequences and fragment lengths are shown in Table 1.

### Western blotting

One dish of AGS cells cultured for 24 h was used as the 0 h sample, and a further 2 dishes of cells were added to medium containing a final concentration of 0.25 μmol/L TSA, and incubated with 5% CO<sub>2</sub> at 37 °C for 12 and 24 h, respectively. The cells were collected after digestion with pancreatin, washed twice with PBS, centrifuged to remove the supernatant, collected and placed on ice for lysis. The proteins were quantified using the BCA method. Protein electrophoresis sodium dodecyl sulfate polyacrylamide gel electrophoresis, membrane-transfer, immunoreactions, development and gel electrophoresis image analysis were performed for p21, p53, Bax, Bcl-2, CDK and CyclinD1.

### Enrichment of lysine-acetylated proteins

Five dishes of AGS cells were added to complete medium containing a final concentration of 0.5 μmol/L TSA, and another five dishes of cells were directly placed in new medium as the control. Cell lysis was performed after incubation in the medium for 24 h, and all protein concentrations were adjusted to 5 mg/mL after determination using the BCA method. Total protein of 20 mg and lysine-acetylated mAb of 0.5 mL (CNBr Activated Sepharose 4B) were mixed, incubated in a table concentrator at 4 °C for 5 h, washed 3 times and collected for vacuum drying. The lysine-acetylated proteins were enriched and dissolved in PBS. Electrophoresis, silver-staining and photographs of the total proteins of 2 μg taken from each dish after the proteins were quantified with BCA were carried out. Western blotting was performed

on all proteins in each group to determine the effect of acetylation (20 μg total protein from AGS cells not treated and treated with 0.5 μmol/L TSA, respectively; 20 μg flow-through proteins incubated with the antibody gel column in AGS cells not treated and treated with 0.5 μmol/L TSA respectively; and 100 ng total proteins enriched after incubation with antibody gel column in AGS not treated and treated with 0.5 μmol/L TSA, respectively). Acetyl-α-tubulin (Lys40) (D20G3) XP<sup>®</sup> Rabbit mAb was the primary antibody and Goat anti-rabbit IgG-HRP was the secondary antibody.

### Identification of in-gel protein with mass spectrometry

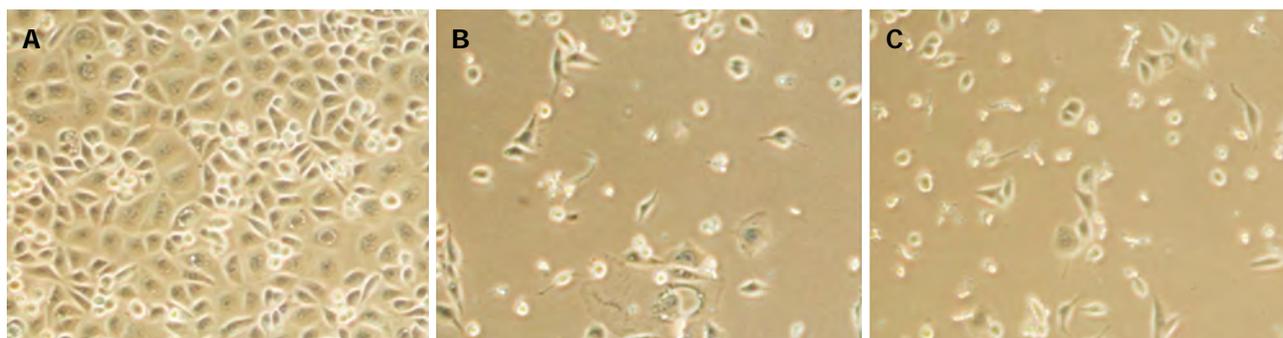

The enriched protein band on silver-stained gel (72 kDa before exposure to TSA and 28 kDa after exposure to TSA), was broken down in the gel with enzyme (trypsin for 20 h), and the decomposed peptide was extracted for ESI MS detection. After the chromatographic column was equilibrated with 95% solution A (0.1% formic acid solution), the sample was fed into a Trap column. From 0 to 50 min, the linear gradient of solution B (78% acetonitrile solution containing 0.1% formic acid) increased from 4% to 50%; from 50 to 54 min, the linear gradient of solution B increased from 50% to 100%; from 54 to 60 min, the linear gradient of solution B was maintained at 100%. Twenty fragmentographies (MS2 scan) were collected by mass-to-charge ratio of the polypeptides and polypeptide fragments after full scan. The raw file was searched with BIOWORKS software in the relevant database to determine the protein. The database was ipi. HUMAN.v3.53. SEQUEST screening parameters were as follows: when Charge + 1, Xcorr ≥ 1.9; when Charge + 2, Xcorr ≥ 2.2; and when Charge + 3, Xcorr ≥ 3.75; wherein DelCN ≥ 0.1.

### Identification of acetylated sites using mass spectrometry

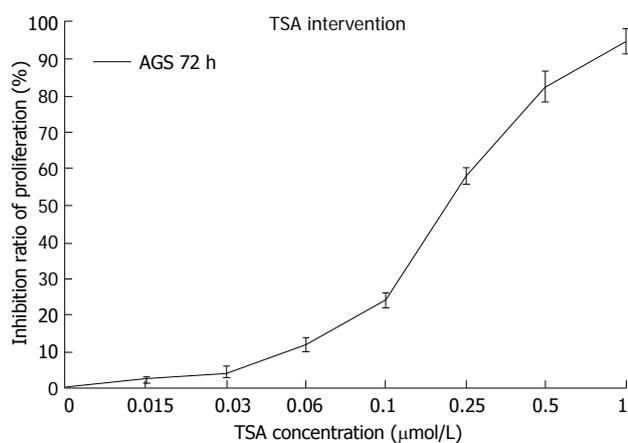

Experimental methods for cell lysis, protein extraction and acetylated peptides affinity enrichment were obtained from published techniques<sup>[8]</sup>. The resulting peptides were assayed by continuous separation using SCX followed by C18 columns (Dionex, Sunnyvale, CA, United States) before being subjected to MS/MS analysis using an LTQ-Orbitrap mass spectrometer (Thermo Electron, Bremen, Germany).

### Protein sequence database search and manual verification

The mass spectrometry data were initially searched against the NCBI database with the aid of the Sequest search engine. Searches for acetylated peptides were done against the *Homo sapiens* proteins database. The search engine MASCOT (Matrix Science, London, United Kingdom) was used for the database search, and extract\_msn.exe version 4.0 was used for peaklist generation. A low cutoff of the peptide score of 20 was selected to maximize the identification of lysine-acetylated peptides. Trypsin was specified as the proteolytic enzyme, and up to 6 missed cleavage sites per peptide were allowed. Carbamidomethylation of cysteine was set as a fixed modification and

**Figure 1** Proliferation of AGS cells exposed to different concentrations of trichostatin A for 72 h. A: AGS cells after treatment with 0  $\mu\text{mol/L}$  trichostatin A (TSA); B and C: AGS cells were significantly reduced after exposed to 0.25  $\mu\text{mol/L}$  TSA (B) and further reduced after treated with 0.5  $\mu\text{mol/L}$  TSA (C).

**Figure 2** Effect of different concentrations of trichostatin A on inhibition of AGS cell proliferation in the cell counting kit-8 experiment. The inhibition of AGS cells was gradually increased with increasing trichostatin A concentration 0, 0.015, 0.03, 0.06, 0.1, 0.25, 0.5 and 1  $\mu\text{mol/L}$ . TSA: Trichostatin A.

oxidation of methionine and acetylation of lysine as variable modifications. Charge states of +1, +2 or +3 were considered for parent ions. Mass tolerance was set to  $\pm 4.0$  Da for parent ion masses and  $\pm 0.6$  Da for fragment ion masses. Acetylated lysine-containing peptides identified with a MASCOT score of 25 were manually verified by the method described by Chen *et al*<sup>[9]</sup>.

#### Detection of acetylated proteins

One dish of normal AGS cells was collected as the 0 h sample after digestion with pancreatin, and a further 3 dishes of cells were added with a final concentration of 0.5  $\mu\text{mol/L}$  TSA and incubated with 5%  $\text{CO}_2$  in an incubator at 37  $^\circ\text{C}$  for 6, 12 and 24 h. The collected cells were digested with pancreatin, re-suspended, and decomposed by ultrasound on ice. The decomposed cells were centrifuged at 15000  $g$  and 4  $^\circ\text{C}$  for 30 min and the supernatant was obtained for identification of protein concentration using the BCA. Five mg of total protein was mixed with 50  $\mu\text{g}$  of the M2 isoform of pyruvate kinase antibody (anti-PKM2) and the ATP synthase subunit O antibody (anti-ATP5O) (covalently cross-linked with CNBr Activated Sepharose 4B) and incubated in an incubator at 4  $^\circ\text{C}$  for 5 h. The gel column was washed 3 times and the

washed proteins were collected. The protein content of ATP5O<sup>[10]</sup> and PKM2<sup>[11]</sup> in the 4 samples was determined using Western blotting. After binding, the washed proteins with the anti-acetylated lysine antibodies, and the protein content of ATP5O and PKM2 in the 4 samples were detected using Western blotting.

## RESULTS

### Effect of TSA on AGS cell proliferation, apoptosis and cell cycle

CCK-8 experiments showed that AGS cells were significantly reduced after the addition of 0.25  $\mu\text{mol/L}$  TSA and AGS cell proliferation was more obviously inhibited after the addition of 0.5  $\mu\text{mol/L}$  TSA. Therefore, TSA significantly inhibited proliferation of the gastric cancer cell line (Figures 1 and 2). The bivariate scatter diagram of flow cytometry showed more apoptotic and necrotic AGS cells after treatment with 0.25  $\mu\text{mol/L}$  TSA (Figure 3). The flow cytometry cycle diagrams showed that the AGS cell cycle ratio before TSA treatment was as follows: %G1 = 26, %S = 53.5, %G2 = 17.7, and the AGS cell cycle ratio after 0.25  $\mu\text{mol/L}$  TSA treatment was as follows: %G1 = 44.6, %S = 20.9, %G2 = 31.3. Therefore, TSA induced apoptosis and necrosis of AGS cells, and cycle arrest mainly occurred in G0/G1 and G2/M phases, especially in G0/G1 phase (Figure 4).

### Observation of p21, p53, Bax, Bcl-2, CDK2 and CyclinD1 expression levels after TSA treatment using real-time PCR and Western blotting

Real-time PCR results showed that more p21, p53 and Bax mRNA was expressed after AGS cells were exposed to 0.25  $\mu\text{mol/L}$  TSA, and the expression levels were increased with TSA treatment duration, while less Bcl-2, CDK2 and CyclinD1 mRNA was expressed after TSA treatment, and the expression levels were decreased with TSA treatment duration (Figure 5). The expression levels of the above six cell cycle-related proteins in AGS cells shown in Western blotting were the same as the levels shown in real-time PCR (Figure 6).

### Enrichment of lysine-acetylated proteins

In AGS cells enriched with lysine-acetylated monoclonal

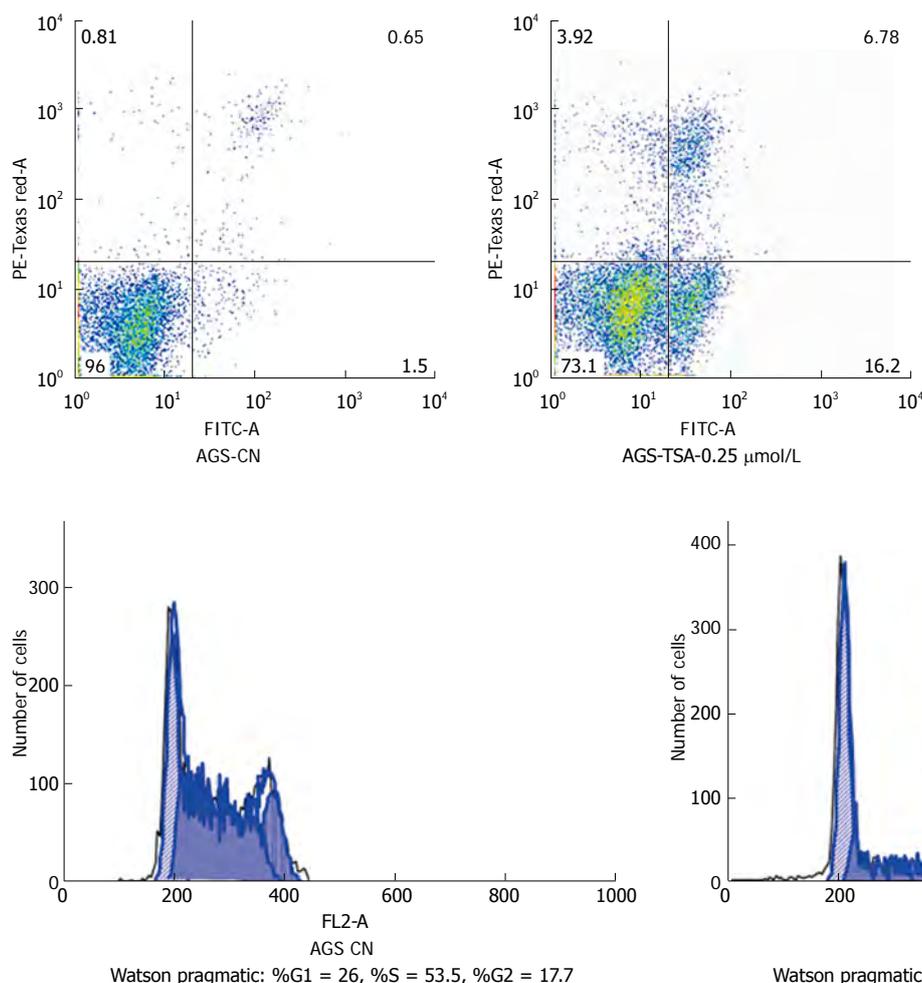

Figure 3 AGS cell apoptosis changes before and after trichostatin A exposure by flow cytometry. Fluorescence staining was mainly seen in normal areas, but rarely in apoptotic and necrotic areas of unexposed AGS cells; staining appeared in the apoptotic and necrotic areas of AGS cells exposed to 0.25  $\mu\text{mol/L}$  trichostatin A (TSA).

Figure 4 AGS cell cycle changes before and after trichostatin A exposure by flow cytometry. The AGS cell cycle ratio before TSA treatment was: %G1 = 26, %S = 53.5, %G2 = 17.7, and the AGS cell cycle ratio after 0.25  $\mu\text{mol/L}$  trichostatin A treatment was: %G1 = 44.6, %S = 20.9, %G2 = 31.3. Cycle arrest occurred in G0/G1, G2/M phases, especially in G0/G1 phase. TSA: Trichostatin A.

antibodies, the enriched proteins were located at 72 kDa before exposure to 0.5  $\mu\text{mol/L}$  TSA shown by silver-staining, but appeared at 55, 28 and 17 kDa after exposure to 0.5  $\mu\text{mol/L}$  TSA, which was consistent with the Western blotting results (Figure 7). Some studies have shown that the enriched proteins at 55 and 17 kDa were tubulin and histone protein, respectively. In our experiments which were designed to determine the modified proteins enriched by lysine-acetylated monoclonal antibodies, total protein in the cytoplasm, flow-through proteins, and enriched proteins all showed obvious bands. No obvious bands for these three proteins were found before TSA treatment (Figure 8), which indicated that the protein enrichment method with lysine-acetylated monoclonal antibodies was effective and credible.

#### Identification of in-gel proteins by mass spectrometry

Mass spectrometry was carried out on the unknown protein bands, 72 kDa (before TSA treatment) and 28 kDa (after TSA treatment), which were enriched and modified by lysine acetylation to obtain ESI MS total ion chromatography (Figure 9). We searched the protein database ipi.

HUMAN.v3.53 with the SEQUEST program according to the set screening parameters. The results indicated that 72 kDa (before TSA treatment) was PKM2, and 28 kDa (after TSA treatment) was ATP5O in AGS cells (Figure 10).

#### Identification of acetylated sites using mass spectrometry and detection of acetylated proteins

We screened all peptide sequences obtained by detection of the acetylated sites using mass spectrometry. In the plasmosin of normal AGS cells, we found 602 acetylated peptides, 171 unique peptides and 136 acetylated sites (Table 2). Cell cycle G0 analysis showed that the identified proteins contained chromatin, nucleosome, DNA components as well as chromatin modification, protein acetylation, glucose metabolism and other biological processes. These components were mainly involved in cellular components such as chromatin, nucleoplasm and organelles, and these molecular functions were mainly associated with cell proliferation and apoptosis (Figure 11). In these acetylated peptides, the presence of ATP5O indicated that ATP5O had modified sites (Figure 12). In the mass spectrometry results, most of the identified proteins had a

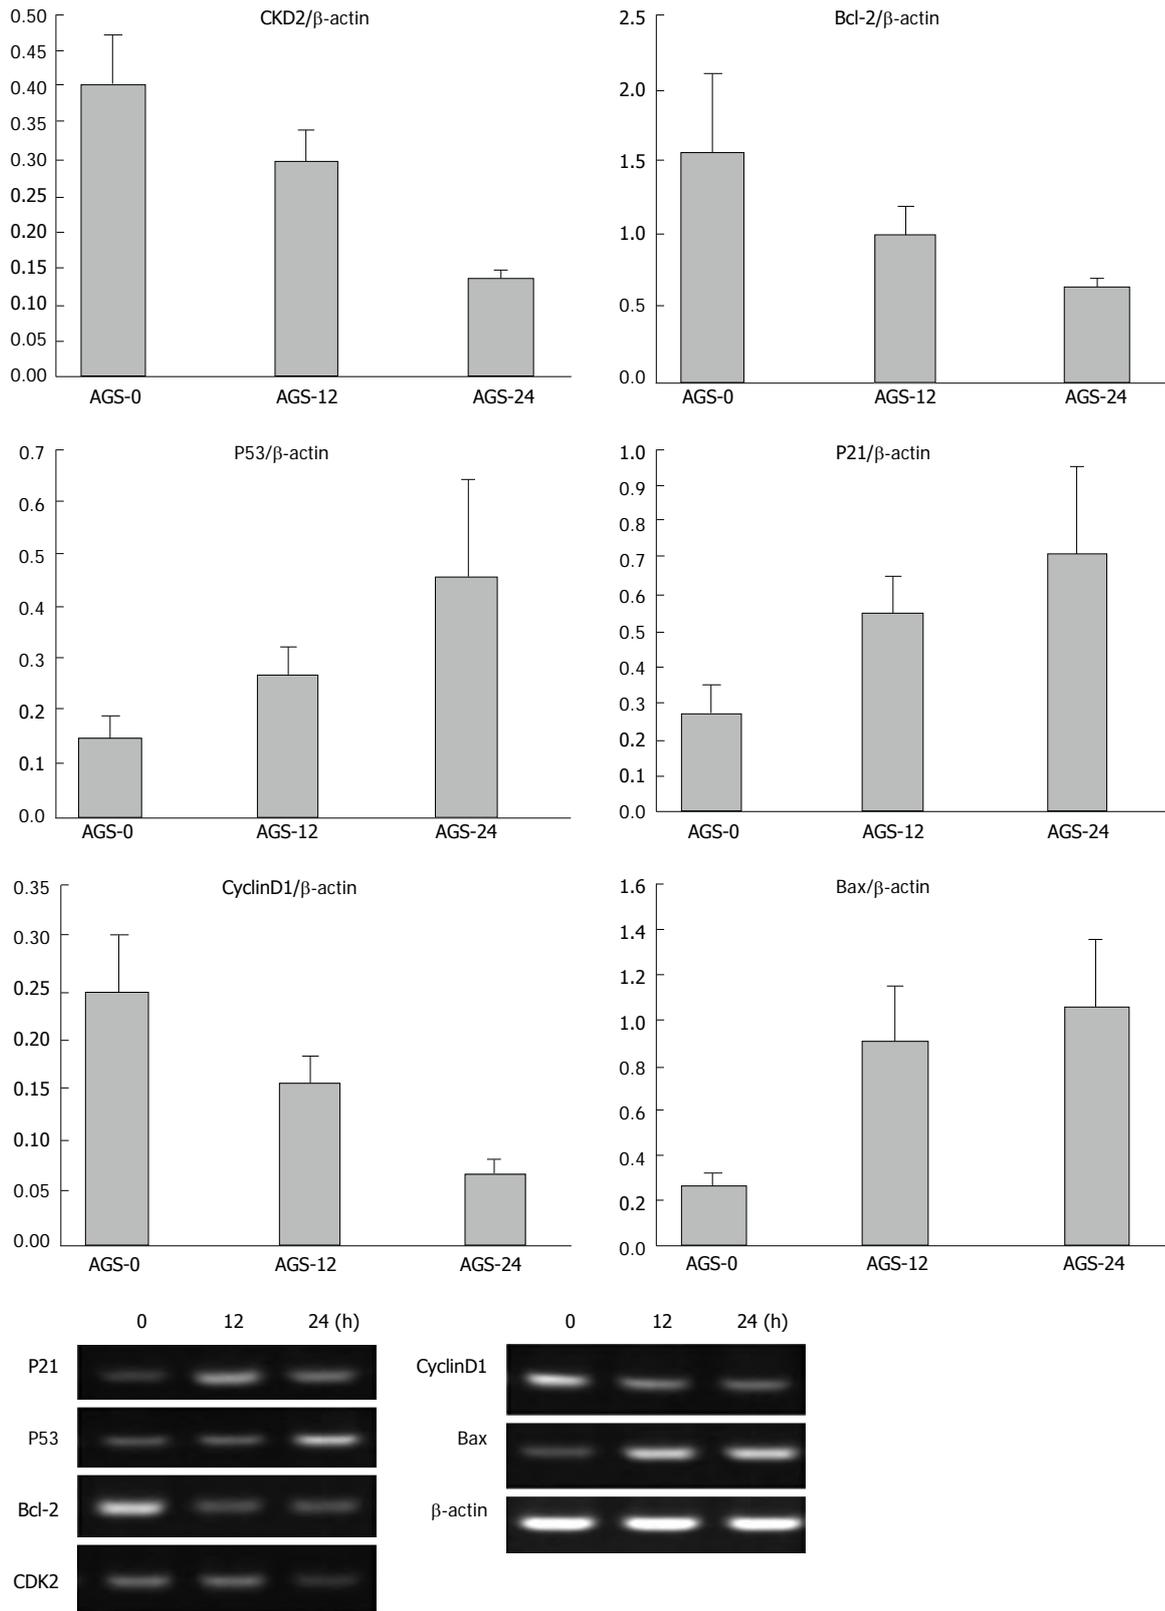

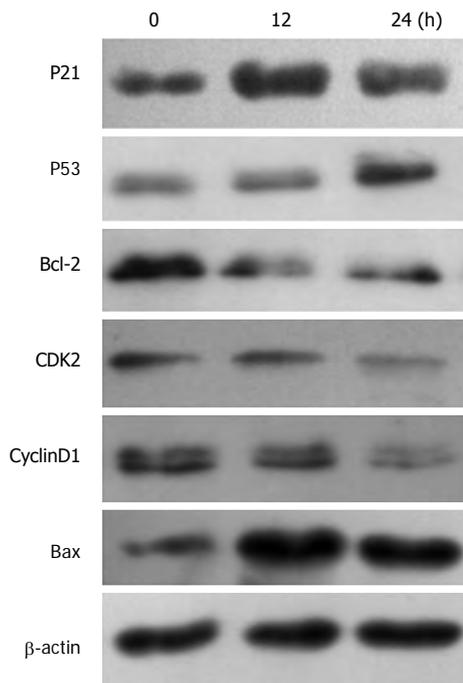

Figure 5 mRNA expression levels of p21, p53, Bax, Bcl-2, CDK2 and CyclinD1 in AGS cells exposed to 0.25  $\mu\text{mol/L}$  trichostatin A shown by real-time polymerase chain reaction. The mRNA expression levels of Bcl-2, CDK2 and CyclinD1 were decreased and the mRNA expression levels of p21, p53 and Bax were increased 12 h after AGS cells were exposed to 0.25  $\mu\text{mol/L}$  trichostatin A. The mRNA expression levels of Bcl-2, CDK2 and CyclinD1 were further decreased and the mRNA expression levels of p21, p53 and Bax were further increased 24 h after exposure.

cover percent greater than 20%, and a score greater than 25, which proved that the mass spectrometry identifica-

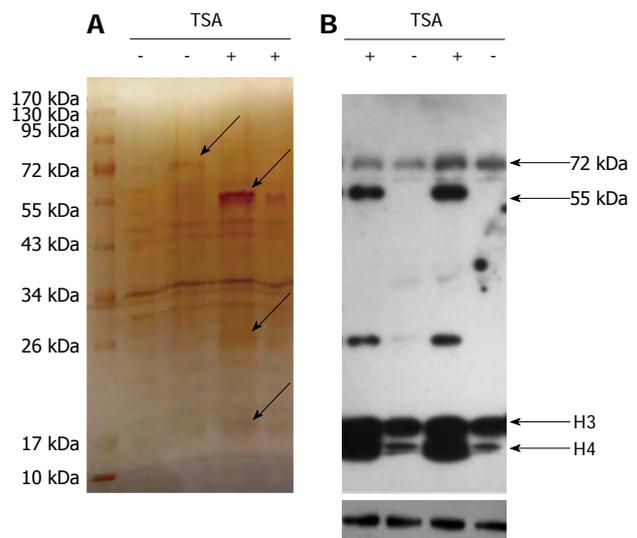

**Figure 6** Protein expression levels of p21, p53, Bax, Bcl-2, CDK and cyclin after AGS cells were exposed to 0.25 μmol/L trichostatin A shown by Western blotting. The protein expression levels of Bcl-2, CDK2 and CyclinD1 were decreased and the protein expression levels of p21, p53 and Bax were increased 12 h after AGS cells were exposed to 0.25 μmol/L trichostatin A. The protein expression levels of Bcl-2, CDK2 and CyclinD1 were further decreased and the protein expression levels of p21, p53 and Bax were further increased 24 h after exposure.

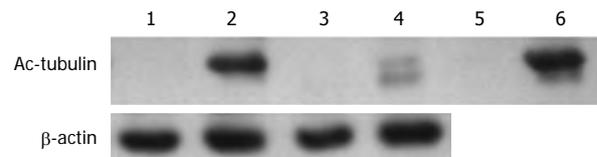

tion results were correct. Further validation of the acetylated proteins, ATP5O and PKM2, showed that the total amount of ATP5O and PKM2 proteins did not change with the treatment duration of 0.5 μmol/L TSA, however, more ATP5O was acetylated than PKM2 (Figure 13), which indicated acetylation of ATP5O and deacetylation of PKM2 after TSA treatment.

## DISCUSSION

Modern oncology theories have revealed that genetic defects and gene epigenetic changes lead to malignant tumors. Epigenetics has shown acetylation of DNA methylation and histone, which are involved in gene transcription and expression, thus regulating DNA functions<sup>[12-14]</sup>. TSA derives from a natural hydroxamic acid, HDACi, which inhibits the activity of HDACs by binding the hydroxamic acid ligand with zinc ions at the bottom of the HDAC tubular structure<sup>[15]</sup>. Cancer research has discovered that TSA can arrest cell cycle, induce cell apoptosis, regulate cell differentiation and inhibit cell migration in the absence of cytotoxicity<sup>[16-18]</sup>. We found that the proliferation of normally grown AGS gastric cancer cells was significantly inhibited after exposure to 0.25 μmol/L TSA, *i.e.*, more apoptotic and necrotic cells. In addition, flow cytometry showed that the cycle arrest of AGS cells exposed to TSA occurred in G0/G1 and G2/M phases, which is consistent with other previous reports<sup>[19-22]</sup>. In

**Figure 7** Identification of differential proteins of lysine acetylation after trichostatin A treatment. A: Silver staining showed the differential proteins of lysine acetylation in AGS cells after trichostatin A (TSA) treatment; B: Western blotting showed the differential proteins of lysine acetylation in AGS cells after TSA treatment, “-” before TSA intervention; “+” after TSA intervention, Acetyl-α-tubulin (Lys40) (D20G3) XP<sup>®</sup> Rabbit mAb was the primary antibody and Goat anti-rabbit IgG-HRP was the secondary antibody.

**Figure 8** Identification of the effectiveness of lysine-acetylated antibodies enriching acetylated proteins. Line 1: 20 μg total protein from AGS cells unexposed to trichostatin A (TSA); Line 2: 20 μg total protein from AGS cells exposed to 0.5 μmol/L TSA; Line 3: 20 μg flow-through protein from AGS cells unexposed to TSA, which was incubated with an antibody gel column; Line 4: 20 μg flow-through protein from AGS cells exposed to 0.5 μmol/L TSA, which was incubated with an antibody gel column; Line 5: 100 ng enriched protein from AGS cells unexposed to TSA, which was incubated with an antibody gel column; and Line 6: 100 ng enriched protein from AGS cells exposed to 0.5 μmol/L TSA, which was incubated with an antibody gel column.

the present study, cycle arrest in G0/G1 phase was more obvious.

Current studies indicate that TSA can activate histone acetylation to loosen the chromosome structure, thus endonuclease can easily access DNA, and TSA can block signal transduction pathways associated with cell proliferation by activating death receptors and mitochondrial apoptotic pathways, promoting transcription of tumor suppressor genes, which directly or indirectly induces tumor cell apoptosis<sup>[23,24]</sup>. Our research showed that the expression levels of tumor suppressor genes, *p21*, *p53* and *Bax*, were increased after AGS cells were exposed to 0.25 μmol/L TSA, which increased with treatment duration, and the protooncogenes *Bcl-2*, *CDK2* and *CyclinD1* showed the opposite trend. These results are consistent with those of previous publications<sup>[22,25-29]</sup>, but different from some reports. The research of Suzuki *et al.*<sup>[20]</sup> showed that TSA could reduce *p53* expression level, although

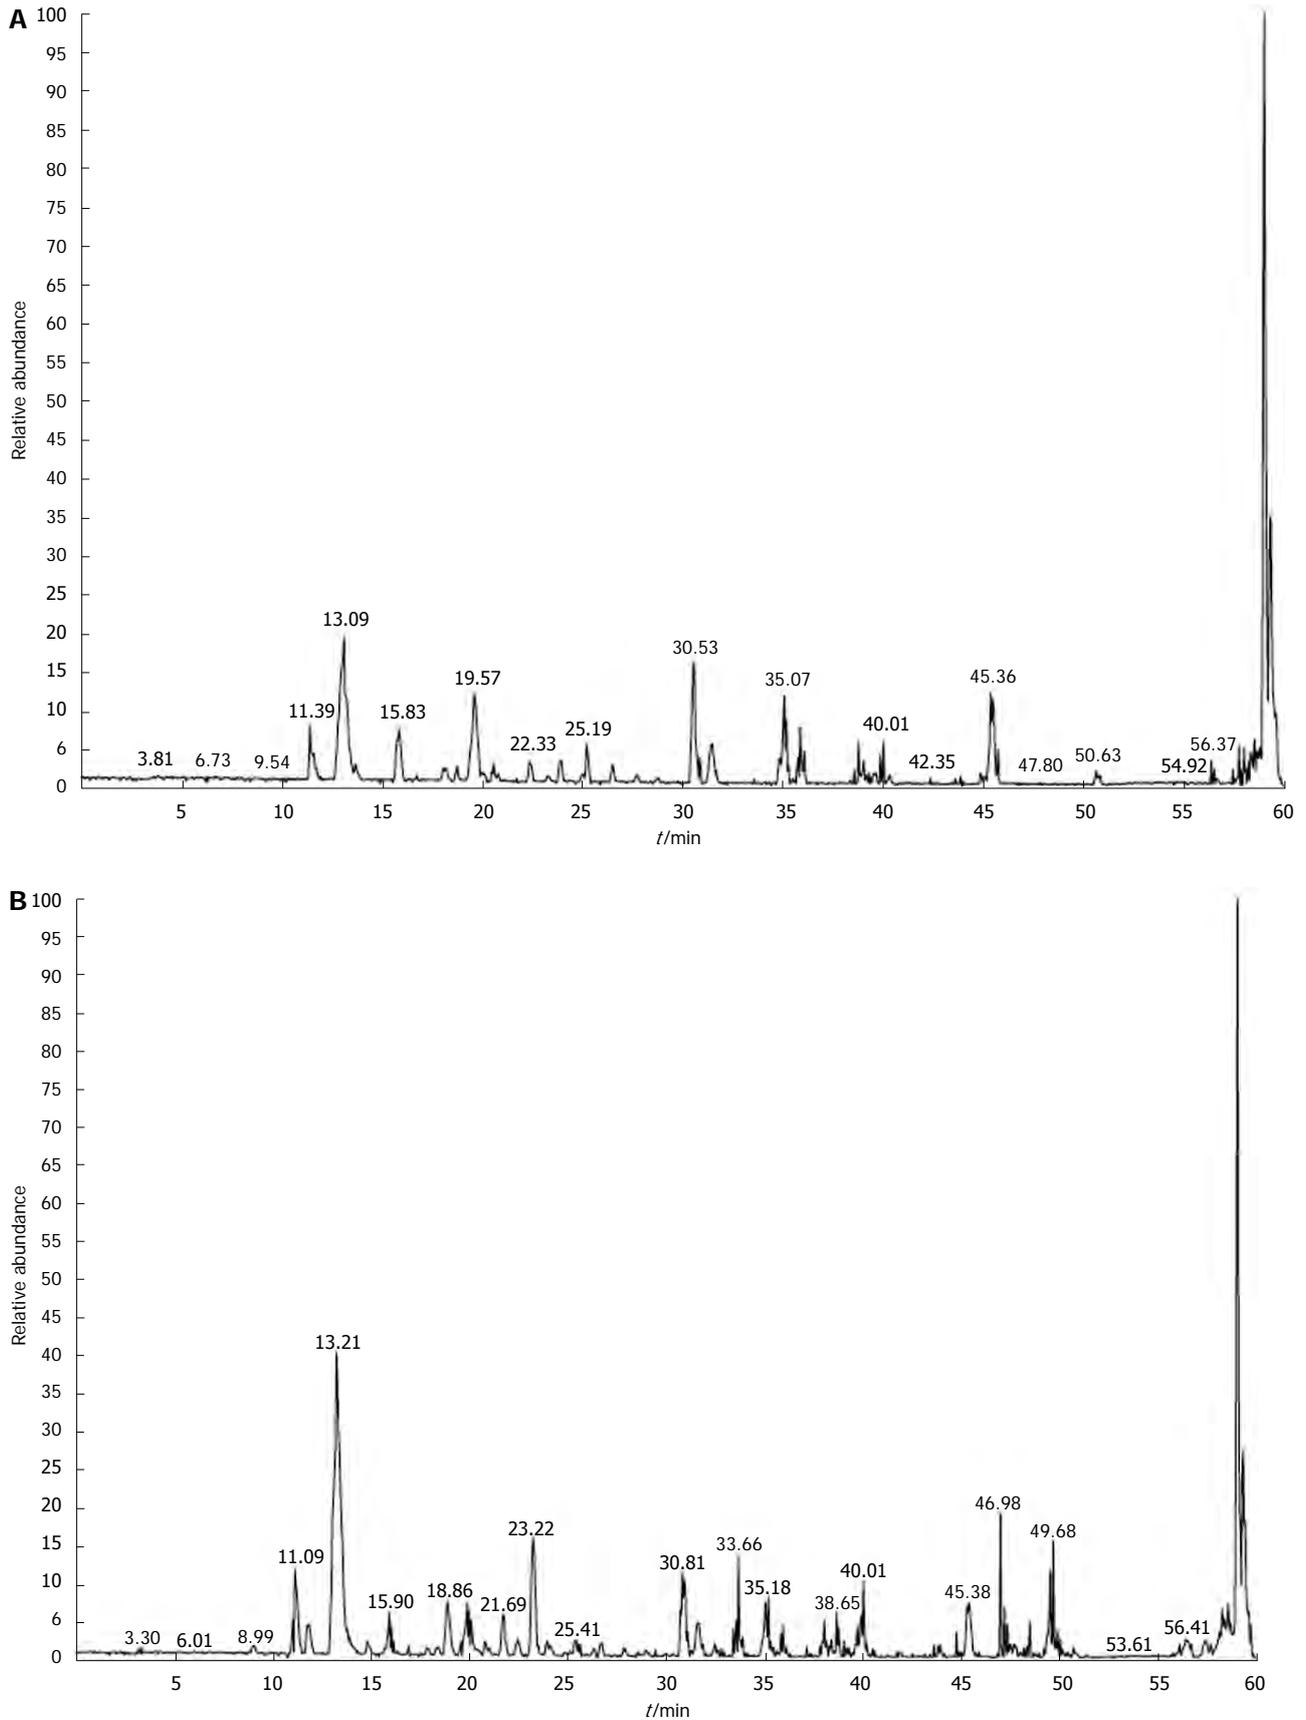

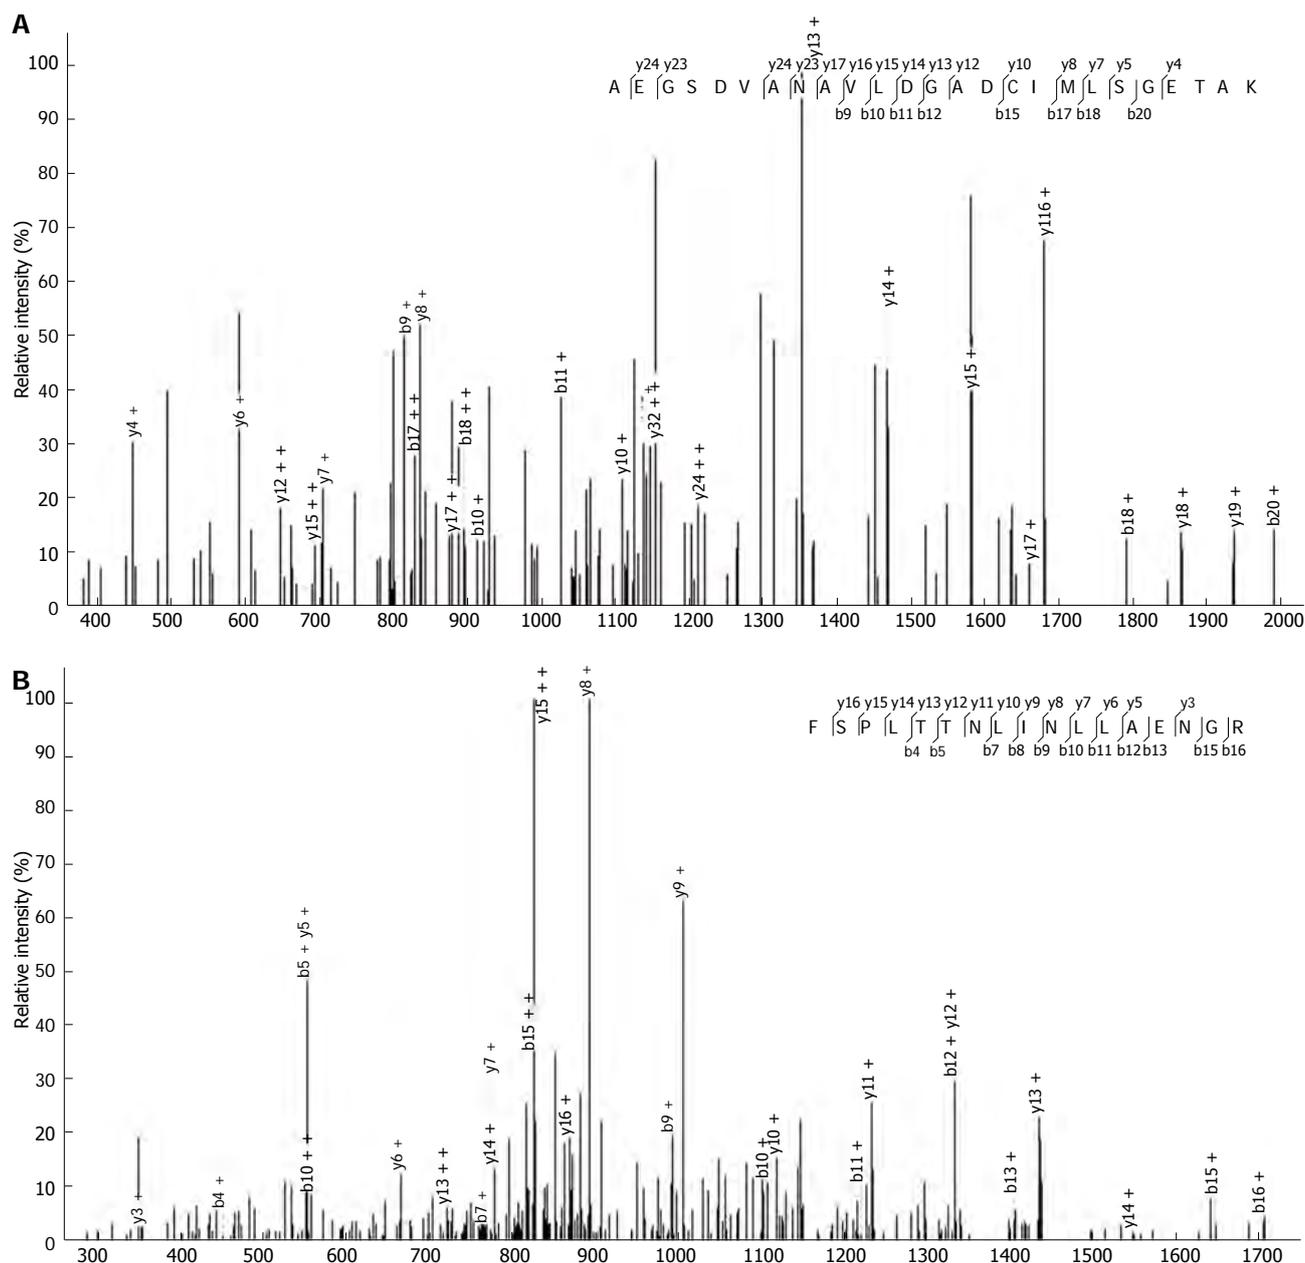

Figure 9 Mass spectrometry total ion chromatography. A: 72 kDa band of lysine-acetylated protein in AGS cells before trichostatin A (TSA) treatment; B: 28 kDa band of lysine-acetylated protein in AGS cells after TSA treatment.

**Figure 10** Mass spectrometry identification of peptides from silver staining gel. Mass spectra of 2 acetylated peptides from PKM2 and ATP5O are presented. A: PKM2 “AEGSDVANAVLDGADCIMLSGETAK”; B: ATP5O “FSPLTTNLLAENGR”.

p21 and Bax expression levels were enhanced. The research of Juan *et al*<sup>[30]</sup> showed that deacetyltransferase can specifically lower *p53* and *p53*-dependent genes. These different results may be the result of different group designs and study objectives, which need to be confirmed. In most research studies, *P21waf1/cip1* is used as the transcript of target gene at p53 downstream, a suppressor of cyclin and cyclin-dependent kinase, which can be combined with a variety of cyclins/CDK complexes by phosphorylation to inhibit cell growth in G2/M phase, thus inhibiting proliferation of tumor cells. It is believed that *P21waf1/cip1* silencing mechanisms in tumor cells may be decided by epigenetic modifications of their chromatins, and their expression levels are regulated by histone acetylation<sup>[31]</sup>. Some research studies confirmed that HDACi-

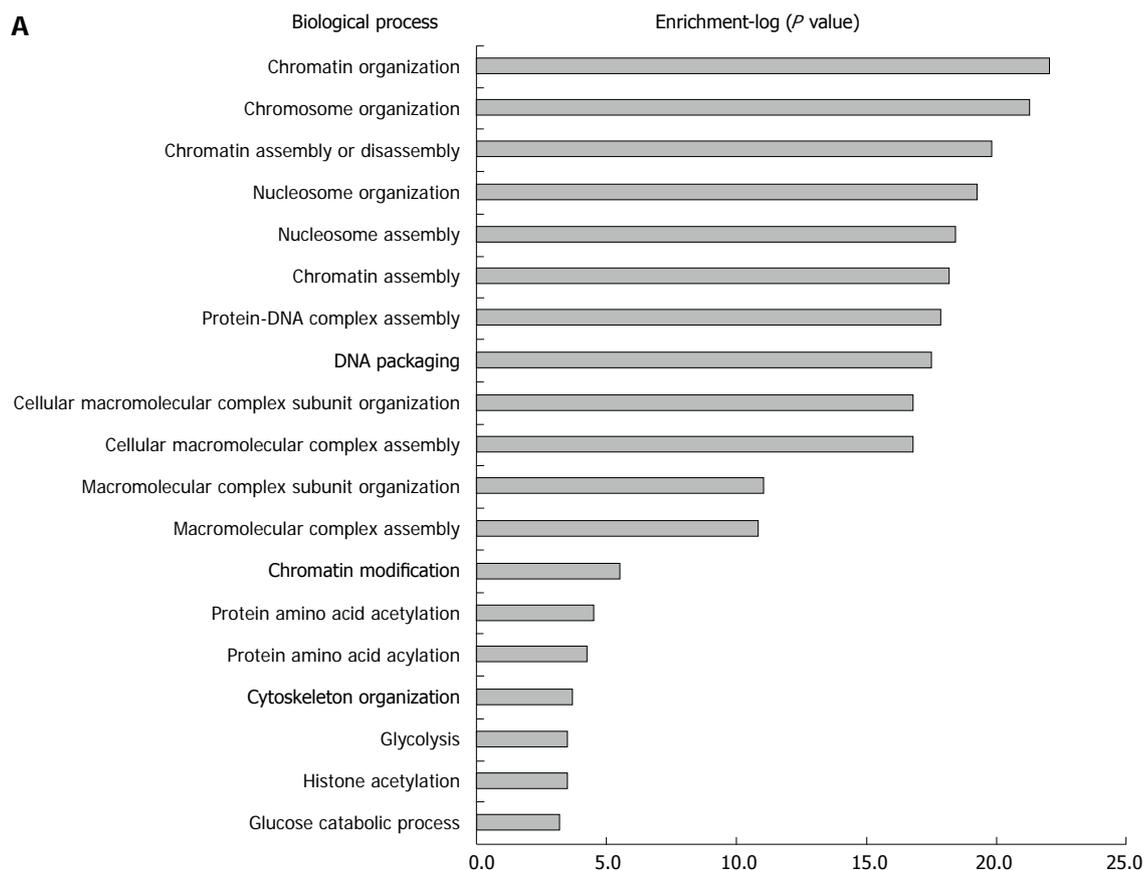

induced histone is acetylated in the *P21waf1/cip1* gene promoter region, and *P21waf1/cip1* may be a direct target of TSA<sup>[32]</sup>.

It is clear that TSA plays a role in histone acetylation, however, the function of TSA in non-histone acetylation in the inhibition of tumor growth has rarely been reported. Therefore, we immunoprecipitated AGS cells before and after exposure to TSA with lysine-acetylated monoclonal antibodies, and found an enriched protein band at 72 kDa before exposure and three enriched protein bands at 55, 28 and 17 kDa after exposure. The enriched proteins at 55 and 17 kDa were found to be tubulin and histone, respectively. We extracted two unknown protein bands at 72 and 28 kDa with gel and identified them by in-gel mass spectrometry and found that the 28 kDa

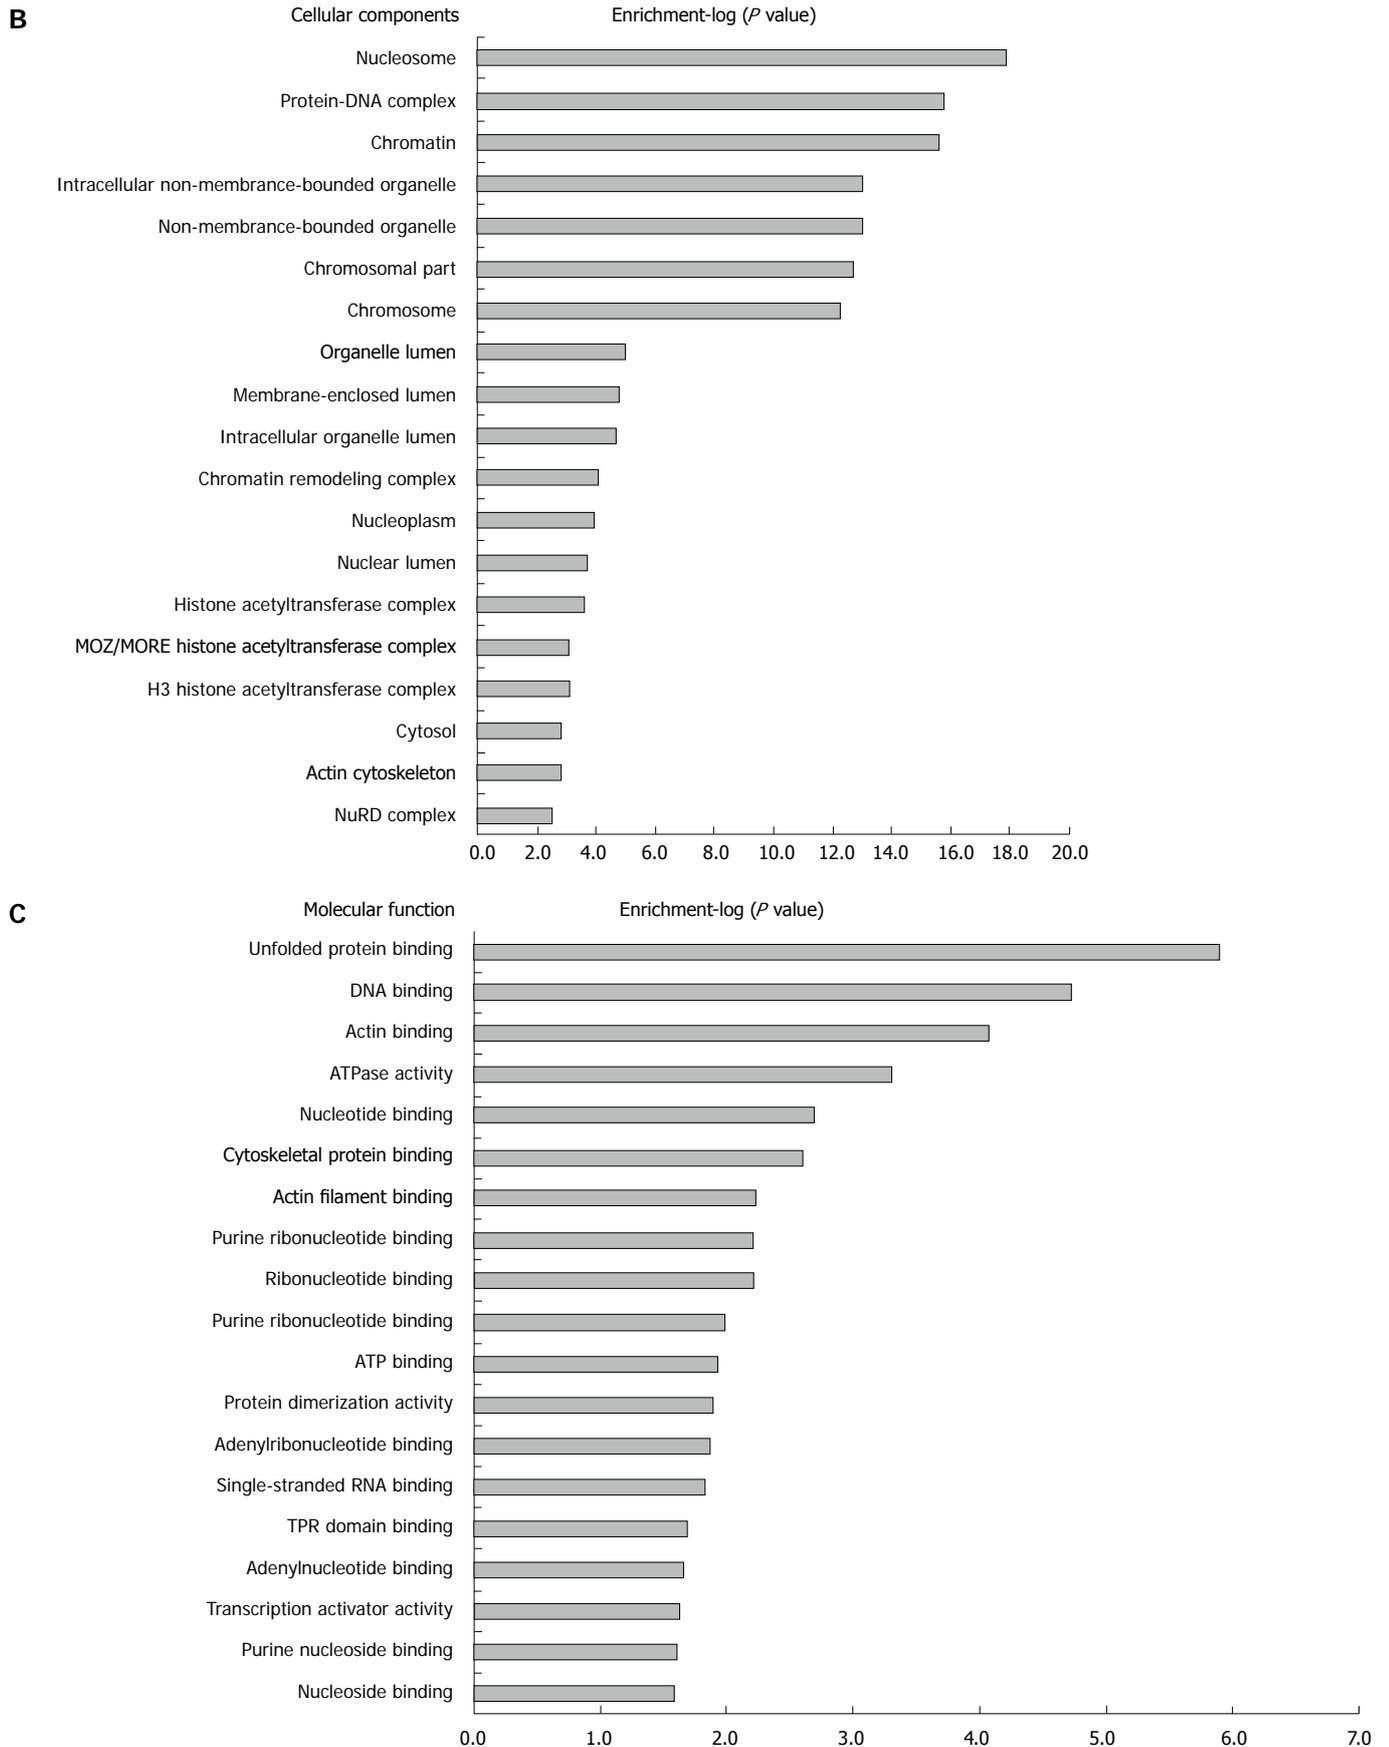

Figure 11 G0 contents based on biological process, cellular components and molecular function in which differently modified proteins were significantly enriched. A: Biological process; B: Cellular components; C: Molecular function.

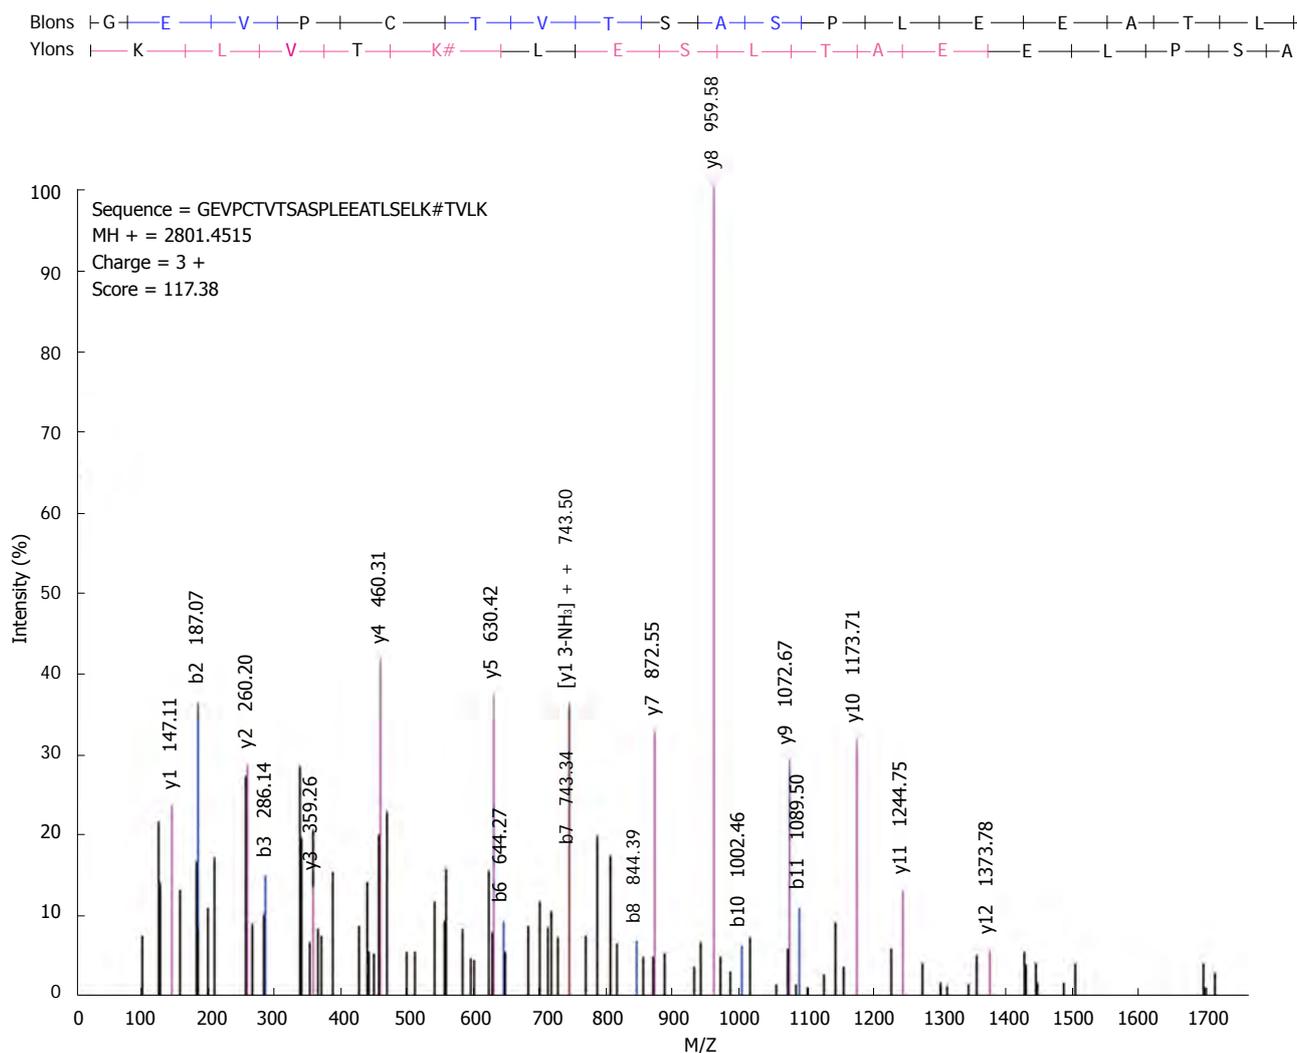

Figure 12 High-resolution MS/MS spectra of acetylated peptide at lysine 158 (GEVPCTVTSASPLEEATLSELK\*TVLK) in ATP5O.

protein band was ATP5O. To further determine whether ATP5O showed lysine acetylation, we performed mass spectrometry on the acetylated sites of normal AGS cells. The results confirmed that ATP5O had acetylated sites. The verification experiment of acetylated protein showed that the degree of acetylation of ATP5O was increased with exposure time, while ATP5O expression level was not changed during the process. ATP5O is the main component of the oligomycin-sensitivity donor protein subunit, ATP synthase, and located in human chromosome 21q22.1-Q22.2<sup>[33]</sup>. It is important for oxidation and phosphorylation. The component is not only associated with oxidative stress due to neurodegeneration, but also with human recombinant superoxide dismutase-1. Proteomics has become a main theme in life science research. Mass spectrometry has high sensitivity, high accuracy, and easy automation. Therefore, mass spectrometry-based identification methods have gradually become a standard for proteomics. We found that ATP5O was significantly acetylated after AGS cells were exposed to the deacetyltransferase inhibitor, TSA, using mass spectrometry technology, which indicated that the acetylation

of ATP5O was dynamically regulated in cells. At present, no ATP5O acetylation mechanisms have been reported in the domestic or international literature. Further studies are needed to determine what role this dynamic regulation plays in tumor cells and through which paths ATP5O affects tumor generation and growth after acetylation. In addition, mass spectrometry showed that a large amount of acetylated PKM2 (isoform of modified pyruvate kinase) existed in differential proteins before AGS cells were exposed to TSA, however, acetylated PKM2 was significantly reduced after exposure to TSA. PKM2 is an isoenzyme of pyruvate kinase, and a specific protein in embryos and differentiated cells<sup>[34]</sup>. Mazurek<sup>[35]</sup> revealed that PKM2 is a crucial factor in tumor metabolism, promoting cell proliferation and leading to tumors. Lv *et al*<sup>[36]</sup> confirmed that PKM2 K305 acetylation decreases PKM2 enzyme activity and promotes its lysosomal-dependent degradation *via* chaperone-mediated autophagy (CMA). Acetylation increases the interaction between PKM2 and HSC70, a chaperone for CMA, and its association with lysosomes. Ectopic expression of an acetylation mimetic K305Q mutant accumulates glycolytic intermediates and

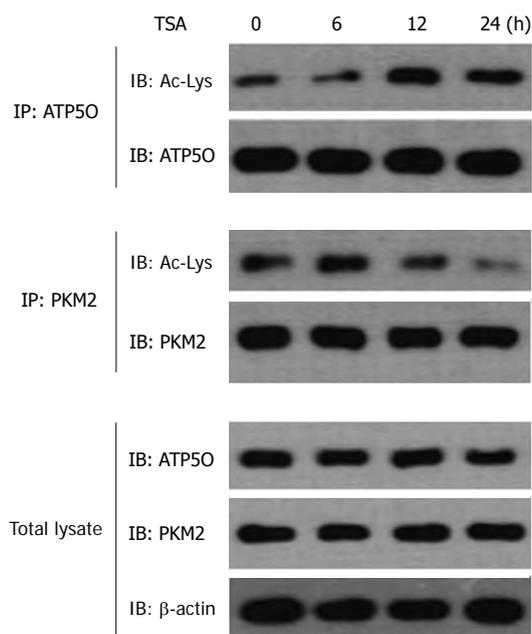

Figure 13 AGS cells were exposed to 0.5  $\mu\text{mol/L}$  trichostatin A for the indicated time periods and then ATP50 and PKM2 protein were immunoprecipitated using an anti-ATP50 antibody and an anti-PKM2 antibody. Total ATP50 and acetylation of ATP50 were detected using an anti-ATP50 antibody and an antibody specific to acetylated lysine, respectively. Total PKM2 and deacetylation of PKM2 were detected using an anti-PKM2 antibody and an antibody specific to deacetylated lysine, respectively. ATP50, PKM2 and  $\beta$ -Actin protein levels in the total lysate are also shown.

promotes cell proliferation and tumor growth. Further research is required on why acetylated PKM2 is reduced after AGS cells are exposed to TSA, what mechanisms affect the process, and whether TSA induces PKM2 deacetylation by activating other signaling pathways.

One field of tumor research is to explore deacetyltransferase inhibitors which have little toxicity and good efficacy, and combine deacetyltransferase inhibitors with clinical cancer treatment, including the combination of deacetyltransferase inhibitors with chemotherapeutics or with gene therapies or other tumor apoptosis or differentiation-inducing agents to determine better individual therapy for all tumors. Our experiments demonstrated that TSA played a role in inhibiting proliferation, promoting apoptosis and affecting the normal cell cycle of AGS cells. Besides activation of a variety of tumor-related signaling pathways and involvement in histone acetylation, TSA may also influence the growth and metabolism of gastric cancer cells by acetylation of non-histone, such as modification of ATP50. Exploring more deacetyltransferase inhibitors and their action sites is favorable in the development of new drugs.

## COMMENTS

### Background

The prevalence and mortality of gastric cancer in East Asia are higher than the world average values. In China, more than 400000 new patients are diagnosed every year. In absence of targets, the traditional chemotherapies have severe side effect. Therefore cancer treatment and research are now focusing on the

molecular targeted therapy due to its high selectivity, good efficacy and little side effects.

### Research frontiers

This study is the first to select acetylated differential proteins before and after gastric cancer cells are exposed to trichostatin A (TSA) to explore the effect of lysine acetylation of related proteins on regulating the proliferation of gastric cancer cells. Moreover, sketch the lysine-acetylated proteins and the modified sites of AGS cells.

### Innovations and breakthroughs

Previous researches are with the acetylation modification of deacetyltransferase inhibitor on histone, but rare studies focus on the acetylation modification of deacetyltransferase on non-histone. The study is on whether the acetylated non-histones is involved in tumor growth and metabolism, a high-resolution mass spectrometer is applied to detect the acetylated proteins and modified sites.

### Applications

The study provides an experimental basis for future studies on exploring more deacetyltransferase inhibitors and action sites thereof is favorable to the development of new drugs for cancer.

### Peer review

The authors explored TSA can inhibit gastric cancer cell proliferation and ATP50 was obviously acetylated after TSA intervenes. Simultaneously, they sketched the acetylated proteins and modified sites in AGS cells. The paper is well presented and the results are interesting.

### Abstract

**AIM:** To investigate the survival of individuals with colorectal cancer (CRC) with inflammatory bowel disease (IBD-associated CRC) compared to that of individuals without IBD diagnosed with CRC.

**METHODS:** Epidemiologic, clinical, and follow-up data were obtained from the Colon Cancer Family Registry (Colon CFR). IBD-associated cases were identified from self-report of physician diagnosis. For a subset of participants, medical records were examined to confirm self-report of IBD. Cox proportional hazards regression was applied to estimate adjusted hazard ratios (aHR) and 95%CI of mortality, comparing IBD-associated to non-IBD-associated CRC, adjusted for age at CRC diagnosis, sex, Colon CFR phase, and number of prior endoscopies. Following imputation to complete CRC stage information, adjustment for CRC stage was examined.

**RESULTS:** A total of 7202 CRC cases, including 250 cases of IBD-associated CRC, were analyzed. Over a twelve year follow-up period following CRC diagnosis, 2013 and 74 deaths occurred among non-IBD associated CRC and IBD-associated CRC patients, respectively. The difference in survival between IBD-associated and non-IBD CRC cases was not statistically significant (aHR = 1.08; 95%CI: 0.85-1.36). However, the assumption of proportional hazards necessary for valid inference from Cox regression was not met over the entire follow-up period, and we therefore limited analyses to within five years after CRC diagnosis when the assumption of proportional hazards was met. Over this period, there was evidence of worse prognosis for IBD-associated CRC (aHR = 1.36; 95%CI: 1.05-1.76). Results were similar when adjusted for CRC stage, or restricted to IBD confirmed in medical records.

**CONCLUSION:** These results support the hypothesis

that IBD-associated CRC has a worse prognosis than non-IBD-associated CRC.

**Key words:** Colorectal cancer; Inflammatory bowel disease; Outcomes research; Cancer survival; Inflammation

**Core tip:** Inflammatory bowel disease (IBD) - and more generally, inflammation - increases risk of colorectal cancer (CRC). Inflammation may also promote cancer progression and metastasis, and therefore, inflammation might be associated with shorter survival with CRC. This study examined whether CRC that occurs in patients with IBD has a worse prognosis than CRC in patients without IBD.

## INTRODUCTION

Inflammatory bowel disease (IBD), comprising ulcerative colitis (UC) and Crohn's disease (CD), is an inflammatory disease affecting the gastrointestinal tract<sup>[1]</sup>. IBD is associated with a substantial increase in the risk of colorectal cancer (CRC), especially after 8-10 years of active disease<sup>[2-4]</sup>. Implicated mechanisms include persistent activation of cyclooxygenase-2 and nuclear factor kappa-B pathways and increased oxidative stress<sup>[5,6]</sup>, leading IBD to be considered a model for understanding the role of chronic inflammation in CRC etiology<sup>[2,7]</sup>.

IBD-associated CRCs have distinct molecular and clinical features compared to sporadic CRCs<sup>[6,8]</sup>. Specifically, CRC arising in association with IBD has an initiation and progression sequence that differs from the canonical sequence of adenoma-to-cancer characterizing sporadic CRC. Furthermore, IBD-associated CRC typically affects individuals at an earlier age than sporadic CRC, and the distribution of histologic type and site within the colon may differ<sup>[6,8]</sup>. Despite these differences, the results of many studies support the concept that inflammation at levels more subtle than that seen in IBD is associated with CRC risk<sup>[2]</sup>; in this model, inflammation acts primarily as a tumor-promoter following environmental mutagenic insult. Non-IBD-associated CRC tumors show infiltration by inflammatory immune cells and elevated inflammatory cytokines<sup>[2]</sup>. Epidemiologically, circulating C-reactive protein, a marker of inflammation, has been associated with increased risk<sup>[9,10]</sup>, regular use of anti-inflammatory medication such as aspirin reduces risk of CRC<sup>[11-15]</sup>, and genetic variation in inflammatory path-

way genes may also modulate CRC risk<sup>[16,17]</sup>. Inflammation is also hypothesized to enhance metastasis in both IBD-associated and non-IBD-associated CRC<sup>[18]</sup>.

Recent evidence suggests that the use of non-steroidal anti-inflammatory drugs (NSAIDs) improves survival following CRC diagnosis<sup>[19,20]</sup>. From this it may be inferred that inflammation is involved in disease progression. If this is true, survival of individuals with IBD-associated CRCs would be predicted to be worse than for those with sporadic CRCs. However, the evidence that IBD negatively affects the prognosis of CRC comes primarily from small, hospital-based studies<sup>[21-24]</sup> and is inconsistent. Among the largest previously published studies, one observed an approximately 20% higher risk of mortality among UC-associated IBD patients compared to other CRC patients<sup>[25]</sup> and two others found no difference<sup>[26,27]</sup>.

We accessed data from the large, multi-center Colon Cancer Family Registry (Colon CFR)<sup>[28]</sup> to compare the survival of patients with IBD-associated CRC to those without IBD diagnosed with CRC.

## MATERIALS AND METHODS

### Study population: The Colon CFR

This study includes incident invasive CRC cases diagnosed between 1997 and 2009 registered with the Colon CFR, an international resource comprising seven sites that has been previously described in detail<sup>[28]</sup>. Case ascertainment and recruitment methodology differed between Colon CFR centers and between registry phases (1997-2001 and 2002-2009)<sup>[28]</sup>, and included population-based recruitment in addition to targeted recruitment of CRC cases under age 50 or with a family history of CRC. CRC cases associated with familial adenomatous polyposis ( $n = 89$ ) or Lynch syndrome ( $n = 1438$ ) were excluded. Invasive CRC cases were eligible if age, sex, and self-reported IBD information was available; for the primary analysis both population-based cases and cases recruited through clinics associated with Colon CFR centers were included. Of 7297 eligible cases, 7202 records had complete information on analytical covariates other than CRC stage, and were included in multivariate adjusted analyses.

### Inflammatory bowel disease assessment

IBD prior to CRC diagnosis was assessed through self-report during the Colon CFR baseline epidemiologic and medical history interview. Consecutive questions asked whether a participant had ever been told by doctor that they had CD, UC, irritable bowel syndrome, or diverticulitis. The UC question included a statement that UC is not a stomach ulcer. Each affirmative answer was followed with a question ascertaining the participant's age or calendar year in which the diagnosis was reported to the participant. Participants reporting either UC or CD diagnosis were counted as having IBD in the primary analysis. Participants reporting irritable bowel syndrome or diverticulitis were not considered to have IBD and included with all other CRC cases.

Clinical records at two Colon CFR centers, Ontario and Seattle, were reviewed for references to UC or CD. Of 169 self-reported IBD diagnoses from these centers, at least some medical or pathology records were available for 150 patients.

### Covariate assessment

During the study interview, information was collected on family history of CRC, medical history related to digestive disease including endoscopy and hemoccult testing, height and weight, demographics, and lifestyle (*e.g.*, cigarette smoking, physical activity, and alcohol consumption)<sup>[28]</sup>. A reference date of 2 years prior to CRC diagnosis was used to categorize participants' exposures prior to diagnosis, except for endoscopy and hemoccult testing. Hemoccult testing was categorized as never, 1-4, or 5 or more total tests. Similarly the total lifetime number of reported endoscopies (colonoscopies and sigmoidoscopies) was categorized as none or 1, 2, or 3 or more.

### Tumor characteristics

Cancer stage, histologic type (*i.e.*, adenocarcinoma, mucinous adenocarcinoma, signet ring cell carcinoma), and anatomic site of the tumor were obtained from registry or pathology reports<sup>[28]</sup>. For analysis, tumors in the cecum, ascending colon, hepatic flexure, transverse colon, and splenic flexure (ICD-O-3 codes C180, C182-185) were considered proximal; tumors in the descending colon (C186) and sigmoid colon (C187) were grouped as distal colon tumors; and rectosigmoid junction (C199), rectum (C209), and overlapping lesion of the anus and rectum (C218) were considered rectal tumors. Stage information was obtained by Colon CFR centers from the Surveillance Epidemiology and End Results (SEER) registry (Seattle and Hawaii) or medical records and pathology review (all other centers). Records included American Joint Committee on Cancer staging on tumor extent (T-stage), lymph node positivity (N-stage; number of nodes positive for malignant cells), and the presence of distant metastases (M-stage). From these indices, stage was summarized as local, regional, or distant following SEER guidelines. Microsatellite instability (MSI) status was characterized for 4422 cases with available tumor samples in the Colon CFR, combining the results of genetic analysis of a 10-marker panel and immunohistochemical staining of DNA mismatch repair proteins as previously described<sup>[28-33]</sup>.

### Imputation of stage of CRC

Of 7202 cases eligible for this analysis, 4450 (62%) initially could not be categorized in a SEER summary stage. Of these, 4343 could not be classified in part because of missing M-stage information, primarily because ascertaining distant metastases required medical records not accessible at all Colon CFR centers. However, 2859 of these cases without M-stage information included T- or N-stage information. Missing stage information was imputed in two steps. First, cases without M information but with N information indicating that no lymph nodes tested positive

for malignant cells were coded as having no distant metastases. If T-stage information was also available, SEER summary stage was updated to local or regional. In total 1509 of 4450 cases (34%) originally missing SEER summary stage were completed through this direct imputation.

Following direct imputation, multiple imputation with chained equations was used to complete the remaining cases missing stage information<sup>[34]</sup>. T-stage (T1-3, T4) and N-stage (N0, N > 0) were reduced to dichotomous variables. Fifty datasets were generated with T, N and M imputed using chained logistic regression based on all variables considered in the primary survival analysis (see below), and additional potential predictors of stage: time at risk, vital status, delay between CRC diagnosis and Colon CFR enrollment, histologic type, partial colectomy (ever, never, missing), and tumor site (proximal, distal, rectal, overlapping/NOS). Imputation regression excluded cases with incomplete information in one or more predictors ( $n = 889$ ). In total, 6313 cases were included in multiple imputation regression; T, N or M were imputed for 1677, 1697 and 2438 cases, respectively. Following imputation, SEER summary stage was derived from imputed T, N and M following SEER coding<sup>[35,36]</sup>. Together with cases whose records originally included SEER summary stage or were completed with direct imputation, described above, a total of 6809 cases with SEER summary stage were included in analyses involving stage.

### Vital status

Vital status was updated at each Colon CFR center through linkage to population-based tumor registries and death indices, in addition to active follow-up 4-5 years after initial enrollment and routine contact with enrollees and family members<sup>[28]</sup>.

### Ethical considerations

Each Colon CFR center Institutional Review Board/ethics board approved all study protocols and all participants provided informed consent.

### Statistical analysis

Cox proportional hazards regression was used to estimate adjusted hazard ratios (aHRs) of death from any cause with 95% CIs. Time at risk was measured in days from CRC diagnosis, with participants entering observation on the date of Colon CFR baseline interview. Participants alive at the most recent time of confirmed contact were censored at that date. Parallel analyses were completed for the full follow-up time, and with administrative censoring of all participants 5 years after CRC diagnosis. The proportional hazard assumption was examined graphically and by allowing the variable representing IBD status to interact with the logarithm of failure time, and testing the significance of the time-varying factor<sup>[37]</sup>.

To adjust for age at CRC diagnosis, participants were divided into approximate quartiles of age (cut-points at 47, 56 and 65 years) and a piecewise linear model of hazard of death was constructed. Additional *a priori* can-

<sup>1</sup>Numbers do not sum to total due to missing values; <sup>2</sup>2 years prior to colorectal cancer (CRC) diagnosis; <sup>3</sup>Mean of 50 imputed datasets. Colon CFR: Colon Cancer Family Registry; NSAID: Non-steroidal anti-inflammatory drugs; BMI: Body mass index.

didate adjustment variables were Colon CFR phase of enrollment (1997-2001 or 2002-2009), Colon CFR center, sex, cigarette smoking history, use of NSAIDs, education, race, body mass index (BMI), first degree family history of CRC, and utilization of hemoccult tests or endos-

copy. Colon CFR center, NSAID use, BMI, education, race, smoking, hemoccult tests, and family history were omitted from final statistical models because inclusion did not appreciably change aHRs associated with IBD. CRC stage, when included, was parameterized as SEER summary stage (localized, regional, or distant disease).

## RESULTS

Of 7202 eligible CRC patients, 250 (3.5%) reported a physician's diagnosis of IBD (Table 1). IBD-associated CRC patients were younger at CRC diagnosis than non-IBD cases. In addition, IBD-associated CRC patients were less likely to have ever regularly smoked cigarettes, and were leaner on average than other patients with CRC. IBD-associated CRC patients were much more likely than sporadic CRC patients to be white, report a family history of CRC, or have had multiple endoscopies.

Compared to non-IBD cases, a larger proportion of IBD-associated CRC patients were diagnosed with tumors in the proximal colon (Table 1). Among tumors assayed for MSI, no difference in the distribution of MSI between IBD-associated and other CRC was observed. The distribution of SEER summary stage differed only slightly between IBD-associated CRC and other CRC following completion of missing stage information with multiple imputation. However, a more pronounced, but not statistically significant, difference in stage distribution between IBD-associated and sporadic CRC was noted among patients diagnosed before age 50 year; in this age group, 24% of non-IBD associated CRC cases were diagnosed after distant metastases has occurred, compared to 18% of IBD-associated CRC cases (not shown;  $\chi^2$  test  $P > 0.15$ ).

Over a total follow-up of 12.2 years (median of 4.6 years), 2013 and 74 deaths were reported among non-IBD-associated and IBD-associated CRC cases, respectively. Results of Cox proportional hazards regression using the full follow-up period indicated no association between IBD and risk of mortality from any cause (Figure 1 and Table 2).

Graphical inspection of the Kaplan-Meier survival curve (Figure 1) and formal testing of time-varying coefficients (not shown), indicated that the proportional hazards assumption was violated by the variable representing IBD status. Ending follow-up at no later than 5 years following diagnosis for all participants resolved the proportional hazards violation based on time-varying models (not shown).

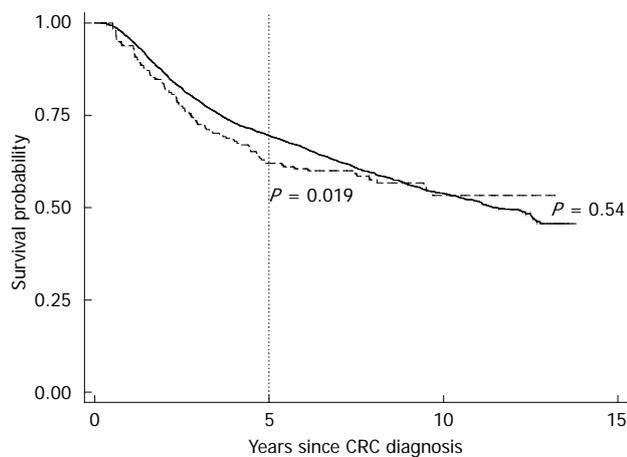

Results from analyses including only the 5 years following diagnosis, but otherwise identical to analysis across the entire follow-up time, showed that IBD-associated CRC patients were at 36% (95%CI: 5%-76%) higher risk of death (Figure 1 and Table 2). Following imputation of CRC stage, additional adjustment for stage left resulting aHR estimates largely unchanged.

Medical and pathology records of 169 eligible cases enrolled at the Seattle and Ontario CFR centers were reviewed; for 14 IBD-associated CRC cases no records

<sup>1</sup>Adjusted for age, recruitment phase, sex, and endoscopy; <sup>2</sup>Additional adjustment for surveillance epidemiology and end results summary stage (local, regional, distant); <sup>3</sup>Inflammatory bowel disease (IBD) confirmed from medical and pathology records at Seattle and Ontario centers only, non-IBD associated cases restricted to these centers. aHR: Adjusted hazard ratio.

**Figure 1** Adjusted survival probability for non-inflammatory bowel disease-associated (solid line) and inflammatory bowel disease-associated colorectal cancer (dashed line). *P* values are from Wald test of coefficient of inflammatory bowel disease from Cox regression. CRC: Colorectal cancer.

were available for review, for 43 only pathology reports or death certificates were available, and for 107 pathology and at least partial medical records were available. During review, 81 of these 169 self-reported IBD diagnoses were confirmed. When proportional hazards regression analysis was repeated including confirmed IBD diagnoses and non-IBD-associated CRC only from the Seattle and Ontario Colon CFR centers, and thus excluding unconfirmed self-reported IBD from analyses, results suggested that IBD was associated with a 52% (95%CI: 0%-130%) higher risk of mortality following CRC diagnosis (Table 2).

In exploratory sub-group analyses of survival through 5 years post-CRC diagnosis, the association between IBD and risk of death did not vary by MSI status of the tumor (not shown). However, IBD was more strongly associated with risk of death among patients with distal or rectal CRC tumors (aHR = 1.62, 95%CI: 1.17-2.26) than among patients with tumors in the proximal colon (aHR = 0.98; 95%CI: 0.64-1.50), although the interaction between IBD and tumor site was not statistically significant (*P* = 0.06). Survival also did not differ by duration of IBD prior to CRC diagnosis (< 8 years IBD, aHR = 1.38, 95%CI: 0.96-1.99; ≥ 8 years IBD, aHR = 1.38, 95%CI:

0.96-2.00). Patients reporting only CD were apparently at higher risk of mortality than those with UC only, although the difference was not statistically significant (CD, aHR = 1.74, 95%CI: 1.09-2.79; UC, aHR = 1.18, 95%CI: 0.85-1.63, *P* = 0.16).

Restriction of analysis to 4144 population-based cases enrolled during phase I did not appreciably alter the association between IBD and hazard of mortality within 5 years of CRC diagnosis (aHR = 1.47, 95%CI: 1.08-2.01). Incorporation of probability weights based on the sampling scheme of the Colon CFR<sup>[28]</sup> also did not change results of death, IBD compared to non-IBD-associated CRC (aHR = 1.62, 95%CI: 1.04-2.54).

## DISCUSSION

We observed a higher risk of death from any cause among patients with IBD-associated CRC compared to those with non-IBD-associated CRC when attention was restricted to the first five years following CRC diagnosis. The increase in risk was of borderline statistical significance. However, no increase in risk of death was seen when all available follow-up data were analyzed. The violation of the proportional hazard assumption made the analysis using all available follow-up time difficult to interpret; in contrast, the period within 5 years following CRC diagnosis showed no violations of the proportional hazards assumption.

CRC stage at diagnosis is a strong predictor of survival, and IBD patients may undergo surveillance designed to detect CRC at early stages. Therefore, we compared CRC stage distribution between cases with and without IBD, and conducted stage-adjusted survival analyses. Our results suggest that IBD-associated CRC is only slightly more frequently diagnosed at local or regional stage than non-IBD-associated CRC. This may be due to active endoscopic surveillance for CRC among IBD patients, consistent with earlier reports<sup>[38]</sup>. We observed that the shift in stage distribution was larger, but not statistically significant, among CRC patients diagnosed prior to age 50 years; this group would generally not receive screening endoscopy in the absence of gastrointestinal symptoms or a strong family history of CRC.

When we repeated survival analysis adjusted for stage, our results still suggested increased risk of mortality among IBD-associated CRC patients. Further exploration revealed that after adjustment for the lifetime number of endoscopic procedures, adjustment for SEER summary stage did not substantially alter the aHR associated with IBD, as would be expected if endoscopy utilization was an important determinant of CRC stage at diagnosis. Examination of our multiple imputation model for CRC stage confirmed that endoscopy was among the strongest predictors of CRC stage. Thus, our results indicate that survival was poorer for IBD-associated CRC patients than for other CRC patients diagnosed at the same SEER stage.

Our results are consistent with reports from several previous studies<sup>[24,39]</sup> including the largest previous population-based studies of this topic<sup>[25,40]</sup>, which included a similar number of UC- and CD-associated CRC cases. These studies reported about 20% or 50% higher mortality among UC-associated CRC patients<sup>[25]</sup> and CD-associated CRC patients<sup>[40]</sup>, respectively, compared to other CRC patients, adjusted for CRC stage. A large Japanese study observed worse prognosis for UC-associated CRC but the relationship was restricted to stage III CRC<sup>[27]</sup>. In contrast with our results, a relatively large ( $n = 290$  IBD-associated CRC cases) clinic-based study did not observe differential risk of death between IBD-associated and other CRC cases, possibly because of the clinical basis of the study<sup>[26]</sup>. Thus, our overall results, based on a set of relatively unselected cases and confirmed in the population-based portion of the Colon CFR, agree with the population-based results<sup>[25,40]</sup>, and strengthen the evidence that the prognosis for IBD-associated CRC is worse than for non-IBD-associated CRC.

Our study has additional important methodological strengths. Approximately 57% of participants in this study were drawn from Colon CFR centers that utilize population-based case ascertainment strategies. Therefore, our results are likely to provide more general insight into the survival of IBD-associated CRC than clinic-based case series. Although our sample size was limited by the rarity of both IBD and CRC, the large, multi-site Colon CFR included a broad spectrum of CRC. Furthermore, because of the size of the Colon CFR, the cases in this study were recruited over 12 years, in comparison to previous reports that required 20 or more years to recruit a comparable number<sup>[25,27]</sup>.

An important limitation of this study was our reliance on participant report of either UC or CD. We believe that our inability to confirm about 50% of self-reported UC or CD in patients from Ontario and Seattle resulted mainly from lack of access to complete medical records prior to CRC diagnosis. Although we expected IBD to be noted on pathology or medical records related to CRC diagnosis, we cannot be sure why information might be missing; the self-report of UC or CD might be incorrect, or the limited records available for review may be incomplete. Nonetheless, when we restricted analysis to confirmed IBD cases, removing unconfirmed IBD from analysis, the association between IBD-associated CRC and

risk of mortality was strengthened. This could be because we successfully reduced misclassification of IBD. Alternatively, IBD confirmed in medical records may have been, on average, more severe than unconfirmed IBD, perhaps because available medical records were those related to CRC diagnosis.

Because we lacked detailed IBD-specific medical records, we were also unable to determine how medications such as 5-aminosalicylic acid (5-ASA) used to treat IBD may have affected our results. In some studies, 5-ASA use has been associated with a reduced risk of CRC in IBD patients<sup>[41,42]</sup>, and IBD patients who are never diagnosed with CRC are not included in our analysis. Like other anti-inflammatory drugs<sup>[19,20]</sup>, 5-ASA treatment prior to CRC may reduce the risk of CRC mortality, and this may account in part for the relatively small difference in survival we observed between IBD-associated and sporadic CRC.

We also lacked specific cause of death information for deaths recorded outside of the Seattle, Ontario, and Mayo Clinic Colon CFR centers. However, at these centers, CRC was the underlying cause of death for 24 of 31 (77%) IBD-associated CRC patients and 499 of 651 (77%) of non-IBD CRC patients who died within 5 years of CRC diagnosis. Therefore, it is likely that most of the deaths included in the 5-year analysis across all Colon CFR centers were due to CRC, and differences in cause of death between IBD-associated and other CRC is unlikely to have influenced our results.

Finally, our sample size was limited to fully evaluate this association. IBD is associated with a strong increase in CRC risk<sup>[2,3,43]</sup>, and we noted a higher prevalence of IBD, approximately 3.5%, among CRC cases than would be expected in the underlying population in which these CRC cases arose. For example, the prevalence of IBD in the United States is less than 1%<sup>[44,45]</sup>. However, the number of IBD-associated CRC cases in our study is approximately equal to the largest previous study comparing survival with non-IBD-associated CRC<sup>[25]</sup>. Nonetheless, sparse numbers certainly hindered our analysis and suggest that cautious interpretation is warranted. Future progress may perhaps be achieved by combining multiple populations through pooled or meta-analyses.

Our observation that IBD-associated CRC appears to have a worse prognosis than non-IBD-associated CRC, even when stage at diagnosis is taken into account, is consistent with evidence that inflammation negatively impacts CRC survival<sup>[19,20]</sup>. The mechanisms through which this may occur remain to be determined.

## COMMENTS

### Background

Inflammatory bowel disease (IBD) - more generally, inflammation - increases risk of colorectal cancer (CRC). Inflammation may also be associated with a poorer prognosis in patients with CRC, perhaps because inflammation may promote tumor progression (growth) and metastasis.

### Research frontiers

The prevalence of IBD is growing worldwide. It remains unclear whether individuals diagnosed with CRC in the context of IBD are at higher risk of death from CRC, compared to CRC patients without IBD.

### Innovations and breakthroughs

The rarity of both IBD and CRC make studying IBD-associated CRC difficult. This study includes a relatively large number of IBD-associated CRC cases, recruited from multiple populations rather than a single clinic case-series. The results suggest that survival with IBD-associated CRC is shorter than survival with CRC arising outside of IBD. This is observed even when comparing CRC cases diagnosed at the same stage, suggesting that IBD-associated CRC progresses more rapidly. However, it may also be due to other factors such as differences in CRC treatment, which could not be measured well in this study.

### Applications

This study suggests that more effort is needed to understand why patients with IBD who are later diagnosed with CRC do worse than patients with CRC.

### Peer review

The study lacked information on how IBD patients were treated for IBD prior to CRC, and whether they received surveillance for CRC incidence (as is commonly prescribed for this group under certain conditions). Surveillance is intended to catch CRC at early stage in IBD patients and therefore could improve survival with CRC in this group. This is a weakness of the paper. However, the study attempted to account for this by adjusting for stage of CRC at diagnosis (comparing cases diagnosed at the same stage) and noted that there was very little overall stage difference between IBD-associated and other CRC. Also, the difference in survival was noted only for 5 years following CRC diagnosis, but not over a long time (12 years), although most deaths occurred within the first 5 years. The study is interesting and may support the hypothesis that inflammation is worse for CRC survival.

### Abstract

**AIM:** To develop novel biomarkers of rectal radiotherapy, we measured gene expression profiles on biopsies taken before and during preoperative radiotherapy.

**METHODS:** Six patients presenting with a locally advanced rectal cancer (T>T2, N0/Nx, M0) eligible for preoperative radiotherapy (45 Gy in 25 fractions) were selected in a pilot study. Six tumor and 3 normal tissues biopsies were taken before and during radiotherapy,

after a dose of 7.2 Gy at a median time of 1 h following irradiation (0:27-2:12). Tumor or normal tissue purity was assessed by a pathologist prior to RNA extraction. Mean RNA content was 23 µg/biopsy (14-37) before radiotherapy and 22.7 µg/biopsy (12-35) during radiotherapy. After RNA amplification, biopsies were analysed with 54K HG-U133A Plus 2.0 Affymetrix expression micro-arrays. Data were normalized according to MAS5 algorithm. A gene expression ratio was calculated as: (gene expression during radiotherapy - gene expression before radiotherapy)/gene expression before radiotherapy. Were selected genes that showed a ratio higher than  $\pm 0.5$  in all 6 patients.

**RESULTS:** Microarray analysis showed that preoperative radiotherapy significantly up-regulated 31 genes and down-regulated 6 genes. According to the Gene Ontology project classification, these genes are involved in protein metabolism (*ADAMDEC1; AKAP7; CAPN5; CLIC5; CPE; CREB3L1; NEDD4L; RAB27A*), ion transport (*AKAP7; ATP2A3; CCL28; CLIC5; F2RL2; NEDD4L; SLC6A8*), transcription (*AKAP7; CREB3L1; ISX; PABPC1L; TXNIP*), signal transduction (*CAPN5; F2RL2; RAB27A; TNFRSF11A*), cell adhesion (*ADAMDEC1; PXDN; SPON1; S100A2*), immune response (*CCL28; PXDN; TNFRSF11A*) and apoptosis (*ITM2C; PDCD4; PVT1*). Up-regulation of 3 genes (*CCL28; CLIC5; PDCD4*) was detected by 2 different probes and up-regulation of 2 genes (*RAB27A; TXNIP*) by 3 probes.

**CONCLUSION:** Micro-arrays can efficiently assess early transcriptomic changes during preoperative radiotherapy for rectal cancer, and may help better understand tumor radioresistance.

## INTRODUCTION

In patients with rectal adenocarcinoma, preoperative radiotherapy (RT), either alone or combined with chemotherapy, reduces the 5-year rate of local recurrence by 5% to 10%<sup>[1]</sup>. However, owing to high inter-individual variation, 6-18 patients have to be treated in order to avoid one recurrence. Identifying patients likely to benefit is thus essential.

End outcomes after preoperative RT can hardly be predicted by analyzing the expression of known proteins on pre-treatment biopsies<sup>[2]</sup> or clinical parameters<sup>[3]</sup>. However, micro-array gene expression profiling can help define diagnostic, prognostic and predictive factors for response to RT<sup>[4]</sup>. Transcriptomic profiles obtained on pre-RT biopsies can be used to identify patients with rectal adenocarcinoma who are likely to relapse despite appropriate treatment<sup>[5]</sup>. Validation studies on larger cohorts are ongoing.

Sequential biopsies have highlighted changes in tumor dynamics (proliferation, cell cycle, apoptosis) during pelvic RT and identified treatment targets that might modify RT outcomes in patients with cervical cancer, where tumor access is easier than for the rectum<sup>[6,7]</sup>. Although sequential biopsies have also revealed histological changes in rectal mucosa due to radiation toxicity, data are few<sup>[8-11]</sup>. Very recently, biopsy specimens could be obtained 7 d after starting chemoradiotherapy and provided interesting biomarkers of response to treatment in rectal cancer patients<sup>[12]</sup>.

A study of radiation-induced cellular and biochemical changes in rectal tumors might help better understand radiation-induced cell death and identify new targets for enhancing RT efficacy. We postulated that sequential biopsies could be used to detect transcriptional changes

during preoperative RT of rectal cancer and help detect new predictors for response to radiation. A large-scale prospective study is needed to test this hypothesis. To eliminate the risk of increasing toxicity from repeated biopsy, we first conducted a pilot study to assess the safety of pre- and post-RT rectal tumor biopsies, and also the feasibility of detecting gene expression changes on biopsies from irradiated tumors.

## MATERIALS AND METHODS

### Patients

Patients presenting with locally advanced rectal cancer (T>T2, N0/Nx, M0) and eligible for preoperative RT were enrolled into the study. Exclusion criteria were: anti-coagulant therapy, cardiac valvular disease, and pelvic pain from prior biopsies. All patients gave their informed written consent to the study, which was approved by the University of Nantes Institutional Review Board for human studies.

### Biopsies

Patients were delivered 45 Gy (1.8 Gy/fraction, over 5 wk, 5 d per week). Six tumor and 3 normal tissue biopsies were taken from each patient before RT and one hour after a dose of 7.2 Gy (4<sup>th</sup> fraction) during RT. Patients were assessed for biopsy toxicity (infection or bleeding) during RT. Tumor purity was measured on tumor cell smears.

### RNA isolation and microarray procedures

Tissues were frozen immediately in liquid nitrogen and disrupted using a mortar and pestle. Samples were homogenized in lysis buffer using a syringe and needle. Total RNA was prepared using the RNeasy<sup>®</sup> Mini kit (Qiagen, Valencia, CA, United States). The integrity of the RNA was assessed for each sample using an Agilent 2100 Bioanalyzer (Agilent, Palo Alto, CA, United States). Double-stranded complementary DNA (cDNA) and labeled complementary RNA were synthesized from the total RNA and hybridized to the Affymetrix Human U133 plus 2 gene chips (Affymetrix, Santa Clara, CA, United States). The chips were further processed and scanned according to the manufacturer's protocol. The arrays were scanned with a laser scanner and the data was visualized and normalized using the MAS 5.0 Affymetrix software (Affymetrix, Santa Clara, CA, United States). Over- and under-expressed genes were classified by Gene Ontology category<sup>[13]</sup>.

### Statistical analysis

Data were normalized according to the MAS5 algorithm. The ratio "gene expression during RT/gene expression before RT" was calculated. Genes with a ratio > 2.5 or < 0.4 in all patients and a false discovery rate (FDR) of < 11%, as estimated by significance analysis of microarrays, were selected.

**Table 1 Patient characteristics**

| Patient | Age (yr) | Disease stage | > G1 radiotherapy toxicity | Surgical toxicity | Surgical stage | Outcome at 2 yr of follow-up | Tumor purity in biopsies | Mean RNA content (µg) |                   |
|---------|----------|---------------|----------------------------|-------------------|----------------|------------------------------|--------------------------|-----------------------|-------------------|

**RESULTS**

Seven patients with rectal cancer (median age: 66 years, range 55-84 years) were included in the study but one later refused to participate (Table 1). Six patients underwent biopsy before and during RT. The median time of the biopsy was 1 h after the 4<sup>th</sup> RT session (0:27-2:12). No grade 2 biopsy-induced toxicity was reported. Surgery was performed at a median time of 6 wk after RT. No

grade 2 intra-operative toxicity was reported.

Mean RNA content was 23 µg/biopsy (range 14-37 µg/biopsy) before RT and 22.7 µg/biopsy (range 12-35 µg/biopsy) during RT (Table 1). Microarray analysis showed that preoperative RT significantly up-regulated 31 genes and down-regulated 6 genes (the full names of the genes are given in Table 2). According to the Gene Ontology project classification, these genes are involved in protein metabolism (*ADAMDEC1*; *AKAP7*; *CAPN5*;

*CLIC5*; *CPE*; *CREB3L1*; *NEDD4L*; *RAB27A*), ion transport (*AKAP7*; *ATP2A3*; *CCL28*; *CLIC5*; *F2RL2*; *NEDD4L*; *SLC6A8*), transcription (*AKAP7*; *CREB3L1*; *ISX*; *PABPC1L*; *TXNIP*), signal transduction (*CAPN5*; *F2RL2*; *RAB27A*; *TNFRSF11A*), cell adhesion (*ADAMDEC1*; *PXDN*; *SPON1*; *S100A2*), immune response (*CCL28*; *PXDN*; *TNFRSF11A*) and apoptosis (*ITM2C*; *PDCD4*; *PVT1*)<sup>[13]</sup>. Up-regulation of 3 genes (*CCL28*; *CLIC5*; *PDCD4*) was detected by 2 different probes and up-regulation of 2 genes (*RAB27A*; *TXNIP*) by 3 probes.

## DISCUSSION

Biopsies taken during preoperative RT for rectal cancer were not associated with enhanced toxicity (infection or bleeding). cDNA micro-array analysis on tumor biopsies uncontaminated by normal tissue was possible provided that the extracted RNA was amplified.

Analysis of gene transcription pre- and post-RT detected many up-regulated genes involved in tumor development such as *GOLM1* (prostate cancer)<sup>[14]</sup>, *CAMK2N1* (a tumor suppressor gene in colon cancer)<sup>[15]</sup>, *AGR3* (breast cancer)<sup>[16]</sup> and *PDCD4* (lung and ovarian cancer)<sup>[17]</sup>. However and contrarily to *in vitro* studies<sup>[18]</sup>, it did not detect genes thought to be involved in cell repair after radiation-induced damage.

On the other hand, we detected several early response genes mostly involved in stress such as *CPE* which protects against oxidative stress-induced cell death and ROS-induced cell apoptosis<sup>[19]</sup>, hypoxia-induced *TXNIP* which is regulated by hypoxia-induction factor 1<sup>[20,21]</sup>, *CREB3L1* which codes for a protein that is cleaved in response to stress on the endoplasmic reticulum<sup>[22]</sup>, and *ITM2C* which is over-expressed after alpha radiation but whose role is not known<sup>[23]</sup>.

Many genes implicated in ion channel regulation were up-regulated during radiotherapy, such as *NEDD4L* which regulates sodium channels *via* the Wnt/beta-catenin signaling pathway during colon carcinogenesis<sup>[24]</sup>, *SLC6A8* which codes for a Na<sup>+</sup>Cl<sup>-</sup> dependent creatine transporter<sup>[25]</sup>, *ATP2A3* which encodes an intracellular pump participating in Ca<sup>2+</sup> sequestration, and *CLIC5*, a member of the chloride intracellular channel gene family, structurally homologous to the glutathione-S-transferase superfamily<sup>[26]</sup>.

Among up-regulated genes, we were surprised to find many that are implicated in the immune response, such as *ADAMDEC1* (decysin) which plays a key role in the interaction between dendritic cells and germinal center T-helper cells<sup>[27]</sup>, *ITM2C* which is involved in TNF-induced cell death<sup>[28]</sup>, *TNFRSF11A* which codes for a protein of the TNF receptor superfamily, *CCL28*, a member of the small cytokine CC gene subfamily<sup>[29]</sup>, *RAB27* which regulates exocytosis of neutrophil granules<sup>[30]</sup>, and *PDCD4* (programmed cell death 4) which is regulated by several interleukins (IL-2, IL-15 and IL-12) in natural killer and T cells<sup>[31]</sup>. This was the only gene of our list that has been reported to be a predictor of response to

preoperative radiochemotherapy in pre-treatment biopsies of patients with rectal cancer<sup>[32]</sup>. It codes for a tumor suppressor protein that inhibits translation initiation factor eIF4A which lies downstream of the AKT/mTOR pathway and plays a role in response to DNA damage<sup>[33-35]</sup>. *PDCD4* mRNA levels during RT may thus be an interesting surrogate marker in studies of mTOR inhibitors plus RT for rectal cancer.

Three of the up-regulated genes we detected (*GALNT12*, *CMAH* and *SPON1*) are involved in metabolic processes and interactions with glycans, and would seem to occupy a key role in triggering an immune response<sup>[36]</sup>. *SPON1* protein belongs the thrombospondin type 1 repeat superfamily of proteins that bind transforming growth factor- $\beta$ <sup>[57]</sup>. By analogy with *SPON2*, it might be involved in mechanisms of activation of innate and adaptive immune responses<sup>[38]</sup>.

Apart from *PDCD4* and *SPON1*, we identified at least two other genes that might constitute novel therapeutic targets in preoperative RT for rectal cancer. *TXNIP* (the gene coding for thioredoxin interacting protein) is a key regulator of redox status. Thioredoxin is released from cells in response to oxidative stress and its plasma or serum level is a good marker of cancer-related oxidative stress. Because thioredoxin mediates redox-induced cell death in colon cancer cells, it is an attractive target for anti-tumor therapy<sup>[39]</sup>. Thioredoxin inhibitors are currently under investigation<sup>[40]</sup>. *Rab27A* gene expression was also up-regulated during RT. *Rab27A* is a small G protein which regulates secretory activity in colon cancer cells and promotes invasiveness and metastasis in breast cancer cells<sup>[41,42]</sup>. Novel inhibitors of Rab geranylgeranyl-transferase might thus prove to be inhibitors of rectal tumor cell proliferation and RT enhancers<sup>[43]</sup>. Interestingly, the highly up-regulated clone 5745639 was found by Blast analysis 2022 bp from the 3' end of the Ras-related protein Rab-27A.

A limitation of our study is the small number of tumors analyzed. Our results are thus essentially hypothesis generating. Future attention should focus on the genes that have yielded the most robust results (low FDR and detected by several probes).

In conclusion, biopsies taken during early RT sessions may be used for *in vivo* measurement of tumor sensitivity and have low morbidity. Many genes involved in triggering immune response seem to be expressed during RT. We hypothesize that the changes in gene profiles observed early during RT may help predict rectal tumor response to preoperative RT, whether alone or combined with chemotherapy. Gene profiling may help: (1) identify predictors of resistance to RT that will enable exclusion of patients likely to be cured by surgery alone; (2) assess the validity of surrogate markers during phase I testing of new radiosensitizing drugs which are used together with RT to treat selected resistant rectal tumors; and (3) define new targets for improving the efficacy of preoperative RT of rectal cancer. To test our hypothesis, larger cohorts of patients are needed and the best time for gene

profiling during and after RT needs to be determined.

## COMMENTS

### Background

Because 6-18 patients have to be treated in order to avoid one recurrence, identifying patients with rectal adenocarcinoma likely to benefit from preoperative radiotherapy is essential. End outcomes after preoperative radiotherapy (RT) can hardly be predicted by analyzing pre-treatment clinical parameter, the expression of known proteins or transcriptomic profiles.

### Research frontiers

Sequential biopsies have highlighted changes in tumor dynamics during pelvic RT and identified treatment targets that might modify RT outcomes. The authors postulated that sequential biopsies could be used to detect transcriptional changes during preoperative RT of rectal cancer and help detect new predictors for response to radiation.

### Innovations and breakthroughs

Analysis of gene transcription pre- and post-RT detected many up-regulated genes involved in tumor development. However and contrarily to *in vitro* studies, it did not detect genes involved in DNA repair. Several early response genes mostly involved in stress response and genes involved in ion channel regulation were up-regulated during radiotherapy. Surprisingly, many genes that are implicated in the immune response were found to be up-regulated.

### Applications

Biopsies taken during early RT sessions can be used for *in vivo* measurement of tumor sensitivity and have low morbidity. Many genes involved in triggering immune response seem to be expressed during RT. The changes in gene profiles observed early during RT may help predict rectal tumor response to preoperative RT, whether alone or combined with chemotherapy.

### Terminology

DNA microarray is a collection of microscopic DNA spots attached to a solid surface used to measure the expression levels of large numbers of genes in a tumor sample.

### Peer review

In this study, the authors examined the transcriptomic changes during preoperative radiotherapy in French patients with rectal cancer. In general, this is a good attempt to seek transcriptomic biomarkers for patients with rectal cancer and can provide important information for clinicians.

### Abstract

**AIM:** To investigate differences in tolerability and response to treatment in compensated cirrhotic patients affected by hepatitis C virus (HCV) infection before and after liver transplantation.

**METHODS:** Forty-three HCV non-liver transplanted (LT) cirrhotics (mean age  $55 \pm 8$  years, 65.1% male, Child-Pugh-A, genotype 1-4: 65.1%, 2-3: 34.9%) and 17 LT recipients with recurrent HCV-related cirrhosis (mean age  $57 \pm 9$  years, 88.2% male, Child-Pugh-A, genotype 1-4: 76.5%, 2-3: 23.5%) were included in the analysis from retrospective series. All patients received recombinant or pegylated interferon plus ribavirin at a standard dose and duration. Adverse events were recorded and classified according to the Common Terminology Criteria for Adverse Events. The mean duration of follow-up was of  $4.3 \pm 1.8$  years after the end of the treatment.

**RESULTS:** An early virological response (EVR) was

achieved in 30/43 (69.8%) non-LT and in 8/17 (47.1%) LT cirrhotics, a sustained virological response (SVR) in 18/43 (41.9%) and 5/17 (29.4%), respectively. No statistical difference was observed in EVR and SVR rates between the two groups. Among HCV non-LT cirrhotics, 6/43 (13.9%) discontinued the treatment prematurely, 11.6% of them receiving  $\leq 80\%$  of treatment; 8/17 (47%) LT cirrhotics withdrew the treatment, 35.2% of them receiving  $\leq 80\%$  of treatment. If compared with LT-ones ( $P = 0.015$ ), an higher risk of treatment discontinuation could affect LT cirrhotics, who undergo more frequently  $\leq 80\%$  of treatment ( $P = 0.05$ ). None of the non-LT cirrhotics died after the end of the treatment. With no regards to the achievement of SVR, LT cirrhotic patients showed a reduced survival in respect to non-LT ones (87% at 1 year, 76% at 3 and 5 years after the end of treatment).

**CONCLUSION:** HCV antiviral treatment is equally effective in compensated cirrhotics both before and after LT, which patients show a higher risk of premature treatment withdrawal and a reduced survival, independently of the achievement of SVR.

**Key words:** Hepatitis C virus; Hepatitis C virus antiviral treatment; Liver cirrhosis; Liver transplantation; Sustained virological response, Efficacy; Safety

**Core tip:** In patients with hepatitis C virus compensated liver cirrhosis antiviral treatment should be considered in order to prevent short to mid-term complications. However, the results of treatment with pegylated interferon plus ribavirin are worse than in non-cirrhotic patients. Furthermore, in non-liver transplanted (LT) cirrhotics, a sustained virological response to antiviral treatment is associated to improved survival, while, at present, no data regarding LT cirrhotic is available in literature. The present study highlights that cirrhotic

patients who undergo antiviral treatment after liver transplantation have a worse prognosis, compared to non-LT ones, independently of the achievement of sustained virological response.

## INTRODUCTION

Hepatitis C virus (HCV)-related hepatitis is one of the leading cause of end-stage liver disease worldwide, accounting for half of transplantations in many centers<sup>[1]</sup>. The natural history of HCV-related liver cirrhosis is characterized by several complications that could affect patients' survival<sup>[2-6]</sup>; therefore, a good response to combined antiviral treatment with pegylated interferon (PEG-IFN) and ribavirin (RBV) may produce a benefit on patients quality of life and survival.

According to the recent European Association for the Study of the Liver guidelines<sup>[4]</sup>, in absence of contraindications, the antiviral treatment with PEG-IFN and RBV should be considered for patients with compensated cirrhosis in order to prevent short to mid-term complications. However, results are worse than in non-cirrhotics (30.6%), with a more frequent need for treatment discontinuation and dose reduction<sup>[7-11]</sup>. However, patients who experience a favorable response to antiviral treatment show an improved survival rate in respect to non-responders [98% *vs* 86% at 5 years, respectively, patients with sustained virological response (SVR)] and a lower risk of decompensation<sup>[7,8]</sup>.

In liver transplanted (LT) patients, the perspective is quite different. Although several data regarding treatment of post-liver transplant recurrent hepatitis C are already available, data about the treatment of LT cirrhotic patients are scarce. In particular, in different series of LT patients with recurrent hepatitis C, SVR rates range between 30% (genotype 1 HCV) and 60% (genotype 2 and 3 HCV) and the achievement of SVR has resulted in reducing the progression of liver disease and the incidence of decompensation, alongside patients' survival<sup>[12-17]</sup>. However, these beneficial effects of antiviral treatment have not been proven yet in LT HCV patients with HCV-related liver cirrhosis.

The aim of this retrospective study is to analyze the safety (incidence of adverse events) and efficacy (rate of SVR, and impact on patients survival) of combined antiviral treatment with PEG-IFN and RBV in a series of LT compensated cirrhotic patients, in comparison with non-LT ones.

## MATERIALS AND METHODS

Patients with HCV-related compensated liver cirrhosis, either LT or not, treated with combined PEG-IFN and RBV treatment have been included in this retrospective study.

The Agostino Gemelli Hospital database, Division of Internal Medicine and Gastroenterology has been the source for the cirrhotic non-LT patients' information; further, data about LT cirrhotic patients have been collected by the AISF group for the study of hepatitis C recurrence after liver transplantation (RECOLT-C).

Chronic HCV infection has been diagnosed both on the basis of serum positivity for both anti-HCV antibodies and quantitative HCV-RNA, and the presence of complete or incomplete cirrhosis by histological evaluation of liver tissue specimens performed within 6 mo before the beginning of the treatment (staging of 5 or 6 according to the Ishak scoring system<sup>[18]</sup>). The population of non-LT cirrhotic patients have received combined treatment with PEG-IFN a2a or a2b, at the dose of 180 mcg/wk or 1.5 mcg/kg per week respectively, and ribavirin 800-1200 mg, based on body weight and HCV genotype, for a whole duration of 24 wk (genotypes 2 and 3 HCV) or 48 wk (genotypes 1 and 4 HCV) according to the international guidelines<sup>[4]</sup>. On the other hand, the group of LT cirrhotic patients have undergone combined treatment with PEG-IFN a2a or a2b, at the dose of 180 mcg/wk or 1.5 mcg/kg per week respectively, and ribavirin 800-1200 mg based on body weight and HCV genotype, for a whole duration of 48 wk independently of HCV genotype, according to the international guidelines<sup>[4]</sup>. Patients treated before 2003 (17%) have been subjected to standard IFN alpha2b (3 million units thrice weekly) plus ribavirin.

Quantitative serum HCV-RNA determinations have been made available for all patients at week 12 after the beginning of treatment, at the end of treatment and 6 mo after the end of it. Early virological response (EVR) has been defined as undetectable or more than 2 log drop but detectable HCV RNA level at week 12, end of treatment virological response (EOT-VR) as negative HCV RNA at the end of treatment and SVR as negative HCV RNA 6 mo after the end of treatment.

Safety of antiviral treatment has been evaluated by the occurrence of adverse events, either treatment-related (fatigue, flu-like symptoms and depression, defined as "intolerance"; anemia and neutropenia, defined as "hematological toxicity") or related to liver disease decompensation (ascites, encephalopathy and gastrointestinal bleeding, defined as "decompensation"). The severity of adverse events has been described according to the Common Terminology Criteria for Adverse Events (CTCAE) v3.0<sup>[19]</sup> and is shown in Table 1. Grade 1 have been defined as transient, with mild discomfort, no limitation in activity and no need of medical intervention/therapy; grade 2 as a mild to moderate impairment in daily activity, no or minimal medical intervention/therapy required;

**Table 1 Adverse events classification according to Common Terminology Criteria for Adverse Events v3.0**

| Adverse event     | Grade 1  | Grade 2  | Grade 3                                     | Grade 4                                     | Grade 5 |
|-------------------|--|--|---|---|---------|
| Anemia            | Hb < LLN-10.0 g/dL                                 | Hb 10.0-8.0 g/dL   | Hb < 8.0-6.5 g/dL                           | Hb < 6.5 g/dL                               | Death   |
| Neutropenia       | PMN<br>< LLN-1.5 × 10 <sup>9</sup> /L              | PMN<br>< 1.5-1.0 × 10 <sup>9</sup> /L  | PMN<br>< 1.0-0.5 × 10 <sup>9</sup> /L       | PMN<br>< 0.5 × 10 <sup>9</sup> /L           | Death   |
| Intolerance:      |  |  |   |   |         |
| Fatigue           | Mild fatigue over baseline                         | Moderate or causing difficulty performing some ADL   | Severe fatigue interfering with ADL         | Disabling                                   |         |
| Flu-like symptoms | Symptoms present but not interfering with function | Moderate or causing difficulty performing some ADL   | Severe symptoms interfering with ADL        | Disabling                                   | Death   |
| Depression        | Mild mood alteration not interfering with function | Moderate mood alteration interfering with function, but not interfering with ADL; medication indicated | Severe mood alteration interfering with ADL | Suicidal ideation; danger to self or others | Death   |

ADL: Activities of daily living; PMN: Polymorphonuclear neutrophil.

**Table 2 Patients population characteristics *n* (%)**

| Variable               | Non-liver transplanted cirrhotic group frequency ( <i>n</i> = 43) | Liver transplanted cirrhotic group frequency ( <i>n</i> = 17) | <i>P</i> |
|------------------------|---|---|----------|
| Age, yr (mean ± SD)    | 55 ± 8 (39-69)  | 57 ± 9 (38-73)  | 0.753    |
| Sex                    |   |   | 0.073    |
| Male                   | 28 (65.1)   | 15 (88.2)   |          |
| Female                 | 15 (34.9)   | 2 (11.8)  |          |
| Genotype               |   |   | 0.750    |
| 1                      | 2 (58.1)  | 11 (64.7)   |          |
| 2                      | 13 (30.2)   | 3 (17.6)  |          |
| 3                      | 2 (4.7)   | 31 (5.9)  |          |
| 4                      | 3 (7)   | 2 (11.8)  |          |
| Previous treatment     | 16 (37.2)   | 4 (23.5)  | 0.069    |
| HCV RNA 800000 (UI/mL) | 15  | 9   | 0.198    |
| EVR                    | 30 (69.8)   | 8 (47.1)  | 0.100    |
| SVR                    | 18 (41.9)   | 5 (29.4)  | 0.371    |

HCV: Hepatitis C virus; EVR: Early virological response; SVR: Sustained virological response.

grade 3 as a markedly reduction in daily activity, requiring medical intervention/therapy and possible hospitalization or hospice care; grade 4 as extreme limitation to daily activity, significant medical intervention/therapy required and hospitalization or hospice care very common; finally, grade 5 of adverse events always causes death.

### Statistical analysis

Statistical analysis has been performed by reporting continuous variables as mean and standard deviation and categorical ones as absolute and relative frequencies.

Evaluated end-points were antiviral therapy outcome, overall survival and the occurrence of adverse events. Logistic regression has been used to assess the correlation between each variable and antiviral treatment outcome, and the Fisher's exact test was applied to categorical variables to assess the differences between the two groups of cirrhotic LT and non-LT patients. The Kaplan-Meier curve has been employed to analyze patients' survival and the differences between groups have been assessed using log-rank tests.

All tests were 2-sided and  $P \leq 0.05$  has been considered to be statistically significant.

## RESULTS

Baseline patients' characteristics are shown in Table 2. Forty-three patients belonged to the group of non-LT cirrhotics, 17 to the group of LT ones. The majority of patients were male and 9 of them were 65-year-old or more (7 in LT and 2 in non-LT group). All patients were classified in Child-Pugh class A.

Among non-LT cirrhotics, 16/43 (47.1%) experienced a previous unsuccessful antiviral treatment while the rate was 4/12 (33.3%) among the LT ones, for whom the data was available. Most of patients presented with genotype 1 HCV related chronic hepatitis and a high viral replication; HCV RNA levels  $\geq 600000$  UI/mL were indeed detected in 20/43 (46.5%) of non-LT cirrhotics and in 11/17 (64.7%) of LT cirrhotics.

An EVR has been reported respectively in 30/43 (69.8%) non-LT cirrhotic patients and in 8/17 (47.1%) LT cirrhotic ones, a SVR in 18/43 (41.9%) non-LT cirrhotic patients and 5/17 (29.4%) in LT cirrhotic ones. Among the investigated factors (age, sex, HCV genotype, viral load, previous treatment, EVR, treatment discontinuation and less than 80% of treatment) only EVR has seemed to have a positive effect on the achievement of SVR in both groups ( $P = 0.42$ ; OR = 3.3, 95%CI: 0.072-2.287). Statistical analysis has not shown any difference in EVR and SVR rates between the two groups.

Table 3 indicates the general reported adverse events dealing with antiviral treatment safety assessment. No grade 4 or 5 adverse events have been recorded. Six cirrhotic patients (2 non-LT and 4 LT) experienced grade 2 anemia requiring erythropoietin administration, while grade 3 anemia non responsive to RBV dose reduction and erythropoietin administration caused treatment discontinuation in 2 LT cirrhotics. The incidence of grade 3 neutropenia has been reported in 6 non-LT and in 1 LT cirrhotic patients, and has been treated with granulocyte colony stimulating factors (G-CSF), while treatment discontinuation was required in 1 LT cirrhotic patient.

**Table 3** Reported liver-related and treatment-related adverse events

|  | Non-liver transplanted cirrhotics | Liver transplanted cirrhotics |
|--|-----------------------------------|-------------------------------|
| Intolerance (fatigue, flu-like symptoms, depression) |                                   |                               |
| Grade 2  | 1                                 | 0                             |
| Grade 3  | 3                                 | 0                             |
| Anemia   |                                   |                               |

| Grade 2  | 0                                 | 2                             |
| Grade 3  | 6                                 | 1                             |
| Liver decompensation                                 |                                   |                               |
| Grade 1 (encephalopathy)                             | 0                                 | 1                             |
| Other  |                                   |                               |
| Hepatocellular carcinoma                             | 2                                 | 0                             |
| Polytrauma   | 1                                 | 0                             |

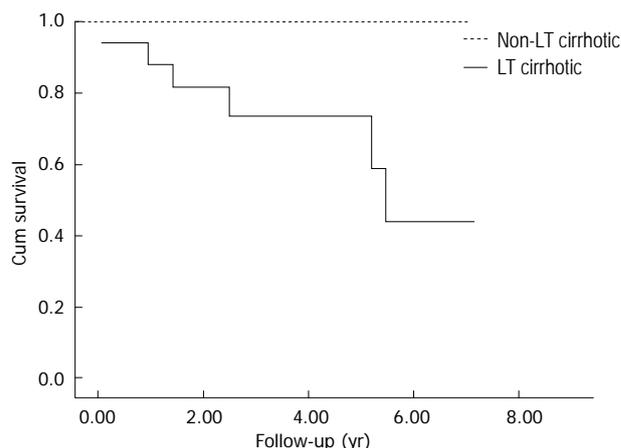

Only 1 liver-related adverse event (encephalopathy) has occurred during the antiviral treatment in LT cirrhotic patients group.

Overall, among HCV non-LT cirrhotics 6/43 (13.9%) patients prematurely discontinued the treatment: 2 due to the development/recurrence of hepatocellular carcinoma, 3 for grade 3 fatigue, 1 for polytrauma. Then, 5 of them (11.6%) received less than 80% of the intended treatment. None of the 6 patients who discontinued the treatment achieved a SVR, except of 2 of them who received 41 and 35 wk of treatment.

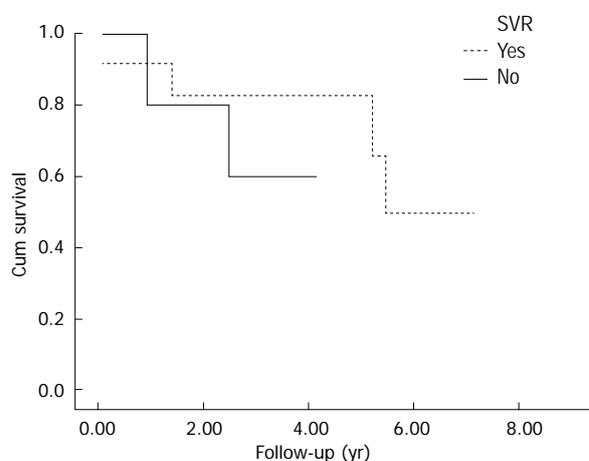

Among HCV LT cirrhotics 8/17 (47%) withdrew the treatment (4 for lack of response and 1 for early relapse, 2 for anemia and 1 for severe neutropenia), 6 of them (35.2%) receiving less than 80% of the intended treatment. None of the 6 patients who discontinued the treatment achieved a SVR, except 2 of them who received 40 and 43 wk of treatment. As a result, we found that LT cirrhotic patients present a higher risk of treatment discontinuation when compared with non-LT ones ( $P = 0.015$ , Fisher's exact test) and undergo more frequently less than 80% of the intended treatment ( $P = 0.05$ , Fisher's exact test).

Patients were followed-up until December 2009. None of the non-LT cirrhotics died and the mean follow-up was of  $4.3 \pm 1.8$  years after the end of the treatment; among LT cirrhotics, 6 deaths occurred (one due to extrahepatic causes, 1 due to sepsis, and 4 due to liver insufficiency), with survival rates of 87% at 1 year and of 76% at 3 and 5 years after the end of treatment (mean follow-up of  $3.3 \pm 2.2$  years, Figure 1).

With no regards to the achievement of SVR, LT cirrhotic patients (Figure 1) showed a reduced survival in respect to non-LT ones. Moreover, SVR didn't show to have a beneficial effect in terms of survival: Kaplan-Meier curve didn't show any difference between LT-cirrhotic patients who achieved SVR in respect to those who did not ( $P < 0.463$ , log-rank test, Figure 2).

**Figure 1** Cumulative survival of non-liver transplantation and liver transplantation cirrhotic patients. LT: Liver transplanted.

**Figure 2** Cumulative survival of liver transplanted patients according to sustained virological response stratification. SVR: Sustained virological response.

## DISCUSSION

### Efficacy and impact on survival

International guidelines recommend to treat HCV hepatitis in non-LT cirrhotic patients, especially those with an early stage liver disease (Child-Turcotte-Pugh, CTP, score A or B7), with genotype 2 HCV infection and in absence of contraindications, since the achievement of SVR is possible in about one third of them<sup>[4,7-11,20]</sup>.

Data previously published about the efficacy of HCV treatment in this subgroup of patients have been confirmed by our series, which includes patients affected by compensated liver cirrhosis (CTP A). In non-LT cirrhotic patients, the achievement of a SVR seems related to an improvement of overall survival<sup>[8]</sup> and 5-year "event-free" survival, also reducing the risk of liver decompensation<sup>[7,8]</sup>. Moreover, an improvement in liver function has been reported in SVR patients (CTP 7.8 *vs* 6.4) in respect to non-responders (CTP 8.0 *vs* 8.7) and to controls (CTP 8.3 *vs* 9.4)<sup>[7]</sup>. Finally, a SVR to combined HCV antiviral treatment preempts liver graft re-infection for those pa-

tients who will undergo LT<sup>[4,9,10,21,22]</sup>.

However, at present, data regarding the impact of SVR on survival of cirrhotic patients undergoing HCV antiviral treatment after liver transplantation, are scarce. As it can be shown by our analysis, independently of the achievement of SVR, LT cirrhotic patients have a worse survival if compared to non-LT ones (Figure 1,  $P < 0.0001$ ). In except of 1 case of an infection, which could be easily explained in immunosuppressed patients such as LT ones, the most common reported cause of death in our series was liver insufficiency, in agreement with literature data<sup>[14,23]</sup>.

Furthermore, no difference in survival has been observed between LT cirrhotic patients who achieved a SVR and those who did not. More to the point, it could be interesting to compare our results in terms of survival with the existing data regarding the natural history of post-liver transplant HCV cirrhosis recurrence, in patients who did not receive an antiviral treatment. Berenguer *et al*<sup>[1]</sup> followed-up 49 patients with genotype 1b HCV recurrent cirrhosis after liver transplant. The 1-year survival rate of those patients with clinically compensated HCV-graft cirrhosis (39/49) was of 74%, lower than that reported by our study (87%, Figure 1). Firpi *et al*<sup>[23]</sup> reported the natural history of 88 HCV LT cirrhotic patients, the major part clinically compensated and of genotype 1; the cumulative probability of survival was 83% at 1 year and 41% at 5 years from the time of diagnosis of compensated cirrhosis. Nevertheless, for those patients who remained free from decompensation, the reported survival was of 90% at 1 year and 70% at 5 years, which is comparable to that reported by our study. Finally, in a series of 55 HCV LT recipients with recurrent cirrhosis, 70 with genotype 1 and 28 with genotype 2-3, Kalambokis *et al*<sup>[24]</sup> reported 90% and 74% rates of survival at 1 and 5 years in those subjects who did not developed liver decompensation.

Then, in the subgroup of LT patients with recurrent HCV-related compensated liver cirrhosis, the achievement of SVR to the antiviral treatment is not able to modify the natural course of the liver disease and, therefore, to improve patients' survival. Probably, the fact that in the liver transplant setting the course of liver cirrhosis has a more rapid and unavoidable progression, difficult to be stopped even with the eradication of HCV infection, is the main reason to support this evidence. Berenguer *et al*<sup>[25]</sup> assessed that the rate of post-transplantation fibrosis progression was significantly higher than pre-transplantation [0.2/year (0.09-0.8)]. The suppression of immune system, on one hand, confirmed by the reported histologic improvements due to immunosuppression weaning-off<sup>[26]</sup>, and the tendency to develop a mild, persistent chronic damage due to rejection, on the other hand, may be the main factors affecting the natural course of post-liver transplant HCV-related cirrhosis. However, the impact of immunosuppression weaning-off on liver histology decreases during the time<sup>[27]</sup>. Moreover, systematic reviews didn't show any significant re-

lationship between IFN treatment and acute or chronic rejection, with incidence rates comparable to the whole population of LT recipients<sup>[28,29]</sup>. Pooling the results of 6 studies<sup>[17,30-33]</sup>, rejection rates seem higher (11%-21% acute rejection; 9%-17% chronic rejection), and a recent review by Selzner *et al*<sup>[34]</sup> reported acute and chronic rejection rates of 0%-35% and 4%-8%, respectively.

It is also well-known that HCV infection itself could be associated with autoimmune diseases (cryoglobulinemia, Sjogren like syndrome, anti-nucleus or anti-liver kidney microsomes antibodies positivity)<sup>[34]</sup>. It has been hypothesized that this kind of liver damage could be a variant of rejection rather than the manifestation of a *de novo* autoimmune hepatitis<sup>[35]</sup>. Several cases following HCV antiviral treatment have been reported<sup>[36,37]</sup>, probably related to the various IFN and RBV immunomodulating effects and often developing after HCV clearance<sup>[34]</sup>.

In conclusion, HCV infection control in liver allografts is certainly linked to the stimulation of immune system, dealing with the risk of developing acute or chronic rejection or *de novo* autoimmune liver damage. These kind of damage may impact negatively on the progression of liver cirrhosis, already faster in LT recipients, even in case of SVR to antiviral treatment. We are, at present, still far from a complete knowledge of the mechanism underlying allograft acceptance or HCV clearance.

### Safety

Among non-LT cirrhotic patients, the reported combined antiviral treatment discontinuation rates are widely variable. In a large series of 568 non-LT cirrhotic patients by Fernández-Rodríguez *et al*<sup>[8]</sup> a 29.6% rate of treatment discontinuation due to adverse events was reported, while in 19.2% and 17.4% of them, respectively, a PEG-IFN or RBV dose reduction was necessary. The overall reported drop-out rate was 66%. In decompensated cirrhotic patients, rates of treatment withdrawal or dose reduction due to adverse events seems almost comparable: 59% by Iacobellis *et al*<sup>[7]</sup>, 65% by Everson *et al*<sup>[22]</sup>, 87% by Crippin *et al*<sup>[11]</sup>, 30% by Forns *et al*<sup>[10]</sup>.

With regards to LT cirrhotics undergoing combined antiviral treatment, Berenguer *et al*<sup>[16]</sup> reported respectively a 37% rate of discontinuation, and a 45% and a 36% rates of PEG-IFN or RBV dose reduction. In the study by Carrión *et al*<sup>[14]</sup>, treatment discontinuation rate was of 39% while 67% and 24% of patients experienced RBV or PEG-IFN dose reduction. Angelico *et al*<sup>[17]</sup> reported a 33% drop-out rate, and a 45% rate of RBV and a 38% rate of PEG-IFN dose reduction.

In non-cirrhotic LT patients, the most frequently reported causes of treatment withdrawal are cytopenia, in particular anemia, neuropsychiatric symptoms, thyroid dysfunction, intolerance and rejection<sup>[12,14,16]</sup>. However, these studies included LT patients with HCV hepatitis recurrence after liver transplant but without liver cirrhosis; data about LT cirrhotic patients are scarce, but it is

likely to expect a higher incidence of adverse events and a consequent higher rate of treatment dose reduction or discontinuation.

In our study, we did not observe the occurrence of any severe or fatal adverse event (grade 4 or 5). Thirteen patients have received supportive therapy with growth factors due to hematological adverse events, such as anemia and leucopenia, and 3 LT cirrhotics withdrew the treatment. None among LT cirrhotics experienced fatigue, flue-like symptoms and depression, while one grade 2 and three grade 3 adverse events (requiring treatment discontinuation) occurred among non-LT ones.

Overall, as a consequence of reduced tolerance to treatment, LT cirrhotics included in the present analysis reported a higher rate of discontinuation than non-LT ones (47% LT *vs* 13.9% non-LT;  $P = 0.015$ ), thus receiving less than 80% of the treatment in a larger proportion of cases (35.2% LT *vs* 11.6% non-LT;  $P = 0.05$ ). It is also interesting that one half of non-LT cirrhotic patients discontinued the treatment due to adverse events unrelated to the treatment itself, such as polytrauma or hepatocellular carcinoma recurrence, while after LT treatment discontinuation was almost related to treatment side effects.

Therefore, LT cirrhotic patients have a higher risk to receive an overall treatment dose is not adequate to achieve a SVR. Indeed, none of the 8 LT cirrhotic patients who discontinued the treatment achieved a SVR, in except of two of them who received respectively 40 and 43 wk of treatment; similarly, among non-LT cirrhotics who discontinued the treatment, only the two patients who underwent 41 and 35 wk of treatment achieved a SVR.

### Concluding remarks

Our series shows that the survival of LT compensated HCV cirrhotic patients is lower if compared to non LT ones; nevertheless, the achievement of SVR seems to have no effect on the natural history of these patients and to not improve survival. Moreover, LT HCV cirrhotic patients have a worse tolerance to antiviral treatment than non-LT ones and experience more frequently adverse events. In this era of important changes in the paradigms and drugs employed in HCV antiviral treatment<sup>[38,39]</sup>, some issues about the new incoming drugs could be raised. Indeed, the real gain in risk/benefit ratio of any antiviral treatment should be carefully evaluated. However, the retrospective nature of the present study, and the discrepancy between the sample size of non-LT and LT cirrhotic patients, make possible to provide speculative considerations only. Future prospective studies evaluating the effects of SVR on the long-term outcome of LT HCV cirrhotic patients, and assessing the efficacy and safety of the new therapeutic regimens in LT HCV cirrhotic patients are necessary to “bring light into the dark”, and to develop specific guidelines for clinical practice.

## COMMENTS

### Background

Hepatitis C virus (HCV)-related hepatitis is one of the leading causes of end-stage liver disease worldwide, accounting for half of liver transplanted (LT) in many centers. Antiviral treatment should be considered for patients with compensated cirrhosis in order to prevent short to mid-term complications. The results of antiviral treatment with pegylated interferon plus ribavirin in patients presenting with compensated liver cirrhosis are worse than in non-cirrhotic ones. However, cirrhotics who experience a favorable response to antiviral treatment show an improved survival rate in respect to non-responders (98% *vs* 86% at 5 years, respectively, for sustained virological response (SVR) and a lower risk of decompensation.

### Research frontiers

The research hotspot is to compare the efficacy and safety of antiviral treatment in LT and non-LT cirrhotic patients, and to understand how it can affect patients' survival, especially after liver transplantation.

### Innovations and breakthroughs

At present, no data regarding the impact of SVR on survival of cirrhotic patients undergoing HCV antiviral treatment after LT are available in literature. The natural history of the underlying liver disease may heavily affect cirrhotic patients' survival, independently of the achievement of a sustained virological response to antiviral therapy. HCV infection control in liver allografts is certainly linked to the stimulation of immune system, dealing with the risk of developing acute or chronic rejection or *de novo* autoimmune liver damage. These kind of damage may impact negatively on the progression of liver cirrhosis, already faster in LT recipients, even in case of sustained virological response to antiviral treatment. The present study highlights that cirrhotic patients who undergo antiviral treatment after LT have a worse prognosis, compared to non-LT ones, independently of the achievement of SVR.

### Applications

The present study suggests that cirrhotic patients have a worse response to antiviral treatment, especially after LT. Probably, a SVR to antiviral treatment could not be able to protect patients with such an advanced liver damage and a complex alteration of the immune response from an unfavorable evolution of the disease.

### Terminology

SVR is the negativization of HCV RNA 6 mo after the end of antiviral treatment.

### Peer review

This is an interesting paper comparing the safety and efficacy of antiviral treatment in patients with HCV infection and cirrhosis before and after transplantation.

### Abstract

**AIM:** To assess the stage and size of rectal tumours using 1.5 Tesla (1.5T) magnetic resonance imaging (MRI) and three-dimensional (3D) endosonography (ERUS).

**METHODS:** In this study, patients were recruited in a phase I/II trial of neoadjuvant chemotherapy for biopsy-proven rectal cancer planned for surgical resection with or without preoperative radiotherapy. The feasibility and accuracy of 1.5T MRI and 3D ERUS were compared with the histopathology of the fixed surgical specimen (pathology) to determine the stage and size of the rectal cancer before and after neoadjuvant chemotherapy. A Philips Intera 1.5T with a cardiac 5-channel synergy surface coil was used for the MRI, and a B-K Medical Falcon 2101 EXL 3D-Probe was used

at 13 MHz for the ERUS. Our hypothesis was that the staging accuracy would be the same when using MRI, ERUS and a combination of MRI and ERUS. For the combination, MRI was chosen for the assessment of the lymph nodes, and ERUS was chosen for the assessment of perirectal tissue penetration. The stage was dichotomised into stage I and stage II or greater. The size was measured as the supero-inferior length and the maximal transaxial area of the tumour.

**RESULTS:** The staging feasibility was 37 of 37 for the MRI and 29 of 36 for the ERUS, with stenosis as a limiting factor. Complete sets of investigations were available in 18 patients for size and 23 patients for stage. The stage accuracy by MRI, ERUS and the combination of MRI and ERUS was 0.65, 0.70 and 0.74, respectively, before chemotherapy and 0.65, 0.78 and 0.83, respectively, after chemotherapy. The improvement of the post-chemotherapy staging using the combination of MRI and ERUS compared with the staging using MRI alone was significant ( $P = 0.046$ ). The post-chemotherapy understaging frequency by MRI, ERUS and the combination of MRI and ERUS was 0.18, 0.14 and 0.045, respectively, and these differences were non-significant. The measurements of the supero-inferior length by ERUS compared with MRI were within 1.96 standard deviations of the difference between the methods (18 mm) for tumours smaller than 50 mm. The agreement with pathology was within 1.96 standard deviations of the difference between imaging and pathology for all tumours with MRI (15 mm) and for tumours that did not exceed 50 mm with ERUS (22 mm). Tumours exceeding 50 mm in length could not be reliably measured by ERUS due to the limit in the length of each recording.

**CONCLUSION:** MRI is preferable to use when assessing the size of large or stenotic rectal tumours. However, staging accuracy is improved by combining MRI with ERUS.

**Key words:** Rectal cancer; Magnetic resonance imaging; Endosonography; Predictive value of tests; Neoadjuvant treatment

**Core tip:** To the best of our knowledge, the possibility of increasing the accuracy of the staging of rectal cancer by combining the strengths of magnetic resonance imaging (MRI) and endosonography (ERUS) in the same patient has not been reported. In neoadjuvantly treated rectal cancer, a combination of lymph node assessment by MRI and assessment of perirectal tissue penetration by ERUS improved the staging accuracy, with stage II as the cut-off. Furthermore, this study showed that ERUS could replace MRI in the measurement of the transaxial area of all non-stenotic tumours and in the measurement of the length of non-stenotic tumours up to 50 mm.

## INTRODUCTION

Radical surgery is the curative treatment option for rectal cancer. The preoperative work-up generally includes an assessment of the stage and size of the rectal tumour to optimise the treatment plan. This work-up ranges from early tumours possibly eligible for local excision to advanced cancers for which long-term radiochemotherapy is indicated prior to full-scale resection. To decrease recurrence, preoperative short-course radiotherapy is generally indicated in stages II-III, and long-course radiochemotherapy is usually indicated in “ugly” tumours with threatened surgical margins<sup>[1]</sup>. New strategies have been tested, including the use of preoperative chemotherapy, regardless of any radiotherapy, to potentially downstage and downsize the tumour. This approach has been tried, and further studies are on-going<sup>[2,3]</sup>. Furthermore, local excision is normally only indicated in T1 tumours with a diameter of less than 30 mm, and Zlobec *et al*<sup>[4]</sup> found that a diameter greater than 34 mm predicts late T-stage. These preoperative treatment strategies demand improved staging and enhanced responses for evaluating neoadjuvant therapy using accurate and accessible size measurement methods.

The main instruments for the preoperative assessment of rectal tumours are magnetic resonance imaging (MRI) and endorectal ultrasound (ERUS). Many groups have concluded that MRI is superior to ERUS in the staging of rectal tumours<sup>[5-7]</sup>. However, Bipat *et al*<sup>[8]</sup> found that ERUS was more accurate than MRI for perirectal tissue invasion and that the assessment of lymph nodes and invasion of adjacent organs was comparable in a meta-analysis that

included all stages. Some studies have shown that MRI is preferable in advanced and stricturing tumours and in the assessment of lymph node involvement, whereas ERUS is advantageous in assessing the wall penetration of the early stages of rectal cancer<sup>[9-14]</sup>. Many of these studies used 1 Tesla (1T) MRI and two-dimensional (2D) ERUS<sup>[15,16]</sup>, and the results may be improved in newer models of the MRI and ERUS equipment. Increased specificity has been reported with 3T MRI machines compared with 1T or 1.5T<sup>[17]</sup>. However, Maas *et al*<sup>[18]</sup> did not find that 3T MRI improved the accuracy compared with 1.5T in borderline T2-T3 rectal cancer. Diffusion-weighted MRI appears promising, but the specificity in lymph node detection is still limited<sup>[19]</sup>. Compared with 2D ERUS, the development of 3D ERUS has resulted in increased accuracy, but a problem remains regarding the detection of lymph nodes and the margins of the mesorectal fascia<sup>[20]</sup>. Earlier studies of the measurement of the rectal tumour size have primarily involved MRI<sup>[21]</sup>. Torkzad *et al*<sup>[22]</sup> showed that rectal tumours can be measured on MRI images, with results that correlated well with the histopathology results, and Nougaret *et al*<sup>[23]</sup> showed that MRI volumetry may predict early responders to neoadjuvant therapy. Murad-Regadas *et al*<sup>[24]</sup> found that size measurement by ERUS was useful in the selection of possible sphincter-saving surgery after neoadjuvant therapy. In many parts of Western Europe, MRI is preferred for the assessment of rectal cancer, except in the disease’s early stage, but in other parts of the world, ERUS is still the method of choice for the initial evaluation of rectal cancer at all stages<sup>[16,20,25]</sup>. Even in parts of Western Europe, this issue was not settled in 2012<sup>[7,26]</sup>. Many authors regard the methods as complementary<sup>[12,14,27,28]</sup>. Some authors have argued that a combination of both MRI and ERUS may increase the accuracy of the preoperative staging<sup>[13,14,27]</sup>. The restaging of advanced rectal cancer after neoadjuvant therapy has been studied for MRI<sup>[15,29,30]</sup> and ERUS<sup>[15,31,32]</sup>. In this context, MRI appears more promising, but there is a problem with accuracy for both methods.

In this study, 1.5T MRI and 3D ERUS were compared with histopathology of the fixed surgical specimen (pathology) to determine the stage and size of the rectal cancer before and after neoadjuvant chemotherapy. Our hypothesis was that the staging accuracy would be the same when using MRI, ERUS and a combination of MRI and ERUS. For the combination, MRI was chosen for the assessment of the lymph nodes, and ERUS was chosen for the assessment of perirectal tissue penetration because studies have reported that these are the respective strengths of the two methods<sup>[11,27,28,33]</sup>. Furthermore, we hypothesised that the MRI and ERUS results would be in agreement with regard to the tumour size measurement. The aims of the study were to evaluate the feasibility and accuracy of MRI and ERUS in staging and to measure the supero-inferior length and maximal transaxial area before and after neoadjuvant chemotherapy compared with postoperative histopathology.

## MATERIALS AND METHODS

The present study was conducted in cooperation with a prospective phase I /phase II study of neoadjuvant treatment with pemetrexed in rectal cancer set at a university hospital in Sweden (Alimta trial)<sup>[2]</sup>. Briefly, the study included 37 patients with rectal cancer who all received three cycles of chemotherapy prior to surgery. They underwent MRI scans before and after chemotherapy. Radiotherapy followed by resection surgery was conducted as established by national guidelines. The study concluded that the treatment concept was feasible, with limited risks of side-effects and a majority of the patients experiencing symptom relief and downsizing of the tumour.

All patients who participated in the Alimta trial were asked to participate in the associated MRI-ERUS study. The demographic data of the included patients are shown in Table 1. The intention was to match the scheduled investigations using MRI with ERUS before and after chemotherapy to enable a comparison of the staging and size measurements, including paired analyses. All surgically removed specimens were routinely sent for histopathological examination, which also provided a comparison between MRI, ERUS and the fixed specimen in terms of both stage and size. The supero-inferior length was compared between MRI, ERUS and the fixed specimen. The maximal transaxial area in a dimension perpendicular to the long axis of the rectum at the site of the cancer was compared between MRI and ERUS. The MRI and ERUS were performed as detailed below. When the reports included more than one stage, the more advanced stage was chosen in the analysis. The order in which the MRI and ERUS were conducted was not controlled. Investigations with a time lapse between the MRI and ERUS greater than four weeks were not included in the analysis. The study is schematically presented in Figure 1. The protocol was approved by the local hospital ethics committee. Patients provided written consent to participate in the investigation.

### MRI

Philips Intera 1.5T was used together with a cardiac 5-channel synergy surface coil (Philips) for an optimal signal. Antispasmodic drugs, 40 mg of buscopan and 1 mg of glucagon, were administered before the start of the examination. There was no bowel preparation of the patient.

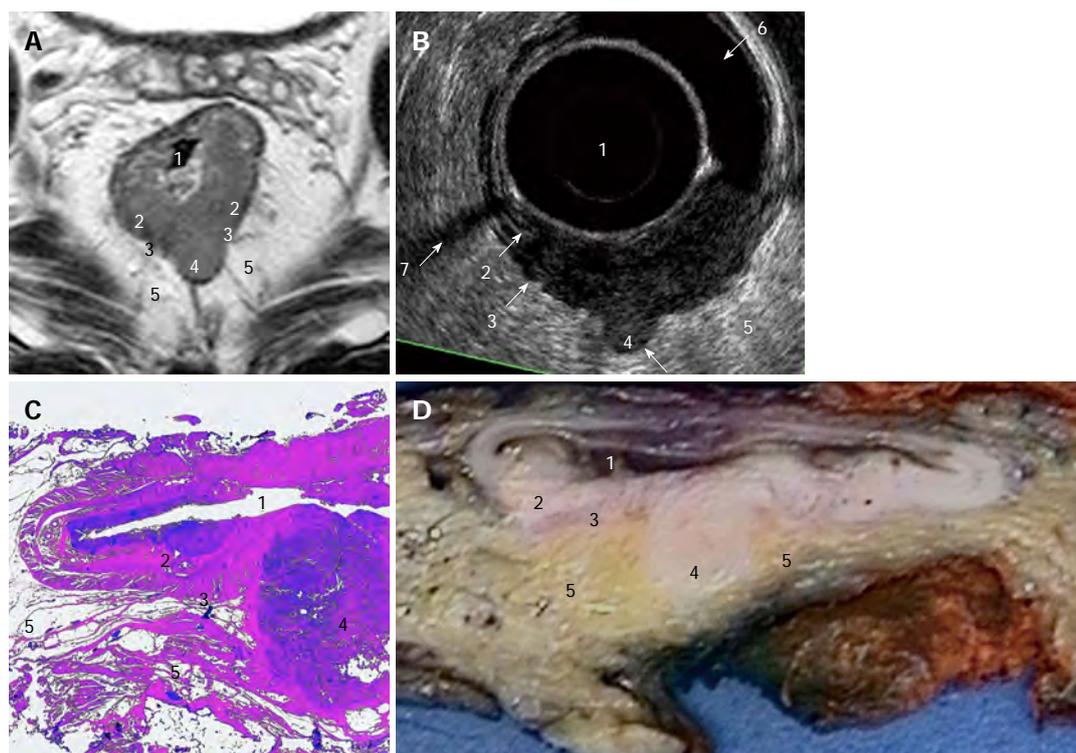

**Figure 1 Study algorithm of the treatment and the examinations.** The stages and sizes using magnetic resonance imaging (MRI) were compared with the corresponding stages and sizes using endosonography (ERUS) before and after chemotherapy and with postoperative histopathology. The figure shows the assessments for size. <sup>1</sup>Another 10 patients before chemo and 5 after chemo had complete pairs of MRI and ERUS assessments for stage.

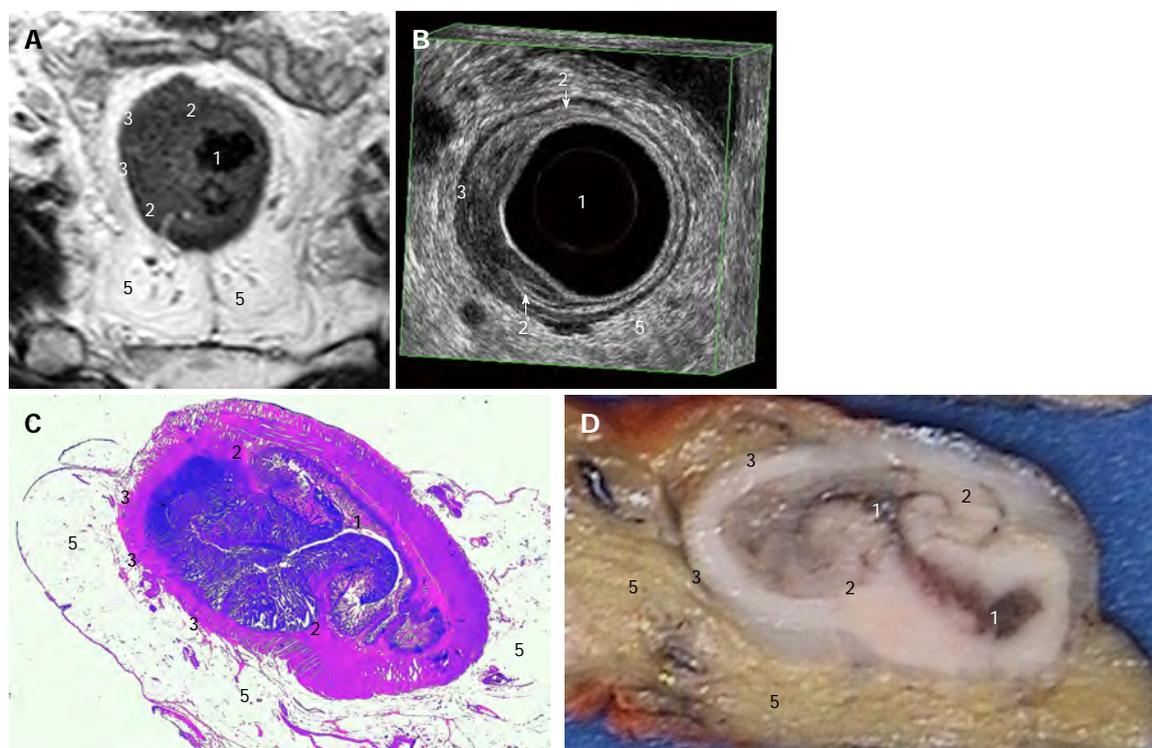

The protocol included three T2-weighted turbo spin-echo sequences in the sagittal, oblique axial and oblique coronal planes. The following conditions were used: slice thickness 3 mm, gap 0.3 mm, turbofactor between 20-22, field-of-view (FOV) 20-22 cm, 30-36 slices and in-plane resolution 0.67-0.7 mm. The echo time (TE) was 90 ms, and the repetition time (TR) of 2800-3400 ms was dependent on the sequence and number of signals acquired (NSA) 4. The scan time varied between 4-6 min per sequence. At the end, an additional oblique axial contrast-enhanced 3D T1-weighted gradient echo sequence with fat sat in the venous phase (Thrive, Philips, Eindhoven, The Netherlands) was used with the following conditions: 2 mm slices, FOV 26 cm, NSA 2, TR 9.1 ms, TE 4.5 ms, flip 10 degrees, scan time 1.49 min, and voxel size 0.81 mm. On average, each investigation lasted 40 min, during which the patients were required to lie still. The MRI images were interpreted by one radiologist (Kålebo P). The measurements were performed using a software function and recorded in millimeter. The TN staging (Figures 2A and 3A), supero-inferior length and maximal transaxial area in a dimension perpendicular to the long axis of the rectum at the site of the cancer were registered.

### ERUS

A B-K Medical Falcon 2101 EXL, 3D-Probe, 13 MHz was used for the ERUS. The ERUS was performed by one of two investigators who had at least four years of experience. The preparation included an enema. The investigation was conducted in the left lateral position using a probe covered by a condom filled with water and introduced through a rigid proctoscope. The maximum length of one recording was 60 mm. The measurements were recorded in mm. The recordings were saved in the 3D-mode (Figures 2B and 3B).

**Figure 2** Images of a stage II (T3N0) rectal tumour. The numbers denote the bowel lumen (1), the submucosal layer (2) and the interface (3) between the muscularis layer and the perirectal tissue (5) and a definite protrusion (4) through the muscularis layer. A: Magnetic resonance imaging gives a good view of the surrounding structures; B: Endosonography (ERUS) shows the bowel lumen (1) expanded by a condom filled with water and details of the bowel wall with an interruption of the submucosal layer (2). The artefacts from an air pocket (6) and some bowel remnants (7) can be a problem in ERUS; C: The histologic slice (hematoxylin and eosin staining); D: The specimen after the first part of fixation and cutting.

**Figure 3** Images of a stage I (T2N0) rectal tumour. The numbers denote the bowel lumen (1), the submucosal layer at its interruptions (2) and the smooth interface (3) between the muscularis layer and the perirectal tissue (5). A: Magnetic resonance imaging gives a good view of the surrounding structures; B: Endosonography shows the bowel lumen (1) expanded by the probe (the black space inside the innermost white ring) and the condom filled with water (the black space between the probe and the bowel wall). The arrows show the middle white ring corresponding to the submucosal layer (2), in this case interrupted by tumour penetration beyond the submucosa into the muscularis propria. The interface (3) between the muscularis layer and the perirectal tissue was smooth as a sign of no penetration beyond the muscularis layer; C: The histologic slice (hematoxylin and eosin staining); D: The specimen after the first part of fixation and cutting.

**Table 2** Feasibility and accuracy of the tumour node metastasis staging, with stage II as the cut-off, using magnetic resonance imaging, endosonography and a combination (combo) of assessments of lymph nodes using magnetic resonance imaging and assessments of perirectal tissue penetration using endosonography compared with the histopathology of resected specimens in 23 patients before and after chemotherapy

|   | MRI-pre | ERUS-pre | Combo-pre | MRI-post | ERUS-post | Combo-post |
|---|---------|----------|-----------|----------|-----------|------------|
| Feasibility of stage                          | 1.00    | 0.81     |           |          |           |            |

MRI: Magnetic resonance imaging; ERUS: Endosonography.

### Histopathology

The histopathological assessments of the resected surgical specimens were performed after fixation. The specimens were immersed in 4% formaldehyde for 48-72 h. The specimens were then cut (Figures 2D and 3D) and again immersed in formaldehyde for another 12 h before dehydration overnight. Then, the specimens were embedded in paraffin and sectioned. Routine staining was used (Figures 2C and 3C). The slides were analysed by specialist pathologists according to the everyday protocol utilized in the pathology department. The diameter in three directions and the TN staging were recorded. The histology report did not include an area measurement.

### Statistical analysis

The SPSS 18.0 statistics software was used for the analyses. The tumour stage (I-IV) was dichotomised into stage I and stages II-IV because this was a cut-off for the indication for radiotherapy at the time of the study. Accuracy was defined as the number of correct positive and negative predictions divided by the total. Sensitivity was defined as the number of correct predictions of stage II or higher divided by the number of stage II or higher based on pathology. Specificity was defined as the number of correct predictions of stage I or lower divided by the number of stage I or lower based on pathology. Understaging was defined as the number of incorrect predictions, given as stages that were too low (or too early), divided by the total. Staging with MRI and ERUS

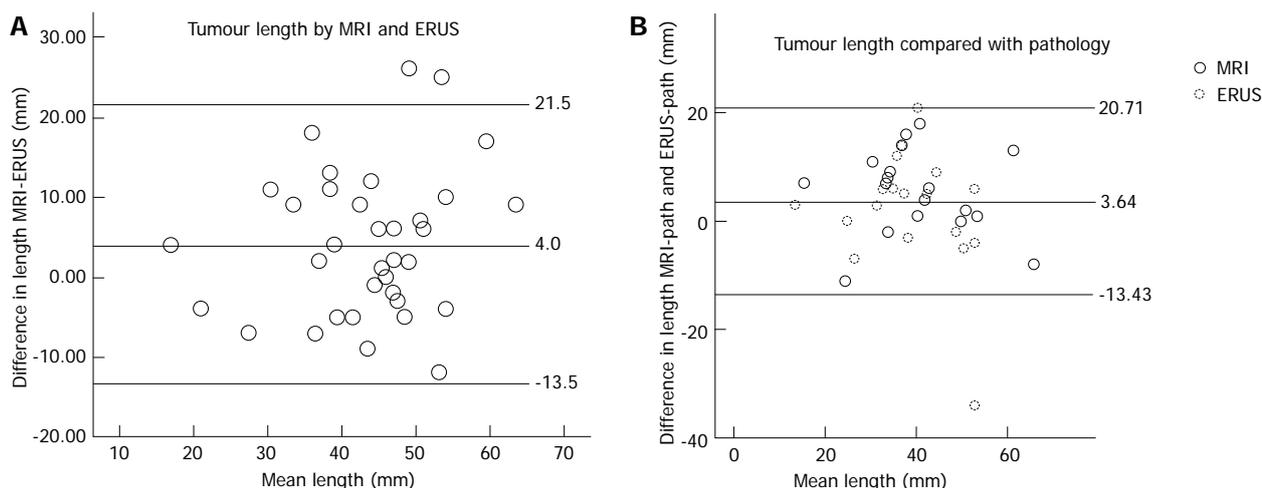

was compared with histopathology, which was regarded as the gold standard. The measurement correlations among MRI, ERUS and histopathology were shown in Bland-Altman plots, and a related samples comparison was applied to the correct stage predictions, lengths and areas by MRI, ERUS and histopathology using the non-parametric related samples Wilcoxon Signed Rank Test.

## RESULTS

Of the 37 eligible patients, 19 were assessed for size before chemotherapy, and 18 were assessed for size after chemotherapy using both MRI and ERUS within a period of four weeks (Figure 1). Another 10 patients were assessed for stage before chemotherapy, and five were assessed for stage after chemotherapy using both MRI and ERUS. The stage estimates are summarised in Table 2. A comparison of the supero-inferior length of the resected specimen by histopathology was conducted with the 18 post-chemotherapy measurements using MRI and ERUS. The size estimates are summarised in Table 3.

### Feasibility

The staging feasibility was 37 of 37 for MRI and 29 of 36 for ERUS. The feasibility of the size assessment was 36 of 37 for MRI and 25 of 34 for ERUS. The inability to lie still for approximately 40 min was the reason for noncompliance in the MRI and stenosis or pain on examination was the reason for noncompliance in the ERUS.

**Figure 4** Measurements of supero-inferior length using magnetic resonance imaging and endosonography. A: 37 pairs of measurements using both methods in the same patients before (19) and after (18) chemotherapy. The Bland-Altman plot illustrates the agreement between the methods. The reference lines are set at the mean difference and plus and minus 1.96 standard deviation from the mean difference; B: Measurements in 18 patients after chemotherapy compared with the resected specimens after fixation. The middle reference line shows the mean of differences in length between magnetic resonance imaging (MRI) and endosonography (ERUS) and pathology. The outer lines show plus and minus 1.96 the mean standard deviation from the mean difference.

In a number of patients, air pockets within the bowel lumen and remnants of bowel contents compromised the quality of ERUS but not of MRI (Figure 2A and B). The assessment of size demanded higher quality examinations than the assessment of stage for both MRI and ERUS. For example, relative stenosis could allow a sufficient view to assess a tumour as stage II or higher but did not allow for a precise assessment of size.

### Stage

The staging accuracy of the perirectal tissue penetration was 0.48 and 0.52 by MRI and 0.70 and 0.78 by ERUS before and after chemotherapy, respectively. The staging accuracy of the lymph node metastases was 0.74 and 0.74 by MRI and 0.56 and 0.74 by ERUS before and after chemotherapy, respectively.

The accuracy of the TNM staging, with stage II as the cut-off, by MRI, ERUS and the combined MRI and ERUS examinations was 0.65, 0.70 and 0.74, respectively, before chemotherapy and 0.65, 0.78 and 0.83, respectively, after chemotherapy. Thus, the post-chemotherapy staging by MRI alone was improved by a combination of MRI assessment of the lymph nodes and ERUS assessment of the perirectal tissue penetration ( $P = 0.046$ , Wilcoxon signed rank test). The post-chemotherapy understaging frequency by MRI, ERUS and the combined MRI and ERUS exams was 0.18, 0.14 and 0.045, respectively, but the differences were not significant.

### Size

For tumours smaller than 50 mm, measurements of the supero-inferior length by ERUS compared with MRI were within 1.96 standard deviations of the difference between the methods (18 mm). For all tumours, agreement with the histopathology of the resected specimen after fixation was within 1.96 standard deviations of the difference

between imaging and pathology for MRI (15 mm), and agreement with the histopathology of the resected specimen after fixation was within 1.96 standard deviations of the difference between imaging and pathology for ERUS (22 mm) for tumours that did not exceed 50 mm. There was an overestimation of the supero-inferior length by MRI ( $P = 0.016$ ) compared with histopathology and ERUS/histopathology ( $P = 0.021$ ). The ERUS measurement of tumour downsizing did concur ( $P < 0.05$ ) with the MRI size assessments. The measurements of length are shown by Bland-Altman plots in Figure 4.

The measurements of the maximal transaxial area by ERUS compared with MRI were within 1.96 standard deviations of the difference between the methods (684 mm<sup>2</sup>) for all tumours. An area measurement was not obtained by histopathology.

## DISCUSSION

The aim of this study was to assess the feasibility and accuracy of 1.5T MRI and 3D-ERUS compared with histopathology to determine the stage and size of rectal tumours. The staging feasibility was 37 of 37 for MRI but only 29 of 36 for ERUS. The accuracy of the staging with stage II as the cut-off was improved by combining the results of the lymph node assessments by MRI with the results of the perirectal tissue penetration by ERUS. Overstaging and understaging were observed in 17% of the patients by MRI both before and after chemotherapy. Overstaging could be explained by downstaging due to neoadjuvant therapy, but this does not explain understaging. Understaging with stage II as the cut-off means that the patients are likely to be incorrectly denied preoperative radiotherapy. Overstaging, in contrast, means that the patients will likely be given unnecessary radiotherapy. If a combination of MRI and ERUS could increase

the accuracy in patients on the cut-off edge between stages I and II, performing both examinations might be worthwhile, even if this approach increases the number of investigations.

The staging accuracy of both modalities was lower in this study than those reported in many other studies<sup>[33]</sup>. Still, only a fair agreement between MRI and histopathology was reported by Tytherleigh *et al.*<sup>[34]</sup>, and Harewood<sup>[35]</sup> showed that the ERUS staging was lower outside the initial studies. Ashraf reported that ERUS staging in “real world” practice in the United Kingdom is much lower than that shown in many studies<sup>[36]</sup>. These authors have concluded that the accuracy of MRI or ERUS can be expected to be lower in clinical practice than often reported from dedicated institutions. Another possible explanation for the low accuracy could be that the neoadjuvant chemotherapy treatment caused a desmoplastic reaction, making correct staging more difficult. A reduction in accuracy has been noted after neoadjuvant radiochemotherapy<sup>[13,32]</sup>. Another reason may be the overrepresentation of T2-T3 tumours, which are difficult to distinguish from each other using both MRI and ERUS<sup>[14,18]</sup>.

One central issue in preoperative staging is the possible presence of tumour-affected lymph nodes. This issue is important in standard resection surgery because the risk of node involvement affects the use of short-course preoperative radiotherapy before surgery<sup>[1]</sup>. Preoperative staging of lymph node involvement is certainly central when considering local resections and could be of great value when assessing patients who could benefit from a neoadjuvant chemotherapy regime. Several groups have found that MRI is the preferred method for lymph node involvement<sup>[37]</sup>, whereas ERUS is the preferred method for wall and perirectal tissue penetration<sup>[8,33]</sup>. However, Halefoglou *et al.*<sup>[12]</sup> reported that MRI can be better in more advanced stages, even in cases of wall penetration. Some authors have suggested that the two methods complement each other, which concurs with the findings of the present study<sup>[12,14,27,28]</sup>. As previously reported, MRI tends to be superior in the assessment of the lymph nodes, whereas ERUS tends to be superior in the assessment of the penetration of the bowel wall and perirectal tissue<sup>[11,27,28,33]</sup>; however, the possibility of increasing accuracy by combining the strengths of each modality in the same patient has not yet been reported to the best of our knowledge.

MRI has several advantages for use in the measurement of tumour size. Its feasibility in stenosing tumours and in patients who are sensitive to pain on introduction of the probe was important as in approximately 1/4 of the cases, these factors made ERUS measurements impossible. Furthermore, the probe used for ERUS provided a view that was 60 mm in supero-inferior length at most. Tumours larger than this could not be reliably measured with ERUS because of the necessity for multiple recordings. Thus, MRI had a better agreement with histopathology in the tumours with a supero-inferior length greater than 50 mm. The measurements of the supero-inferior tumour length by ERUS compared with MRI agreed

within 1.96 standard deviations (18 mm) for tumours up to 50 mm. Accepting, at most, an 18 mm deviation, ERUS can only replace MRI in the measurement of supero-inferior length for tumours up to approximately 50 mm in length. A deviation by 18 mm seems large, but even MRI deviated up to 15 mm compared with pathology. The measurement of the maximum transaxial area agreed within 1.96 standard deviations of the difference between the two methods (684 mm<sup>2</sup>) for all tumours. For ERUS, the transaxial area appears more reproducible than the supero-inferior length for large tumours.

Both MRI and ERUS overestimated the tumour length compared with histopathology. This difference is not explained by specimen, shrinkage as studies have indicated that the specimen slightly increases in size (up to 8%) due to fixation<sup>[38]</sup>. A more likely explanation could be that both MRI and ERUS overestimate length due to desmoplastic reactions, which may not be distinguished from the tumour itself<sup>[28]</sup>. Another explanation could be the short-course preoperative radiotherapy; however, this explanation is less likely because Brown *et al.*<sup>[38]</sup> found no stage effect. A theoretical cause of size difference could also be a further anti-tumoural effect from the chemotherapy administered in the Alimta study.

This study focused on the accuracy of the staging and size measurements. There were limitations to this study, including the low number of patients. However, this study does involve a special group of patients and includes information on the examinations before and after treatment, as well as histopathological data. Its other strengths are that all of the MRI measurements were performed by one radiologist and that the ERUS was performed by one of two senior surgeons. The measurement of the size of the rectal tumours by MRI compared with ERUS has not been extensively described previously. The increase in the staging accuracy using a combination of MRI and ERUS is interesting and could warrant further studies.

For staging rectal tumours, 1.5T MRI was more feasible than 3D ERUS because of a higher yield in stenotic tumours. The level of accuracy did not differ in the tumours assessed using both methods. A combination of lymph node assessment by MRI and assessment of perirectal tissue penetration by ERUS improved the staging accuracy, with stage II as the cut-off. For the measurement of tumour size, MRI is more feasible and accurate when large and stenotic tumours are included. However, in non-stenotic tumours, ERUS could replace MRI in the measurement of the transaxial area of all tumours and in the measurement of the length of tumours up to 50 mm.

## ACKNOWLEDGMENTS

We thank the Gothenburg Medical Association, the Lions Cancerfond Väst and the Björnsson Foundation for financial support. We would also like to express our gratitude to study nurse Hillevi Björkqvist for assisting in the collection and registration of data and samples and to

biomedical scientist Karin Blomqvist for helping in the preparation of the pathology images.

## COMMENTS

### Background

Magnetic resonance imaging (MRI) and endorectal ultrasound (ERUS) are the most widely used methods to assess the stage and size of rectal cancer to select the patients who benefit from neoadjuvant therapy. Lymph node metastasis, which is an indication for neoadjuvant therapy, is difficult to detect in early stages. Therefore, all patients with T3-tumours are often given neoadjuvant radiotherapy because a high rate of non-detectable lymph node metastases can be anticipated. Accurate preoperative assessment of both lymph node involvement and wall penetration is vital in this context. Likewise, reliable measurements of tumour size are important to monitor the effects of neoadjuvant therapy.

### Research frontiers

Several studies have shown that MRI is more accurate in staging of lymph nodes and the relation of the tumour margins to the surrounding structures, while ERUS is more accurate in staging of early wall penetration. Measurement of tumour size using either MRI or ERUS has been described but not in comparison to each other.

### Innovations and breakthroughs

In neoadjuvantly treated rectal cancer, a combination of lymph node assessment by MRI and assessment of perirectal tissue penetration by ERUS improved the staging accuracy, with stage II as the cut-off. Furthermore, this study showed that ERUS could replace MRI in the measurement of the trans-axial area of all non-stenotic tumours and in the measurement of the length of non-stenotic tumours up to 50 mm.

### Applications

To increase staging accuracy, MRI and ERUS may be combined in the same patient, paying more attention to the strengths of each method. A combined examination may especially be considered in tumours at the cut-off between stage I and II for more correct use of preoperative radiotherapy. To measure tumour size, MRI is better suited in large and stenotic tumours, while ERUS is a sufficient alternative in small tumours passable by proctoscopy.

### Terminology

MRI with 1.5 Tesla strength of the magnetic field is widely used in assessment of rectal cancer. Three-dimensional (3D) ERUS saves a 3D image, which may be assessed in several planes. 2D-versions allow assessment in one plane only. Neoadjuvant chemo- and/or radio-therapy is given before surgery to decrease the risk of tumour recurrence.

### Peer review

The paper compares imaging of neoadjuvantly treated rectal cancer using MRI and ERUS. Among weaknesses are a relatively small number of patients with many assessments lost. The strength of the paper is the application of everyday clinical practice in imaging of rectal cancer.

### Abstract

**AIM:** To investigate whether matrix metalloproteinases-9 (MMP-9) or trypsinogens could serve as histological markers for an aggressive disease course in pediatric ulcerative colitis (UC).

**METHODS:** We identified 24 patients with pediatric onset ( $\leq 16$  years) UC who had undergone surgery during childhood/adolescence a median of 2.1 years (range 0.1-7.4 years) after the diagnosis (between 1990 and 2008) in Children's Hospital, Helsinki, Finland. We also identified 27 conservatively treated UC patients and matched them based on their age at the time of diagnosis and follow-up at a median of 6 years (range 3-11 years) to serve as disease controls. Twenty children for whom inflammatory bowel disease (IBD)

had been excluded as a result of endoscopy served as non-IBD controls. Colon biopsies taken by diagnostic endoscopy before the onset of therapy were stained using immunohistochemistry to study the expression of MMP-9, trypsinogen-1 (Tryp-1), Tryp-2, and a trypsin inhibitor (TATI). The profiles of these proteases and inhibitor at diagnosis were compared between the surgery group, the conservatively treated UC patients and the non-IBD controls.

**RESULTS:** The proportions of Tryp-1 and Tryp-2 positive samples in the colon epithelium and in the inflammatory cells of the colon stroma were comparable between the studied groups at diagnosis. Interestingly, the immunopositivity of Tryp-1 (median 1; range 0-3) was significantly lower in the epithelium of the colon in the pediatric UC patients undergoing surgery when compared to that of the conservatively treated UC patients (median 2; range 0-3;  $P = 0.03$ ) and non-IBD controls (median 2; range 0-3;  $P = 0.04$ ). For Tryp-2, there was no such difference. In the inflammatory cells of the colon stroma, the immunopositivities of Tryp-1 and Tryp-2 were comparable between the studied groups at diagnosis. Also, the proportion of samples positive for TATI, as well as the immunopositivity, was comparable between the studied groups in the colon epithelium. In the stromal inflammatory cells of the colon, TATI was not detected. In UC patients, there were significantly more MMP-9 positive samples and a higher immunopositivity in the stromal inflammatory cells of the colon when compared to the samples from the non-IBD patients ( $P = 0.006$  and  $P = 0.002$ , respectively); the immunopositivity correlated with the histological grade of inflammation (95%CI: 0.22-0.62;  $P = 0.0002$ ), but not with the other markers of active disease. There were no differences in the immunopositivity or in the proportions of MMP-9 positive samples when examined by epithelial staining. The staining profiles in the ileal biopsies were comparable between the studied groups for all of the studied markers.

**CONCLUSION:** For pediatric UC patients who require surgery, the immunopositivity of Tryp-1 at diagnosis is lower when compared to that of patients with a more benign disease course.

**Key words:** Children; Ulcerative colitis; Inflammatory bowel disease; Matrix metalloproteinase-9 resection; Trypsin inhibitor

**Core tip:** The risk factors for aggressive pediatric ulcerative colitis (UC) were studied in 24 patients who had undergone surgery by staining diagnostic tissue samples for matrix metalloproteinase-9 and trypsinogen-1 (Tryp-1) and Tryp-2, as well as a trypsin inhibitor. In the UC group, there were significantly more samples that were matrix metalloproteinase-9 positive in comparison to the samples from non-inflammatory bowel disease patients. UC patients undergoing colectomy showed lower immunopositivity of Tryp-1 in the colon epithelium in their diagnostic biopsies when compared to that of conservatively treated patients and non-inflammatory bowel disease patients. The discovery of a low trypsinogen level at diagnosis warrants further study.

## INTRODUCTION

Inflammatory bowel disease (IBD) is a common name for Crohn's disease (CD), ulcerative colitis (UC), and unclassified colitis. Some patients may have only one episode of active disease and remain in remission for the rest of their lives, while others will suffer from a relapsing or continuously active disease and require colectomy<sup>[1-3]</sup>. The studied risk factors for an aggressive disease course (steroid dependency<sup>[4]</sup>, pancolitis<sup>[4,5]</sup>, extraintestinal manifestations<sup>[5]</sup>, severe disease at diagnosis<sup>[6]</sup>, or disease extension from the primary site of the active disease) are related to the clinical presentation and thus it is impossible to foresee the phenotype of the disease at diagnosis.

Since many pediatric UC patients present with aggressive disease during their disease course, it would be beneficial to find biomarkers that at the onset of disease could distinguish patients with complicated disease behavior and a high risk for surgery from those with a more benign course. The current opinion, however, is that immunosuppressive treatment is needed for a patient with a complicated disease. If it was possible to recognize an aggressive disease with biomarkers in the early disease phase, then

such patients could be introduced to immunosuppressive treatment aiming to improve the disease outcome. Previous pediatric data show the benefits of immunosuppressive treatment<sup>[7-9]</sup>, although biological treatment with a tumor necrosis factor- $\alpha$  (TNF- $\alpha$ ) antagonist has, disappointingly, not reduced the surgery rates<sup>[10]</sup>.

Matrix metalloproteinases (MMPs), a family of 24 zinc-dependent enzymes, comprise a group of proteinases<sup>[11]</sup> that degrade the extracellular matrix and basement membrane proteins in tissue remodeling processes both in normal and in pathological conditions<sup>[11]</sup>. In IBD the most abundantly expressed MMP is MMP-9<sup>[12]</sup>. Previously, we have shown that the immunopositivity of MMP-9 in the colon decreases after TNF- $\alpha$  antagonist treatment in adult CD<sup>[13]</sup>. Trypsinogens are serine proteases that are capable of degrading extracellular matrix proteins and the pro-forms of acute phase reaction proteins<sup>[14]</sup>, such as TNF- $\alpha$ , which cause damage to the mucosal barrier and UC-like inflammation<sup>[15]</sup>. The exact role of trypsinogens in IBD for the most part remains unknown, but it is known that trypsins activate promatrix metalloproteinases (proMMPs), especially the IBD-related proMMP-9<sup>[16-19]</sup>. Tumor associated trypsin inhibitor (TATI), also called pancreatic secretory trypsin inhibitor<sup>[20]</sup>, inhibits trypsin in a 1:1 molar ratio<sup>[21]</sup>. Extrapancreatically secreted TATI is assumed to play additional roles in ulcer healing and tissue regeneration<sup>[22]</sup>. TATI also takes part in preventing the excessive digestion of gastrointestinal (GI) mucus<sup>[22,23]</sup>. As with trypsinogens, the role of TATI in IBD-related inflammation is mostly unknown.

Matrix and serine proteases may be regarded as "regulators" of the barrier and inflammation cascade of the gut<sup>[14]</sup>. Accordingly, we hypothesized that the presence of expression of such proteases would be associated with the severity of the course of IBD. The hypothesis was tested by comparing the results of immunohistochemical stainings with MMP-9, trypsinogen-1 (Tryp-1), Tryp-2, and TATI on the biopsy material of pediatric patients who underwent surgery *vs* conservatively treated patients and subjects without IBD.

## MATERIALS AND METHODS

### Patients and controls

We reviewed all pediatric onset ( $\leq 16$  years old) UC patients from the IBD patient registry of Children's Hospital, Helsinki University Central Hospital who had been diagnosed between 1990 and 2008. From this database, we identified 24 UC patients who had undergone surgery (time from diagnosis to surgery, maximum 7 years) and 27 conservatively treated disease controls. The latter group had been diagnosed at the same age as the operated patients and the follow-up took place within the period of time that had elapsed between the diagnosis and the surgery in the index case. None of the disease controls underwent an operation during follow-up (median 6 years). All of the patients had undergone diagnostic ileocolonoscopy and upper gastrointestinal endoscopy,

**Table 1** Clinical data of the pediatric study groups at the time of diagnostic endoscopy

| Patient groups                                      | Surgery          | Disease controls | Non-IBD controls |
|---|------------------|------------------|------------------|
| No. of patients (male)                              | 24 (11)          | 27 (15)          | 20 (10)          |
| Age at diagnosis (yr), median (range)               | 13.1 (3.1-16.0)  | 12.1 (2.8-16.6)  | 13.5 (2.7-16.8)  |
| Time from diagnosis to surgery (yr), median (range) | 2.1 (0.1-7.4)    | -                | -                |
| Follow-up (yr), median (range)                      | -                | 6.3 (2.8-10.7)   | 1.0 (0.0-4.0)    |

| CRP (mg/L)  | 20 (< 3-92)      | 9 (< 5-36)       | < 3 (< 3-< 5)    |
| WBC (E9/L)  | 9.6 (6.7-26.3)   | 7.5 (4.1-15.9)   | 5.1 (3.0-16.3)   |
| Alb (g/L)   | 34.6 (28.0-40.0) | 36.2 (23.6-42.6) | 42.3 (39.8-47.2) |

<sup>1</sup>For the non-inflammatory bowel disease (IBD) controls, data were missing in one case. Alb: Albumin; CRP: C-reactive protein; ESR: Erythrocyte sedimentation rate; Hb: Haemoglobin; WBC: White blood cell count.

and during follow-up the diagnosis remained consistent for the UC patients. Table 1 presents the background data of the study groups. The data on the indications and type of surgical therapy of the patients is shown in Table 2. Twenty children who had undergone ileocolonoscopy with biopsies and who did not suffer from IBD served as non-IBD controls. The indications for endoscopy in these children were as follows: suspected IBD ( $n = 12$ ), abdominal pain ( $n = 4$ ), colorectal bleeding ( $n = 3$ ), and pancreatic insufficiency ( $n = 1$ ).

For all of the patients and controls, tissue samples from the diagnostic ileocolonoscopy (colonic and ileal biopsies) were stained with immunohistochemistry to test for MMP-9, Tryp-1, Tryp-2, and TATI antibodies (see below). Based on the patient records, we reviewed the laboratory values of albumin, C-reactive protein (CRP), the erythrocyte sedimentation rate (ESR), the white blood cell count (WBC), and the haemoglobin at the time of the ileocolonoscopy.

### Inflammatory score and disease severity

The disease was considered to be acute and severe if the patient required hospitalization at diagnosis and the PU-CAI score was over 65<sup>[24]</sup>. The endoscopic distribution of the disease at the time of the diagnostic colonoscopy was scored as 0, indicating no inflammation, as 1 for proctitis, as 2 for left-sided colitis, and as 3 for pancolitis. The degree of histological inflammation was recorded based on the primary diagnostic histological examination reports provided by experienced pathologists. The samples

were graded according to the presence of ulceration, the frequency of acute and chronic inflammatory cells, crypt distortion, and goblet cell depletion recorded on a scale of 0 to 2 (0 no inflammation, 1 mild inflammation, 2 moderate to severe inflammation) (modified from Beattie *et al*<sup>[25]</sup>). The presence of backwash ileitis in the diagnostic ileocolonoscopy was also recorded.

### Immunohistochemistry

Formalin-fixed, paraffin-embedded tissue sections (4- $\mu$ m) were deparaffinized in xylene and rehydrated in graded concentrations of ethanol and water. To block endogenous peroxidase activity, the sections were treated with 0.3% Dako REAL Peroxidase-Blocking Solution (DAKO, Glostrup, Denmark) for 5 min. For the antigen retrieval tissue, the sections were treated in the pretreatment module of the Autostainer (LabVision UK Ltd) in a Tris-HCl buffer (pH 8.5) for 20 min at 98 °C (Tryp-1 and MMP), a 0.1% pepsin solution for 15 min at 37 °C (Tryp-2), or a 0.01% trypsin solution for 30 min at 37 °C (TATI). After pretreatment, a Lab Vision Autostainer TM 480 (LabVision, Fremont, CA, United States) was used for immunohistochemistry. The sections were incubated with antibodies against Tryp-1 at a dilution of 1:500 (MAB 1482, Chemicon, Temecula, CA, United States), against MMP-9 (RB-1539-PO, LabVision Fremont, CA) at a dilution of 1:1000, and against Tryp-2 (8F7)<sup>[26]</sup> and TATI (6E8)<sup>[27]</sup> at dilutions of 1:200 and 1:500, respectively. The incubation times were one hour for Tryp-1, MMP-9, and TATI and overnight for Tryp-2. Subsequently, the sections were incubated with a peroxidase-conjugated Dako REAL EnVision/HRP, Rabbit/Mouse (ENV) reagent for 30 min. The final visualization was performed by incubating the sections in DAKO REAL DAB+ Chromogen for 10 min. Between the staining steps, the slides were washed with 0.04% PBS. Mayer's hematoxylin was used for counterstaining. Finally, the sections were rinsed in tap water for 10 min and mounted in an aqueous mounting medium (Aguamount, BDH, Poole, United Kingdom). As positive controls, we used formalin-fixed, paraffin-embedded sections of pancreatic papillary carcinoma (Tryp-1), pancreatic adenocarcinoma (Tryp-2 and TATI), and ventricular adenocarcinoma (MMP-9). A

<sup>1</sup>Both UC patient groups had significantly more positively stained inflammatory cells in their colonic epithelium when compared to the non-IBD controls;

<sup>2</sup>The patients who had undergone surgery had significantly lower immunopositivity when compared to the conservatively treated and non-IBD controls;

<sup>3</sup>Both UC patient groups had significantly higher immunopositivity when compared to the non-IBD controls. IBD: Inflammatory bowel disease; UC: Ulcerative colitis; TATI: Trypsin inhibitor; Tryp-2: Trypsinogen-2; MMP-9: Matrix metalloproteinase-9.

tissue sample without a primary antibody served as a negative control during each staining.

### Interpretation of staining results

The immunohistochemical specimens were scored independently by two investigators (Piekkala M and Hagström J) in a semi-quantitative fashion under a light-field microscope at  $\times 100$  magnification using a marking and staining immunopositivity scale. This was done as follows: negative immunoreactivity was scored as 0, a diffuse weak positivity was scored as 1, a moderately positive or focally strongly positive immunopositivity was scored as 2, and a homogeneously strong immunopositivity was scored as 3 (modified from Böckelman *et al.*<sup>[28]</sup>). An experienced pathologist (Hagström J) confirmed the identity of the cell types producing each Tryp-1, Tryp-2, TATI, or MMP-9.

### Ethics

The National Supervisory Authority for Welfare and Health gave its permission for use of the tissue samples. In accordance with Finnish regulations, no informed consent is required for this kind of study.

### Statistical analysis

Because of the small number of patients, the non-parametric Mann-Whitney's test and Kruskal-Wallis test were used to compare the significance of the differences in the level of immunopositivities between the studied groups. An independent samples *t* test (Spearman), and Fisher's

exact test were performed to investigate the significance of the association between the level of immunopositivities and the clinical markers. A  $P < 0.05$  was considered significant.

## RESULTS

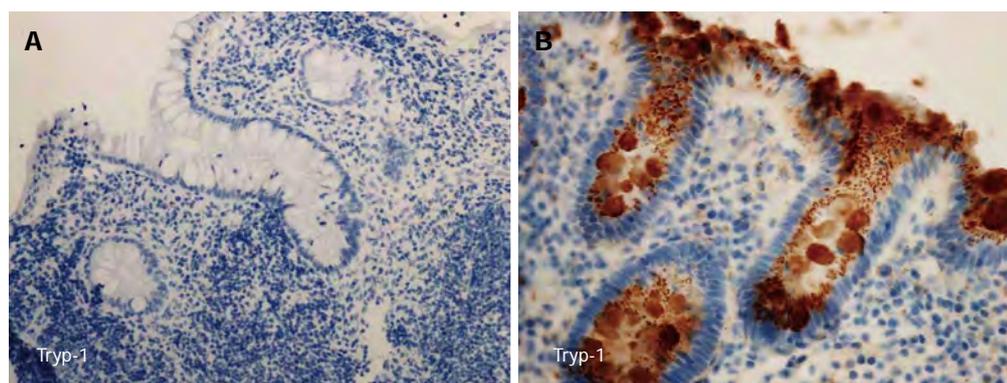

### Disease severity and distribution and medication

The endoscopic distribution of inflammation was comparable between the UC groups ( $P = 0.7$ ). During the diagnostic biopsies, we detected mild inflammation in 16 of 51 (31%) and moderate to severe inflammation in 35 of 51 UC patients (69%), without major differences between surgical and conservative groups ( $P = 0.2$ ). Of the 24 patients requiring surgery (median two years after diagnosis), 46% ( $n = 11$ ) had an acute severe disease at diagnosis. This was significantly more than in the disease controls (15%,  $n = 4$ ) ( $P = 0.03$ ). In total, 15 of 51 UC patients (30%) had an acute severe disease at diagnosis (73% of them underwent surgery).

### Staining results in the colon

Table 3 shows the proportions of Tryp-1, Tryp-2, TATI, and MMP-9 positive samples, the median levels of immunopositivity, and the *P* values when comparing the proportions of positive samples and the level of immunopositivity between the surgery group and the conservatively treated or non-IBD groups.

**Tryp-1:** Tryp-1 was stained in the colon epithelium and

**Figure 1** Immunohistochemistry for trypsinogen-1. A: Lack of immunopositivity for trypsinogen-1 (Tryp-1) in a colonic sample at the diagnosis of a pediatric patient with ulcerative colitis who was operated on two years after diagnosis ( $\times 200$ ); B: Immunopositivity for Tryp-1 in the colonic epithelial cells of a diagnostic tissue sample from a conservatively treated patient with seven years follow-up from the diagnosis ( $\times 400$ ).

in the inflammatory cells of the stroma. The staining of Tryp-1 was granular. The immunopositivity in the colon epithelium was significantly lower in the samples from the surgery group (Figure 1A) when compared to that of the conservatively treated (Figure 1B) and non-IBD controls (Table 3). No difference in the immunopositivity of the colon epithelium was found between the conservatively treated and non-IBD controls. The proportion of positive samples and the level of immunopositivity in the inflammatory cells of the stroma were similar in the studied groups (Table 3).

**Tryp-2:** Tryp-2 was stained in the epithelium. All of the samples, regardless of the study group, had the same level of Tryp-2 immunopositivity in the inflammatory cells of the colon stromal tissue (Figure 2A and B). The proportion of positive samples and the level of immunopositivity in the epithelium were comparable between the surgery group, the conservatively treated, and non-IBD controls (Table 3). In total, 83% (39 of 47) of the samples that were Tryp-1 positive in the colon epithelium were also Tryp-2 positive.

**TATI:** TATI was only detected in the colon epithelium, the inflammatory cells of the colon stroma being negative for TATI (Figure 2C and D). The proportion of TATI positive samples and the level of immunopositivity were comparable between the surgery group and the conservative and non-IBD groups (Table 3). The immunopositivity of TATI did not relate to the expression of Tryp-1 or Tryp-2 (data not shown).

**MMP-9:** In the colon, MMP-9 was mainly found in the stromal inflammatory cells and positive staining was detected in the epithelium (Figure 2E and F). The proportion of MMP-9 immunopositive samples and the level of immunopositivity in both the inflammatory cells and the epithelium were similar for the surgery group and the conservative group (Table 3). When compared to non-IBD patients, the proportion and immunopositivity of MMP-9 in the inflammatory cells was higher in the

UC patients, but we detected no differences when considering the epithelial positivity (Table 3). There was no association between the expression of MMP-9 and the expression of Tryp-1, Tryp-2, or TATI (data not shown).

#### Staining results in the ileal samples

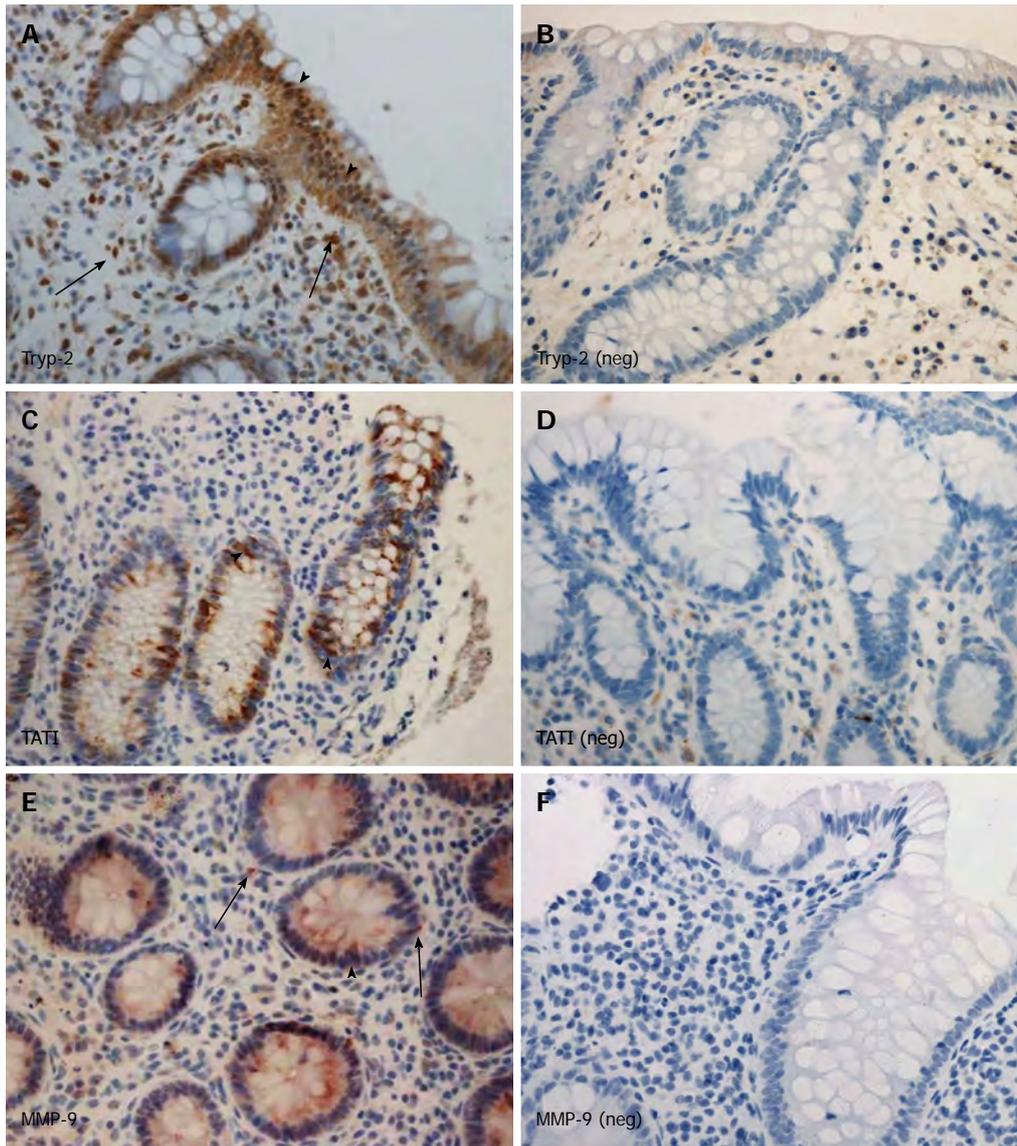

In 59% of the ileal samples (available for 36 UC patients and 14 non-IBD controls), the epithelium was Tryp-1 positive. Of the inflammatory cells in the stroma, 33% were Tryp-1 positive. The comparative staining proportions were 100% for Tryp-2 (positivity of the epithelium and inflammatory cells), 82% for TATI (positivity of the epithelium, inflammatory cells negative) and 28% and 26% for MMP-9 (positivity of the epithelium and of the inflammatory cells of the stroma, respectively). The proportions of positively stained samples for Tryp-1, Tryp-2, and TATI were comparable between the studied groups. All UC patients, regardless of treatment outcome, had significantly more MMP-9 positivity in the ileal epithelium than non-IBD patients ( $P = 0.005$ ). The staining intensities of the studied markers were similar in all of the study groups (data not shown).

#### Association between disease activity and immunohistochemistry

The immunopositivity of MMP-9 in the inflammatory cells was positively associated with the grade of inflammation in the colon (95%CI: 0.22-0.62;  $P = 0.0002$ ). However, there was no association with MMP-9 immunopositivity and the other markers of active disease. The staining intensities of the other markers in the epithelium of the colon or in the inflammatory cells of the stroma did not associate with the initial disease severity at diagnosis, the grade of inflammation at diagnosis, the endoscopic distribution of the disease at diagnosis, or the presence of backwash ileitis.

#### Laboratory markers

All of the primary laboratory values in the surgery group and disease controls were comparable. The blood inflammatory markers (CRP, ESR, WBC) were significantly

**Figure 2** Trypsinogen-2 was stained in the epithelium. A: Immunopositivity for trypsinogen-2 (Tryp-2); B: Immunonegativity for Tryp-2; C: Immunopositivity for tumor associated trypsin inhibitor (TATI); D: Immunonegativity for TATI; E: Immunopositivity for matrix metalloproteinase-9 (MMP-9); F: Immunonegativity for MMP-9. Arrows (A, E): Immunopositivity in the stromal inflammatory cells; Arrowheads (A, C, E): Immunopositivity in the epithelial cells. A-F,  $\times 400$ .

higher and the albumin level lower in UC patients compared to the non-IBD controls (data not shown).

## DISCUSSION

The exact roles of the active inflammation markers trypsinogens, TATI, and MMP-9 have not been studied in pediatric UC patients in relation to the disease outcome. Therefore, we compared the immunohistochemical positivity of Tryp-1, Tryp-2, TATI, and MMP-9 in diagnostic colonoscopic tissue samples from pediatric UC patients who required surgery with those of conservatively treated patients and non-IBD controls.

For the first time serine proteases Tryp-1 and Tryp-2 were demonstrated in the epithelium and in the inflammatory cells of the colon and ileum and TATI was found in the epithelium of the colon and ileum in pediatric UC

patients. At the time of the diagnosis, the immunopositivity of Tryp-1 in the colon epithelium is lower when comparing patients that have aggressive disease requiring surgery with those who have conservative treatment. We could also confirm that MMP-9 expression correlated with the grade of inflammation of the colon similarly, as reported earlier in adult and pediatric IBD patients<sup>[12]</sup>.

### Trypsinogens in pediatric UC

It is known that serine proteases regulate the gut barrier and inflammation cascade<sup>[14]</sup>, and that they also take part in protease-activated receptor signaling, which has been shown to activate intestinal inflammation<sup>[29]</sup>. Thus, our finding of a low Tryp-1 level in the colon epithelium of the surgery group is important because as many as 75% of the patients had more than mild inflammation and nearly half had acute severe disease at the time of diag-

nosis. Acute inflammation is, however, not the only background factor explaining the low expression of Tryp-1 in patients undergoing surgery; in addition, the immunopositivity did not associate with the degree of inflammation at diagnosis. The expression of Tryp-2 was also low in all of the studied groups. These findings, when taken together, indicate that trypsinogens are weakly expressed in the colon and not upregulated by inflammation in UC patients. Since they are also expressed in the healthy colon, their role might be mainly physiological. It may be speculated that severe inflammation suppresses the physiological secretion rate of Tryp-1 but not Tryp-2 and TATI. At the moment, however, the exact role of trypsins Tryp-1 and Tryp-2 in intestinal inflammation remains unknown.

### **Trypsin inhibitor TATI**

In healthy subjects proteases are expressed in the GI tract at low concentrations. An increase in concentrations is regarded as destructive; thus the balance between the proteases and their inhibitors is considered important<sup>[14]</sup>. It is known that TATI inhibits both Tryp-1 and Tryp-2 equally<sup>[21]</sup>. We found no correlation between the expression of the major trypsin inhibitor TATI and trypsinogens. Since the expression of TATI was low, the weak expression of trypsinogens could not be explained by the upregulation of TATI. The low expression of TATI in pediatric UC patients is in line with earlier findings showing reduced intestinal TATI in IBD and other GI conditions associated with abnormalities in the internal mucous layer<sup>[30]</sup>. However, as TATI and trypsinogens were also expressed in healthy colon, their low expression might be physiological.

### **MMP-9 association with trypsinogens**

This study reports for the first time together the expression of MMP-9 and trypsinogens in pediatric UC patients. However, the immunopositivity of MMP-9 had no association with that of Tryp-1 or Tryp-2. However, the small sample size in the present study has to be considered, and this finding does not either contradict or support the earlier report that trypsins associate with proMMP-9<sup>[16-19]</sup>. MMP-9 is expressed in the neutrophils but not in the colon epithelium in pediatric IBD<sup>[31]</sup>. In the present study we showed, in addition to the upregulated MMP-9 expression in the inflammatory cells, epithelial immunopositivity for MMP-9 as well. This may be a novel finding as we validated our staining with care to avoid any unspecific staining reactivity. Of the MMP inhibitors (TIMPs), TIMP-3 is expressed in pediatric IBD<sup>[14,30,32,33]</sup>, and it correlates with the degree of inflammation<sup>[30]</sup>. Unfortunately, the TIMP levels could not be assessed in this study.

### **Strengths and limitations of the study**

The aim of the study was to compare two pediatric UC groups: those who would undergo surgery during childhood or adolescence and patients whose disease course is more benign. Although the patient population in this study is quite small, one strength of the study was that the

patient age and disease extension at diagnosis were comparable. Also, the duration of disease of patients who had undergone surgery and the disease controls was matched. Restorative proctocolectomy was performed at a median of 2 years after diagnosis (median age 15 years), and all the patients were followed-up at least until that time. In total, the disease controls were followed up for a median of 6 years and none of them had undergone surgery during this time period. We also had control samples from non-IBD children, which demonstrated the natural expression of studied markers in non-inflammatory bowel disease.

In terms of the limitations of the results, we could only use one method for assessing trypsinogens, TATI, and MMP-9 profiles because the biopsy samples were very small and did not allow further analysis. Using molecular biological methods such as reverse transcription-polymerase chain reaction or Western blotting to analyze the expression of the studied markers would have given more strength to the study. However, we had the unique possibility to study the diagnostic samples and relate the data to the disease course of the patients. Furthermore, two investigators blinded to the patient data assessed the samples. The discovery of a low Tryp-1 level related to an aggressive disease course is preliminary and was not related to the altered expression of its major inhibitor, TATI. Thus, the physiological mechanisms underlying these findings require further studies.

In conclusion, significant proportions of pediatric UC patients suffer from aggressive disease and require surgery. It is estimated that approximately one in four pediatric patients undergo colectomy during the first decade after the diagnosis<sup>[2,3,34]</sup>. No change in the surgery rate has been seen between the years 1994 and 2007<sup>[55]</sup>. By current diagnostic modalities, it is impossible to foresee the disease outcome at the time of the diagnosis of UC, although an initial aggressive disease increases the risk of colectomy<sup>[6]</sup>. We found the expression of Tryp-1 to be weaker in the epithelial cells of patients with aggressive disease but the mechanism and significance of that finding remained unclear. Therefore, there is a need for further investigations on Tryp-1 and other biomarkers to identify patients with aggressively proceeding UC.

## **ACKNOWLEDGMENTS**

The authors thank Ms Anne Nikkonen for her excellent help in collecting the patient data and Ms Päivi Peltokangas for her skilful technical assistance.

## **COMMENTS**

### **Background**

Significant proportions of pediatric patients with ulcerative colitis (UC) suffer from aggressive disease and require surgery. It is estimated that approximately one out of four pediatric patients undergo colectomy during the first decade after the diagnosis. No change in the surgery rate was observed between the years 1994 and 2007.

### **Research frontiers**

By current diagnostic modalities, it is impossible to foresee the disease out-

come at the time of the diagnosis of UC, even though an aggressive initial disease presentation increases the risk of colectomy. If it was possible to recognize an aggressive disease course by biomarkers in the early disease phase, such patients could be introduced to early immunosuppressive treatment aimed at improving the disease outcome. The role of matrix metalloproteinase-9 (MMP-9) is scarcely reported in pediatric inflammatory bowel disease (IBD). Trypsinogens and a trypsin inhibitor (TATI) have not been studied at all in pediatric UC patients. Accordingly, the authors hypothesized that the expression of such proteases would be associated with the severity of the course of the UC. The hypothesis was tested by comparing the results of immunohistochemical staining on the diagnostic biopsy material of pediatric patients who underwent surgery vs conservatively treated patients and subjects without inflammatory bowel disease.

### Innovations and breakthroughs

For the first time, the presence of the serine proteases trypsinogen-1 (Tryp-1) and Tryp-2 was demonstrated in the epithelium and in the inflammatory cells of the colon and ileum in pediatric UC. Accordingly, this is the first study to describe the expression of their inhibitor, TATI, in the epithelium of the colon and in the ileum in pediatric UC patients. The authors found that at the time of the diagnosis, the immunopositivity of Tryp-1 in the colon epithelium is lower when comparing pediatric UC patients who have an aggressive disease course requiring surgery to those managed by non-operative treatment. The authors could also confirm that the expression of MMP-9 correlated with the grade of inflammation of the colon similarly, as reported earlier in adult and pediatric IBD patients.

### Applications

By demonstrating the protease profile of the colon mucosa of pediatric patients who will suffer from aggressive UC, this study may aid experts in characterizing the molecular environment of aggressive UC. The final goal is to find clinically applicable biomarkers for an aggressive disease.

### Terminology

UC is a chronic inflammatory disease of the colon and the rectum that is of unknown origin; it is characterized by bloody diarrhea, abdominal pain, and weight loss; MMP, a family of 24 zinc-dependent enzymes, comprise a group of proteinases that degrade the extracellular matrix and basement membrane proteins in tissue remodeling processes both in normal and in pathological conditions; Tryps are serine proteases that are capable of degrading extracellular matrix proteins and the pro-forms of acute phase reaction proteins, such as tumor necrosis factor, which cause damage to the mucosal barrier and UC-like inflammation. Tumor associated TATI inhibits trypsin in a 1:1 molar ratio.

### Peer review

This is an interesting study delineating the colonic expression of key proteases in the setting of paediatric UC.

### Abstract

**AIM:** To examine the possible ameliorative effect of breastfeeding and the uptake of human colostrum against coeliac disease in autistic rats.

**METHODS:** Female rats were fed a standard diet and received a single intraperitoneal injection of 600 mg/kg sodium valproate on day 12.5 after conception. In study 1, neonatal rats were randomly subjected to blood tests to investigate autism. In study 2, the 1<sup>st</sup> group was fed by the mother after an injection of interferon- $\gamma$  (IFN- $\gamma$ ) and administration of gliadin. The pups in the 2<sup>nd</sup> group were prevented from accessing maternal milk, injected IFN- $\gamma$ , administered gliadin, and hand-fed human colostrum. The normal littermates fed by the table mothers were injected with physiological saline and served as normal controls in this study.

**RESULTS:** The protein concentration was higher in group 2 than in group 1 in the duodenum ( $161.6 \pm 9$  and  $135.4 \pm 7$  mg/g of tissue, respectively,  $P < 0.01$ ). A significant increase ( $P < 0.001$ ) in body weight was detected in human colostrum-treated pups on post natal day (PND) 7 and 21 *vs* suckling pups in group 1. A delay in eye opening was noticed in the treated rats in group 1 on PND 13 compared with the control group and group 2. Administration of a single intraperitoneal injection of 600 mg/kg sodium valproate on day 12.5 after conception resulted in significantly reduced calcium and vitamin D levels in study 1 compared with the control groups ( $P < 0.001$ ). However, human colostrum uptake inhibited increases in the level of transglutaminase antibody in autistic pups with coeliac disease.

**CONCLUSION:** The effects of early-life nutrition and human colostrum on the functional maturation of the duodenal villi in autistic rats with coeliac disease that might limit or prevent the coeliac risk with autism.

**Key words:** Autism; Breastfeeding; Coeliac disease; Human colostrum

**Core tip:** Research examining the potential benefits of using breastfeeding and/or human colostrum for a wide range of gastroenterologic conditions of coeliac disease in autistic rats which is never studied before. Early results are encouraging and we envisage the standard use of human colostrum in the clinical management of gastrointestinal diseases within the next decade.

## INTRODUCTION

Two retrospective studies, which analysed representative populations of children with autism, have reported gastrointestinal tract (GI) symptoms in 20% of young children previously diagnosed with autism<sup>[1]</sup>. In contrast, prospective reports from paediatric gastroenterology and general autism clinics have described GI symptoms in 46%-84% of patients with autism spectrum disorder (ASD)<sup>[2]</sup>. However, there are few prevalence estimates from population-based epidemiologic studies. Reported GI abnormalities include low activities of disaccharidase enzymes, defective sulphation of ingested phenolic amines (Tylenol), bacterial overgrowth with a greater diversity and number of clostridial species, more numerous Paneth cells, increased intestinal permeability, and positive effects on behavioural cognition following dietary intervention<sup>[3]</sup>. Coeliac disease (CD) exhibits a multifactorial aetiology, and both genetic and environmental factors contribute to disease development. CD is a human leukocyte antigen (HLA)-associated disorder, and the majority of CD patients express HLA-DQ2 and HLA-DQ8 to a lesser extent<sup>[4]</sup>. Disease development is a consequence of the ingestion of immunogenic fragments in gluten by genetically predisposed subjects<sup>[5]</sup>. The treatment of CD involves a lifelong diet, which may cause difficulties, because avoiding gluten completely is almost impossible. However, over the last few years, new studies have suggested that prevention of CD may be possible<sup>[6]</sup>. The statement "prevention is better than a cure" is desirable for every disease, but is especially true for CD. Primary prevention avoids the development of a disease. In CD, primary prevention aims to avoid CD by intervening before the onset of the initial disease processes. In this context, we will outline the rationale for primary prevention in CD, which is based on factors contributing to CD and the possibility to improve tolerance to (food) allergens. Breastfeeding and colostrum provide immunological integration between the mother and neonate. Breastfeeding has immunological advantages, which allow it to prevent infections. Moreover, there is evidence that breastfeeding protects against cardiovascular disorders, obesity, Crohn's disease, colitis ulcerosa, allergies, Diabetes mellitus type I and other (autoimmune) disorders such as CD<sup>[7]</sup>. The risk of these disorders could increase if the duration of breastfeeding is less than 3-6 mo<sup>[8]</sup>. During the lactation period, breast milk undergoes three different phases with different milk compositions: colostrum, first milk and mature milk<sup>[9]</sup>. Colostrum is the first milk produced after birth and is particularly rich in immunoglobulins, antimicrobial peptides (*e.g.*, lactoferrin and lactoperoxidase), and other bioactive molecules, including growth factors. Colostrum is important for the nutrition, growth, and development of new-born infants

and contributes to the immunologic defence of neonates. The composition of mammary secretions changes continuously throughout the suckling period; however, for the purposes of this research, we define colostrum as the milk produced in the first 48 h after birth. Breast milk contains all of the immunoglobulins (IgA, IgE, IgG, IgD and IgM)<sup>[10]</sup>. However, for new-borns, the most important immunoglobulins are IgA and IgG. IgA, specifically secretory IgA, provides mucosal defence, and IgG antibodies support tissue defence. Several studies describe the detection of wheat gliadins and other gluten peptides in breast milk along with specific IgA-antibodies against gliadin<sup>[11]</sup>.

The low levels of gluten in breast milk could potentially be involved in the induction of oral tolerance to gluten in breastfed infants. The concentration of IgA anti-gliadin is highest in colostrum and decreases after one month<sup>[11]</sup>. Many studies have been published regarding the preventive effect of breastfeeding in CD. An important systematic review and meta-analysis of observational studies on breastfeeding and CD by Akobeng *et al.*<sup>[12]</sup> concludes that breastfeeding offers protection against the development of CD. However, it is unclear whether breastfeeding permanently protects against the development of CD or whether it only delays the onset of symptoms<sup>[11]</sup>. The mechanism of protection against CD by breast milk is not well understood. Hanson *et al.*<sup>[9]</sup> suggested that breastfeeding modulates the early exposure of the neonate's intestinal mucosa to microbes and limits bacterial translocation through the gut mucosa. In addition, by preventing inflammation in the gut, breastfeeding also diminishes the passage of gluten peptides into the lamina propria and prevents the development of CD<sup>[10]</sup>. Another possible preventive mechanism is that human colostrum may decrease tissue transglutaminase expression in the gut and diminish the generation of deaminated gluten peptides<sup>[13]</sup>. The immune-modulating properties of human colostrum may also be exerted through a T-cell-specific suppressive effect, which has been shown in experiments on peripheral lymphocytes stimulated with phytohaemagglutinin, OKT3 and allo-antigens<sup>[11]</sup>. Thus, human colostrum may be an ideal antimicrobial for selective targeting in the gastrointestinal tract in autistic rats with coeliac disease.

## MATERIALS AND METHODS

### *Rat model of autism and CD*

Female Wistar rats with controlled fertility cycles were mated overnight. The morning when spermatozoa were found was designated as the first day of gestation. The females were fed a standard diet and received a single intraperitoneal injection of 600 mg/kg of sodium valproate on day 12.5 after conception. The control females were fed a normal standard diet and injected with physiological saline. Sodium valproate (Sigma) was dissolved in saline at a concentration of 250 mg/mL. Administration of this dose of sodium valproate to rats during

embryogenesis has been shown to result in a maximum level of total VPA (900 µg/mL) in maternal plasma in less than 1 h with a mean plasma elimination half-life of 2.3 h<sup>[14]</sup>. The dams were housed individually and were allowed to raise their own litters. To induce coeliac disease, autistic male neonatal rats from valproate-treated females were divided into 2 experimental groups (twenty pups/group) and treated with interferon-γ (IFN-γ) (1000 U per animal administered intraperitoneally) after birth. Gliadin (0.5 and 3 mg) was intragastrically administered to the pups of both groups on day 0 and 3, and a 30 mg challenge dose was administered on day 20 (24 h before the termination of the experiment)<sup>[15]</sup>. The control pups from control females received physiological saline until the experiment was terminated.

### Animals

In study 1, male Wistar neonatal rats were randomly selected from the above experimental groups before the treatment and were subjected to blood tests to investigate autism. Study 2 consisted of two experimental groups of new-born male autistic rats. The pups in group 1 were randomly assigned to be mother-fed after injection of IFN-γ and administration of gliadin. The pups in group 2 were collected from the mothers immediately after birth to prevent suckling of maternal milk. No foster nursing took place because the major objective was to study pup viability. The animals were injected with IFN-γ, administered gliadin, placed in an infant incubator to control body temperature and hand-fed human colostrum every 3-4 h using a silicone rubber tube. The method was both time and labour intensive; however, the method was essential because gastrotomy of new-born rats is associated with a very high surgery-related death rate. Normal littermates fed by control mothers were injected with physiological saline and served as normal non-treated controls in this study.

### DNA and protein measurements on post natal day 21

The total DNA content in tissue was assayed using the diphenylamine method of Burton<sup>[16]</sup> and determined by spectrophotometry. Assays for total protein content<sup>[17]</sup> were performed on homogenates and supernatants; the concentrations were determined using spectrophotometry (SpectraMAX Plus, Molecular Devices, Sunnyvale, CA, United States).

### Postnatal growth and maturation development

On post natal day (PND) 0, the pup weights were determined, and the pups were examined for malformations. The measurement of the pup weights was repeated on PND 7, 14 and 21 when the offspring were weaned from their mothers in all of the experimental groups. Eye opening was observed once daily from day 12 to 16 and rated as follows: on day 0, both eyes were closed; on day 1, one eye opened; and on day 2, both eyes opened.

### Blood test

**Study 1 (to investigate autism):** In study 1, blood samples from each experimental group (ten pups) from groups 1 and 2 and the control group were pooled for analyses before the administration of IFN-γ and gliadin in groups 1 and 2 or physiological saline in the control group. The samples were obtained from the eye using capillary tubes and were collected in ethylene diamine tetraacetic acid tubes containing aprotinin at 0 °C and centrifuged at 1600 g for 15 min. The plasma was analysed for 1-epinephrine, norepinephrine, catecholamine, and 2-serotonin using high performance liquid chromatography as previously described<sup>[18,19]</sup>. The serum was analysed for 3-calcium and 25-OH vitamin D after collection in microfuge tubes using a chemiluminescent microparticle immunoassay<sup>[20]</sup>.

**IFN-γ:** Recombinant rat IFN-γ (PRP24; Serotec, Oxford, United Kingdom) was used in this study. IFN-γ was lyophilised (0.1 mg), reconstituted in 0.3 mL of distilled water, and stored until use in aliquots of 50 µL (10000 U) at -70 °C. A dose of 1000 U was used for each new-born rat. After application of IFN-γ, the pups were fed either milk from their mother or human colostrum.

**Gliadin administration:** Gliadin (from wheat gluten, G-3375; Sigma, St. Louis, MO, United States) was administered intragastrically using a silicon tube. Young rats were repeatedly administered gliadin in the following doses: day 0, 0.5 mg in one intragastric dose and day 3, 3 mg in one intragastric dose. The pups in each group were euthanised at 21 d of age after receiving a provocative dose of 30 mg of gliadin per animal 24 h before euthanasia (on postnatal day PND 20).

### Blood test study 2 (to investigate coeliac disease):

Study 2 aimed to investigate coeliac disease in autistic pups on PND 21. After the application of interferon-γ in group 1 (suckling pups receiving gliadin) and group 2 (human colostrum and gliadin), serum tissue transglutaminase tTG antibody titres were measured quantitatively by an enzyme-linked immunosorbent assay (QuantaLite tTG, Inova Diagnostics, CA, United States). Additionally, all the chemical analyses for study 1 were repeated on PND 21 for the two experimental groups and the control group.

### Transmission and scanning electron microscopic study

Small samples from the duodenum of each experimental group on PND 21 were immediately fixed in 3% phosphate-buffered glutaraldehyde (pH = 7.4; 4 °C) for 2 h. The tissues were postfixed in 1% aqueous osmium tetroxide in an appropriate buffer for 1 h and embedded in Epon. Ultrathin sections (80-100 nm) were prepared and stained with uranyl acetate and lead citrate. To examine the duodenum using scanning electron microscopy, the tissues were fixed as described previously, dehydrated,

mounted on aluminium stubs with conductive carbon glue, and sputter coated with a 100 Å layer of gold. The control and treated samples were examined using a Joel EX 1200 transmission electron microscope at the central lab of King Saud University.

### Statistical analysis

SPSS 13.0 was used for the statistical analysis. The data were expressed as the mean ± SD and were analysed using one-way analysis of variance followed with a post-hoc test for multiple comparisons. The differences were considered significant at the *P* < 0.05 level.

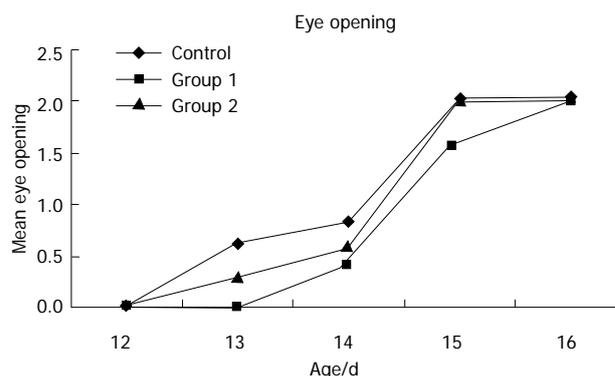

## RESULTS

### Changes in the protein and DNA content in the duodenum of the different experimental groups on PND 21

As shown in Table 1, the duodenal DNA and protein concentrations were significantly different between group 1 and group 2 and significantly higher in group 2 compared with the control animals. The protein concentration in the duodenum was significantly higher in group 2 compared with group 1 (151.6 ± 9 mg/g *vs* 122.4 ± 7 mg/g of tissue, respectively). However, no significant difference in the duodenal DNA concentration was observed between group 1 and the control group *P* > 0.05 (6.1 ± 0.06 *vs* 6.3 ± 0.03, respectively).

### Changes in body weight and postnatal growth

As shown in Table 2, the pup weight decreased significantly (*P* < 0.001) in the autistic neonatal pups on PND 0 (study 1) compared with the normal control pups. The animals from group 1 (suckling pups administered gliadin) exhibited a statistically significantly (*P* < 0.001) reduced increase in body weight until weaning compared with the control group. (21.40 ± 2.36 g *vs* 33.4 ± 2.7 g, respectively). A significant increase (*P* < 0.001) in body weight was detected in human colostrum-treated pups on PND 7 and 21 compared with suckling pups in group 1.

**Figure 1 Mean eye opening age in the studied groups.**

However, no significant difference was noticed between the two groups on PND 0 (*P* > 0.05). The stools were sticky, and the animals showed long bone malformations in autistic rats (results not shown).

### Eye opening

As shown in Figure 1, there was a delay in eye opening in the treated rats in group 1 on PND 13 compared with the control group and group 2. No difference was observed on PND 12 and 16 between group 1 and group 2 (*P* > 0.05) *vs* the control group.

### Changes in biochemical parameters in the control group and study 1 on PND 0

Table 3 shows the changes in biochemical parameters of control and autistic neonatal pups on PND 0. The mean concentrations of epinephrine, norepinephrine and serotonin were greatly increased in study 1 compared with the control group (*P* < 0.001). Administration of a single intraperitoneal injection of 600 mg/kg sodium valproate on day 12.5 after conception resulted in significantly reduced calcium and vitamin D levels in study 1 *vs* the control group (*P* < 0.001).

**Mean vitamin D:** As shown in Table 4, a significant difference in the vitamin D level was observed between group 2 and the control group (33.62 ± 0.581 ng/mL *vs* 44.36 ± 0.302 ng/mL; *P* < 0.05). Furthermore, on PND 21, the pups in group 1 exhibited a significantly lower mean vitamin D level *vs* the control group and group 2 (9.4 ± 0.225 ng/mL *vs* 44.36 ± 0.302 ng/mL and 33.62 ± 0.581 ng/mL; *P* < 0.01). Treatment with human colostrum inhibited decreases in the level of vitamin D in autistic pups with coeliac disease (*P* < 0.01).

**Mean serotonin:** As shown in Table 4, a significant increase in the mean serotonin levels was detected in group 1 *vs* the control pups (30.5 ± 0.565 ng/L *vs* 9.12 ± 0.126 ng/L; *P* < 0.001). A significant decrease in the serotonin level was detected in group 2, which was treated with human colostrum, *vs* group 1 (15.32 ± 0.367 ng/L *vs* 30.5 ± 0.565 ng/L; *P* < 0.001).

**Table 3** Changes in biochemical parameters in the control group and study 1 on post natal day 0 (mean  $\pm$  SD)

| Parameters | Vitamin D (ng/mL)            | Serotonin ( $\mu$ g/L)       | Epinephrine (ng/L)            | Norepinephrine (ng/L)          | Calcium (mg/dL)              |

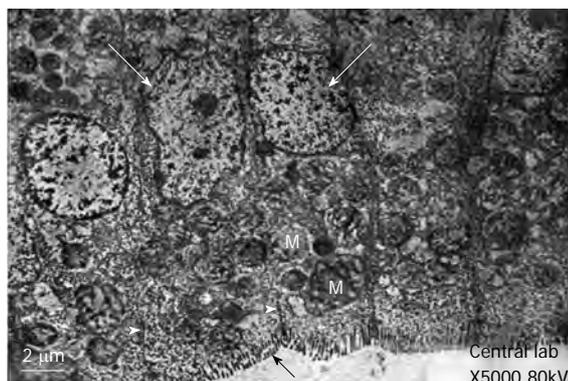

Figure 2 Transmission electron-micrograph of duodenum of rat of control group showing regularly arranged enterocytes with vesicular nucleus (white arrows) and continuous microvillus border (black arrow). Notice the cell junction (white arrowhead) between the enterocytes and abundant mitochondria (M).

**Mean epinephrine:** As shown in Table 4, the mean epinephrine concentration was significantly increased ( $P < 0.001$ ) in all of the treated groups including group 1 and group 2 on PND 21 *vs* the control group (76.22  $\pm$  1.15 ng/L and 56.15  $\pm$  0.071 ng/L *vs* 21.73  $\pm$  290 ng/L, respectively). However, the epinephrine level was significantly ( $P < 0.01$ ) decreased in group 2 pups *vs* group 1 pups (56.15  $\pm$  0.071 ng/L *vs* 76.22  $\pm$  1.15 ng/L, respectively).

**Mean norepinephrine:** As shown in Table 4, the mean norepinephrine concentration was significantly increased ( $P < 0.01$ ) in all of the treated groups including group 1 and group 2 on PND 21 *vs* the control group (204.87  $\pm$  1.83 ng/L and 155.42  $\pm$  0.086 ng/L *vs* 110.46  $\pm$  0.990 ng/L, respectively). Moreover, a significant change was detected in group 2 *vs* group 1 pups ( $P < 0.05$ ).

**Mean transglutaminase:** As shown in Table 4, the mean transglutaminase concentrations were significantly

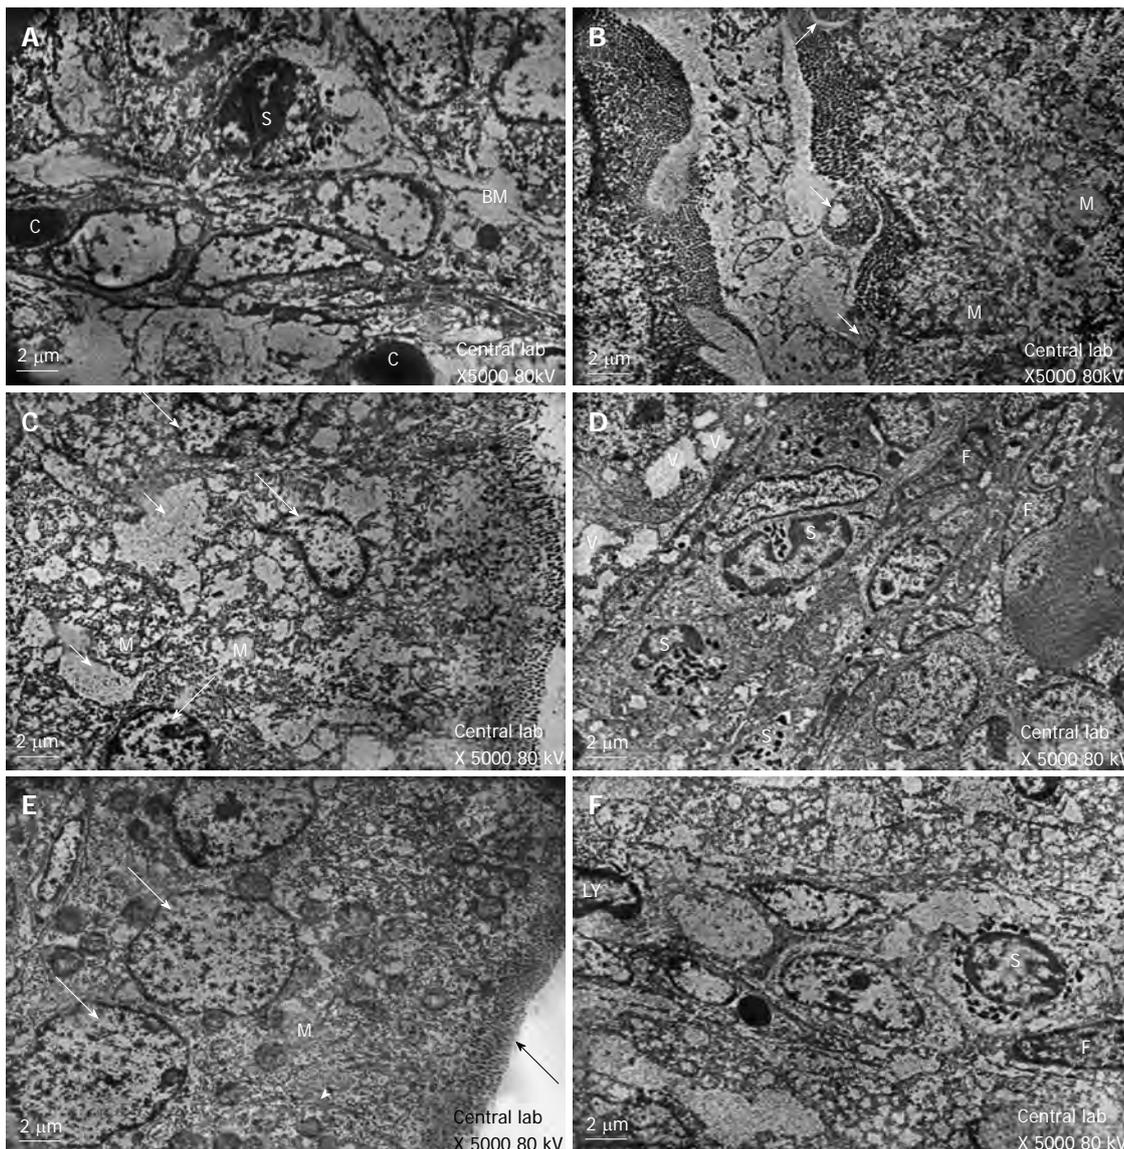

increased ( $P < 0.01$ ) in all of the treated groups including group 1 (suckling pups administered gliadin) and group 2 (human colostrum and gliadin) on PND 21 *vs* the normal controls (3.1  $\pm$  0.149 g/L and 1.6  $\pm$  1.021 g/L *vs* 0.9  $\pm$  0.066 g/L, respectively). Furthermore, the mean transglutaminase level was significantly ( $P < 0.01$ ) increased in the group 1 pups *vs* the group 2 pups. Moreover, a significant change was detected in the group 2 pups compared with the control pups. Treatment with human colostrum inhibited the increased level of transglutaminase in autistic pups with coeliac disease *vs* group 1 suckling pups.

**Mean calcium:** As shown in Table 4, the calcium level was decreased in group 1 *vs* the control group and group 2 (7.31  $\pm$  0.411 *vs* 10.91  $\pm$  0.241 and 10.12  $\pm$  0.819;  $P < 0.05$ ). No significant difference in the calcium level was observed between group 2 and the control group ( $P > 0.05$ ). Therefore, the human colostrum treatment was more effective than mother's milk in increasing the calcium level.

#### Transmission and scanning electron microscopy of the duodenal villi on PND 21

**Control group:** Transmission electron microscopy showed that the enterocytes exhibited a regular microvillus border, and cell junctions were typically observed between the enterocytes (Figure 2) along with scattered abundant mitochondria (Figure 2). The cores of the villi possessed normal appearances with normal capillaries and connective tissue cells (Figure 3A). The surface of the duodenal villi was examined using scanning electron microscopy and revealed some villi with intact tips and borders. The openings of goblet cells were observed on the surface of the villi (Figure 4A).

**Group 1:** The electron microscopic study showed localised areas of loss of the microvillus borders in the

**Figure 3** Transmission electron microscopy results showed. A: Transmission electron-micrograph of duodenum of rat of control group showing normal appearance of the core of the villi. Note eosinophil leucocytes (S) and close proximity of blood capillary (C) to the enterocyte basement membrane (BM); B: Transmission electron-micrograph of duodenum of breastfeeding rat group 1 showing local loss of microvillus border (long arrows) and swollen mitochondria with remnants cristae (M); C: Transmission electron-micrograph of duodenum of breastfeeding rat group 1 showing irregular nuclei (long arrow) with intercellular oedema (short arrow) and swollen mitochondria (M); D: Transmission electron-micrograph of duodenum of breastfeeding rat group 1 showing increased eosinophil leucocytes (S). Notice the nuclei of fibroblasts (F) and vacuolated enterocytes (V); E: Transmission electron-micrograph of duodenum of rat treated with human colostrum group 2 showing the enterocytes with vesicular nuclei (arrow) and regular microvillus border (black arrow). Notice the cell junction (head arrow) and abundant mitochondria (M); F: Transmission electron-micrograph of duodenum of rat treated with human colostrum showing normal appearance of the core of the villi with nuclei of lymphocyte (LY), nuclei of fibroblast (F) and eosinophil leucocytes (S).

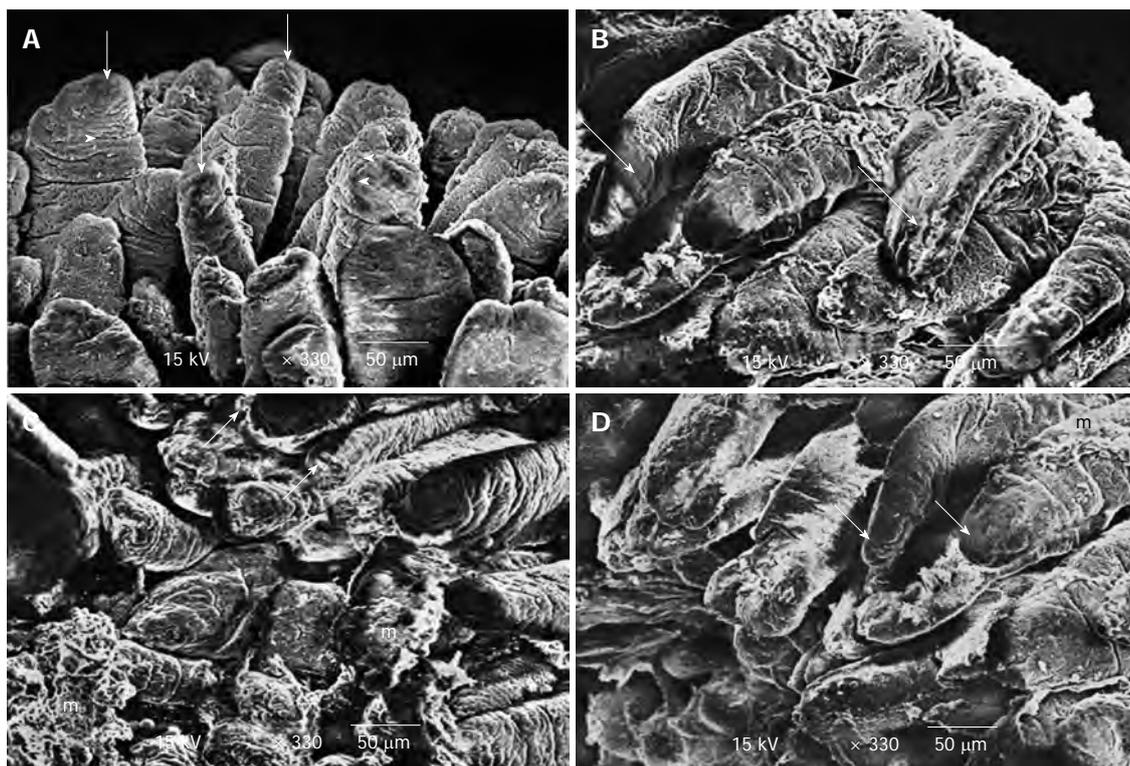

enterocytes with swollen mitochondria and vacuolation in the cytoplasm (Figure 3B). Irregular appearance of the nuclei of the enterocytes was also observed (Figure 3C), and the core of the villi showed cellular infiltration (Figure 3D). Scanning electron microscopy showed deformed villi (Figure 4B), villi with distorted appearances and the accumulation of mucous (Figure 4C).

**Group 2:** The ultrastructure of the enterocytes of the duodenal villi was similar to that of the control group. The microvillus border was regular and continuous. The enterocytes showed vesicular nuclei and abundant mito-

chondria (Figure 3E). The core of the villi appeared to be normal with normal capillaries (Figure 3F). Scanning electron microscopy showed that the villi of the duodenum of group 2 appeared to be normal and were similar to the control group (Figure 4D).

## DISCUSSION

In this investigation, the repeated administration of human colostrum until weaning in group 2 increased the mucosal restitution of duodenal tissue as shown in Figures 3E, 3F and 4D, which was observed by electron mi-

**Figure 4** Scanning electron microscopy results showed. A: Scanning electron-micrograph of duodenal villi of control group showing the villi with intact tips and border (short arrow). Notice the opening of goblet cells on the surface of the villi (arrow head); B: Scanning electron micrograph of duodenum of breastfeeding rat group 1 showing some of the villi are seen to be deformed (long arrow). Notice short villus (arrow head) is clearly seen; C: Scanning electron micrograph of duodenum of breastfeeding rat group 1 showing some villi with necrotic tips (short arrow). Notice distorted appearance of the other villi with accumulation of mucous (m); D: Scanning electron-micrograph of duodenum of rat treated with human colostrum group 2 showing duodenal villi with intact tips and borders (short arrow). Notice the presence of mucous on some villi (m).

scopy. However, the breast feeding in group 1 could not overcome the atrophy of the gut caused by coeliac disease in autistic rats as shown in Figures 3B-D, 4B and 4C. This suggested that epidermal growth factor (EGF) in colostrum (200  $\mu\text{g/L}$ ) and milk (30-50  $\mu\text{g/L}$ ) in humans and many other species acts as a luminal surveillance peptide that prevents gut damage<sup>[21]</sup> and stimulates the repair process at sites of injury<sup>[22]</sup>. Transforming growth factor- $\alpha$  (TGF- $\alpha$ ) is a 50-amino acid molecule present in human colostrum and milk at much lower concentrations (2.2-7.2  $\mu\text{g/L}$ )<sup>[23]</sup> than EGF and occurs in the gastrointestinal mucosa at sites of injury, which supports its role in mucosal growth and repair. TGF- $\beta$ -like molecules are present in high concentrations in both bovine milk (1-2 mg/L) and colostrum (20-40 mg/L)<sup>[24]</sup>. The concentrations are sufficient enough to mediate the ability to maintain gastrointestinal integrity in suckling neonates. The previous results are consistent with our previous report, which shows that treatment with bovine colostrum has a positive effect on duodenum injury in autistic rats with coeliac disease<sup>[25]</sup>. Insulin-like growth factor (somatomedins) (IGF-I) concentrations are much higher in bovine colostrum compared with human colostrum (500  $\mu\text{g/L}$  vs 18  $\mu\text{g/L}$ )<sup>[26,27]</sup>. And even lower concentrations in mature bovine milk (10  $\mu\text{g/L}$ ) are observed<sup>[28]</sup>. IGF-I is known to promote protein accretion (*i.e.*, it is an anabolic agent<sup>[29]</sup>) and is at least partially responsible for mediating

the growth-promoting activity of growth hormone. In rodents, two growth factors play an important role in the process of regeneration and proliferation of intestinal enterocytes: EGF and transforming TGF- $\alpha$ . However, TGF- $\alpha$  has not been found in rat maternal milk<sup>[30]</sup>. This may explain the decreased bone malformation in group 2, which was treated with human colostrum (results not shown), compared with group 1 rats. Growth factors are so named because they stimulate the growth of various cell lines *in vitro*; however, the functions of these peptide-based molecules are diverse. There are also marked species differences in the nature and concentration of growth factor constituents. For example, human colostrum contains much higher concentrations of EGF than bovine colostrum, while the reverse is true for insulin-like IGFs- I and II. In our investigation, the uptake of human colostrum in group 2 showed significant improvements compared with suckling pups in group 1 when assessed by body weight. The mean body weight measured in group 2 was highest at the end of weaning ( $29.6 \pm 1.75$ ) and significantly differed from the mean body weight observed on other days in group 1 and compared with the control. An additional consequence of different routes of immunoglobulin transmission relates to the changes in the relative contents of immunoglobulins, which occurs during the transition from colostrum to milk in certain species. For example, the profile of immunoglobulins in

human colostrum is similar to milk; the IgA level is high in both colostrum and milk (88%-90% of total immunoglobulin). IgA protects the gastrointestinal tract (GIT) from various diseases in new-borns, which is reflected in large changes in the profile of immunoglobulins during the transition from colostrum to mature milk<sup>[31]</sup>. IgA-deficient patients predominantly suffer from respiratory and gastrointestinal infections because secretory IgA has important functions in protecting mucosal surfaces<sup>[31]</sup>. Human colostrum has a low IgG content (2%), and the IgG required to provide systemic immunity is transferred across the placenta before birth<sup>[32]</sup>. In contrast, the colostrum IgG content in many other species is typically greater than 75% of the total immunoglobulin content.

Based on the aforementioned information, in our study, we used this unique model to induce gluten enteropathy. We found that the concurrent administration of IFN- $\gamma$  intraperitoneally and gliadin intragastrically in group 1 followed by a second intragastric dose of gliadin resulted in a failure to detoxify antigens from the gut, which may lead to cognitive impairments and coeliac crises on day 14. The impairments included loose stools with short and deformed duodenal villi in some pups, while other pups exhibited sloughing of the tips as observed by scanning electron microscopy. Local loss of the brush border, irregular nuclei and vacuolation of some enterocytes were observed using transmission electron microscopy on day 21. The previous result may be due to the presence of antigens in the diet that can cross into the mucosa more easily *via* a disrupted intestinal barrier. The antigens may cause local inflammatory reactions and generate proinflammatory cytokine signals that affect the GIT. The previously described damage was not observed in group 2, which was administered human colostrum until weaning, using scanning and transmission electron microscopy as shown in Figures 3E, 3F and 4D. This could be explained by the report from another group<sup>[33]</sup>, who revealed that the concentration of IgA anti-gliadin is the highest in colostrum and decreases after a month. This may diminish the effect of gluten peptides on the lamina propria and prevent the initiation of damage to intestinal villi that was observed in group 1.

Leptin levels, which supports duodenal protection in colostrum and milk, was correlated with the whole fat and choline phospholipid content of colostrum. The association between leptin and fat globule membrane content results from its protective properties during gut transit in the new-born animal<sup>[34]</sup>. Leptin receptor expression has been found in the small intestine, which suggests that the intestinal epithelium is a direct target of leptin action<sup>[35]</sup>. The concentration of leptin was 56% lower in mature milk (day 10) *vs* colostrum (13.90 g/L *vs* 6.14 g/L, respectively;  $P < 0.001$ ). The colostrum and milk leptin levels correlated with fat (0.90;  $P < 0.001$ ) and choline phospholipid (0.76;  $P < 0.05$ ). Thus, leptin is present in large quantities in colostrum, smaller and more variable quantities in untreated milk and is likely decreased in skim milk<sup>[3,4]</sup>. Our results revealed increased levels of

serotonin ( $33.3 \pm 0.244$ ), epinephrine ( $84.25 \pm 0.595$ ) and norepinephrine ( $184.29 \pm 8.44$ ) in autistic pups (study 1) due to maternal prenatal exposure to VPA. Furthermore, we observed a significant decrease in serum vitamin D and calcium levels in autistic neonatal rats in study 1 on PND 0 and group 1 on PND 21. Both epinephrine and norepinephrine were significantly increased in autistic pups on PND 0 and group 1 pups on PND 21 compared with the control group.

Colostrum is high in calcium and magnesium, which share bonding characteristics as functional groups. Both organic calcium and organic magnesium in colostrum enhance the absorption of other minerals and vitamins in our body. Colostrum also provides higher levels of vitamin D and vitamin A than normal milk<sup>[36]</sup>. In addition, vitamin D and IgD can help our body absorb a sufficient amount of calcium to enhance physiological functions<sup>[36]</sup>. Our investigation revealed that the uptake of human colostrum in group 2 inhibited the decrease in levels of vitamin D and calcium in autistic pups with coeliac disease as shown in Table 4.

An initial mucosal assault due to a gut infection or the toxic effects of gliadin may cause upregulation of tissue transglutaminase (tTG), which causes cross-linking of various proteins, including gliadin. This tTG-gliadin complex represents a "new antigen" (neoantigen), which could trigger the production of tTG antibodies<sup>[37]</sup>. Tissue TG plays a role in maintaining the integrity of both the intestinal crypt micro-architecture and the dermal-epidermal junction. Therefore, the development of villous atrophy in group 1 could be explained by the production of tTG antibodies ( $3.1 \pm 0.149$  g/L) due to repeated administration of gliadin, which may disturb the integrity of the duodenum in breastfeeding pups. However, human colostrum uptake inhibited the increase in the levels of transglutaminase antibody ( $1.6 \pm 1.021$  g/L) in autistic pups with coeliac disease.

The outcomes of the present investigation elucidated the effects of early-life nutrition from human colostrum on the functional maturation of the duodenal villi in autistic rats with coeliac disease, which might help to limit or prevent coeliac risk. There are numerous pathways that may lead to the diagnosis of ASD. In some, ASD may begin with genetic susceptibility, and in others, infection or immune abnormalities may play a key role. Further study of the reciprocal actions of the nervous, immune, and endocrine systems may help to unravel the mystery of ASD. Moreover, while many of the observations discussed herein are involved in the pathogenesis of autism, comprehensive studies of autism and coeliac disease with age-matched control individuals and their families are necessary to provide more conclusive results.

## COMMENTS

### Background

Coeliac disease (CD) exhibits a multifactorial aetiology, and both genetic and environmental factors contribute to disease development. CD is a human leuko-

cyte antigen (HLA)-associated disorder, and the majority of CD patients express HLA-DQ2 and HLA-DQ8 to a lesser extent. Disease development is a consequence of the ingestion of immunogenic fragments in gluten by genetically predisposed subjects. The treatment of CD involves a lifelong diet, which may cause difficulties, because avoiding gluten completely is almost impossible.

### Research frontiers

Many studies have been published regarding the preventive effect of breastfeeding in CD. An important systematic review and meta-analysis of observational studies on breastfeeding and CD by Akobeng *et al.* concludes that breastfeeding offers protection against the development of CD.

### Innovations and breakthroughs

Human colostrum may be an ideal antimicrobial for selective targeting in the gastrointestinal tract in autistic rats with coeliac disease.

### Applications

This investigation revealed that the uptake of human colostrum inhibited the decrease in levels of vitamin D and calcium in autistic pups with coeliac disease

### Peer review

This paper explores the effect of breastfeeding and human colostrums on the prevention of coeliac disease in autistic rats. The paper is well structured and the study is well designed. The article is sufficiently novel and interesting to warrant publication.

### Abstract

**AIM:** To investigate gastric antisecretory and gastro-protective activity of bovine hemoglobin (B-Hb) in rats.

**METHODS:** Adult Albino-Wistar rats were divided into groups of 6 animals each. B-Hb in doses of 100, 300 and 900 mg/kg body weight was tested for gastric acid secretion and antiulcer activity. Gastric secretions were measured 6 h after pylorus ligation in rats pretreated with B-Hb. The acidity was measured by titrating gastric contents against 0.01 mol/L NaOH to pH 7. Indomethacin ulcers were produced by oral administration of 30 mg/kg *bw* in the rats pretreated with B-Hb one hour before indomethacin. Six hours after indomethacin stomach removed and ulcer index was recorded. Ethanol ulcer were produced by 1 mL of ethanol in the rats pretreated with B-Hb 30 min before the ethanol.

One hour after ethanol stomach were cut open to score ulcers. Histological examination and analysis of gastric wall mucus, non-protein sulfhydryl groups (NP-SH), and myeloperoxidase (MPO) were carried in gastric tissue following ethanol administration.

**RESULTS:** In control rats pylorus ligation for 6 h resulted in the accumulation of  $8.1 \pm 0.61$  mL of gastric secretion. The treatment of the rats with 100, 300 and 900 mg/kg of B-Hb produced a significant decrease in the volume of gastric secretion  $5.6 \pm 0.63$ ,  $5.5 \pm 0.75$  and  $4.7 \pm 0.58$  mL respectively as compared to the control group [analysis of variance (ANOVA)  $F = 4.77$ ,  $P < 0.05$ ]. The lesion area in the control group was found to be  $22.4 \pm 3.2$  mm<sup>2</sup> six hours after the administration of indomethacin. Treatment of rats with B-Hb at doses of 100 mg/kg ( $24.3 \pm 3.29$  mm<sup>2</sup>), 300 mg/kg ( $16.2 \pm 1.45$  mm<sup>2</sup>) and 900 mg/kg ( $12.6 \pm 1.85$  mm<sup>2</sup>) produced a dose dependent decreased the lesion scores (ANOVA  $F = 4.50$ ,  $P < 0.05$ ). The ulcer index following one hour after 1 mL ethanol was  $7.1 \pm 0.31$ . Pretreatment of rats with B-Hb at the doses of 100 mg/kg ( $2.5 \pm 0.42$ ), 300 mg/kg ( $2.1 \pm 0.4$ ) and 900 mg/kg ( $0.7 \pm 0.21$ ) significantly inhibited the formation of gastric lesions (ANOVA  $F = 63.26$ ,  $P < 0.0001$ ). Histological examination of gastric mucosa following ethanol showed significant lesions in the form of gastric pits with detachment of the surface epithelium; vacuolation of epithelial cells and elongation of microvessels. The changes were dose-dependently attenuated by B-Hb. The treatment of rats with ethanol significantly decreased the Alcian blue binding capacity of gastric wall mucus ( $480 \pm 25.6$   $\mu$ g Alcian blue/g of tissue) as compared to control rats ( $667 \pm 25.8$   $\mu$ g). Pretreatment of rats with B-Hb at the doses of 100 mg/kg ( $516 \pm 31.6$   $\mu$ g/g), 300 mg/kg ( $558 \pm 28.8$   $\mu$ g/g) and 900 mg/kg ( $654 \pm 33.8$   $\mu$ g/g) significantly attenuated ethanol induced depletion of gastric wall mucus (ANOVA  $F = 8.05$ ,  $P < 0.005$ ). A significant and dose dependent increase of gastric mucosal NP-SH (ANOVA  $F = 19.62$ ,  $P < 0.001$ ) and decrease in MPO activity (ANOVA  $F =$

3.1,  $P < 0.05$ ) was observed in B-Hb treated rats.

**CONCLUSION:** B-Hb possesses significant gastric antisecretory and gastroprotective activity against experimentally induced gastric lesion. The gastroprotective effects of B-Hb are accompanied by inhibition of neutrophils activity, reduction of oxidative stress and maintenance of mucosal integrity.

**Key words:** Bovine hemoglobin; Gastric ulcers; Indomethacin; Ethanol; Ischemic injury; Rats

**Core tip:** In the recent years the treatment strategies for gastric ulcer diseases have significantly changed, mirroring the revolution in the understanding of its pathogenesis. Improved oxygenation in critically ischemic gastric mucosa has emerged as a method of choice to accelerate epithelization of erosive and ulcerative defects. Bovine hemoglobin (B-Hb) has been used in a wide range of applications including restoration of tissue oxygenation in ischemic condition. Our data show that B-Hb has significant anti-gastric acid secretory and gastroprotective activity. Further studies are warranted to determine the role of B-Hb in prophylaxis/treatment of gastric ulcer disease.

Al Asmari AK, Al Omani S, Elfaki I, Tariq M, Al Malki A, Al Asmary S. Gastric antisecretory and antiulcer activity of bovine hemoglobin. *World J Gastroenterol* 2013; 19(21): 3291-3299 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i21/3291.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i21.3291>

## INTRODUCTION

A variety of noxious factors and substances like alcohol, drugs, psychological stress, smoking and bacterial infection by *Helicobacter pylori*, to which the man is exposed in the present day life are known to have deleterious effect on gastric mucosa<sup>[1]</sup>. Organized at several levels the mucosal defense system comprise the pre-epithelial mucosal layer, the epithelial cell barrier, the mucosal microvasculature, the supply of the mucosa by enteric, extrinsic sensory and extrinsic autonomic neurons and mucosal immune system<sup>[2]</sup>. Maintenance and repair of gastric mucosa is a dynamic process associated with proliferation and migration of epithelial cells and connective tissue to maintain/regain mucosal architecture<sup>[3]</sup>. It involves complex host of mechanisms which work in tandem to protect gastric mucosa from damage as well as trigger the mechanism to repair mucosal defects by proliferating and migrating epithelial cells and connective tissue resulting in reconstruction of mucosal architecture<sup>[4]</sup>. Numerous studies have demonstrated the importance of gastric mucosal haemo-dynamics as a defensive factor of the gastric mucosa against injury<sup>[5-7]</sup>. Treatment with some prostaglandin

derivatives such as prostaglandin E<sub>2</sub> have been shown to increase mucosal blood flow and protect gastric mucosa against indomethacin and ethanol induced gastropathy by improving mucosal haemodynamics<sup>[8,9]</sup>. Oxygen delivery to the gastric mucosa is not only a function of blood flow but also depends on oxygen content in the arterial inflow. A possible strategy would be to supplement oxygen using hyperbaric oxygen (HBO) to overcome ischemic injury<sup>[10]</sup>. The use of HBO in the treatment of peptic ulcer raised the efficacy of the multimodality therapy and accelerated the epithelization of erosive and ulcerative defects<sup>[11,12]</sup>. An alternative method to improve oxygenation in critically ischemic tissue has emerged, which consists of using oxygen carriers, such as hemoglobin (Hb) or Hb based products<sup>[13]</sup>. These biomaterials have been initially developed to avoid the drawbacks of blood transfusions including immunologic reactions, blood-borne transmitted infections, limited availability and restricted storage time<sup>[14]</sup>.

Hb is the iron-containing oxygen-transport metalloprotein in the red blood cells of all vertebrates. In blood Hb carries oxygen from the respiratory organs to the rest of the body where it releases the oxygen to burn nutrients to provide energy to power the functions of the organism, and collects the resultant carbon dioxide to bring it back to the respiratory organs to be dispensed from the organism. In mammals, Hb makes up about 97% of the red blood cells dry content, and around 35% of the total content including water<sup>[15]</sup>. Hemoglobin has an oxygen binding capacity of 1.34 mL per gram of hemoglobin<sup>[16]</sup>, which increases the total blood oxygen capacity seventy-fold compared to dissolved oxygen in blood. A single mammalian hemoglobin molecule can bind (carry) up to four oxygen molecules<sup>[17]</sup>. Based on these properties cell free hemoglobin (CF-Hb) products have been successfully used in a variety of ischemic/hypoxic conditions<sup>[18,19]</sup>.

Bovine hemoglobin (B-Hb) has been used for a wide range of applications, including their use to enhance oxygen delivery to tissues during conditions of ischemia or hypoxia<sup>[20,21]</sup>. Strate *et al*<sup>[13]</sup> reported that B-Hb is much more potent than autologous red blood cells in restoring tissue oxygenation in ischemic conditions. In view of the superiority of CF-Hb compared to erythrocyte and whole blood we studied the efficiency of B-Hb against experimentally induced gastric mucosal injury.

## MATERIALS AND METHODS

Adult Albino Wistar rats of either sex, weighing 150-200 g and fed on standard chow diet were used. They were divided into groups of 6 animals each. The distribution of animals into groups and the treatment allotted to each group were randomized. All the experiments were started between 8:00 and 10:00 in the morning. The protocol of the study was approved by the Institutional Research and Ethical Committee.

The aqueous solution of ulcerogens and B-Hb were freshly prepared before administration. The concentra-

tions of drug were prepared in such a way that each rat received 0.5 mL of drug solution/100 g body weight.

### Gastric secretions

**Pylorus ligated (Shay) rats:** The animals were fasted for 36 h with access to water *ad libitum* before the pylorus was ligated under ether anesthesia, care being taken not to cause bleeding or to occlude blood vessels<sup>[22]</sup>. B-Hb in doses of 100, 300 and 900 mg/kg body weight was given by gavage (*ig*) half an hour before pylorus ligation by oral route. The animals were sacrificed at 6 h after the pylorus ligation. The stomachs were removed, contents collected, volume measured, centrifuged and subjected to analysis for titratable acidity against 0.01 mol/L NaOH to pH 7 using a pH meter and total acid output was calculated.

**Indomethacin-induced gastric lesion:** Indomethacin was suspended in 1% carboxymethylcellulose in water and administered by gavage at the dose of 30 mg/kg body weight<sup>[23]</sup>. B-Hb in the doses of 100, 300 and 900 mg/kg body weight was administered by gavage 1 h before indomethacin. The animals were sacrificed 6 h using ether after indomethacin administration. The stomach were removed and opened along the greater curvature. After washing with saline the gastric lesions were quantified by a person unaware of the treatment protocol. The ulcer were scored according to the method of Valcavi *et al.*<sup>[24]</sup>. The circular ulcer induced by indomethacin were assessed on the basis of their diameter: deep circular ulcers more than 8 mm diameter = 10; 7-8 mm = 8; 6-7 mm = 7; 5-6 mm = 6; 4-5 mm = 5; 3-4 mm = 4; 2-3 mm = 3; 1-2 mm = 2; and < 1 mm = 1. Deep linear ulcers 10 mm or more in length were scored 6, and linear ulcers less than 10 mm in length were scored 3. The scores of each single lesion were then summed up for determination of the ulcer index.

**Gastric lesions induced by ethanol (cytoprotection studies):** The animals were administered (*ig*) with 1 mL of absolute ethanol<sup>[25]</sup>. B-Hb in the doses of 100, 300 and 900 mg/kg body weight was given (*ig*) 30 min before the administration of ethanol. One hour after the administration of ethanol the animals were sacrificed and examined for the lesions in stomachs. The patchal lesions of stomach induced by ethanol were scored according to the method described by Schiantarelli *et al.*<sup>[26]</sup> using the following scale: 0 = normal mucosa; 1 = hyperemic mucosa or up to 3 small patches; 2 = from 4 to 10 small patches; 3 = more than 10 small or up to 3 medium-sized patches; 4 = from 4 to 6 medium-sized patches; 5 = more than 6 medium-sized or up to 3 large patches; 6 = from 4 to 6 large patches; 7 = from 7 to 10 large patches; 8 = more than 10 large patches or extensive necrotic zones. "small" was defined as up to 2 mm across (max diameter), "medium-sized" as between 2 and 4 mm across and "large" as more than 4 mm across.

Two separate batches of ethanol treated rats were used for biochemical and histological studies. The assay of gastric wall mucus, non-protein sulfhydryl group (NP-

SH), and myeloperoxidase (MPO) in the rats 1 h after ethanol exposure has been described below:

**Determination of gastric wall mucus:** Gastric wall mucus was determined according to the modified procedure of Corne *et al.*<sup>[27]</sup>. The glandular segment of the stomach was separated from the lumen of the stomach, weighed, and transferred immediately to 10 mL of 0.1% w/v Alcian blue solution (in 0.16 mol/L sucrose solution buffered with 0.05 mL sodium acetate at pH 5). Tissue was stained for two hours in Alcian blue, excess dye was removed by two successive rinses with 10 mL of 0.25 mol/L sucrose, first for 15 min and then for 45 min. Dye complexed with the gastric wall mucus was extracted with 10 mL of 0.5 mol/L magnesium chloride which was intermittently shaken for 1 min at 30 min intervals for 2 h. Four milliliters of blue extract was then vigorously shaken with an equal volume of diethyl ether. The resulting emulsion was centrifuged at 3600 *g* for 10 min and the absorbance of aqueous layer was recorded at 580 nm. The quantity of Alcian blue extracted per gram of wet glandular tissue was then calculated.

**Estimation of NP-SH:** Gastric mucosal NP-SH was measured according to the method of Sedlak and Lindsay<sup>[28]</sup>. The glandular part of stomach was homogenized in ice-cold 0.02 mmol/L ethylenediaminetetraacetic acid. Aliquots of 5 mL of the homogenates were mixed in 15 mL test tubes with 4 mL of distilled water and 1 mL of 50% trichloroacetic acid. The tubes were shaken intermittently for 10-15 min and centrifuged at 3000 *g*. Two milliliters of supernatant were mixed with 4 mL of 0.4 mol/L Tris buffer at pH 8.9; 0.1 mL of 5,5'-dithio-bis-(2-nitrobenzoic acid) (DTNB) was added and the sample was shaken. The absorbance was read within 5 min of addition of DTNB at 412 nm against a reagent blank with no homogenates.

**Determination of MPO:** MPO activity in the gastric mucosa was measured according to the methods described earlier<sup>[29]</sup>. Preweighed tissue was homogenized (1:10 wt/vol) in 0.5% hexadecyltrimethyl ammonium bromide in 50 mmol potassium phosphate buffer (pH 6.0) before sonication in an ice bath for 20 s. Three freeze/thaw cycles were performed followed by sonication (20 s in ice bath). The samples were centrifuged at 17000 *g* (5 min, 4 °C) and MPO in the supernatant was assayed by mixing of 0.1 mL of supernatant with 2.9 mL of 50 mmol/potassium phosphate buffer (pH 6.0) containing 0.167 g/L *O*-dianisidine dihydrochloride and 0.0005% hydrogen peroxide. The change in absorbance at 460 nm was measured for 4 min using ultraviolet (UV)-visible spectrophotometer (UV-160A, Shimadzu, Kyoto, Japan).

**Histology of ethanol-induced gastric lesions:** The stomach was opened along the greater curvature, washed with saline and fixed in 10% neutral buffered formalin for 24 h. The specimens were then processed overnight

**Table 1** Effect of bovine hemoglobin on the volume of gastric secretion and acidity in 6 h pylorus ligated rats

| Treatment  | Dose of B-Hb (mg/kg) | Gastric secretion (mL)  | Total acid output (mEq)   |
|------------|----------------------|-------------------------|---------------------------|
| Control    | 0                    | 8.1 ± 0.61              | 498.7 ± 31.8              |
| Hemoglobin | 100                  | 5.6 ± 0.63 <sup>a</sup> | 471.1 ± 75.0              |

for dehydration and clearing steps, using an automatic tissue processor (Shandon Processor MKII; Runcorn, Cheshire, United Kingdom). The specimens were embedded in paraffin blocks and sections of 5 µm thickness were stained with hematoxylin-eosin for light microscopy observations.

### Statistical analysis

Data were analyzed by one-way analysis of variance (ANOVA) followed by Dunnett's multiple comparison test. Differences with *P* < 0.05 were considered as statistically significant.

## RESULTS

### Effect of B-Hb on gastric secretion in 6 h pylorus-ligated rats

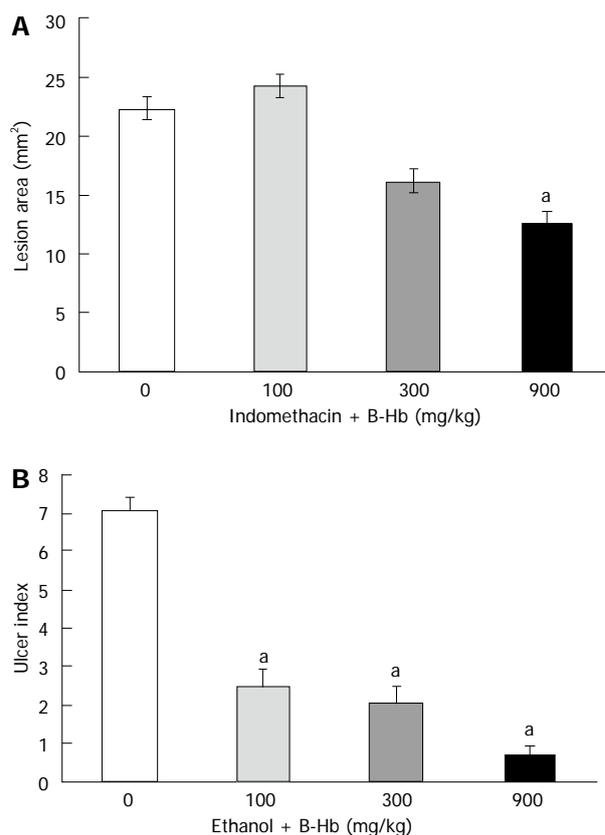

In control rats pylorus ligation for 6 h resulted in the accumulation of 8.1 ± 0.61 mL of gastric secretion and total acid output of 498.7 ± 31.8 mEq (Table 1). The treatment of the rats with 100, 300 and 900 mg/kg of B-Hb produced a significant decrease in the volume of gastric secretion 5.6 ± 0.63, 5.5 ± 0.75 and 4.7 ± 0.58 mL respectively as compared to the control group. Treatment with B-Hb also dose dependently reduced total acid output in the rats treated with 100 mg/kg (471.1 ± 75 mEq) and 300 mg/kg (438.4 ± 65.6 mEq). However a significant reduction in total acid output was observed in a dose of 900 mg/kg (287.6 ± 24.6 mEq) of B-Hb.

### Effect of B-Hb on indomethacin-induced gastric mucosal damage

The administration of indomethacin resulted in production of gastric lesions mainly in the glandular stomach of all the animals. The lesion area in the control group was found to be 22.4 ± 3.2 mm<sup>2</sup>. Pretreatment of rats with B-Hb at doses of 100 mg/kg (24.3 ± 3.29 mm<sup>2</sup>), 300 mg/kg (16.2 ± 1.45 mm<sup>2</sup>) and 900 mg/kg (12.6 ± 1.85 mm<sup>2</sup>) produced a dose dependent decrease of the lesion area (ANOVA *F* = 4.50, *P* < 0.05, Figure 1A).

### Effect of B-Hb on ethanol-induced gastric lesions

The treatment of rats with absolute ethanol produced extensive gastric lesion in the glandular mucosa of the stomach. These lesions were characterized by multiple hemorrhagic red bands (patches) of different sizes along

**Figure 1** Effect of bovine hemoglobin. A: On indomethacin-induced gastric mucosal damage; B: On ethanol-induced gastric mucosal damage. B-Hb: Bovine hemoglobin. <sup>a</sup>*P* < 0.05 vs B-Hb 0 mg/kg.

the axis of the glandular stomach. The ulcer index in the control group 1 h after ethanol administration was 7.1 ± 0.31. Pretreatment of rats with B-Hb at the doses of 100 mg/kg (ulcer index = 2.5 ± 0.42), 300 mg/kg (2.1 ± 0.4) and 900 mg/kg (0.7 ± 0.21) significantly inhibited the formation of gastric lesions (ANOVA *F* = 63.26, *P* < 0.0001, Figure 1B). Histological examination of gastric mucosa showed the appearance of these lesions in the form of gastric pits with detachment of the surface epithelium; vacuolation of epithelial cells and elongation of microvessels. Pretreatment with B-Hb dose-dependently prevented ethanol-induced mucosal damage (Figure 1).

### Effect B-Hb on ethanol-induced changes in gastric wall mucus

The treatment of rats with ethanol significantly decreased the Alcian blue binding capacity of gastric wall mucus (480 ± 25.6 µg Alcian blue/g of tissue) as compared to control rats (667 ± 25.8 µg). Pretreatment of rats with B-Hb at the doses of 100 mg/kg (516 ± 31.6 µg/g), 300 mg/kg (558 ± 28.8 µg/g) and 900 mg/kg (654 ± 33.8 µg/g) significantly enhanced the binding capacity of Alcian blue to gastric mucosa (ANOVA *F* = 8.05, *P* < 0.005, Table 2).

### Effect of B-Hb on ethanol-induced depletion of gastric mucosal NP-SH

The level of NP-SH in the gastric mucosa of control rats

**Table 2** Effect of bovine hemoglobin on ethanol induced changes in Alcian blue binding capacity, non-protein sulfhydryl groups levels and myeloperoxidase in gastric mucosa of rats

| Treatment   | Dose of B-Hb (mg/kg) | Alcian blue binding (mg/g tissue) | Non-protein sulfhydryl (mmol/g tissue) | Myeloperoxidase activity (DA/g tissue) |
|-------------|----------------------|-----------------------------------|--|--|
| Control     | 0                    | 667 ± 25.8                        | 4.59 ± 0.29                            | 15.94 ± 1.6                            |

| EtOH ± B-Hb | 100                  | 516 ± 31.6                        | 3.11 ± 0.35 <sup>d</sup>               | 24.30 ± 4.2                            |
| EtOH ± B-Hb | 300                  | 558 ± 28.8 <sup>d</sup>           | 3.73 ± 0.42 <sup>d</sup>               | 14.25 ± 2.6 <sup>c</sup>               |
| EtOH ± B-Hb | 900                  | 654 ± 33.8 <sup>d</sup>           | 5.36 ± 0.34 <sup>d</sup>               | 17.21 ± 0.98 <sup>c</sup>              |

Values are mean ± SE. <sup>b</sup>*P* < 0.01 *vs* control; <sup>c</sup>*P* < 0.05, <sup>d</sup>*P* < 0.01 *vs* EtOH group using Dunnett's multiple comparison test. B-Hb: Bovine hemoglobin.

was  $4.59 \pm 0.29$   $\mu\text{mol/g}$  of tissue, which was significantly decreased to  $1.60 \pm 0.12$   $\mu\text{mol/g}$  of tissue following the administration of ethanol. A significant and dose dependent reversal of NP-SH was observed following administration of B-Hb in low ( $3.11 \pm 0.35$  mmol/g of tissue), medium ( $3.73 \pm 0.42$  mmol/g of tissue) and high dose ( $5.36 \pm 0.34$  mmol/g of tissue) (ANOVA *F* = 19.62, *P* < 0.001, Table 2).

#### Effect of B-Hb on ethanol-induced changes in gastric MPO activity

The MPO activity in the normal gastric mucosa was  $15.96 \pm 1.9$  mmol/g of wet tissue which increased significantly to  $24.54 \pm 1.9$  mmol/g following ethanol administration. The MPO activity was slightly reduced to  $24.30 \pm 4.2$  mmol/g in the rats treated with low dose of B-Hb prior to ethanol administration. However medium and high dose of B-Hb significantly reversed ethanol induced increase in MPO the value of MPO in these two groups being  $14.25 \pm 2.6$  mmol/g and  $17.21 \pm 0.98$  mmol/g respectively (ANOVA *F* = 3.21, *P* < 0.05, Table 2).

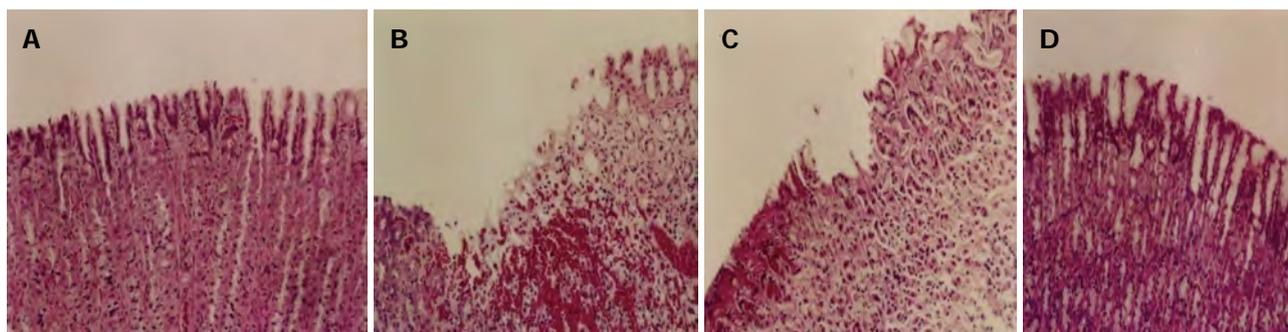

## DISCUSSION

The result of this study showed a dose dependent reduction in the volume and acidity of gastric secretions following intra-gastric administration of B-Hb (Table 1). Our findings are supported by several earlier investigators who showed that gastric hemorrhage or intra-gastric administration of blood or blood products exerts inhibitory effect on gastric acid secretions<sup>[30-32]</sup>. As early as 1953, Chandler *et al.*<sup>[33]</sup> reported that gastro-duodenal hemorrhage leads to a temporary absence of hydrochloric acid (achlorhydria) causing a significant decrease in gastric acid secretions. Fullarton *et al.*<sup>[34]</sup> also showed that gastro-duodenal blood infusion significantly inhibits pentagastrin stimulated gastric acid and pepsin secretion. Paradoxically, intra-gastric blood/blood products including hemoglobin which constitute a protein meal instead of stimulating gastric secretions result in gastric antisecretory activity<sup>[35,36]</sup>. Gastric acid secretion is an elaborate and dynamic process that is regulated by neural (efferent and afferent), hormonal (*e.g.*, gastrin), and paracrine (*e.g.*, histamine, ghrelin, somatostatin) pathways as well as mechanical (*e.g.*, distention) and chemical (*e.g.*, amino acids) stimuli<sup>[31]</sup>. It has been suggested that intra-gastric blood induced increase in plasma gastric inhibitory polypeptide, secretin or glucagon may

modulate gastric acid secretion in animals<sup>[32,34,37,38]</sup>. These mediators inhibit gastric acid secretions through somatostatin release<sup>[39-41]</sup>. However this hypothesis has been challenged by some other investigators<sup>[42]</sup>.

Pretreatment of rats with B-Hb dose dependently ameliorated indomethacin-induced gastric mucosal damage (Figure 1). Protective effect of cell free hemoglobin has been reported against a variety of experimentally induced disease models including cardiac ischemic reperfusion injury<sup>[18,43,44]</sup>, pancreatitis<sup>[45]</sup>, renal injury<sup>[46]</sup> and neuronal injury<sup>[18,19,47-49]</sup>. The mechanism by which B-Hb exerts its protective effect against indomethacin induced gastropathy is far from clear. Indomethacin causes gastric mucosal damage via several mechanisms, including the impairment of the barrier properties of the mucosa, suppression of gastric prostaglandin synthesis, reduction of gastric mucosal blood flow and interference with the tissue repair mechanism<sup>[50]</sup>. The ability of non-steroidal anti-inflammatory drugs (NSAIDs) to reduce gastric mucosal blood flow has been recognized for several decades<sup>[9]</sup>. Prostaglandins (PGs) of the E and I series are potent vasodilators that are continuously produced by the vascular endothelium, inhibition of PG synthesis by NSAIDs lead to a reduced vascular tone and hypoxic injury<sup>[51]</sup>. Cell free hemoglobin is able to readily diffuse in the microcirculation and transport O<sub>2</sub> to hypoxic tissue because of its high O<sub>2</sub> affinity, low viscosity and small mean diameter as compared to red blood cells<sup>[52]</sup>. Once in microcirculation Hb offloads oxygen to the ischemic tissue, which is unlike the vasoconstrictive effect of Hb on large vessels<sup>[53-56]</sup>. Hence the mitigation of pathogen induced ischemic injury by CF-Hb may be attributed to its ability to transient oxygen delivery<sup>[15,57]</sup> and preservation of energy metabolism<sup>[58]</sup>. Moreover, the presence of acid in the lumen of the stomach also contributes to the pathogenesis of indomethacin -induced ulcers and bleeding, by impairing the restitution process, interfering with hemostasis and inactivating several growth factors that are important in mucosal defense and repair<sup>[9]</sup>. Our experiments using Shay rats model clearly showed an inhibition of gastric acid secretion following B-Hb administration (Table 1). Thus the reduction of acid content in stomach by B-Hb may to some extent contribute to its gastroprotective effect against indomethacin induced ulcers.

The oral administration of absolute ethanol produced significant ulcers in glandular part of gastric mucosa of rats (Figure 2). Our histopathological studies of gastric

**Figure 2** Light micrographs showing the effect of bovine hemoglobin on ethanol-induced gastric lesions in rats ( $\times 200$ ). A: Normal mucosa; B: Ethanol produced lesion; C: Pretreatment of rats with bovine hemoglobin (B-Hb) 100 mg/kg; D: Pretreatment of rats with B-Hb 900 mg/kg.

mucosa showed a significant loss of glandular cells, disruption of epithelium, sub mucosal edema and infiltration of neutrophils following ethanol administration (Figure 2). A significant decrease in Alcian blue binding capacity of gastric mucosa following exposure to ethanol (Table 2) clearly suggests depletion of mucosal gel lining adhering to the gastric surface which is considered the first line of defense in stomach against endogenous and exogenous ulcerogens<sup>[59]</sup>. Numerous mechanisms have been proposed to explain necrotizing agent induced gastropathy<sup>[60]</sup>. Besides the direct deleterious effect of ethanol on gastric tissues, disruption of mucosal barrier also results from mucosal capillary necrosis, vascular congestion and thrombosis in the sub-epithelial microvasculature<sup>[61]</sup>. Oral administration of ethanol results in low or no blood flow to the stomach leading to transient hypoxic mucosal damage<sup>[62]</sup>. It is well accepted that gastric mucosal protective mechanism largely depend on appropriate microcirculation which help to orchestrate the defense mechanism at various levels of gastric mucosa<sup>[63]</sup>. Pre-treatment of animal with B-Hb dose dependently attenuated ethanol induced gastric ulcer with almost complete protection in higher dose of 900 mg/kg body weight (Figure 2). The gastroprotective effect of B-Hb against ethanol induced ulcers may to some extent be attributed to its ability to inhibit gastric acid secretions and enhanced oxygen delivery as discussed earlier. Moreover the cytoprotective effect of B-Hb was accompanied by attenuation of ethanol-induced increase in MPO (a marker of neutrophil activity) in glandular tissue of stomach (Table 2). Neutrophils are the major inflammatory cell type infiltrating the injured mucosa following exposure to ethanol<sup>[64]</sup>. Strategies to counteract the infiltration and/or activation of neutrophils have been shown to protect animals against gastric ulcers<sup>[65,66]</sup>. Activated neutrophils injure the microvasculature via the release of oxygen derived free radicals (ODFR) and proteases<sup>[67,68]</sup>. We observed a significant decrease in gastric NP-SH following ethanol administration clearly suggesting a massive generation of ODFR in stomach (Table 2). Our findings are in agreement with earlier reports showing depletion of sulfhydryls in ethanol-induced gastric lesions<sup>[69,70]</sup>. The treatment of rats with glutathione depletors has been shown to significantly potentiate ulcerogen-induced gastric mucosal injury<sup>[71]</sup>,

whereas increase in mucosal NP-SH exerts a gastroprotective effect<sup>[72,73]</sup>. These findings suggest that gastroprotective effects of B-Hb may to extent be attributed to its antioxidant activity. Dual effect of Hb as prooxidant and antioxidant has been reported earlier<sup>[74,75]</sup>. In fact, more than 100 years ago Hb was shown to readily react with  $H_2O_2$ <sup>[76]</sup> and peroxidase activity of Hb has been reported as early as by Wu<sup>[77]</sup>. Thus the active site of heme protein in Hb share peroxide cleavage properties of peroxidase to present antioxidant activity<sup>[78]</sup>. On the other hand the oxidation of Hb generates potentially cytotoxic products such as ferryl heme intermediate ( $Fe^{4+}$ ), methemoglobin ( $Fe^{3+}$ ), hemichromes and free heme or iron<sup>[79,80]</sup>. Comproportionation of cytotoxic ferryl hemoglobin with oxyhemoglobin has been shown to result in antioxidant function in which ferryl heme intermediate is quenched and resultant methemoglobin is re-reduced by methemoglobin reductase<sup>[81]</sup>. Moreover there is strong evidence to suggest that Hb exerts its cytoprotective effect through adaptive cytoprotection. The presence of Hb in the tissue has been shown to induce heme oxygenase-1 (HO-1) the enzyme responsible for heme degradation<sup>[82]</sup>. Studies with HO-1 knock out mice have demonstrated that HO-1 ameliorates NSAIDs induced gastric tissue damage<sup>[83,84]</sup>. It has been shown that HO-1 exerts its cytoprotective action against necrotizing agents by scavenging the prooxidant heme which is a major hemoglobin degradation product<sup>[84,85]</sup>. To sum up it may be suggested that cytoprotective effect of B-Hb is complex and involve multiple mechanisms.

In conclusion our data show that B-Hb has significant anti-gastric acid secretory and gastroprotective activity. Further studies are warranted to determine the role of B-Hb in prophylaxis/treatment of gastric ulcer disease.

## COMMENTS

### Background

In the recent years, the treatment strategies for gastric ulcer diseases have sig-

nificantly changed, mirroring the revolution in the understanding of its pathogenesis. Improved oxygenation in critically ischemic gastric mucosa has emerged as a method of choice to accelerate epithelization of erosive and ulcerative defects. Bovine hemoglobin (B-Hb) has been used in a wide range of applications including restoration of tissue oxygenation in ischemic condition.

### Research frontiers

Strategies to improve oxygen delivery to ischemic tissues could potentially protect gastric mucosa and other tissues from hypoxic injury. Cell free hemoglobin is able to readily diffuse in the microcirculation and transport O<sub>2</sub> to hypoxic tissue because of its high O<sub>2</sub> affinity, low viscosity and small diameter.

### Innovations and breakthroughs

Recent studies showed protective effect of cell free hemoglobin against disease models of ischemic reperfusion injury including neuronal injury, nephropathy, pancreatitis and myocardial infarction. This study first time demonstrated anti-secretory and gastric antiulcer activity of B-Hb. The gastroprotective effect could be attributed to the ability of B-Hb to improve oxygenation, reduction of oxidative stress and lowering of neutrophil activity.

### Applications

The result of this study suggests that bovine hemoglobin besides having significant anti-gastric acid secretory activity protects rats against ethanol and indomethamine induced gastric ulcers. B-Hb being animal protein can be safely explored clinically for the oral treatment of hyperacidity and gastric ulcer diseases.

### Terminology

Hb is the iron-containing oxygen-transport metalloprotein in red blood cells of all vertebrates. Hemoglobin is autonomous: it binds oxygen and release it without the need for any cofactor. Cell free Hb has been used for wide range of applications including enhanced oxygen delivery to ischemic tissue. Bovine hemoglobin is superior to autologous red blood cells in restoring tissue oxygen in ischemic conditions.

### Peer review

This is the first study showing antisecretory and gastric anti-ulcer activity of bovine hemoglobin. Reduction of oxidative stress and lowering of neutrophil activity might contribute to B-Hb induced gastroprotective effects. The results are valuable to explore pharmacological potential of B-Hb in a variety of ischemichypoxic conditions.

### Abstract

**AIM:** To investigate the effects of proteins purified from sweet potato storage roots on human colorectal cancer cell lines.

**METHODS:** 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl-tetrazolium bromide (MTT) assay, Hoechst 33258 nuclear staining and Boyden transwell chamber methods were used to determine whether purified sweet potato protein (SPP) from fresh sweet potato roots affected proliferation, migration and invasion, respectively, of human colorectal cancer SW480 cells *in vitro*. The inhibitory effects of SPP on growth of human colorectal

cancer HCT-8 cells intraperitoneally xenografted in nude mice and spontaneous lung metastasis of murine Lewis lung carcinoma 3LL cells subcutaneously transplanted in C57 BL/6 mice were also investigated *in vivo*.

**RESULTS:** SPP inhibited the proliferation of SW480 cells in a dose-dependent manner, with an IC<sub>50</sub> value of 38.732 μmol/L ( $r^2 = 0.980$ ,  $P = 0.003$ ) in the MTT assay. Hoechst 33258 nuclear staining further revealed inhibition of cell viability and induction of apoptosis by SPP. The transwell assay disclosed significant reduction in migrated cells/field by 8 μmol/L SPP ( $8.4 \pm 2.6$  vs  $23.3 \pm 5.4$ ,  $P = 0.031$ ) and invaded cells/field through the ECMatrix by 0.8 μmol/L SPP, compared with the control ( $25.2 \pm 5.2$  vs  $34.8 \pm 6.1$ ,  $P = 0.038$ ). Both intraperitoneal (*ip*) and intragastric (*ig*) administration of SPP led to significant suppression of growth of intraperitoneally inoculated HCT-8 cells in nude mice to  $58.0\% \pm 5.9\%$  ( $P = 0.037$ ) and  $43.5\% \pm 7.1\%$  ( $P = 0.004$ ) of the controls, respectively, after 9 d treatment. Bloody ascites additionally disappeared after *ip* injection of trypsin inhibitor. Notably, *ig* and *ip* administration of SPP induced a significant decrease in spontaneous pulmonary metastatic nodule formation in C57 BL/6 mice ( $21.0 \pm 12.3$  and  $27.3 \pm 12.7$  nodules/lung vs  $42.5 \pm 4.5$  nodules/lung in controls, respectively,  $P < 0.05$ ) after 25 d treatment. Moreover, the average weight of primary tumor nodules in the hind leg of mice decreased from  $8.2 \pm 1.3$  g/mice in the control to  $6.1 \pm 1.4$  g/mice in the *ip* group ( $P = 0.035$ ).

**CONCLUSION:** SPP exerts significant antiproliferative and antimetastatic effects on human colorectal cancer cell lines, both *in vitro* and *in vivo*.

**Key words:** Sweet potato protein; Colorectal cancer; Cell proliferation; Cell invasion; Metastasis

**Core tip:** Sweet potato protein (SPP) is a type of serine protease inhibitor that suppresses the activity of trypsin. The current study showed that SPP significantly inhibited proliferation, migration and invasion of human colorectal cancer SW480 cells *in vitro*. Moreover, the protein significantly suppressed the growth of intraperitoneally xenografted human colorectal cancer HCT-8 cells and volume of bloody ascites formed in nude mice. Spontaneous lung metastasis of a murine lung carcinoma cell line was significantly inhibited by SPP in mice. Notably, both intragastric infusion and intraperitoneal injection of SPP were effective in animal models.

## INTRODUCTION

Colorectal cancer (CRC) is one of the most commonly diagnosed cancer types in both men and women<sup>[1]</sup>. Annually, about 49380 Americans die of CRC, accounting for 9% of all cancer-related deaths<sup>[2]</sup>. Surgical resection is currently the primary curative therapy for CRC. However, surgery alone provides a high cure rate only for patients with early-stage disease. In the later stages of CRC, the presence of clinically occult micrometastases often leads to disease recurrence and death. Numerous natural or synthetic compounds have been tested for their ability to suppress degradation of the extracellular matrix (ECM) and subsequent invasion and metastasis of cancer cells, with the aim of preventing cancer metastasis<sup>[3,4]</sup>. Among these, protease inhibitors have been increasingly shown to have significant antimetastatic effects in various cancers<sup>[5-8]</sup>. The sweet potato [*Ipomoea batatas* (L.) Lam] is a dicotyledonous plant that belongs to the *Convolvulaceae* family. Its tuberous roots contain 0.49%-2.24% crude proteins on a fresh weight basis. Proteins isolated from sweet potato can be separated into sporamin A (31 kDa) and sporamin B (22 kDa) *via* non-reducing sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), which merge into a single band of about 25 kDa under reducing conditions<sup>[9,10]</sup>. Previous studies have identified the sweet potato protein (SPP) as a type of Kunitz-type trypsin inhibitor (KTI)<sup>[9]</sup> with potential therapeutic effects in a variety of cancer models. For instance, Huang *et al*<sup>[11]</sup> reported that KTI purified from sweet potato inhibited proliferation and induced apoptosis of NB4 promyelocytic leukemia cells. Additionally, Yao *et al*<sup>[12]</sup> showed that SPP inhibited proliferation and induced apoptosis of human tongue carcinoma Tca8113 cells *via* downregulation of the Akt/glycogen synthase kinase (GSK)-3 pathway. In addition, KTIs isolated from other sources, such as human urine and soybeans, have been shown to exert

antiproliferative, anti-invasion and antimetastatic activities in a variety of malignant cells, animal models and cancer patients<sup>[13-15]</sup>. The present study focused on the inhibitory effects of SPP on proliferation, migration and invasiveness of malignant cells in a number of CRC cell lines *in vitro* as well as *in vivo*.

## MATERIALS AND METHODS

### Cell culture

Human colorectal cancer SW480 cells were maintained in culture medium comprising RPMI 1640 supplemented with 10% fetal bovine serum (FBS),  $1 \times 10^5$  U/L penicillin and streptomycin. Cells were grown in T-75 culture flasks at 37 °C in a humidified atmosphere containing 5% CO<sub>2</sub> and 95% air.

### SPP preparation

SPP was purified from fresh sweet potato tuberous roots, as reported previously<sup>[16]</sup>. Purity of SPP exceeded 99% of the dry weight. A stock solution was freshly prepared before each experiment by dissolving SPP in culture medium, filtered through a sterile 0.22- $\mu$ m membrane, and further diluted with culture medium to achieve the final concentrations, as indicated.

### Protein and TI activity staining of SPP on 12% polyacrylamide gels

Purified SPP was detected using both protein and TI activity staining on 12% SDS-PAGE. For protein staining, samples were mixed with sample buffer (60 mmol/L Tris-HCl, pH 6.8, 2% SDS, 25% glycerol, and 0.1% bromophenol blue) and  $\beta$ -mercaptoethanol. Coomassie brilliant blue R-250 stain was used. For TI activity, native gels were stained according to the method of Huang *et al*<sup>[11]</sup>. Briefly, upon completion of non-denaturing PAGE, the gel was immersed and shaken twice in 25% vol/vol isopropanol in 10 mmol/L Tris buffer (pH 7.9) for 10 min each. Next, the gel was dipped into 10 mmol/L hydrogen peroxide in the same buffer for at least 30 min with gentle shaking, and washed in 10 mmol/L Tris buffer (pH 7.9) for 10 min, followed by incubation in trypsin solution (50  $\mu$ g bovine trypsin/mL, 10 mmol/L Tris buffer pH 7.9) for 20 min at 37 °C. After rinsing with the same buffer to remove excess trypsin, the gel was incubated at 37 °C for at least 30 min in the dark with 160 mL substrate dye solution prepared immediately before use. The substrate dye solution consisted of 40 mg *N*-acetyl-D,L-phenylalanine  $\beta$ -naphthyl ester in 16 mL of *N,N*-dimethylformamide made up to 160 mL with 144 mL of 10 mmol/L Tris buffer (pH 7.9) in which 80 mg tetrazotized *O*-dianisidine was dissolved. The gel was destained with 10% acetic acid for at least 30 min.

### 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide assay

SW480 cells were seeded into a 96-well plate (Corning, Cambridge, MA, United States) at a density of  $1.5 \times 10^4$

cells/well. After achieving confluence, cells were incubated in medium containing different concentrations of SPP. Following SPP treatment, 20  $\mu\text{L}$  3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (5 mg/mL) was added to each well and incubated for a further 4 h. Next, 200  $\mu\text{L}$  dimethyl sulfoxide was added to cells in each well, mixed for 10 min, and optical density measured at 492 nm.

### Hoechst 33258 staining

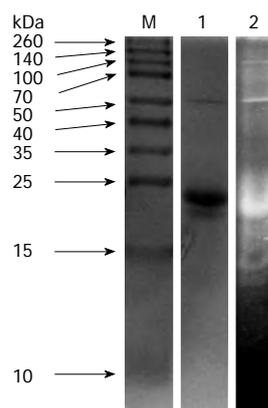

Cell viability was assayed morphologically using Hoechst 33258 (Sigma, St Louis, MO, United States) staining. SW480 cells were plated onto a 24-well plate ( $1.2 \times 10^5$  cells/well) and allowed to grow for 24 h. After confluence, cells were serum-starved for 16 h and treated with various concentrations of SPP for 48 h. Cells were fixed in 2% glutaraldehyde for 4 h and washed twice with 0.9% NaCl before staining with 1  $\mu\text{g}/\text{mL}$  Hoechst 33258 for 30 min under ice cooling in the dark. After washing twice with 0.9% NaCl, cells were observed under a fluorescence microscope (Olympus IX71) with excitation at ultraviolet (360 nm).

### Cell migration and invasion

SW480 cells were seeded into the upper chamber of a Transwell insert (Millipore, Billerica, MA, United States) in RPMI 1640 at a density of  $3 \times 10^5$  cells/well. Medium containing 10% FBS was placed in the lower chamber to act as a chemoattractant. After adherence, cells were treated with various concentrations of SPP for 10 h in serum-free medium. Cells migrating through 8.0  $\mu\text{m}$  polycarbonate membranes to the lower surface were stained with 0.1% crystal violet, whereas non-migratory cells remaining on the upper chambers were removed by scraping the upper surface of the membrane with a cotton swab. Migrating cells were quantified by counting stained cells under a microscope ( $\times 200$ ). Five random fields were selected for each well. The assay was performed in triplicate, and repeated three times. Invasion assays were performed in a similar manner to the migration assays, except that inserts were precoated with ECM substitute ECMatrix (Chemicon, Temecula, CA, United States) and cells were treated with SPP for 24 h.

### In vivo experiments

Two animal experiments were conducted. In the first experiment,  $2 \times 10^5$  human colorectal cancer HCT-8 cells were inoculated into the peritoneal cavity of 15 BALB/c nude mice (5 wk old,  $14 \pm 2$  g), which were randomly divided into three groups (5 animals per group). From the second day of inoculation, SPP was administered to two of the three groups either intraperitoneally (2  $\mu\text{mol}/\text{L}$  per kg/d) or intragastrically (80  $\mu\text{mol}/\text{L}$  per kg/d) for 9 d, while the remaining group served as a vehicle control receiving only intraperitoneally injected physiological saline during the experiment. After treatment with SPP for the indicated times, animals were sacrificed, and the number of tumor nodules in the peritoneal cavity was compared between groups. In the second animal experiment, we

**Figure 1** Protein (lane 1) and trypsin inhibitor activity (lane 2) staining of sweet potato protein on polyacrylamide gel electrophoresis gels (12%) with  $\beta$ -mercaptoethanol. A 10  $\mu\text{L}$  aliquot of staining of sweet potato was loaded in each lane. M: Molecular standards.

examined the effects of SPP on metastatic capacity of cancer cells. Lewis lung cancer cells were inoculated subcutaneously into the hind legs of 18 female C57BL/6 mice (5 wk old,  $14 \pm 2$  g) divided into three groups (6 animals per group). From the second day of inoculation, SPP was administered either intraperitoneally (2  $\mu\text{mol}/\text{L}$  per kg/d) or intragastrically (120  $\mu\text{mol}/\text{L}$  per kg/d) to animals for 25 d. After sacrifice, the number of the metastatic nodules formed in lungs of mice were counted under a stereomicroscope ( $\times 10$ ), and compared between the three treatment groups.

### Statistical analysis

Data were expressed as mean  $\pm$  SD, and analyzed using analysis of variance with DPS7.55 software (Refine Information Tech Company, Hangzhou, China). Two-tailed values of  $P < 0.05$  were considered significant.

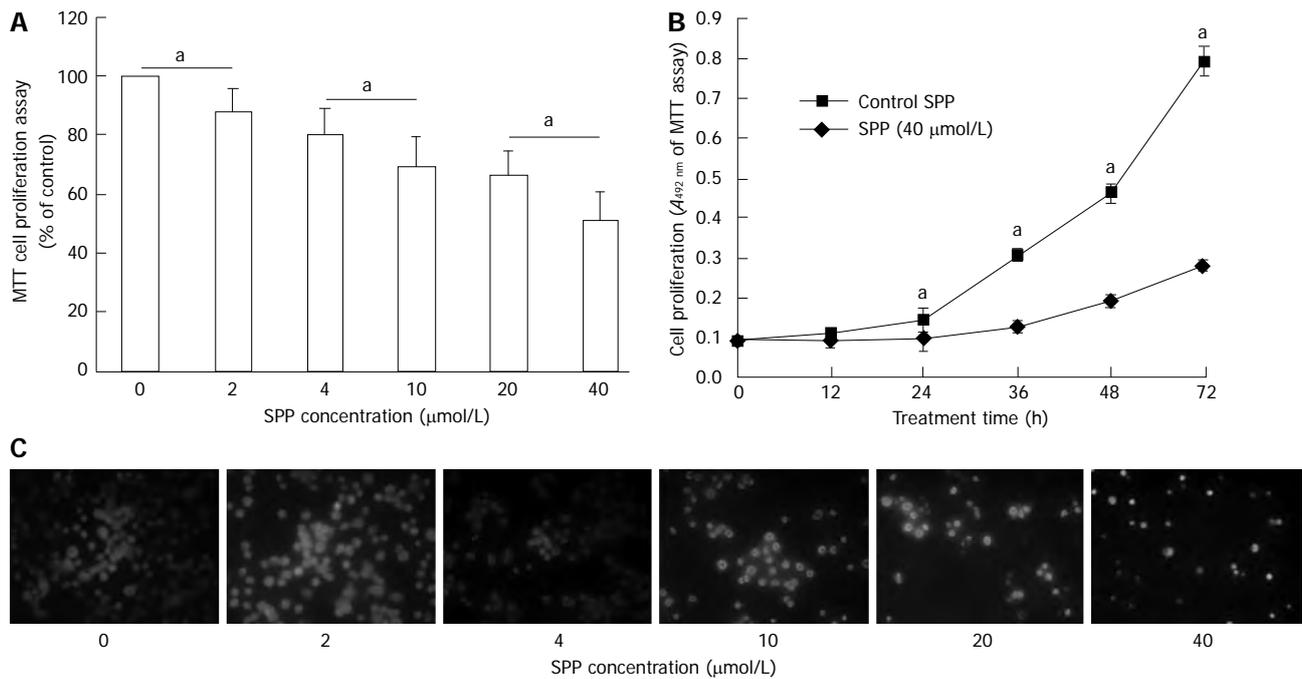

## RESULTS

### SPP purification and TI activity staining

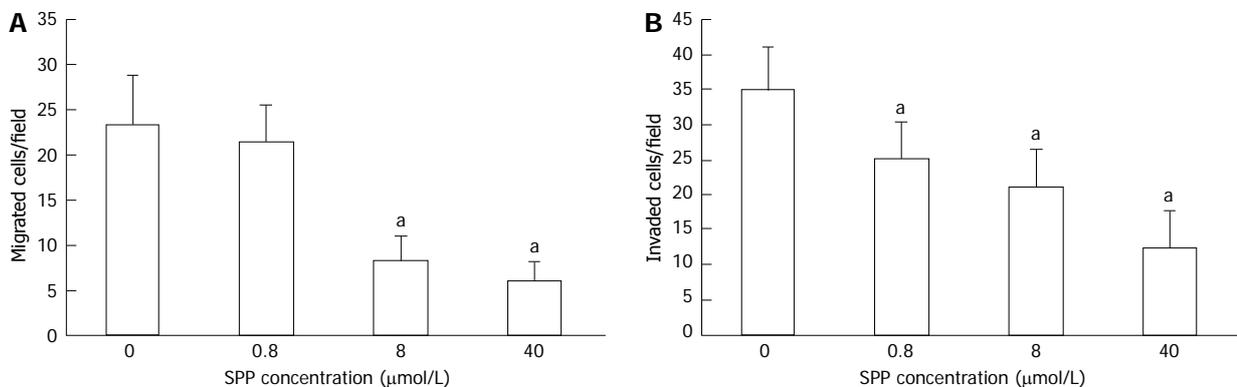

SPP was purified from fresh sweet potato tuberous roots, as reported previously<sup>[16]</sup>. Purity of SPP exceeded 99% of its dry weight. Protein (lane 1) and TI activity (lane 2) staining of purified SPP with  $\beta$ -mercaptoethanol treatment on 12% SDS-PAGE are depicted in Figure 1. Consistent with previous reports, extracted SPP had an average molecular weight of about 25 kDa. Both the monomeric protein and its 50-kDa dimer exhibited strong trypsin inhibitory activity *in vitro*.

### Effect of SPP on cell proliferation

Dose-dependent inhibition of SW480 proliferation was observed upon incubation of cells with increasing doses of SPP for 48 h. Doses of 2, 4, 10, 20 and 40  $\mu\text{mol}/\text{L}$  SPP reduced cell proliferation by 12% ( $P = 0.013$ ), 20% ( $P = 0.005$ ), 31% ( $P = 0.001$ ), 34% ( $P = 0.001$ ) and 49% ( $P = 0.001$ ), respectively (Figure 2A). Proliferation was inhibited in a time-dependent manner upon treatment of cells with 40  $\mu\text{mol}/\text{L}$  SPP (Figure 2B). After 48 h treat-

**Figure 2** Anti-proliferative effect of sweet potato protein on human colorectal cancer SW480 cells. **A:** Effects of various concentrations of sweet potato protein (SPP) on SW480 cell proliferation. We observed dose-dependent inhibition by SPP.  $^aP < 0.05$  between groups; **B:** Effect of various treatment times with 40 μmol/L SPP on SW480 cell proliferation. Time-dependent inhibition was observed.  $^aP < 0.05$  vs control; **C:** Hoechst 33258 nuclear staining. SW480 cells were incubated in the absence or presence of various concentrations of SPP for 48 h, stained with Hoechst 33258 dye, and observed under a fluorescent microscope (magnification,  $\times 400$ ). Images are representative of at least two independent experiments, with similar results.

**Figure 3** Effects of various concentrations of sweet potato protein on migration (**A**) and invasion (**B**) of SW480 cells in the Transwell assay. Inhibition of cell migration was observed with 0.8, 8 and 40 μmol/L sweet potato protein (SPP).  $^aP < 0.05$  vs control.

ment with various concentrations of SPP, fluorescent Hoechst 33258 nuclear staining indicated dose-dependent suppression of cell proliferation by SPP. Specifically, Hoechst 33258 staining revealed blue, round nuclei in viable cells and condensed or fragmented nuclei in apoptotic, compared to non-apoptotic cells. Apoptotic cells were detected when the SPP concentration exceeded 10 μmol/L (Figure 2C).

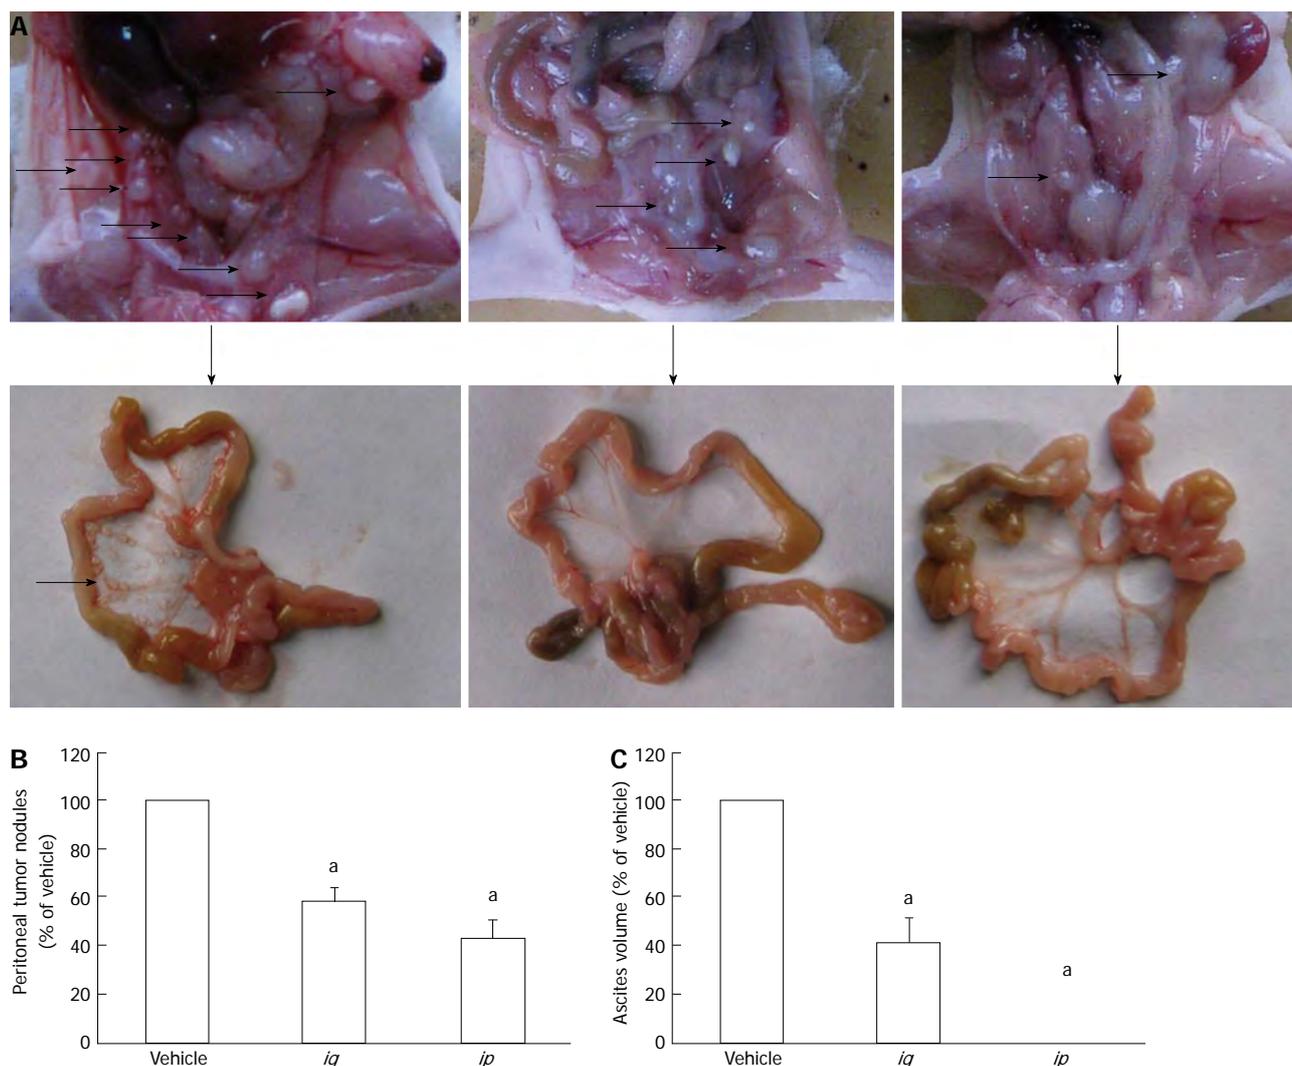

#### Effect of SPP on cell migration

Migration of SW480 cells through the 8-μm polycarbonate membrane of Transwell inserts was significantly decreased following treatment with SPP for 10 h. Doses of

0.8, 8 and 40 μmol/L SPP induced reduction of migrated cells/field from  $23.3 \pm 5.4$  in the control group to  $21.5 \pm 3.9$  ( $P = 0.068$ ),  $8.4 \pm 2.6$  ( $P = 0.031$ ) and  $6.1 \pm 2.1$  ( $P = 0.017$ ), respectively (Figure 3A).

#### Effect of SPP on cell invasion

Invasiveness of SW480 cells through the artificial basement membrane ECMatrix of Transwell inserts was significantly decreased upon incubation with SPP for 24 h. Doses of 0.8, 8 and 40 μmol/L SPP reduced the invaded cells/field from  $34.8 \pm 6.1$  in the control group to  $25.2 \pm 5.2$  ( $P = 0.038$ ),  $12.5 \pm 4.9$  ( $P = 0.024$ ) and  $6.1 \pm 2.1$  ( $P = 0.005$ ), respectively (Figure 3B).

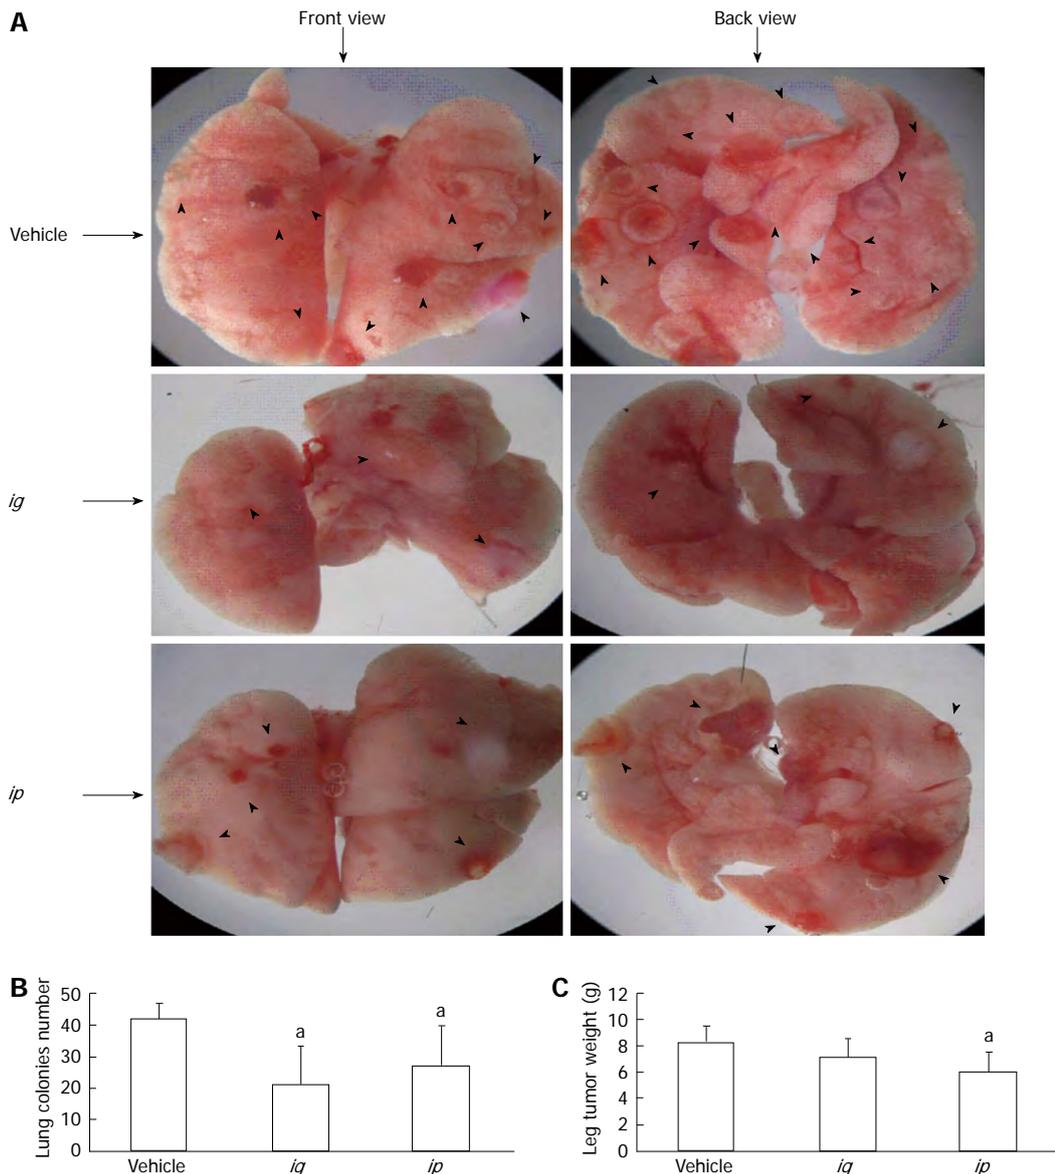

**Figure 4** Effect of sweet potato protein on growth of intraperitoneally inoculated human colorectal cancer HCT-8 cells in nude mice. A: Representative images of growth status of tumor nodules in the peritoneal cavity of nude mice after treatment with intraperitoneally injected or intragastrically infused sweet potato protein (SPP); B: Comparison of the number of tumor nodules formed in the peritoneal cavity of nude mice between different treatment groups; C: Volume of bloody ascites generated in the peritoneal cavity of nude mice. Arrows indicate the nodules formed. <sup>a</sup> $P < 0.05$  vs vehicle.

### Effects of SPP on malignant cell growth and metastasis in vivo

The growth of intraperitoneally inoculated human colorectal cancer HCT-8 cells was significantly suppressed by intraperitoneal (*ip*) or intragastric (*ig*) administration of SPP into nude mice (Figure 4). After 9 d inoculation, a significant number of tumor nodules formed in the vehicle group, which was markedly reduced to 58.0% ± 5.9% ( $P = 0.037$ ) and 43.5% ± 7.1% ( $P = 0.004$ ), respectively, compared to the vehicle, with *ig* infusion and *ip* injection of SPP (Figure 4B). Upon sacrifice, bloody ascites were found in the vehicle group, which were collected with a microsyringe, and the volumes compared between groups. The volume of ascities was significantly decreased following administration of SPP (Figure 4C). In the *ig* group, the volume decreased to 41.2 ± 10% of that of vehicle ( $P = 0.002$ ), and ascites was barely detectable in the *ip* group.

To investigate the inhibitory effect of SPP on the

metastatic capacity of malignant cells, murine Lewis lung carcinoma 3LL cells were inoculated subcutaneously into the hind legs of C57BL/6 mice, and primary tumor growth and formation of spontaneous lung metastatic colonies examined after 25 d of SPP treatment. As shown in Figure 5, after 25 d, apparent spontaneous pulmonary metastasis was evident in the vehicle-treated group (42.5 ± 4.5 nodules/lung), which was significantly inhibited following *ig* and *ip* administration of SPP into mice (21.0 ± 12.3 nodules/lung and 27.3 ± 12.7 nodules/lung, respectively,  $P < 0.05$ ). The antimetastatic effect was more significant in the *ig* than *ip* group (Figure 5B). A possible explanation for this phenomenon is that orally administered SPP is absorbed into the blood circulation and functions in the lung. However, this hypothesis requires further validation. The weights of primary tumor nodules in the hind leg of mice were additionally examined. The weight was 8.2 ± 1.3 g/mouse in the control group, which decreased to 6.1 ± 1.4 g in the *ip* group

**Figure 5** Effect of sweet potato protein on spontaneous metastasis of murine Lewis lung cancer 3LL cells in C57BL/6 mice. A: Representative images of lungs of mice after inoculation of cancer cells for 25 d; B: Number of spontaneous lung metastatic colonies formed after 25 d of inoculation; C: Weight of subcutaneously inoculated tumor nodules after 25 d. Arrowheads indicate the nodules formed. <sup>a</sup> $P < 0.05$  vs vehicle.

( $P = 0.035$ ; Figure 5C). The observed reduction in the *ig* group ( $7.1 \pm 1.5$  g/mouse,  $P > 0.05$ ) was not statistically significant, suggesting that *ip* administration had a more significant effect than *ig* administration.

In both animal experiments, changes in the body weight of mice were monitored. After tumor cell transplantation, body weight stopped increasing. However, SPP treatment did not significantly affect the growth of mice during the experimental period, compared with the vehicle group (Table 1). Moreover, no apparent adverse effects of SPP were observed.

## DISCUSSION

The present study showed that SPP promotes dose- and time-dependent inhibition of human colorectal cancer SW480 cell proliferation, migration and invasion. The an-

tiproliferative and antimetastatic effects of SPP were subsequently confirmed in nude and C57BL/6 mice *in vivo*.

SPP isolated from sweet potato had a strong trypsin inhibitory effect, as shown in Figure 1, consistent with previous findings<sup>[9]</sup>. In recent years, several families of proteases, including matrix metalloproteinases and serine and cysteine proteases, have been shown to play important roles in tumor invasion and metastasis, because formation of metastasis requires degradation of ECM<sup>[17]</sup>. The initial hypothesis that the inhibitors function in suppressing cancer invasion and metastasis was confirmed in subsequent studies. For instance, urokinase-type plasminogen activator (uPA), a serine protease, plays a critical role in cancer cell migration, ECM invasion, and metastasis in a variety of tumors<sup>[18-21]</sup>. In contrast, several serine protease inhibitors, including urinary KTI bikunin and soybean KTI, have been shown to suppress the expres-

**Table 1** Body weights of mice before and after sweet potato protein treatment

|-----------|-----------------|------------|-------------|------------|
|           | Before          | After      | Before      | After      |
| Vehicle   | 14.3 ± 0.9      | 14.6 ± 1.0 | 13.9 ± 0.6  | 14.1 ± 0.7 |
| <i>ig</i> | 14.6 ± 0.6      | 14.8 ± 0.6 | 13.4 ± 0.5  | 13.9 ± 0.7 |
| <i>ip</i> | 14.5 ± 0.5      | 14.7 ± 0.6 | 13.8 ± 0.5  | 13.9 ± 0.6 |

sion of uPA and its receptor, uPAR, at both the gene and protein levels<sup>[22,23]</sup>. Bikunin is reported to suppress invasiveness in a number of malignant cell lines by directly inhibiting tumor-cell-associated serine protease plasmin activity, as well as uPA and uPAR expression<sup>[24,25]</sup>. Notably, the therapeutic efficacy of orally administered bikunin against human ovarian cancer HRA cells growing in the peritoneum of nude mice and human cancer has been demonstrated<sup>[26]</sup>. Specifically, bikunin (30 mg/kg per day) induced a 40% decrease in tumor load in mice. In cancer patients, bikunin exhibited biological activity, as the post-treatment uPA levels in uterine cervical carcinoma tissue specimens were significantly decreased<sup>[26]</sup>. Analogous to SPP in the present study, soybean KTI is a natural trypsin inhibitor that has a similar effect as bikunin on the uPA signaling cascade and cancer cell invasion<sup>[27]</sup>. Dietary supplementation with soybean KTI (15 and 50 g/kg) also significantly reduced the tumor burden in an *in vivo* spontaneous metastasis assay in C57BL/6 mice<sup>[28]</sup>. KTIs isolated from sweet potato clearly have an anticancer effect. For example, Huang *et al.*<sup>[11]</sup> observed growth inhibition and apoptotic effects of TI from sweet potato in NB4 promyelocytic leukemia cells. More recently, Yao *et al.*<sup>[12]</sup> reported a significant antiproliferative effect of SPP in human tongue carcinoma Tca8113 cells. The group used the same method to isolate SPP from sweet potato roots as that used in the present study. The anticancer effects of SPP reported by our group are therefore consistent with earlier findings.

Several mechanisms have been proposed to explain the mechanism of action of SPP. First, as a serine protease inhibitor, SPP may directly suppress degradation of the ECM by tumor cells, similar to bikunin and soybean KTI. Second, it may exert its role indirectly by suppressing signaling pathways involved in the proliferation and invasion of cancer cells<sup>[12,15,23]</sup>. Yao *et al.*<sup>[12]</sup> have suggested that the effect of SPP results partly from induction of apoptosis of tongue cancer cells *via* downregulation of the Akt/GSK-3 pathway. Huang *et al.*<sup>[11]</sup> have demonstrated that sweet potato TI induces apoptosis in NB4 cells through a mitochondria-dependent pathway, associated with activation of the caspase-3 and -8 cascades. Moreover, an anti-inflammatory effect of KTIs has been reported, including suppression of proinflammatory cytokines, such as tumor necrosis factor- $\alpha$ , interleukin (IL)-1 $\beta$  and IL-6<sup>[29]</sup>. This may additionally, in part, explain their effects on tumor development. Bikunin therapy leads to significant inhibition of angiogenesis-related molecules (vascular endothelial growth factor and fi-

broblast growth factor- $\beta$ ), and this antiangiogenic effect also partly explains the effect of KTIs in cancer cells<sup>[30]</sup>. Shakiba *et al.*<sup>[27]</sup> have reported that soybean KTI has a strong inhibitory effect on human umbilical vein endothelial cell migration and tubulogenesis in fibrin matrix. These findings collectively indicate that KTIs present multiple mechanisms of action that are cell type dependent. The results from the current study clearly show that SPP suppresses growth of cancer cells, both *in vitro* and *in vivo*. Moreover, the invasiveness of cancer cells is inhibited by SPP. However, the specific mechanisms of action involved in the anticancer activity of SPP remain to be established.

Another particularly interesting finding of the present study was that although *ip* injection of SPP had a more significant suppressive effect on primary tumors (Figure 5C), the antimetastatic effect against spontaneous lung metastasis of cancer cells was better in the *ig* than *ip* group (Figure 5B). One possible explanation for this phenomenon is that orally administered SPP is absorbed into the blood circulation and exerts its activity in the lung. This theory is supported by the finding that dietary supplementation of soybean and urinary KTIs is effective<sup>[26,28]</sup>. It is also possible that the SPP is digested in the gastrointestinal tract and its active peptides absorbed into the circulation. However, this hypothesis needs validation.

In summary, our results demonstrate that the SPP markedly inhibits proliferation, migration and invasion of human colorectal cancer SW480 cells *in vitro*. Moreover, SPP administered both orally and intraperitoneally exerts its effect on cancer cells *in vivo*. The antiproliferative activity of SPP may be triggered through induction of apoptosis of malignant cells, and anti-invasive activity through inhibition of the uPA signaling pathways. Antiangiogenic and anti-inflammatory activities may, at least in part, explain its effects on malignant cells in tumor-bearing animals. However, further studies are required to elucidate the mechanisms underlying the protective effects of SPP in CRC.

## COMMENTS

### Background

Colorectal cancer (CRC) is one of the major contributors to cancer-induced mortality worldwide. Sweet potato protein (SPP), a type of trypsin inhibitor (TI) that induces apoptosis and suppresses growth of various malignant cells, is a potentially effective anticancer agent for CRC.

### Research frontiers

Previous studies suggest that SPP inhibits growth and induces apoptosis in promyelocytic leukemia and human tongue carcinoma cells. A similar TI extracted from wampee (*Clausena lansium*) seeds has a growth inhibitory effect in human leukemia and hepatoma cells. However, the issue of whether SPP affects the growth and metastasis of CRC cells has remained unclear until now. In the current study, the antiproliferative and antimetastatic effects of SPP on human colorectal cancer cells were investigated *in vitro* and *in vivo*.

### Innovations and breakthroughs

Several recent studies have demonstrated that SPP affects the growth of malignant cancer cells, although the issue of whether SPP plays a role in CRC is yet to be established. The current study is believed to be the first thorough investigation focusing on the antiproliferative and antimetastatic effects of SPP on CRC cell lines, both *in vitro* and *in vivo*.

## Applications

Elucidation of the effects of SPP on CRC cell lines *in vitro* and *in vivo* may present an effective strategy for prevention or treatment of CRC in the clinic.

## Terminology

TIs are a group of peptides present in various sources, such as soybean, egg white and sweet potato, which mask or inhibit the active site of the trypsin molecule. Storage proteins are biological reserves of metal ions and amino acids used by organisms. Amino acids of storage proteins are used during the embryonic development of animals or plants.

## Peer review

This was a good experimental study in which authors investigated the effects of SPP on malignant cancer cells in different cell lines and animal models. The results are interesting, and support the utility of SPP as a potential therapeutic agent for preventing and treating CRC.

### Abstract

**AIM:** To compare the efficacy of capecitabine and oxaliplatin (XELOX) with 5-fluorouracil, folinic acid and oxaliplatin (FOLFOX6) in gastric cancer patients after D2 dissection.

**METHODS:** Between May 2004 and June 2010, patients in our gastric cancer database who underwent D2 dissection for gastric cancer at the First Affiliated Hospital of Sun Yat-Sen University were retrospectively analyzed. A total of 896 patients were enrolled into this study according to the established inclusion and exclusion criteria. Of these patients, 214 received the XELOX

regimen, 48 received FOLFOX6 therapy and 634 patients underwent surgery only without chemotherapy. Overall survival was compared among the three groups using Cox regression and propensity score matched-pair analyses.

**RESULTS:** Patients in the XELOX and FOLFOX6 groups were younger at the time of treatment (median age 55.2 years; 51.2 years *vs* 58.9 years), had more undifferentiated tumors (70.1%; 70.8% *vs* 61.4%), and more lymph node metastases (80.8%; 83.3% *vs* 57.7%), respectively. Overall 5-year survival was 57.3% in the XELOX group which was higher than that (47.5%) in the surgery only group ( $P = 0.062$ ) and that (34.5%) in the FOLFOX6 group ( $P = 0.022$ ). Multivariate analysis showed that XELOX therapy was an independent prognostic factor (hazard ratio = 0.564,  $P < 0.001$ ). After propensity score adjustment, XELOX significantly increased overall 5-year survival compared to surgery only (58.2% *vs* 44.2%,  $P = 0.025$ ) but not compared to FOLFOX6 therapy (48.5% *vs* 42.7%,  $P = 0.685$ ). The incidence of grade 3/4 adverse reactions was similar between the XELOX and FOLFOX6 groups, and more patients suffered from hand-foot syndrome in the XELOX group ( $P = 0.018$ ).

**CONCLUSION:** Adjuvant XELOX therapy is associated with better survival in patients after D2 dissection, but does not result in a greater survival benefit compared with FOLFOX6 therapy.

© 2013 Baishideng. All rights reserved.

**Key words:** Gastric cancer; D2 dissection; Adjuvant; Capecitabine and oxaliplatin; 5-fluorouracil, folinic acid and oxaliplatin

**Core tip:** This original study retrospectively analyzed the efficacy of adjuvant chemotherapy and compared the effects of adjuvant capecitabine and oxaliplatin (XELOX) therapy with 5-fluorouracil, folinic acid and oxaliplatin

(FOLFOX6) therapy in gastric cancer patients undergoing D2 dissection. Propensity score matched-pair analysis was performed to account for biases associated with retrospective data. Adjuvant XELOX was significantly associated with improved survival after D2 dissection compared to surgery alone following multivariate Cox regression and propensity score matched analyses, however, the XELOX regimen did not result in a greater survival benefit compared with the FOLFOX6 regimen. Our findings suggest that adjuvant XELOX therapy should be considered in curable gastric cancer patients.

Wu Y, Wei ZW, He YL, Schwarz RE, Smith DD, Xia GK, Zhang CH. Efficacy of adjuvant XELOX and FOLFOX6 chemotherapy after D2 dissection for gastric cancer. *World J Gastroenterol* 2013; 19(21): 3309-3315 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i21/3309.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i21.3309>

## INTRODUCTION

Gastric cancer (GC) is the fourth prevalent cancer and second most common cause of cancer-related deaths worldwide, with half of all patients in East Asia<sup>[1-4]</sup>. Radical resection remains the only curative treatment for GC<sup>[1,5,6]</sup>. Radical gastrectomy with D2 lymphadenectomy is the standard treatment for patients with resectable GC in Eastern countries<sup>[1,6,7]</sup> and is now recommended in Western countries<sup>[3,8-10]</sup>. However, even if radical resection is performed, about 50% patients have recurrence within 5 years of surgery<sup>[5,11,12]</sup> and 50%-90% of patients die due to disease relapse<sup>[13]</sup>. Therefore, novel approaches such as multimodality therapies are being explored to improve treatment outcome. Adjuvant chemotherapy has been intensively investigated for several decades, but definitive evidence is limited especially in patients after D2 dissection<sup>[14-16]</sup>.

The chemotherapeutic regimen after GC resection is heterogeneous throughout the world and the optimal regimen has not yet been determined<sup>[15,17]</sup>. S-1 plus cisplatin is considered the standard regimen for advanced GC in Japan<sup>[18,19]</sup>, while its application outside Japan remains uncertain. In the United States, the standard of care is adjuvant bolus 5-fluorouracil (5-FU)-based chemoradiotherapy for resected GC based primarily on the results of the Intergroup 116 trial<sup>[20]</sup>. In European countries, the epirubicin, cisplatin and 5-FU (ECF) regimen was associated with survival benefits in the MAGIC trial<sup>[21]</sup>, but not in the Intergroup CALGB 80101 trial<sup>[22]</sup>. Recently, the CLASSIC trial<sup>[23]</sup> carried out in 37 centers in South Korea, China and Taiwan showed that 6 mo of adjuvant capecitabine and oxaliplatin (XELOX) chemotherapy improved 3-year disease-free survival compared with surgery alone. However, this was a pre-specified interim efficacy analysis and not yet formally validated. Nevertheless, based on published data, adjuvant chemotherapy might improve survival, however, further definite evidence is needed, and a clearly superior strategy has not yet emerged. Adjuvant XELOX

and 5-FU, folinic acid and oxaliplatin (FOLFOX6) chemotherapy has been widely used in GC patients. However, few studies have directly compared their efficacy.

In the present study, we used our GC database prospectively established since 1994 and retrospectively analyzed the efficacy of adjuvant XELOX and FOLFOX6 therapy in GC patients undergoing D2 dissection. This study aimed to: (1) examine the benefit of adjuvant chemotherapy; (2) compare the prognosis of patients undergoing D2 dissection plus XELOX or FOLFOX6 with that of patients undergoing surgery only; and (3) account for biases associated with treatment selection of adjuvant chemotherapy in retrospective data through propensity score adjusted analysis.

## MATERIALS AND METHODS

### Patient population

From May 2004 to June 2010, 1083 patients in our database underwent gastrectomy with D2 nodal dissection for GC at the First Affiliated Hospital of Sun Yat-Sen University. This study was approved by the Ethical Review Committee of the First Affiliated Hospital of Sun Yat-Sen University. All patients signed an informed consent. The stage of gastric carcinoma was determined according to the TNM Classification of Malignant Tumors established by the International Union against Cancer 7<sup>th</sup> edition<sup>[24]</sup>.

### Inclusion and exclusion criteria

The inclusion criteria for this study were as follows: (1) histologically proven advanced GC, radical gastrectomy with D2 lymph-node dissection and R0 surgery; (2) patients aged between 20 and 75 years; (3) no preoperative chemotherapy, immunotherapy or radiotherapy; (4) patients receiving chemotherapy 4 wk after surgery; and (5) no synchronous or metachronous cancers.

Five exclusion criteria were employed: (1) age > 75 or < 20 years; (2) hepatic, renal, pulmonary or cardiac dysfunction; (3) severe postoperative complications, such as anastomotic fistula and pancreatic fistula; (4) less than 15 lymph nodes retrieved; and (5) loss to follow-up.

According to the inclusion and exclusion criteria, a total of 896 patients were included in the final analysis. Of these patients, 214 (23.9%) received XELOX chemotherapy (the XELOX group), 48 (5.4%) received FOLFOX6 chemotherapy (the FOLFOX6 group), and 634 (70.7%) underwent surgery only without chemotherapy (the surgery only group).

### Chemotherapy regimen

The XELOX regimen consisted of 3-wk cycles of oral capecitabine (1000 mg/m<sup>2</sup> twice daily on days 1-14 of each cycle plus intravenous oxaliplatin (130 mg/m<sup>2</sup> on day 1 of each cycle). The FOLFOX6 regimen consisted of 2-wk cycles of intravenous oxaliplatin 85-100 mg/m<sup>2</sup> and leucovorin 200 mg/m<sup>2</sup> over 2 h on day 1 of each cycle plus 5-FU 400 mg/m<sup>2</sup> bolus with infusional 5-FU 2400 mg/m<sup>2</sup> in 48 h of each cycle. The median chemo-

therapy duration was 8 cycles in the XELOX group and 7 in the FOLFOX6 group. All patients underwent weekly clinical evaluation and routine blood examinations during chemotherapeutic treatment. Chemotherapeutic adverse reactions were graded on a 0-4 scale for acute and sub-acute toxicity in accordance with the WHO guidelines for anti-cancer drugs.

### Follow-up

Follow-up assessments were performed every 3 mo for the first 2 years after surgery and then every 6 mo until the patient's death. The survival status of patients was ascertained in December 2011. Median follow-up was 39.7 mo (range 6-87.6 mo).

### Statistical analysis

Analyses were performed using the SPSS 18.0 software (SPSS, Inc., Chicago, IL, United States). The overall survival was recorded from the date of surgery to the date of death from any cause or last follow-up. Survival curves and overall 5-year survival rates were established according to the Kaplan-Meier and Log-Rank methods. Hazard ratios for death were calculated by Cox regression analysis with backward model selection. The potential prognostic factors entered into the Cox regression model were as follows: chemotherapy (surgery only *vs* XELOX *vs* FOLFOX6); age (continuous variable); gender; tumor location (whole stomach *vs* upper *vs* middle *vs* lower *vs* remnant stomach); pathological T category (T1 and 2 *vs* T3 *vs* T4a *vs* T4b); pathological N category (N0 *vs* N1 *vs* N2 *vs* N3a *vs* N3b); macroscopic Borrmann type (I and II *vs* III *vs* IV and V); and tumor differentiation (undifferentiated *vs* differentiated). Two-sided *P* values were calculated for all tests. *P* values less than 0.05 were considered statistically significant.

To reduce selection biases associated with retrospective data, propensity score matched-pair analysis was performed with 1 to 1 matching (XELOX and surgery only; XELOX and FOLFOX6). The propensity score method was used to determine the probability of an individual patient having received a certain treatment as a function of several confounding covariates that were collapsed into a single predictor<sup>[25-27]</sup>. Individuals were matched for age, gender, tumor location, Borrmann type, number of retrieved nodes, tumor differentiation, pathological T category and pathological N category. In total, there were 370 patients in the XELOX *vs* surgery only analysis (*n* = 185 for adjuvant XELOX and *n* = 185 for surgery only) and 74 patients in the XELOX *vs* FOLFOX6 analysis (*n* = 37 for XELOX and *n* = 37 for FOLFOX6). Kaplan-Meier methods and Log-Rank analyses were then performed.

## RESULTS

The clinicopathological characteristics of the 896 patients are shown in Table 1. Compared to the surgery only group, patients in the XELOX and FOLFOX6 groups were younger at the time of treatment (median age 55.2

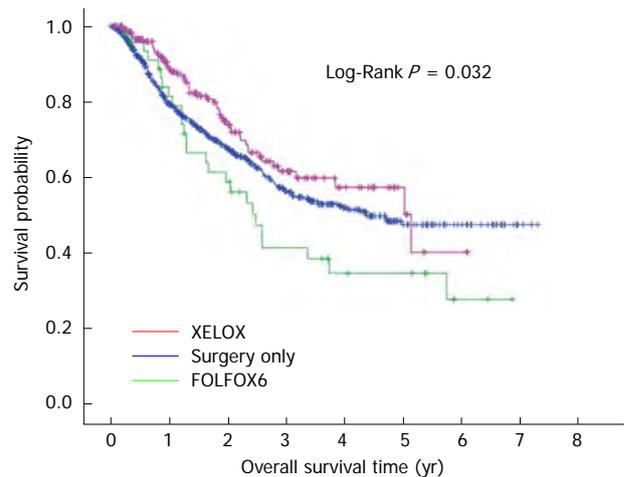

Figure 1 Overall survival analysis according to the Kaplan-Meier method for patients in the surgery only group (*n* = 634), the capecitabine and oxaliplatin group (*n* = 214) and the 5-fluorouracil, folinic acid and oxaliplatin group (*n* = 48). Overall survival was higher in the capecitabine and oxaliplatin (XELOX) group *vs* the surgery only group (*P* = 0.069) and 5-fluorouracil, folinic acid and oxaliplatin (FOLFOX6) groups (*P* = 0.022).

years; 51.2 years *vs* 58.9 years), had more undifferentiated tumors (70.1%; 70.8% *vs* 61.4%), and more lymph node metastases (80.8%; 83.3% *vs* 57.7%), respectively. There were no significant differences in baseline features between the XELOX and FOLFOX6 groups.

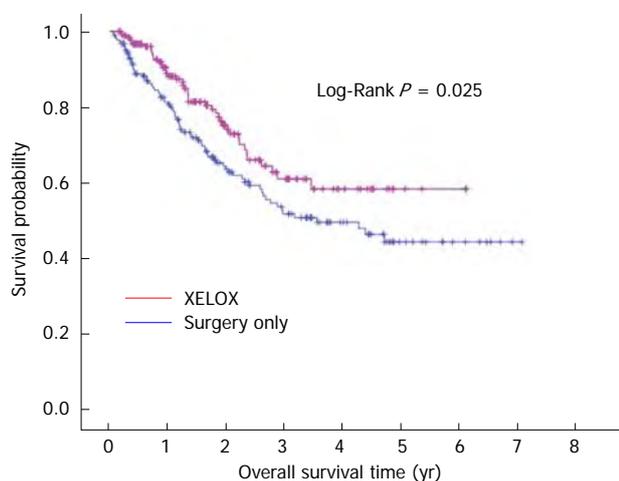

In the 896 patients, the overall mean and median survival were 57.8 and 52.7 mo, respectively. Overall 3-year and 5-year survival rates were 56.4% and 47.5% in the surgery only group, 61.5% and 57.3% in the XELOX group, and 41.3% and 34.5% in the FOLFOX6 group, respectively. Overall survival rate in the XELOX group was higher than that in the surgery only group (*P* = 0.069) and the FOLFOX6 group (*P* = 0.022) (Figure 1). Following multivariate analysis, adjuvant chemotherapy was found to have a prognostic influence on the hazard ratio (HR) for death (*P* = 0.001), and the HR for death was 0.564 (95%CI: 0.416-0.765; *P* < 0.001) for XELOX therapy (Table 2). In addition, pathological T category, pathological N category, tumor location, and macroscopic Borrmann type were also prognostic factors for overall survival. Recurrence rate was 24.3% (52/214) in the XELOX group, 31.3% (15/48) in the FOLFOX6 group and 32.8% (208/634) in the surgery only group. Recurrence rate in the XELOX group was lower than that in the surgery only (*P* = 0.021) and the FOLFOX6 (*P* = 0.36) groups.

In an attempt to eliminate treatment selection bias associated with retrospective data, a propensity score matched-pair analysis was performed using the following variables: age, gender, tumor location, Borrmann type, number of retrieved nodes, tumor differentiation, pathological T category and pathological N category. This resulted in a total of 370 patients for the XELOX *vs* surgery only analysis with 185 cases per treatment arm, and a total of 74 patients for the XELOX *vs* FOLFOX6 analysis with 37 cases per treatment arm. There were no significant differences (*P* > 0.05) among the matched

<sup>1</sup>Capecitabine and oxaliplatin (XELOX) group *vs* 5-fluorouracil, folinic acid and oxaliplatin (FOLFOX) group.

**Figure 2 Overall survival analysis according to the Kaplan-Meier method for patients in the D2 surgery only group (*n* = 185) and in the D2 surgery plus capecitabine and oxaliplatin group (*n* = 185) after propensity score matched-pair adjustment. XELOX: Capecitabine and oxaliplatin.**

variables by treatment group (results not shown). On matched analysis, adjuvant XELOX therapy significantly improved overall survival compared to surgery only with longer mean overall survival (51.2 mo *vs* 48.9 mo) and better 3-year (60.9% *vs* 51.7%) and 5-year survival (58.2% *vs* 44.2%, *P* = 0.025) (Figure 2). However, there was no

significant difference in overall survival between the XELOX and FOLFOX6 groups (*P* = 0.685). Overall 3-year survival was 42.7% in the FOLFOX6 group and 48.5% in the XELOX group with a median survival of 37.5 and 44.7 mo, respectively.

Grade 3/4 adverse reactions in the XELOX and FOLFOX6 groups are shown in Table 3. A total of 75 patients in the XELOX group (35%) experienced grade 3/4 adverse events similar to the rate in the FOLFOX6 group (19 patients, 39.6%, *P* = 0.618). More patients in the XELOX group experienced hand-foot syndrome than in the FOLFOX6 group (9.8% *vs* 0%, *P* = 0.018).

## DISCUSSION

This study showed that adjuvant XELOX was significantly associated with improved survival after D2 dissection for GC compared to D2 dissection alone, regardless of age, tumor differentiation, and nodal status. After adjustment for confounders in the propensity score analysis, adjuvant XELOX therapy improved 5-year overall survival by approximately 14% (*P* = 0.025) compared to surgery only, but was not associated with a greater survival benefit than FOLFOX6 therapy (48.5% *vs* 42.7%, *P* = 0.685). These results demonstrated that adjuvant XELOX therapy should be considered in curable GC patients.

D2 gastrectomy has been the standard surgical proce-

HR: Hazard ratio; FOLFOX6: 5-fluorouracil, folinic acid and oxaliplatin; XELOX: Capecitabine and oxaliplatin.

ture for GC in Eastern countries for several decades. For accurate pathological N category, at least 15 nodes should be retrieved for pathological examination according to the International Union against Cancer 7<sup>th</sup> edition<sup>[24]</sup>. Accurate tumor stage supports correct prognostic evaluation. This is why patients with less than 15 nodes were excluded in the current study. However, few studies have compared D2 surgery only with D2 surgery plus adjuvant chemotherapy in patients with GC. The JCOG 9206-1 clinical trial<sup>[28]</sup> failed to demonstrate the survival benefits of adjuvant chemotherapy with intravenous mitomycin, fluorouracil, and cytarabine followed by oral fluorouracil after D2 or greater dissection. The JCOG 9206-2 phase III trial also showed no survival benefit with adjuvant intraperitoneal and intravenous cisplatin followed by oral fluorouracil in serosa-positive GC after D2 dissection compared to D2 dissection alone<sup>[29]</sup>. However, the phase III CLASSIC study<sup>[23]</sup> reported a significant improvement in 3-year disease-free survival with the XELOX regimen compared to surgery alone. Our study demonstrated that adjuvant XELOX significantly improved 5-year survival compared to D2 dissection only. As one center involved in the CLASSIC trial, results in the current study were consistent with the preliminary 3-year report of the CLASSIC trial and further confirmed the efficacy of adjuvant XELOX chemotherapy after D2 dissection in the Chinese population based on overall 5-year survival data. Compared to the CLASSIC trial, the 3-year overall survival rate was relatively low in our study (61.5% *vs* 83%

AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; FOLFOX6: 5-fluorouracil, folinic acid and oxaliplatin; XELOX: Capecitabine and oxaliplatin.

in the XELOX group and 57.3% *vs* 78% in the control group). The main reasons for this may be related to the different population and advanced disease in our study. To eliminate selection biases associated with retrospective data, propensity score adjusted and matched-pair analyses were performed, and adjuvant XELOX therapy showed improved survival after D2 dissection in GC patients compared to surgery only. Our findings demonstrated that adjuvant XELOX was an effective therapy for patients with resectable GC.

In this study, adjuvant XELOX therapy was associated with a significantly higher overall survival than FOLFOX6 before propensity score adjusted analysis. However, this significant difference disappeared after propensity score matched analysis. A similar phenomenon occurred during a comparison between XELOX therapy and surgery only with or without propensity score analysis. These discrepant results showed that unbalanced features associated with retrospective data existed between these two groups, even if no significant unbalanced baseline factors were found before propensity score adjustment. The relatively small sample size in the FOLFOX6 group limited the efficacy of propensity score analysis and the reliability of our conclusion. Different chemotherapy regimens lead to different effects, and some chemotherapy regimens may not result in survival improvement<sup>[30]</sup>. The main differences between the XELOX and FOLFOX6 regimens were oral capecitabine and intravenous 5-FU. Although 5-FU is the most established single-agent drug in palliative chemotherapeutic GC care, the tumor response to 5-FU was reported to be inadequately predicted in SCID mouse models with sometimes no antitumor effects observed<sup>[31]</sup>. A retrospective study compared the effects of the XELOX regimen with the FOLFOX6 regimen in GC patients after D2 dissection and found no survival difference (5-year survival rate: 34% *vs* 29%) between these two regimens<sup>[32]</sup>. A meta-analysis showed that the HR for death for oral capecitabine-containing regimens was 0.94 (95%CI: 0.89-1.00; *P* = 0.0489) in patients with advanced

gastrointestinal cancers compared to 5-FU-containing regimens<sup>[33]</sup>. Our study showed no survival benefit for XELOX therapy compared to FOLFOX6 therapy and similar severe side effects were observed in these two groups. However, oral capecitabine was found to be more convenient and less dangerous than intravenous 5-FU. Few patients had nausea and vomiting during XELOX therapy, although more patients suffered from hand-foot syndrome. Most patients undergoing FOLFOX6 therapy did not complete all the required treatment courses due to frequent hospital visits for biweekly treatment and adverse effects related to eating, drinking and sleeping. This may be why more patients and doctors preferred the XELOX regimen.

In conclusion, this study demonstrated that adjuvant XELOX therapy was associated with survival benefits in GC patients after D2 dissection and provides a superior option for curable GC patients.

## COMMENTS

### Background

The clinical treatment of gastric cancer (GC) is challenging and overall survival is poor. Adjuvant chemotherapy has been intensively investigated for several decades but definitive evidence is limited especially for patients after D2 dissection.

### Research frontiers

Adjuvant capecitabine and oxaliplatin (XELOX) and 5-fluorouracil, folinic acid and oxaliplatin (FOLFOX6) chemotherapy have been widely used in GC patients. However, few studies have directly compared their efficacy and the optimal regimen of adjuvant chemotherapy has not yet been determined.

### Innovations and breakthroughs

The authors found that adjuvant XELOX was significantly associated with improved survival after D2 dissection compared to surgery alone following multivariate Cox regression and propensity score matched analyses. However, the XELOX regimen did not result in a greater survival benefit than the FOLFOX6 regimen.

### Applications

The findings in this study demonstrated that adjuvant XELOX therapy should be considered in curable GC patients.

### Terminology

The propensity score method is used to determine the probability of an individual patient having received a certain treatment as a function of several confounding covariates that are collapsed into a single predictor.

### Peer review

The optimal chemotherapeutic regimen after resected advanced GC is still one of the clinical challenges. Based on previous studies, whether adjuvant chemotherapy can improve GC survival is still uncertain. Although XELOX (capecitabine and oxaliplatin) and FOLFOX6 (5-fluorouracil, folinic acid and oxaliplatin) regimens have been widely used in clinics, few studies have shown direct evidence to indicate their efficacy. This study compared the efficacy of XELOX and FOLFOX6 for GC patients after D2 dissection, and the findings have some scientific and clinical significance.
