Abstract

AIM: To investigate the reasons for the occurrence of the pink-color sign of iodine-unstained lesions.

METHODS: In chromoendoscopy, the pink-color sign of iodine-unstained lesions is recognized as useful for the diagnosis of esophageal squamous cell carcinoma. Patients with superficial esophageal neoplasms treated by endoscopic resection were included in the study. Areas of mucosa with and without the pink-color sign were evaluated histologically. The following histologic features that were possibly associated with the pink-color sign were evaluated. The keratinous layer and basal cell layer were classified as present or absent. Cellular atypia was classified as high grade, moderate grade or low grade, based on nuclear irregularity, mitotic figures, loss of polarity, chromatin pattern and nuclear/cytoplasmic ratio. Vascular change was assessed based on dilatation, tortuosity, caliber change and variability in shape. Vessels with these four findings were classified as positive for vascular change. Endoscopic images of the lesions were captured immediately after iodine staining, 2-3 min after iodine staining and after complete fading of iodine staining. Quantitative analysis of color changes after iodine staining was also performed.

RESULTS: A total of 61 superficial esophageal neoplasms in 54 patients were included in the study. The lesions were located in the cervical esophagus in one case, the upper thoracic esophagus in 10 cases, the mid-thoracic esophagus in 33 cases, and the lower thoracic esophagus in 17 cases. The median diameter of the lesions was 20 mm (range: 2-74 mm). Of the 61 lesions, 28 were classified as pink-color sign positive and 33 as pink-color sign negative. The histologic diagnosis was high-grade intraepithelial neoplasia (HGIN) or cancer invading into the lamina propria in 26 of the 28 pink-color sign positive lesions. There was a significant association between pink-color sign positive epithelium and HGIN or invasive cancer (P = 0.0001). Univariate analyses found that absence of the keratinous layer and cellular atypia were significantly associated with the pink-color sign. After Bonferroni correction, there were no significant associations between the pink-color sign and presence of the basal membrane or vascular change. Multivariate analyses found that only absence of the keratinous layer was independently associated with the pink-color sign (OR = 58.8, 95%CI: 5.5-632).

Quantitative analysis was performed on 10 superficial esophageal neoplasms with both pink-color sign positive and negative areas in 10 patients. Pink-color sign positive mucosa had a lower mean color value in the late phase (pinkish color) than in the early phase (yellowish color), and had similar mean color values in the late and final phases. These findings suggest that pink-color positive mucosa underwent color fading from the color of the iodine (yellow) to the color of the mucosa (pink) within 2-3 min after iodine staining. Pink-color sign negative mucosa had similar mean color values in the late and early phases (yellowish color), and had a lower mean color value in the final phase (pinkish color) than in the late phase. These findings suggest that pink-color sign negative mucosa did not undergo color fading during the 2-3 min after iodine staining, and underwent color fading only after spraying of sodium thiosulfate.

CONCLUSION: The pink-color sign was associated with absence of the keratinous layer. This sign may be caused by early fading of iodine staining.

Key words: Chromoendoscopy; Esophageal cancer; Esophageal squamous neoplasia; Iodine staining; Pink-color sign

Core tip: The pink-color sign of iodine-unstained lesions is useful for the diagnosis of esophageal squamous cell carcinoma. We investigated histologic findings of esophageal neoplasms, and found that absence of the keratinous layer because of neoplastic cell proliferation may be responsible for the pink-color sign. Quantitative analysis of color showed that pink-color sign positive mucosa underwent early color fading from the color of the iodine (yellow) to the color of the mucosa (pink) within 2-3 min. Based on these results, we speculated on the mechanism underlying the pink-color sign. These findings may improve our understanding of the characteristics of esophageal neoplasms.

INTRODUCTION

Esophageal cancer is the sixth most common cause of cancer-related mortality worldwide[1]. The overall survival of patients with esophageal cancer remains poor, regardless of histologic type. However, a favorable prognosis can be expected after treatment with esophagectomy[2,3], chemoradiotherapy[4,5] or endoscopic resection[6-9] if the cancer is detected at an early stage.

Conventional endoscopy has limited usefulness for the treatment of esophageal cancer, because it is not easy to identify early neoplastic changes[10,11]. Chromoendoscopy with iodine staining is reported to be more sensitive for the early diagnosis of esophageal squamous cell carcinoma[12,13], but has low specificity and requires multiple biopsy specimens[10,14]. A dramatic color change after iodine staining, from the initial yellow color to a pink color 2-3 min later, is known as the pink-color sign, and is useful for identifying cancerous lesions[15,16]. This sign has been reported to dramatically improve specificity for esophageal high-grade intraepithelial neoplasia (HGIN) and invasive cancer[15,16]. Choosing adequate biopsy sites is sometimes difficult, especially in patients with scattered-type staining of the esophagus, which is characterized by multiple Lugol-voiding lesions[17]. Some of these iodine-unstained lesions may indicate inflammation or low-grade intraepithelial neoplasia (LGIN), and in such cases a lack of iodine staining is not a good indication for taking a biopsy specimen. Because of its high specificity, the pink-color sign is a good indicator for choosing adequate biopsy sites in patients with scattered-type staining. However, the mechanism underlying the occurrence of the pink-color sign has not been fully investigated. Improved understanding of this mechanism may improve our understanding of the characteristics of the relevant lesions, and increase the likelihood of accurate diagnosis. This study therefore aimed to clarify the histologic changes responsible for the occurrence of the pink-color sign in esophageal squamous neoplasia.

MATERIALS AND METHODS

Endoscopic examination and resection

The current clinical investigation was conducted during routine endoscopic procedures for resection of esophageal squamous lesions. Patients with superficial esophageal neoplasia confirmed by histologic examination were included in the study. Superficial esophageal neoplasia was defined as a lesion limited to the submucosa. Typical endoscopic findings were superficial protruding type, superficial flat type and superficial excavated type. If a lesion had a large broad-based protrusion, crater and stiffened wall, it was diagnosed as advanced cancer. Patients were excluded if they had previously undergone surgery, chemotherapy or radiotherapy for esophageal cancer. The endoscopic procedures were performed using a high-resolution magnifying upper-gastrointestinal endoscope (GIF-Q240Z or GIF-H260Z; Olympus, Tokyo, Japan). The structure enhancement function of the video processor was set at level B8 for narrow-band imaging (NBI). A black soft hood (MB-162 for GIF-Q240Z or MB-46 for GIF-H260Z; Olympus) was mounted on the tip of the endoscope to maintain an adequate distance between the tip of the endoscopic zoom lens and the mucosal

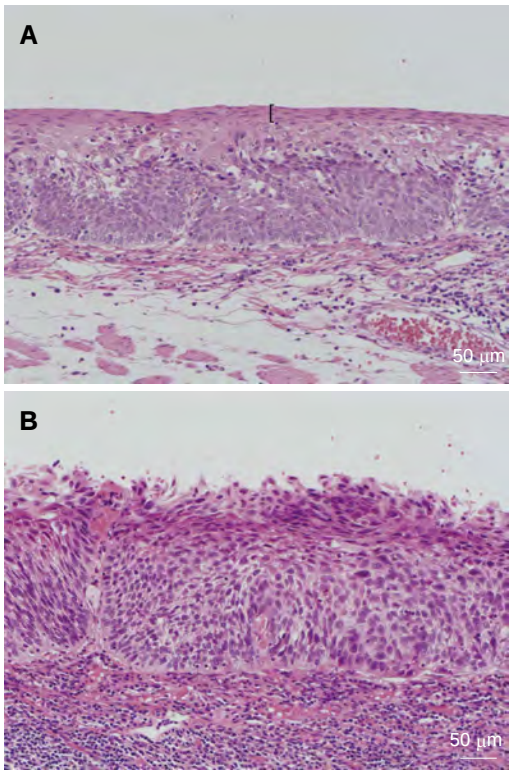

Figure 1 Histologic findings of esophageal lesions. A: Esophageal lesion with keratinous layers, shown by black parentheses; B: Esophageal lesion without keratinous layers.

surface during observations. The endoscopic procedure was performed under intravenous sedation with midazolam (Dormicam; Yamanouchi Pharma, Tokyo, Japan) and pentazocine (Pentazin; Sankyo Pharmaceuticals, Tokyo, Japan).

The esophageal mucosa was initially examined using white-light imaging or NBI. A catheter was then used to spray 20-40 mL of 0.6%-1.2% iodine solution until the esophageal mucosa was evenly stained, and the subsequent color changes were observed. Immediately after spraying of the iodine solution, the normal mucosa was dark brown, whereas abnormal mucosa suspicious of dysplasia or cancer was yellow. The iodine-unstained (yellow) areas were classified as pink-color sign positive or pink-color sign negative. In pink-color sign positive mucosa, the yellow areas changed to pink within 2-3 min of spraying, and in pink-color sign negative mucosa, these areas remained yellow after 3 min. Representative areas (2-5 mm diameter) were marked with marker dots, and the lesions were resected by endoscopic submucosal dissection or endoscopic mucosal resection. Iodine staining and marking of pink-color sign positive and negative areas were performed immediately before resection. Considering the potential disadvantages of intraoperative endoscopy and iodine staining, patients requiring surgical resection were excluded. To ensure that the study protocol was strictly followed, marking before endoscopic resection and confirmation of marking after endoscopic resection were performed by one of two endoscopists (Ishihara R or Kanzaki H). Procedures that were performed without these two endoscopists in attendance were excluded from the study. Written informed consent was obtained from all patients before endoscopic examination and resection of lesions. Institutional review board approval was granted for a retrospective chart review and analysis of the data.

Histologic evaluation

All specimens were cut into 2-mm slices and embedded in paraffin. Sections were cut from the paraffin blocks and stained with hematoxylin and eosin. The pink-color sign positive and negative lesions marked by the marker dots were examined histologically. The depth of cancer involvement was classified according to the Japanese Classification of Esophageal Carcinoma[18], and intraepithelial neoplasms were classified as LGIN or HGIN, according to the World Health Organization classification[19]. Intraepithelial cancer was included in HGIN.

The following histologic features that were possibly associated with the pink-color sign were evaluated. The keratinous layer (Figure 1) and basal cell layer were classified as present or absent. Cellular atypia was classified as high grade, moderate grade or low grade, based on nuclear irregularity, mitotic figures, loss of polarity, chromatin pattern and nuclear/cytoplasmic ratio. Vascular change was assessed based on dilatation, tortuosity, caliber change and variability in shape. Vessels with these four findings were classified as positive for vascular change[20]. All histologic assessments were performed by the same pathologist (SI), who was blinded to the endoscopic and clinical findings.

Quantitative analysis of color

This study included esophageal cancers those have both pink-color sign positive and pink-color sign negative areas. The esophageal mucosa was initially examined with white-light imaging or NBI. A catheter was used to spray 20-40 mL of 1.2% iodine solution until the normal esophageal mucosa was evenly stained, and the subsequent color changes were examined. Sodium thiosulfate solution was then sprayed to relieve symptoms caused by the iodine, which also accelerated the color fading by reduction of the iodine.

The digital images were used to perform quantitative analysis of the color changes after iodine staining. Endoscopic images of the lesions were captured immediately after iodine staining, 2-3 min after iodine staining and after complete fading of iodine staining, taking care to ensure that all images were obtained from a similar direction and a similar distance, to enable accurate analysis (Figure 2). All the images were captured under the instruction of one endoscopist (Ishihara R). The images were stored in bitmap format (.bmp) with a resolution of 640 × 480 pixels. A small region of interest was chosen in both the pink-color sign positive and pink-color sign negative areas. These regions of interest were carefully chosen to be of similar size in each area (Figure 3). The red-green-blue components of each region of interest were calculated

using Image J software (National Institutes of Health, Bethesda, MD, United States), and color diagrams were created using the graphing function of Microsoft Excel (Microsoft Corp., Redmond, WA, United States).

The LU'V' color system is a uniform color space that was adopted by the Commission Internationale de l'E' clairage in 1976 and is used to systematically represent the different colors[21,22]. A color system is a model for representing colors in terms of intensity values. Generally, colors are described using color systems with three or four dimensions (red-green-blue or cyan-magenta-yellow-black). The diagram of the LU'V' system has U' and V' coordinates that represent the chromaticity values of each color. This color space is designed to be perceptually uniform, meaning that a given change in value roughly corresponds to the same perceptual difference over any part of the space. Using this system, color can be quantified and evaluated on a two-dimensional plane. However, determining the range of color is challenging because there is no clear border between colors.

Statistical analysis

The relationships between the pink-color sign and each histologic finding were analyzed. If more than one lesion was resected from a patient, each lesion was considered separately for the purposes of statistical analysis. Univariate analyses of the relationships between the pink-color sign and the histologic findings were performed using the χ^2 test with Yates' correction. Factors independently associated with the pink-color sign were identified using multivariate logistic regression analysis. The model fit was assessed using the Hosmer-Lemeshow test. A two-sided P value of < 0.05 was considered statistically significant. A Bonferroni-adjusted P-value was used for multiple comparisons to control for experimental errors due to multiple testing. All analyses were performed using SPSS software version 11.0 (SPSS Inc, Chicago, IL, United States).

RESULTS

Histologic evaluation of pink-color sign positive areas

A total of 97 patients with superficial esophageal cancer were treated by endoscopic resection at the Osaka Medical Center for Cancer and Cardiovascular Diseases from May 31, 2011 to March 1, 2012. Of these, 10 patients were excluded because of previous radiation, 29 were excluded because endoscopic resection was performed without the attendance of the two endoscopists (Ishihara R or Kanzaki H) and 4 were excluded because no images were captured at 2-3 min after iodine staining. A total of 61 superficial esophageal neoplasms in 54 patients were included in the study. The lesions were located in the cervical esophagus in one case, the upper thoracic esophagus in 10 cases, the mid-thoracic esophagus in 33 cases, and the lower thoracic esophagus in 17 cases. The median diameter of the lesions was 20 mm (range: 2-74 mm) (Table 1). Of the 61 lesions, 28 were classified as pink-color sign positive and 33 as pink-color sign negative. The histologic diagnosis was HGIN or cancer invading into the lamina propria in 26 of the 28 pink-color sign positive lesions. Two lesions that were classified as pink-color sign positive were diagnosed as LGIN. One of these lesions had a thin keratinous layer and mild cellular atypia. This lesion showed an obscured pink-color sign, which was classified as positive in this study. In retrospect, it is possible that this lesion should have been classified as pink-color sign negative.

Table 1 Characteristics of patients and lesions

Characteristics	*n*

Histological diagnosis of the marked area	
LGIN	21
HGIN	37
LPM	3

LGIN: Low-grade intraepithelial neoplasia; HGIN: High-grade intraepithelial neoplasia; LPM: Cancer invading into the lamina propria.

Table 2 Associations between histologic diagnosis, keratinous layer and pink-color sign

	HGIN or invasive cancer	LGIN	*P* value
Pink-color-sign			0.0001
Positive	26	2	
Negative	14	19	
Keratinous layer			0.0007
Present	19	20	
Absent	21	1	

HGIN: High-grade intraepithelial neoplasia; LGIN: Low-grade intraepithelial neoplasia.

The other lesion did not have a keratinous layer and had moderate cellular atypia. However, this lesion showed surface differentiation and was diagnosed as LGIN because obvious cytological abnormalities were confined to the lower half of the squamous epithelium. There was a significant association between pink-color sign positive epithelium and HGIN or invasive cancer ($P = 0.0001$) (Table 2). There was also a significant association between the presence of a keratinous layer and HGIN or invasive cancer ($P = 0.0007$).

Univariate analyses (Table 3) found significant associations between the pink-color sign and absence of the keratinous layer or cellular atypia. After Bonferroni correction, there were no significant associations between the pink-color sign and presence of the basal membrane or vascular change. Multivariate analyses (Table 4) showed that absence of the keratinous layer was independently associated with the pink-color sign (OR = 58.8, 95%CI: 5.5-632). Hosmer-Lemeshow testing indicated that the model achieved a sufficient goodness-of-fit ($P = 0.678$).

Quantitative analysis of the pink-color sign

A total of 1373 patients underwent esophagogastroduodenoscopy at the Osaka Medical Center for Cancer and Cardiovascular Diseases from September 21, 2012

to December 5, 2012. Of these, 29 were diagnosed with esophageal squamous cell carcinoma. Fourteen of these 29 patients were excluded for the following reasons: history of chemoradiotherapy (8 patients), the entire lesion was pink-color sign positive (4 patients), or the pink-color sign was negative (2 patients). Ten of the 15 patients that had lesions with both pink-color sign positive and pink-color sign negative areas were examined under the instruction of the endoscopist (Ishihara R) and were included in the analysis. Endoscopic images of the lesions immediately after iodine staining (early phase), 2-3 min after iodine staining (late phase) and after complete fading of iodine staining (final phase) were analyzed (Figure 4). The mean U' and V' values of the pink-color sign positive and negative areas are shown in Figure 5. Pink-color sign positive mucosa had a lower mean V' value in the late phase (pinkish color) than in the early phase (yellowish color), and had similar mean U' and V' values in the late and final phases (Figure 5A). These findings suggest that pink-color positive mucosa underwent color fading from

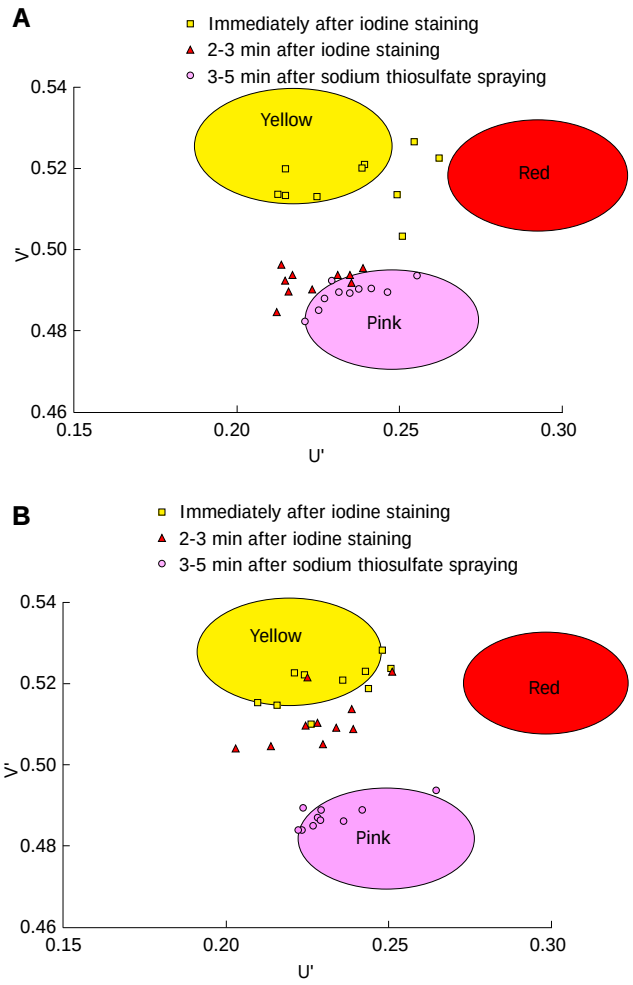

Figure 4 The U' and V' values of the pink-color sign positive mucosa and negative mucosa in the early, late and final phases were plotted on a color diagram. A: Pink-color sign positive mucosa; B: Pink-color sign negative mucosa.

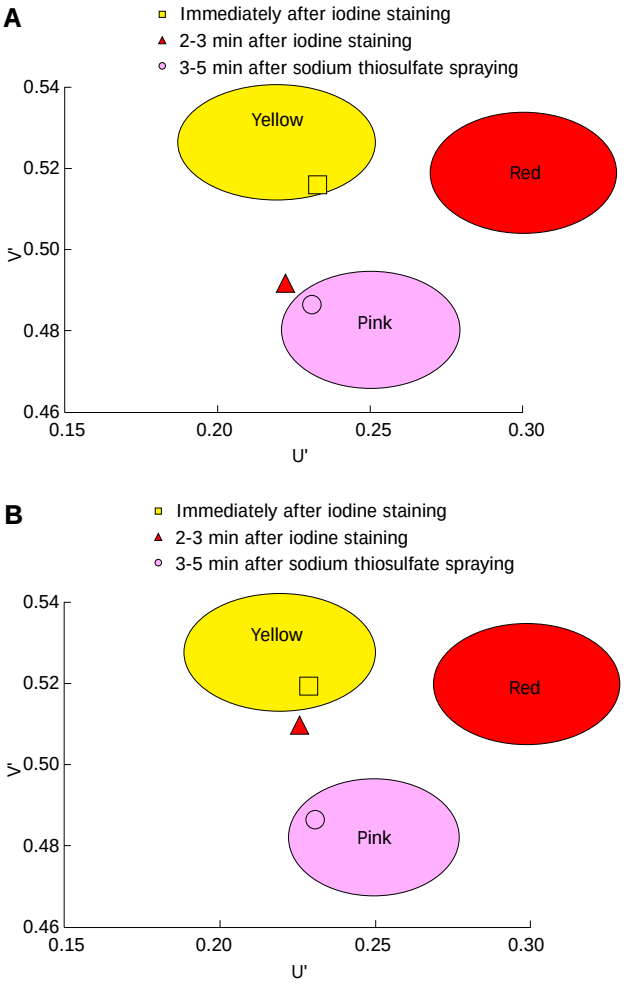

Figure 5 Mean U' and V' values of the mucosa in the early, late and final phases were plotted on a color diagram. A: Pink-color sign positive mucosa had a lower mean V' value in the late phase (pinkish color) than in the early phase (yellowish color), suggesting that the pink-color sign positive mucosa underwent a color change from yellow to pink. The mucosa had similar mean U' and V' values in the late and final phases, suggesting that the color of pink-color sign positive mucosa in the late stage was similar to the color of mucosa after complete fading of iodine staining; B: Pink-color sign negative mucosa had similar mean U' and V' values in the early and late phases (yellowish color), suggesting that pink-color sign negative mucosa did not change in color during this time period.

the color of the iodine (yellow) to the color of the mucosa (pink) within 2-3 min after iodine staining. Pink-color sign negative mucosa had similar mean U' and V' values in the late and early phases (yellowish color), and had a lower mean V' value in the final phase (pinkish color) than in the late phase (Figure 5B). These findings suggest that pink-color sign negative mucosa did not undergo color fading during the 2-3 min after iodine staining, and underwent color fading only after spraying of sodium thiosulfate.

DISCUSSION

Analysis of the endoscopic and histologic findings of this study found that absence of the keratinous layer was independently associated with the pink-color sign. Quantitative analysis of color changes found that pink-color sign positive mucosa changed from yellowish to pinkish within 2-3 min after iodine staining, suggesting that the mucosa underwent early color fading from the color of the iodine (yellow) to the color of the mucosa (pink).

This study did not include all patients who met our inclusion criteria, because we wanted to ensure that all procedures were of high quality to obtain accurate results. Marking before endoscopic resection and confirmation of marking after endoscopic resection were performed by one of two endoscopists (Ishihara R or Kanzaki H) to accurately identify the region of interest. All endoscopic images were captured under the instruction of one endoscopist (Ishihara R) to ensure that they were captured under similar conditions. This may have caused some selection bias, but it was felt necessary to limit the number of endoscopists involved for this detailed analysis.

Figure 6 shows our speculated mechanism for the occurrence of the pink-color sign. Locally administered iodine is usually absorbed into the epithelium by passive diffusion[23]. In normal esophageal epithelium, absorbed iodine combines with glycogen in the micro-granules of the prickle cells[24]. The resulting glycogen-iodine complex

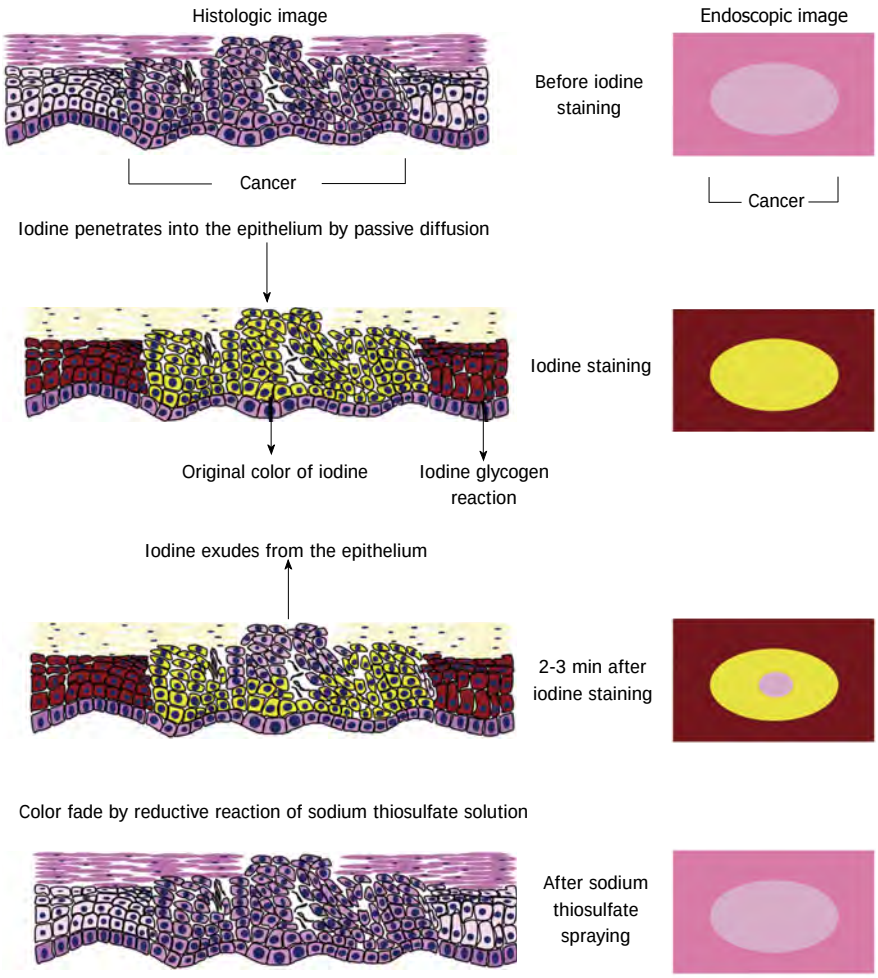

Figure 6 Speculated mechanism of the pink-color sign.

gives the epithelium a brown color. In the epithelium of neoplastic lesions, the prickle-cell layer is usually replaced by neoplastic cells, and no glycogen-iodine complex is formed. The yellow iodine solution therefore gives the epithelium a yellow color.

In the epithelium of neoplastic lesions, the yellow color may fade because of reduction of the iodine, absorption of iodine into the bloodstream, or leakage of iodine into the esophageal lumen. Application of sodium thiosulfate solution reduces the adverse effects of iodine staining and accelerates color fading by reduction of the iodine[25]. However, iodine is a strong oxidizing agent[26], and reduction of iodine requires a strong reducing agent. Absorption of iodine by the blood stream may occur in the esophagus[27]. However, iodine is mainly absorbed in the small intestine[28] and the amount of iodine absorbed by the esophagus is not large. Leakage of iodine into the esophageal lumen may therefore be the main cause of color fading, rather than reduction of iodine or absorption of iodine into the bloodstream.

Epithelium plays an important role in regulating the permeability of mucosa, and serves as a barrier between the outside world and the internal milieu of the organism[29,30]. The barrier function of epithelium is determined by its microstructure, and varies among different types of epithelium. The keratin layer of squamous epithelium has a barrier function[29,30], and may play an important role in preventing leakage of iodine from the epithelium. Disruption of the normal epithelial structure, especially of the keratin layer, may increase early leakage of iodine and early color fading. Considering the association between the absence of the keratinous layer and the pink-color sign, this may be the mechanism underlying the occurrence of the sign.

Neoplastic lesions show less staining when exposed to iodine solution than normal mucosa. However, both cancer and LGIN result in iodine-unstained areas. Assessment of iodine staining without assessment of the pink-color sign is therefore not very accurate for the diagnosis of cancer[10,14]. The keratinous layer was found to be absent in areas where most of the epithelium was replaced by neoplastic cells. Most areas that were pink-color sign positive had a proliferation of neoplastic cells in the upper half of the epithelium. The pink-color sign was associated with HGIN or cancer, those are both characterized by abnormal cells in the upper half of the epithelium. Accurate endoscopic diagnosis of esophageal lesions is therefore possible by assessment of the pink-color sign after iodine staining.

Differentiating HGIN or cancer from LGIN is im-

portant when deciding on a treatment strategy, because resection of the lesion is required for HGIN and cancer[19]. Histologic diagnosis of biopsy specimens may result in misdiagnosis if the correct area was not biopsied. Areas that are pink-color sign positive should always be biopsied, because this finding is closely associated with HGIN and cancer. Moreover, the keratinous layer is usually absent in areas that are pink-color sign positive, and it may therefore be relatively easy to biopsy neoplastic cells from these areas. However, if further studies confirm that the accuracy of endoscopic diagnosis is similar to that of biopsy diagnosis, cancer could eventually be diagnosed based on the pink-color sign without a need for biopsy.

In conclusion, the pink-color sign was closely associated with absence of the keratinous layer. The pink-color sign may be caused by early leakage of iodine into the esophageal lumen because of impaired barrier function of the epithelium.

COMMENTS

Background

A dramatic color change after iodine staining, from the initial yellow color to a pink color 2-3 min later, is known as the pink-color sign, and is useful for identifying cancerous lesions of the esophagus. This sign has been reported to dramatically improve specificity for esophageal squamous high-grade intraepithelial neoplasia and invasive cancer.

Research frontiers

The mechanism underlying the occurrence of the pink-color sign has not been fully investigated. Improved understanding of this mechanism may improve our understanding of the characteristics of the relevant lesions, and increase the likelihood of accurate diagnosis.

Innovations and breakthroughs

This study clarified the histologic changes responsible for the occurrence of the pink-color sign in esophageal squamous neoplasia as follows. Analysis of the endoscopic and histologic findings of this study found that absence of the keratinous layer was independently associated with the pink-color sign. Quantitative analysis of color changes found that pink-color sign positive mucosa changed from yellowish to pinkish within 2-3 min after iodine staining, suggesting that the mucosa underwent early color fading from the color of the iodine (yellow) to the color of the mucosa (pink). The pink-color sign may be caused by early leakage of iodine into the esophageal lumen because of impaired barrier function of the epithelium.

Applications

The pink-color sign is a good indicator for choosing adequate biopsy sites, because of its high specificity. Improved understanding of this mechanism may improve their understanding of the characteristics of the relevant lesions, and increase the likelihood of accurate diagnosis.

Terminology

Pink-color sign: A dramatic color change after iodine staining, from the initial yellow color to a pink color 2-3 min later. Keratinous layer: The outer layer of the squamous epithelium, which contain a tough, fibrous protein. This layer acts as a protective barrier against outside elements.

Peer review

This study investigated the detailed histologic findings of esophageal neoplasms, and found that absence of the keratinous layer because of neoplastic cell proliferation may be responsible for the pink-color sign. Quantitative analysis of color changes showed that pink-color sign positive mucosa changed from yellowish to pinkish within 2-3 min after iodine staining, suggesting that the mucosa underwent early color fading from the color of the iodine (yellow) to the color of the mucosa (pink). Based on these results, the authors speculated on the mechanism underlying the pink-color sign. These findings may improve understanding of the characteristics of these lesions, and increase the accuracy of diagnosis of esophageal neoplasms.

Abstract

AIM: To investigate Krüppel-like factor 8 (KLF8) expression in gastric cancer and its relationship with angiogenesis and prognosis of gastric cancer.

METHODS: One hundred and fifty-four patients with gastric cancer who underwent successful curative resection were retrospectively enrolled in the study. Fifty tumor-adjacent healthy gastric tissues (≥ 5 cm from the tumor margin) obtained during the original resection were randomly selected for comparative analysis. *In situ* expression of KLF8 and CD34 proteins were examined by immunohistochemistry. The intratumoral microvessel density (MVD) was determined by manually counting the immunostained CD34-positive endothelial cells in three consecutive high-magnification fields (× 200). The relationship between differential KLF8 expression and MVD was assessed using Spearman's correlation coefficient test. χ^2 test was performed to evaluate the effects of differential KLF8 expression on clinicopathologic factors. Kaplan-Meier and multivariate Cox survival analyses were used to assess the prognostic value of differential KLF8 expression in gastric cancer.

RESULTS: Significantly higher levels of KLF8 protein were detected in gastric cancer tissues than in the adjacent non-cancerous tissues (54.5% *vs* 34.0%, $P < 0.05$). KLF8 expression was associated with tumor size ($P < 0.001$), local invasion ($P = 0.005$), regional lymph node metastasis ($P = 0.029$), distant metastasis ($P = 0.023$), and tumor node metastasis (TNM) stage ($P = 0.002$), as well as the MVD ($r = 0.392$, $P < 0.001$). Patients with KLF8 positive expression had poorer overall survival ($P < 0.001$) and cancer-specific survival ($P < 0.001$) than those with negative expression. Multivariate analysis demonstrated that KLF8 expression independently affected both overall and cancer-specific survival of gastric cancer patients ($P = 0.035$ and 0.042, respectively).

CONCLUSION: KLF8 is closely associated with gastric tumor progression, angiogenesis and poor prognosis, suggesting it may represent a novel prognostic biomarker and therapeutic target for gastric cancer.

Key words: Gastric cancer; Krüppel-like factor 8; Angiogenesis; Prognosis

Core tip: In this study, we found that the expression of Krüppel-like factor 8 (KLF8) was up-regulated in resected gastric cancer tissues. The differential KLF8

expression was significantly associated with enhanced malignant potential, including tumor size, local invasion, regional lymph node metastasis, distant metastasis, and tumor node metastasis stage, as well as the intratumoral microvessel density. Multivariate analysis indicated that KLF8 expression independently affected both overall and cancer-specific survival of gastric cancer patients. Collectively, our findings suggest that KLF8 may be a predictive marker of clinical outcome and represent a novel target for anti-angiogenic therapy of gastric cancer patients.

INTRODUCTION

Gastric cancer is one of the most common malignant tumors worldwide, accounting for the second highest rate of cancer-related death[1]. Despite the decline in gastric cancer mortality has occurred over the past few decades, this disease remains a significant burden in China, with approximately 400000 newly-diagnosed cases being reported each year[2]. Patients with gastric cancer are often asymptomatic or display nonspecific symptoms in the early stages, and by the time symptoms appear the disease has generally reached an advanced stage, when treatment options are limited and the prognosis for long-term survival is poor. Therefore, there remains a critical need for discovery of novel biomarkers that will reflect not only gastric cancer onset but also its progression and risk of mortality; such diagnostic and prognostic indicators may also represent novel therapeutic targets for treating gastric cancer patients at various stages.

Krüppel-like factor 8 (KLF8) was initially identified as a ubiquitously expressed transcriptional repressor[3]. Like other members of the KLF transcription factor family, KLF8 harbors three conserved C2H2 zinc finger DNA-binding domains in its C-terminus, but also has a unique sequence in its N-terminus that is believed to mediate its functional specificity through interactions with other protein binding partners[4,5]. KLF8 activity has been implicated as crucial to a wide range of cellular processes, such as cell cycle progression[6-9], oncogenic transformation[10], epithelial-to-mesenchymal transition, migration and invasion[11,12]. Moreover, overexpression of KLF8 has been found in several human malignant tumors, including those of ovarian, renal and breast origin[13-15]. *In vitro* studies using gastric cancer cell lines have revealed that lentivirus-mediated knockdown of KLF8 inhibits cell growth and invasion[16,17]. Yet, the clinical significance of KLF8 overexpression in relation to clinicopathologic features of gastric cancer and patient prognosis remains unknown.

Angiogenesis, the formation of new capillary blood vessels, is essential for the growth, progression and metastasis of malignant tumors[18,19]. The microvessel density (MVD) is now widely used to evaluate the degree of tumor angiogenesis and has been proven to be associated with the metastasis and prognosis of a wide range of human tumors[20-22]. One previous study has shown that transfection with KLF8-RNAi lentivirus significantly decreases tumor vessels in a mouse model of liver cancer[11], suggesting that KLF8 may play potentially interesting roles in tumor angiogenesis. However, the angiogenic property of KLF8 protein in primary gastric cancer remains unclear.

In the present study, we detected the expression status of KLF8 by immunohistochemistry in surgically resected gastric cancer, and further explored its potential correlations with clinicopathologic parameters, tumor angiogenesis and prognosis of the patients with gastric cancer.

MATERIALS AND METHODS

Patients and follow-up

Between July 2004 and October 2006, a total of 161 gastric cancer patients underwent curative resection in the Department of General Surgery at Qilu Hospital of Shandong University (Jinan, China). Of these 161 patients, seven cases were lost to follow-up, so a total of 154 patients were eventually enrolled in this study. Retrospective review of the patients' medical records and direct communication with the patients provided complete diagnosis, treatment and follow-up data for all cases. The resected tumor specimens had been immediately formalin-fixed and paraffin-embedded. Each paraffin block was cut into serial sections at 4 μm intervals for future analysis. In addition, we randomly selected 50 normal gastric tissues (at least 5 cm from the margin of the tumor) as normal controls. The postoperative pathological TNM staging was evaluated based on the 2009 criteria of the International Union Against Cancer (UICC). This study was approved by the Ethics Committee of Qilu Hospital, and written informed consent was obtained from each patient.

None of the patients had received preoperative adjuvant therapy. All patients were followed-up at the outpatient clinic at 3-6 mo intervals, with the follow-up durations ranging from 5-77 mo (median, 45 mo). The follow-up examinations included laboratory testing, physical examination, ultrasound scan, and, if necessary, fibergastroscopy.

Immunohistochemical staining for KLF8 and CD34

Paraffin-embedded tissue sections were baked at 60 ℃, dewaxed by soaking in xylene, and rehydrated by passing through an alcohol gradient series. Antigen retrieval was carried out by boiling samples (*via* microwave) in EDTA

(pH 9.0). After cooling to room temperature, the sections were immersed in 3% hydrogen peroxide for 15 min to inhibit endogenous peroxidase activity, followed by blocking in 10% goat serum to reduce nonspecific binding. An overnight incubation at 4 ℃ was then carried out with anti-KLF8 or anti-CD34 primary antibodies (1:100 in phosphate-buffered saline (PBS); both from Santa Cruz Biotechnology, Santa Cruz, CA), which was followed by incubation with the corresponding horseradish peroxidase-conjugated secondary antibody (Zhongshan Golden Bridge Biotechnology, Beijing, China). The peroxidase reactivity was visualized using 3,3'-diaminobenzidine as substrate. Finally, the sections were counterstained with hematoxylin, dehydrated, and mounted with neutral balsam. Negative controls were generated by the same procedure, except with the primary antibody being replaced by PBS alone.

Evaluation of KLF8 expression and MVD

Microscopic evaluation of the immunostained sections was carried out by two pathologists working independently, who were not associated with this study and who were blinded to the patients' clinicopathologic factors and outcomes. In cases of discrepancy, the slides were re-assessed jointly by both pathologists using a multi-head microscope to establish a consensus result.

KLF8 protein expression was semi-quantitatively assessed by scoring both the immunoreactive staining intensity (0: no staining; 1: weak staining; 2: moderate staining; 3, strong staining) and the proportion of positively-stained cells (0: 0%-9%; 1: 10%-25%; 2: 26%-50%; 3: 51%-75%; 4: > 75%). The overall staining score was then calculated as (percentage score × intensity score), with final scores of 0 indicating negative expression, of 1-5 indicating weakly positive expression, and of ≥ 6 indicating strongly positive expression[11].

MVD was assessed by immunohistochemical staining of CD34, according to the international consensus on the methodology and criteria of evaluation of angiogenesis quantification in solid human tumors[23]. The entire sections were scanned at low magnification (× 100) initially to select regions with the highest vascularity ("hot spots") for focused investigation using high magnification (× 200) to manually count the stained microvessels present in three consecutive fields. A single, countable microvessel was defined as any brown-stained endothelial cell (or cluster) clearly separated from the adjacent microvessels. The average microvessel counts in the three fields under high magnification (× 200) were recorded as the final value of MVD.

Statistical analysis

All statistical analyses were performed using the SPSS software suite, version 17.0 (SPSS, Chicago, IL, United States). χ^2 test was used to assess the correlations between KLF8 protein expression and clinicopathologic factors. The relationship between KLF8 protein expression and MVD was determined by Spearman's correlation coefficient test. Survival curves were calculated by the Kaplan-Meier method, and the significance of intergroup differences in survival was determined by log-rank test. Multivariate survival analysis based on the Cox proportional hazard model was carried out to identify the significant independent prognostic factors. A P value < 0.05 was considered statistically significant.

RESULTS

Correlation of KLF8 expression with clinicopathologic factors

Immunohistochemical analyses of the 154 gastric cancer tissues and 50 adjacent non-cancerous tissues showed KLF8 protein staining of various intensities in both the nuclear and cytoplasmic compartments. Overall, 54.5% (84/154) of the gastric cancer tissues showed KLF8-positivity, including 25.3% which were strongly positive and 29.2% which were weakly positive, and only 34.0% (17/50) of the adjacent non-cancerous tissues showed KLF8-positivity. The difference in KLF8 staining between the gastric cancer and adjacent normal tissues was statistically significant ($P < 0.05$). Figure 1 shows representative cases with different expression levels of KLF8 protein. Moreover, as shown in Table 1, KLF8-positivity was significantly related to tumor size, local invasion,

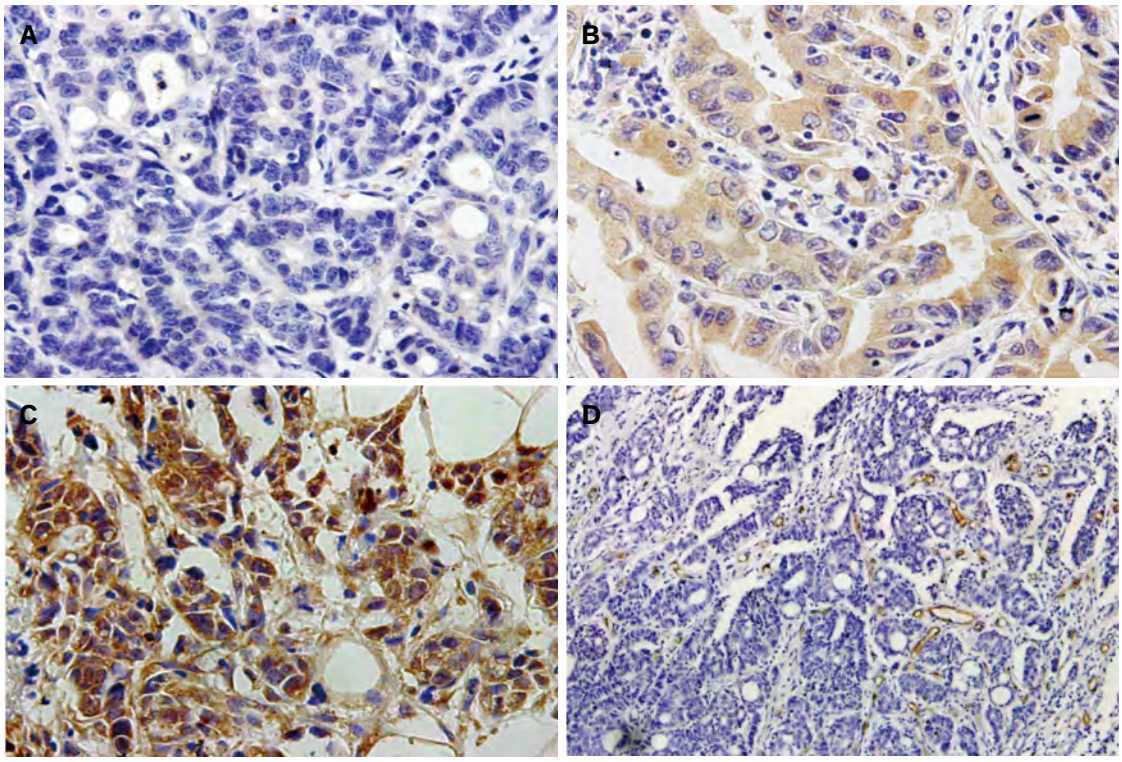

Figure 1 Immunohistochemical staining of Krüppel-like factor 8 and CD34 in gastric cancer specimens. A: Negative expression of Krüppel-like factor 8 (KLF8) in cancer cells; B: Weakly positive expression of KLF8 in cancer cells; C: Strongly positive expression of KLF8 in cancer cells; Magnification: × 400; D: Intratumoral microvessels detected by anti-CD34 antibody (brown) in gastric cancer tissues; Magnification: × 200.

regional lymph node metastasis, distant metastasis, and TNM stage (all $P < 0.05$); however, no significant associations were detected for KLF8 expression with patient sex, age, or degree of tumor differentiation (all $P > 0.05$).

Correlation of KLF8 expression with tumor angiogenesis

As shown in Figure 1D, the intratumoral MVD was determined by CD34 immunohistochemical staining. The MVD values of the 154 cancer specimens ranged from 14 to 62 (mean, 32.0 ± 8.8). When this mean value was applied as a cut-off point, 86 cases (55.8%) were categorized as low MVD (< 32) and 68 cases (44.2%) were categorized as high MVD (≥ 32). KLF8 expression was found to be significantly positively correlated with MVD ($r = 0.392$, $P < 0.001$; Table 2).

Prognostic significance of KLF8 expression in gastric cancer

Of the 154 patients, 101 (65.6%) cases died during the follow-up period. Among them, the majority ($n = 97$) died from cancer-related causes, and four cases died from other causes. The 5-year overall and cancer-specific survival rates were 34.4% and 35.3%, respectively.

Kaplan-Meier analysis indicated that KLF8 expression was significantly associated to the survival of gastric cancer patients. The overall 5-year survival rate of patients with KLF8-positive expression was significantly shorter than those with KLF8-negative expression ($P < 0.001$; Figure 2A). Consistent with this trend, the patients with KLF8-positive expression also had a poorer 5-year cancer-specific survival ($P < 0.001$; Figure 2B). In addition, we compared the prognostic value of KLF8 strongly positive expression to that of weakly positive expression, and found that there was no significant difference between the two groups for either overall survival ($P = 0.116$) or cancer-specific survival ($P = 0.224$). Multivariate analysis using Cox regression indicated that KLF8-positive expression in gastric cancer was a significant independent prognostic factor for both overall survival (95%CI: 1.035-2.539, $P = 0.035$) and cancer-specific survival (95%CI: 1.017-2.554, $P = 0.042$) (Table 3).

DISCUSSION

Surgical resection is the most effective treatment for gastric cancer patients with curative potential, yet the clinical outcomes of these patients are generally poor, largely due to a high ratio of postoperative metastasis or recurrence[24]. In China, the overall 5-year survival rate of gastric cancer patients is only about 40%[25]. Identification of novel biomarkers that can be used as prognostic predictors or therapeutic targets will likely benefit these patients and help to ease the burden of this disease. Aberrant expression of KLF8 has been detected in several types of human malignant tumors and closely associated with oncogenic transformation and tumor progression[10-15]. To the best of our knowledge, however, the study described herein is the first to evaluate the clinicopathologic and prognostic significance of KLF8 in gastric cancer patients.

Our findings confirmed the remarkable up-regulation

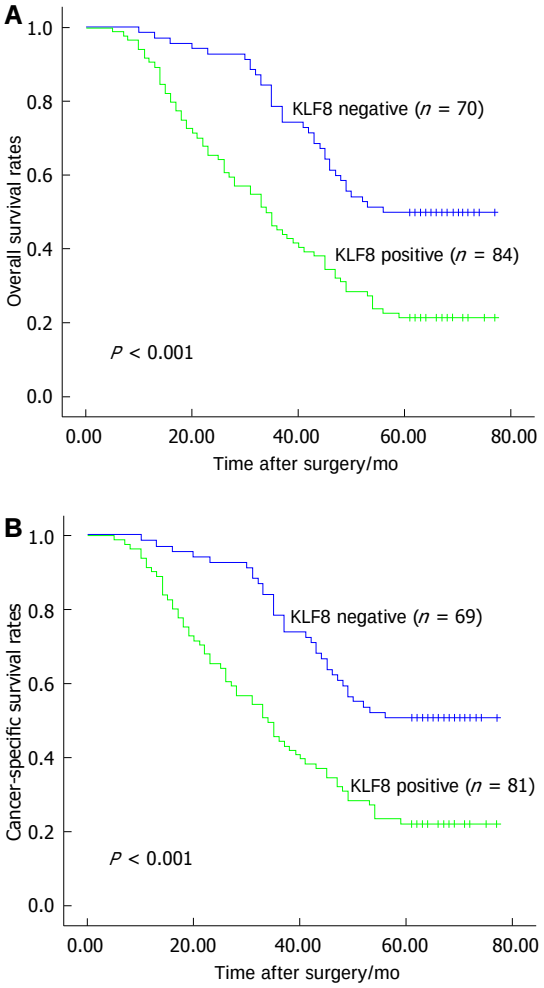

Figure 2 Kaplan-Meier survival curves of overall and cancer-specific survival in gastric cancer patients based on Krüppel-like factor 8 expression. Patients with Krüppel-like factor 8 (KLF8)-positive (weakly and strongly) expression had poorer overall (A) and cancer-specific (B) survival as compared to those with KLF8-negative expression.

of KLF8 in gastric cancer tissues and indicated significant associations for KLF8 expression with prognosis-related features, including tumor size, local invasion, regional lymph node metastasis, distant metastasis, and TNM stage. Thus, it is likely that KLF8 plays important roles in gastric cancer progression. Consistent with our results, previous study of renal cell carcinoma has shown that overexpression of KLF8 is strongly associated with larger tumor size and higher clinical stage[14]. However, future studies are still needed to investigate the detailed mechanism of KLF8-mediated gastric cancer progression.

Predicting the clinical outcomes of patients with malignant tumors may provide valuable information for better treatment stratification and personalized therapeutic regimens. Previous study demonstrated that KLF8 overexpression was significantly related with early tumor recurrence and poor prognosis in hepatocellular carcinoma[11]. However, no clinical data has indicated the potential benefit of KLF8 as a biomarker for predicting prognosis of gastric cancer patients. In the current study, multivariate survival analysis based on the Cox proportional hazard model revealed that, among all the factors analyzed, KLF8 expression was a significant independent prognostic factor for both overall and cancer-specific survival of gastric cancer patients following curative resection. These findings clearly demonstrate that aberrant expression of KLF8 may be closely associated with gastric cancer progression in our patient cohort, and suggest its potential as a prognostic biomarker of gastric cancer outcome.

Table 2 Correlations between Krüppel-like factor 8 expression and the microvessel density in gastric cancer

MVD	KLF8 expression		*P* value	*r*
	Negative	Positive		
Low	54	32	< 0.001	0.392
High	16	52		

KLF8: Krüppel-like factor 8; MVD: Microvessel density.

It is well known that tumors are endowed with angiogenic capability, and their growth, invasion, and metastasis are angiogenesis-dependent[26]. The survival rate of patients with highly-vascularized gastric cancer is significantly lower than those with less-vascularized gastric cancer[27]. The findings from the current study indicated a close correlation between KLF8-positivity in tumor specimens and the extent of intratumoral MVD (as determined by CD34 staining), suggesting that KLF8 may facilitate tumor progression *via* induction of angiogenesis. Therefore, KLF8 may represent a potential novel target of anti-angiogenic therapy for gastric cancer patients. It is important to note, however, that tumor angiogenesis is a complex process involving dynamic interplay of various factors[28], and further studies are needed to elucidate the detailed molecular mechanisms underlying KLF8-mediated tumor angiogenesis before the precise molecular targets of KLF8 are identified and used to develop an optimal treatment for gastric cancer patients.

When interpreting the results presented herein, several inherent limitations to the study design must be considered. First, only gastric cancer patients who underwent curative resection were enrolled in the present study, which restricted the total study population to a relatively low number. Second, the retrospective design provided only previously resected human gastric cancer tissues that were not originally collected with the intent of detecting the prognostic value of KLF8. To address this limitation, multicenter, randomized studies should be conducted to confirm whether KLF8 can be used as an accurate prognostic maker for gastric cancer. In addition, the impact of postoperative adjuvant therapy on prognosis was not evaluated in this study, due to the fact that some gastric cancer patients received different therapeutic regimens (*i.e.*, agents, doses, and cycles of treatment), and not all patients completed the adjuvant therapy because of severe side effects or economic-related restrictions.

In conclusion, this study confirmed the up-regulated expression of KLF8 in gastric cancer tissues and, for

Table 3 Multivariate analysis of prognostic factors in patients with gastric cancer

Variables	Multivariate analysis					
	Overall survival			Cancer-specific survival		
	RR	95%CI	*P* value	RR	95%CI	*P* value

MVD	2.801	1.790-4.381	0.000	2.782	1.751-4.419	0.000

KLF8: Krüppel-like factor 8; MVD: Microvessel density; TNM: Tumor node metastasis.

the first time, demonstrated its clinicopathologic and prognostic significance. Specifically, positive expression of KLF8 was shown to be significantly correlated with enhanced malignant potential, tumor angiogenesis, and poor prognosis. Furthermore, Cox regression model analysis showed that KLF8-positivity in resected gastric tumors was a meaningful independent prognostic factor for both overall and cancer-specific survival. Collectively, these findings demonstrate that KLF8 may have clinical potential not only as a prognostic marker, by which individuals with risk of poor clinical outcome may be identified, but also as a novel target for anti-angiogenic therapy of gastric cancer patients.

ACKNOWLEDGMENTS

The authors wish to thank Cheng-Jun Zhou (Department of Pathology, The Second Hospital, Shandong University) and Jun-Hui Zhen (Department of Pathology, Qilu Hospital, Shandong University) for their excellent immunostaining evaluation. The authors are also grateful to Shu-Hai Li (Department of Thoracic Surgery, Qilu Hospital, Shandong University) for his expert commentary on the manuscript.

COMMENTS

Background

Gastric cancer remains one of the most common malignancies worldwide, and accounts for the second highest rate of cancer-related death. Despite recent advances in comprehensive therapeutic strategies, the clinical outcome of gastric cancer patients remains poor, mainly due to delayed clinical presentation and a high ratio of postoperative metastasis or recurrence. Therefore, it is necessary to identify novel biomarkers that can be used as prognostic indicators or therapeutic targets for gastric cancer patients.

Research frontiers

Aberrant expression of Krüppel-like factor 8 (KLF8) has been detected in several types of human malignant tumors, including those of ovarian, renal and breast origin. Considerable evidence has indicated that KLF8 expression is closely associated with oncogenic transformation and tumor progression. One previous study showed that lentivirus-mediated interference of KLF8 expression significantly decreased tumor vessels in a mouse model of liver cancer. However, the angiogenic property and prognostic significance of KLF8 in gastric cancer has not been fully elucidated.

Innovations and breakthroughs

In this study, KLF8 expression and microvessel density (MVD) were assessed by immunohistochemical analysis of resected tumors from patients with gastric cancer. Results indicated that the level of KLF8 was significantly higher in gastric cancer tissues than in adjacent non-cancerous tissues. Moreover, the high KLF8 expression was found to be closely associated with prognosis-related features, including tumor size, local invasion, regional lymph node metastasis, distant metastasis, and TNM stage. KLF8-positive expression in tumor specimens was significantly positively correlated with MVD. Patients with KLF8-positive expression had poorer overall and cancer-specific survival than those with KLF8-negative expression. Multivariate analysis demonstrated that the KLF8 expression in tumors independently affected both overall and cancer-specific survival of gastric cancer patients.

Applications

Collectively, the findings from this study demonstrate that KLF8 may have clinical potential not only as a prognostic biomarker, by which individuals with risk of poor clinical outcome may be identified, but also as a novel target for anti-angiogenic therapy of gastric cancer patients.

Terminology

KLF8, which is located on Xp11.21, was initially identified as a ubiquitously expressed transcriptional repressor belonging to the KLF family of transcription factors. Like other members of the KLF family, KLF8 shares three conserved C2H2 zinc finger DNA-binding domains in its C-terminus, but harbors a unique sequence in the N-terminus that is thought to mediate its functional specificity through interactions with other proteins.

Peer review

The authors demonstrated that KLF8 was significantly up-regulated in clinical specimens of gastric cancer, and evaluated its angiogenic property and prognostic significance. The results suggest that KLF8 may represent a novel prognostic biomarker and therapeutic target for gastric cancer.

Abstract

AIM: To investigate the clinical value of endoscopic papillectomy indicated by feasibility and safety of the procedure in various diseases of the papilla in a representative number of patients in a setting of daily clinical and endoscopic practice and care by means of a systematic prospective observational study.

METHODS: Through a defined time period, all consecutive patients with tumor-like lesions of the papilla, who were considered for papillectomy, were enrolled in this systematic bicenter prospective observational study, and subdivided into 4 groups according to endoscopic and endoscopic ultrasonography (EUS) findings as well as histopathological diagnosis: adenoma; carcinoma/neuroendocrine tumor (NET)/lymphoma; papilla into which catheter can not be introduced; adenomyomatosis, respectively. Treatment results and outcome were characterized by R0 resection, complication, recurrence rates and tumor-free survival.

RESULTS: Over a 7-year period, 58 patients underwent endoscopic papillectomy. Main symptoms prompting to diagnostic measures were unclear abdominal pain in 50% and cholestasis with and without pain in 44%. Overall, 54/58 patients [inclusion rate, 93.1%; sex ratio, males/females = 25/29 (1:1.16); mean age, 65 (range, 22-88) years] were enrolled in the study. Prior to papillectomy, EUS was performed in 79.6% (*n* = 43/54). Group 1 (adenoma, *n* = 24/54; 44.4%): 91.6% (*n* = 22/24) with R0 resection; tumor-free survival after a mean of 18.5 mo, 86.4% (*n* = 19/22); recurrence, 13.6% (*n* = 3/22); minor complications, 12.5% (*n* = 3/24). Group 2 (carcinoma/NET/lymphoma, *n* = 18/54; 33.3%): 75.0% (*n* = 10/18) with R0 resection; tumor-free survival after a mean of 18.5 (range, 1-84) mo, 88.9% (*n* = 8/9); recurrence, 11.1% (*n* = 1/9). Group 3 (adenomyomatosis, *n* = 4/54; 7.4%). Group 4 (primarily no introducible catheter into the papilla, *n* = 8; 14.8%). The overall complication rate was 18.5% (*n* = 10/54; 1 subject with 2 complications): Bleeding, *n* = 3; pancreatitis, *n* = 7; perforation, *n* = 1 (intervention-related mortality, 0%). In summary, EUS is a sufficient diagnostic tool to preoperatively clarify diseases of the papilla including suspicious tumor stage in conjunction with postinterventional histopathological investigation of a specimen. Endoscopic papillectomy with curative intention is a feasible and safe approach to treat adenomas of the papilla. In high-risk patients with carcinoma of the papilla with no hints of deep infiltrating tumor growth, endoscopic papillectomy can be considered a reasonable treatment option with low risk and an approximately 80% probability of no recurrence if an R0 resection can be achieved. In patients with jaundice and in case the catheter can not be introduced into the papilla, papillectomy may help to get access to the bile duct.

CONCLUSION: Endoscopic papillectomy is a challenging interventional approach but a suitable patient- and local finding-adapted diagnostic and therapeutic tool with adequate risk-benefit ratio in experienced hands.

Key words: Papilla of Vater; Papillectomy; Endoscopic ultrasonography; Adenoma; Carcinoma; Carcinoid-like tumor; Adenomyomatosis

Core tip: Taken together, endoscopic ultrasonography is an essential and sufficient diagnostic tool and plays an eminent role in the diagnostic spectrum to preoperatively clarify lesions and diseases of the papilla in conjunction with the competent postinterventional histopathological investigation of a specimen. Endoscopic papillectomy with curative intention is a feasible and safe approach to treat adenomas of the papilla, *i.e.*, it is only reasonable if there is no infiltrating tumor growth. In high-risk patients with carcinoma of the papilla but no hints of deep infiltrating tumor growth, endoscopic papillectomy can be considered a reasonable treatment option with reduced risk and an approximately 80% probability of no recurrence if an R0 resection can be achieved. In patients with jaundice and in case the catheter can not be introduced into the papilla, papillectomy may help to get access to the bile duct to avoid more traumatic surgery. Endoscopic papillectomy is therefore not only used for therapeutic but also for diagnostic purpose. There is a high clinical value of endoscopic papillectomy for well defined indications not only for adenoma but also for carcinoma/neuroendocrine tumor/lymphoma (uT1 and high-risk patient), and adenomyomatosis. Follow-up investigations according to a defined schedule appear to be reasonable including macroscopic assessment, taking a representative biopsy and subsequent histopathological investigation. In addition, continuous systematic investigation of endoscopic papillectomy in daily clinical practice is indicated for the purpose of quality assurance.

INTRODUCTION

The adequate management of diseases of the papilla of Vater (papilla) is challenging. There are several morphological changes and lesions of the papilla such as functional dysfunction, inflammation, stenosis or malignant tumor growth. For instance, a stenosis of the papilla is subdivided based on an autopsy registry as follows: Benign lesions, 42.7% (frequency); adenoma (premalignant lesion), 19.6%; carcinoma, 37.7%[1].

The incidence of malignant tumor lesions of the papilla has been reported to be 0.5/100000. Based on the concept of an anticipated adenoma-carcinoma sequence even at the papilla[2,3], adenoma is considered a premalignant tumor lesion[4-7], *e.g.*, adenomatous portions can be found in 35% to 91% of the histologically detected carcinomas. In this context, the incidence of an occurring carcinoma in papillary adenoma is 1 over 15.5 patient years.

Diagnostic measures of pathological changes at the papilla are a complex challenge since a differential and stage-adapted treatment depends on the early set-up of the correct diagnosis. Combination of clinical exam, laboratory parameters and abdominal ultrasound provides a sensitivity of up to 100% to diagnose cholestasis. However, the accuracy in characterizing the cause of cholestasis is considerably lower.

Endoscopic ultrasonography (EUS) may solve the dilemma since it allows to clarify etiopathogenesis and actual diagnosis in the vast majority of cases[1]. In addition, this diagnostic measure provides a sensitivity of up to 100% in detecting tumor-like lesions at the papilla or within the peripapillary region and, in addition, it enables the investigator to characterize tumor infiltration status and possible involvement of lymphatic tumor growth according to TNM staging[8]. Furthermore, taking a biopsy becomes possible by an adequate imaging.

Whether in case of a tumor lesion of the papilla, endoscopic intervention such as papillectomy or surgical intervention is used depends on tumor entity, tumor stage and individual characteristics of the patient[9-11].

Today, the spectrum of indications for endoscopic papillectomy comprises adenoma, carcinoma of stage uT1N0[12-18], neuroendocrine tumor (NET)[8,19,20], non-introducible catheter into the papilla[21], cholestasis and diagnostic purpose. Ponchon *et al*[22] reported on endoscopic papillectomy and Binmoeller *et al*[9] for the first time. Further therapeutic options in adenoma are kephal pancreaticoduodenectomy and local surgical resection (ampullectomy) *via* a transduodenal approach. But in case of resectable carcinoma of the papilla, surgical intervention is the treatment of choice since there is a probability of approximately 20%-40% of manifest lymph node metastases if there is a submucosal infiltration.

The aim of the study was to investigate the clinical value of endoscopic papillectomy indicated by feasibility[16] and safety of the procedure in various diseases of the papilla in a representative number of patients in a setting of daily clinical and endoscopic practice and care by means of a systematic prospective observational study, to balance advantages and disadvantages of the endoscopic approach, as well as, in particular, to elucidate: (1) Which were the main and propper indications? (2) What results of resections could be achieved? or (3) What was the long-term outcome in various diseases of the papilla?

MATERIALS AND METHODS

Through a defined time period, all consecutive patients with tumor-like lesions of the papilla who were selected for an endoscopic approach, were enrolled in this systematic bicenter prospective observational study (design). In addition to physical exam and laboratory analysis, the patients underwent upper gastrointestinal (GI) endoscopy including EUS. Endoscopic papillectomy (modified

procedure according to Han and Kim[23]) was chosen in case of promising potential for R0 resection, in uT1 lesions with no hints of deep infiltrating tumor growth and/or in high-risk patients (balancing risk-benefit ratio of open surgery) after appropriate diagnostics (imaging and/or biopsy) and additional decision-making in the institutional multi-disciplinary GI tumor board. It was performed by only 2 experienced interventional endoscopists as follows, in brief: Patients underwent papillectomy during upper GI endoscopy after signing informed consent the day before intervention, in particular, containing information on risk, complication profile and major complications such as acute pancreatitis, perforation and bleeding as well as necessary follow up and prognosis of each specific procedure as appropriate, "npo" for 12 h, and premedication with 5-10 mg Midazolam (Midazolam Ratioph®, Ratiopharm GmbH, Ulm, Germany) under antibiotic prophylaxis with ceftriaxone (Rocephin®, 2 g; Hoffmann-La Roche AG, Grenzach-Wyhlen, Germany) and cardiopulmonal monitoring.

Using a duodenoscope [Olympus Optical Co. (Europe) GmbH, Hamburg, Germany], peripapillary region was endoscopically inspected (Figures 1 and 2) eventually completed by diagnostic EUS (Hitachi Medical Systems, Lübbecke, Germany) (Figure 2B), and cholangiography was performed if possible (catheter which can be introduced into the papilla). Papillectomy was executed using high frequency diathermia loop (MTW Endoskopie, Wesel, Germany) (Figure 1C and D). If required, sphincterotomy using papillotome [Olympus Optical Co. (Europe) GmbH, Hamburg, Germany] to prevent postinterventional stenosis; stent implantation into the pancreatic duct

Table 1 Spectrum and frequency of preinterventional endoscopic investigations in the whole group of patients with following endoscopic papillectomy (n = 54)

(5-French plastic endoprosthesis; GIP Medizintechnik GmbH, Achenmühle, Germany) for 4-5 d to drain the pancreas sufficiently because of possible postinterventional swelling of the papilla and peripapillary region[24]; and/or APC (Erbe APC, Medika, Hof, Germany), in particular, to encrust tumor residuals with electrocoagulation were combined. Bleedings were immediately tried to be controlled as appropriate using adrenalin injection (dilution, 1:10000), fibrin glue application (Baxter Deutschland GmbH, Heidelberg, Germany) and/or placement of hemoclips [Olympus Optical Co. (Europe) GmbH, Hamburg, Germany]. Specimens were immediately transferred to routine histopathological investigation (Figure 2C) and followed by specific stainings and/or immunohistochemistry if necessary.

Data such as clinicopathological features (age, sex, gender, symptomatology leading to initiation of diagnostic, diagnostic profile and findings, spectrum of diagnoses, tumor size, TNM stage and occurrence of metastases in case of malignancy, profile of indications for papillectomy) were prospectively collected, documented using a computer-based registry and retrospectively evaluated using SPSS for Windows (version 13.0, Chicago, IL, United States).

The patients were subdivided into 4 groups according to endoscopic and EUS findings as well as the histopathological diagnosis: Group 1: Adenoma; Group 2: Carcinoma/NET/lymphoma; Group 3: Papilla into which catheter can not be introduced; Group 4: Adenomyomatosis.

Treatment results were characterized by R0 resection and complication rate, the latter one further specified by periinterventional morbidity and intervention-related mortality. Outcome was assessed by recurrence rate as well as general and tumor-free survival after a long-term period of follow-up investigations which were performed using clinical exam, abdominal ultrasound and endoscopy with biopsy as well as EUS (if required) every 3-6 mo for 2 years followed by time intervals of 6 mo in cases of adenomas and malignant tumor growth (but immediately if required and indicated by suspicuous symptomatology).

Study was performed according to the guidelines of the Declaration of Helsinki for Biomedical Research from 1964 and the standards of the Institutional Review Board.

Statistical analysis

Data were evaluated by descriptive statistics and further analyzed using SPSS for Windows (version 13.0, Chicago, IL, United States) to proof validity of the preinterventional histopathological diagnosis by means of binary diagnostic tests such as 2 × 2 square panel, which allows to determine sensitivity, specificity, negative and positive predictive values as appropriate.

RESULTS

Through a 7-year study period, endoscopic papillectomy was performed in 58 patients at the Departments of Gastroenterology of the University Hospital in Jena (Germany) and the Municipal Hospital in Gera (Germany). Overall, 54 patients were evaluated (inclusion rate, 91.6%; 25 males (M), 29 females (F); sex ratio, M/F = 1:1.16). The mean age was 64.4 years in males, in females 67 years (range, 22-88 years).

The main clinical symptoms were predominated by abdominal pain in 50% of cases followed by cholestasis in 33%. The combination of both was found in 11% (others, 6%).

All tumors were detectable, imaged and characterized with regard to the locoregional tumor growth using various diagnostic tools (detection rate, 100%). Tumor size ranged between 1 and 4.5 cm. The spectrum and frequency of endoscopic investigations to proof the indication of endoscopic papillectomy is shown in Table 1. It clearly shows that EUS was the most frequent endoscopic procedure in more than half of cases (79.6%). Endoscopic retrograde cholangiopancreatography (ERCP) was only used in less than 50% of patients (44.8%; gastroscopy, 51.8%). Interestingly, gastroscopy contributed to achieve a histopathological finding by taking a biopsy in the majority of cases.

Histopathological diagnosis was determined in 32 patients in whom preinterventional histopathological investigation was performed which was distributed as indicated in Table 2 whereas slightly different, there was a profile and frequency of indications, which led to endoscopic papillectomy as a result of preinterventional diagnostic measures (n = 54; Table 2), and finally endoscopic papillectomy with subsequent histopathological investigation resulted in the distribution of definitive histopathological diagnoses as listed in Table 2 (n = 54).

This resulted in a cumulative sensitivity and specificity for preinterventional histopathological findings such as adenoma and carcinoma/NET/lymphoma of 64.2% and 55.0%, respectively. The negative and positive predictive values were 65.5% and 56.5%, respectively. Interestingly and in combining the diagnoses adenoma and carcinoma/NET/lymphoma in the preinterventional diagnostic measures, there were a sensitivity of 64.2%, a specificity of 65.5%, a negative predictive value of 65.5% and a positive predictve value of 56.5%, respectively, for the preinterventional diagnostic measures (Table 3).

In adenomas (patient group 1, Table 4), there was a tumor recurrence rate of 13.6% (n = 3/22). Interestingly, there were two cases in whom no R0 resection was achieved but aspects of recurrent adenomatous tumor

Table 4 Characteristics of adenoma patients after endoscopic papillectomy *n* (%)

	Adenoma					
	In total	Resectiom status				
		R0	Rx	R0 + Rx	R1	R2
Case	24	9 (37.5)	13 (54.2)	22 (91.6)	1 (4.2)	1 (4.2)
Recurrence		1 (11.1)	2 (15.4)	3 (13.6)		

Rx, resection status could not be defined because of loss of specimen or no detectable adenoma cells in the resected specimen despite adenoma finding in the histopathological investigation of the preinterventional biopsy. Recurrence, only related to "R0 + Rx" according to the definition of recurrent tumor growth, namely, tumor-free resection area.

Table 5 Characteristics of patients with a malignant tumor lesion (adenocarcinoma, neuroendocrine tumor and lymphoma) after endocopic papillectomy *n* (%)

	In total	Resection status				
		R0	Rx	R0 + Rx	R1	R2
All stages						
Case	18	8 (44.4)	2 (11.1)	10 (55.5)	1 (5.5)	7 (38.8)
Recurrency		1 (12.5)	1 (50.0)	2 (20.0)		
T1 stage only						
Case	12	8 (66.7)	1 (8.3)	9 (75.0)	1 (8.3)	2 (16.6)
Recurrence		1 (12.5)	0 (0.0)	1 (11.1)		

Rx, resection status could not be defined because of loss of specimen or no detectable adenoma cells in the resected specimen despite adenoma finding in the histopathological investigation of the preinterventional biopsy. Recurrence, only related to "R0 + Rx" according to the definition of recurrent tumor growth, namely, tumor-free resection area.

growth have not been observed yet during the follow-up investigation period. Recurrent adenomas were re-approached using endoscopic papillectomy with good success.

Considering all patients with malignant tumor growth, *i.e.*, all tumor lesions and stages (Table 5; patient group 2; *n* = 18:13 patients with adenocarcinoma, 4 individuals with NET, and one subject with a lymphoma), there was a recurrence rate of 20.0% [*n* = 2/10 (R0 + Rx)] after a mean follow-up investigation period of 18.5 (range, 1-84) mo. The two cases out of ten with recurrent carcinoma were transfered to abdominal surgery with favorable outcome. According to the results listed in Table 5, 12 patients with the more relevant uT1 carcinoma for a minimally invasive, endoscopic approach underwent endoscopic papillectomy with curative intention, in whom R0 resection status was achieved in 9 patients (75%) while no tumor recurrence was found in 88.9% of patients (*n* = 8/9). The one patient with R1 and the seven patients with R2 resection status were re-approached using Argon beamer with a good long-term result (no recurrent tumor growth within the reported follow-up investigation period). Rescue surgical intervention did not become necessary in case of R1/R2 resection since all of these patients had been classified of high perioperative risk.

In cases of a papilla into which catheter can not be introduced (*n* = 8; patient group 3) for which there are no data from the literature, the catheter placement was achieved in 87.5% (*n* = 7/8) of cases after endoscopic papillectomy. A re-intervention because of a stent occlusion became necessary in 2 patients (no table shown).

If an adenomyomatosis (*n* = 4) was diagnosed (patient group 4), there was a successful papillectomy in 100% of cases with no necessary reinterventions (again, no table shown).

Overall, there was a successful endoscopic papillectomy with regard to R0/Rx resection and/or placement of a catheter into the papilla in case of former not introducible catheter in 87.5% (*n* = 42/48) according to technical success rate, but related to no tumor recurrence

Table 6 Number and percentage of complications depending on the tumor entity and/or indication for endoscopic papillectomy *n* (%)

	Case (*n*)	Complications
Adenoma	24	3 (12.5)
Carcinoma/NET/lymphoma	18	3 (16.6)
Papilla into which catheter can not be introduced	8	2 (25.0)
Adenomyomatosis	4	2 (50.0)
In total	54	10 (18.5)
Major complication		1 (1.9)

NET: Neuroendocrine tumor.

and/or placement of a catheter into the papilla in 79% (n = 38/48) according to clinical success rate. The basis for this calculation was the number of 48 patients since there were 6 patients with a tumor stage T > 1Nx (Table 5; n = 18 min n_{uT1} = 12).

As shown in Table 6, complications occured in 18.5% (n = 10/54), in particular, bleeding (n = 3); pancreatitis (n = 7) and perforation (n = 1; the only case with need for rescue surgical intervention) (Table 6), in 12.5% (n = 3/24) of adenoma patients (Table 6) but no postinterventional stenosis of the orifice at the papilla was observed (major complication rate, 1.9%; n = 1/54; Table 6). There was no intervention-related death (mortality, 0%).

DISCUSSION

In addition to clinical exam, laboratory analysis, and abdominal ultrasound, EUS[8] and ERCP[25,26] are the appropriate diagnostic measures for suspected tumor (-like) lesions of the papilla. Furthermore, magnetic resonance cholangiopancreatography, magnetic resonance imaging and/orcomputed tomography can be performed to further assess local tumor growth including possible tumor infiltration to the neighboring organs and to detect distant metastases (suggested institutional diagnostic algorithm including therapeutic measures, Figure 3). However, EUS appears to be the best diagnostic tool, which is able to reliably predict the correct diagnosis with a high percentage prior to papillectomy[1].

In a suspected local tumor lesion, a papillectomy can be helpful to clarify the diagnosis, in particular, in getting access to the obstructed bile duct; to remove a representative specimen; or to even provide adequate resection[9,10,24] since in non-clear benign or malignant tumor growth, an early, correct and reliable diagnosis-finding allows an appropriate subsequent therapeutic decision-making according to differential diagnosis and stage of disease[2].

Interestingly, a curative resection is possible by the means of minimally invasive endoscopic intervention under certain circumstances such as adenoma of smaller size[5-7,9,10,24] and uT1 carcinoma[12] with no hints of deep infiltrating tumor growth if R0 resection status can be achieved or in high-risk patients[6] though carcinoma is usually an indication for surgical intervention[2].

Also in case of a catheter which can not be introduced into the papilla (into the minor papilla[27] if there is a suspected "pancreas divisum" or into the major papilla after previous gastric resection [Billroth Ⅱ] or because of a carcinoma of the papilla[12]) and even if an adenomyomatosis is detected, there is need for endoscopic papillectomy since, on one hand, access to the pancreaticobiliary system is needed and, on the other hand, adenomyomatosis can not be macroscopically distinguished from an adenoma.

If an R0 resection was achieved, recommended follow-up investigation periods are every 6 mo for 2 years followed by further endoscopic control in case of suspicious symptoms[2]. In addition, a colonoscopy is basicly recommended. If there is an incomplete resection of an adenoma, the case needs to be controlled within 2-3 mo.

Interestingly, complication rate was similar or lower than those reported in the literature[4,9,13,14,16-19,25].

The tumor recurrence rate of 20.0% [n = 2/10 (R0 + Rx); Table 5] appears well comparable with data from the literature (Bohnacker *et al*[5], 15%)[10,13,14,16-18,25] as well as within the range of results in local surgical resection and kephal pancreatoduodenectomy.

The endoscopic approach in uT1 carcinoma (n_{uT1} = 12 out of n = 18 including all tumor stages, Table 5) correlates with recommendations of specific guidelines that endoscopic papillectomy can be reasonable in patients with uT1 and increased perioperative risk because of considerable comorbidity[2,6,10,12].

To our knowledge, this is one of the rare reports on the systematic investigation of endoscopic papillectomy in suspicious tumor lesions of the papilla in a representative number of patients[4,9,10,19,22,25] and their variety of tumor (-like) lesions as shown since there is a lack of extensive experiences because of their low incidence and the fact that optimal management of such tumor lesions has not yet been established[28].

The results justify endoscopic papillectomy as a reasonable, suitable and safe therapeutic measure in experienced hands[2,4,9,13-19,24] for the management of the broad spectrum of possible findings at the papilla or the minor papilla[27] in our institution and as occuring in daily clinical practice.

Finally, endoscopic papillectomy is considered a reasonable alternative to the "precut" or to PTCD. For comparison, endoscopic drainage provides a success rate of 95.4% (mortality, 0%) in acute cholangitis according to the literature whereas surgical intervention is associated with a lower success rate of 58% but a mortality of up to 12.4%.

However, there are limitations of the study with regard to the overall treatment results, which can be related to: the impact of the learning curve despite only two experienced interventional endoscopists performed papillectomy; the pitfalls of papillectomy such as potential of no achievable R0 resection despite curative intention, and the complication profile (including bleeding and perfora-

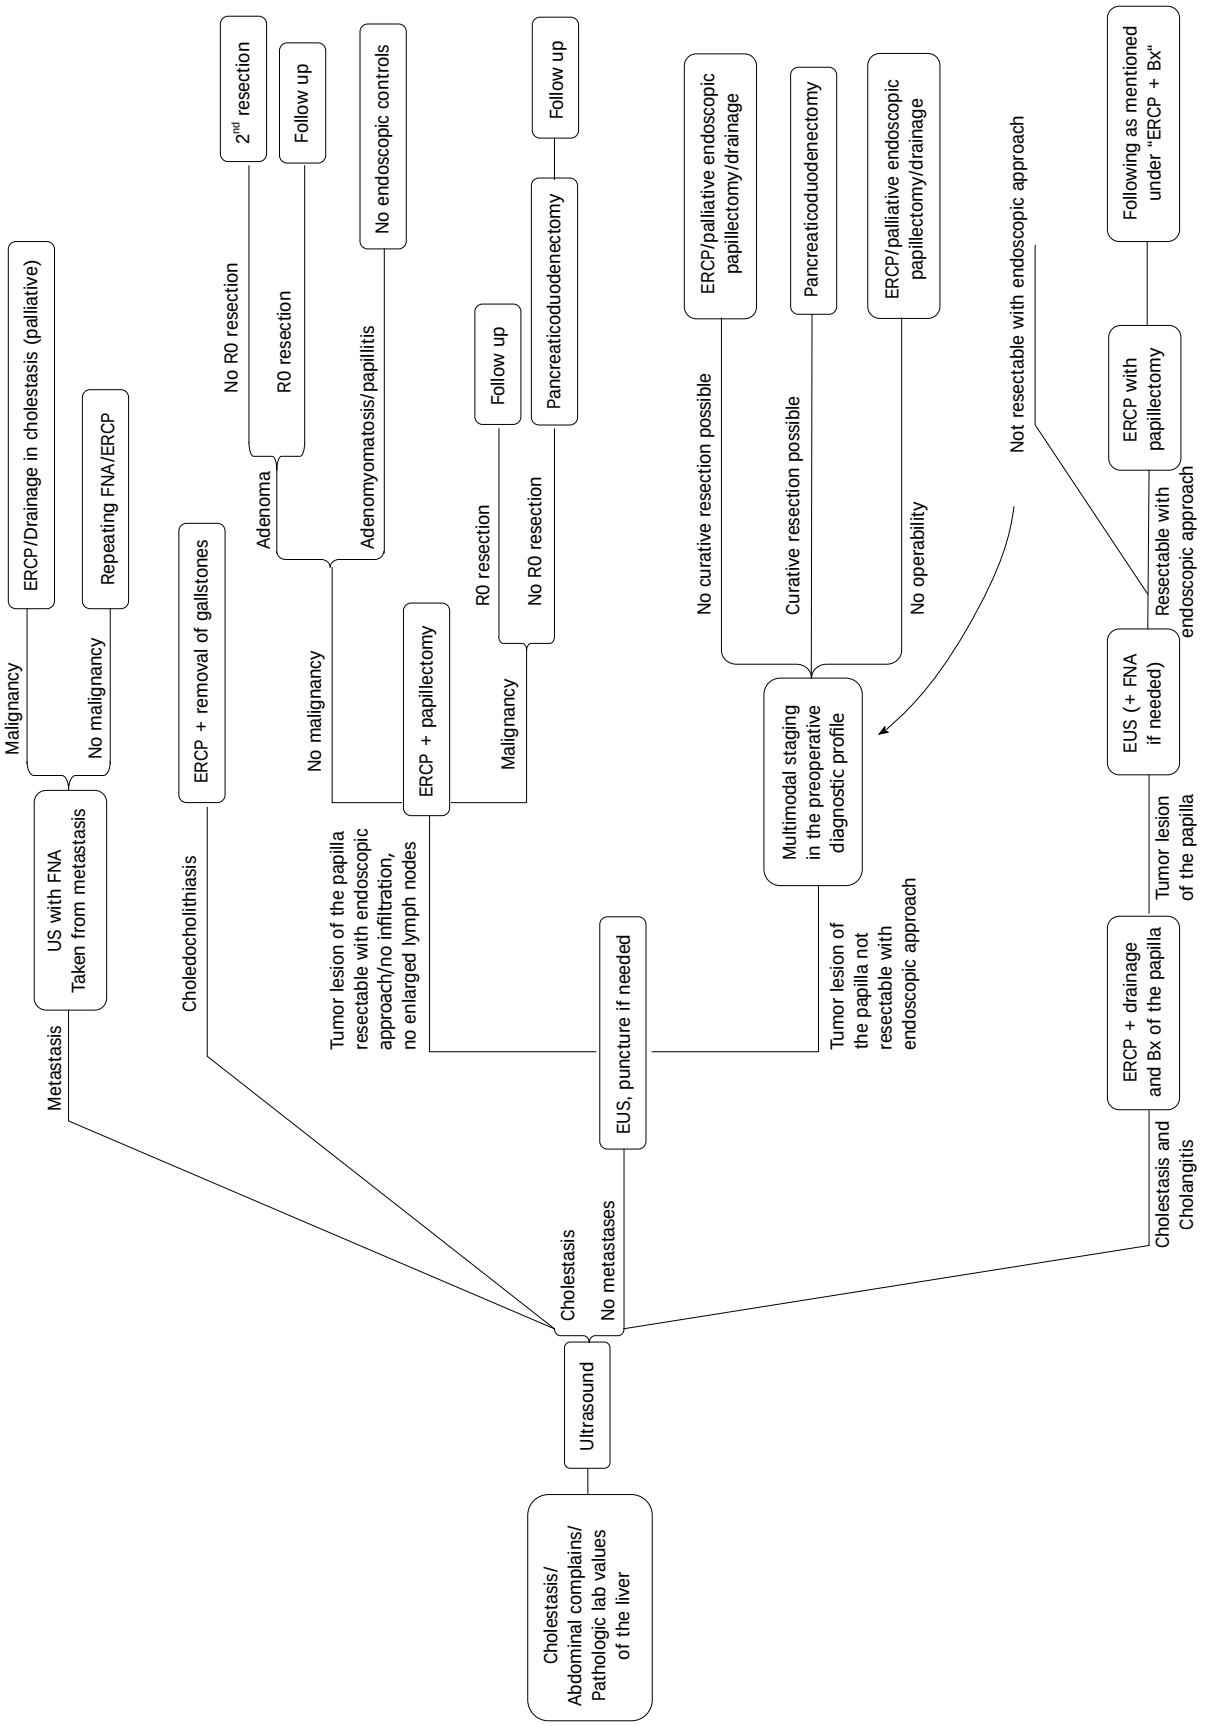

Figure 3 Suggested institutional algorithm on the diagnostic and therapeutic endoscopic approach in suspicious tumor-like lesions of the papilla of Vater. ERCP: Endoscopic retrograde cholangiopancreatography. EUS: Endoscopic ultrasonography.

tion with possible need of surgery); and no strict study inclusion criteria since study design represents a "systematic prospective bicenter observational study" reflecting daily clinical practice and consecutive but not selected patients.

In conclusion, endoscopic papillectomy is a challenging interventional approach but a suitable patient- and local finding-adapted diagnostic and therapeutic tool with adequate risk-benefit ratio in experienced hands.

COMMENTS

Background

The adequate management of diseases of the papilla of Vater (papilla) is challenging. There are several morphological changes and lesions of the papilla such as functional dysfunction, inflammation, stenosis or malignant tumor growth. For instance, a stenosis of the papilla is subdivided based on an autopsy registry as follows: Benign lesions, 42.7% (frequency); adenoma (premalignant lesion), 19.6%; carcinoma, 37.7%. For the treatment of tumor lesions of the papilla, it is required in addition to a sufficient histopathological investigation to achieve an adequate pretherapeutic tumor staging, which allows a decision-making toward the appropriate treatment (surgical intervention, papillectomy, papillotomy) according to the patient´s specific finding. These requirements can be fulfilled by endoscopic ultrasonography (EUS) for the majority of tumor (-like) lesions. For the specific clinical status of the single patient (*e.g.*, high risk because of accompanying diseases) and to cover the need of lower invasiveness and interventional trauma for a more favorite outcome as well as earlier reconvalescence, an additional approach to open surgery (providing transduodenal papillectomy/ampullectomy but with a substantial complication rate) is required-this might be provided by the very specific interventional endoscopic approach, named endoscopic papillectomy.

Research frontiers

To provide a substantial contribution to the important field of interventional endoscopy with a low number of valuable studies and case numbers on (endoscopic) papillectomy/tumor (-like) lesions of the papilla, the aim of the study was to investigate the clinical value of endoscopic papillectomy (to broaden the spectrum of therapeutic options in managing tumor lesions of the papilla of Vater) indicated by feasibility and safety of the procedure in various diseases of the papilla in a representative number of patients in a setting of daily clinical and endoscopic practice and care by means of a systematic prospective observational study, which can be considered one of the rare study approaches existing so far and emphasizing this measure of interventional endoscopy on one hand and, on the other hand, this type of study to sufficiently characterize daily clinical (endoscopic) practice in addition to rather specifically initated comparative (controlled randomized) studies.

Innovations and breakthroughs

Endoscopic papillectomy (based on sufficient preinterventional diagnostics by, among others (in particular), EUS as a sufficient diagnostic measure to preoperatively clarify diseases of the papilla including suspicious tumor stage in conjunction with postinterventional histopathological investigation of a specimen) is a challenging interventional approach. Thus, endoscopic papillectomy can be considered a valuable addition in the (diagnostic and) therapeutic management of (peri-) ampullary (tumor-like) lesions if treated patients are systematically and prospectively analyzed for quality assurance and adequately followed, *e.g.*, with appropriate follow-up investigations within reasonable time intervals.

Applications

Again, endoscopic papillectomy is a challenging interventional approach but a suitable patient- and local finding-adapted diagnostic and therapeutic tool with adequate risk-benefit ratio in experienced hands. Derived from this, an increasing number of interventional endoscopists may (based on and derived from the experiences analyzed in the systematic clinical prospective observational study presented here) begin with the endoscopic approach of papillectomy in their own endoscopic practice.

Terminology

Papilla of Vater: important anatomic structure at the mouth of the bile duct and/or pancreatic duct with possible inflammatory and neoplastic lesions leading to unspecific or varying symptomatology. Papillectomy: interventional (challenging endoscopic) or open surgical procedure intending to completely remove papilla of Vater in specific, in particular, neoplastic [benign or malignant (in early lesions)] findings to provide low invasiveness and complication rate but making sure a case-, finding- and risk-adapted approach. Endoscopic ultrasonography: very suitable diagnostic tool, in particular, for the periampullary region but also feasible for image-guided interventional endoscopic procedures such as papillectomy (or removal of small tumor lesions, biopsy, puncture, injection). Adenoma is considered a benign neoplastic lesion originating from adenoid structures such as the superficial layer of the gastrointestinal (GI) tract and, in particular, is an important lesion of the anatomic region such as papilla of Vater or the periampullary region.

Peer review

The manuscript provides additional information to the existing literature obtained by a systematic prospective observational study characterizing in particular daily clinical practice in interventional endoscopy of a GI endoscopy center on feasibility and safety of endoscopic papillectomy for various tumor (-like) lesions of the papilla in a representative number of patients, which can be considered one of the rare study approaches existing so far and emphasizing this measure of interventional endoscopy on one hand and, on the other hand, this type of study to sufficiently characterize daily clinical (endoscopic) practice in addition to rather specifically initated comparative (controlled randomized) studies. In detail, endoscopic papillectomy was found to be feasible and safe in experienced hands. The clinical researchers and experienced/advanced GI endoscopists should be encouraged to further pursue this type of study, lesions and patients experiencing this challenging type of tumor (-like) lesion of the papilla, for which only a few experts can provide similar results and expertise.

Abstract

AIM: To assess the safety and effect of the supplementation of a patented blend of dietary phytoestrogens and insoluble fibers on estrogen receptor (ER)-β and biological parameters in sporadic colonic adenomas.

METHODS: A randomized, double-blind placebo-controlled trial was performed. Patients scheduled to undergo surveillance colonoscopy for previous sporadic colonic adenomas were identified, and 60 eligible patients were randomized to placebo or active dietary intervention (ADI) twice a day, for 60 d before surveillance colonoscopy. ADI was a mixture of 175 mg milk thistle extract, 20 mg secoisolariciresinol and 750 mg oat fiber extract. ER-β and ER-α expression, apoptosis and proliferation (Ki-67 LI) were assessed in colon samples.

RESULTS: No adverse event related to ADI was recorded. ADI administration showed a significant increases in ER-β protein (0.822 ± 0.08 *vs* 0.768 ± 0.10, $P = 0.04$) and a general trend to an increase in ER-β LI (39.222 ± 2.69 *vs* 37.708 ± 5.31, $P = 0.06$), ER-β/ER-α LI ratio (6.564 ± 10.04 *vs* 2.437 ± 1.53, $P = 0.06$), terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (35.592 ± 14.97 *vs* 31.541 ± 11.54, $P = 0.07$) and Ki-67 (53.923 ± 20.91 *vs* 44.833 ± 10.38, $P = 0.07$) approximating statistical significance. A significant increase of ER-β protein (0.805 ± 0.13 *vs* 0.773 ± 0.13, $P = 0.04$), mRNA (2.278 ± 1.19 *vs* 1.105 ± 1.07, $P < 0.02$) and LI (47.533 ± 15.47 *vs* 34.875 ± 16.67, $P < 0.05$) and a decrease of ER-α protein (0.423 ± 0.06 *vs* 0.532 ± 0.11, $P < 0.02$) as well as a trend to increase of ER-β/ER-α protein in ADI *vs* placebo group were observed in patients without polyps (1.734 ± 0.20 *vs* 1.571 ± 0.42, $P = 0.07$).

CONCLUSION: The role of ER-β on the control of apoptosis, and its amenability to dietary intervention, are supported in our study.

Key words: Estrogen receptor-β; Estrogen receptor-α; Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling; Sporadic adenomatous polyposis; Phytoestrogens; Insoluble fibers

Core tip: Active dietary intervention, a mixture of phytoestrogens and insoluble fibers, was administered in

patients with sporadic colonic adenomas in a randomized, double-blind placebo-controlled trial. Dietary supplementation induced an increase in estrogen receptor (ER)-β protein and the ER-β/ER-α ratio with a general trend towards an increase in epithelial proliferation and apoptosis. These results, even if limited by the small number of subjects and short period of dietary supplementation, suggest the possibility of an interaction with epithelial apoptosis by means of mediating ER-β levels.

INTRODUCTION

There is considerable evidence, both observational and interventional, to suggest that estrogens may have a chemopreventive activity for colorectal cancer (CRC). Women have a lower rate of colonic adenomas and cancers than men before menopause but the differences progressively lessen after menopause[1]. The mortality from CRC has been decreasing progressively in women compared to men since 1950[2] and this decrease is correlated with the time frames of increasing use of hormone replacement therapy (HRT), as confirmed by controlled trials[3,4].

Any chemopreventive effect of estrogens for CRC would likely be mediated by the interaction of circulating estrogens with estrogen receptors (ERs) in the colonic epithelium[5]; the presence of these receptors has been investigated by different methods, in many papers since the 1980s[6-8]. There are two distinct types of estrogen receptors (ERs) in human tissues. ER-α is primarily expressed in the breast and endometrium, whereas ER-β is found in a wide variety of tissues that are traditionally considered non-hormonal, including the colon. ER-α and ER-β activation may lead to biologically opposite patterns, as demonstrated in cancer cell lines (HC 11, LoVo)[9,10]. Thus, it is reasonable to hypothesize that estrogens could have dissimilar biological consequences in different tissues according to the amount and type of ERs[11]; the ER-β/ER-α ratio has therefore been developed to measure this phenomenon[12]. There is a substantial body of evidence suggesting that the level of ER-β expression itself, and/or the ER-β/ER-α ratio, is related to colonic carcinogenesis in both humans and animal models of CRC. ER-β is abundantly expressed in the normal colon but its expression is progressively decreased in adenomas and CRC in relation to the disease aggressiveness[13-15]. Similarly, familial adenomatous polyposis shows progressively lowered ER-β levels and a reduced ER-β/ER-α ratio in pre-neoplastic and neoplastic tissue[14]. Finally, the results of different studies suggest that some herbal supplements may exert significant and potentially beneficial effects on decreasing the amount of precancerous lesions by inducing apoptosis in the large intestine[16-19]. In an adenomatous polyposis coli$^{Min/+}$ (Apc$^{Min/+}$) mouse model, dietary supplementation significantly counteracted the intestinal tumorigenesis and increased the ER-β expression in the colon[20]. Moreover, observational studies suggest that phytoestrogens intake in whole grain, as well as enterolignans and silibinin, may be associated with a decreased incidence of advanced colon adenomas and cancers in both men and women[21-24].

On these bases, we conducted a randomized, double-blind placebo-controlled study to determine whether short term administration of dietary phytoestrogens and insoluble fibers, (silymarin, secoisolariciresinol diglycoside from flaxseed and insoluble fibers from oat extract, (Eviendep® CMD Pharma Limited. A Nestle Health Science Company, London, United Kingdom) can selectively alter ERs expression in the normal appearing colonic mucosa of patients undergoing surveillance colonoscopy after a previous polypectomy. Epithelial proliferation and apoptosis were assessed at the same time.

The expression of these biomarkers was evaluated in two steps: firstly analysis after administration of the active dietary intervention (ADI, Eviendep) *vs* the placebo, and then a further subdivision into 4 subgroups: ADI *vs* placebo, with, or without polyp recurrence.

MATERIALS AND METHODS

Study design and patient population

The study was approved by the Ethics Committee of the University Hospital of Bari (No. 1410). All patients signed informed consent, in accordance with the Helsinki Declaration, revision 1983. The study was registered at Clinical Trial.gov (ID: NCT01402648). In accordance with the CONSORT statement flowchart, the study design and flow is described in Figure 1.

All subjects with endoscopic records, males or postmenopausal females (defined as the absence of a menstrual cycle for at least 2 years prior to enrollment) aged at least 50 years, who had undergone a previous endoscopic polypectomy and were enrolled in follow-up for surveillance colonoscopy to be performed 3 or 5 years later, according to standard guidelines, were screened for study eligibility. Six hundred patients, potentially eligible by chart-review, were contacted by the EC authorized Clinical Investigators by telephone-interview to explain the study and invite them to participate.

Inclusion criteria were based on biochemical evaluation of blood samples *i.e.*, hemoglobin $\geq$ 12.0 g/dL; platelets $\geq$ 120000/mm^3; international normalized ratio $\leq$ 1.5; alanine aminotranferease or aspartate aminotransferase $\leq$ 1.5 times the upper limit of normal values (ULN); alkaline phosphatase $\leq$ 1.5 times ULN; bilirubin $\leq$ 1.5 times ULN; blood urea nitrogen $\leq$ 40 mg/dL and normal blood pressure or controlled hypertension.

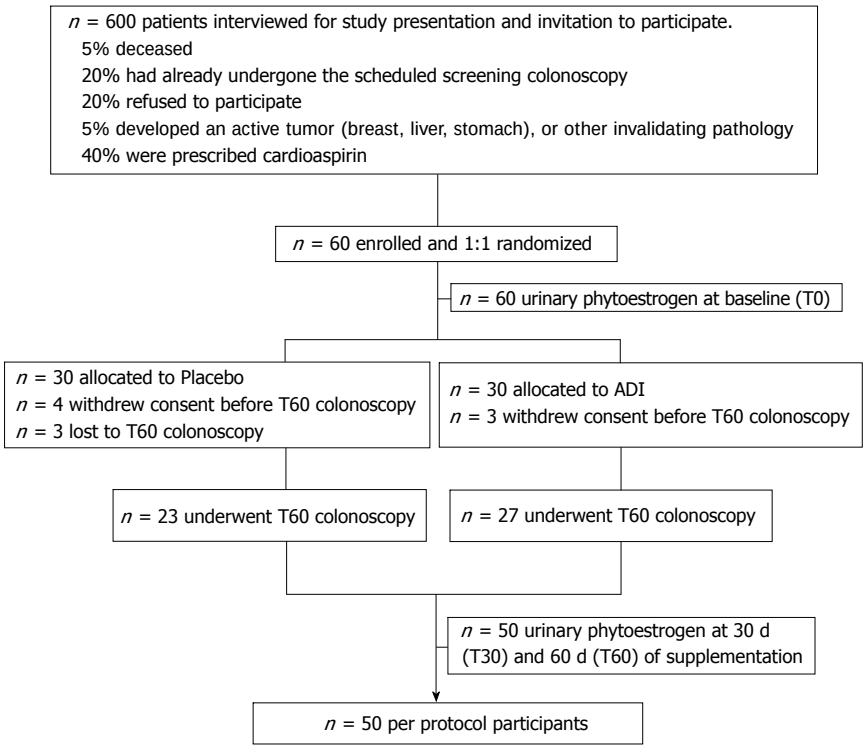

Figure 1 Diagram of study design.

The following were exclusion criteria: chronic inflammatory bowel disease, intestinal and/or extra-intestinal malignant neoplasms, acute or chronic renal disease, anemia, coagulation disorders or a body mass index (BMI) > 30 kg/m^2, anti-cancer treatment and/or systemic corticosteroids within 6 mo of enrollment; anticoagulants or platelet anti-aggregants and antibiotics within 30 d of enrollment, HRT, selective estrogen receptor modulator, *e.g.*, tamoxifene and related compounds or other supplemented phytoestrogens, aspirin and nonsteroidal antiinflammatory drugs within the previous 6 mo.

Sixty consenting, eligible patients, out of 600 interviewed, were randomly allocated to placebo (PL) or ADI (Eviendep) in a 1:1 ratio at baseline (T0), *i.e.*, 60 d in advance of their scheduled surveillance colonoscopy (T60). The period of 60 d of supplementation was chosen as adequate for complete turnover of the colonic epithelial cells (migration from the crypt and release into the lumen) approximately eight times and, therefore, for the reliability of the biological evaluation[25].

ADI was provided as a sachet composed of 750 mg insoluble and indigestible oat fiber (cellulose, hemicellulose and lignin), 50 mg flaxseed dry extract (containing 20% secoisolariciresinol diglycoside), and 175 mg milk thistle extract (70% silymarin by UV and 30% silibinin by high performance liquid chromatography). PL sachets contained maltodextrins (910 mg), and 100% of ADI excipients. The ADI and PL were provided by the Sponsor in identical boxes and sachets, and labeled with the protocol code and the allocated participant number. The ADI and PL were stored and distributed, according to the assigned treatment group, to the participants through the Hospital Pharmacy. The patients and investigators were blinded to assignment. There were no dietary restrictions.

Computer-generated randomization, study monitoring, database acquisition and statistical analysis were conducted through a contract with medical trial analysis (Ferrara, Italy), an independent Clinical Research Organization.

Safety was assessed by vital signs (heart rate, blood pressure); and blood homeworks at baseline (T0), and after 30 d (T30) and 60 d (T60).

Phytoestrogen intake, and compliance were assessed by urinary measurements *i.e.*, enterolignans enterodiol (ED) and enterolactone (EL), at T0, T30 and T60[19,20]. A few d before colonoscopy, all patients were asked to avoid fruit and vegetable intake and received bowel cleansing with PEG 4000 (1120 g/4 L water solution).

Endoscopy and histology

The number, location and size of all visualized polyps were recorded during endoscopy. A standard protocol for polyp removal was followed. Diminutive polyps (0.5 cm) were ablated with electrocoagulation, whereas all polyps > 0.5 cm in size were removed and submitted for histological assessment. Eight biopsies of the normal appearing sigmoidal mucosa were collected from all participants; seven of the biopsies were frozen in liquid nitrogen for biochemical and biologic endpoint analyses and one was well-oriented on blotting paper and then fixed in 4% formalin for immunostaining. The polyps were classified as hyperplastic or dysplastic by a gastrointestinal pathologist.

Biochemical and biologic endpoint analyses

Colonic biopsies were assessed for ER-β and ER-α

mRNA by reverse transcriptase (RT)-polymerase chain reaction (PCR), and protein by Enzyme-Linked ImmunoSorbant Assay. Total RNA was extracted from biopsies using the RNA easy mini kit (Qiagen), according to the manufacturer's instructions. RNA concentration and quality were assessed by spectrophotometric readings at 260 and 280 nm. ER-β and ER-α cDNA were generated by Reverse Transcription of 0.5 μg of total RNA in a 20 μL reaction volume (iScript Select cDNA Synthesis Kit, Biorad), according to the manufacturer's instructions. Two rounds of amplification (PCR-1 and PCR-2) were performed. The outer and inner primers used to detect ER-β and ER-α mRNAs at exon 3 have been previously described[26]. PCR-1 was performed in 50 μL final volume (iTaq DNA Polymerase Kit-Biorad) containing 2 μL cDNA and 40 pmol of outer primers through a denaturation step (95 ℃ for 3 min), 30 cycles (94 ℃ for 30 s, 55 ℃ for 30 s, 72 ℃ for 30 s) and a final primer extension step (72 ℃ for 10 min). For PCR-2, PCR-1-derived ER-β and ER-α were diluted tenfold, and a 3 μL aliquot was amplified with 40 pmol of inner primers as per PCR1 conditions. β-actin cDNA (0.5 μL) served as internal control. DNA fragments were separated on a 2% agarose gel stained with ethidium bromide and size assessed by comparison with 100 bp DNA marker using Molecular Imager ChemiDOC XRS+ (Biorad). After normalization to the fluorescent β-actin PCR band intensity, ER-β and ER-α mRNA were expressed as arbitrary units of fluorescence.

For the extraction of proteins, colonic biopsies were homogenized in lysis buffer [100 mmol/L Tris-HCl (pH 7.5), 300 mmol/L NaCl, 4 mmol/L EDTA, 2% NP40, 0.5% Na deoxycholate, 1 mmol/L sodium orthovanadate and a protease inhibitor cocktail-Roche]. Supernatants were collected after centrifugation (13000 *g* for 25 min) and the total protein concentration was measured by the Bradford method (Biorad). ER-β and ER-α were measured using QuantiSir specific gene knockdown quantification specific kits (Epigentek, Brooklyn, NY, United States), following the manufacturer's instructions. ERs content was normalized to GAPDH and expressed as optical densities (*A*) by computer-assisted densitometry.

Human urine spot samples (fasting) were extracted and measured by mass spectroscopy using a waters quattro premier mass spectrometer and waters acquity equipment. The lower and upper limit of quantitation (LLOQ and ULOQ) were 0.5 ng/mL and 2000 ng/mL for EL and ED, respectively. Two full calibration lines prepared in surrogate matrix (phosphate buffered saline; PBS), corresponding to five different EL and ED concentrations over the LLOQ and ULOQ, served as quality control (QC) samples. Duplicate QC samples prepared in the calibrated range were run together with the clinical samples. The concentration of ED and EL (ng/mL) and the coefficient of variation [CV (%) = SD of results/mean of results × 100] were measured.

Immunohistochemistry and immunofluorescence

Immunohistochemistry evaluated ERs expression, cell proliferation by Ki-67 and apoptosis by both terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling (TUNEL) and caspase-3. In all cases, IHC data was expressed as labeling index (LI), *i.e.*, the percent of immunostained colonocytes over the total counted cells along the length of 10 well oriented crypts. A further evaluation was based on the intensity of IHC staining divided into weak, moderate and strong. Both LI and intensity staining were calculated by two independent observers (MPS, ST) in a blinded fashion. Diagnostic agreement was revealed by a weighted *k* statistics coefficient > 0.8.

IHC was performed only on the sections of biopsies taken from non-adenomatous mucosa[4,14]. After permeabilization and antigen retrieval under shaking conditions in TBS buffer with TWEEN 0.025% for ER-β (15 min) and by microwave irradiation in citric buffer at pH 6.0 for ER-α (3 cycles of 5 min), the slides were covered with 5% goat serum for 30' at room temperature (RT) to block non-specific binding. The slides were incubated with primary antibodies diluted 1:50 in PBS, at 4 ℃ overnight (anti-ER-β: Novocastra Menarini, Milano, Italy and anti-ERα: Santa Cruz, CA, United States). Negative controls were obtained by dipping slides in PBS without primary antibodies. Reactions were detected by a polymer-based visualization kit (EnVision, Dako, Glostrup, Denmark). Slides were then incubated with the chromogen 3, 3-diaminobenzidine-tetrahydrochloride (DAB, Vector laboratories) for 40 min at RT, and Harris hematoxylin (Sigma) served for nuclear counterstaining.

Ki-67 expression was evaluated by monoclonal antibody (clone MIB-1, Dako, Glostrup, Denmark). The sections were treated in a microwave oven twice for 5 min in citrate buffer (pH 6.0) at high power (750 W) before primary antibody incubation for 1 h at RT. The secondary peroxidase-conjugated antibody (EnVision, Dako, Glostrup, Denmark) was applied to the sections. Peroxidase activity was visualized by diaminobenzidine chromogen (DAB, Vector laboratory) and counterstained with hematoxylin.

TUNEL was investigated by the *in situ* cell death detection kit, Roche. In brief, sections were treated with 0.1 mol/L citrate buffer (pH 6.0) cooled to an internal temperature of sub-boiling in the microwave oven at 350 W for 10 min, incubated with TUNEL probe at 37 ℃ for 1 h and counterstained with TOPRO 3 (Invitrogen Molecular Probes), diluted at 1:5000. All sections were observed at × 400 magnification by confocal microscopy (Leica TSC SP2 confocal laser scanning microscope).

Caspase-3 was detected with a methodological approach allowing evaluation of both its exclusive expression and co-expression with ER-β. In detail, a rabbit polyclonal antibody from cell signaling (clone D 175) was used. Antigen retrieval was performed by rocking the slides in TBS buffer with TWEEN 0.025% for 10 min followed by microwave irradiation in citric buffer at pH 6.0 for 10 min at 750 watts; slides were incubated for 1 h at room temperature in 1% BSA blocking solution and then dipped in a mixture of the two primary antibodies (ER-β 1:50, Caspase-3 1:30) at 4 ℃ overnight.

Table 1 Urinary enterolignans (ng/mL) in study groups at different timepoints (mean ± SD)

	Placebo (n = 23)	ADI (n = 27)	P value
ED + ELT0	697.8 ± 963.3	410.3 ± 336.9	0.270
ED + ELT30	472.4 ± 475.5	3300.1 ± 1535.5	< 0.001
ED + ELT60	116.0 ± 235.2	327.5 ± 313.1	< 0.001

ED: Enterodiol; EL: Enterolactone; ADI: Active dietary intervention.

Table 2 T60 colonoscopy: Estrogen receptor-β and estrogen receptor-α expression values in the normal sigmoid mucosa of study groups (mean ± SD)

	Placebo (n = 23)	ADI (n = 27)	P value
ER-β protein	0.768 ± 0.10	0.822 ± 0.08	0.04
ER-β mRNA	0.994 ± 0.99	1.266 ± 1.24	0.10
ER-β protein	0.510 ± 0.11	0.490 ± 0.12	0.50
ER-β mRNA	0.139 ± 0.28	0.230 ± 0.24	0.20
ER-β/ER-α protein	1.571 ± 0.42	1.734 ± 0.20	0.07

ER: Estrogen receptor; ADI: Active dietary intervention.

The sections were covered with the secondary antibody, Alexa 555 fluorescent-conjugated Goat anti-Rabbit (Invitrogen), diluted to 1:100 in PBS. TOPRO-3 (Invitrogen-Molecular Probes) diluted in PBS and incubated for 10' at room temperature, providing nuclear counterstaining. Cells were counted at × 400 magnification, by confocal microscopy (Leica TSC SP2 confocal laser scanning microscope).

Statistical analysis

Sample size estimation was based on the assumption of an equivalence margin between the study arms of 0.05 and an actual difference ($mean_{ADI}$ - $mean_{PL}$) of 1, SD_{ADI} = 2 and SD_{PL} = 2. Sixty patients were required to complete the study for an 80% powered study and a two-tailed 0.05 *a* error. The non parametric, two sided Wilcoxon Rank Sums test weighted ERs and biomarkers expression in study groups. ANOVA, χ^2 or *t* test were used to compare demographics and all the other functional parameters. Spearman's correlation was applied to assess relationships among ERs and the other biomarkers with the common diet and the allocated supplements. All analyses were performed using SAS version 8.2 (Statistical Analysis Software, Cary, NC). Diagnostic agreement was tested by calculating the weighted *k* statistics coefficient interpreted in accordance with the benchmarks of Landis and Koch. *A* value below 0.4 indicated poor agreement, a value between 0.4 and 0.8 moderate to good agreement, and a value of more than 0.8 excellent agreement[26].

RESULTS

A flow diagram of the study is shown in Figure 1. A total of 60 eligible consenting subjects were identified from 600 interviewed potential participants. They were enrolled and randomly assigned 1:1 to placebo or ADI. The groups were matched for age, gender, BMI, and season of enrollment; this last character displayed the absence of biases in phytoestrogen intake.

Ten out of 60 subjects dropped out, as reported in Figure 1. The final per protocol population consisted of 50 participants who completed the 60 d treatment with dietary supplements and underwent surveillance colonoscopy.

Endoscopy and histology findings

In 21 subjects (42%) polyps were found; the majority of these (58%) were electrocoagulated while the remainders were processed for histological examination. None showed high grade dysplasia.

Adverse events and compliance

No adverse events or biochemical modifications were reported in either the ADI or the placebo group.

Urinary enterolignan levels (ED, EL and ED + EL: ng/mL) were comparable between the study groups at baseline (Table 1). ADI treatment induced a significant increase in all urinary enterolignan levels at T30 and T60.

At T60 an expected fall in urinary lignans occurred in both groups due to the dietary restriction of fruits, vegetables and the colonoscopy bowel cleansing.

Molecular estrogen receptors assay

The effect of ADI on ER-β and ER-α protein and mRNA content at T60 is shown in Table 2. ADI induced a statistically significant increase of ER-β protein. ER-β mRNA levels were higher in the ADI than placebo group but the difference did not reach significance. ER-α protein and mRNA content were similar between the two groups; the ER-β/ER-α protein ratio showed a trend to an increase in the ADI group.

The median value of ER-β and ER-α proteins, referred to all 50 patients enrolled, were 0.82 and 0.47 *A*, respectively. The patients distribution around these numbers was different for the two proteins. The ADI group showed a spread above the value of ER-β in a higher percentage as compared to the placebo group (62.96% *vs* 34.78%; $P < 0.05$) while, on the contrary, in the ADI group the median value of ER-α protein decreased as compared to the placebo group (66.7% *vs* 34.8%; $P = 0.02$).

Treatment-related immunohistochemical biomarkers

Analysis of agreement between the observers provided κ = 0.87 (95%CI: 0.76-0.98). The assessment of intensity staining did not affect the results of LI, as the percentage of weakly stained cells was less than 10% and the results were referred only to moderate-strong intensity.

Table 3 reports the effect of ADI on the LI of ER-β, ER-α, Ki-67, TUNEL and caspase-3. The ADI treated patients had a trend towards an increase in ER-β LI (P = 0.06), the ER-β/ER-α LI ratio (2.5 fold compared to PL; P = 0.06), TUNEL (P = 0.07) and Ki-67 (P = 0.07) as compared to the placebo group, although none of these differences reached statistical significance.

Table 3 T60 colonoscopy: Labeling index (mean ± SD)

LI	Placebo (n = 23)	ADI (n = 27)	P value
ER-β	37.708 ± 5.31	39.222 ± 2.69	0.06
ER-β	20.416 ± 10.71	16.481 ± 10.67	0.20
ER-β/ER-α	2.437 ± 1.53	6.564 ± 10.04	0.06
TUNEL	31.541 ± 11.54	35.592 ± 14.97	0.07
Caspase-3	29.717 ± 7.98	32.937 ± 13.54	0.10
Ki-67	44.833 ± 10.38	53.923 ± 20.91	0.07

LI: Labeling index; ER: Estrogen receptor; TUNEL: Terminal deoxynucleotidyl transferase-mediated dUTP nick end labeling; ADI: Active dietary intervention.

Spearman correlation showed that, in the ADI group, the ER-β LI was directly correlated with the TUNEL LI (r = 0.406, P = 0.03) and caspase-3 LI (r = 0.529, P < 0.004). The relationship between ER-β and apoptosis was confirmed by the IHC evidence of ER-β caspase 3 co-localization, as clearly shown in Figure 2. In the PL group these correlations showed the same direction but did not reach statistical significance (r = 0.379, P = 0.07 and r = 0.134, P = 0.55, respectively).

Biomarker expression in patients with or without polyp recurrence

The expression of biomarkers in the normal mucosa of patients with (recurrent) and without (non-recurrent) polyps, was assessed. Table 4 shows that in patients without recurrence, there was a significant increase of the ER-β pattern (mRNA, protein and LI) and a decrease of ER-α protein in the ADI *vs* the placebo group. An increased ER-β/ER-α protein ratio (P = 0.01, not shown in the table) was also observed.

In patients with recurrence, a higher ER-β protein (P = 0.04) and a lower ER-α LI (P = 0.02), were also demonstrated in the ADI group.

DISCUSSION

There are substantial observational human data to suggest the possibility that ERs expression might be a marker of colon cancer risk. The $Apc^{Min/+}$ mouse model of intestinal neoplasia has been used to study this association. Barone *et al*[20] reported that the ER-β level and ER-β/ER-α ratio was substantially lower in the normal small intestinal mucosa of $Apc^{Min/+}$ mice than in syngenic wild type mice, and there was a consequent decrease of intestinal apoptotic activity. This fall was regulated by silymarin and an insoluble fibers (consisting of 6% lignin, known to be intestinally converted to the active enterolignans, enterodiol and EL) mixture. In this combination, silymarin is a potent ER-β agonist[27,28] and lignans have a substantial phytoestrogenic activity[29]. The silymarin/lignan combination also markedly decreased the number and size of intestinal tumors in $Apc^{Min/+}$ mice[20]. Moreover, it was demonstrated that oophorectomy in female $Apc^{Min/+}$ mice led to an increased number of polyps, which could be abolished by the administration of estrogens[3] or a ER-β selective agonist[4] like coumestrol. Similarly, in intact male $Apc^{Min/+}$ mice, ER-β up-regulation *via* administration of a dietary ER-β selective agonist can reduce the number of adenomas with high grade dysplasia[22]. Giroux *et al*[31] addressed this relationship directly, showing that ER-β deficiency induced by ER-β knockout in female $Apc^{Min/+}$ mice led to enhanced small intestine tumorigenesis.

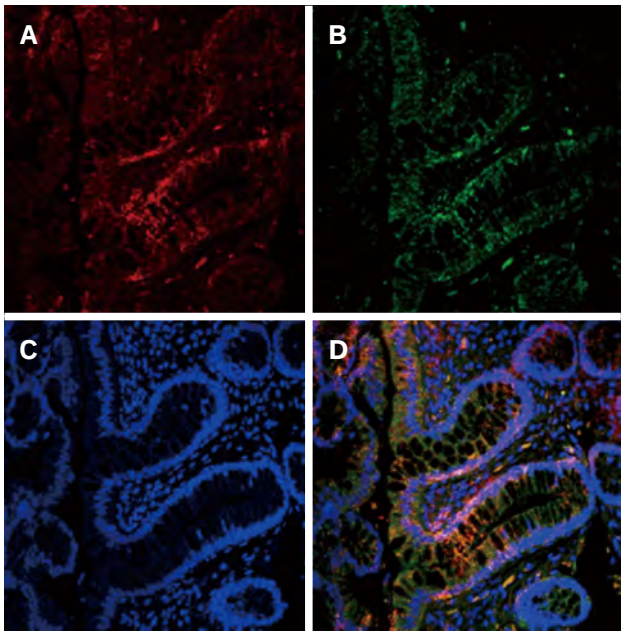

Figure 2 Colocalization estrogen receptor-β receptor and caspase-3. A: Nuclear estrogen receptor (ER)-β expression (red signal); B: Nuclear caspase-3 expression (green signal); C: Nuclear contrast with TOPRO-3 (blue signal); D: merge of the three signals. Both molecules are localized in the upper third of the crypts (Confocal microscope × 400).

The current study was designed to investigate whether a similar dietary supplement could modify ERs levels in humans. ADI (Eviendep® CMD Pharma Limited, United Kingdom), a dietary supplement containing a patented combination of insoluble fibers and dietary phytoestrogens (silymarin and lignans) can substantially increase phytoestrogen levels in humans. We determined whether ADI affects the balance of expression of the ERs, as well as between proliferation and apoptosis, in the colonic mucosa of men and post-menopausal women undergoing surveillance colonoscopy for previous adenomas. The expression of these parameters was evaluated in two study steps, firstly analysis of the situation after active treatment *vs* placebo, and then a further analysis of the same biomarkers in 4 subgroups: supplement *vs* placebo, with, or without recurrence.

In the first step, in comparison with the placebo group, the ADI group showed a mild but significant increase in the mean ER-β protein content (P = 0.04), as well as a trend towards increase of the ER-β/ER-α ratio (P = 0.07), while ER-α protein (P = 0.5) and the mRNA content (P = 0.2) were similar between the two

Table 4 Estrogen receptor-β and estrogen receptor-α, apoptosis and mitosis in non-recurrent patients

groups. In our study, we found that ADI induced a statistically significant increase of ER-β protein, whilst ER-β mRNA levels were higher than in placebo group but the difference did not reach significance. Moreover, both the protein and mRNA were significantly increased in the subjects without the finding of polyps at endoscopy. A possible explanation of our result may be due to an increased synthesis as well as a reduced degradation of ER-β protein. Indeed, the transcription, synthesis and degradation of ER protein are processes subjected to mechanisms of complex control through highly regulated adjustment systems. Degradation, in particular, takes place in the cell by a cytosolic complex, the proteasome. It is mediated by ubiquitin that binds to the ligand binding domain of the receptor (ubiquitination)[32,33]. It is possible that these mechanisms may be different in the colonic mucosa prepared or not the development of polyps. Furthermore, TUNEL (P = 0.07) and Ki-67 (P = 0.07) approximated statistical significance. Finally, correlation tests suggested a link between ER-β and apoptosis, thus confirming previous experiences[20]. Moreover, it has been shown that ER-β *in vitro* can up-regulate Lo Vo cells, which in turn activate the caspase 3 and 8 to induce apoptosis in Lo Vo cells, *i.e.*, transient transfected cellular elements used with the aim of evaluating a relationship between ERs and apoptosis[9]. Therefore, in the context of our randomized, double-blind placebo-controlled study, short-term exposure to ADI increased ER-β without substantially affecting ER-α in the normal colonic mucosa of patients who had had a previous polypectomy, regardless of whether they had adenomas at T60 surveillance colonoscopy. The overall increase in the ER-β/ER-α ratio in the ADI group was associated with an increased apoptotic rate in the normal appearing colonic mucosa. Indeed, the real goal was the assessment of biomarkers (estrogen receptors and indicators of proliferation/apoptosis) after a short period of diet. Merely for diet duration, highly significant results were not in our expectations, although a trend of our dietary supplementation to modify the biomarkers is clear from our study.

The second step led us to conclude that ADI administration was unable to affect polyp recurrence, but it should be remembered that the period of administration was not designed for this purpose. Of course, we failed to prove ADI clinical effects since the aim of our study could not be to demonstrate that our dietary supplementation had a chemopreventive effect on the growth of intestinal polyps. Indeed, a long time is needed for the development of these lesions (years), whilst the duration of the diet was very short (2 mo). However, we demonstrated that ADI significantly reduces ER-α and increases ER-β independently of polyp recurrence. Moreover, ADI induces apoptosis through TUNEL and caspase 3 expression. To our knowledge this is the first demonstration that ER-β expression can be modified in humans. If loss of ER-β is a marker of risk for CRC, high levels of ER-β, induced by ADI, might have chemoprotective effects and the mixture of sylimarin and lignans could increase ER-β signaling by increasing and activating the receptor signaling pathway.

As far as the safety of ADI treatment is concerned, there were no adverse events nor changes in blood chemistry. Moreover, the absence of an ER-α expression (mRNA, protein and immunochemically stained cells) increase after ADI supplementation empirically supported this evidence.

As expected, ADI substantially increased phytoestrogen levels, as indirectly measured by urinary enterolignan (ED and EL) levels. Although total urinary enterolignans were decreased in both the ADI and placebo groups at T60 due to dietary restriction of fruits and vegetables prior to colonoscopy, they were significantly increased (8 fold) at T30 in the ADI group. This assay was conducted to demonstrate the adherence to the diet of the subjects as well as to avoid that external dietary factors could affect our results. This evaluation could be an indirect index of phytoestrogen level increase in ADI group. Additionally, literature evidences showed that a high estrous cycle duration, increased corticosterone and 17 β-estradiol levels with an overexpression of receptors ER-α and ER-β in animal model[34] thus suggesting that increased estrogen levels may raise the expression of specific receptors.

Our results suggest that dietary supplements may be able to modulate ER-β, a potentially important biomarker of colon cancer risk. Additional studies of this possibility seem warranted. In conclusion, the role of ER-β in the control of apoptosis and its amenability to dietary intervention are supported by our study. Our data could encourage further, perhaps larger, studies to be undertaken with the aim of demonstrating the secondary chemopreventive potential of ADI against CRC.

COMMENTS

Background

Studies in the adenomatous polyposis coli ($Apc^{Min/+}$) mouse model suggest that estrogen receptor β (ER-β) expression is lower in the intestinal mucosa as compared to APC wild type mice, while dietary supplementation significantly counteracted the intestinal tumorigenesis by increasing ER-β expression. This plot is a start-up to apply in human studies as well.

Research frontiers

Estrogens may have chemopreventive activity for colorectal cancer (CRC), of which sporadic adenoma is a direct precursor. This study assessed the safety and effect of supplementation of a patented blend of dietary phytoestrogens and insoluble fibers, active dietary intervention (ADI), on ER-β expression and on cellular proliferation and apoptosis in patients with recurrent sporadic colonic adenomas. The study was not designed to obtain a chemoprevention for the short diet duration.

Innovations and breakthroughs

ADI is an innovative, brand new mixture which has proved safe in humans and effective in increasing ER-β expression, that may offset intestinal carcinogenesis in patients with a positive history of recurrence for sporadic adenomas

Applications

In the future authors would like to analyze the possibility of prolonging treatment with ADI for longer than in this study (*i.e.*, 2 mo) and to perform endoscopy before and after treatment, compatibly with the compliance of enrolled patients. This could help to increase the strength and to enhance the statistical significance of the results already obtained; the treatment may be shown to play a role in the prophylaxis of adenoma recurrence.

Terminology

ERs, estrogen receptors, α and β, are widespread in human tissue. ER-α is primarily expressed in the breast and endometrium, whereas ER-β is present in a wide variety of tissues that are traditionally considered non-hormonal, including the colon. ER-α and ER-β activation may lead to biologically opposite patterns, as demonstrated in cancer cell lines

Peer review

The protective role of estrogen is a well-known topic in the literature, the interaction of a modified diet (ADI) with the expression of the receptors is an issue that may pose in the future of the implications on chemoprevention of CRC. The work is well structured methodologically, certainly a larger sample could provide greater and more extensive statistical significance

Abstract

AIM: To examine performances regarding prediction of polyp histology using high-definition (HD) i-scan in a group of endoscopists with varying levels of experience.

METHODS: We used a digital library of HD i-scan still images, comprising twin pictures (surface enhancement and tone enhancement), collected at our university hospital. We defined endoscopic features of adenomatous and non-adenomatous polyps, according to the following parameters: color, surface pattern and vascular pattern. We familiarized the participating endoscopists on optical diagnosis of colorectal polyps using a 20-min didactic training session. All endoscopists were asked to evaluate an image set of 50 colorectal polyps with regard to polyp histology. We classified the diagnoses into high confidence (*i.e.*, cases in which the endoscopist could assign a diagnosis with certainty) and low confidence diagnoses (*i.e.*, cases in which the endoscopist preferred to send the polyp for formal histology). Mean sensitivity, specificity and accuracy per endoscopist/image were computed and differences between groups tested using independent-samples *t* tests. High *vs* low confidence diagnoses were compared using the paired-samples *t* test.

RESULTS: Eleven endoscopists without previous experience on optical diagnosis evaluated a total of 550 images (396 adenomatous, 154 non-adenomatous). Mean sensitivity, specificity and accuracy for diagnosing adenomas were 79.3%, 85.7% and 81.1%, respectively. No significant differences were found between gastroenterologists and trainees regarding performances of optical diagnosis (mean accuracy 78.0% *vs* 82.9%, P = 0.098). Diminutive lesions were predicted with a lower mean accuracy as compared to non-diminutive lesions (74.2% *vs* 93.1%, P = 0.008). A total of 446 (81.1%) diagnoses were made with high confidence. High confidence diagnoses corresponded to a significantly higher mean accuracy than low confidence diagnoses (84.0% *vs* 64.3%, P = 0.008). A total of 319 (58.0%) images were evaluated as having excellent quality. Considering excellent quality images in conjunction with high confidence diagnosis, overall accuracy increased to 92.8%.

CONCLUSION: After a single training session, endoscopists with varying levels of experience can already

provide optical diagnosis with an accuracy of 84.0%.

Key words: Colonoscopy; High-definition i-scan; Optical diagnosis; Colorectal polyps; Training

Core tip: Several studies examined the feasibility of optical diagnosis of colorectal polyps using chromoendoscopy, either dye-based or digital techniques, while only a few studies examined the performances using the high-definition (HD) i-scan technology. In addition, experience on prediction of polyp histology using HD i-scan has been reported in an expert setting only, was based on various classification criteria, and paid only a limited attention to the impact of training. In the current study, at our university hospital, we investigated the effect of training on the diagnostic performances of endoscopists with varying levels of experience. We found that, after a short didactic training session, all endoscopists, trainees as well as gastroenterologists, can predict polyp histology with a mean accuracy of 84%.

INTRODUCTION

Image enhanced endoscopy techniques, such as dye-based or digital based chromoendoscopy [*i.e.*, narrow band imaging (NBI), high-definition (HD) i-scan or Fujinon Intelligent Color Enhancement (FICE)] have become largely available in daily practice, yet their additional diagnostic value remains unclear[1,2]. Several studies have demonstrated that expert endoscopists can accurately differentiate adenomatous from non-adenomatous polyps (*i.e.*, optical diagnosis) using such technologies[3-5], thereby enabling an individualized treatment, in which small adenomas are resected without pathologic examination, while small non-adenomatous polyps of the rectosigmoid are left *in situ*[6,7]. In addition, optical diagnosis might offer an alternative to histologic diagnosis in case polyps cannot be retrieved for histopathology[8]. This practical approach may downsize the pathology costs and reduce the risk of complications, which in turn would increase the efficiency and cost-effectiveness of colonoscopic procedures[6,9].

A large number of studies have focused on the contribution of image enhanced endoscopy techniques in the detection of colorectal polyps[10-14], while information on their role in histologic characterization is still expanding. Feasibility studies on optical diagnosis have been performed using chromoendoscopy[15,16] or NBI[3,14-18], especially in expert setting, while only a few studies examined the feasibility of HD i-scan technology[5,17,19-22], and none of them has been conducted outside an expert setting. Of note, in a study examining diagnostic performances for optical diagnosis of small colorectal polyps using HD i-scan, Chan *et al*[22] found a 30% difference in accuracy (63% *vs* 93%) between 2 experienced endoscopists, highlighting the need for training and use of standardized criteria. It is important to understand whether incorporating basic principles of optical diagnosis in the education of practicing endoscopists is sufficient to attain and maintain skills in optical diagnosis[2,7]. At our institution, training on recognition of colorectal lesions, with focus on non-polypoid adenomas, is currently incorporated in the educational curriculum[23]. In the current study, we further extended this training by developing a short training module on optical diagnosis using HD i-scan images. We sought to examine the performances in predicting polyp histology in a group of endoscopists with varying levels of experience. We hypothesized that endoscopists can accurately predict polyp histology after a short training session, irrespective of their prior endoscopy practice experience.

MATERIALS AND METHODS

We conducted a prospective educational study at the Maastricht University Medical Center, the Netherlands. No ethical review was required by the local Institutional Review Board.

Colonoscopy and image collection

We created a library of digital photographs using HD i-scan colonoscopes (Pentax, 90i series, 1.3×10^6 pixels). Twin-pictures [surface enhancement (SE); tone enhancement (TE)] were obtained from consecutive colorectal polyps. Location, size and morphology of colorectal polyps were registered. Colorectal polyps were subdivided according to location into proximal lesions (*i.e.*, located proximal from the rectosigmoid) and distal lesions (*i.e.*, detected in the rectosigmoid), as described previously[18,24]. The size of the polyp was categorized as diminutive (*i.e.*, < 6 mm) or non-diminutive (*i.e.*, $\geqslant 6$ mm). Moreover, colorectal lesions were classified according to morphology into polypoid and non-polypoid (*i.e.*, lesions with a height of less than half of their diameter)[25]. All colonoscopies were performed by one colonoscopist (Sanduleanu S), with previous experience on image enhanced endoscopy techniques[26-28], including the HD i-scan technology. After digital documentation, all colorectal polyps were removed and sent for histopathological assessment. Colorectal polyps were assessed by two experienced gastrointestinal pathologists and classified according to the World Health Organization classification[29]. Tubular adenomas, tubulovillous adenomas, villous adenomas and carcinomas were categorized as adenomatous whereas hyperplastic polyps, other (*i.e.*, inflammatory of lesions) and normal tissue were categorized as polyps with a non-

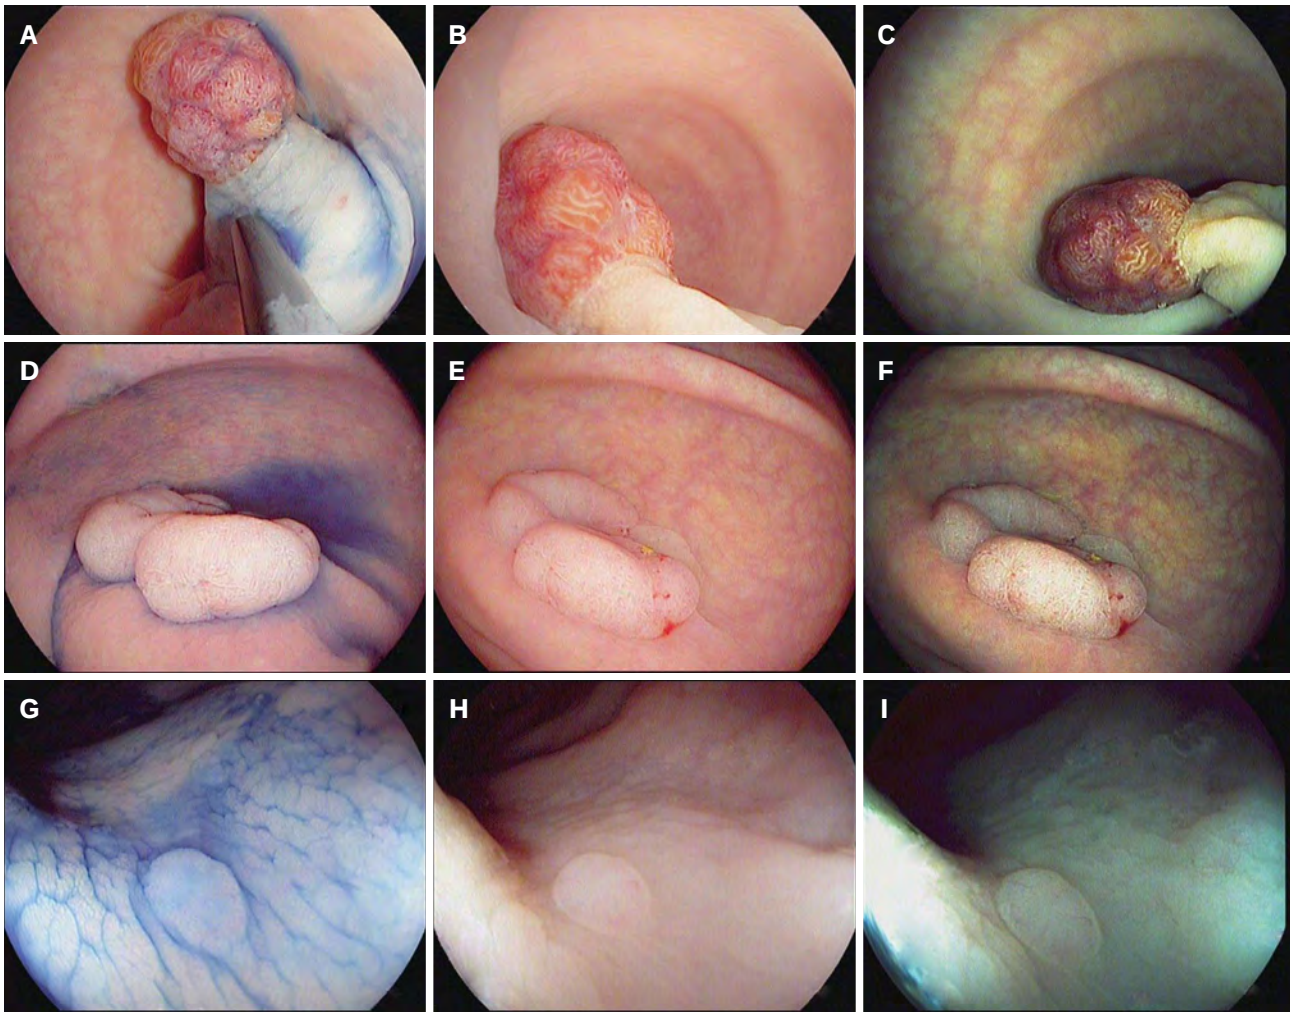

Figure 1 Characterization of colorectal polyps using chromoendoscopy with indigo carmine 0.4% (A, D and G) and high-definition i-scan, surface enhancement (B, E and H)/tone enhancement (C, F and I), the i-scan classification for endoscopic diagnosis. A-C: 20 mm sized pedunculated polyp (Paris Ip). Image enhanced endoscopy shows reddish color, prominent vessels and a type Ⅳ pit pattern of the epithelial surface. Histopathology showed a tubulovillous adenoma with low-grade dysplasia; D-F: 40 mm sized non-polypoid (Paris IIa) lesion. Image enhanced endoscopy shows reddish color, dilated, irregular vessels and a type Ⅳ pit pattern of the epithelial surface. Histopathology showed a tubulovillous adenoma with high-grade dysplasia; G-I: 3 mm sized non-polypoid (Paris IIa) lesion. Image enhanced endoscopy shows pale color, isolated, lacy vessels and a type Ⅱ pit pattern. Histopathology showed a hyperplastic polyp.

adenomatous histology. Sessile serrated adenomas/polyps were categorized as non-adenomatous polyps, in line with recent insights on the pit pattern of these lesions[30-32].

Training and development of classification table

Pilot phase: We established features associated with adenomatous and non-adenomatous histology, using a different set of 20 colorectal polyps which were examined using both chromoendoscopy and HD i-scan (Figure 1). We built upon previously described, international pit pattern classifications using (digital) chromoendoscopy, namely the Kudo classification and the NBI international colorectal endoscopic classification (NICE classification)[33,34]. We developed a simple classification (i-scan classification for endoscopic diagnosis, ICE-classification), in which the following parameters were separately rated: color, epithelial surface pattern and vascular pattern (Table 1). The quality of images was evaluated by 2 independent examiners and categorized as excellent or good.

Study: For the purpose of this educational study, we assembled an image set of twin pictures (SE; TE) from 50 colorectal polyps to create a test which can be accomplished within 1 h. We developed a training module (Microsoft PowerPoint) including the following information: (1) potential clinical relevance of optical diagnosis; (2) basic principles of the HD i-scan technology; (3) differential criteria of adenomatous *vs* non-adenomatous polyps using HD i-scan; and (4) clinical examples. Eleven endoscopists, working at our university center, with varying levels of experience, but who did not routinely use HD i-scan prior to this study were invited to participate. All endoscopists received a 20-min didactic training session aiming to familiarize them with the ICE classification of colorectal polyps using HD i-scan. Hereafter, the endoscopists evaluated an image set of 50 colorectal polyps, placed in random order by a computer-generated random number sequence, assessing polyp histology with high- or low confidence levels. High confidence was defined as

Table 1 Classification system for diagnosis of non-adenomatous and adenomatous colorectal polyps using high-definition i-scan (ICE classification)

	Non-adenomatous	Adenomatous
Color	Pale	Reddish
	Similar to adjacent mucosa	Different from adjacent mucosa
	Indiscrete borders	Clearly demarcated
Surface pattern	Round pits of uniform size, no definite pits	Oval, tubular or branched pits
Vessel pattern	Isolated, lacy vessels	Dilated, irregular vessels

cases in which the endoscopist could assign a diagnosis with certainty and low confidence in cases in which the endoscopist preferred to send the polyp for formal histopathology.

Statistical analysis

Numbers (percentages) were used to describe categorical variables. Sensitivity, specificity and accuracy in predicting polyp histology were calculated using formal histopathology as gold standard. The positive and negative predictive values (PPVs and NPVs) are highly dependent on the prevalences of adenomatous and non-adenomatous polyps. As our image set may not truly reflect the prevalence of these lesions in the general population, we further calculated the PPVs and NPVs based on our sensitivity and specificity data combined with literature data about the prevalence of adenomatous and non-adenomatous polyps in the general population (*i.e.*, approximately 50% of all colorectal polyps detected during colonoscopy are adenomatous, while 50% non-adenomatous[8,35,36]). A two-step procedure was used to account for the dependency between repeated measurements. First, mean sensitivity, specificity and accuracy per endoscopist were computed and the differences between groups (*i.e.*, gastroenterologists *vs* trainees) were tested using independent-samples *t* tests. High *vs* low confidence diagnoses were compared using the paired-samples *t* test. For the effect of location, size, morphology and image quality, the data were first summarized per image and differences between groups (*i.e.*, distal *vs* proximal lesions, diminutive *vs* non-diminutive lesions, polypoid *vs* non-polypoid lesions and excellent *vs* good quality images) were compared using the independent-samples *t* test. We finally used *k* statistics to assess the agreement of predicted histology with formal histopathology. We considered a *kappa* value < 0.20 to indicate poor agreement, 0.21-0.40 slight agreement, 0.41-0.60 moderate agreement, 0.61-0.80 substantial agreement and 0.81-1.00 almost perfect agreement[37]. Two-sided *P* values ≤ 0.05 were considered statistically significant. Statistical analyses were conducted using the SPSS version 20.0.

RESULTS

A total of eleven endoscopists (4 gastroenterologists and 7 trainees) participated. Median (range) duration of colonoscopic experience was 12 years (range 7-15 years) for the participating gastroenterologists and 3 years (range 0-4 years) for the trainees. A total of 50 twin pictures (Figure 2) were incorporated into the test set, consisting of 14 (28.0%) non-adenomatous and 36 (72.0%) adenomatous polyps. Table 2 depicts the endoscopic and pathologic characteristics of the polyps incorporated into our test set. The majority (65.3%) of colorectal polyps were diminutive in size and 49.0% were located in the distal colon. Moreover, 29 (59.2%) cases had a polypoid and 20 (40.8%) a non-polypoid endoscopic appearance[38]. Image quality was rated as excellent in 29 (58.0%) cases and good in the remaining 21 (42.0%) cases.

Table 2 Endoscopic and pathologic characteristics of the colorectal polyps incorporated in our test set *n* (%)

Characteristic	Polyps
Total number of colorectal polyps	50
Location[1]	
Proximal colon	25 (51.0)
Distal colon	24 (49.0)
Size[1]	
Diminutive	32 (65.3)
Non-diminutive	17 (34.7)

Endoscopic features of non-adenomatous and adenomatous polyps

The endoscopic characteristics of non-adenomatous and adenomatous polyps are depicted in Figure 2. The frequencies of endoscopic features predictive of adenomatous and non-adenomatous polyps observed by the eleven endoscopists are shown in Table 3. Reddish color, surface epithelium different from the surrounding mucosa, clear demarcation and oval, tubular or branched pits were frequently seen in adenomatous polyps, whereas thick vessels were observed in only 40.9% of all adenomatous polyps. In contrast, pale color, surface epithelium similar to the adjacent mucosa, indiscrete borders, round pits of uniform size or no definite pits and isolated, lacy vessels were all frequently noticed in non-adenomatous polyps. The surface pattern remained unclear in 9.3% of

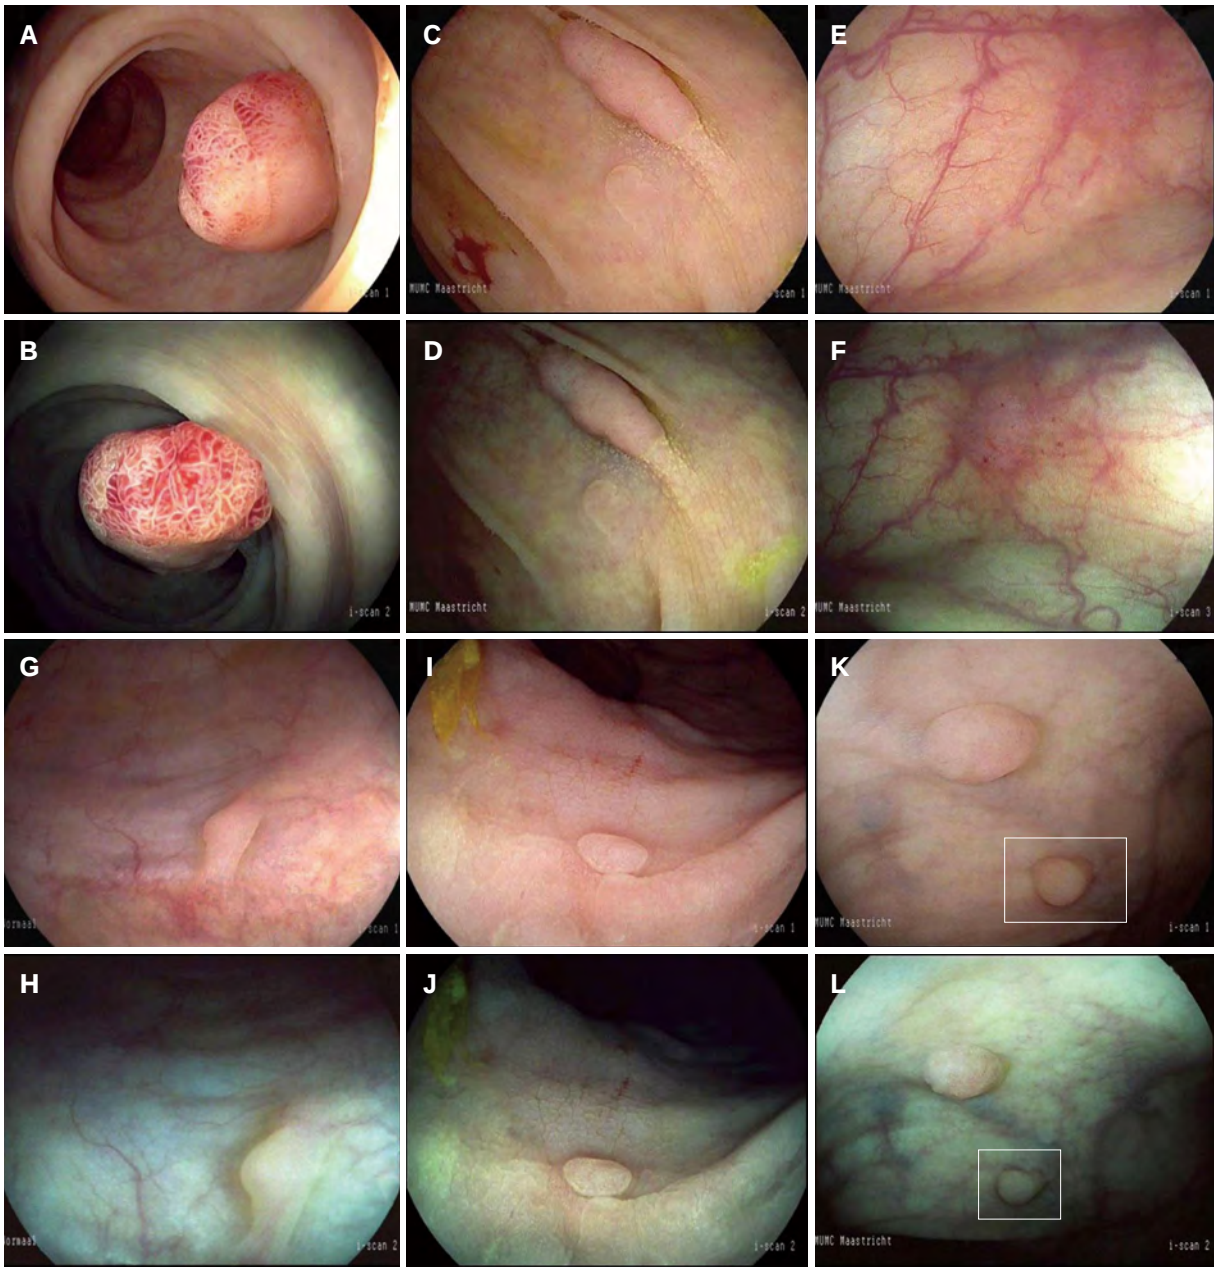

Figure 2 Endoscopic features of non-adenomatous and adenomatous polyps. High-definition (HD) i-scan surface enhancement (SE) (A) and tone enhancement (TE) (B) of a 12 mm pedunculated polyp located in the rectum characterized by a reddish color, prominent vessels and a branch-like (type Ⅳ) pit pattern. All endoscopists diagnosed this lesion as adenomatous with high confidence. Histopathology showed a tubulovillous adenoma with low-grade dysplasia. HD i-scan SE (C) and TE (D) of a 20 mm non-polypoid lesion in the ascending colon characterized by a reddish color, irregular vessels and a tubular (type Ⅲs) pit pattern. Adenomatous histology was predicted by all endoscopists with high confidence. Histopathology showed a tubular adenoma with low-grade dysplasia. HD i-scan SE (E) and TE (F) of a 4 mm non-polypoid lesion located in the proximal colon characterized by a reddish color, surface epithelium different from the surrounding mucosa and indiscrete borders while the vascular pattern could not be clearly observed. Polyp histology was predicted with low confidence by 6 of the 11 endoscopists. Histopathology showed a tubular adenoma with low grade dysplasia. SE (G) and TE (H) of a 3 mm sessile lesion in the sigmoid characterized by a pale color, no vessels and no definite pit pattern. Non-adenomatous histology was predicted with high confidence by 10 of the 11 endoscopists. Histopathology showed normal mucosa. SE (I) and TE (J) of a 3 mm non-polypoid lesion in the rectum characterized by a pale color, no vessels and round pits of uniform size. Non-adenomatous histology was predicted with high confidence by all endoscopists. Histopathology showed a hyperplastic polyp. SE (K) and TE (L) of a 3 mm sessile lesion in the rectum characterized by a pale color and epithelium similar to the adjacent mucosa while the surface pattern and vessel pattern are unclear. Histopathology was predicted with low confidence by 5 out of 11 endoscopists. Histopathology showed a hyperplastic polyp.

all adenomatous polyps and 15.6% of all non-adenomatous polyps, whereas a clear vascular pattern could not be observed in 16.2% of the adenomas.

Diagnostic performances in optical diagnosis using HD i-scan

A total of 550 images were evaluated by the eleven en-

Table 3 Frequencies of endoscopic features predictive of adenomatous and non-adenomatous polyps

	Adenomatous polyps	Non-adenomatous polyps
Features predictive of adenomas		
Reddish	62.6%	2.6%
Different adjacent mucosa	74.7%	11.7%
Clearly demarcated	72.5%	33.1%
Oval, tubular or branched pits	71.7%	11.0%
Thick vessels	40.9%	8.4%
Features predictive of non-adenomas		
Pale	32.3%	92.9%

GE: Gastroenterologist; PPV: Positive predictive value; NPV: Negative predictive value.

doscopists. Mean sensitivity, specificity and accuracy for diagnosing adenomas were 79.3%, 85.7% and 81.1%, respectively (Table 4). The corresponding PPV and NPV were 84.7% and 80.5%, respectively.

Factors influencing the diagnostic performances of the endoscopists

The effects of the level of experience, polyp characteristics and image quality for the prediction of polyp histology on the diagnostic performances of the endoscopists are shown in Table 4. We found no significant difference in mean sensitivity (76.4% *vs* 81.0%, $P = 0.320$), mean specificity (82.1% *vs* 87.8%, $P = 0.378$) and mean accuracy (78.0% *vs* 82.9%, $P = 0.098$) for predicting polyp histology between gastroenterologists and trainees. Of note, mean accuracy for prediction of histology was significantly higher in non-diminutive *vs* diminutive polyps (93.1% *vs* 74.2%, $P = 0.008$). With regard to location, colorectal polyps located in the distal colon were predicted with a higher mean accuracy as compared to colorectal polyps located in the proximal colon, although not statistically significant (86.0% *vs* 75.6%, $P = 0.187$). With regard to the morphology, no significant differences were observed between polypoid and non-polypoid lesions (83.1% *vs* 77.3%, $P = 0.470$). Of all images, 319 (58.0%) were considered to be of excellent quality. As expected, excellent quality images were predicted with a significantly higher mean accuracy as compared to good quality images (90.3% *vs* 68.4%, $P = 0.007$).

High confidence diagnoses

A total of 446 (81.1%) diagnosis could be made with high confidence. High confidence diagnoses corresponded to a significantly higher mean accuracy (84.0% *vs* 64.3%, $P = 0.008$) than low confidence diagnoses. A total of 281 (88.1%) excellent quality images were diagnosed with high confidence. High confidence diagnosis in combination with excellent quality images resulted in a significantly higher mean accuracy (92.8% *vs* 62.3%, $P = 0.014$) as compared to low confidence diagnosis in combination with high quality images. PPVs and NPVs of high confidence diagnoses were 90.2% and 82.8%, respectively.

Agreement with formal histology

The *kappa* value, reflecting agreement of the endoscopist prediction with formal histology, ranged from 0.453 to 0.737 among the eleven endoscopists (Table 5). Analysis of high confidence diagnoses only improved the kappa value ranging from 0.519 to 0.821 indicating a moderate to substantial agreement.

A total of 319 (58.0%) images were rated as excellent quality images. Taking into consideration these images only, the kappa values ranged from 0.621 to 0.828. When considering high confidence diagnoses in combination with excellent quality images, the kappa values ranged from 0.709 to 0.900 indicating substantial to almost perfect agreement.

DISCUSSION

The present study shows that after a short didactic training session on optical diagnosis using HD i-scan, endoscopists can already predict colorectal polyp histology,

Table 5 Kappa values reflecting agreement of the endoscopist prediction with formal histopathology

	Kappa range	Interpretation[1]
All images (n = 50)		
All predictions	0.453-0.737	Moderate–substantial agreement
High confidence predictions	0.519-0.821	Moderate-substantial agreement
Excellent quality images (n = 29)		
All predictions	0.621-0.828	Substantial-almost perfect agreement
High confidence predictions	0.709-0.900	Substantial-almost perfect agreement

[1]Interpretation according to Landis and Koch (reference 37).

with a mean accuracy of 84.0% for high confidence diagnosis. In addition, we found that specific polyp characteristics might negatively affect the diagnostic performances of endoscopists, in particular a diminutive size.

It is important to systematically evaluate the benefit of new image enhanced endoscopy techniques, as these have become widely available and might enable refinement of diagnosis and a more efficient treatment of colorectal polyps in routine practice[1,2]. Accurate optical diagnosis may allow the endoscopist to leave diminutive non-adenomatous polyps of the rectosigmoid in place and remove and discard diminutive adenomas, thereby reducing the pathology costs and potential risks of complications[6,7]. In addition, these technologies may offer a substitute for histopathology in case colorectal polyps are not retrieved for formal histopathology[8] (*i.e.*, about 8% of all colorectal polyps are histologically uninterpretable in routine practice due to lack of retrieval after polypectomy or damaged material[39]).

Several studies demonstrated optical diagnosis is feasible using chromoendoscopy[15,16] or NBI[3,14-17], while only few studies examined the feasibility using HD i-scan technology[5,17,19-22], and none of them was conducted outside an expert setting. We therefore developed a simple classification system of colorectal polyps using HD i-scan (ICE classification) and evaluated the diagnostic performances for prediction of histology in a group of non-expert endoscopists.

In line with previously reported data[5,17,19-22], the current study shows that endoscopists can predict polyp histology with a mean accuracy of 84.0% (high confidence diagnosis) using HD i-scan still images. Hoffman *et al*[5,19] reported accuracy rates ranging from 96% to 99% in two single centre studies. All procedures in these studies were conducted by endoscopists with high-level of expertise on image enhanced endoscopy techniques[40], including HD i-scan, and using electronic magnification, which might explain the high accuracy rates observed in these studies[5,19]. The results of our study are consistent with the findings reported in a study by Pigò *et al*[21] in which an experienced endoscopist predicted the histology of 150 colorectal polyps during colonoscopy with a sensitivity, specificity and accuracy of 95%, 82% and 92%, respectively. Subsequently, still images of these 150 colorectal polyps were evaluated by four other endoscopists after a short teaching session with an overall sensitivity of 88%, specificity of 62% and accuracy of 82%. When evaluating good/excellent quality images only, their overall accuracy improved to 94%, which is in line with our data. A possible explanation for the higher accuracy rates reported by real-time visual assessment compared to still images is perhaps the dynamic observation of lesions (*e.g.*, air insufflation, closer inspection) which may provide additional details. It is therefore plausible that our data underestimate the true diagnostic performances of the endoscopists in routine practice, when polyp histology is predicted by real-time visual assessment.

The present study indicates that a 20 min didactic training session is an effective and efficient way to familiarize endoscopists with the basic principles of optical diagnosis. This is in agreement with existing literature data showing a short and rapid learning curve for accurate evaluation of still images using new image enhanced endoscopy techniques[41,42]. Although several studies showed experienced endoscopists can accurately predict polyp histology[5,14,17], recent data reported lower performances of endoscopists in a community setting[18]. It is possible such lower performances and operator-dependency may reflect different levels of training[6,22], thus emphasizing the need for learning programs comprising both an *ex vivo* and *in vivo* phase. By analogy with our previous experience regarding training in detection and management of non-polypoid lesions[23], we suggest the following steps might be considered. First, a short didactic training session might be offered to the endoscopists to familiarize them with the basic principles of optical diagnosis. Second, video training can help to further shape their skills. Finally, individual feedback during colonoscopy by an experienced endoscopists and self-learning (*i.e.*, comparison of optical diagnosis with formal histopathology) might be important to achieve and maintain proficiency in optical diagnosis.

In this study we paid special attention to identify specific factors which may negatively impact prediction of histology, as this may help to establish targets for improvements. We found that colorectal polyps of diminutive size, proximally located or with non-polypoid morphology are more likely predicted with a lower accuracy. In a recent study by our group, proximal neoplasms appeared to be in general more frequently diminutive and have a non-polypoid shape[27]. Taken together these findings emphasize the need for careful inspection of proximal lesions, which might be both more challenging to detect and also to characterize histologically. Optimal bowel preparation, which may be more difficult to achieve in the proximal colon[43] has definitely a key role in reaching these targets.

In this study, we developed a simple classification system (*i.e.*, the ICE classification) of colorectal polyps by means of HD i-scan, applying similar criteria to those described by the NICE classification using NBI[34]. Although several studies now investigated the performance

characteristics of optical diagnosis using different image enhanced technologies[4,17,26], the outcomes are difficult to compare due to heterogeneity in the diagnostic criteria used. Implementation of a simple, universal classification system, irrespective of the endoscopic technology used, is essential for comparing the outcomes across studies.

According to the American Society for Gastrointestinal Endoscopy recommendations, a NPV of at least 90% should be attained for a safe implementation of a leave in place approach for diminutive non-adenomatous polyps in routine practice[44]. These benchmarks can be already achieved by expert endoscopists[45], yet data in a non-expert setting are scarce and controversial. In our experience, excellent quality images in conjunction with high confidence diagnosis resulted in a mean accuracy of 92.8%. Studies are currently underway at our institution to assess the performance characteristics of real-time optical diagnosis in a non-expert setting.

Some methodological aspects of this study need further consideration. As a strength, endoscopists with varying levels of experience, and who were previously familiarized on the recognition and management of non-polypoid colorectal neoplasms participated[27,28]. Second, we used a simple classification system (ICE classification), based on previously defined and validated criteria[34]. Third, we examined the influence of polyp characteristics, image quality and use of confidence levels on the diagnostic performances to highlight potential targets for training. As a limitation, we used a selection of images consisting of small and larger colorectal polyps whereas optical diagnosis seems to be applicable for small and diminutive polyps only, given the low rate of advanced histology in these lesions[8]. We assume, however, that simple observation and recognition of the pit-patterns may be the first step when developing educational skills in optical diagnosis. Second, the diagnostic performances of the endoscopists involved in this study did not reach the threshold recommended for a safe implementation of a leave in place approach of non-adenomatous polyps[44]. This was not unexpected, as HD i-scan was only recently introduced at our institution, and hence, the endoscopists might have been still early in their learning curves. Third, the diagnostic performances might have been underestimated as endoscopists predicted polyp histology based on still images instead of real-time visual assessment. Finally, in this study we assigned the sessile serrated adenomas/polyps to the group of non-adenomatous polyps. However, as only 1 out of the 50 colorectal polyps examined turned to be a sessile serrated adenoma/polyp, its re-classification into adenomatous lesion is unlikely to change the results and conclusions of this study.

In conclusion, the present study indicates that optical diagnosis using HD i-scan is feasible for endoscopists with varying levels of experience, with a mean accuracy of 84.0% for high confidence diagnosis. A short training module is an effective tool to familiarize the practicing endoscopists with the basic principles of optical diagnosis, although continuous training and practice may be needed to optimize the skills in optical diagnosis.

ACKNOWLEDGMENTS

We are grateful to all endoscopists, especially Michel Aquarius, José Conchillo, Jeoffrey Haans, Chantal Hoge, Reggy Jaspers, Yolande Keulemans, Ger Koek, Johanna Kruimel, Wout Mares, Tamara Munnecom and Jennifer Wilbrink at the Division of Gastroenterology and Hepatology for their enthusiastic participation in this study.

COMMENTS

Background

Image enhanced endoscopy techniques, such as chromoendoscopy either dye-based or digital [narrow band imaging, high-definition (HD) i-scan or Fujinon Intelligent Color Enhancement] techniques became largely available. Such technologies offer the opportunity to accurately differentiate adenomas from non-adenomatous polyps, allowing their individualized treatment, which in turn may increase the efficiency of colonoscopic procedures.

Research frontiers

Currently, data about the diagnostic performances using HD i-scan are scarce. None of these studies was conducted outside an expert setting, nor applied standardized diagnostic criteria, and none specifically addressed the impact of training.

Innovations and breakthroughs

In this study, authors found that, after a short didactic session, all endoscopists, trainees as well as gastroenterologists, could already predict polyp histology with a mean accuracy of 84%. Authors additionally propose a simple classification of diagnostic criteria of colorectal polyps using HD i-scan (i-scan classification for endoscopic diagnosis), which might represent a practical tool for optical diagnosis in the community setting.

Applications

This study highlights the importance of training in attaining practical skills in optical diagnosis using new image enhanced endoscopy techniques.

Terminology

The HD i-scan technology is a new image enhanced endoscopy technique that allows digital chromoendoscopy *via* the Pentax EPKi processor.

Peer review

They present the result of examining performances regarding prediction of polyp histology using HD i-scan in a group of endoscopists with varying levels of experience. The authors conclude that endoscopists with varying levels of experience can already provide optical diagnosis with an accuracy of 84.0%. This is a relevant study as optical diagnosis of colorectal polyps might offer an alternative to histologic diagnosis and may downsize the pathology costs and reduce the risk of complications. This manuscript is a well-written paper, however, it may be refined with a minor revision by authors.

Abstract

AIM: To investigate adherence rates in tumor necrosis factor-α (TNF-α)-inhibitors in Crohn's disease (CD) and rheumatoid arthritis (RA) by systematic review of medical literature.

METHODS: A structured search of PubMed between 2001 and 2011 was conducted to identify publications that assessed treatment with TNF-α inhibitors providing data about adherence in CD and RA. Therapeutic agents of interest where adalimumab, infliximab and etanercept, since these are most commonly used for both diseases. Studies assessing only drug survival or continuation rates were excluded. Data describing adherence with TNF-α inhibitors were extracted for each selected study. Given the large variation between definitions of measurement of adherence, the definitions as used by the authors where used in our calculations. Data were tabulated and also presented descriptively. Sample size-weighted pooled proportions of patients adherent to therapy and their 95%CI were calculated. To compare adherence between infliximab, adalimumab and etanercept, the adherence rates where graphed alongside two axes. Possible determinants of adherence were extracted from the selected studies and tabulated using the presented OR.

RESULTS: Three studies on CD and three on RA were identified, involving a total of 8147 patients (953 CD and 7194 RA). We identified considerable variation in the definitions and methodologies of measuring adherence between studies. The calculated overall sample size-weighted pooled proportion for adherence to TNF-α inhibitors in CD was 70% (95%CI: 67%-73%) and 59% in RA (95%CI: 58%-60%). In CD the adherence rate for infliximab (72%) was highercompared to adalimumab (55%), with a relative risk of 1.61 (95%CI: 1.27-2.03), whereas in RA adherence for adalimumab (67%) was higher compared to both infliximab (48%) and etanercept (59%), with a relative risk of 1.41 (95%CI: 1.3-1.52) and 1.13 (95%CI: 1.10-1.18) respectively. In comparative studies in RA adherence to infliximab was better than etanercept and etanercept did better than adalimumab. In three studies, the most consistent factor associated with lower adherence was female gender. Results for age, immunomodulator use and prior TNF-α inhibitors use were conflicting.

CONCLUSION: One-third of both CD and RA patients treated with TNF-α inhibitors are non-adherent. Female gender was consistently identified as a negative determinant of adherence.

Key words: Adherence; Tumor necrosis factor-α inhibitors; Systematic review; Crohn's disease; Rheumatoid arthritis

Core tip: This study assessed adherence with tumor ne-

crosis factor-α (TNF-α) inhibitors in Crohn's disease (CD) and rheumatoid arthritis (RA) by systematic review. We found only two-third of the patients with CD and RA receiving TNF-α inhibitors adherent to therapy. Definitions of measurement of adherence varied widely between studies and there is no clarity on what levels of adherence are required for optimal results of therapy. Future research on adherence should focus on therapy outcome, by using uniform definitions of adherence.

Low rates of adherence for tumor necrosis factor-α inhibitors in Crohn's disease and rheumatoid arthritis: Results of a systematic review. *World J Gastroenterol* 2013; 19(27): 4344-4350 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4344.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4344

INTRODUCTION

Crohn's disease (CD) and rheumatoid arthritis (RA) are chronic inflammatory conditions characterized by episodes of remission and flare-ups that have a major impact on the patient's physical, emotional and social well-being. The management of these diseases has been profoundly modified by the introduction of tumor necrosis factor-α (TNF-α) inhibitors, *i.e.*, infliximab, adalimumab and etanercept (only in RA), and these agents have become an integral part of the therapeutic arsenal. In RA TNF-α inhibitors have shown to rapidly improve symptoms, retard radiographic disease progression and improve functional status and health-related quality of life[1]. Also in CD TNF-α inhibitors are highly efficacious for induction and maintenance therapy and reduce rates of hospitalization and surgery[2].

Clinical effectiveness of TNF-α inhibitors is dependent on adequate adherence, and failure to stick to the prescribed drug regimen contributes to failure of treatment and disease recurrence. For both RA and CD, good adherence is associated with more effective treatment, including limited loss of response[3,4]. Fernández-Nebro *et al*[4] reported that in CD the probability of premature failure of TNF-α inhibitors was 61% less in patients with good adherence.

For patients with inflammatory bowel disease, reported non-adherence rates for oral medication range in most studies between 30%-45%[5]. Low adherence has an impact on healthcare budgets by increasing number of treatment failures, subsequent diagnostic procedures and unnecessary change of therapy. A Cochrane review on adherence concluded that improving medicine intake may have a far greater impact on clinical outcomes than an improvement in treatments[6]. In line with this statement Kane *et al*[7] pointed out that all-cause and CD-related medical costs were 81% and 94% higher, respectively, for non-adherent patients in comparison to adherent patients.

Although it has been 15 years since TNF-α inhibitors were introduced for the treatment of CD and RA, our understanding of patient's compliance to TNF-α inhibitors is minimal and reported rates of adherence vary widely, depending on the definition of adherence. In order to assess the adherence rates for TNF-α inhibitors in CD and RA, we systematically reviewed literature and performed meta-analysis.

MATERIALS AND METHODS

We conducted a structured search of PubMed to identify potentially relevant English-language publications that assessed adherence to TNF-α inhibitors in CD. In our search strategy, the following keywords and search strings were used: (infliximab OR Remicade OR adalimumab OR Humira OR etanercept OR Enbrel OR anti-TNF OR biological) AND Crohn AND (adherence OR compliance). In the same way, we conducted a search of PubMed to identify potentially relevant publications that assessed adherence with TNF-α inhibitors in RA, thereby substituting the search term "Crohn" for "RA". During the whole process the exact reporting guidelines as described in the PRISMA statement (www.prisma-statement.org) were followed.

Two investigators (Fidder HH and Singendonk MMJ) independently reviewed identified titles and abstracts of all citations in the literature search results. Potentially relevant studies were retrieved and the following predefined inclusion criteria were applied: (1) original research article; (2) adult patients; (3) definition of adherence provided; (4) methodology of measurement of adherence described; and (5) data based on number of patients. From selected abstracts, full articles were retrieved, reviewed and included if they contained data regarding adherence to TNF-α inhibitors in CD or RA. Disagreements between reviewers were adjudicated by discussion and consensus with a third-party arbiter (MvO).

The following information was extracted for each selected study: TNF-α inhibitors used, study design, sample size, definition of adherence measurement and the levels of adherence reported. We also sought for determinants of adherence in included studies, and tabulated the following factors of interest by using the presented OR: gender, age, duration of disease and therapy, prior and concomitant therapy. The data obtained from the selected articles describing adherence with TNF-α inhibitors were tabulated and also presented descriptively.

Given the large variations in definitions and methodologies of measurement of adherence and patient samples of the studies included, we used the definitions of adherence used by the authors in order to calculate the sample size-weighted pooled proportions of patients that were adherent to therapy and to compare adherence rates between adalimumab, infliximab and etanercept. To portray these data for each therapeutic agent, we graphed them alongside two axes; adherence rate re-

Table 1 Characteristics of included studies on Crohn's disease and rheumatoid arthriti

	Number of patients	Anti-TNF treatment	Definition of adherence	Adherence
Crohn's disease				
Kane *et al*[7]	571	Infliximab	≥ 7 infusions in first year of treatment	66%
Billioud *et al*[17]	108	Adalimumab	Neither delaying nor missing > 1 injection in 3 mo	55%
Kane *et al*[18]	274	Infliximab	No "No show" designation during study period	85%
Rheumatoid arthritis				
Borah *et al*[19]	2537	Etanercept	Medication possession ratio ≥ 0.80	71%
	1292	Adalimumab		67%
Harley *et al*[20]	853	Etanercept	Medication possession ratio ≥ 0.80	68%
	141	Infliximab		81%
Li *et al*[21]	1359	Etanercept	Proportion of days covered ≥ 0.80	32%
	1012	Infliximab		43%

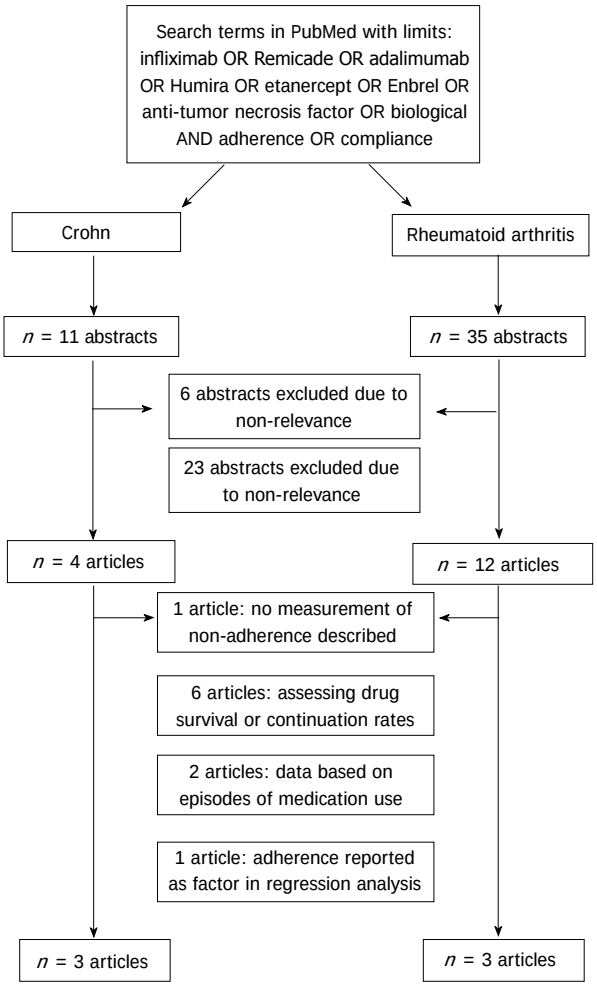

Figure 1 Results of literature search.

ported by the selected study for each agent and number of patients included.

RESULTS

Literature search

The search identified 11 studies regarding CD and 35 regarding RA, of which respectively 7 and 32 articles were excluded in two selection procedures. The main reason for exclusion of studies on CD was the absence of data on adherence or compliance (Figure 1)[8]. Exclusion of studies on RA was mainly based on the fact that these studies assessed drug survival or continuation rates only, but not compliance and/or adherence[4,9-13]. Three other studies were excluded: two studies based their data on episodes of medication use instead of number of patients[14,15] and one study only reported adherence as a factor in regression analysis[16]. Six articles that met our inclusion criteria remained, three on CD[7,17,18] and three on RA[19-21]. Characteristics of included studies are shown in Table 1.

CD

Two out of three studies on CD reported on adherence to infliximab[7,18] and one on adalimumab[17]. There were no comparative studies. We identified considerable variation in the definitions and methodologies of measuring adherence between studies. The adherence rate for all TNF-α inhibitors as calculated by the sample size-weighted pooled proportion was 70% (95%CI: 67%-73%). For adalimumab, the reported adherence rate was 55%[17] and for infliximab the reported rates were 66%[7] and 85%[18] (Table 1). Adherence to adalimumab (55%) was statistically significantly lower than infliximab (72%) therapy, with a relative risk of 0.76 (95%CI: 0.64-0.91) (Figure 2)[7,17,18].

RA

For RA we only found comparative studies: two of the included studies assessed adherence to both etanercept and infliximab[20,21] and one study compared etanercept with adalimumab[21]. In RA, measurement of adherence was based on medication possession ratios in two studies and one study measured adherence as the proportion of days covered (PDC). Medication possession rate (MPR) is defined as the sum of days supply for all fills in period divided by the number of days in a period. PDC is the number of days in a period covered by medication divided by the days in a period. In all studies patients were considered adherent if MPR or PDC was ≥ 0.8.

Reported adherence rates ranged from 32% to 81% (Table 1)[19-21]. The overall adherence rate was 59% (95%CI: 58%-60%), as calculated by the sample size-weighted pooled proportion. In the two studies compar-

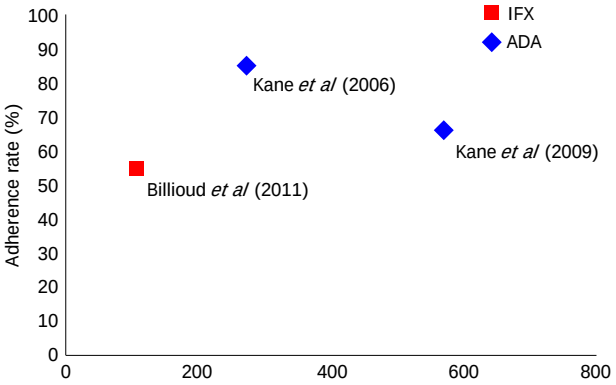

Figure 2 Adherence rates reported by the included studies on Crohn's disease for infliximab and adalimumab. The vertical axis rank-orders the therapeutic agents by the adherence rates and the horizontal axis by number of patients included. IFX: Infliximab; ADA: Adalimumab.

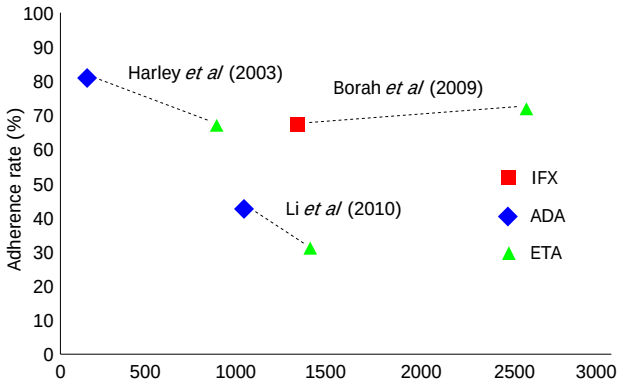

Figure 3 Adherence rates reported by the included studies on rheumatoid arthritis for infliximab, adalimumab and etanercept. The vertical axis rank-orders the therapeutic agents by the adherence rates and the horizontal axis by number of patients included. IFX: Infliximab; ADA: Adalimumab; ETA: Etanercept.

ing infliximab to etanercept adherence to infliximab was consistently higher (Figure 3)[20,21]. In the study comparing etanercept to adalimumab, patients using etanercept were slightly more adherent than adalimumab users[19]. After pooling the published adherence rates, we found the highest adherence rate for adalimumab (67%) compared to both infliximab (48%) and etanercept (59%), with a relative risk of 1.41 (95%CI: 1.3-1.52) and 1.13 (95%CI: 1.10-1.18) respectively.

Predictors

Five studies have formally explored possible predictors of (non)-adherence to TNF-α inhibitors (Table 2)[7,19-21]. The most consistent factor associated with lower adherence (reported by three studies) was female gender[7,20,21]. Increasing duration of therapy was reported as a factor negatively associated with adherence and duration of disease as factor associated with better adherence[7,18]. Results for age, immunomodulator use and prior TNF-α inhibitors use were conflicting[7,19].

DISCUSSION

We systematically reviewed adherence rates to TNF-α inhibitors in CD and RA. Although literature on adherence rates to TNF-α inhibitors in other rheumatological diseases exists, we did not assess adherence for these diseases given the relatively small patient numbers. Given the central position of TNF-α inhibitors in the management of CD and RA and the importance of adherence for effective treatment, the total number of six studies that adequately assessed adherence to anti-TNF therapy was surprisingly low. Our analysis of the included studies on CD and RA has three key findings. First, we found that adherence to TNF-α inhibitors in CD and RA is low, with only two-thirds of the patients being adherent to therapy. Second, adherence rates for adalimumab were lower compared to infliximab in CD. Last, we found that female gender was consistently associated with non-adherence to TNF-α inhibitors.

Our findings of rather low adherence to TNF-α inhibitors are in line with figures reported for adherence to oral medication in inflammatory bowel disease, that range between 28% and 93% of patients adherent to prescribed therapy[5,22,23]. In a comparative cohort study mesalazine and azathioprine were associated with the lowest compliance[24]. In RA the adherence rates for TNF-α inhibitors has been reported between 30% and 80%, depending on definitions used[25]. The low adherence to TNF-α inhibitors are especially worrisome since long treatment intervals are associated with infusion reactions and loss of response as result of increased antibody formation against TNF-α inhibitors[26-28]. Moreover, non-adherence in adalimumab treated patients predicts higher hospitalization rates and increased medical service costs[7]. Adherence to continuous maintenance treatment with TNF-α inhibitors is important for the efficacy of treatment.

Although the different routes and schedules of administration of TNF-α inhibitors and the different measures of adherence across studies may impede a direct comparison, we found lower adherence rates with adalimumab and etanercept. In RA, pooling the adherence rates gave higher adherence for adalimumab over infliximab but all comparative studies reported higher adherence rates for infliximab as well. Differences in patient numbers between studies and a difference between the number of studies used for calculating the pooled adherence rates for the single treatment modalities are underlying this conflicting finding. In addition, Li *et al*[21] assesses adherence rates with etanercept and infliximab by using the PDC, which is a more conservative estimate for adherence compared to the MPR. Discrepant adherence between treatment options may be explained by a number of reasons including dosing frequency and route of administration. Etanercept and adalimumab are self-administered subcutaneously, whereas infliximab is administered intravenously, by a healthcare professional in a clinical setting. As patients need to visit infusion sites, adherence is more controllable in favor of infliximab. Indeed, in the two comparative studies between infliximab and etanercept[20,21], higher adherence was found for the intravenously administered infliximab. In the study of

Table 2 Determinants of adherence in Crohn's disease and rheumatoid arthritis

	Studies on Crohn's disease			Studies on rheumatoid arthritis	
	Kane *et al*[7]	Billioud *et al*[17]	Kane *et al*[18]	Borah *et al*[19]	Li *et al*[21]
Female gender	OR < 1		OR < 1; P < 0.05		OR < 1
Increasing age		OR < 1			OR > 1
Immunomodulator use	OR > 1		OR < 1		OR > 1; P < 0.05[1]
Prior biologic use	OR < 1; P < 0.05			OR > 1; P < 0.05	
Increasing duration of therapy			OR < 1; P < 0.05		
Increasing disease duration		OR > 1; P < 0.05			

[1]Significant at P < 0.05 for age 55-64 years (OR = 1.49).

Borah *et al*[19] adherence of etanercept - which is injected once or twice a week - was slightly higher than adalimumab, which is mostly self-administered using a bi-weekly schedule. But still, even for the more controllable intravenously administered modalities, adherence rates are well below 100%.

In order to improve adherence, it is essential to identify and understand risk factors for non-adherence. Although several factors were reported as determinants of adherence by the reviewed studies, we did not find any of these factors consistently associated with non-adherence, with the exception of female gender. This is in contrast with a previous study on oral therapies in inflammatory bowel disease that identified female gender as a positive determinant of adherence[29]. Also in other fields of medicine attempts to identify clinical, demographic and treatment factors that consistently predict adherence have proven quite disappointing[6]. Jackson *et al*[5] who systematically reviewed factors associated with non-adherence to oral medication specifically for inflammatory bowel disease pointed out that that simple factors such as demographics or treatment regimens could not reliably predict adherence. Far more important determinants were psychological distress, patients' beliefs about therapy, and doctor-patient interactions[5]. For the clinician, it is essential to be aware of the importance of psychological factors in non-adherence and that significant improvement in terms of adherence may be achieved by fine-tuning doctor-patient communication and addressing patients' individual beliefs about disease and medications.

Our study has several strengths and limitations. We provided a detailed and systematic review of published literature and studied adherence rates on both CD and RA with TNF-α inhibitors. Koncz *et al*[30] reviewed compliance and persistence for TNF-α inhibitors only in RA patients. Contrary to this review we included only studies that assessed adherence rates based on number of patients included and reported individual adherence results. Furthermore, we identified potential predictors of adherence. In the evaluation of potential predictors of adherence, we had no access to original research data and therefore we were dependent on the analyses performed by others and could not perform an individual patient data meta-analysis. The major drawback of this approach is the lack of agreement in terminology and methodologies for measurement of therapy behaviour, making the results of studies assessing this issue difficult to interpret and compare. Compliance, persistence and adherence are definitions used for assessing this. The medication possession ratios of infliximab, etanercept and adalimumab ranged between 63% and 90% and PDC around 40%. The PDC provides a more conservative estimate of adherence compared to MPR when patients are switching drugs or using dual-therapy in a class. The differences between these terms have been defined in a report for the National Institute for Health Research by Mikkelsen *et al*[31] Compliance can be defined as "the extent to which the patients" behaviour matches the prescriber's recommendations' quantified as "a percentage of number of doses taken or therapy days available in relation to a fixed period of time". Persistence refers to how long the patient takes the medicine for and is therefore measured by units of time. Adherence covers both these aspects of medication taking behaviour. Although these definitions seem clear, methodologies of measurement vary and therefore hinder comparability of findings. These differences in measurement of adherence cannot be shrugged aside, but at this stage, based on currently available literature, we provided more insight in the TNF-α therapy behaviour of patients with CD and RA. Despite the mentioned limitations, it is still clear that adherence with TNF-α therapy is low for all different modalities. However, there is no clarity on what levels of adherence are required for optimal results of therapy yet and these levels might vary depending on disease activity and localization. Therefore, in the future adherence should be assessed in combination with therapy outcome in order to determine optimal treatment schedules by using uniform definitions of compliance, adherence and persistence.

In conclusion, through systematic review we found that only two-third of the patients with CD and RA receiving TNF-α inhibitors were adherent to therapy. Developing methods that properly assess medication adherence could provide tools for improvement of therapy outcome. Although female gender was identified as a negative determinant of adherence, one should be aware that mechanisms underlying adherence are complicated and probably not determined by simple patient's and treatment characteristics.

COMMENTS

Background

Crohn's disease (CD) and rheumatoid arthritis (RA) are chronic inflammatory conditions characterized by episodes of remission and flare-ups that have a major impact on the patient's physical, emotional and social well-being. The management of these diseases has been profoundly modified by the introduction of tumor necrosis factor-α (TNF-α) inhibitors.

Research frontiers

Clinical effectiveness of TNF-α inhibitors is dependent on adequate adherence, and failure to stick to the prescribed drug regimen contributes to failure of treatment and disease recurrence. For both RA and CD, good adherence is associated with more effective treatment, including limited loss of response.

Innovations and breakthroughs

The analysis of the included studies on CD and RA has three key findings. First, the authors found that adherence to TNF-α inhibitors in CD and RA is low, with only two-thirds of the patients being adherent to therapy. Second, adherence rates for adalimumab were lower compared to infliximab in CD. Last, they found that female gender was consistently associated with non-adherence to TNF-α inhibitors.

Applications

The authors found that only two-third of the patients with CD and RA receiving TNF-α inhibitors were adherent to therapy. Developing methods that properly assess medication adherence could provide tools for improvement of therapy outcome.

Peer review

This article investigated adherence rates inTNF-α-inhibitors in CD and RA by systematic review of medical literature, and is informative and well-presented.

Abstract

AIM: To present a new technique of end-to-side, duct-to-mucosa pancreaticojejunostomy with seromuscular jejunal flap formation, and insertion of a silicone stent.

METHODS: We present an end-to-side, duct-to-mucosa pancreaticojejunostomy with seromuscular jejunal flap formation, and the insertion of a silicone stent. This technique was performed in thirty-two consecutive patients who underwent a pancreaticoduodenectomy procedure by the same surgical team, from January 2005 to March 2011. The surgical procedure performed in all cases was classic pancreaticoduodenectomy, without preservation of the pylorus. The diagnosis of pancreatic leakage was defined as a drain output of any measurable volume of fluid on or after postoperative day 3 with an amylase concentration greater than three times the serum amylase activity.

RESULTS: There were 32 patients who underwent end-to-side, duct-to-mucosa pancreaticojejunostomy with seromuscular jejunal flap formation. Thirteen of them were women and 19 were men. These data correspond to 40.6% and 59.4%, respectively. The mean age was 64.2 years, ranging from 55 to 82 years. The mean operative time was 310.2 ± 40.0 min, and was defined as the time period from the intubation up to the extubation of the patient. Also, the mean time needed to perform the pancreaticojejunostomy was 22.7 min, ranging from 18 to 25 min. Postoperatively, one patient developed a low output pancreatic fistula, three patients developed surgical site infection, and one patient developed pneumonia. The rate of overall morbidity was 15.6%. There was no 30-d postoperative mortality.

CONCLUSION: This modification appears to be a significantly safe approach to the pancreaticojejunostomy without adversely affecting operative time.

Key words: Whipple; Pancreaticojejunostomy; Technique; Seromuscular jejunal flap; Pancreatic fistula

Core tip: Pancreaticojejunostomy represents one of the most challenging technical aspects of the Whipple procedure, mainly due to its failure, and to the resulting morbidity and mortality rates. Several technical variations have been proposed, in an effort to minimize postoperative pancreatic fistula rates. The technique we describe is an end-to-side, duct-to-mucosa two-layer pancreaticojejunostomy intended to promote enhanced healing process, through the creation of a seromuscular

jejunal flap. This technique appears to be safe and reliable; however, these are preliminary results.

A new pancreaticojejunostomy technique: A battle against postoperative pancreatic fistula. *World J Gastroenterol* 2013; 19(27): 4351-4355 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4351.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4351

INTRODUCTION

The first pancreaticoduodenectomy was performed by a German surgeon, Kausch, in 1909[1-3]. It has been considered the surgical procedure of choice for ampullary cancer, after Whipple *et al*[4] had described three cases in 1935. Nowadays, it has become the standard procedure in the management of pancreatic head and periampullary carcinoma[2]. In recent years, the mortality rate of pancreatico-duodenectomy has been decreased to below 5%[5-7]. However, the postoperative morbidity rate remains high, ranging from 30% to 50%[7-10]. Pancreatic fistula[11,12] is the most common complication and its reported incidence varies from 2% to 40%[8,11,13]. Several different anastomotic surgical techniques have been used, in order to minimize pancreatic fistula occurrence after pancreaticoduodenectomy, although it is still debated which of them has any clear advantage[2,9,10,14,15]. We present a modification for duct to mucosa end-to-side pancreaticojejunostomy, with a seromuscular jejunal flap, in order to increase the safety of the anastomosis.

MATERIALS AND METHODS

During the period January 2005 to March 2011, 32 consecutive patients underwent pancreaticoduodenectomy by the same surgical team. There were 13 women and 19 men, with a mean age of 64.2 years (range 55-82 years). The underlying diseases of these patients are shown in Table 1. The surgical procedure performed in all cases was classic pancreaticoduodenectomy, without preservation of the pylorus. The diagnosis of pancreatic leakage was defined as a drain output of any measurable volume of fluid on or after postoperative day 3 with an amylase concentration greater than three times the serum amylase activity[11].

Technique

A scalpel is used to sharply transect the pancreas at the level of the portal vein. Hemostasis of the bleeding points of the pancreatic stump is achieved either with 4-0 non-absorbable suture and/or with electrocautery. After the pancreaticoduodenectomy specimen has been removed, the pancreatic remnant is dissected free of the underlying structures for a distance of approximately 2 cm. The transected jejunum is brought through the bed of the resected duodenum (*i.e.*, posterior to the mesenteric vessels).

Table 1 Underlying diseases of the patients who underwent end-to-side, duct to mucosa pancreaticojejunostomy with seromuscular jejunal flap formation after pancreaticoduodenectomy

Disease	Patients (*n*)
Pancreatic head carcinoma	15
Ampullary carcinoma	12
Distal common bile duct carcinoma	5
Total	32

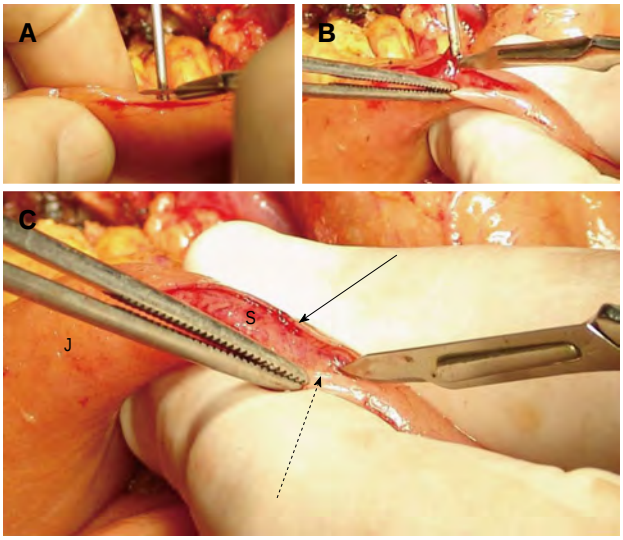

Figure 1 Preparation of the jejunal stump. A: Incision on the jejunum; B: Seromuscular flap formation; C: The seromuscular layers are dissected free from the submucosa. J: Jejunum; S: Submucosa; Arrow: Posterior seromuscular flap; Dotted arrow: Anterior seromuscular flap.

The jejunal seromuscular layer is incised starting about 2 cm distal to the jejunal stump, along the antimesenteric border. The length of this incision is just smaller than the cephalo-caudal diameter of the pancreatic stump. Using a scalpel the seromuscular layer of the jejunum is dissected free from the underlying submucosa, towards both sides of the aforementioned incision, in order to create two seromuscular flaps (*i.e.*, one dorsal and one ventral flap), and to expose the underlying submucosa, which must remain intact (Figure 1). The extent of the dissection is determined by the antero-posterior diameter of the pancreatic stump, in order to fit the surface of the pancreatic cut edge on the surface area of the exposed mucosa.

Following this, a segment of nelaton catheter is inserted into the main pancreatic duct, and is fixed with a 4-0 absorbable monofilament suture (polydioxanone, PDS Ⅱ, Ethicon, Inc.). The tube girth is selected to exactly fit the diameter of the main pancreatic duct. On the intraductal part of the stent, several holes are created on different positions, at a distance of 1 cm from each other, in order to ensure uninhibited outflow of the pancreatic fluid. The extraductal part of the stent left is about 5 cm in length.

The next step is to create the first of all four suturing

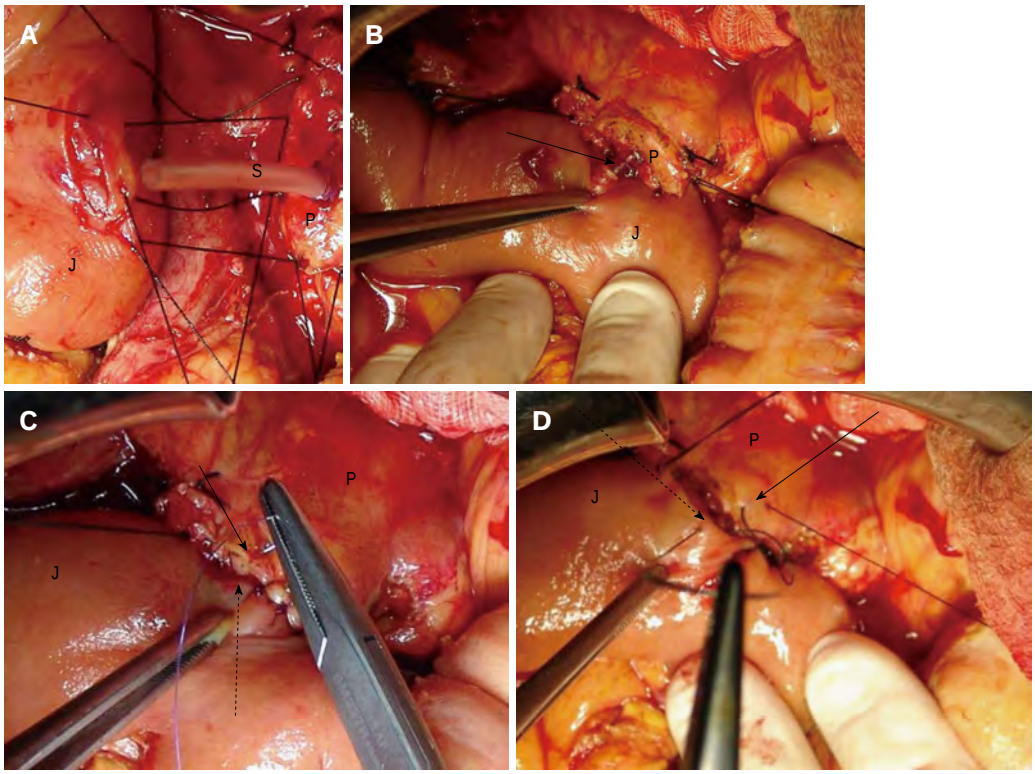

Figure 2 The posterior, anterior external layer of sutures and stent in place. A: The posterior (dorsal) external layer of sutures; B: Stent in place. Arrow: The stent enters the jejunal small opening, which has been created in the middle of the dissected submucosal surface; C: The anterior (ventral) internal layer of sutures. Arrow: Anterior pancreatic cut edge border; Dotted arrow: Anterior seromuscular flap; D: The anterior (ventral) external layer of sutures. Arrow: Anterior pancreatic part of the capsular parenchyma; Dotted arrow: Anterior part of the jejunal seromuscular layer. J: Jejunum; S: Stent; P: Pancreatic stump cut surface.

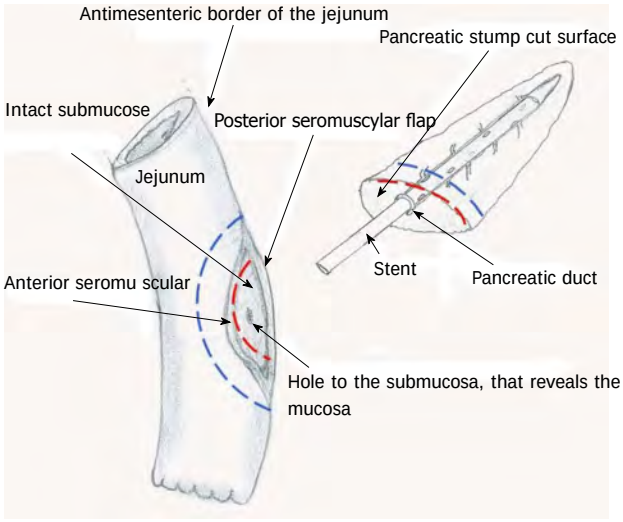

Figure 3 This is a schema that shows the dissected surface of the jejunum and the cut surface of the pancreas that are approximated. The red dotted line represents the ventral internal suturing layer (*i.e.*, the 3rd one). The blue dotted line represents the ventral external suturing layer (*i.e.*, the 4th one).

layers. The dorsal part of the jejunal seromuscular layer and the dorsal part of the capsular parenchyma of the pancreatic stump are sutured with 3-0 silk interrupted stitches of 0.5-1 cm distance from each other. This is the dorsal external suturing layer (Figure 2A).

Then, the dorsal cut edge border of the pancreatic stump is sutured to the edge of the dorsal jejunal seromuscular flap with 4-0 polydioxanone sutures (PDS) Ⅱ interrupted stitches 0.5 to 1 cm apart. This is the dorsal internal layer.

A small hole in the jejunal mucosa is made, in accordance with the diameter of the main pancreatic duct. The free end of the stent tube is advanced through this hole into the jejunal lumen (Figure 2B). The mucosa at the site of the hole and the edge of the main pancreatic duct are sutured with two interrupted stitches of 4-0 PDS Ⅱ.

The third layer is created by the approximation of the ventral cut edge border of the pancreatic stump and the edge of the ventral jejunal seromuscular flap with 4-0 PDS Ⅱ interrupted stitches, 0.5-1 cm apart (Figure 2C). This is the ventral internal layer.

The final layer of sutures, the ventral external layer, is created by suturing the ventral part of the jejunal seromuscular layer and the ventral part of the capsular parenchyma of pancreatic stump, with 3-0 silk interrupted stitches (Figure 2D). Figure 3 shows a drawing of the jejunal and pancreatic sites of anastomosis.

Statistical analysis

There were only descriptive measures used, since there was no control group in this study and its main purpose was to describe a surgical technique.

RESULTS

There were 32 consecutive patients that underwent pan-

creaticoduodenectomy with the above described pancreaticojejunostomy technique. There were 13 women and 19 men, with a mean age of 64.2 years (range 55-82 years). The underlying diseases of these patients are shown in Table 1. The mean operative time was 310.2 ± 40.0 min, and the mean time needed to perform the pancreaticojejunostomy was 22.7 min (range 18-25 min). One patient developed low output pancreatic fistula. Three patients developed surgical site infection and one patient developed pneumonia, postoperatively. The overall morbidity rate was 15.6%. There was no postoperative mortality.

DISCUSSION

Pancreaticojejunostomy represents one of the most challenging technical aspects of the Whipple procedure, because of its failure rates, as well as the resulting morbidity and mortality. Several technical variations have been proposed, in an effort to minimize postoperative pancreatic fistula rates[1,2,9,10,14-20]. The most important risk factors identified are technique, soft pancreatic texture and main pancreatic duct diameter of 3 mm or less[13,21-26]. The technique we describe is an end-to-side, duct-to-mucosa two-layer pancreaticojejunostomy. Each step of the procedure already described adheres to a rationale focused on the elimination of pancreatic leakage. First, the exposure of intact jejunal mucosa was thought to promote vascularization and enhance the healing process between the mucosa and the cut surface of the pancreatic stump[27]. Such an approach has been employed in the past with favorable results, but still carried a significant fistula occurrence.

With this in mind, we incorporated the dissection of the seromuscular flaps and their fixation to the border of the pancreatic stump aiming to offer a more reliable sealing of the anastomosis. In the same context, we proposed the internal layer of sutures, which was not previously employed, in order to keep the two traumatic surfaces firmly in contact to further favor the healing process between them. Finally, stenting the main pancreatic duct ensures duct patency, while eliminating undesired distention. In one of our cases, the stent was present in situ even on the six-year follow-up.

In conclusion, this technique appears to be safe and reliable. Because this is a preliminary report of a small series, it is of essential importance that it is evaluated via a prospective study in a larger series, before firm conclusions can be drawn.

Furthermore, while of sound reasoning, the assumption that healing is significantly augmented by exposing the intestinal submucosa is yet to be experimentally proved.

COMMENTS

Background

Pancreatic fistula following pancreaticoduodenectomy is a serious complication associated with high morbidity rates. Various factors have been implicated as contributors to pancreatic anastomotic leak, the incidence of which has been as high as 28% in some series.

Research frontiers

Pancreatic texture, main pancreatic duct diameter and anastomotic technique are considered the most significant factors contributing to higher risk for pancreatic fistula. Among them, anastomotic technique is the only factor that can be evolved.

Innovations and breakthroughs

The authors present a modification for duct to mucosa end-to-side pancreaticojejunostomy, with a seromuscular jejunal flap, in order to increase the safety of the anastomosis.

Applications

This modification appears to be a significantly safe approach to the pancreaticojejunostomy without adversely affecting operative time.

Peer review

In this manuscript, authors have presented the new procedure of pancreaticojejunostomy in pancreaticoduodenectomy to prevent pancreatic fistula. They concluded the new procedure could decrease the occurrence rate of pancreatic fistula. The results are basically interesting for readers.

Abstract

AIM: To investigate the side effects of a zinc sulphate therapy in a cohort of Polish pediatric patients with Wilson's disease.

METHODS: We retrospectively analyzed a cohort of 53 pediatric patients with Wilson's disease treated at the Children's Memorial Health Institute in Warsaw, Poland between the years 1996 and 2011 with zinc sulphate. Patients were diagnosed with Wilson's disease according to the scoring system of Ferenci, with 49 cases confirmed by mutation analysis. Data about the dosage scheme of zinc sulphate, side effects and efficacy and toxicity of the treatment were collected and recorded in the patient's medical chart at each visit to the hospital.

RESULTS: Mean age of diagnosis for the entire cohort was 10 years (range, 2.5-17 years). Duration of treatment with zinc sulfate was 83.3 wk (range, 8-344 wk). Side effects, all of gastrointestinal origin, were observed in 21 patients (40% - 9 males and 12 females), irrespective of the duration of therapy. Thirteen out of 21 patients were over the age of 10 years. The most common ATP7B mutation was p.H1069Q. Esophagogastroduodenoscopy, performed in 7 patients (33.3%) suffering from persistent and severe abdominal pain, revealed gastrointestinal ulcerations or erosions with negative *Helicobacter pylori* tests in all subjects investigated. The above mentioned 7 patients were treated with proton pump inhibitors. Three of those experienced resolution of symptoms, whereas proton-pump inhibitors failed to alleviate symptoms of the remaining four children and conversion of therapy to *D*-penicillamine was needed.

CONCLUSION: Zinc sulphate appears to cause significant gastrointestinal side effects, which children on therapy for Wilson's disease should be closely monitored for.

Key words: Wilson's disease; Zinc; Abdominal pain; Gastrointestinal ulcer; Therapy

Core tip: The present study demonstrates a considerably higher rate and severity of gastrointestinal adverse effects secondary to zinc sulphate therapy in pediatric patients as previously reported. A total of 40% of our treated patients experienced gastrointestinal symptoms, of which the more severe cases were associated with endoscopically evident gastric ulcerations and erosions. Furthermore it was shown, that proton pump inhibitors were not effective in treating patients with severe zinc associated gastrointestinal side effects, requiring a switch to an alternative treatment regimen.

INTRODUCTION

Wilson's disease is an autosomal recessive disorder of copper metabolism, which results in impaired copper excretion by the liver. Toxic copper accumulates both in the liver and in the central nervous system. Various therapies are used, which include copper chelators like *D*-penicillamine and trientine or tetrathiomolybdate, as well as zinc preparations, such as zinc sulphate and zinc acetate. Liver transplantation is used mainly in acute liver failure. In Poland trientine is not registered and the most popular drugs are *D*-penicillamine (Cuprenil®, Teva Pharmaceuticals Polska) and zinc sulphate (Zincteral®, Teva Pharmaceuticals Polska). Zinc acetate (Wilzin®, Orphan Europe) is registered but not commonly used due to its high costs, which are not covered by the state and often unaffordable for patients.

The most common side effects of zinc therapy described are nausea and abdominal pain. Other complications, secondary to zinc-induced copper deficiency such as hematologic abnormalities, specifically leukopenia (fever, chills, sore throat), neutropenia (oropharyngeal ulcers) and sideroblastic anemia (fatigue, general weakness) are very uncommon but may occur[1-3]. A mild, harmless increase in serum amylase and lipase concentrations without clinical or radiologic evidence of pancreatitis[4] and a 20% reduction of high-density lipoprotein cholesterol in male patients (associated with reduction in total cholesterol) have been described[5]. Zinc may have immunosuppressant effects and reduce leukocyte chemotaxis, however one study found no adverse effects on lymphocyte function with chronic use[6].

Although many potential adverse effects of zinc therapy have been described, zinc sulphate is regarded to be an overall safe and well-tolerated drug. According to Wiggelinkhuizen's systematic review[7], 12.5% of adult patients with Wilson's disease suffered from side effects secondary to zinc therapy, all of gastrointestinal origin. There are only few studies focusing on pediatric patients, most of them reporting gastrointestinal adverse effects of zinc sulphate or acetate in children to be uncommon and mild, generally handled by changing dosage scheme or resolving spontaneously[8-12]. However, the analysis of our cohort with 53 pediatric patients with Wilson's disease led to differing results. Gastrointestinal side effects were detected in a considerably greater proportion of patients and range of severity was clearly wider, with some cases associated with severe and poorly tolerated symptoms and endoscopically evident ulcerations, a finding not been described earlier. Based on this detailed retrospective analysis of Polish children, we raised the concern about the safety of zinc sulphate therapy in pediatric patients with Wilson's disease.

MATERIALS AND METHODS

The study included 53 patients with hepatic presentation of Wilson's disease treated at the Children's Memorial Health Institute in Warsaw, Poland between the years 1996 and 2011. Wilson's disease was diagnosed according to the scoring system of Ferenci[13,14], with confirmation by mutational analysis in 49 cases. All patients treated with zinc sulphate were selected to the main analysis. Zinc sulphate was used as first choice therapy for 50/53 cases and 3/53 patients were initiated on *D*-penicillamine and later switched to zinc sulphate as a maintenance therapy (Table 1). Data about dosage scheme of zinc sulphate and adverse effects during therapy were collected and recorded in the patient's medical chart at each hospital visit. The Local Ethics Committee approved the study. Zinc sulphate was administered at a dose of 135 mg of elemental zinc daily in three divided doses for children with a body weight more than 50 kg. Three patients (males, 14, 15 and 16 years old) received a different zinc sulphate regiment with 180 mg of elemental zinc daily. The dose for younger and smaller children dosage was twice daily 45 mg of elemental zinc. One 9-year-old patient was given a daily dose of 45 mg of elemental zinc. At each visit (for the first year of therapy once every 3 mo, subsequently twice a year) patients were followed for efficacy and toxicity of treatment by measuring liver function tests (alanine transaminase, bilirubin), complete blood count and coagulation parameters, and by physical examination. Adequacy of zinc therapy was monitored with zinc serum levels and with 24-h urinary excretion of copper. Zinc serum

levels less than 125 μg/dL and urine copper above 75 μg/d were defined as treatment failure, suggesting non-response or non-compliance. Patients with poor tolerance for zinc sulphate were started on zinc acetate or *D*-penicillamine.

Statistical analysis

The data were collected from patient's medical charts and analyzed retrospectively. Patients who underwent upper tract endoscopy due to persistent abdominal pain were carefully described. The frequency of findings was presented in numbers and in percentages. Conclusions were based on careful description of findings, as low numbers of patients with presented features did not allow performing statistical analysis.

RESULTS

Characteristics of patients presenting with side effects during treatment with zinc sulphate are illustrated in Table 2. Mean age of diagnosis for our cohort of 53 patients was 10 years (range, 2.5-17 years). Median duration of treatment with zinc sulfate was 83.3 wk (range, 8-344 wk). Side effects secondary to zinc sulphate were observed in 21 children (21/53, 40% of investigated children, 9 males, 12 females; 13/21, 62% aged over 10 years), all symptoms were of gastrointestinal origin: abdominal pain, nausea or vomiting. Adverse ef-

Table 3 Characteristic of patients with persistent abdominal pain

EGD: Esophagogastroduodenoscopy; PPI: Proton pump inhibitor.

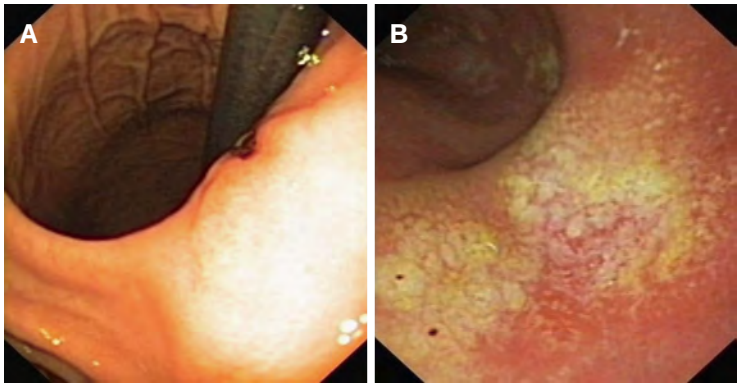

Figure 1 Endoscopic image. A: Endoscopic image of patient 6. Deep ulcer on the minor curvature of the stomach; B: Endoscopic image of patient 1. Flat mucosal ulcerations of the greater curvature of the stomach, about 1 cm in diameter covered with a flat fibrous coating.

fects associated with alternative therapies were noted as well within this group of 21 patients: rash (1 patient) and abdominal pain (1 patient) on *D*-penicillamine and elevated transaminases with zinc acetate treatment (1 patient).

Esophagogastroduodenoscopy (EGD) was performed in 7 children (7/21, 33%, 6 females, 1 male) experiencing persistent and severe abdominal pain. Gastritis with ulcerations or erosion was evident in all cases. There was no history of nonsteroidal antiinflammatory drugs use in any of the cases. Histopathology of biopsies showed mild to moderate lymphocytic infiltrations. All subjects investigated tested negative for *Helicobacter pylori* (*H. pylori*). Tests were performed during endoscopy by urea test (Table 3 and Figure 1). Three of these seven patients experienced resolution of symptoms on proton pump inhibitors (PPIs) (3 mo therapy: 1 patient; 6-wk therapy: 1 patient; unknown therapy duration due to lack of data: 1 patient). Adverse effects while on PPIs or recurrence of symptoms with discontinuation of PPIs were not observed. Effectiveness of therapy was confirmed by follow up EGD in one case.

Treatment with PPIs failed to alleviate symptoms of the remaining four patients, requiring a switch to *D*-penicillamine. Follow up EGDs were performed on two of these four patients.

One of the remaining 14 patients presented with GERD symptoms and improved clinically on PPIs, an EGD was not performed.

Three other patients experienced amelioration of symptoms following a conversion to zinc acetate. Two of the latter mentioned three cases had initially been converted to *D*-penicillamine. However side effects, such as rash in one case and abdominal pain in the other, required a second switch to zinc acetate. With eight patients, amelioration of clinical symptoms was achieved after converting therapy to *D*-penicillamine. One of those eight cases, although remission of gastrointestinal symptoms had been attained after switching from zinc sulphate to acetate, elevated transaminases necessitated another switch to *D*-penicillamine. Two other patients improved on the alternative zinc sulphate dosage scheme.

Table 4 illustrates the distrubution of mutations between the two groups: patients with and without side effects during zinc sulphate therapy. However conclusions regarding susceptibility towards adverse effects cannot be drawn from this data.

Table 4 Characteristic of mutation analysis in two groups of patients with Wilson's disease: with and without side effects during zinc sulphate therapy

Mutation analysis	No. of patients during zinc sulphate therapy	
	Without side effects	With side effects
Homozygous for p.H1069Q mutation	16	3
Compound heterozygous for p.H1069Q mutation	8	5
Carrier for p.H1069Q mutation	4	1
Carrier for a mutation other than p.H1069Q	0	5
Mutation other than p.H1069Q on two alleles	2	2
Lack of data	2	5

DISCUSSION

The first line therapy for asymptomatic patients and for those with mild hepatic disease is zinc sulphate. It is also being used as a maintenance therapy for patients, whose hepatic symptoms improved under *D*-penicillamine[15,16]. Another indication for zinc sulphate is the presentation of neurological symptoms[16,17]. The guidelines of the American Association for the Study of Liver Diseases recommend a daily dose for older children and adults of 150 mg in three divided doses[18,19]. However, compliance with the three times per day dosage may be problematic, and it has to be taken at least twice daily to be effective[15,18,19]. For smaller children, with a body weight under 50 kg, the dose is 75 mg/d in three divided doses[18-20]. The dose for children under 5 years of age is not well defined. It is worth noting that taking zinc with food interferes with its absorption[21] and therefore with the effectiveness of treatment. Adequacy of treatment with zinc sulphate can be estimated by measuring serum zinc levels or 24-h urinary zinc excretion. Other goals of treatment monitoring are to ensure patients compliance with therapy, and identify adverse side effects. Patients should be monitored at least twice a year. More frequent observation is needed during the initial phase of treatment, for patients experiencing worsening of symptoms or side effects and for those suspected of noncompliance with therapy[18,19]. Brewer *et al*[20] advise to test zinc serum and urine copper levels during therapy. A zinc serum level less than 125 μg/dL generally indicates poor compliance. According to the authors the best monitoring tool may be following urine copper levels, with maximum levels around 50 μg/d. Roberts *et al*[18,19] recommend that urinary copper excretion should not exceed 75 μg/d on a stable treatment. Many studies report sustained elevation of alanine aminotransferase during zinc therapy, which may indicate poor compliance and which may results in fewer and milder side effects. Our patients mostly adhered to zinc therapy but many of them presented sporadically with increased copper excretion in the urine indicating treatment failure.

There are only few studies focusing on side effects of zinc therapy in pediatric patients with Wilson's disease, and those available studying only small numbers of patients. Abdel Ghaffar *et al*[11] described nine Egyptian children with Wilson's disease on a zinc sulphate monotherapy and reported vomiting and epigastric pain, which improved when zinc was taken with a small amount of protein. Most studies however analyzed effectiveness and safety of zinc acetate, which is known to be better tolerated than zinc sulphate. Brewer *et al*[20] treated 34 children with zinc acetate, with the only side effect being mild gastric irritation in four patients. These were handled by taking the first dose mid-morning, rather than on arising. In cases more difficult to treat, zinc was taken with a small protein meal. Only mild nausea was described by Mizuochi *et al*[10] in three of four children treated with zinc acetate, while Brewer *et al*[20] did not observe any adverse effects secondary to zinc acetate in eleven pediatric patients.

More data is available about zinc associated adverse effects in adults. Clinical data of 117 Wilson's disease patients were analyzed retrospectively by Bruha *et al*[22]. Side effects associated with zinc sulphate were mild with only 5 patients requiring a switch to zinc acetate (four cases due to gastrointestinal intolerance, one patient due to eosinophilia). No adverse events were noted for zinc acetate therapy.

In a systematic study of Japanese patients with Wilson's disease zinc acetate was shown to be safe and efficacious. Although more than 50% (20 patients) of their patients experienced adverse effects, including gastrointestinal symptoms and decreased blood iron levels, reported events were mild and patients were able to be continued on the zinc treatment[23].

The present study demonstrates side effects secondary to zinc sulphate therapy in 40% of treated patients, considerably higher compared to previous reports[6,7,11,24]. Complaints were of gastrointestinal origin: epigastric pain, vomiting, nausea or loss of appetite. Seven of these 21 symptomatic children were diagnosed with gastric ulcerations or erosions with negative *H. pylori* tests and were started on proton pump inhibitors. While three of those patients were relieved of their symptoms, PPIs failed to be effective for the other four, requiring a conversion of their therapy from zinc sulphate to *D*-penicillamine (Table 2). Most studies report gastrointestinal adverse effects of zinc sulphate or acetate in children to be mild and generally handled by changing the dosage scheme or even resolving spontaneously[10,11]. This maneuver proved to be effective in only two of our patients. One child with abdominal pain experienced relief of symptoms when zinc was taken with a small protein meal given early in the morning and in one case first dose of zinc was taken 30 min after the meal. Still, there are very few reports on side effects of zinc therapy in children. Adult patients with Wilson's disease experienced mild side effects secondary to zinc sulphate and treatment was converted from zinc sulphate to acetate or gluconate[9,22], in selected cases a switch to *D*-penicillamine was necessary[24]. Treatment with zinc acetate resulted in only mild complaints and patients were able to continue therapy without any modifications. In his systematic review of zinc sulphate therapy, Wiggelinkhuizen describes that

12.5% (28/224) of patients suffered from side effects, all of gastrointestinal origin and in only two cases discontinuation of therapy was required[7]. However, in the present study, therapy had to be converted from zinc sulphate to *D*-penicillamine in twelve patients and to zinc acetate in three other probands. One child (Table 2) was converted to *D*-penicillamine after a failed attempt to treat with zinc acetate and two patients were switched to zinc acetate after unsuccessful *D*-penicillamine therapy.

We described the distribution of genetic mutations between the two groups of patients, those who experienced side effects and the ones that remained asymptomatic throughout the therapy (Table 4). However, due to the small number of patients, conclusions regarding susceptibility towards adverse effects cannot be drawn from this data.

EGD in children is indicated, only in the presence of severe symptoms and in younger children endotracheal intubation is required to perform an endoscopy. Therefore, there are very little data available on endoscopic findings especially in younger children. We decided to perform endoscopy only in those cases where side effects were expected to cause a withdrawal of treatment. To our knowledge this is the first study to document gastric ulcerations as a significant complication of zinc treatment in Wilson's disease patients. In the present study we recorded severe side effects secondary to zinc sulphate in seven out of 21 patients and EDG performed in all cases revealed gastritis with mucosal ulceration or erosion. *H. pylori* test was negative in all subjects investigated. Histopathology of biopsies was unspecific, showing mild to moderate lymphocytic infiltrations. A case report from 1978 by Moore[25], about a 15 year old girl who had been taking zinc sulphate for acne, was the first to describe hemorrhagic gastric erosions associated with zinc sulphate therapy. The ulcerative effect of zinc sulphate was thought to be secondary to the corrosive zinc chloride, which is most likely formed by the action of gastric hydrochloric acid on zinc sulphate[26]. This could explain its isolated effect on the gastric mucosa, leaving the duodenal mucosa intact.

Taking into account the fact that peptic ulcer disease is uncommon in children with an estimated prevalence of 1 in 3000 hospital admissions[27], the high frequency of peptic ulcer disease observed in our study was disquieting. Epidemiological studies show a constant increase in incidence and prevalence of peptic ulcer disease in children[28]. Symptoms in children with suspected peptic ulcer disease commonly include pain associated with food intake, vomiting, bleeding, and a positive family history, and are crucial factors for the diagnosis of peptic ulcer disease in childhood. Poorly localized abdominal pain of a dull character is the most common symptom, but may be localized to the epigastric or periumbilical area in some cases. Unequivocal epigastric pain is relatively uncommon in children and should always prompt further investigation[27]. Esophagogastroduodenoscopy is the diagnostic procedure of choice for children with suspected peptic ulcer. Non-*H. pylori* ulcer disease can be treated effectively with acid-suppression (proton pump inhibitors, histamine 2 receptor inhibitors)[27]. Our data however demonstrate a failure of PPIs in severe cases of zinc sulphate related abdominal symptoms. Four of our seven patients with gastrointestinal ulcerations or erosions needed to be switched to *D*-penicillamine due to uncontrollable symptoms despite a treatment with PPIs.

Zinc sulphate is still a commonly used drug to treat Wilson's disease, especially in patients who otherwise cannot afford therapy. Therefore, it is very important to assess its efficacy and tolerability. Gastrointestinal side effects especially in children are not well studied. They may cause incompliance, which seems to be a major reason for treatment failure[29,30]. To address this problem we performed endoscopy in selected symptomatic patients and identified gastric ulcer disease as the underlying cause of symptoms in 7/21 patients.

The limitation of our study is the retrospective character of data analysis and the relatively small size of the patient group. However, this rare disease limits the options to perform randomized prospective trials.

Adverse reactions such as abdominal pain, nausea and even gastritis are common in children with Wilson's disease treated with zinc sulphate. They may occur at different stages of therapy. The high frequency of gastritis in patients with chronic abdominal pain indicates the need to perform gastroscopy in selected patients. Discontinuation of zinc sulphate is often inevitable and conversion to *D*-penicillamine or zinc acetate may be a safer option for these patients. Zinc sulphate appears to cause significant side effects, which should be seriously considered during monitoring the therapy of Wilson's disease.

COMMENTS

Background

Wilson's disease represents a metabolic disorder caused by excessive accumulation of copper in tissues. Penicillamine and zinc compounds are used in therapy. Due to costs and availability zinc sulphate is commonly used for treating Wilson's disease in Poland. It is regarded safe and well tolerated, but there are little data available on side effects, especially in children.

Research frontiers

The most common side effect of zinc therapy described is nausea and abdominal pain. Other uncommon complications are: hematologic abnormalities, specifically leucopenia, neutropenia and sideroblastic anemia, a mild increase in serum amylase and lipase concentrations without clinical or radiologic evidence of pancreatitis, 20% reduction of high-density lipoprotein cholesterol in male patients (but with reduction in total cholesterol) or reduction leukocyte chemotaxis. According to the results of Wiggelinkhuizen's systematic review in adult patients with Wilson's disease 12.5% of them suffered from side effects of zinc therapy, all of gastrointestinal origin. There are only few studies focusing on pediatric patients but most of them report gastrointestinal adverse effects of zinc sulphate or acetate in children also to be uncommon and mild, generally handled by changing dosage scheme or resolved spontaneously.

Innovations and breakthroughs

The present study demonstrates side effects secondary to zinc sulphate therapy in 40% of treated patients, which is higher compared to previous reports. The common complaints were of gastrointestinal origin: epigastric pain, vomiting, nausea or loss of appetite. The clinical observation led to conclusions that some side effects seemed to be poorly tolerated by children and endoscopic investigations revealed ulcerations which had not been described earlier. Apart from that authors have some evidence derived from this analysis that proton pump inhibitors may not be effective in zinc sulphate treated children experiencing persistent abdominal symptoms and modification of treatment is necessary.

Applications

The study results suggest that zinc sulphate can cause significant side effects as gastritis or gastric ulcer which should be seriously considered during monitoring the therapy of Wilson's disease in children. The high frequency of gastritis in patients with chronic abdominal pain indicates the need to perform gastroscopy in selected patients. Discontinuation of zinc sulphate is often inevitable and conversion to penicillamine or zinc acetate may be a safer option for these patients.

Peer review

The manuscript is tackling an important issue in the treatment and management of Wilson's disease patients. It has excellent introduction and very good discussion, and is well written.

Abstract

AIM: To investigate large tumor suppressor 1 (*LATS1*) expression, promoter hypermethylation, and microsatellite instability in colorectal cancer (CRC).

METHODS: RNA was isolated from tumor tissue of 142 CRC patients and 40 colon mucosal biopsies of healthy controls. After reverse transcription, quantitative polymerase chain reaction (PCR) was performed, and *LATS1* expression was normalized to expression of the *ACTB* and *RPL32* housekeeping genes. To analyze hypermethylation, genomic DNA was isolated from 44 tumor CRC biopsies, and methylation-specific PCR was performed. Microsatellite instability (MSI) status was checked with PCR using BAT26, BAT25, and BAT40 markers in the genomic DNA of 84 CRC patients, followed by denaturing gel electrophoresis.

RESULTS: Decreased *LATS1* expression was found in 127/142 (89.4%) CRC cases with the average ratio of the LATS1 level 10.33 ± 32.64 in CRC patients *vs* 32.85 ± 33.56 in healthy controls. The lowest expression was found in Dukes' B stage tumors and G1 (well-differentiated) cells. Hypermethylation of the *LATS1* promoter was present in 25/44 (57%) CRC cases analyzed. *LATS1* promoter hypermethylation was strongly associated with decreased gene expression; methylated cases showed 162× lower expression of *LATS1* than unmethylated cases. Although high-grade MSI (mutation in all three markers) was found in 14/84 (17%) cases and low-grade MSI (mutation in 1-2 markers) was found in 30/84 (36%) cases, we found no association with *LATS1* expression.

CONCLUSION: Decreased expression of *LATS1* in CRC was associated with promoter hypermethylation, but not MSI status. Such reduced expression may promote progression of CRC.

Key words: Large tumor suppressor 1; Colorectal cancer; Quantitative polymerase chain reaction; Reduced expression; Promoter hypermethylation; Microsatellite

instability; Salvador-Warts-Hippo pathway

Core tip: Searching for new colorectal cancer (CRC) molecular markers is a very important objective, because CRC is one of the most common malignancies in the world and one of the most fatal of human neoplasms. Decreased expression of large tumor suppressor 1 in CRC was associated with promoter hypermethylation, but not microsatellite instability status. Such reduced expression may promote progression of CRC.

Underexpression of *LATS1* TSG in colorectal cancer is associated with promoter hypermethylation. *World J Gastroenterol* 2013; 19(27): 4363-4373 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4363.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4363

INTRODUCTION

Colorectal cancer (CRC) is one of the most common malignancies in the world and one of the most fatal human neoplasms. Almost 1.2 million new cases occur annually, accounting for 608700 related deaths in 2008[1]. Although nearly 90% of patients may be successfully cured with surgery in early stages, CRC is frequently diagnosed in late stages, *i.e.*, Dukes' C and D, when the prognosis is poor[2,3]. Therefore, the search for CRC molecular markers, as well as elucidation of epigenetic factors that are responsible for variability in the expression of putative markers, is very important.

Human large tumor suppressor 1 (*LATS1*, also known as *WARTS*) was discovered in 1999[4] as a highly conserved homolog of the *Drosophila melanogaster* (*D. melanogaster*) lats gene[5]. *LATS1* encodes a serine/threonine kinase, which is involved in the regulation of various cellular processes. Before mitotic division, the presence of LATS1 is crucial for control of the R1 tetraploidy checkpoint[6]. During the early phase of mitosis, LATS1 associates with cell division control protein 2 homolog[7], and the progress of cytokinesis occurs only after association of the MOB kinase activator 1A cytoplasmic protein with LATS1[8,9].

More recently, genetic studies in *Drosophila* have identified LATS as a central mediator in a tumor suppressing pathway called the Salvador-Warts-Hippo (SWH) pathway[10,11]. The SWH pathway is also a critical factor in the regulation of organ size in *D. melanogaster* and mammals[12,13]. Moreover, deregulation of SWH pathway activity has been implicated in the genesis of multiple human cancers[11,14-16]. Several mammalian factors are involved in signal transduction in the SWH pathway, including the tumor suppressor proteins neurofibromin 2, Ras association family member 1-6, serine/threonine kinase 3, LATS1, and an oncogene called Yes-associated protein (YAP). YAP, a transcription coactivator that associates with various transcription factors, is overexpressed in human carcinomas including ovarian, liver, and prostate cancers[13]. LATS1 kinase is a main negative regulator of YAP. LATS1 inhibits the transcriptional activity/function of YAP *via* phosphorylation of Ser 127 in YAP[17]. Moreover, LATS1-phosphorylated YAP is involved in a p53-independent apoptosis pathway in which phosphorylated YAP plays a role in transcriptional activation of the pro-apoptotic gene, p53 up-regulated modulator of apoptosis[18]. Overexpression of *LATS1* in *LATS1*$^{-/-}$ mouse cells (by introducing human *LATS1* with adenovirus-mediated gene transfer) and HeLa cells suppresses tumorigenicity *in vivo* and *in vitro* by inducing apoptosis[18,19].

LATS1 is considered to play a suppressor role in some tumors. Decreased *LATS1* expression is found mainly in soft tissue-derived tumors, including sarcomas[20] and astrocytomas[21]. However, *LATS1* quiescence was also observed in breast[22], cervical[23] cancers and head and neck squamous cell carcinoma[24]. In the gastrointestinal tract, decreased *LATS1* expression has been recently observed in gastric cancer[25], but in a small sample of CRCs, *LATS1* overexpression was found[26].

Hypermethylation of CpG islands (GC-rich sequences) in regulatory portions of a gene is an important epigenetic mechanism responsible for decreased gene expression or gene silencing[27-30]. Aberrant methylation of CpG islands in the promoter region of *LATS1* has been found in breast and ovarian cancers[4,22,31] and soft-tissue sarcomas[20]. Our preliminary results suggested that *LATS1* expression is decreased in CRC and is associated with promoter hypermethylation[32]. In the present study, we used quantitative polymerase chain reaction (QPCR) to determine the expression profile of *LATS1* in a relatively large group of CRC patients. We also examined the hypermethylation status of the *LATS1* promoter as a putative epigenetic mechanism affecting gene expression.

MATERIALS AND METHODS

Patients

The study was approved by the local ethics committees, and informed, written consent regarding the use of tissue was obtained before surgery or colonoscopy from all CRC and control patients, respectively. The specimens were obtained from four gastrointestinal endoscopic units and surgical clinics located in geographically different parts of Poland from 2008 to 2011. Clinical and demographic data were collected at the time of enrollment (Table 1). The study included 142 patients with CRC (87 males and 55 females; mean age 68 ± 10.8 years; range, 37-90 years). No CRC patients had a second neoplastic disease. None of the patients had undergone previous chemo- or radiotherapy. Tumors located in the anal canal and anus were not included in this study. The control group comprised 40 healthy individuals (17 males and 23 females; mean age 53 ± 14.2 years; range, 21-76 years) who underwent colonoscopy as part of routine surveillance for CRC. None of the CRC patients or controls

suffered from inflammatory bowel disease or had a family history of CRC. Patients were not on medication at the time of investigation. Before medical examination, blood samples were collected for routine testing from all CRC patients.

Collection of colon samples

All steps of material collection, including patients' clinical data, tissue collection, storage, shipment, and laboratory processing, followed The Cancer Genome Atlas (TCGA) instructions and were standardized in all collaborative clinics[33,34]. Briefly, CRC samples were obtained during surgical hemicolectomy, and control group specimens were collected during colonoscopy. For histopathologic examination and molecular studies, samples (5 mm × 5 mm × 5 mm) from macroscopically altered tumor tissue were taken within 20 min after tumor resection. For control patients, one biopsy (2 mm × 2 mm × 2 mm) was fixed in 10% neutral buffered formalin, and two specimens from the adjacent location to the biopsy site were collected for nucleic acid analyses. The formalin-fixed samples were obtained for the routine histological survey; if the result of histological examination showed pathological condition of the patient's tissue, the adjacent biopsies were excluded from the control group analyzed in this study. Both tumor samples and mucosal biopsies were immediately placed in sterile vials containing RNAlater (Ambion-Life Technologies, Grand Island, NY, United States), incubated for 6 h at 4 ℃, and then stored at -25 ℃ until further analysis.

Nucleic acid extraction and reverse transcription

Total RNA was extracted from a portion of the tumor samples (ca. 3 mm × 5 mm × 5 mm) and the entire mucosal biopsies of control patients using a Total RNA kit (A&A Biotechnology, Gdynia, Poland). Isolated RNA was quantified with spectrophotometry (Nanodrop ND 1000, Thermo Fisher Scientific, Fitchburg, WI, United States). DNA was digested with RNase-free DNase I (Fermentas-Thermo Fischer Scientific, Fitchburg, WI, United States) for 30 min at 37 ℃. Then, the DNase was inactivated by adding EDTA and incubating at 65 ℃ for 10 min. Before storing at -85 ℃, RNA integrity was analyzed with agarose gel electrophoresis. Total RNA (2 μg) was reverse transcribed using 0.5 μg oligo(dT)$_{18}$ primers (Sigma-Aldrich, Munich, Germany) and 200 U RevertAid M-MuLV Reverse Transcriptase (Fermentas-Thermo Fischer Scientific, Fitchburg, WI, United States) in a total volume of 20 μL, and the resulting cDNA was stored at -25 ℃. In 84 of the CRC cases, 1 mL venous blood that was collected in sterile K2-EDTA vials was used for DNA isolation using a Blood Mini DNA kit (A&A Biotechnology, Gdynia, Poland). From these same patients, DNA was also extracted from a portion of the tumor samples (ca. 3 mm × 5 mm × 5 mm) adjacent to the tumor fragments used for the RNA study using the Genomic Mini AX Tissue kit (A and A Biotechnology, Gdynia, Poland) and stored at -25 ℃.

QPCR assay to determine the LATS1 mRNA level

Quantification of *LATS1* gene expression was carried out using iQ Cycler (Bio-Rad, Hercules, CA, United States) with Sybr® Green I as a fluorophore. *LATS1* expression was determined with Livak's comparative method $2^{-\Delta\Delta Ct}$[35] relative to the geometric mean of the expression levels of two housekeeping genes: β-actin (*ACTB*; GenBank acc. No. NM_001101.3) and ribosomal protein L32 (*RPL32*; NM_000994.3). These genes showed very stable expression in CRC in our previous studies[36,37] and studies of other investigators[38]. Except for the *ACTB* assay[39], all primers were designed by us using GenBank data. QPCR conditions were validated and showed 90%-100% efficiency for all assays. The amplification primer pairs were 5'-TGCACTGGCTTCAGATGGACAC-3' and 5'-ATGTGCTAGACATCGCTGGTGC-3'; for *LATS1* (functional transcript, ENSEMBL No. ENST00000543571, GenBank No. NM_004690.2), 5'-TGTGCCCATCTACGAGGGGTATGC-3' and 5'-GGTACATGGTGGTGCCGCCAGACA-3' for *ACTB*[39], and 5'-TGACAACAGGGTTCGTAGAAGAT-3' and 5'-GTTCTTGGAGGAAACATTGTGAG-3' for *RPL32*. The reaction mixture (17 μL) included 0.4 μL cDNA, 0.2 μmol/L each forward and reverse primers, and real-time PCR iQ SYBR Green SuperMix (Bio-Rad). All reactions were performed in duplicate. The amplification parameters were denaturation for 5 min at 95 ℃, followed by 38 cycles of denaturation for 15 s at 95 ℃, annealing for 20 s at 55 ℃ for *RPL32*, 57 ℃ for *LATS1*, and 60 ℃ for *ACTB*, extension for 15-25 s at 72 ℃, and fluorescence reading for 5 s at 77 ℃-80 ℃. Dynamic melting curve analysis was performed for all reactions. Data were automatically collected and analyzed with iCycler iQ Optical Software ver. 3.0a (Bio-Rad).

Microsatellite instability status analysis

Microsatellite instability (MSI) status was determined according to the National Cancer Institute Workshop on Microsatellite Instability for Cancer Detection and Familial Predisposition[40] and was based on polymorphism analysis of three markers: BAT26 for *MSH2*, BAT25 for the *c-kit* oncogene, and BAT40 for the *HSD3B2* suppressor gene. BAT sequences were obtained from the UniSTS database (http://www.ncbi.nlm.nih.gov/unists), and the methodology was based on our previous results[41]. Briefly, the PCR reaction contained 0.5 U Taq polymerase, PCR buffer (Fermentas-Thermo Fischer Scientific, Fitchburg, WI, United States), 200 nmol/L each primer pair, 0.1 mmol/L each dNTP, and 30 ng DNA in a final volume of 15 μL and was performed using the following parameters: denaturation for 5 min at 95 ℃, 35 cycles of denaturation for 15 s at 95 ℃, annealing for 20 s at 49 ℃ (BAT25, BAT26) or 54 ℃ (BAT40), and extension for 30 s at 72 ℃. Denaturing acrylamide gel electrophoresis was performed in a Sequi-Gen Ⅱ Sequencing Cell (Bio-Rad) followed by silver staining ($AgNO_3$; POCH, Gliwice, Poland) for identification of extra DNA bands, which were considered mutations in the selected BAT markers. Low-

and high-grade MSI (MSI-L and MSI-H, respectively) were confirmed by 1-2 and all 3 mutated markers, respectively. If no mutation was observed in the paired tumor and blood DNA samples, the sample was confirmed as microsatellite stable (MSS).

Bisulfite modification and methylation-specific PCR

Because the method of bisulfite conversion of DNA requires at least 1 μg DNA, we performed this analysis with only 44 tumor samples with sufficient material using the EZ DNA Methylation™ kit (Zymo Research, Orange, CA, United States). Briefly, 1 μg tissue DNA was denatured using 0.2 mol/L NaOH and subsequently incubated with a sodium salt of bisulfite ion (HSO_3^-) at 50 ℃ for 16 h. Next, the mixture was desulfonated, and DNA was purified on silica-membrane columns to a final volume of 10 μL. Bisulfite-modified DNA was stored at -25 ℃. The methylation status of the *LATS1* promoter region was determined with methylation-specific PCR (MSPCR). Bisulfite-modified DNA was amplified with primers specific for methylated or unmethylated sequences. The methylated DNA was amplified using M primers: sense 5'-TCGTTTTGTCGTTTAGGTTGG-3' and antisense 5'-CGACGTAATAACGAACGC-3', and unmethylated DNA was amplified using UM primers: sense 5'-TAGGTTGGAGTGTGGTGGT-3' and antisense 5'-CCCAACATAATAACAAACACCT-3'. All primer sequences were previously published[20-22] except for the M sense primer, which was redesigned *de novo* using the GenBank database and methPrimerDB online software. For the methylation assay, Human HCT116 DKO Non-methylated DNA and Human HCT116 DKO Methylated DNA (Zymo Research) after bisulfite modification were used as positive controls in MSPCR. Briefly, 0.6 μL bisulfite-modified DNA was amplified in a total volume of 15 μL containing reagents from the Zymo*Taq*™ DNA Polymerase kit (Zymo Research) and 400 nmol/L each primer. MSPCR reactions were as follows: denaturation for 5 min at 95 ℃, five cycles of denaturation for 30 s at 95 ℃, annealing for 30 s at 52 ℃, extension for 20 s at 72 ℃; 30 cycles of denaturation for 30 s at 95 ℃, annealing for 30 s at 50 ℃, extension for 20 s at 72 ℃; final extension for 5 min at 72 ℃. PCR products (10 μL) were run on a 2% agarose gel, stained with ethidium bromide, and visualized under ultraviolet illumination. Images were stored using a Gel Doc apparatus and software (Bio-Rad).

Statistical analysis

Normality of the QPCR data was assessed with the Shapiro-Wilk test. Parametric data such as red blood cells, hematocrit, hemoglobin, and *LATS1* mRNA levels between various groups were evaluated using the Mann-Whitney *U* test. Comparison of *LATS1* mRNA ratios between CRC subgroups with various histological and MSI grades and methylation status was calculated using the Kruskal-Wallis analysis of variance (ANOVA) test. Fisher's exact test was used to assess correlations between the methylation status and clinical-pathological variables. The statistical analyses were performed using Statistica ver. 10 program (Stat Soft Inc., Tulsa, OK, United States), and the level of significance was set at $P < 0.05$.

RESULTS

Relationship between LATS1 expression and clinical parameters

Clinico-pathological data including tumor stages according to tumor location, Dukes' classification, and G grade[42,43] are presented in Table 1. We found no statistical differences in geographic location of patients, sex, age, tumor location, and disease progression. We found a relationship between tumor location and erythrocyte counts, hematocrit level, and hemoglobin concentration; patients with a tumor on the right side were characterized by decreased values compared with patients whose tumor was on the left side ($P < 0.05$, Table 1). No associations between blood parameters and Dukes classification, TNM, and G grading of CRC were found.

Quantification of *LATS1* mRNA was performed in colorectal tumor samples from 142 CRC patients and compared with tissue samples from 40 healthy persons. Decreased *LATS1* gene expression was found in 127 of 142 (89.4%) tumors in the CRC cases ($P < 0.05$). Because QPCR data were not normally distributed (mean values: 10.33 ± 32.64 *vs* 32.85 ± 33.56, $P < 0.05$), the median expression ratio was 0.075 (range, 0.003-210.672) in CRC patients *vs* 40.097 (range, 0.004-98.228) in controls ($P < 0.05$). Thus, the average expression of *LATS1* was many times lower in tumor tissue than in normal colon mucosa of controls. No correlations between *LATS1* mRNA level and gender, age, or tumor location were found. Also, no statistical differences in the mRNA ratio were observed in patients who lived in different regions of Poland.

Comparison of *LATS1* expression levels with patients' clinico-pathological data revealed 8 times lower *LATS1* levels in Dukes' A stage compared to controls (Figure 1). The lowest *LATS1* expression was observed in Dukes' B stage, which was 42 times lower than in controls, whereas in more advanced CRC cases described as Dukes' C and D stage, *LATS1* expression was 24 and 14 times lower than in controls, respectively. We found a weak negative correlation between tumor progression and the *LATS1* mRNA level ($R^2 = -0.25$, $P < 0.05$, Spearman's test, plot not shown). When the histological G grade of cancer cells was considered, *LATS1* mRNA levels were significantly decreased in both G2 and G3 grades (Figure 1). However, due to the low number of G1 cases (well-differentiated cells) and G4 (undifferentiated cells) cases (three each), no comparison with grades G2 and G3 was possible.

MSI status and clinicopathological data

We analyzed 84 of the 142 CRC cases for MSI status. The highest rate of mutation was found in the BAT26 marker ($n = 28/84$; 33%), followed by 26 cases for BAT40 (31%) and 25 for BAT25 (30%) (Table 1). Our analysis revealed

Table 1 Clinical and histopathological characteristics of colorectal cancer patients and results of large tumor suppressor 1 mRNA quantification using quantitative polymerase chain reaction *n* (%)

Clinical parameter			Blood parameters (mean ± SD)				MSI results (*n* = 84)					QPCR results

[1]Statistically significant difference between analyzed subgroup and control; [2]Statistically significant difference between subgroups, Kruskal-Wallis analysis of variance test. RBC: Red blood cells count; Ht: Hematocrit; Hb: Hemoglobin; WBC: White blood cells; MSI: Microsatellite instability; BAT26: Marker for MSH2; BAT25: Marker for the c-kit oncogene; BAT40: Marker for the HSD3B2; MSI-L: Low grade MSI, mutation in 1-2 BAT markers; MSI-H: High grade MSI, mutation in 3 BAT markers; CRC: Colorectal cancer; M: Male; F: Female.

MSI-L in 30 cases and MSI-H in 14 cases, which equates to 44 (52%) cases with the MSI genotype and 40 (48%) with MSS. The BAT25 and BAT40 markers were different according to the Dukes' stage (Kruskal-Wallis ANOVA test, $P < 0.05$), followed by higher occurrence of mutations in CRC cases with positive lymph node metastasis (any T, N1-2, any M) *vs* negative metastasis (Kruskal-Wallis ANOVA test, $P < 0.05$). We found no relationship between MSI status and *LATS1* expression.

MSI status and LATS1 expression

To check if the MSI phenotype influenced the expression pattern of *LATS1*, we compared QPCR results of *LATS1* expression ratios in MSS, MSI-L, and MSH-H cases (Figure 2). Although we found that MSI-L and MSI-H samples were characterized by higher *LATS1* levels than MSS cases, we found no statistical differences among those ratios (Figure 2).

Methylation status of the LATS1 gene promoter and its relationship with mRNA levels, clinical data and MSI data

To assess the methylation profile of *LATS1* during CRC progression, we analyzed 44 CRC cases with different clinico-pathological outcomes. Hypermethylation of the *LATS1* promoter was present in 25/44 cases (57%), whereas in 19 CRC tumor samples, no hypermethylation was found. No correlations were observed between *LATS1* hypermethylation and gender, age, tumor location, Dukes' stage, or G grading. Hypermethylation of the *LATS1* promoter was found in all patients with Dukes' A and D stages, and in 31% and 58% cases with Dukes' B and C stages, respectively (Table 2).

Comparison of *LATS1* promoter methylation status with *LATS1* mRNA levels in the analyzed tumor specimens (Table 2 and Figure 3) revealed a very significant reduction in *LATS1* expression in hypermethylated cases *vs* non-hypermethylated cases ($P < 0.05$). The biggest difference was observed in Dukes' C stage in which the *LATS1*

Table 2 Relationship between large tumor suppressor 1 promoter methylation status, large tumor suppressor 1 mRNA level, and histopathological and microsatellite instability data in colorectal cancer *n* (%)

M: Hypermethylation of large tumor suppressor 1 (*LATS1*) promoter; UM: Unmethylation of *LATS1* promoter; MSI: Microsatellite instability; MSS: Microsatellite stable; MSI-L: Low grade MSI, mutation in 1-2 BAT markers; MSI-H: High grade MSI, mutation in 3 BAT markers; NS: Noy significant.

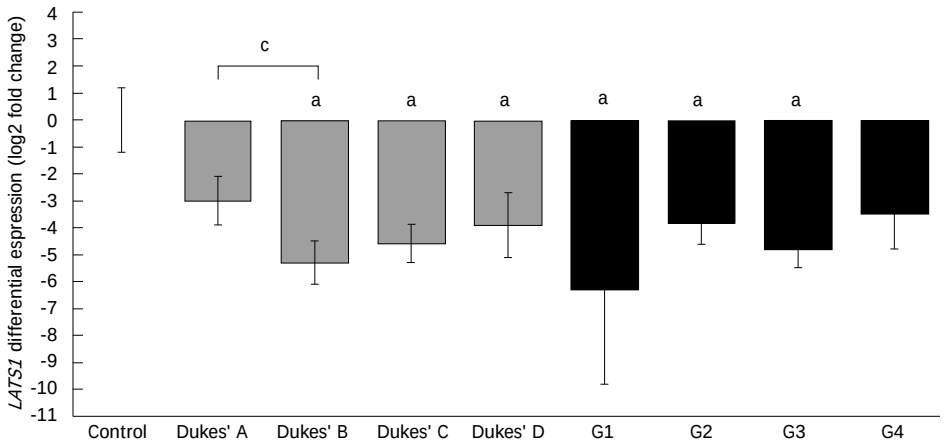

Figure 1 Large tumor suppressor 1 mRNA levels in colorectal cancer and control colon biopsies. Quantitative polymerase chain reaction results of large tumor suppressor 1 (*LATS1*) expression in 142 colorectal cancer (CRC) samples compared with 40 colon biopsies of healthy patients. CRC cases were divided according to clinicopathological data: tumor stage - Dukes' A (*n* = 27), B (*n* = 41), C (*n* = 54), D (*n* = 20); histological differentiation of tumor cells (G staging): G1 (*n* = 3), G2 (*n* = 48), G3 (*n* = 88), G4 (*n* = 3). Vertical bars represent *LATS1* fold ratio calibrated to the average C_t of control ($\Delta\Delta C_t^{LATS1} = \Delta C_t^{LATS1, sample} - \Delta C_t^{LATS1, control}$), error bars: SE. $^aP < 0.05$ *vs* control group; $^cP < 0.05$ between subgroups (Mann-Whitney *U* test).

expression level was 305 times lower in methylated CRC samples than in unmethylated samples ($P < 0.05$, plot not shown). The lowest *LATS1* ratio was found in Dukes' D stage (1263 times lower than in control). However, we found that all analyzed samples in this subgroup showed a hypermethylation pattern, and thus, statistical comparison between methylated and unmethylated cases in D stage could not be evaluated. Interestingly, *LATS1* expression in unmethylated CRC cases was not statistically different from that in controls.

When the methylation status of the *LATS1* promoter was analyzed in patients with and without the presence of metastatic cells in regional lymph nodes and/or distant organs, we found a strong relationship between the metastatic potency of cancer and reduced expression of *LATS1* and hypermethylation of its promoter. The *LATS1* ratio was 381 times lower in hypermethylated *vs* unmethylated in metastatic CRC cases ($P < 0.05$, dark grey boxes in Figure 3, Table 2), and only 8 times lower in hypermethylated *vs* unmethylated in non-metastatic CRC cases ($P < 0.05$, light grey boxes in Figure 3, Table 2). Moreover the expression of *LATS1* in unmethylated metastatic CRC samples was 49 times reduced as compared to unmethylated non-metastatic CRC cases ($P < 0.05$, Figure 3, Table 2).

Comparison of the histological grading of CRC (G), methylation status, and *LATS1* mRNA levels revealed the highest proportion of hypermethylation (71% of analyzed cases) in poorly differentiated (G3) CRC cases (Table 2). However, the difference in the *LATS1* expression level in methylated cases was only ca. 4 times lower than in unmethylated cases in the G3 subgroup ($P < 0.05$, Table 2, Figure 4). On the contrary, the difference in the *LATS1* mRNA level between methylated and unmethyl-

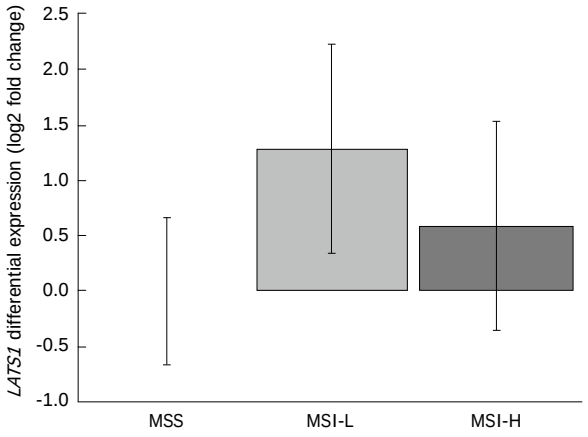

Figure 2 Microsatellite instability status and large tumor suppressor 1 expression. Comparison of large tumor suppressor 1 (*LATS1*) mRNA levels in cases divided by the mutations observed in the BAT26, BAT25, and BAT40 microsatellite markers. Samples were considered to have microsatellite stability (MSS; no mutation), microsatellite instability-low grade (MSI-L; 1-2 mutations, light grey box), and microsatellite instability-high grade (MSI-H; mutations in all three markers, dark grey box). MSS (n = 40), MSI-L (n = 30), MSI-H (n = 14). Vertical bars represent *LATS1* fold ratio calibrated to the average C_t of MSS cases - ($\Delta\Delta C_t^{LATS1} = \Delta C_t^{LATS1, MSI} - \Delta C_t^{LATS1, MSS}$), error bars: SE.

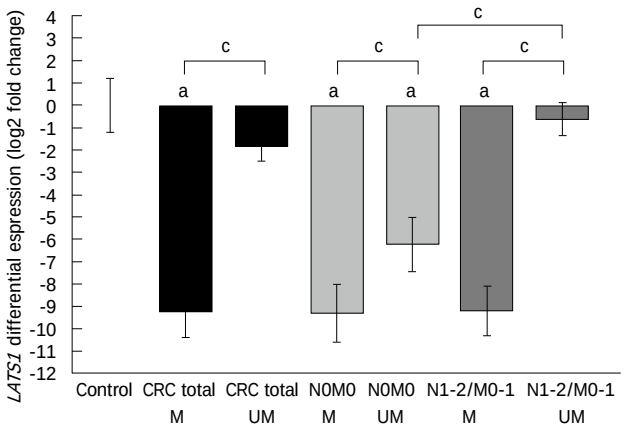

Figure 3 Large tumor suppressor 1 expression in colorectal cancer in relation to promoter methylation status. Comparison between large tumor suppressor 1 (*LATS1*) mRNA expression and epigenetic hypermethylation (M) or absence of hypermethylation (UM) of CpG islands located within the *LATS1* promoter region in a total of 44 colorectal cancer (CRC) cases (black vertical bars, n = 25 for M and n = 19 for UM). Vertical bars represent the *LATS1* fold ratio calibrated to the average C_t of control ($\Delta\Delta C_t^{LATS1} = \Delta C_t^{LATS1, sample} - \Delta C_t^{LATS1, control}$), error bars: SE. CRC cases were further divided into two subgroups: absence or presence of metastasis in lymph nodes/distant organs: N0M0: Light grey bars (n = 20; M: n = 9; UM: n = 11); N1-2/M0-1: Dark bars (n = 24; M: n = 16; UM: n = 8), respectively. $^aP < 0.05$ *vs* control group; $^cP < 0.05$ between subgroups (Mann-Whitney *U* test).

ated CRC tissue was much more pronounced in moderate-differentiated G2 cells ($P < 0.05$, Figure 4). Moreover, the *LATS1* ratio in G2 unmethylated cases was not statistically different from that in control healthy patients. Interestingly, G3 unmethylated cases showed much lower (ca. × 100) *LATS1* expression than G2 unmethylated biopsies ($P < 0.05$, Figure 4). Finally, we did not observe any statistically significant correlation between G grading and the *LATS1* mRNA level or hypermethylation of its promoter.

When we focused on MSI and the *LATS1* methylation status, we did not find any significant relationship because the statistical distribution of the results was very broad (Table 2, figure not shown). Most methylated cases (27/44) were considered MSS with no significant difference between methylated and unmethylated cases. MSI-L and MSI-H samples were also characterized as having relatively small differences in *LATS1* expression between methylated and unmethylated cases.

DISCUSSION

LATS1 is a tumor suppressor gene involved in several important mitotic processes, which are crucial in the development of CRC[7,44]. The most recent data suggest that the SWH pathway may play a very important role in CRC progression[45]. LATS1 is a key transducer of this pathway, and reduced expression of *LATS1* is connected with deregulation of SWH, thus activating the *YAP* oncogene[18]. Moreover, p53, a "genome guardian" protein, is indirectly regulated by LATS1[46]. MDM2, the regulator of p53 ubiquitination, is sequestered by native cellular LATS1, so that in the case of reduced *LATS1* expression, degradation of p53 cannot be triggered by MDM2[46]. Those observations suggest that studies on the role of *LATS1* in CRC should be intensified. Our investigation provides the first analysis of the *LATS1* expression profile in a relatively large group of CRC patients compared with 40 healthy persons as well as analysis of *LATS1* promoter hypermethylation as a putative quiescence factor for *LATS1* expression in CRC. The results of our quantitative study, which demonstrated decreased *LATS1* expression in 89% of CRC patients, are consistent with the decreased *LATS1* expression found in other tumors[20-22]. However, Bianchini *et al*[26] reported 3.11-fold increased expression of *LATS1* in 25 CRC patients compared with 13 non-cancerous adjacent tissue samples from the surgical margin. This discrepancy may be due to important methodological differences between the two studies. First, Bianchini *et al*[26] compared their CRC data to 13 non-cancerous adjacent tissue samples from the surgical margin, whereas in our study of 142 CRC (Dukes' stages A-D) patients, the histologically normal mucosa of 40 healthy controls was used as a reference sample. Second, Bianchini *et al*[26] used the microarray technique to generate expression profiles of 19200 different transcripts normalized to glyceraldehyde 3-phosphate dehydrogenase expression in only Dukes' B and C stage CRC patients. Seven transcripts are generated from *LATS1* (Ensembl database), however, Bianchini *et al*[26] did not specify the isoform they analyzed. Our QPCR assay was designed to amplify the functional isoform of *LAST1* that was also analyzed in other tumors[20-22]. Hence, our data cannot be directly compared with the contradictory results of Bianchini *et al*[26]. Moreover, we are not aware of any other reports suggesting increased *LATS1* expression in cancer. Immunohistochemical analysis of LATS1 protein expression in gastric cancer revealed lower expression

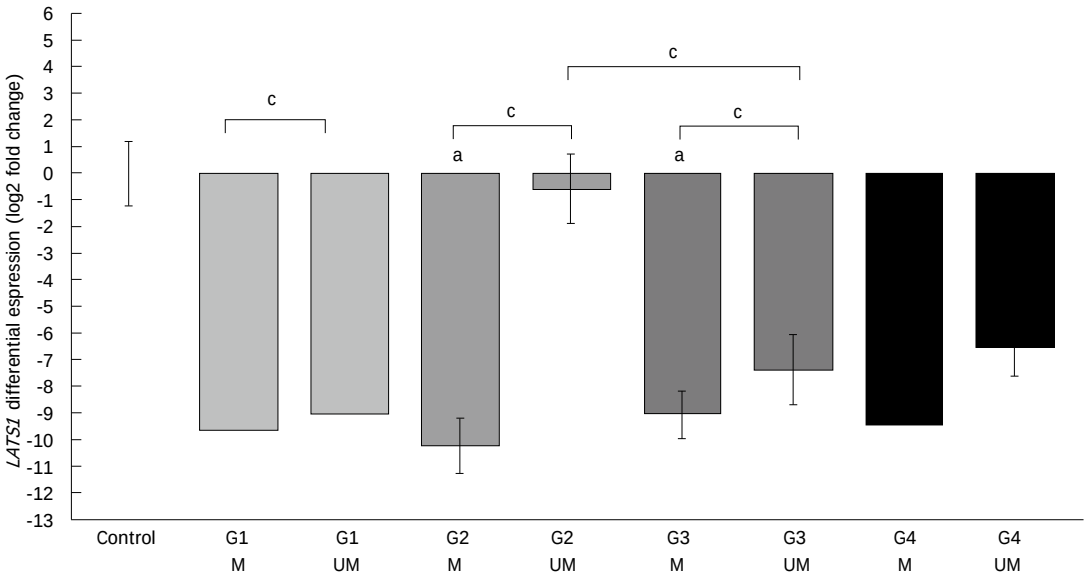

Figure 4 Methylation status of large tumor suppressor 1 in relation to the expression ratio and histological staging of cells. Forty-four colorectal cancer cases were classified according to histological examination: G1: Well-differentiated cells, *n* = 2 (light grey bars), G2: Moderately differentiated cells, *n* = 11 (grey bars), G3: Poorly differentiated cells, *n* = 28 (dark grey bars), G4: Undifferentiated cells, *n* = 3 (black bars). G1 epigenetic hypermethylation (M) (*n* = 1), G1 absence of hypermethylation (UM) (*n* = 1), G2 M (*n* = 3), G2 UM (*n* = 8), G3 M (*n* = 20), G3 UM (*n* = 8), G4 M (*n* = 1), G4 UM (*n* = 2). Vertical bars represent the large tumor suppressor 1 (*LATS1*) fold ratio calibrated to the average C_t of control ($\Delta\Delta C_t^{LATS1} = \Delta C_t^{LATS1, sample} - \Delta C_t^{LATS1, control}$), error bars: SE. $^aP < 0.05$ *vs* control group; $^cP < 0.05$ between subgroups (Mann-Whitney *U* test).

levels in 40 of 78 tumor lesions compared with normal gastric mucosa. The expression of LATS1 protein was significantly lower in gastric cancer with lymph node metastases than in cases without lymph node involvement[25]. Furthermore, in a group of 117 breast cancer patients, LATS1 mRNA was significantly decreased in the tumor tissue, and its decreased level was associated with a large tumor size, high lymph node metastasis rate, and poor prognosis[22]. In 30 astrocytoma cases, the level of LATS1 was 2-10 times lower as quantified by QPCR compared with 10 samples from normal brain tissue[21]. The most recent data showed that reduced expression of *LATS1* was correlated with the occurrence of metastatic glioma and poor survival of patients in a group of 17 cases[47]. Hence, decreased expression of *LATS1* in tumor tissue may suggest a suppressor role in CRC and other tumors.

MSI status has been regarded as one of the most important genetic markers and is strongly associated with molecular data, clinical findings, medical treatment, and patient outcome[48,49]. Our finding based on three BAT markers showed that more than half of the CRC patients had MSI tumors. Because we obtained samples from various clinics in different locations in Poland, our findings add to the observations by Smigiel *et al*[50] who observed MSI-L and MSI-H in 20% and 20.1% of cases, respectively, in a group of 143 CRC patients in the Lower Silesia region, which was not included in our analysis. The MSI phenotype may affect expression patterns of different proteins[51], and thus, we tried to estimate if decreased expression of *LATS1* was associated with MSI. Our findings excluded MSI-L and MSI-H as factors that may affect *LATS1* expression in the studied sample of CRC patients.

Inactivation of a typical tumor suppressor gene is generally induced by epigenetic factors such as mutation of one allele and/or loss of heterozygosity (LOH) of the other allele[52,53] or hypermethylation of CpG islands in the regulatory region of the gene[27-30]. Such factors may lead to a complete loss of gene function in cancer[54,55]. Expression of the *LATS1* transcript can be epigenetically decreased by hypermethylation of CpG islands located within the 5' upstream regulatory region of the gene[20-22]. Because *LATS1* was reduced in several malignancies, we decided to assess the hypermethylation status of the *LATS1* CpG island. Our study is the first report of the hypermethylation status of *LATS1* in CRC, showing an association between hypermethylation and decreased *LATS1* expression. *LATS1* hypermethylation was observed in 17/30 (56%) breast cancers and was associated with decreased *LATS1* expression; methylated cases showed a 3-fold decreased expression compared with unmethylated cases[22]. *LATS1* hypermethylation was found in 13/54 (24%) cases of head and neck cancer[24] and in 64% (56/88) of astrocytomas[21]. Moreover, in astrocytomas, the methylation status was associated with decreased *LATS1* expression[21]. A similar relationship between decreased *LATS1* expression and its hypermethylation was observed in our study in 57% of analyzed CRC cases. Interestingly, other known epigenetic factors do not seem to be involved in reduced *LATS1* expression in cancer. In a group of 25 breast cancers, LOH at 6q24-25.1 (*LATS1* locus) was found in only one case (4%), whereas no mutation was found and only two gene polymorphisms were observed. However, neither polymorphism caused amino acid substitution[31]. As further support that hypermethylation may be the major epigenetic factor in *LATS1* silencing, the expression of *LATS1* in the

hypermethylated cell lines U251 (an established glioma cell line) and SHG-44 (a human malignant glioma cell line) was restored by addition of 5-aza-deoxycytidine, and apoptosis of cancer cells results[21].

Decreased expression of *LATS1* that is associated with promoter hypermethylation may contribute to suppression of the SWH pathway[10,11,13,18]. This pathway is prone to deregulation because few proteins involved in signal transduction are both tumor suppressors and oncoproteins. Altered expression of *YAP*, *RASSF1A*, *LATS1*, and *MST2* in cancer cell lines leads to higher resistance of the cells to apoptosis[10,13,17,18]. Moreover, reduced expression of other genes that are not directly involved in the SWH pathway, such as WW and C2 domain containing 1 (*KIBRA*) and salvador homolog 1 (*SAV1*), may contribute to the quiescence of this pathway[11,16,56]. Such suppression of the SWH pathway is related to epithelial-to-mesenchymal transition features and poor prognosis in breast cancer[16].

In conclusion, this is the first study to show decreased expression of *LATS1* in CRC, confirming its tumor suppressor function and linking its downregulation to the epigenetic hypermethylation of the *LATS1* promoter region.

ACKNOWLEDGMENTS

The authors would like to thank Professor Marian Smoczynski, Chair of the Department of Gastroenterology and Hepatology; Dr. Janusz Chybicki and Dr. Andrzej Babicki from the Department of General Surgery, Hospital Ministry Internal Affairs in Gdansk; and Dr. Sebastian Dobrowolski from the Department of General, Transplant and Endocrinological Surgery for providing tumor samples; the contribution of Dr. Michal Zmijewski and Dr. Tomasz Slebioda from the Department of Histology to the data analysis is also highly acknowledged.

COMMENTS

Background

Searching for new colorectal cancer (CRC) molecular markers is a very important objective, because CRC is one of the most common malignancies in the world and one of the most fatal of human neoplasms. The molecular mechanisms of CRC are still unknown, but deregulation of mitotic division as well as apoptosis resistance are clearly associated with CRC progression.

Research frontiers

Human large tumor suppressor 1 (*LATS1*) encodes a serine/threonine kinase, which mediates a tumor suppressor pathway called the Salvador-Warts-Hippo (SWH) pathway. Abnormal expression of *LATS1* was observed in some tumors, and its expression in CRC has not been analyzed quantitatively.

Innovations and breakthroughs

This is the first study of a large group of CRC patients that shows quantitatively reduced *LATS1* expression at the mRNA level. Decreased levels of *LATS1* were strongly associated with hypermethylation of its promoter, particularly in metastatic tumors.

Applications

With knowledge regarding the decreased expression of *LATS1* in CRC, focusing on its intracellular signaling pathways in CRC and the probable involvement of this gene in CRC pathogenesis as a molecular marker may be possible.

Terminology

LATS1 is a putative tumor suppressor gene that shows reduced expression in several malignancies. LATS1 is important in karyo- and cytokinesis and is part of the SWH pathway. Hypermethylation of the *LATS1* promoter is a common epigenetic factor responsible for downregulation and silencing of this gene.

Peer review

The authors collected and processed samples of CRC tumors and control colon biopsies from four collaborative clinics from four different regions of Poland. Molecular quantitative assays based on quantitative polymerase chain reaction revealed strongly reduced expression of *LATS1* in CRC tumors. Furthermore, this downregulation was strongly associated with the occurrence of hypermethylation of the *LATS1* promoter but not with microsatellite instability. This observation confirms the suppressor role of *LATS1* in carcinogenesis in this first study on a large group of CRC patients.

Abstract

AIM: To validate the usefulness of screening endoscopy findings for predicting *Helicobacter pylori* (*H. pylori*) infection status.

METHODS: *H. pylori* infection status was determined by histology, serology, and the urea breast test in 77 consecutive patients who underwent upper endoscopy. Based on the findings, patients were categorized as *H. pylori*-uninfected, -infected, or -eradicated cases. Using six photos of certain sites in the stomach per case, we determined the presence or absence of the following endoscopic findings: regular arrangement of collecting venules (RAC), linear erythema, hemorrhage, fundic gland polyp (FGP), atrophic change, rugal hyperplasia, edema, spotty erythema, exudate, xanthoma, and mottled patchy erythema (MPE). The diagnostic odds ratio (DOR) and inter-observer agreement (*Kappa* value) for these 11 endoscopic findings used in the determination of *H. pylori* infection status were calculated.

RESULTS: Of the 77 patients [32 men and 45 women; mean age (SD), 39.7 (13.4) years] assessed, 28 were *H. pylori* uninfected, 28 were infected, and 21 were eradicated. DOR values were significantly high (< 0.05) for the following *H. pylori* cases: uninfected cases with RAC (11.5), linear erythema (24.5), hemorrhage (4.1), and FGP (34.5); for infected cases with atrophic change (8.67), rugal hyperplasia (15.8), edema (14.2), spotty erythema (11.5), and exudate (3.52); and for eradicated cases with atrophic change (32.4) and MPE (103.0). *Kappa* values were excellent for FGP (0.93), good for RAC (0.63), hemorrhage (0.79), atrophic change (0.74), and MPE (0.75), moderate for linear erythema (0.51), rugal hyperplasia (0.49), edema (0.58), spotty erythema (0.47), and exudate (0.46), and poor for xanthoma (0.19).

CONCLUSION: The endoscopic findings of RAC, hemorrhage, FGP, atrophic change, and MPE will be useful for predicting *H. pylori* infection status.

Key words: Diagnostic odds ratio; Endoscopic finding; Eradication therapy; *Helicobacter pylori*; Inter-observer agreement

Core tip: To determine useful findings for predicting *Helicobacter pylori* (*H. pylori*)-uninfected, -infected,

or -eradicated cases, we evaluated following 11 endoscopic findings, regular arrangement of collecting venules (RAC), linear erythema, hemorrhage, fundic gland polyp (FGP), atrophic change, rugal hyperplasia, edema, spotty erythema, exudate, xanthoma, and mottled patchy erythema (MPE). Among these, RAC, hemorrhage, FGP, atrophic change, and MPE were found to be predictive findings for *H. pylori* infection status on screening endoscopy. The knowledge of these findings may contribute to the early detection of gastric cancer.

Predictive findings for *Helicobacter pylori*-uninfected, -infected and -eradicated gastric mucosa: Validation study. *World J Gastroenterol* 2013; 19(27): 4374-4379 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4374.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4374

INTRODUCTION

Gastric cancer remains the second leading cause of cancer death, accounting for 600000 deaths annually worldwide[1]. The incidence of gastric cancer is particularly high in Asia, especially in China, Japan and Korea where *Helicobacter pylori* (*H. pylori*) infection is highly prevalent. The risk of gastric cancer can differ depending on whether individuals are uninfected or infected with *H. pylori* or whether the infection has been eradicated[2-4]. It is therefore extremely important in the early detection of gastric cancer that *H. pylori* infection status is determined for each of these groups of individuals.

Endoscopy is an essential diagnostic tool for gastric cancer, enabling various findings induced by histological inflammation of the gastric mucosa to be detected. The development of histological gastritis is regarded as rare in *H. pylori*-uninfected cases, but it is usually noted in *H. pylori*-infected cases and improved by eradication therapy. This difference is reflected in the appearance of the gastric mucosa, which has been reported in the form of endoscopic findings in several studies[5-12]. However, the predictive value of the findings has not yet been validated.

In this study, we assessed, in a systematic manner, 11 endoscopic findings in dyspeptic patients and evaluated which of the findings were associated with *H. pylori*-uninfected, -infected, and -eradicated cases.

MATERIALS AND METHODS

Subjects

A total of 148 consecutive patients with dyspepsia who had undergone upper gastrointestinal endoscopy and had been strictly diagnosed with *H. pylori* infection between December 2008 and April 2009 at the National Center for Global Health and Medicine (NCGM) were identified from an endoscopic electronic database. The exclusion criteria applied were the use of non-steroidal anti-inflammatory drugs or anti-thrombogenic drugs and a history of gastric surgery, hemorrhagic disease, liver cirrhosis, renal failure, heart failure, or early or advanced gastric cancer, because these conditions could affect the mucosal appearance of the stomach[13-16]. After exclusion, 77 cases remained for analysis.

Written informed consent was obtained from all participants in accordance with the Declaration of Helsinki and its subsequent revision. The study protocol was approved by the Ethics Committee of NCGM (approval No. 811).

Diagnosis of H. pylori infection status

H. pylori infection status was evaluated by the presence of serum immunoglobulin G antibody against *H. pylori* (HM-CAP enzyme immunoassay, Enteric Products, Westbury, NY, United States), the [13C]-labeled urea breath test (13C-UBT, with a cut-off value of 2.5‰; Ubit, Otsuka Pharmaceuticals, Tokyo, Japan), and histological examination with toluidine blue staining of 3 endoscopic biopsy specimens taken from the greater curvature of the upper gastric body, angulus, and antrum, respectively. When all three methods yielded negative results, *H. pylori* infection status was considered "uninfected". When one or more of these methods yielded a positive result and there was no history of previous eradication therapy, *H. pylori* infection status was considered "infected". When histological examination and 13C-UBT yielded negative results and a history of eradication therapy was recorded, *H. pylori* infection status was considered "eradicated".

Endoscopic findings evaluated

All endoscopies were performed by well-trained endoscopists using a high resolution videoendoscope (GIF-260H, Olympus Co., Tokyo, Japan) with a pre-endoscopic oral solution containing dimethylpolysiloxane (Balgin Antifoaming Oral Solution 2%, Kaigen Co., Ltd., Osaka, Japan). In all cases, around 50-60 endoscopic images had been routinely recorded at fixed sites in the esophagus, stomach, and duodenum and saved to the electronic endoscopic database (Solemio ENDO, Olympus Co.). Six of the recorded images - specifically of the antrum, angulus, lesser and greater curvature of the lower body, greater curvature of the upper body, and cardia of the stomach - were used for analysis in each case.

The presence or absence of the following 11 distinctive endoscopic findings were evaluated (Figures 1 and 2): regular arrangement of collecting venules (RAC)[5], linear erythema[9], hemorrhage[9], fundic gland polyp (FGP)[10], atrophic change[6,7], severity of atrophy (open/closed)[6,7], rugal hyperplasia[8], edema[9] (which is visible as a thickened mucosal layer especially at the angulus and cardia), spotty erythema[9], exudate[9], xanthoma[11], and mottled patchy erythema (MPE)[12]. A well-experienced endoscopist (Kobayakawa M) assessed the findings, and to determine inter-observer agreement, another experi-

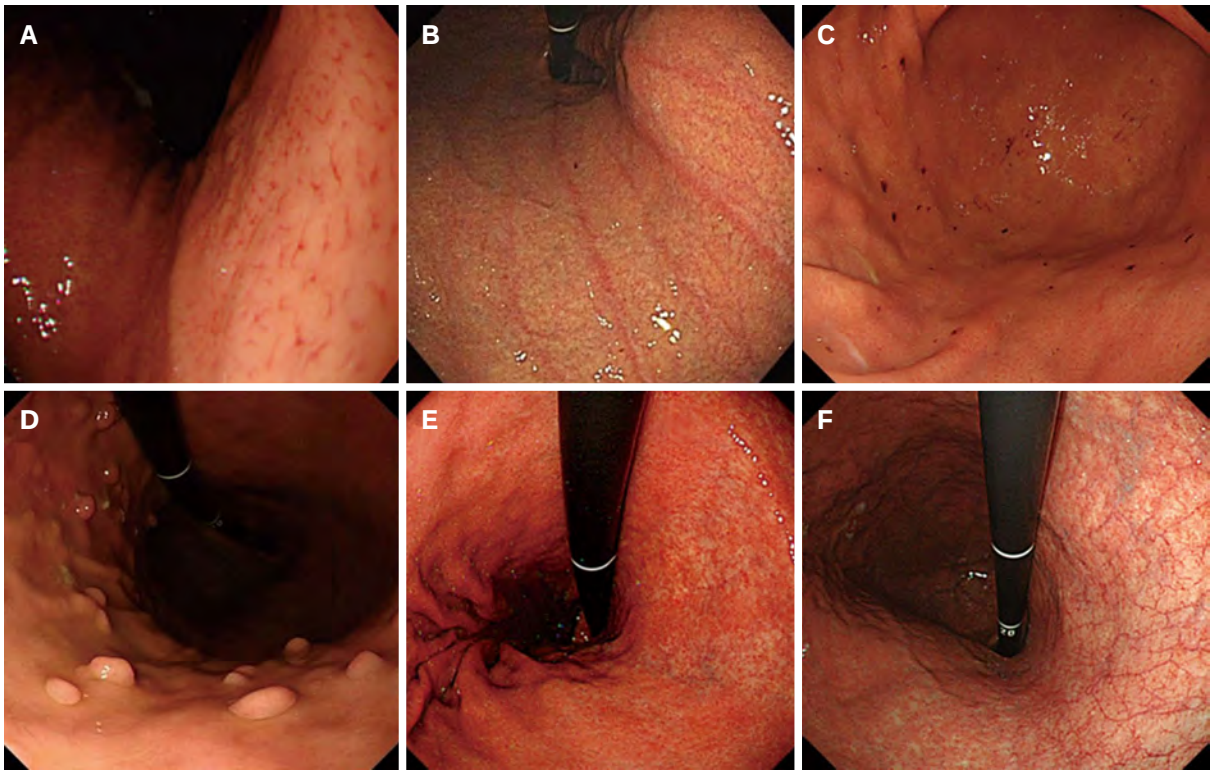

Figure 1 Five of the 11 endoscopic findings evaluated in this study. Table 1 Diagnostic odds ratios of endoscopic findings in the diagnosis of three groups of *Helicobacter pylori* infection status

Endoscopic finding	*H. pylori*		
	Uninfected	Infected	Eradicated
RAC	11.5 (3.73-35.1)	0.03 (0.00-0.14)[a]	1.65 (0.61-4.47)[a]
Linear erythema	24.5[1] (4.12-146)	0.05[1] (0.00-0.83)[a]	0.18 (0.00-1.20)[a]
Hemorrhage	4.11 (1.54-11.0)	0.03 (0.00-0.19)[a]	2.52 (0.92-6.95)[a]
Fundic gland polyp	34.5[1] (1.89-632)	0.10[1] (0.01-1.81)[a]	0.15[1] (0.01-2.81)[a]
Atrophic change	0.01 (0.00-0.06)	8.67[1] (2.11-35.6)[a]	32.4[1] (1.87-562)[a]
Rugal hyperplasia	0.02[1] (0.00-0.34)	15.8 (4.86-51.4)[a]	0.66 (0.22-2.03)
Edema	0.10 (0.03-0.31)	14.2 (4.52-44.1)[a]	0.66 (0.24-1.81)
Spotty erythema	0.09 (0.00-0.60)	11.5 (3.03-42.7)[a]	0.35 (0.00-1.54)
Exudate	0.27 (0.00-1.18)	3.52 (1.16-11.6)[a]	0.77 (0.21-2.93)
Xanthoma	0.86 (0.22-3.46)	2.45 (0.64-9.29)	0.30 (0.00-2.02)
Mottled patchy erythema	0.07[1] (0.00-1.17)	0.07[1] (0.00-1.17)	103[1] (5.64-1888)[a]

Values of odds ratios (95%CI) are shown. [1]Odds ratios were estimated using the substitution formula. 0.5 was added to all cell frequencies before calculation. [a]$P < 0.05$ *vs* uninfected. RAC: Regular arrangement of collecting venules; *H. pylori*: *Helicobacter pylori*.

enced endoscopist (Sakurai T) also assessed these findings. Both were blinded to clinical information in the cases examined.

Statistical analysis

To identify the predictive endoscopic findings for *H. pylori* infection status from among the 462 endoscopic images for the 77 patients, diagnostic odds ratios (DOR) for the 11 endoscopic findings in *H. pylori*-uninfected, -infected, and -eradicated cases were calculated. In addition, 95%CI were also estimated. DOR is defined as the positive likelihood ratio divided by the negative likelihood ratio. Positive likelihood ratio was calculated by sensitivity/1-specificity, and negative likelihood ratio was calculated by specificity/1-sensitivity[17].

The inter-observer agreement for each endoscopic finding among the two endoscopists was measured using *kappa* statistics. *Kappa* values (k) > 0.80 denoted excellent agreement, > 0.60-0.80 good, > 0.40-0.60 moderate, > 0.20-0.40 fair, and ≤ 0.20 poor[18]. Values of $P < 0.05$ were considered significant. All statistical analysis was performed using Stata version 10 software (StataCorp, Lakeway Drive College Station, TX, United States).

RESULTS

Patient characteristics

Of the 77 patients [32 men and 45 women; mean age (SD), 39.7 (13.4) years] assessed, 28 were *H. pylori* uninfected, 28 were infected, and 21 were eradicated.

Diagnostic odds ratio of endoscopic findings

The DOR for each endoscopic finding in the diagnosis of the three groups of *H. pylori* infection status are shown in Table 1. In cases diagnosed as *H. pylori* uninfected, RAC (11.5), linear erythema (24.5), hemorrhage (4.1), and FGP (34.5) had high DORs and were significantly associated ($P < 0.05$). In infected cases, atrophic change (8.67), rugal hyperplasia (15.8), edema (14.2), spotty erythema (11.5), and exudate (3.52) had high DORs and were significantly associated ($P < 0.05$). Lastly, in eradicated diagnosis, atrophic change (32.4) and MPE (103.0) had high DORs and were significantly associated ($P < 0.05$).

Open type atrophy was significantly ($P < 0.05$) more frequent on endoscopy in *H. pylori* infected patients (20/28, 71.4%) than in *H. pylori* eradicated patients (8/21, 38.1%).

Table 2 Inter-observer agreement for the 11 endoscopic findings evaluated

Endoscopic finding	*Kappa* value
RAC	0.63
Linear erythema	0.51
Hemorrhage	0.79
Fundic gland polyp	0.93
Atrophic change	0.74
Rugal hyperplasia	0.49
Edema	0.58
Spotty erythema	0.47
Exudate	0.46
Xanthoma	0.19
Mottled patchy erythema	0.75

RAC: Regular arrangement of collecting venules.

Inter-observer agreement for the endoscopic findings evaluated

The *kappa* value indicating agreement between the two endoscopists for each endoscopic finding is shown in Table 2.

DISCUSSION

This study identified several endoscopic findings that are clearly associated with uninfected, infected, and eradicated *H. pylori* infection. Some endoscopic findings have been previously reported to be correlated with *H. pylori* infection. Atrophic change was found to be associated with the infection in an aged group (OR = 9.8)[19] as well as in general[7,20]. Rugal hyperplasia was reported to be correlated with *H. pylori* infection[21]. Edema, with or without exudate, and spotty erythema were considered to be a result of mucosal inflammation, but these positive findings were not definitive[9]. Lastly, xanthoma, which refers to yellowish-white small nodules or plaques in the gastric mucosa, is considered to be related with *H. pylori* infection[11]. Among these findings, we clarified that all of them - atrophic change, rugal hyperplasia, edema, spotty erythema, and exudate - are valuable endoscopic findings of *H. pylori* infection.

In regard to the predictive findings related with *H. pylori* uninfected mucosa, RAC has been well studied and showed a positive association[5,22]. Fundic gland polyp is also considered to be a finding associated only with uninfected cases[10]. In the present study these endoscopic findings showed high odds ratios and thus support the results of earlier studies. While hemorrhage and linear er-

ythema were found to be associated with well-preserved gastric acid secretion, they were not clearly associated with *H. pylori* uninfected mucosa[9]. In the present study, however, these two findings had high odds ratios, suggesting they are valuable for predicting *H. pylori*-uninfected cases.

This study also investigated *H. pylori*-eradicated cases, because the preventive effect of *H. pylori* eradication therapy for gastric cancer has been reported[3,4] and therefore an increasing number of patients will likely receive *H. pylori* eradication therapy into the future[23,24]. Gastric cancer can, however, still occur in eradicated cases, but it is generally difficult to diagnose and few predictive endoscopic findings have been reported. Of those that have been suggested are the disappearance of rugal hyperplasia[8] and hyperplastic polyp[25], but as these findings need to be compared before and after eradication therapy, on their own it seems difficult to apply them to clinical use. Atrophic change, occurring as a result of *H. pylori* infection, is thought to remain after eradication therapy[26]. Moreover, in our previous study, MPE, which is recognized as a flat or slightly depressed reddish lesion that is distinguishable from the congested mucosa, emerged after *H. pylori* eradication therapy[12]. In the study too, atrophic change and MPE was highly predictive of *H. pylori* eradicated mucosa, suggesting that a combination of these findings is highly valuable in clinical practice.

In regard to the reproducibility of endoscopic image evaluation for these 11 findings, among the positive endoscopic findings found, RAC, hemorrhage, fundic gland polyp, atrophic change, and MPE all showed good inter-observer agreement, suggesting that these findings can be easily identified and will be generally useful. The other positive findings of edema, rugal hyperplasia, and spotty erythema showed moderate agreement, suggesting that they could also be suitable for general use.

There are several important strengths of this study, including that the diagnosis of *H. pylori* infection status was accurate, made on the basis of a combination of three different diagnostic tests to overcome any shortcomings of a single test. Moreover, DOR was used to estimate the diagnostic value: DOR is not influenced by prevalence rate, so the results are applicable in other populations with a different prevalence of *H. pylori* infection.

Nonetheless, this study has several limitations. First, the sample size of 77 patients is relatively small, and did not permit multivariate analysis to exclude confounders. Second, the population consists of relatively young patients, therefore cases in whom *H. pylori* is naturally eradicated without eradication therapy as a result of long-term course of severe atrophic gastritis, may not be included. Furthermore, photographic not video images were used for analysis and therefore the whole stomach was not observed, so some findings that may be present were not assessed.

In conclusion, the endoscopic findings associated with *H. pylori* infection status that are common and have good inter-observer agreement were clarified to be RAC, hemorrhage, fundic gland polyp, atrophic change, and MPE. These findings should be generally useful in clinical practice and contribute to the early detection of gastric cancer.

COMMENTS

Background

The risk of gastric cancer can differ among *Helicobacter pylori* (*H. pylori*) uninfected, infected, and eradicated patients, therefore it is important to determine *H. pylori* infection status. Endoscopic prediction of *H. pylori* infection status can be extremely useful for early detection of gastric cancer, but the diagnostic value of *H. pylori* related endoscopic findings has not yet been validated.

Research frontiers

Some endoscopic findings were reported to be related with *H. pylori* uninfected, infected case, and little has been reported on eradicated case. The accuracy of these findings varies in each studies, and have not been well examined. In this study, the authors demonstrate the accuracy and reproducibility of endoscopic findings which have been previously reported to be correlated with *H. pylori* infection.

Innovations and breakthroughs

This is the first study which evaluate the value of predictive endoscopic findings separately for 3 groups of *H. pylori* infection status; uninfected, infected, and eradicated. Moreover, the authors used diagnostic odds ratio (DOR) to estimate the diagnostic value of endoscopic findings. DOR is not influenced by prevalence rate, so the results are applicable in other populations with a different prevalence of *H. pylori* infection.

Applications

The endoscopic findings associated with *H. pylori* infection status that are common and have good reproducibility were clarified to be regular arrangement of collecting venules, hemorrhage, fundic gland polyp, atrophic change, and mottled patchy erythema. These findings should be generally useful in clinical practice and contribute to the early detection of gastric cancer.

Terminology

DOR is defined as the positive likelihood ratio divided by the negative likelihood ratio. DOR is single indicator of diagnostic test, and higher value is indicative of better test performance, irrespective of prevalence rate.

Peer review

The authors showed endoscopic features of gastric mucosa according to *H. pylori* infection status. Although most endoscopists are usually aware of the correlation between endoscopic findings and *H. pylori* status, the simplification and clarification of the correlation by showing typical endoscopic findings and their diagnostic odds ratios may be worth publication.

Abstract

AIM: To evaluate the effects of DA-9701 on the gastric emptying of a solid meal using the ^{13}C-octanoic acid breath test in a mouse model.

METHODS: Male C57BL/6 mice aged > 8 wk and with body weights of 20-25 g were used in this study. The solid test meal consisted of 200 mg of egg yolk labeled with 1.5 L/g ^{13}C-octanoic acid. The mice were placed in a 130 mL chamber flushed with air at a flow speed of 200 mL/min. Breath samples were collected for 6 h. The half-emptying time and lag phase were calculated using a modified power exponential model. To assess the reproducibility of the ^{13}C-octanoic acid breath test, the breath test was performed two times at intervals of one week in ten mice without drug treatment. To assess the gastrokinetic effects of DA-9701, the breath test was performed three times in another twelve mice, with a randomized crossover sequence of three drug treatments: DA-9701 3 mg/kg, erythromycin 6 mg/kg, or saline. Each breath test was performed at an interval of one week.

RESULTS: Repeatedly measured half gastric emptying time of ten mice without drug treatment showed 0.856 of the intraclass correlation coefficient for the half gastric emptying time (P = 0.004). The mean cumulative excretion curve for the ^{13}C-octanoic acid breath test showed accelerated gastric emptying after DA-9701 treatment compared with the saline control (P = 0.028). The median half gastric emptying time after the DA-9701 treatment was significantly shorter than after the saline treatment [122.4 min (109.0-137.9 min) *vs* 134.5 min (128.4-167.0 min), respectively; P = 0.028] and similar to that after the erythromycin treatment [123.3 min (112.9-138.2 min)]. The lag phase, which was defined as the period taken to empty 15% of a meal, was significantly shorter after the DA-9701 treatment than after the saline treatment [48.1 min (44.6-57.1 min) *vs* 52.6 min (49.45-57.4 min), respectively; P = 0.049].

CONCLUSION: The novel prokinetic agent DA-9701 accelerated gastric emptying, assessed with repeated measurements in the same mouse using the ^{13}C-octanoic acid breath test. Our findings suggest that DA-9701 has therapeutic potential for the treatment of functional dyspepsia.

Key words: DA-9701; Gastric emptying; Prokinetic agent; Breath test; Functional dyspepsia

Core tip: DA-9701 is a newly formulated prokinetic agent obtained from extracts of Pharbitis Semen and Corydalis Tuber. The ^{13}C-octanoic acid breath test is a reliable and responsive method for measuring gastric

emptying in small laboratory animal. This technique can be performed repeatedly in the same animal and reflect exact pharmacological effects without sacrifice of the animal. This study demonstrated the gastrokinetic effects of DA-9701, using repeated ^{13}C-octanoic acid breath tests in the same animal. The gastrokinetic effect of DA-9701 could have therapeutic potential for the treatment of familial dysautonomia.

Effect of DA-9701 on gastric emptying in a mouse model: Assessment by ^{13}C-octanoic acid breath test. *World J Gastroenterol* 2013; 19(27): 4380-4385 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4380.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4380

INTRODUCTION

DA-9701 is a newly formulated prokinetic agent obtained from extracts of Pharbitis Semen and Corydalis Tuber. Both the seed of Pharbitis Semen and the root of Corydalis Tuber have been used in traditional Oriental medicine for the treatment of gastrointestinal symptoms. DA-9701 and its components accelerated gastric emptying and improved gastric accommodation in animal model[1-4]. A previous study demonstrated the gastrokinetic effect of DA-9701 in a rat model[1], using the method of Ozaki *et al*[5]. With this model, the animal must be killed to assess gastric emptying, and consequently, gastric emptying can only be measured at that one point in time. The disadvantage of this method is that it is impossible to assess gastric emptying repeatedly in the same animal. Therefore, the utility of the model is limited for evaluating pharmacologically induced gastric emptying because there is great intersubject variability.

Stable isotope breath tests are indirect noninvasive tests for measuring gastric emptying. Their advantages include the absence of a radiation hazard, ease of handling, and no requirement for positioning, unlike scintigraphic tests[6]. Breath tests offer an attractive method of measuring gastric emptying in small laboratory animals because the animal need not be killed, thus allowing repeated measurements to be made in the same animal. With the ^{13}C-octanoic acid breath test, gastric emptying can be assessed noninvasively, and the differences in gastric emptying induced in small laboratory animals by pharmacological agents can be quantified[7-11]. This test is a useful tool in the development of new prokinetic agents that modulate gastric emptying. The aim of this study was to evaluate the effects of DA-9701 on the gastric emptying of a solid meal using the ^{13}C-octanoic acid breath test in a mouse model.

MATERIALS AND METHODS

Animals

Male C57BL/6 mice, aged > 8 wk and with body weights of 20-25 g, were used for the breath test. Ten mice were used to assess the reproducibility of the ^{13}C-octanoic acid breath test and another 12 mice were used to evaluate the effects of DA-9701. Sample sizes were calculated from the equation below by referring to a previous study using C57BL/6 mice[8]: $n = 2 + C (s/d)^2$, where s is SD, d is expected difference between two means, and C is constant. A sample size of 12 mice was suitable to identify, with a power of 0.8, the expected difference in half gastric emptying time of 50 min with an alpha significance level of 0.05. All the mice were housed in a room maintained at 21 ℃-23 ℃ on a 14/10 h light/dark cycle. The mice had continuous access to water and a standard commercial diet. All experiments were approved by the Institutional Animal Care and Use Committee of the Catholic University of Korea, Seoul, South Korea.

Test meal

The gastric emptying rates were assessed for a solid egg yolk meal. ^{13}C-Octanoic acid (Octanoic acid-1-^{13}C, 99 atom % ^{13}C, Sigma-Aldrich Co. LLC, St Louis, Missouri, United States) was added to raw yolk at a concentration of 1.5 μL/g. The yolk was homogenized and heated in water at 60 ℃ for 120 min. The test meal (200 mg) was given to each animal after an overnight fast with free access to water and was completely consumed by the mouse within 1 min in the breath test chamber.

Breath test protocol

To assess the gastric emptying rate using the ^{13}C-octanoic acid breath test with measurements made up to 360 min, the mice were fasted overnight[7,8]. They were then placed in a 130 mL gas-tight rubber-sealed chamber with room air. The flow rate of air was 200 mL/min, which was selected because this rate was sufficient to flush any residual CO_2 from the chamber between the sampling time points. Three-way valves were connected to the chamber for air inlet and outlet to allow sampling. To collect a breath sample, the airflow through the chamber was stopped for 4 min. At the end of the breath-accumulation period, 10 mL of breath was syringed from the chamber, and the airflow through the chamber was restored. Each mouse was maintained in the chamber for the whole 360 min sampling procedure. A baseline breath sample was taken before the test meal was consumed. Further breath samples were collected at 5 min intervals for the first 30 min, and at 15 min intervals thereafter until 360 min after the consumption of the test meal.

Reproducibility of the breath test

To assess the reproducibility of the ^{13}C-octanoic acid breath test, the breath test was performed two times at intervals of 1 wk in ten mice without drug treatment.

Drug treatment

This study was designed as a randomized crossover study. DA-9701 (3 mg/kg) was the test drug, erythromycin (6 mg/kg) the positive control, and normal saline the

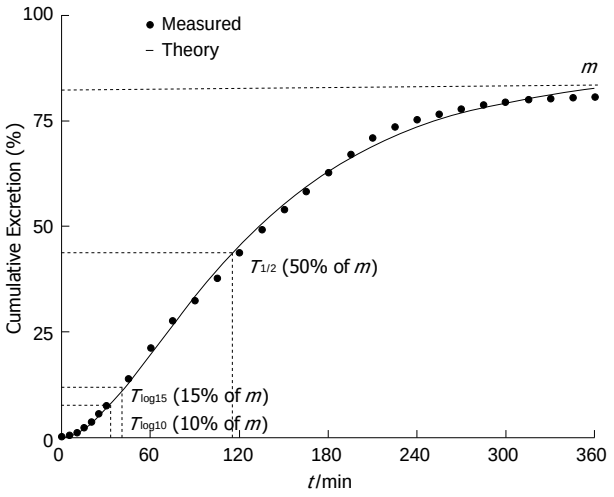

Figure 1 Typical excretion curve of the ^{13}C-octanoic acid breath test in the mouse model. *m*: The total cumulative ^{13}C recovery when time is infinite; $T_{1/2}$: Half gastric emptying time; T_{lag10}: Lag phase of 10 % emptying; T_{lag15}: Lag phase for 15% emptying.

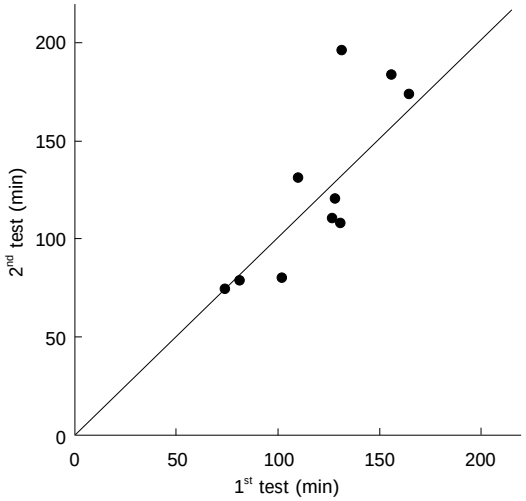

Figure 2 Reproducibility of the ^{13}C-octanoic acid breath test in ten mice.

placebo. There were six possible permutations of the drug treatment sequences, and two animals were allocated to each permutation. The test drug and the positive control were suspended in distilled water for their oral administration. A 10 mL/kg volume of DA-9701, erythromycin, or saline was given orally to each mouse by gavage 1 h before the breath test. The breath test was performed three times in each animal at intervals of 1 wk.

Data analysis

The $^{13}CO_2$ content of each breath sample was analyzed using a HeliView isotope ratio mass spectrometer (Medichems, Seoul, South Korea). The [^{13}C]/[^{12}C] ratio (δ) was expressed as parts per thoUnited Statesnd relative to the Pee Dee Belemnite calcium carbonate international primary standard. The gastric emptying rates were calculated from the resultant $^{13}CO_2$ excretion curves. The CO_2 production rate of the mice was assumed to be 40 mL/kg per minite based on normal values for the resting metabolic parameters measured in C57BL/6 mice[12]. The percentage $^{13}CO_2$ cumulative values were fitted using a modified power exponential model[13]: $y = m\ (1 - e^{-kt})^{\beta}$, where y is the cumulative percentage of $^{13}CO_2$ excretion in breath at time t (h), and m, k and β are estimated parameters. In this model, m is interpreted as the total cumulative ^{13}C recovery when the time is infinite. The cumulative $^{13}CO_2$ excretion cannot reach 100% because a substantial amount of the orally administered dose is fixed in the bicarbonate pool in the body. Because the cumulative excretion reaches a steady state, sampling up to 360 min allows the calculation of m, the theoretical recovery after infinite time. The half gastric emptying time ($T_{1/2}$), the lag phase for 10% emptying (T_{lag10}), and the lag phase for 15% emptying (T_{lag15}) in the breath test were calculated from this model as $T_{1/2} = (-1/k) \times \ln[1 - (0.5^{1/\beta})]$; $T_{lag10} = (-1/k) \times \ln[1 - (0.1^{1/\beta})]$; $T_{lag15} = (-1/k) \times \ln [1 - (0.15^{1/\beta})]$.

Statistical analysis

The results are expressed as medians and interquartile ranges. The reproducibility of breath test was evaluated using the intraclass correlation coefficient. A repeated measurements ANOVA followed by post hoc test at the point of every 60 min was performed for comparison of total cumulative excretion curve after drug treatment. Differences in the data were evaluated using the Wilcoxon signed-rank test for comparisons of the half gastric emptying times and lag phases after drug treatment. A difference was considered significant when the P value was less than 0.05.

RESULTS

A typical excretion curve for ^{13}C-octanoic acid breath test of a mouse is presented in Figure 1. Repeatedly measured half gastric emptying time of ten mice is presented Figure 2. The half gastric emptying times of the first and second breath tests were 127.5 min (96.7-137.6 min) and 115.4 (79.9-176.4 min). The half gastric emptying times of the first and second breath tests showed good correlation (intraclass correlation coefficient = 0.856, $P = 0.004$). The effects of the drug treatments on gastric emptying are shown in Figure 3. The cumulative excretion curve for ^{13}C-octanoic acid breath showed accelerated gastric emptying after treatment with DA-9701 compared with that after treatment with saline ($P = 0.028$). The effect of DA-9701 treatment on gastric emptying was similar to that of erythromycin.

The half gastric emptying times and lag phases are presented in Table 1. Both DA-9701 and erythromycin treatments induced significantly shorter half gastric emptying times compared with that induced with saline ($P = 0.028$ and $P = 0.049$, respectively). There was no significant difference in the half gastric emptying times of the DA-9701- and erythromycin-treated mice. There was no significant difference in T_{lag10} among the treatments. T_{lag15} was significantly shorter in mice treated with DA-9701

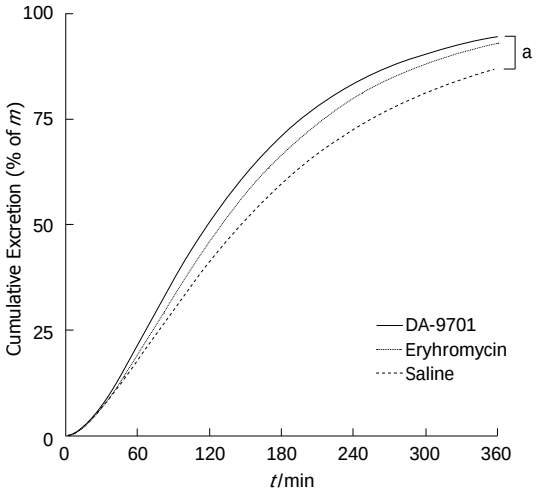

Figure 3 Mean excretion curve of the ^{13}C-octanoic acid breath test in mice treated with DA-9701, erythromycin, and saline. m: The total cumulative ^{13}C recovery when time is infinite. $^{a}P < 0.05$ between DA-9701 and saline.

Table 1 Half gastric empting time and lag phase measured by the ^{13}C-octanoic acid breath test in the mice treated with DA-9701, erythromycin, and saline

	DA-9701 (n = 12)	Erythromycin (n = 12)	Saline (n = 12)
$T_{1/2}$ (min)	122.4 (109.0-137.9)[1]	123.3 (112.9-138.2)[2]	134.5 (128.4-167.0)
T_{lag10} (min)	38.5 (33.2-46.4)	37.9 (35.8-41.4)	39.5 (35.2-45.3)
T_{lag15} (min)	48.1 (44.6-58.5)[2]	49.3 (46.5-53.3)	52.6 (48.9-57.6)

Data represent median with interquartile range in parentheses. [1]P = 0.028, [2]P = 0.049 *vs* saline treatment (Wilcoxon's signed ranks test). $T_{1/2}$: Half gastric emptying time; T_{lag10}: Lag phase for 10 % emptying; T_{lag15}: Lag phase for 15% emptying.

than in mice treated with saline (P = 0.049). The half gastric emptying time and T_{lag15} for each mouse treated with saline, DA-9701, or erythromycin is presented in Figure 4.

DISCUSSION

Dyspeptic symptoms are common problem in primary health care and gastroenterology practice. Although the precise pathophysiology of functional dyspepsia (FD) is not fully understood, disturbed gastric emptying is one of the important abnormalities in FD patients[14,15]. Current treatment approaches to FD include gastric acid suppression and gastroprokinetic drugs as primary treatment options[16]. However, no satisfactory therapeutic approach is currently available in clinical practice. There is an increasing need for the development of safe and effective prokinetic drugs without adverse effects[17-19].

We have demonstrated the effects of DA-9701 on gastric emptying, using repeated ^{13}C-octanoic acid breath tests in the same animal. DA-9701 shortened both the half emptying time and the lag phase, and these effects were similar to those of erythromycin. The half gastric emptying times achieved with the placebo and erythromycin in our model were similar to those reported in previous studies that

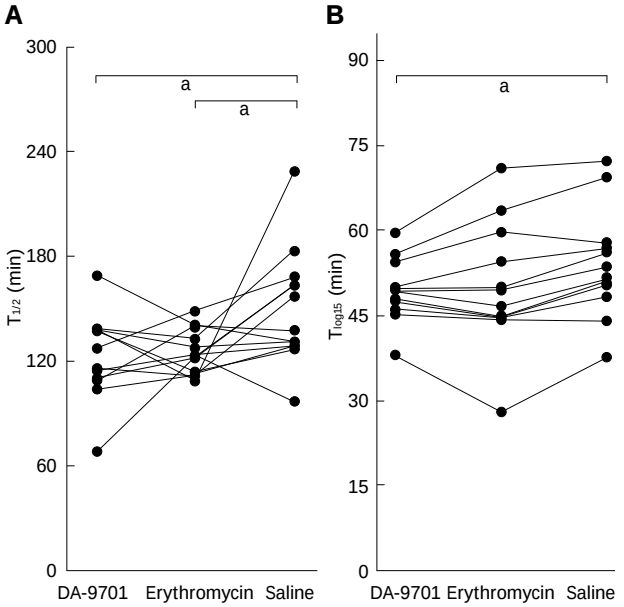

Figure 4 Half gastric emptying time and lag phase for 15% emptying measured by the ^{13}C-octanoic acid breath test in the each mouse treated with DA-9701, erythromycin, and saline. A: Half gastric emptying time ($T_{1/2}$); B: Lag phase for 15% emptying (T_{log15}). $^{a}P < 0.05$ *vs* saline.

used the same breath test[8]. We selected a dose of 3 mg/kg DA-9701 based on a previous study of the appropriate DA-9701 doses in a rat model, which showed dose-dependent effects in the range from 0.03 to 3 mg/kg[1]. Another experiment in which DA-9701 was administered at 3 mg/kg also showed accelerated gastric emptying in a model of delayed gastric emptying induced with apomorphine and cisplatin. DA-9701 and its components (corydaline and tetrahydroberberine) accelerated gastric emptying in a rat model when a method that requires the animals to be killed was used, although comparisons within the same animal were impossible[1-3]. We performed the repeated breath tests in each mouse after treatment with either DA-9701, the positive control, or the placebo, according to all possible permutations of the drug treatment sequence, and identified the prokinetic effects of DA-9701.

DA-9701 is a newly formulated prokinetic agent obtained from extracts of Pharbitis Semen and Corydalis Tuber. Both the seed of Pharbitis Semen and the root of Corydalis Tuber have been used in traditional Oriental medicine for the treatment of gastrointestinal symptoms. As well as accelerating gastric emptying, DA-9701 and its components improved gastric accommodation in a dog model with a barostat[1-4]. DA-9701 is composed of several isoquinoline alkaloid compounds, including corydaline, berberine, protopine, and palmatine[20-23]. Although the exact mechanism of its action has not been identified, tetrahydroberberine from DA-9701 has the properties of a D_2 receptor antagonist and a 5-HT_{1A} receptor agonist, with micromolar affinities for the dopamine D_2 and 5-HT_{1A} receptors[2]. DA-9701 significantly improved the symptoms of patients with FD, with efficacy similar to that of itopride and a comparable safety profile[24].

In this study, we have demonstrated the gastrokinetic

effect of DA-9701 using the ^{13}C-octanoic acid breath test in mice. A variety of techniques have been used to assess gastric emptying in small laboratory animals. Most techniques require the animal to be killed and the contents of the stomach and intestine to be quantified by measuring their radioactivity, counting the glass beads remaining, or measuring the concentration of a marker. The ^{13}C-octanoic acid breath test has been reported to be a reliable and responsive method for measuring gastric emptying in small laboratory animal[7,8,10,25], and has several advantages over other techniques. First, it allows repeated measurements to be made in the same animal, allowing exact pharmacological effects to be identified and minimizing the number of animals killed. Second, it does not require the animals to be handled or restrained, in contrast to scintigraphic tests. The results can also be expressed as rate curves and cumulative excretion curves. Therefore, the breath test can be used to determine the effects of physiological or pharmacological interventions on gastrointestinal motility, especially in developmental programs for new prokinetic drugs. However, to measure gastric emptying, the breath test requires a relatively long time and considerable effort to sample the animals' breath.

In conclusion, DA-9701 accelerates gastric emptying, and its effect is similar to that of erythromycin. The ^{13}C-octanoic acid breath test can be a useful tool to reflect physiological or pharmacological effects on gastric motility, especially in developmental programs for new prokinetic drugs. The gastrokinetic effect of DA-9701 could have therapeutic potential for the treatment of FD.

ACKNOWLEDGMENTS

We would like to thank Professor Gianrico Farrugia of Mayo Clinic for providing the breath test chambers. We also would like to thank Vet. Yong Sam Kwon of Dong-A Pharmaceutical Co., Ltd for providing technical supports in animal handling.

COMMENTS

Background

Dyspeptic symptoms are common problem in primary health care and gastroenterology practice. Disturbed gastric emptying is one of the important abnormalities in functional dyspepsia (FD) patients. Gastroprokinetic drugs in one of the primary treatment options. There is an increasing need for the development of safe and effective prokinetic drugs without adverse effects

Innovations and breakthroughs

A previous study demonstrated the gastrokinetic effect of DA-9701 in a rat model using the method of Ozaki and Sukamoto. With this model, the animal must be killed to assess gastric emptying, and consequently, gastric emptying can only be measured at that one point in time. The disadvantage of this method is that it is impossible to assess gastric emptying repeatedly in the same animal. This study demonstrated the gastrokinetic effect of DA-9701 using repeated the ^{13}C-octanoic acid breath test in same animal with minimizing the number of animals killed.

Applications

The gastrokinetic effect of DA-9701 could have therapeutic potential for the treatment of FD. The ^{13}C-octanoic acid breath test can be a useful tool to reflect physiological or pharmacological effects on gastric motility, especially in developmental programs for new prokinetic drugs.

Terminology

^{13}C-octanoic acid breath test is one of stable isotope breath tests for measuring gastric emptying. The test meal containing ^{13}C-labelled substrates is retained in the stomach and emptied into the duodenum. The ^{13}C-labelled substrates are rapidly absorbed and transported to the liver. They are oxidized to $^{13}CO_2$ in the liver and excreted in the breath. Gastric emptying is the rate-limiting step that makes it possible to use the rate of $^{13}CO_2$ appearance in the breath approximate to the gastric emptying rate.

Peer review

This study examines the effects of DA-9701, a novel phyto-derived prokinetic agent, on gastric emptying of normal C57BL/6 mice. The authors used ^{13}C-octanoic acid breath test to investigate gastric emptying of three treatments (DA-9701, erythromycin *vs* saline, the latter used as placebo) with a randomized crossover design. This study is interesting and original in its methodological part because it presents a novel method to assess gastric emptying over time rather than evaluating a single moment after sacrificing laboratory animals. The authors precisely describe their experiments using the breath test technique, including a power calculation. Compared to saline, DA-9701 evoked a more rapid emptying similarly to erythromycin. The finding of a prokinetic effect of DA-9701 on gastric emptying is very promising in view of potential therapeutic options in FD.

Abstract

AIM: To evaluate the efficacy and safety of baclofen for treatment of refractory gastroesophageal reflux-induced chronic cough (GERC) unresponsive to standard anti-reflux therapy.

METHODS: Sixteen patients with refractory GERC were given an 8-wk course of baclofen 20 mg three times a day as an add-on therapy to omeprazole. Changes in the cough symptom score, cough threshold to capsaicin, reflux symptom score and possible adverse effects were determined after treatment. The variables of multi-channel intraluminal impedance combined with pH monitoring were compared between responders and non-responders to baclofen.

RESULTS: Twelve of 16 patients completed treatment. Cough disappeared or improved in 56.3% (9/16) of patients, including 6 patients with acid reflux-induced cough (66.7%) and 3 patients with non-acid reflux-induced cough (33.3%). With baclofen treatment, the cough symptom score began to decrease at week 2, was clearly decreased at week 6 and reached a minimum at week 8. At the end of therapy, the lowest concentration of capsaicin required for induction of $\geqslant$ 2 and $\geqslant$ 5 coughs increased from 0.98 (1.46) to 1.95 (6.82) μmol/L (Z = -2.281, P = 0.024) and from 1.95 (7.31) to 7.8 (13.65) μmol/L (Z = -2.433, P = 0.014), respectively, and the reflux symptom score decreased from 8.0 ± 1.6 to 6.8 ± 0.8 (t = 2.454, P = 0.023). The number of acid reflux episodes was significantly lower in responders than in non-responders. The main adverse effects were somnolence, dizziness and fatigue.

CONCLUSION: Baclofen is a useful, but suboptimal treatment option for refractory GERC.

Key words: Baclofen; Cough; Esophageal pH monitoring; Gastroesophageal reflux; Proton pump inhibitors

Core tip: This study evaluated the efficacy and safety of baclofen in a cohort of patients with refractory gastroesophageal reflux-induced chronic cough (GERC) unresponsive to 8 wk of standard anti-reflux therapy consisting of omeprazole twice daily and domperidone. Baclofen is found to be a useful, but suboptimal treatment option for refractory GERC.

INTRODUCTION

Gastroesophageal reflux-induced chronic cough (GERC) is a clinical syndrome manifested predominantly by chronic cough caused by the backflow of gastric acid or other gastric contents into the esophagus[1]. Acid suppression by proton pump inhibitors alone or in combination with prokinetic agents is currently considered as the standard therapy for GERC, and can improve or eradicate reflux-related cough in the majority of patients, even though there is controversy on the therapeutic effects of these agents[2,3]. Unfortunately, some patients do not respond to standard therapy. Refractory GERC can be defined as cough due to reflux which does not respond to 8 wk of standard anti-reflux treatment with proton pump inhibitors alone twice daily before meals or in combination with prokinetic agents[4]. The management of refractory GERC remains a challenge.

Although anti-reflux surgery such as fundoplication may be an option and benefit some patients in this situation, its role has not been clearly defined and its application is restricted[5]. At present, intensified medical therapy is still the major treatment for refractory GERC. Baclofen, an inhibitor of transient lower esophageal sphincter relaxations (TLESRs)[6], can inhibit both acid and non-acid reflux and is now used in the treatment of refractory gastroesophageal reflux disease[7]. We previously showed in a case report that baclofen was helpful in resolving cough in patients with GERC resistant to standard anti-reflux medical therapy[4]. However, more clinical data are needed for the accurate assessment of its therapeutic efficacy.

Therefore, a prospective and open interventional clinical investigation was performed to evaluate the efficacy and safety of baclofen in a cohort of patients with refractory GERC.

MATERIALS AND METHODS

Patients

Sixteen patients with suspected refractory GERC were recruited from our respiratory clinic between October 2010 and November 2011, including 3 patients reported previously[4]. Their clinical characteristics are shown in Table 1. The inclusion criteria were as follows: (1) chronic cough with or without typical upper gastrointestinal symptoms such as regurgitation, heartburn and chest pain; (2) multichannel intraluminal impedance combined with pH monitoring (MII-pH) confirmed abnormal acid or non-acid reflux, as shown by a DeMeester score of ⩾ 14.72 and/or syndrome association probability (SAP) for acid or non-acid reflux of ⩾ 95%[8]; (3) cough fails to improve with 2 mo of standard anti-reflux treatment consisting of omeprazole 20 mg twice daily plus domperidone 10 mg three times a day; and (4) other causes of chronic cough such as upper airway cough syndrome, cough variant asthma and eosinophilic bronchitis were excluded.

This study was approved by the Ethics Committee of Tongji Hospital and was registered with the Chinese Clinical Trials Register (http://medresman.org) number ChiCTR-ONC-13003123. All patients gave informed consent before entering the study.

Table 1 Demographic characteristics of 16 patients with refractory gastroesophageal reflux-induced cough

Variables	Value
Sex (male/female)	9/7
Age (yr)	47.8 ± 11.6
Cough duration (mo)	36.0 (27.7)
FEV1 (% predictive value)	93.3 ± 8.3
FVC (% predictive value)	98.1 ± 11.1
FEV1/FVC (%)	80.3 ± 6.1
Cough symptom score	
Daytime	3 (0)
Nighttime	1 (1)
DeMeester score	33.1 ± 10.7
SAP (%)	
SAP for acid reflux	73.1 (28.2)
SAP for non-acid reflux	71.2 (37.6)

Data on cough duration, cough symptom score and SAP are presented as median (25%-75% interquartile) or mean ± SD. FEV1: Forced expiratory volume in one second; FVC: Forced vital capacity; SAP: Symptom association probability.

Cough severity was rated using the cough symptom score described by Hsu *et al*[9]. Cough sensitivity to inhaled capsaicin was determined according to a previously described method[10]. Cough threshold was defined as the lowest concentration of capsaicin required for the induction of ⩾ 2 (C2) and ⩾ 5 coughs (C5). Reflux-related symptoms were scored by a Chinese version of the gastroesophageal reflux diagnostic questionnaire (GerdQ) provided by the designer[11].

MII-pH was performed to evaluate the probability of GERC prior to the commencement of standard anti-reflux treatment as previously described by us[12]. Briefly, a 2.1-mm diameter combined MII-pH catheter with a six impedance channel sensor (K6011-E10632, MMS, Switzerland) and an antimony pH electrode (819100, MMS, The Netherlands) was inserted transnasally into the patient's esophagus, with the impedance channel sensor located at 3, 5, 7, 9, 15 and 17 cm above the manometrically located proximal border of the lower esophageal sphincter, and the pH electrode positioned at 5 cm above the proximal border of the lower esophageal sphincter. The catheter was connected to a portable data logger (Ohmega, MMS, The Netherlands) which recorded data from all seven channels (six impedance and one pH) with a frequency of 50 Hz over 24 h. Using appropriate software (Database soft, 8.7 version, Medical Measurement System BV, The Netherlands), the data were manually analyzed for reflux episodes, and classified as liquid, gas and mixed reflux on the basis of impedance values, or categorized as acidic (pH < 4.0), weakly acidic (pH 4.0-7.0) or weakly alkaline reflux (pH > 7.0). Combined with diary cards, SAP for acid or non-acid reflux was calculated respectively[13]. The DeMeester score was automatically calculated as described previously[14]. Furthermore, the number of reflux episodes, proximal reflux episodes, time of bolus exposure, time of bolus clearance and time

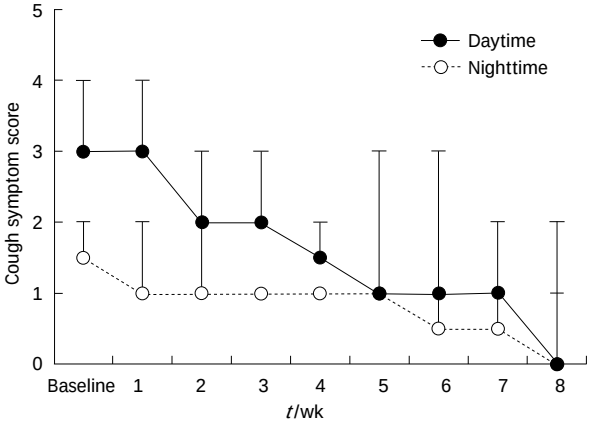

Figure 1 Changes in cough symptom score against the duration of treatment with baclofen. The data are presented as median (25%-75% interquartile).

of acid clearance were analyzed.

Procedures

Initial assessments included the collection of patients' general information and recording of the cough symptom score, reflux symptom score, cough sensitivity to capsaicin and study of MII-pH. The 16 patients with GERC resistant to standard anti-reflux treatment were then given an 8-wk course of baclofen 20 mg three times a day as an add-on therapy to omeprazole 20 mg twice a day, but discontinued domperidone. The patients received weekly follow-up. Responses to therapy, the cough symptom score and possible side effects were evaluated at each follow-up. When treatment was complete, reflux symptom score and cough sensitivity to capsaicin were repeated once more. Cough was considered controlled when it disappeared completely, improved when the cough symptom score decreased by one or more, and failed when the cough worsened or was not alleviated to a noticeable degree[15,16]. The patients who responded favorably to baclofen continued on this therapy for 1 mo and then the dose of baclofen was decreased by 10 mg every month with the lowest maintenance dose of 20 mg daily, while patients who did not improve with baclofen moved to the intensified acid suppression trials and given double dose of omeprazole (40 mg twice a day) for 4 wk and double dose of omeprazole combined with ranitidine 150 mg twice a day for 4 wk in a sequential manner. Refractory GERC was determined if the cough was controlled or improved by treatment with either baclofen, double dose of omeprazole or the combination of ranitidine with double dose of omeprazole.

Statistical analysis

Data with normal distribution were expressed as mean ± SD, or as median (25%-75% interquartile) if the distribution was skewed. A comparison of pre- and post-treatment was made using paired *t* tests for the data with normal distribution or with the Mann-Whitney *U* test for the data with skewed distribution. Software (SPSS version 17.0, Chicago, IL, United States) was used for statistical calculation. A *P* value of < 0.05 was considered significant.

RESULTS

Treatment efficacy

Of 16 patients, 4 withdrew from therapy due to intolerable and persistent nausea and diarrhea following the initiation of baclofen for a week ($n = 1$) and deterioration or no improvement in cough in the third week ($n = 3$). Among 12 patients who completed the treatment course of baclofen, cough was controlled in 7 patients (58.3%), improved in 2 patients (15.7%) and failed to improve in 3 patients (25.0%). The overall therapeutic efficacy of baclofen was 56.3% (9/16). Cough in patients responsive to baclofen was considered to be due to acid reflux in 6 (66.7%) and due to non-acid reflux in 3 (33.3%). In the remaining 7 patients who withdrew baclofen therapy ($n = 4$) or were resistant to treatment ($n = 3$), cough was resolved by subsequent therapies of double dose of omeprazole in 5 patients and double dose of omeprazole combined with ranitidine in 2 patients.

Changes in cough symptom score, cough threshold and reflux symptom score

With baclofen treatment, the cough symptom score was reduced at week 2, obviously decreased at week 6 and reached a minimum at week 8 (Figure 1). With the exception of 3 non-responders, baclofen treatment resulted in an increase in cough threshold to capsaicin in 9 patients. Cough threshold C2 increased from 0.98 (1.46) to 1.95 (6.82) μmol/L and C5 increased from 1.95 (7.31) to 7.8 (13.65) μmol/L (Figure 2). In contrast, the reflux symptom score reduced from 8.0 ± 1.6 to 6.8 ± 0.8 at the end of therapy (Figure 3).

Comparison of variables in MII-pH between responders and non-responders to baclofen

Most MII-pH variables were comparable between the responders and non-responders to baclofen treatment (Table 2). However, the number of acid reflux episodes was lower in the responders than in the non-responders ($Z = -2.277$, $P = 0.023$).

Adverse effects

The main adverse effects of baclofen were somnolence, dizziness and fatigue (Table 3). These adverse effects were usually tolerable and waned within 1-3 wk despite persistent somnolence and fatigue in 2 (12.5%) patients throughout the entire duration of treatment.

DISCUSSION

To date, the definition of refractory GERC remains to be elucidated. According to a widely accepted definition for refractory gastroesophageal disease, cough due to reflux can be considered refractory when the patient does not respond to 4-8 wk of treatment with proton pump inhibitors twice daily[17,18]. However, attention should be paid

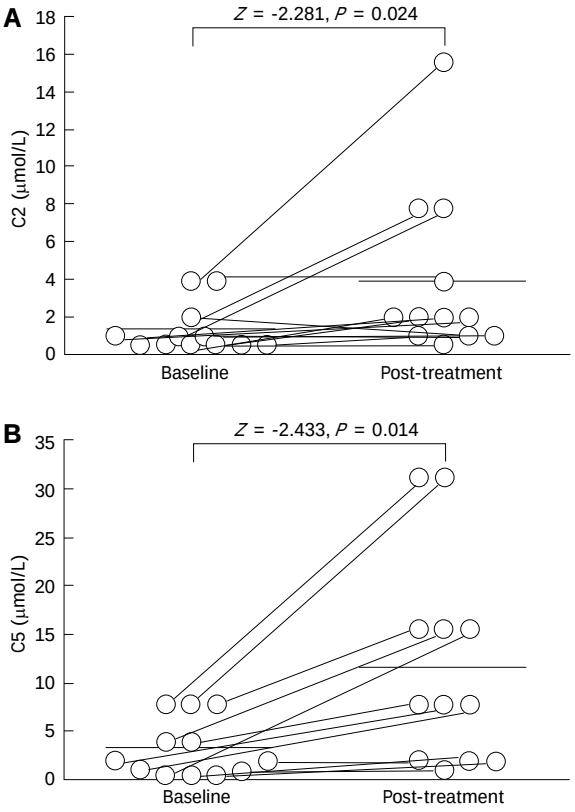

Figure 2 Changes in cough threshold to inhaled capsaicin after treatment with baclofen.

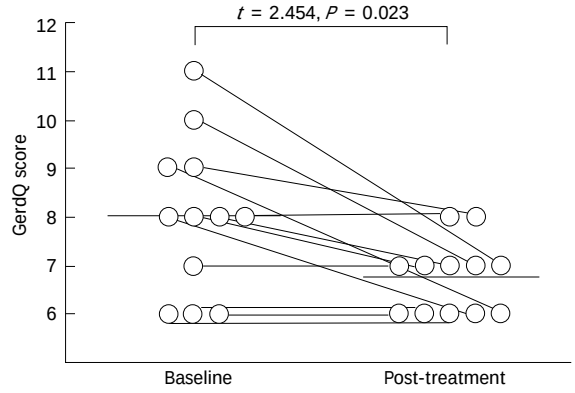

Figure 3 Changes in gastroesophageal reflux diagnostic questionnaire score after treatment with baclofen. GerdQ: Gastroesophageal reflux diagnostic questionnaire.

to the limitations of the diagnostic standard for refractory gastroesophageal reflux disease. Unlike regurgitation and heartburn, cough is an atypical symptom of gastroesophageal reflux disease and can be caused by a number of diseases other than GERC. A temporal cause-effect relationship between reflux and cough established by MII-pH, as indicated by the positive SAP, does not mean that reflux is the true cause of cough and must be verified by specific anti-reflux therapy[1,19]. In our cohort of patients, cough did not improve with a standard course of acid suppression therapy, but resolved after adjustment of the anti-reflux regimen. Therefore, the diagnosis

Table 2 Comparison of variables in multi-channel intraluminal impedance combined with pH monitoring between patients responsive and unresponsive to baclofen

Variables	Responsive (n = 9)	Unresponsive (n = 7)
DeMeester score	17.9 ± 5.1	45.0 ± 18.0
SAP (%)		
SAP for acid reflux	70.0 (28.2)	75.3 (56.0)
SAP for non-acid reflux	87.9 (35.0)	61.6 (59.1)
Acid reflux (n)	26.0 (31.1)	65.0 (51.0)[a]
Weakly acidic reflux (n)	22.8 (28.7)	22.0 (28.0)
Weakly alkaline reflux (n)	4.0 (22.0)	2.3 (21.7)
Gas reflux (n)	12.0 (51.0)	13.9 (10.0)
Liquid reflux (n)	26.0 (11.0)	24.0 (18.6)
Mixed reflux (n)	45.0 (43.0)	30.4 (33.7)
Proximal extent (n)	13.8 (12.6)	10.5 (11.5)
Bolus exposure (%)	1.1 (1.6)	1.3 (1.2)
Bolus clearance (s)	9.3 (9.1)	8.9 (6.2)

Except for the DeMeester score, the data are presented as median (25%-75% interquartile). [a]$P < 0.05$ *vs* responsive patients. SAP: Symptom association probability.

Table 3 Adverse effects in 16 patients during treatment with baclofen n (%)

Adverse effects	Frequency
Somnolence	5 (31.25)
Dizziness	2 (12.50)
Fatigue	3 (18.75)
Nausea	1 (6.25)
Diarrhea	1 (6.25)

of refractory GERC in these patients was confirmed.

TLESRs refer to periods of spontaneous (not preceded by a swallow) relaxation of the lower esophageal sphincter lasting 10-60 s[20]. TLESRs play a physiological role in venting air from the stomach, but are also the main mechanism for gastroesophageal reflux[21]. In patients with gastroesophageal reflux disease, TLESRs are usually more frequent and are twice as likely to be associated with a reflux event[22]. Proton pump inhibitors can increase the pH value and reduce the volume of the refluxate, and even decrease reflux episodes in combination with prokinetic agents, and thus improve or resolve the symptom in patients with GERC[23]. However, they essentially have no ability to rectify dysfunction in the lower esophageal sphincter and eliminate reflux episodes. In addition, proton pump inhibitors are often ineffective for non-acid (weakly acid or weakly alkaline) reflux[8]. This might explain why patients with GERC failed to respond to initial standard anti-reflux therapy. In this case, inhibitors of TLESRs may help to control the cough. Inhibitors of TLESRs previously under development include gamma-aminobutyric acid B receptor agonists, metabotropic glutamate receptor 5 antagonists and cannabinoid receptors agonists[21]. Inhibitors of TLESRs have primarily been utilized as an add-on treatment for patients with gastroesophageal reflux disease who failed proton pump inhibitors[7,18].

Baclofen is a selective agonist of the gamma-aminobutyric acid B receptor and can inhibit TLESRs by modification of the vagal reflex pathway[24]. There are several lines of evidence to show that baclofen can reduce the frequency of TLESRs, decrease reflux episodes[6,25,26], and reduce acid reflux-related symptoms by 72% and non-acid reflux-related symptoms by 21%[27]. Moreover, baclofen has direct antitussive activity and has been used for the treatment of refractory chronic cough of unknown cause[28,29]. Our results showed that baclofen, as an add-on therapy, reduced cough severity and cough sensitivity to capsaicin in 56.3% of patients with refractory chronic cough due to acid as well as non-acid reflux, which partially confirms our previous observations in a case report[4].

Our results also revealed that the therapeutic efficacy of baclofen was suboptimal, as more than 40% patients with refractory chronic cough due to acid reflux were resistant to baclofen, as characterized by significantly more acid reflux episodes in non-responders than in responders, and further augmented acid suppression eliminated the cough in patients who failed baclofen. This may be explained by the incomplete inhibition of TLESRs by baclofen. There is evidence that baclofen at the dose currently used only reduced the frequency of TLESRs by 40%-60% and decreased the reflux episodes by 43%[6,25,26]. Although studies in dogs have shown that baclofen can abolish TLESRs at higher doses[30], such high doses cannot be administered to humans due to side-effects. In addition, reflux may be secondary to the reduced pressure difference between the stomach and esophagus due to the lower baseline pressure of the lower esophageal sphincter, and may be unrelated to TLESRs[31]. Baclofen and the GABAB agonist lesogaberan have consistently been demonstrated to increase basal pressure of the lower esophageal sphincter in humans[32], which may contribute to the reduction in reflux episodes, but not the absence of reflux episodes. Residual reflux can continue to stimulate sensors with increased sensitivity located at the mucosa in the distal esophagus and cause cough through esophageal-tracheobronchial reflexes[33].

The main side-effects of baclofen emanating from the central nervous system limited its value in the treatment of refractory GERC[34]. Other adverse effects include dry mouth, nausea, vomiting, diarrhea and constipation. Our findings showed that drug-related somnolence, fatigue and dizziness, although common, waned within 3 wk and did not influence treatment in most patients. Considering that the dose of baclofen is gradually increased for the treatment of spasticity in clinical practice, perhaps a similar increase in the dose of baclofen from 5 to 20 mg may help improve tolerance in patients and reduce severe adverse effects[21].

There are several limitations in the present study. First, only a small number of patients with refractory GERC were recruited, and this may have limited the strength of the study. A recent multi-center survey showed that GERC is relatively rare in China[35], and patients with refractory GERC account for a small number. Therefore, it is difficult to enroll a large number of patients. Second, we were unable to directly evaluate the inhibitory efficacy of baclofen on acid or non-acid reflux as the patients refused to undergo a repeat invasive MII-pH study at the end of the treatment period. Moreover, it is difficult to exclude the contribution of the nonspecific non-reflux-related antitussive activity of baclofen. Nevertheless, the obvious parallel reduction in GerdQ suggests that the improvement in cough, at least in part, can be attributed to the blockade of abnormal reflux. Finally, the broad utility of baclofen in clinical practice can be criticized as it only resolves the cough in partial patients with refractory GERC. Nevertheless, considering the negative impact of chronic cough on patient's quality of life[36] and the difficulty in the management of refractory GERC, we believe that baclofen has its position in the treatment of refractory GERC, even though its effectiveness is limited.

In conclusion, baclofen may be useful for the treatment of refractory GERC. When a standard therapy for GERC fails, baclofen can at least be considered as a treatment option, even though its therapeutic efficacy is suboptimal.

COMMENTS

Background

Gastroesophageal reflux-induced chronic cough (GERC) is a special form of gastroesophageal reflux disease with a predominant chronic cough. Refractory GERC resistant to proton pump inhibitors alone twice daily or in combination with prokinetic agents is difficult to treat as there is currently no satisfactory therapy available.

Research frontiers

Baclofen, a selective agonist of the gamma-aminobutyric acid B receptor, can inhibit both acid and non-acid reflux by reducing the frequency of transient lower esophageal sphincter relaxations and is now used in the treatment of refractory gastroesophageal reflux disease. The authors previously showed in a case report that baclofen successfully resolved the cough in three patients with GERC as an add-on therapy to omeprazole. However, more clinical data are needed to assess its therapeutic efficacy.

Innovations and breakthroughs

In this prospective study involving 16 patients, the authors demonstrated that baclofen, as an add-on therapy to omeprazole, can eliminate or improve cough in 56.3% of patients with refractory GERC, and modify cough hypersensitivity to capsaicin. However, the study also revealed that the therapeutic efficacy of baclofen is suboptimal for the treatment of refractory GERC.

Applications

The study results suggest that baclofen may be considered as an option for the treatment of refractory GERC.

Terminology

Refractory GERC: Refractory GERC is defined as cough caused by reflux which persists despite 8 wk of standard anti-reflux treatment with the combination of proton pump inhibitors twice daily before meals with prokinetic agents.

Peer review

It is an interesting study and will add new information to the treatment of refractory cough due to reflux.

Abstract

AIM: To investigate the prevalence and risk factors of polypoid lesions of the gallbladder (PLGs) in petrochemical employees in Ningbo, Zhejiang Province, China.

METHODS: All active and retired employees aged 20-90 years (n = 11098) of a refinery and chemical plant in eastern China were requested to participate in a health survey. The participants were subjected to interview, physical examination, laboratory assessments and ultrasonography. All the participants were invited to have a physical examination after a face-to-face interview. Fasting blood samples were obtained from the antecubital vein, and the samples were used for the analysis of biochemical values. Abdominal ultrasonography was conducted.

RESULTS: A total of 10461 (7331 men and 3130 women) current and former petrochemical employees attended for screening. The overall prevalence of post-cholecystectomy, gallstones and PLGs was 0.9%, 5.2% and 7.4%, respectively. Compared with the increased prevalence of either gallstones or post-cholecystectomy in older persons, PLGs were more common in the middle-aged, peaking in those aged 40-59 years. Excluding the patients with gallstones, gallstones mixed with PLGs, or those who had undergone cholecystectomy, in the remaining 9828 participants, the prevalence of PLGs in men (8.9%) was significantly higher than that in women (5.5%, $P < 0.001$). The analyzed risk factors with increased OR for the development of PLGs were male gender (OR = 1.799, $P < 0.001$), age $\geqslant$ 30 years (OR = 2.699, $P < 0.001$) and hepatitis B surface antigen (HBsAg) positivity (OR = 1.374, $P = 0.006$).

CONCLUSION: PLGs are not rare among Chinese petrochemical employees. Male gender, HBsAg positivity, and middle age are risk factors for developing PLGs.

Key words: Prevalence; Risk factors; Polypoid lesions; Gallbladder; Chinese

Core tip: Polypoid lesions of the gallbladder (PLGs) are commonly encountered in clinical practice. This study investigated the prevalence and risk factors of PLGs in a cohort of petrochemical employees in the city of Ningbo, Zhejiang Province, China. It was demonstrated that 7.4% of the petrol-chemical employees studied had PLGs; and male, hepatitis B surface antigen positive and middle-aged employees, especially those aged

between 30 and 59 years, had higher risks for developing PLGs.

INTRODUCTION

The widespread application and improved image quality of abdominal ultrasonography in modern clinical practice have led to an increase in the detection of abnormalities of the biliary tree, including polypoid lesions of the gallbladder (PLGs)[1,2]. The significance of PLGs is still poorly understood. In general, PLGs represent a heterogeneous group of changes in the gallbladder wall and include entities such as cholesterol polyps, inflammatory polyps, adenomas, leiomyomas and lipomas[3]. As a result, clinicians are ever more frequently confronted with the question of how to proceed in cases of incidentally discovered PLGs[3]; and patients with PLGs usually require repeated ultrasonography and follow-up[4], enduring a certain degree of anxiety.

The prevalence of PLGs is reported in the range 0.3%-9.5%, depending on the population studied and on the study design. Prevalence in Western studies falls in the range 1.0%-6.1%[5,6], which is lower than that reported in Southeast Asian populations, mainly in Japan, South Korea and Taiwan[7-10]. To date, only a few studies have investigated the prevalence of and risk factors for PLGs in the mainland of China. Yang *et al*[11] have reported that the prevalence of PLGs in Shanghai was 4.2%. Xu *et al*[12] have reported that the prevalence in Beijing was 6.9%. However, these two studies were retrospective analyses. To understand better the prevalence of and risk factors for PLGs in Chinese petrochemical employees in Zhejiang Province, a prospectively observational study of 10461 stable participants was conducted in 2009, which is expected to provide a comprehensive update to the results of the previous studies. This cohort of employees will be followed up in the next 5 years. All participants will be invited for annual reassessment, including similar questions, laboratory measurement, ultrasonography, and collection of biological material at baseline. In addition, the progression of PLGs will be observed prospectively.

MATERIALS AND METHODS

Study population

The study of PLGs was carried out as part of the petrochemical employees annual health check-up survey[13]. In 2009, a descriptive cross-sectional study was performed in a stable population of all employees of a refinery and chemical plant in the city of Ningbo, Zhejiang Province, in the eastern region of China. Chinese law requires state-owned companies to provide annual health check-ups for all employees. The study population included all regular employees with at least 1 mo service at the Zhenhai Refinery and Chemical Plant of the SINO-Petrol Chemical Company, in northeastern Ningbo between January 1 and December 31, 2009.

Invitation to participate was by letter and non-responders received one reminder. A research nurse interviewed subjects at Zhenhai Lianhua Hospital, the former Workers Hospital of the Zhenhai Refinery and Chemical Plant.

The present study was conducted in accordance with the Declaration of Helsinki, as amended in Scotland (2000). The protocol and statement of informed consent were approved by the Ethics Committee of Zhenhai Lianhua Hospital, Ningbo. Written informed consent was obtained from each participant.

Interview and physical examination

An appointment was made for each participant at the check-up center of Zhenhai Lianhua Hospital, where a face-to-face interview was conducted by a trained nurse to complete a two-page self-assessment questionnaire that included a gallbladder-related question: "Have you ever had gallbladder surgery?"

All individuals were invited to have a physical examination after the face-to-face interview. They were required to fast overnight. Body measurements were performed by a trained medical professional using a standardized protocol. Body weight and standing height were measured in light indoor clothing without shoes. Weight was measured to the nearest 0.1 kg using a calibrated hospital spring scale. Height and waist circumference (WC) were measured in centimeters. WC was measured between the lowest rib and the iliac crest, horizontally through the narrowest part of the torso. Body mass index (BMI) was then calculated as weight in kilograms divided by height in meters squared. Individuals were grouped into two categories based on BMI (< 25 and $\geqslant 25$ kg/m^2) and WC (< 90 and $\geqslant 90$ cm for men, and < 80 and $\geqslant 80$ cm for women)[14]. Blood pressure was measured using an automated sphygmomanometer with the subject in a sitting position. Systolic blood pressure and diastolic blood pressure were measured at the first and fifth Korotkoff phases, respectively.

Laboratory tests

Fasting blood samples were obtained from an antecubital vein, and the samples were used for the analysis of biochemical values. The values included triglyceride, total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol, uric acid, and fasting plasma glucose (FPG). All values were measured by an Olympus AU640 auto-analyzer (Olympus, Kobe, Japan) using standard methods. Hepatitis B surface antigen (HBsAg) was detected with a second-generation enzyme-linked immu-

Table 1 Population characteristics (n = 10461) n (%)

nosorbent assay (VITROS ECi Immunodiagnostic System; Ortho Clinical Diagnostics, Inc., Johnson and Johnson, Raritan, NJ, United States). The reagents used were offered by the same company. The tests were undertaken strictly according to the instructions of the manufacturers.

Ultrasonography

All participants were asked to come to a morning examination after an overnight fast of ⩾ 8 h. Abdominal ultrasonography was conducted using a scanner equipped with a 2.0-5.0-MHz transducer (Voluson 730, GE Healthcare, Pittsburgh, PA, United States). The ultrasongraphers were unaware of the participants' clinical and laboratory characteristics. Gallstones were present if the gallbladder contained echoes that moved with gravity, except when the stones were large, a septum existed in the gallbladder, or there was an enclosed infundibulum. PLGs were diagnosed as immobile echoes protruding from inside the gallbladder wall into the lumen. The ultrasonic characteristics of PLGs included hyperechoic structures without acoustic shadow, unequivocal visualization in two planes (longitudinal and in cross-section), no change in position of the wall change secondary to change in subjects' position. In patients with multiple polyps, the size of the largest polyp was measured. Subjects with both gallstones and PLGs were classified into the gallstones group.

Statistical analysis

Data on quantitative characteristics were expressed as mean ± SD. Data on qualitative characteristics were expressed as percentage values or absolute numbers as indicated. The data analysis was performed with SPSS (version 11.5, SPSS Software, Chicago, IL, United States). For continuous variables, non-parametric tests (two-tailed Mann-Whitney U test) were used. Group differences between the numbers of subjects were analyzed using χ^2 test (normal data) and analysis of variance (continuous data). A multiple stepwise regression analysis (backward: Wald; cutoff for entry: 0.05, for removal: 0.10) was performed in order to evaluate independent relationships between sex, age and PLG. $P < 0.05$ was considered statistically significant.

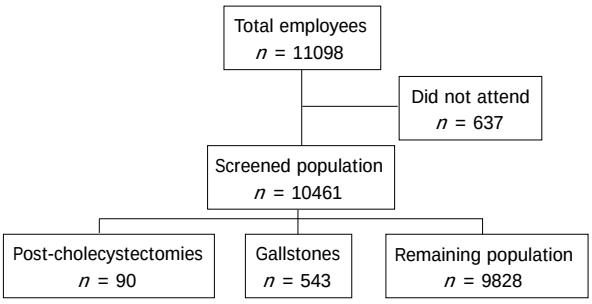

Figure 1 Recruitment flow chart.

RESULTS

Population studied

All of the 11098 active and retired employees were invited to participate in the study. There were 7760 (69.9%) men and 3338 (30.1%) women. We excluded 637 subjects for not attending the health check program. In all, 7331 (94.5%) of the invited men and 3130 (93.8%) of the women participated in the study. Figure 1 displays the recruitment flow chart. Demographic data on the 10461 attending individuals are shown in Table 1.

Prevalence of post-cholecystectomy, gallstones and PLGs

There were 90 (0.9%) patients who had undergone cholecystectomy. The overall prevalence of PLGs was 7.4% (777/10461), which was higher than that for gallstones, which was 5.2% (543/10461, $P < 0.001$). Nineteen subjects with both gallstone and PLG were classified into the group of gallstones. The prevalence was further stratified by age among post-cholecystectomy, gallstones and PLGs (Figure 2A). Compared with the increased prevalence of either gallstones or post-cholecystectomy in older persons, the PLGs were more common in the middle-aged, peaking in those aged 40-59 years. The difference between men and women was stratified with age (Table 2). The prevalence of gallstones and post-cholecystectomy in men was lower than that in women in all age groups. In contrast, the prevalence of PLGs in men was higher than that in women in all age groups. Overall, men had a significantly higher prevalence of PLGs compared to women (8.5% *vs* 5.0%, $P < 0.001$). In patients with PLGs, the proportion of large polypoid lesions (⩾ 10 mm) was small (14/777, 1.8%; 11 male, 3 female). This equated to a general population prevalence of larger PLGs of 0.1%. None of these 14 patients underwent cholecystectomy.

Characteristics of subjects according to PLG status

After excluding 543 patients with gallstones and 90 who underwent cholecystectomy, the remaining 9828 participants (93.9% of the total attending population) were further analyzed. Characteristics were compared between the group with PLGs and a control group. Controls were confirmed not to have gallstones, post-cholecystectomy or PLGs in our screening program. The control group consisted of 9051 subjects, including 6332 men and 2719

Data are expressed as absolute numbers (percentage) or mean ± SD. HBsAg: Hepatitis B surface antigen; LDL: Low-density lipoprotein; HDL: High-density lipoprotein; PLG: Polypoid lesions of the gallbladders.

women (Table 3). Of the remaining 9828 subjects, the overall prevalence of PLGs was 7.9% (777/9828); 8.9% (620/6952) in men and 5.5% (157/2876) in women.

The differences in the prevalence of PLGs in the remaining population between men and women were investigated for every age decade (Figure 2B). The prevalence of PLGs in men was significantly higher in women ($P < 0.001$). In men, the prevalence was highest among those in their 40s (10.5%), followed by those in their 50s (10.1%), 30s (9.2%), 60s (6.9%), 70s or above (4.9%), and 20s (4.0%). In women, the prevalence was highest among those in their 50s (7.5%), followed by those in their 40s (5.8%), 60s (4.7%), 30s (4.4%), 70s or above (4.3%), and 20s (0.9%). In men, the overall difference in the age-dependent change in prevalence was found to be statistically significant ($\chi^2 = 31.994$, $P < 0.001$). In women, the overall difference in the age-dependent change in prevalence was also significant ($\chi^2 = 13.074$, $P = 0.023$). The highest prevalence (10.5%) of PLGs was found in male participants aged 40-49 years.

Logistic regression analysis of relevant risk factors for PLGs

The factors significantly associated with PLGs were male sex ($P < 0.001$), age ⩾ 30 years ($P < 0.001$), HBsAg positivity ($P = 0.005$) and cigarette smoking ($P = 0.002$) (Table 3). In order to identify the risk factors, we performed multivariate logistic regression analysis (backward stepping) (Table 4.) There was no significant difference between the PLG-positive and -negative groups for cigarette smoking (OR = 1.020, 95%CI: 0.854-1.220, $P = 0.823$). Male gender (OR = 1.799, 95%CI: 1.472-2.199, $P < 0.001$), age ⩾ 30 years (OR = 2.699, 95%CI:

Table 4 Multivariate logistic regression analysis for polypoid lesions of the gallbladders

Variables	*B*[1]	OR	95%CI	*P* value
Sex (male)	0.587	1.799	1.472-2.199	< 0.001
Age (yr)				
≥ 30	0.993	2.699	1.762-4.133	< 0.001
30-59	1.078	2.938	1.914-4.511	< 0.001
≥ 60	0.697	2.009	1.243-3.245	0.004
HBsAg (+)	0.318	1.374	1.097-1.721	0.006

[1]Regression coefficient. The dependent variable was the presence or absence of polypoid lesions of the gallbladders. The covariates include sex, age ≥ 30 years (divided into age 30-59 years and ≥ 60 years), body mass index ≥ 25.0 kg/m^2, systolic blood pressure ≥ 130 mmHg, diastolic blood pressure ≥ 85 mmHg, fasting blood glucose ≥ 5.6 mmol/L, triglyceride level ≥ 1.7 mmol/L, high-density lipoprotein cholesterol level ≥ 1.03 mmol/L in men or ≥ 1.29 mmol/L in women, and waist circumference ≥ 90 cm in men or ≥ 80 cm in women. HBsAg: Hepatitis B surface antigen.

1.762-4.133, $P < 0.001$) and HBsAg positivity (OR = 1.374, 95%CI: 1.097-1.721, $P = 0.006$) were still positively correlated with PLGs. However, the risk of PLGs was 2.938 times higher in middle-aged (30-59 years) subjects than in young persons, and old (≥ 60 years) people had a 2.009 times higher risk of PLGs than young people.

DISCUSSION

This large population-based survey of current and former petrochemical employees provides a unique opportunity to study the prevalence of gallbladder polyps and the distribution by age and sex in the eastern coastal region of China.

In this stable population, nearly 14% of men and 13% of women aged 20-90 years had gallbladder disorders, including post-cholecystectomy, gallstones and PLGs. Cholecystectomy had been performed in 0.5% of men and 1.7% of women. Gallstones were diagnosed in 4.7% of men and 6.4% of women. PLGs were diagnosed in 8.5% of men and 5.0% of women.

The prevalence of post-cholecystectomy (0.9%) was so low that only 90 participants underwent cholecystectomy. The prevalence of gallstones in this study (5.2%) is similar to that in previous sonographic screening studies conducted in Japan, Taiwan and Korea, where gallstones were identified in 3.6%-11.0% of the population[15-17]. The current study demonstrated a higher prevalence of gallstones in women than in men in all age groups and showed that prevalence increased with age, which is in agreement with previous studies[10].

The prevalence of PLGs was higher than that of gallstones in participants aged < 60 years, and lower than that of gallstones in participants aged ≥ 60 years in this study. These findings are comparable with other studies that have indicated that PLGs were prevalent in middle-aged patients, whereas prevalence of gallstones and cholecystectomy increased with age[18,19]. The true reason for diminishing the prevalence of PLGs with age cannot be clarified in our study. The reported risks for gallstones, such as age, large body size[20,21] and metabolic disorders[22] were not risk factors for development of PLGs in the present study. This difference in risk factors may have been due to the different pathogenesis of these common gallbladder diseases.

PLGs are not rare in Taiwan or in the mainland of China[10-12]. The present study indicated that petrochemical employees in Ningbo had a similar prevalence (7.4%) of PLGs, although a little lower than that in Taiwan (9.5%)[10], but higher than that in Shanghai (4.2%)[11] and Beijing (6.9%)[12]. After excluding 633 patients with gallstones or those who underwent cholecystectomy, in the remaining 9828 participants, the overall prevalence of PLGs was 7.9%; 8.9% in men and 5.5% in women, which was higher than that in Denmark (4.3%)[5], Japan (5.2% and 5.6%)[7,8] and Germany (6.1%)[23]. These differences in the prevalence of PLGs among the Chinese, Japanese, Danish and German people deserve further consideration.

The present study demonstrated that men had a higher prevalence of PLGs than women at all ages. The prevalence of PLGs was highest in middle-aged men in their 40s and 50s. In women, the prevalence of PLGs was highest in those in their 50s. These results were in accordance with a Japanese study[7]. In contrast, the prevalence of post-cholecystectomy or gallstones was higher in women than in men at all ages. However, this study did not identify the mechanisms mediating this sex-related risk.

Hepatitis B virus infection is endemic in China and the HBsAg-positive rate in the general population is approximately 10.0%[24]. The current study found that compared with the PLG-negative group, the PLG-positive group had a significantly higher incidence of HBsAg positivity. Logistic regression analysis showed that HBsAg positivity is a risk factor for PLGs. These results are in agreement with those of some previous studies in the Chinese population[10-12,25], but contrary to others[17,26]. The inconsistent findings may be related to the number of cases, sex ratio, ethnic difference and other factors. The pathophysiology of the association between PLGs and HBsAg positivity deserves further study.

The associations between PLG and sex, age, BMI, WC, blood pressure, serum uric acid, serum lipid level, history of hypertension, history of diabetes, cigarette smoking, and alcohol consumption were all tested independently. Male sex, age ≥ 30 years and cigarette smoking were statistically significant for the PLG group using the χ^2 test. Other variables were not significant by univariate analysis. In the multivariate analysis, male sex and age ≥ 30 years were still positively correlated with PLGs. This agreed with previous studies in which male sex was a major risk factor for PLGs. However, cigarette smoking was no longer associated with PLGs, which was in contrast with some previous studies. Okamoto *et al*[27] have reported that cigarette smoking is inversely related to PLGs in Japanese men. Significant effects of other demographic variables such as BMI, blood pressure, alcohol consumption, and history of hypertension and diabetes on the prevalence of PLGs were not identified

in the present study. Similarly, there was no relationship between PLGs and biochemical parameters such as FPG, lipid profile and uric acid.

The present study had some strengths and limitations. First, the employees were a stable population. The demographic characteristics of this group may not be completely generalizable, for example, there were substantially more men than in the general population, but that may be more representative than many other studies in the literature. Second, pathological data were not available for 777 subjects with PLGs, although a proportion (14/777, 1.8%) of the large-sized polyps are likely to develop neoplasms[4,28]. In general, polypoid lesions > 10 mm are an important predictor for malignancy. For small PLGs < 10 mm, it has been shown that most of these lesions are benign and remain so for several years[29,30]. Nevertheless, it is not possible in a screening study to establish the histopathological nature of polypoid lesions. Therefore, a longitudinal study with the same cohort is now underway to observe the progression of PLGs, especially for the 14 cases of larger PLGs.

In conclusion, this study demonstrated that 7.4% of the petrochemical employees had PLGs. Male sex and HBsAg positivity were associated with prevalence of PLGs; and age ≥ 30 years, especially 30-59 years, was positively associated with PLGs. Further research on the prevalence of and risk factors for PLGs is therefore necessary in the general population in the mainland of China.

COMMENTS

Background

The widespread application and improved image quality of abdominal ultrasonography in modern clinical practice have led to an increase in the detection of biliary tree abnormalities, including polypoid lesions of the gallbladder (PLGs). The reported prevalence of PLGs is 0.3%-9.5%, depending on the population studied and on the study design. To date, only a few studies have investigated the prevalence and risk factors for PLGs in China. This study investigated the prevalence of and risk factors for PLGs in a cohort of petrochemical employees in the city of Ningbo, China.

Research frontiers

This large population-based survey provided a unique opportunity to study the prevalence of gallbladder polyps and the distribution by age and sex in the eastern coastal region of China. This study demonstrated that men had a higher prevalence of PLGs than women at all ages. The prevalence of PLGs was highest in middle-aged men in their 40s and 50s. The demographic characteristics of this group may not be completely generalizable, for example, there were substantially more men than in the general population, but that may be more representative than many other studies in the literature.

Innovations and breakthroughs

The prevalence and risk factors of gallbladder polyps from 10461 subjects in eastern China were investigated. The results suggest that these populations do not have a low prevalence of PLGs, and middle-aged men or both sexes positive for hepatitis B surface antigen (HBsAg) have a high risk. These results provide an important reference for the prevention and treatment of gallbladder polyps.

Applications

To understand better the prevalence of and risk factors for PLGs in petrochemical employees in Zhejiang Province, China, a prospective observational study of 10461 stable participants was conducted in 2009, which is expected to provide a comprehensive update to the results of previous studies. The results provide an important evidence for the prevention and treatment of gallbladder polyps.

Terminology

PLGs represent a heterogeneous group of changes in the gallbladder wall and include entities such as cholesterol polyps, inflammatory polyps, adenomas, leiomyomas and lipomas.

Peer review

In this paper, the prevalence and risk factors of gallbladder polyps from 10461 subjects in eastern China were investigated. The results suggest that these populations do not have a low prevalence of PLGs, and middle-aged men or people of both sexes positive for HBsAg have a high risk. These results provide an important reference for the prevention and treatment of gallbladder polyps. Nevertheless, further clarification or revision in some places of the paper are needed.

Abstract

AIM: Our study aimed to compare the results of liver transplantation (LT) and liver resection (LR) in patients with hepatocellular carcinoma (HCC) that met the Milan criteria after successful downstaging therapy.

METHODS: From February 2004 to August 2010, a consecutive series of 102 patients were diagnosed with advanced-stage HCC that met the modified UCSF down-staging protocol inclusion criteria. All of the patients accepted various down-staging therapies. The types and numbers of treatments were tailored to each patient according to the tumor characteristics, location, liver function and response. After various downstaging therapies, 66 patients had tumor characteristics that met the Milan criteria; 31 patients accepted LT in our center, and 35 patients accepted LR. The baseline characteristics, down-staging protocols, postoperative complications, overall survival and tumor free survival rate, and tumor recurrence rate were compared between the two groups. Kaplan-Meier analyses were used to estimate the long-term overall survival and tumor-free survival rate. Meanwhile, a Cox proportional hazards model was used for the multivariate analyses of overall survival and disease-free survival rate.

RESULTS: No significant difference was observed between the LT and LR groups with respect to the down-staging protocol, target tumor characteristics, and baseline patient characteristics. Fifteen patients suffered various complications after LT, and 8 patients had complications after LR. The overall complication rate for the LT group was 48.4%, which was significantly higher than the LR group (22.9%) (P = 0.031). The overall in-hospital mortality in hospital for the LT group was 12.9% *vs* 2.9% for the LR group (P = 0.172). The overall patient survival rates at 1-, 3- and 5-years were 87.1%, 80.6% and 77.4%, respectively, after LT and 91.4%, 77.1% and 68.6%, respectively, after LR (P = 0.498). The overall 1-, 3- and 5-year tumor recurrence-free rates were also comparable (P = 0.656). Poorer tumor differentiation (P = 0.041) and a higher post-downstage alpha-fetoprotein (AFP) level (> 400 ng/mL) (P = 0.015) were the two independent risk factors for tumor recurrence in the LT and LR patients who accepted successful down-staging therapy.

CONCLUSION: Due to the higher postoperative morbidity and similar survival and tumor recurrence-free rates, LR might offer better or similar outcome over LT, but a larger number and further randomized studies may be needed in the future for drawing any positive conclusions.

Key words: Liver; Resection; Transplantation; Downstage; Survival; Complication; Recurrence; Comparison

Core tip: We compared advanced-stage hepatocellular carcinoma (HCC) patients who underwent liver trans-

plantation (LT) or liver resection (LR) after successful downstaging therapy, and the recurrence rates and survival outcomes were similar, although the postoperative complication rate was higher for the LT group. The Milan criteria are one of the most strict and accepted criteria for HCC patients to determine eligibility for LT or LR. Therefore, our use of this selection criteria may make this study more ideal than others. Meanwhile, all of our patients accepted successful pre-operative downstaging therapy, the long waiting time can successful avoid the selective bias. So our comparison and results are more credible.

INTRODUCTION

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors and the fourth most common cause of mortality[1,2]. HCC is more common in northeast Asia due to the high prevalence of hepatitis B infection and in Western countries and Japan due to the high prevalence of hepatitis C infection[3,4]. HCC is difficult to manage compared to other malignancies due to the underlying liver cirrhosis caused by viral hepatitis. Fortunately, liver resection (LR) and liver transplantation (LT) are potentially curative treatments for early-stage HCC[5]. The most commonly accepted conditions for transplantation for HCC are the Milan criteria (early stage): a solitary tumor with a diameter < 5 cm or 2-3 cm tumors with the largest diameter < 3 cm and the absence of macroscopic vascular invasion or extrahepatic metastasis[6]. However, the lack of regular physical examination has led to more advanced HCCs at the time of diagnosis in developing countries, especially in China; thus, these advanced-stage HCC patients have lost the opportunity for an immediate cure, and downstaging therapy becomes the initial treatment option. Numerous loco-regional therapies, which serve as downstaging therapies, have been introduced for advanced-stage HCC patients: transarterial chemo-embolization (TACE), radiofrequency ablation (RFA), alcohol injection (EI), LR, and transarterial chemoinfusion (TACI) and sorafenib[7-10]. After successful downstaging therapy leading to a tumor that meets the Milan criteria for LT, another problem has emerged: which surgical method should be used, LR or LT? The choice of therapy has been debated for a long time. Considering the risk of recurrence and impaired liver function associated with cirrhosis, LT could be viewed as the optimal treatment for HCC because LT treats the tumor and the underlying liver disease[11]. However, this benefit may be offset by problems specifically related to transplantation: graft rejection, immunosuppression complications, recurrent viral hepatitis, increased mortality and a shortage of organ donors[6,12]. Since LT was introduced to HCC patients, the comparison of LR and LT has been constant[6,13-15]. Nevertheless, the optimal treatment strategy (LR or LT) for HCC patients who meet the Milan criteria after successful downstaging therapy has not been established. This study aimed to compare the outcomes of HR and LT in patients with HCC that met the Milan criteria after successful downstaging therapy.

MATERIALS AND METHODS

Patient characteristics

From February 2004 to August 2010, a consecutive series of 102 patients were diagnosed with advanced-stage HCC that met the modified UCSF down-staging protocol[7,16]. The eligibility criteria for down-staging were as follows: a single tumor with a diameter up to 8 cm, two to three tumors with individual diameters up to 5 cm and a total diameter up to 8 cm, and no vascular invasion by imaging criteria. The diagnosis of HCC was based on a serum hepatitis B virus (HBV) or heptatitis C virus (HCV) test, contrast-enhanced ultrasound, double-phase helical computed tomography (CT) scan, and a serum alpha-fetoprotein (AFP) level. A bone or a total body scan was used to identify possible metastasis. A biopsy was not routinely performed for every patient. All of the data were collected from the Chinese Liver Transplant Registry (http://www.cltr.org).

Downstaging protocol

The patients underwent various downstaging protocols. The type and number of treatments used were tailored to each patient according to tumor characteristics and response. Two local-regional therapies (TACE, RFA) were used for downstaging therapy. Patients who underwent accepted resection as a downstaging therapy were excluded from our study. The approach for RFA included percutaneous, laparoscopic and open techniques. The choice for the technique was individualized to a particular patient and based on local expertise. For tumors < 3 cm in size, RFA was recommended. As the tumor increases in size, the likelihood of incomplete treatment with RFA increases; thus, TACE or combination therapy was recommended for larger tumors[16].TACE was performed using standard techniques[17]. TACE was performed using 30 mg of mitomycin, 30 mg of adriamycin and 100 mg of cisplatinum mixed with lipiodol as the drug carrier. Then, embolization using permanent occlusive particles was performed. RFA was performed by using a "cool-tip" needle that contained an exposed 2- to 3-cm electrode and an internal water-cooling system (Radionics TM, Burlington, MA, United States); meanwhile, color-Doppler ultrasound was used as a guide for the percutaneous puncture or during intraoperative approach, and a laparoscopic ultrasonic probe was used during the laparoscopic cases.

Post-downstaging therapy evaluation and follow up

The response to downstaging therapy was evaluated by serum AFP once a month and contrast-enhanced CT bi-monthly in our center. Once the imaging examination indicated HCC characteristics that met the Milan criteria and the serum AFP was less than 500 ng/mL for patients with an initial AFP > 1000 ng/mL[8], LT or resection was offered to these patients. Resection was firstly considered for cirrhotic patients with well preserved liver function, LT was used if subtotal hepatic resection was not anatomically feasible and the living or deceased donor liver graft can be available, the patients with Child Class C were introduced to accept LT and excluded from our study. Additionally, these patients were advised to undergo a repeat bone scan and total body CT scan to identify any possible metastasis. After LT or LR, patients received bi-monthly follow up, and we retrospectively collected the data for these patients, comparing the baseline characteristics, postoperative complications, the 1-, 3-, and 5-years survival rates, and tumor recurrence-free rate. All of the LRs were open abdominal surgeries and regular liver lobectomy or segmentectomy. The detailed surgical procedure protocols and postoperative management for LR[18] and deceased donor LT (DDLT) have been presented in previous reports. No prisoner donors were used in our study. Living donor LT (LDLT) was performed after approval from the Ethics Committee of Sichuan University, and local authorization was obtained. All of the donations were voluntary and altruistic. We informed the donors and their families of the possible risks of donor hepatectomy. Written consent was provided by the donors for the storage of their information in the hospital database and its use for research. The inclusion and exclusion criteria[19] and surgical techniques[20] that were used for LT have been described previously. For the transplant recipients, tacrolimus or cyclosporine, mycophenolate and prednisone were used for the triple-drug immunosuppression regimen. The dose of tacrolimus and cyclosporine was adjusted based on the measured serum level. Prednisone was generally discontinued within 3 mo after transplantation[21]. Nucleoside analogues were used for all LR patients after LR if the HBV-DNA was positive pre-operation, hepatitis B hyper-immune globulin (HBIG) combined with nucleoside analogues were used for all LT patients post-transplantation.

Statistical analysis

The quantitative variables are expressed as the mean ± SD or median values with the range in parentheses, and qualitative variables were expressed as absolute numbers with the percentages in parentheses. Descriptive data for various patient characteristics were calculated separately for patients who received LT or LR. Continuous variables were compared using a nonparametric Wilcoxon test because some of the measurements did not follow a normal distribution. Categorical data were compared using a χ^2 test or Fisher's exact test, if necessary. Kaplan-Meier estimates of the long-term overall survival and tumor-free survival rates were calculated using the intention-to-treat principle and compared using the log-rank test. A Cox proportional hazards model was used for the multivariate analyses for survival and disease-free survival. The inclusion of variables into the final model was based on biological and statistical considerations. The statistical analyses were performed using the SAS statistical software package (version 9.1.3, SAS Institute, Inc, Cary, NC, United States), and a 2-sided P value < 0.5 was considered to be statistically significant.

Table 1 Downstaging treatments *n* (%)

	LT group	LR group
Number of treatments	31	35
TACE only	15 (48.4)	18 (51.4)
One time	5	7
Two times	8	7
Three times	2	4
RAF only	7 (22.6)	10 (28.6)
One time	5	6
Two time	2	4
TACE + RAF	4 (12.9)	3 (8.6)
TACE + TACE + RAF	3 (9.7)	2 (5.7)
TACE + RAF + TACE	2 (6.5)	2 (5.7)

TACE: Transarterial chemo-embolization; RFA: Radiofrequency ablation; LT: Liver transplantation; LR: Liver resection.

RESULTS

Downstaging protocols and results

TACE and RFA were performed for all advanced-stage HCC patients. After single or combined down-staging therapy, 66 patients (58.8%) showed successful down-staging. The details of these patients are shown in Table 1. In both groups, more patients underwent TACE than RAF as a single loco-regional therapy. Fewer patients in the LT group received only one kind of loco-regional therapy compared to the LR group (71% *vs* 80%, respectively), but this difference did not reach statistical significance (P = 0.396). Patients who received only TACE were more likely to undergo the therapy more than once, whereas patients who underwent RFA were more likely to undergo the therapy only once. Combination was performed for nine patients (29.0%) in the LT group and seven patients (20%) in the LR group (P = 0.396). There was no significant difference between the two groups for the type and number of down-staging treatments (P = 0.696).

Demographic data and tumor characteristics

Table 2 compares the characteristics of the 66 patients with successful downstaging who accepted LT (31 cases) or LR (35 cases). The two groups had similar demographic characteristics, and there were no significant differences in the number of tumors (P = 0.721), total tumor diameter (P = 0.376), tumor differentiation (P = 0.960) and the liver fibrosis degree scored by using the Ishak system (P = 0.069). Although the serum AFP level in the LT group (1425.4 ng/mL) was higher

Table 2 Baseline demographic and tumor characteristics in the two groups

	LT group (n = 31)	LR group (n = 35)	P value
Age (yr)	43.0 ± 8.2	45.5 ± 8.1	0.212
Gender (male:female)	20:11	20:15	0.544

LT: Liver transplantation; LR: Liver resection; HBV: Hepatitis B virus; HCV: Heptatitis C virus; AFP: Alpha-fetoprotein; BMI: Body mass index.

than in the LR group (1332.9 ng/mL) at baseline, after downstaging therapy, the reduction in AFP in the LT group was much greater than the LR group. However, no significant difference was observed for changes in AFP. Five patients (16.1%) prior to LT had a serum AFP greater than 400 ng/mL but a CT indicative of successful downstaging therapy, compared to eight patients (22.9%) in the LR group (P = 0.496).

Major postoperative complications and mortality

Complications developed in 15 patients after LT and 8 patients after LR, and the overall complication rate in the LT group (48.4%) was significantly higher than the LR group (22.9%) (P = 0.031). The overall mortality for the LT group was 12.9% *vs* 2.9% for the LR group (P = 0.172).This difference did not reach statistical significance (Table 3). One 42-year-old man was diagnosed with acute rejection by biopsy 1 mo after discharge, and he eventually died from this rejection. According to the Clavien scoring system for complications, the complication rates in the LT group for each grade were 16.1%, 9.7%, 6.5%, 3.2% and 12.9%, respectively, compared to 8.6%, 5.7%, 5.7%, 0.0% and 2.9% in the LR group, respectively (P = 0.026). The patients who died in hospital after LR or LT did not have any proof of HCC recurrence in the liver, and they were excluded from the recurrence rate calculation.

Table 3 Complications after liver transplantation or liver resection

Complications	LT group (n = 31)	LR group (n = 35)
Bile leakage	2 (Grade Ⅰ, Ⅰ)	1 (Grade Ⅰ)
Intra-abdominal bleeding	2 (Grade Ⅰ, Ⅴ)	2 (Grade Ⅱ, Ⅲ)
Wound infection	2 (Grade Ⅰ, Ⅰ)	1 (Grade Ⅰ)
Pleural effusion	1 (Grade Ⅲ)	2 (Grade Ⅰ, Ⅱ)
Respiratory failure	2 (Grade Ⅳ, Ⅴ)	1 (Grade Ⅴ)
Ileus	1 (Grade Ⅱ)	0
Hepatic artery thrombosis	1 (Grade Ⅱ)	0
Subphrenic abscess	1 (Grade Ⅲ)	1 (Grade Ⅲ)
Liver failure	1 (Grade Ⅴ)	0
Rejection	2 (Grade Ⅱ, Ⅴ)	0

Grade Ⅰ: Treated conservatively without any drugs; Grade Ⅱ: Treated with pharmacology; Grade Ⅲ: Intervention with anesthesia; Grade Ⅳ: Organ dysfunction; Grade Ⅴ: Death. LT: Liver transplantation; LR: Liver resection.

Survival and recurrence rates

The mean follow up was 3.6 ± 1.8 years for the LT group and 3.7 ± 1.6 years for the LR group (P = 0.838). The overall patient survival rates at 1-, 3- and 5-years were 87.1%, 80.6% and 77.4%, respectively, after LT and 91.4%, 77.1% and 68.6%, respectively, after LR (P = 0.498) (Figure 1A). The in-hospital deaths that occurred within one year are described above. One patient suffered a car accident and died seven months after tumor resection, and no tumor recurrence was observed during his follow up. Another 43-year-old man developed brain metastases and died 11 mo after LR. One year after the operation, the main cause of mortality was tumor recurrence, except for two LT patients. One recipient had a biliary stricture and underwent cholangioenterostomy, but the patient died from a lung infection three years after his living donor LT. Another 45-year-old woman died from chronic rejection four years after a deceased donor LT.

Three of 27 (11.1%) patients developed a recurrent tumor at a median of 1.8 years after LT, and 5 of 34 (14.7%) patients had a tumor recurrence at a median of 2.2 years after LR. A trend toward a longer time to recurrence after LR (2.2 ± 1.1 years) compared to LT (1.8 ± 1.4 years) was observed; however, this difference did not reach statistical significance (P = 0.664). The overall 1-, 3- and 5-year recurrence-free rates were 83.8%, 74.2%, and 67.7%, respectively, for the LT group and 88.6%, 74.3%, and 60.0%, respectively, for the LR group (P = 0.656) (Figure 1B). The most common site for tumor recurrence was the liver, followed by the lungs, lymph nodes, and rarely the bones and brain. There was no difference in the site of recurrence between the LT and LR groups (P = 0.872). In the LT group, 2 of 3 recipients had extrahepatic recurrences (lung and abdominal lymph node).

Table 4 Risk factors for tumor recurrence in the two groups

Factors	Odds	95%CI	*P* value
Tumor differentiation	2.225	1.365-3.882	0.041
Post-downstaging AFP level > 400 ng/mL	2.113	1.971-3.104	0.015

AFP: Alpha-fetoprotein.

In the LR group, of the five recurrences, 3 patients had an extrahepatic recurrence (lungs, abdominal lymph node and bones).

Risk factors for tumor recurrence

To clarify the prognostic factors for tumor recurrence in each group, multivariate data (*e.g.*, patient age, gender, weight, height, BMI, underlying liver disease, blood group, liver function, number of tumors, total diameter of the tumors, baseline AFP level, post-downstage AFP level, number of downstage therapies, the presence of satellite nodules, and tumor differentiation level, intrahepatic micrometastases and extrahepatic micrometastases) were analyzed and compared in each group using a stepwise, multivariate logistic regression analysis (step-down). The predictive factors for recurrence were similar in the two groups and were related to poorer tumor differentiation ($P = 0.041$) and a higher post-downstage AFP level (> 400 ng/mL) ($P = 0.015$) (Table 4). As a result, these two factors may become independent predictive factors for recurrence in LT and LR patients who underwent successful downstaging therapy.

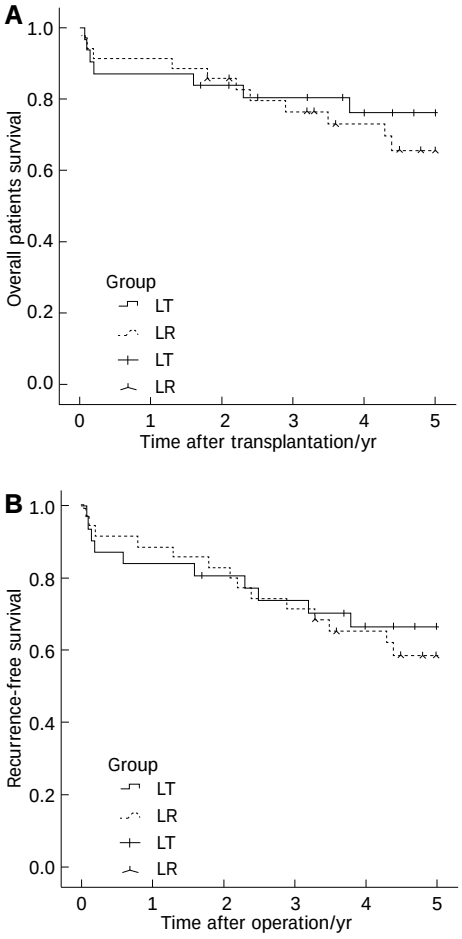

Figure 1 Comparison of liver transplantation and liver resection. A: The overall survival rates ($P = 0.498$); B: the recurrence-free rates ($P = 0.838$). LT: Liver transplantation; LR: Liver resection.

DISCUSSION

The majority of HCC patients are diagnosed at a late stage and therefore are not eligible for potentially curative treatment, such as resection or LT[22]. Ideal candidates based on the Milan criteria for LT or LR comprise fewer than 10% of the diagnosed HCC cases[23]. For patients with advanced HCC, LT yields a disappointing 5-year survival rate (18%-32%), largely due to tumor recurrence. Fortunately, disease down-staging using locoregional therapy may offer patients, who are not initially candidates, a chance to undergo a curative treatment, such as LT or LR[24]. TACE and RFA remain perhaps the most commonly used palliative treatments for unresectable HCC. However, to our knowledge, there has been no comparison of the outcomes between advanced HCC patients who underwent LR or LT after successful downstaging therapy (tumors that met the Milan criteria).

LT, including living donor LT and deceased LT, offers the theoretical advantage of removing the tumor and the organ at risk of developing future malignancy and is an established therapy for small, early-stage HCC in patients with cirrhosis[25]. The above are the greatest advantages of LT over resection, whereas resection is more easily and immediately available[26,27], effective[28-31], safer[32-34] and simpler[35]. Consequently, there is no consensus regarding the best surgical treatment for patients with well-compensated cirrhosis and early HCC that meets the Milan criteria[6], so LT should not be considered as the first choice for mild or even some cases of moderate cirrhosis because proper patient selection for resection may yield equal or better outcomes. Many comparisons have been made, but no consensus has been reached. In our study, we compared advanced-stage HCC patients who underwent LT or LR after successful downstaging therapy, and the recurrence rates and survival outcomes were similar, although the postoperative complication rate was higher for the LT group.

In our study, the complication rate after LT was much higher than after LR, but the in-hospital mortality was not significantly different between the two groups. Bellavance *et al*[36] reported the morbidities for patients whose tumor met the Milan criteria was 49% for the LR group and 65% for the LT group, which were both higher than in our study (22.9% for the LR group and 48.4% for the LT group). No difference was observed in the 1-year survival rates for the LR and LT patients in his study. However, the 5-year survival rate in his report was only 46% for the LR patients, which was lower than 66% in the LT group and much lower than the 68.6% observed in our study. The reported morbidity for early-stage HCC (within

the Milan criteria) ranged from 30% to 49% for LR patients and from 44% to 80%, and almost all of the reports demonstrated a higher morbidity for the LT group than for the LR group[6,37-39]. The higher morbidity in the LT group may be due to the longer operation time, more difficult operative procedure and the reconstruction of the hepatic vessel and bile duct. Another reason for the lower morbidity for the LR patients was that the resection avoided the risks associated with immunosuppression. These risks include toxicities (especially nephrotoxicity), infectious complications, and post-transplantation de novo neoplasms[6].

Although four LT patients died in the hospital from serious complications, only one patient died after LR. Although this result did not reach statistical significance, this trend for greater mortality in the LT group is well known. Of the 204 LR patients, no patient died in the hospital after LR, whereas the mortality rate was 3.4% for the LT group in Poon's report[28]. A similar conclusion was reached in Bigourdan *et al*[39], but in Margarit *et al*[40], the mortality for LR patients (5.6%) was higher than for LT patients (3.4%). A recent review of almost 60 cases of either LR or LT found that the mortality following transplantation was 60% higher than following resection (5%)[41]. Recipients who received an allogeneic liver graft, either full or partial size, all needed to take an immunosuppressant, such as tacrolimus, mycophenolate mofetil or steroids, and nephrotoxicity and immunosuppression may affect graft and patient survival[32,42]. In a series of 1000 liver transplant patients treated with tacrolimus immunosuppression, post-transplantation infection was the most common cause of death (34% of 360 deaths)[42].

As for long-term results, this study showed that LT and LR had similar recurrence-free survival and overall survival rates. Various overall and recurrence-free survival rates have been reported for patients undergoing LR or LT. Most of these results have shown that the rates of long-term survival and recurrence after transplantation are superior to those observed following resection[29,36,40,43,44]. Others have shown similar overall survival rates for the two groups and a higher recurrence-free survival rate for the LT group[40,45]. In a retrospective study, Otto *et al*[14] compared 50 patients who underwent LT and 52 patients who underwent LR and concluded that no significant difference was observed between the two groups for the 3-year survival and recurrence rates. In this study, tumor size was the only independent factor for recurrence. The notable difference among these reports may be caused by a superior eradication of gross or microscopic disease or by selection bias[14,36]. The use of too many different staging systems may be one cause of this bias because 18 different staging or scoring systems have been reported to be used. In our study, we used the Milan criteria as the selection criteria. The Milan criteria are one of the most strict and accepted criteria for HCC patients to determine eligibility for LT or LR. Therefore, the use of this selection criteria in our study may make this study more ideal than others. Meanwhile patients who are successfully down-staged and undergo operation may have a higher recurrence-free survival rate[46], and all of the patients accepted successful down-staging therapy, that is the reason for our higher tumor recurrence free survival rate. In our study, most of the patients in the LT and LR groups had their HCC recurrence within three years. Only two patients had tumor recurrence four years after LT or LR. These results were contrary to Lee's report[15], in which most recurrences happened within 2 years after LT and only rarely after that. Meanwhile, the post-operative antiviral therapies may also contribute to the good outcome after resection and LT in our study, it is because controlling viral replication halts disease progression and decreases the risk of tumor recurrence or developing new lesions[12]. However, the tumor recurrence rate after LR increased over time, and the long-term survival rates between the LR and LT groups differed significantly.

Many studies have reported predictors of prognosis based on univariate analyses combining LR and LT patients. Zhou *et al*[47] reported three factors were significant predictors of disease-free survival: microscopic venous invasion, tumor size-plus-number (> 4 cm *vs* ≤ 4 cm), and treatment (HR *vs* LT). However, his study included patients that did not meet the Milan criteria. AFP is a tumor marker that is expressed by HCC and is secreted into the serum of approximately 70% of patients with HCC. AFP have been widely used to diagnose[48] and monitor HCC. Previous studies have demonstrated that the baseline AFP level is a significant prognostic factor for various stages of HCC[49-51]. EA Pomfret[16] suggested that successful down-staging requires a significant decrease in the AFP, to < 500 ng/mL for patients with an initial AFP > 1000 ng/mL. For patients with an AFP > 500 ng/mL, the lack of evidence of a tumor by imaging, indicating either no cancer is present or there is a diffuse, small, and highly aggressive malignancy with a poor prognosis, is required. In the Bologna study[8], an AFP level ≥ 400 ng/mL was an exclusion criterion for LT after down-staging therapy. Many other reports have demonstrated that the change in AFP after LT or resection is valuable in predicting tumor recurrence for HCC patients[52,53]. In our study, another predictor for HCC recurrence and overall survival was the tumor differentiation level. In Imamura *et al*[54], an AFP ≥ 32 ng/mL was a risk factor for early tumor recurrence, and the gross tumor classification was a risk factor for late tumor recurrence after resection. Histological grade has been accepted as a significant predictor of the patient survival as showed in our study[28,55].

Our study does have some limitations, a randomized study would have been the best type of clinical study to resolve the debate regarding use of LT *vs* LR for HCC patients after successful downstaging therapies. This ideal study is indeed difficult to realize, if at all feasible, given the complex decision-making process involved in LT. In addition, we performed our analysis using only about 30 cases in each group, the total numbers presented in this series are low, however, all of the HCC patients in our

study were out of criteria for LR or LT at first, and all of them met the Milan criteria after successful downstaging therapies. So a larger multicenter study comparing an larger number of patients with HCC after successful downstaging therapies in both groups (LR and LT) would be ideal.

In conclusion, the present study shows that, the LT group had a significantly higher morbidity rate than the LR patients; however, the mortality rate did not differ between the two groups. There was no significant difference in the overall survival and HCC-free survival rates between the two groups. For the HCC patients who accepted successful downstaging therapies and be with compensated liver function (Child Class A or B), LR might offer better or similar outcome over LT; and that further randomized studies on a larger number of patients is warranted before drawing any conclusions.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is one of the most common malignant tumors and the fourth most common cause of mortality. Fortunately, liver resection (LR) and liver transplantation (LT) are potentially curative treatments for early-stage HCC. The most commonly accepted conditions for transplantation for HCC are the Milan criteria (early stage). However, the lack of regular physical examination has led to more advanced HCCs at the time of diagnosis in developing countries, thus, these advanced-stage HCC patients have lost the opportunity for an immediate cure, and downstaging therapy becomes the initial treatment option. After successful downstaging therapy leading to a tumor that meets the Milan criteria for LT, another problem has emerged: which surgical method should be used, LR or LT? The choice of therapy has been debated for a long time.

Research frontiers

LR and LT are potentially curative treatments for early-stage HCC, all of them have advantages and disadvantages, considering the risk of recurrence and impaired liver function associated with cirrhosis, LT could be viewed as the optimal treatment for HCC because LT treats the tumor and the underlying liver disease. However, this benefit may be offset by problems specifically related to transplantation: graft rejection, immunosuppression complications, recurrent viral hepatitis, increased mortality and a shortage of organ donors.

Innovations and breakthroughs

There is no consensus regarding the best surgical treatment for patients with well-compensated cirrhosis and early HCC that meets the Milan criteria previously. Many comparisons have been made, but no consensus has been reached. In authors' study, authors compared advanced-stage HCC patients who underwent LT or LR after successful downstaging therapy, and the recurrence rates and survival outcomes were similar, although the postoperative complication rate was higher for the LT group. In authors' study, authors used the Milan criteria as the selection criteria. The Milan criteria are one of the most strict and accepted criteria for HCC patients to determine eligibility for LT or LR. Therefore, the use of this selection criteria in their study may make this study more ideal than others. Meanwhile, all of their patients accepted successful preoperative down-staging therapy, the long waiting time can successful avoid the selective bias. So authors' comparison and results are more credible.

Applications

This study result suggest that LT may not be considered as the primary treatment for patients with HCC that meets the Milan criteria after successful downstaging therapy.

Terminology

LT is a surgical method to cure end-stage liver disease, removing the liver with disease and implant one or part of new liver from donor; Down-staging therapy was a method to reduce the size or the number of tumor.

Peer review

It is interesting and important to investigate the advantages and risks of LT and LR in patients with advanced HCC that met the Milan criteria after successful downstaging therapy.

Abstract

Development of oedema and hypoproteinaemia in a liver transplant recipient may be the first signs of graft dysfunction and should prompt a full assessment. We report the novel case of a patient who, years after liver transplantation developed a functional blind loop in an incisional hernia, which manifested as oedema and hypoproteinaemia secondary to protein losing enteropathy. After numerous investigations, the diagnosis was made by flurodeoxyglucose positron emmision tomography (FDG-PET) imaging. Surgical repair of the incisional hernia was followed several months later by resolution of the protein loss, and confirmed at a post operative FDG-PET scan at one year.

Key words: Protein losing enteropathies; Bacterial overgrowth; Hypoproteinaemia; Incarcerated hernia; Liver transplantation.

Core tip: This report presents a rare case of protein losing enteropathy as a result of bacterial overgrowth in the blind loop of an incisional hernia following liver transplantation. Surgical repair of the incisional hernia in this case brought about resolution of protein loss.

INTRODUCTION

Hypoproteinaemia and peripheral oedema are common manifestations of advanced liver disease. In most patients oedema resolves after transplantation with the return of synthetic function of the graft to full capacity, the timing of which may vary from days to several months in extreme cases. Reappearance of oedema in a transplant patient is a cause for concern and may be the first indication of graft failure, which could be the result of recurrent disease or chronic rejection. Chronic graft failure culminates in synthetic failure and in some cases ensuing portal hypertension, which may lead to enteropathy. With the long standing portal hypertension, oedema of the gastric or intestinal mucosa leads to impaired lymphatic circulation and absorption of proteins further augmenting hypoalbuminaemia[1]. Therefore in those presenting with low albumin and peripheral oedema graft failure is considered the first differential diagnosis, and in this light some of the simple but rare aetiological conditions may be overlooked.

Apart from advanced liver disease, aetiology of hypoalbuminaemia ranges from malnutrition and poor protein intake to increased protein loss from body due to various reasons. The renal and gastrointestinal tracts are common sites of protein loss. So called "blind loop

syndrome" refers to a segment of bowel that is bypassed in normal gastrointestinal functions, allowing overgrowth of pathogenic bacteria[2]. The case reported here illustrates a patient who presented many years after liver transplant with peripheral oedema and hypoalbuminaemia, the aetiology of which was traced to a "blind loop" located in an incisional hernia at the site of the transplant incision.

CASE REPORT

A 52-year-old female with hypertension and type Ⅱ diabetes underwent orthotopic liver transplantation for hepatitis C cirrhosis. This was followed two weeks later by early re-transplantation for hepatic artery thrombosis. Over the following ten years, she suffered a number of episodes of cholangitis and required percutaneous transhepatic cholangiography and balloon dilatation of a biliary stricture on two occasions. She also developed an incisional hernia adjacent to her liver transplant scar five years after her transplants, which was managed conservatively. She had stable liver graft function throughout, and was maintained on cyclosporine based immunosuppression regime. She had mild degree of renal impairment attributed to calcineurin inhibitors and her serum creatinine was 106 mmol/L.

Twelve years following her transplant and aged 64 years she developed abdominal bloating and peripheral oedema. Her serum albumin fell to 21 g/dL and total serum protein to 50 g/dL but her other liver function tests were unremarkable. Liver biopsy demonstrated a mild degree of inflammation and fibrosis. Oesophagastroduodenoscopy (OGD) revealed mild hypertensive gastropathy but in the absence of splenomegaly or thrombocytopenia portal hypertension was deemed an unlikely cause for her hypoproteinaemia. She had no evidence of excessive renal protein loss with a negative urine dipstick for protein, an albumin creatinine ratio of 2 and 24-h urinary protein of 126 mg. She had no diarrhoea or other symptoms or signs of inflammatory bowel disease. Duodenal biopsy demonstrated normal duodenal mucosa whilst on capsule endoscopy no significant pathology was found apart from scattered angioectasia throughout the jejunum and ileum and a suggested small polypoidal mass in caecum.

Over the two years that followed, she suffered repeated episodes of oedema, bloatedness and a drop in serum albumin to levels around 20 g/dL requiring multiple albumin infusions. These increased in frequency when she required 27 units of albumin (100 mL 20% HAS) over 2 mo, and was admitted for further evaluation of the cause of her protein losing enteropathy. All biochemical investigations including serum caeruloplasmin, faecal elastase, faecal alpha-1 antitrypsin and celiac screen was normal. Colonoscopy did not identify the possible polypoid lesion showed on capsule endoscopy. Repeat OGD revealed normal villi but a few scattered pearly white spots thought to represent lymphangiectasia. Pathological analysis of duodenal biopsies revealed normal villous architecture, no intraepithelial lymphocytes but a few distended lymphatic spaces.

It was suggested that she was likely to have a degree of bacterial overgrowth in loop of hernia but in absence of watery diarrhoea and vitamin deficiency, the chances of her symptoms being due to protein losing enteropathy was deemed unlikely. In the absence of any other definitive aetiology for continued protein loss she was subjected to a fluorodeoxyglucose computed tomography positron emission tomography (FDG CT-PET) scan which demonstrated increased uptake in the bowel in the region of her incisional hernia indicating increased metabolic activity or infection in the blind loop of the hernia (Figure 1). A month later she underwent uncomplicated repair of her incisional hernia. Her requirement for albumin infusions decreased over the following 9 mo and at present she has been 3 mo without an albumin infusion and is maintaining a steady serum albumin level of 34 g/dL and total protein of 60 g/dL with no symptoms. A repeat CT-PET scan one year post hernia repair has demonstrated no increased uptake in the bowel around the site of her previous incisional hernia (Figure 2).

DISCUSSION

Protein losing enteropathy (PLE) is a rare condition in which protein loss into the gastrointestinal tract results in hypoproteinaemia which is manifested as peripheral oedema, ascites and sometimes pleural or pericardial effusions. The causes of PLE are numerous but can be divided broadly into mucosal injury, either erosive or non-erosive, increased central venous pressure, mesenteric lymphatic obstruction or small intestinal bacterial overgrowth (SIBO), which was the cause in this case[1]. Abdominal hernia, internal or external, have been implicated in SIBO and PLE but only a very limited number of cases are reported in the literature[3,4]. The present case is the first reported of its kind, and the learning point lies on the diagnostic dilemma. Nevertheless systematic investigations helped localise the problem and FDG-PET scan was an invaluable diagnostic tool.

SIBO can result from a number of processes and may be considered as either functional or anatomical, and in some cases a combination of both. Functional causes include hypochlorhydria, dysmotility and some immunodeficiency syndromes[5]. Anatomical situations predisposing to SIBO include resection of the ileo-caecal valve or gastro-colic and jejuno-colic fistulae in which colonic bacteria can translocate to the small bowel, or in situations where a surgical "blind loop" is created by an end to side or roux-en-y anastomosis or as part of a Billroth Ⅱ gastrectomy[5,6]. A small bowel loop in an incarcerated hernia is similar to a functional blind loop in that patients often do not present with features of mechanical bowel obstruction and the classic features of

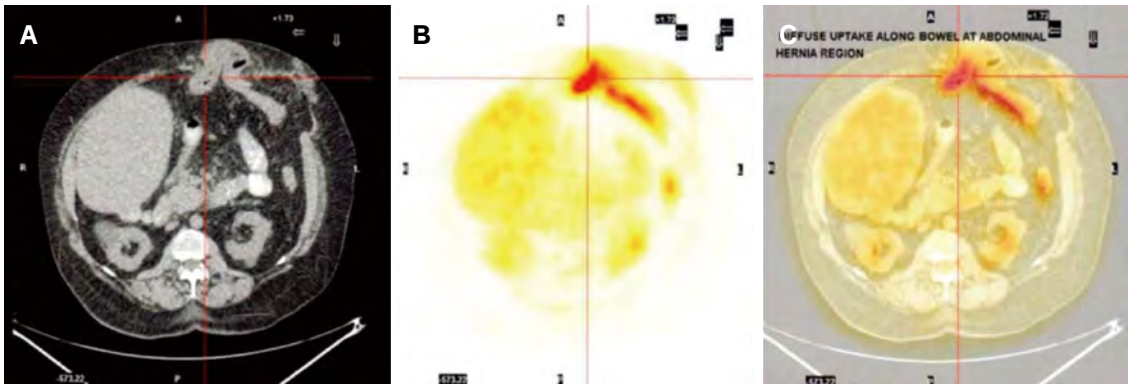

Figure 1 Computed tomography scan (A), flurodeoxyglucose positron emmision tomography (B) and combined computed tomography positron emission tomography image (C) across the site of incisional hernia. A: Incarcerated hernia with a loop of bowel; B: Confirms "hot spot" with increased flurodeoxyglucose uptake which corresponds with the centre of the incarcerated bowel loop within the hernia with some activity along the efferent loop distal to the hernia.

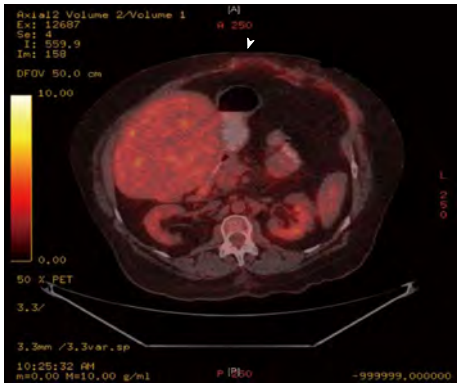

Figure 2 Computed tomography positron emission tomography image **12 mo following the incisional hernia repair.** The arrow heads points to the previous hernia site now repaired anatomically and the "hot spot" has now disappeared.

intestinal obstruction are not usually present. Decreased motility of the incarcerated segment however provides the home for bacterial overgrowth due to the loss of normal mechanical clearing action usually present in the bowel. Initially an overgrowth of intestinal type bacteria occurs but with longstanding functional obstruction colonic bacteria also may translocate to the site of the obstructed bowel[7]. The exact mechanism of protein loss in SIBO is by way of a combination of mechanisms including impaired digestion and absorption of proteins and increased secretion of protein rich fluid into the intestinal loop as a result of chronic ongoing mucosal inflammation[8]. It has been proposed that the immune system plays a role in the regulation of intestinal flora[9], and the induced immunosuppressed state in this patient may have been contributory however there is no documented evidence to prove this theory in circumstances such as these.

In summary, this is an extremely rare presentation of protein-losing enteropathy as a result of an incisional hernia following liver transplantation. Incisional hernia is a common surgical complication following liver transplantation, the incidence of which increases further with re-transplantation[10]. Impaired wound healing and loss of muscle mass in the immunosuppressed patient transplanted for end stage liver disease account for this higher incidence of incisional herniae, and the majority of these are managed conservatively if they remain asymptomatic or further surgery is contraindicated[11,12]. Bacterial overgrowth in an incarcerated segment of bowel leading to blind loop syndrome and hypoalbuminaemia may mimic some features of late liver graft failure and should be considered in such situations.

Abstract

Crohn's disease (CD), a variant of chronic inflammatory bowel disease, frequently affects the terminal ileum and coecal region. The clinical symptoms are often subtle and depend on the inflammatory activity of disease. In women of child-bearing age, florid intestinal endometriosis can simulate CD. Moreover, current pathophysiological concepts include intestinal endometriosis as a putative founder lesion for consecutive CD establishment. The report summarizes clinical and histomorphological data of a 35-year-old woman with the rare coincidence of florid intestinal endometriosis and CD both affecting the terminal ileum. The patient was suffering over 10 years from strong abdominal disorders including constipation, diarrhea, weight loss, and diffuse abdominal pain. In magnetic resonance imaging-Sellink, strong inflammation and intestinal obstruction of the terminal ileum were found. The laparoscopy revealed further evidence for existence of an inflammatory disease like CD, but brownish spots on the peritoneum were found indicative for endometriosis. Surgical resection of the terminal ileum and the coecal segment was performed followed by histopathological investigations. In transmural sections of the terminal ileum, histomorphological features of florid endometriosis intermingled with florid CD was found. The diagnostic findings were substantiated with a panel of immunohistological stainings. In conclusion, the findings demonstrate that florid endometriosis persists in florid CD lesions and the putative link between intestinal endometriosis and CD is more complex than previously assumed.

Key words: Crohn's diseases; Intestinal endometriosis; Pathogenesis

Core tip: A 35-year-old woman with the rare constellation of a strong mixture of florid intestinal endometriosis and Crohn's disease in the terminal ileum is presented. Our findings suggest that there exist a putative link between the pathogenesis of both entities, which is more complex than previously assumed.

INTRODUCTION

Crohn's disease (CD), a variant of chronic inflammatory bowel disease, is of unknown aetiology. Changes of the intestinal mucosal barrier are considered to play a role in

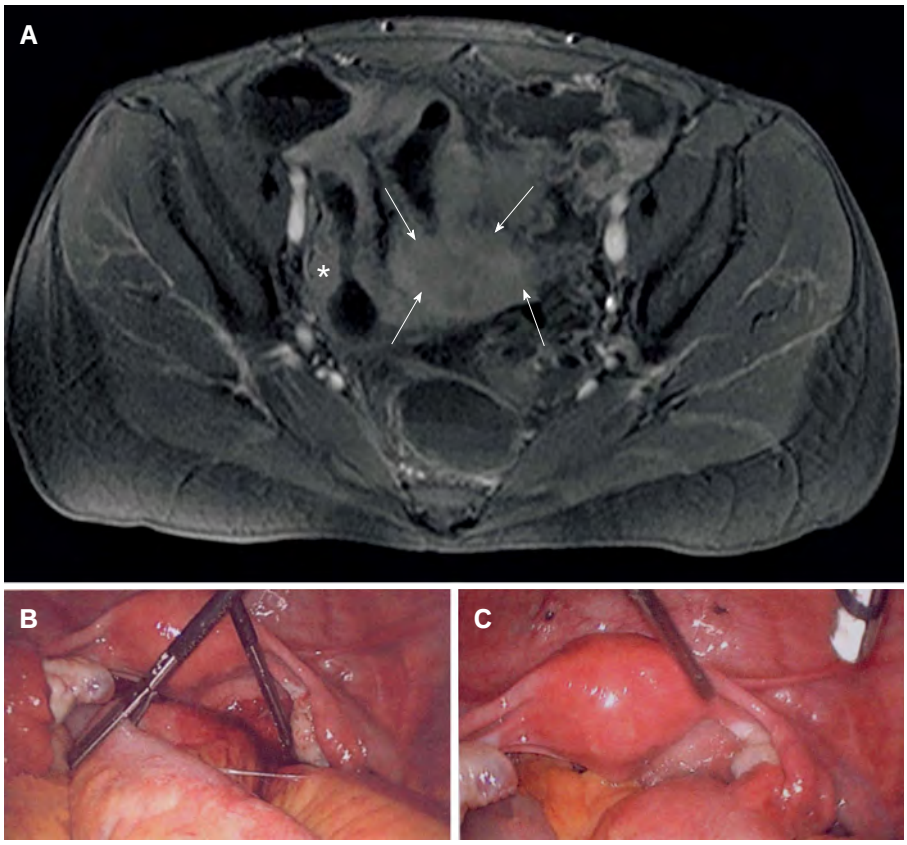

Figure 1 Radiological and surgical aspects of florid intestinal endometriosis and Crohn's disease coincidence. A: Magnetic resonance imaging-Sellink of the lower pelvis (axial T1 FS plus contrast agent). Bauhin's valve and coecum are marked with a asterisk. The arrows highlight an uncharacteristic tissue mass involving the bowel; B: Laparoscopically, adhesion of the distal small bowel to the pelvis wall; C: Brownish spots on the pelvis and bladder peritoneum are indicating for endometriosis.

the pathogenesis. Its incidence peaks in the 2nd and 3rd decades of life. CD most commonly affects the terminal ileum and coecal region, but may be found in any segment of the gastrointestinal tract. Clinical signs and symptoms of CD are often subtle and depend on the location and severity of the gastrointestinal involvement as well as inflammatory activity. CD related symptoms may include abdominal pain, severe diarrhea (sometimes with blood), weight loss and even malnutrition[1]. Growth retardation may occur in pediatric patients[2]. Other important symptoms which could be associated with CD are intestinal obstruction, perirectal or perianal abscesses, perforation and fistulas[3]. Because a plethora of non characteristic symptoms can be found in CD, a large list of differential diagnosis exists.

When the terminal ileum is affected in a woman of child-bearing age, endometriosis should be included in the differential diagnosis because this entity can simulate CD not only clinically[4]. Endometriosis is characterized by proliferation of endometrial tissue at extrauterine sites including ovaries, peritoneum and the intestinal tract. At present, the etiology of endometriosis is not fully understood. Its incidence peaks in the 3rd decade of life. About 5%-10% of women in menstruating age are affected[5]. Importantly, endometriosis affecting the intestinal tract is found in 3%-37% of women. Rectosigmoid, proximal/middle colon, appendix, and ileum are the most commonly affected sites. Similar to CD, the symptoms in intestinal endometriosis are not characteristic and include abdominal pain, (bloody) diarrhea, constipation, and segmental inflammation[6].

We present here the rare case of coincidence of active CD and florid endometriosis both affecting the terminal ileum of a 35-year-old woman.

CASE REPORT

The patient, a 35-year-old woman, was admitted to our surgical department first in August 2012. She was suffering from strong abdominal disorders over 10 years with constipation, diarrhea, and diffuse abdominal pain resulting in impaired nutrition and weight loss. The abdominal disorders were not related to the period, and dysmenorrhea was not given. Manifestation of CD was suggested years ago but not further substantiated or medical treated. The patient had a 12-year-old daughter, negative family history for chronic inflammatory bowel diseases and cancer. The last coloscopy in July 2012 showed a swelling of the intestinal mucosa of the ileocecal region. In biopsies, uncharacteristic moderate inflammation was found.

In order to clarify the obscure abdominal disorder, magnetic resonance imaging-Sellink was performed. Using this technique, strong inflammation and intestinal obstruction affecting a long part of the distal small intestinal bowel, Bauhin's valve, and coecum were found. In the lower pelvis, an uncharacteristic mass of tissue involving the bowel was additionally visible (Figure 1A). All results so far were unspecific but lead us to the estimated diagnosis of CD with severe intestinal obstruction and tumour like transformation. So we decided to perform laparoscopic intervention.

The laparoscopy revealed an inflammatory disease

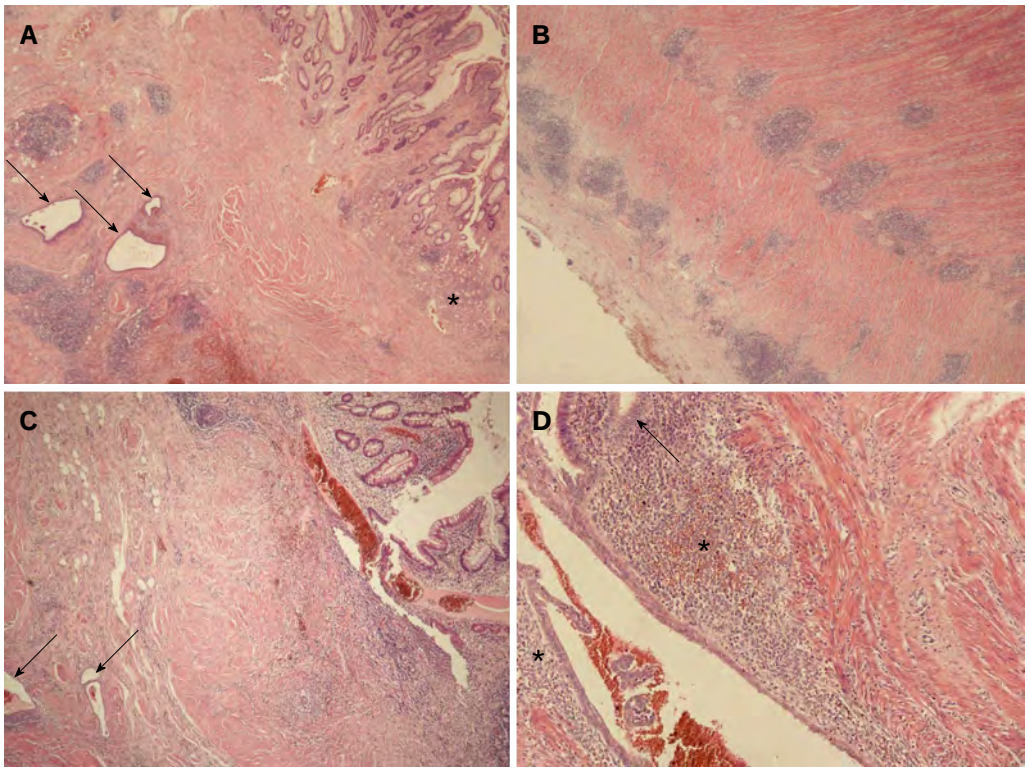

Figure 2 Coincidence of florid intestinal endometriosis and Crohn's disease in small intestinal wall. A: Complex inflammatory mucosal injury with establishment of pyloric gland metaplasia (asterisk). In deeper layers severe lymphoid aggregates (arrows) accompanied by endometrial glands exist (HE, × 10); B: Strong lymphoid hyperplasia partially affecting the prominent neuronal plexus, and serositis (HE, × 10); C: Florid aphthous mucosal lesion (HE, × 10), the arrows indicate endometriosis. D: Higher magnification of intestinal endometriosis(HE, × 100). Examples of epithelial proliferates are marked by an arrow. The cytogenic stroma is highlighted by asterisks. Note the intraglandular aggregates of erythrocytes.

affecting the distal small bowel with strong tumour like adhesion to the pelvis, but inconspicuous uterus and adnexa (Figure 1B). In addition, some brownish spots on the pelvis and bladder peritoneum were found that macroscopically appeared as endometriosis (Figure 1C). By laparoscopical intervention, it was impossible to free the intestinal segment. Consequently, a longitudinal laparotomie was performed. The tumour like inflamed small intestinal segment and the ileocoecal portion were resected. Both ureters were not affected by the inflammation. Following a gynaecological council and the fact that intraoperative frozen sections of the tumour-like lesion in the spatium rectovaginale did not demonstrate endometriosis, the inflamed mass in the lower pelvis was not resected. It was taken into account that resection of the tumour-like lesion, probably an additional manifestation of CD, was impossible without anterior rectum resection.

In the follow-up, the patient recovered quickly with one day observation on the intensive care unit. With the fast track concept the patient was quickly activated and within 4 d nutrition was increased to normal. Intestinal anastomosis (ileo-ascendostomia) and all wounds healed primarily and without any complications. Using anti-inflammatory and antibiotic therapies, the inflamed mass in the lower pelvis was diminished. The patient is now incorporated in our follow-up care system and will be systematically re-evaluated.

Pathologic studies and findings

The resected specimen was fixed in 10% formaldehyde for about 24 h followed by tissue preparation. Representative tissues were embedded in paraffin and sectioned. Tissue sections were stained with HE, sometimes with PAS. In addition, an extensive panel of immunohistochemical routine stains were performed using the DAKO Autostainer Link 48 system and commercially available primary antibodies and detection systems (all DAKO Deutschland, Hamburg, Germany). The primary antibodies included CD45 (dilution 1:2000), CD10 (dilution 1:50), K7 (dilution 1:1000), K20 (dilution 1:200), CDX2 (dilution 1:50), and progesterone receptor (dilution 1:350). With the exception of CDX2, all antigens were uncovered with pre-treatment at pH 6.1 as recommended by the supplier. In order to detect the CDX2 antigen, tissues slides were pre-treated at pH 9.0.

The surgical specimen includes a 32 cm small intestine with a 6 cm coecal segment, 4.5 cm appendix, and 1.5 cm mesenteric fatty tissue. High grade stenosis of the small intestine with wall thickening, several aphthous lesions, and destruction of Bauhin's valve were found. Macro-sections revealed diffuse fibrosis of the intestinal wall and aspects of serositis.

Tissue sections of the small intestinal bowel wall demonstrated a mixture of two histomorphological patterns (Figure 2). At first, a multifocal erosive-ulcerative, aph-

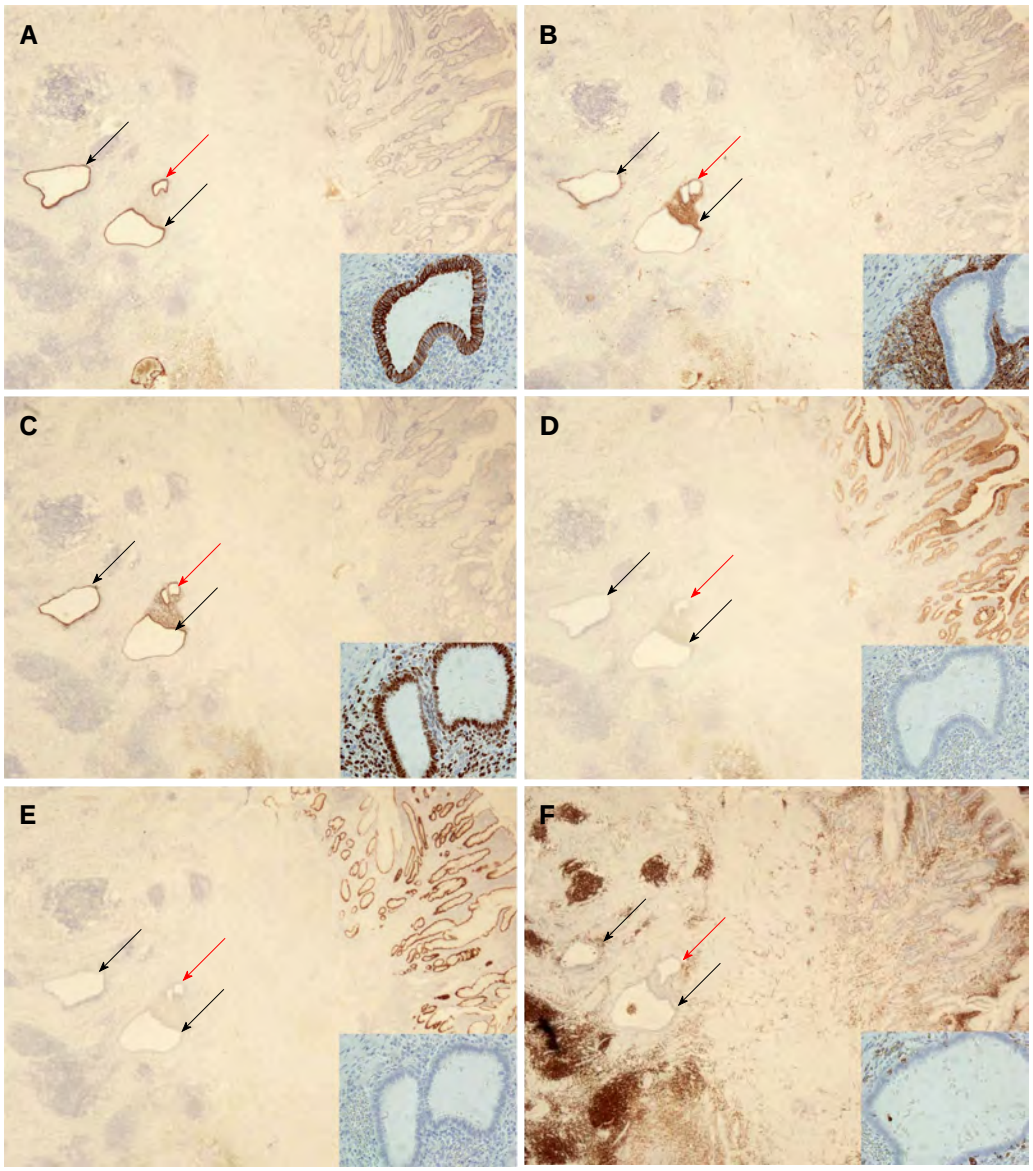

Figure 3 Immunohistochemical characterization of florid intestinal endometriosis and Crohn's disease. The intramural glandular structures (arrows in A-F) are positive for keratin 7 (A), CD10 (B), and progesterone receptor (C), but negative for keratin 20 (D) and CDX2 (E) which is vice versa to the mucosal staining; Strong anti-CD45 immunostaining illustrates severe lymphoid hyperplasia in CD (F). A-F: To illustrate immunostainings in detail always the intramural gland designated by a red arrow is shown in insets (original magnification: × 10; inset: × 250).

thous process with transmural lymphoid aggregates and chronic inflammation of serosal tissue layers was found. Moreover, pyloric gland metaplasia was frequently established in the mucosa layer. Despite missing granulomas, the morphological aspects were diagnostic for manifestation of CD (activity score Ⅲ). In addition to CD, a second histomorphological pattern was found. Several areas with gland forming epithelial cells adjacent to a cell rich matrix were distributed within the CD lesions, reflecting florid endometriosis in CD. The endometriosis glands were sometimes accompanied by few siderophages. The endometriosis was distributes throughout the small intestinal wall and preferentially found in the inner layer of the tunica muscularis. The basic histomorphological findings were further characterized by immunohistochemistry (Figure 3).

DISCUSSION

CD is an important variant of inflammatory bowel disease and it is assumed as a disorder with polyetiological background. Modern pathophysiological concepts include intestinal endometriosis as a putative risk factor to promote development of inflammatory bowel disease in particular CD. Following results from a Danish long-term study group in 2011 it is suggested that likelihood of CD in women with endometriosis is higher than in the control population[7]. In detail, the data reflects the situation that endometriosis gives a basis for the manifestation of CD and possible autoimmune triggered diseases even in the long term after the diagnosis of endometriosis. In this study the risk of CD manifestation was highest among women diagnosed with endometriosis below the

age of 25 years. The possible link between both diseases is substantiated by the following points: (1) both are inflammatory diseases; (2) the CD is preferentially found in women; and (3) both diseases are characterized by intermittent appearance. Common immunological features or an impact of endometriosis treatment with oral contraceptives on risk of CD must be also discussed as possible links[8,9]. In view with these studies, occurrence of florid CD mixed-up with florid small intestinal endometriosis as presented here is a rare constellation.

In contrast to CD, terminal ileal involvement from endometriosis is uncommon and occurs only in 1%-7% of all patients with intestinal endometriosis[10]. Patients with intestinal endometriosis of the terminal ileum are usually young nulliparous women who present with intermittent or persistent abdominal pain and possible obstruction. These features apply only partially to the case presented here.

The data presented here have some parallels to a Belgian case series[11]. In the Belgian study, clinical and histological findings from eight females with simultaneous histological diagnosis of intestinal endometriosis and CD were addressed. However, the strong mixture of active CD and florid intestinal endometrial deposits in terminal ileum tissues was not recorded. From this point of view, our case clearly demonstrates that both florid entities can mixed-up in the terminal ileum.

It could be speculated from our findings and the Belgian study that the sequence of events in manifestation of CD after endometriosis is high variable including persistence of intestinal endometriosis[11]. In addition, the strong mixture of the two histological patterns as demonstrated here raises the possibility that intestinal CD lesions are secondary involved by intestinal endometriosis. This hypothesis could be further substantiated by anamnestic data of our patient, where CD was assumed years ago, but (intestinal) endometriosis was never assumed.

Non-invasive diagnostic separation of intestinal endometriosis and CD raises several problems. This is due to the fact that both diseases may affect the bowel and may cause abdominal pain. They are associated with inflammation, tissue induration, wall thickening and structuring. In addition, both diseases have a known fairly long delay from onset to diagnosis. Immunological features of endometriosis, including serological alterations as raised cytokine levels, decreased cell apoptosis, B- and T-cell abnormalities are comparable to those seen in CD[12].

Finally, it has to be stressed that intestinal endometriosis and CD are important differential diagnoses in view of therapeutic procedures. Pharmaceutical therapies are completely different between intestinal endometriosis and CD. Concerning surgical intervention it should be stressed that intestinal segment resection could be therapeutic in intestinal endometriosis, whereas in CD patients resections are always symptomatic treatment.

Here we demonstrate the rare constellation of a strong mixture of florid intestinal endometriosis and CD in the terminal ileum of a 35-year-old patient. Our findings suggest that the putative link between the pathogenesis of both entities is more complex than previously assumed.

Abstract

We report on a 24-year-old male patient with history of bloody diarrhea, abdominal pain and vomiting. Endoscopy revealed massive ulcerative discontinuous proctosigmoiditis with deep, sharply demarcated epithelial denudations and enterotoxigenic methicillin-resistant *Staphylococcus aureus* (MRSA) was detected in mucosal biopsies. After treatment with linezolide and steroids, a significant amelioration of colitis was detected and testing for MRSA became negative. In face of the case presented here, we suggest that in patients with refractory inflammatory bowel disease (IBD), microbiological assessment should be performed to detect a possible *Staphylococcus aureus* infection in order to initiate an antimicrobial treatment in addition to IBD-specific treatment.

Key words: Inflammatory bowel disease; Crohn's disease; Infectious colitis; *Staphylococcus aureus*; Methicillin-resistant *Staphylococcus aureus*

Core tip: The case presented here displays the complex situation of Crohn's disease aggravated by an intestinal bacterial infection, which is a commonly observed clinical scenario. However, the presence of enterotoxigenic methicillin-resistant *Staphylococcus aureus* (MRSA) in colonic mucosal biopsies is a very rare finding. Nevertheless, in face of the increasing prevalence of MRSA infections, clinicians should be aware of unusual opportunistic infections demanding a sophisticated antimicrobial screening and treatment to be combined with inflammatory bowel disease - specific medical therapy.

INTRODUCTION

Patients with inflammatory bowel disease (IBD) are hospitalized more frequently compared to the general population. In addition, regular use of antibiotics and immunomodulating drugs further increase the patients risk to acquire antimicrobial resistant organisms. Recently, Nguyen *et al*[1]. demonstrated a 1.4-fold increased prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) colonisation of hospitalized IBD patients as compared

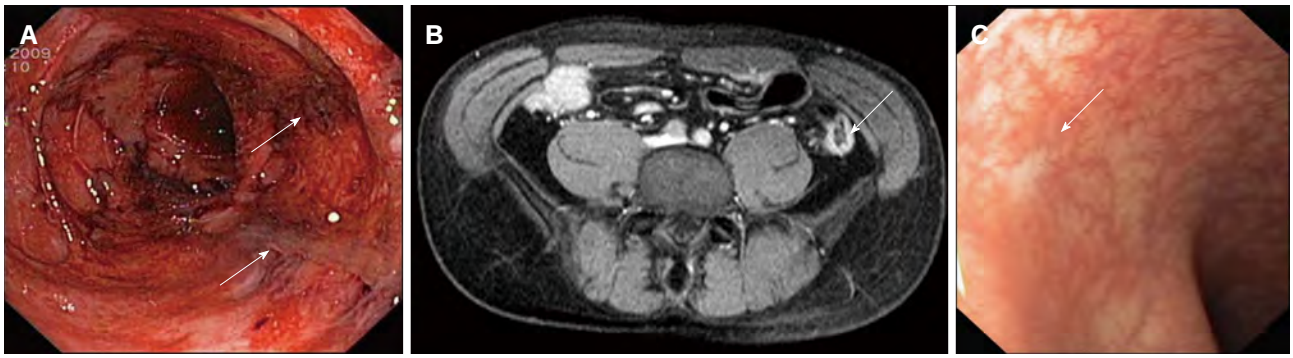

Figure 1 Massive colonic inflammation was detected by endoscopy and magnetic resonance imaging and ameliorated after antibiotic treatment. A: Sigmoidoscopy of the distal colon: Massive ulcerative proctosigmoiditis in a discontinuous pattern with deep and sharply delineated epithelial denudations (arrows) could be detected; B: Magnetic resonance imaging of the abdomen: contrast enhancement of the colonic wall in the area of the descending colon indicated inflammatory changes (arrow); C: Flexible sigmoidoscopy after ten days of antibiotic therapy with linezolid: Macroscopically, a near-total mucosal healing of colitis was detectable (arrow).

to general medical patients. This was associated with a seven-fold relative increase in in-hospital mortality. However, the clinical impact of intestinal MRSA infection on the course of IBD still remains unclear.

CASE REPORT

We report on a 24-year-old male Caucasian pig farmer who was transferred to our hospital with history of bloody diarrhea, abdominal cramping and vomiting for a 3-mo period. The preliminary diagnosis in the referring hospital was Crohn's disease (CD). However, the patient had not received neither immunosuppressive treatment nor steroid medication when he was admitted to our department. Physical examination provided no evidence of tenderness or a pathological abdominal mass. There were no signs of suspicious peripheral lymph nodes. Laboratory findings showed elevated values of inflammatory parameters, including elevated CRP (5 mg/dL) and leukocyte count (13.000/μL) as well as marked anemia (hemoglobin, 7.6 g/dL). Blood cultures for bacteria and polymerase chain reaction (PCR) results for cytomegalovirus (CMV), adenovirus, epstein-barr virus, herpes simplex virus type (HSV)-1, HSV-2 and varicella zoster virus were negative. Ultrasonographic examination of the abdomen revealed a thickened wall of the terminal ileum. On our ward, the patient collapsed due to anemia caused by rectal bleeding requiring blood transfusion. Esophago-gastro-duodenoscopy detected gastritis and a duodenal ulcer without evidence for *Helicobacter pylori* growth. Histological examination was without any signs of specific inflammation. To evaluate the severity of colonic inflammation, sigmoidoscopy was performed, revealing massive ulcerative proctosigmoiditis in a discontinuous pattern with deep, sharply delineated epithelial denudations (Figure 1A). Biopsies showed a massive infiltrate of inflammatory cells in the mucosa as well as in the submucosa resembling acute Crohn's colitis, however, granuloma formation was absent. CMV antigen and RNA was undetectable in mucosal biopsies. Furthermore, stool examination was negative for *Clostridium difficile*, *Salmonella spp.*, *Shigella spp.*, *Campylobacter spp.* and *Yersinia enterocolitica* as well as for helminth eggs and protozoan parasites, including *Giardia lamblia*. Therefore, the patient initially did not receive antimicrobial treatment. Magnetic resonance imaging of the abdomen showed inflammatory changes, predominantly in the area of the descending colon and the left colonic flexure (Figure 1B). Finally, microbiological assessment of four mucosal biopsies indicated growth of MRSA in all biopsies obtained. The MRSA was found to belong to *spa*-type t003. The strain was tested PCR-positive for *sed* encoding the staphylococcal enterotoxin D. Other pyrogenic toxin superantigen genes (*tst*, *sea*, *seb*, *sec* and *see*) as well as the exfoliative (epidermolytic) toxin encoding genes (*eta* and *etb*) and the genes encoding Panton-Valentine leukocidin (PVL) were tested negative applying sets of multiplex PCRs as previously described[2,3]. Remarkably, MRSA was found solely in perianal skin swabs, but not in swabs obtained from nostrils, scalp, axilla, and groin. We decided to commence antibiotic treatment with linezolid (600 mg *iv* bid). Additionally, steroid therapy with 100 mg prednisolone daily *iv* was continued. Furthermore, a decolonization therapy for MRSA was performed. Within days, the patient's clinical condition improved. After 10 d, a further sigmoidoscopy was performed revealing near-total mucosal healing of colitis. Histologically, moderate inflammatory infiltrations were found to be remaining. Diagnostic follow-up was conducted one month later. Meanwhile, the clinical symptoms had improved significantly. Abdominal pain and diarrhea were no longer present. Blood test results for blood count and CRP were normal. Esophago-gastro-duodenoscopy provided neither macroscopical nor histological evidence of inflammation. The duodenal ulcer was no longer detectable. Complete ileo-colonoscopy was performed displaying discrete pancolitis with mucosal friability and reduced vascular pattern. In the distal colon, multiple pseudopolypoid lesions were detectable, along with fibrin-coated ulcers as a correlate of inflammatory changes. The histological examination of colonic biopsies was again indicative of discrete discontinuous colitis resembling findings typical of CD. Microbiologic testing of

mucosal specimens and all skin swabs (including perianal) was now negative for MRSA. Again, no sign of CMV infection was found. Consecutively, the steroid medication was tapered.

Six weeks later, follow-up flexible sigmoidoscopy was performed. No acute inflammatory changes were detectable (Figure 1C). Histologically, mild signs of acute and chronic inflammation with interspersed crypt abscesses were found. At this time, the patient was on 5 mg prednisolone daily and had no complaints. Repeat MR enteroclysis was without signs of small intestinal IBD. Endoscopic follow-up 3 mo later again was showing complete mucosal healing. Histology was indicative of changes in the mucosa as well as a small hyperplasic polyp of the rectosigmoid colon. No signs of an acute flare-up occurred in a follow-up of further 12 mo. In addition, MRSA rescreening by nasal swabs applying polymerase chain reaction was performed and yielded negative results.

DISCUSSION

Staphylococcus aureus (*S. aureus*) is a leading cause of human bacterial infections worldwide aggravated by the continuing threat of multi-resistant strains as represented by the different clonal lineages of MRSA. It is estimated that 30% of healthy individuals are colonised with commensal *S. aureus* in their anterior nares that were found to represent the major source and an independent risk factor for subsequent nosocomial infections[4]. Inadequate antibiotic prescribing and poor adherence to infection control guidelines are the two main reasons for the development and spread of MRSA[5]. While the percentage of MRSA among *S. aureus* clinical isolates is believed to be 35%-70% in the United States[6], pan-European surveillance data on bloodstream infections showed marked variability in the proportion of MRSA ranging from less than 1% to more than 50%[7].

In the context of IBD, the presence of opportunistic infections and infections is of special interest, since infections were found to trigger an acute disease flare[8]. Moreover, the occurrence of opportunistic infections in patients with IBD has become a key safety issue especially with widespread use of immunosuppressive and immunomodulatory drugs[9]. Recently, it was shown that the use of any anti-inflammatory drugs such as corticosteroids, thiopurines, and anti-tumor necrosis factor alpha agents (*e.g.*, infliximab) is associated significantly with an increased risk of opportunistic infection in IBD patients[10]. In addition, the number of immunosuppressive agents combined appears to determine the individual risk of opportunistic infections[10].

Since the course of IBD is often chronically relapsing, IBD patients are frequently hospitalized and, thus, are at higher risk of hospital-associated infections[1]. Dysregulated barrier function of the intestinal surface epithelial lining is believed to represent a key factor for mucosal bacterial invasion. In active IBD, a disrupted epithelial barrier could therefore predispose for colonic *S. aureus* infections. In literature, only few reports on the possible correlation between IBD and MRSA infection are reported. One report published by Ishiyama *et al*[11] described an MRSA-associated diarrhea with positive stool cultures in patients after colorectal surgery. Recently, a first systematic analysis regarding this topic was performed by Nguyen *et al*[1]. It could be demonstrated that hospitalized IBD patients are at increased risk for MRSA infection as compared to non IBD-gastrointestinal and general medicine patients. Moreover, Nguyen *et al*[1] showed that the presence of MRSA is associated with seven-fold increased in-hospital mortality in the cohort of IBD patients. Further recognized risk factors for MRSA infection include bowel surgery, parenteral nutrition, and long hospitalization.

In our patient, the severe onset of the first acute flare of CD is striking and unusual. Endoscopically and histologically, massive inflammatory changes were present which resulted in relevant GI bleeding with anemia and hypotension. Furthermore, it is remarkable that microbiological testing for MRSA was completely negative except in specimens from colonic mucosa and perianal skin swabs. Lu *et al*[12] showed that *S. aureus* enterotoxins B might be associated with acute inflammatory response in mice. The detection of the enterotoxin D encoding gene in the patient's MRSA isolate makes a toxin-associated trigger of colitis plausible. It is likely that the presence of MRSA in our patient was no simple coincidence but a factor further worsening the disease course. This hypothesis is substantiated by the observation that the treatment with MRSA active antibiotic was accompanied by a rapid amelioration of colitis with mucosal healing.

Although the patient is working as a pig farmer, the MRSA subtype found in this patient belongs to a typical epidemic hospital-acquired MRSA clone and does not belong to the known livestock-associated clonal lineages (CC011/ST398). The relationship to the pig farming seems not to be epidemiologically relevant in this case and an earlier contact to healthcare seems more plausible as a source of colonization. In IBD patients, the risk of severe disease course may be increased. Yet, future studies are needed to define the putative connection between *S. aureus* and the course of IBD, the influence of the production of staphylococcal enterotoxins on IBD course, and if co-infection with (enterotoxigenic) *S. aureus* may be a predictor for severe disease course in IBD patients.

In case of refractory courses of IBD, microbiological assessment should be considered to rule out opportunistic *S.aureus* infection in order to initiate an antimicrobial treatment in addition to the IBD-related treatment.

Abstract

Unlike hepatic haemorrhage following blunt abdominal trauma, spontaneous abdomen bleeding is rare, even in the presence of a hepatocellular adenoma (HA) or carcinoma. However, the diagnosis of a tumour underlying a haematoma after liver trauma is unusual, especially when it occurs more after two years after the accident. Here, we report a case of a ruptured HA due to blunt abdominal trauma. A 36-year-old woman was admitted to our hospital with sudden onset of upper abdominal pain. Her medical history revealed a blunt abdominal trauma two years prior. Initial abdominal computed tomography scan revealed a large haematoma measuring more than 16 cm in diameter in the right lobe of the liver. Magnetic resonance imaging showed haemorrhagic areas and some regions with hepatocyte hyperplasia, suggesting HA. The patient underwent right hepatic lobectomy, and a histopathological examination confirmed a diagnosis of HA. In conclusion, it is important to consider that abdominal trauma may hide old, asymptomatic and not previously detected injuries, as in the case reported.

Key words: Hepatic adenoma; Treatment; Hemoperitoneum; Trauma; Computed tomography

Core tip: This paper clarifies that surgical liver diseases should be evaluated by experts at specialized centers. In addition, experts should pay attention to unusual situations as reported. Asymptomatic liver tumors are more common than imagined, even when presented underlying other acute disease, such as blunt trauma.

Cotta-Pereira RL, Valente LF, De Paula DG, Eiras-Araújo AL, Iglesias AC. Rupture of a hepatic adenoma in a young woman after an abdominal trauma: A case report. *World J Gastroenterol* 2013; 19(27): 4422-4426 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4422.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4422

INTRODUCTION

Hepatocellular adenoma (HA) is rare, benign lesion occasionally found in young women with a long-term history of oral contraceptive use[1-3]. However, there are other predisposing factors, such anabolic androgenic steroids (AAS) use[4], diabetes mellitus, beta-thalassemia and glycogen storage disease[5-7].

The majority of patients with HA are asymptomatic, but the occurrence of large and multiple adenomas

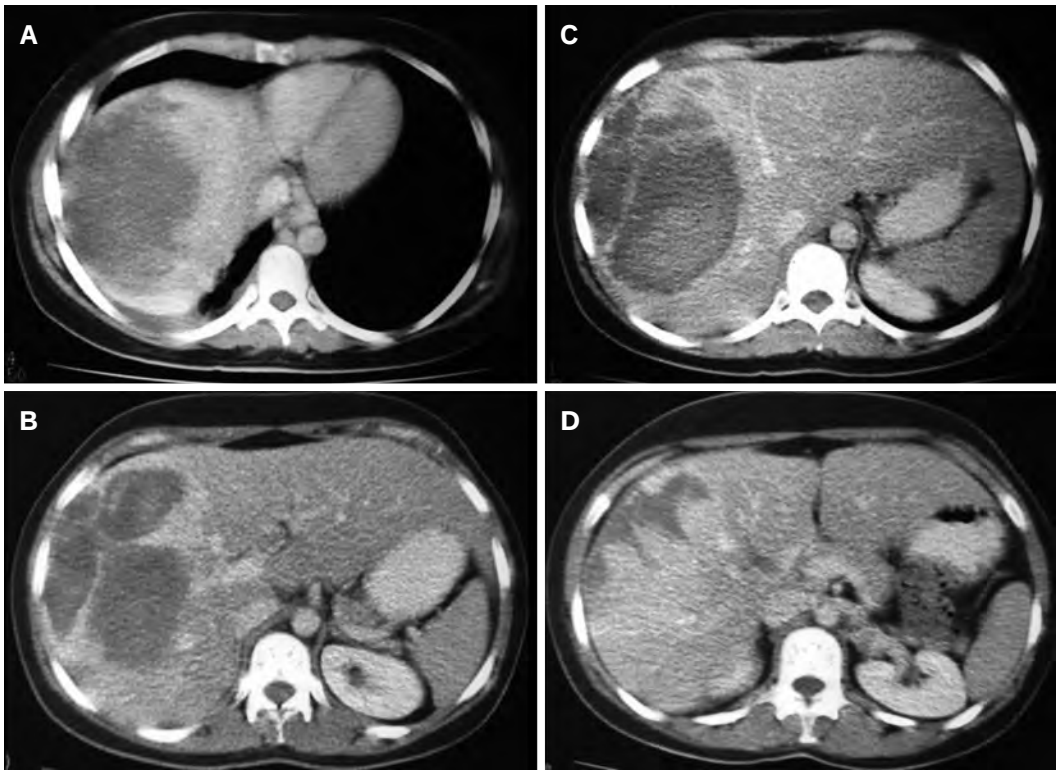

Figure 1 Unenhanced computed tomography scan showing liver injury with bleeding area, but also with areas of contrast enhancement. A-D: The existence of bleeding denotes a hepatic laceration, but the presence of vascularization reinforces the presence of a focal lesion.

is frequently associated with complications. The most important complications of HA are haemorrhage and malignant transformation into hepatocellular carcinoma (HCC), but the underlying pathophysiology is not fully known. Some data suggest that HA patients with beta-catenin mutations are more likely to undergo malignant transformation[8-10]. Symptomatic patients usually present with right upper quadrant pain secondary to HA bleeding, which can present as internal haemorrhage with necrotic changes (mostly observed in adenomas > 4 cm) or spontaneous rupture that causes subcapsular haematoma and possible haemoperitoneum[11].

In clinical practice, ultrasound (US), computed tomography (CT) and magnetic resonance imaging (MRI) are used to determine the diagnosis, but it is difficult to accurately distinguish between HA and other lesions, such as focal nodular hyperplasia (FNH). In such cases, a liver biopsy is sometimes necessary to establish a diagnosis[11,12]. It is important to emphasise that the presence of HA in trauma situations is quite rare[13].

CASE REPORT

A 36-year-old woman visited our hospital for evaluation of her abdominal discomfort and anaemia. Her past medical history revealed a fall down the stairs of her building two years prior. At that time, the patient was admitted to a tertiary hospital and underwent laboratory blood tests, US and CT (Figure 1). The diagnosis was haematoma after liver trauma, and a conservative treatment approach was proposed. No surgery or drainage was required. The patient was discharged after seven days and was referred for follow-up care. Two years after the accident, the patient had non-specific abdominal pain in the right hypochondrium and symptomatic anaemia. Upon physical examination of the patient at our hospital, tenderness in the upper right quadrant and a palpable mass were detected. CT revealed a large mass with areas of low attenuation in segments Ⅵ, Ⅶ and Ⅷ of the right lobe of the liver (Figure 2A). Laboratory exams revealed slight alterations of liver function (alanine aminotransferase: 132.30 IU/L, aspartate aminotransferase: 37.40 IU/L) and elevated alkaline phosphatase (20049 IU/L), but the levels of gamma-glutamyl transferase, total and fractionated bilirubin, cholinesterase, glycaemia and serum electrolytes were all within normal limits. The results of coagulation tests were entirely normal, as were the alpha-fetoprotein serum levels. Hepatitis virus markers, including hepatitis B and C, were negative.

A CT scan revealed a large, complex lesion in the right lobe of the liver with two distinct components. The upper component was moderately hyperdense with an attenuation coefficient of 52.4 UH and was not enhanced on a contrast-enhanced CT scan, suggesting liquefaction due to bleeding (Figure 2A and C). The lower component of the lesion was solid, markedly hypervascular and nourished via calibrous branches of the right hepatic artery (Figure 2B and D). There was no evidence of traumatic damage to the right thoracic-abdominal wall. The cutaneous, subcutaneous, muscular and osseous planes had

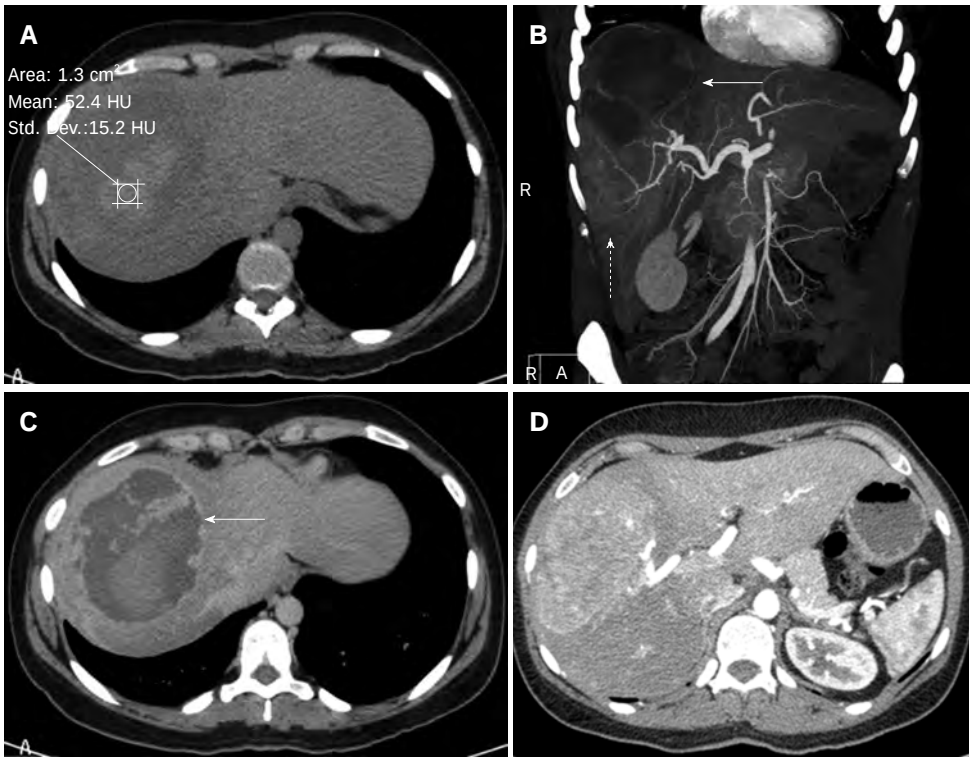

Figure 2 Computed tomography. A: Unenhanced computed tomography (CT) scan showing the upper component of the lesion with a relatively high density of 52.4 UH, suggestive of bleeding; B: Contrast-enhanced CT in the coronal plane showing both components of the lesion. The upper portion (arrow) has a low density due to the absence of impregnation. The lower component (dotted arrow) is solid and hypervascular with internal calibrous arteries; C: Contrast-enhanced CT. The haematic component illustrates a contrast-enhanced capsule (arrow); D: Contrast-enhanced CT. The study after contrast in the arterial phase at the level of the solid component exhibits an area with greater permeability than the liver, suggestive of hypervascularity.

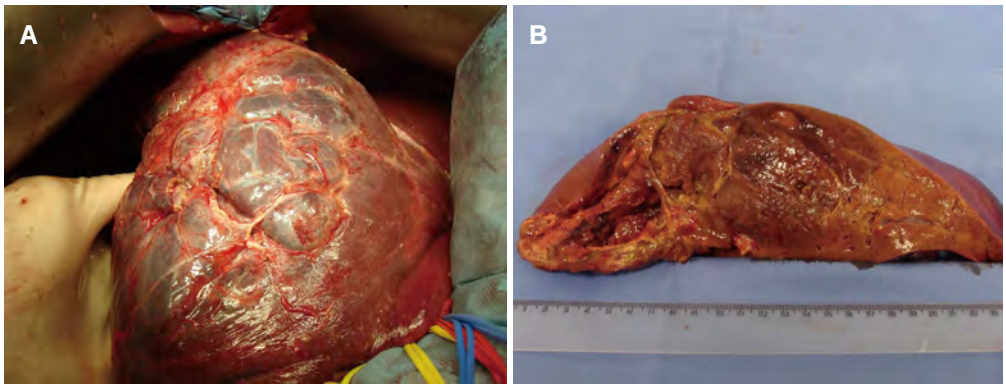

Figure 3 Entire right lobe of the liver. A: Intraoperative image of the lesion. Mobilised liver after ligament release, demonstrating the heterogeneous mass occupying almost the entire right lobe of the liver (segments Ⅵ, Ⅶ and Ⅷ), which was partially exophytic; B: Resected and sagittally cleaved surgical section at the transition between segments Ⅶ-Ⅵ and Ⅷ-Ⅴ. Note the adenomatous lesion with cavernomatous and haemorrhagic areas.

normal anatomy and densities. These features suggest the possibility of a pre-existing hepatic lesion associated with bleeding, which may or may not have been facilitated by the traumatic event. The CT images also showed signs of cirrhosis. These data, along with the age and sex of the patient, were suggestive of a diagnosis of bleeding HA.

We identified a heterogeneous mass with soft tissue density occupying almost the entire right lobe of the liver (Figure 3). The patient underwent right hepatectomy, and the surgical specimen was sent for pathological analysis. There were no postoperative complications, and the patient was discharged five days after surgery.

Histopathology examination revealed an HA with focal areas of haemorrhage (Figure 4). The lesion showed a heterogeneous pattern, indicating the existence of haemorrhagic areas in the tumour. The presence of a heterogeneous liver mass with internal haemorrhage and/or haemoperitoneum was suggestive of HA.

DISCUSSION

The treatment of blunt liver trauma has changed in the last several years, and conservative management is often prioritised over surgical treatment, even in patients with severe hepatic trauma[14,15]. The use of helical CT in the diagnosis and management of trauma injuries allows the option for nonsurgical treatments[15]. The American Association for the Surgery of Trauma (AAST) developed a CT-based liver injury grading system that allows physicians to select the best treatment option based on the imaging parameters[14-17]. Nonoperative treatment and detection of complications is based on clinical signs [*e.g.*, pain, meteorism, pulse, tension, urine, ventilation and biochemical tests (*e.g.*, haematocrit, haemoglobin and hepatic constants)]. This follow-up can take place in the intensive care unit and includes blood gas analysis and intra-abdominal pressure management[17]. Still, delayed laparotomies and late complications can occur, and the decreased rates of morbidity and mortality indicate that conservative options are better, even for patients with major liver trauma[14-19]. In our article, we point to an unusual event, which is the possibility of misdiagnosis following trauma.

Hepatic masses can exist prior to blunt abdominal trauma[20], and hepatic incidentalomas are not uncommon. As previously reported, the patient described herein already had a large adenoma when the trauma occurred, which resulted in rupture of the mass. Because she was seen at a centre that does not specialise in hepatic surgery, the correct diagnosis was not made, which could have been fatal[20]. The imaging diagnosis was a hepatic lesion (laceration/haematoma) due to trauma. Admittedly, adenomas may rupture spontaneously[13,18], and their propensity to haemorrhage is explained by their histological features.

Adenomas consist of large plates or cords of dilated sinusoids with poor connective tissue support. Classically, HA is a soft, well-demarcated tumour with little or no fibrous capsule and is composed of hepatocyte plates that are only mildly thickened and irregular. The tumour parenchyma is supplied by thin-walled arteries with minimal connective tissue[10-14,18]. Therefore, trauma to an adenoma most likely enhances their tendency to haemorrhage. Furthermore, it should be remembered that HA greater than 5 cm the indication for surgery should be given because of the high risk of tumor-related complications[21].

Currently, CT is the most frequently used modality in evaluating patients with liver injuries; it is a key element in the initial evaluation of haemodynamically stable patients who have suffered abdominal traumas[1-3]. Dramatic advances in multi-detector technology have significantly improved the accuracy of CT and dynamic contrast-enhanced CT, which can identify imaging characteristics of intrahepatic lesions, especially for rare changes caused by uncommon disease entities[1,4]. Emphasis should be laid on detecting the haemoperitoneum, then localising the source of bleeding and finally detecting the primary cause.

Spontaneous hepatic bleeding not related to trauma or anticoagulant therapy is a rare condition. This situation can be caused by underlying liver disease. Common causes are non-traumatic are HA or HCC. CT scans may be able to characterise and localise bleeding and to identify the underlying liver lesion[12]. Therefore, it is important to note that seemingly harmless blunt abdominal trauma may be very damaging when it is associated with an underlying hepatic lesion.

In conclusion, we note the importance of referring patients with liver trauma and possible hepatic disorders to specialised centres for the appropriate treatment.

Abstract

Endoscopic retrograde cholangiopancreatography (ERCP) using a double-balloon enteroscope (DBE) in patients with bowel reconstruction due to a previous abdominal surgery is now widely accepted. In particular, a short DBE, which has a 2.8-mm working channel and 152-cm working length, is useful for ERCP because of its good rotational and straightening ability and the availability of various conventional ERCP accessories through the working channel. Herein we report a case of intrahepatic cholangiocarcinoma *via* ERCP with a short DBE. This is the first report in which the pre-cutting and the brush cytological examination were performed successfully under a DBE to diagnose intrahepatic cholangiocarcinoma pathologically. The short DBE allowed us to perform all diagnostic and therapeutic procedures accepted in conventional ERCP in patients with surgically altered anatomies.

Key words: Double-balloon enteroscope; Diagnosis; Endoscopic retrograde cholangiopancreatography; Intrahepatic cholangiocarcinoma; Cytology

Core tip: This is the first report in which the pathological diagnosis of intrahepatic cholangiocarcinoma could be made using the brush cytological examination *via* endoscopic retrograde cholangiopancreatography with a double-balloon enteroscope (DB-ERCP). In this paper, the methods of these procedures during DB-ERCP such as biliary cannulation, pre-cutting, and cytological examination are demonstrated in detail. Therefore, we believe that this paper must expand awareness of the utility of DB-ERCP for diagnosis of pancreatobiliary disease in patients with bowel reconstruction due to a previous abdominal surgery.

INTRODUCTION

Performing endoscopic retrograde cholangiopancreatography (ERCP) using a conventional duodenoscope in patients with bowel reconstruction due to a previous abdominal surgery is challenging because it is frequently

impossible to reach the papilla or the hepatico/choledochojejunal and pancreaticojejunal anastomosis owing to the insufficient scope length and unusual postsurgical conditions such as intestinal adhesions and anastomosis angulation. However, the use of a double-balloon enteroscope (DBE), which was originally developed for the management of small bowel diseases[1], has been shown to make it more feasible to perform ERCP in patients with bowel reconstruction[2-7]. Recently, ERCP using a DBE (DB-ERCP) is now widely accepted. In particular, a short DBE, which has a 2.8-mm working channel and 152-cm working length, is useful for ERCP because of its good rotational and straightening ability and the availability of various conventional ERCP accessories through the working channel. ERCP using a short DBE was reported to be useful and safe for diagnostic and therapeutic interventions such as sphincterotomy, stone extraction, and stent placement[8-11]. In this paper, we report a case of a post-surgical patient diagnosed as having intrahepatic cholangiocarcinoma *via* ERCP with a short DBE. We aimed to demonstrate the feasibility of successfully achieving access to the biliary duct by pre-cutting under a DBE and obtaining the pathological diagnosis by tissue sampling *via* DB-ERCP.

CASE REPORT

A 74-year-old man, who had undergone partial gastrectomy with gastrojejunostomy and Roux-en-Y reconstruction for gastric carcinoma five years before, presented to another hospital to evaluate a mass lesion in hepatic segment Ⅷ. A fluorine-18-fluorodeoxyglucose positron emission tomography scan revealed a pathological uptake pattern with a maximum standardized uptake value of 5.6 in the mass, suggestive of a malignant tumor. An ultrasound-guided percutaneous needle biopsy was performed to obtain a pathological diagnosis of the mass. However, the biopsy finding revealed no sign of malignancy. In addition, the patient developed biliary peritonitis after the liver biopsy and therefore required hospitalization and conservative treatment for approximately 1 mo. One month after discharge from the hospital, an ultrasound image revealed the mass lesion remained constant in size; however biliary stricture with upstream dilatation, which appeared to result from the mass lesion, was noted on magnetic resonance cholangiopancreatography (MRCP). Hence, he was referred to our hospital to undergo evaluation for malignancy by tissue sampling from the biliary stricture.

On admission, the patient was asymptomatic. The physical examination results were unremarkable. He had no history of alcohol abuse. The serum examination results indicated that the levels of the tumor markers and transaminase in the liver were within normal limits. T2-weighted magnetic resonance imaging showed a slightly hyperintense lesion around the dilated intrahepatic duct in segment Ⅷ (Figure 1A). On MRCP, a focal biliary stricture with upstream dilatation in the branch arising from the right anterior duct was observed (Figure 1B). The patient underwent ERCP with a short DBE (EC-450BI5; Fujifilm, Osaka, Japan) in the prone position with carbon dioxide (CO_2) insufflations. At first, a short DBE was carefully inserted into the blind loop and reached the papilla. Subsequently, standard biliary cannulation using a straight cannula (PR-10Q; Olympus, Tokyo, Japan) was attempted after the papilla was moved to the lower endoscopic field of view by keeping the overtube balloon inflated and rotating the enteroscope (Figure 2A), as described in a previous report[8]. However, we were unable to obtain cholangiography, but only pancreatography. Therefore, a 0.025-inch guide wire (Jagwire; Boston Scientific Japan, Tokyo, Japan) was inserted into the main pancreatic duct (Figure 3A), and the pre-cut technique was carried out with a wire-guided sphincterotome (Autotome RX, Boston Scientific, Japan). The incision was started toward the biliary direction and was stopped at the lower one-third of the ampullary mound (Figure 2B). After the incision, the orifice of the biliary duct became visible (Figure 2C), and selective biliary cannulation with a straight cannula was performed successfully (Figure 3B). After contrast enhancement of the biliary duct, a focal stricture in the branch of the right intrahepatic duct was identified under radiographic guidance (Figure 3C). A guide wire followed by a cannula was successfully passed through the stricture after several negotiations (Figure 3D). Subsequently, tissue sampling for cytological examination was performed at the level of the stricture using a brush device (Cytomax Ⅱ DLB 35-1.5; Cook, Osaka, Japan) introduced by a guide wire (Figure 3E). Finally, the nasobiliary drainage tube was placed at the distal side to collect the bile for cytological examination (Figure 3F). The day after the ERCP, a slight increase in the serum amylase level was observed, but the patient did not complain of abdominal pain. The result of the cytological examinations of the sample obtained by the brush and nasobiliary drainage tube was positive for malignancy. On the basis of the cytological finding, the patient underwent segmentectomy of the

A: A guide wire was inserted deeply into the main pancreatic duct to perform the pre-cutting; B: After the pre-cutting, selective biliary cannulation was achieved; C: Cholangiography revealed a focal stricture in the branch of the right intrahepatic duct (arrow); D: A guide wire was passed through the biliary stricture; E: The brush cytological examination was carried out at the stricture; F: The placement of nasobiliary drainage tube was performed to collect the bile for cytology.

left lobe. The final pathological report indicated intrahepatic cholangiocarcinoma.

DISCUSSION

With the advent of DBEs, the endoscopic management of pancreaticobiliary diseases has become more feasible in patients with previous gastrointestinal surgery such as Billroth Ⅱ gastrojejunostomy, Roux-en-Y reconstruction, and Whipple's resection[2-6]. Accordingly, in these years, the number of published reports on the utility of DB-ERCP has been increasing. In most of these previous reports, a standard DBE (EN-450T5; Fujifilm)[2-6] and a single-balloon enteroscope[7] were used. However these enteroscopes have a limitation with regard to the availability of its accessories because of its 200-cm working length. In contrast, a short DBE has a 2.8-mm working channel and 152-cm working length, for which various diagnostic and therapeutic accessories used in conventional ERCP, including sphincterotome, balloon catheter, basket, biopsy forceps, brush, intraductal ultrasonic probe and biliary stent, are available without modification[8-11].

The use of a short DBE appears to not only widen the parameters of the procedures which we can perform in DB-ERCP, but also increase the success rate of the procedure owing to its good maneuverability. In fact, with a short DBE, we reported higher success rates in deep insertion [100/103 (97%)], cholangiography [98/100 (98%)], and therapeutic interventions [98/98 (100%)], compared with the previous reports[8].

Deep cannulation to the biliary duct is the most important step for successful ERCP. The failure rate for cannulation of the naive papilla in conventional ERCP is reported to be up to 10% of the ERCP procedures[12,13]. In general, this rate in DB-ERCP might be even higher because of the difficult location of the papilla and the instability of the manipulation of the enteroscope and cannula. In the case of a difficult biliary cannulation in conventional ERCP, the pre-cut techniques have been used as a widely accepted option to facilitate the biliary access[14,15]. The pre-cut techniques include needle knife sphincterotomy and wire assisted transpancreatic sphincterotomy. In contrast with conventional duodenoscopy, a DBE is forward viewing and has no elevator function, making the pre-cutting technically more challenging. From our experience, we recommend wire-guided transpancreatic sphincterotomy in performing the pre-cutting under a DBE, because the direction, depth, and length of incision are easier to control, compared with needle knife papillotomy performed freehand.

Although intrahepatic stricture frequently results from malignant disease such as cholangiocarcinoma and hepatocellular carcinoma, it is important to confirm the malignant cells histopathologically by the tissue sampling method, because an accurate diagnosis is crucial for the choice of an appropriate therapeutic strategy. In general, percutaneous needle biopsy is accepted for histological diagnosis when the mass causing the intrahepatic stricture can be detected on ultrasonography. However, the potential disadvantage of this technique is that complications such as pneumothorax, hemorrhage, biliary leakage, biliary peritonitis, and tumor seeding can occur[16,17]. In contrast, the transpapillary tissue sampling methods during ERCP include brush cytological examination, bile cytological examination, and biopsy. In particular, brush cytological examination is commonly used because it is relatively simple and safe. Although the specificity of this method for the diagnosis of cholangiocarcinoma is almost 100%, the sensitivity is by no means satisfactory, ranging from 44% to 81%[18]. In our institution, when brushing is performed, bile cytological examination is also performed *via* a nasobiliary drainage tube placed subsequently after brushing. We believe that such a combination of specimen collection methods enhances the cancer detection rate.

In conclusion, the short DBE allowed us to perform all diagnostic and therapeutic procedures accepted in conventional ERCP in patients with surgically altered anatomies.

Abstract

Positron emission tomography (PET) using ^{18}F-fluorodeoxyglucose (^{18}F-FDG) is an imaging modality which reflects cellular glucose metabolism. Most malignant cells accumulate and trap ^{18}F-FDG, allowing the visualisation of increased uptake. It is hence widely used to differentiate malignant from benign lesions. "False positive" findings of hepatic lesions have been described in certain instances such as hepatic abscesses, but are rare in cases involving hepatocellular adenomas. To our knowledge, there have been only 7 reports in the English literature documenting PET-avid hepatocellular adenomas; 6 of the 7 reports were published in the last 3 years with the first report by Patel *et al*. We report the case of a 44-year-old Chinese female patient with a history of cervical adenocarcinoma, referred for a hepatic lesion noted on a surveillance computed tomography (CT) scan. A subsequent CT-PET performed showed a hypermetabolic lesion (standardized uptake value 7.9) in segment Ⅳb of the liver. After discussion at a multidisciplinary hepato-pancreato-biliary conference, the consensus was that of a metastatic lesion from her previous cervical adenocarcinoma, and a resection of the hepatic lesion was performed. Histology revealed features consistent with a hepatocyte nuclear factor-1 α inactivated steatotic hepatocellular adenoma.

Key words: Hepatic adenoma; Positron emission tomography; ^{18}F-fluorodeoxyglucose; Hepatocellular adenoma; Hepatocyte nuclear factor-1 α

Core tip: This case illustrates a unique example of a false-positive finding on the computed tomography-positron emission tomography (CT-PET) due to a hepatic adenoma mimicking a metastatic lesion in the liver. It serves to highlight that not all CT-PET findings are associated with malignancy. In equivocal cases where CT-PET findings are discordant with other imaging modalities and/or clinical/biochemical features, further evaluation with different imaging modalities or novel PET tracers may be considered. This is especially pertinent in this day and age, where the PET scan is widely used in clinical practise to differentiate benign from malignant lesions, as well as a modality in cancer surveillance and staging.

Hepatic adenoma mimicking a metastatic lesion on computed tomography-positron emission tomography scan. *World J Gastroenterol* 2013; 19(27): 4432-4436 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4432.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4432

INTRODUCTION

Positron emission tomography (PET) using ^{18}F-fluorodeoxyglucose (^{18}F-FDG) is an imaging modality which reflects cellular glucose metabolism. In most malignant cells, the relatively low level of glucose-6-phosphate leads to accumulation and trapping of ^{18}F-FDG intracellularly, which in turns results in its visualization. As such, the PET scan is widely used for differentiating benign from malignant lesions, as well as a modality in cancer surveillance and staging. With regards to lesions in the liver, computed tomography (CT)-PET imaging classically shows increased uptake for moderately/poorly-differentiated hepatocellular carcinoma (HCC) and extra hepatic metastatic disease[1]. False-positive results have generally been described in hepatic abscesses, and false-negative results described in well-differentiated HCC[2].

Hepatocellular adenoma (HCA), also known as hepatic adenoma, is a benign tumor of the liver and the second most common benign liver neoplasm after focal nodular hyperplasia[3,4]. It occurs predominantly in women within their reproductive years with a male-to- female ratio of 1:8-10[5,6]. The estimated incidence is about 1 per million in women who have never used oral contraceptives (OCP), up to a significantly higher incidence of 30-40/million in long-term OCP users[3,4].

"False positive" findings in PET/CT are rare in HCA. To our knowledge, there have been only 7 reports in the English literature documenting PET-avid HCAs; 6 of the 7 reports were published in the last 3 years with the first report in 1997 by Patel *et al*[7-13].

CASE REPORT

A 44-year-old female patient, with a history of International Federation of Gynecology and Obstetrics stage IB2 cervical adenocarcinoma was referred to our hepato-pancreato-biliary (HPB) service for further management of a hepatic lesion noted on her surveillance CT scan (Figure 1). Her cervical adenocarcinoma was treated with a radical hysterectomy 6 mo prior to this presentation. The hepatic lesion measured 2.3 cm × 1.8 cm and was located in segment Ⅳb of the liver. A CT-PET was performed to further delineate the nature of the hepatic lesion and exclude extrahepatic metastases; the liver lesion appeared hypermetabolic with a standardized uptake value (SUV_{max}) of 7.9 (Figure 2). This was discussed at a multi-disciplinary HPB tumor conference and the consensus was that it was a solitary metastasis from the cervical adenocarcinoma without evidence of extrahepatic disease. In view of the patient's previous surgery and the need for a lymphadenectomy, a decision was made for open surgical resection of the liver lesion with a perihilar lymphadenectomy.

On presentation, the patient was asymptomatic and recovered well from her hysterectomy. Clinical examination was largely unremarkable. Laboratory results and tumor biomarkers were within normal ranges [liver function test, complete blood count, carcinoembryonic antigen, α-fetoprotein, carbohydrate antigen (CA) 19-9, CA125]. Her hepatitis B and C virology markers were negative. She had no family history of liver cancer or OCP usage.

Figure 1 Surveillance computed tomography scan showing hypodense lesion in segment IVb of liver. Cross-sectional image of the hypodense lesion in segment IVb of the liver (arrow).

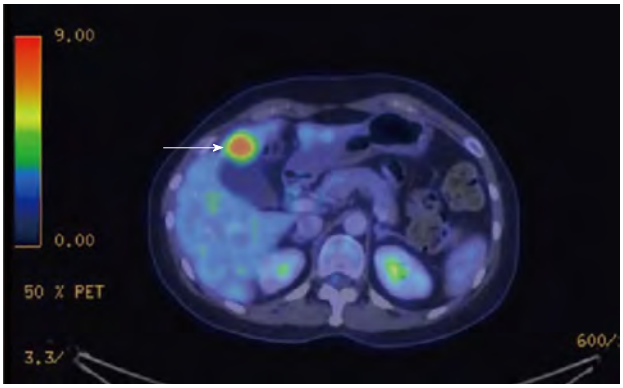

Figure 2 Computed tomography-positron emission tomography scan revealing the positron emission tomography avid lesion in segment Ⅳb of the liver. Cross-sectional image of the positron emission tomography avid lesion in segment Ⅳb of the liver (standardized uptake value 7.9) (arrow).

After exploration to exclude any peritoneal metastases, an open resection of this segment IVb hepatic lesion, cholecystectomy and perihilar lymphadenectomy was performed. A 3 cm × 2.5 cm segment IVb lesion was removed with clear margins. The patient recovered uneventfully.

Histology revealed a well demarcated lesion composed of bland uniform hepatocytes displaying clear vacuolated macrovesicular fat globules predominantly. No bile ducts, entrapped portal tracts or ecstatic vessels were identified. No central scar was seen. Reticulin staining showed normal trabeculae without expanded thickened areas. Glypican-3 was negative. Overall features were consistent with a hepatocyte nuclear factor-1 α (HNF-1α) steatotic adenoma (Figure 3). All lymph nodes excised were also negative for malignancy.

DISCUSSION

This case illustrates a unique example of a false-positive

finding on the CT-PET due to a HCA mimicking a metastatic lesion in the liver. Hepatic adenomas can be classified by their molecular phenotypes into four main groups: HNF-1α inactivation, β-catenin activating, inflammatory and unclassified[14,15]. The presence of the diffuse steatotic appearance and histological features in this case was consistent with a HNF-1α inactivated HCA. Radiological features of HNF-1α inactivated adenomas on Magnetic resonance imaging (MRI) include a diffuse signal dropout on T1-weighted chemical shift sequence, isosignal or slight hypersignal on T2-weighted images and moderate enhancement in the arterial phase, with no persistent enhancement in the portal venous and delayed phases. These appearances have been shown to have a high sensitivity and specificity for the diagnosis of steatotic adenomas[16,17].

There is an increasing importance in the role of FDG-PET in the evaluation of liver lesions to distinguish between benign and malignant. Its uses also include the surveillance, staging and monitoring of therapy for patients with cancer e.g. colorectal cancer. However, some of the limitations of PET/CT in evaluation of liver lesions are emerging[18,19]. The overall sensitivity of FDG PET/CT in detecting HCC is low with a reported range of 50%-65%, contributed mainly by the poor sensitivity in low-grade HCC[20,21].

The liver can have an unpredictable ^{18}F-FDG uptake[19]. Glucose-6-phosphatase enzyme and glucose transporter activity have a wide variation in HCC. As a further confounder, the liver is the major producer of non-dietary glucose and a major regulator of glucose homeostasis. This limitation of PET/CT in HCC handicaps the usefulness of PET/CT in the evaluation of HCA, as one of the major concerns of HCA is its malignant potential and it harboring a foci of HCC within[6].

This case highlights that not all "hot" hepatic lesions on the PET are associated with malignancy. Benign examples of high FDG activity in the liver include focal steatosis, hepatic adenomatosis (*e.g.*, inflammatory subtype) and infectious or inflammatory processes in the liver (*e.g.*, liver abscess, hepatic tuberculosis). These can consequently lead to "false-positive" PET results[10,19,22,23]. Due to the limitations of CT/PET as an imaging modality, it is not possible to distinguish a PET-avid HCA from a liver abscess or a hepatic tuberculoma solely from its features on CT/PET. Other information is required to make such a distinction, such as clinical history and laboratory investigations. For example, patients with liver abscess may have signs and symptoms of infection such as fever/chills and pain; liver function test may be mildly abnormal with leukocytosis and inflammatory makers such as C-reactive protein and erythrocyte sedimentation rate may be elevated. Patients with HCA will not have such signs/symptoms of infection but may have a history of OCP usage and tend to be females in the reproductive age group. There is no evidence in the literature to suggest that CT/PET alone can distinguish PET-avid HCA from a liver abscess/tuberculoma.

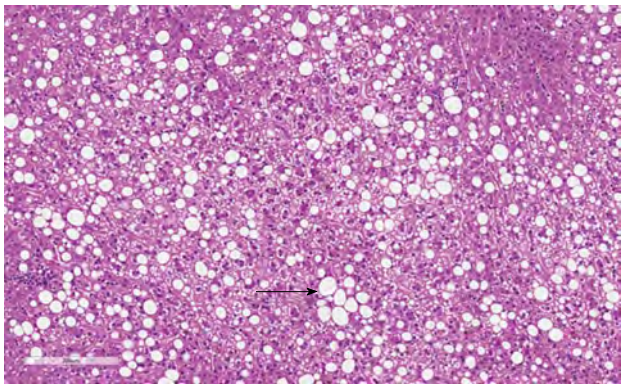

Figure 3 Representative histological slide of the hepatic adenoma. Medium power HE of the hepatic adenoma shows trabeculae with normal thickness composed of hepatocytes with moderate to severe steatotic changes (arrow) and bland uniform nuclei. No large cell or small cell change is identified. Notably, bile ducts, entrapped portal tracts or ecstatic vessels were absent. There is a circumscribed border without a thick capsule (HE, × 200).

Comparing our case to existing case reports of PET-avid HCAs in the literature, only 3 out of the 7 previous cases provided a detailed description of the histological findings[7-13]. Similar to our case, these 3 cases showed predominantly fatty change[8,9,11]. Of these 3 cases, only one report further classified the lesion as a HNF-1α hepatic adenoma[8].

Several hypotheses can explain the positive radiotracer uptake in such situations. In infections or inflammation, increased FDG uptake in lesions can be explained by the presence of inflammatory cells, which result in enhanced glucose metabolism or increased cell density[24-26]. However, pathological examination of the HCA in our patient revealed no evidence of inflammation. Also, none of the reported PET-avid HCAs in the literature included any of the inflammatory HCA subtype.

Radiotracer activity can increase at an early stage of malignant transformation and present as a "hot" lesion; activated β-catenin HCA has a higher malignant potential and may harbor small foci of HCC. In both our patient and the cases in the literature, none of the PET-avid HCAs were activated β-catenin mutated.

Focal fatty infiltration of the liver has been reported to be PET-avid. As a response to fat accumulation, a subacute inflammatory hepatic reaction with infiltration of activated Kupffer cells occur, resulting in a higher SUV_{max} than adjacent normal liver parenchymal[27,28]. Fat necrosis has been reported to have increased FDG uptake in benign lesions as well[29]. In the literature, 3 cases reported prominent fatty change but there was no mention of any inflammatory infiltrate (including our case), perhaps the fatty change itself was sufficient to evoke a PET-avid response without significant histological evidence of inflammatory infiltrate.

Lastly, hypervascularity of a HCA can induce an accumulation of glucose by the relative local increased blood flow to the lesion without a sufficient "washout". This hypothesis was suggested for HCA without any

evidence of inflammation, fatty content or malignant change[11].

In conclusion, hepatocellular adenomas are a heterogeneous group of liver benign neoplasms that are characterized by varied genetic and molecular abnormalities, pathology, tumor biology and radiological features. Positron emission tomography is increasingly utilized in cancer surveillance and work-up. This case highlights that "false-positives" can arise in case of benign liver lesions such as HCA. In equivocal cases where CT-PET findings are discordant with other imaging modalities, and/or clinical/biochemical features, further evaluation with different imaging modalities (*e.g.*, contrast enhanced sonography or MRI with liver-specific contrast) or novel PET tracers (*e.g.*, ^{11}C-acetate or ^{18}F-fluorocholine PET) should be considered[1,30-33].

Abstract

Hepatoid adenocarcinoma of the stomach (HAS) is a rare form of gastric cancer that has unique clinicopathological features and an extremely poor prognosis. Here, we report on three patients with suspected gastric cancer who were referred to our hospital. Gastrointestinal fiberscopy on the three patients revealed two lesions in the antrum and a third lesion in the gastroesophageal junction. The alpha fetoprotein (AFP) serum levels were markedly elevated in all cases. At the time of diagnosis, two cases were advanced stages with lymph nodes and/or liver metastases. Two patients underwent exploratory laparotomy. A total gastrectomy was performed on the operable lesion, and an expanded gastrectomy was completed in the case with hepatic metastases. Histopathological analysis revealed that the tumors displayed two pathological changes: hepatoid-like foci and adenocarcinomatous. Furthermore, the tumor cells were immunohistochemically positive for AFP, alpha-1 antitrypsin, and alpha-1 antichymotrypsin. All three patients received chemotherapy. The follow-up duration ranged from 8-36 mo. Our experience and previous published studies have suggested that HAS is an aggressive type of adenocarcinoma. However, radical surgery and chemotherapy may positively impact clinical outcomes.

Key words: Hepatic adenocarcinoma; Gastric cancer; Alpha fetoprotein; Prognosis; Stomach

Core tip: Hepatoid adenocarcinoma of the stomach is a rare but important type of gastric cancer that has unique clinicopathological features and an extremely poor prognosis. We analyzed the relationship between clinicopathological features, treatment courses and prognosis using three case reports combined with previously published studies.

INTRODUCTION

Hepatoid adenocarcinoma (HAC) is a rare type of extrahepatic tumor that has a morphological similarity to hepatocellular carcinoma (HCC)[1]. The first description of HAC was in the stomach, which is the most common location; however, HAC has been reported to develop in a variety of organs, such as gallbladder, lung, urinary bladder, esophagus, pancreas, peritoneum, Jejunum, colon, rectum, renal pelvis, ureter, ovaries, uterus and papilla of Vater[2-5]. Hepatoid adenocarcinoma of the stomach (HAS) is a relatively rare gastric carcinoma and

has an extremely poor diagnosis. Only a few cases have been previously reported. In this report, we describe three cases of HAS, and review the literature concerning its clinicopathological aspects.

CASE REPORT

Case 1

A 58-year-old Chinese male was admitted to our gastroenterology ward on February 12, 2010 with upper abdominal dull pain that had persisted for 1 mo. The patient had no relevant past medical history. The results of the physical examinations were unremarkable. A laboratory investigation showed that the patient's serum alpha fetoprotein (AFP) level was elevated to 5845 ng/mL. However, additional tumor markers were normal. Additionally, hepatitis B surface antigen and antibody and hepatitis C antibody were all negative. A gastroduodenoscopy revealed a gigantic mass with a central ulceration at the lesser curvature extending from the angle to the antrum of the stomach (Figure 1A). A gastric biopsy revealed poorly differentiated adenocarcinoma. Computed tomography (CT) scans of the abdomen and pelvis was performed and revealed thickening of the wall of the antrum, enlarged lymph nodes at the lesser curvature, multiple hepatic tumors in the bilateral lobes of the liver and tumor thrombus in the portal vein and its branches (Figure 2A and B). However, no cirrhotic change was observed in the liver. A diagnosis of AFP-producing gastric cancer with multiple liver metastases was made. The patient received systemic chemotherapies, including a regimen of four cycles of epirubicin-oxaliplatin-fluorouracil and a regimen of six cycles of oxaliplatin plus capecitabine. During the chemotherapy intermission, the liver metastases were treated with transcatheter arterial chemoembolization and CT-guided radiofrequency ablation. All treatments were provided by our gastric multidisciplinary team. These treatments resulted in partial remission (Figure 1B), and the patient's serum AFP levels decreased to 518.8 ng/mL. The CT scan showed that the patient's enlarged lymph nodes had decreased in size and that the liver metastatic foci were stable (Figure 2C and D). A distal gastrectomy with a lymph node dissection and a left lateral liver lobectomy was performed on June 11, 2011.

The distal gastrectomy resected a 2.0-cm gastric hepatoid adenocarcinoma at the lesser curvature, which infiltrated the muscularis propria (pT2) with no vascular invasion (V0). Additionally, a regional lymph node assessment revealed 16 lymph nodes with no cancer metastasis (pN0). However, there were several necrotic nodules in the left lateral lobe of the liver, but no cancer was detected. The histopathologic examination showed poorly differentiated adenocarcinoma with hepatoid features. The carcinoma was composed of polygonal tumor cells with abundant eosinophilic cytoplasm and round nuclei occasionally exhibiting obvious nucleoli with high mitotic activity. The tumor cells were arranged mainly in a trabecular pattern, whereas a smaller area of glandular formations was also observed (Figure 3A). Immunohistochemistry (IHC) revealed that the neoplastic cells were diffusely positive for alpha-1 antitrypsin (AAT), alpha-1 antichymotrypsin (ACT), cytokeratins 8, 18, 19 and carcinoembryonic antigen (CEA). Interestingly, many neoplastic cells showed cytoplasmic staining for AFP (Figure 4A). These IHC findings combined with the morphological features described above supported a diagnosis of HAS.

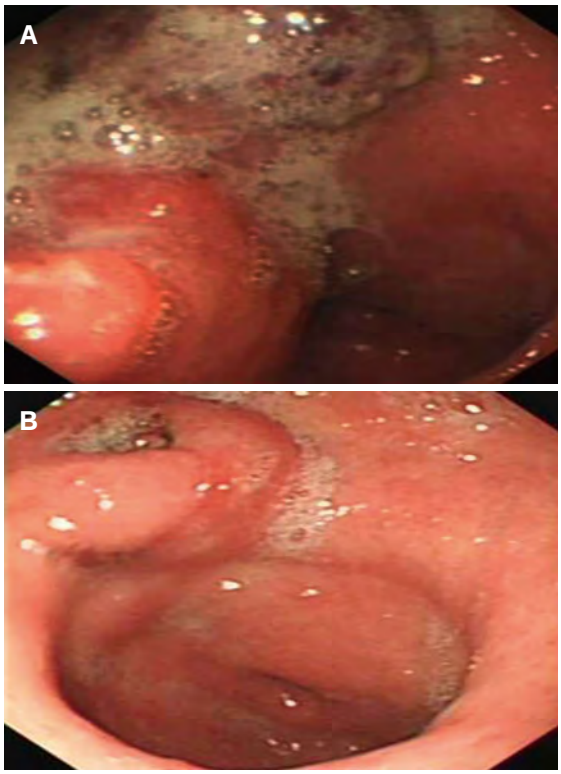

Figure 1 Endoscopic imaging of the gastric tumor. A: A gigantic mass with a central ulceration at the lesser curvature extending from the angle to antrum of the stomach; B: Partial remission of the gastric tumor after chemotherapy.

The patient recovered soon after surgery with no major complications. The total hospital stay for the surgical procedures was 15 d. Adjuvant chemotherapy with capecitabine was recommended, and the patient completed six cycles of chemotherapy. The patient's serum AFP levels returned to normal within one month post-surgery. No progress has been observed after reexamination with CT, and the serum AFP levels were stable at 20 mo post-surgery.

Case 2

A 54-year-old Chinese male presented to a local doctor with a one-month history of retrosternal pain. An endoscopy revealed an elevated tumor at the esophagogastric junction. Furthermore, a gastric biopsy discovered a poorly differentiated adenocarcinoma. The patient was referred to our hospital on March 3, 2011 for further examination. Upon physical examination, mild abdominal tenderness was detected under the xiphoid. A laboratory investigation showed that the patient's serum AFP levels were elevated to 858.1 ng/mL. Furthermore, the results

A and B: Computed tomography-scan revealing thickening of the wall of antrum, enlarged lymph nodes at the lesser curvature, multiple hepatic tumors in the bilateral lobes of the liver, tumor thrombus in the portal vein and its branches; C and D: After comprehensive therapies, enlarged lymph nodes had decreased in size and the liver metastatic foci were stable.

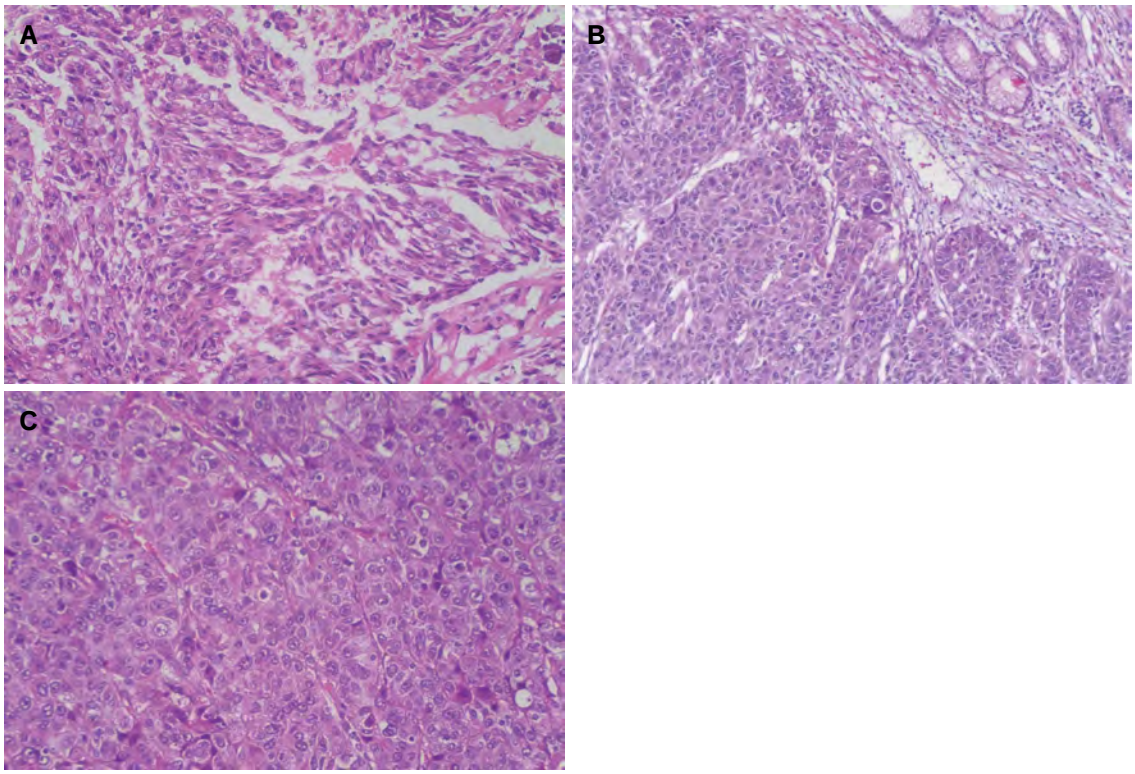

Figure 3 Presentations of hematoxylin and eosin stains: A: Tumor cells are arranged in a trabecular pattern (× 200); B: Tumor cells are arranged with cancer nests and adenoids (× 100); C: Tumor cells are featured with eosinophilic cytoplasm and round nuclei occasionally exhibiting obvious nucleoli (× 200).

of additional laboratory tests, including routine blood and liver function tests, were all within normal limits. In

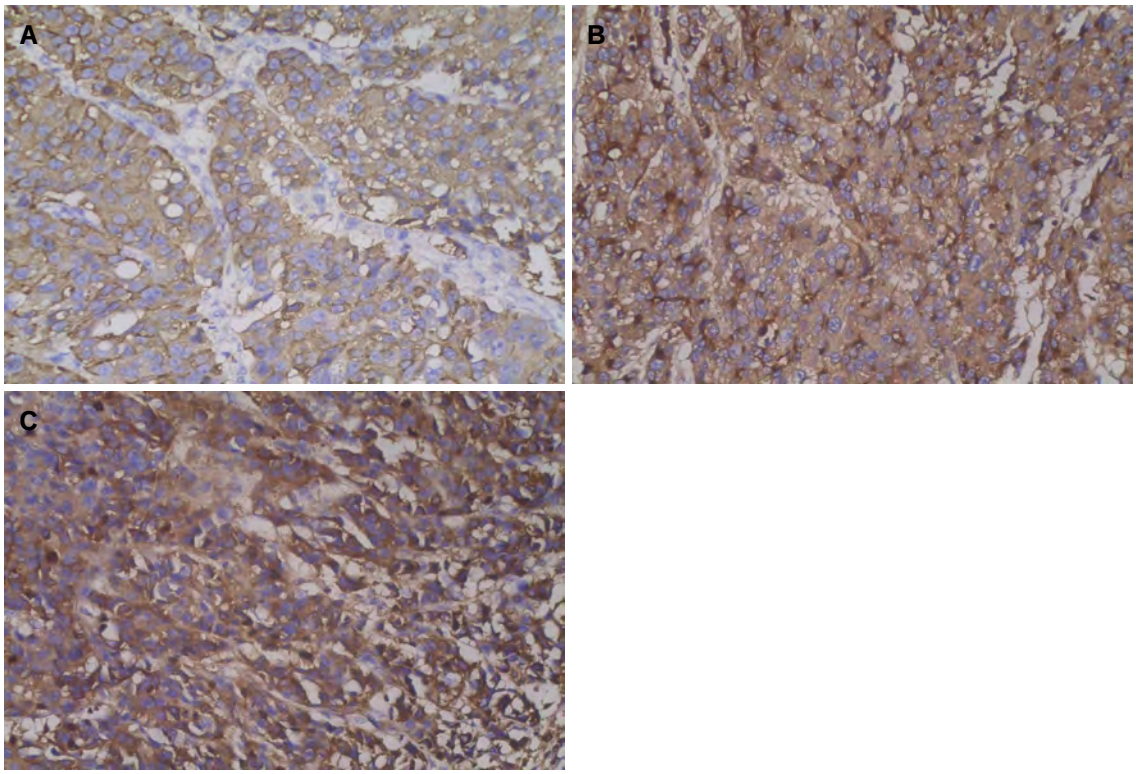

Figure 4 Presentations of immunohistochemical stains: A: Positively-stained alpha fetoprotein (× 200); B: Positively-stained alpha-1 antitrypsin (× 200); C: Positively-stained alpha-1 antichymotrypsin (× 200).

addition, hepatitis B surface antigen and antibody and hepatitis C antibody were all negative. Upper gastrointestinal radiological studies showed an irregular structure, filling defect and wall stiffness at the esophagogastric junction. A CT scan showed thickening of the wall of the esophagogastric junction; however, no metastasis was observed. AFP-producing gastric cancer was diagnosed, and a total gastrectomy with lymph node dissection was performed on March 12, 2011.

The surgically resected specimen showed an elevated tumor (4.0 cm in maximal diameter) at the gastroesophageal junction, with central ulceration and surface erosion. Light microscopic examination revealed that the tumor invasion was limited to the area from the mucosa to the proper muscle layer. The tumor was diagnosed as HAS based on the pathological and IHC findings (Figure 3B). However, no cancer metastasis was detected in the 23 lymph nodes examined. The tumor was diagnosed as stage IB (pT2N0M0) according to the American Joint Committee on Cancer guidelines[6].

Postoperatively, the patient underwent a regimen of six cycles of oxaliplatin plus fluorouracil adjuvant chemotherapy. The serum AFP levels decreased to 8.2 ng/mL within the first two months, but they increased again to 99.9 ng/mL at 5 mo post-surgery. Furthermore, the CT scan showed lung metastases. Therefore, a chemotherapy regimen with paclitaxel and capecitabine was administered. However, after two cycles of second-line chemotherapy, the serum AFP levels increased to 8431 ng/mL, and the lung metastases progressed. Therefore, the patient declined additional therapy and was discharged. A careful follow-up of this patient revealed growth of the lung metastases; the patient died 18 mo post-surgery.

Case 3

A 61-year-old woman was admitted to the clinic of our hospital on January 27, 2012 with epigastric pain that had persisted for one-month. The patient had no relevant medical history. A systematic review disclosed a weight loss of 5 kg in 1 mo but no hematemesis, hematochezia or melena. A physical examination revealed mild upper abdominal tenderness. A laboratory investigation showed a hematocrit of 27% with a hemoglobin concentration of 8.5 g/dL; the mean corpuscular volume was 70.8 fL, and the red cell distribution width was 18%. In addition, the AFP levels were > 50000 ng/mL. Additional tumor markers were normal. Furthermore, the hepatitis B and C panel was negative.

A gastroduodenoscopy revealed a large gastric antrum ulcer, and a CT scan showed wall thickening in the stomach, massive lymph node swelling around the lesser curvature of the stomach, head of pancreas, portal and splenic vein tumor thrombosis and multiple low density nodules in the spleen.

A histopathologic examination of the antral ulcer biopsy showed a moderately differentiated adenocarcinoma with hepatoid features (Figure 3C). The results from the IHC study revealed the expression of AFP, AAT and ACT in tumor cells (Figure 4B and C). The final diagnosis in this case was advanced stage HAS with lymph node

metastases. The patient underwent chemotherapy with oxaliplatin plus S-1. However, no remission was observed in the stomach tumor. The AFP levels were > 50000 ng/mL after four cycles of chemotherapy. Meanwhile, the patient had grade 4 myelosuppression and hepatic dysfunction (Child-Pugh class B). Therefore, further chemotherapy was terminated. The patient died 8 mo after admission.

DISCUSSION

HAC is a rare but important type of extrahepatic tumor that has a morphologic similarity to HCC[1]. HAC was first reported as an AFP-producing tumor in 1970[7]. Kodama *et al*[8] described two histological types of AFP-producing gastric carcinoma: the medullary type and the well-differentiated papillary or tubular type. The two types of gastric carcinomas were occasionally found to coexist in a single tumor. Ishikura *et al*[9,10] proposed the term "hepatoid adenocarcinoma of the stomach" for primary gastric carcinomas that are characterized by both hepatoid differentiation and the production of large amounts of AFP. The reported incidence of AFP producing gastric cancer includes 1.3%-15% of all gastric cancer cases[11]. Later, Ishikura *et al*[12] reported on primary AFP-negative gastric carcinomas with characteristic histologic features mimicking hepatocellular carcinoma. Moreover, Nagai *et al*[13] reported that 46% of HAS demonstrated negative AFP levels by IHC staining and that microscopically hepatoid features, regardless of AFP-staining, were more important for a positive prognosis. Currently, the diagnosis of HAS is not dependent on whether AFP is produced, but it is based on the characteristic histological features.

Similar to most hepatic cellular carcinoma, HAC can produce AFP, AAT and ACT. Furthermore, specific well-differentiated HAC can secret bile[14]. Hepatoid carcinoma has a tubular adenocarcinomatous component, but the relationship between the tubular adenocarcinomatous and the hepatoid component remains unclear. A recent analysis by Kumashiro *et al*[15] compared the cellular phenotypes of 23 cases of hepatoid adenocarcinoma of the stomach and showed tubular adenocarcinomatous components with 69 cases of non-hepatoid adenocarcinoma of the stomach. The results suggested that hepatoid adenocarcinoma was derived from an adenocarcinoma with an intestinal phenotype and that its hepatoid component was related to reduced CDX2 expression levels.

Hepatoid adenocarcinoma of the stomach frequently occurs in older people. The average patient age is 63.5 years, and the male-to-female ratio is 2.32:1. The most common location is the antrum (60.2%), followed by the cardia and fundus. Moreover, epigastric pain and generalized fatigue caused by anemia are the most common symptoms[11]. In most patients, metastases to the liver and/or lymph nodes are detected preoperatively[11].

The diagnosis of HAS depends on the recognition of the characteristic histological features[13]. Histopathologically, the tumor is composed of two closely related areas, including hepatoid-like foci and adenocarcinomatous. Tumor cells in the hepatoid foci resemble the morphology of HCC, and immunohistochemically can be positive for AFP, AAT and ACT. Additionally, polyclonal CEA staining shows a "canalicular" pattern, which is characteristic of hepatoid features. The adenocarcinomatous component may be well or poorly differentiated, often with clear cells and a papillary pattern[10,16]. In differential diagnosis, additional AFP-producing gastric tumors and metastasizing germ cell tumors should be excluded[17]. HCC should be excluded particularly when HAS metastasizes to the liver[18]. Generally, in HCC, neighboring cirrhotic lesions are found, and tumor cells are positive for Hep Par-1 antibody, a sensitive and specific immunohistochemical marker for hepatocyte differentiation, whereas in metastatic HAS Hep Par-1 is often negative, and neighboring cirrhotic lesions are rare[16]. A recent finding indicated that the immunostaining of the palate, lung and nasal epithelium carcinoma-associated protein could be used as a novel marker to distinguish HAS from primary HCC[19].

In terms of treatment, there are few data in the literature specifically pertaining to HAS. The disease is treated similarly to common gastric adenocarcinoma. Radical surgery is the optimal treatment for HAS and may effectively prolong survival. Additionally, the liver metastases should undergo simultaneous resections[20]. Adjuvant chemotherapy and radiotherapy should be given according to current gastric cancer indications, despite the fact that no specific data on the adjuvant treatment of HAS are available. For patients with metastasis, chemotherapy is the primary treatment modality[20]. It has been reported that a better prognosis might be associated with good performance and active treatment, including palliative gastrectomy and chemotherapy[21]. Palliative chemotherapy is recommended to all patients with advanced gastric cancer and good performance statuses[22], although there is no standard chemotherapy protocol for HAS.

According to the literature, the prognosis of HAS is poorer than that of ordinary gastric adenocarcinoma. Nagai *et al*[13] reported that hepatoid adenocarcinoma had a poorer prognosis compared with AFP-producing non-hepatoid adenocarcinoma. However, the reasons for the poor prognosis are not clearly understood. One possibility is that hepatoid adenocarcinoma produces AAT and/or ACT as well as AFP. AAT and ACT have immunosuppressive and protease-inhibitory properties that enhance invasiveness[11].

The three patients in our study had an average age of 57 years, and their serum AFP levels were elevated. Two patients were found in the advanced stage with lymph nodes and/or liver metastases at the time of diagnosis, and the third patient developed lung metastasis seven months postoperatively. Two patients underwent surgery. Although all three patients had received chemotherapies, their outcomes were not satisfactory. In the first case, the patient who underwent curative gastrectomy and adjuvant chemotherapy showed a relatively good prognosis.

In conclusion, HAS is a relatively rare tumor with

unique hepatoid features and a poor prognosis. Aggressive therapies, including surgery and chemotherapy, may yield good survival outcomes.

Abstract

A 72-year-old male with an early stage "node-negative" sigmoid colon cancer developed 2 separate "node-negative" early stage colon cancers during a subsequent colonoscopy surveillance regimen, the first in the descending colon 7 years later, and the second in the cecum almost 14 years after the first cancer was resected. After the initial symptomatic cancer, all subsequent neoplastic disease, including malignant cancers were completely asymptomatic. This entity, multiple primary cancers, likely reflected the use of a colonoscopic surveillance regimen.

Key words: Colorectal cancer; Surveillance colonoscopy; Multiple primary cancer syndrome; Metachronous colorectal cancer

Core tip: Detection of increasing numbers of asymptomatic metachronous colon cancers may result from widening use of surveillance colonoscopy in patients with a previously treated early stage colon cancer.

Freeman HJ. Triple metachronous colon cancer. *World J Gastroenterol* 2013; 19(27): 4443-4444 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4443.htm DOI: http://

TO THE EDITOR

An article recently published in the *World Journal of Gastroenterology* concerning a patient with quadruple malignancies involving different organ sites, but with survival over more than 20 years is rare (below 0.1%) and has special significance[1]. The authors suggest that the incidence of multiple primary cancers (MPC) is rising, possibly related to individual genetic susceptibility and other factors[1]. The patient described here below emphasizes that this rising incidence in MPC may also result from increasing use of surveillance colonoscopy regimens aimed at high risk groups, specifically those with early stage ("node-negative") colon cancer.

A 72-year-old otherwise healthy male developed constipation and rectal bleeding in June 1997. Subsequent colonoscopic evaluation revealed a 4 cm ulcerated mass in the distal sigmoid colon. Anterior resection revealed a moderately differentiated adenocarcinoma invading just through the muscularis propria (T3). Lymph nodes were negative for malignancy with no lymphovascular invasion. Subsequent annual colonoscopies showed small tubular adenomas that were resected. In addition, biopsies of the prior anastomosis were negative. In 2004, additional tubular adenomas were resected and a diminutive ulcerated sessile polypoid lesion in the rectum revealed severely dysplastic mucosa. Because of the high suspicion for an invasive malignancy, another laparotomy was done. The previous anastomosis was resected and revealed no evidence for malignancy and a further resection of the descending colon was done revealing a second infiltrative moderately differentiated colonic adenocarcinoma measuring 1 cm in diameter and extending into the muscularis propria (T2). Lymph nodes were negative for malignancy with no lymphvascular invasion. Subsequent colonoscopies in 2004, 2005 and 2006 revealed diminutive tubular adenomas that were resected. In 2010, a further colonoscopy revealed a single small tubulovillous adenoma in the ascending co-

lon that was removed. Another ulcerated polypoid lesion was detected in the cecum and biopsies confirmed a third moderately differentiated adenocarcinoma. Subsequent right hemicolectomy revealed extension through the muscularis propria with negative lymph nodes and no lymphovascular invasion (T3). In summary, despite 3 separate "node-negative" cancers, all treated by surgical resection alone, this patient remains well, now over 15 years. As a direct result of surveillance, the last 2 colon cancers were detected at an early and asymptomatic stage.

After complete resection of a colonic adenocarcinoma, colonoscopy guidelines recommend ongoing surveillance to exclude subsequent development of metachronous colon cancer[2]. A high intensity form of surveillance is often recommended for the initial 5 years[2]. In our experience, longer term colonoscopic surveillance after endoscopic removal of either malignant polyps[3] or more sessile early stage ("node-negative") colon cancers[4] have also yielded significant numbers of patients with metachronous colon cancers, a specific form of MPC[1], at an early asymptomatic stage of the disease. This experience underlines the importance of colonoscopy surveillance of high risk categories, particularly prior colonic cancer patients with "node-negative" disease. With the expectation that these highly-selected patients will survive for extended periods, colonoscopic surveillance *per se* can be expected to yield increasing numbers of patients with colonic metachronous MPC in the future.

Abstract

The therapeutic potential of long-term ketotifen in irritable bowel syndrome and postoperative ileus is currently under investigation. Ambiguous results of prolonged postoperative ketotifen use on gastrointestinal passage have been found. The current data point at a hampered gastrointestinal transit after prolonged postoperative ketotifen use in a rodent ileus induction model. Therefore, caution should be taken when administering ketotifen in the perioperative phase.

Key words: Ketotifen; Gastrointestinal transit; Postoperative ileus

Core tip: Prolonged postoperative ketotifen impairs gastrointestinal transit in a rodent ileus induction model.

Word of caution before implementing ketotifen for gastrointestinal transit improvement. *World J Gastroenterol* 2013; 19(27): 4445-4446 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4445.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4445

TO THE EDITOR

Postoperative ileus has a major impact on length of hospital stay after bowel resection[1]. Currently, the therapeutic potential of long-term ketotifen in postoperative ileus and irritable bowel syndrome is under investigation[2,3]. The underlying mechanism, however, remains unclear as ketotifen exerts both mast cell stabilizing and H1 receptor blocking effects. Furthermore, the long-term effects on gastrointestinal (GI) transit deserve definition. The and colleagues showed that ketotifen improved gastric emptying at 24 h follow-up; however continuing treatment up to 48 h postoperatively produced ambiguous results on GI passage[2]. Therefore, we performed a rat study to assess the influence of prolonged use of ketotifen on GI transit time at 5 d follow-up after ileus induction.

The same postoperative ileus induction model was used as previously described[4]. Male Wistar rats (250-300 g) were anesthetized using buprenorphine 0.1 mg/kg *sc* and anesthesia was maintained using 2.5% isoflurane. Subsequently, rats underwent a laparotomy *via* a midline abdominal incision under aseptic conditions. The small intestine was placed on moist gauze pads outside the abdomen, manipulated with moist cotton swab sticks for 5 min and kept moist at all times. After manipulation, the small intestine was placed back in the abdomen and the abdomen closed in 2 layers with continuous sutures. Rats (6 in each group) received either ketotifen in a high-dose (1 mg/kg) or low-dose (0.1 mg/kg), mast cell stabilizer cromoglicic acid (50 mg/kg) or vehicle (saline). The high dose of ketotifen is comparable to doses prescribed for humans. Cromoglicic acid prevents the release of mediators from mast cells through a non-H1/2-receptor pathway. Doses were administered twice daily in a volume of 1.5 mL *via*

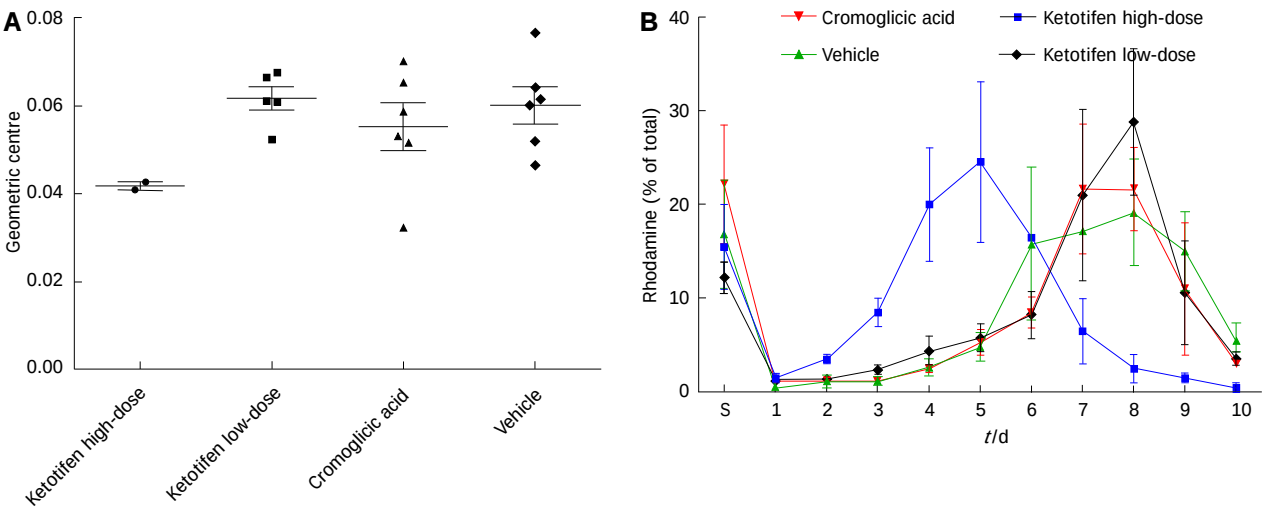

Figure 1 Geometric centre of recovered rhodamine, calculated as (Σ% fluorescence per segment × segment number)/100 (A), and amount of recovered rhodamine per bowel segment (ketotifen high-dose, *n* = 2; all other groups, *n* = 6) (B).

oral gavage starting at 2 d preoperatively until sacrifice. GI transit time was measured at the time of sacrifice (5 d postoperatively, by cervical dislocation after anesthesia with 4% isoflurane) by evaluating the GI distribution of rhodamine-B-labeled dextran (Sigma-Aldrich, St. Louis, MO, United States). Rhodamine [200 μL of 6.25 mg/mL in phosphate buffered saline (PBS)] was administered *via* oral gavage. One hour after administration the animals were sacrificed, the small bowel divided in 10 equal parts (part 1: beginning at jejunum, part 10: ending at the transition of ileum to coecum) and resected together with the stomach. A fluorescence reader was used to quantify the rhodamine-containing gut content in the supernatant after vigorous mixing and centrifuging of the gastric and bowel contents in 2 mL PBS. A histogram of fluorescence distribution per segment (% of total recovered rhodamine) was plotted for transit analysis and expressed as geometric center for statistical analysis. Geometric centers were calculated for each animal as (Σ% fluorescence per segment × segment number)/100.

In the high-dose ketotifen group, 4 out of 6 rats died before reaching 5 d follow-up with an extremely distended stomach at necropsy. The geometric centers of the surviving animals were also markedly lower than the other groups, but numbers ($n = 2$) were too low to allow for statistical analysis (Figure 1). However, GI transit times in the low-dose group were comparable with the control group ($P = 0.66$, Mann-Whitney U test) implying that the beneficial ketotifen effects after postoperative ileus are dose-dependent and probably restricted to the very early postoperative period, *i.e.*, less than 5 d. GI transit in the cromoglicic acid group was comparable to control ($P = 0.70$, Mann-Whitney U test). These results suggest that the effects of ketotifen on GI transit may indeed not, or not fully, depend on mast cell stabilization but rather a H1 receptor pathway.

As stated earlier by The *et al*[2], caution should be taken when administering ketotifen in the perioperative phase as prolonged postoperative treatment may have an inhibitory effect on enteric smooth muscle contraction. Indeed, the current data point at a hampered GI transit after prolonged postoperative ketotifen use. A careful treatment regimen as proposed by de Jonge *et al*[5], *i.e.*, preoperative treatment only, is therefore mandatory.

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2012 Impact Factor: 2.547 (34/74); Total Cites: 19145 (6/74); Current Articles: 944 (1/74); and Eigenfactor® Score: 0.06035 (6/74).

Abstract

Crohn's disease representing a clinical phenotype of inflammatory bowel disease is a polygenic immune disorder with complex multifactor etiology. Recent genome-wide association studies of susceptibility loci have highlighted on the importance of the autophagy pathway, which previously had not been implicated in disease pathology. Autophagy represents an evolutionarily highly conserved multi-step process of cellular self-digestion due to sequestration of excessive, damaged, or aged proteins and intracellular organelles in double-membranous vesicles of autophagosomes, terminally self-digested in lysosomes. Autophagy is deeply involved in regulation of cell development and differentiation, survival and senescence, and it also fundamentally affects the inflammatory pathways, as well as the innate and adaptive arms of immune responses. Autophagy is mainly activated due to sensors of the innate immunity, *i.e.*, by pattern recognition receptor signaling. The interplay of genes regulating immune functions is strongly influenced by the environment, especially gut resident microbiota. The basic challenge for intestinal immune recognition is the requirement of a simultaneous delicate balance between tolerance and responsiveness towards microbes. On the basis of autophagy-related risk genetic polymorphisms (*ATG16L1*, *IRGM*, *NOD2*, *XBP1*) impaired sensing and handling of intracellular bacteria by innate immunity, closely interrelated with the autophagic and unfolded protein pathways seem to be the most relevant immunobiologic events. Autophagy is now widely considered as a key regulator mechanism with the capacity to integrate several aspects of Crohn's disease pathogenesis. In this review, recent advances in the exciting crosstalk of susceptibility coding variants-related autophagy and innate immunity are discussed.

Key words: Crohn's disease; Innate immunity; Autophagy genes; Autophagy; Gut microbiota

Core tip: In case of Crohn's disease, on the basis of autophagy-related risk genetic polymorphisms impaired sensing and responding of intracellular bacteria by innate immunity, closely interrelated with the autophagic and unfolded protein pathways seem to be the most relevant immunobiologic events. Autophagy represents a key regulator mechanism with the capacity to integrate several aspects of Crohn's disease pathogenesis.

DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4447

INTRODUCTION

Crohn's disease (CD) and ulcerative colitis, the main clinical phenotypes of (idiopathic, relapsing-remitting) inflammatory bowel disease (IBD) are systemic disorders affect-

ing the gastrointestinal-tract with frequent extraintestinal manifestations and associated autoimmune conditions[1]. IBD is considered as a polygenic immune disorder with complex multifactor etiology. Generally, IBD is arising in susceptible individuals in whom upon environmental triggers a sustained disturbed, deleterious mucosal immune reaction is provoked towards commensal microbiota[2]. In chronic inflammatory conditions, when organs with large epithelial surfaces are affected, like in IBD the epithelial barrier function is critical for the disease onset. Since the epithelium is densely inhabited by a resident microbial flora the role of native immunity is particularly appreciated in recognizing and distinguishing commensal enteric bacteria from the invading ones, and thus, in maintaining tolerance and homeostasis[2]. Subsequently, the chronic unrestrained inflammatory response that occurs in IBD is mainly driven by a disintegrated host immune regulatory network. In IBD development the host genetic susceptibility represents an important etiologic factor. In CD the genetic component is strongly indicated by familial aggregation, and further, by an approx. Twenty-six-fold greater population-based sibling risk, and an approximately 30%-35% of concordance rate in monozygotic twins[3,4]. The introduction of genome-wide association studies (GWAS) has yielded an expansion in studying the genetic basis of IBD. Nowadays more than 70 loci are associated with CD[5]. Further, in CD pathogenesis GWAS highlighted on certain earlier not really suspected biological pathways, such as autophagy. In polygenic diseases functional variants of single genes could be identified. Indeed, many of the recently identified genetic risk loci in CD are related to various cell types and pathways, suggesting the involvement of fairly different aspects of host immune responses in the IBD phenotype. Missing heritability in CD cannot be simply explained by genetic alterations[2]. Moreover, the fact of the worldwide considerable increase in disease incidence and prevalance emphasizes the importance of additional, environmental and epigenetic contributions[6,7]. The interplay of genes regulating immune functions is strongly affected by the environment, especially gut resident microbiota. On the basis of genetic alterations in CD impaired sensing and handling of intracellular bacteria by the innate immunity, that is closely interrelated with the autophagic and unfolded protein pathways seem to be the most relevant pathophysiologic features[8].

AUTOPHAGY MACHINERY

Besides the proteasomal degradation pathway autophagy represents an additional, evolutionarily highly conserved multi-step process of cellular self-digestion due to sequestration of excessive, damaged, or aged proteins and intracellular organelles in double-membranous vesicles of autophagosomes, terminally self-digested in lysosomes[9]. Autophagy is deeply implicated in the regulation of numerous physiologic functions including cell development and differentiation, survival and senescence, and it also affects fundamentally the inflammatory process, and the innate and adaptive arms of immune responses[10]. On a basal level intact autophagy serves constantly and constitutively as a critical adaptive and surveillance mechanism in maintaining cellular homeostasis[11]. Nevertheless, autophagy is inducible in response to different cellular metabolic stress conditions, such as nutrient and growth factor deprivation in order to preserve cell viability. Further, autophagy is upregulated in cases of protein aggregation and accumulation of misfolded proteins, *i.e.,* when the structural remodeling is mandatory. In respect of innate immunity, however, autophagy plays an essential role during infections by degrading intracellular pathogens[10,12]. Different types of autophagy according to the route of delivery to lysosomes and the main physiological functions have been characterized, such as macro- and micro-autophagy, and chaperon-mediated autophagy[11]. Upon specific targeted degradation of cytosolic aggregated proteins, lipids, and organelles (ribosomes, nucleosomes, peroxisomes, mitochondria, endoplasmic reticulum), selective forms of autophagy (aggregophagy, lipophagy, ribophagy, nucleophagy, pexophagy, mitophagy, reticulophagy) can further be classified[9,11]. In addition, elimination of intracellularly infective pathogens represents another selective form of autophagy, namely xenophagy (Figure 1). Xenophagy can be considered as a substantial element of the innate immune system. Generally (macro)autophagy refers to cytoplasmatic bulk, non-selective degradation of subcellular constituents. Within this complex catabolic pathway tightly regulated by a limited number of autophagy genes (*ATGs*) various morphologic stages of the assembly process are distinguishable[12]. It is initiated with the phagophore (isolation membrane) formation around different molecules or particles to be sequestred, and is followed by elongation and maturation into the autophagosome, leading finally to fusion with lysosomes[9,12]. Subsequently, the phagophore is controlled by *Beclin1 (ATG6)* and *ATG14* genes, and both the inhibitory class1 canonical phosphatidylinositol 3'-kinase/AKT (PI3K/AKT) mammalian target of rapamycin (mTOR) and the promoting c-Jun N-terminal kinases (JNK1) pathways[13,14]. The intricate formation of autophagosome is regulated mainly by the ATG5-ATG12 complex, then stabilized by ATG16L1, and further processed by microtubule-associated protein light chain (LC3/ATG8) under the strict control of ubiquitin-like conjugation systems (ATG10, ATG7, ATG3). The engulfment of random or selective cargo, closure of the autophagosome, and fusion with the lysosomal compartment is orchestrated by LC3, and the Beclin1-UV-irradiation resistance-associated gene (UVRAG) complex[13,14]. Defects in basal autophagy may yield accumulation of cytotoxic materials, damaged DNA, and thus, genomic instability, while alterations of induced autophagy especially lead to reduced cell survival[10,12]. By compromising cellular fitness defective autophagy has been ultimately related to several chronic inflammatory disease conditions, such as inflammatory bowel disease, like CD and cancer, neurodegeneration, and infectious disorders[10,11,15]. Gener-

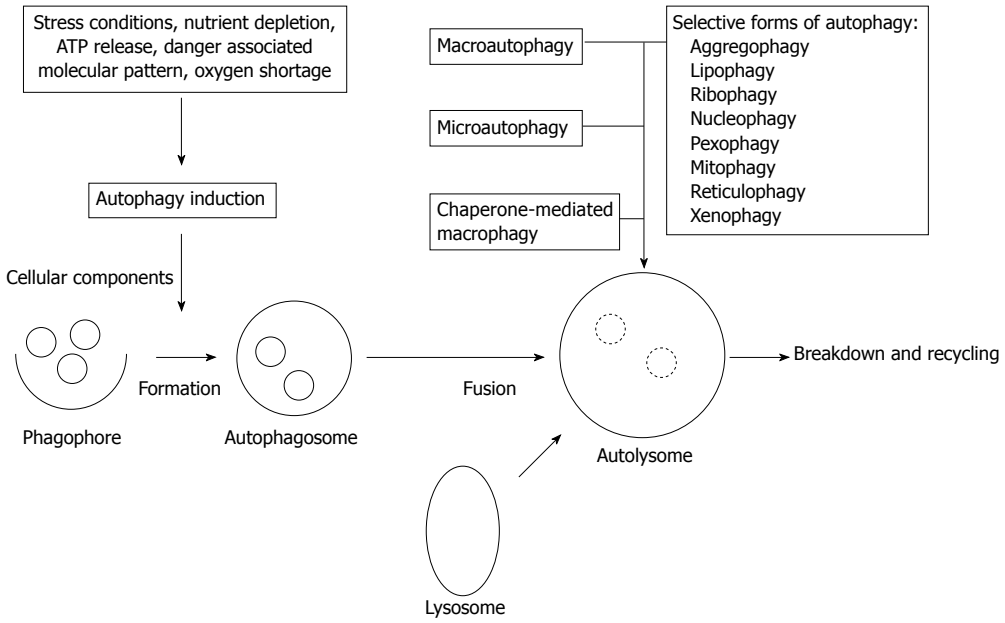

Figure 1 The autophagic process and types of autophagy.

ally autophagy deficiency is closely related to accelerated tumorigenesis. In autophagy-incompetent cells upon induced oxidative stress cell-autonomous mechanisms are exhibited in forms of accumulated DNA damage and chromatin instability[16]. However, inflammatory events as a non-cell-autonomous mechanism along with defective apoptosis could independently contribute to malignant transformation and cancer progression, partly by favoring cell necrosis[17]. Similar situation has been found in human IBD with high risk of malignancy, and in experimental cases of *Atg5*-/- or *Atg7*-/- mice displaying abnormalities resembling human IBD[18]. Autophagy and stress-responsive cellular degradation pathways of intrinsic and extrinsic apoptosis can fundamentally alter, activate or inhibit each other *via* an extensive molecular crosstalk, and in fact, cell destiny is determined by their actual functional status and interplay[19]. Their crosstalk is primarily regulated by the current status of the ATG6/Beclin-1 complex, a Bcl-2/Bcl-xL interacting element, since Bcl2 is a potent autophagy inhibitor. Dissociation of this complex can be achieved by toll-like receptor (TLR) adaptors (MyD88, TRIF), or activation of mitogen activated phosphokinase (MAPK)-JNK cascade, as well as by translocation of the damage-associated molecular pattern (DAMP) protein high-mobility-group B (HMGB)-1[13,19]. There is also diverse interaction between autophagy and the nuclear factor-κB (NF-κB) signaling pathways through positive and negative feedback regulatory loops[14]. The tumor suppressor *p53* gene exerts a typical dual role in autophagy regulation, depending primarily on its subcellular, nuclear or cytoplasmic distribution[13,14].

NOD-LIKE RECEPTORS AND CROHN'S DISEASE

NOD-like receptors (NLRs) are pattern recognition receptors (PRRs) and belong to the family of innate immune receptors sensing pathogen-associated molecular patterns (PAMPs). Nucleotide-binding oligomerization domain-containing protein 2 (NOD2) is constitutively expressed intracellularly in macrophages and dendritic cells, and to lesser extent in intestinal epithelial cells and T cells. The centrally located motifs of NLRs are referred to NOD domains that are interacted with the caspase activation and recruitment domain ones. NOD2 recognizes *N*-acetyl--muramyl-peptide (MDP), a bacterial peptidoglycan component, and upon activation the induced receptorial conformation changes result a multiprotein, the inflammasome (NLRP3). Ligation of NOD2 triggers recruiment of the adaptor protein receptor interacting protein 2 (RIP2) causing a TRAF6-mediated ubiquitination of inhibitor of κB-kinase gamma (IKKγ; NEMO), and hence results in activation of downstream signaling pathways implicating NF-κB, MAPKs and proinflammatory caspases[20,21]. The Crohn's disease-associated *NOD2* genetic variants are located in the leucine-rich repeat (LRR) region of NOD2, *i.e.*, in the ligand-binding domain of this intracellular PRR[22]. The altered amino acid sequence is related either to insertion resulting in a frame-shift mutation, or to non-synonymous SNPs resulting in amino acid exchanges. The more commonly observed genetic variants (of missense or nonsense mutations) in CD are the SNP8 (R702W), SNP12 (G908R), and SNP13 (L1007fsC), respectively, however a number of rare *NOD2* variants have also been discovered, being localized again almost exclusively to the LRR region[22,23]. Upon MDP ligation the Crohn's disease-associated "loss-of-function" NOD2 variants abrogate RIP2 binding, and so fail to activate NF-κB[24,25]. Further, NOD2 is involved in the modulation of TLR signaling, as well. Thus, in case of Crohn's disease-related gene polymorphisms the TLR2-induced NF-κB activation is also decreased[26,27].

However, yet it is difficult to correctly interpret the real functional consequences of given mutations since they may activate additional, compensatory mechanisms resulting in a definite inflammatory phenotype. On the other hand NOD2 has a pivotal role in direct antibacterial defense by the induced release of defensins. NOD2-/- mice and patients with the CD NOD2 variants display diminished expression of antimicrobial α-defensins in Paneth cells, that contributes to impaired antibacterial capacity and decreased epithelial barrier function[28,29]. In contrast to hypomorphic functions the frame-shift gene mutation variant encodes a "gain-of-function" by actively suppressing interleukin-10 (IL-10) transcription[30].

AUTOPHAGY AND CROHN'S DISEASE

The autophagy machinery in IBD represents a recently developed pathway fundamentally contributing to the pathogenesis[10]. Functional polymorphisms of the autophagy genes *ATG16L1* (T300A) and immunity-related GTPase family M protein *(IRGM*; C313T) have been found as definite risk factors for CD[31-34]. The ATG16L1 protein is widely expressed in intestinal epithelial cells, and also in macrophages and lymphocytes. The ubiquitous *ATG16L1* seems to be fundamental in selective autophagy, *i.e.,* in xenophagy, nonetheless its defect has only been described within the gut[35].

In CD patients homozygous for the risk *ATG16L1* allele the "loss-of-function" deficiency due to failures of autophagosome formation results in impaired engulfment and degradation of cytoplasmic content (microbes), defective presentation of bacterial antigens to $CD4^+$ T cells, and further, in alterations of Paneth cell granule formation causing a disrupted granule exocytosis[18,36-38]. Additionally, ATG16L1-deficient Paneth cells in CD display a "gain-of-function" defect by increasing expression of inflammatory cytokines[18,38]. Moreover, upon stimulation with NOD2 ligands or with lipopolysaccharides (LPS) through TLR4, macrophages and myeloid cells with the ATG16L1 risk variant generate high levels of reactive oxygen species (ROS), and respond with inflammasome overactivation leading to enhanced IL-1β and IL-18 production *via* Myd88 and TRIF-dependent activation of caspase-1[36-38]. Generally, aberrant activation of PRR signaling pathways may result critically severe inflammation. *IRGM* is the only human gene representative for innate immunity-related GTPases, necessary for γ-interferon-mediated resistance to intracellular pathogens[39]. During initiation of autophagy IRGM expression is essentially required for the proper clearance of bacteria. The risk polymorphism of *IRGM* due to the impaired protein expression can lead to functional abnormalities in xenophagy[32,33]. Since IRGM is possibly regulated in a cell specific manner the CD risk allele may cause cell specific phenotypes.

NOD2 and autophagy

Functionally NOD2 is closely associated with autophagy, and yet interacts mechanically (*i.e.,* immunoprecipitated) with ATG16L1, therefore autophagy seems to be a key factor in CD[37,40,41]. Autophagy is mainly activated due to sensors of the innate immunity, *i.e.,* by PRR signaling upon recognition of PAMPs (MDP, LPS, ss/ds RNA, methylated DNA/CpG), but it could also be induced by DAMPs (like ATP, ROS, and misfolded proteins), pathogen receptors (like CD46), IKK, JNK and HMGB proteins[10,12,19,38]. Sensory PRR-molecules include TLRs, NLRs and RIG-I-like receptors (RLRs). Induction of NOD2 in dendritic and epithelial cells by bacterial ligands and leaving bacteria results in ATG16L1-dependent formation of autophagic vacuoles. However, the NOD2 variants of CD lack this activity, and further MDP-induced autophagy is also absent in cells with the ATG16L1 risk variant, suggesting that both NOD2 and ATG16L1 co-localized on plasma membrane are required for an optimal innate immune signaling[40-42]. In addition, a NOD2-dependent failure in autophagy-induction and consequently a diminished bacterial killing was found for *Salmonella typhimurium*, *Shigella flexneri*, and enteroadherent invasive *Escherichia coli* (*E. coli*)(AIEC)[40,41,43]. The normal NOD2, but not the CD-associated variants recruits ATG16L1 to the plasma membrane preferentially at the bacterial entry side, so physiologically NOD2 is critical for engulfing invading pathogens by autophagosomes[41,42]. Furthermore, in dendritic cells NOD2-dependent autophagy is also essential for the appropriate antigen processing and presentation and a subsequent induction of $CD4^+$ T-cells[41]. Dendritic cells from CD patients with either NOD2 or ATG16L1 variants display a failure to translocate bacteria to lysosomes and relocate MHC II to cell surface, as well[40]. When the disease-associated *ATG16L1* and *NOD2* alleles are present in combination, a synergistic genetic epistasis, *i.e.,* an increase in CD susceptibility was observed, underscoring the importance of a signaling crosstalk regarding the inflammasome and autophagy[44].

Endoplasmic reticulum stress and autophagy

The unfolded protein response (UPR) induced by endoplasmatic reticulum (ER) stress represents another pathway in IBD pathophysiology[45]. Genetically ER stress is associated with both forms of IBD and occurs upon excessive accumulation of misfolded or unfolded proteins in the ER, leading to UPR especially in cells with high secretory capacity, like goblet cells and Paneth cells[35,46]. UPR is regulated by different pathways (and related transcription factors) with the preference of the inositol-requiring enzyme 1/X-box binding protein 1 (IRE1/XBP1) axis[47]. *Via* this axis there is a conserved link between innate immunity (TLR and NOD signaling) and the UPR[47]. GWAS-based candidate gene studies revealed the role of *XBP1* SNPs in IBD-related ER-stress[48,49]. Decreased or absent XBP1 function in the intestinal epithelial cell (IEC) compartment through IRE1 hyperactivation results in uncontrolled ER-stress, *i.e.,* a proinflammatory overactivation, and further in dysfunction and premature apoptotic depletion of Paneth cells, with

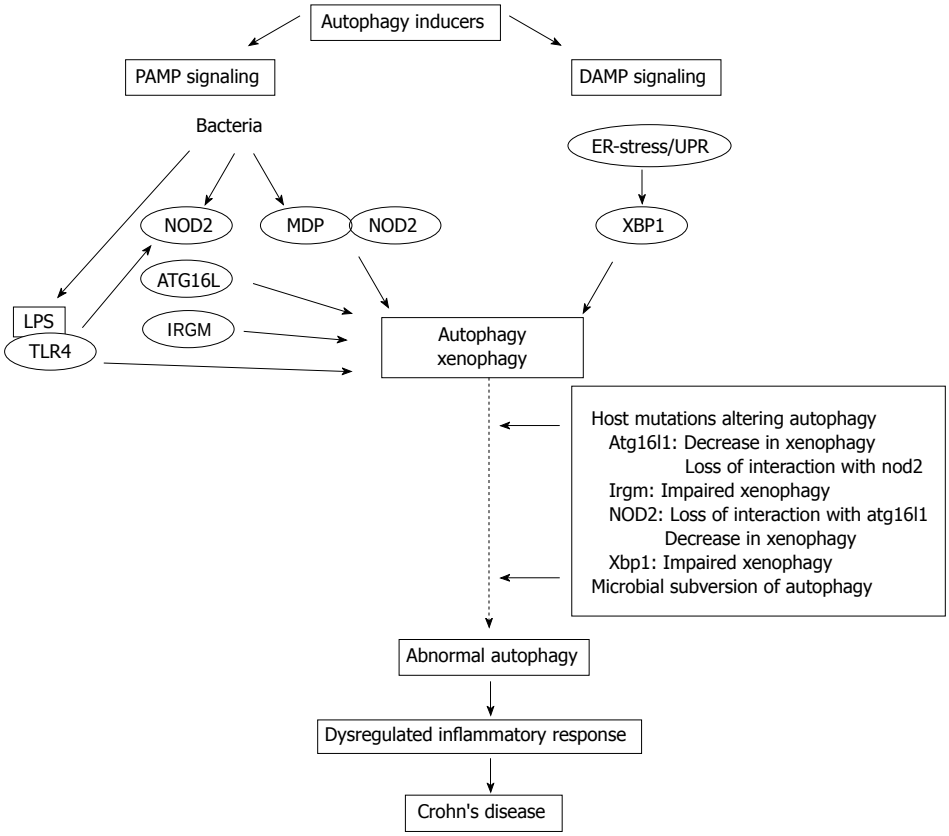

Figure 2 Schematic illustration of the crosstalk between autophagy and innate immunity in Crohn's disease. PAMP: Pathogen-associated molecular patterns; DAMP: Damage-associated molecular pattern; ER: Endoplasmic reticulum; UPR: Unfolded protein response; NOD: Nucleotide-binding oligomerization domain-containing protein; MDP: *N*-acetyl-muramyl-peptide; LPS: Lipopolysaccharide; TLR: Toll-like receptor; XBP1: X-box binding protein 1; IRGM: Immunity-related GTPase family M protein.

the consequent impaired handling of the microbiota[49]. Under ER stress autophagy is induced *via* JNK (downstream of IRE1), which is overactivated by the hypomorphic XBP1[50,51]. However, even defective autophagy *per se* is able to provoke ER stress, especially when the ATG7 protein involved in regulation of autophagosome formation is also depressed[52]. Regarding PI3K there is an antagonistic action, since in UPR it is responsible for the activation of XBP1, but in the contrary autophagy is suppressed by the canonical AKT-TOR pathway[53,54]. In IBD, IECs presumably are affected both by impaired UPR signaling and aberrant autophagy, but their exact interplay needs to be further clarified.

GUT MICROBIOTA AND CROHN'S DISEASE

The intestinal microbiota, which normally colonize mucosal surfaces in symbiotic mutualism with the host is unique and quite stable over time[55]. The basic challenge for the intestinal immune recognition is the requirement of a simultaneous delicate balance between tolerance and responsiveness towards microbes[56]. Several data suggest the existence of immune tolerance to antigens of the individual own bacterial flora, whereas its breakdown definitely contributes to IBD pathogenesis[37,57]. In CD there is a profound and complex host defect in sensing and responding intestinal (lumenal and mucosal) microbiome. Accordingly, reprogramming in the microbial composition, *i.e.,* a significant decreased load of commensal, protective resident bacteria (like *Bifidobacteria, Lactobacilli* and *Firmicutes*) along with the impaired immunity against the putative pathogenic (harmful) ones (such as *Bacteriodetes*, and *Proteobacteria*, including *E. coli*) provoke a deleterious inflammatory condition, corresponding to CD[58]. The exact nature of the distinct mucosal flora (dysbiosis), however has not yet been fully elicited. Specific strains of *E. coli* (termed AIEC) in CD affect especially the epithelial layer with the ability to adhere, invade and replicate in IECs, and further, a subpopulation even resides and survives within macrophages, and thereby induces increased production of tumor necrosis factor-α[43,59]. ATG16L1 and IRGM-deficient autophagosomes promote the AIEC survival as well[43]. Moreover, in the presence of CD-associated NOD2 variants or hypomorphic XBP1 dendritic cells exhibit diminished intracellular bacterial killing[41]. It is hypothesized, that AIEC possesses the capacity to circumvent innate immune responses leading to activation of NF-κB[60]. Thus, regarding the host interactions with microbes genetic risk factors of CD functionally render pathways of the innate immunity to converge to a deeply impaired autophagic process.

CONCLUSION

Overall, there is no doubt that autophagy can be considered as an apparently difficult regulatory network, being in close connection with several signal transduction pathways and cellular programs. Principle elements of immunological autophagy include the direct cell-autonomous pathogen elimination, the regulation of PRRs, and inflammasome activation, and the cytoplasmic antigen processing for MHC presentation to T cells. Recently significant advances have been achieved in understanding the importance of autophagy in CD, which previously had not been implicated in IBD pathology. In CD functional consequences of the underlying autophagy-related gene defects (*ATG16L1, IRGM, NOD2, XBP1*), in particular the inappropriate stimulation of antimicrobial and inflammasome pathways eventually result in uncontrolled inflammation (Figure 2). Therefore, autophagy in CD is predicted as a key regulator mechanism with the capacity to integrate several aspects of disease pathogenesis. Theoretically the complex autophagy signaling in CD offers a promising novel therapeutic target, since due to its induction potentially not only the load of cytoinvasive bacteria, and the perturbed immune responses, but the resulting inflammatory process, as well may simultaneously be reduced. Thus, autophagy boosting would represent an efficient biologic manipulation, and could provide an alternative therapeutic option. Several candidate pathways, *e.g.*, inhibition of mTOR, decrease of ER-stress, lowering of inositol triphosphate (IT3), *etc.*, could be considered. On the other hand, however, much cautiousness is required regarding its pleiotropic physiological repertoire, since pharmacologic autophagy modulation can initiate additional biologic effects not expected in CD. Further detailed functional analyses of the Crohn's disease-associated genetic polymorphisms are needed to explore and define more precisely the subcellular and molecular basis of the crosstalk between autophagy and the innate immune axis, hopefully allowing the introduction of selective new therapeutic approaches into daily practice.

Abstract

Autoimmune hepatitis (AIH) is a rare chronic inflammatory disease of the liver, which affects a group of patients who lost their immunological tolerance to antigens of the liver. It is clinically characterized by hypergammaglobulinemia, elevated liver enzymes, presence of autoantibodies and histological changes. Although being rare in children, it represents a serious cause of chronic hepatic disease that can lead to cirrhosis and hepatic failure. Clinical findings, exclusion of more common liver disorders and the detection of antibodies antinuclear antibodies, smooth muscle antibodies and anti-LKM1 are usually enough for diagnosis on clinical practice. The pathogenic mechanisms that lead to AIH remain obscure, but some research findings suggest the participation of immunologic and genetic factors. It is not yet knew the triggering factor or factors that stimulate inflammatory response. Several mechanisms proposed partially explain the immunologic findings of AIH. The knowledge of immune factors evolved might result in better markers of prognosis and response to treatment. In this review, we aim to evaluate the findings of research about genetic and immune markers and their perspectives of application in clinical practice especially in pediatric population.

Key words: Autoimmune hepatitis; Genetics; Clinical practice; Immunophenotype

Core tip: In this review article, we reported recent data on autoimmune hepatitis in pediatric patients highlighting the importance of genetic and immune markers. We also discuss the perspectives of the application of these new biomarkers in clinical practice.

INTRODUCTION

Autoimmune hepatitis (AIH) is a chronic inflammatory disease of the liver that is rarely found in children and adolescents. AIH affects a group of patients who have lost their immunological tolerance to antigens of

the liver[1-4]. It is more frequent in female patients and is characterized by hypergammaglobulinemia, elevated liver enzymes, the presence of autoantibodies and histological changes[4-7]. The age of onset usually ranges from months to 75 years old, but it is very rare before the age of two years old, and the highest incidence occurs between 10 and 30 years old[2]. In addition to being considered rare in children, AIH represents a serious cause of chronic hepatic disease, which can result in cirrhosis and its complications. Immunosuppressive treatment results in a good response, but a delay in or absence of treatment can result in cirrhosis and liver failure[2,6]. This condition can also be complicated by association with autoimmune cholangitis, in which bile duct disease is present together with hepatitis, particularly in children[2,7,8].

Clinical and laboratory diagnosis

Because histological activity index (HAI) is a rare disorder, one crucial point for diagnosis is the exclusion of more common pathologies. The diagnosis is confirmed by clinical findings, laboratory and histopathology tests and the exclusion of other causes of chronic liver disease[4,6,7,9]. The clinical spectrum is broad, ranging from asymptomatic laboratory abnormalities to clinical symptoms similar to fulminant acute viral hepatitis. The classical presentation is jaundice, dark urine, fever, asthenia, anorexia and increased abdominal volume in an acute or insidious presentation[6,10]. Hepatomegaly, splenomegaly and signs of chronic liver disease, such as spider veins, collateral circulation and abdominal ascites, might be present. Approximately 20% of cases are associated with other autoimmune disorders[8].

According to the presence of autoantibodies, AIH can be classified into two forms: type 1 autoimmune hepatitis, in which antinuclear antibodies (ANAs) and/or anti-smooth muscle antibodies (SMAs) are detected; and autoimmune hepatitis type 2, in which anti-liver-kidney (anti-LKM1) autoantibodies are detected[9,11-13]. In adult patients, the presence of anti-soluble liver-kidney antigen and anti-liver-pancreas might be understood as a third form of AIH (AIH type 3), despite clinical features similar to type 1[14]. Type 1 is the most common type of AIH in any age group, while type 2 usually occurs in younger patients, with courses having a greater likelihood of acute liver failure[2,3].

During treatment, ANA and SMA levels can decrease, but neither level seems to have a correlation with prognosis[15-17]. Therefore, 10%-15% patients are negative for ANAs, SMAs and LKM-1 at clinical presentation but later show detectable levels of these autoantibodies, with only five percent remaining negative over time[15,18]. Other autoantibodies could facilitate in diagnosis and/or act as prognostic markers, and their possible clinical applications are listed in Table 1[19-38].

Most services do not perform routine assessment of the autoantibodies shown in Table 1, which remain reserved for research situations. The antibodies ANA, SMA and anti-LKM1 are usually sufficient for diagnosis in clinical practice. More research is needed to establish the clinical use of these autoantibodies and to investigate the presence of these autoantibodies in pediatric patients, thereby elucidating their role in this group of patients.

Diagnostic criteria

The International Autoimmune Hepatitis Group diagnostic criteria for AIH, published in 1993 and revised in 1999, guide diagnosis and facilitate early treatment[39-41]. A simplified scoring system, created in 2008, considers transaminases levels, autoantibodies, immunoglobulin G levels, liver biopsy, exclusion of Wilson disease and of viral hepatitis and cholangiogram[41,42]. The use of these criteria could also be helpful in children, but limitations must be recognized[43]. In children, it is difficult to differentiate AIH from primary sclerosing cholangitis or to identify autoimmune cholangitis overlap syndrome. The diagnosis of fulminant hepatitis cases has not been well determined because the use of 1/40 as a titer for autoantibodies is high to use in children (1/20 for ANA and SMA and 1/10 for anti-LKM1 are considered positive in this age group)[3,43]. For these reasons, histology is often included in the diagnostic criteria for HAI in children[3,44]. On histological examination, characteristic findings include the presence of piecemeal necrosis (interface hepatitis), lymphoplasmocytic infiltrates with numerous plasmocytes, and rosette formation[44,45]. Histology is a powerful tool for diagnosis, with high specificity (81%-99%) and predictability (62%-91%) but low sensitivity (36%-57%)[45]. Some cases also demonstrate biliary duct alterations, such as inflammatory infiltration of duct cells, cholestasis and ductopenia, which might represent an overlapping syndrome[46].

Genetic and immunologic markers

Some studies have unveiled the association of AIH with genetic markers, and the impact of immunophenotyping on clinical practice has been described.

Although the pathogenesis of AIH is not fully understood, susceptibility is partly determined by the presence of genes related to major histocompatibility complex Ⅱ (MHC Ⅱ) and most directly to human leukocyte antigen (HLA)[7,47]. The main associations are with HLA-DR3 and HLA-DR4 (DRB1*03 and DRB1*04) in Europeans and North Americans[48]. In children, HLA-DRB1*1301 is related to susceptibility to HAI, determining the prognosis and response to treatment[47,49]. The findings of the immunophenotyping in HAI are shown in Table 2.

Some conclusions can be drawn from these studies, in addition to some controversial findings[48-57]. Fortes Mdel *et al*[50] showed that patients presenting the HLA-DRB1*1301 allele were associated with a higher likelihood of developing cirrhosis. Czaja *et al*[56] concluded that patients with -DRB1*03 were younger at disease onset than patients with -DRB1*04, and they also had worse responses to corticotherapy. Patients expressing HLA

Table 1 Autoantibodies studies and their findings

Type of AIH	Autoantibodies	Antigen	Meaning
AIH type 1	Anti-actin	Actin	Poor response to treatment with corticosteroids[19-21]
AIH types 1 and 2 (80%-90% of cases)	Anti-asialoglycoprotein receptor	Asialoglycoprotein receptor	Liver specific antigen and indicative of prognosis[22,23]
AIH types 1 and 2 (8%-20% of cases)	Antimitochondrial antibody-M2	Mitochondria	Favorable response to corticosteroids[24,25]
AIH type 1 (39% of cases)	Anti-chromatin	Chromatin	High titers of immunoglobulin G and shows disease activity[26,27]
AIH type 2 (32% of cases)	Anti-liver-cytosol type 1	Enzyme formiminotransferase cyclodeaminase	Diagnostic tool and marker of liver inflamation[28-30]
AIH type 1	Antibody to histone and dsDNA	dsDNA	High titers of immunoglobulin G and poor-immediate response to corticosteroids[26]
AIH type 1 (47.5% of cases)	Anti-soluble liver antigen	t-RNAs	Presence of severe forms, associated with fatal outcome[31-35]
AIH type 2 (5%-19% of cases)	LKM-3	Uridinediphosphateglucuronyl tranferase	Allows diagnosis, being sometimes the only marker identified[36]
AIH type 1	Perinuclear antinuclear neutrophil cytoplasmic antibodies	Peripheral nuclear and perinuclear antigen	Presence of severe forms; Most frequent in primary sclerosing cholagitis and primary biliary cirrhosis[36-38]

AIH: Autoimmune hepatitis; dsDNA: Double-stranded DNA.

DRB1*04 are more often women, with a greater risk of comorbidity with other immune diseases and with good responses to corticosteroids[56,58].

In contrast, MHC Ⅱ antigens have shown significant heterogeneity among different ethnicities. Patients with HLA-DRB1*13 and -DRB1*03 have an earlier onset of disease compared to other patients, possibly because their ethnic groups that have a tendency toward AIH onset at younger ages. Moreover, certain ethnic groups have low prevalences of these immunophenotypes, such as the populations of Mexico and Japan, where HLA-DRB1*04 is more common, and these low rates seem to establish increased susceptibility to the disease in older people[50-52]. Few studies have demonstrated the role of immunophenotypes in HAI in children; to apply these markers as indicators of response to treatment and prognosis, more studies are needed.

The known physiopathological mechanism in AIH consists of an inflammatory response with T-lymphocyte cells, principally helpers, and B lymphocytes, macrophages and natural killer cells. The triggering factor or factors that stimulate this inflammatory response are not yet known. Several mechanisms have been proposed that would partially explain the immunologic findings of AIH[7,59].

Studies in adults and children have identified some potential pathways for the damage observed in AIH, such as the deregulation of immunoregulatory mechanisms. Some of the studies have shown that AIH patients have reductions in the number and function of T lymphocytes $CD4^+CD25^+$, which is one of the regulatory cells (T-regs) that normally represent 5%-10% of CD4 T cells in healthy humans[7,59-66]. These cells suppress the proliferation and cytokine responses of effectors CD4 and CD8 T cells, and they down-regulate the functions of macrophages, dendritic cells, natural killer cells, and B lymphocytes[62].

All immune findings are more pronounced in the initial presentation than after remission with treatment[61,62,66,67]. T-reg immunosuppressive functioning causes the production of anti-inflammatory cytokines, such as interleukin-4 (IL-4), interleukin-10 (IL-10) and transforming growth factor (TGF)-beta[68,69]. The surface markers involved in anti-inflammatory mechanisms are glucocorticoid-induced tumor necrosis factor receptor (CD62L), cytotoxic T lymphocyte-associated protein-4 (CTLA-4) and fork head/winged helix transcription factor (FOXP3)[62,70]. If the mechanisms of failure become known, new treatments, based on recuperation of the function of T-regulation, could be used in AIH[70-72].

Natural killer T cells ($CD3^+$ and $CD56^+$) are found in reduced numbers, producing lower levels IL-4 and IL-2 in AIH patients. These lower levels result in reduction of the surface expression of CTLA-4 in $CD4^+$T cells, playing a pivotal role in liver autoaggression, especially during the active phase of the disease[61,72]. Kurokohchi *et al*[73] also found that the levels of CTLA-4 were reduced in inflammatory cells from the peripheral blood of AIH patients, compared with controls, while levels of $CD80^+$ and $CD86^+$ were increased in liver-infiltrating cells. Other research has shown that the CCR5 cytokine receptor was preferentially expressed on Th1 cells. This cytokine plays a pivotal role in the recruitment of interferon-gama (IFN-γ) (a pro-inflammatory cytokine), producing $CD4^+$ T cells at inflammatory sites, such as hepatic tissue, and promoting hepatocyte damage in AIH[73,74]. Another possibility involves the presence of CD4 and/or CD8 self-reactive T cells, which could damage liver cells. These cells are found in healthy people, but in AIH patients, they are 10-fold higher in number[68,75].

Studies have also suggested that mutations in these genes act as precursors of the surface markers of immune cells and might also have significance in autoimmune diseases because changes in HLA (MHC) are absent in some patients. Mutations of several lympho-

Table 2 Major histocompatibility complex class Ⅱ human leukocyte antigen and its association with autoimmune hepatitis patients

Ref.	Total No. of patients/ controls (No. of children)	What was evaluated	Conclusions
Donaldson *et al*[48]	96/100 (no)	HLA-DR	HLA-DR3 and DR4 genes independently confer susceptibility to autoimmune hepatitis
Fortes Mdel *et al*[50]	41/111 (13)	HLA-A, -B, -C, -DR and DQ	Regarding HLA-A and -C there were no significant differences between groups; For HLA class Ⅰ, an increase in the frequency of B*08, B*18, B*45 and B*50 was observed. HLA B*40 was more frequent in healthy controls; For HLA class Ⅱ, an increase in the frequency of HLA-DQB1*02, -DQB1*04, HLA-DRB1*03, DRB1*13 and DRB3 was observed. HLA-DRB1*1301 and -DRB1*0301 were more frequent in children
Ota *et al*[51]	51/no (no)	HLA-DR and -DQ	Increased frequency of all HLA-DRB1*04 alleles, principally -DRB1*0405. Secondary association with -DRB1*15 and DRB1*16
Vázquez-García *et al*[52]	30/175 (not cited)	HLA-A, -B, -C, -DR and -DQ	A significant association with HLA-DRB1*0404 was found. It was present in patients with average age onset. DQB1*0301 had a low frequency in patients and may represent a protective factor; No association was found with any class Ⅰ antigen
Fainboim *et al*[53]	52/197 (all)	HLA-A, -B, -C, -DR and -DQ	No significant associations with HLA class Ⅰ antigens were found; HLA-DR6 group (HLA-DRB1) showed increased frequency, principally HLA-DRB1*1301; The analyses of HLA-DQ group showed an associations of HLA-DQB1*0603
Pando *et al*[54]	206/208 (122)	HLA-DR and -DQ	The frequencies of HLA-DRB1*1301, -DRB1*0301, -DQA1*0103, -DQB1*0603 were significantly increased on AIH patients; HLA-DRB1*1301 was associated with younger age at disease onset, being the allele associated with AIH in children and HLA-DRB1*1302 worked as a protective factor
Bittencourt *et al*[55]	139/129 (74)	HLA-DRB and -DQB1	In AIH type 1, there was significant increase in the HLA-DRB1*13, -DRB1*03, -DRB3 and -DQB1*06 alleles in patients. HLA-DRB1*13 was more frequent in children than adults. The low frequency of HLA-DQB1*0301 may indicate a protective role of this allele; In AIH type 2, a significant increase in DRB1*07, DRB1*03, DRB4 and DQB1*02 was observed
Czaja *et al*[56]	86/102 (not cited)	HLA-A, -B, -C, -DR and -DQ	DRB4*0103 is associated with immune diseases, DRB1*0301 with a poor treatment response, and DRB1*0401 with a lower frequency of hepatic death or transplantation
Czaja *et al*[57]	210/396 controls with other chronic liver disease/102 healthy controls (no)	HLA-DR B1*03, -DRB1*04 and -DRB1*13	The frequency of HLA DRB1*13 was higher in patients without -DRB1*03 and -DRB1*04; Primary sclerosing cholangite patients showed a similar frequency of HLA-DRB1*13 when compared with AIH patients

HLA: Human leukocyte antigen; MHC: Major histocompatibility complex; AIH: Autoimmune hepatitis.

cyte surface markers studied could represent molecular markers of autoimmunity in AIH. Among them is the CTLA-4 (CD152) gene mutation, which has appeared in controversial reports of the phenotypes that represent susceptibility to AIH[76-81]. For instance, in the Brazilian study by Bittencourt *et al*[77] no association was established between exon 1 *CTLA-4* gene polymorphisms at position 49 and AIH susceptibility, contradicting findings in a North American population[78].

CTLA-4, which is expressed on the surface of T cells, induces peripheral tolerance by biding CD80 and CD86 on antigen-presenting cells. In doing so, CTLA-4 competes with the co-stimulatory molecule CD28, reducing the immune response[47]. CTLA-4 is considered a critical coordinator in immune regulation. Based on this finding, some researchers have attempted to find a drug that simulates its mechanism and that could be used in the treatment of autoimmune conditions; one such drug is an immunoglobulin G-CTLA-4 (Abatacept), which was recently approved by the FDA for use in rheumatoid arthritis[82,83].

Furthermore, some studies have aimed to evaluate whether a *Fas* gene polymorphism or its increased expression on lymphocyte surfaces could be key mechanisms for autoimmunity in AIH. Fas (CD95) is part of the tumor necrosis factor family, and it induces receptor-mediated programmed cell death (apoptosis) through engagement with its ligand (FasL/CD95L). It indirectly controls the number of antigen-activated lymphocytes[84]. Ogawa *et al*[85] showed that AIH patients show an increase in CD95 (Fas)-positive $CD4^+$ and $CD8^+$ T cell numbers. These individuals show disease courses with high levels of conversion of naive $CD45RO^-$ to primed $CD45RO^+$ $CD4^+$ T cells. This course could indicate that constant activation of T lymphocytes and/or the persistent presence of activated lymphocytes requires continuous work from regulation cells, such as $CD95^+$ T $CD4^+$[85]. Tsikrikoni *et al*[86] also found a greater number of Fas^+ and $FasL^+$ cells in the mononuclear cells of AIH patients and increased TNF-α and IFN-γ production in cultured cells, suggesting that these cytokines could be involved in accelerating apoptosis. They also showed an increase in $CD14^+$ monocyte cell numbers, in accordance with the increased

expression of apoptotic markers, such as $CD14^+$ cells, responding to the clearance of apoptotic cells[87]. Concomitantly, the results of genetic studies have shown that some mutations can affect the function of Fas receptors, but more research is needed to determine these receptors' relationship with AIH[88-91].

A lack of consistent evidence has persisted for studies evolving genes of cytokines, such as tumor necrosis factor; TGF-beta1, and TBX21, (a regulator of T lymphocyte lineage development and a controller of the expression of IFN-γ)[91-98].

TREATMENT

An important feature of AIH is response to treatment with corticosteroids and immunosuppressants[2,6,99]. Prednisone alone or in combination with azathioprine is the main form of treatment[99]. This treatment has the goal of reducing hepatic inflammation, the induction of clinical remission, relief of symptoms and improvement of survival. The treatment response characterizes clinical improvement and a reduction of aminotransferases to normal or to no more them two times of the maximum of the reference value, while remission lies in clinical improvement, normalization of aminotransferases and gamma globulin, autoantibody reduction or extremely low titers of autoantibodies and histological resolution of inflammation with a reduction in fibrosis[3,44]. Moreover, relapse is characterized by increased transaminases after remission has been achieved, as shown by Ferreira *et al*[44,100]. Relapse is common during treatment and occurs in up to 40% of patients, requiring a temporary increase in the dose of corticosteroid[3,99]. Noncompliance play a prominent role in a percentage of relapses[44,100]. Some medications offer alternative treatment, such as cyclosporine, tacrolimus and mycophenolate mofetil. These drugs are reserved for patients who fail to respond to the first treatment choice[2,6]. In cases of autoimmune sclerosing cholangitis and autoimmune cholangitis, the use of ursodeoxycholic acid can be necessary to control bile duct disease[2].

Liver transplantation is the last-line treatment indicated for patients who have not responded to medication. The need for transplantation is present in 8.5% of children with HAI[8]. The total duration of immunosuppressive therapy has not been established, but in the face of the possible side effects with medication, discontinuation of treatment should be considered when the remission criteria are met in patients with type 1 AIH[3]. To meet this goal, the patient must present histological resolution of inflammation after at least two years of clinical and laboratory remission (normal liver enzymes, liver function and gamma globulin and autoantibodies in low or undetectable titers)[3]. Approximately 20% of patients with type 1 AIH can remain in remission after discontinuation of treatment, but relapses are frequent after the suspension of treatment[6,8,100]. In type 2 AIH, treatment discontinuation is not recommended because relapses are more frequent, and failure of remission upon suspension is almost certain in this condition[8].

The prognosis of patients who respond to immunosuppressive treatment is good, even when there is cirrhosis at baseline; there is a good quality of life and, in general, use of low doses of medication[2-4]. Except for the changed autoantibodies that were initially detected, no markers are currently used in clinical practice to choose and follow treatment.

CONCLUSION

In conclusion, recent studies have shown new possibilities for the diagnosis and prognostic evaluation of AIH, except for in the pediatric age group, which remains unrepresented in these assessments. Susceptibility to autoimmune diseases is multifactorial, but genetic and immunological factors play pivotal roles. MHC Ⅱ antigens could represent a susceptibility marker for AIH, considering the differences between ethnic groups, or they might predict treatment response and prognosis. Finally, in pediatric populations, the prevalence and titers of autoantibodies can be different from in adults, such as for the MHC Ⅱ HLA-DRB1*1301, which can be a marker of susceptibility in the pediatric population.

Perhaps in the future, knowledge of autoimmune mechanisms will reveal better markers for the diagnosis, monitoring and treatment of AIH and other autoimmune diseases, but there are still only few available studies with good suggestions for markers.

Abstract

AIM: To investigate the effects of glutamine on oxidative/nitrosative stress and the vascular endothelial growth factor (VEGF)-Akt-endothelial nitric oxide synthase (eNOS) signaling pathway in an experimental model of portal hypertension induced by partial portal vein ligation (PPVL).

METHODS: Portal hypertension was induced by PPVL. The PPVL model consists of a partial obstruction of the portal vein, performed using a 20 G blunt needle as a guide, which is gently removed after the procedure. PPVL model was performed for 14 d beginning treatment with glutamine on the seventh day. On the fifteenth day, the mesenteric vein pressure was checked and the stomach was removed to test immunoreactivity and oxidative stress markers. We evaluated the expression and the immunoreactivity of proteins involved in the VEGF-Akt-eNOS pathway by Western blotting and immunohistochemical analysis. Oxidative stress was measured by quantification of the cytosolic concentration of thiobarbituric acid reactive substances (TBARS) as well as the levels of total glutathione (GSH), superoxide dismutase (SOD) activity, nitric oxide (NO) production and nitrotyrosine immunoreactivity.

RESULTS: All data are presented as the mean ± SE. The production of TBARS and NO was significantly increased in PPVL animals. A reduction of SOD activity was detected in PPVL + G group. In the immunohistochemical analyses of nitrotyrosine, Akt and eNOS, the PPVL group exhibited significant increases, whereas decreases were observed in the PPVL + G group, but no difference in VEGF was detected between these groups. Western blotting analysis detected increased expression of phosphatidylinositol-3-kinase (PI3K), P-Akt and eNOS in the PPVL group compared with the PPVL + G group, which was not observed for the expression of VEGF when comparing these groups. Glutamine administration markedly alleviated oxidative/nitrosative stress, normalized SOD activity, increased levels of total GSH and blocked NO overproduction as well as the formation of peroxynitrite.

CONCLUSION: Glutamine treatment demonstrated to reduce oxidative damage but does not reduce angiogenesis induced by PH in gastric tissue, demonstrating a beneficial role for the PI3K-Akt-eNOS pathway.

Key words: Partial portal vein ligation; Oxidative stress; Glutamine; Portal hypertension; Rats

INTRODUCTION

Portal hypertension (PH) is a clinical syndrome that is usually secondary to obstruction of the intra- or extra-hepatic portal flow. It is considered the main complication of liver disease, being responsible for the development of other liver diseases, such as portal hypertensive gastropathy, ascites, spontaneous bacterial peritonitis, hepatorenal syndrome, hepatopulmonary syndrome, portopulmonary hypertension, hyperkinetic syndrome and hepatic encephalopathy[1].

PH is characterized by an increase in pressure above 5 mmHg in the portal venous system. When the pressure reaches 8 to 10 mmHg, in the esophagus and stomach, gastroesophageal varices arise, which develop from a network of collateral circulation through the vessels that form the splanchnic circulation. Bleeding from gastroesophageal varices can occur when the portal pressure gradient reaches values above 12 mmHg[2-4].

Numerous veins dilate, including the hemorrhoidal plexus, abdominal wall and esophagogastric junction. The umbilical vein communicates with and dilates the superficial veins of the abdominal wall, and the presence of abdominal collateral circulation is an important clinical sign of portal hypertension, which is characterized by dilated and tortuous veins radiating from the navel to the upper abdomen and lower chest[5,6]. Collateral circulation of the left gastric vein to the azygos vein is responsible for esophagogastric varicose veins and increased circulation in the gastric mucosa, which characterize the complications of portal hypertension referred to as portal hypertension gastropathy (PHG)[5].

The vascular endothelium releases vasodilators, including nitric oxide (NO) and prostacyclins, and vasoconstrictors, including endothelin, angiotensin and thromboxane. The function of vascular tone is maintained by balancing these agents. The increased peripheral resistance is maintained by elevation of vasoconstrictors or vasodilators or by reducing the levels of both. The blood exerts a force against endothelial cells, which are the main agonist in the release of NO[7].

Increases in NO synthesis have also been reported in the liver of rats with PH. Moreover, NO production has been implicated in the pathogenesis of PHG, with increases in NO serum levels being detected in patients with PHG[5]. When present in high concentrations, NO acts as a free radical, forming two molecules of dinitrogen trioxide (N_2O_3) or peroxynitrite (ONOO), which are responsible for cytotoxic effects such as inflammation and septic shock. Recently, NO has been presented as an important signal of the maintenance of homeostasis, as well as a cytotoxic agent involved in numerous diseases[8-10].

Increased formation of blood vessels in the splanchnic region occurs through the process of angiogenesis, which is involved in the maintenance of hyperdynamic circulation in portal hypertension. This hypothesis is based on recent studies that demonstrate the presence of increased splanchnic angiogenesis and neovascularization, which are responsible for the formation of portosystemic collaterals in experimental models of PH[11]. The stimulus for the proliferation of new blood vessels occurs through a complex cascade of angiogenic events, and it is the main modulator of this mechanism, vascular endothelial growth factor, vascular endothelial growth factor (VEGF), that stimulates the proliferation and migration of endothelial cells. Overproduction of NO is stimulated by endothelial nitric oxide synthase (eNOS), which can be stimulated by both VEGF and phosphatidylinositol-3-kinase (PI3K). In turn, PI3K-Akt also receives stimulation through the VEGF pathway, and the shear stress that occurs in PH can be a factor in stimulation *via* PI3K-Akt as well[12-14]. The Akt protein directly stimulates eNOS by increasing the capacity of eNOS to generate NO. There are several ways to stimulate the Akt pathway, including through growth factors, cytokines and the mechanical force of shear stress in a blood vessel, which activates the NO release mechanism in a PI3K-dependent manner[15,16]. Overproduction of vascular NO plays a central role in both systemic and splanchnic vasodilations, which are characteristics of portal hypertension that cause it to be recognized as a major complication of liver cirrhosis. The increased expression and activity of eNOS are well-established events in chronic models of portal hypertension[17,18].

Glutamine, a nonessential amino acid, has received increasing attention because it becomes essential during stress and catabolic conditions[19]. Glutamine administration can result in an enhanced antioxidant capacity in various situations, such as critical illness or sepsis[20]. In the stomach, glutamine is able to protect against peptic ulceration and improves the healing of ulcers[21]. The present study was designed to investigate the potential beneficial effects of glutamine administration on gastric oxidative stress and to evaluate the role of the VEGF-PI3K-Akt-eNOS pathway in NO overproduction in an experimental model of PHG.

MATERIALS AND METHODS

Ethics

All animals received humane care according to the criteria outlined in the Guide for the Care and Use of Laboratory Animals prepared by the National Academy of Sciences and published by the National Institutes of Health (NIH publication 86-23, revised 1985).

Animals and experimental groups

Male Wistar rats with a mean weight of 250 g were used. The animals were obtained from the Center for Breeding

of Laboratory Animals of the Federal University of Rio Grande do Sul. The rats were held in cages at 20-24 ℃ with a 12 h light/dark cycle and given free access to food and water. They were randomly divided into the following four groups of fourteen animals each: (1) [sham-operated (SO) rats receiving only NaCl as a vehicle]; (2) SO + G (SO rats receiving glutamine); (3) PPVL (PPVL rats receiving vehicle); and (4) PPVL + G (PPVL rats receiving glutamine).

Partial portal vein ligation and sham operation

During the procedure, rats were anesthetized with a ketamine (Ketalar, Parke Davis, 100 mg/kg) and xylazine 2% (Rompun, Bayer, 50 mg/kg) cocktail *ip*. PH was induced by partial portal vein ligation (PPVL) as described by Moreira *et al*[22]. Briefly, the portal vein was isolated, and a 3-0 silk ligature was tied around both the portal vein and an adjacent 20 gauge blunt-tipped needle. The needle was subsequently removed, and the vein was allowed to re-expand. The abdomen was then closed, and the animal was allowed to recover. Control rats underwent a similar operation but without ligature of the portal vein. Sham-operated animals received only vehicle (NaCl, 1 mL/kg, *ig*). Glutamine was administrated daily (14 mg/kg, daily, *ig*) for 7 d beginning on the eighth day after the surgical protocol. All rats were anesthetized and sacrificed on the fifteenth day of the protocol. Their stomachs were immediately removed and divided into four subsamples that were stored in a freezer at -80 ℃ for analysis of oxidative stress, total glutathione, immunohistochemistry and Western blotting.

Oxidative stress determinations

Gastric oxidative stress was determined by measuring the concentration of aldehydic products (TBARS). Briefly, the frozen tissue was homogenized in a solution containing 140 mmol KCl and 20 mmol phosphate buffer (pH 7.4) and centrifuged at 14000 *g* for 10 min. For TBARS analysis, the amount of aldehydic products generated by lipid peroxidation was measured *via* the thiobarbituric acid reaction using 3 mg of protein per sample. The samples were incubated at 90 ℃ for 30 min following the addition of 500 mL of 0.37% thiobarbituric acid in 15% trichloroacetic acid and then centrifuged at 2000 *g* for 15 min. The spectrophotometric absorbance of the supernatant was determined at 535 nm[23].

Nitric oxide quantification

Nitric oxide production in the gastric tissue was measured indirectly using a quantitative colorimetric assay based on the Griess reaction. This method is sensitive for both nitrite and nitrate ions[24]. Briefly, the samples were deproteinized and subsequently centrifuged for 20 min at 12000 *g*. After incubation of the supernatants with *E. coli* nitrate reductase (37 ℃, for 30 min) to convert nitrates to nitrites, 1 mL of Griess reagent (0.5% naphthylethylenediamine dihydrochloride, 5% sulfonylamide, 25% phosphoric acid) was added. The reaction was allowed to proceed at room temperature for 20 min, after which the absorbance at 546 nm was measured using a sodium nitrate solution as a standard.

Antioxidant enzyme activities

Cytosolic superoxide dismutase (SOD; EC 1.15.1.1) was assayed spectrophotometrically based on the rate of epinephrine autooxidation, which is progressively inhibited by increasing amounts of SOD in the homogenate; the amount of enzyme that results in 50% of the maximum inhibition of autooxidation is defined as 1 unit of SOD activity[25]. For analysis of glutathione (GSH) and GSSG, the livers were homogenized with 5% (w/v) metaphosphoric acid. After centrifugation (16000 *g* for 2 min), the tissue homogenate was assessed spectrophotometrically (415 nm) in a microplate reader employing a modified version of the 5,5'-dithiobis (2-nitrobenzoic acid) (DTNB, Sigma)/GSSG reductase (Sigma) recycling method using the 43 *N*-ethylmaleimide (NEM, Fluka) conjugating sample preparation technique for GSSG. Samples (10 L) for both GSH and GSSG determination were assayed in 96-well polystyrene plates (Corning) at 37 ℃ in the presence of 10 mmol DTNB, 0.17 mm β-NADPH (Sigma, dissolved in 0.5% (w/v) $NaHCO_3$ as a Stabilizing agent) and 0.5 U/mL GSSG reductase[26].

Western blotting analysis

The technique used for this measurement was protein expression by Western blotting analysis employing the system described by Laemmli[27] for electrophoresis and the blotting technique described by Towbin *et al*[28]. Proteins (80 g) were separated in a 10%-15% polyacrylamide gel and transferred electrically to polvinylidene difluoro membranes (Millipore, Bedford, MA, United States). Subsequently, the membranes were placed in Tris/saline-tamponade/Tween-20 blocking solution (TBST-5% milk powder in Tris-buffered saline containing 0.05% Tween 20) for 60 min at 37 ℃. The membrane was incubated overnight at 4 ℃ with polyclonal eNOS and VEGF (Santa Cruz Biotechnology, Santa Cruz, CA, United States), P-Akt and PI3K (Cell Signaling Technology, Danvers, MA, United States). Thereafter, the membranes were washed with TBST and incubated for one hour at room temperature with an anti-rabbit immunoglobulin antibody coupled to HRP (SIGMA, Glostrup, Denmark). The proteins were detected by chemiluminescence using a commercial ECL kit (Amersham Pharmacia Biotech, Uppsala, Sweden), and the density of specific bands was quantified using a densitometer image (Image J, United States).

Immunohistochemistry

Tissues sections (4 m) soaked in a formalin fixative and embedded in paraffin were subjected to immunohistochemical analysis[29]. This technique consisted of the following steps: deparaffinization, rehydration, antigen retrieval, inactivation of endogenous peroxidase and blocking of nonspecific reactions. The samples were incubated with the primary antibody for 12 h at 4 ℃ us-

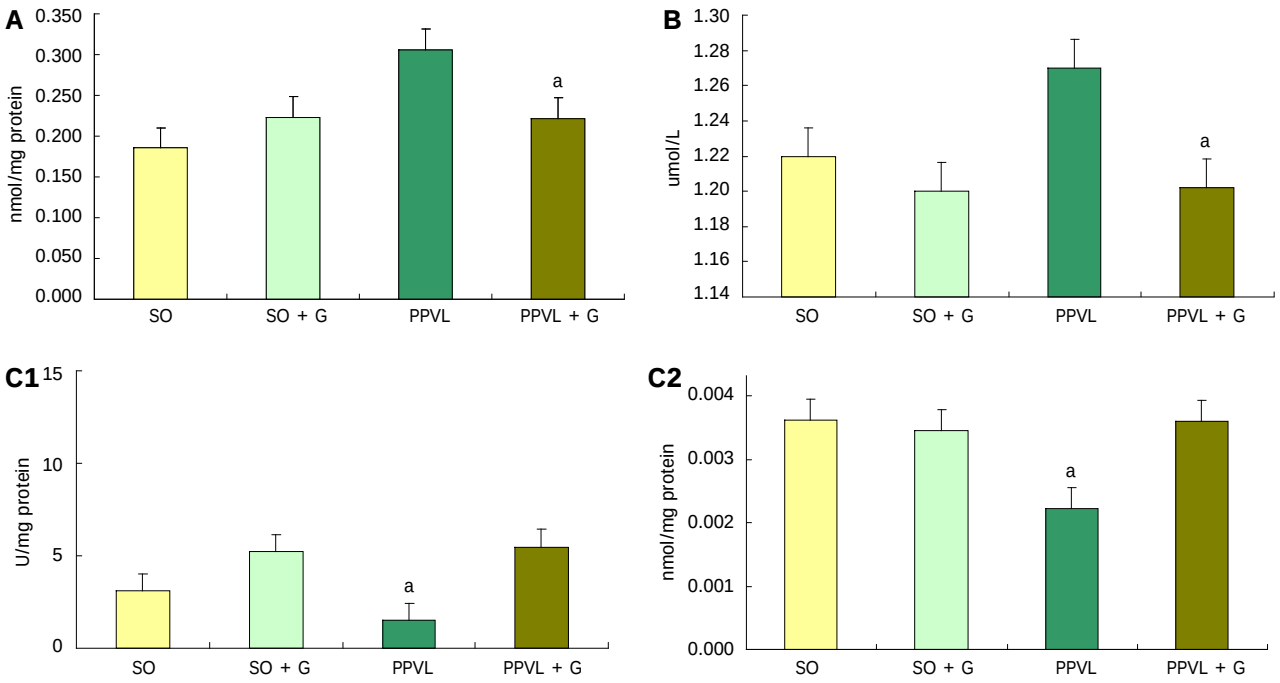

Figure 1 Effect of partial portal vein ligation and glutamine administration on gastric oxidative stress, nitric oxide production, antioxidant enzyme activities. ing the specific dilution of each antibody indicated in the instructions. After we applied the streptavidin-biotin complex (LSAB, DAKO) using a diaminobenzidine revelation tetrahydrochloride Kit (DAB, DAKO) and the samples were counterstained with hematoxylin. The antibodies used in the gastric mucosa samples were eNOS and VEGF (Santa Cruz Biotechnology, Santa Cruz, CA, United States), AKT (Cell Signaling Technology, Danvers, MA, United States) and NTT (Sigma, United States).

Statistical analysis

The data were calculated and analyzed using analysis of variance. A *post hoc* multiple comparisons test was performed using the Student Newman-Keuls test. Values were considered significant when $P < 0.05$. All calculations were performed using the statistical program Graphpad Prism, version 14.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

Markers of oxidative stress

The cytosolic concentration of TBARS increased in PPVL group, compared to SO. And decrease significantly on PPVL + G group compared to PPVL. Glutamine administration was effective in diminishing TBARS production (Figure 1A).

Nitric oxide levels

The concentrations of nitrites in the gastric tissue (Figure 1B), the values were significantly higher in PPVL group compared to SO. Moreover, nitrite concentrations were similar to PPVL + G and SO groups. This parameter was restored to baseline levels in animals PPVL receiving glutamine.

Antioxidant enzyme activities

Analysis of antioxidant enzyme activities showed that portal vein ligation induced a considerable reduction of gastric SOD in PPVL group compared to SO, SO + G and PPVL + G. Glutamine treatment increased SOD activity and GSH activity (Figure 1C) on PPVL + G group.

Western blotting analysis

Analyses of the protein expression of PI3K (Figure 2B), P-Akt (Figure 2A) and eNOS (Figure 3A) showed that there was reduced expression in the PPVL + G group compared with the PPVL group. This effect was not observed for the expression of VEGF (Figure 3B), for which a significant increase was observed in the PPVL group compared with the SO group, although no reduction was observed when compared with the PPVL + G group.

Immunohistochemistry

Analyses of the reactivity of the eNOS (Figure 4A), Akt (Figure 4C) and NTT (Figure 4D) proteins in the gastric mucosa of rats showed that there was reduced expression in the PPVL + G group compared with the PPVL group. This effect was not observed for the expression of VEGF (Figure 4B), for which a significant increase

was observed in the PPVL group compared with the SO group, although no reduction was observed when compared with the PPVL + G group.

DISCUSSION

PHG is recognized as a clinical condition in PHI, but the exact pathogenesis of PHG is still unclear. The PPVL model has been extensively studied and found to be a useful tool for understanding the pathophysiology of PHI and PHG. This model has been developed in different animal species, such as rats, mice and rabbits, and it is presently accepted to be suitable for investigating the pathogenesis of PHI and PHG because is highly reproducible and easy to perform, and portal hypertension develops very rapidly. The model used in our study is characterized by prehepatic portal hypertension with maintenance of hepatic structure, hyperdynamic circulation and portal-systemic shunting. Treatment of portal hypertension to prevent complications, particularly gastrointestinal bleeding, is of fundamental importance and occurs under three clinical scenarios: prevention of first bleeding (primary prophylaxis), treatment after an episode of bleeding and prevention of secondary bleeding (secondary prophylaxis). These treatments can be performed using vasoconstrictors, which reduce portal venous flow; vasodilators, which reduce intrahepatic resistance; or a combination of both treatments[30].

Treatment using chemicals or natural products that would prevent complications of PH would represent a significant advance in therapy and could be a way to decrease mortality. Development of experimental models exhibiting pathogenic characteristics similar to those of human disease may help in understanding the mecha-

The PPVL + G group showed reduced expression of this enzyme *vs* the PPVL group. Analysis of the field was carried out precisely in the submucosal region, where there is evidence of edema and vasodilatation. eNOS staining; original magnification × 10. $^{a}P < 0.05$ *vs* the SO group.

nisms of portal hypertension and allow testing of new therapeutic modalities. Thus, an experimental model of PH was employed in this study and has contributed to improving our understanding of the pathophysiological conditions presented in humans. PH may be triggered by various agents, leading to cirrhosis.

A study assessing the damage caused by oxidative stress in the gastric mucosa showed that there was an increase of LPO and decreases in the levels of the enzymes SOD, CAT and GPx in injured animals, suggesting that oxidative stress is involved in gastric tissue damage[31]. When we assessed lipid peroxidation in the stomachs of rats, an increase in the level of substances reacting with thiobarbituric acid (TBA-RS) was detected in the PPVL group compared with the SO group, which is suggested to be related to increased oxidative stress. This conclusion was supported by the amounts of TBA-RS observed in the PPVL + G group compared with the PPVL group. Similar results have been shown in other studies that used the flavonoid quercetin and *N*-acetylcysteine, suggesting that the amino acid glutamine exhibits antioxidant potential[32]. In the present study, glutamine reduced submucosal edema and vasodilation as well as reducing lipid peroxidation in homogenized stomachs from animals in the PPVL + G group. Glutamine, as a potential antioxidant, appears to protect the gastric mucosa and decrease oxidative damage to the gastrointestinal tract, which was observed both in this study and in previous studies of colitis employing glutamine[33].

The enzyme SOD, which is responsible for the dismutation of superoxide anion radicals into hydrogen peroxide, is the first line of defense against cellular oxidative stress. The SOD activity determined in the gastric mucosa in a study of patients with liver disease showed that this enzyme is found at reduced levels in these patients compared with control subjects with cirrhosis. However, individuals with chronic liver disease showed no significant changes in the levels of SOD. In liver diseases such as hepatitis, cirrhosis and hepatocellular carcinoma, there are high levels of LPO in the stomach, suggesting involvement of oxidative stress in gastric mucosal lesions in these liver diseases[34]. Studies relate the decrease in SOD enzyme activity to increased oxidative stress[35,36]. In the present study, we observed a decrease in SOD activity in the PPVL group compared with other groups, which could be related to the inactivation of superoxide anions, as this enzyme was acting in the dismutation of EAOS and the formation of H_2O_2. In contrast, animals in the PPVL + G group maintained values of SOD enzyme activity similar to controls. This increased activity of SOD in the PPVL group was due to the increased formation of EAOS, causing oxidative stress. Total GSH has a special physiological importance because glutamine serves as a substrate for glutathione formation. Studies have demonstrated the direct involvement of GSH in colitis[37]. A relationship was shown with glutathione colitis, in which rats with experimental colitis caused by TNBS showed a significant decrease in the level of glutathione compared with the control group[38].

In the evaluation of NO metabolites in stomach homogenates, we observed a reduction in the production of these metabolites in the PPVL + G group compared to the PPVL group. This increase in NO production in the PPVL group can be explained by the process of angiogenesis, which occurs in this model for the purpose of shunting of blood from the obstructed area to the systemic circulation. Moreover, these increased levels of nitric oxide could be reacting with superoxide anions to form peroxynitrite radicals, which are extremely harmful. This NO release becomes more pronounced due to the need for the formation of new blood vessels so that blood can reach the systemic circulation, triggering an increase in RL, thus stimulating lipid peroxidation and oxidative stress[39].

Oxidative stress plays an important role in the pathogenesis of PH because in association with the overproduction of superoxide anions and nitric oxide observed in the model of partial portal vein ligation, peroxynitrite formation occurs. Researchers have noted specific actions of ONOO as a modulator of intracellular signaling pathways regulating inflammatory responses, including induction of angiogenesis and VEGF.

The significant reduction of lipid peroxidation observed in animals in the PPVL + G group demonstrates effective action of the glutamine in the process of lipid peroxidation. This result is consistent with the expected capacity of glutamine in the formation of inactivating EAOS, especially in reducing the formation of peroxynitrite. Peroxynitrite reacts with free tyrosine and tyrosine residues in protein molecules to produce nitrotyrosine. Alternatively, EAOS can activate tyrosine to form tyrosyl, a radical that in turn oxidizes NO to produce nitrotyrosine (NTT)[40,41]. The generation of peroxynitrite was assessed based on the level of expression and immunoreactivity of NTT, with significant reductions being observed for both parameters in animals in the PPVL + G group, demonstrating the effectiveness of glutamine with respect to the oxidative/nitrosative damage that occurs in the gastric mucosa.

Upregulation of eNOS initiates the post-translational level mediated by Akt, which increases its activity at any concentration of cytosolic Ca^{2+}[42]. During early cirrhosis, this pathway is stimulated by different types of stimuli, such as VEGF, inflammatory cytokines and mechanical shear forces[42]. In advanced stages of portal hypertension, bacterial translocation also activates eNOS *via* tumor necrosis factor, increasing tetrahydrobiopterin, which is an essential element that acts as a cofactor of the enzyme. According to several studies, other mechanisms, such as changes in the subcellular localization of eNOS[43], *S*-nitrosylation[44] or degradation of asymmetrical dimethylarginine, may be involved in regulating the activity of eNOS[45]. We observed in this study that glutamine reduced eNOS protein expression and the immunoreactivity of the enzyme in the gastric mucosa of animals in the PPVL + G group. One explanation for

this finding is that glutamine, due to its involvement in NO synthesis, is involved in reduction of the cytosolic levels of Ca^{2+}, which is related to the levels of Akt; in turn, Akt levels are stimulated by mechanical stress shear. Throughout this process, this hemodynamic mechanism would be inhibited due to reduced levels of NO triggered by the action of glutamine.

Angiogenesis is characterized by the formation of new vascular structures and a pathophysiological phenomenon that has been further investigated in recent years due to the critical role it plays in the pathogenesis of disease and its potential as a therapeutic target. Additionally, angiogenesis contributes to a number of physiological processes, such as wound healing and the reproductive cycle[46]. NO released by dilation and increased vascular permeability as well as the migration, proliferation and survival of endothelial cells plays a crucial role in angiogenesis. Many molecules have been implicated as modulators of the angiogenic process, such as tumor necrosis factor, interleukins, angiopoeitins and growth factors, including VEGF. Indeed, VEGF stimulates NO production by NOS, increasing vascular permeability and the proliferation and survival of endothelial cells[47].

Furthermore, overproduction of ONOO, which is formed by the reaction of superoxide anions and nitric oxide, is observed under inflammatory conditions[48], whereas cytotoxic actions of ONOO have been reported *via* the modulation of intracellular signaling pathways that regulate inflammatory responses, including induction of angiogenesis and increased levels of VEGF. Studies in the retina of rats with diabetes induced by streptozotocin demonstrated the formation of nitrotyrosine and increased effects regarding stimulation of VEGF. These conditions have been studied because they induce the generation of reactive oxygen species (ROS). EAOS are involved in triggering the overexpression of VEGF in various cell types[49,50], but the molecular mechanisms underlying this effect remain to be elucidated. Studies in patients, in animals and *in vitro* indicate that formation of nitrotyrosine, a marker of ONOO, is associated with increased VEGF expression during diabetic microvascular disease, atherosclerosis and tumor angiogenesis[51,52]. In addition, studies using a cultured cell line showed that formation of ONOO stimulates an increase in VEGF[53]. In the present study, we observed increased expression and immunoreactivity of VEGF in animals in the PPVL group, but there was no significant reduction of these parameters in animals in the PPVL + G group. We suggest that these results demonstrate direct action of glutamine on NO synthesis to reduce its levels, rather than only affect the action of growth factors and the associated cascade of events.

VEGF also acts by stimulating PI3K, which activates eNOS in an Akt-dependent manner, resulting in activation of eNOS and increased NO production. PI3K phosphorylates Akt, which can rapidly activate eNOS[54]. The Akt pathway has emerged as a signaling pathway in all cells of higher eukaryotes, and Akt has been found to be one of the most important and versatile kinases for understanding human physiology and disease. Recent studies have been performed to elucidate the molecular details of the regulation of Akt and its role in human disease. The NO released due to eNOS stimulation is involved in vasodilation, vascular remodeling and angiogenesis[55]. The Akt signaling pathway also leads to increased production of transcription factors induced by hypoxia (HIF1α and HIF2α), partly through the activation of an mTOR-dependent mechanism[56]. The activation of eNOS through Akt/B kinase leads to increased NO production, vasodilatation and increased splanchnic circulation[57]. Akt activation occurs due to an increase in shear stress-induced endothelial disruption, although other mechanisms may be involved[58].

In this study, we observed a significant increase in the expression and immunoreactivity of Akt in the PPVL group and a reduction in these parameters in the PPVL + G group. These results can be explained by the role that glutamine plays in the production of NO, which in turn, triggers a chain reaction, is overproduced and dilates the splanchnic vessels, gradually increasing shear stress, which is the mechanical stimulus for the activation of Akt. In addition, it was observed that VEGF levels are unchanged in the PPVL + G group compared to the PPVL group, and the VEGF RTK pathway acts as a means for the release of PIK3, eNOS and P-Akt, leading to the production of more NO, which is a feature present in the hyperdynamic circulation associated with PH. Therefore, glutamine acts to mitigate this situation not by reducing the levels of NO *via* VEGF, but by reducing the shear stress triggered by NO synthesis through inhibition of *L*-arginine, thereby reducing the levels of Akt, which is stimulated by mechanical stress in blood vessels. In conclusion, we describe the beneficial effects of glutamine treatment on oxidative stress, including reduced portal pressure, normalization of SOD and reduction of NO production by eNOS, mediated by the PI3K-Akt-eNOS pathway. VEGF levels tended to decrease, although this trend was not found to be statistically significant.

COMMENTS

Background

Portal hypertension (PH) is the main complication of cirrhosis and is through its development is arising other liver diseases. Among them we mention the gastropathy of portal hypertension, which is characterized by the development of hyperdynamic splanchnic circulation. The main modulator of this process is nitric oxide release and their pathways in the pathophysiology of PH is still being studied. As there is no effective treatment for PH, it was decided to study the role of glutamine, an amino acid that has been used in the treatment of colitis, the clinic and evaluate its involvement both in oxidative stress, as in the intracellular stimulus for release nitric oxide.

Research frontiers

Studies are relevant in clinical hypertension, especially in hepatology. In addition, PH may be associated with other diseases such as schistosomiasis and budd-chiari syndrome. Therefore, the study of PH has a great clinical relevance for gastroenterology, since there is still no effective therapeutic treatment.

Innovations and breakthroughs

There are numerous studies using the experimental model of partial portal vein ligation,with which it mimics the complications of PH. Have been evaluated for

treatment of other molecules such as PH, quercetin and *N*-acetylcysteine. The results were similar with glutamine to these molecules, but there is when the comparative results on the role of intracellular pathways.

Applications

These results suggest that the amino acid glutamine is a molecule with therapeutic potential and can be used in the treatment of portal hypertension, reducing damage to the gastric mucosa caused by hypertension portal gastropathy.

Terminology

PH is characterized by increased vascular resistance and/or blood splanchnic flow; Glutamine: Essential amino acid involved in several cellular functions, among them acting as a substrate for the synthesis of antioxidants such as glutathione; Gastropathy of portal hypertension: Clinical syndrome secondary to cirrhosis, which is characterized by the formation of edema and dilation of gastric submucosal tissue.

Peer review

This is a quantitative study, in which the authors analyze the antioxidant effect and the possible involvement of glutamine in the gastric mucosa in an animal model of PH. The results are interesting and show that this molecule may have therapeutic potential in treatment of gastric mucosal lesions triggered by PH.

Abstract

AIM: To describe the role of resistin in liver fibrosis.

METHODS: For the *in vivo* animal study, Sprague Dawley rats were subjected to bile duct ligation (BDL) for 4 wk. Rat liver, adipose tissue (epididymal fat) and serum were analyzed for resistin expression. For the *in vitro* experiment, rat primary hepatic stellate cells (HSCs) and Kupffer cells (KCs) were used. HSCs were exposed to recombinant resistin, and collagen Ⅰ, transforming growth factor β1, α smooth muscle actin, tissue inhibitor of metalloproteinase 1 and connective tissue growth factor expression were analyzed. Resistin gene and protein expression was quantified as was the expression of pro-inflammatory cytokines including tumor necrosis factor α (TNFα), interleukin (IL)-1, IL-6, IL-8 and monocyte chemotactic protein-1 (MCP-1). The effects of resistin on HSC proliferation, migration and apoptosis were determined. The effects of resistin on KCs were also investigated.

RESULTS: Following BDL, rat epididymal fat and serum rather than liver showed higher resistin expression compared to control rats. In liver, resistin was expressed in quiescent HSCs and KCs. Resistin treatment resulted in enhancement of *TNFα*, *IL-6*, *IL-8* and *MCP-1* gene expression and increased IL-6 and MCP-1 protein in HSCs. Resistin activated HSC phospho-MAPK/p38, and p38 inhibition diminished IL-6 and MCP-1 expression. Furthermore, resistin facilitated HSC proliferation and migration, but decreased apoptosis which was *via* an IL-6 and MCP-1 mechanism. Finally, resistin-induced transforming growth factor β1 from KCs enhanced HSC collagen Ⅰ expression.

CONCLUSION: Resistin directly and indirectly modulates HSC behavior towards a more pro-fibrogenic phenotype.

Key words: Resistin; Hepatic stellate cell; Kupffer cell; Liver fibrosis; Monocyte chemotactic protein-1

Core tip: Resistin activated hepatic stellate cells (HSCs) phospho-MAPK/p38, and p38 inhibition diminished interleukin 6 (IL-6) and monocyte chemotactic protein-1 (MCP-1) expression. Furthermore, resistin facilitated HSC proliferation and migration, but decreased apoptosis which was *via* an IL-6 and MCP-1 mechanism. Finally, resistin-induced transforming growth factor β1 from Kupffer cells enhanced HSC collagen Ⅰ expression. Resistin directly and indirectly modulates HSC behavior towards a more pro-fibrogenic phenotype.

INTRODUCTION

Metabolic alterations such as glucose intolerance, increased energy expenditure, and negative nitrogen balance with depletion of fat and skeletal muscle mass are frequently encountered in patients with cirrhosis[1,2]. In particular, glucose intolerance and insulin resistance are almost universal[3,4] and, in part, mediate the progression of fibrosis[5]. However, the mechanisms whereby metabolic alterations mediate disease progression are unclear. Adipose tissue secreted proteins (adipokines) such as leptin and adiponectin modulate metabolic homeostasis and have direct effects on the hepatic fibrogenic cascade. For example, leptin promotes liver fibrosis, while adiponectin is anti-inflammatory and anti-fibrotic[6-9]. Resistin, another adipokine, has been reported to be associated with impaired insulin sensitivity and glucose intolerance[10-13], but its role in hepatic fibrosis has not been adequately delineated[14-17].

Resistin is almost exclusively expressed in the white adipose tissue of rodents, but is expressed in humans predominantly by monocytes/macrophages[18]. Several reports indicate that the serum levels of resistin are elevated in cirrhosis[14-16], increasing progressively with worsening liver function as determined by the Child-Pugh class[17]. Furthermore, in patients with liver disease, resistin levels are correlated with the extent of insulin resistance and with clinical complications and prognosis[16]. In a recent animal study[19], hyperinsulinemia and increased tumor necrosis factor α (TNFα) secretion following bile duct ligation (BDL) were shown to up-regulate adipose tissue resistin gene expression which could subsequently contribute to liver fibrosis. A recent human study noted that resistin expression was low in normal liver, but was increased in severe fibrosis, suggesting that intra-hepatic resistin derived from monocytes/macrophages might contribute to fibrosis[15,20,21].

In the present study, we undertook *in vivo* and *in vitro* studies to elucidate the role of resistin in liver fibrosis. We show that resistin has increased expression in the epididymal fat and serum of cirrhotic rats. Resistin has a pro-inflammatory role in mediating the release of TNFα, interleukin (IL)-6, IL-8 and monocyte chemotactic protein-1 (MCP-1) in hepatic stellate cells (HSCs). Importantly, we demonstrate that resistin directly and indirectly mediates HSC activated phenotype in IL-6/MCP-1 and transforming growth factor (TGF) β1 dependent mechanisms, respectively, indicating that resistin contributes to the pro-inflammatory and pro-fibrotic phenotype of activated HSCs.

MATERIALS AND METHODS

Materials

Recombinant mouse resistin protein, recombinant IL-6, and MCP-1 ELISA kits, IL-6, MCP-1 and TGFβ1 antibodies were purchased from RD Systems (Minneapolis, MN, United States). Nycodenz, α smooth muscle actin (αSMA) mouse antibody was purchased from Sigma-Aldrich (St. Louis, MO, United States). Pronase E, DNase I and collagenase B were purchased from Roche Applied Sciences (Indianapolis, IN, United States). Resistin rabbit polyclonal antibody was purchased from Abbiotec TM (San Diego, CA, United States). p-p38, pERK1/2, pJNK, nuclear factor κB (NF-κB), p-p65 and p-p50 mouse monoclonal antibodies, p-p38 inhibitor (SB203580) and pJNK inhibitor (SP600125) were purchased from Cell Signaling Technology, Inc (Beverly, MA, United States). The BrdU ELISA kit was purchased from Roche Diagnostics (Castle Hills, NSW, Australia). Anti-mouse IgG conjugated to horseradish peroxidase was purchased from GE Healthcare Life Sciences (Piscataway, NJ, United States). DMEM medium was obtained from Invitrogen (Carlsbad, CA, United States).

Animals

Male Sprague Dawley (SD) rats were obtained from the Animal Resources Centre (Perth, Australia). All animals were maintained under 12-h light/dark cycles with food and water *ad libitum*. For the *in vivo* experiment, BDL or a sham surgical procedure was performed on rats. After 4 wk, rat liver, epididymal fat and serum were collected for resistin quantification. All experimental protocols were approved by the Sydney West Area Health Service Animal Research Ethics Committee.

Isolation and culture of rat hepatic stellate cells and Kupffer cells

Rat HSCs were isolated by a two-step (collagenase B and pronase E) perfusion method under ketamine and xylazine anesthesia as reported previously[6]. Briefly, rat liver was perfused through the portal vein using Ca^{2+}- and Mg^{2+}-free Gey's Balanced Salt Solution (GBSS, Sigma, United States) and then sequentially with pronase E followed by collagenase B (Roche Applied Science, Castle Hills, NSW, Australia). The liver was excised, gently dispersed in GBSS containing 0.01% DNase I and the cell suspension filtered through a sterile nylon mesh and subjected to low-speed centrifugation. The resultant cell pellet was mixed with 30% Nycodenz to obtain an 11% final Nycodenz/cell suspension. After centrifugation at 1400 *g* for 20 min, HSCs were collected, resuspended in culture medium, and plated on 6 well plates with 10% FCS/DMEM at a density of 0.8×10^6 cells/well. Cell viability was assessed by trypan blue exclusion and was routinely more than 95%. Purity was 95% as determined by morphology, vitamin A autofluorescence and desmin positivity. HSCs were maintained in 95% air and 5% CO_2 in DMEM (Gibco, United States) with 10% FCS and 1% penicillin/streptomycin. KCs were further obtained and purified by elutriation[6]. KCs were identified by their ability to phagocytose latex beads; viability was > 96% and purity > 98%. KCs were cultured in 10% FCS/DMEM/1% penicillin-streptomycin.

Treatments: For recombinant mouse resistin (RD Systems, Minneapolis, MN, United States), we undertook a dose ranging study based on previous reports[20-23] using 10, 50, 250 and 500 ng/mL. We found that 500 ng/mL

was the optimal dose which was used in all subsequent experiments. Primary rat HSCs and KCs were cultured for the time periods indicated and serum starved (0.2%) for 4 h prior to treatment. Subsequently, control (vehicle) and resistin (500 ng/mL) were added to the culture wells. After 24 h or extended culture as indicated, total RNA and protein were extracted. For the KC-HSC co-culture experiment, control (vehicle) and resistin (500 ng/mL) were added to cultured KCs at day 2 for 24 h, then KCs were washed three times with PBS and fresh medium was added and cultured for another 24 h. Afterwards, KC conditioned medium (KM) was transferred to HSCs at day 4 for 24 h co-culture. In one experiment, lipopolysaccharide (LPS, 50 ng/mL) was used to further activate cultured KCs.

Real-time reverse transcription polymerase chain reaction

Total cellular RNA was prepared from HSCs using TRI@ REAGENT (Molecular Research Center, INC., Cincinnati, OH, United States). Complementary DNA (cDNA) was synthesized from 1 μg RNA using Super-Script Ⅲ reverse transcriptase and 0.5 nmol of random primers (Invitrogen, Carlsbad, CA, United States). Real-time quantitative reverse-transcription polymerase chain reaction (qRT-PCR) was performed using SYBR Green Platinum SYBR Green SuperMix (Invitrogen, United States). The synthesized cDNA was amplified using the following sequence specific primers: resistin 5'-CAAGACTTCAGCTCCCTACTGC-3' (forward) and 5'-GACGGTTGTGCCTTCTGG-3' (reverse); collagenα1 (Ⅰ) 5'-TTCACCTACAGCACGCTTGTG-3' (forward) and 5'-TCTTGGTGGTTTTGTATTC-GATGA-3' (reverse); TGFβ1 5'-TCGACATGGAGCT-GG TGAAA-3' (forward) and 5'-GAGCCT-TAGTTTGGACAGGATCTG-3' (reverse); αSMA5'-CGATAGAACACGGCATCATC-3' (forward) and 5'-CATCAGGCAGTTCGTAGCTC-3' (reverse); tissue inhibitor of metalloproteinase 1 (TIMP1) 5'-AAGGGC-TACCAGAGCGATCA-3' (forward) and 5'-GGTATT-GCCAGGTGCACAAAT-3' (reverse); connective tissue growth factor (CTGF) 5'-CGCCAACCGCAAGATTG-3' (forward) and 5'-ACACGGACCCACCGAAGAC-3' (reverse); IL-6 5'- CCCTTCAGGAACAGCTATGAA-3' (forward) and 5'-ACAACATCAGTCCCAAGAAGG-3' (reverse); IL-1 α 5'-ACATCCGTGGAGCTCTCTT-TACA-3' (forward) and 5'-TTAAATGAAC-GAAGTGAACAGTACAGATT-3' (reverse); IL-1β 5'-TACCTATGTC TTGCCCGTGGAG-3' (forward) and 5'-ATCATCCCACGAGTCACAGAGG-3' (reverse); TNFα 5'-GCCCAGACCCTCACACTC-3' (forward) and 5'-CCACTCCAGCTGCTCCTCT -3'(reverse); IL-8 5'-TCTGCAGCTCTGTGTGAAGG-3' (forward) and 5'-AATTTCTGGTT TGGCGCAGT-3' (reverse); MCP-1 5'-AGCATCCACGTGCTGTCTC-3' (forward) and 5'-GATCATCTTGCCAGTGAATGAG-3' (reverse). The relative amount of mRNA was calculated by reference to a calibration curve. The final result for each sample was normalized to the respective β actin value.

Immunoblotting: Cell culture media were removed and the cells washed with PBS and lysed on ice in a buffer containing 20 mmol/L Tris, 0.5 mmol/L $MgCl_2$, 1 mmol/L Dithiothreitol (DTT), 3 mmol/L NaN_3, and a mixture of protease and phosphatase-inhibitors. Cell lysates were disrupted using a sonicator on ice. After centrifugation at 13000 *g* for 15 min, the supernatant was collected as cytoplasmic protein. Nuclear protein was extracted as described previously[6]. The protein concentration was determined using the Bradford Protein Assay (Bio-Rad, Sydney, Australia). Immunoblotting was performed as previously described with some modifications[6,24]. Total protein (20 μg per lane) was resolved by electrophoresis on 12% sodium dodecyl sulfate polyacrylamide gels (SDS-PAGE) under reducing conditions. The electrophoresed proteins were electrotransferred onto Polyvinylidene difluoride membranes (Immobilin-P, Millipore, Bedford, MA, United States). The membranes were blocked with 5% skim milk (Resistin, TGFβ1, p-p38, pERK1/2, pJNK, NF-κB p-p65, NF-κB p-p50 and αSMA) for 60 min and then incubated overnight with primary antibody (Resistin 1:200, p-p38 1:1000, pERK1/2 1:1000, pJNK 1:1000, p-p65 1:1000, p-p50 1:1000, TGFβ1 1:500, αSMA 1:2000) at 4 ℃. After 3 washes with 0.05% Tween-20/TBS, anti-mouse IgG (peroxidase conjugate) secondary antibody was applied. Blots were visualized by enhanced chemiluminescence (Pierce Perbio, Rockford, IL, United States). All images were quantified by densitometry.

Sirius red staining and quantification of collagen in HSCs

Sirius red staining and collagen quantification were performed according to a previously published protocol[6,25]. Briefly, Sirius red F3BA solution (0.1% in saturated picric acid) was added to cell layers fixed in Bouin's solution. After 1 h the cell layers were washed in tap water and again in 0.01 mol/L HCl to remove unbound dye. For collagen quantification, the dye was dissolved in 0.1 mol/L NaOH and absorbance determined at 450 nm. The amount of collagen was normalized to the protein concentration using the Bradford Reagent. Assays were performed in duplicate.

Enzyme-linked immunosorbent assay

The media were collected from cultured HSCs following 24 h stimulation with resistin (500 ng/mL). Levels of IL-6 and MCP-1 in the media were determined according to the manufacturer's instructions (RD Systems). Rat serum was collected and resistin concentration detected using a resistin rat ELISA kit (Boivendor) according to manufacturer's instructions.

HSC proliferation: Cell proliferation was analyzed using a BrdU-based enzyme-linked immunosorbent assay (Roche Diagnostics) according to the manufacturer's

instructions. HSCs at day 4 were treated with resistin (500 ng/mL) or other agents as indicated for 24 h. The cells were subsequently labeled with BrdU for 2 h at 37 ℃. Cells were then fixed and incubated with a peroxidase-conjugated anti-BrdU antibody for 90 min at room temperature. After adding the peroxidase substrate, 3,3',5,5'-tetramethylbenzidine, BrdU incorporation was determined by measuring optical densities at 450 nm (background 620 nm).

HSC migration: HSC migration was assessed both with the wound scratch assay and a modified Boyden chamber. For the wound scratch assay, using a sterile 200 μL pipette tip, three separate wounds were generated through the cell monolayer. HSCs (90% confluence) at day 6 cultured in 12-well plates were treated with resistin (500 ng/mL) or other agents as indicated. The scratch area was photographed immediately and 6 h after scratching and cell migration into the scratch area calculated as the area covered by cells in the percentage of the initial scratch area. For the second method, a cell culture insert (12 well, BD) was used and the porous membrane (pore size 8 μm) of the filter was coated with 30 μg/mL collagen I at 37 ℃ for 30-60 min. HSCs at day 6 were trypsinized and placed into the upper chamber (10^5 cells/mL). The lower wells were filled with resistin (500 ng/mL) or other agents as indicated. After 6 h of incubation at 37 ℃, cells adhering to the upper side of the filter were removed with a cotton swab. The filters were then fixed with 100% methanol and stained with HEMA-3. The numbers of HSCs on the lower side of the filter were counted in five randomly chosen microscopic fields at a magnification of × 400 by changing the focus.

HSC apoptosis: Annexin-V/PI labeling was used to detect HSC apoptosis. Briefly, trypsinized HSCs were washed twice in PBS, stained with annexin-V (10 μL) and PI (5 μL) for 10 min, and the apoptotic rate quantified by FACS Calibur flow cytometry (Becton Dickinson Inc.) at 488 nm. More than 1×10^4 cells were detected, and the results were analyzed with FlowJo software (Treestar, United States). The population of apoptotic cells was identified as annexin V+/PI-. The percentage of apoptotic cells was calculated according to total annexin V+/PI- divided by total cells.

Statistical analysis

The results are expressed as mean ± SD. Comparisons between 2 groups were analyzed using the Student *t* test. For the comparison of more than two groups, we used two-way ANOVA. *P* values < 0.05 were considered statistically significant. All calculations were performed using Statistical Program for Social Sciences (SPSS) software 13.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

Resistin expression is up-regulated in cirrhotic rats

Resistin expression in liver, epididymal fat and serum in BDL and sham rats was examined. We noted that resistin expression in epididymal fat was considerably higher than that in liver in the BDL or sham rats (Figure 1A and B, all $P < 0.01$). BDL rat epididymal fat mRNA and protein level were further up-regulated compared to sham rats (Figure 1A and B, both $P < 0.05$). Similarly, BDL rat serum resistin level was also elevated (Figure 1C, $P < 0.05$). However, liver resistin mRNA and protein were unchanged in the BDL and sham groups (Figure 1A and B). These findings suggest that increased adipose resistin rather than liver resistin may play a vital role in resistin-mediated liver injury in rodents. Therefore, we undertook detailed *in vitro* experiments in order to explore the impact of exogenous resistin on HSC activated phenotype.

Resistin is expressed in quiescent HSCs and KCs

Resistin mRNA was detected in quiescent rat HSCs (Figure 1D) at day 1 and was reduced by 90% ($P < 0.01$) following activation for 8 d on plastic. Resistin mRNA was expressed in quiescent KCs (day 1) and activated KCs (3 d), without significant changes over time. LPS (50 ng/mL for 24 h) stimulation of KCs at day 3 did not enhance resistin expression (Figure 1D). Consistent with the mRNA data, resistin protein expression declined 6-fold in HSCs at day 8 with no change in KCs at day 3 and after LPS stimulation (Figure 1E). These data indicated that autocrine HSC resistin and paracrine KC resistin are unlikely to be of major importance in mediating any effects on activated HSCs.

Resistin promotes a pro-inflammatory phenotype in HSCs

Pro-inflammatory cytokines and chemokines play a permissive role in liver fibrosis[26-29] and previous reports suggest that resistin increases MCP-1 secretion. We evaluated the expression of TNFα, IL-1α, IL-1β, IL-6, IL-8 and MCP-1 in rat HSCs after stimulation with resistin. As demonstrated, resistin (500 ng/mL) stimulation for 24 h markedly up-regulated the expression of TNFα, IL-6, IL-8 and MCP-1 mRNA (Figure 2A, all $P < 0.05$), but not that of IL-1α and IL-1β. To rule out any potential effects of inadvertent endotoxin contamination, we repeated these studies in the presence of Polymyxin B and noted no difference in the gene expression profile (data not shown). Finally, using trypan blue staining and LDH assays at 24, 48 and 72 h, we excluded the possibility of direct cellular toxicity due to the resistin dose used (data not shown). Since IL-6 and MCP-1 are well documented to play a role in mediating hepatic fibrosis, their protein concentrations were estimated in conditioned medium. As shown in Figure 2B, resistin administration increased IL-6 and MCP-1 concentrations 1.7 and 1.8 fold after 24-h of treatment (both $P < 0.05$).

Resistin enhances HSC proliferation and migration but diminishes HSC apoptosis via an IL-6 and MCP-1 pathway

During the process of chronic liver injury, activated

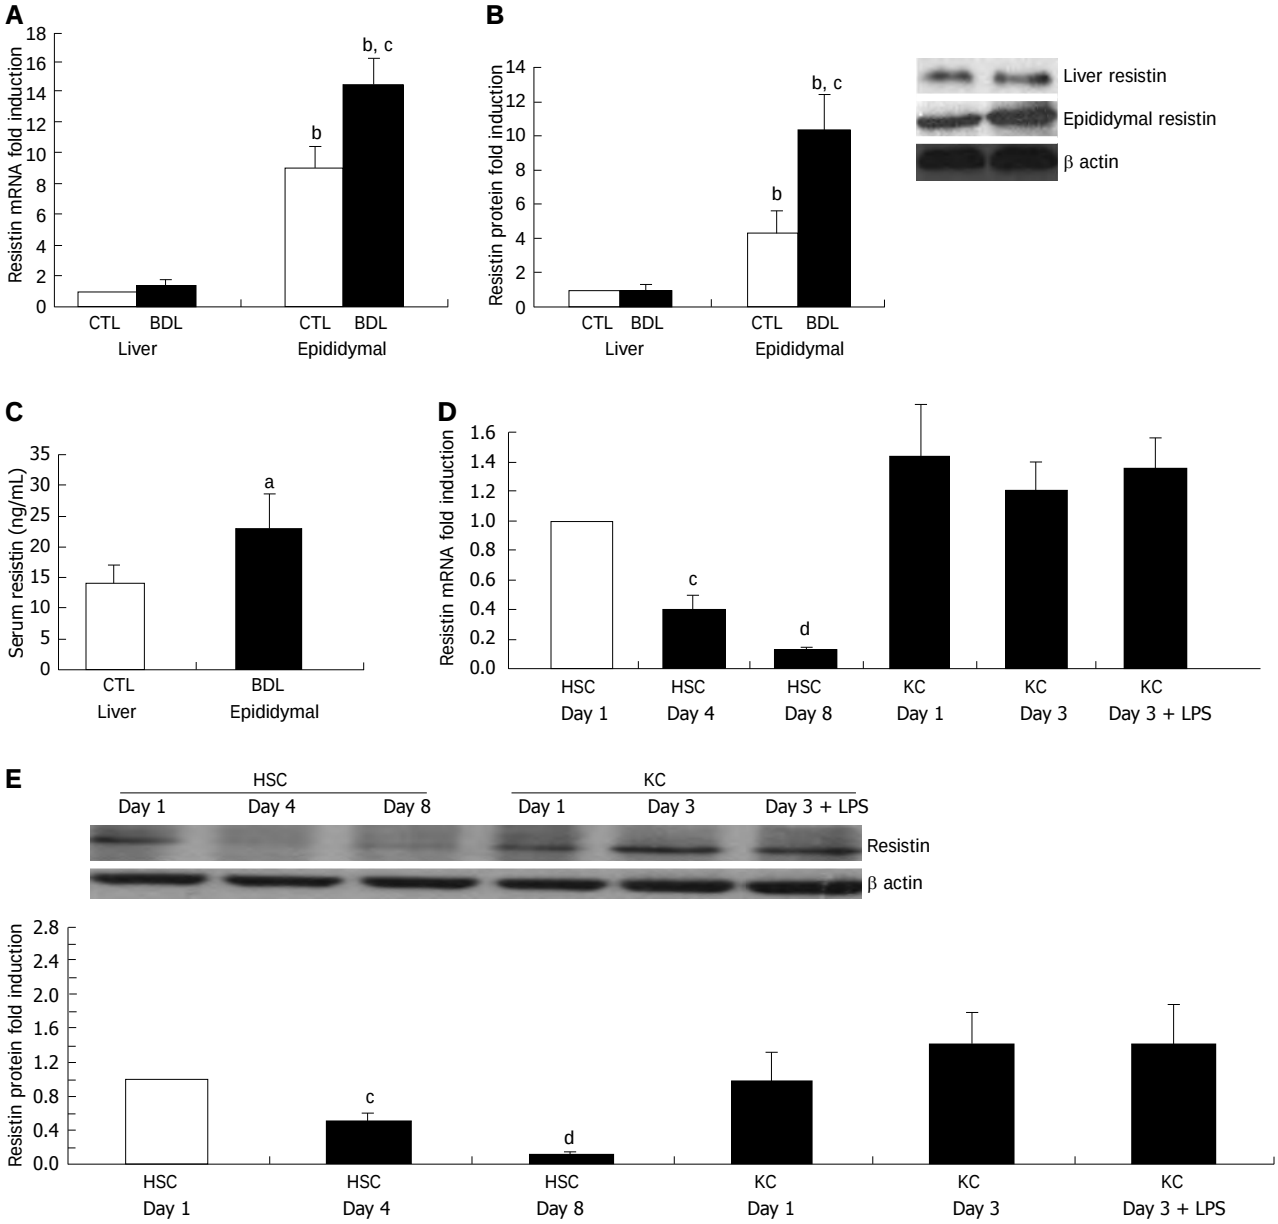

Figure 1 Rat extrahepatic but not intrahepatic resistin is up-regulated in cirrhosis. For the *in vivo* animal study, Sprague Dawley rats were subjected to bile duct ligation (BDL) for 4 wk. Liver, adipose tissue (epididymal fat) and serum were collected to determine resistin expression by quantitative polymerase chain reaction (qPCR), immunoblot and enzyme-linked immunosorbent assay. For the cell culture study, rat hepatic stellate cells (HSCs) and Kupffer cells (KCs) were isolated and cultured on plastic. HSC and KC total RNA/protein were extracted at different culture times (day 1, 4 and 8 for HSCs; day 1 and 3 for KCs). One group of KCs at day 2 were treated with Lipopolysaccharide (LPS) (50 ng/mL) for 24 h. qPCR and Immunoblot were performed for quantification of resistin mRNA and protein. β actin was used as an internal control. A: mRNA expression of resistin in liver and epididymal fat; B: Protein expression of resistin in liver and epididymal fat; C: Serum resistin concentrations; D: mRNA expression of resistin in HSCs and KCs on different culture days; E: Protein expression of resistin in HSCs and KCs on different culture days. Results are mean ± SD of at least three independent experiments performed in triplicate. $^{a}P < 0.05$ and $^{b}P < 0.01$ increased *vs* rat liver, HSC control at day 1 or sham rat serum; $^{c}P < 0.05$ and $^{d}P < 0.01$ decreased *vs* liver of control sham rat or HSC control at day 1.

HSCs proliferate and migrate to sites of inflammation and have reduced apoptosis. This phenotype is part of the expected adaptive wound healing response to injury. Hence, we sought to determine the role of resistin in mediating activated HSC behavior. As demonstrated in Figure 3A, resistin enhanced HSC proliferation by approximately 90% compared to the control ($P < 0.01$). Using the wound scratch assay and a modified Boyden chamber, compared to the control, resistin treatment resulted in an approximately 80% and approximately 220% increase in HSC migration, respectively ($P < 0.05$, Figure 3A and B). We next examined the role of resistin on HSC apoptosis. In contrast, resistin significantly reduced HSC apoptosis (56%, $P < 0.05$, Figure 3A), as shown by annexin V/IP flow cytometry. Finally, we determined whether up-regulation of IL-6 and MCP-1 was responsible for the changed HSC phenotype by resistin. As expected, resistin-mediated HSC proliferation, migration and apoptosis were partially, but significantly reversed (all $P < 0.05$, Figure 3A and B) by IL-6 (5 μg/mL) and

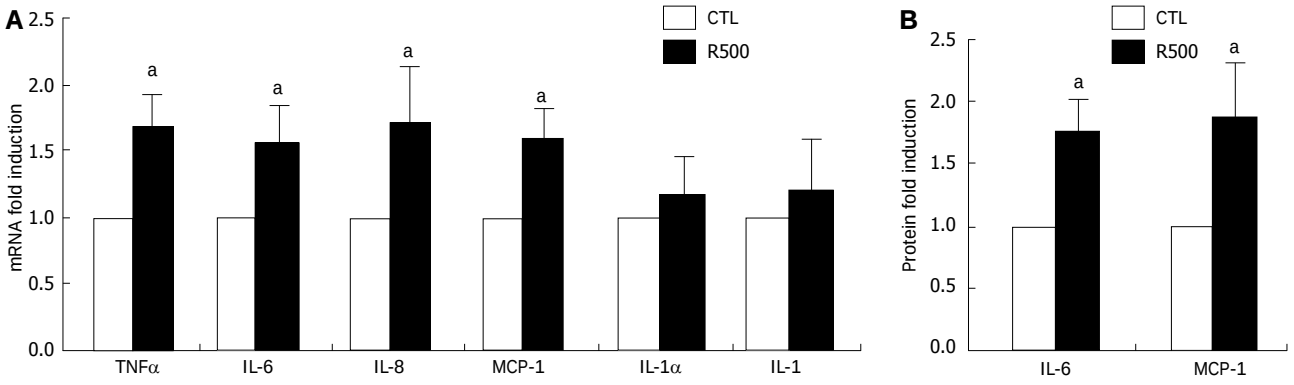

Figure 2 Resistin enhances the expression of tumor necrosis factor α, interleukin 6, interleukin 8 and monocyte chemotactic protein-1 in hepatic stellate cells. Rat hepatic stellate cells (HSCs) at day 4 were cultured with resistin (500 ng/mL) (R500) for 24 h. Total RNA was extracted and quantitative polymerase chain reaction was performed to quantify mRNA expression. Media were collected and enzyme-linked immunosorbent assay conducted to determine interleukin 6 (IL-6) and monocyte chemotactic protein-1 (MCP-1) protein concentrations. A: mRNA expression of tumor necrosis factor α (TNFα), IL-6, IL-8, MCP-1, IL-1α and IL-1; B: IL-6 and MCP-1 protein levels. Data are expressed as mean ± SD. At least three independent experiments were conducted in triplicate for data analysis. [a]*P* < 0.05 *vs* controls (untreated).

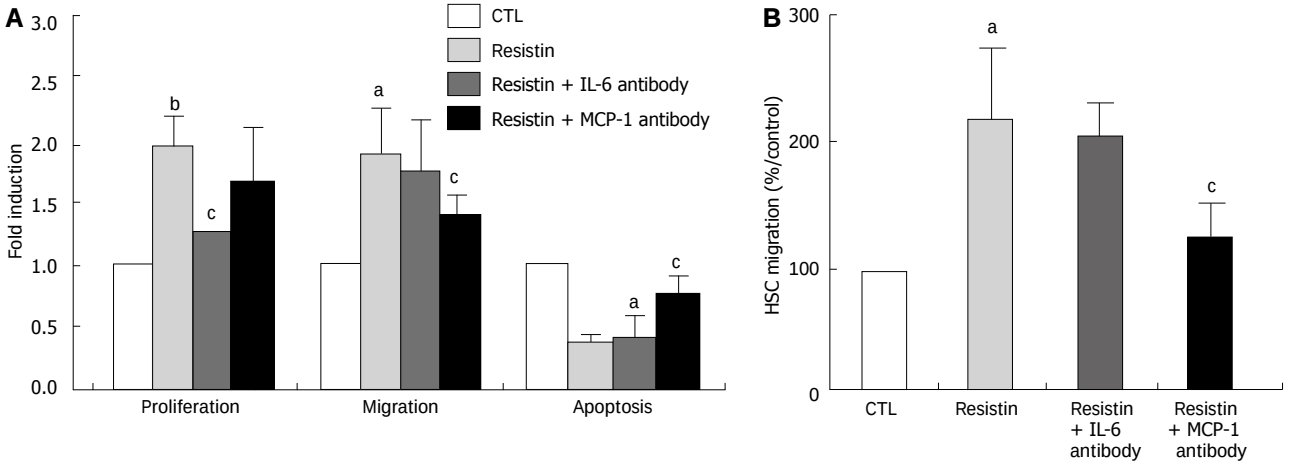

Figure 3 Resistin promotes hepatic stellate cells proliferation and migration but decreases hepatic stellate cells apoptosis in an interleukin 6 and monocyte chemotactic protein-1 dependent mechanism. BrdU, enzyme-linked immunosorbent assay, Wound Scratch Assay (or Boyden chamber) and annexin V/IP flow cytometry were performed to determine hepatic stellate cells (HSCs) proliferation, migration and apoptosis, respectively. For the interleukin 6 (IL-6) and monocyte chemotactic protein-1 (MCP-1) inhibition experiments, IL-6 and MCP-1 neutralizing antibodies (5 μg/mL and 10 μg/mL, respectively) were added to the culture 1 h before resistin (500 ng/mL) administration. Resistin (500 ng/mL) was added to rat HSCs at day 4 for 24 h. Absorbance was measured and apoptosis assessed. For the migration assay, rat HSCs at day 6 were used. After a scratch wound was made, resistin (500 ng/mL) was added and the cells were cultured for 6 h and photographed. For the Boyden chamber assay, the detailed procedure is described in the Materials and Methods section. A: Resistin promoted HSC proliferation and migration, but inhibited HSC apoptosis, while IL-6 and MCP-1 antibodies reversed the resistin-induced HSC phenotype; B: The Boyden chamber assay confirmed that resistin enhanced HSC migration and MCP-1 neutralization reversed this effect. Results are mean ± SD of at least three independent experiments performed in triplicate. [a]*P* < 0.05 and [b]*P* < 0.01 *vs* control (untreated); [c]*P* < 0.05 *vs* resistin treatment alone.

MCP-1 (10 μg/mL) neutralization, respectively. These data suggest that resistin triggered HSC IL-6 and MCP-1 production, thereby modulating HSC phenotype.

Resistin activates HSC MAPK/p38 and nuclear NF-κB p65

Mitogen-activated protein kinases (MAPK) and NF-κB play critical roles in the induction of pro-inflammatory cytokines and chemokines, and regulate cell biological behaviors. Therefore, we determined whether resistin activates HSC MAPK (p38, ERK1/2 and JNK) and NF-κB. Phoshor-p38, ERK1/2 and JNK in the cytoplasm as well as NF-κB p65 and p50 in cytosolic and nuclear extracts were analyzed by immunoblotting. The results showed that cytoplasmic p-p38 and nuclear p-p65 were up-regulated (both $P < 0.05$, Figure 4A and C). Changes in cytosolic pERK1/2, pJNK (data not shown), p65 and cytosolic and nuclear p-p50 (data not shown) were not observed. In the p-p38 inhibition experiment using SB203580, we found that p-p38 activation was responsible for IL-6 and MCP-1 induction in HSCs ($P < 0.05$, Figure 4B). Furthermore, resistin (500 ng/mL) enhanced NF-κB DNA binding ability (luciferase mRNA. $P < 0.05$, Figure 4D). As expected, NF-κB inhibition by pyrrolidine dithiocarbamate (PDTC) (100 μmol/L) attenuated the resistin-induced increase in nuclear p-p65 and NF-κB DNA binding ability ($P < 0.05$, Figure 4C and D). Similarly, PDTC reversed resistin-induced up-regulation of IL-6 and MCP-1 (Figure 4E).

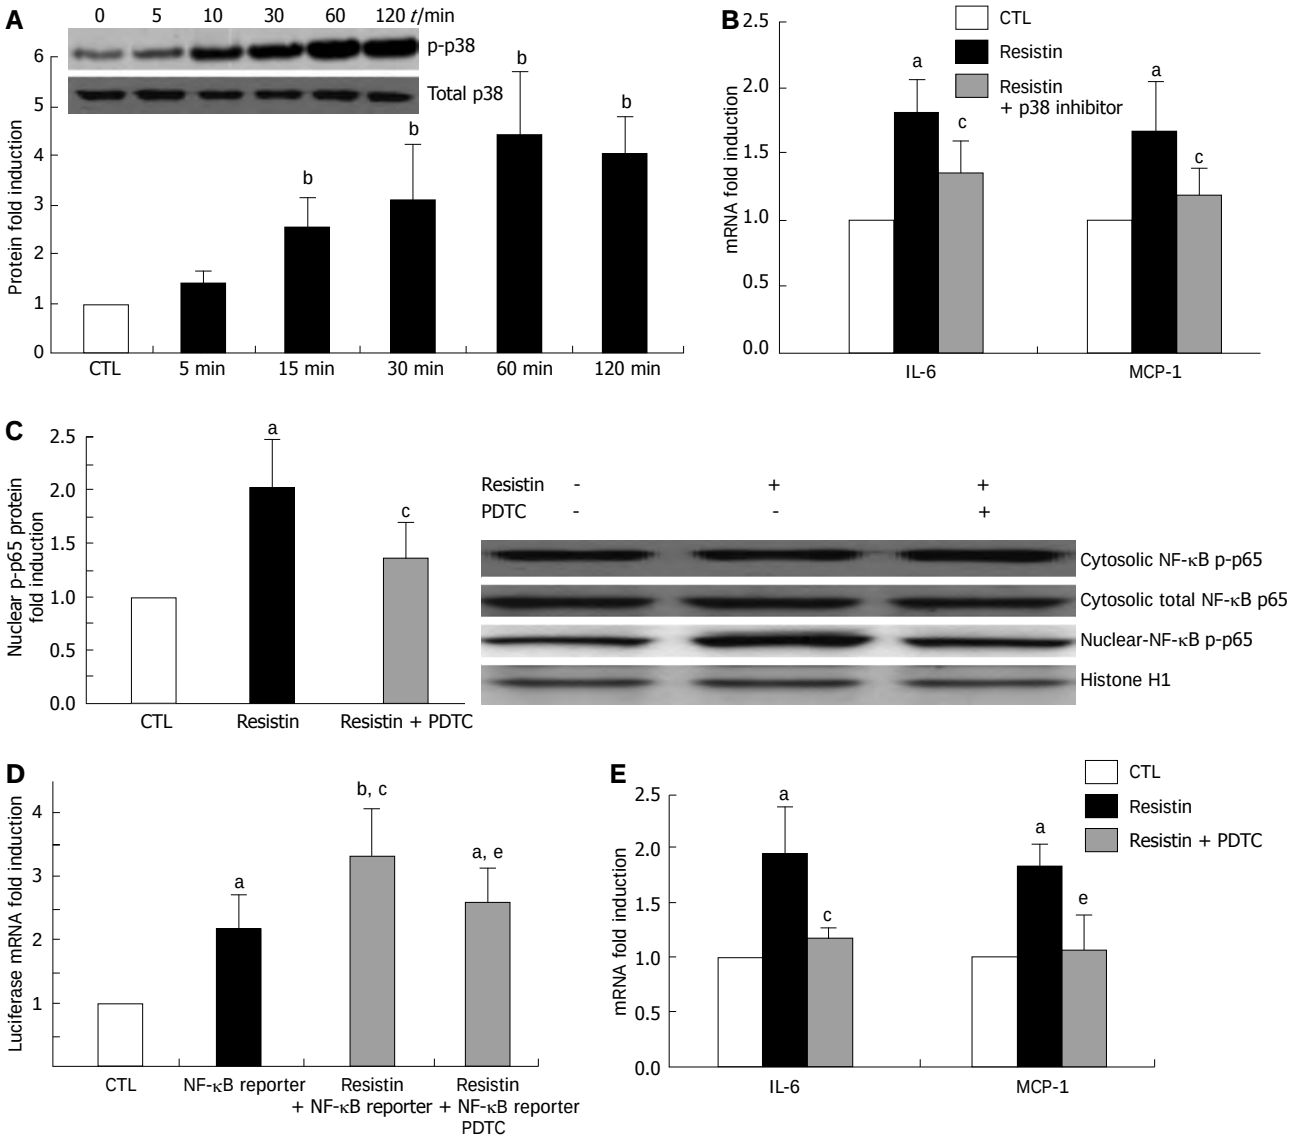

Figure 4 Resistin activates hepatic stellate cells MAPK/p38 and nuclear factor κB p65. Rat hepatic stellate cells (HSCs) at day 4 were cultured with resistin (500 ng/mL) for 120 min. Cytosolic and nuclear proteins were extracted and Immunoblot performed to quantify p-p38 and nuclear factor κB (NF-κB) p-p65. For NF-κB DNA binding capacity, 3 × NF-κB /Luc reporter was added to the culture for 24 h and Luciferase mRNA quantified by quantitative polymerase chain reaction. For the p-p38 and NF-κB inhibition experiments, SB203580 (20 μmol/L, p-p38 inhibitor) or pyrrolidine dithiocarbamate (PDTC) (100 μmol/L, NF-κB inhibitor) was added 1 h before resistin treatment. Resistin (500 ng/mL) was added to rat HSCs for 24 h. A: p-p38 was enhanced by resistin; B: p-p38 inhibition (24 h) diminished resistin-induced interleukin 6 (IL-6) and monocyte chemotactic protein-1 (MCP-1) increase by HSCs; C: Nuclear p-p65 was increased by resistin exposure and decreased by PDTC (120 min); D: Luciferase mRNA was augmented by resistin and diminished by PDTC (24 h); E: PDTC reversed resistin-induced enhancement of IL-1 and MCP-1 (24 h). Data are expressed as mean ± SD. At least three independent experiments were conducted in triplicate for data analysis. [a]$P < 0.05$ and [b]$P < 0.01$ *vs* controls (untreated); [c]$P < 0.05$ *vs* resistin treatment alone or NF-κB reporter treatment alone; [e]$P < 0.05$ *vs* combination of resistin and NF-κB reporter.

Resistin indirectly promotes HSC collagen I expression through the actions of KCs

To determine whether resistin affects KCs and whether KCs participate in the process of resistin-mediated HSC phenotype, the appropriate experiments were undertaken. As shown in Figure 5A and B, resistin up-regulated TGFβ1 and CTGF mRNA in KCs and enhanced TGFβ1 protein in KC medium (both $P < 0.05$). Co-culture of HSCs and KC conditioned medium resulted in a significant increase in HSC collagen I and CTGF expression (Figure 5C and D, all $P < 0.05$), however, TGFβ1 (10 μg/mL) neutralization diminished this increase (Figure 5C and D, all $P < 0.05$). Downstream signaling responsible for increased KC TGFβ1 and CTGF expression by resistin were further analyzed. We found that pJNK and p-p38 were activated following exposure to resistin. Furthermore, pJNK and p-p38 inhibition partially, but significantly reversed resistin-induced TGFβ1 and CTGF enhancement (Figure 5E and F, $P < 0.05$ and 0.01). These data suggest that resistin affected HSC activated phenotype by increased TGFβ1 from KCs.

DISCUSSION

Resistin is suggested to play a pathogenic role in insulin resistance and altered glucose metabolism in rodents[3,4].

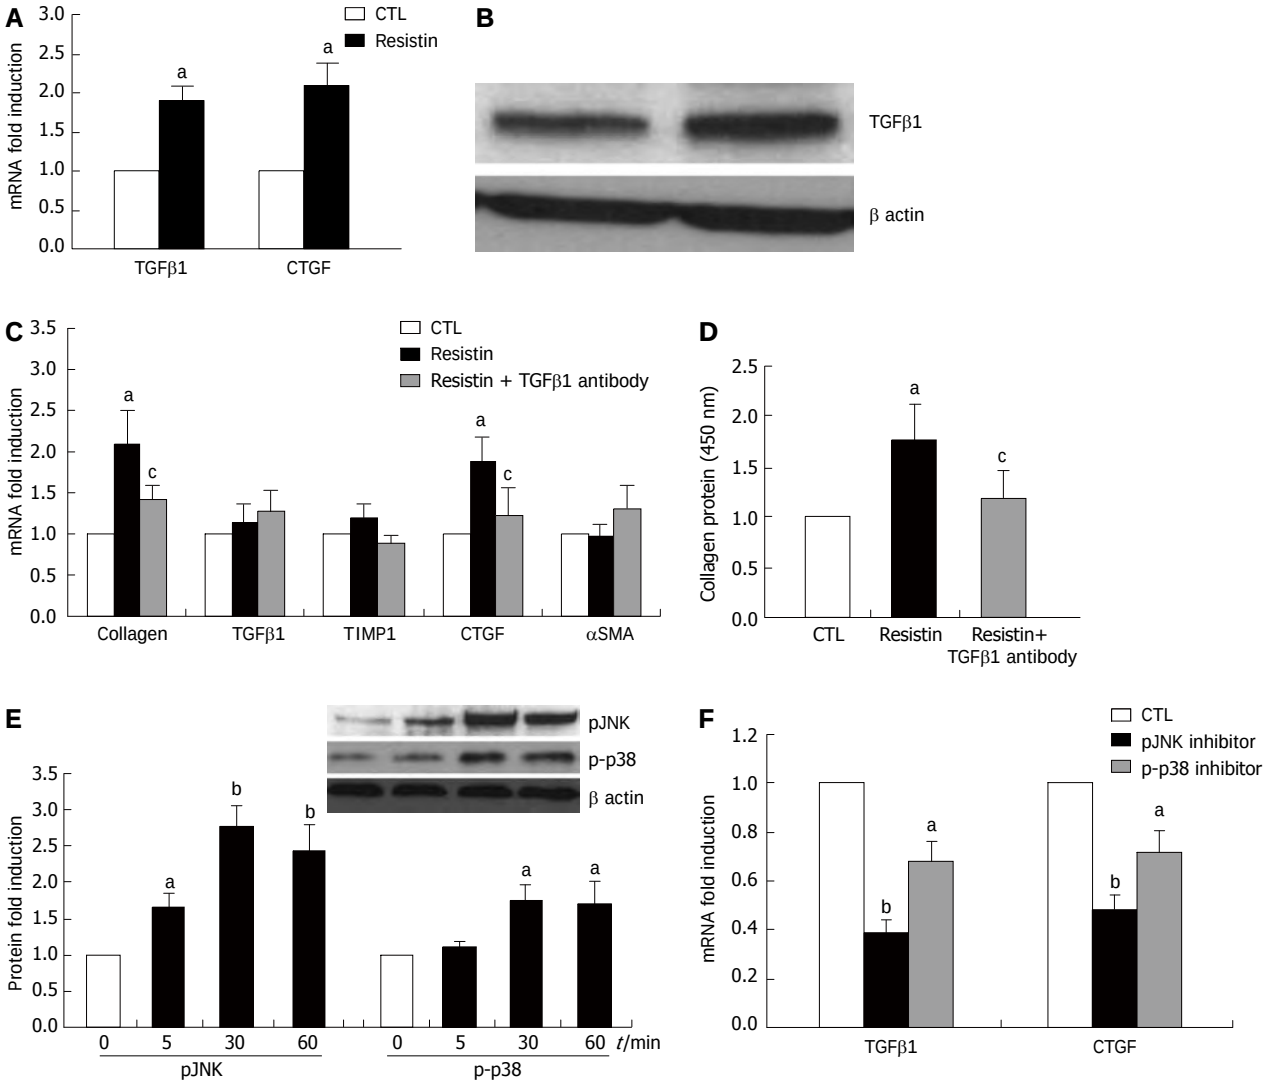

Figure 5 Resistin indirectly enhances hepatic stellate cells collagen I expression through a transforming growth factor β1 dependent mechanism *via* the action of Kupffer cells. Rat Kupffer cells (KCs) at day 2 were cultured with resistin (500 ng/mL) for 24 h. Total RNA was extracted and quantitative polymerase chain reaction was performed. Transforming growth factor β1 (TGFβ1) protein expression in KC conditioned medium (KM) was quantified by immunoblotting. Sirius red was used for collagen I protein quantification in the medium. For the KC-hepatic stellate cell (HSC) co-culture experiment, KCs at day 2 were incubated with resistin for 24 h and then washed three times with phosphate-buffered saline, fresh medium was subsequently added to the culture for another 24 h. KM was then transferred to HSCs at day 4 for 24 h. HSC collagen I , TGFβ1, tissue inhibitor of metalloproteinase 1 (TIMP1), connective tissue growth factor (CTGF) and α smooth muscle actin (αSMA) expression were determined. For inhibition experiments, TGFβ1 monoclonal antibody (10 μg/mL), SP600125 (50 μmol/L) and SB203580 (20 μmol/L) were added to KCs for 24 h. A: Resistin promoted KC T*GFβ1* and *CTGF* gene expression; B: Resistin augmented TGFβ1 expression in KM medium; C: HSC collagen I and CTGF mRNA were augmented by resistin conditioned KM reversed by TGFβ1 neutralization (10 μg/mL); D: HSC collagen protein was increased by resistin conditioned KM but reversed by TGFβ1 neutralization (10 μg/mL); E: Resistin increased KC JNK and p38 phosphor-protein; F: pJNK inhibitor (50 μmol/L, SP600125) and p-p38 inhibitor (20 μmol/L, SB203580) partially, but significantly reversed resistin-induced TGFβ1 and CTGF expression by KCs. Data are expressed as mean ± SD. At least three independent experiments were conducted in triplicate for data analysis. $^{a}P < 0.05$ and $^{b}P < 0.01$ *vs* controls (untreated); $^{c}P < 0.05$ *vs* resistin treatment alone.

For example, lowering plasma resistin in insulin-resistant mice decreases blood glucose levels and improves insulin sensitivity[10,30,31], while treatment of normal mice with resistin impairs glucose tolerance and insulin actions[10,30]. Resistin may also play a pivotal role in inflammation since it up-regulates IL-6 and TNFα expression in human peripheral blood mononuclear cells *via* NF-κB activation[22]. Furthermore, the addition of resistin protein from both mice and humans to macrophages results in enhanced secretion of pro-inflammatory cytokines including TNFα and IL-12[32]. In human cirrhosis, resistin levels in the liver and plasma are elevated and increase further with the severity of liver disease[14-17,33]. This suggests that the pro-inflammatory activities of resistin may modulate liver inflammation and drive disease progression in cirrhosis.

This study provides evidence that in cirrhotic rats, adipose tissue (epididymal fat) and blood resistin are up-regulated, and adipose tissue may be the main source of resistin secretion. Rat liver, HSCs and KCs express resistin, but are unlikely to be important sources of resistin secretion in cirrhosis. Resistin exerts pro-inflammatory activities on HSCs with enhanced secretion of pro-

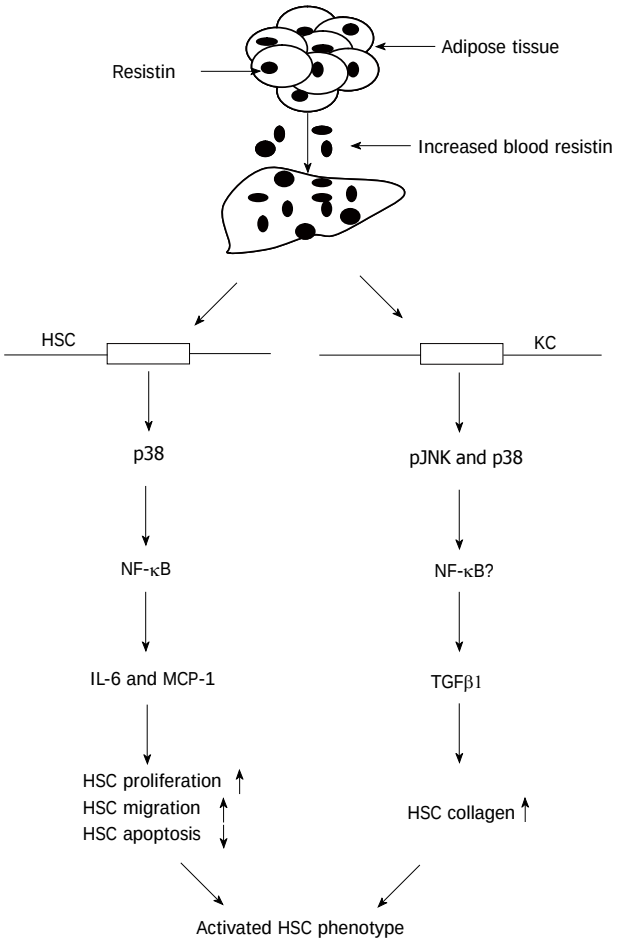

Figure 6 Schematic diagram illustrating a possible mechanism by which resistin potentiates hepatic stellate cells profibrogenic phenotype. Adipose tissue is a predominant source of resistin expression and secretion in rodents. Increased adipose resistin released into the bloodstream and liver stimulates HSCs to produce increased amounts of pro-inflammatory cytokines and chemokines (IL-6 and MCP-1), leading to enhanced HSC proliferation and migration, but attenuation of HSC apoptosis. In addition, resistin promotes KC TGFβ1 which subsequently activates HSC by up-regulation of collagen I. Therefore, resistin is considered one of the pro-fibrogenic adipocytokines. TGFβ1: Transforming growth factor; NF-κB: Nuclear factor κB; IL-6: Interleukin 6; MCP-1: Monocyte chemotactic protein-1; HSCs: Hepatic stellate cells.

inflammatory cytokines (TNFα, IL-6, IL-8 and MCP-1). Most importantly, resistin promotes HSC proliferation and migration, while inhibiting their apoptosis *via* an IL-6 and MCP-1 mechanism. KCs participate in this process by up-regulating HSC collagen I through increased TGFβ1. Taken together, our data suggest that resistin promotes the progression of liver injury.

Resistin is almost exclusively expressed by white adipose tissue in rodents, but is expressed by monocytes and macrophages in humans[18,34,35]. Liver infiltrating CD43 cells and KCs have been suggested as key sources of resistin in the liver of cirrhotic patients[20,21], thus resistin was more abundant in adipose tissue than in human liver[20,21]. In this study, although rat quiescent HSCs expressed resistin, it declined markedly on activation. The relevant mechanism is unclear, however, adipogenic transcriptional regulation may be required for maintenance of the quiescent HSC phenotype[26]. KCs also expressed resistin but no change was found on activation or LPS stimulation. Therefore, it is unlikely that resistin derived from HSCs and KCs contributed to the increase in serum resistin in BDL rats, thus HSCs and KCs are non-critical sources of resistin. However, other liver cell types may not represent a likely source of resistin production as hepatocytes and endothelial cells do not express resistin[15]. Thus, adipose tissue, including epididymal fat, could be the predominant source of resistin in liver injured rodents. It has been demonstrated in *in vivo* and *ex vivo* studies, that increased TNFα and insulin in BDL cirrhotic rats stimulate adipose resistin expression[14,15,19].

Why LPS was unable to trigger resistin secretion by KCs is unknown. KCs belongs to the macrophage family, and many studies have shown that LPS exposure induced resistin production in human and rodent macrophages[36,37]. The mechanisms involved require further clarification.

As expected, HSC expression of TNFα, IL-6, IL-8 and MCP-1 mRNAs was increased on resistin exposure, as was IL-6 and MCP-1 protein. Bertolani *et al*[20] reported similar findings in human HSCs and noted that resistin up-regulated human HSC MCP-1 that was dependent on a Ca^{2+}/NF-κB-dependent pathway[20]. We further demonstrated that resistin directly augmented HSC proliferation and migration, but reduced HSC apoptosis *via* an IL-6 and MCP-1 mechanism. These novel data imply that IL-6 and MCP-1 inhibition may prevent resistin-induced liver fibrogenesis. The pro-fibrogenic effects of IL-6 and MCP-1 are well documented in the literature[38-40]. Moreover, we found that resistin was able to promote KC activation as it stimulated enhancement of KC TGFβ1 expression. Thus, increased TGFβ1 led to up-regulation of HSC collagen I and HSC activation. This is an important finding, as TGFβ1 is a potent profibrogenic cytokine. Interestingly, this phenomenon is similar to our previous report[6]. We observed that the profibrogenic role of leptin could be achieved at least through TGFβ1 from KCs[6]. Collectively, these data indicate that resistin is able to modulate HSC behaviors towards a more pro-fibrogenic phenotype.

Although many functions of resistin in inflammation and inflammation-related diseases have been described, the relevant intracellular signaling pathway of resistin is not yet completely understood. We further demonstrated that resistin mediated HSC IL-6 and MCP-1 *via* p38 and KC TGFβ1 *via* pJNK and p-p38 (Figure 6). These results may provide evidence to prevent resistin-mediated liver injury/fibrosis using relevant signaling inhibitors.

In summary, this study demonstrates that in rodents, resistin production in the context of liver injury is principally non-hepatic in origin. Extrahepatic resistin could contribute to liver fibrosis by its direct and indirect pro-fibrogenic effects on HSCs. Further studies on resistin knockout and transgenic animals are needed.

COMMENTS

Background

Metabolic abnormalities usually cause the progression of liver fibrosis. To date, the mechanism whereby metabolic alterations mediate disease progression are unclear. Resistin, an adipokine, has been reported to be associated with metabolic alterations, however, its role in hepatic fibrosis has not been clearly investigated.

Research frontiers

Although many functions of resistin in inflammation and inflammation-related diseases have been described, the relevant intracellular signaling pathways of resistin in liver fibrosis are not yet completely understood.

Innovations and breakthroughs

To date, there have been a limited number of studies regarding the impact of resistin on the phenotype of hepatic stellate cells and how it functions in liver fibrosis. In this study, the authors employed a direct analysis to identify the significant correlation between resistin and hepatic stellate cells (HSCs). The authors confirmed that resistin mediated-HSCs move towards a more pro-fibrotic phenotype which is dependent on interleukin 6/monocyte chemotactic protein and/or transforming growth factor β1.

Applications

By understanding the mechanism whereby resistin mediates HSC activation, this study may provide evidence to prevent resistin-mediated liver injury/fibrosis using relevant signaling inhibitors.

Terminology

The serum levels of resistin are elevated in cirrhosis, and the changed phenotype of HSCs play an important role in the pathogenesis of liver fibrosis. Resistin is involved in this process.

Peer review

The paper reported the effects of the adipokine resistin on the biology of hepatic stellate cells and Kupffer cells. It is well presented.

Abstract

AIM: To investigate the potential roles of Delta-like ligand 4 (DLL4) on the biological behavior of gastric cancer cells and its molecular mechanisms.

METHODS: A recombinant eukaryotic expression vector containing human *DLL4* gene was constructed and transfected into the human gastric cancer cell line SGC7901. Clones with up-regulated DLL4 were selected and amplified. The effect of DLL4 up-regulation on gastric cancer cell growth was assessed using cell growth assay. The migration and invasion were assessed using a transwell migration assay and matrigel invasion assay. Matrix metalloproteinases were detected using the zymogram technique. Cells were implanted subcutaneously into male BALB/c nu/nu mice. Tumor volumes were then calculated and compared. DLL4 staining in the implanted tumor was performed using immunohistochemistry technique.

RESULTS: Growth curves over a six-day time course showed significantly promoted cell proliferation of SGC7901 cells with up-regulated DLL4. DLL4 up-regulation in SGC7901 cells promoted the migration (205.4 ± 15.2 *vs* 22.3 ± 12.1, $P < 0.05$) and invasion (68.8 ± 5.3 *vs* 18.2 ± 6.0, $P < 0.05$) *in vitro* and tumorigenicity *in vivo* (2640.5 ± 923.6 mm^3 *vs* 1115.1 ± 223.8 mm^3, $P < 0.05$). Furthermore, significantly increased mRNA level and increased secretion of matrix metalloproteinase-2 (MMP-2) proenzyme were observed in SGC7901 cells with up-regulated DLL4. However, increased MMP-9 mRNA level but decreased extracellular MMP-9 proenzyme level was observed.

CONCLUSION: Our observations indicated a mechanism by which activation of DLL4-mediated Notch signaling promotes the expression and secretion of MMP-2 proenzyme and influences the progress of gastric cancer.

Key words: Gastric cancer; Delta-like ligand 4/Notch; Matrix metalloproteinase; Migration; Invasion

Core tip: Delta-like ligand 4 (DLL4), one of the five notch signaling ligands in mammals, has been researched mainly with regard to vasculogenesis and tumor angiogenesis. To the best of our knowledge, there is rare study to investigate its role and mechanism in human gastric cancers. We found that DLL4

promotes cellular proliferation, migration, invasion and tumorigenicity in gastric cancer cells. Furthermore, increased mRNA level and increased secretion of matrix metalloproteinase-2 proenzyme, while increased matrix metalloproteinase (MMP)-9 mRNA levels but decreased extracellular MMP-9 proenzyme levels were observed. These results indicated a mechanism by which activation of DLL4-mediated Notch signaling promotes the expression and secretion of MMP-2 proenzyme and influences the progress of gastric cancer.

INTRODUCTION

Gastric cancer is one of the most common cancers and lethal malignancies worldwide[1,2]. Approximately 738000 patients with gastric cancer died in 2011[2]. Of these, 80% died within a short period after curative surgery due to locoregional recurrence (87%) and distant metastases (30%)[3,4]. The 5-year survival of gastric cancer is less than 40%, even with adjuvant chemo-radiotherapy[5]. Therefore, there is an urgent need for new therapeutic strategies to improve clinical outcomes of this disease.

Notch signaling, as an evolutionarily conserved signaling pathway, is involved in a variety of cellular processes including cell fate, differentiation, proliferation, survival rate, and apoptosis[1,6]. The Notch signaling in mammals consists of five ligands [Delta-like ligand 41/3/4 (DLL1/3/4) and Jagged 1/2] and four receptors (Notch 1-4). Notch proteins are synthesized as full-length unprocessed proteins and cleaved at the S1 site by furin-like convertase to generate the mature receptor. Notch-ligand binding induces the cleavages of a Notch receptor by metalloprotease and γ-secretase to release the Notch intracellular domain (NICD). The NICD subsequently translocates to the nucleus, where it forms a complex with the members of the CSL (C-promoter binding factor-1, suppressor of hairless in *Drosophila* and lag in *Caenorhabditis elegans*) transcription factor family and regulates the expression of downstream genes such as Hairy/Enhancer of Split (*HES1/5/6/7*) and the HES-related proteins (*HEY1/2/L*)[6-10].

Interestingly, Notch signaling may play distinct biological roles in different tumors. It acts as an oncogene in pancreatic cancer[11], colon cancer[12], breast cancer[13] and most other solid tumors[14,15], whereas it acts as an anti-oncogene in some types of skin cancer[16], lung cancer[17] and prostate cancer[18]. Compared with other solid tumors, less literature relates to the role of DLL4-mediated Notch signaling in gastric cancer.

Although most Notch-related genes are expressed in multiple tissue and cell types, DLL4 is largely restricted to the vascular endothelia and has been researched mainly with regard to vasculogenesis and tumor angiogenesis[7,19-21]. Blockade of DLL4 signaling has been shown to lead to inhibition of tumor angiogenesis by nonproductive angiogenesis in some types of murine tumor models[20,21]. However, the precise function and mechanism of DLL4 in gastric cancer remain unclear. In the present study, we up-regulated the expression of DLL4 in the gastric cancer cell line SGC7901, and assessed its biological function both *in vitro* and *in vivo*.

MATERIALS AND METHODS

Cell lines and animals

Human gastric cancer cell line SGC7901 was purchased from the Type Culture Collection of the Chinese Academy of Sciences, Shanghai, China. Cells were propagated in RPMI-1640 medium (Gibco-Invitrogen, Carlsbad, CA, United States) supplemented with 10% fetal bovine serum (FBS) (Gibco-Invitrogen), penicillin (100 units/mL) and streptomycin (100 μg/mL) in a humidified atmosphere containing 5% CO_2 at 37 ℃.

Animal studies were carried out in accordance with the recommendations in the Guide for the Care and Use of Laboratory Animals of the National Institutes of Health and the protocol was approved by the Animal Research Committee of Zhejiang University, Hangzhou, China. Mouse protocols were conducted in accordance with stringent regulations laid out by Zhejiang University Laboratory Animal Center. Twenty-four 4-wk-old male BALB/c nu/nu mice (Shanghai SLAC Laboratory Animal Co, Shanghai, China) weighing 10-12 g used for subcutaneous tumor implantation were randomly divided into control, SGC7901-vector and SGC7901-DLL4 groups. Animals were housed in a sterile environment, and maintained on daily 12-h light/12-h dark cycle, which was controlled by qualified staff in the Zhejiang University Laboratory Animal Center.

Recombinant eukaryotic expression vector pEGFP-C1-DLL4 construction

A human full-length DLL4 cDNA fragment was amplified using a forward primer 5'-GGAATTCACCATGGCGGCAGCGTCC-3' and a reverse primer 5'-CGGGATCCTTATACCTCCGTGGCAATGACAC-3', verified by sequencing, and then *Eco*RI-*Bam*HI-digested. The 2-kb fragment was purified using a AxyPrep DNA Gel Extraction Kit (Axygen, Union City, CA, United States) and was ligated to a EcoRI-BamHI-digested pEGFP-C1 vector DNA (Clontech, Mountain View, CA, United States). Positive clones were further confirmed by *Eco*RI-*Bam*HI digestion and sequencing.

Transfection and clone selection

SGC7901 cells in logarithmic growth phase were collected and seeded into six-well plates at 4×10^5 cells/well to obtain approximately 80% confluence after overnight

Table 1 Primer sequences for real-time polymerase chain reaction

Genes	Forward sequences	Reverse sequences	Product size (bp)
DLL4	5′-CCCTGGCAATGTACTTGTGAT-3′	5′-TGGTGGGTGCAGTAGTTGAG-3′	73
Notch1	5′-GCCTCAACATCCCCTACAAGA-3′	5′-CCACGAAGAACAGAAGCACAAA-3′	120
HES1	5′-GTCAACACGACACCGGATAA-3′	5′-TTCAGCTGGCTCAGACTTTC-3′	113
HES5	5′-TGGAGAAGGCCGACATCCT-3′	5′-GGCGACGAAGGCTTTGC-3′	65
HEY1	5′-CGCGTTATCTGAGCATCATT-3′	5′-TGGGAAGCGTAGTTGTTGAG-3′	88
MMP-2	5′-GCTGACGGTAAGGACGGACTC-3′	5′-CGTTGCCATTGAACAAGAAGG-3′	158

incubation. Cultured SGC7901 cells were divided into three groups: (1) transfected cells with recombinant pEGFP-C1-DLL4 vector (SGC7901-DLL4 group); (2) transfected cells with pEGFP-C1 vector (SGC7901-vector group); and (3) nontransfected cells (control group). Transfection was performed using Lipofectamine 2000 reagent (Invitrogen) according to the manufacturer's instructions. The cells were then cultured in RPMI-1640 medium containing 10% FBS and G418 (600 μg/mL) for 21 d. G418-resistant clones were selected and amplified in complete medium containing G418 (300 μg/mL). Up-regulation of DLL4 was verified by real-time polymerase chain reaction (PCR) and Western blotting assay.

RNA extraction and real-time PCR

Extraction of total RNA from cultured cells was performed using the TRIzol method (Invitrogen). Total RNA (1 μg) was reverse-transcribed using RevertAid First Strand cDNA Synthesis Kit (Fermentas, ThermoFisher Scientific, Waltham, MA, United States). Real-time PCR was performed in triplicate using SYBR Green PCR Master Mix (TaKaRa, Tokyo, Japan) in an ABI PRISM Stepone Plus Sequence Detection System (Applied Biosystems, Foster City, CA, United States) according to the manufacturer's instructions. Forty cycles were used to amplify DLL4/Notch-related genes (denaturation at 95 ℃ for 5 s, annealing and extension at 60 ℃ for 32 s). Relative quantitation of gene expression was detected using the method described by Pfaffl[22]. The primers for real-time PCR were described in Table 1.

Western blotting analysis

Total protein extracts were prepared and run on 10% polyacrylamide gels. Fractionated proteins were electrotransferred to polyvinylidenefluoride membranes. Antibodies against human DLL4 (1:1000, Abcam, Cambridge, United Kingdom) and β-actin (1:1000, Abcam) were used for detection at 4 ℃ overnight. Horseradish peroxidase-conjugated anti-rabbit antibody was applied as a secondary antibody at 25 ℃ for 1 h. Antigens were identified by luminescent visualization using an ECL Western blotting Detection System (Millipore, Billerica, MA, United States). Signal intensity was measured using a Bio-Rad XRS chemiluminescence detection system (Bio-Rad).

Cell growth assay and growth curve

3-(4,5-dimethyl-2-yl)-5-(3-arboxymethoxyphenyl)-2-(4-sulfophenyl)-2H-tetrazolium (MTS) assays using the CellTiter 96 AQueous nonradioactive cell proliferation MTS agent (Promega, Madison, WI, United States) were performed to evaluate cell growth. Approximately 500 cells in 100 μL of medium with 0.5% FBS were plated in 96-well plates and allowed to attach for 24 h. Then 20 μL of the Promega MTS reagent was added to each well, and further incubation was conducted in a humidified incubator for 2 h. Absorbance of each well at 490 nm was determined using a Microplate Reader (Bio-Rad). The cell-growth curve was plotted using the optical densities obtained over 6 consecutive days.

Transwell migration assay

Transwell units with 8.0-μm pore-size polycarbonate filters (Corning Costar, Tewksbury, MS, United States) were used to investigate chemotactic cell migration. Cells were harvested and suspended at approximately 4×10^5 cells/mL in RPMI 1640 medium containing 0.5% FBS. A total volume of 100 μL of suspension was added into the upper compartment of the transwell unit. After 30 min of attachment, the units were transferred to wells containing 600 μL RPMI 1640 medium with 20% FBS as a chemoattractant, and further incubation was conducted for 20 h. After removing the cells on the upper surface of the membrane with a cotton bud and 15-min staining with 0.1% crystal violet, cell numbers on the underside were determined using light microscopy. Five randomly selected fields were counted per insert.

Matrigel invasion assay

Transwell units with 8.0-μm pore-size polycarbonate filters (Corning Costar) were precoated with 50 μL of 1:5 diluted matrigel (Becton Dickinson Biosciences, Franklin Lakes, NJ, United States) and used to investigate cell invasion. A total volume of 100 μL of suspension containing approximately 40000 cells was added to each upper compartment of precoated units. After 30 min of attachment, the units were transferred to wells containing 600 μL RPMI 1640 medium with 20% FBS as a chemoattractant, and incubation was conducted for 20 h. After removing the cells and Matrigel on the upper surface of

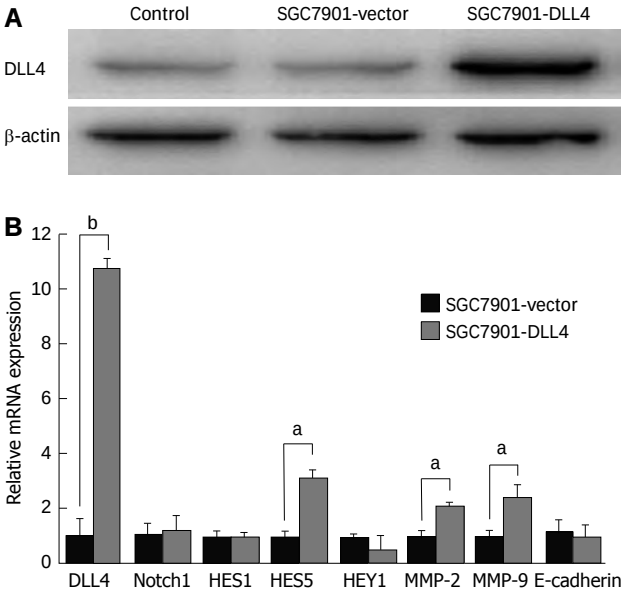

Figure 1 Up-regulation of Delta-like ligand 4 changed downstream gene expression in SGC7901 cells. A: Western blotting confirmed the up-regulation of Delta-like ligand 4 (DLL4) in the SGC7901-DLL4 group at the protein level; B: Real-time polymerase chain reaction was used to assess *Notch1*, *DLL4*, and downstream genes *HES1*, *HES5*, *HEY1*, as well as the matrix metalloproteinases-2 (*MMP-2*), *MMP-9*, and the adhesion protein E-cadherin at the mRNA level. The results showed increased expression of *DLL4*, *HES5*, *MMP-2*, and *MMP-9*, but no significant change of *HES1* and *HEY1* ($^aP < 0.05$, $^bP < 0.01$ *vs* the SGC7901-vector group). Data show mean ± SD of gene expression compared with the control group. Endogenous references was glyceraldehyde 3-phosphate dehydrogenase; SGC7901-vector: SGC7901 cells transfected with an empty vector; SGC7901-DLL4: SGC7901 cells transfected with a vector encoding human *DLL4* gene; Control: Non-transfected SGC7901 cells.

the membrane with a cotton bud and 15-min staining with 0.1% crystal violet, cell numbers on the underside were determined using light microscopy. Five randomly selected fields were counted per insert.

Gelatin zymography

Matrix metalloproteinases (MMPs) were detected using the zymogram technique according to the standard procedure[23]. Cells were allowed to grow in serum-free medium for 24 h. Then the medium was collected and diluted 1:1 with × 2 sample buffer and run on 10% polyacrylamide gels containing gelatin (1 mg/mL) until the bromophenol blue tracking dye reached the bottom of the gel. After electrophoresis, the gel was washed twice in Triton X-100 solution (2.5%) at room temperature for 15 min, transferred to 100 mL of development buffer containing 2 mL of Triton X-100 solution, and incubation was conducted at 37 ℃ for 72 h. Staining with Coomassie Blue R-250 solution proceeded overnight, then destaining was performed until the bands were clearly visible. Areas of protease activity appeared as clear bands against a dark blue background where the protease has digested the substrate.

Mouse tumor models

Twenty-four 4-wk-old male BALB/c nu/nu mice weighing 10-12 g were purchased and randomly divided into control, SGC7901-vector and SGC7901-DLL4 groups. Cells (1×10^6 cells/animal) in a total volume of 0.1 mL of PBS were implanted subcutaneously into the flank of each mice on day 0. Tumor size was measured on days 7, 14, 28, 35, 42. The tumor volume was calculated using the formula: volume = $D \times d^2 \times$ pi/6, where D and d represent the longer diameter and shorter diameter respectively.

Immunohistochemistry

For DLL4 staining, we used a rabbit monoclonal anti-human DLL4 antibody (1:200, Abcam). Paraffin-embedded tissue blocks were serially sectioned 4 μm in thickness, dewaxed, and rehydrated in serial alcohol washes. Endogenous peroxidase activity was blocked with 0.03% hydrogen peroxide in PBS for 20 min. Immunostaining for DLL4 was done by incubation for 1 h with primary antibody in blocking buffer and visualized using 3,3'-diaminobenzidine chromogen (Invitrogen) with hematoxylin (Invitrogen) counterstaining after treatment with HRP-conjugated Goat anti-rabbit immunoglobulin G (1:100 dilution).

Statistical analysis

Numerical results are shown as mean ± SD. Data were analyzed using SPSS ver. 13.0 statistical software (SPSS, Inc., Chicago, IL, United States). Differences among three groups were examined using one-way analysis of variance analysis. Means between two groups were compared using the Student's t test. Statistical significance was considered a P value of < 0.05. All experiments were performed at least three times.

RESULTS

Up-regulation of DLL4 changed downstream gene expression in SGC7901 cells

SGC7901 cells were transfected with vector encoding human *DLL4* (SGC7901-DLL4 group) or empty vector (SGC7901-vector group) and were then selected by G418 for at least 3 wk. Non-transfected SGC7901 cells were used as a control group. The up-regulating effect of the vector on DLL4 protein levels in the SGC7901-DLL4 group was confirmed by western blot assay (Figure 1A). Real-time PCR was further used to assess the expression of *Notch1*, *DLL4*, and downstream genes including *HES1*, *HES5*, *HEY1*, as well as the mRNA levels of MMP-2, MMP-9 and the adhesion protein E-cadherin. The results show that the mRNA level of DLL4 in the SGC7901-DLL4 group was approximately 10-fold higher than in the SGC7901-vector group. Accordingly, up-regulation of *DLL4* expression resulted in increased expression of *HES5*, *MMP-2* and *MMP-9* (Figure 1B).

Effects of DLL4 up-regulation on gastric cancer cell proliferation

MTS cell proliferation assays (Promega) were used to investigate the effect of DLL4 transfection on gastric

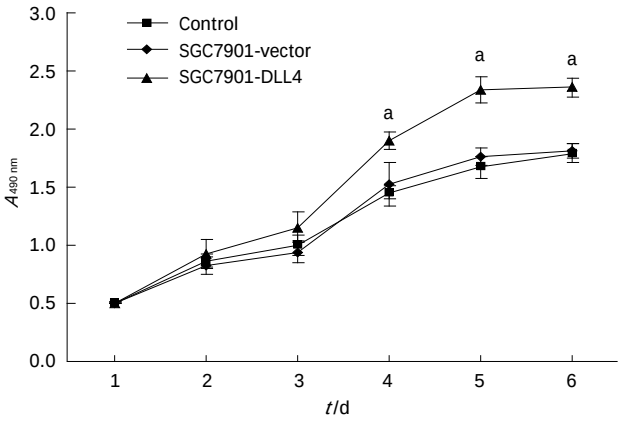

Figure 2 Up-regulation of Delta-like ligand 4 promoted cell proliferation in SGC7901 cells. Growth curve comparing SGC7901-Delta-like ligand 4 (DLL4), SGC7901-vector and SGC7901 cells over a 6-d time course. Up-regulation of DLL4 significantly promoted the proliferation of SGC7901 cells *in vitro*. Data are shown as the mean ± SD of three independent experiments ($^aP < 0.05$ *vs* the SGC7901-vector group); SGC7901-vector: SGC7901 cells transfected with an empty vector; SGC7901-DLL4: SGC7901 cells transfected with a vector encoding human *DLL4* gene; Control: Non-transfected SGC7901 cells.

cancer cells. A growth curve was plotted based on the optical densities obtained during the 6 d after attachment. The results showed that up-regulation of DLL4 resulted in significantly accelerated cell proliferation in the SGC7901-DLL4 group when compared to the SGC7901-vector group ($P < 0.05$, Figure 2).

Up-regulation of DLL4 accelerated migration of SGC7901 cells

The effects of DLL4 up-regulation on SGC7901 cell migration were investigated using 8.0-μm pore-size Corning Costar Transwell units. Approximately 4×10^4 cells from each of the groups were plated on the insert. The results show that the number of SGC7901 cells transfected with DLL4, which migrated across the insert, was 8.3 times higher than those transfected with empty vector (205.4 ± 15.2 *vs* 22.3 ± 12.1, $P < 0.05$) (Figure 3).

Up-regulation of DLL4 accelerated invasion of SGC7901 cells

Matrigel invasion assays were performed using 8.0-μm pore-size Corning Costar transwell units precoated with 50 μL Matrigel (1:5 diluted), which permitted cell migration across the filter. Approximately 4×10^4 cells from each group were plated in the insert. The results show that the number of SGC7901 cells transfected with DLL4, which migrated across both the Matrigel and the insert, was 2.83 times higher than those transfected with an empty vector (68.8 ± 5.3 *vs* 18.2 ± 6.0, $P < 0.05$) (Figure 3).

Effect of DLL4 up-regulation on the secretion and activation of extracellular MMPs

Gelatin zymography was used to analyze the effect of DLL4 up-regulation on the secretion and activation of MMPs, such as MMP-2 and MMP-9. From each group, 20 μL of culture supernatant were diluted 1:1 with × 2 sample buffer, incubated for 30 min at 25℃, and added to a zymogram comprising 10% polyacrylamide, 1 mg/mL gelatin, and electrophoresed at a constant voltage of 110 V until the bromophenol blue tracking dye reached the bottom of the gel. Coomassie Blue R-250 staining of the zymogram revealed significantly increased MMP-2 proenzyme level but decreased MMP-9 proenzyme level in the medium of the SGC7901-DLL4 group compared to the SGC7901-vector group (Figure 4).

Up-regulation of DLL4 accelerated tumor growth in vivo

To examine the effect of DLL4 up-regulation on gastric cancer growth *in vivo*, 24 four-wk-old male BALB/c nu/nu mice were divided randomly and averagely into three groups and implanted subcutaneously with control/SGC7901-vector/SGC7901-DLL4 cells. Six weeks after inoculation, the gastric cancer cells grew as subcutaneous implants in each nude mouse (100%). The size of subcutaneously formed tumor masses of the SGC7901-DLL4 group (2640.5 ± 923.6 mm^3) ($P < 0.05$ relative to the SGC7901-vector group) was significantly larger than the control (1011.1 ± 273.6 mm^3) and SGC7901-vector groups (1115.1 ± 223.8 mm^3) (Figure 5A). Immunohistochemistry staining of DLL4 confirmed the up-regulation of DLL4 expression in the SGC7901-DLL4 group (Figure 5B).

DISCUSSION

The finding that DLL4/Notch signaling participates in vascular development and homeostasis, as well as the evidence that DLL4 is predominantly expressed in the developing endothelium and in some tumor endothelia, suggest that DLL4-mediated Notch signaling activation is involved in tumor angiogenesis[24-26]. However, literature regarding the biological properties of DLL4-mediated Notch signaling in gastric cancer is very limited. The aim of our study is to investigate the potential roles of DLL4 on the biological behavior of gastric cancer cells and its molecular mechanisms.

In this study, we investigated the effect of DLL4 up-regulation on cell growth, migration and invasion *in vitro* and tumor growth *in vivo*. The results showed that up-regulation of DLL4 significantly promotes proliferation, migration, and invasion of SGC7901 gastric cancer cells *in vitro* and tumor growth *in vivo*. Our findings indicate the oncogenic function of DLL4/Notch signaling in gastric cancers, which is in accord with previous studies on other cancers. For example, small interfering RNA (siRNA)-induced knockdown of DLL4 resulted in decreased proliferation, increased apoptosis and retarded growth of tumor *in vitro* and *in vivo*[27-31]. Other Notch-targeting approaches such as chemical inhibitors of gamma-secretase significantly suppressed cell growth in colon cancer cell lines[32,33] and sensitized oxaliplatin- and 5-Fu-induced apoptosis and growth inhibition[34]. These findings indicate that DLL4/Notch signaling is an important molecular pathway involved in oncogenesis and chemoresis-

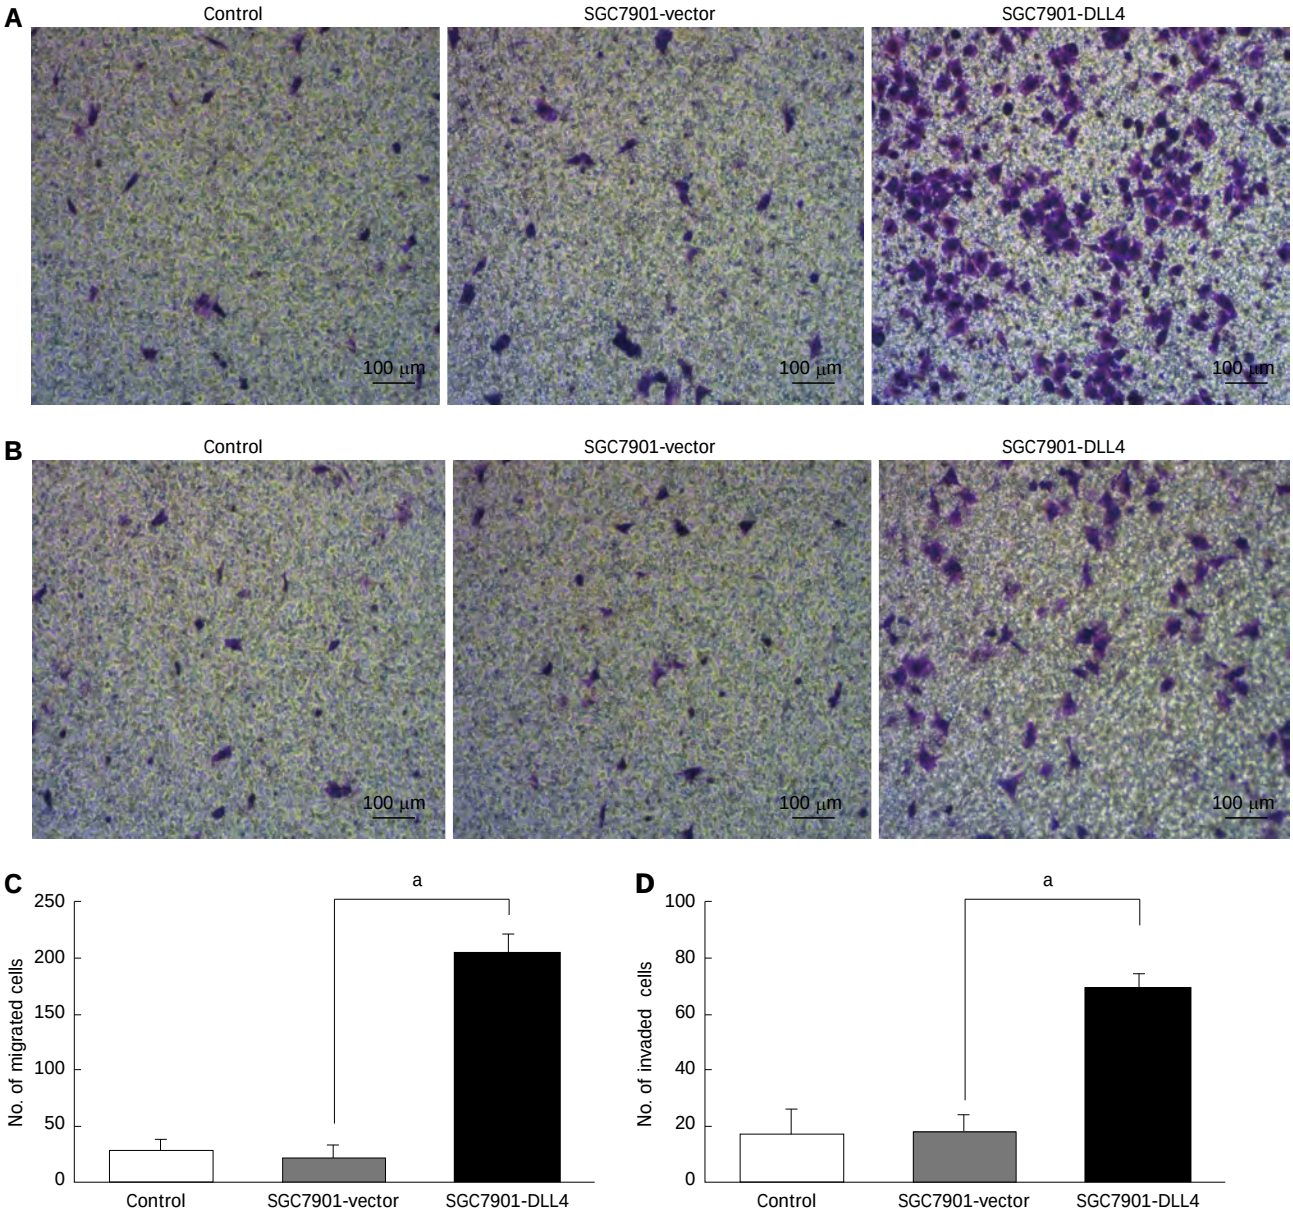

Figure 3 Up-regulation of Delta-like ligand 4 promoted cell migration and invasion in SGC7901 cells. A: Crystal violet staining revealed the migrated cells of each group; B: Crystal violet staining reveals invaded cells from each of the groups; C: The number of cells in the SGC7901-Delta-like ligand 4 (DLL4) group that had migrated was 8.31 times higher than those transfected with an empty vector (205.4 ± 15.2 *vs* 22.3 ± 12.1, $^{a}P < 0.05$); D: The number of cells in the SGC7901-DLL4 group that had migrated across both the Matrigel and the insert was 2.83 times higher than that in the SGC7901-vector group (68.8 ± 5.3 *vs* 18.2 ± 6.0, $^{a}P < 0.05$). Figure 4 Effect of Delta-like ligand 4 up-regulation on the secretion and activation of extracellular matrix metalloproteinases. Twenty microlitres of culture supernatant from each group was used. Coomassie Blue R-250 staining of the zymogram revealed significantly increased matrix metalloproteinases (MMP)-2 proenzyme but decreased MMP-9 proenzyme in the SGC7901-Delta-like ligand 4 (DLL4) group *vs* the SGC7901-vector group. SGC7901-vector: SGC7901 cells transfected with an empty vector; SGC7901-DLL4: SGC7901 cells transfected with vector encoding human *DLL4* gene; Control: Non-transfected SGC7901 cells.

tance. Targeting DLL4/Notch signaling might constitute a novel molecular therapy for cancers.

Wang *et al*[31] reported that inactivation of Notch signaling in prostate cancer cells leads to decreased expression and activity of MMP-9, which contributes to the inhibition of cell migration and invasion. Our study shows that up-regulation of DLL4 leads to decreased activity of MMP-9 with increased MMP-9 expression at mRNA level. One explanation for this observation could be that Notch signaling targeting genes, as well as MMP-9, have complex post-transcriptional regulations. This explanation might also contribute to diverse roles of Notch signaling in different types of cancers. Another possible explanation is that the activation of MMP-9 is inhibited by

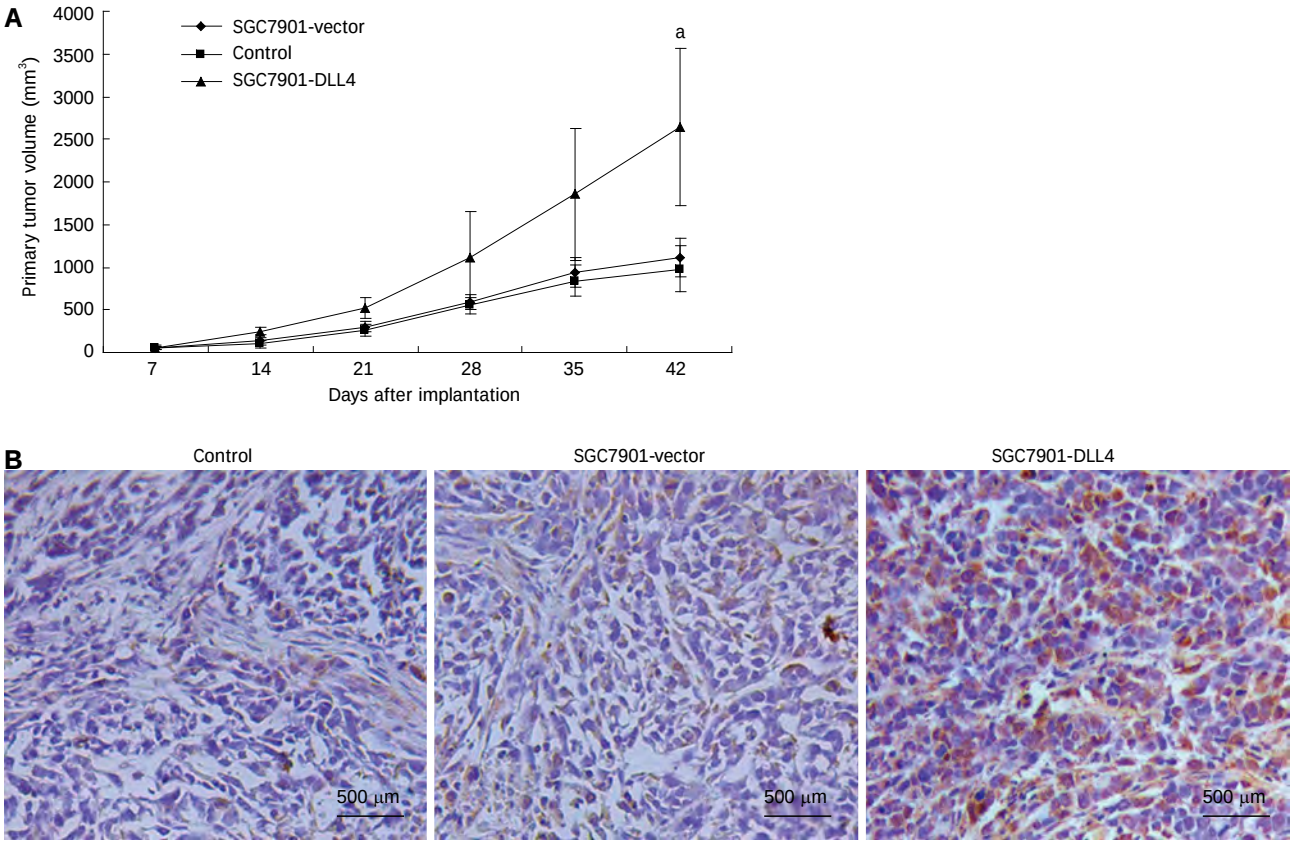

Figure 5 Up-regulation of Delta-like ligand 4 promoted tumorigenesis of SGC7901 cells *in vivo*. Twenty-four 4-wk-old male BALB/c nu/nu mice were divided randomly into three groups and implanted subcutaneously with control/SGC7901-vector/SGC7901-Delta-like ligand 4 (DLL4) cells. A: Six weeks after inoculation, the size of subcutaneous formed tumor masses of the SGC7901-DLL4 group (2640.5 ± 923.6 mm^3) was significantly larger than the control (1011.1 ± 273.6 mm^3) and SGC7901-vector groups (1115.1 ± 223.8 mm^3); B: Immunohistochemistry staining of DLL4 confirmed the up-regulation of DLL4 in the SGC7901-DLL4 group. $^aP < 0.05$ *vs* the SGC7901-vector group.

other signaling pathways or molecules induced by DLL4 up-regulation, such as tissue inhibitor of metalloproteinase-1 (TIMP-1), TIMP-2, or other TIMPs. Furthermore, significantly increased mRNA levels and secretion of MMP-2 proenzymes were observed in gastric cancer cells with up-regulated DLL4. These results suggest that MMP-9 signaling might not be sufficient to exert an effect alone in gastric cancer progression[35], while other molecules such as MMP-2 might play a major role.

In summary, to our knowledge, activation of DLL4-mediated Notch signaling effectively promotes proliferation, migration, and invasion of gastric cancer cells, and desensitizes the cells to chemotherapeutically induced cell senescence. Our data suggest that DLL4-mediated Notch signaling may play an important role in the progression of gastric cancer, and that DLL4-mediated Notch signaling could be a potential target for gastric cancer biotherapy. Meanwhile, we identified MMP-2 as a novel target of DLL4-mediated Notch signaling in gastric cancer cells. However, the precise molecular mechanism of DLL4-mediated Notch signaling in gastric cancer remains unclear. Further studies are required to elucidate possible downstream target genes or potential interacting molecules of DLL4-mediated Notch signaling.

In summary, up-regulation of DLL4 significantly promoted cellular proliferation, migration, and invasion *in vitro* and tumor growth *in vivo*. Significantly increased MMP-2 expression at both the mRNA and the protein level was observed in gastric cancer with up-regulated DLL4. Our observations indicated a mechanism by which activation of DLL4-mediated Notch signaling promotes the expression and secretion of MMP-2 proenzyme and influences the progress of gastric cancer.

COMMENTS

Background

Gastric cancer is one of the most common cancers and lethal malignancies worldwide. Discovering novel biomarkers that correlate with gastric cancer may present opportunities to reduce the severity of this disease. As one of the five Notch signaling ligands in mammals, Delta-like ligand 4 (DLL4) has been researched mainly with regard to vasculogenesis and tumor angiogenesis. However, the precise function and mechanism of DLL4 in gastric cancer remain unclear.

Research frontiers

Notch signaling, as an evolutionarily conserved signaling pathway, is involved in a variety of cellular processes, including cell fate, differentiation, proliferation and apoptosis. Previous data indicates its distinct biological roles in different tumors. It may work as an oncogene or anti-oncogene. Their observations indicated a mechanism by which activation of DLL4-mediated Notch signaling promotes the expression and secretion of matrix metalloproteinase (MMP)-2 proenzyme and influences the progress of gastric cancer.

Innovations and breakthroughs

Previous studies indicated that DLL4 is largely restricted to the vascular endothelia. Recent reports were focused on its roles on vasculogenesis and tumor

angiogenesis. The authors discovered that DLL4 up-regulation promotes cellular proliferation, migration, invasion and tumorigenicity in gastric cancer cells. Increased mRNA level and increased secretion of matrix metalloproteinase-2 proenzyme, while increased MMP-9 mRNA level but decreased extracellular MMP-9 proenzyme level were observed.

Applications

In understanding the role and mechanism of DLL4-mediated Notch signaling in gastric cancer, this study may represent a future strategy as a therapeutic target and/or a way to improve clinical treatment for gastric cancer.

Peer review

The authors found that ectopic expression of DLL4 significantly promoted cellular proliferation, migration, invasion *in vitro* and tumor growth *in vivo*. Significantly increased mRNA levels and secretion of MMP-2 proenzymes were observed, increased MMP-9 mRNA but decreased extracellular MMP-9 proenzyme were observed. The paper is well presented and the results are interesting.

Abstract

AIM: To further analyse cancer involvement of basic transcription factor 3 (BTF3) after detection of its up-regulation in gastric tumor samples.

METHODS: BTF3 transcription rates in human gastric tumor tissue samples (n = 20) and adjacent normal tissue (n = 18) specimens as well as in the gastric cancer cell lines AGS, SGC-7901, MKN-28, MKN-45 and MGC803 were analyzed *via* quantitative real-time polymerase chain reaction. The effect of stable BTF3 silencing *via* infection with a small interfering RNA (siRNA)-BTF3 expressing lentivirus on SGC-7901 cells was measured *via* Western blotting analysis, proliferation assays, cell cycle and apoptosis profiling by flow cytometry as well as colony forming assays with a Cellomic Assay System.

RESULTS: A significant higher expression of BTF3 mRNA was detected in tumors compared to normal gastric tissues (P < 0.01), especially in section tissues from female patients compared to male patients, and all tested gastric cancer cell lines expressed high levels of BTF3. From days 1 to 5, the relative proliferation rates of stable BTF3-siRNA transfected SGC7901 cells were 82%, 70%, 57%, 49% and 44% compared to the control, while the percentage of cells arrested in the G_1 phase was significantly decreased (P = 0.000) and the percentages of cells in the S (P = 0.031) and G_2/M (P = 0.027) phases were significantly increased. In addition, the colony forming tendency was significantly decreased (P = 0.014) and the apoptosis rate increased from 5.73% to 8.59% (P = 0.014) after BTF3 was silenced in SGC7901 cells.

CONCLUSION: BTF3 expression is associated with enhanced cell proliferation, reduced cell cycle regulation and apoptosis and its silencing decreased colony forming and proliferation of gastric cancer cells.

Key words: Basic transcription factor 3; Gastric cancer; Small interfering RNA; Proliferation; Apoptosis; Cell cycle

Core tip: After we found that basic transcription factor 3 (BTF3) transcription rates in human gastric tumor tissue samples were significantly higher than in adjacent normal tissues, we extended our study on gastric cancer cell lines. We silenced BTF3 in SGC7901 cells, which led to 82%, 70%, 57%, 49% and 44% proliferation rates of the control within the first 5 d after infection with a

small interfering RNA-BTF3 containing lentivirus. After BTF3 silencing, the percentage the G_1 phase arrested SGC7901 cells was decreased (P = 0.000), the percentages of cells in the S (P = 0.031) and G_2/M (P = 0.027) phases were increased and the apoptosis rate increased from 5.73% to 8.59% (P = 0.014).

INTRODUCTION

Basic transcription factor (BTF3) is a 27 kD protein that in humans is encoded by the *BTF3* gene[1,2] and evolutionarily conserved in a variety of cells[3]. BTF3 was initially discovered as a member of the general transcription machinery and functions as a transcriptional initiation factor from proximal promoter elements by forming a stable complex with RNA polymerases[4,5]. There are two ubiquitously expressed isoforms of the *BTF3* gene that encode BTF3a and BTF3b proteins. The BTF3a is the transcriptional active form of BTF3, while the isoform BTF3b, which lacks the first 44 amino acids of the BTF3a N-terminus is transcriptionally inactive, although it is able to bind to the RNA polymerase Ⅱ[6]. However, previous studies indicated that BTF3 was not in fact essential for specific, *in vitro* initiation of transcription, but its biological importance was shown by the fact that mouse embryos, homozygous for a loss of function mutation in the *BTF3* gene, died at the early stage of development indicating its important role during development[7]. In addition, BTF3 was up-regulated strongly in mouse pregnancy, indicating an involvement in alveolar growth[8]. In cancer, it has been reported that the *BTF3* gene has been overexpressed in colorectal cancer, glioblastomas and hepatocellular carcinomas[9-12]. In the pancreatic ductal adenocarcinoma, the median level of the BFT3 and BFT3a mRNA was increased by 1.3 and 4.6 folds compared to the normal tissues, respectively. Down-regulation of the BTF3 expression using small interfering RNA (siRNA) resulted in reduced expression of several cancer-associated genes, including ephrin receptor B2, which is mainly expressed during development and involved in tumor cell survival[13,14] and heparanase 2 an extracellular matrix degrading enzyme involved in cell adhesion. In addition, ataxia-telangectasia mutated gene, which is implicated in cell cycle arrest[15], DNA repair[16] or apoptosis and the oncogene V-abl Abelson murine leukemia viral oncogene homolog 2, a nuclear protein tyrosine kinase for cell differentiation, cell division and cell adhesion were also had reduced expression[17]. By BFT3 silencing, up-regulated genes were *k-ras* oncogene-associated gene, related ras viral oncogene homolog 2, nuclear factor kappa-B, murine retrovirus integration site 1 and mucosal vascular addressing cell adhesion molecule 1, all known to be involved in tumor development[18]. In addition, BTF3 interacts with either 17β-estradiol or epidermal growth factor activated estrogen receptor α (ERα) *via* its AF1 domain in the breast cancer cell line MCF-7 and up-regulates transcriptional responses of ERα reporter genes[19,20]. In this study, we analyzed the expression of BTF3 mRNA and protein in gastric tumors and normal samples and compared BTF3 expressions in different gastric tumor cell lines. Finally we used siRNA-BTF3 to down-regulate BTF3 expressions in gastric tumor cells and measured the changes of proliferation and apoptosis to investigate the relationship between BTF3 and gastric cancer.

MATERIALS AND METHODS

Patients

Human tissue samples of gastric tumor (n = 20) and adjacent normal tissue (n = 18) specimens were obtained from patients with a median age of 63 years (range, 35-83 years) who received gastric resections from November 2011 to March 2012 in the Second Xiangya Hospital of Central South University, Changsha, China. All samples were confirmed histologically. Freshly removed tissues (within 5 min after surgical excision) were: (1) fixed in paraformaldehyde solution for 12-24 h and then paraffin embedded for histological analysis; (2) kept in RNAlater (Ambion Ltd., Huntingdon, Cambridgeshire, United Kingdom) for RNA analysis; or (3) snap-frozen in liquid nitrogen and maintained at -80 ℃ for protein analysis. All studies were approved by The Human Ethics Committee of the First Affiliated Hospital of Hunan Normal University in China, and written informed consent was obtained from all patients.

Cell culture

Gastric cancer cell lines (AGS, SGC-7901, MKN-28, MKN-45 and MGC803) were grown in complete DMEM medium (Gibco, New York, United States), supplemented with 10% fetal calf serum (Gibco, New York, United States) and 5 U/mL penicillin, and incubated at 37 ℃ in 5% CO_2 atmosphere.

Plasmid and vector construction

The selected and optimized siRNA (sense: GCCGAAGAAGCCTGGGAATCA, anti-sense: TGATTCCCAGGCTTCTTCGGC) against human BTF3 and negative control (sense: TTCTCCGAACG TGTCACGT, anti-sense: ACGTGACACGTTCGGAGAA) were used in generating the lentiviral vector. Basically, the BTF3 siRNA transcript template was synthesized, digested with Age I/EcoRI enzymes, and then ligated with pGCSIL-GFP vector. After checking by agarose electrophoresis, successful BTF3-siRNA-pGCIL-GFP recombinants were amplified, purified and sequenced. In order to evaluate the inhibitive effect of BTF3 sequences, the confirmed pGCSIL-GFP recombinants were transfected into 293T cells (data not shown). The expressed BTF3 protein was detected by Western blotting.

BTF3: Basic transcription factor 3; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

Quantitative real-time polymerase chain reaction

Cells were split during the log-phase growth before plating into the 6-well plate with complete medium, and incubated at 37 ℃ with 5% CO_2. An appropriate amount of lentiviral vectors was added to cells when 30% confluence was reached. Total RNA was extracted 5 d after treatment from cells with GFP expression by Trizol (Invitrogen, San Diego, United States). RNA (2 μg) was reversely transcribed using M-MLV-RTase (Promega, Madison, United States) following manufacturer's instructions. Real-time polymerase chain reaction (PCR) was performed using the tested primer set (Table 1) and SYBR Master Mixture (*TAKARA, DRR041B*) following the manufacturer's instructions with a TAKARA's TP800 Real Time PCR Instrument. Following the normalization with glyceraldehyde-3-phosphate dehydrogenase (*GAPDH*) gene, relative quantification of BTF3 expression was done by the comparative CT method ($2^{-\Delta\Delta C}$ method).

Total protein extraction, sodium dodecyl sulfate-polyacrylamide gel electrophoresis and immunoblotting

Cells were harvested 36-48 h following the transfection. Pellets were washed twice with cold phosphate-buffered saline (PBS) (Gibco, New York, United States) and then cells were lysed on ice for 10-15 min using proper lysis buffer [1 mol/L Tris-HCl 100 mmol/L, 2% 2-mercaptoethanol, 20% glycerol, 4% sodium dodecyl sulfate (SDS) (Life Technologies, New York, United States)]. After sonication, total protein extraction was performed by centrifugation at 1200 *g* for 15 min at 4 ℃. Protein was separated using SDS-polyacrylamide gel electrophoresis (SDS-PAGE), with 4% separating and 3%-15% gradient stacking gel. After SDS-PAGE, protein samples were wet transferred to polyvinylidenfluorid (PVDF) (Life Technologies, New York, United States) membranes for immunoblotting. To detect the target protein, the PVDF membrane was incubated with appropriate primary antibodies, either 2 h at the room temperature or overnight in the cold room (Mouse Anti-GFP Santa-Cruz SC-9996, 1:2000, Mouse anti-GAPDH Santa-Cruz SC-32233 1:5000), following 3 times of 10 min TBS-Tween 20 buffer (Life Technologies, New York, United States) washes, membranes were incubated with secondary antibodies for 2 h at room temperature (Goat Anti-Mouse IgG Santa-Cruz SC-2005 1:5000). After further 3 times washing, target proteins were detected using ECL™ Western blotting system (Amersham Cat. No. RPN2135).

Flow cytometric assays

Cells were harvested by Trypsin/EDTA (Life Technologies, New York, United States) solution from the 6-cm dishes at 80% confluence followed by setting up the designed assays. Pellets were then washed with PBS and collected into 5 mL centrifuge tubes in triplicate. After fixation using pre-cooled 4 ℃ 70% ethanol for 1 h, cells were washed again and then stained with propidium iodide (FACSCalibur, BD, New York, United States).

Colony forming assay

Five hundred cells were plated per well in 96-well plates in triplicate. After the colony number reached more than 5 in most of the wells, the colonies were scanned using Cellomics system following the manufacturer's protocol. The colony size and cell numbers within each colony were analyzed by Cellomics system (Thermo, Philadelphia, United States). The data were then statistically analyzed.

Statistical analysis

Results of all calculations were expressed as mean ± SD. Analysis of variance (ANOVA) with multiple comparisons using Bonferroni's test or one-way ANOVA was performed where appropriate. The difference between two groups was analyzed by unpaired *t* test GraphPad Prism (version 3.02-2000). The results of statistical tests were considered significant if the *P* value was < 0.05 and < 0.01.

RESULTS

Level of BTF3 expression in gastric cancer and tumor cell lines

A quantitative real-time PCR was performed to identify the transcription levels of the *BTF3* gene in 20 human gastric tumors and the relative tumor free margins ($n = 18$) as healthy tissue control. A significantly higher transcription of BTF3 mRNA was detected in tumors compared to normal gastric tissues (Figure 1A, $P < 0.01$), especially in female patients' section tissues compared to male patients (Figure 1B) and between the gastric body tumor and adjacent normal tissue, but no significant difference was detectable between gastric antrum or cardia tumor and adjacent normal tissues (Figure 1C). In order to further confirm that the *BTF3* gene was widely expressed in our gastric tumor cell lines, quantitative real-time PCR was performed in five different cell lines AGS, SGC-7901, MKN-28, MKN-45 and MGC803. SGC-7901, MKN-45 and MGC803 which are all poorly differentiated adenocarcinomas, while the MKN-28 and AGS are high and moderately differentiated cell lines. The expected products of BTF3 mRNA were detected in all the above five cell lines (Figure 1D).

Silencing of BTF3 by siRNA

Based on the significant BTF3 up-regulation from the clinical data, we sought that the regulation of BTF3 in gastric tissue might be related to cancer initiation promotion and progression. To investigate this, the gene was

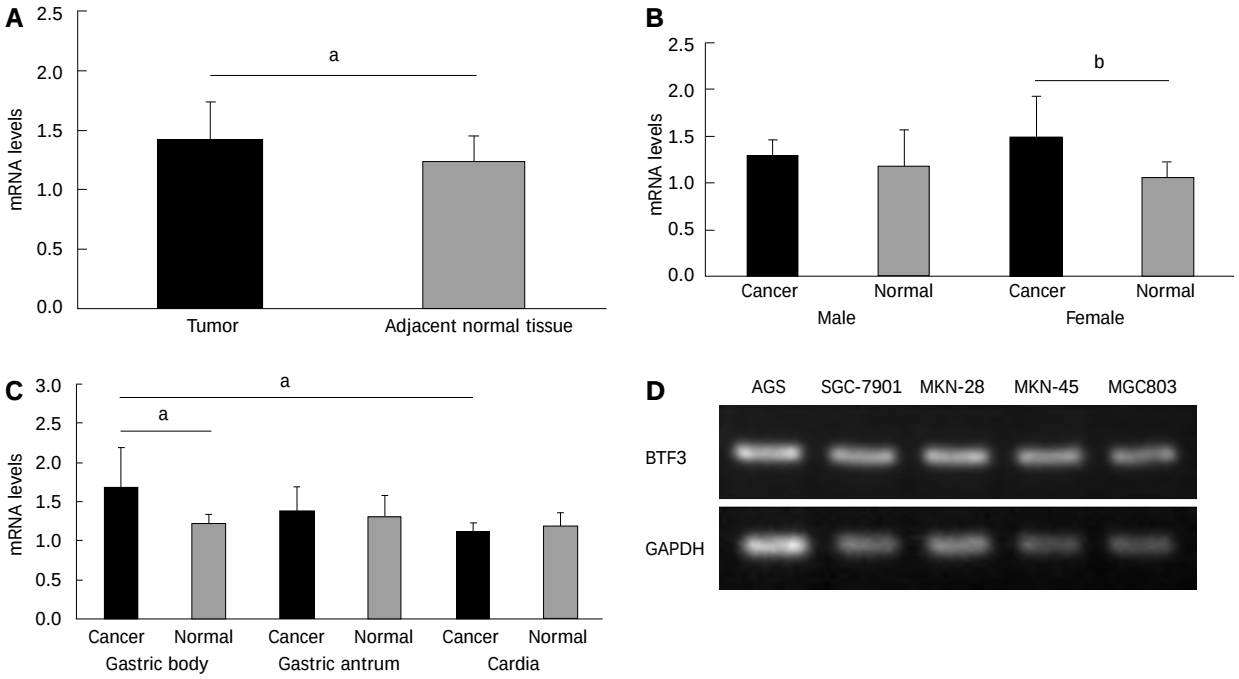

Figure 1 Level of basic transcription factor 3 expression in gastric cancer and tumor cell lines. A: Bar charts represent the mRNA levels of basic transcription factor 3 (BTF3) in gastric tumor and adjacent normal tissue measured by quantitative real-time polymerase chain reaction (PCR); B: BTF3 mRNA expression data from (A) further classified by gender; C: BTF3 expression pattern among gastric body, gastric antrum and cardia tumors; D: The expression of BTF3 mRNA was detected by quantitative real-time PCR among different cell lines. Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as the reference gene. Black bars represent tumors and gray bars normal tissues. The difference in BTF3 expression, $^{a}P < 0.05$, $^{b}P < 0.01$ between groups was assessed by unpaired *t* test and considered significantly different.

silenced using lentiviral vectors expressing the specifically designed synthetic siRNA-BTF3. In pilot experiments, the siRNA-BTF3 was successfully transfected into human SGC7901 and 293T cell lines for mRNA expression profiles and protein analyses *via* GFP expression to estimate the transfection efficiency (Figure 2A). In SGC7901 cells, a significant down-regulation of the *BTF3* gene was measured after siRNA-BTF3 application (Figure 2B). The BTF3 transcription in siRNA transfected cells was 12.4% of the negative control transfected cells ($P = 0.0066$). The BTF3 protein levels in SGC7901 cells, detected by Western blotting 48 h after siRNA-BTF3 transfection, were reduced compared to the control (Figure 2C).

BTF3 silencing effect in SGC7901 cells

In order to identify the effect on gastric tumor cells, proliferation, cell cycle, apoptosis and colony forming assays were performed with siRNA-BTF3 transfected SGC7901 cells. The silencing of BTF3 significantly slowed down the SGC7901 cell growth in the proliferation assay (Figure 3). On day 1, the siRNA transfected cells already started to show an 18% slower proliferation rate compared with the negative controls. The difference became increasingly significant and peaked at the end of the proliferation assay on day 5, on which the proliferation rate in the siRNA transfected cells was only 44% of the negative control. From days 1 to 5, the relative proliferation rates of siRNA transfected SGC7901 were 82%, 70%, 57%, 49% and 44%, respectively. In summary, an obvious effect on proliferation of SGC7901 was induced by silencing BTF3 (Figure 3, BTF3-siRNA). A cell cycle profile of the siRNA-BTF3 transfected cells using PI-FACS and Annexin V showed that the percentage of cells arrested in the G_1 phase was significantly decreased, while the percentages of cells at the S and G_2/M phases were significantly increased (Figure 4). The knockdown of BTF3 in SGC7901 cells also induced an increased level of apoptosis. Cells with good transfection efficiency were harvested on day 5 for flow cytometry (Figure 5). The negative control group which was transfected with empty vectors showed 5.73% and 0.76% apoptosis, while the apoptosis rate of siRNA-BTF3 transfected group was 8.59% and 1.1% (Figure 5B and D). The down-regulation of BTF3 increased the apoptosis rate by nearly 2 folds. To detect the long-term effect on SGC7901 cells following BTF3 silencing, a colony forming assay was performed. Colonies were scanned and analyzed using the Cellomic Assay System. Cells after BTF3 silencing showed a significantly lower colony forming ability compared with the negative controls (Figure 6A). In the silenced group, 14 d following the initiation of the assay in average 10 colonies were detected, whereas a significantly higher number of 22 colonies (mean) was detected in the negative group ($P = 0.014$) (Figure 6B). In addition, the number of cells in each siRNA-BTF3 transfected SGC7901 cell colony was also reduced compared with the control.

DISCUSSION

In cells, multiple protein complexes are required to be

Glyceraldehyde-3-phosphate dehydrogenase (GAPDH) was used as internal control.

orderly assembled on proximal promoter elements such as the TATA box and CAAT box sequences in order to initiate the gene transcription. At the very early stage of the transcription initiation, transcription factor class Ⅱ D (TFⅡD), which belongs to the transcription factor class Ⅱ (TFⅡ) family is required to be stably bound to the transcription factor assembling TATA box. The BTF3 protein, which works as an additional TFⅡ re-

lated protein, does not directly associate with the proximal promoter, but forms a stable complex with RNA polymerase Ⅱ and is part of the gene transcription initiation complex[4,5]. Several studies have reported that expression pattern of transcription factors is frequently changed in gastric tumors. For example, the transcription factor Sp1 has been reported to be higher in malignant gastric tissues, and might serve as an independent prognostic factor, by influencing the tumor infiltration and progression[21]. Another transcription factor, the E2F transcription factor 1, which plays a critical role in cell cycle regulation and other biological processes of the cells, is also up-regulated in human gastric cancer tissues, but further analysis revealed that its overexpression slowed down the cancer cell growth rate[22]. Other transcription related genes were reported to be differentially expressed in gastric tumors compared to normal tissues. Some genes like the antitumor genes *GATA-4* and *GATA-5* were down-regulated[23,24], whereas others like the oncogenes Forkhead box protein M1[25], and phosphorylated Forkhead box protein O1, which are related to angiogenesis[26] were up-regulated. In addition, the activating transcription factor 4[27], which is cell protective and thereby leading to multidrug resistance, also had enhanced expression. In the present study, we found that the expression of BTF3 is up-regulated in 20 gastric tumor samples compared with normal tissues. We further investigated the expression levels of BTF3 in different malignant gastric tumor cell lines and found uniform expression levels among them (Figure 2). This is in agreement with previous information, because high BTF3 protein levels in gastric cancers have been reported in the Human Protein Atlas[28]. Hence BTF3 is a transcription factor and related to apoptosis[29-32], we thought that the expression level of BTF3 might be important for cell cycle check points, proliferation and further potentially linked with human tumor development and progression. In order to elucidate this, we silenced BTF3 in SGC7901 cells (Figure 3). As a result, the cell cycle arrest shifted from the G_1 to the G_2/M and S phases with a significantly increased apop-

tosis rate, which was also reflected in our colony forming assay with significantly less cell growth after BTF3 silencing (Figure 6). This data indicated that BTF3 silencing might induce G2/M check point failure, which led to the inhibition of cell cycle completion and enhanced apoptotic activity.

In summary, our data indicated that BTF3 has a potential link with gastric cancer development and progression. Low expression or silencing of BTF3 might inhibit tumor growth and be beneficial for cancer treatment. However, the clinical data revealed that the tumors had different BTF3 levels possibly due to the different stages of the gastric tumors examined.

COMMENTS

Background

It has been reported that the basic transcription factor 3 (*BTF3*) gene has been overexpressed in colorectal cancer, glioblastomas as well as pancreatic ductal adenocarcinoma. Down-regulation of the BTF3 expression using small interfering RNA (siRNA) resulted in changed expression of several cancer associated genes involved in tumor cell survival, cell adhesion and cell cycle.

Research frontiers

BTF3 was upregulated in all gastric cancer samples measured in this study. The authors demonstrated that silencing of BTF3 in SGC7901 cells led to a significant decline of proliferation due to enhanced cell cycle arrest and a concomitant higher apoptosis rate. The long-term effect of BTF3 silencing led to a lower amount of colony forming with less cell survival.

Innovations and breakthroughs

In gastric cancer tissues, enhanced expression of BTF3 was reported in the Human Protein Atlas, but the exact role of BTF3 in gastric cancer was not further analyzed. In this study, BTF3 was found to play an essential role in gastric cancer cell proliferation.

Applications

BTF3 was upregulated in all gastric cancer tissues derived from surgical interventions. Silencing of BTF3 led to less proliferation with an enhanced apoptosis rate in SGC7901 cells. The findings may be useful for the diagnosis and treatment of gastric cancer in the future.

Terminology

BTF3 was initially discovered as a member of the general transcription machinery and functions as a transcriptional initiation factor from proximal promoter elements by forming a stable complex with RNA polymerases, and mouse embryos, homozygous for a loss of function mutation in the *BTF3* gene, died at the early stage of development. In later developmental stages, the role of BTF3 has been described as transcriptional regulator and modulator of apoptosis.

Peer review

The authors analyzed the BTF3 expression in human gastric cancer tissues and compared the rates with expression in adjacent non-tumor tissues. As a result, all cancer tissues showed enhanced BTF3 expression. Further analysis *via* stable silencing of BTF3 in gastric cancer SGC7901 cells revealed that inhibiting BTF3 activity led to lower proliferation and enhanced apoptosis rates. The results are interesting and BTF3 might be a target gene for gastric cancer treatment.

Abstract

AIM: To explore the association of neurotensin receptor 1 (NTSR1) with inflammatory bowel diseases (IBD) and colitis-associated neoplasia.

METHODS: NTSR1 was detected by immunohistochemistry in clinical samples of colonic mucosa with IBD colitis, colitis-associated raised low-grade dysplasia (LGD) including dysplasia-associated lesions or masses (DALMs, *n* = 18) and adenoma-like dysplastic polyps (ALDPs, *n* = 4), colitis-associated high-grade dysplasia (HGD, *n* = 11) and colitis-associated colorectal carcinoma (CACRC, *n* = 13), sporadic colorectal adenomatous polyp (SAP, *n* = 17), and sporadic colorectal carcinoma (SCRC, *n* = 12). The immunoreactivity of NTSR1 was semiquantitated (as negative, 1+, 2+, and 3+) and compared among different conditions.

RESULTS: NTSR1 was not detected in normal mucosa but was expressed similarly in both active and inactive colitis. LGD showed a significantly stronger expression as compared with non-dysplastic colitic mucosa, with significantly more cases showing > 2+ intensity (68.75% in LGD *vs* 32.26% in nondysplastic mucosa, *P* = 0.001). However, no significant difference existed between DALMs and ALDPs. CACRC and HGD showed a further stronger expression, with significantly more cases showing 3+ intensity than that in LGD (61.54% *vs* 12.50% for CACRC *vs* LGD, *P* = 0.022; 58.33% *vs* 12.50% for CACRC/HGD *vs* LGD, *P* = 0.015). No significant difference existed between colitis-associated and non-colitic sporadic neoplasia.

CONCLUSION: NTSR1 in colonic epithelial cells is overexpressed in IBD, in a stepwise fashion with sequential progress from inflammation to dysplasia and carcinoma.

Key words: Neurotensin; Neurotensin receptor; Inflammatory bowel diseases; Dysplasia; Colitis-associated neoplasia; Dysplasia-associated lesion or mass; Sporadic adenoma; Colorectal carcinoma

Core tip: Neurotensin receptor 1 (NTSR1) in colonic epithelial cells is overexpressed in inflammatory bowel diseases, in a stepwise fashion with the sequential progress from inflammation to low-grade dysplasia, high-grade dysplasia, and carcinoma. Both colitis-associated and sporadic dysplasia/carcinoma showed a similar pattern of NTSR1 overexpression. NTSR1 could be a potential pharmacological target in the treatment of inflammatory bowel diseases and prevention of colitis-associated neoplasia.

plasia. *World J Gastroenterol* 2013; 19(28): 4504-4510 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4504.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4504

INTRODUCTION

Neurotensin (NTS) is a 13-amino-acid peptide secreted by neurons and specialized endocrine cells (N-cells) in the small intestine, which acts as a paracrine and endocrine modulator of various gut functions. The biological activities of NTS are mediated mainly through the high-affinity neurotensin receptor 1 (NTSR1), a member of the G-protein-coupled receptor family[1].

Many studies have suggested a possible role of NTS/NTSR-1 in the pathogenesis of inflammatory bowel disease (IBD) and colitis-associated neoplasia. The NTS/NTSR-1 signaling pathway has a complex dual effect (both proinflammatory and proregenerative) in the regulation of intestinal mucosal inflammation. NTS/NTSR-1 enhances the progression of acute colonic inflammation. NTS enhances mast cell degranulation and neutrophil recruitment[2-4]. NTSR-1 expression is increased in the human colonic mucosa with active ulcerative colitis (UC)[5,6] as well as in rodent colitis induced by *Clostridium difficile* toxin A[4] or by dextran sulfate sodium (DSS)[6], whereas pretreatment of NTSR-1 antagonist SR48692 inhibits the inflammatory changes[4]. Both NTS and NTSR1 expression are also increased in the mesenteric fat of mice during trinitrobenzenesulfonic-acid-induced colitis[7]. Moreover, NTS/NTSR1 activation in colonocytes stimulates interleukin (IL)-8 secretion from colonocytes through activating GTPase-mediated nuclear factor κ-light-chain-enhancer of activated B cells, mitogen-activated protein kinase, and protein kinase C[8-11]. NTS/NTSR-1 augments mucosal healing and regeneration following chronic colitis[5,6]. Pretreatment with NTSR1 antagonist worsens the severity of experimentally induced colitis and delays mucosal healing, whereas coadministration of exogenous NTS exerts the opposite effect[5,6,12,13]. NTS also stimulates colonic epithelial cell migration and proliferation through *COX-2* gene expression[5,6].

As a part of their diverse bioactivities, NTS/NTSR1 signaling is also involved in the early carcinogenesis and progression of colonic carcinoma. First, NTSR-1 is overexpressed in colonic neoplasms. A previous investigation of one of the present authors (Gui X) showed a stepwise increase in NTSR-1 mRNA with progression of colonic adenoma to adenocarcinoma[14]. Second, NTS is an epidermal growth factor (EGF)-like factor in a number of tumors[15-18]; it transactivates EGF receptor, hence it works synergistically with EGF[19,20]. Third, *NTSR-1* gene activation is linked with the *Wnt/APC/Tcf/β-catenin* pathway in colonic neoplasia. Upregulation of NTSR-1 in colorectal adenocarcinoma is the result of *Wnt/APC* pathway activation, and the increased NTSR-1 expression correlates with β-catenin cytosolic or nuclear accumulation. Additionally, *NTSR-1* gene can be activated by agents that cause β-catenin cytosolic accumulation[21]. Recently, it was also found that NTSR1 activation stimulates the expression of miRNAs 21 and 155 in colonocytes, in the experimentally induced colonic cancer (HCT-116 xenograft tumors) in mice as well as in human colonic carcinoma tissues[22].

It is well known that long-standing colitis (IBD) predisposes to the development of colorectal carcinoma (CRC). The relative risk of the development of CRC in IBD patients is 10-40-fold higher compared to that in the general population[23]. This so-called colitis-associated colorectal cancer (CACRC) is the most serious complication and the major cause of death of IBD patients. The carcinogenesis of CACRC is believed to be initiated and/or promoted by persistent active inflammation of colorectal mucosa[24,25] in the inflammation-dysplasia-carcinoma sequence, which differs from the adenoma-carcinoma sequence in sporadic CRC.

The bidirectional effect of NTS/NTSR1 on colonic mucosal inflammation-particularly the stimulation of cytokines/chemokines production and promotion of epithelial cell growth-makes NTS/NTSR1 signaling a possible unique link between chronic mucosal inflammation and carcinogenesis. For example, IL-8 [or chemokine CXC ligand (CXCL)8], an inflammatory component as a chemotactic factor for leukocytes, affects cancer (including colon cancer) progression through mitogenic, angiogenic, and motogenic effects[26]. The secretion of IL-8 can be stimulated by NTSR1 activation in colonic epithelial cells under either inflammatory or neoplastic conditions[27].

Taken together, it seems reasonable to postulate that NTSR1 in colonic epithelial cells is upregulated in IBD and that NTSR1 overexpression may play a role in the development of colitis-associated dysplasia/neoplasia. In this study, we analyzed the expression of NTSR1 in human colonic mucosa with various pathological changes characteristic of IBD and IBD-associated dysplasia and carcinoma. In order to demonstrate whether the change in NTSR1 was specific to IBD-associated neoplasia, we compared it to the sporadic colorectal neoplasia that developed in non-colitic patients.

MATERIALS AND METHODS

Study subjects

All cases were retrieved retrospectively from the surgical pathology files of the Calgary Laboratory Services in 2009 and 2010. The study was approved by the Research Committee of Calgary Laboratory Services, and ethical approval was granted by the University of Calgary Conjoint Health Research Ethics Board. The classification and grading of IBD, dysplasia and carcinoma were carried out on hematoxylin and eosin (HE)-stained slides, based on the morphological features and according to the standardized histological consensus criteria used widely

in clinical pathology practice. An attempt was made to distinguish, based on the strict morphological criterion currently available, between dysplasia-associated lesions or masses (DALMs) and adenoma-like dysplastic polyps (ALDPs) for the raised dysplastic lesions developed in a background of IBD. DALMs were defined as lesions that met all of the following criteria: (1) location within areas of chronic colitis; (2) irregularly elevated and broad-based with indistinct boundaries; and (3) surrounding mucosa also dysplastic, and in a full-thickness or "bottom-up" pattern of dysplasia. ALDPs were defined by the presence of well-circumscribed typical adenoma-looking polyps seen in the colitic regions; mostly in a "top-down" pattern of dysplasia. ALDPs are considered most likely to be sporadic adenoma.

Four separate groups of cases were included in the study.

Group 1: Eighteen colectomy cases of long-standing IBD complicated by colorectal neoplasia (14 males, 4 females, aged 26-84 years), including 13 UC, three Crohn's disease, and two indeterminate colitis. In this group, we looked for sequential histological changes of inflammation/dysplasia/carcinoma. In each case, the tissue blocks were selected from those with proven histology of normal/unremarkable colonic mucosa (n = 16), active colitis (n = 16), inactive colitis (n = 14), raised low-grade dysplasia (LGD, n = 16), high-grade dysplasia (HGD, n = 11), and adenocarcinoma (CACRC, n = 13). For the LGD lesions, 12 DALMs and four ALDPs were subgrouped.

Group 2: Eighteen colonoscopic biopsies of DALMs detected in longstanding IBD patients (10 males, 8 females, aged 23-68 years) for neoplasia surveillance.

Group 3: Seventeen randomly selected biopsies of sporadic colorectal adenomatous polyps detected in non-IBD patients (10 males, 7 females, aged 35-79 years) for colon cancer screening.

Group 4: Twelve randomly selected cases of colectomy for sporadic colorectal adenocarcinoma (SCRC) detected in non-IBD patients (7 males, 5 females, aged 42-85 years).

Detection of NTR-1 in colonic epithelial cells

The expression of NTSR1 was detected by immunohistochemistry of deparaffinized sections using the avidin-biotin-peroxidase complex method. The formalin-fixed paraffin-embedded tissue sections were pretreated in CINTec Epitope Retrieval Solution (10 mmol/L Tris/1 mmol/L EDTA, pH 9.0) for 20 min at 95-100 ℃, and then cooled down slowly to room temperature. The NTSR1 antibody was a rabbit polyclonal antibody (Imgenex, San Diego, CA, United States) against the third cytoplasmic domain of human NTSR1. All slides were stained with Ventana Nexes IHC autostainer at 1:40 dilution using UltraView Universal DAB Detection (Ventana 760-500). Immunoreactivity of NTSR1 appeared in a cytoplasmic pattern. Only the surface and cryptal epithelial cells of colonic mucosa were analyzed (in order to eliminate the variability of mononuclear cells in lamina propria). The positivity and intensity of the immunoreactivity of NTSR1 were semiquantitated independently by two pathologists as absent (negative), weak (1+), moderate (2+), and strong (3+). If the signal intensity was heterogeneous, the level assigned was based on the intensity in at least 50% of tumor cells or epithelial cells. A comparison of NTSR1 expression was analyzed between the different groups (active *vs* inactive colitis, dysplastic *vs* non-dysplastic lesions, DALMs *vs* ALDPs, colitis-associated dysplasia *vs* sporadic non-colitic dysplasia, and colitis-associated CRC *vs* sporadic non-colitic CRC).

Table 1 Neurotensin receptor 1 expression in 18 cases of inflammatory bowel diseases with colectomy *n* (%)

Histology	Case				*P* value
	Negative	1+	2+	3+	
Normal	12 (100.00)	0 (0.00)	0 (0.00)	0 (0.00)	
Colitis	1 (3.23)	20 (64.52)	10 (32.36)	0 (0.00)	
Active	0 (0.00)	12 (75.00)	4 (25.00)	0 (0.00)	
Inactive	1 (6.67)	8 (53.33)	6 (40.00)	0 (0.00)	0.338[1]
LGD	0 (0.00)	3 (18.75)	11 (68.75)	2 (12.50)	0.007[2]
DALM	0 (0.00)	3 (25.00)	7 (58.33)	2 (16.67)	
ALDP	0 (0.00)	0 (0.00)	4 (100.00)	0 (0.00)	0.298[1]
HGD	0 (0.00)	1 (9.09)	4 (36.36)	6 (54.55)	0.063[3]
CACRC	0 (0.00)	1 (7.69)	4 (30.77)	8 (61.54)	0.022[3]

[1]Within two subgroups (active *vs* inactive); [2]As compared with colitis; [3]As compared with low-grade dysplasia (LGD). HGD: High-grade dysplasia; DALM: Dysplasia-associated lesions or masses; ALDP: Adenoma-like dysplastic polyps; CACRC: Colitis-associated colorectal carcinoma.

Statistical analysis

Analysis of variance test was used to determine the statistical significance of the NTSR1 expression intensity between different groups. Differences were considered significant if P was < 0.05.

RESULTS

NTSR1 expression in colonic mucosa is associated with stepwise progression from colitis to LGD, HGD and carcinoma

Within the 18 colectomy specimens, relatively normal (uninvolved/colitis-spared) mucosa was identified in 12 cases. NTSR1 was not detected in any of the samples of normal mucosa. In the colitic mucosa, however, NTSR1 was detected in 30 out of 31 representative tissue samples and expressed similarly in both active and inactive colitis, as shown in Table 1 and Figure 1.

LGD lesions were identified in 16 of the 18 cases. The epithelium with LGD showed a significantly stronger expression of NTSR1 as compared to the non-dysplastic colitic mucosa, with most cases showing a $\geqslant$ 2+ intensity (68.75% in LGD *vs* 32.26% in non-dysplastic mucosa, P = 0.001) but fewer cases showing a 1+ intensity (18.75%

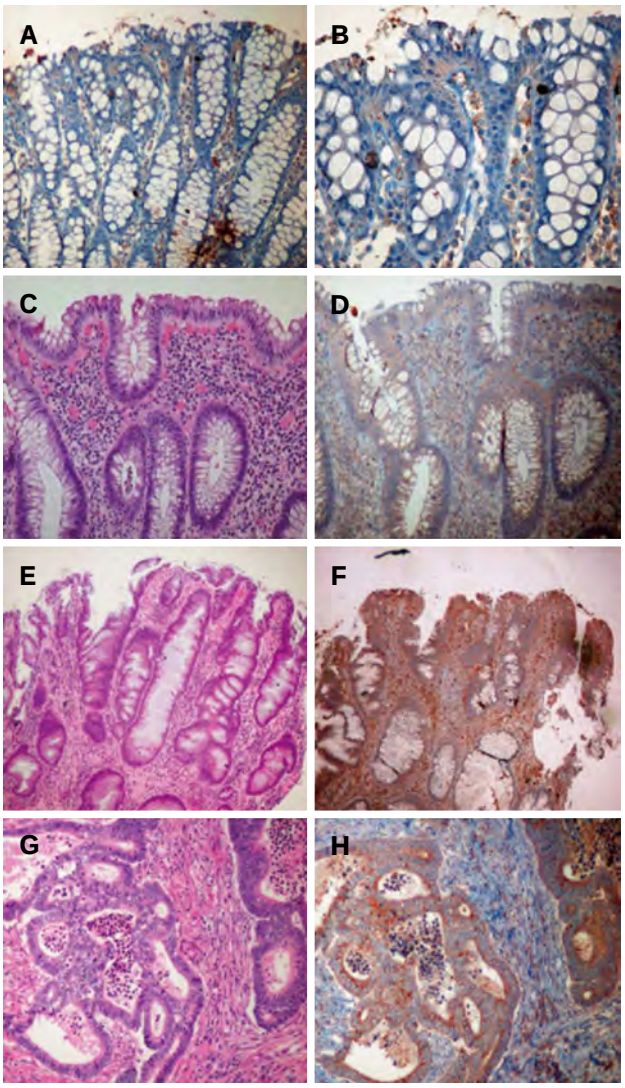

Figure 1 Neurotensin receptor 1 expression in colonic mucosa under different conditions. A and B: Normal colonic mucosa; C and D: Active chronic colitis; E and F: Dysplasia-associated lesions or masses with low-grade dysplasia; G and H: Invasive adenocarcinoma (hematoxylin and eosin histology and neurotensin receptor 1 expression immunohistochemistry).

in LGD *vs* 64.52% in non-dysplastic mucosa, $P = 0.007$). However, no significant difference existed between DALMs and ALDPs, as shown in Table 1 and Figures 1 and 2.

HGD was identified in 11 cases, and CACRC was identified in 13. As shown in Table 1 and Figures 1 and 2, expression of NTSR1 in the CACRC and HGD samples was stronger, with significantly more cases showing a 3+ intensity than in LGD of both DALMs and ALDPs (61.54% *vs* 12.50% for CACRC *vs* LGD, $P = 0.022$; 58.33% *vs* 12.50% for CACRC/HGD *vs* LGD, $P = 0.015$). However, no significant difference existed between CACRC and HGD ($P = 0.942$).

NTSR1 expressed similarly between DALMs and non-colitic sporadic adenoma

In the cases of colitis-associated DALMs ($n = 18$) and non-colitis sporadic adenomas ($n = 17$), the increased expression of NTSR1 showed a similar pattern, as shown in Table 2 and Figure 2.

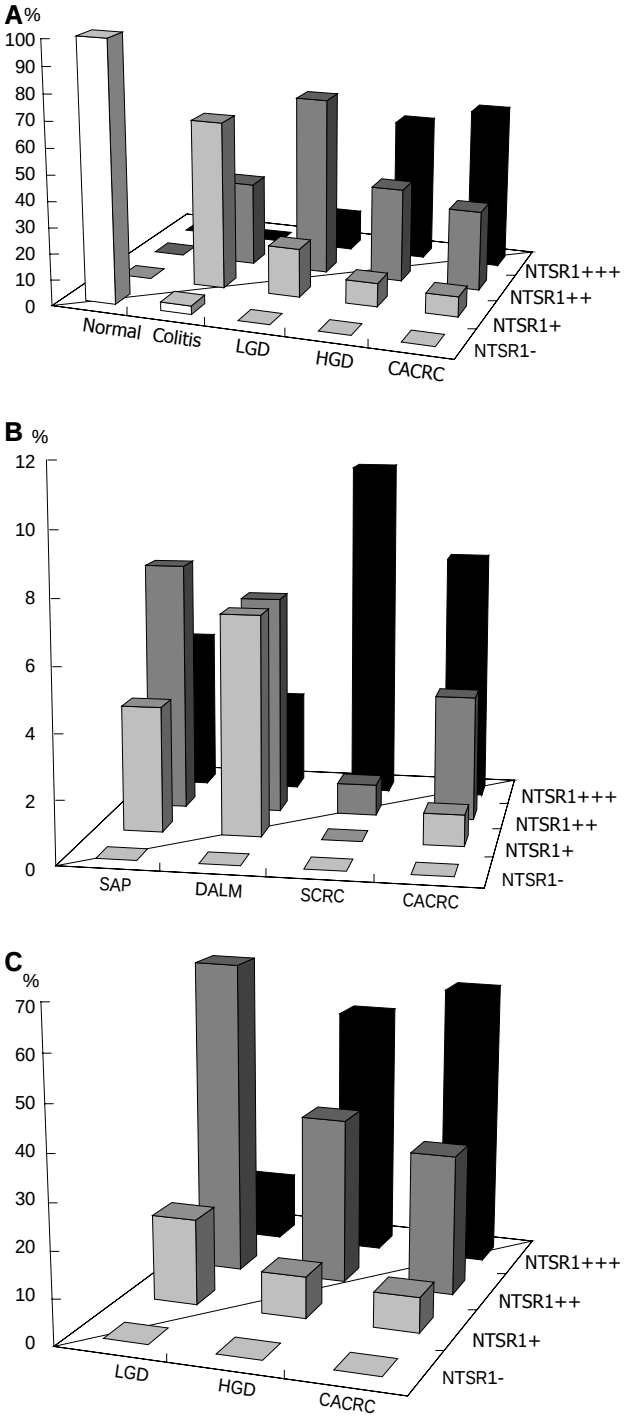

Figure 2 Neurotensin receptor 1 expression. A: Neurotensin receptor 1 (NTSR1) expression in colonic mucosa under different conditions in cases of colectomy for inflammatory bowel diseases (IBD) (percentage of cases in each subgroup); B: NTSR1 expression in colonic mucosa with dysplasia and carcinoma in cases of colectomy for IBD (percentage of cases in each subgroup); C: Comparison of colonic mucosal NTSR1 expression in sporadic neoplasia and colitis-associated neoplasia (percentage of cases in each subgroup). LGD: Low-grade dysplasia; HGD: High-grade dysplasia; DALM: Dysplasia-associated lesions or masses; CACRC: Colitis-associated colorectal carcinoma; SAP: Sporadic colorectal carcinoma; SCRC: Sporadic colorectal adenomatous polyp.

Table 2 Neurotensin receptor 1 expression *n* (%)

	Negative	1+	2+	3+
SAP	0	4 (23.53)	8 (47.06)	5 (29.41)
DALM	0	7 (41.42)	7 (41.42)	3 (17.65)
SCRC	0	0	1 (8.33)	11 (91.67)
CACRC	0	1 (7.69)	4 (30.77)	8 (61.54)

Comparison between colitis-associated dysplasia/carcinoma and sporadic dysplasia/carcinoma. Sporadic colorectal adenomatous polyp (SCRC) *vs* colitis-associated colorectal carcinoma (CACRC), $P = 0.198$; Dysplasia-associated lesions or masses (DALMs) *vs* CACRC, $P = 0.028$; DALMs *vs* sporadic colorectal carcinomas (SAPs), $P = 0.50$.

NTSR1 expressed similarly between colitis-associated and sporadic CRC

The increased expression of NTSR1 also showed a similar pattern to that in CACRC and in conventional sporadic colorectal carcinoma (SCRC, $n = 12$), as shown in Table 2 and Figure 2.

DISCUSSION

Through the detection of NTSR1 expression directly in human colonic mucosa with various IBD-related pathologies and those with sporadic colonic neoplasia in non-IBD patients, the present study demonstrated that both active and inactive IBD colitis upregulated NTSR1 in colonic epithelial cells; colitis-associated LGD to HGD and carcinoma was associated with stepwise higher expression of NTSR1; and the overexpression of NTSR1 showed a similar pattern in colitis-associated and non-colitic sporadic dysplasia/neoplasia, which suggests that NTSR1 is commonly unregulated in colonic neoplasia with or without a background of colitis.

The first two findings support the hypothesis that the upregulation of NTSR1 is involved in IBD inflammation and colitis-associated neoplasia. The findings corroborate various studies carried out in the past in animal models and *ex vivo* systems. In a similar study reported by Bossard *et al*[28], identical findings were shown with a slightly different methodology. Their study also demonstrated that coexpression of NTS/NTSR1 is present in a majority of the inflammatory and neoplastic/dysplastic lesions, suggestive of a self-activation of NTSR1 secondary to increased production of ligands; and β-catenin nuclear translocation is seen in a minority of the dysplastic and carcinomatous lesions in which no NTS was detected, suggestive of a different pathway.

To the best of our knowledge, the finding that NTSR1 is similarly overexpressed in colitis-associated dysplasia/neoplasia and sporadic dysplasia/neoplasia in non-IBD patients has not been reported previously. This finding indicates that NTSR1 is a neoplastic marker irrespective of its underlying etiology. In other words, the NT/NTSR1 signaling pathway is intrinsic and common to the tumorigenesis of all colorectal carcinomas, regardless of the tumor-promoting factors or the predisposing/initiation processes. This finding and interpretation are supported by an animal study reported recently by Bugni *et al*[29]. They developed a chemical-carcinogen-induced colonic adenoma by administration of azoxymethane to mice with or without DSS-induced colitis. NTSR1-deficient (gene knockout) mice had a < 50% chance, compared to wild-type mice, of developing colonic adenoma in the absence of colitis (*i.e.*, a model of sporadic colonic neoplasia). The difference, however, disappeared in the mice that had colitis (*i.e.*, a model of colitis-associated colonic neoplasia), even though significantly higher levels of IL-6 and CXCL2 (the mouse homolog of IL-8, both known as tumor-promoting cytokines) were seen in the latter. Our study, as well as that of Bugni *et al*[29], suggests that NTS/NTSR1 are not particularly responsible for the link between chronic inflammation and neoplasia in IBD, although it is commonly involved in the entire multistep process as an intrinsic regulator. The tumorigenetic process in colitis-associated dysplasia/neoplasia appears far more complex. However, it is still possible that increased NTSR1 expression associated with pre-existent or coexistent chronic colitis may further enhance the carcinogenesis.

It was noted in a minority of cases that NTSR1 expression was less upregulated, which occurred nonspecifically for each of the conditions and in different cases. We have no solid explanation for these relative negative cases. It is possible that NTSR1 expression in the epithelium is regulated by multiple factors, including a variety of cytokines and other gut peptides in the local mucosa or circulation that are not always the same in different patients.

Overall, our findings further provide a rationale for exploring the anti-NTSR1 approach in the treatment of IBD and in the chemoprevention of IBD-associated colorectal neoplasia as well as the treatment of sporadic colonic neoplasia. Hopefully, the development of clinically useful NTSR1 blockers will become a reality in the near future with the recent better understanding of the chemical structure of NTSR1[30].

COMMENTS

Background

Inflammatory bowel diseases (IBD) are chronic and debilitating inflammatory conditions of the colon, which also increase the relative risk of colorectal cancer. Identification of the factors associated with both mucosal inflammation and colitis-associated carcinogenesis could lead to novel treatments.

Research frontiers

Neurotensin (NTS) is a 13-amino-acid peptide that acts as a paracrine and endocrine modulator of various gut functions. Its bioactivities are mediated mainly through the high-affinity neurotensin receptor 1 (NTSR1). The NTS/NTSR1 signaling pathway has dual effects (both proinflammatory and proregenerative) in the regulation of intestinal mucosal inflammation. NTS/NTSR1 signaling is also involved in the carcinogenesis and progression of colonic carcinoma. It is suggested that NTSR1 in colonic epithelial cells is upregulated in IBD and NTSR1 overexpression may play a role in the development of colitis-associated dysplasia/neoplasia.

Innovations and breakthroughs

The present study used colonic tissue samples to detect the expression of NTSR1 in the context of various pathological conditions of IBD, with a focus on NTSR1 expression in the progressive changes from active inflammation to low-grade dysplasia, high-grade dysplasia, and carcinoma. A stepwise increase in NTSR1 expression was identified in the sequential progression. Moreover, a similar pattern of NTSR1 overexpression in colitis-associated and sporadic dysplasia/neoplasia was also determined for the first time.

Applications

The findings provide a rationale for exploring the anti-NTSR1 approach in the treatment of IBD and in the chemoprevention of IBD-associated colorectal neoplasia, a clinically useable anti-NTSR1 agent becomes available in the near future.

Terminology

Colitis-associated dysplasia and carcinoma develop in association with the longstanding chronic colitis in IBD patients. It is now well recognized that this type of colorectal carcinogenesis is clearly initiated and/or promoted by chronic, persistent and repetitively active mucosal inflammation. This type of colorectal carcinoma (CRC) develops and progresses in an inflammation-dysplasia-carcinoma sequence and therefore differs from the adenoma-carcinoma sequence in the sporadic CRC.

Peer review

The study investigates the relationship between NTSR1 expression in IBD and the possibility of its association with mucosal inflammation and colitis-associated neoplasia. They found a strong correlation with the progression from normal mucosa to colitis, degree of dysplasia, and carcinoma. The methodological approach was correct and the findings are interesting.

Abstract

AIM: To investigate activity, toxicity, and prognostic factors for survival of erlotinib and fixed dose-rate gemcitabine (FDR-Gem) in advanced pancreatic cancer.

METHODS: We designed a single-arm prospective, multicentre, open-label phase Ⅱ study to evaluate the combination of erlotinib (100 mg/d, orally) and weekly FDR-Gem (1000 mg/m^2, infused at 10 mg/m^2 per minute) in a population of previously untreated patients with locally advanced, inoperable, or metastatic pancreatic cancer. Primary endpoint was the rate of progression-free survival at 6 mo (PFS-6); secondary endpoints were overall response rate (ORR), response duration, tolerability, overall survival (OS), and clinical benefit. Treatment was not considered to be of further interest if the PFS-6 was < 20% (p0 = 20%), while a PFS-6 > 40% would be of considerable interest (p1 = 40%); with a 5% rejection error (α = 5%) and a power of 80%, 35 fully evaluable patients with metastatic disease were required to be enrolled in order to complete the study. Analysis of prognostic factors for survival was also carried out.

RESULTS: From May 2007 to September 2009, 46 patients were enrolled (male/female: 25/21; median age: 64 years; median baseline carbohydrate antigen 19-9 (CA 19-9): 897 U/mL; locally advanced/metastatic disease: 5/41). PFS-6 and median PFS were 30.4% and 14 wk (95%CI: 10-19), respectively; 1-year and median OS were 20.2% and 26 wk (95%CI: 8-43). Five patients achieved an objective response (ORR: 10.9%, 95%CI: 1.9-19.9); disease control rate was 56.5% (95%CI: 42.2-70.8); clinical benefit rate was 43.5% (95%CI: 29.1-57.8). CA 19-9 serum levels were decreased by > 25% as compared to baseline in 14/23 evaluable patients (63.6%). Treatment was well-tolerated, with skin rash being the most powerful predictor of both longer PFS (P < 0.0001) and OS (P = 0.01) at multivariate analysis (median OS for patients with or without rash: 42 wk *vs* 15 wk, respectively, Log-rank P = 0.03). Additional predictors of better outcome were: CA 19-9 reduction, female sex (for PFS), and good performance status (for OS).

CONCLUSION: Primary study endpoint was not met. However, skin rash strongly predicted erlotinib efficacy, suggesting that a pharmacodynamic-based strategy for patient selection deserves further investigation.

Key words: Pancreatic cancer; Gemcitabine; Fixed dose-rate; Erlotinib; Prognostic factors; Cutaneous rash; Phase Ⅱ trial

Core tip: The most important finding reported in this study is the strong predictive value of the appearance of skin rash, related to epidermal growth factor receptor (EGFR)-pathway inhibition. Our data suggest that patients developing any grade of skin rash during the treatment, can achieve disease control and survival comparable to those obtained with more intensive and more toxic chemotherapy. These findings underline the relevance of further investigation of the biological mechanisms related to the occurrence of skin rash upon EGFR blockade in order to identify clinical/molecular biomarkers predicting toxicity and efficacy and to prospectively select a subset of patients who could potentially benefit from Gem/erlotinib.

INTRODUCTION

Pancreatic adenocarcinoma (PDAC) is arguably the most aggressive solid malignancy, with nearly as many deaths as the number of newly diagnosed cases each year. In 2012 an estimated 43920 new cases and an estimated 37390 deaths are expected to occur, making pancreatic carcinoma the fourth leading cause of cancer-related death in the United States. The prognosis of pancreatic cancer is extremely poor due to difficulties in early detection and early metastatic dissemination, with a 5-year survival rate of only 6%[1].

The majority of PDAC patients present with metastatic or inoperable disease. In this setting, systemic chemotherapy remains the treatment of choice, with a palliative objective and a disappointing, marginal, survival advantage. Single-agent gemcitabine (Gem), administered as weekly 30-min *iv* infusions, has become the standard care for advanced PDAC based on a small but statistically significant advantage over bolus 5-fluorouracil (5-FU), in terms of both clinical benefit (CB) and survival[2].

Until recently, efforts to improve on single-agent Gem efficacy[3], by combining Gem with either a second cytotoxic drug or a molecularly targeted agent, have failed[4,5]. The addition of erlotinib, an oral epidermal growth factor receptor (EGFR) tyrosine kinase inhibitor, to Gem has produced a minimal, albeit statistically significant, improvement in overall survival (OS), leading to FDA approval of the Gem/erlotinib combination in the setting of advanced, inoperable PDAC[6]. On the other hand, pharmacokinetic Gem modulation, achieved by prolonging its infusion time, is justified by the observation that deoxycytidine kinase, the enzyme converting Gem into its active triphosphate metabolite, is rapidly saturated at plasma concentrations achieved with the standard 30-min infusion. Consequently, the infusion of Gem over a prolonged period at the constant dose rate of 10 mg/m^2 per min (FDR-Gem) avoids enzyme saturation and permits greater intracellular accumulation, possibly increasing Gem antitumor activity. This strategy has proven promising in a randomized phase Ⅱ trial, in which FDR-Gem significantly improved time to treatment failure as compared with the standard 30-min infusion[7]. Although formally negative, a phase Ⅲ trial comparing standard Gem with either FDR-Gem or the GEMOX combination, produced a clear signal in favor of FDR-Gem, which was as effective as the GEMOX combination[8].

Recently, a four-drug combination including 5-FU, folinic acid, oxaliplatin and irinotecan (FOLFIRINOX regimen) has demonstrated to improve objective response rate (ORR), progression-free survival (PFS) and OS over single-agent Gem administered by standard 30-min infusion in metastatic PDAC patients[9]. However, such improved efficacy comes at the price of significantly higher toxicity (both hematological and non-hematological), which restricts the use of such regimen to accurately selected, young and fit patients.

Based on our previous experience with a modified FDR-Gem regimen, which utilizes a lower Gem dose (1000 mg/m^2) as compared with the original FDR-Gem described by Tempero *et al*[7] (1500 mg/m^2) resulting in reduced hematological toxicity[10,11], we prospectively investigated the activity and tolerability of FDR-Gem in combination with erlotinib in advanced, inoperable PDAC patients.

MATERIALS AND METHODS

Patient population

Patients with cytologically or histologically proven, treatment-naïve, unresectable or metastatic PDAC and measurable disease were eligible for the study. Prior radiation for the management of local disease was allowed, provided that disease progression had been documented, all toxicities had resolved and treatment was completed at least 4 wk before study enrollment. Prior chemotherapy was not permitted, except for fluorouracil or Gem given concurrently with RT for radiosensitization purposes. Other inclusion criteria included: age > 18 years; Eastern Cooperative Oncology Group (ECOG) performance status (PS) ≤ 3; life expectancy > 12 wk; adequate hematological, renal, hepatic function; absence of other relevant medical conditions, potentially precluding the delivery of the planned treatment. The study was

reviewed and approved by the institutional review board of the Regina Elena National Cancer Institute (Rome, Italy), and written informed consent, according to Institutional requirements, was obtained from all patients before entering the study.

Treatment and study design

This was a single-arm, open-label, multicenter phase II study, evaluating the activity and tolerability of the combination of FDR-Gem and erlotinib in patients with advanced PDAC. Study patients received Gem at the dose of 1000 mg/m^2, administered as a 10 mg/m^2 per min FDR *iv* infusion (100 min total infusion time)[10,11], weekly for 7 consecutive weeks and on days 1, 8, and 15 of a 4-wk cycle thereafter for a maximum of 6 cycles in the absence of progressive disease (PD) or unacceptable toxicity; erlotinib was administered as a daily oral dose of 100 mg from day 1 until PD or unacceptable toxicity. Toxicities were recorded according to the National Cancer Institute-Common Toxicity Criteria Version 3.0. Appropriate dose reductions of each study agent were planned in case of severe toxicities. Tumor assessments were performed

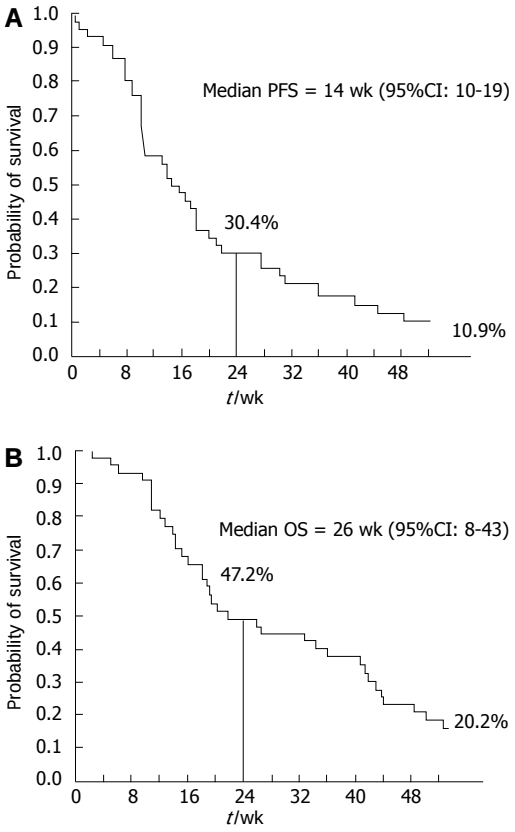

Figure 1 Kaplan-Meier analysis of progression-free survival and overall survival in the intent to treat population. A: Progression-free survival (PFS); B: Overall survival (OS).

at the end of cycle 1 and every 2 cycles thereafter.

Response and progression were evaluated using the Response Evaluation Criteria in Solid Tumours (RECIST 1.0)[12]. All patients who had measurable lesions and who had at least one objective tumour assessment after baseline were considered evaluable for response. The composite end point of CB was evaluated according to the criteria established by Burris *et al*[2] and included the assessment of pain (pain intensity and analgesic consumption) and functional impairment (assessed by Karnofsky PS) as primary measures and weight change (assessed by body weight) as a secondary measure. Each patient was classified as positive, stable, or negative for each of the primary CB measures (pain intensity or PS)[2]. For all patients, positive indicated a sustained (≥ 4 wk) improvement over baseline. If the patient was stable on both primary measures of clinical benefit, the patient was then classified as either positive or non-positive on the basis of the secondary clinical benefit measure of weight. For patients to achieve an overall rating of a positive CB, they had to be positive for at least one parameter without being negative for any of the others.

Statistical analysis

PFS rate at 6 mo (PFS-6) was selected as the primary study endpoint. Secondary endpoints were ORR, response duration, tolerability, OS, and CB. Sample size

was computed according to the exact single-stage Phase II design described by A'Hern[13]. The treatment was not considered to be of further interest if the PFS rate at 6 mo was < 20% (p0 = 20%). The alternate hypothesis assumed that a PFS rate at 6 mo of > 40% would be of considerable interest (p1 = 40%). With a 5% rejection error (α = 5%) and a power of 80%, a total of 35 fully evaluable patients were needed to complete the study. In order to have enough power to also analyze the 'pure' metastatic sub-population separately, 46 patients were planned to enter the study, taking into account a dropout rate of approximately 15%. The Kaplan-Meier method was used to estimate PFS and OS[14]. PFS was defined as the time from the first day of treatment to the first observation of disease progression or death due to any cause and OS was defined as the time from the first day of treatment to death from any cause. ORR was estimated as the proportion of patients evaluable for response who met RECIST criteria for complete or partial response (CR or PR). Response duration was calculated for all patients achieving a PR or CR as the time from first objective status assessment of CR/PR to the first time documented PD or death. Cox proportional hazards models were used to compare survival among different patient/disease characteristics and treatment response groups[15]; hazard ratios were appropriately derived from these models. The SPSS statistical software package version 20.0 (SPSS, Inc, Chicago, IL, United States) was used for all statistical analyses.

RESULTS

Between May 2007 and September 2009, 46 patients with advanced-stage PDAC were enrolled in the study from 3 institutions. Patient characteristics are shown in Table 1.

Treatment outcome

All 46 patients were evaluable for response according to RECIST criteria. PR and stable disease (SD) were observed in 5/46 (10.9%) and 21/46 (45.7%) patients, respectively, for an overall disease control rate (DCR), defined as the percentage of patients who had CR, PR or SD as their best response, of 56.5% (95%CI: 42.2-70.8); PD was documented at the first response assessment in 20 patients (43.5%). Median response duration was 27.4 wk (range 11-45 wk); median duration of stable disease was 27.6 wk (range 10-85 wk). Fifteen out of 35 evaluable patients (42.9%) experienced a positive CB. CA 19-9 serum levels were decreased by > 25% as compared to baseline in 14/23 evaluable patients (63.6%). Similar results were obtained in the pure metastatic population

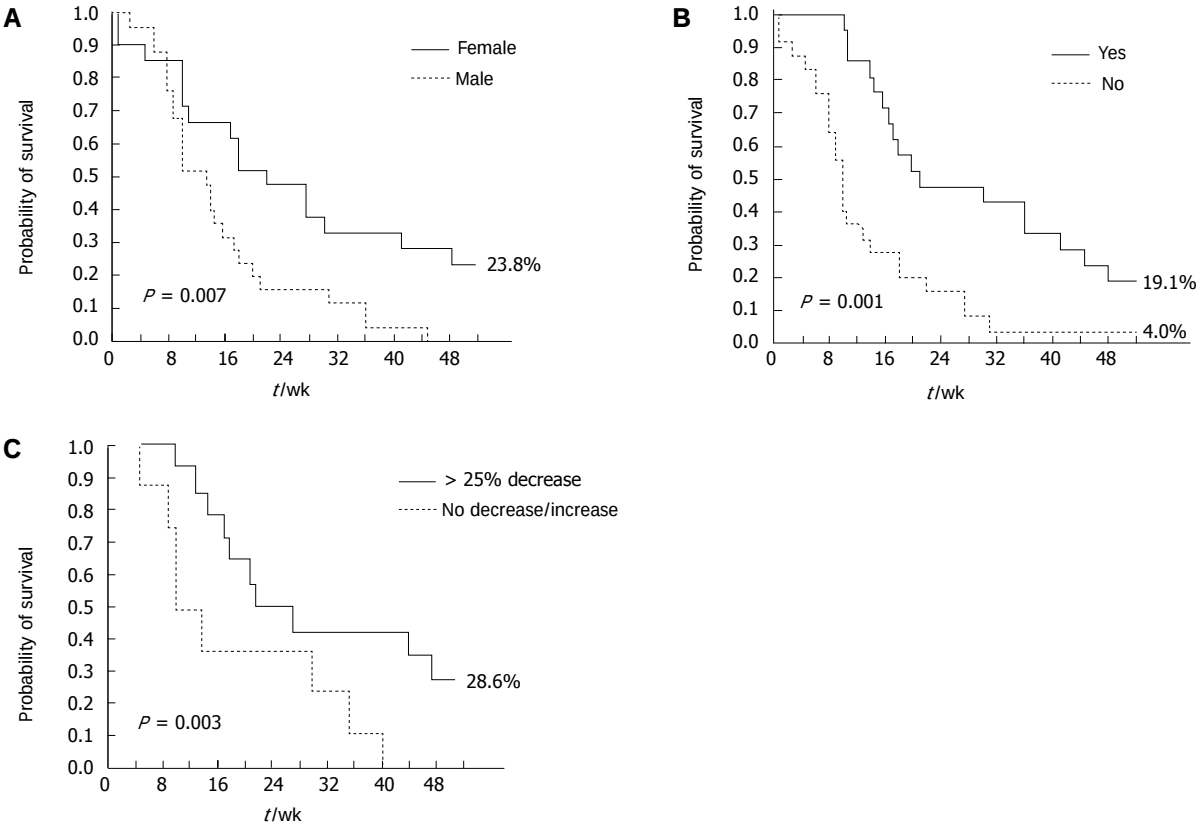

Figure 2 Kaplan-Meier analysis of independent progression-free survival predictors. A: Progression-free survival (PFS) by sex; B: PFS by skin rash; C: PFS by carbohydrate antigen 19-9 decrease.

(data not shown). At a median follow-up of 23.6 wk (range 2-139 wk), the median PFS and 1-year PFS rate were 14 wk (95%CI: 10-19) and 10.9%, respectively; PFS-6 (primary study endpoint) was 30.4% (Figure 1A). The median OS and 1-year OS rate were 26 wk (95%CI: 8-43 wk) and 20.2%, respectively (Figure 1B). In the pure metastatic population the corresponding figures were: median PFS: 14 wk, PFS-6: 24.4 %, median OS: 20 wk, 1-year OS: 12.7% (Table 2, data not shown).

Toxicity

All patients were evaluable for toxicity. Main hematological and non-hematological toxicities are summarized in Table 3. Treatment protocol was well tolerated, with only 3 serious adverse events that required hospitalization: 2 episodes of GI bleeding and 1 duodenal perforation. Three patients (7%) reported grade 4 toxicities (neutropenia in 2 patients and asymptomatic transaminase elevation in 1 patient). Grade 3 hematological toxicity was also rare: anemia in 4 patients (9%), neutropenia in 8 patients (18%), thrombocytopenia in 5 patients (11%); only 1 patient (2%) experienced febrile neutropenia. The main non-hematological toxicity were: asymptomatic serum transaminase elevation and hyperbilirubinemia (grade 3 in 9% of patients); grade 3 diarrhea in 1 patient (2%); grade 2 and 3, erlotinib-related skin rash in 11% and 4% of patients, respectively. Median time to rash was 7 d. Gem and erlotinib doses were reduced in 14 and 3 patients, respectively. No toxic deaths were recorded.

Clinical predictors of response and survival

A positive CB and skin rash (any grade) were significant, independent predictors of DCR at multivariate analysis, in both the overall and pure metastatic populations. Female gender ($P = 0.03$) and skin rash (any grade, $P < 0.0001$) were significant, independent predictors of longer PFS (Table 4). ECOG PS (0-1, $P = 0.01$), skin rash (any grade, $P = 0.03$), and carbohydrate antigen (CA 19-9) decrease (> 25% relative to baseline, $P = 0.04$) were significantly associated with longer OS at multivariate analysis (Table 4). Conversely, the occurrence of other Gem- or erlotinib-related toxicities, such as hematological toxicity and diarrhea, did not significantly impact on survival outcomes. The impact of these factors on PFS and OS was further confirmed by Kaplan-Meier analysis (Figures 2 and 3): in particular, median PFS and median OS were both significantly longer in patients experiencing any grade of skin rash (21 wk *vs* 10 wk, Log-rank $P = 0.001$, and 42 wk *vs* 15 wk, Log-rank $P = 0.03$, respectively) (Figures 2A and 3A). In the "pure metastatic" population, gender and skin rash ($P = 0.007$ and $P = 0.002$), and gender, PS, CB and skin rash ($P = 0.01$, $P = 0.06$, $P = 0.02$ and $P = 0.02$) were significant, independent predictors of PFS and OS, respectively, at multivariate analysis (data not shown).

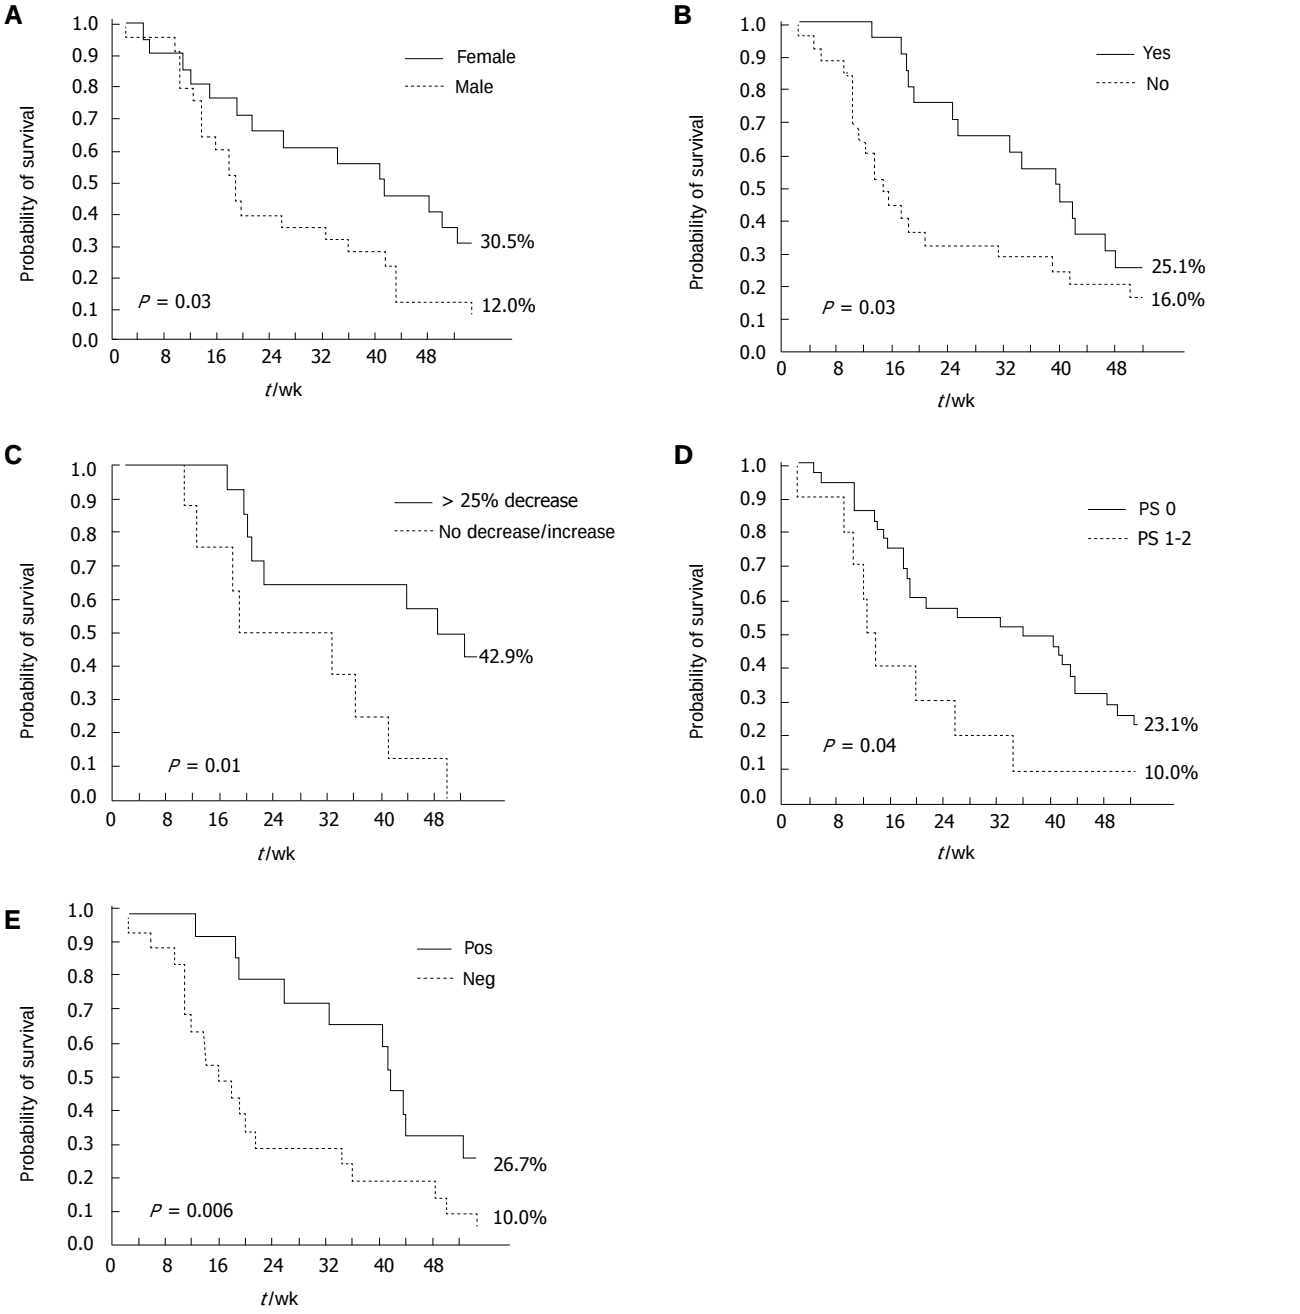

Figure 3 Kaplan-Meier analysis of independent overall survival predictors. A: Overall survival (OS) by sex; B: OS by skin rash; C: OS by carbohydrate antigen 19-9 decrease; D: OS by Eastern Cooperative Oncology Group performance status (PS); E: OS by clinical benefit. Pos: Positive; Neg: Negative.

DISCUSSION

In this study, performed in an unselected patient population, the administration of FDR-Gem in combination with erlotinib proved to be feasible, well tolerated, and moderately active. However, the planned goal to obtain a PFS-6 > 40% was not reached (PFS-6: 31.8%). Thus, the addition of erlotinib to an FDR-Gem backbone in unselected patients is unlikely to improve on historical result; indeed 1-year OS (21.6%), median OS (26 wk, 95%CI: 9-43), and activity in terms of responses, with a DCR of 59% are within the ranges reported with single-agent Gem, administered either as a 30-min *iv* infusion or as FDR, or with the combination of Gem and erlotinib[2,6-8,10].

The safety profile of the tested FDR-Gem/erlotinib combination is extremely manageable, an important issue in advanced PDAC patients, who are often frail and at a high risk of an adverse impact of treatment on quality of life. In particular, we confirm here that administering FDR-Gem at 1000 mg/m^2, as in previous experiences from our group[10,11], decreases hematological toxicity in comparison with the original FDR-Gem schedule developed by Tempero *et al*[7], where FDR-Gem was administered at the 1500 mg/m^2 dose level (grade 3-4 neutropenia 23% in the present trial *vs* 48.8% in Tempero's trial).

Other experiences with a different EGFR-TKI (gefitinib) have also confirmed an extremely safe and manageable toxicity profile of Gem-FDR at a lower dose (1200 mg/m^2), thus suggesting these combinations as feasible platforms for associations with additional chemotherapeutics or different targeted agents[16].

Though the combination under study proved feasible and well tolerated, the question remains as to whether such a strategy (*i.e.*, adding an EGFR kinase inhibitor to a FDR-Gem backbone in unselected patients) is worthy pursuing if it does not improve efficacy. As the results of the trial are technically negative (primary endpoint was not met), the easiest answer would be that this combination does not merit further investigation, particularly in a scenario, such as that of advanced PDAC treatment, where novel polychemotherapy strategies (FOLFIRINOX and Gem/nab-paclitaxel combinations) are moving the field forward and, for the first time in almost 20 years, show increased efficacy and improved survival as compared with single-agent Gem. However, survival analysis of the present trial and of two other recently reported experiences[17,18] clearly show that, at least in some patients, the addition of erlotinib to Gem has both biological and clinical activity: indeed, the most relevant finding reported herein is the strong predictive value of the appearance of skin rash. Patients developing erlotinib-related skin toxicity experience a more than doubled median OS (42 wk *vs* 15 wk, $P = 0.03$), and PFS (21 wk *vs* 10 wk, $P = 0.001$); conversely, the occurrence of other toxicities, such as hematologic toxicity or diarrhea, has no impact on treatment activity and/or survival outcomes. A similar predictive effect had already been described in the registration trial of erlotinib in PDAC, where patients experiencing grade 2 skin rash had a 1-year survival of 43%[6] and is shared by other agents targeting the EGFR pathway, either small molecules or monoclonal antibodies, regardless of the disease setting[19-25]. The trial exploring the addition of bevacizumab to Gem and erlotinib, also showed a significantly better outcome for patients developing skin rash, regardless of the treatment arm[26]. A more recent randomized trial showed that skin rash is able to dichotomize patients receiving erlotinib between good and poor prognosis[27].

In addition to skin rash, survival analysis of the current study also underlines the importance of two other treatment-modified factors to guide the management of advanced PDAC patients: clinical benefit and decline in CA 19-9 levels. Though chosen as the primary end-point in the Gemcitabine registration trial by Burris *et al*[2], the relationship between CB and OS has never been validated. Interestingly, in the present trial the occurrence of CB was a significant independent predictor of longer OS, while objective response, as assessed by RECIST criteria, was not, a finding of great clinical relevance in the context of a disease with dismal prognosis, where symptom control represents a real issue for clinical practice. A reduction in CA 19-9 levels > 25% from baseline was also an independent prognostic factor for survival, thus adding to the numerous evidence supporting the prognostic role (and clinical utility) of a CA 19-9 reduction, regardless of the chosen cut-off point[28-31].

In conclusion, although the study reported herein failed to meet its primary endpoint of prolonging PFS with the addition of erlotinib to FDR-Gem, intriguing data on skin rash do suggest that a subset of advanced PDAC patients could actually achieve disease control and survival comparable to those obtained with more intensive (and more toxic) polychemotherapy approaches, such as FOLFIRINOX and Gem/nab-paclitaxel combinations, with a well tolerated and easily manageable regimen, potentially also suitable for elderly and unfit patients. However, in order for this strategy to become a concrete treatment option, an in-depth investigation of the biological mechanisms underlying the occurrence of skin rash upon EGFR blockade is required to identify clinical/molecular biomarkers predicting toxicity and efficacy and to prospectively select patients who could potentially benefit from Gem/erlotinib combinations.

COMMENTS

Background

Pancreatic adenocarcinoma has a dismal prognosis. Although the disappointing survival advantage obtained in many studies, chemotherapy is the only treatment option for the majority of patients, and single agent gemcitabine (Gem) remains standard care for many of them. Recently, the polychemotherapy regimen named FOLFIRINOX has produced an improvement in survival over single agent Gem but require an accurate selection of young and fit patients to limit treatment-related toxicities. In order to improve Gem efficacy, pharmacokinetic Gem modulation and combination with other chemotherapeutic agent has been proposed. To this regard, the prolonged infusion at constant dose rate has shown promising results in phase Ⅱ and Ⅲ trials and the addition of erlotinib to Gem has provided a minimal, albeit statistically significant, improvement in survival.

Research frontiers

In the field of advanced pancreatic adenocarcinoma (PDAC), the research hotspot is to find active regimen, for patients not suitable for aggressive combination chemotherapy, able to improve survival over single agent Gem, without worsening tolerability. In the context of targeted therapies, applied to PDAC, but also any other malignancy, the opportunity of prospectively select patients who could benefit from targeted therapy plays a fundamental role.

Innovations and breakthroughs

The combination of fixed dose-rate (FDR)-Gem at 1000 mg/m^2 and erlotinib appears feasible, well tolerated and extremely manageable. In comparison to other FDR-Gem schedules with different doses (1500 or 1200 mg/m^2), the regimen shows a reduced hematological toxicity profile. This suggests that the schedule is a feasible platform for combining targeted therapies. In the study, a strong predictive value of the appearance of skin rash is demonstrated. Patients developing erlotinib-related skin toxicity experienced a more than doubled median overall survival, comparable to that obtained with more intensive polychemotherapy approaches. This relation has not been reported for other toxicities (hematologic toxicities or diarrhea). Moreover, occurrence of clinical benefit and reduction in carbohydrate antigen levels > 25% from baseline also proved to be an independent prognostic factor for survival. All these data confirm these factors as an important guide for the management of advanced PDAC patients.

Applications

The study results suggest the importance of investigating the biological mechanisms underlying the occurrence of skin rash upon epidermal growth factor receptor blockade. The identification of clinical/molecular biomarkers is strongly required to predict toxicity and efficacy and to prospectively select patients who

could potentially benefit from Gem/erlotinib combinations.

Peer review

This study investigated activity, toxicity, and prognostic factors for survival of erlotinib and FDR-Gem in advanced pancreatic cancer. They highlighted the correlation between the rash and efficacy. The similar studies were published in the past and they had the similar results, furthermore there were randomized controlled trials among them. This study is the confirmation of result of those studies, but it has reference to clinical practice.

Abstract

AIM: To assess the rate of recurrent bleeding of the small bowel in patients with obscure bleeding already undergone capsule endoscopy (CE) with negative results.

METHODS: We reviewed the medical records related to 696 consecutive CE performed from December 2002 to January 2011, focusing our attention on patients with recurrence of obscure bleeding and negative CE. Evaluating the patient follow-up, we analyzed the recurrence rate of obscure bleeding in patient with a negative CE. Actuarial rates of rebleeding during follow-up were calculated, and factors associated with rebleeding were assessed through an univariate and multivariate analysis. A *P* value of less than 0.05 was regarded as statistically significant. The sensitivity, specificity, and positive and negative predictive values (PPV and NPV) of negative CE were calculated.

RESULTS: Two hundred and seven out of 696 (29.7%) CE studies resulted negative in patient with obscure/overt gastrointestinal bleeding. Overall, 489 CE (70.2%) were positive studies. The median follow-up was 24 mo (range 12-36 mo). During follow-up, recurrence of obscure bleeding was observed only in 34 out of 207 negative CE patients (16.4%); 26 out of 34 with obscure overt bleeding and 8 out of 34 with obscure occult bleeding. The younger age (< 65 years) and the onset of bleeding such as melena are independent risk factors of rebleeding after a negative CE (OR = 2.6703, 95%CI: 1.1651-6.1202, *P* = 0.0203; OR 4.7718, 95%CI: 1.9739-11.5350, *P* = 0.0005). The rebleeding rate (CE+ *vs* CE-) was 16.4% *vs* 45.1% (χ^2 test, *P* = 0.00001). The sensitivity, specificity, and PPV and NPV were 93.8%, 100%, 100%, 80.1%, respectively.

CONCLUSION: Patients with obscure gastrointestinal bleeding and negative CE had a significantly lower rebleeding rate, and further invasive investigations can be deferred.

Key words: Capsule endoscopy; Enteroscopy; Anemia; Obscure gastrointestinal bleeding; Rebleeding

Core tip: Although capsule endoscopy (CE) is widely used as a first-line diagnostic modality for obscure gastrointestinal bleeding after the execution of a work-out negative for gastrointestinal bleeding properly done by following the guidelines proposed by American Gas

Association, the rebleeding rate after negative CE varies according to different studies. We tried to elucidate the outcomes after a negative CE for obscure gastrointestinal bleeding (OGIB) and to determine the risk factors associated with rebleeding. Based on the results of our study patients with OGIB and negative CE had a significantly lower rebleeding rate, and further invasive investigations can be deferred.

INTRODUCTION

Obscure gastrointestinal bleeding (OGIB) remains a major clinical challenge. Many instances of OGIB originate from the small bowel, which is beyond the reach of an ordinary endoscope, including an esophagogastroduodenoscope (EGD) and colonoscope. The scene was recently revolutionized by the availability of the capsule endoscopy (CE), which is noninvasive and well tolerated by patients.

CE is currently indicated as part of the workup for OGIB (obscure-overt or obscure-occult), undiagnosed iron deficiency anemia, Crohn's disease, polyposis syndromes and cancer, celiac disease, for monitoring after small bowel transplant and, occasionally, for undiagnosed abdominal pain or diarrhea[1-5]. Since its development, several studies have compared the diagnostic yield of CE with other modalities commonly used to investigate the small bowel. Many studies have shown CE to be more sensitive and more effective compared with either push enteroscopy or small bowel follow-through[6-20]. The sensitivity and specificity of CE have been cited to be as high as 89% and 95%, respectively[20]. Although many papers have attempted to estimate the effectiveness of CE based on its diagnostic yield, few studies have considered the utility of a negative CE. In fact, only one of them[21-23] has considered a negative CE as a failure.

A great amount of data about a positive CE and its therapeutic and prognostic implications are available in literature. However, few data on the outcomes of patients with a negative CE are available. It is also somewhat more difficult to ascertain the value of a negative test. Previous studies have considered objective measures such as whether a negative test leads to other tests or therapeutic interventions. The impact on patients' overall outcome remains poorly defined, particularly in patients with OGIB. It remains uncertain that CE findings predict rebleeding.

A negative CE, though it does not confirm a specific diagnosis, may still be useful, because it allows the physician to quit a certain line of investigation, thereby impacting patient care.

MATERIALS AND METHODS

We reviewed the medical records of all patients referred to the Digestive Endoscopy Unit of the Catholic University in Rome to undergo a CE analysis for the investigation of OGIB between December 1st, 2002 and January 30th, 2011. All of them presented an overt or occult gastrointestinal bleeding as clinical presentation according to the guidelines of the American Gastroenterological Association (AGA)[24]. All patients had undergone both EGD and ileo-colonoscopy resulted negative before to referral for CE.

All patients, opportunely consented, underwent a CE with the PillCam capsule endoscopy system (Given Imaging, Yoqneam, Israel), according to the standard protocols endorsed by the American Society for Gastrointestinal Endoscopy[25]. All the procedures were performed in an out patient setting, after fasting for 8 h without any bowel preparation. The PillCam small bowel (Given Imaging) was then administered. The patients had a light breakfast 2 h after and a light meal 4 h after the administration of the PillCam as recommended in the standard protocol. After 8 h, they returned to the Endoscopy Unit, data recorder was removed and images were downloaded on the computer. The recordings of CE were reviewed by 2 experienced endoscopists/gastroenterologists independently (Riccioni ME, Urgesi R) at 8-10 frames per second using the Rapid® Reader (version 5.0). When possible, the stomach and the colon were also observed. The interobserver difference in interpretation about any findings was less than 5% and if and when it existed, it was resolved by reexamination.

A positive CE was defined as the presence of CE findings that may account for the clinical bleeding (angiodysplasia, ulcers or erosions, tumor, Crohn's disease, and active bleeding with no identifiable source), whereas a negative CE was defined as the absence of abnormalities on CE as reason of the bleeding.

In all cases in which CE did not reach the valve or with inadequate small bowel cleansing the examination was repeated. The analysis was considered negative when the second procedure rule out any GI abnormalities[26].

The median follow-up for all patients, strictly monitored for rebleeding, was 24 mo (range 12-36 mo). Patients' records, including blood tests, hospital admissions (especially for anemia and/or recurrent gastrointestinal bleeding), blood transfusions, need of iron supplementation, additional endoscopies (including push endoscopies), and surgery were considered from the date of the CE. Overt clinical rebleeding was defined as passing melena or fresh blood per rectum with a drop in hemoglobin of 2 g/dL or more. Occult rebleeding was defined as an unexplained hemoglobin drop of more than 2 g/dL in the absence of melena or hematochezia.

We defined patients with no recurrent obscure gastrointestinal bleeding or anemia during follow-up as "negative for rebleeding" and those with a confirmed bleeding source identified by an invasive interventions, clinical rebleeding, or recurrent unexplained anemia (using standardized and published criteria: blood haemoglobin level

of < 13.8 g/dL for men, < 11.5 g/dL for postmenopausal women, and < 11 g/dL for pre-menopausal women, with a plasma ferritin level of < 30 μg/L and a mean corpuscular volume of < 80 fL[26]) as "positive for rebleeding".

Statistical analysis

The Statistical Package for Social Science (version 13.0; SPSS Inc., Chicago, IL, United States) was used for all statistical computation. Actuarial rates of rebleeding during follow-up were calculated, and factors associated with rebleeding were assessed through an univariate and multivariate analysis. A *P* value of less than 0.05 was regarded as statistically significant.

The sensitivity, specificity, and positive and negative predictive values (PPV and NPV) were calculated[27] using as "gold standard" the patients negative for obscure bleeding.

RESULTS

CE indications included obscure overt bleeding (532), obscure occult bleeding (164) and several other indications (282). CE studies resulted negative in 207 out of 696 (29.7%) with obscure/overt gastrointestinal bleeding: 110 male (53.1%) and 97 female (46.8%) with a median age of 61.4 years (range 8-92 years). Overall, 489 patients (70.2%) were positive patients. The flowchart of the selection process of patients involved in the study and characteristics of the patients with negative CE are showed in Figure 1 and Table 1 respectively.

Follow-up

The median follow-up for all patients closely monitored for rebleeding was 24 mo (range 12-36 mo). Clinical recurrence of bleeding was observed during follow-up in 34 (16.4%) out of 207 patients with CE "negative for bleeding". In details, 2 out of 34 patients had a new episode of melena, otherwise 32 patients had a recurrence of obscure occult bleeding with anemia and positive fecal occult blood test.

A Meckel diverticulum and a gastrointestinal stromal tumor were respectively diagnosed in the two patients presenting a new episode of obscure overt bleeding. In the group of 32 patients affected by a recurrence of obscure occult bleeding, the cause was undiagnosed in 13 cases (40.6%), whereas an extra-intestinal disease was diagnosed in 11/32 (34.3%) patients, a parasitic infestation in 3/32 (9.37%) and the chronic use of NSAIDs was indicated as the probable cause of the recurrence of bleeding in 5/32 (15.62%) patients. Moreover, we note that 2 out of 34 (5.8%) patients with negative CE and episodes of early rebleeding were receiving chronic therapy with oral anticoagulation, at 10 mo of follow-up.

Data analysis

The results of univariate and multivariate analysis about factors associated with rebleeding in patients with negative CE and reccurence re-bleeding are summarized in Table 2. Patients with OGIB and negative CE have a low percentage of probability of rebleeding (34/207). The statistical analysis of our data shows that the age of onset of the first episode of bleeding < 65 years and the type of bleeding (melena) are the only factors that statistically significantly influence the risk of re-bleeding (OR = 2.6703, 95%CI: 1.1651-6.1202, *P* = 0.0203; OR = 4.7718, 95%CI: 1.9739-11.5350, *P* = 0.0005) (Table 3). Other parameters considerated during our survey such as gender, number of blood transfusions, hemoglobin level, intake of anticoagulants, number of hospitalizations didn't show a statistically significant correlation with rebleeding episodes. The final diagnosis and treatment of these patients are summarized in Table 3.

The patients "negative for rebleeding" with CE negative didn't need a hospital admission at the time of rebleeding and no blood transfusions were required.

Regarding CE "positive" patients, clinical rebleeding was observed in 221 out of 489 (45.1%) patients. Rebleeding rate was 16.4% *vs* 45.1% (χ^2 test, *P* = 0.00001). The sensitivity, specificity, and PPV and NPV were 93.8%, 100%, 100%, 80.1%, respectively. Most rebleedings occurred within the first 12 mo after the CE examinations (18/34; 52.9%).

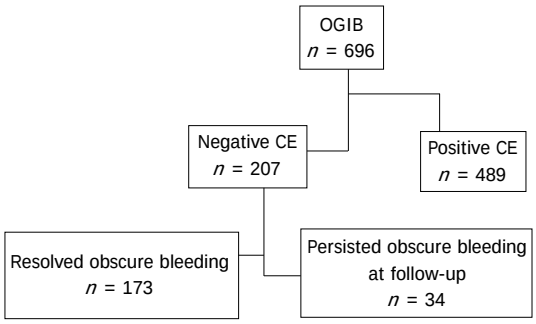

Figure 1 Flow chart of the selection process of patients involved in the study. CE: Capsule endoscopy; OGIB: Obscure gastrointestinal bleeding.

Table 1 Characteristics of patients with negative capsule endoscopy

Variables	Total patients	Negative for rebleeding	Rebleeding patients
n	207	173	34
Age (yr)	56.8	56.8	57.1
Sex (M/F)	110/97	70/59	22/12
Obscure-overt bleeding	157	121	2
Obscure-occult bleeding	50	52	32
Median Hb level	8.2	8.8	8.2
OAT/LMWH	36	32	4
Rebleeding time			
At 10 mo of follow-up			28
At 24 mo of follow-up			34

[1]Variables with $P < 0.05$ are significant. Variables with $P < 0.125$ entered in the multivariate analysis (logistic regression): (χ^2 test). Likelihood ratio: 22.1037; $P = 0.0002$. The younger age (< 65 yr) and the onset of bleeding such as melena are an independent risk factor of rebleeding after negative capsule endoscopy (CE). M/F: Male/female.

Table 3 The final diagnosis and treatment of the 34 negative capsule endoscopy patients with rebleeding

Type of rebleeding	*n*	Final diagnosis	Treatment
Obscure overt bleeding	2		Surgery
		Extraluminal GIST	
		Meckel's diverticulum	
Obscure occult bleeding	32		
	13	Causes not found	SR
	5	Myelodisplastyc syndrome	MT
	3	Uterine fibroma	Surgery
	1	Metastatic breast cancer	Surgery + MT
	3	Giardia lamblia infection	MT
	5	Chronic use of NSAID	
	2	Erosive gastritis	MT

GIST: Gastrointestinal stromal tumor; SR: Spontaneous resolution; MT: Medical therapy.

conventional diagnostic techniques, the impact of this relatively new investigation on patient outcome remains poorly defined. In particular, few CE studies used long-term rebleeding as the primary outcome. In this study, we determined the long-term clinical outcome and characteristics of patients with OGIB after negative CE. As reported previously[22,23,28,29], CE could not identify all bleeding lesions in patients with OGIB. Up to 36.7% of patients in this study had a negative CE despite overt clinical bleeding at presentation. Notably, this group of patients with negative CE had a low (19.8%) rebleeding rate in a more than 1 year follow-up. The rebleeding rate was significantly lower in patients with negative CE than in cases with positive CE. Moreover, considering the group of patients with negative CE, chronic therapy with oral anticoagulation and NSAIDs seems to be related to a higher risk of rebleeding. In accordance with our findings, Neu *et al*[30] found that rebleeding occured in 20% of patients with negative CE after a median follow-up of 13 mo. In a more recent study Lorenceau-Savale *et al*[31] showed as in 35 patients with a history of OGIB and negative CE and a minimum follow-up duration of one year (median: 15.9 mo) eight patients presented a recurrence of bleeding, with an overall rebleeding rate of 23%. Four women with recurrence before new investigations. In the four remaining patients, repeat endoscopy work-ups after negative CE were performed and revealed previously missed lesions with bleeding potential, mainly in the stomach. Overall, 13 patients, with or without rebleeding, had repeated endoscopy work-ups after a negative CE, leading to a definitive diagnosis in nine patients, with lesions located in the stomach and colon in eight of them.

Since the patients with OGIB and a negative CE had a low rate of rebleeding, further interventions or investigations could be deferred until clinical rebleeding occurs. In these cases, after ruling out a gastrointestinal lesions as causes of the recurrence of bleeding after the execution of a work-out negative for gastrointestinal bleeding properly done by following the guidelines proposed by AGA, the search for causes of obscure bleeding outside of the digestive system should be "necessarily" done.

Otherwise, patients with positive CE had a significantly higher rebleeding rate on long-term follow-up. Recently, Kim *et al*[32] performed CE in 125 patients with OGIB. The complete visualization of the small bowel was achieved in 93 patients (74.4%). Of the 63 patients (50.4%) with negative CE results, 60 patients did not receive any further specific treatment for OGIB. Rebleeding episodes were observed in 16 out of 60 patients (26.7%). Substantial rebleeding events were observed with similar frequency both after negative CE without subsequent treatment (26.7%) and after positive CE without specific treatment (21.2%) ($P = 0.496$). The Authors conclude that in some cases despite a negative CE, approach such as double balloon endoscopy (DBE) should be considered as complementary procedures for further evaluation.

Our study confirms, also in accordance with Lai *et al*[33] that patients with positive CE have a high rebleeding rate, a longer hospital stay and require more units of blood transfused than those with negative CE; in accordance with Kim *et al*[32], the device-assisted enteroscopy (DBE or single-balloon enteroscopy) could be helpful in patients with a high index of suspicion for small bowel pathologies and with a high risk of rebleeding and negative CE.

The limits of the present study are discussed below. First, the lack of a gold standard for small bowel diagnosis limits the accuracy in the determination of CE performance. It is highly possible that some lesions may be

missed despite an extensive investigation. However, unlike many published studies, we used long-term clinical rebleeding instead of small bowel lesions as the primary end point for the determination of CE performance. It may be interesting to determine, in future studies, whether the use of the recently available methods of device-assisted enteroscopy[34,35] and their future technical developments could overcome this problem. Secondly, all our "negative for rebleeding" patients refused to undergo further endoscopic examinations for various reasons. Third, we only recruited patients with "genuine" OGIB, meaning that these patients had undergone multiple upper and lower gastrointestinal endoscopies by experienced endoscopists to rule out other possible sources of bleeding. Consequently, these results could not necessarily be generalized to all patients with suspected small bowel bleeding.

In conclusion, even if additional studies are warranted to confirm these results, we found that in a follow-up of a mean 24 mo, patients with OGIB and negative CE had a significative low long-term rebleeding rate, suggesting that further invasive investigations could be deferred and may not be necessary in this group of patients. Only an accurate and careful clinical observation can help us to identify false negative patients at CE.

COMMENTS

Background

Obscure gastrointestinal bleeding (OGIB) remains a major clinical challenge to gastroenterologists. Many instances of OGIB originate from the small bowel, which is beyond the reach of an ordinary endoscope, including an esophagogastroduodenoscope and colonoscope.

Research frontiers

The scene was recently revolutionized by the availability of capsule endoscopy (CE), which is noninvasive and well tolerated by patients. In this study the authors assess the rate of recurrent bleeding of the small bowel in patients with obscure bleeding already undergone CE with negative results.

Innovations and breakthroughs

Recent reports have highlighted the importance of CE in the clinical assessment of patients with presumed small bowel diseases. For OGIB, CE is recommended as an investigation modality for the detection of a bleeding source after traditional endoscopy. However, even after full evaluation of the small bowel, CE is not able to highlight the bleeding focus. In the present study, they sought to reveal the outcomes after negative CE for OGIB and the risk factors associobscure bleeding already undergone CE with negative results.

Applications

By understanding the value of negative CE and the value of long-term of follow-up in these patients. Patients with OGIB and negative CE had a significantly lower rebleeding rate, and further invasive investigations can be deferred. However, when a confirmatory diagnosis is made by CE study, specific treatments can be applied according to the diagnosis.

Terminology

CE is the most innovative and less invasive resource for the study of the small bowel playing an essential role in the diagnosis of small bowel diseases until now disregarded and the setting of therapeutic decisions.

Peer review

The authors retrospectively present information on 696 patients who underwent CE for OGIB with negative standard tests. They excluded for detailed analysis 489 patients an instead concentrated on outcome in 207 patients in whom the CE proved negative. They found a statistically lower rebleed rate over a median of 24 mo in these CE negative patients compared to the CE positive group. The CE-patients had various other explanations found later in 60%. No explanation was found in the rest. In multivariate analysis age < 65 years and melena on presentation were found to be predictors of rebleed in CE-patients.

Abstract

AIM: To determine the factors affecting the decision to perform surgery, and the efficiency of ultrasonography (USG) in detecting gallbladder polyps (GP).

METHODS: Data for 138 patients who underwent cholecystectomy between 1996 and 2012 in our clinic with a diagnosis of GP were retrospectively analyzed. Demographic data, clinical presentation, principal symptoms, ultrasonographic and histopathological findings were evaluated. Patients were evaluated in individual groups according to the age of the patients (older or younger than 50 years old) and polyp size (bigger or smaller than 10 mm) and characteristics of the polyps (pseudopolyp or real polyps). χ^2 tests were used for the statistical evaluation of the data.

RESULTS: The median age was 50 (26-85) years and 91 of patients were female. Of 138 patients who underwent cholecystectomy with GP diagnosis, only 99 had a histopathologically defined polyp; 77 of them had pseudopolyps and 22 had true polyps. Twenty-one patients had adenocarcinoma. Of these 21 patients, 11 were male, their median age was 61 (40-85) years and all malignant polyps had diameters > 10 mm (P < 0.0001). Of 138 patients in whom surgery were performed, 112 had ultrasonographic polyps with diameters < 10 mm. Of the other 26 patients who also had polyps with diameters > 10 mm, 22 had true polyps. The sensitivity of USG was 84.6% for polyps with diameters > 10 mm (P < 0.0001); however it was only 66% in polyps with diameters < 10 mm.

CONCLUSION: The risk of malignancy was high in the patients over 50 years old who had single polyps with diameters > 10 mm.

Key words: Gallbladder; Polyps; Ultrasound; Cholecystectomy; Malignancy

Core tip: Early stage gallbladder cancers can often be detected as polyps in imaging studies. The aim of this study was to determine the factors affecting surgery by analyzing the incidence of malignancy of gallbladder polyps (GP) and the efficiency of ultrasonography in detecting GP. Of 138 patients with GP on imaging, 99 had polyps and 21 had histopathologically confirmed adenocarcinoma. Of these 21 patients, all malignant polyps were solitary and had a diameter > 10 mm. In our study, the risk of malignancy correlated with age over 50 years old, solitary polyp and polyp diameter > 10 mm.

INTRODUCTION

Gallbladder polyps (GP) present as masses protruding from the gallbladder mucosa. They are found in 0.3% to 12% of healthy individuals[1]. The actual prevalence is

unknown; however, at present, GPs are diagnosed more frequently because of the widespread use of abdominal imaging techniques. GPs are usually asymptomatic and are diagnosed incidentally during radiological examinations done for other reasons. GPs are classified as pseudopolyps or true polyps. Pseudopolyps consist of cholesterol polyps/cholesterolosis, adenomatous polyps, adenomyoma, inflammatory polyps and hyperplastic polyps; these are all benign lesions. True polyps are grouped into benign (adenoma), premalignant (dysplastic polyps) and malignant (adenocarcinoma)[2]. Cholesterol polyps are the most frequently observed GPs. Therefore, most GPs are benign lesions. Occasionally, early stage gallbladder cancers can be detected as a polyp in imaging studies.The prevalence of malignant polyps of GPs can reach 27%[3]. In patients older than 50 years old, the presence of polyps larger than 10 mm has been reported as a risk factor for malignancy[3-8]. The most commonly used imaging modality for diagnosis is ultrasonography (USG). However, USG is poor at differentiating benign and malignant polyps. Additional diagnostic tools comprise computed tomography and endoscopic USG.

In this study, patients in our clinic diagnosed with-GPs who had surgery were examined; and indication for surgery, frequency of polyp types, malignancy rates of polyps and reliability of USG in identification and differentiation of polyps were investigated.

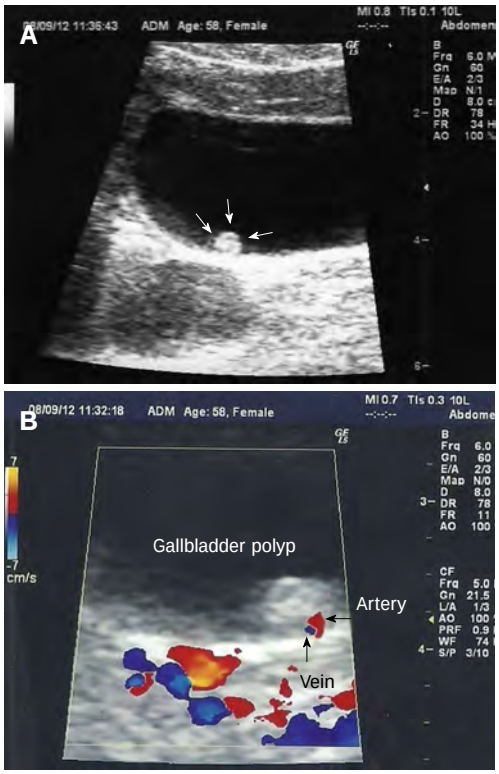

Figure 1 The ultrasonographic image of a 6-mm gallbladder polyp (A) and the same polyp with a feeding artery in Doppler ultrasonography (B).

MATERIALS AND METHODS

Patients

Age, sex, clinical signs and symptoms, preoperative ultrasound and histopathological diagnoses of patients were analyzed retrospectively in patients admitted to our clinic with GP and underwent cholecystectomy from 1996-2012. All the patients were evaluated with USG before surgery in the Radiology Department of Uludag University Faculty of Medicine. Hyperechoic lesions that had no acoustic shadowing and didnot move with position change represented a confirmed diagnosis of GP[8]. Detection of polyps > 10 mm, suspicious findings in USG (such as a vascularization pattern, Figure 1), growth during follow-up, and personal request of the patient were indications for surgery.

Polyp size, number and presence of stones were evaluated in preoperative USG reports, and compatibility of these findings with histopathological data was analyzed.

According to histopathological diagnoses, cholesterol polyps/cholesterolosis, hyperplastic and adenomatous polyps were assembled under the title of "pseudopolyp"; adenoma and adenocarcinoma were assembled under the title of "real polyps". In addition, patients were evaluated in individual groups according to the age of the patients (older or younger than 50 years old) and polyp size (bigger or smaller than 10 mm).

Statistical analysis

The χ^2 test was used, when appropriate, to calculate the statistical significance of the different demographic and clinical variables. *P* values of < 0.05 were deemed significant.

RESULTS

Demographic and clinical characteristics of patients with PLG

Cholecystectomy was performed in 5832 patients between 1996-2012 and surgical indication of 138 patients (2.3%) was GPs. Ninety-one of the patients were female and 47 of them were male, with a median age of 55 (26-85) years. Polyps were detected in 99 of the 138 patients (71.7%) undergoing surgery for GPs; gallbladder stones were detected in the remaining 39. Thus, the false positive rate was 28% in ultrasound evaluation of polyps. Remarkably, the polyps in all of these cases were < 10 mm.

Sixty-six patients (66.6%) did not have any symptoms at the time of presentation; however, 33 patients with polyps were symptomatic. Sixty-two of 66 asymptomatic patients elected to have surgical treatment because of possible future risks. Three of four asymptomatic patients had a cholecystectomy because their polyp increased to > 10 mm in 6 mo; the remaining patient had a cholecystectomy because of their age and sex (65 years old male). On pathological examination, the polyps of these four patients were detected as cholesterol polyps and adenomatous polyps. The 33 symptomatic patients presented with complaints of right upper quadrant pain and dyspepsia, and had surgery upon detection of polyps in USG (Table 1). Gallstones were accompanied with

Table 1 Characteristics of 99 patients diagnosed with gallbladder polyps by histopathological examination

Characteristics		Pseudopolyp	True polyp (n = 22)		P value[1]

	> 10	4	21	0	

[1]In terms of true polyp incidence between data.

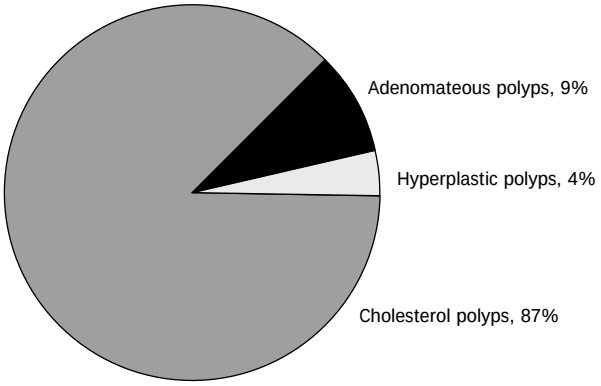

Figure 2 Distribution of pseudopolyp cases.

polyps in 18 (54.5%) of these symptomatic patients. Only in two of the malignant cases was a polypoid structure accompanied by gallstones.

As shown in Table 1, 54.5% of patients were under the age of 50 and 90% of true polyps were seen in patients over 50 years old. In addition, the incidence of polyps was 3.7% under 50 years of age, rising to 44% in patients over 50 years of age ($P < 0.0001$).

Sonograhic characteristics of the patients

While gallstones were detected only in 1 of 26 patients who had lesions of 10 mm diameter in preoperative USG, postoperative diagnoses was true gallbladder polyp in 21 (84.6%) of the remaining 25 patients. The other four patients were reported to have pseudopolyps. Preoperative USG diagnosed 96% of lesions over 10 mm accurately and 84% of them were found to be true polyps (adenoma/adenocarcinoma). Histopathological diagnoses reported polyps only in 74 of 112 patients who had lesions < 10 mm. Thus, the accuracy of USG for polyps < 10 mm decreased to 66% and only one of these 74 cases was a true polyp (adenoma). There was a statistically significant difference in the diagnosis of true polyps between polyps < 10 mm or > 10 mm ($P < 0.0001$).

Histopathological examinations of GP

The mean polyp diameter of the polyps from 99 patients (histopathologically defined as 77 pseudopolyps and 22 true polyps) was 8.8 mm (range 3-19 mm). The most commonly seen GP was a cholesterol polyp (Figure 2). Twenty-one of 22 patients with true polyps were diagnosed with adenocarcinoma, and the other one was adenoma. All the malignant polyps were > 10 mm and solitary. Eleven patients with malignancy were male and the median age was 61 (40-85) years. In our series, the incidence of malignant GP was 21.2% (21 of 99 cases). The incidence dropped to 15.2% when all 138 patients with preoperative diagnoses of polyps were taken into consideration.

Results of malignant patients

Cholecystectomy only was performed in 16 of 21 patients with malignancy, and cholecystectomy with liver S-5 resection and lymph node dissection was performed in the remaining five patients. No additional treatment other than cholecystectomy was performed in 10 patients with T1 tumors limited to the mucosa and submucosa. The other 7 patients did not accept additional treatment. Eight patients received chemotherapy treatment after surgery. Ten of these patients were still alive and 11 of them died. Survival was 14.8 mo (range 4-38 mo).

DISCUSSION

GPs are common gallbladder lesions and should not be ignored because of their association with malignancy. In the literature, the incidence of GP has been reported as between 0.3% and 12.0%[9,10]. In our clinical series of 5832 patients undergoing cholecystectomy, GPs were an indication for cholecystectomy in 2.3% (138 patients) of cases. Thirty-nine of these patients were diagnosed with only cholelithiasis; therefore, the true incidence of GPs was 1.7%.

There are different concepts about the effect of demographic factors such as age and gender on the incidence of GPs. Some studies reported that GPs are more frequently seen in males[2,11-14] or females[9-15], and some studies even suggest that there is no effect of gender on GPs[14-21]. Approximately 2/3 of cases in our study were-women and the true polyp ratio was 29.7% in men and 17.7% in women (Table 1). Ito *et al*[17] reported that the mean age was 59 years in their 417 patients series. Although 53% of patients in our study were under the age of 50, 90% of true polyps were detected in patients over 50 years old. As demonstrated in Table 1, the incidence of true polyps was 3.8% under the age of 50 years and 44% over the age of 50 years ($P < 0.05$).

Ultrasonography is the most frequently used and most valuable diagnostic tool for preoperative evaluation of gallbladder pathologies[8]. One hundred thirty eight patients in our series were diagnosed with GP using USG. Considering that 39% of them were also diagnosed with cholelithiasis, the accurate diagnosis rate of USG was 71.7%. The sensitivity of USG for GPs has beenreported to be between 32% and 90%[5,18]. While USG can

usually detect polyps > 5 mm, it becomes more accurate if the polyp is > 10 mm[19]. Indeed, USG detected almost all polyps > 10 mm accurately (25 of 26 cases) and these polyps were true polyps (adenoma/adenocarcinoma). However, the accuracy of USG diagnosis lesions < 10 mm was 66%. In addition, GPs were detected as < 10 mm in 39 patients who were thought to have GPs preoperatively but in whom no polyps were detected postoperatively. Postoperatively, the pathological diagnoses of these 39 patients were chronic cholecystitis and cholelithiasis. Cholesterolosis occurs as a result of accumulation of esterified cholesterol and triglycerides in macrophages of the lamina propria, and they are often mistaken as small polyps in USG[17]. Gallbladder stones attached to the wall of the gallbladder can easily be interpreted as a polyp in USG[18]. The presence of stones in the gallbladder reduces the success rate of USG in the diagnosis of GPs; USG diagnosis of GPs is to 99% accurate in the absence of any stones. On the other hand, in our patients, GPs did not usually cause any symptoms. Association of stones with GPs may cause symptoms and prompts the patient to consult a doctor, making the diagnosis easier. In our study, gallstones accompanied GPs in only 18.1% (18 patients) of patients. All patients with stones were symptomatic. However, there were no stones in 15 of the 33 symptomatic patients and GPs caused the symptoms in these patients. In our series of patients, being symptomatic did not have any impact on detection of true polyps ($P = 0.71$).

Another important factor associated with malignancy in GPs is the diameter of the polyps[6,20]. Kozuka *et al*[21] reported that the critical limit for differentiation of benign and malignant GPs was 12 mm and suggested cholecystectomy for GPs larger than 12 mm. Kubota *et al*[22] compared postoperative pathological data of 72 patients with GPs and preoperative ultrasound. They reported 22% of neoplastic polyps of the gallbladder as > 10 mm. They also reported that evaluation of the polyp shape may be beneficial, but it is not enough to distinguish cholesterol polyps from adenoma and cancer. Sugiyama *et al*[23] tried to make a distinction between benign and malignant polyps using preoperative USG and endoscopic USG. They detected adenoma or cancer in 14% of polyps with diameters of 6-10 mm in preoperative USG. Zielinski *et al*[2] emphasized that there is a significant increase in the risk of neoplasia in polypoid lesions > 6 mm; they suggest performing cholecystectomy in these patients. In our study, the majority of polyps (73 of 74 cases) < 10 mm were pseudopolyps, and the remaining polyps were adenomas. None of the malignant polypswere < 10 mm. Eight-four percent of polyps > 10 mm were true polyps (adenoma/adenocarcinoma) and all of the these true polyps were found to be adenocarcinoma. This suggests that a limit of 10 mm is very important ($P = 0.0001$). Similarly, no true polyps were detected in the setting of multiple polyps. Remarkably, 28% of single polyps were diagnosed as adenocarcinoma.

The literature suggests that patients over 50 years old, polyps > 10 mm, polyps with a broad base or long pedicle, polyps associated with cholecystitis or cholelithiasis, or irregular thickening of the gallbladder in the setting of biliary colic are indications for cholecystectomy[4,23,24]. In our study, 21 (21.2%) of 99 patients with GPs were diagnosed with malignancy, all of whom were older than 50 years with single polyps > 10 mm. In addition, the success rate of USG for diagnosing GPs > 10 mm was more evident and an important point. Patients had surgery mostly because of their extreme sensitivity and anxiety. We found that surgery was not beneficial in patients with multiple polypoid lesions or polyps < 10 mm. For this reason, the surgical team should reassure and relax the patients and avoid unnecessary cholecystectomies.

In conclusion, being male and over 50 years old with a solitary polyp > 10 mm benefited most from cholecystectomy.

COMMENTS

Background

Gallbladder polyps (GP) are frequently detected incidentally. They are usually misdiagnosed as gallstones in sonographic examinations. There is no consensus for treatment and follow-up of GP because of its particularly rare incidence of malignancy. There are some risk factors associated with high risk of malignancy. Early diagnosis and surgical treatment of GP affects survival of gallbladder carcinomas.

Research frontiers

Many studies have investigated risk factors that increase the incidence of malignancy of GP. Age, gender, polyp size, polyp number, accompanying gallstones and the inflammatory status of the gallbladder are significant risk factors.

Innovations and breakthroughs

In this study, all the malignant polyps were solitary and over 10 mm in size. Malignant polypsweredetermined in 44% of the patients aged over 50. The authors failed to show an association between gender and malignancy for GP. Ultrasonography (US) was more sensitive for polyps over 10 mm. US was more helpful in showing malignancy for cases with polyps under 10 mm.

Applications

This study will facilitate surgeons' decision making for treatment and follow-up of patients with GP.

Terminology

Histopathologically, cholesterol polyps/colestherolosis, hyperplastic and adenomateous polyps are defined as pseudopolyps, while adenomas and adenocarcinomas are defined as true polyps.

Peer review

This manuscript, which was written on a subject of considerable controversy in general surgery, has been generally well designed.

Abstract

AIM: To perform wire-guided cannulation using a newly designed J-shaped tip guidewire, and to verify feasibility and safety for use.

METHODS: The study was conducted on endoscopic retrograde cholangiopancreatography (ERCP) patients with naïve papilla undergoing diagnosis and treatment of biliary diseases between September 2011 and July 2012. We performed ERCP in a succession of 50 cases with a J-shaped tip guidewire. The first insertion attempt began with a trainee who had 5 min to complete cannulation, followed if necessary by the trainer for another 5 min. We assessed the primary success rate of selective biliary cannulation within 10 min and adverse events such as post-ERCP pancreatitis (PEP), bleeding or perforation.

RESULTS: The primary success rate was 90% (45/50) within 10 min, the initial success rate within 5 min by trainee staff was 76% (38/50). The rate of PEP was 6% (3/50), but all 3 cases were mild pancreatitis. All patients were managed successfully with conservative treatment. There was no bleeding or perforation.

CONCLUSION: A newly designed J-shaped tip guidewire has the possibility to facilitate selective biliary cannulation for ERCP and appears to be safe.

Key words: J-shaped tip guidewire; Wire-guided cannulation; Endoscopic retrograde cholangiopancreatography; Biliary tract; Cannulation technique; Perforation

Core tip: We conducted a feasibility study that performed endoscopic retrograde cholangiopancreatography (ERCP) with a newly designed J-shaped tip guidewire. This new guidewire has a strongly-flexed atraumatic tip with hydrophilic coating; therefore, it may contribute to the improvement of the passage through the intra-duodenal biliary segment and to the decrease of adverse events such as post-ERCP pancreatitis. We assessed the primary success rate of selective biliary cannulation within 10 min and rate of post-ERCP pancreatitis. The primary success rate was 90% (45/50); the rate of post-ERCP pancreatitis was 6% (3/50), but all 3 cases were mild. The J-shaped tip guidewire may facilitate selective biliary cannulation in ERCP.

Newly designed J-shaped tip guidewire: A preliminary feasibility study in wire-guided cannulation. *World J Gastroenterol* 2013; 19(28): 4531-4536 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4531.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4531

INTRODUCTION

Endoscopic retrograde cholangiopancreatography (ERCP) is used to diagnose and treat biliary disease. Deep cannulation of the common bile duct is required for this procedure, and the current success rate for the relatively difficult conventional contrast-guided cannulation (CGC) technique ranges from 50%-90%[1-5]. Wire-guided cannulation (WGC) is a recently developed alternative to CGC that has been shown to increase primary biliary cannulation rate[6-11], chiefly by reducing incidence of post-ERCP pancreatitis (PEP)[12-20]. However, despite efficiency improvements, the sharp tips of guidewires are sometimes associated with perforation[21-23]. Even without perforation, complications can occur when the guidewire tip hits the fold and flexion of the intra-duodenal biliary segment. While a looped tip guidewire has been developed, its utility in avoiding perforation has not sufficiently been evaluated[24].

Here, we assessed the efficiency of ERCP using a newly designed J-shaped tip guidewire with a strongly flexed atraumatic tip and hydrophilic coating designed to improve passage through intra-duodenal biliary segments and decrease the adverse events, such as PEP, bleeding or perforation.

MATERIALS AND METHODS

Patients

Fifty patients with naïve papilla undergoing diagnosis and treatment for biliary diseases between September 2011 and July 2012 received ERCP using J-shaped tip guidewires. Patients were excluded if only their pancreatic ducts were diagnosed or treated, if they had previously undergone endoscopic sphincteroplasty, or if they had duodenal stenosis or Billroth Ⅱ or Roux-en-Y anastomosis, or refused to provide informed consent.

Patients were sedated *via* intravenous administration of midazolam (5-10 mg) and buprenorphine (0.2 mg). Scopolamine butylbromide (20 mg) or glucagon (1 mg) was injected intravenously to inhibit gastrointestinal peristalsis, and each patient received nafamostat mesilate (20 mg/d) prior to ERCP. Blood samples collected 2 h after ERCP were used to determine complete blood counts and serum amylase levels, and those collected after 18-24 h also measured hepatobiliary enzymes and C-reactive protein. We did not place a pancreatic duct stent for the prevention of pancreatitis in either procedure.

J-shaped tip guidewire

The guidewire (RWHJ-2545A, 0.025-inch; Paiolax Medical Devices, Inc., Kanagawa, Japan) tip was bent to attain a 1-mm radius, and a hydrophilic coating was applied starting 50 mm from the tip. The shaft was covered by a sheath and the jacket coated with water-repellent material (Figure 1).

Endoscopic procedure

Endoscopy was performed with JF-260V (Olympus, Tokyo, Japan) or ED-530XT8 (Fujinon, Tokyo, Japan) endoscopes, after catheters were preloaded with guidewires. In the present study, in general, a regular catheter was chosen except for the case undergoing sphincterotomy. First, catheters (CleverCut3 V, Olympus, Tokyo, Japan; Tamdem XL, Boston Scientific, Natick, MA, United States) were preloaded with guidewires, the guidewire tip was extended 5 mm from the catheter, bent into a "J" shape, and then the guidewire was pulled back into a stand-by position (Figure 2A). Endoscopists controlled the direction parallel to the axis of bile duct of the catheter by inches. Assisting endoscopists participated in the guidewire manipulation in all cases. An assisting endoscopist moved the guidewire back and forth in small motions by using a tactile feedback (in-and-out movement method). No fluoroscope was used during attempts of insertion, but once the guidewire was inserted without resistance then fluoroscopy was used only after insertion to confirm success (Figure 2B). The catheter was then inserted into the biliary system along the guidewire, and contrast medium was injected (Figure 2C). No test injection was performed before successful cannulation.

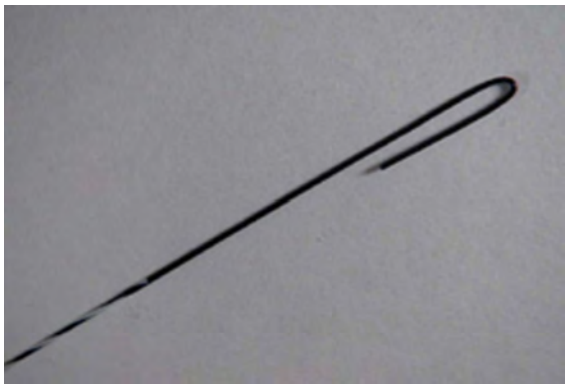

Figure 1 Newly designed J-shaped tip guidewire. The shape of the tip is a radius of 1 mm; 50 mm from the tip is the start of a hydrophilic coating.

The first insertion attempt began with a trainee who had 5 min to complete cannulation, followed if necessary by a trainer with career experience of over 500 ERCPs (Maetani I or Shigoka H or Omuta S) for another 5 min. If both attempts failed, efforts continued with a standard biliary guidewire (Jagwire 0.035 angle type, Boston Scientific) for another 10 min (second attempt) and were repeated as necessary according to the trainers' recommendations (exchange of endoscopist or guidewire, pancreatic duct guidewire placement method, or pre-cutting sphincterotomy).

Definitions

Success was defined as completing cannulation with the J-shaped tip guidewire and obtaining a cholangiogram within 10 min. Cannulation time was defined as from when a tip of the guidewire first touched the orifice of the papilla to the obtainment of cholangiogram. PEP was defined as continued abdominal pain ⩾ 24 h after ERCP, with more than 3 times the normal (upper limit) serum-

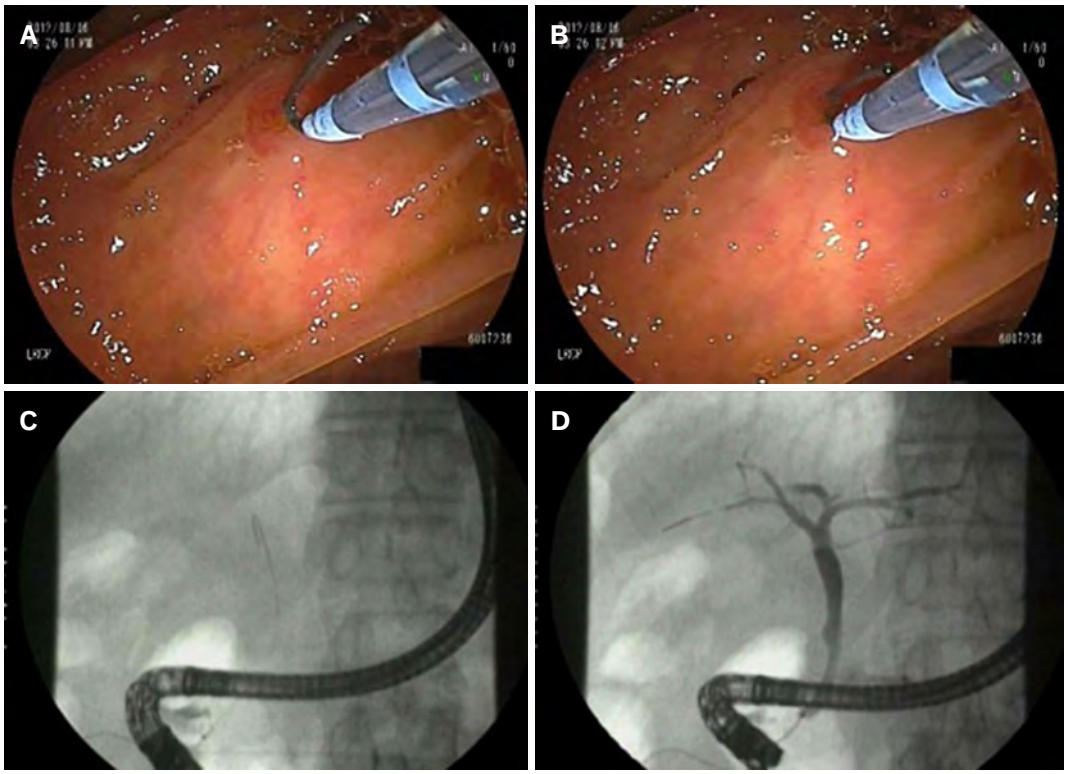

Figure 2 Endoscopic and fluoroscopic images showing the technique with J-shaped tip guidewire. A: Assistant endoscopist extended approximately 5 mm of the guidewire tip and restored it to the original "J" configuration (stand-by position); B: Selective biliary cannulation was attempted under endoscopic control without fluoroscopy; C: The guidewire was moved in an in-and-out motion by an assisting endoscopist. Once the guidewire was advanced without resistance, fluoroscopy was used to confirm successful cannulation; D: Contrast medium was injected after confirmation of successful biliary cannulation.

amylase level[25]. Pancreatitis severity was classified using the Atlanta International Symposium criteria[26]. Suspected sphincter of Oddi dysfunction was defined according to the revised Milwaukee classification[27]. Sphincter of Oddi manometory was not performed. Hyperamylasemia was defined as 3 times the normal (upper limit) amylase level 18-24 h after ERCP.

Ethics

The protocol adhered to the Helsinki Declaration and was approved in advance by the Institutional Ethical Review Board. The trial was registered with the University hospital Medical Information Network Clinical Trials Registry (UMIN000007526). All participants gave written informed consent beforehand.

Outcome measurement

The primary study endpoint was the success rate of cannulation with the J-shaped tip guidewire performed within 10 min. The secondary endpoints were as follows: (1) the rate of the occurrence of PEP; (2) time to selective biliary cannulation; (3) number of attempts for selective biliary cannulation; and (4) number of accidental pancreatic duct insertions. Data are presented as median and interquartile ranges (IQR).

RESULTS

Baseline characteristics and indications are summarized in Table 1, and details of the endoscopic procedure are given in Table 2.

The overall success rate of endoscopy was 90% (45/50, Table 3), with cannulation achieved within the first 5 min in 38 patients (76%). Cannulation was achieved on the second attempt in 3 patients. The median time to cannulation for these 48 patients was 42.5 s (IQR: 5-262 s). Of the remaining two patients, one required pancreatic duct guidewire placement and the other a pre-cutting sphincterotomy. The median number of attempts was 2.0 (IQR:

1.0-6.0), and the median number of accidental pancreatic duct insertions was 1.0 (IQR: 0.0-3.0). The median serum-amylase level was 148 IU/L (IQR: 94-331 IU/L), and hyperamylasemia occurred in 4 patients.

Mild PEP occurred in 3 patients (6%); in 2 of these, success was achieved within 5 min after endoscopic papillary large balloon dilation, while the third patient received the pre-cutting sphincterotomy mentioned above. All patients were managed successfully with conservative treatment. There were no other adverse events including bleeding or perforation.

DISCUSSION

The success rate for selective biliary cannulation using a J-shaped tip guidewire was comparable to that found in previous studies[6-16,28,29], and no guidewire-related adverse events such as bleeding or perforation occurred. Although ours was a preliminary study, the atraumatic and blunt tip of the new guidewire may facilitate selective biliary cannulation (Figure 3A) and reduce instances of perforation and bleeding.

Although straight and angled tips are the most common types used in WGC[1-20,28,29], these sharp tips often stick in the intra-duodenal biliary segment (Figure 3B). While the superiority of the J-shaped tip cannot be definitively shown without controls, the success rate, speed of cannulation, and facility of use appear improved compared to other studies. While similar procedures using standard guidewires resulted in a 77.9% overall success rate (trainees and trainer combined)[28], here we achieved a 76% success rate with trainees, and an overall success rate of 90%. Additionally, the 6% PEP rate is similar to that of other studies[14,18,19,20].

WGC was first introduced by Siegel *et al*[30]. Meta-analysis has shown that the reduction of pancreatic duct opacification is another possible advantage over CGC[14,18,19]. Further, WGC has been suggested to decrease the risk of PEP[14,18,19], facilitating its spread across the globe as a potential first-line method.

Usually, when guidewires are extended from the tip of a catheter without enough space for advancement, the wire may act like a needle and pierce the epithelium. The J-shape of the guidewire protrudes from the catheter before approaching the biliary orifice, and reduces this likelihood. We therefore believe our J-shaped design to be the aspect that improved insertion into the biliary system. Limitations to this study include small sample size, no controls, a single institution, and involvement of multiple endoscopists. A randomized comparison is warranted for objective evaluation of its performance. One drawback of the J-shaped tip guidewire is the 1-mm radius, which is wider than a standard guidewire and may hamper selective cannulation through a narrow orifice.

In conclusion, a newly designed guidewire with a

J-shaped tip may facilitate selective biliary cannulation in ERCP. However, a large prospective randomized control trial is necessary to verify the performance of this guidewire in comparison with standard guidewires.

COMMENTS

Background

Selective biliary cannulation is essential for diagnosis and therapeutic endoscopic retrograde retrograde cholangiopancreatography (ERCP) in biliary diseases. Wire-guided cannulation (WGC) increases the primary biliary cannulation rate and decreases the risk of post-ERCP pancreatitis (PEP). Therefore, WGC is now widely performed. However, even experts meet with difficulty and the possible risk of bleeding and perforation due to the guidewire.

Research frontiers

The authors performed ERCP using a newly designed J-shaped tip guidewire. A J-shaped tip guidewire with a strongly flexed atraumatic tip and hydrophilic coating was designed to improve passage through intra-duodenal biliary segments and decrease the adverse events, such as PEP, bleeding and perforation. The authors conducted a feasible study.

Innovations and breakthroughs

This is a single center pilot study. The primary success rate was 90% (45/50) within 10 min. The rate of PEP was 6% (3/50), but all 3 cases were mild pancreatitis. All patients were managed successfully with conservative treatment. There was no bleeding or perforation.

Applications

A newly designed J-shaped tip guidewire may facilitate selective biliary cannulation and the structure of the tip may contribute to decrease PEP and bleeding, or perforation. However, it is necessary to conduct a large prospective randomized control trial to verify the performance.

Peer review

This is a single center pilot study of a newly designed J-shaped tip guidewire for wire-guided cannulation. The authors hypothesized that the J-shaped tip prevented perforation or PEP during cannulation. The limitation of this study is a small sample size without a control group as the authors discussed.

Abstract

AIM: To evaluate clinical outcomes of patients that underwent surgery, transarterial embolization (TAE), or supportive care for spontaneously ruptured hepatocellular carcinoma (HCC).

METHODS: A consecutive 54 patients who diagnosed as spontaneously ruptured HCC at our institution between 2003 and 2012 were retrospectively enrolled. HCC was diagnosed based on the diagnostic guidelines issued by the 2005 American Association for the Study of Liver Diseases. HCC rupture was defined as disruption of the peritumoral liver capsule with enhanced fluid collection in the perihepatic area adjacent to the HCC by dynamic liver computed tomography, and when abdominal paracentesis showed an ascitic red blood cell count of > 50000 mm^3/mL in bloody fluid.

RESULTS: Of the 54 patients, 6 (11.1%) underwent surgery, 25 (46.3%) TAE, and 23 (42.6%) supportive care. The 2-, 4- and 6-mo cumulative survival rates at 2, 4 and 6 mo were significantly higher in the surgery (60%, 60% and 60%) or TAE (36%, 20% and 20%) groups than in the supportive care group (8.7%, 0% and 0%), respectively (each, $P < 0.01$), and tended to be higher in the surgical group than in the TAE group. Multivariate analysis showed that serum bilirubin (HR = 1.09, $P < 0.01$), creatinine (HR = 1.46, $P = 0.04$), and vasopressor requirement (HR = 2.37, $P = 0.02$) were significantly associated with post-treatment mortality, whereas surgery (HR = 0.41, $P < 0.01$), and TAE (HR = 0.13, $P = 0.01$) were inversely associated with post-treatment mortality.

CONCLUSION: Post-treatment survival after surgery or TAE was found to be better than after supportive care, and surgery tended to provide better survival benefit than TAE.

Key words: Ruptured hepatocellular carcinoma; Surgery; Transarterial embolization

Core tip: We have shown here that overall survival rates of patients with ruptured hepatocellular carcinoma (HCC) is significantly higher in patients with surgery or transarterial embolization (TAE) than in those with supportive care, and tended to be higher in patients with surgery than in those with TAE. To date, there has been a dearth of reliable clinical evidence on the merits of surgical treatment versus those of TAE, in the context of survival benefit in patients with a spontaneous HCC rupture. Therefore, the present study may provide useful information for clinicians to determine the most appropriate treatment option for spontaneously ruptured HCC.

Survival outcome of patients with spontaneously ruptured hepatocellular carcinoma treated surgically or by transarterial embolization. *World J Gastroenterol* 2013; 19(28): 4537-4544 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4537.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4537

INTRODUCTION

Hepatocellular carcinoma (HCC) is the worldwide health problem and the third leading cause of cancer-related death globally[1-3]. Despite recent considerable advances in the understanding of tumor biology and the continued progression and development of diagnostic and therapeutic tools[4-7], the overall prognosis of HCC remains disappointing. In particular, due to its hypervascularity, HCC can exhibit rapid progression with direct invasion of surrounding tissues or it can invoke spontaneous tumor rupture[8]. HCC rupture is one of the life-threatening complications of HCC, and therefore, the most efficient treatment modality should be selected and rapidly applied to patients with ruptured HCC.

The incidence of spontaneous HCC rupture has decreased due to the earlier detection of HCC. Nevertheless, its incidence has been reported to be high as 3%-15% and its in-hospital mortality rate to range from 25% to 75% in the acute phase[9-12]. Open surgery was the main method used to treat HCC rupture from the 1960s to the 1980s[13-15]. Recently, survival benefit by transarterial embolization (TAE) has been reported[16-18]. However, to the best of our knowledge, no definite recommendation has been issued regarding optimal treatment of HCC rupture, and the comparative survival benefits of surgery and TAE remain unclear.

Therefore, in this retrospective study, we undertook to evaluate survival outcomes according to treatment modalities, that is, surgery, TAE, or supportive care, in patients with a spontaneously ruptured HCC, and sought to identify the factors that predispose post-treatment mortality in these patients.

MATERIALS AND METHODS

Study subjects

Between August 2003 and February 2012, 1765 consecutive patients were initially diagnosed as having HCC at Inha University Hospital. Of these 1765 patients, 61 (3.5%) patients were clinically diagnosed as having spontaneously ruptured HCC. No patient had recent history of HCC treatment such as surgery or transarterial chemoembolization (TACE) within one month prior to the diagnosis of HCC rupture. HCC was diagnosed according to the diagnostic guidelines issued by the American Association for the Study of Liver Diseases[19]. HCC rupture was defined as disruption of the peritumoral liver capsule with enhanced fluid collection in the perihepatic area adjacent to the HCC by dynamic liver computed tomography (CT)[20], and when abdominal paracentesis showed an ascitic red blood cell count of > 50000 mm^3/mL in bloody fluid[21,22].

Of the 61 patients, 4 patients were excluded because they underwent two-staged surgical treatment after TAE for ruptured HCC (n = 3) and they had concurrent malignancy (gastric cancer, n = 1). Three patients were also excluded because they did not meet the diagnostic criteria of a ruptured HCC although HCC rupture was clinically suspected based on right upper quadrant abdominal pain and a reduced serum hemoglobin level. Therefore, 54 patients finally constituted the study cohort and their retrospective database was analyzed.

Evaluation of patients with ruptured HCC

Database information at time of diagnosis of ruptured HCC was reviewed: age, gender; vital signs; medical history; white blood cell count, hemoglobin, and platelet count; international normalized ratio (INR); serum alanine aminotransferase, bilirubin, albumin, and creatinine; viral hepatitis findings including hepatitis B surface antigen, and anti-hepatitis C virus antibody findings; serologic tests for human immunodeficiency virus; alpha-fetoprotein; and vasopressor requirement. Furthermore, we evaluated HCC tumor statuses namely tumor number, size, presence of portal vein tumor thrombosis, and presence of extra-hepatic metastasis. Intrahepatic HCC lesion size was recorded as the longest diameter of the largest lesion in at least one dimension. Liver cirrhosis was diagnosed based on clinical evidence of portal hypertension (encephalopathy, esophageal varices, ascites, splenomegaly, or platelet count < 100000/mm^3)[23] or by previously performed ultrasonography[24]. Child-Turcotte-Pugh (CTP) and Model for End-stage Liver Disease (MELD) scores were assessed, and HCC staging was performed using the Barcelona Clinic Liver Cancer (BCLC) staging system[25].

Treatment of ruptured HCCs

Immediately following a diagnosis of HCC rupture, patients were transferred to an intensive care unit. At time of HCC rupture, liver functions can be much more ag-

gravated by hemorrhage or shock than after the condition was relatively well controlled. Therefore, frequent assessments of liver function were required concurrently with volume replacement and coagulopathy correction, and liver function was closely monitored before definite treatment decision making. Norepinephrine was infused intravenously as the primary vasopressor if shock event developed, and all 54 patients were administered 3rd generation cephalosporin antimicrobial therapy.

The need for emergency hemostasis, such as, open surgery or TAE, was explained to all patients in the absence of a contraindication and their family members. They were informed of the risks and benefits of emergency surgery or TAE in detail. To avoid any coercion, written informed consent was obtained from all patients and a family member before intervention of hemostasis. The follow were viewed as surgical contraindication: the presence of poorly controlled chronic ascites; the presence of poorly controlled chronic hepatic encephalopathy; the presence of a poor liver function; or a poor performance status. Of the 54 patients enrolled, 6 (11.1%) underwent surgery and 25 (46.3%) TAE, and the remaining 23 (42.6%) patients received supportive care without hemostatic intervention (Figure 1). Successful control of hemorrhage was defined as hemodynamic stabilization, a normal hemoglobin level, and no requirement for further transfusion. During follow-up period after treatment, dynamic liver CT images and serum alpha-fetoprotein levels were obtained every 1-3 mo.

TAE group: In hemodynamically unstable patients with an obvious continuous hemorrhage, TAE was considered if reserved liver function was relatively good regardless of the correction of coagulopathy. Briefly, the tumor location, the active bleeding site, and portal vein patency were determined angiographically. Thereafter, embolization of the feeding artery was performed with gelfoam, which is the small cube of approximately 1 mm^3 sized absorbable gelatin sponge particles. Two patients who underwent TACE were included in the TAE group. However, TACE/TAE was not performed if the main portal vein was completely occluded by tumor thrombus.

Surgical group: After stabilizing hemodynamic status by volume replacement and transfusion, patients underwent a full clinical assessment to evaluate the possibility of surgical treatment. Segmentectomy with perihepatic packing (n = 3, 50%), lobectomy (n = 2, 33.3%), or liver wedge resection with feeding artery ligation (n = 1, 16.7%) were performed depending on circumstances (Figure 1).

Supportive care group: Patients contraindicated for surgery or TACE/TAE received only vigorous and careful conservative treatments with replacement of blood or albumin, correction of coagulopathy, antimicrobial therapy, and analgesics, diuretics, *etc*.

The study protocol was approved by the Institutional Review Board at Inha University Hospital, Incheon 400-711, South Korea.

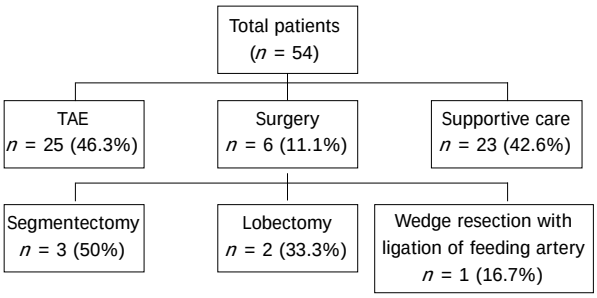

Figure 1 Flow diagram showing the treatment of 54 patients. Of the 54 patients enrolled, 6 (11.1%) underwent surgery and 25 (46.3%) transarterial embolization (TAE), and the remaining 23 (42.6%) patients received supportive care without hemostatic intervention.

Statistical analysis

The baseline characteristics of patients are expressed as medians (ranges) and frequencies. Differences between categorical or continuous variables were analyzed using the χ^2 test, Fisher's exact test, or the Student's t test. Post-treatment cumulative mortality rates were analyzed using Kaplan-Meier survival curves, and group differences were compared using the log-rank test. In patients that received supportive care, survival was defined from diagnosis of HCC rupture to patients' death. Multivariate analysis was performed using a Cox regression hazard model to identify predictors of post-treatment mortality in patients with spontaneously ruptured HCC. Two-tailed P values of less than 0.05 were considered statistically significant in all analyses. Statistical analysis was performed using SPSSv18.0 (SPSS Inc, Chicago, IL, United States).

RESULTS

Baseline characteristics of patients

The baseline characteristics of the 54 patients are summarized in Table 1. Median age was 54 years (range, 30-87 years) and 47 (87.0%) were male. The most common etiology of HCC was hepatitis B virus infection, which was observed in 36 (66.7%) patients. Of the 54 patients, 6 (11.1%) were of CTP class A, 23 (42.6%) were of CTP class B, and 5 (46.3%) were of CTP class C. Eleven (20.4%) of the 54 patients had a single HCC and 43 (79.6%) patients had multiple HCC. Median tumor size was 8.5 cm (range, 2.9-25.5 cm), and 4 (7.4%) patient had HCCs within Milan criteria. Forty-seven (87.7%) patients had nodular type HCC. Before treatment, 0 (0%), 5 (9.3%), 9 (16.7%), 15 (27.8%), and 25 (46.3%) patients were found to have BCLC 0, A, B, C, or D stage HCC, respectively. Median alpha-fetoprotein concentration at diagnosis of HCC rupture was 1158 ng/mL (range, 3.0×10^4-6.1×10^4 ng/mL). Thirteen (24.1%) patients required a vasopressor due to shock at presentation. Ruptured HCC was located on the surface of liver in all the patients.

Comparison of clinical parameters by treatment modality

Clinical variables in the three treatment groups are summarized in Figures 2 and 3, and Table 2. Mean tumor

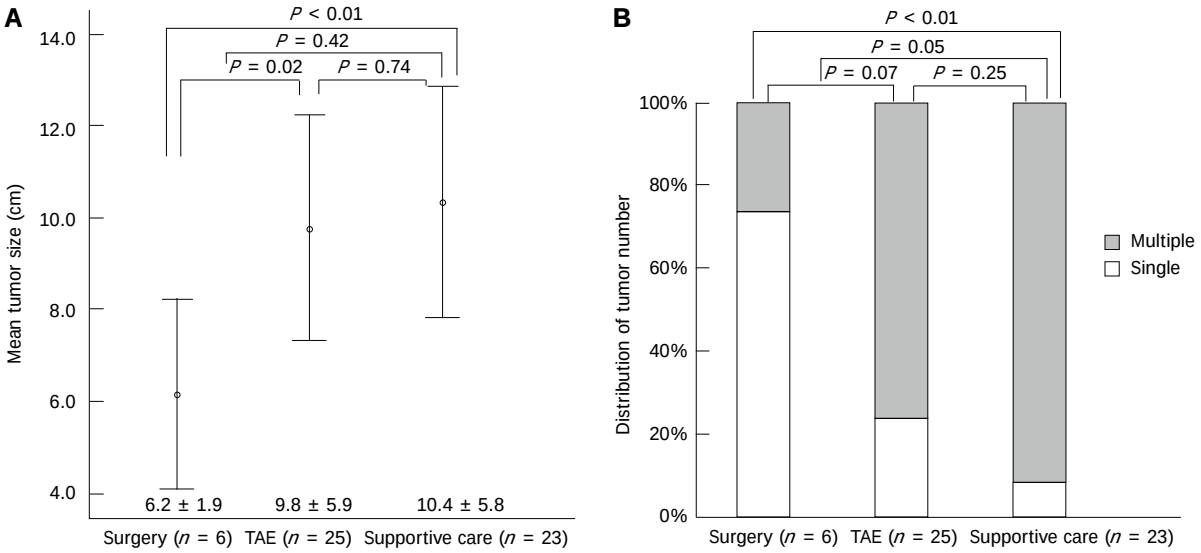

Figure 2 Comparison of clinical parameters in the three treatment groups. A: Mean tumor size was significantly smaller in the surgical group than in the transarterial embolization (TAE) (P = 0.02) or supportive care (P < 0.01) groups; B: The single tumor rate was significantly higher in the surgical group than in the supportive care group (P < 0.01).

Table 1 Baseline clinical characteristics of the 54 patients with ruptured hepatocellular carcinoma *n* (%)

Variable	Total (n = 54)
Age[1], yr	54 (30-87)
Gender (male)	47 (87.0)
Etiology	
HBV/HCV/alcohol/others	36 (66.7)/6 (11.1)/7 (13.0)/5 (9.3)
CTP classification	
A/B/C	6 (11.1)/23 (42.6)/25 (46.3)

Within Milan criteria	4 (7.4)
BCLC stage	
0/A/B/C/D	0 (0.0)/3 (5.6)/8 (14.8)/15 (27.8)/28 (51.9)
Vasopressor requirement	13 (24.0)
Alpha-fetoprotein[1], ng/mL	1158 (3.0×10^4-6.1×10^4)

[1]Median (range). HBV: Hepatitis B virus; HCV: Hepatitis C virus; CTP: Child-Turcotte-Pugh classification; BCLC: Barcelona Clinical Liver Cancer.

size was significantly smaller in the surgical group than in the TAE (P = 0.02) or supportive care (P < 0.01) groups (Figure 2A). The single tumor rate was significantly higher in the surgical group than in the supportive care group (P < 0.01) (Figure 2B). Furthermore, the surgical group had better reserve hepatic function (CTP class) than the other two groups (both P < 0.01) (Figure 3A). Mean MELD score was higher in the supportive care group than in the other two groups (both P = 0.01), but was not different in the surgical and TAE groups (P = 0.24) (Figure 3B).

Serum platelet count (P = 0.03), total bilirubin (P < 0.01), and creatinine levels (P < 0.01) were significantly lower in surgical group than supportive care group (Table 2). The other clinical parameters including age, gender, and tumor type showed no difference among three treatment groups. Incomplete hemostasis occurred in 1 (16.7%) patient in the surgical group and in 5 (20%) patients in the TAE group (P = 1.00), and post-treatment liver failure occurred in 0 (0%) patient in the surgical group and in 1 (5%) patient in the TAE group (P = 0.31). Rebleeding after complete hemostasis was observed in 0 (0%) patients in the surgical group and in 1 (5%) patient in the TAE group (P = 1.00), and they received supportive care (Table 2).

Cumulative overall survival of ruptured HCC patients according to treatment types

One-month overall cumulative mortality for the 54 study subjects was 63.8%. Cumulative survival rates at 2-, 4- and 6-mo were 60.0%, 60.0% and 60.0%, respectively, in the surgical group and 36.0%, 20.0% and 20.0%, respectively in the TAE group, and 8.7%, 0% and 0%, respectively in the supportive care group (each, P < 0.01). Cumulative survival rates at 2-, 4- and 6-mo were tended to be higher in the surgical group than in the TAE group despite the statistical insignificance (P = 0.14) (Figure 4A). Cumulative survival rates at 2-, 4- and 6-mo were 50.2%, 40.1% and 33.1%, respectively in the intervention group such as surgery or TAE, and 8.7%, 0% and 0%, respectively, in the supportive care group (P < 0.01) (Figure 4B).

Multivariate analysis for predictors of post-treatment mortality

Multivariate analysis showed that surgery (HR = 0.41, P < 0.01), and TAE (HR = 0.13, P = 0.01) were inversely associated with post-treatment mortality in ruptured HCC patients. Serum bilirubin (HR = 1.09, P < 0.01), creatinine (HR = 1.46, P = 0.04), and vasopressor use (HR = 2.37, P = 0.02) were positively associated with post-treatment mortality. Age, gender, INR, albumin, tumor

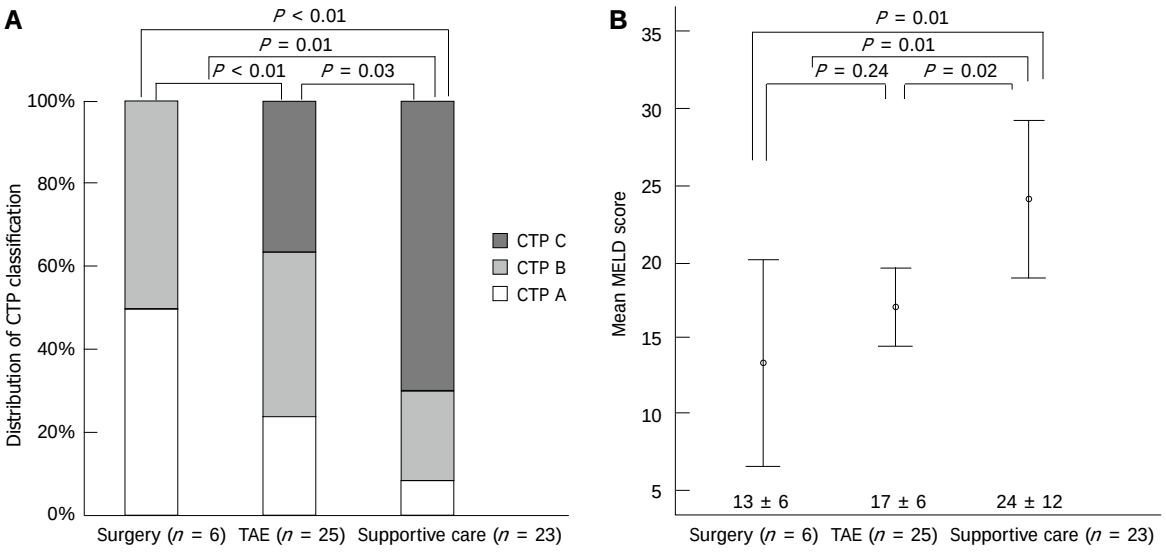

Figure 3 Comparison of Child-Turcotte-Pugh and Model for End-stage Liver Disease scores in the three treatment groups. A: The surgical group had better reserve hepatic function [Child-Turcotte-Pugh (CTP) class] than the other two groups (both $P < 0.01$); B: Mean Model for End-stage Liver Disease (MELD) score was higher in the supportive care group than in the other two groups (both $P = 0.01$), but was not different in the surgical and transarterial embolization (TAE) groups ($P = 0.24$).

size, and tumor number were not found to be associated with post-treatment mortality (Table 3).

DISCUSSION

We have shown here that overall survival rates of patients with ruptured HCC is significantly higher in patients with surgery or TAE than in those with supportive care, and tended to be higher in patients with surgery than in those with TAE. Furthermore, high serum bilirubin and creatinine levels, and vasopressor requirement were found to be significantly associated with post-treatment mortality. To our knowledge, this is the first study to investigate the survival benefit of surgery *vs* TAE. Although several previous studies have evaluated the therapeutic efficacy of surgery or TAE, in patients with spontaneous HCC rupture, direct comparative information is little available regarding survival outcomes after surgery and TAE in such patients.

Spontaneous HCC rupture is likely to occur in patients with advanced staged HCC with reported incidences of 10.0% in Japan[15], 12.4% in Thailand[10], and about 3.0% in the United Kingdom[26]. In the present study, the estimated incidence of spontaneous HCC rupture was 3.5%, and the overall 1-mo mortality was a high as 64% in our cohort, which are the similar to the outcomes of previous studies[10,11,27]. However, despite its high mortality, survival benefits for surgical treatment[13-15] and for TAE[16-18] have been reported in patients with a spontaneous HCC rupture. Likewise, in the present study, the

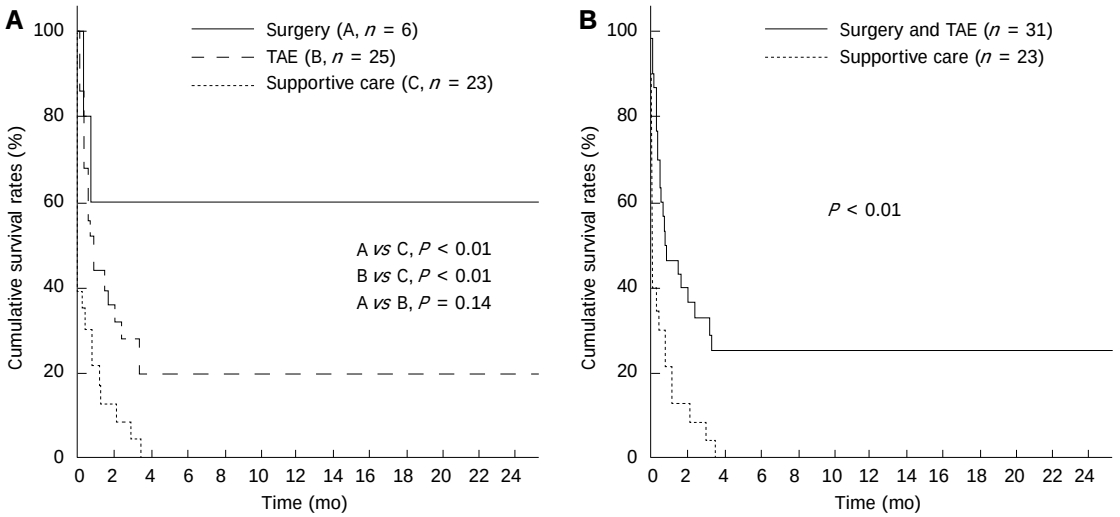

Figure 4 Cumulative overall survival according to treatment types. A: Cumulative survival rates at 2-, 4- and 6-mo in the surgical group or in the transarterial embolization (TAE) group were significantly higher in the supportive care group (each, $P < 0.01$); B: Cumulative survival rates at 2-, 4- and 6-mo were significantly higher in the intervention group such as surgery and TAE than in the supportive care group ($P < 0.01$).

Subjects, $n = 54$; event, patient death after treatment ($n = 47$). [1]Cox proportional hazards model. CTP: Child-Turcotte-Pugh classification; AFP: Alpha-fetoprotein; TACE: Transarterial chemoembolization; TAE: Transarterial embolization; INR: International normalized ratio.

overall survivals of patients with surgery or TAE were significantly higher than that in those with supportive care, especially in those in a hemodynamically stable state with a low serum bilirubin level, and good renal function. However, to date, there has been a dearth of reliable clinical evidence on the merits of surgical treatment versus those of TAE, in the context of survival benefit in patients with a spontaneous HCC rupture. Therefore, the present study may provide useful information for clinicians to determine the most appropriate treatment option for spontaneously ruptured HCC.

Ruptured HCC is a catastrophic disorder characterized by fatal complications, such as, coagulopathy, hemodynamic instability, or liver insufficiency. Thus, treatment should be considered carefully based on adequate information. As has been found in previous studies[13-15], surgical treatment was found to provide significant survival benefit as compared with supportive care in the current study. Furthermore, surgical group had relatively better hepatic function reserve, smaller tumors, and smaller numbers of tumors than the supportive care groups, although bias might have been introduced by selection for surgery. Nonetheless, the cumulative overall survival rate was higher in surgical group than in the supportive care group, and surgical treatment was found to be independent predictor of post-treatment survival by multivariate analysis. Although not all patients could have undergone surgery due to a poor hepatic function or an unstable vital status, surgical hemostasis can be considered if hepatic dysfunction or hemodynamic instability can be maximally corrected immediately after initial rupture of a hepatoma. Furthermore, post-surgical complications need to be considered before treatment decision-making despite the absence of an immediate severe complication after surgical intervention in the present study.

It has been reported that TAE is effective in achiev-

ing immediate hemostasis for ruptured HCC. In the present study, the overall survival rate was better in the TAE group than in the supportive care group. Advanced angiographic techniques enable the tumor location, active bleeding focus, and portal vein patency to be assessed, but life-threatening complications, such as, liver failure can developed after TAE, at rates ranging from 12% to 34%[12,17]. In the present study, post-TAE liver failure and technical failure for immediate hemostasis was observed in 6 (24%) and 5 (20%) patients of the TAE group, respectively, which suggests that TAE should be selectively administered in patients with good reserved hepatic function, tolerable coagulopathy, and a patent main portal vein.

In terms of comparison of survival benefits between the surgical and TAE groups, the current study failed to show a significant difference, although the cumulative overall survival rate tended to be higher in the surgical treatment group. Although TAE is less invasive than open surgical hemostasis, we suppose that open surgical treatment offer a higher chance of successfully achieving hemostasis by removing the bleeding focus or by allowing complete ligation of feeding artery. In previous studies, the 30-d mortality rate after TAE group has been reported to be lower than that after open surgical group[12,17,28]. However, in the present study, cumulative overall 1-mo survival rates were statistically similar between two groups. Moreover, at 1 mo after operative treatment, cumulative survival was clinically higher in the surgical group than in the TAE group despite the statistical insignificance (Figure 4). However, it should be borne in mind that this lack of significance may have been due to small patient numbers. Therefore, large number of patients who underwent surgical treatment need to be evaluated in the comparative study in the future.

Patients with a poor liver function reserve cannot tolerate surgical resection or aggressive angiographic intervention. Therefore, CTP class or MELD score, which reflect reserved hepatic function, could be important pretreatment factors. However, in the present study, of variables comprising the CTP class, only serum bilirubin was found to be independently associated with post-treatment survival. Likewise, of the variables comprising the MELD scores, only serum bilirubin and creatinine were found to be independent factors. Therefore, we estimated individual variables of CTP class or MELD score to avoid overestimation of the other factors in the multivariate analysis of post-treatment survival in patients with spontaneous HCC rupture.

Elevated serum creatinine and vasopressor requirements are likely to reflect multiorgan failure[29], and decreased effective circulating volume or the presence of superimposed infection may induce alterations in organ perfusion and in hemodynamic stability. Moreover, inflammatory reactions triggered by hepatocellular necrosis after HCC rupture may contribute to liver insufficiency, and subsequent multiorgan failure. Although decreased serum albumin level and a prolonged prothrombin time suggest reduced liver synthetic function, they can be corrected by albumin and coagulation factor replacement. On the other hand, serum bilirubin level cannot be rapidly and artificially corrected immediately after parenchymal liver damage. Therefore, serum bilirubin may be an independent factor of patient survival, unlike serum albumin or INR. Furthermore, the importance of serum bilirubin level in patients with HCC rupture has been previously reported[17,30]. However, during treatment decision-making, age, INR, albumin, and tumor size and number may also be clinically important variables despite their lack of statistical significance in the present study.

Our study has several limitations. First, the study is inherently limited by its retrospective study design. However, we enrolled all eligible patients. Second, the varied clinical and tumor statuses of patients and the critical disease status prevented randomization, and probably introduced bias. Furthermore, it takes long time to collect the prospective database of patients due to low incidence of the disease. Third, the absolute number of patients who underwent surgery was small, and therefore, there might be no significant difference in cumulative survival rate between surgery and TAE groups. Accordingly, we suggest a large-scale study be conducted to confirm our study.

In conclusions, the present study suggests that the post-treatment outcomes of surgery or TAE are better than that of supportive care in patients with spontaneous HCC rupture, and that surgical hemostasis might provide better survival benefit than TAE. However, we advise that serum bilirubin, creatinine, and hemodynamic status should be considered during treatment decision making. Regardless of its shortcomings, we believe that the present study would provide important information that aids decision making in patients with spontaneous HCC rupture.

COMMENTS

Background

Hepatocellular carcinoma (HCC) rupture is one of the life-threatening complications of HCC, and therefore, the most efficient treatment modality should be selected and rapidly applied to patients with ruptured HCC.

Research frontiers

Recently, survival benefit by transarterial embolization (TAE) has been reported. However, no definite recommendation has been issued regarding optimal treatment of HCC rupture, and the comparative survival benefits of surgery and TAE remain unclear.

Innovations and breakthroughs

The present study suggests that the post-treatment outcomes of surgery or TAE are better than that of supportive care in patients with spontaneous HCC rupture, and that surgical hemostasis might provide better survival benefit than TAE.

Applications

This study may provide useful information for clinicians to determine the most appropriate treatment option for spontaneously ruptured HCC.

Peer review

It is a rare situation specially for Western Europe, so it is good to know the experience of the group.

Abstract

AIM: To investigate the differences in the mutation spectra of the *SLC25A13* gene mutations from specific regions of China.

METHODS: Genetic analyses of *SLC25A13* mutations were performed in 535 patients with neonatal intrahepatic cholestasis from our center over eight years. Unrelated infants with at least one mutant allele were enrolled to calculate the proportion of *SLC25A13* mutations in different regions of China. The boundary between northern and southern China was drawn at the historical border of the Yangtze River.

RESULTS: A total of 63 unrelated patients (about 11% of cases with intrahepatic cholestasis) from 16 provinces or municipalities in China had mutations in the *SLC25A13* gene, of these 16 (25%) were homozygotes, 28 (44%) were compound heterozygotes and 19 (30%) were heterozygotes. In addition to four well described common mutations (c.851_854del, c.1638_1660dup23, c.615+5G>A and c.1750+72_1751-4dup17insNM_138459.3:2667 also known as IVS16ins3kb), 13 other mutation types were identified, including three novel mutations: c.985_986insT, c.287T>C and c.1349A>G. According to the geographical division criteria, 60 mutant alleles were identified in patients from the southern areas of China, 43 alleles were identified in patients from the border, and 4 alleles were identified in patients from the northern areas of China. The proportion of four common mutations was higher in south region (56/60, 93%) than that in the border region (34/43, 79%, χ^2 = 4.621, P = 0.032) and the northern region (2/4, 50%, χ^2 = 8.288, P = 0.041).

CONCLUSION: The *SLC25A13* mutation spectra among the three regions of China were different, providing a basis for the improvement of diagnostic strategies and interpretation of genetic diagnosis.

Key words: Citrin deficiency; Mutation spectrum; Intrahepatic cholestasis; *SLC25A13*

Core tip: Genetic testing of *SLC25A13* gene was performed in individuals from southern, border and northern regions of China. The proportion of four common mutations was significant higher in southern region than in the border region and the northern region, so mutation screening for the common 4 mutations an appropriate test in the southern region. In the border and northern region, DNA sequencing is probably more practical.

Chen R, Wang XH, Fu HY, Zhang SR, Abudouxikuer K, Saheki T, Wang JS. Different regional distribution of *SLC25A13* mutations in Chinese patients with neonatal intrahepatic cholestasis. *World J Gastroenterol* 2013; 19(28): 4545-4551 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4545.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4545

INTRODUCTION

Citrin deficiency is estimated to be the most common urea cycle disorder in the world. It is an autosomal recessive disorder which includes adult-onset type Ⅱ citrullinemia (CTLN2; OMIM #60347)[1,2] and neonatal intrahepatic cholestasis caused by citrin deficiency (NICCD; OMIM #605814)[3-5]. Most NICCD patients show symptoms which ameliorate by 1 year of age[6], but some patients may progress to liver failure and even require liver transplantation during infancy[7-10]. Others may develop CTLN2 more than a decade later[11,12]. Dietary treatment has shown to ameliorate symptoms and may prevent the need for transplant[13,14]. Therefore, prompt diagnosis and appropriate management are important for achieving a favorable long term prognosis for this disease.

Citrin deficiency is caused by mutations in the *SLC25A13* gene[1,15]. The protein product of the *SLC25A13* gene is citrin, a polypeptide of 675 amino acid residues with a molecular weight of 74 kDa. Citrin contains four EF-hand domains and six mitochondrial transmermbrane (TM)-spanning domains, and resides in the mitochondrial inner membrane[1]. Citrin is expressed in the liver and functions as calcium (Ca^{2+})-stimulated aspartate-glutamate carrier (AGC) for cytosolic glutamate and protons[16]. Over 60 different functional proved mutations in the human *SLC25A13* gene have been identified. These show significant differences in their racial distribution[13,17-20]. In China, the carrier frequency of 4 most common known mutations shows significant regional difference[19,20]. The estimated carries in population are 1/48 in south of the Yangtze River and 1/940 are carries of the river in the North[19].

Currently common mutation screening is used for rapid molecular diagnosis[21]. However, the appropriateness of use in specific populations needs to be established in that population. Therefore, we undertook the present study to investigate the regional distribution of *SLC25A13* mutations spectrum in Chinese patients with neonatal intrahepatic cholestasis. Our results will facilitate the design of appropriate screening strategies for this disorder in different regions.

MATERIALS AND METHODS

Subjects

Between June 2003 and December 2011, patients with cholestasis who were referred to the pediatric liver center of Children's Hospital of Fudan University for conjugated hyperbilirubinemia were enrolled. The inclusion criteria included the onset of conjugated jaundice before 6 mo of age; serum total bilirubin < 5 mg/dL and conjugated bilirubin > 1 mg/dL, or total bilirubin > 5 mg/dL and conjugated bilirubin > 20%[22]. We excluded other diseases that may affect the extrahepatic biliary system, such as biliary atresia, choledochal cyst, tumor, inspissated bile, or hemangioma, by imaging the hepatobiliary system. The imaging procedures included ultrasound scanning and hepatobiliary iminodiacetic acid (HIDA) scintigraphy in each case and laparotomic cholangiography in selected cases. Cases (n = 535) met the inclusion criteria and written informed consent was obtained from their parents.

The study protocol conforms to the ethical guidelines of the Declaration of the Helsinki of 1975 and was approved by the Ethics Committee on human research of the Children's Hospital of Fudan University.

Mutation identification

DNA was extracted from peripheral blood samples, which were obtained from each participant and his or her parents using the Tiangen Blood Genomic DNA Isolation Kit according to the manufacturer's instructions (Tiangen Biotech, Shanghai, China). Four common mutations (c.851_854del, c.1638_1660dup23, c.615+5G>A and c.1750+72_1751-4dup17insNM_138459.3:2667 also known as IVS16ins3kb)[1,20,23] were screened in all subjects. In patients for whom only one mutation was identified by the above screening or who had hyperaminoacidemia were subject to DNA sequencing as described previously[24]. Selection process of patients with mutant allele for analysis is given in Figure 1. The mutation alleles were verified in their parents by the target sequencing to establish segregation. Genomic sequences were obtained at the National Center for Biotechnology Information with RefSeq NM_014251.2 as *SLC25A13* reference. Nomenclature of *SLC25A13* variants was assigned following the guidelines of Human Genome Variation Society (http://www.hgvs.org/mutnomen)[25].

Geographical division

The population boundary between northern and southern China is drawn at the historical border of the Yangtze River during early Neolithic times (3000-7000 years ago)[26]. According to this criteria, Zhejiang, Jiangxi, Fujian, Guangdong, Hunan, Guizhou, Taiwan are classified as southern areas as they are south of Yangtze River; the provinces of Jiangsu, Shanghai, Anhui, Hubei, Sichuan and Chongqing are classified as border areas as they are in the basin of the Yangtze River; and the provinces of Henan, Liaoning, Shanxi, Jilin, Shandong, Hebei and Ningxia are classified as northern areas as they are in north of Yangtze River (Figure 2).

Patients with at least one mutated *SLC25A13* allele were selected. To calculate the mutation spectra, the mutations observed in the related family members were counted only once. If the patient was a heterozygote or a compound heterozygote and the parents were from

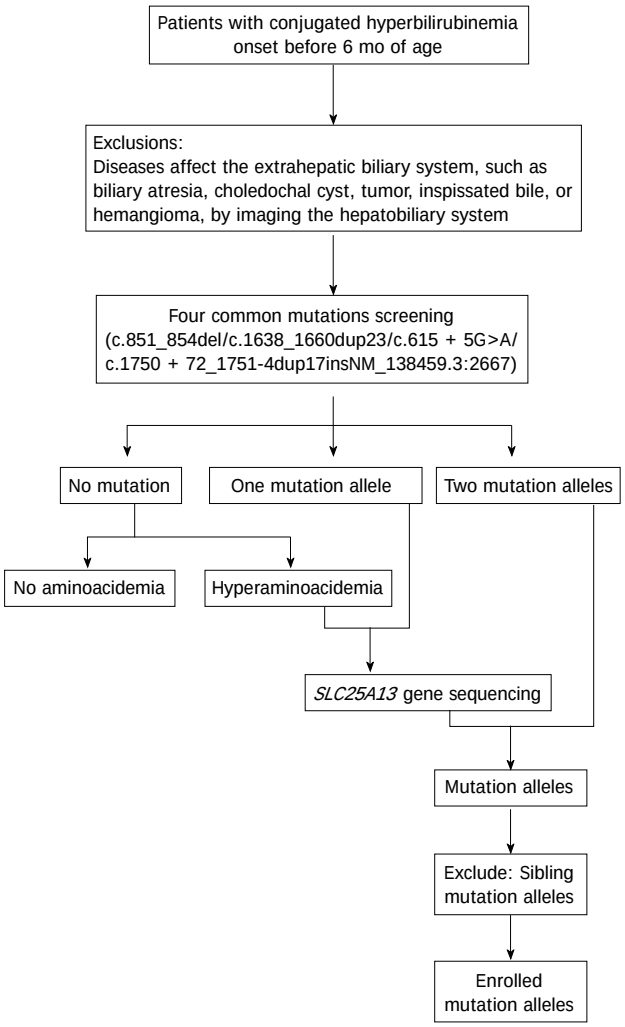

Figure 1 Selection process of patients with mutant allele for analysis.

different regions, the parent's sample was tested to determine the origin of the allele(s). Except for two patients who were born from consanguineous parents, all other infants were to our knowledge unrelated.

Homology and structural predictions

The homology between the mutated Citrin protein and the human reference, as well as Citrin from other species, were surveyed using Clustal X software (European Bioinformatics Institute, Hinxton, Saffron Walde, United kingdom). PolyPhen-2 (Polymorphism Phenotyping version2.2.2), which is available at http://genetics.bwh.harvard.edu/pph2/, was used to predict the possible impact of an amino acid substitution on the structure and function of the Citrin protein. MutationTaster was used to evaluate the disease-causing potential of sequence alterations, at http://mutationtaster.org/MutationTaster/index.html. A *P* value close to 1 indicates a high 'security' of the prediction. MutationTaster employs a Bayes classifier to eventually predict the potential of an alteration causing disease. The Bayes classifier is fed with the outcome of all tests and the features of the alterations and calculates probabilities for the alteration to be either disease causing or not.

Statistical analysis

Statistical tests on the distribution of mutant genotypes in the three areas of China were assessed by performing a 2×2 χ^2 test with the SPSS version 17.0 software (University of Chicago, Chicago, IL, United States) package. A P value < 0.05 was considered to be statistically significant. When there are small expected values in the 2×2 table, the result of fisher's exact test was used.

RESULTS

General information

Among the 535 patients, 183 originated from the southern area, 291 were from the border area and 61 were from the northern area. Sixty-nine patients with at least one *SLC25A13* gene mutation were found, including 6 sibling pairs. These sixty-three unrelated patients, including 25 females and 38 males, were further analyzed. Sixteen (25%) were found to be homozygotes for one mutation, 28 (44%) were compound heterozygotes and 19 (30%) heterozygotes for only one mutation. The distribution of carriers according to the state of origin is depicted in Figure 2.

Mutation types

A total of 17 mutations, including 14 mutations that had been previously reported by us and others (c.851_854del, c.1638_1660dup23, c.615+5G>A, c.1750+72_1751-4dup17insNM138459.3:2667, c.1019_1177del, c.1801G>A, c.550C>T, c.1078C>T, c.955C>T, c.1754G>A, c.775C>T, c.1092_5delT, c.615+1G>A, c.254T>C)[17,20,24,27-30] and 3 novel mutations (c.985_986insT, c.287T>C, c.1349A>G),were observed in the present investigation (Table 1).

Analysis of 3 previously unreported variants

The c.287T>C mutation in exon 4 is predicted to result in the substitute of phenylalanine to serine at position 96 (p.F96S). This mutation was found in a compound heterozygote state with the mutations c.851_854del. p.F96S is located between the second and third EF-hand domain, which is highly conserved in different species (Table 2). The Polymorphism Phenotyping for the variant amino acid p.F96S from Polyphen 2 is 1.000, indicating that the missense mutation has a high chance of affecting protein function. The *P* value from MutationTaster is 0.997, suggesting that is most likely a disease-causing mutation.

Mutations c.985_986insT and c.1349A>G were found in compound heterozygote state in a patient. The mutation c.985_986insT was found to be derived from this patient's paternal allele and predicted to result in a frame shift and the introduction of a premature stop codon at position 372. Mutation c.1349A>G (p.E450G) was derived from the patient's maternal allele, which is located in the loop between the TM3 and TM4 spanning regions. Conservation analysis in different species indicated that the amino acid in this position is highly conserved (Table 2). The Polymorphism Phenotyping for the variant amino

Figure 2 Distribution of mutant alleles enrolled in this study. As shown in the map, the provinces were separated into three parts by the Yangtze River. The numbers in parentheses are the number of mutation c.851_854del/c.1638_1660dup23/c.615+5G>A/c. 1750+72_1751-4dup17ins NM_138459.3:2667/other alleles.

Allele counts for the mutations are given together with their relative frequencies expressed as percentage value (in brackets). Novel mutations found in this study are indicated by bold letters. Variation in allele proportion (counts) between the three regions: $^1\chi^2 = 4.621$, $P = 0.032$, common mutation in south *vs* in border; $^2\chi^2 = 8.288$, $P = 0.041$, common mutation in south *vs* in north. GenBank reference sequences were NT_079595 and NM_014251.2.

acid p.E450G was 1.000, indicating a high chance of affecting protein function. The *P* value from MutationTaster is more than 0.999, suggesting that the mutation might affect the protein's features.

Distribution of SLC25A13 gene mutations

The distribution of *SLC25A13* mutations in carriers originating from different regions of China is given in Figure 1. Sixty (56%) mutant alleles originated from the southern region with Zhejiang, Jiangxi, Fujian, Guangdong, Hunan, Guizhou, and Taiwan accounting for 27, 15, 9, 1, 4, 3 and 1 mutant allele, respectively. Forty-three mutant alleles (40%) originated from the border region, with Jiangsu, Shanghai, Anhui, Hubei, Sichuan, and

Chongqing accounting for 14, 6, 12, 4, 5 and 2, respectively. In the northern region, only four mutant alleles (4%) were found, including 1 from Henan, 1 from Liaoning and 2 from Shanxi provinces.

The *SLC25A13* mutation spectra among the three regions of China presented significant differences. The four common mutations exhibited maximal relative frequencies in the southern China (56/60, 93%), and four other mutations were detected, including two novel mutations. On the contrary, in the area bordering the Yangtze River, there was a wide range of mutation types. The four common mutations accounted for 79% (34/43) of the mutant alleles, and eight other mutation types were found, including one novel mutation. In northern China the mutation c.851_854del accounted for 50% (2/4) of the mutant alleles. The other two mutations were c.1019_1177del and c.1078C>T. The proportion of the four common mutations was higher in south region (93%) than that in the border region (79%, χ^2 = 4.621, P = 0.032) and that in the north (50%, χ^2 = 8.288, P = 0.041) (Table 1).

Among the four common mutations, c.851_854del was the most. Proportion accounts for 68% (41/60) in southern region, 51% (22/43) in the border region and 50% (2/4) in the northern region. The difference of the proportion between the southern and border part of China was marginally significant (χ^2 = 3.109, P = 0.078).

DISCUSSION

The mutation spectra for the *SLC25A13* gene differ within the Asian population[18-20]. A different carrier rate for the common mutations between different parts of China has been reported[19,30]. Here we demonstrate that the mutation spectrum of *SLC25A13* gene varies considerably among specific regions of China with common mutations having a higher proportion in the southern region than in the border and northern regions.

In the southern region of China, four common mutations accounted for 93% and c.851_854del is the predominant mutation accounting for 68%. This is consistent with the published data[19,30]. The c.851_854del mutation is a common ancestral mutation, and the frequency difference between various regions of China may be associated with ancient migration.

The mutations found in patients from the border region exhibited significant variety. The total mutant allele number in patients from the border was less than that in patients from the southern region (43 *vs* 60), but the mutation types were much greater than that in the southern area (12 *vs* 8). In total, seven private mutations were found in patients from the border, compared with three private mutations found in patients from the southern region. This divergence may reflect the ethnic diversity of this area. Previously, the data on *SLC25A13* mutations in this region were very limited. This study is the first paper providing an estimate for the border region and significantly increases the data on southern and northern China. Considering the high proportion of uncommon mutations, the previously reported *SLC25A13* mutation carrier rate in this region may be underestimated and sequencing may be a prefect method for testing.

The c.851_854del mutation was the only one of the four common mutations detected in the northern region. The explanation for this may be that other common mutations are rare in that part of China. Two mutant c.851_854del alleles were found among the 4 known mutant alleles, suggesting mutation 851del4 is the frequent mutation in this region.

Since variants c.287T>C and c.1349A>G have not undergone functional testing, so we analyzed the data without these and statistical significance was reached even when those two variants were removed from the analysis. The proportion of the four common mutations was also higher in southern region (95%) than the border (81%, χ^2 = 4.929, P = 0.048) and the northern region (50%, χ^2 = 10.343, P = 0.029). Thus the primary conclusion remains valid.

This paper is the first study conducted the *SLC25A13* mutation spectrum in neonatal intrahepatic cholestasis

from different parts of China. The previous study evaluated the population frequency for the common mutations and conducted that the carrier frequency in China is 1/79-1/65[17,19]. Conversely only 94% (59/63) of cases with suspected citrin deficiency in our study had the common mutations. This suggests that point mutation testing alone is not sufficient to exclude citrin deficiency even in cases from the southern region but may be a cost effective way of confirming the diagnosis as the first step.

There were limitations of this study. Firstly, only a small number of patients came from the north of the Yangtze River, and only limited cases were reported from that area, so the sampling bias needs to be considered. The current literature has not shown a significant difference between *SLC25A13* mutation types and the phenotype observed, so the smaller sample size is not likely to lead to referral bias in favor of null or missense mutations in this study. Secondly, for 19 of the 126 alleles, we could not find any mutations. One possible explanation could be that the patients with one detected mutant allele are carriers and this may be a risk factor for cholestasis or they may have an alternate cause for cholestasis. Alternatively, as previously described[31,32] they may have a second mutation not detected by Sanger sequencing or the targeted test for the IVS16ins3kb rearrangement such as intronic mutations or large rearrangements.

In conclusion, the mutation spectra of the *SLC25A13* gene are significantly different among patients with neonatal intrahepatic cholestasis from different parts of China. These differences should be considered when establishing a molecular diagnostic strategy or interpreting their results.

ACKNOWLEDGMENTS

We thank David P Dimmock for helpful discussions and comments on an initial version of the manuscript. We also thank the patients and their parents for their kind cooperation as well as the physicians who referred the patients.

COMMENTS

Background

SLC25A13 gene mutations lead to Citrin deficiency, which includes adult-onset type Ⅱ citrullinemia and neonatal intrahepatic cholestasis caused by citrin deficiency. The carrier frequency is high in Asian populations, and the mutation spectrum of *SLC25A13* gene in Chinese population (most came from southern China) was found to be different from that of other population groups in East Asia.

Research frontiers

The mutant alleles of *SLC25A13* gene was conducted in southern, border and northern regions of China, providing a basis for the improvement of diagnostic strategies and interpretation of genetic diagnosis.

Innovations and breakthroughs

The proportion of four common mutations was higher in the southern region (56/60, 93%) than that in the border region (34/43, 79%, χ^2 = 4.621, P = 0.032) and the northern region (2/4, 50%, χ^2 = 8.288, P = 0.041). Three novel mutations were found, which has expanded the *SLC25A13* mutation spectrum.

Applications

The mutation spectra of the *SLC25A13* gene are significantly different among patients with neonatal intrahepatic cholestasis from different parts of China. These differences should be considered when establishing a molecular diagnostic strategy or interpreting their results.

Terminology

An allele is a single copy of a gene. For autosomal genes, an individual inherits two alleles at each locus, with one from each parent. Genotypes are described as homozygous if the two alleles are the same and as heterozygous if the alleles are different. The mutant allele is the mutated form of a gene.

Peer review

This is a retrospective study aimed at investigating the regional distribution of *SLC25A13* mutations in Chinese patients with neonatal intrahepatic cholestasis. The topic is relevant, since biochemical diagnosis of citrin deficiency is not widely available and mutation analysis of the *SLC25A13* gene is crucial to diagnosis. The study was well-conducted and the manuscript is reasonably well written with good scientific value.

Abstract

AIM: To investigate the efficacy and safety of capecitabine and oxaliplatin (CapeOx) for extrahepatic metastasis after local treatment of hepatocellular carcinoma (HCC).

METHODS: Thirty-two patients with extrahepatic metastasis of HCC after local treatment were prospectively enrolled. The CapeOx regimen consisted of capecitabine 1000 mg/m^2 taken orally twice daily on days 1-14, and oxaliplatin was administered at a total dose of 100 mg/m^2 on day 1. The treatment was repeated every 3 wk until disease progression or unacceptablle toxicity. Efficacy and safety were assessable for all enrolled patients. The primary objective of this study was to assess the overall response rate. The secondary objectives were to evaluate the overall survival (OS), the time to tumor progression (TTP) and the toxicity profile of the combined strategy. TTP and OS were assessed by the Kaplan-Meier method and differences between the curves were analyzed using the log-rank test. The statistical software SPSS version 15.0 for Windows (SPSS Inc., Chicago, IL, United States) was used for statistical analysis. All *P* values were 2-tailed, with statistical significance defined by $P \leqslant 0.05$.

RESULTS: Thirty-two patients were assessable for efficacy and toxicity. The median follow-up duration was 15 mo (range, 12-20 mo). At the cut-off date of March 31, 2012, 27 patients died due to tumor progression and one patient died of myocardial infarction. Four patients were still alive (three patients with disease progression). OR was 21.9% (n = 7), the stabilization rate was 40.6% (n = 13), and the disease control rate was 62.5%. The responses lasted from 4 to 19 mo (median, 6 mo). Median TTP was 4.2 mo (95%CI: 2.5-7.4), and the median OS time was 9.2 mo (95%CI: 6.5-17.8). The 1-year survival rate was 43.6% (95%CI: 29.0-66.0). In a multivariate analysis, OS was significantly longer in patients with a Child-Pugh class A compared with class B patients (P = 0.014), with a median OS of 10.1 mo *vs* 5.4 mo, and there were trends towards longer OS (P = 0.065) in patients without portal vein tumor thrombosis. There were no significant effects of age, gender, performance status, cirrhosis, metastatic sites, and level of alpha fetoprotein (AFP) or hepatitis B virus-DNA on OS. Among the 22 patients with elevated AFP levels at baseline ($\geqslant$ 400 ng/mL), the level fell by more than 50% during treatment in 6 patients (27.3%). The most frequent treatment-related grade 3 to 4 toxicities included leucopenia/neutropenia, transient elevation of aminotransferases, hand-foot syndrome and fatigue.

CONCLUSION: CapeOx showed modest anti-tumor activity in metastatic HCC. However, the manageable

toxicity profile and the encouraging disease control rate deserve further study for these patients.

Key words: Hepatocellular carcinoma; Extrahepatic metastasis; Capecitabine; Oxaliplatin; Local treatments

Core tip: Distant metastases are still obstacles in improvement of outcome in hepatocellular carcinoma (HCC) patients after local treatment. Although, sorafenib is used as a standard systemic treatment for those patients, it is not suitable for patients with intermediate HCC who were not eligible to or failed in the locoregional therapy. This study reports the capecitabine and oxaliplatin regimen for extrahepatic metastasis after local treatment of HCC. The objective response rate was 21.9%, and 40.6% of patients had stable disease, and the median overall survival and the time to tumor progression were 4.2 and 9.2 mo, respectively. Furthermore, the result of this study showed that toxicity profile was tolerated well.

INTRODUCTION

Hepatocellular carcinoma (HCC) is the second leading cause of cancer-related deaths worldwide, with the incidence on the rise[1]. The overall 5-year survival rate for all HCC patients has remained no more than 5%[2]. Surgical resection, local ablation, transarterial chemoembolization (TACE) and liver transplantation are the mainstay of treatment of localized HCC, but local recurrence and distant metastasis are still obstacles in the further improvement of outcome in HCC patients after local treatments. Sorafenib, a small molecule multikinase inhibitor, was the first systemic agent used to prolong survival of patients with advanced HCC, as demonstrated in two phase Ⅲ trials and it is now the reference standard for systemic treatment of these patients[3,4]. However, its efficacy and safety have not been demonstrated in patients with poor liver function (Child-Pugh class B)[5]. Moreover, patients with extrahepatic metastasis had a greater risk of death than those with intrahepatic disease treated by sorafenib[6]. Systemic treatment with oral targeted therapy may be lifelong and expensive. In addition, sorafenib is not covered in the scope of health insurance for advanced HCC in China. Therefore, systemic treatment options remain to be defined in patients with extrahepatic metastasis of HCC after local treatments.

Capecitabine is a rationally designed, orally administered, tumor-selective fluoropyrimidine that mimics continuous infusion of 5-fluorouracil (5-FU). Capecitabine was found to be safe in patients with cirrhosis and provided an 11% response rate (RR) including radiologically confirmed complete response (CR) in one patient[7]. Oxaliplatin has consistently shown preclinical and clinical anti-tumor activity against gastrointestinal cancers. In metastatic colorectal cancer, oxaliplatin in combination with 5-FU resulted in response rates of 20%-50% and median progression-free survival (PFS) of approximately 7.5-9.0 mo in randomized trials[8]. A phase Ⅲ study of 5-FU/oxaliplatin conducted in Asian patients suffering from inoperable or metastatic HCC showed the feasibility and demonstrated its superior efficacy compared with doxorubicin[9].

Response evaluation for intrahepatic lesions in patients with advanced HCC is difficult because of variability of both tumor growth pattern and results of previous local treatments including TACE, ablation or radiation therapy[10]. Therefore, this study selected advanced HCC patients with at least one measurable extrahepatic metastatic lesion. The regimen of capecitabine and oxaliplatin (CapeOx) for patients with extrahepatic metastatic HCC was based on (1) the synergy of these two drugs in patients with advanced or metastatic solid tumors[11]; (2) the regimen of oxaliplatin and 5-FU with a manageable toxicity profile in cirrhotic Child-Pugh class A-B or liver transplanted patients[12]; (3) the clinical activity and favorable toxicity profile of capecitabine alone and in combination with oxaliplatin in advanced or metastatic colorectal cancer[13,14]; (4) no dose adjustment required for capecitabine and oxaliplatin due to hepatic dysfunction[15]; and (5) the feasibility and efficacy of CapeOx alone or in combination with antiretroviral therapy in patients with human immunodeficiency virus- (and hepatitis C virus-co-) infection and HCC[16]. This study aims to evaluate the efficacy and safety of CapeOx regimen in patients with extrahepatic metastasis following local treatment.

MATERIALS AND METHODS

Patients

From March 2009 to March 2012, we enrolled 32 patients with extrahepatic metastasis. Eligibility criteria included the following: (1) initially received surgery, thermal ablation, TACE or TACE combined with radiotherapy; (2) at least one measurable extrahepatic lesion; (3) no previous systemic treatment; (4) World Health Organization (WHO) performance status (PS) 0-2; (5) Child-Pugh class of A or B; and (6) age between 18-70 years and adequate bone marrow, renal and hepatic function (absolute neutrophil count $\geqslant 1.5 \times 10^9$/L and platelet count $\geqslant 80 \times 10^9$/L; serum creatinine $\leqslant$ 1.5 mg/dL; aspartate aminotransferase and alanine aminotransferase $\leqslant 2.5 \times$ upper limits of normal; total bilirubin $\leqslant 1.5 \times$ upper limits of normal). Study entry required a complete medical history, physical examination, complete blood cell with a differential count, biochemistry panel, and a coagulation panel

and serum alpha-fetoprotein (AFP), chest or abdominal computed tomography (CT) scan or magnetic resonance imaging (MRI). Main exclusion criteria were Child-Pugh class C, previous systemic treatment, central nervous system metastases, severe cardiac and/or respiratory failure, concurrent malignancy, and baseline sensitive peripheral neuropathy; pregnant or lactating females. This work has been carried out in accordance with the Declaration of Helsinki (2000) of the World Medical Association. The study was approved by the local ethics committee. Informed consent was obtained from all participants.

Before registration, complete blood cell and platelet counts were examined weekly, and physical examination, biology [serum alpha-fetoprotein (AFP), transaminases, alkaline phosphatases, bilirubin, lactate dehydrogenase, γ-glutamyltransferase, albumin, prothrombin time, and creatinine], and safety assessments were performed before each cycle of chemotherapy. Analysis of AFP level and tumor assessment by CT scan or MRI were undertaken every two cycles. Objective response (OR) was confirmed by a second evaluation 4 wk later. Objective and discordant responses were reviewed by an independent radiologist. Treatment was discontinued because of either disease progression and unacceptable toxicity, or patient's refusal. Other treatments were proposed in the event of disease progression.

Treatment protocol

CapeOx regimen was administered in a 3-wk cycle. In each cycle, oxaliplatin (ELOXATIN®, Sanofi-Aventis, Hangzhou, China) was administered at a total dose of 100 mg/m^2 as a 2-h *iv* infusion on day 1, and capecitabine (XELODA®, Shanghai Roche Shanghai, China) 1000 mg/m^2 was taken orally twice daily (total daily dose 2000 mg/m^2) on days 1-14. Hepatitis B surface antigen positive patients were treated with lamivudine (HEPTODIN®, GlaxoSmithKline, Suzhou, China) 100 mg/d before the first CapeOx cycle to prevent severe hepatitis during treatment. All patients with bone metastases received bisphosphonates treatment once a month. Depending on the severity of side effects, chemotherapy was paused or the dose was reduced. A 20% dose reduction was required based on predefined criteria. Briefly, capecitabine dose was reduced by 20% due to recurrence of grade 3 or 4 diarrhea or hand/foot syndrome. Oxaliplatin dose was reduced by 20% in case of grade 1 or 2 peripheral neuropathy, whereas in case of grade 3 or 4 neuropathy (defined as permanent functioning discomfort), oxaliplatin was discontinued and capecitabine was administered alone as initially scheduled. Patients were considered assessable for toxicity if they had received a minimum of one cycle of treatment.

Assessment of responses

Baseline evaluation included physical examination, assessment of medical history, evaluation of performance status, and blood counts. During treatment, patients were evaluated before each cycle of therapy with the above parameters. Response was assessed after every two cycles of chemotherapy by CT scan or MRI using the Response Evaluation Criteria in Solid Tumors 1.1 (RECIST 1.1) criteria[17]. CR was defined as the disappearance of all target and non-target lesions compared to baseline. Partial response (PR) was defined as at least a 30% decrease in the longest diameters of all target lesions, taking as a reference the baseline sum of the diameters with no new lesions appearing. Patients were considered to have progressive disease (PD) if any new lesions appeared, if the tumor size increased by at least 20% in the diameters of the target lesions, taking as reference the smallest sum on study, or if there was unequivocal progression of existing non-target lesions. A patient who did not meet the definition of CR, PR or PD was classified as having stable disease. The percentage of patients who had the best responses (other than PD) according to the RECIST 1.1 criteria, and had those responses maintained for at least 28 d after the first radiologic evaluation, was defined as the disease control rate (DCR). AFP and hepatitis B virus (HBV)-DNA levels were determined every 2 mo. Body weight, PS, and symptoms were recorded before each cycle. Toxic effects of chemotherapy were evaluated according to the National Cancer Institute-Common Terminology Criteria for Adverse Events version 3.0. This specific scale was used to assess oxaliplatin neurotoxicity[18].

Statistical analysis

The primary objective of this study was to assess the overall response rate. The secondary objectives were to evaluate the overall survival (OS), the time to tumor progression (TTP) and the toxicity profile of the combined strategy. TTP was the interval from the starting date of therapy to the date of progression; OS was defined as the time interval between the first cycle of chemotherapy and death due to any cause or the last clinical follow-up. TTP and OS were assessed by the Kaplan-Meier method and differences between the curves were analyzed using the log-rank test. For the statistical analysis, the statistical software SPSS version 15.0 for Windows (SPSS Inc., Chicago, IL, United States) was used. All P values were 2-tailed, with statistical significance defined by $P \leqslant 0.05$.

RESULTS

Thirty-two patients (21 men and 11 women) were enrolled between March 2009 and March 2012. Median age of the patients was 59 years (range 19-70 years). Chronic HBV infection was the most common etiology of underlying liver disease (23 patients, 71.9%). Two patients (6.3%) had a history of alcohol abuse. Twenty-two (68.8%) patients belonged to Child-Pugh class A and 10 (31.2%) to Child-Pugh class B. Cirrhosis was present in 12 patients (37.5%), and 22 patients (68.8%) had serum AFP (≥ 400 ng/mL). Four patients received curative HCC resection and 19 patients were treated with TACE, 4 patients were treated by TACE combined with radiotherapy after diagnosis. Five patients underwent ablation of HCC. Patients' other baseline characteristics are summarized in Table 1.

Table 1 Patient and tumor characteristics at baseline (n = 32)

Characteristics	Patients, n (%)
Age (yr), median (range)	56 (19-70)

ECOG: Eastern Cooperation Oncology Group; HBV: Hepatitis B virus; TACE: Transarterial chemoembolization; AFP: Alpha fetoprotein.

In total, 142 cycles of CapeOx were administered, with a median of four cycles (range 1-9 cycles) per patient. Dose reductions including oxaliplatin in 9/32 patients (28.1%) were due to grade 1/2 toxicities, and capecitabine in 9/32 patients (28.1%) because of grade 3/4 toxicities. Oxaliplatin was discontinued in 2 patients with grade 3 neurotoxicity. Thirty-two patients were assessable for efficacy and toxicity. The median follow-up duration was 15 mo (range 12-20 mo). At the cut-off date of March 31, 2012, 27 patients died due to tumor progression and one patient died of myocardial infarction. Four patients were still alive (3 patients with disease progression). OR was 21.9% (n = 7), the stabilization rate was 40.6% (n = 13), and the DCR was 62.5%. The responses lasted 4-19 mo (median, 6 mo). Median TTP was 4.2 mo (95%CI: 2.5-7.4), and the median OS time was 9.2 mo (95%CI: 6.5-17.8; Figure 1A). The 1-year survival rate was 43.6% (95%CI: 29-66). In a multivariate analysis, OS was significantly longer in patients with a Child-Pugh

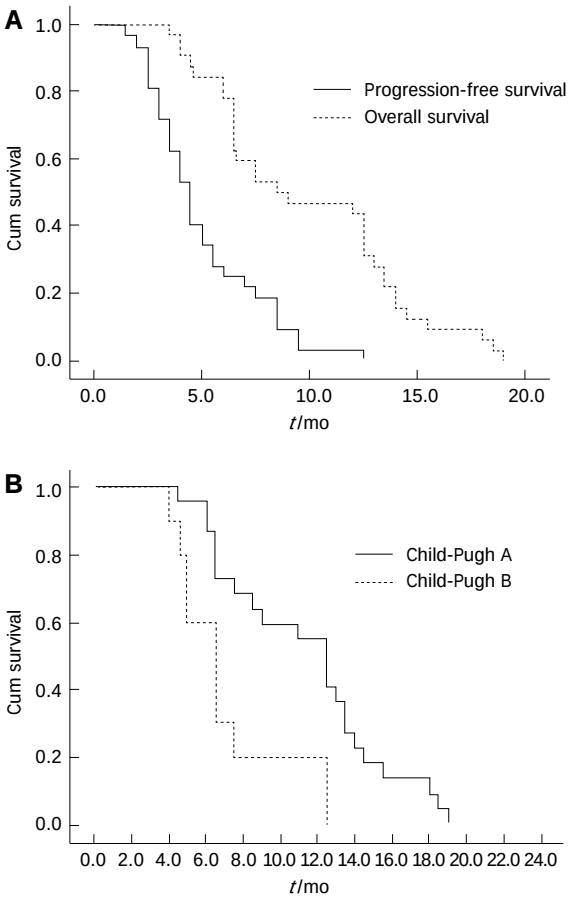

Figure 1 Kaplan-Meier estimation. A: Progression-free survival and overall survival (n = 32); B: Overall survival by Child-Pugh class group (n = 32).

class A compared with class B patients (P = 0.014), with a median OS of 10.1 mo *vs* 5.4 mo (Figure 1B), and there were trends towards longer OS (P = 0.065) in patients without portal vein tumor thrombosis. There were no significant effects of age, gender, PS, cirrhosis, metastatic sites, and level of AFP or HBV-DNA on OS (data not shown). Among the 22 patients with elevated AFP levels at baseline (⩾ 400 ng/mL), the level fell by more than 50% during therapy in 6 patients (27.3%). Moreover, 2 of the 5 patients whose initial PS was equal to 2, improved to 1 after two cycles of treatment. Three of 23 patients treated with lamivudine therapy switched to entecavir therapy because the level of HBV-DVA had exceeded the baseline level (⩾ 1.0e3 cps/mL) during treatment.

Safety

Toxicities are summarized in Table 2. Treatments were generally well tolerated in the majority of patients, and there were no treatment-related deaths. Thirty-two patients were assessable in toxicity. Grade 3-4 toxicity occurred in 11 patients (34.4%). Hematologic toxicity was the most common severe toxicity, including thrombocytopenia (6.3%; no bleeding events) and neutropenia (6.3%; fever in only one case). Grade 3 neurotoxicity was the most common severe non-hematologic toxicity, affecting 2 patients (6.39%), whereas grades 1 and 2 neurotoxicity

Table 2 Treatment-related toxicities in 32 patients

Adverse event	Grade 1	Grade 2	Grade 3	Grade 4
Neutropenia	2	2	1	1
Thrombocytopenia	4	3	1	1
Anemia	5	1	0	0
Nausea/vomiting	6	3	1	0
Mucositis	4	2	0	0
Stomatitis	3	2	1	0
Diarrhoea	0	1	1	0
Transaminases	7	3	1	0
Hyperbilirubinemia	2	0	0	0
Neurotoxicity	5	8	2	0
Hand-foot syndrome	4	2	1	0

Hepatitis B virus DNA level (real-time polymerase chain reaction, Abbott, Wiesbaden, Germany).

occurred in 6 (18.8%) and 3 (9.4%) patients, respectively.

Additional treatments

Nine patients had received additional treatments due to tumor progression. Six patients with bone metastasis received local palliative radiotherapy, and three patients received sorafenib therapy.

DISCUSSION

Sorafenib is currently considered standard of care systemic therapy for patients with advanced HCC. The use of sorafenib is based on phase Ⅱ and phase Ⅲ data in patients with metastatic HCC, with the treatment group showing close to a 3-mo survival advantage over the non-treated group in Child-Pugh class A[3,19]. In contrast, Child-Pugh class B patients did not seem to derive any benefit from sorafenib in phase Ⅲ trials[5,20]. Similarly, in a series of Asian patients, only patients with a score of B7 seemed to benefit from sorafenib, at the cost of higher rates of bleeding events[21]. National Institute for Health and Clinical Excellence does not recommend sorafenib for patients with advanced hepatocellular carcinoma, because it does not provide enough benefit to patients to justify its high cost[22]. In addition, the results of SOFIA study showed that only dose-adjusted, but not full-dose sorafenib was a cost-effective treatment compared to best supportive care in intermediate and advanced HCC. There was no cost-effective treatment for patients with intermediate HCC who were not eligible to or failed locoregional therapy even if they were treated with dose-adjusted sorafenib[23].

The survival rates of HCC patients have risen greatly concomitant with the progress in diagnostic and treatment methods. However, the survival prognosis for treatment-resistant progressive liver cancers is extremely poor[24]. Although surgical resection was used as treatment for pulmonary metastasis from HCC, the treatment might be only beneficial for patients with few than three lung lesions[25]. Chemotherapy used in combination with interferon is considered to be effective but lacks adequate scientific evidence[26].

From general point of view and in line with previous reports[12,27,28], CapeOx seems feasible and suitable for palliative care in patients with advanced HCC. With lack of renal toxicity of oxaliplatin[29], the low incidence of myelosuppression observed with capecitabine[30], the synergistic anti-tumor activity and safety of capecitabine and oxaliplatin combination in advanced HCC[31], and the absence of dose adjustment required for both agents in case of hepatic dysfunction, make the CapeOx regimen attractive in advanced HCC patients with cirrhosis or chronic HBV infection[15,32]. A multicenter, open-label, phase Ⅱ study of CapeOx reported a response rate of 6% and a disease control rate of 72%[33], however, patients who had not undertaken local therapies were eligible for this study. For patients with extrahepatic metastasis from HCC, systemic chemotherapy of carboplatin and 5-FU had demonstrated a statistically significant improvement in OS (10.7 mo *vs* 5.1 mo) in comparable patients with non-chemotherapy[34].

For these patients who had extrahepatic metastasis after local treatments and who had no significant alteration of their liver function, palliative chemotherapy can be delivered with tolerable toxicity[35]. Recently, research combining the use of CapeOx and cetuximab for advanced HCC reported an RR of 12.5%, TTP of 3.3 mo and overall survival of 4.4 mo[36]. Another phase Ⅱ trial of CapeOx with bevacizumab for advanced HCC in 2011 showed tumor response and disease control rates of 20% and 77.5%, respectively[31]. The median OS and PFS were 9.8 and 6.8 mo, respectively. In our study, although only the cytotoxic chemotherapy drugs oxaliplatin and capecitabine were used for patients with extrahepatic metastasis, the result was encouraging for both efficacy and toxicity. Partial response was seen in 21.9% patients, and 62.5% had their disease controlled. The study also showed a median TTP of 4.2 mo and a median OS of 9.2 mo in a patient population of 50% with Eastern Cooperation Oncology Group PS 1-2, and more than 31% of the patients with Child- Pugh class B disease status.

Obviously the underlying liver cirrhosis increases the risk of severe adverse events as many chemotherapeutic drugs are metabolized or eliminated *via* the liver. Moreover, severe complications might occur if a cytotoxicity-related side effect appears on a cirrhotic liver. Certain causes of the underlying cirrhosis, such as hepatitis B virus infection, may be reactivated after chemotherapy induced immunosuppression, producing an additive toxic effect[37].

In conclusion, palliative chemotherapy can be delivered to patients with extrahepatic metastasis from HCC following local treatments with tolerable toxicity. However, the efficacy was not satisfactory. More effective systemic chemotherapy regimens are needed for this subgroup of patients.

ACKNOWLEDGMENTS

We would like to express our heartfelt gratitude to Dr. Chel-

sea Gilft and Dr. Koung Fang Pei (MD, Anderson Cancer Center) for modifying the language of the manuscript.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is the second leading cause of cancer-related deaths worldwide. The overall 5-year survival rate for all HCC patients has remained no more than 5%. Sorafenib is the first agent to demonstrate a survival advantage over supportive care in HCC. Nevertheless, in a relatively fit group of sorafenib-treated patients (95% Childs-Pugh A), median survival was only 10.7 mo. The purpose of this study was to evaluate the safety and efficacy of the capecitabine-oxaliplatine combination (CapeOx) in patients with extrahepatic metastatic HCC following local treatments.

Research frontiers

Local recurrence and distant metastasis are still obstacles in further improvement of outcome in HCC patients after local treatments. Doxorubicin, until recently considered the standard chemotherapeutic for HCC, is associated with an objective response rate of approximately 10%. In this study, the authors aimed to valuate the efficacy and safety of CapeOx regimen in patients with extrahepatic metastasis from HCC following local treatments.

Innovations and breakthroughs

Sorafenib is currently considered standard of care systemic therapy for patients with advanced HCC, but results from recent several studies showed it not suitable in some patients with advanced HCC. In this study, CapeOx regimen showed modest anti-tumor activity in metastatic HCC and tolerated toxicities.

Applications

This study may represent a future strategy for therapeutic intervention in the treatment of patients with extrahepatic metastasis from HCC following local treatments even if with liver cirrhosis.

Terminology

Capecitabine is an orally administered, tumor-selective fluoropyrimidine that mimics continuous infusion of 5-fluorouracil. Oxaliplatin s a new platinum complex, diaminocyclohexane compound, which is thought to result from inhibition of DNA synthesis in cancer cells. The combination of oxaliplatin and capecitabine has also shown some promise in HCC because both drugs are tolerated in the setting of hepatic dysfunction.

Peer review

This study is an uncontrolled phase 2 evaluation of capecitabine and oxaliplatin for locally controlled HCC with extrahepatic metastases involving 32 patients, the majority of whom were hepatitis B virus infected and non-cirrhotic. The majority of patients' metastases were pulmonary or intra-abdominal with 6/32 being confined to bone. Twenty-eight percent of patients required dose reduction of capecitabine due to grade 3/4 toxicity but only 2 grade 3 oxaliplatin toxicities occurred. Ninety-seven percent of patients died or manifested tumor progression. Median time to tumor progression was 4.2 mo and median overall survival was 9.2 mo. This is an interesting prospective study on efficacy of CapeOx combination regimen for extrahepatic metastasis of HCC following local treatments, and gives a practical point of view in management of these patients.

Abstract

AIM: To assess whole-body fluorodeoxyglucose (FDG) positron emission tomography/computed tomography (PET/CT) in the management of small bowel obstructions (SBOs) secondary to gastric cancer and its role in treatment strategies.

METHODS: The medical records of all of the patients who were admitted for an intestinal obstruction after curative resection for gastric cancer were retrospectively reviewed. PET/CT was performed before a clinical treatment strategy was established for each patient. The patients were divided into 2 groups: patients with no evidence of a tumor recurrence and patients with evidence of a tumor recurrence. Tumor recurrences included a local recurrence, peritoneal carcinomatosis or distant metastases. The primary endpoint was the 1-year survival rate, and other variables included patient demographics, the length of hospital stay, complications, and mortality.

RESULTS: The median time between a diagnosis of gastric cancer and the detection of a SBO was 1.4 years. Overall, 31 of 65 patients (47.7%) had evidence of a tumor recurrence on the PET/CT scan, which was the only factor that was associated with poor survival. Open and close surgery was the main type of surgical procedure reported for the patients with tumor recurrences. R0 resections were performed in 2 patients, including 1 who underwent combined adjacent organ resection. In the group with no evidence of a tumor recurrence on PET/CT, bowel resections were performed in 7 patients, adhesiolysis was performed in 7 patients, and a bypass was performed in 1 patient. The 1-year survival curves according to PET/CT evidence of a tumor recurrence *vs* no PET/CT evidence of a tumor recurrence were significantly different, and the 1-year survival rates were 8.8% *vs* 93.5%, respectively. There were no significant differences (P = 0.71) in the 1-year survival rates based on surgical *vs* nonsurgical management (0% with nonoperative treatment *vs* 20% after exploratory laparotomy).

CONCLUSION: ^{18}F-FDG PET/CT can be used to identify the causes of bowel obstructions in patients with a history of gastric cancer, and this method is useful for planning the surgical management of these patients.

Key words: Positron emission tomography/computed tomography; Small bowel obstructions; Gastric cancer; Clinical treatment strategy

Core tip: The management of patients who present with a small bowel obstruction (SBO) after treatment of primary carcinoma challenges the clinical judgement of

even the most experienced surgeons when the feared cause is metastatic disease. It is difficult to predict whether the quality and/or the quantity of life in this group of patients will be improved by surgery. This study evaluated the clinical role of ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography/computed tomography (PET/CT) in identifying SBOs and its role in subsequent clinical treatment strategies. We found that ^{18}F-FDG PET/CT is an appropriate method to identity the causes of bowel obstructions secondary to gastric cancer, and this method is useful for the surgical management of these patients.

Surgical management of patients with bowel obstructions secondary to gastric cancer. *World J Gastroenterol* 2013; 19(28): 4559-4567 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4559.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4559

INTRODUCTION

An intestinal obstruction is a common problem in patients with an advanced malignancy. Approximately 3%-15% of all terminal cancer patients will develop an intestinal obstruction[1,2]. In advanced abdominal and pelvic malignancies, 5%-51% of patients with ovarian malignancies and 10%-28% of patients with gastrointestinal cancers will develop an intestinal obstruction[3-8]. An intestinal obstruction may be due to intra-abdominal adhesions, intra-abdominal hernias, local cancer recurrences, peritoneal carcinomatosis, or distant metastases from other tumors. Small bowel obstructions (SBOs) secondary to malignant disease are often a sign of end-stage disease and are associated with poor survival. The treatment of such patients presents a dilemma for the surgeon. Inappropriate surgery will not significantly improve morbidity and mortality outcomes and often has limited success in relieving symptoms. Nonoperative treatment is often ineffective at restoring bowel function, and when relief is obtained, early reobstruction frequently occurs[9,10]. The management of patients who present with a bowel obstruction after treatment of primary carcinoma challenges the clinical judgment of even the most experienced surgeons when the feared cause is metastatic or recurrent disease[11]. The management of these patients is difficult, and it is unclear which patients will benefit from surgery and which patients will have similar outcomes from medical management because many patients may have diffuse peritoneal metastatic disease and/or adhesions from previous surgery. It is difficult to predict whether the quality and/or the quantity of life in this group of patients will be improved by surgery because these patients have a poor prognosis at the time of presentation[12]. In addition, the management of these patients presents an additional difficulty because the intestinal obstruction may be due to more than one physiopathological process, such as an intraluminal obstruction from polypoid lesions that occlude the bowel lumen, an intramural obstruction from the infiltration of a tumor within the muscular coat of the bowel wall, and an extramural obstruction from mesenteric and omental masses and extrinsic compression from malignant adhesions.

Positron emission tomography (PET) with ^{18}F-fluorodeoxyglucose (FDG) detects the increased utilization of glucose by malignant cells to provide diagnostic information and is more accurate than conventional diagnostic methods in cases of primary and recurrent gastrointestinal tumors[12-15]. To date, the usefulness of integrated FDG PET/computed tomography (CT) in the treatment decisions for patients with bowel obstructions secondary to malignant disease has not been investigated. This study evaluated the clinical role of whole-body FDG PET/CT in the management of SBOs secondary to gastric cancer and its role in the formulation of subsequent clinical treatment strategies.

MATERIALS AND METHODS

Patients

This retrospective chart review was approved by the institutional review board and was performed at the Department of General Surgery, Xinhua Hospital, School of Medicine, Shanghai Jiaotong University. A retrospective review of our electronic database was conducted to find all patients with a history of curative resection for gastric cancer who were admitted for an intestinal obstruction from August 1, 2008 to January 1, 2010. Adult patients with discharge diagnoses of bowel obstructions and gastric cancer were enrolled. Patients whose cancer was first diagnosed with the bowel obstruction and patients without radiographic confirmation of an obstruction were excluded. Patients with an early postoperative bowel obstruction, which is generally defined as a mechanical obstruction that occurs within 1 mo of abdominal surgery, were excluded. No patient with a bowel obstruction before a cancer diagnosis was included in this study. The diagnosis of a bowel obstruction was based on a combination of clinical signs and symptoms and radiologic findings. The enrolled patients had at least one of the following symptoms along with radiographic confirmation of an obstruction: nausea and vomiting, colicky pain, abdominal bloating, obstipation, or an inability to tolerate PO intake. Radiographic confirmation of the obstruction was usually by either plain abdominal films or a CT scan. In addition, at least one of the following findings was required: dilated loops of bowel with a paucity of air in the colon, air/fluid levels, or a transition from a dilated bowel to a decompressed bowel[16]. PET/CT was performed for each patient before the clinical treatment strategy was established. Based on the PET/CT results, the patients were divided into 2 groups: patients with no evidence of a tumor recurrence and patients with evidence of a tumor recurrence, which included a local recurrence, peritoneal carcinomatosis or distant metastases.

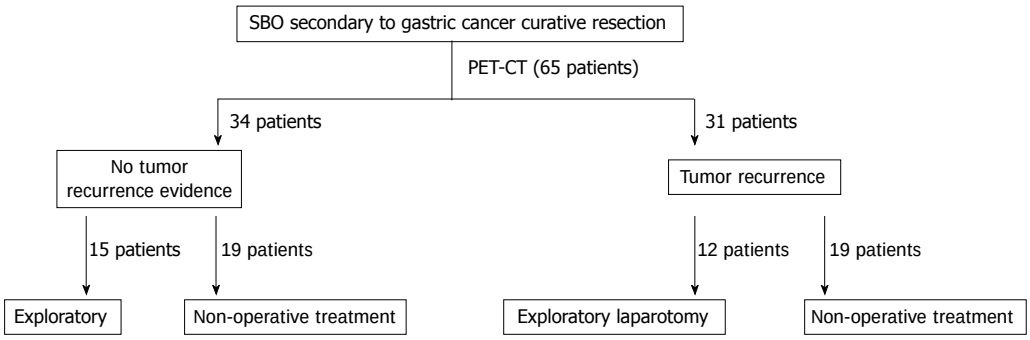

Figure 1 The treatment decision-making process. PET/CT: Positron emission tomography/computed tomography; SBO: Small-bowel obstruction.

PET/CT

PET/CT imaging was performed using a GE Discovery ST 8-slice scanner. The patients were scanned after 6 h of fasting. Blood glucose levels were checked immediately before the scan. An average of 296-370 MBq (*i.e.*, 8-10 mCi) FDG was injected intravenously, and whole-body images were obtained 1 h later. Low-dose CT images were used for attenuation correction. An oral contrast agent was administered to all of the patients for PET/CT imaging. A semiquantitative and visual analysis was made. The images were evaluated by 2 nuclear medicine specialists, and a consensus was required to prevent interobserver variability. The FDG uptake was defined as qualitatively positive when the focal FDG uptake was higher than the normal biodistribution of background FDG activity. In addition, to exclude the physiologic uptake, the FDG uptake in the bowel was considered positive only when wall thickening of the same bowel was simultaneously detected by CT. The PET/CT images were analyzed for the number and the sites with positive FDG uptake, and the standardized uptake value value of all of the positive FDG uptake values was measured.

Operative and non-operative management

The patients with an obstruction were divided into 2 treatment groups: patients who received conservative treatment and patients who underwent surgical management. The standard nonoperative management of small bowel obstructions consisted of fluid and electrolyte replacement, bowel rest, and tube decompression. A nonoperative course may be followed for 24-48 h. If the obstruction has not resolved within that time period, it is unlikely that the obstruction will ever resolve and laparotomy is usually advised. In the patients who underwent surgery for a bowel obstruction after curative resection of gastric cancer, the type of operation was determined by 3 expert gastrointestinal surgeons depending on the overall medical status of the patient, the wishes of the patient, and the abdominal examination. The primary endpoint of the analysis of surgical *vs* non-surgical treatment for the bowel obstructions in this study was the 1-year survival rate, and other recorded variables included patient demographics, the length of hospital stay, complications, and mortality. The modified Clavien system was used to grade any postoperative complications. In-hospital mortality was defined as the percentage of patients who died before hospital discharge. The length of hospital stay was defined as the number of days from the index procedure to hospital discharge. This study was approved by the Human Research Review Committee of our hospital.

Statistical analysis

Statistical analyses and graphics were generated using the SPSS 13.0 statistical package for Windows (SPSS, Inc., Chicago, IL, United States). If the P value was < 0.05, the results were considered statistically significant. Patency after palliation and the overall survival were estimated using the Kaplan-Meier actuarial method, and the curves were compared using the log-rank test. To identify the independent factors that influenced clinical success and the risk factors that were associated with the 1-year overall survival, univariate and multivariate analyses were performed. The results were expressed as the mean ± SD or as the percentages.

RESULTS

There were 72 cases of bowel obstructions in patients with a history of curative surgery for gastric cancer at our institution during the study period. Seven patients declined PET/CT imaging and were excluded from the analysis. The remaining 65 patients were all admitted for a SBO and were included in the analysis. The surgical decision-making process is shown in Figure 1. The average age at the time of the primary gastric cancer diagnosis was 62.5 ± 17.1 years. The mean age at admission for a SBO was 63.9 ± 15.6 years.

The median time between curative resection of gastric cancer and the detection of a SBO was 1.4 years. The clinicopathological data of the patients are listed in Table 1. Each patient underwent PET/CT before the final clinical treatment strategy was determined. PET/CT indicated that 31 patients (47.7%) had evidence of a tumor recurrence, including a local recurrence, peritoneal carcinomatosis, and distant metastases (Table 2; Figure 2A). The remaining 34 (52.3%) patients had no evidence of a tumor recurrence (Figure 2B). Both the univariate

and multivariate analyses for factors that may have correlated with survival revealed that the only factor that was associated with poor survival was PET/CT evidence of a tumor recurrence (Table 3).

In patients who received surgical treatment, the type of operation was determined by 3 expert gastrointestinal surgeons based on abdominal examinations and the general condition of the patient. A total of 27 patients (12 in the group with PET/CT evidence of a tumor recurrence and 15 with no evidence of a tumor recurrence) underwent laparotomy. The types of surgical procedures that were performed are summarized in Table 4. Open and close surgery was the main type of surgical procedure reported for the patients with tumor recurrences. R0 resections were performed in 2 patients, including 1 who underwent combined adjacent organ resection. In the group with no evidence of tumor recurrences on PET/CT, bowel resections were performed in 7 patients, adhesiolysis was performed in 7 patients, and a bypass was performed in 1 patient. The overall incidence of postoperative complications was 44.4% (12 of 27 patients). There were 7 patients with Clavien grade I complications, including 3 with wound infections and 4 with pleural effusions. Another 3 patients were classified as having grade Ⅱ complications, including 1 with an anastomotic leakage and 2 with pneumonia. One patient had the grade Ⅲb complication of an abdominal abscess, and 1 patient had the grade V complication of multiple organ failure and died in the hospital 1 wk after surgery.

SUV: Standardized uptake value.

The 1-year survival curves according to the PET/CT findings are shown in Figure 3A. There was a significant difference in the survival between patients with and without evidence of recurrences on PET/CT, and the 1-year survival rates were 8.8%, and 93.5%, respectively (P = 0.00). The 1-year survival curves according to exploratory laparotomy and nonoperative treatment are shown in Figure 3B. There were no significant differences (P = 0.71) in the 1-year survival based on surgical *vs* nonsurgical management (0% with nonoperative treatment *vs* 20% after exploratory laparotomy). The 1-year survival curves according to evidence of a tumor recurrence on PET/CT are shown in Figure 3C.

Other variables in the analysis included 30-d readmission, the length of hospital stay, complications, and the mortality rates. These variables are listed in Table 5. In both the PET/CT-positive and -negative groups, exploratory laparotomy resulted in a shorter mean length of hospital stay than nonsurgical management (P < 0.05).

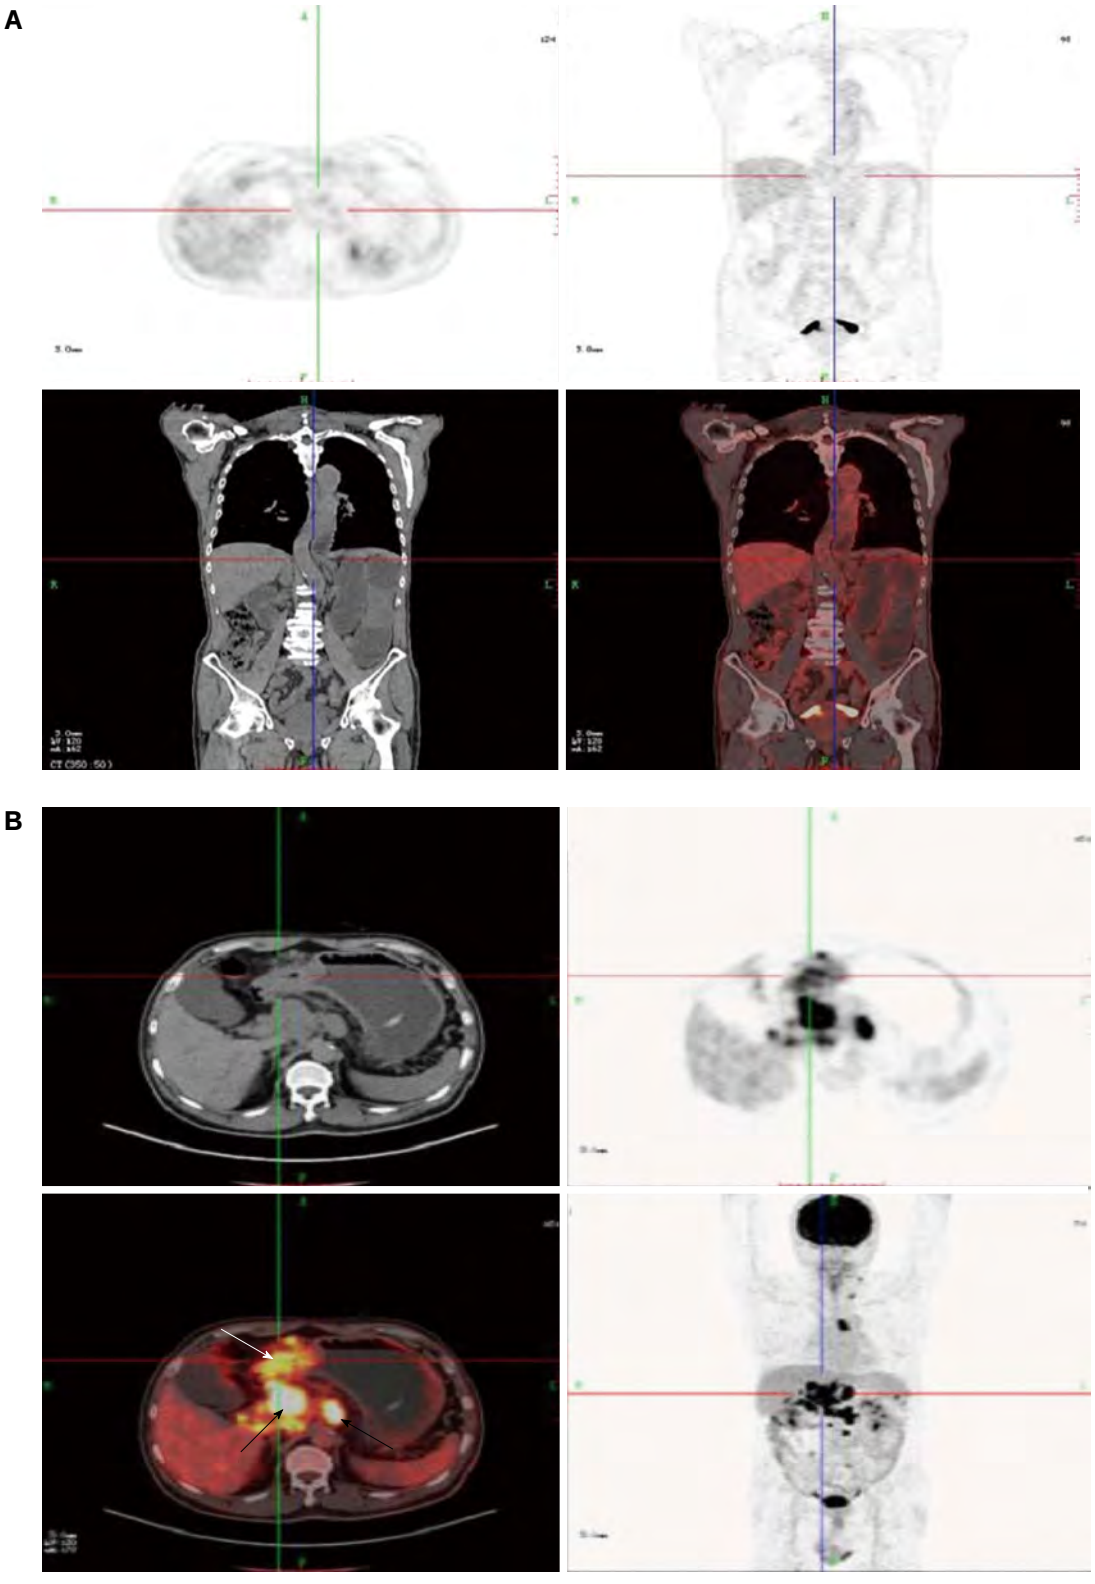

Figure 2 Patients who had had gastric cancer resection underwent positron emission tomography/computed tomography because of small-bowel obstruction. A: A 68-year-men who had had gastric cancer resection 2 years previously underwent positron emission tomography (PET)/computed tomography because of small-bowel obstruction. Whole body PET projection image and axial PET image showed no focal hypermetabolic activity; B: A 38-year-female who had had gastric cancer resection 1 years previously underwent positron emission tomography/computed tomography because of small-bowel obstruction. Whole body PET projection image and axial PET image showed the remnant stomach (white arrow) and lymph-node (black arrow) focal hypermetabolic activity.

DISCUSSION

An intestinal obstruction is a common problem in patients with advanced cancers. Approximately 3%-15% of all terminally ill cancer patients will suffer from an intestinal obstruction and 10%-28% of patients with gastrointestinal cancers will develop an intestinal obstruction. Obstructions in patients with a history of gastric cancer may be secondary to a malignant process, either extrinsic or intrinsic to the bowel, or an underlying benign etiology, such as an intra-abdominal hernia or intraperitoneal adhesions. The current treatment options for patients with a bowel obstruction secondary to malignant disease include surgery to bypass/remove the obstruction, gastrointestinal decompression *via* a nasogastric tube, and medications (*e.g.*, octreotide)[17]. In inoperable cases, decompression *via* a nasogastric tube may be the only treatment available. Nasogastric tube decompression can provide symptomatic relief but may cause mucosal erosion, esophagitis, or aspiration pneumonia, which further diminish quality of life. However, surgical treatment is often contraindicated because of the poor physical status of the patient, and many patients with gynecological malignancies, especially ovarian cancer, are not candidates for surgery because of the presence of diffuse intraperitoneal carcinomatosis, multiple partial obstruction points, ascites, and/or a history of previous radiotherapy. A critical step in the management of patients with a bowel obstruction and a history of curative resection of gastric cancer is to determine whether a malignant process is present. Identifying the underlying etiology of the bowel obstruction, malignant or benign, will significantly impact management decisions. Additionally, distinguishing between a malignant obstruction and a benign obstruction is a key measure in deciding which patients should undergo early operation.

Table 4 Types of surgery performed for small-bowel obstruction

Procedure	*n*
Open and close	10
R0 resection	2
Bypass	1
Bowel resection	7
Adhesiolysis	7

It is well documented that the complete surgical removal of gastric tumors with lymph node dissection is the only curative treatment that is currently available; however, disease recurrence after radical surgery still occurs in approximately 22%-48% of patients, and its prognosis is poor[18-21]. Tumor marker evaluation, endoscopy, and imaging studies have previously been used to monitor patients for gastric cancer recurrences; however, there are several limitations to tumor markers and endoscopy. Tumor markers cannot be used to determine the site of recurrence, and endoscopy cannot detect extraluminal recurrences[22]. The most important limitation of CT in the detection of locally recurrent gastric cancer is the lack of specificity because the diagnostic ability of CT depends on the morphological changes of the involved organs and distorted anatomical features. In addition, CT uses size criteria. These factors result in difficulties in image interpretation, and CT cannot precisely identify the presence and the quality of tumors.

Whole-body ^{18}F-FDG PET detects increased glucose metabolism in malignant cells to produce diagnostic evidence and can be widely applied for staging, re-

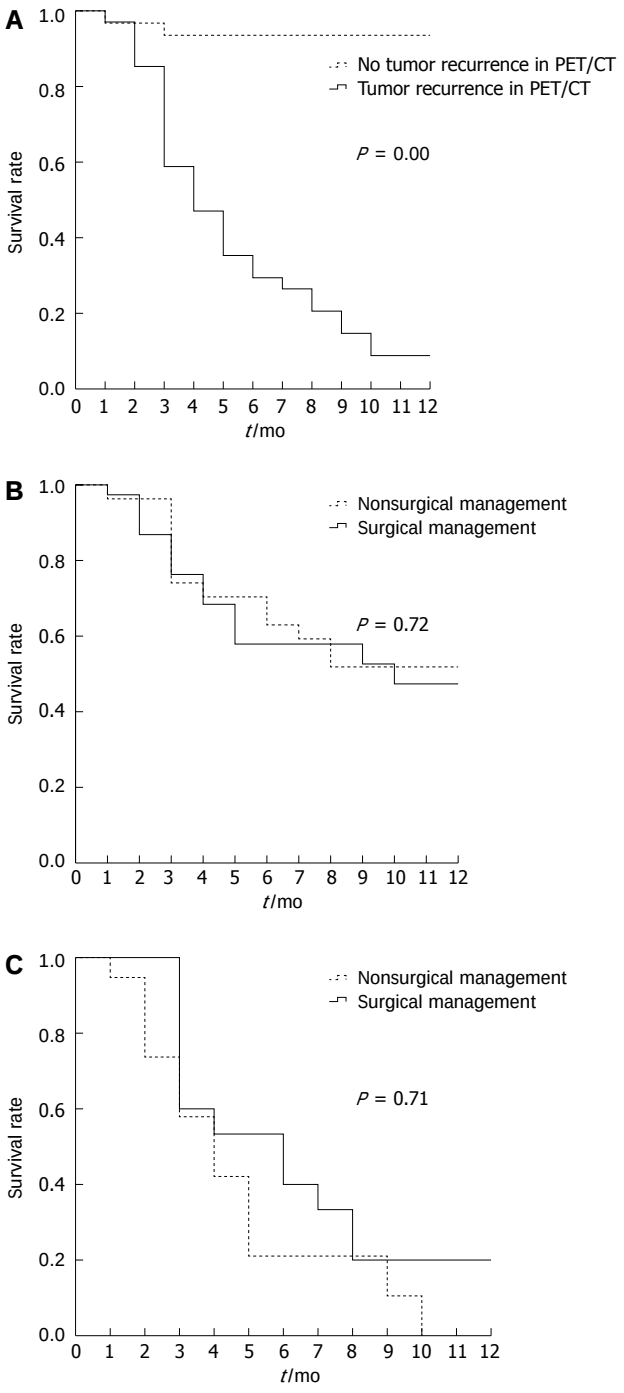

Figure 3 1-year survival curves. A: With respect to no tumor recurrence and tumor recurrence group in positron emission tomography/computed tomography. There was significant difference between two subgroups (P = 0.00). The 1-year survival rate in positron emission tomography/computed tomography (PET/CT) tumor recurrence group is 8.8%, while 93.5% in no tumor recurrence group; B: With respect to exploratory laparotomy and nonoperative treatment group. There was no difference in 1-year survival based on type of surgical *vs* nonsurgical management (P = 0.72); C: With respect to tumor recurrence group in positron emission tomography/computed tomography. The 1-year survival rates for patients in each subgroup were, respectively, 0.0% for tumor nonoperative treatment, and 20% for exploratory laparotomy group. There is also no significant difference between two subgroups (P = 0.71).

staging, and monitoring therapy-induced tumor changes and response to therapy in patients with various cancers. The usefulness of integrated ^{18}F-FDG PET/CT for the diagnosis of recurrences in patients with gastric cancer has been investigated in previous studies, which have indicated that ^{18}F-FDG PET/CT is an effective and helpful diagnostic method in the evaluation of recurrences. Other trials have studied the impact of ^{18}F-FDG PET/CT on the clinical decision-making process[23-25], FDG-PET results led to a radical change in the clinical management of 20% of the patients who were analyzed for resection of colorectal liver metastases. FDG-PET was considered a decisive technique for determining whether to perform surgery, and management was changed in 29% of the patients. This study has confirmed the critical role of whole-body ^{18}F-FDG PET/CT during the clinical course of patients with a bowel obstruction and a history of gastric cancer.

Table 5 Outcomes variables of the 65 patients

Variables	No recurrence in PET/CT		Recurrence in PET/CT	
	Surgical management	Non-surgical management	Surgical management	Non-surgical management

Overall complications	53.30%	0.00%	33.30%	0.00%

PET/CT: Positron emission tomography/computed tomography.

Several patients in our study with a SBO and a history of gastric cancer did not have end-stage disease that was associated with poor survival. Distinguishing between a malignant obstruction and a benign obstruction is a key measure in deciding which patients should undergo early operation. Patients with metastatic cancer who develop a bowel obstruction have a short median survival time (approximately 3 mo)[16], and decisions regarding the treatment of bowel obstructions must be carefully weighed in these patients. Surgery can offer good palliative benefits for these patients; however, surgery may result in complications that reduce quality of life and cause patients to spend an excessive amount of time in the hospital, which could have been avoided. Therefore, optimal palliation may result from the nonoperative and medical management of symptoms and lead to a potential decrease in the length of hospital stay. Attempting surgery in these patients may not be the best decision, and the finding in our study that there were no differences in the survival of patients with recurrent disease based on the type of management shifts the focus of care for these patients from a selection process to surgical *vs* nonsurgical management.

Multiple specialists are usually involved in the treatment of these patients, including gastroenterologists, interventional and diagnostic radiologists, radiation oncologists, and medical and surgical oncologists. These specialists may have divergent opinions regarding definitive individualized treatment. Our results suggest that patients who had evidence of a tumor recurrence on a

PET/CT scan face an end-of-life scenario and optimal symptom control is the goal for these patients. In addition, FDG PET/CT is a superior post-therapy surveillance modality for the diagnosis of recurrent gastric cancer compared with other imaging methods after initial surgery. In addition, FDG PET/CT has been specifically helpful in optimizing treatment plans and may play an important role in treatment stratification in the future[26]. Miller *et al*[11] compared operative therapy with nonoperative therapy in patients with small bowel obstructions secondary to malignant disease and found a rate of reobstruction that was 15% higher in the nonoperative group. Additionally, they reported shorter times to a reobstruction in patients who had received conservative nonoperative therapy, and they observed that a palpable abdominal mass was an important predictor of poor outcomes in their series. In this study, we concluded that patients with a history of gastric cancer who present with a SBO and who have no evidence of a tumor recurrence on PET/CT will receive benefits in both survival and quality of life after surgery to relieve the obstruction.

In conclusion, ^{18}F-FDG PET/CT can be used to identify the causes of bowel obstructions in patients with a history of curative resection of gastric cancer, and this method is useful for planning the surgical management of these patients. Surgical intervention in a patient who has an obstruction after curative resection of gastric cancer and who has no evidence of a tumor recurrence on a PET/CT examination benefits the quality of life of the patient. Patients with poor survival, including patients with PET/CT evidence of a local recurrence, peritoneal carcinomatosis or distant metastases, would not benefit from surgery.

COMMENTS

Background

The management of patients who present with a small bowel obstruction (SBO) after treatment of primary carcinoma challenges the clinical judgement of even the most experienced surgeons when the feared cause is metastatic disease. It is difficult to predict whether the quality and/or the quantity of life in this group of patients will be improved by surgery because these patients have a poor prognosis at the time of presentation. Positron emission tomography (PET) with ^{18}F-fluorodeoxyglucose (FDG) detects the increased utilization of glucose by malignant cells and is more accurate than conventional diagnostic methods for the diagnosis of primary and recurrent gastrointestinal tumors.

Research frontiers

The management of SBOs after treatment of primary carcinoma is difficult, and it is unclear which patients will benefit from surgery and which patients will have similar outcomes from medical management because many patients may have diffuse peritoneal metastatic disease and/or adhesions from previous surgery. It is difficult to predict whether the quality and/or the quantity of life in this group of patients will be improved by surgery because these patients have a poor prognosis at the time of presentation. In addition, the management of these patients presents an additional difficulty because the intestinal obstruction may be due to more than one physiopathological process, such as an intraluminal obstruction from polypoid lesions that occlude the bowel lumen, an intramural obstruction from the infiltration of a tumor within the muscular coat of the bowel wall, and an extramural obstruction from mesenteric and omental masses and extrinsic compression from malignant adhesions.

Innovations and breakthroughs

^{18}F-FDG PET/computed tomography (CT) can be used to identify the causes of bowel obstructions in patients with a history of curative resection of gastric cancer, and this method is useful for planning the surgical management of these patients. Surgical intervention in a patient who has an obstruction after curative resection of gastric cancer and who has no evidence of a tumor recurrence on a PET/CT examination benefits the quality of life of the patient. Patients with poor survival, including patients with PET/CT evidence of a local recurrence, peritoneal carcinomatosis or distant metastases, may not benefit from surgery.

Applications

^{18}F-FDG PET/CT can be used to identify the causes of bowel obstructions in patients with a history of gastric cancer, and this method is useful for planning the surgical management of these patients.

Terminology

PET with ^{18}F-FDG detects the increased utilization of glucose by malignant cells to provide diagnostic information and is more accurate than conventional diagnostic methods in cases of primary and recurrent gastrointestinal tumors.

Peer review

This article is interesting. The authors present their experience of using whole-body PET/CT in the surgical management of patients with bowel obstructions secondary to gastric cancer. PET/CT significantly improves survival because of its ability to identify the causes of bowel obstructions. Overall, the paper is well written and acceptable for publication in its current form.

Abstract

AIM: To investigate the contribution of the fibroblast growth factor receptor 4 (FGFR4) Gly388Arg polymorphism as a genetic risk factor for gastric cancer (GC) and to investigate any associations between this polymorphism and clinicopathological parameters and survival.

METHODS: Tumors and matched adjacent non-cancer tissues were collected from 304 GC patients, and 5 mL of venous blood was collected from 62 GC patients and 392 age- and sex-matched healthy controls without cancer history from the same ethnic population. DNA was extracted, and direct sequencing analyses were performed to genotype the *FGFR4* Gly388Arg polymorphism in all the samples. Differences in the genotype frequencies of the *FGFR4* Gly388Arg polymorphism between GC patients and healthy controls were estimated using the χ^2 test. Binary logistic regression was used for all analysis variables to estimate risk as the ORs with 95%CIs. The relationships between the *FGFR4* genotype and clinicopathological parameters were tested with the χ^2 test. The Kaplan-Meier product-limit method, the log-rank test, and the Cox regression model were applied to evaluate the effect of the *FGFR4* genotype on the overall survival of patients with GC.

RESULTS: In the present GC cohort, 118 patients (38.8%) were homozygous for the Gly388 allele, 124 patients (40.8%) were heterozygous, and 62 patients (20.4%) were homozygous for the Arg388 allele. The frequencies of the Gly/Gly, Gly/Arg, and Arg/Arg genotypes in the healthy controls were 33.6%, 48.0%, and 18.4%, respectively. The distributions of genotypes (χ^2 = 3.589, P = 0.166) and alleles (χ^2 = 0.342, P = 0.559) of the FGFR4 Gly388Arg polymorphism were not different between the GC patients and the healthy controls. Although we observed no correlation between the *FGFR4* Gly388Arg polymorphism and clinicopathological parameters or survival in the total cohort of GC patients, the presence of the Arg388 allele was associated with shorter survival time in patients with GC if the tumor was small (log rank χ^2 = 5.449, P = 0.020), well differentiated (log rank χ^2 = 12.798, P = 0.000), T1 or T2 stage (log rank χ^2 = 4.745, P = 0.029), without lymph node involvement (log rank χ^2 = 6.647, P= 0.010), and at an early clinical stage (log rank χ^2 = 4.615, P = 0.032).

CONCLUSION: Our results suggest that the *FGFR4* Gly388Arg polymorphism is not a risk factor for GC cancer initiation but that it is a useful prognostic marker for GC patients when the tumor is relatively small, well differentiated, or at an early clinical stage.

Key words: Fibroblast growth factor receptor 4; Gly388Arg; Genetic susceptibility; Single nucleotide polymorphism; Gastric cancer

Core tip: This study investigated the contribution of the fibroblast growth factor receptor 4 (FGFR4) Gly388Arg polymorphism as a genetic risk factor for gastric cancer (GC) and any associations between this polymorphism and clinicopathological parameters such as age, gender, clinical stage, tumor grade, human epidermal growth factor receptor 2 status and survival. The results suggested that the FGFR4 Gly388Arg polymorphism was not a risk factor for GC cancer initiation but that it was a useful prognostic marker for GC patients when the tumor was relatively small, well differentiated, or at an early clinical stage.

INTRODUCTION

Gastric cancer (GC) is one of the most common cancers in the world, and it has a complex etiology. Disease development is related to environmental factors, such as diet and *Helicobacter pylori* (*H. pylori*) infection, as well as genetic predisposition. In the last decade, GC incidence rates have steadily declined owing to changing diets and the application of antibiotics to treat *H. pylori* infection[1]. However, the treatment of patients with advanced GC remains a significant challenge. Surgical resection and chemotherapy are only effective for a fraction of patients, and their prognoses remain very poor. Recently, a number of molecularly targeted agents modulating different signal transduction pathways have been researched in clinical trials for many cancer types[2]. Trastuzumab, a monoclonal antibody against human epidermal growth factor receptor 2 (HER2; also known as ERBB2) was demonstrated to be effective in advanced HER2-positive GC. The addition of trastuzumab to chemotherapy improved survival in patients with advanced GC or gastroesophageal junction cancer compared with chemotherapy alone in a Trastuzumab for Gastric Cancer trial[3]. However, only 7% to 34% of GC cases are HER2 positive[4-6], meaning that only a fraction of GC patients can benefit from trastuzumab. Accordingly, there is an urgent need to better understand the genesis of GC to establish a sound basis for future treatments.

Fibroblast growth factor receptor 4 (FGFR4) is a member of the receptor tyrosine kinase family. These receptors have highly conserved structures containing an extracellular ligand-binding domain, a transmembrane domain, and an intracellular tyrosine kinase domain. The FGFR4 protein interacts with specific growth factors, especially acidic fibroblast growth factor, and is critically involved in cell growth, differentiation, migration, angiogenesis, and tumorigenesis. Several prior studies have investigated the role of the FGFR4 signaling pathway in GC. Notably, a soluble variant of FGFR4 was first detected in human gastrointestinal epithelial cells and cancer cells in a study by Takaishi *et al*[7]. Shin *et al*[8] and Ye *et al*[9]. also demonstrated the upregulation of FGFR4 mRNA and protein in GC, suggesting the possibility that FGFR4 signaling could play a role in gastric carcinogenesis.

Recently, a single nucleotide polymorphism (SNP) at codon 388 (cDNA 1162) from G to A, which results in a change of amino acid from glycine to arginine, was identified in the transmembrane domain of the *FGFR4* gene[10]. Significant scientific effort has been put into the investigation of this *FGFR4* Gly388Arg polymorphism in cancer progression, and the results showed that patients with the Arg/Arg or Gly/Arg genotype (compared to those with a Gly/Gly genotype) had a shorter survival time or a higher proportion of nodal involvement in many types of cancer, including breast, lung, colon, prostate, soft tissue sarcoma, melanoma, and head and neck squamous cell carcinoma[10-19]. However, several researchers have opposed the association between this polymorphism and poor outcomes or lymph node involvement[20-23]. Furthermore, it has been reported that the *FGFR4* Arg388 polymorphism may not be involved in tumor initiation in several different tumor types with the exception of prostate cancer[13,14,18,24]. Xu *et al*[25] conducted a meta-analysis of 2618 patients and 2305 controls and demonstrated that the *FGFR4* Gly388Arg polymorphism was associated with both progression and risk in prostate cancer .

Recently, Ye *et al*[26] reported that the FGFR4 Arg allele was an independent prognostic factor in Chinese patients with GC. To our knowledge, this is the only report on the association between the *FGFR4* Gly388Arg polymorphism and the progression of GC in Chinese patients, and it therefore needs further confirmation. Moreover, no study has been conducted on the correlation between this polymorphism and the risk of GC. In the present study, we expanded the sample sizes by enrolling 304 patients with GC and 392 healthy controls and genotyped every sample for the FGFR4 Gly388Arg polymorphism to confirm the findings of Ye *et al*[26] and investigate the association between the FGFR4 Gly388Arg polymorphism and the risk of GC.

MATERIALS AND METHODS

Patients and healthy controls

A total of 304 Chinese patients diagnosed with GC were recruited and underwent surgery between 2007 and 2009 at Ren Ji Hospital, School of Medicine, Shanghai Jiao Tong University. All GC cases were pathologically confirmed, and patient records were used to obtain clinical data. The study included a total of 223 males and 81

GC: Gastric cancer.

females. The age of the patients at the time of surgery ranged from 22 to 87 years, with a median age of 63.5 years. The clinical stage was determined according to the Union for International Cancer Control TNM staging system, and the tumor grade was based on the World Health Organization classification. The expression or amplification of HER2 in GC was detected using standard methods, including immunohistochemistry and fluorescence in situ hybridization. The HER2 status was determined according to the Hofmann HER2 scoring system[6]. Follow-up was performed regularly. The median follow-up time for patients still alive at analysis was 49 mo (range, 20-61 mo).

Tumors and matched adjacent non-cancer tissues were snap frozen in liquid nitrogen immediately after surgical removal and stored at -80 ℃. Each tumor sample was evaluated microscopically, and macro-dissection was performed to ensure that more than 70% of the sample was tumor tissue before DNA extraction. Five milliliters of venous blood was collected from 62 GC patients and 392 age- and sex-matched healthy controls without cancer history from the same ethnic population. Informed consent was obtained from all the patients and controls for the use of their specimens and clinicopathologic data for this study. The study was approved by the Institutional Human Ethics Committee.

Genotyping of the FGFR4 Gly388Arg polymorphism

DNA samples from tumor and normal adjacent tissue were prepared with the Puregene DNA extraction kit (Qiagen, Valencia, CA, United States). Genomic DNA was extracted and purified from the blood of GC patients and the healthy control group using the QIAamp DNA Blood Midi kit (Qiagen, Germany). Sanger sequencing was applied to genotype the *FGFR4* Gly388Arg polymorphism with the following PCR primers: 5'-GCGGCCAGTCTCACCACTGAC-3' and 5'-TGGAGTCAGGCTCTTCCGGCA-3'. Each primer was tagged with the M13 primer as a uniform sequencing primer for individual PCR products to facilitate the sequencing process. All PCR assays were carried out in a 25 μL volume containing 10 ng genomic DNA, 0.1 μmol/L of each primer, and 1 × AmpliTaq Gold Pre Mix (AB). The PCR conditions were as follows: 95 ℃ for 10 min; 30 cycles of 95 ℃ for 30 s, 58 ℃ for 30 s, and 72 ℃ for 30 s; and 5 min at 72℃. The PCR product was 355 bp and was sequenced in both directions using the BigDye Terminator kit 3.1 (Applied Biosystems; Foster City, CA, United States) and ABI Genetic Analyzer3730 × l (Applied Biosystems) according to the manufacturer's instructions. Sequence traces were analyzed for the polymorphism after assembly and quality calling with SeqScape2.5 sequence analysis software (Applied Biosystems).

Statistical analysis

Differences in the general characteristics and genotype frequencies of the *FGFR4* Gly388Arg polymorphism between GC patients and healthy controls were estimated using the χ^2 test. Hardy-Weinberg equilibrium analyses were performed to compare observed and expected genotype frequencies using the χ^2 test. Binary logistic regression was used for all analysis variables to estimate risk as the ORs with 95%CIs. The relationships between the *FGFR4* genotype and clinicopathological parameters were tested with the χ^2 test. The Kaplan-Meier product-limit method, the log-rank test, and the Cox regression model were applied to evaluate the effect of the *FGFR4* genotype on the overall survival of patients with GC. The covariates included in the models were age, gender, clinical stage, tumor grade, HER2 status and *FGFR4* genotype. All analyses were carried out with SPSS for Windows software (SPSS, Chicago, IL, version 16.0). A P value < 0.05 was considered to be statistically significant.

RESULTS

FGFR4 genotype in healthy controls and GC patients

Data from the 62 patients who provided both tumor tissue and blood samples showed that the Gly388Arg genotypes were identical between tumor tissue and blood from the same individual. This result confirms that there were no somatic mutations at this locus in any of these patients.

The clinical characteristics of all the subjects are shown in Table 1. There were no significant differences in age, gender, smoking, hypertension, or diabetes status between the GC patients and healthy controls. The frequencies of the *FGFR4* Gly388Arg polymorphism genotypes are summarized in Table 2. Among the 304 GC patients, 118 patients (38.8%) were homozygous for the Gly388 allele, 124 were heterozygous (40.8%), and 62 were homozygous (20.4%) for the Arg388 allele. In the healthy controls, the frequencies of the Gly/Gly, Gly/Arg, and Arg/Arg genotypes and the Arg allele were 33.6%, 48.0%, 18.4% and 42.3%, respectively. The fre-

quencies were consistent with the Hardy-Weinberg equilibrium in the healthy controls. The genotype (χ^2= 3.589, P = 0.166) and allele frequencies (χ^2 = 0.342, P = 0.559) of the *FGFR4* Gly388Arg polymorphism were not different between the GC patients and the healthy controls. Binary logistic regression analysis indicated that the ORs for the carriers of Gly/Arg, carriers of Arg/Arg, and carriers of the Gly/Arg or Arg/Arg genotypes were 0.738 (95%CI: 0.527-1.033), 0.963 (95%CI: 0.633-1.466) and 0.800 (95%CI: 0.586-1.093), respectively. No differences were observed between patients and healthy controls. The distribution of the Gly388 and Arg388 alleles was not different between patients and healthy controls (OR = 0.938, 95%CI: 0.756-1.163). These results suggest that the *FGFR4* Gly388Arg polymorphism is not an independent risk factor for GC in Chinese patients.

FGFR4 Gly388Arg polymorphism is not associated with any clinicopathological parameters in GC patients

Based on previous reports and due to the requirements for accurate statistical analysis, the 304 GC patients were divided into two groups: patients with the Gly/Gly genotype and patients with the Arg/Arg or Arg/Gly genotypes. As shown in Table 3, no correlation was observed between the *FGFR4* Gly388Arg polymorphism and any of the following clinicopathological parameters: age at diagnosis, gender, tumor size, clinical stage, differentiation and HER2 status.

Impact of the FGFR4 Gly388Arg polymorphism on GC survival

When analyzing the entire patient cohort using Kaplan-Meier survival analysis, no difference was observed in survival between patients with the Gly/Gly genotype and patients with the Gly/Arg or Arg/Arg genotypes (log rank χ^2 = 0.047, P = 0.829). When the patient population was stratified by clinicopathological parameters, such as age at diagnosis, gender, tumor size, differentiation, clinical stage, HER2 status and chemotherapy history (5-fluorouracil and cisplatinum), we found that the presence of the Arg388 allele was associated with a shorter survival time in GC patients if the tumor was small (less than or equal to 3 cm in size) (log rank χ^2 = 5.449, P = 0.020, Figure 1A), well differentiated (log rank χ^2 = 12.798, P = 0.000, Figure 1B), of T1 or T2 stage invasion depth (log rank χ^2 = 4.745, P = 0.029, Figure 1C), without lymph node involvement (log rank χ^2 = 6.647, P = 0.010, Figure 1D), and at an early clinical stage (log rank χ^2 = 4.615, P = 0.032, Figure 1E). No survival differences were observed in any of the other subgroups (Table 4). In addition, the Cox proportional hazard analysis of survival demonstrated that the *FGFR4* Gly388Arg polymorphism was not an independent prognostic factor for GC patients (data not shown).

DISCUSSION

In the present study, the overall frequencies of the Gly/Gly, Gly/Arg, Arg/Arg genotypes and Arg388 allele in healthy controls were 33.6%, 48.0%, 18.4% and 42.3%, respectively. As shown in Table 5, the frequencies of the Arg allele or Arg/Arg genotypes in our study were similar to those of the Chinese patient populations reported by Chen *et al*[27], Zhu *et al*[28], Ma *et al*[29]and Yang *et al*[30]. Interestingly, the Arg388 allele frequencies in the Chinese population are much higher than those in Caucasian cohorts. In a meta-analysis by Xu *et al*[31], the Arg

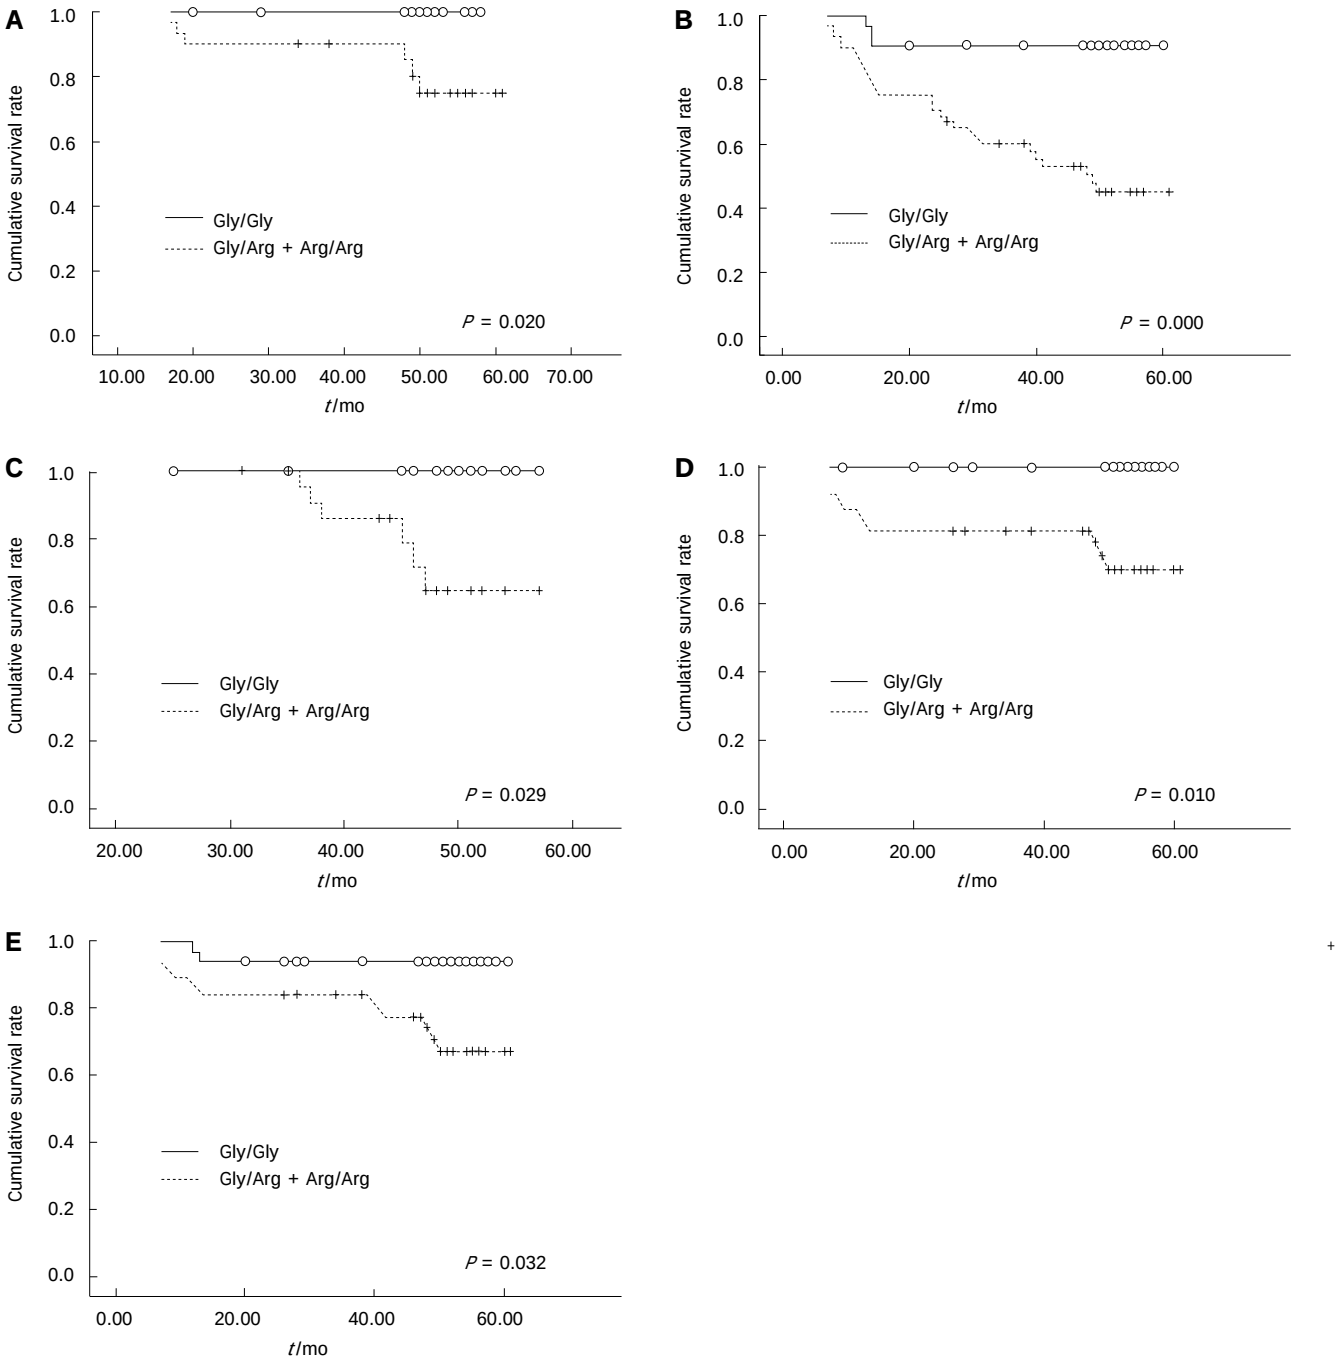

Figure 1 A considerable difference was found between patients with the Gly/Gly genotype and patients with Gly/Arg or Arg/Arg genotypes after stratified Kaplan-Meier survival analysis. A: Patients with tumor size ≤ 3 cm; B: Patients with well-differentiated gastric cancer (grades Ⅰ and Ⅱ); C: Patients classified as stage T1 or T2; D: Patients with no lymph node involvement; E: Patients at an early clinical stage (Ⅰ/Ⅱ).

allele was more highly represented among controls of Asian descent than controls of European and African-American descent. Our findings also support this result, which is contrary to a previous study that reported approximately 50% homo- or hetero-zygous carriers of the Arg allele in healthy controls independent of ethnic background[26].

For the first time, we report the distribution of the *FGFR4* Gly388Arg genotypes and alleles in both GC patients and matched healthy controls. No differences were found between GC patients and healthy controls. Our findings suggest that this polymorphism is not a risk factor for GC initiation in the Chinese population. This result is consistent with previous reports on several cancer types, including breast cancer and lung cancer, in different races[10,18,24]. However, it has been reported that the Arg388 allele is associated with an increased risk of prostate cancer[13,14]. Moreover, this polymorphism also plays a role in some types of non-cancer disease initiation. Zhu *et al*[28] and Ma *et al*[29] found that the *FGFR4* Gly388Arg polymorphism can act as a protective factor against coronary artery disease in the Chinese popula-

tion. Based on a recent case-control study, the *FGFR4* Gly388Arg polymorphism is also considered to be a genetic risk factor that contributes to the aggravation of gallstone disease[27]. Therefore, these findings may reflect a tissue-specific effect of this polymorphism.

In our study, we found a significant difference following stratification by tumor size, differentiation, invasion depth, lymph node involvement or clinical stage ($P < 0.05$). Clinical stage depends on invasion depth and lymph node involvement. Therefore, our results demonstrate that the *FGFR4* Gly388Arg polymorphism is a prognostic factor in relatively small (less than 3 cm), well-differentiated (grades Ⅰ and Ⅱ) and early-stage GC (stages Ⅰ and Ⅱ) tumors but not in the total cohort of GC patients, which is in contrast to previous reports by Ye *et al*[26]. Because this study (and that of Ye *et al*[26]) focused on patients of Chinese origin, we suggest two possibilities to explain the conflicting results. The first possibility is the sample size. One major strength of our study is its large size. Our study included a higher proportion of patients with large tumors and late-stage disease than the study by Ye *et al*[26]. Thus, our results are more reliable given the isolation of the target patients from a pool of varied cases. Second, another possible explanation for the discord is that different DNA analysis methods were used in these two studies. Our study used a direct sequencing approach for genotype analysis, which was a more reliable method than the PCR-RFLP approach used by Ye *et al*[26]. Moreover, we detected the association between HER2 status and the FGFR4 Gly388Arg polymorphism in GC for the first time. No correlation was observed between HER2 status and the FGFR4 genotype ($P = 0.532$), which was consistent with previous reports in breast cancer[32].

The biochemical function of the *FGFR4* Gly388Arg polymorphism in GC is still unclear. No correlation was found between the *FGFR4* genotype and mRNA expression by Ye *et al*[26], and therefore, we do not attribute the polymorphism's effect to FGFR4 up-regulation. The FGFR4 Arg388 allele may be in linkage disequilibrium with other genetic changes that contribute to poor prognosis in GC. A previous study indicated that 39 head and neck cancer cell lines harboring the FGFR4 Arg388 allele exhibited an increased sensitivity to cisplatinum[33]. In breast cancer, no significant survival differences between *FGFR4* genotypes were found in patients without adjuvant systemic therapy. However, with adjuvant systemic therapy, breast cancer patients with the Gly/Gly genotype exhibited better disease-free survival and overall survival duration. Notably, this association seemed to be attributable to relatively poor therapy response in Arg388 carriers[32]. In our study, 156 patients underwent chemotherapy (5-fluorouracil and cisplatinum) following surgery. However, the median survival time of patients with the Gly/Arg and Arg/Arg genotypes did not differ from that of patients with the Gly/Gly genotype who underwent chemotherapy. Therefore, our data do not provide any evidence to support the theory that the FGFR4 Gly388Arg polymorphism is associated with sensitivity to chemotherapy.

In conclusion, our results demonstrate that the *FGFR4* Gly388Arg polymorphism plays no role in the initiation

of GC in Chinese patients, but it may be a factor in the survival of patients harboring relatively small, well-differentiated tumors in early GC stages.

COMMENTS

Background

Gastric cancer (GC) is one of the most common cancers in the world. Surgical resection and chemotherapy are only effective for a limited number of patients, and their prognoses remain very poor. Accordingly, there is an urgent need for a better understanding of the genesis of GC to establish a sound basis for future treatments.

Research frontiers

A germline polymorphism in the fibroblast growth factor receptor 4 (FGFR4) gene resulting in an amino acid change from glycine to arginine was identified several years ago. The presence of the FGFR4 Arg388 allele is associated with decreased disease-free survival in many cancers, including breast, lung, colon, prostate, soft tissue sarcoma, melanoma, and head and neck squamous cell carcinoma. Recently, Ye *et al* reported that the FGFR4 Arg388 allele was an independent prognostic factor in Chinese patients with GC. To our knowledge, this is the only report on the association between the FGFR4 Gly388Arg polymorphism and the progression of GC in Chinese patients, and this association needs further confirmation. Moreover, no study has been conducted on the correlation between this polymorphism and the risk of GC.

Innovations and breakthroughs

The correlation between the *FGFR4* Gly388Arg polymorphism and the risk of GC was investigated for the first time, and the authors suggested that this polymorphism was not a risk factor for GC cancer initiation. Another interesting finding was that the Arg388 allele frequency was much higher in this Chinese population than in Caucasian cohorts. The authors also investigated the associations between the *FGFR4* Gly388Arg polymorphism and clinicopathological parameters and survival in a larger sample series using more reliable methods. This result demonstrates that this polymorphism may contribute to the survival of patients with relatively small, well-differentiated tumors in the early stages of GC.

Applications

The FGFR4 Gly388Arg polymorphism is helpful for predicting the prognosis of early-stage GC patients with relatively small, well-differentiated tumors.

Terminology

Single nucleotide polymorphism (SNP): Genetic polymorphisms are natural variants in the genomic DNA sequence that are present in more than 1% of the population. One SNP represents the DNA variations in a single nucleotide. SNPs are widely used to better understand disease processes, thereby paving the way for genetic-based diagnostics and therapeutics.

Peer review

The results are interesting and may convey a useful prognostic marker for some GC patients.

Abstract

AIM: To investigate the association between *Helicobacter pylori* (*H. pylori*) infection and the prevalence of Crohn's disease (CD).

METHODS: Subjects were selected from patients admitted the gastrointestinal (GI) department at The First Affiliated Hospital School of Medicine (Zhejiang University) for abdominal pain, hematochezia, diarrhea and other GI symptoms between January 2008 and September 2012. CD was diagnosed by endoscopy and biopsy. *H. pylori* infection was detected by a ^{14}C-urea breath test and culturing of the biopsy sample. Demographic, anthropometric and serologic data were collected for each patient. *H. pylori* infection rate was compared between CD and control groups, followed by a subgroup analysis based on extent and severity of CD. Student's *t*, Mann-Whiney *U*, and χ^2 tests were used to analyze the data.

RESULTS: A total of 447 patients were analyzed, including 229 in the CD group and 248 in the control group. There were no significant differences in age, sex, and rates of hypertension or diabetes. However, the CD group showed significantly higher rates of smoking history (34.9% *vs* 18.1%), alcohol intake (17.4% *vs* 8.1%), white blood cell count (9.7 ± 2.9 × 10^9/L *vs* 4.3 ± 0.9 × 10^9/L), and C-reactive protein (36.3 ± 20.8 mg/L *vs* 5.5 ± 2.3 mg/L) but lower body mass index (24.5 ± 2.0 kg/m^2 *vs* 26.0 ± 2.2 kg/m^2) than the control group. The *H. pylori* infection rate in the CD group was 27.1%, significantly lower than that of 47.9% in the control group. Furthermore, the *H. pylori* infection rates in patients with colonic, small intestine, ileocolonic and extensive CD were 31.1%, 28.9%, 26.8% and 25.9% respectively, all of which were significantly lower than in the control group. Finally, the *H. pylori* infection rates in patients with remission, moderate and severe CD were 34.3%, 30.7% and 22.0% respectively, which were also significantly lower than in the control group.

CONCLUSION: Lower *H. pylori* infection in CD patients suggests a correlation between bacterial infection and CD, suggesting caution when considering *H. pylori* eradication in CD patients.

Key words: Crohn's disease; *Helicobacter pylori*; Urea breath test; Biopsy; Pathogenesis; Inflammatory bowel disease; Bacteria

Core tip: The association between *Helicobacter pylori* (*H. pylori*) infection and Crohn's disease (CD) prevalence is still unclear. In this retrospective study, we collected 229 CD patients and 248 control subjects to investigate the risk factors for prevalence, extent and severity of CD. Through extensive analysis, we found significantly lower *H. pylori* infection rates in CD patients having different disease extent and severity, providing evidence for bacteria involvement in CD pathogenesis and serving as a reminder for clinicians to remain cautious when considering *H. pylori* eradication in CD patients.

Xiang Z, Chen YP, Ye YF, Ma KF, Chen SH, Zheng L, Yang YD, Jin X. *Helicobacter pylori* and Crohn's disease: A retrospective single-center study from China. *World J Gastroenterol* 2013; 19(28): 4576-4581 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4576.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4576

INTRODUCTION

Crohn's disease (CD) is a chronic and relapsing inflammatory disease affecting any part of the intestine, most commonly involving the distal ileal, ileocecal and colonic sections[1]. CD is more common in northern Europe and America than in southern Europe and developing countries, and its prevalence has increased since the mid-1970s[2,3]. The pathogenesis of CD is unclear and increasing evidence supports the hypothesis of combinational involvement of genetic predisposition, immune response, and the environment, especially the gut bacteria and antigens[4]. Though several pathogens have been considered as infectious agents in CD, conclusive data is still lacking[5]. Therefore, identifying the correlation between a potential bacteria and CD pathogenesis is of clinical importance.

Helicobacter pylori (*H. pylori*) belongs to the family of curved or spiral flagellated, Gram-negative microaerophilic bacterium that is thought to have co-existed with humans for over 5000 years[6,7]. Since its discovery in 1984[8], *H. pylori* has been characterized as the causative agent for peptic ulceration and has been implicated in various autoimmune diseases[9]. *Helicobacter* are also excellent colonizers of the gastrointestinal surface for their microaerophilic metabolism, spiral shape, and peculiar motility. Considering the immune regulation, the capacity for colonization, and the nature of autoimmune-related damage in CD, it is theoretically plausible that *H. pylori* infection may take part in the pathogenesis of CD.

In immunodeficient rodents, *Helicobacter hepaticus* and *Helicobacter bilis* induce a persistent inflammation of the colon and cecum[10,11]. Nevertheless, the observations from human studies were confusing. *Helicobacter* was absent or only detected in the intestinal mucosa of a small subgroup of patients in both an English and an Australian study[12,13]. In contrast, Bohr *et al*[14] identified enterohepatic *Helicobacter* species in patients with inflammatory bowel disease (IBD). Furthermore, a meta-analysis suggested a protective role of *H. pylori* infection in CD pathogenesis but the heterogeneity among enrolled studies and the possibilities of publication bias limited the confidence of these results[15]. Therefore, we conducted a large-scale case control study to investigate the association between *H. pylori* infection and different severity and types of CD.

MATERIALS AND METHODS

Ethics statement

The protocol was approved by the institutional review board at Zhejiang University and conducted in accordance with the Declaration of Helsinki. We followed guidelines from the STROBE statement when designing the study and preparing the manuscript[16]. Written informed consent was collected from all patients.

Patients

Study subjects were selected from patients who were admitted for abdominal pain, hematochezia, diarrhea, and other GI symptoms between January 2008 and September 2012. Patients either underwent both a *H. pylori* test and endoscopy (gastroscopy, colonoscopy, or capsule) screen during admission or had recorded evidence of current *H. pylori* infection and CD. For the CD group, diagnosis was based on endoscopy manifestation and biopsy, as adopted by the Asia-Pacific consensus[17]. Exclusion criteria included previous acid inhibition or *H. pylori* eradication, 5-aminosalicylic administration and differential diagnosis with intestinal tuberculosis, ulcerative colitis (UC), Behçet's disease, or ischemic colitis. The control group was comprised of patients who underwent the initial screening but were subsequently excluded by negative results for CD and other known GI diseases.

CD patients were further categorized into subgroups according to the severity and extent of disease following the Chinese IBD guidelines[18]. For convenience, we adopted the Harvey-Bradshaw index (HBI)[19], a simplified version of the Crohn's disease activity index (CDAI), to evaluate CD severity. This index comprises general conditions, degree of abdominal pain, frequency of diarrhea, existence of abdominal mass, and complications such as arthritis, nodular erythema, gangrenous pyoderma, aphthous stomatitis, fistula, and abscess. Scores of 0-4 were appointed to each parameter according to disease severity. The HBI score was the summary of scores from each parameter, where $\leqslant 4$ was remission, 5-8 was moderate, and $\geqslant 9$ was severe. In addition, according to the extent revealed from radiology and endoscopy, CD was further divided into small intestinal CD, colonic CD, ileocolonic CD, and extensive CD, where the involved scale was over 100 cm.

Analysis of demographic, anthropometric and serologic data

Demographic and anthropometric data were retrieved

from the medical records of enrolled patients and included age, sex, smoking history, alcohol intake history (with positive designation made according to the Chinese guideline of alcoholic liver disease[20]), hypertension (defined as a patient on antihypertensive drug for blood pressure over 140/90 mmHg), body mass index (BMI; calculated as weight in kilograms divided by height in meters squared), and diabetes mellitus (DM; defined as fasting glucose $\geqslant$ 7.0 mmol/L or with past history of diagnosed DM). Patient blood samples were routinely gathered and tested for general condition and inflammation, including C-reactive protein (CRP) and complete blood cell counts. The main complications of CD were also recorded, including fistula and obstruction.

^{14}C-urea blood test and biopsy sample culture

H. pylori infection was detected by a ^{14}C-urea blood test (UBT) and biopsy sample culture. Serum *H. pylori*-IgG was not accepted as a diagnostic tool, as it does not reflect the current infection status. First described in 1989[21], ^{14}C-UBT is considered a rapid diagnostic procedure for *H. pylori* detection for its ability to convert urea to ammonia and carbon dioxide. UBT is also recommended in leading society guidelines as a preferred non-invasive choice for *H. pylori* detection[22]. According to the manufacturer's instruction (Headway, Shenzhen, China), patients were given a tablet of urea labeled with an uncommon isotope of radioactive carbon-14. In the following 30 min, the amount of isotope labeled carbon dioxide was measured in exhaled breath by scintillation. A positive result indicated the existence of *H. pylori*. For biopsy sample culture, samples from the gastric antrum obtained by gastroscopy were cultured for *H. pylori* as previously described[23].

Statistical analysis

Data were assessed for normality, and log-transformed as needed. Quantitative variants were expressed as mean ± SD, and analyzed by Student's *t* test or Mann-Whiney *U* test. For qualitative variants, percentages or frequencies were calculated and a χ^2 test was used for comparison. SPSS 17.0 software (Chicago, IL, United States) was used for all statistical analyses, and a P value < 0.05 was considered statistically significant.

RESULTS

Characteristics of study subjects

Following careful review of medical records, we identified 1563 patients that had been admitted to our ward for abdominal pain, hematochezia, diarrhea, and other GI symptoms over the past five years. Among these patients, 1231 were selected according to their having undergone both endoscopy and *H. pylori* test. The endoscopic diagnosis of CD was given to 921 patients by colonoscopy, 603 by gastroscopy, and 105 by capsule endoscopy. Furthermore, many of the patients had received more than one type of endoscopy. For the *H. pylori* infection test, 603 patients were investigated by biopsy sample culturing and 628 patients were investigated by ^{14}C-UBT. Among these 1231 subjects, 287 were diagnosed as CD by endoscopy and/or biopsy confirmation, with 18 of these patients having already received 5-aminosalicylic therapy, 11 being under proton pump inhibitor (PPI) therapy for reflux symptoms, and 21 having achieved *H. pylori* eradication. Among the remaining patients, 8 were further excluded due to positive serum *H. pylori*-IgG but negative ^{14}C-UBT or biopsy sample culture results. Finally, a total of 229 patients were enrolled into the CD group. Among them, 132 and 97 patients had ^{14}C-UBT and biopsy sample culture, respectively.

Among 1231 subjects, 251 were diagnosed with UC, 279 with different degrees of hemorrhoids, 41 with ischemic colitis, 7 with antibiotic-associated colitis, 5 with radiation enterocolitis, 11 with intestinal tuberculosis, 71 with sigmoiditis and proctitis, and 2 with Behçet's disease. The remaining 277 patients had GI symptoms but normal endoscopy and biopsy results. Nevertheless, there were still 14 patients under anti-acid therapy (10 with PPI and 4 with H_2 receptor antagonist) and 15 patients in which *H. pylori* had been eradicated. Finally, there were 248 patients enrolled into control group. Among them, 147 and 101 patients had ^{14}C-UBT and biopsy sample cultures, respectively.

Demographic, anthropometric and serologic data of enrolled patients

The average age and sex distribution of patients were balanced between two groups (Table 1). Differences in the rates of hypertension and DM between the two groups were not significant. However, BMI was significantly lower in the CD group than that in the control group, while the rate of smoking history was approximately twice that of the CD group ($P < 0.01$), reinforcing a correlation between smoking history and CD pathogenesis. In addition, percentage of alcohol intake was also significantly higher in the CD group. Finally, the two inflammation-associated markers, CRP and white blood cell (WBC) count, were significantly higher in the CD group, supporting the potential involvement of inflammation in CD.

Association between CD and H. pylori infection

Total *H. pylori* infection rate in the CD group was 27.1%, significantly lower than that of 47.9% in the control group. In the CD group, there were 45 patients with colonic CD, 28 with small intestine CD, 112 with ileocolonic CD, and 34 with extensive CD. In a subgroup analysis, all of the above-mentioned CD subgroups had significantly lower *H. pylori* infection rate than that in the control group, but the differences among these subgroups did not reach statistical significance (Table 2). We further divided the CD group into three subgroups according to severity determined by endoscopic appearance. Briefly, there were 32, 88 and 109 patients

Table 1 Demographic, anthropometric and serologic data of enrolled patients

Group	CD (n = 229)	Control (n = 248)	P value
Age (yr)	46.2 ± 10.2	46.8 ± 9.4	0.79
Sex (male/female)	133/96	141/107	0.07
Smoking history	34.90%	18.10%	< 0.01
Alcohol intake	17.40%	8.10%	< 0.01
BMI (kg/m^2)	24.5 ± 2.0	26.0 ± 2.2	< 0.01
Hypertension	14.80%	16.10%	0.09
Diabetes,	7.90%	6.90%	0.13
CRP (mg/L)	36.3 ± 20.8	5.5 ± 2.3	< 0.01
WBC (× 10^9/L)	9.7 ± 2.9	4.3 ± 0.9	< 0.01

BMI: Body mass index; CRP: C-reactive protein; WBC: White blood cell.

Table 2 *Helicobacter pylori* infection rate between different Crohn's disease types n (%)

Group	*H. pylori*-positive	*H. pylori*-negative	P value
CD	62 (27.1)	167 (72.9)	< 0.01
Colonic CD	14 (31.1)	31 (68.9)	< 0.01
Small intestine CD	11 (28.9)	27 (71.1)	< 0.01
Ileocolonic CD	30 (26.8)	82 (73.2)	< 0.01
Extensive CD	7 (25.9)	27 (74.1)	< 0.01
Control	119 (47.9)	129 (52.1)	

H. pylori: *Helicobacter pylori*; CD: Crohn's disease.

in the CD subgroups of remission, moderate CD, and severe CD, with corresponding *H. pylori*-positive rates of 34.3%, 30.7% and 22.0% respectively (Table 3). All three subgroups had significantly lower *H. pylori* infection rates than the control group. Nevertheless, though there was a decrease trend in *H. pylori* infection rate from the CD remission group to the severe CD group, there was no significant difference among these three groups.

DISCUSSION

Crohn's disease can affect the entire digestive system from mouth to anus, but it is most commonly seen in the final segment of the small bowel and the first part of the colon. The frequency of CD has significantly increased in the last century, becoming a heavy economic burden[24]. The etiology of CD is still not completely understood[25], although *NOD2/CARD15* was the first CD susceptibility gene to be discovered[26]. Oxidative stress, autophagy, endoplasmic reticulum stress and other molecular pathways have been correlated with CD prevalence[27,28]. Moreover, an infectious organism might be the initiating factor for CD pathogenesis. This hypothesis was supported by evidence from animal models showing that spontaneous colitis did not develop in a germ-free environment[29]. Nevertheless, none of suggested bacterial causes have been conclusively proven[5].

The role of *H. pylori* in IBD pathogenesis has been enticing. Generally, *H. pylori* had two main subgroups: gastric *Helicobacter* that preferentially colonize the stomach, and enterohepatic *Helicobacter* that infect the intestinal or hepatobiliary system[30]. Accumulating evidence from gene knockout rodents indicate that the presence of enterohepatic helicobacter worsens the severity or hastens the development of colitis[31,32]. A more causative role was suggested by the observation that *Helicobacter muridarum* can provoke CD in severe combined immunodeficiency mice upon receipt of T cells[33]. In addition, lower *H. pylori* infection rate in CD patients was not influenced by antibiotic use[34]. However, the results from human studies are confusing. The largest study examining the association between *H. pylori* infection and CD was conducted in the Netherlands by Wagtmans *et al*[35], which enrolled 386 CD patients and 277 controls. Though their results supported the positive association between *H. pylori* infection and CD prevalence, the credibility of these findings was weakened by the use of serum *H. pylori*-IgG as the diagnostic tool. A meta-analysis was conducted that supported the involvement of *H. pylori* infection in CD, but study heterogeneity and publication bias decreased its credibility[15]. In contrast, two independent studies found higher *H. pylori* infection in CD patients than in controls (12% *vs* 4% and 14.0% *vs* 1.4%, respectively)[14,36]. Furthermore, other studies investigating *Helicobacter* species in human colon also failed to find any correlation with CD[37,38].

To tackle this discordancy, we retrospectively investigated the association between *H. pylori* infection and CD in a large case control study of Chinese patients. The initial results showed a significantly lower *H. pylori* infection rate in the CD group, which is in accordance with the previous meta-analysis[15]. The ^{14}C-UBT and biopsy sample culture had higher sensitivity and specificity than the serum *H. pylori*-IgG test, increasing the credibility of these findings. The significantly lower BMI in CD patients may be due to malnutrition caused by diarrhea and other GI symptoms. Based on subgroup analysis (Tables 2 and 3), we found significantly lower *H. pylori* infection in each CD subgroup and a trend of decreased *H. pylori* infection paralleling with increased CD severity, increasing the correlation between *H. pylori* infection and CD. Theoretically, it is possible for a protective role of *H. pylori* infection in CD[39]. In detail, *H. pylori* is able to decrease immune-mediated intestinal injury by triggering Th1 dominated cell defense[40] and inhibit other bacterially-induced mucosal damage by inducing antibacterial peptide production[41].

Several limitations of this study should be acknowledged. First, *H. pylori* infection in colon biopsy was not detected, which may decrease disease occurrence rate. Furthermore, other members of the *Helicobacter* family are associated with the development of gut inflammation and some are found more commonly in people with IBD when compared to healthy controls. However, these members colonize the lower gut, rather than having a location limited to the stomach. Therefore, while these data are convincing, it would be helpful to detect them in another independent experiment. Second, it is better to use ^{13}C-UBT instead of ^{14}C-UBT, since the for-

Table 3 *Helicobacter pylori* infection between different severity of Crohn's disease and control *n* (%)

Group	*H. pylori*-positive	*H. pylori*-negative	*P* value
CD	11 (34.3)	21 (65.7)	< 0.01[1]
Colonic CD	27 (30.7)	61 (69.3)	< 0.01[1]
Small intestine CD	24 (22.0)	85 (88.0)	< 0.01[1]
Control	119	129	

[1]*vs* control group. *H. pylori*: *Helicobacter pylori*; CD: Crohn's disease.

mer has no radiation and is safer for patients[42]. We have plans to implement this technique in our laboratory in the future. Third, wireless capsule endoscopy was used to detect small intestine CD. Though the effect of capsule endoscopy in small intestine CD diagnosis has been recognized[43], the lack of biopsy results may decrease its credibility. It would be helpful to include double balloon small bowel endoscopy. Fourth, the trend of decreased *H. pylori* infection paralleling with increased CD severity should be repeated in a larger clinical trial for statistical significance. Fifth, it is better to report *H. pylori* infection rate in IBD, where *H. pylori* in UC should be reported. We found a 30.5% *H. pylori* infection rate in UC patients and are currently preparing these data for submission. Finally, the causative effect of *H. pylori* infection in CD cannot be established through case control studies and further prospective clinical trial data are necessary.

In conclusion, our results provide evidence for the involvement of *H. pylori* in CD prevalence. These findings should serve as an important reminder to clinicians when considering *H. pylori* eradication in CD patients.

COMMENTS

Background

Crohn's disease (CD) is a chronic and relapsing inflammatory disease affecting any part of the intestine, with distal ileal, ileocecal and colonic regions most commonly involved. CD is more common in Northern Europe and America than in Southern Europe and developing countries, with increased incidence since the mid-1970s and unknown etiologies.

Research frontiers

Increasing evidence supports the combinational involvement of genetic predisposition, immune response, and environment, especially gut bacteria and antigens. Though some pathogens have been considered as infectious agents in CD, conclusive data is still lacking. Considering the immune regulation and colonization capacity of *Helicobacter pylori* (*H. pylori*) and the nature of autoimmune-related damage in CD, it is plausible that *H. pylori* infection may take part in the etiology of CD. However, results in humans remain unclear and contradictory. While *Helicobacter* was absent or only detected in the intestinal mucosa of a few patients in English and Australian studies, another study identified enterohepatic *Helicobacter* species in patients with inflammatory bowel disease. Furthermore, a meta-analysis suggested a protective role of *H. pylori* infection in CD pathogenesis. However, the heterogeneity among enrolled studies and the possibilities of publication bias limited the confidence of those results.

Innovations and breakthroughs

The authors conducted a large-scale case control study to investigate the association between *H. pylori* infection and different severity and type of CD. These findings are the first example of a significant correlation between *H. pylori* infection rate in CD patients and different subtypes.

Applications

Lower *H. pylori* infection in CD patients provides evidence for bacterial involvement in the pathogenesis of CD and reminds clinicians remain cautious when considering *H. pylori* eradication in CD patients.

Peer review

Their results supported the potential involvement of *H. pylori* infection in CD pathogenesis and raised concern for the necessity of *H. pylori* eradication in CD patients. This manuscript provides some key information, and builds on the published literature. The authors should be able to enhance this by extensive revisions.

Abstract

AIM: To assess the protective effect of berberine administration and the role of nitric oxide (NO) in visceral hypersensitivity.

METHODS: Fifty male Sprague-Dawley rats were randomly assigned to five groups. An inflammatory bowel disease model was induced in rats by intracolonic instillation of 1 mL 4% acetic acid at 8 cm proximal to the anus for 30 s and restraint stress. After subsidence of inflammation on day 7 of the experiment, the rats were subjected to rectal distension, performed by a balloon (6-Fr, 2 mm external diameter, disposable silicon balloon-urethral catheter for pediatric use) which was rapidly inflated with increasing volumes of prewarmed (37 ℃) water (0.1, 0.2, 0.3, 0.4, 0.6, 0.8 and 1 mL) for 30 s at four-minute intervals, and then the abdominal withdrawal reflex (AWR) and the level of fecal output were measured, respectively. AWR scores either 0, 1, 2, 3 or 4 were obtained by blinded observers. Rats had been pretreated with berberine or aminoguanidine (NO synthetase inhibitor) or berberine + aminoguanidine before measurement.

RESULTS: The rats in the placebo group showed a hypersensitive response to rectal distension (2.69 ± 0.08 *vs* 1.52 ± 0.08, P = 0.000) and defecated more frequently than those in the control group (5.0 ± 0.16 *vs* 0.44 ± 0.16, P = 0.000). Comparing the berberine with placebo group, the AWR scores were reduced for all distension volumes and were significant at 0.2-1 mL (1.90 ± 0.08 *vs* 2.69 ± 0.08, P = 0.000), while the numbers of hard pellets, soft pellets, formless stools, and total fecal output in the placebo group were significantly larger than in the berberine group (5.0 ± 0.16 *vs* 2.56 ± 0.16, P = 0.000). Administration of aminoguanidine or berberine + aminoguanidine before VH score measurement reversed the antinociceptive effect of berberine (2.52 ± 0.08 *vs* 1.90 ± 0.08, P = 0.000; 2.50 ± 0.08 *vs* 1.90 ± 0.08, P = 0.000). The numbers of hard pellets, soft pellets, formless stool, and total of fecal output in aminoguanidine group were significantly larger than the corresponding values in control group, berberine group, and berberine + aminoguanidine group (4.81 ± 0.16 *vs* 0.44 ± 0.16, P = 0.000; 4.81 ± 0.16 *vs* 2.56 ± 0.16, P = 0.000; 4.81 ± 0.16 *vs* 3.75 ± 0.16, P = 0.000). The berberine and berberine + aminoguanidine groups showed reduced defecation, but aminoguanidine alone did not reduce defecation (2.56 ± 0.16 *vs* 4.81 ± 0.16, P = 0.000; 3.75 ± 0.16 *vs* 4.81 ± 0.16, P = 0.000).

CONCLUSION: Berberine had an antinociceptive effect on visceral hypersensitivity, and NO might play a role in this effect.

Key words: Berberine; Irritable bowel syndrome; Visceral hypersensitivity; Nitric oxide

Core tip: Berberine had an antinociceptive effect on visceral hypersensitivity. This effect was reduced by nitric oxide (NO) synthetase inhibitor, thus NO might play a role in the effect of berberine.

INTRODUCTION

It is believed that chronic visceral hypersensitivity (VH), abnormal gastrointestinal motility and altered central processing may be major pathophysiological mechanisms of irritable bowel syndrome (IBS)[1]. Gut hypersensitivity may lead to alterations in gut motility by disturbing regulatory reflex pathways and secretory function[2]. These abnormalities typically reflect the symptom pattern of IBS, which is characterized by abdominal pain or discomfort, and is associated with alterations in defecation frequency, stool passage, and stool form[3,4].

According to the recent Rome Ⅲ Criteria[5], IBS can be diagnosed based on at least 3 mo, with onset at least 6 mo, of recurrent abdominal pain or discomfort associated with two or more of the followings: (1) improvement with defecation; (2) onset associated with a change in stool frequency; and (3) onset associated with a change in stool form (appearance). Additionally, IBS patients are further subdivided into IBS with diarrhea, IBS with constipation, mixed IBS with diarrhea and unspecified IBS.

VH is a consistent finding in a large proportion of patients with IBS and provides a physiological basis for the development of IBS symptoms[2,6]. However, the exact mechanism of its action is still unclear. Recently, it has been documented that increasing the nitric oxide (NO) level in the extracellular space of the target tissue is one of the major mechanisms involved and this has been clarified in recent molecular studies[7]. There is growing evidence from previous studies that NO plays an important role in pain transmission and the antinociceptive action on VH or peritoneal pain[2,6,8-10].

It has been discovered that some drugs can be used to attenuate VH in IBS patients[11]. However, many drug treatments have not been satisfactory, with intractable adverse effects. Therefore, it is necessary to seek an effective and low-cost treatment for IBS. Berberine (Coptis chinensis Franch, var. asperma Don, family Ranunculaceae) is a botanical alkaloid isolated from the root and bark of *Rhizoma coptidis*, an ancient Chinese herb that has been used to treat gastroenteritis for many years, which is preferred for its inexpensiveness and low incidence of adverse effects[12]. It has been demonstrated that berberine has multiple pharmacological activities including anti-inflammatory[13], antimicrobial[14], anticancer[15,16], antidiabetic[17], antiarrhythmic[18], and antiseptic[19] effects. According to former studies, berberine has a significant effect in the treatment of experimental colitis[20-22]. Further evidence has shown that, in relation to the NO pathway, berberine has a significant effect on ethanol-induced gastric ulcers[23], endothelial progenitor cell mobilization and function[24], hyperglycemia-induced cellular injury and endothelial dysfunction[25], the early phase of hepatocarcinogenesis[26], and a rat model of Alzheimer's disease[27]. To establish whether berberine has a beneficial effect in IBS patients through reversal of VH, we examined the effects of berberine in a validated rodent model in which acute inflammation of the colon was associated with VH. The aim of this study was to evaluate whether berberine treatment prevents progression of VH to colorectal distension (CRD), and the involvement of NO in these effects.

MATERIALS AND METHODS

Animals

Male Sprague-Dawley rats, weighing 270-300 g, were obtained from the Animal Facility of Southeast Hospital, Zhangzhou, China. The rats were housed individually in an access-restricted room with controlled conditions (22 ± 1 ℃ and 65%-70% humidity) with free access to standard laboratory food and water. All the experimental protocols in this study were reviewed and approved by the Animal Studies Ethics Committee of Southeast Hospital.

Experiment model

The rats were lightly anesthetized with ether after an overnight fast and colitis was induced by intracolonic instillation of 1 mL 4% acetic acid at 8 cm proximal to the anus for 30 s. Then, 1 mL PBS was instilled to dilute the acetic acid and flush the colon. The control animals were handled identically except that 1 mL saline was instilled instead of 4% acetic acid. Rats were left to recover from colitis for 6 d, and were used for the experiments 7 d after induction of colitis.

Histological examination of inflammation

To examine the extent of colonic inflammation, histological samples were collected at the selected time points (2 and 7 d post-enema in two rats of each group). Sections with a thickness of 5 μm were cut and processed for hematoxylin and eosin staining. The coded slides were analyzed by a pathologist blinded with regard to the treatment group and the time points.

Rectal distension procedure

At 7 d post-enema, eight rats in each group were used for studying progression of VH to CRD. A 6-Fr (2 mm external diameter) disposable silicon balloon-urethral catheter for pediatric use was used. The maximal inflation volume for the balloon was 1 mL and the length of the maximally inflated balloon was 1.2 cm. After an overnight fast, the animals were lightly anesthetized with

ether, and the balloon was carefully inserted into the rectum until the premarked line on the catheter (2 cm distal from the end of the balloon) was positioned at the anus. The catheter was taped to the base of the tail to prevent displacement. After this procedure, the rats were placed in a transparent cubicle (20 cm × 8 cm × 8 cm) on a mirror-based, elevated platform while still sedated, and were allowed to recover and adjust for a minimum of 30 min before testing. The catheter was connected to a pressure transducer *via* a three-way connector. The signals from pressure transducer were processed and recorded on an IBM-compatible computer.

After the animals were fully awake and adjusted to the environment, ascending-limit phasic distension (0.1, 0.2, 0.3, 0.4, 0.6, 0.8 and 1.0 mL) was applied for 30 s every 4 min to induce CRD. The balloon was distended with prewarmed (37 ℃) water. We chose this protocol because hypersensitivity was reported to be best elicited by rapid phasic distension. The abdominal withdrawal reflex (AWR) was semiquantitatively scored as previously described[4]. The AWR score was assigned as follows: 0 = no behavioral response to distension; 1 = brief head movements followed by immobility; 2 = contraction of abdominal muscle without lifting of the abdomen; 3 = lifting of the abdomen; and 4 = body arching and lifting of pelvic structure.

After the experiments, the balloon was withdrawn and immersed in 37 ℃ water. The compliance of balloon was not infinite, therefore, we measured intraballoon pressure at each distension volume in 37 ℃ water, and digitally subtracted the value from that recorded during the CRD experiment to calculate the intrarectal pressure.

Restraint stress procedure

The rats were housed individually with no restrictions on food intake before testing. At 7 d post-enema, eight rats from each group were placed in restraint cages (5 cm × 5 cm × 20 cm), which could limit their body movement, but not restrict breathing. The rats were in the restraint cages for 3 h at room temperature. The feces excreted during restraint stress were divided into three types: hard pellet, soft pellet, and formless, and counted separately.

Experimental protocol

Ten healthy rats without treatment served as controls. In the placebo group, IBS was induced as described above and eight rats were treated once with physiological saline 1 d after enema. In the berberine group, IBS was induced as described above and eight rats were treated once daily with berberine (50 mg/kg) 1 d after enema. In the aminoguanidine group, eight rats were treated once daily with aminoguanidine (100 mg/kg) *via* intraperitoneal injection 1 d after enema. In the berberine + aminoguanidine group, eight rats were treated once daily with berberine (50 mg/kg) 1 d post-enema, and then were treated once daily with aminoguanidine (100 mg/kg) *via* intraperitoneal injection.

Statistical analysis

Data were expressed as mean ± SD. Significant differences between the three groups (AWR score) at each distension volume were statistically analyzed using ANOVA. The relationship between the intraballoon volume and intrarectal pressure was determined by linear regression analysis, and the estimated slope coefficients and intercepts were compared between groups using ANOVA. The level of fecal output was compared using ANOVA and further analyzed using Bonferroni's or Tamhane's *T2* test. Differences with $P < 0.05$ were considered to be significant. Multiple comparisons between the groups were corrected by SPSS version 13.0 software.

RESULTS

Histology of colonic tissue

Figure 1 shows the histology of the distal colon at days 2 and 7 after acetic acid instillation in the control group, placebo group, berberine group, aminoguanidine group, and berberine + aminoguanidine group. Mucosal hemorrhage with an inflammatory infiltrate in the lamina propria and the edematous submucosa were observed in the IBS model group, berberine group, aminoguanidine group and berberine + aminoguanidine group 2 d after acetic acid instillation. At day 7 after induction of colitis, all signs of inflammation had disappeared. No remarkable inflammatory features were detected at 7 d after acetic acid instillation in each group.

Detection of VH

The AWR scores were recorded in at least eight rats in each group after CRD was induced. The changes in AWR score paralleled the balloon volume in CRD, which confirmed that the AWR score reflected the intensity of distension. Comparing the berberine with placebo group, the AWR scores were reduced for all distension volumes and were significant at 0.2-1.0 mL (1.90 ± 0.08 *vs* 2.69 ± 0.08, $P = 0.000$). These data indicated that progression of VH to CRD was attenuated by berberine (Figure 2A). As shown in Figure 2A, rats in the placebo group showed a hypersensitive response to the ascending-limit phasic rectal distension, and berberine effectively reduced VH (2.69 ± 0.08 *vs* 1.90 ± 0.08, $P = 0.000$). However, VH was not effectively reduced in the aminoguanidine and berberine + aminoguanidine groups. The pain threshold (minimal volume to induce AWR 2) was measured in rats that underwent CRD. As shown in Figure 2, berberine significantly increased the nociceptive threshold in rats. Administration of aminoguanidine or berberine + aminoguanidine before VH score measurement reversed the antinociceptive effect of berberine (2.52 ± 0.08 *vs* 1.90 ± 0.08, $P = 0.000$; 2.50 ± 0.08 *vs* 1.90 ± 0.08, $P = 0.000$). In order to examine whether VH in rats was related to changes in rectal compliance, we compared the intraballoon volume-intrarectal pressure relationship in the five groups. A distension volume of 0.2-1.0 mL and

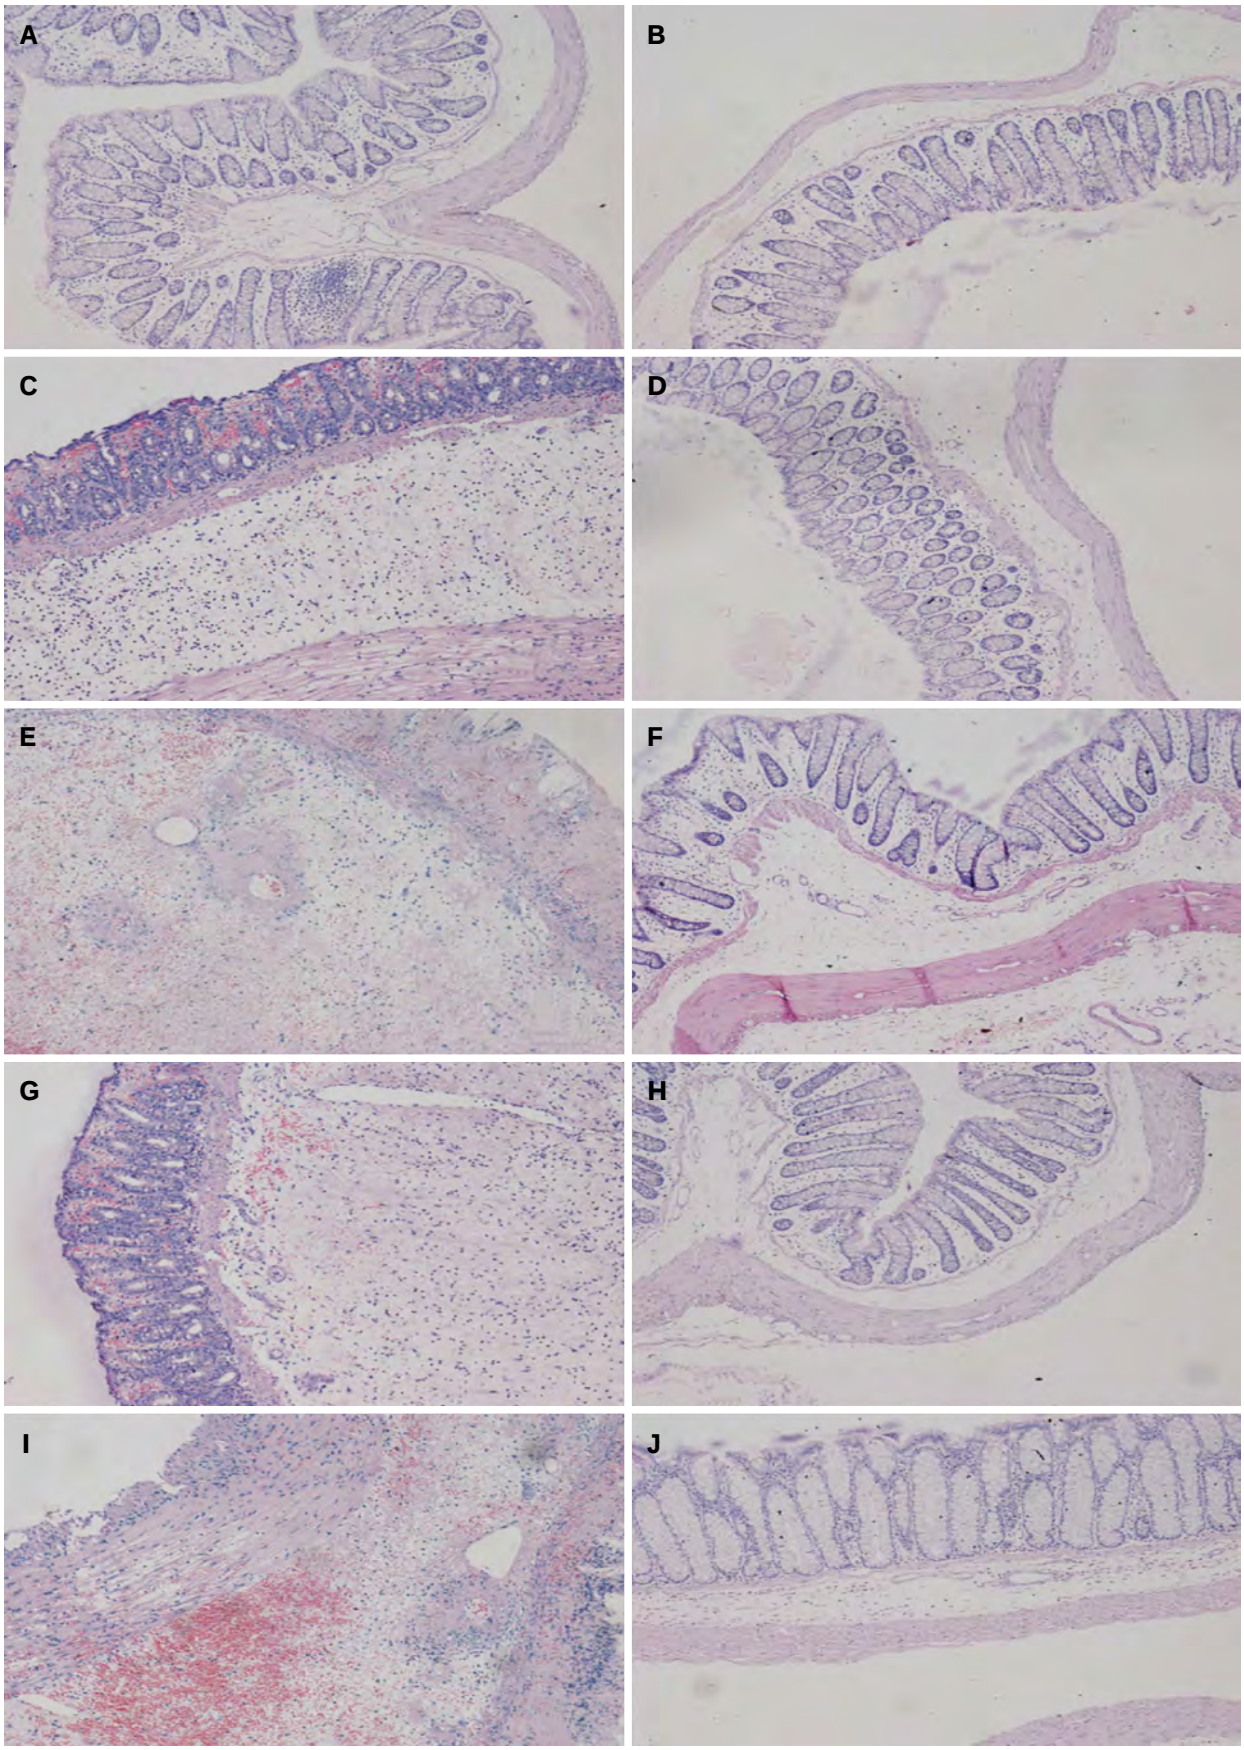

Figure 1 Photomicrographs (hematoxylin and eosin stain, × 100) of distal colon at 2 and 7 d, respectively. A, B: Control group; C, D: Placebo group; E, F: Berberine group; G, H: Aminoguanidine group; I, J: Berberine + aminoguanidine group. At 2 d, histological inflammatory features including mucosal hemorrhage, submucosal edema, and inflammatory infiltration in the lamina propria and the submucosa were observed in the placebo, berberine, aminoguanidine, and berberine + aminoguanidine groups (A, C, E, G, I). At 7 d, there was no marked inflammatory feature compared with the control group (B, D, F, H, J).

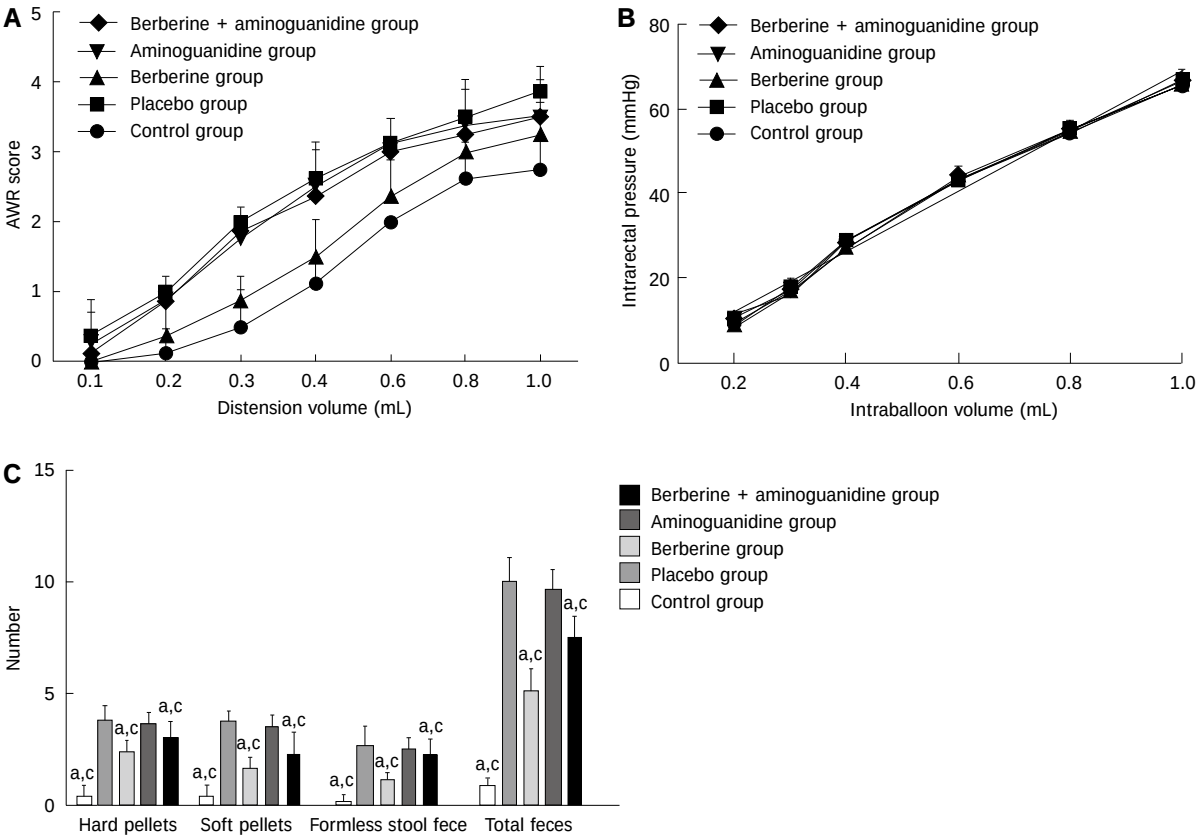

Figure 2 Summarized plots. A: Colorectal distension-induced abdominal withdrawal reflex (AWR) in each group. Comparing the berberine and placebo groups, the AWR scores were reduced at all distension volumes and were significant at 0.2-1.0 mL. The AWR score in the berberine group was significantly lower than in the aminoguanidine and berberine + aminoguanidine groups; B: The relationship between intraballoon volume and intrarectal pressure in each group. The distension volume from 0.2 to 1.0 mL and the corresponding intrarectal pressure were plotted for regression analysis. Intrarectal pressure was linearly increased as the balloon was inflated. The fitted functions of the five groups were not significantly different; C: Restraint-stress-induced defecation in each group. Defecation in the placebo and aminoguanidine groups was significantly more frequent than in the control, berberine and berberine + aminoguanidine groups ($^{a}P < 0.05$ *vs* placebo group; $^{c}P < 0.05$ *vs* aminoguanidine group). The berberine and berberine + aminoguanidine groups showed reduced defecation, but aminoguanidine group alone did not effectively reduce defecation.

the corresponding intrarectal pressure were plotted for regression analysis. Intrarectal pressure increased linearly as the balloon was inflated ($r = 0.9758$, $P < 0.001$, in the control group; $r = 0.9842$, $P < 0.001$, in the placebo group; $r = 0.9822$, $P < 0.001$, in the berberine group; $r = 0.9773$, $P < 0.001$ in the aminoguanidine group; and $r = 0.9827$, $P < 0.001$ in the berberine + aminoguanidine group). The fitted functions of the five groups were not significantly different (Figure 2B).

Restraint-stress-induced defecation

As demonstrated in Figure 2C, the numbers of hard pellets, soft pellets, formless stools, and total fecal output in the placebo were significantly larger than in the berberine groups (5.0 ± 0.16 *vs* 2.56 ± 0.16, $P = 0.000$). As shown in Figure 2C, the number of hard pellets, soft pellets, formless stool,and total of fecal output in aminoguanidine group were significantly larger than the corresponding values in control group, berberine group, and berberine + aminoguanidine group (4.81 ± 0.16 *vs* 0.44 ± 0.16, $P = 0.000$; 4.81 ± 0.16 *vs* 2.56 ± 0.16, $P = 0.000$; 4.81 ± 0.16 *vs* 3.75 ± 0.16, $P = 0.000$). The berberine and berberine + aminoguanidine groups showed reduced defecation, but aminoguanidine alone did not reduce defecation (2.56 ± 0.16 *vs* 4.81 ± 0.16, $P = 0.000$; 3.75 ± 0.16 *vs* 4.81 ± 0.16, $P = 0.000$).

DISCUSSION

This study was performed in order to clarify the effects of berberine administration on VH in a rat model of IBS. Berberine effectively attenuated the heightened visceral nociceptive response, that is, an increase in AWR score to CRD, in rats recovering from experimental colitis. In the placebo group, 7 d after instillation of acetic acid when there was no sign of inflammation in the colon, these rats still had VH and a high frequency of defecation in response to restraint stress. Stool form in the placebo group was softer and more shapeless than in the control group. These findings are in accordance with the clinical symptoms in IBS patients, but there is a great dilemma in using this model to investigate the effect of drugs on IBS.

To avoid the ambiguity that any sign of improvement can be interpreted as a drug effect on colitis, histopathological parameters of inflammation in each group, 2 and 7 d after acetic acid instillation, were evaluated and there

was no difference. Therefore, we concluded that berberine administration, at least at the dose used in our study, had neither a positive nor negative effect on the histopathological parameters of inflammation in the colon, and did not impair establishment of the postinflammatory model. Considering all these factors, we elucidated the effects of berberine administration at a dose that showed a beneficial effect on the inflammatory response. This indicated that berberine significantly reduced VH and stool frequency and increased stool consistency. We investigated the role of NO in the protective effects of berberine using an experimental model with the NO synthetase (NOS) inhibitor aminoguanidine. We demonstrated that aminoguanidine significantly reduced the effect of berberine on VH, which suggests this effect of berberine is at least partly mediated through NOS.

Berberine has been used in the treatment of gastroenteritis and infectious diarrhea in Chinese traditional medicine for thousands of years. Some recent studies have indicated that it has various pharmacological effects, including anti-inflammatory[20] and antimicrobial[28] effects; each of which may contribute to the antidiarrheal effect. The fact that berberine has low bioavailability and shows poor absorption through the colon wall (< 5%)[29] support the thesis that it may exert its antidiarrheal effect on the intestinal epithelial cells before absorption. However, until now the effect of berberine on HV has not been confirmed.

NO is a key neurotransmitter in both short- and long-acting inhibitory motor neurons[7] and plays a critical part in mediating gastrointestinal motility. Some studies have revealed that NOS neuronal activity considerably changes after inflammation and is responsible for some acute postinflammatory consequences in bowel-like ileus[30,31]. Apart from its major role in the peripheral nervous system, such as in the enteric inhibitory nerves of the myenteric plexus, NO is believed to be an intracellular messenger or neurotransmitter in the central nervous system (CNS). It has been verified that due to its free diffusibility, NO acts as a retrograde transmitter in the CNS, mediating some nervous paradigms, for instance, long-term potentiation, and is the key neurotransmitter in descending inhibitory neurons modulating nociception at the spinal level[32]. Furthermore, it proves that NO is involved in the modulation of visceral perception, for example, intraperitoneal injection of acetic acid in rats increases nitrergic neurons in specific regions of the brain, and NOS immunoreactivity has been confirmed in lumbosacral afferents and preganglionic neurons innervating the pelvic viscera[33]. Therefore, some hypotheses can be performed based on our results, which interpret the protective effects of berberine through NO on VH in IBS at the myenteric plexus level, CNS, and smooth muscles. Our results could be interpreted at the myenteric plexus level.

Our findings were similar to a recent study that identified no significant difference in NO-containing neurons of the colonic myenteric plexus between IBS rats and controls[34]. Thus, we hypothesize that basal NO synthesis is not significantly decreased in IBS, and it might be that the positive effects of berberine decrease VH through increasing NO levels. Therefore, we speculate that the positive effects of berberine on VH in the postinflammatory rat model are at least partly exerted through NO synthesis potentiation.

We also examined the effect of aminoguanidine (NOS inhibitor) on stool form (hard pellets, soft pellets, and shapeless) in IBS rats under restraint stress. Aminoguanidine had no noticeable effect on stool form, but it did diminish the protective effects of berberine on stool form. NO plays a major role in mediating gastrointestinal motility, which is critical for stool formation. As a result of the short time between acute drug administration and defecation measurement, aminoguanidine did not produce any change in the stool consistency pattern of rats. The effects of aminoguanidine on stool frequency were more sophisticated and hard to explain. The protective effects of berberine on stool frequency were diminished by aminoguanidine, but the specific mechanism was not established. Further study will be needed to explore the specific mechanism. However, it should be noted that this study investigated only the antinociceptive effect of berberine on VH. One of the limitations of this study is the lack of measurement of NOS inhibitors.

In conclusion, we indicated that berberine administration prevented progression of VH to CRD. It is possible that NO released by berberine may affect colonic hypersensitivity. All of our data suggest that berberine may be of interest in the treatment of visceral hyperalgesia, particularly in IBS.

COMMENTS

Background

It is believed that chronic visceral hypersensitivity (VH), abnormal gastrointestinal motility, and altered central processing may be major pathophysiological mechanisms of irritable bowel syndrome (IBS). Berberine is an ancient Chinese herb that has been used to treat gastroenteritis for many years, which is preferred for its low cost and low incidence of adverse effects. Recently, berberine has been shown to have a considerable effect in the treatment of experimental colitis. However, the mechanism remains unknown.

Research frontiers

Berberine was used to treat rats with VH induced by 4% acetic acid. Berberine administration significantly increased the nociceptive threshold in rats, whereas the administration of aminoguanidine or berberine + aminoguanidine before VH measurement reversed the antinociceptive effect of berberine. The mechanism underlying the effect of berberine on VH of rats appears to be partly mediated by nitric oxide (NO).

Innovations and breakthroughs

Recently, it has been demonstrated that berberine has multiple pharmacological activities. In this study, authors indicated that berberine may be of interest in the treatment of VH, particularly in IBS.

Applications

The present study demonstrated that berberine administration prevented progression of VH to colorectal distension in a rat model of IBS. The effect of berberine is mediated by NO pathways, thus providing evidence for the treatment of VH in IBS.

Terminology

IBS is a common gastrointestinal disorder characterized by chronic visceral pain and bloating in association with altered gut movements. Berberine is an ancient Chinese herb that might play a role in the treatment of IBS.

Peer review

This paper describes positive effects of berberine on VH in rats with IBS. It is reported that berberine administration significantly increased the nociceptive threshold in rats, whereas administration of aminoguanidine or berberine + aminoguanidine before VH measurement reversed the antinociceptive effect of berberine. The results presented are crucial for clinicians and for the fundamental scientific community as well.

Abstract

AIM: To compare matrix metalloproteinase (MMP)-9 and tissue inhibitor of metalloproteinase (TIMP)-1 in gastric ulcer (GU) and chronic superficial gastritis (CSG).

METHODS: This study enrolled 63 patients with GU and 25 patients with CSG. During upper gastroduodenal endoscopy, we took samples of gastric mucosa from the antrum and ulcer site from patients with GU, and samples of antral mucosa from patients with CSG. Mucosal biopsy tissues were cultured for 24 h, and the culture supernatant was measured for levels of MMP-9 and TIMP-1. After receiving eradication therapy for *Helicobacter pylori* (*H. pylori*) and 8 wk proton-pump inhibitor therapy for GU, follow-up endoscopy examination was performed after 6 mo and whenever severe symptoms occurred.

RESULTS: Levels of MMP-9 and TIMP-1 at the ulcer site or in the antrum were significantly higher in GU than CSG patients. MMP-9 levels at the ulcer site were significantly higher than in the antrum in GU patients, and had a significantly positive correlation with TIMP-1. MMP-9 levels were significantly higher in *H. pylori*-positive than *H. pylori*-negative GU and CSG patients. Levels of MMP-9 or TIMP-1 at the ulcer site were associated with the histological severity of activity and inflammation. About 57 GU patients were followed up, and seven had GU recurrence. *H. pylori*-infection and MMP-9 levels were risk factors for the recurrence of GU adjusted for age and sex by multiple logistic regression analysis.

CONCLUSION: MMP-9 may perform an important function in gastric ulcer formation and recurrence.

Key words: Gastric ulcer; Matrix metalloproteinase-9; Tissue inhibitor of metalloproteinase-1; *Helicobacter pylori*

Core tip: Gastric ulcer is a multifaceted process including acid secretion, reactive oxygen species generation, prostaglandin inhibition, and extracellular matrix degradation. Gastric mucosal damage is directly associated with extracellular matrix degradation in which matrix metalloproteinases (MMPs) play a crucial role. In this study, the authors compared MMP-9 and tissue inhibitor of metalloproteinase-1 levels in patients with gastric ulcer or chronic superficial gastritis.

Li SL, Zhao JR, Ren XY, Xie JP, Ma QZ, Rong QH. Increased expression of matrix metalloproteinase-9 associated with gastric ulcer recurrence. *World J Gastroenterol* 2013; 19(28): 4590-4595 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4590.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4590

INTRODUCTION

Gastric ulcer (GU) is a multifaceted process including acid secretion, reactive oxygen species generation, prostaglandin inhibition, and extracellular matrix (ECM) degradation[1]. Gastric mucosal damage is directly associated with extracellular matrix degradation in which matrix metalloproteinases (MMPs) play a crucial role[2]. MMPs are endopeptidases that perform important functions in ECM remodeling, cell proliferation, and inflammatory processes. Recent studies have indicated that gastric ulceration is associated with cleaving and remodeling of the ECM by MMPs[3,4]. In several animal studies of GU, attention has focused on the role of MMP-1, MMP-2, MMP-3, MMP-9 and MMP-13[4-6]. In particular, MMP-9 is important in the early phase of chronic GU[7]. However, these data are mostly derived from animal studies, and human clinical data remains rare, especially in assessing MMPs expression in GU formation and recurrence. Here, we compared MMP-9 and tissue inhibitor of metalloproteinase (TIMP)-1 in patients with GU or chronic superficial gastritis (CSG), and how they correlated with GU recurrence.

MATERIALS AND METHODS

Patient selection

We examined 63 consecutive patients with GU and 25 with CSG who were diagnosed during upper gastroduodenal endoscopic examination at Liaocheng People's Hospital between January and December 2010. The patients were enrolled in the study if they met the following criteria: (1) age 18-75 years; (2) no nonsteroidal anti-inflammatory drugs (NSAIDs), antibiotics, or bismuth compounds in the 2 wk prior to the study; and (3) acute phase GU. Patients were excluded as follows: (1) a history of gastric or duodenal surgery; (2) allergy to the study drugs; (3) required long-term treatment with NSAIDs, corticosteroids, aspirin, or anticoagulant agents; (4) pregnant women; and (5) active cancer, acute serious medical illness, or terminal illness. The study protocol was approved by the Ethics Committee of our institution. All patients gave written informed consent before participating in the study.

Endoscopic examination

During endoscopic examination, three antral specimens were taken from all patients, including one for rapid urease test (Triwizard, Fujian, China), one for histological examination, and one for *in vitro* culture for measurement of levels of MMP-9 and TIMP-1. Two additional specimens were taken from the margin of the ulcer in GU patients; one for histological examination and one for *in vitro* cultures for MMP-9 and TIMP-1.

Helicobacter pylori infection detection

Helicobacter pylori (*H. pylori*) infection was confirmed by positive results for at least two of three diagnostic tests, namely rapid urease test, ^{13}C-urea breath test, or identification of the organism on tissue sections by Giemsa stain. Absence of infection was defined by a negative result in all three tests. Cases satisfying at least two test results were defined as positive for infection.

Tissue cultures and MMP-9, TIMP-1 assay

Mucosal biopsy tissues were weighed and then cultured in a 5% CO_2 incubator for 24 h in a culture bottle (Xiangya Gene Technology, Changsha, China) containing 5 mL RPMI 1640 medium with 5% heat-inactivated fetal calf serum, 15 mmol/L HEPES buffer, 100 U/mL penicillin-G, 100 mg/mL streptomycin and 10 mg/mL phytohemagglutinin-P. At the end of the culture period, the supernatant was drawn off and stored at -70 ℃ until measured by enzyme-linked immunosorbent assay for MMP-9 and TIMP-1 (Boster, Wuhan, China). A modified version of the Lowry method was used to assay total protein in biopsy homogenates (Boster). The amount of MMP-9 and TIMP-1 was expressed relative to protein content in the biopsy tissue homogenate (per milligram of biopsy protein).

Histology

Tissue sections stained with hematoxylin-eosin were used to assess activity, inflammation, glandular atrophy, and intestinal metaplasia. Grading was done on a four-item scale of 0, 1, 2 and 3, corresponding to none, mild, moderate and severe, respectively, in accordance with the updated Sydney system[8].

Follow up

H. pylori-positive GU patients received eradication treatment with triple therapy using lansoprazole (30 mg, *bid*), amoxicillin (1000 mg, *bid*), and clarithromycin (500 mg, *bid*) for 1 wk, and subsequently received lansoprazole (30 mg, *qd*) for 8 wk, whereas *H. pylori*-negative GU patients received lansoprazole (30 mg, *qd*) for 8 wk. After that, the presence of the ulcer scar was confirmed by endoscopy, and six patients who still had active ulcer were excluded from follow-up. An additional ^{13}C urea breath test or rapid urease test was conducted to assess the final *H. pylori* status after 6 mo for all GU patients. Follow-up endoscopy examination was performed at the end of the 6 mo and whenever severe symptoms occurred. Ulcer recurrence was defined as a lesion of white coat with a distinct depressed area and a diameter of $\geqslant$ 5 mm.

Statistical analysis

All data were expressed as mean ± SD. Frequency variables were compared using the χ^2 test. Quantitative variables were analyzed using Student's *t* test. Correlation was analyzed by Pearson's correlation or Spearman's rank correlation. Logistic analysis was used for risk factors for GU recurrence. SPSS version 17.0 (Chicago, IL, United States) was used, and $P < 0.05$ was regarded as significant.

RESULTS

A total of 88 patients were enrolled. The 63 GU patients

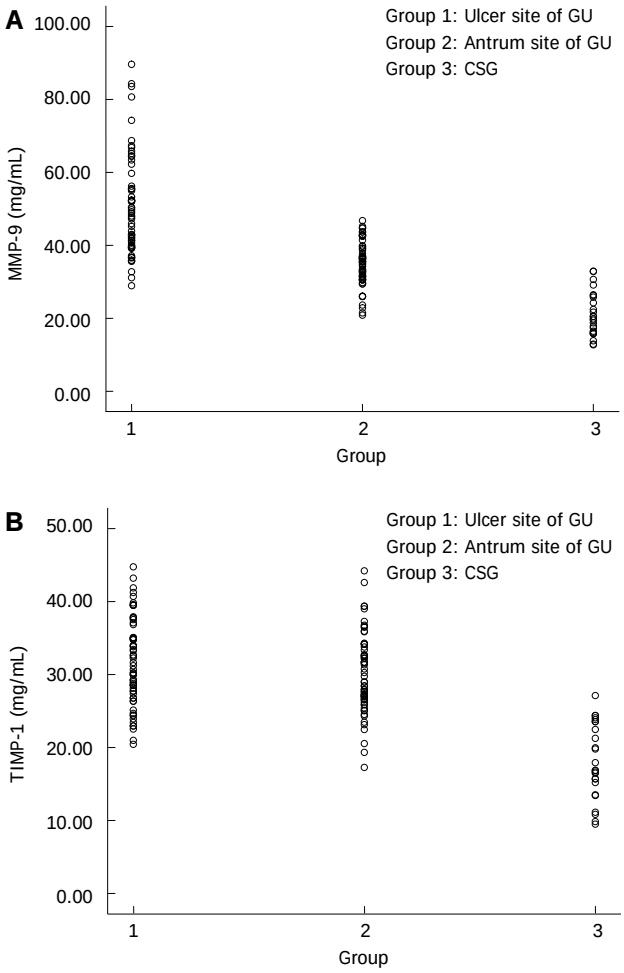

Figure 1 Production of matrix metalloproteinase-9 or tissue inhibitor of metalloproteinase-1 by gastric mucosa in patients with gastric ulcer (*n* = 63) or chronic superficial gastritis (*n* = 25). A: Tissue culture was performed for 24 h. Matrix metalloproteinase (MMP)-9 concentration in tissue culture supernatants was measured by enzyme-linked immunosorbent assay (ELISA); B: Tissue inhibitor of metalloproteinase (TIMP)-1 concentration in tissue culture supernatants was measured by ELISA. GU: Gastric ulcer; CSG: Chronic superficial gastritis.

Table 1 Clinical characteristics of the patients enrolled in the study *n* (%)

Characteristics	GU group (*n* = 63)	CSG group (*n* = 25)
Sex		
Male	31 (49.2)	15 (60.0)
Female	32 (50.8)	10 (40.0)
Age, yr (mean ± SD)	47.8 ± 12.9	51.3 ± 8.5
H. pylori infection		
Positive	54 (85.7)	10 (40.0)
Negative	9 (14.3)	15 (60.0)
Position of ulcer		
Corpus	18 (28.6)	-
Antrum	45 (71.4)	-

GU: Gastric ulcer; CSG: Chronic superficial gastritis; *H. pylori*: *Helicobacter pylori*.

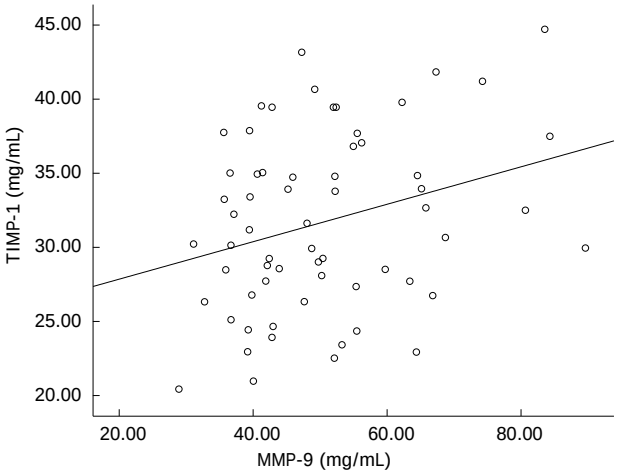

Figure 2 Correlation between matrix metalloproteinase-9 or tissue inhibitor of metalloproteinase-1 production by gastric mucosa in gastric ulcer patients (*n* = 63). Linear regression analysis showed a significant correlation between the two mediators ($r = 0.29$, $P = 0.021$). A significant positive correlation was observed between levels of matrix metalloproteinase (MMP)-9 and tissue inhibitor of metalloproteinase (TIMP)-1 at the ulcer site.

included 31 males and 32 females, with an average age of 47.8 years (range, 24-71 years). The 25 CSG patients included 15 males and 10 females, with an average age of 51.3 years (range, 29-68 years). Fifty-four GU patients were positive and nine were negative for *H. pylori*, and 10 CSG patients were positive and 15 were negative for *H. pylori* (Table 1). There were no significant difference between the GU and CSG patients in age and sex, except in *H. pylori* infection ($\chi^2 = 18.86$, $P < 0.01$).

In all patients, MMP-9 levels (Figure 1A) were significantly higher at the margin of the ulcer (50.50 ± 13.72 mg/mL, $t = 13.96$, $P < 0.01$) or in the antrum (35.08 ± 6.07 mg/mL, $t = 9.78$, $P < 0.01$) of the GU patients than the CSG patients (21.06 ± 6.04 mg/mL). In the GU patients, MMP-9 levels were significantly higher ($t = 8.16$, $P < 0.01$) at the margin of the ulcer (50.50 ± 13.72 mg/mL) than in the antrum (35.08 ± 6.07 mg/mL).

With regard to TIMP-1 levels (Figure 1B), a significant difference was seen between at the margin of the ulcer (18.17 ± 5.14 mg/mL *vs* 31.71 ± 5.97 mg/mL, $t = 9.96$, $P < 0.01$) or in the antrum (18.17 ± 5.14 mg/mL *vs* 30.07 ± 5.42 mg/mL, $t = 9.42$, $P < 0.01$) of the GU and CSG patients. There was no significant difference between the antrum and the margin of the ulcer (30.07 ± 5.42 mg/mL *vs* 31.71 ± 5.97 mg/mL, $t = 1.62$, $P = 0.108$) of the GU patients. A significant positive correlation was observed between levels of MMP-9 and TIMP-1 (50.50 ± 13.72 mg/mL *vs* 31.71 ± 5.97 mg/mL, $r = 0.29$, $P = 0.021$) at the margin of the ulcer in the GU patients (Figure 2).

For the GU patients, ulcers were classified according to their anatomical location, that is, 18 patients had corpus or fundus ulcers, and 45 had antral or prepyloric ulcers. Both MMP-9 (47.45 ± 11.92 mg/mL *vs* 51.72 ± 14.32 mg/mL, $t = -1.12$, $P = 0.267$) and TIMP-1 (30.85 ± 5.93 mg/mL *vs* 32.05 ± 6.02 mg/mL, $t = -0.72$, $P = 0.476$) levels were not significantly different at the margin of the ulcer between corpus or fundus ulcers and antral or prepyloric ulcers.

In the GU patients, levels of MMP-9 (Figure 3A) at

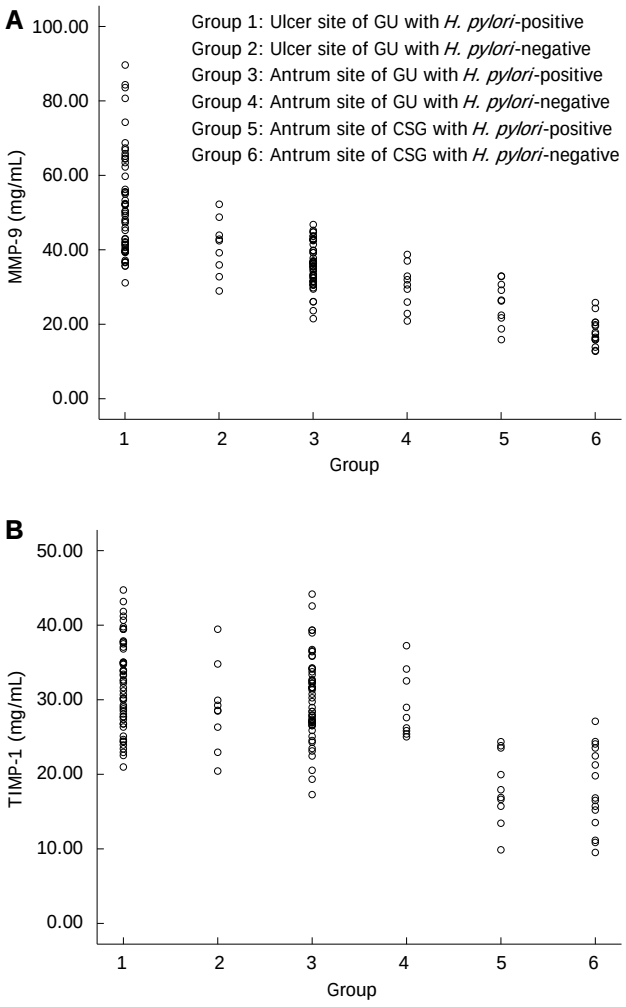

Figure 3 Production of matrix metalloproteinase-9 or tissue inhibitor of metalloproteinase-1 by gastric mucosa with negative or positive H. pylori-infection in patients with gastric ulcer (n = 63) or chronic superficial gastritis (n = 25). A: Tissue culture was performed for 24 h. Matrix metalloproteinase (MMP)-9 concentration in tissue culture supernatants was measured by enzyme-linked immunosorbent assay (ELISA); B: Tissue culture was performed for 24 h. Tissue inhibitor of metalloproteinase (TIMP)-1 concentration in tissue culture supernatants was measured by ELISA. GU: Gastric ulcer; CSG: Chronic superficial gastritis; *H. pylori*: *Helicobacter pylori*.

the margin of the ulcer or in the antrum in the *H. pylori*-positive patients were significantly higher than in the *H. pylori*-negative patients (52.12 ± 13.90 mg/mL *vs* 40.77 ± 7.43 mg/mL, t = 2.38, P = 0.020; 35.92 ± 5.72 mg/mL *vs* 30.03 ± 6.01 mg/mL, t = 2.84, P = 0.006, respectively). In the CSG patients, levels of MMP-9 in the *H. pylori*-positive patients were significantly higher than in the *H. pylori*-negative patients (25.70 ± 5.89 mg/mL *vs* 17.96 ± 3.82 mg/mL, t = 4.00, P = 0.001).

In the GU patients, levels of TIMP-1(Figure 3B) at the margin of the ulcer or in the antrum in the *H. pylori*-positive patients did not differ significantly from those in the *H. pylori*-negative patients (32.18 ± 5.94 mg/mL *vs* 28.91 ± 5.71 mg/mL, t = 1.53, P = 0.130; 30.21 ± 5.60 mg/mL *vs* 29.22 ± 4.40 mg/mL, t = 0.50, P = 0.617, respectively). In the CSG patients, levels of TIMP-1 in the *H. pylori*-positive patients also did not differ significantly from those in the *H. pylori*-negative patients (18.22 ± 4.76 mg/mL *vs* 18.13 ± 5.55 mg/mL, t = 0.04, P = 0.967). Levels of MMP-9 (35.92 ± 5.72 mg/mL) and TIMP-1 (30.21 ± 5.60 mg/mL) in the antrum in the *H. pylori*-positive GU patients were significantly higher (t = 5.17, P < 0.01; t = 6.35, P < 0.01, respectively) than in the *H. pylori*-positive CSG patients (25.70 ± 5.89 mg/mL and 18.22 ± 4.76 mg/mL, respectively).

Table 2 Association between levels of matrix metalloproteinase-9 and tissue inhibitor of metalloproteinase-1 and the histological degree at the margin of the gastric ulcer

Variables		Activity	Inflammation	Atrophy	Metaplasia
MMP-9	r	0.280	0.310	0.180	-0.030
	P	0.026[1]	0.014[1]	0.163	0.842
TIMP-1	r	0.270	0.280	0.120	0.050
	P	0.030[1]	0.025[1]	0.371	0.687

[1]By Spearman correlation analysis. MMP: Matrix metalloproteinase; TIMP: Tissue inhibitor of metalloproteinase.

For the GU patients, we compared levels of MMP-9 and TIMP-1 *in vitro* with the severity of histological gastritis (activity, inflammation, atrophy, and metaplasia) at the margin of the ulcer. A significant association was identified between levels of MMP-9 or TIMP-1 and the histological degree of activity and inflammation, but not with the degree of glandular atrophy or intestinal metaplasia (Table 2).

Of the 63 GU patients, six were excluded because they still had active ulcer after 8 wk PPI treatment. Among 57 follow-up patients, seven (12.3%) had recurrence at the time of or before endoscopy examination at the end of 6 mo. There were nine patients with *H. pylori* infection. A multivariate logistic regression analysis adjusted for age and sex demonstrated that *H. pylori* infection (OR = 17.705, 95%CI: 2.091-149.929, P = 0.008) and MMP-9 levels (OR = 1.078, 95%CI: 1.007-1.154, P = 0.031) were GU recurrence risk factors.

DISCUSSION

We found that MMP-9 production was increased in the gastric mucosa at the margin of the ulcer in GU patients. This increase had a significant positive correlation with production of TIMP-1, an MMP-9 inhibitor. Several studies have investigated the association between MMPs and GU. Indomethacin-induced ulcerated gastric tissues exhibited about 12-fold higher pro-MMP-9 activity as compared to control tissues. Similarly, ethanol induced about 22-fold higher pro-MMP-9 activities in rat gastric tissues[5]. One study showed that significant up-regulation of MMP-9 expression in indomethacin-induced GU in mice was correlated with increased activity of activator protein-1, and oxidative stress was preceded by chronic inflammation that enhanced expression of MMP-9[9].

MMPs have recently been shown to be up-regulated in gastric epithelial cells infected with *H. pylori*, and might contribute to the pathogenesis of peptic ulcer. Our study

showed that MMP-9 levels were associated with *H. pylori* infection. Significantly elevated serum levels of MMP-9 and reduced serum levels of TIMP-1 have been demonstrated in patients with *H. pylori* gastritis as compared to *H. pylori*-negative controls[10]. *H. pylori*-infected GUs had even higher MMP-9 and TIMP-1 expression in epithelial cells than in NSAID-related GU[11]. One study showed that there were no significant differences in serum levels of MMP-9 between *H. pylori*-positive and *H. pylori*-negative children[12].

We showed that levels of MMP-9 correlated with the histological degree of activity and inflammation at the margin of the ulcer. In BALB/c mice, NSAIDs caused dose-dependent induction in MMP-9 activity and expression in ulcerated gastric tissues, along with significant infiltration of inflammatory cells and disruption of the gastric mucosal layer[13]. GU is associated with infiltration of the gastric mucosa by neutrophils, lymphocytes, monocytes, and plasma cells. Inflammatory cells secrete an array of pro-inflammatory cytokines and growth factors (epidermal growth factor, platelet-derived growth factor, transforming growth factor-β, vascular endothelial growth factor, angiopoietins). MMPs can be induced by the activity of pro-inflammatory cytokines such as tumor necrosis factor-α, interleukin (IL)-1, IL-6 and IL-8[1,9,14]. Oxidative stress is preceded by chronic inflammation that enhances the expression of MMP-9. By decreased synthesis and secretion of MMP-9, as well as infiltration of inflammatory cells and oxidative damage in gastric tissues, we may block or heal acute GU[3,13].

The C/C genotype of MMP-9-1562 C/T gene polymorphism might be associated with *H. pylori* infection[15]. *H. pylori* infection increases the secretion of MMPs in the gastric mucosa, leading to severe mucosal damage. Genetic variations in the *MMP-9* gene may be part of a complex genetic risk profile to develop GU in chronic *H. pylori* infection[16]. MMP-9 levels decrease consistently and significantly after successful *H. pylori* eradication, whereas the elevated levels remain unchanged when treatment fails[17].

We found that patients with high levels of MMP-9 and *H. pylori* infection were the risk factors for GU recurrence. *H. pylori* infection associated with GU recurrence has been verified[18]. Some studies found that severity of GU was strongly correlated with increased secretion of proMMP-9 in ethanol-induced acute gastric ulceration in rats[19,20]. Higher levels of MMP-9 in chronic wound fluid correlate with a clinically worse wound[21]. Measurements of MMP-9 and TIMP-1 may help to identify diabetic foot ulcers at risk of poor healing[22]. These findings suggest that MMP-9 may be indicative of inflammation and poor wound healing, and that we can reduce GU recurrence by inhibition of MMP-9 activity.

In conclusion, we observed increased expression of MMP-9 and TIMP-1 in GU patients and found a significantly positive correlation between MMP-9 and TIMP-1 production at the margin of the ulcer. Increased production of MMP-9 was significantly correlated with increased GU recurrence. These results suggest that MMP-9 may play an important role in the occurrence of GU. A clearer understanding of the significance and implications of these findings may provide insights into ulcer healing. Further study is needed to clarify the roles of MMP-9 and elucidate any potential clinical implications in the healing of GU.

COMMENTS

Background

Gastric ulcer (GU) is a multifaceted process including acid secretion, reactive oxygen species generation, prostaglandin inhibition, and extracellular matrix (ECM) degradation. Gastric mucosal damage is directly associated with ECM degradation in which matrix metalloproteinases (MMPs) play a crucial role. In several animal studies of GU, attention has focused on the role of MMP-1, MMP-2, MMP-3, MMP-9 and MMP-13. However, these data are mostly derived from animal studies, and human clinical data remains rare, especially in assessing MMPs expression in GU formation and recurrence.

Research frontiers

In this study, the authors compared levels of MMP-9 and tissue inhibitor of metalloproteinase (TIMP)-1 in GU patients, and how they correlated with GU recurrence.

Innovations and breakthroughs

This study enrolled 63 patients with GU and 25 patients with superficial gastritis (CSG). Samples of gastric mucosa from the antrum and the ulcer site were harvested from GU patients and samples of antral mucosa were taken from CSG patients during upper gastroduodenal endoscopy. Levels of MMP-9 and TIMP-1 at the ulcer site or in the antrum were significantly higher in GU than CSG patients. MMP-9 levels at the ulcer site were significantly higher than in the antrum in GU patients, and had a significantly positive correlation with TIMP-1. MMP-9 levels were significantly higher in *Helicobacter-pylori*-positive than -negative GU and CSG patients. Levels of MMP-9 or TIMP-1 at the ulcer site were associated with the histological severity of activity and inflammation.

Applications

The authors found that the MMP-9 may perform an important function in gastric ulcer formation and recurrence.

Peer review

This study compared MMP-9 and TIMP-1 levels in GU and CSG patients. The authors measured the levels of MMP-9 and TIMP-1 from the tissues. The levels of MMP-9 and TIMP-1 at the ulcer site or in the antrum were significantly higher in GU than CSG patients. MMP-9 levels at the ulcer site were significantly higher than in the antrum in GU patients, and had a significantly positive correlation with TIMP-1. They concluded that MMP-9 may perform an important function in gastric ulcer formation and recurrence.

Abstract

AIM: To investigate the effect of being overweight on the surgical results of patients with gastric cancer.

METHODS: Comprehensive electronic searches of the PubMed, Web of Science, and Cochrane Library databases were conducted. Studies were identified that included patients with surgical complications from gastric cancer who were classified as normal weight [body mass index (BMI) < 25 kg/m^2] or overweight (BMI $\geqslant$ 25 kg/m^2). The operative time, retrieved lymph nodes, blood loss, and long-term survival were analyzed. A subgroup analysis was conducted based on whether patients received laparoscopic or open gastrectomy procedures. All statistical tests were performed using ReviewerManager 5.1.2 software.

RESULTS: This meta-analysis included 23 studies with 20678 patients (15781 with BMI < 25 kg/m^2; 4897 with BMI $\geqslant$ 25 kg/m^2). Overweight patients had significantly increased operation times [MD: -29.14; 95%CI: -38.14-(-20.21); P < 0.00001], blood loss [MD: -194.58; 95%CI: -314.21-(-74.95); P = 0.001], complications (RR: 0.75; 95%CI: 0.66-0.85; P < 0.00001), anastomosis leakages (RR: 0.59; 95%CI: 0.42-0.82; P = 0.002), and pancreatic fistulas (RR: 0.486; 95%CI: 0.34-0.63; P < 0.00001), whereas lymph node retrieval was decreased significantly in the overweight group (MD: 1.69; 95%CI: 0.75-2.62; P < 0.0001). In addition, overweight patients had poorer long-term survival (RR: 1.14; 95%CI: 1.07-1.20; P < 0.0001). No significant difference was detected for the mortality and length of hospital stay.

CONCLUSION: This meta-analysis demonstrates that a high BMI not only increases the surgical difficulty and complications but also impairs the long-term survival of patients with gastric cancer.

Key words: Overweight; Body mass index; Gastric cancer; Gastrectomy

Core tip: Surgical and postoperative complications are believed to be greater for overweight patients with gastric cancer, but this is controversial due to conflicting results from previous studies. This meta-analysis identified 23 studies with a total of 20678 patients, and the results indicate that overweight patients had significantly increased operation times, blood loss, complications, anastomosis leakages, and pancreatic fistulas, whereas lymph node retrieval was decreased significantly in the overweight group. In addition, overweight patients had poorer long-term survival. Therefore, being overweight not only increased the surgical difficulty and complications but also impaired the long-term survival of patients with gastric cancer.

Impact of being overweight on the surgical outcomes of patients with gastric cancer: A meta-analysis. *World J Gastroenterol* 2013; 19(28): 4596-4606 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4596.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4596

INTRODUCTION

The increasing global prevalence of overweight and obese individuals is problematic[1,2] for Western countries[3] and is also a concern for Eastern countries such as China[4] and South Korea[5]. Consequently, abdominal surgeries are increasingly more difficult because increasing numbers of surgeries are performed on overweight and obese individuals. In particular, gastric cancer studies[6,7] reported that excess body weight is associated with unfavorable surgical results, including longer operating times, decreased lymph node retrieval, increased postoperative complications, and decreased survival rates. Radical gastrectomy with D2 node dissection is the recommended surgical approach for patients with resectable (curable) gastric cancer[8]. However, the results of postoperative morbidity, mortality, and long-term survival after D2 node dissection differed significantly between different studies from Asia and Europe[8-14]. This discrepancy may be due to the variable prevalence of overweight patients in Western and Eastern countries. Excess visceral fat in overweight patients theoretically complicates manipulation of the omentum and impedes lymph node dissection during radical gastrectomy due to decreased visualization of the branches of the arteria celiaca, which could increase surgical and postoperative complications and mortality. However, a number of studies[15-18] reported conflicting results about the effect of being overweight on both the short-term and long-term surgical outcomes for patients with gastric cancer. To more comprehensively understand this issue, we conducted a meta-analysis.

MATERIALS AND METHODS

Search strategy

Two authors (Wu XS and Wu WG) independently conducted comprehensive electronic searches of the PubMed, Web of Science, and Cochrane Library databases for all dates prior to January 2013. The search strategy was unrestricted for English-language journals and used combinations of MeSH and text words for overweight, body mass index (BMI), gastric cancer, and gastrectomy, *e.g.*, the string "Body Mass Index" (Mesh) or "overweight" (MeSH Terms) or overweight (Text Word) and "gastrectomy" (MeSH Terms) or gastrectomy (Text Word) or "stomach neoplasms" (MeSH Terms) or gastric cancer (Text Word). In addition, reference lists of all retrieved articles were manually searched for additional studies that were missed by the electronic search.

Inclusion and exclusion criteria

The inclusion criteria for the meta-analysis were studies that examined the influence of body weight on gastric cancer surgical outcomes (morbidity, anastomotic leakage, pancreatic fistula, postoperative mortality, operative time, lymph node retrieval, blood loss, postoperative hospital stay, and long-term survival). In the studies we chose, there were patients with normal-weight and overweight presurgical BMIs based on World Health Organization definitions (overweight BMI $\geqslant$ 25 kg/m^2; healthy-weight BMI < 25 kg/m^2)[19,20]. Reviews, case reports, and series reports were excluded. When data were presented in more than one publication, publications with smaller data sets were excluded. Disagreements regarding a study's eligibility were resolved based on a consensus of reviews from two additional authors (Li ML and Yang JH).

Outcome measures analyzed

Three outcome variables, including the operation time, number of retrieved lymph nodes, and blood loss, were analyzed as indices of the surgical difficulty. We estimated the influence of a high BMI on surgical safety, morbidity, anastomotic leakage, pancreatic fistula, postoperative mortality, and postoperative hospital stay. The long-term survival of overweight and healthy-weight patients was also compared as an index of successful clinical resolution.

Data extraction and risk of bias assessment

Data were extracted from each study by two independent reviewers (Ding QC and Zhang L), who also rated the overall quality of each outcome according to the recommendation of the Cochrane Handbook for Systematic Reviews of Interventions[21]. The criteria to assess nonrandomized studies were taken from the Grading of Recommendations Assessment, Development, and Evaluation Working Group[22]. By combining the aforementioned recommendations, the following aspects of each included study were evaluated: the application of an internal control, adequate control of confounding factors, adequate reporting of outcomes, and the absence of a variable definition. Agreement for ratings was achieved *via* author consensus, as needed.

Statistical analysis

The statistical analysis was performed using Reviewer-Manager (Version 5.1.2, 2011, The Nordic Cochrane Centre, Cochrane Collaboration, www.cochrane-handbook.org). Statistical methods were based on the *Cochrane Handbook for Systematic Reviews of Interventions*[21]. Heterogeneity was checked using χ^2 tests, and $P < 0.1$ was the cutoff for statistical significance. A random effects model was applied for the meta-analysis using a more conservative perspective. Data from different trials reporting the same or similar outcomes were combined. The results were expressed using the RR for binary variables and the MD for continuous variables. Methods for relevant data extraction were based on Tierney *et al*[23]. The cutoff for

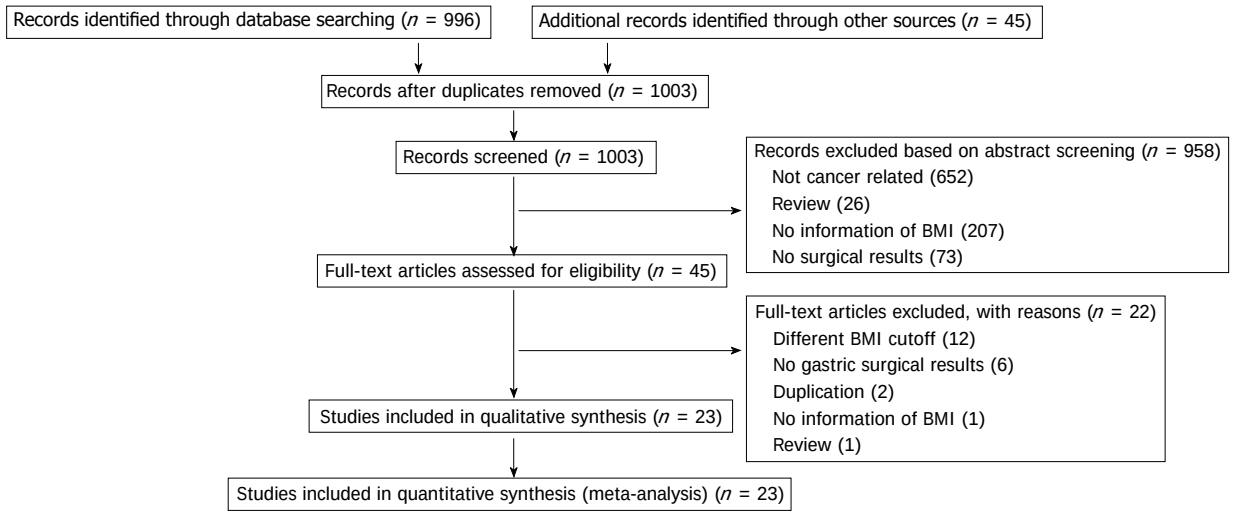

Figure 1 PRISMA flow chart showing study selection process. BMI: Body mass index.

statistical significance was $P < 0.05$, and the 95%CI was presented for each effect measure. Subgroup analysis was conducted based on whether patients received a laparoscopic gastrectomy or a total gastrectomy. Whenever possible, all analyses were based on the intention-to-treat principle. Publication bias exploration using a funnel plot and Egger's regression method[24] was performed if at least 10 trials were included in an outcome variable. Publication bias was considered to exist for $P < 0.05$.

RESULTS

Description of the included trials

We retrieved 996 records from the PubMed search and 45 records from the manual search. Twenty-three trials[15-18,25-43], which included multiple study types, procedures, percentages of patients with early gastric cancer, therapeutic modalities, and BMI cutoffs, met the eligibility criteria and were included in the meta-analysis (Table 1). Excluded reports largely had irrelevant topics. Twelve studies were excluded because they did not define overweight patients using the 25 kg/m^2 criteria. Figure 1 shows the flow chart for the selection of articles based on the Preferred Reporting Items for Systematic Reviews and Meta-Analyses[44]. This meta-analysis identified patients with healthy-weights (BMI < 25 kg/m^2) (n = 15781) and patients who were overweight (BMI ⩾ 25 kg/m^2) (n = 4897). For five included studies[27,28,30,33,35] that classified patients using more than one BMI cutoff point, binary variables were successfully combined, but it was not possible to pool these studies' continuous variables. Only four studies[16,17,32,35] were considered to have a low risk of bias, and all others were considered to have high risk of bias. Most of them were considered high risk because of the selective reporting or absence of variables definition.

Surgical results for all patients

Overweight patients had significantly longer operation times [MD: -29.14; 95%CI: -38.14-(-20.21); $P < 0.00001$, Figure 2A], greater blood loss [MD: -194.58; 95%CI: -314.21-(-74.95); $P = 0.001$], reduced lymph node retrieval (MD: 1.69; 95%CI: 0.75-2.62; $P < 0.0001$) (Table 2), and more postoperative complications (RR: 0.75; 95%CI: 0.66-0.85; $P < 0.00001$, Figure 2B). Specifically, anastomotic leakage (RR: 0.59; 95%CI: 0.42-0.82; $P = 0.002$, Figure 2C) and pancreatic fistula (RR: 0.486; 95%CI: 0.34-0.63; $P < 0.00001$, Figure 2D) were significantly greater in the overweight cohort. There was no significant difference between the two cohorts for the postoperative mortality or postoperative hospital stay. Patients in the normal-weight cohort had higher cancer-specific survivorship (RR: 1.14; 95%CI: 1.07-1.20; $P < 0.0001$, Figure 2E).

There was significant heterogeneity in the operation time, morbidity, anastomotic leakage, blood loss, long-term survival, and postoperative hospital stay results. No heterogeneity was detected for any of the other assessed outcomes. No publication bias was detected for the morbidity outcomes ($P = 0.05$), anastomotic leakage ($P = 0.291$), or mortality ($P = 0.272$).

Surgical results for patients receiving open gastrectomy

Overweight patients who received open gastrectomy had longer operation times [MD: -25.24; 95%CI: -33.53-(-16.95); $P < 0.00001$], greater intraoperative blood loss [MD: -212.93; 95%CI: -301.04-(-124.82); $P < 0.00001$], increased postoperative complications (RR: 0.78; 95%CI: 0.66-0.94; $P = 0.007$), more anastomotic leakage (RR: 0.58; 95%CI: 0.38-0.89; $P = 0.01$), and increased pancreatic fistulas (RR: 0.46; 95%CI: 0.38-0.67; $P < 0.0001$) compared with patients with healthy weights (Table 2). There were no significant differences between the cohorts for mortality, postoperative hospital stay, or number of retrieved lymph nodes. Non-overweight patients had better overall survival results than overweight ones (RR: 1.14; 95%CI: 1.07-1.20; $P < 0.0001$).

There was significant heterogeneity in the morbidity, anastomotic leakage, operative time, number of retrieved

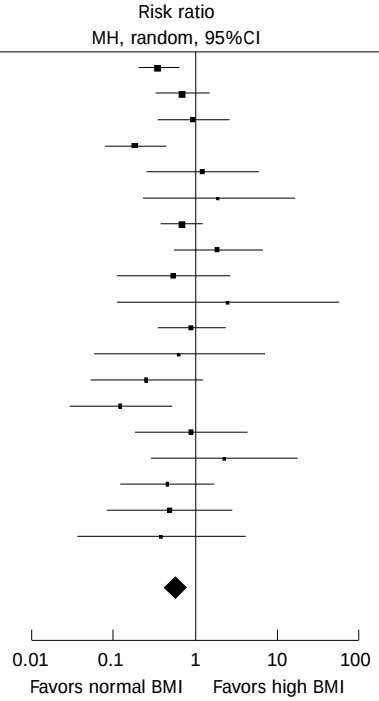

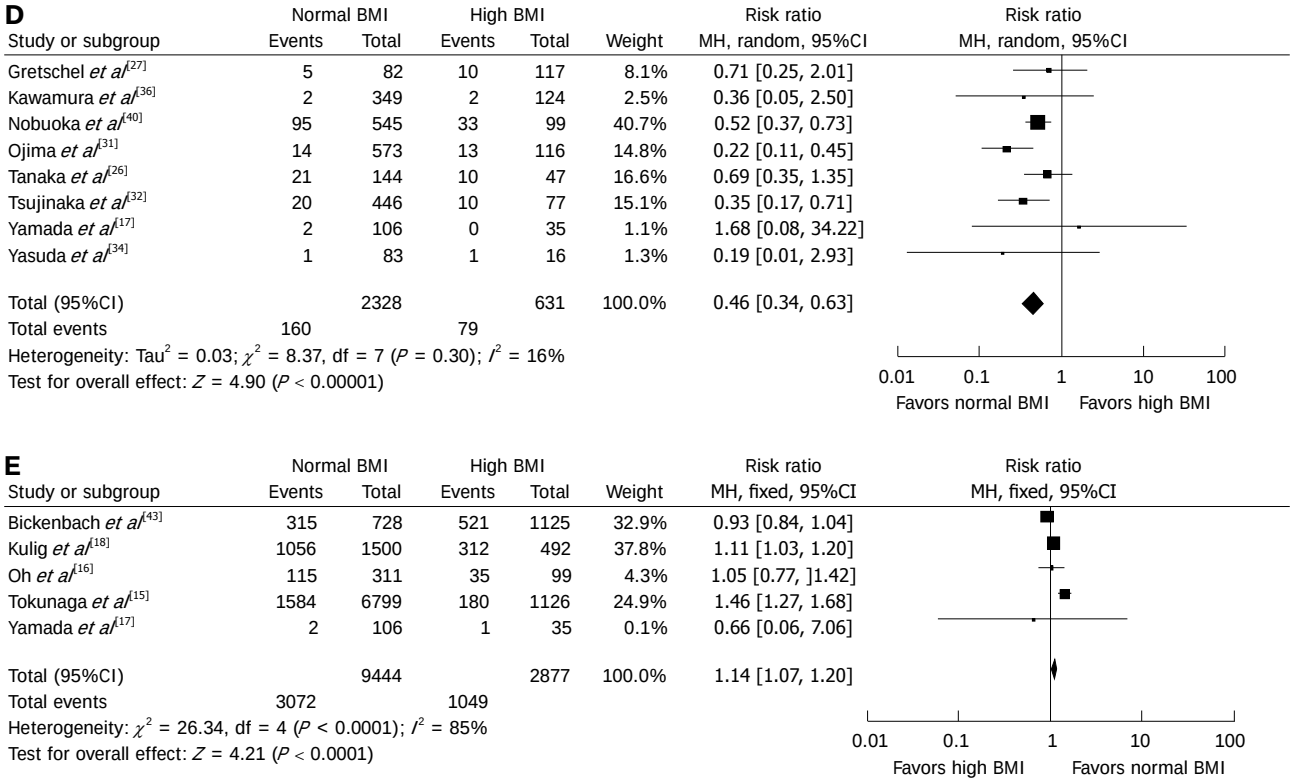

Figure 2 Forest plot. A: For operative time showing overweight in association with longer duration of operative time than non-overweight; B: For morbidity showing overweight in association with more postoperative complication than non-overweight; C: For anastomotic leak indicating that overweight correlates with higher rate of anastomotic leak; D: For pancreatic fistula showing overweight in association with more pancreatic fistula than non-overweight; E: For long-term survival favoring normal weight with better survival results. BMI: Body mass index.

lymph nodes, blood loss, and postoperative hospital stay. No heterogeneity was found in any of the other assessed outcomes. There was no evidence of publication bias ($P > 0.05$ for all 3 of the following outcomes: morbidity, anastomotic leakage, and mortality).

Surgical results for patients receiving laparoscopic gastrectomy

Overweight patients receiving laparoscopic gastrectomies had increased complications (RR: 0.48; 95%CI: 0.29-0.79; $P = 0.004$), longer operation times [MD: -15.06; 95%CI: -17.41-(-12.70); $P < 0.00001$], more blood loss [MD: -47.83; 95%CI: -68.12-(-27.53); $P < 0.00001$], and fewer retrieved lymph nodes (MD: 2.11; 95%CI: 1.35-2.88; $P < 0.00001$) than healthy-weight patients (Table 2). There were no significant differences in any of the other outcomes. Morbidity was a heterogeneous outcome with very low quality, whereas the other outcomes were rated as low quality. Egger's regression method was not applied in this subgroup analysis because none of the outcome variables included at least 10 trials.

Surgical results for patients receiving total gastrectomy

Overweight patients receiving total gastrectomies had increased complications (RR: 0.68; 95%CI: 0.56-0.84; $P = 0.0003$), more pancreatic fistulas (RR: 0.56; 95%CI: 0.42-0.74; $P < 0.0001$), longer operation times [MD: -23.94; 95%CI: -32.62-(-15.25); $P < 0.00001$], more blood loss [MD: -293.84; 95%CI: -401.80-(-185.87); $P < 0.00001$], and fewer retrieved lymph nodes (MD: 3.99; 95%CI: 1.14-6.83; $P = 0.006$) than healthy-weight patients. There were no significant differences in any of the other outcomes.

Surgical results for patients receiving subtotal gastrectomy

Overweight patients receiving subtotal gastrectomies had increased complications (RR: 0.61; 95%CI: 0.40-0.94; $P = 0.02$), longer operation times [MD: -22.02; 95%CI: -29.18-(-14.86); $P < 0.00001$], and more blood loss [MD: -58.36; 95%CI: -93.56-(-23.45); $P = 0.001$] than healthy-weight patients. There were no significant differences in any of the other outcomes, including pancreatic fistulas and the number of retrieved lymph nodes.

DISCUSSION

Theoretically, comorbidity risk factors[45] and surgical complications could cause prolonged surgical times, increased blood loss, more postoperative complications, and greater intraoperative mortality. However, the effects of comorbidity risk factors are uncertain because published papers[25-43] assessing the relationship between being overweight and poor surgical outcomes have reported conflicting results, especially for the outcome variables, such as morbidity, mortality, and long-term survival.

Table 2 Summary statistics of pooled data comparing normal body mass index *vs* high body mass index for overall patients, patients receiving open gastrectomy and laparoscopic gastrectomy

Outcome variables	Studies	Pooled patients	Pooled RR or MD or HR	95%CI	Test for overall effect		Test for heterogeneity

We evaluated the operation time, intraoperative blood loss, and number of retrieved lymph nodes as indices of the surgical difficulty. Both the operation time and blood loss for overweight patients with gastric cancer were significantly higher than for the normal-weight cohort, regardless of whether open gastrectomy or laparoscopic gastrectomy was performed. Being overweight was also correlated with significantly fewer retrieved lymph nodes. Two reasons may contribute to the lower number of retrieved lymph nodes[6]. First, the excess fat tissue in the abdomen could limit the node dissection for overweight patients. Second, pathologists would have difficulty obtaining lymph nodes from a large amount of adipose tissue.

The relationship between high BMI and surgical safety for patients with gastric cancer is controversial. In the 17 trials providing data about morbidity, ten studies[18,29,33-36,38,39,42,43] did not indicate that being overweight affected the overall postoperative complication rate, whereas the remaining 7[15,16,25,28,30,32,40] did. Our meta-analysis strongly suggests that overweight patients have more complications. More specifically, the rates of pancreatic fistula and anastomotic leakage were significantly higher in the overweight patients, which also was true in the subgroup analysis of patients receiving open gastrectomy. According to these results, it is clear that overweight patients have high risks of postoperative complications. However, it is still uncertain whether a high BMI has a direct influence on the postoperative morbidity. High BMIs directly affect the operation times for cholecystectomies, colectomies, and unilateral mastectomies but have no direct relationship with complications[46]. Increased operation times and blood loss secondary to high BMI are also responsible for high postoperative complication rates[28,31], which is likely because prolonged operative times prolong the duration of anesthesia and increase the risk of thromboembolic, cardiac, and respiratory complications. Our study found strong evidence (RR < 0.5) for an association between being overweight and high rates of pancreatic fistula, as suggested in earlier reports[13,32]. This effect on the occurrence of a pancreatic fistula could be because removal of overweight patients' pancreatic capsules is difficult; they have poor differentiation between the pancreas and excess pancreatic fat deposition[47,48]. This could also hamper peripancreatic node dissection and increase the potential for iatrogenic injury to pancreatic tissue. More interestingly, according to one included study[26], minimal damage to the pancreatic tissue, which would never cause a pancreatic fistula in patients with low visceral fat area (VFA), could result in pancreatic fistula in high-VFA patients. Visceral fat maybe play an important role in the pathogenesis from pancreatic injury to pancreatic fistula. Therefore, being overweight could have a direct influence on the postoperative complication rate, as is the case for pancreatic fistulas. Although overweight patients suffered

more complications, no difference was detected for mortality, which might be attributed to the advancement of perioperative management. Changes in perioperative management have dramatically decreased the death rate from serious postoperative complications such as pancreatic fistula and anastomotic leakage. Thus, it is safe to perform radical gastrectomy in overweight patients.

Relevant studies reported conflicting results on the relationship between being overweight and long-term survival[6,7,28,31,40,49,50]. Theoretically, excess visceral fat and being overweight could negatively affect survivorship by increasing the rates of coexisting disease and postoperative complications. In addition, according to Adachi *et al*[6], incomplete lymph node dissection in overweight patients could result in retention of metastatic nodes that are responsible for the worse survivorship. Increased long-term survival in normal-weight patients was found in the current review and is consistent with the hypothesis that excess accumulation of visceral fat could impair patient survival and promote tumor recurrence. Unfortunately, among the 23 analyzed studies, only five were included in the analysis of survivorship; thus, the survivorship results, with fewer data points, are less convincing. However, during the data extraction, we noticed that the percentage of patients with early gastric cancer was greater for the overweight cohort. Compared with advanced gastric cancer patients, patients with early gastric cancer have a significantly higher long-term survival rate[51]. Although the overweight cohort had more patients with early gastric cancer, who might have a more promising prognosis, the overall long-term survival was still significantly lower in this cohort. This is indirect evidence that being overweight can impair the long-term survival of gastric patients. In addition, we do not think that the decreased long-term survival was caused by the increasing comorbidity related to being overweight, such as diabetes and cardiovascular disease because we used cancer-specific survival as the indicator of long-term survival.

High BMIs increase the difficulty and decrease the safety of laparoscopic gastrectomy procedures, as is the case with open gastrectomy. These findings are consistent with some previous studies[25,30,36]. However, other studies[37-39] did not show significant differences in the morbidity between overweight and normal-weight cohorts for laparoscopic gastrectomy. Unlike open gastrectomy, laparoscopic gastrectomy can achieve excellent visibility even for overweight patients because the pneumoperitoneum creates sufficient extra space in the abdominal cavity. Although the laparoscopic procedure has these advantages, the results of our study still suggest that being overweight negatively affects the difficulty and safety of laparoscopic gastrectomy.

Moreover, being overweight increases the difficulty and impairs the safety of both total and subtotal gastrectomies. However, a subtotal gastrectomy seems to be safer than a total gastrectomy for overweight patients because subtotal gastrectomy did not increase the rate of pancreatic fistula occurrence in the overweight group, which is a severe complication after gastric surgery. In addition, after subtotal gastrectomy, the numbers of retrieved lymph nodes did not differ significantly between the two cohorts, while there was a difference in the number of lymph nodes retrieved after total gastrectomy.

Because of the relationship between being overweight and impaired surgical safety, surgeons should be more careful when performing radical gastrectomy in the future. In addition, for suitable cases, performing a subtotal gastrectomy might be safer than performing a total gastrectomy.

This meta-analysis has some limitations. First, most of the studies in this meta-analysis were rated as low or very low quality due to their retrospective study designs. All included studies are nonrandomized in nature and have a risk of bias. Although randomized trials are the gold standard for study design, random allocation of patients with different BMIs is hardly feasible. To overcome this limitation in the future, more rigorously designed studies with a good balance of other confounding factors, such as age and tumor-node-metastasis stage, are needed. Second, although BMI $\geqslant$ 25 kg/m^2 was used as a criterion for classifying patients as overweight, it may be not the best index because the distribution of fat tissue could differ greatly between individuals, even those with the same BMI[26,52]. Therefore, individuals with the same BMI could have different surgical outcomes due to their different fat distributions. Some studies[26,39,53] have indicated that the VFA is a better index than BMI. Third, the procedure type and extent of node dissection differed among the studies in our meta-analysis. Moreover, gastric cancer was more prevalent in Eastern countries than Western ones. As a result, surgeons from Eastern countries could have more experience in performing the surgeries and dealing with the postoperative complications. Additionally, the higher incidence of gastric cancer has led to earlier diagnosis in Asian countries. Therefore, the proportions of early gastric cancer cases differed between studies from the East and West in this review. All these factors could account for the heterogeneity of some results and jeopardize the reliability of the conclusions. The limitations in the previously published data could potentially affect the analysis of both groups. Publication bias was a possible source of bias during the meta-analysis because positive results are more likely to be published. Several methods have been proposed for detecting bias and, in this review, we detected publication bias by a funnel plot and Egger's regression method, which is reliable when the number of included trials is not less than 10. It turned out that our results did not show significant publication bias ($P > 0.05$) for the parameters in this review.

In conclusion, this meta-analysis indicates that overweight patients with gastric cancer have increased surgical complications and worse short-term operative outcomes than patients with healthy weights, and these results were consistent for patients who underwent either a laparoscopic gastrectomy or an open gastrectomy. Although no

evidence was detected to indicate that being overweight had higher postoperative morbidity, being overweight decreased the long-term survival.

COMMENTS

Background

The increasing global prevalence of overweight and obese individuals is problematic for Western countries and is also a concern for Eastern countries such as China and South Korea. Surgical results and postoperative complications are believed to be greater for overweight patients with gastric cancer, but this is controversial due to conflicting results from previous studies.

Research frontiers

The postoperative morbidity, mortality, and long-term survival after D2 node dissection differed between different studies from Asia and Europe. It is possible that this discrepancy is due to the differing prevalence of overweight patients in Western and Eastern countries. However, different studies have conflicting results for the effect of being overweight on both the short-term and long-term surgical outcomes for gastric cancer patients.

Innovations and breakthroughs

To the knowledge, this is the first meta-analysis studying the effect of being overweight on the surgical results of gastric cancer patients. The authors found that overweight patients with gastric cancer have increased surgical complications and worse short-term operative outcomes than patients with healthy weights, and these results were consistent for patients who underwent either a laparoscopic gastrectomy or an open gastrectomy.

Applications

This meta-analysis emphasizes the influence of being overweight on gastric cancer surgical results. Surgeons should pay particular attention when they perform radical gastric cancer surgery.

Peer review

Overall, this manuscript provides a detailed and comprehensive review of the influence of elevated patient body mass index on outcomes following gastrectomy as a treatment for cancer. This article includes information about the complications of gastric surgery and has potential clinical implications. Finally, this meta-analysis demonstrates that being overweight is significantly correlated with surgical difficulty, a high rate of postoperative complications, and poor survival in patients with gastric cancer.

Abstract

AIM: To undertake a meta-analysis on the value of urinary trypsinogen activation peptide (uTAP) in predicting severity of acute pancreatitis on admission.

METHODS: Major databases including Medline, Embase, Science Citation Index Expanded and the Cochrane Central Register of Controlled Trials in the Cochrane Library were searched to identify all relevant studies from January 1990 to January 2013. Pooled sensitivity, specificity and the diagnostic odds ratios (DORs) with 95%CI were calculated for each study and were compared to other systems/biomarkers if mentioned within the same study. Summary receiver-operating curves were conducted and the area under the curve (AUC) was evaluated.

RESULTS: In total, six studies of uTAP with a cut-off value of 35 nmol/L were included in this meta-analysis. Overall, the pooled sensitivity and specificity of uTAP for predicting severity of acute pancreatitis, at time of admission, was 71% and 75%, respectively (AUC = 0.83, DOR = 8.67, 95%CI: 3.70-20.33). When uTAP was compared with plasma C-reactive protein, the pooled sensitivity, specificity, AUC and DOR were 0.64 *vs* 0.67, 0.77 *vs* 0.75, 0.82 *vs* 0.79 and 6.27 *vs* 6.32, respectively. Similarly, the pooled sensitivity, specificity, AUC and DOR of uTAP *vs* Acute Physiology and Chronic Health Evaluation Ⅱ within the first 48 h of admission were found to be 0.64 *vs* 0.69, 0.77 *vs* 0.61, 0.82 *vs* 0.73 and 6.27 *vs* 4.61, respectively.

CONCLUSION: uTAP has the potential to act as a stratification marker on admission for differentiating disease severity of acute pancreatitis.

Key words: Acute pancreatitis; Urinary trypsinogen activation peptide; C-reactive protein; Acute Physiology and Chronic Health Evaluation Ⅱ score; Meta-analysis

Core tip: Currently, the assessment of acute pancreatitis severity on admission remains a challenge to clinicians. A single, rapid biochemical marker is the preferred choice than clinical and computed tomography scoring systems. In this study, the value of urinary

trypsinogen activation peptide (uTAP), on admission, in predicting severity of acute pancreatitis was assessed. It was found that the ability of uTAP to predict severity of acute pancreatitis on admission was comparable to C-reactive protein (at 48 h) and was potentially better than the Acute Physiology and Chronic Health Evaluation Ⅱ score (at 48 h), the most frequently used biochemical marker and clinical scoring system in acute pancreatitis, respectively.

Prediction of the severity of acute pancreatitis on admission by urinary trypsinogen activation peptide: A meta-analysis. *World J Gastroenterol* 2013; 19(28): 4607-4615 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4607.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4607

INTRODUCTION

Acute pancreatitis causes up to 210000 admissions in the United States annually and remains a diagnostic, prognostic and therapeutic dilemma for surgeons and physicians[1]. Although mild acute pancreatitis is associated with virtually no mortality, severe acute pancreatitis continues to be at the other end of the spectrum with mortality reaching up to 30%, mainly due to pancreatic necrosis and organ failure[2].

As severe acute pancreatitis may progress very quickly and is normally associated with a complicated clinical course and higher mortality, it is vital to identify these patients as early as possible to initiate appropriate supportive management, especially within the first 24 h after symptoms onset[3]. Therefore, in the last few decades many biomarkers[4], radiological[5] and clinical scoring systems[6,7] have been developed and validated to fulfil this role. These, however, have not been entirely successful. The Glasgow[8], Acute Physiology and Chronic Health Evaluation Ⅱ (APACHE Ⅱ)[9], and Ranson[10] scoring systems and plasma C-reactive protein (CRP)[11] are still the most widely used parameters and form part of many guidelines, however, their use does come with its own limitations.

There is enough evidence to establish trypsinogen activation as one of the earliest steps in the pathophysiology of the disease[12,13], and consequently, trypsinogen activation peptide (TAP) has been shown to be an excellent marker for severity stratification in different experimental acute pancreatitis models[14]. In human acute pancreatitis, TAP is rapidly excreted in urine and in urinary[15] and peritoneal fluid[16]. TAP concentrations correlate well with disease severity. Therefore, it is reasonable to hypothesize that pancreas-specific activation peptides would be elevated (in the urine) from the onset of disease and could potentially serve as early biomarkers. Urinary TAP (uTAP) is the most studied peptide for predicting severity of acute pancreatitis[17], but its diagnostic value in severe acute pancreatitis has not been systematically assessed. In this study, a meta-analysis was carried out to evaluate existing evidence of uTAP in predicting the severity of acute pancreatitis.

MATERIALS AND METHODS

Study selection

A comprehensive literature search of Medline, Embase, Science Citation Index Expanded and the Cochrane Central Register of Controlled Trials in The Cochrane Library was carried out to identify studies evaluating the prognostic efficacy of uTAP from January 1990 (the first human study)[15] to February 2013. The following medical subject headings (MeSH) and keywords were used: "trypsinogen activation peptide" or "activation peptide" and "acute pancreatitis" or "severe acute pancreatitis" or "post endoscopic retrograde cholangiopancreatography (ERCP) pancreatitis". Equivalent free-text search terms were used in the search strategy. All abstract supplements from published literature or from relevant international meetings were searched manually. Relevant papers were also identified from the reference lists of previous papers. Only studies which were published in English as full-text articles were included. Final inclusion of articles was determined by consensus; when this failed, a third author adjudicated. Severe acute pancreatitis was defined as the development of organ failure and/or local complications[15,18].

Inclusion and exclusion criteria

Two authors independently identified and screened the search findings for potentially eligible studies.

Inclusion criteria: (1) English language studies published as full text articles in peer-reviewed journals; (2) Human studies; (3) Studies with available data; and (4) When similar studies were reported by the same institution, the best quality study was included.

Exclusion criteria: (1) Abstracts, letters, editorials, expert opinions, reviews and case reports; (2) Where only concentration or *P* value was reported; (3) Studies assessing the efficacy of serum/plasma TAP in predicting the severity of acute pancreatitis; and (4) Studies assessing the efficacy of uTAP in diagnosing acute pancreatitis.

Data extraction and quality assessment

Data were extracted by two independent observers using standardized forms. The recorded data included study design, demographics (age, gender, etiology and country of origin), severity of disease, duration from symptoms onset to admission, time point for the collection of samples and cut-off values. Diagnostic parameters including true positivity (TP), false positivity (FP), false negativity (FN) and true negativity (TN) were extracted directly or by calculating the sensitivity and specificity of uTAP for predicting the severity of acute pancreatitis. TP, FP, FN and

TN were also extracted for serum CRP and APACHE Ⅱ score at the highest diagnostic values during the first 2 d after admission if these were reported in the included studies. The quality of the included studies was assessed independently by two reviewers using the Standards for Reporting of Diagnostic Accuracy (STARD) initiative guidelines[19]. Studies with a STARD score of ⩾ 16 were considered as high quality studies.

Statistical analysis

The meta-analysis was performed with Meta-DiSc 1.4 software (Hospital Ramón y Cajal, Madrid, Spain). Pooled sensitivity, specificity, and diagnostic odds ratio (DOR) with diagnostic value Q were calculated. The mentioned parameters were pooled respectively with a corresponding 95%CI. Receiver operating characteristics were also generated and expressed by area under curve (AUC). The AUC represents the accuracy of diagnosis and DOR indicates its diagnostic capability for differentiating disease groups from negative groups[20]. Heterogeneity was evaluated using Cochran's Q test and a P value of 0.1 was considered significantly different. I^2 statistics were used to measure the percentage of total variation across the studies due to heterogeneity (I^2 of 50% or more indicating the presence of heterogeneity)[21]. The publication bias of included studies was assessed using a funnel plot of the effect of effective sample size weighted regression tests of asymmetry[22]. The meta-analysis was performed using a fixed-effect model if there was no heterogeneity among the studies, otherwise the random effects model was used[23]. The sensitivity analyses were undertaken by excluding each study from the analysis to ascertain its effect on the overall results. Subgroup analyses were dependent on the following items: high quality studies, sample size ⩾ 50 in each study, single center studies and severity defined by the 1992 Atlanta Classification[18].

RESULTS

Description of included trials in the meta-analysis

Details of the literature research are shown in Figure 1 and 16 clinical studies were identified. Seven studies were excluded: one due to lack of data for analysis[24], one studied peritoneal fluid TAP[25], two studied serum/plasma TAP[26,27], three for diagnosing acute pancreatitis, but not for assessing the severity[28] or post-ERCP pancreatitis[29,30]. Of the 9 studies[15,31-38] that were potentially useful for analysis, only six had the cut-off of 35 nmol/L; it being variable in the remaining three and therefore, these six studies were included in the final analysis.

Study and patient characteristics

Table 1 describes the included studies and patient characteristics. All of the six included studies were prospectively designed and were of high quality (STARD score ⩾ 16). There were 2 multicenter[32,37] and 4 single center[33-35,38] trials. Five studies[32-35,38] defined the severity of acute pancreatitis by the 1992 Atlanta Classification, in which severe cases included the moderate and the severe groups according to the revised Atlanta Classification[39]. One

AUC: Area under the curve; DOR: Diagnostic odds ratios.

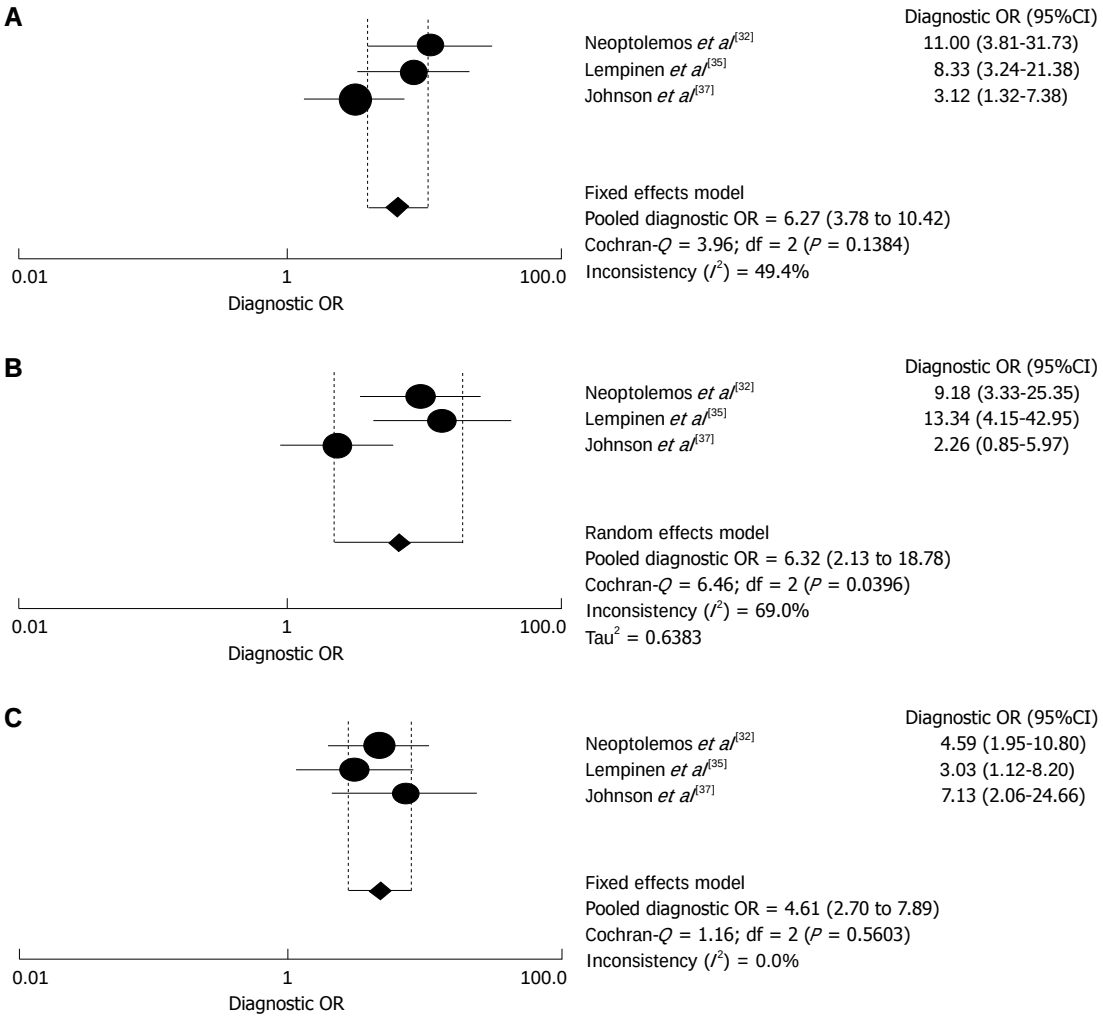

Figure 3 Forest plots of diagnostic OR for urinary trypsinogen activation peptide *vs* serum C-reactive protein and urinary trypsinogen activation peptide *vs* Acute Physiology and Chronic Health Evaluation Ⅱ score in predicting severe acute pancreatitis. The pooled diagnostic odds ratios of on-admission urinary trypsinogen activation peptide (A), plasma C-reactive protein at 48 h (B) and Acute Physiology and Chronic Health Evaluation Ⅱ score at 48 h (C).

On admission uTAP for predicting the severity of acute pancreatitis: Data from the six included studies (775 patients with 726 analyzed) revealed that the pooled sensitivity, specificity, AUC and DOR were 71% (95%CI: 63-78), 75% (95%CI: 72-79), 0.83 and 8.67 (95%CI: 3.70-20.33), respectively. Data are shown in Figure 2 and Table 3. These data suggest that uTAP has the potential to predict the severity of acute pancreatitis.

uTAP *vs* plasma CRP for severity stratification: There were 3 studies[32,35,37] that compared the prognostic value of on admission uTAP (440 patients analyzed) with plasma CRP (458 patients analyzed) within the first 48 h after admission in the severity stratification for acute pancreatitis. The pooled sensitivity, specificity, AUC value and DOR were 0.64 *vs* 0.67, 0.77 *vs* 0.75, 0.82 *vs* 0.79 and 6.27 *vs* 6.32, respectively (Figure 3A and B) for uTAP and CRP (best diagnostic values at 48 h). As suggested by the data, prognostic efficacy of the two markers was found to be similar.

uTAP *vs* APACHE-Ⅱ score for severity stratification: There were 4 studies[32,34,35,37] that compared the prognos-

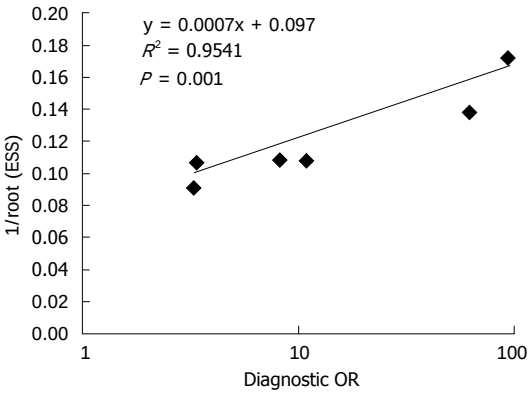

Figure 4 Funnel plot of the effect of effective sample size weighted regression tests of asymmetry for included studies. ESS: Effective sample size.

tic value of on admission uTAP with APACHE Ⅱ score within first 48 h after admission. Of these, 3 studies[32,35,37] used an APACHE Ⅱ score ⩾ 8 (422 patients analyzed) for defining severity and compared with uTAP (440 patients analyzed). The pooled sensitivity, specificity, AUC value and DOR were 0.64 *vs* 0.69, 0.77 *vs* 0.61, 0.82 *vs* 0.73 and 6.27 *vs* 4.61 for uTAP (values on admission) and APACHE Ⅱ score (best diagnostic values at 48 h), respectively (Figure 3A and C). These data suggest that uTAP may have a better prognostic value than the APACHE Ⅱ score in predicting the severity of acute pancreatitis.

Sensitivity and subgroup analysis: Outcomes for sensitivity and subgroup analysis are shown in Table 3. All six studies included were of high quality and sensitivity analysis demonstrated that significant heterogeneity still existed in these high quality studies (Q = 15.88, P = 0.0072, I^2 = 68.5%). Subgroup analysis showed that significant heterogeneity also existed in studies with sample size ⩾ 50 (Q = 10.28, P = 0.0360, I^2 = 61.1%), single center (Q = 12.92, P = 0.0048, I^2 = 76.8%), and severity defined by the 1992 Atlanta Classification (Q = 13.65, P = 0.0085, I^2 = 70.7%).

Publication bias: A funnel plot was created to demonstrate bias in the studies. The shape of the funnel plot showed asymmetry and this was confirmed by P = 0.001, showing that more significant results were present in smaller studies (Figure 4).

DISCUSSION

Upon admission, severity prediction of acute pancreatitis is crucial. This is still controversial, not universal and is mired by institutional differences. The current commonly used severity prediction systems include clinical assessment, biochemical markers, and both clinical and radiological scoring systems[40,41]. Clinical assessment provides a relatively high specificity (83%-98%) for ruling out mild acute pancreatitis, but has poor sensitivity (34%-64%) for the same[40]. When compared with clinical scoring systems, contrast-enhanced computed tomography (CECT) was not found to be superior in predicting outcomes of acute pancreatitis on admission[5].

Ideally, the best biomarker for predicting disease severity should be accurate, rapid, inexpensive and non-invasive. The pancreas-specific biomarkers are generally thought to be related to disease severity[14]. In 1988, a TAP assay with a detection limit of 10 picomolar concentration was developed by Hurley *et al*[42], enabling the detection of TAP in the body fluid to become more feasible. In a multicenter study conducted by Neoptolemos *et al*[32] that recruited 172 acute pancreatitis patients, uTAP concentration was found to be significantly different between mild and severe acute pancreatitis from 0-96 h after symptoms onset. Most importantly, uTAP values at both 24 and 48 h after admission provided the highest prognostic values for severe acute pancreatitis when compared to plasma CRP and clinical scoring systems (APACHE-Ⅱ, Glasgow and Ranson).

For the six studies included in this meta-analysis, the pooled results indicated that uTAP has potential for predicting the severity of acute pancreatitis upon hospital admission (AUC = 0.83, DOR = 8.67, 95%CI: 3.7-20.33). This is at least comparable with the current in-use biomarkers[6]. While most of the currently used biomarkers are non-specific in nature (specific for inflammation and other aspects), TAP is specific to the pancreas and is liberated within the first few hours after the onset of symptoms[15,32]. The prognostic value of uTAP (on admission) was similar to the APACHE-Ⅱ score obtained 24 h after admission in this meta-analysis. It is noteworthy that despite the APACHE-Ⅱ score being one of the most frequently used clinical scores to assess the severity of acute pancreatitis, it is cumbersome to use and has dubious use in certain settings; *i.e.,* in critical care environments where physiology has been corrected. Therefore, there is a need for simple and quick severity prediction techniques.

The prognostic value of an on-admission uTAP was also compared with plasma CRP (obtained 0-48 h after admission), currently the most widely used severity biomarker in acute pancreatitis and other acute inflammatory diseases[43]. uTAP had a relatively higher diagnostic value than plasma CRP, which suggested that uTAP might be a highly valuable biomarker for the quick assessment of acute pancreatitis severity on admission. It is unsurprising, therefore, that the revised Atlanta Classification[39] introduced the potential use of uTAP for severity stratification, although, as yet, it has not been widely adopted in the clinical arena.

To investigate the presence of heterogeneity, sensitivity and subgroup analyses were performed, based on sample size, study center and definition of severity. There was significant heterogeneity among studies with sample size ⩾ 50, single center and severity defined by the 1992 Atlanta Classification. It has been shown in many previous studies that multicenter studies tend to have better and more reliable results than single center studies. Similar to increasing sample size. Most of our studies used the Atlanta criteria for severity stratification, albeit one which represented a small proportion of the same cohort. From a clinical perspective, heterogeneity may also be caused by the defi-

nition of severity. All the severe acute pancreatitis cases included in this meta-analysis had two distinct entities: the moderate and the severe categories according to the revised Atlanta Classification. The proportion of moderate and severe cases may have had a significant impact on the results of uTAP. On the other hand, the proportion of patients who had pancreatic necrosis may also have an impact on the uTAP levels. Moreover, whether etiology plays a role in this regard remains unknown. Unsurprisingly, there was publication bias towards more significant effects reported in smaller sample sizes. This may have implications on the interpretation of the pooled sensitivity and specificity. These problems can only be overcome in the future by larger studies being performed.

The 1992 Atlanta Classification defines severe acute pancreatitis if organ failure/or local complications such as pancreatic necrosis, abscess, or pseudocyst are present[17]. Pancreatic necrosis, however, is only characterized by an area more than 30% necrosis non-enhanced on CECT, which might lead to false negative results of uTAP when pancreatic necrosis is less than 30%. The revised Atlanta Classification categorizes severity of acute pancreatitis into mild, moderate and severe classes[39]; the determinant-based classification stratifies severity of acute pancreatitis into mild, moderate, severe and critical categories[44]. These classifications consider pancreatic necrosis and persistent organ failure as the key determinants of outcome of acute pancreatitis. Compared to the 1992 Atlanta Classification, the new definition of pancreatic necrosis is described as the detection of any area of non-enhancement or every heterogeneous peri-pancreatic collection on CECT. These updated definitions and classifications might prove to be very useful in re-assessing the importance of an on-admission uTAP for the quick assessment of severity in acute pancreatitis. One might postulate that uTAP may have high prognostic accuracy in identifying patients with a disease course that is at least moderate to severe or for ruling out mild patients.

This review suffers from a relatively small sample size, publication bias in smaller studies and heterogeneity in some of the inclusion criteria. To the best of our knowledge, this is the most comprehensive meta-analysis on the subject to date. We have tried to summarize the existing data, identify problems in undertaking that, point out potential areas of improvement and suggest guidelines for future studies.

In summary, uTAP is a rapid assay for the assessment of acute pancreatitis severity on admission and provides good prognostic accuracy for severe acute pancreatitis based on the 1992 Atlanta Classification. New studies should assess its value in a larger patient cohort with uniform inclusion criteria and in line with the newly proposed classification systems.

COMMENTS

Background

Assessment of the severity of acute pancreatitis is crucial upon admission. Currently, clinical assessment, biochemical markers, and both clinical and computed tomography scoring systems are used individually or in combination to fulfil the need. However, a single, inexpensive and rapid biochemical marker is preferred due to practical and economic reasons. In this regard, urinary trypsinogen activation peptide (uTAP) has been developed and validated in many clinical studies, showing good diagnostic value in predicting severe acute pancreatitis. However, these results have not been systematically assessed.

Research frontiers

To conduct a meta-analysis on the value of uTAP in predicting the severity of acute pancreatitis on admission.

Innovations and breakthroughs

The Revised Atlanta Classification has introduced the potential use of uTAP in the prediction of severity stratification. However, current clinical studies regarding this topic have not been systemically analyzed to provide evidence on uTAP to ensure its wide adoption in the clinical arena. This is the first meta-analysis summarizing data obtained from six studies in which the uTAP cut-off concentration (35 nmol/L) was the same for severity stratification. The meta-analysis showed that the diagnostic value of uTAP (on admission) for the severity of acute pancreatitis was comparable to CRP (at 48 h after admission) and was potentially better than the APACHE-Ⅱ score (at 48 h after admission), the most frequently used biochemical marker and clinical scoring system in acute pancreatitis, respectively.

Applications

The results of the meta-analysis encourage the use of uTAP in routine clinical practice, although this needs to be established in further well designed studies with possible comparisons to the new severity classification systems.

Peer review

This is a well written study that provides useful data on the usefulness of uTAP in the diagnostic/staging algorithm for acute pancreatitis. It is a powerful study that essentially means that uTAP is unlikely to find a widespread place in acute pancreatitis prognostic scoring as there are other more widely used tests available that are equivalent.

Abstract

Neuroendocrine carcinoma (NEC) of the extrahepatic bile duct is rare, and only 22 cases have been reported. Only two of these were large-cell NEC (LCNEC); the vast majority were small-cell NEC. Here, we report a third case of LCNEC of the extrahepatic bile duct. A 76-year-old male presented to a local hospital with painless jaundice. Imaging studies revealed a tumor at the hepatic hilum. The patient underwent right hepatic lobectomy, bile duct resection, and cholecystectomy. The resection specimen showed a 5.0-cm invasive neoplasm involving the hilar bile ducts and surrounding soft tissue. Histologically, the tumor consisted of nests of medium to large cells with little intervening stroma. The tumor invaded a large portal vein branch. All four excised lymph nodes were positive for metastasis, and metastatic deposits were also present in the gallbladder wall. The tumor was diffusely positive for synaptophysin and focally positive for chromogranin A. Approximately 70%-80% of the tumor cells were positive for Ki-67, indicating strong proliferative activity. A diagnosis of LCNEC was made. A few bile ducts within and adjacent to the invasive tumor showed dysplasia of the intestinal phenotype and were focally positive for synaptophysin and chromogranin A, suggesting that the dysplastic intestinal-type epithelium played a precursor role in this case. A postoperative computer tomography scan revealed rapid enlargement of the abdominal and retroperitoneal lymph nodes. The patient died 21 d after the operation. NEC of the bile duct is an aggressive neoplasm, and its biological characteristics remain to be better defined.

Key words: Neuroendocrine neoplasm; Large cell neuroendocrine carcinoma; Small cell neuroendocrine carcinoma; Extrahepatic bile duct; Dysplasia

Core tip: The authors report a case of large-cell neuroendocrine carcinoma (LCNEC) of the hilar bile duct. Concurrent dysplasia with intestinal and neuroendocrine differentiation was suggested to be a precursor in this case. Neuroendocrine carcinoma (NEC) of the bile duct occurs more frequently in men (male:female ratio 1.9:1). The mid-portion of the common bile duct appears to be the commonest site of involvement. All three reported cases of LCNEC died within 12 mo and the prognosis of NEC of the bile duct appears to be equally poor in both small-cell NEC and LCNEC. Multimodal treatment may improve outcome in this highly aggressive cancer.

INTRODUCTION

Neuroendocrine neoplasms of the extrahepatic bile ducts are rare, with carcinoid tumors representing the most

common type. Neuroendocrine carcinoma (NEC) is defined as a poorly differentiated, high-grade, malignant neuroendocrine neoplasm, which is classified as either small-cell NEC (SCNEC) or large-cell NEC (LCNEC)[1]. NEC of the extrahepatic bile ducts is exceedingly rare, and only 22 cases have been reported in the literature (Table 1)[2-23]. Of these, most cases are SCNEC, and only two cases of LCNEC have been reported to date. Since LCNEC was first described in the lung by Travis *et al*[24] in 1991, similar lesions have been described in extrapulmonary sites, including the gastrointestinal tract[25]. LCNEC shows immunohistochemical evidence of epithelial and neuroendocrine differentiation and is characterized by a diffuse growth pattern or neuroendocrine architecture (organoid, palisaded, rosettes, or trabeculae)[24,26]. Large cell size, low nuclear to cytoplasmic ratio, and frequent nucleoli are key cytologic features that help distinguish LCNEC from SCNEC. LCNEC of the biliary tract was first described in the gallbladder by Papotti *et al*[27] a little more than a decade ago; however, reported cases are still few, particularly in the extrahepatic bile ducts. Because of the paucity of cases, patient prognosis and responsiveness to anticancer treatments for LCNEC of the biliary tract largely remain to be elucidated. Most of the reported cases of LCNEC of the biliary tracts showed an aggressive course and short survival times; however, one case of LCNEC arising in the gallbladder achieved long survival (69 mo from the initial diagnosis) following multimodal treatment that included surgery, chemotherapy, and radiation therapy[28].

The origin of neuroendocrine neoplasms of the biliary tracts is unclear. They may arise from metaplastic epithelia, where there are a variety of epithelial cells (including neuroendocrine cells, goblet cells, and gastric-type epithelial cells) that are not found in the normal biliary epithelium. In fact, intestinal and/or gastric-type metaplasias are not uncommon in non-neoplastic mucosa adjacent to a variety of neuroendocrine neoplasms of the gallbladder, including carcinoid tumor, SCNEC, and LCNEC[27,29,30].

Here, we report a case of LCNEC of the hilar bile duct. The bile duct mucosa adjacent to the LCNEC showed high-grade dysplasia of the intestinal phenotype, which may have been the precursor in this case. While the presence of concurrent nearby dysplasia was described in 2 previously reported cases of SCNEC[4,16], neuroendocrine differentiation or metaplastic change has not been demonstrated in dysplastic epithelium. Therefore, we aimed to perform detailed immunophenotypic characterization of the dysplastic epithelium and demonstrated intestinal and neuroendocrine differentiation in the dysplastic epithelium. Another objective of this article is to provide a comprehensive literature review on NEC of the bile duct. Despite the paucity of cases, an attempt was made to compare the clinicopathologic characteristics and outcomes between SCNECs and LCNECs.

CASE REPORT

A 76-year-old male presented to a local hospital with a 2 wk history of increasing yellowish discoloration of the skin and dark-colored urine. The patient had no abdominal pain, nausea, or vomiting. He had a history of hypertension, rheumatoid arthritis, peptic ulcer disease, status post-stent placement for ischemic heart disease, and status post-right inguinal hernia repair. The patient denied any family history of cancer. His medication included metoprolol and benazepril. The patient was admitted to the local hospital for 7 d, during which time an abdominal computed tomography (CT) scan revealed a tumor involving the hepatic hilum. Endoscopic retrograde cholangiopancreatography demonstrated a stricture at the common hepatic duct, and two biliary stents were placed. The imaging studies suggested a malignant biliary stricture, but this could not be confirmed with biopsy. After the stent placement, the patient's serum bilirubin, which was initially reported to be 10 mg/dL, decreased to approximately 5 mg/dL and the yellowish discoloration of his skin normalized. The patient was transferred to the department of Surgery at the University of Pittsburgh Medical Center for further work-up and treatment. On admission, the patient's vital signs were within normal limits. The patient was obese with a body mass index of 34 kg/m^2. The sclerae were slightly icteric. The patient had normal cardiac and respiratory examinations and did not have cervical, axillary, or supraclavicular lymphadenopathy. Examination of the abdomen showed mild epigastric tenderness to deep palpation with no rebound tenderness or guarding. The right inguinal area had a well-healed scar from an inguinal hernia repair in the 1950s. The patient's complete blood count and serum biochemistry data on admission were as follows: white blood cells, 11300/mm^3; hemoglobin, 13.4 g/dL; hematocrit, 39.5%; platelets, 377000/mm^3; blood glucose, 122 mg/dL; total bilirubin, 3.5 mg/dL; aspartate aminotransferase, 106 IU/L; alanine aminotransferase, 88 IU/L; and gamma-glutamyl transpeptidase, 80 IU/L. Carbohydrate antigen 19-9 was 32.9 U/mL. Chest X-ray was normal. The patient underwent an operation in October 2011 with the presumed diagnosis of hilar cholangiocarcinoma (Klatskin tumor). The tumor of the hepatic hilum was resected with a right hepatic lobectomy, bile duct resection, and cholecystectomy. The patient had markedly enlarged lymph nodes in the hepatic hilum and retropancreatic area, which were also resected. There was no evidence of extrahepatic disease other than lymphadenopathy. Reconstruction was performed with a Roux-en-Y hepaticojejunostomy. In the resection specimen, the neoplasm diffusely involved the perihilar bile ducts and the surrounding portal connective tissue and measured 5.0 cm at its greatest dimension (Figure 1). The tumor had also invaded a large, right portal vein branch and formed an intraluminal mass. Histologically, the tumor cells were poorly differentiated with no evidence of glandular or squamous differentiation. The tumor cells were arranged in cellular nests and sheets with a small amount of intervening fibrovascular stroma (Figure 2A). The tumor cells had medium to large hyperchromatic nuclei with fine to coarse granular chromatin and occasional small nucleoli. The tumor cells had a small to

SCNEC: Small cell neuroendocrine carcinoma; NEC: Nneuroendocrine carcinoma, not otherwise specified; AD: Adenocarcinoma; LCNEC: Large cell neuroendocrine carcinoma; Bm: Mid portion of common bile duct; Bi: Inferior or distal common bile duct; CBD: Common bile duct, not otherwise specified; Bs; Superior or proximal common bile/hepatic duct; Bh: Hilar bile duct; DOD: Died of disease. N/A: Information not available; F: Female; M: Male.

moderate amount of amphophilic cytoplasm (Figure 2B). They showed brisk apoptotic activity and frequent mitotic figures (15-18 mitoses per 10 high-power fields). The tumor showed perineural and angiolymphatic invasion. All four lymph nodes were positive for metastatic tumor. The resected gallbladder had microscopic metastatic deposits in the perimuscular layer. No gallstones were present. The tumor cells were negative for mucicarmine stain. Immunohistochemical stains revealed that the tumor cells were strongly positive for synaptophysin (Figure 2C). They were also focally positive for chromogranin A, pancytokeratin, cytokeratin (CK) 7, CK 19, and MOC-31. Fewer than 1% of the tumor cells were weakly positive for thyroid transcription factor-1. They were negative for napsin-A, surfactant apoprotein A, alpha-fetoprotein, vimentin, CK5/6, p63, leukocyte common antigen, and S100. Approximately 70%-80% of the tumor cells were positive for Ki-67 (Figure 2D). The histologic findings and the immunoprofile of the neoplasm were consistent with LCNEC. A few foci of intermediate- to high-grade dysplasia were also identified

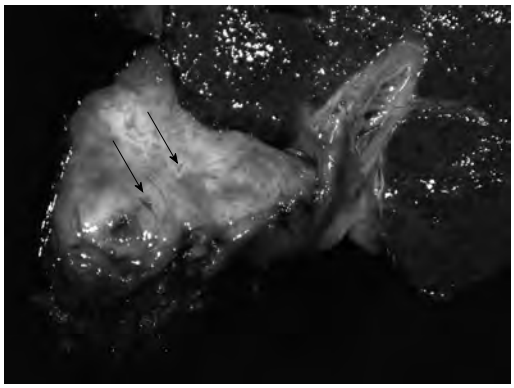

Figure 1 Gross appearance of the hilar neoplasm. The resected specimen showed a firm, tan-grey tumor measuring 5.0-cm in greatest dimension with extensive involvement of the perihilar bile ducts and surrounding soft tissue. Some of the small ducts and vessels within the lesion showed severe luminal narrowing (arrows).

in the perihilar bile ducts located within and adjacent to the invasive neoplasm (Figure 3A). The dysplastic epithelium contained some goblet cells. The dysplastic epithelial cells were immunoreactive for CK19, CK20, and CDX2 (Figure 3B and C). The goblet cells were positive for mucin (MUC)2 and negative for CK7, MUC1, MUC5AC, and MUC6. The immunoprofile of the dysplastic epithelium, together with the presence of goblet cells expressing MUC2 was consistent with an intestinal phenotype. The epithelial cells of this lesion were also positive for synaptophysin (Figure 3D) and chromogranin A but with less extensive and intense immunoreactivity compared to the invasive neoplasm. The findings of the in situ component were suggestive of a premalignant or preinvasive lesion rather than intraepithelial spread from the invasive neoplasm. The patient's immediate postoperative course was uncomplicated; however, a CT scan of the abdomen eight days after the operation revealed extensive enlargement of his abdominal and retroperitoneal lymph nodes, which was suggestive of rapid metastasis. The patient had poor oral intake, hypovolemia, and significant back pain. Postoperative chemotherapy or radiation therapy was not performed because of the patient's poor general condition. The patient died 21 d after operation. An autopsy was not performed.

DISCUSSION

According to the most recent World Health Organization (WHO) classification, neuroendocrine neoplasms of the digestive system are classified into three general categories based on histologic features and proliferation fraction[1,31]. These include NET, NEC, and mixed adenoneuroendocrine carcinoma (MANEC). A NET is defined as well-differentiated neuroendocrine neoplasm with mild to moderate nuclear atypia and a low proliferation fraction (≤ 20 mitoses per 10 high-power fields or ≤ 20% Ki67 index). This category encompasses neoplasms termed carcinoid tumors. A NEC is a poorly differentiated, high-grade malignant neuroendocrine neoplasm composed of either small or intermediate to large cells with marked nuclear atypia and a high proliferation fraction (> 20 mitoses per 10 high-power fields or > 20% Ki67 index). This category includes SCNEC and LCNEC, but a dichotomous subclassification of small cell *vs* non-small cell may also apply[25]. MANEC has a phenotype that is morphologically recognizable as both gland-forming epithelial and neuroendocrine carcinomas. Arbitrarily, at least 30% of either component should be identified to qualify for this definition.

Neuroendocrine neoplasms of the extrahepatic bile ducts are rare, and the majority of the reported cases are NET/carcinoid, which represent 0.1%-0.2% of all gastrointestinal carcinoids/NET[32]. According to the data obtained from the Surveillance, Epidemiology, and End Results program of the National Cancer Institute, there were 31 cases of carcinoid, 17 of SCNECs, and 10 of NECs of not-otherwise-specified type of the gallbladder and extrahepatic bile ducts between 1973 and 2005[33]. Thus, NEC of the extrahepatic bile duct is exceedingly rare and is probably less frequent than NET/carcinoid. According to the literature, 23 cases of NEC of the extrahepatic bile ducts, including the case described here, have been reported. The most common histologic subtype of NEC of the extrahepatic bile ducts is SCNEC (19 of 23 cases; Table 1). Only two cases of LCNEC of the common bile duct were previously reported (Table 1, cases 21 and 22); therefore, this is the third reported case of LCNEC arising in the extrahepatic bile duct. The reported cases of NEC include 15 males and 8 females, with a male to female ratio of 1.9: 1. Patient age ranged from 32-85 years with a mean age of 67.2 years. The mean age of LCNEC was higher than that of SCNEC (72.3 years *vs* 65.9 years), but this difference was not statistically significant. NEC can occur anywhere in the extrahepatic bile duct, but the mid portion of the common bile duct appears to be the most common site of involvement. Two cases had biliary stones (Table 1, cases 8 and 17). Concurrent *Clonorchis sinensis* infestation was seen in two cases (Table 1, cases 7 and 18). The presence of concurrent nearby dysplasia was described in three of 23 cases, including ours (Table 1, cases 3, 15 and 23). Eight cases were composite neuroendocrine and adenocarcinoma (Table 1, cases 15-22). Some of these composite cases may be classified as MANEC rather than NEC according to the current WHO classification system, depending on the proportion of the adenocarcinoma component. When NEC coexisted with adenocarcinoma, a gradual transition between areas of NEC and adenocarcinoma was observed in six of eight cases (Table 1, cases 15-17 and 19-21). In three of eight cases (Table 1, cases 18, 19 and 21), the adenocarcinoma component was located in the superficial portion of the tumor, and the NEC component was located mainly in the deeper portion of the tumor. No other particular spatial relationships between NEC and adenocarcinoma components have been described.

NEC of the gastrointestinal tract can show a spectrum of morphologic features ranging from classic SCNEC to LCNEC, and some cases have features between

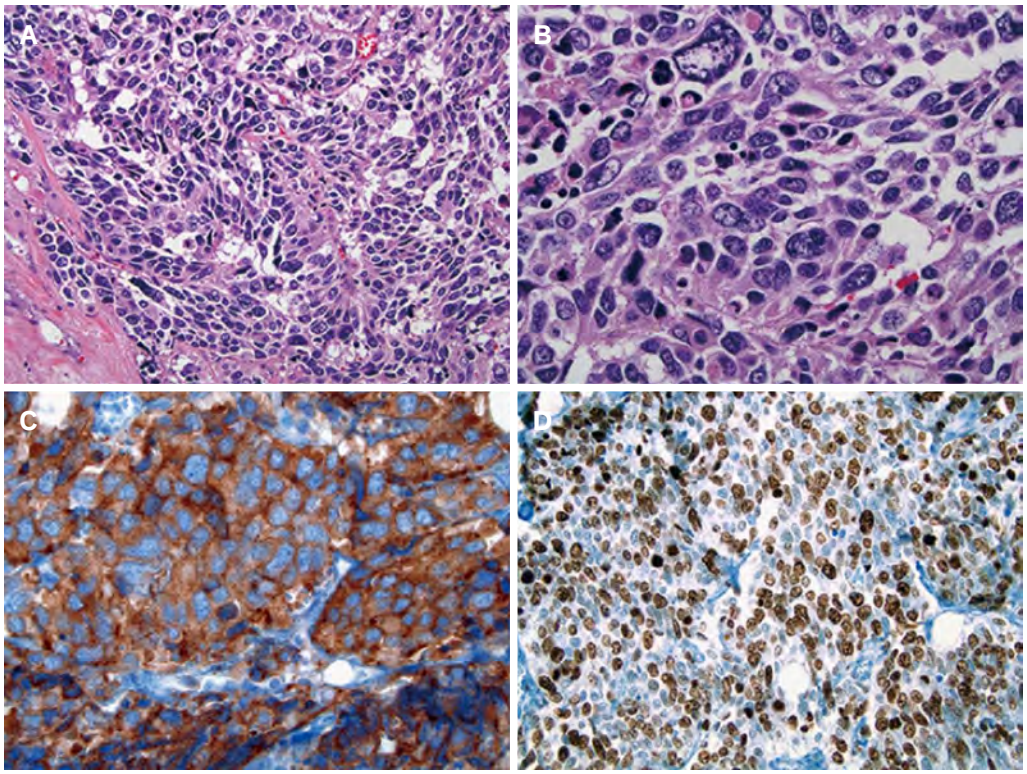

Figure 2 Histologic features of the hilar neoplasm. A: The tumor cells were arranged in cellular nests and sheets with little intervening fibrovascular stroma [Hematoxylin and eosin (HE), × 200]; B: The tumor cells had a small to moderate amount of amphophilic cytoplasm and medium to large hyperchromatic nuclei with fine to coarse granular chromatin and occasional small nucleoli (HE, × 400); C: The tumor cells were strongly positive for synaptophysin (× 400); D: 70%-80% of the tumor cells were positive for Ki-67 (× 200).

these two types. As Shia *et al*[25] previously pointed out, there were no criteria for classifying NEC of the GI tract with non-small cell morphology before the most recent WHO classification. Therefore, NEC of the extrahepatic bile ducts and gallbladder with non-small cell morphology may have been diagnosed inconsistently. In fact, histologic features of some of the previously reported cases of SCNEC of the extrahepatic bile ducts are not morphologically typical of SCNEC. For example, the NEC tumor component reported as a part of composite adenocarcinoma and SCNEC of the hilar bile duct by Yamamoto *et al*[18] (Figure 2B in their manuscript) showed prominent nucleoli and moderately abundant cytoplasm, which is not typical of SCNEC (Table 1, case 17). Thus, some of the non-small cell type NECs or LCNEC may have been diagnosed or reported as SCNEC because of the previous lack of a distinct diagnostic category.

LCNEC of the extrahepatic bile ducts is extremely rare. Both of the previously reported cases contained a minor component of adenocarcinoma (10%-20% of the entire tumor). One tumor was located in an intra-pancreatic portion of the common bile duct (Table 1, case 21), and another was located in the perihilar bile duct (Table 1, case 22). The adenocarcinoma component of one case (Table 1, case 21) showed focal expression of a neuroendocrine marker (chromogranin A), and the other case did not express neuroendocrine markers (Table 1, case 22). The coexistence of adenocarcinoma in these cases, as well as in the aforementioned six cases of composite adenocarcinoma and SCNEC suggests that NEC of the common bile duct may arise from pluripotent progenitor cells. This idea is further supported by the observation of transitional zones between NEC and adenocarcinoma components in the majority of cases. The invasive tumor described here was composed entirely of LCNEC. Although no adenocarcinoma component was identified, a few perihilar bile ducts located within and adjacent to the LCNEC showed dysplasia of the intestinal phenotype with focal endocrine differentiation. Although data on the histogenesis of neuroendocrine neoplasm of the biliary tracts in the literature are limited, neuroendocrine neoplasm of the bile duct and gallbladder may arise from neuroendocrine cells in intestinal or gastric metaplasia, where there may be progenitor cells with a greater ability to differentiate into neuroendocrine cells[29,34]. The presence of intestinal type dysplasia in our case suggests that LCNEC may have arisen from metaplastic epithelium, although we cannot exclude the possibility that the metaplastic/neuroendocrine phenotype may have been acquired at the time of or subsequent to the dysplasia. Regardless, the progression from dysplasia with an intestinal/neuroendocrine phenotype to an aggressive NEC may have occurred in the case described.

The prognosis of NEC of the bile duct appears to be poor. Among the 21 cases with follow-up data, 57% (12/21) of the patients died of disease 3 to 20 mo after surgery, and only two patients have been reported to survive more than 2 years (Table 1, cases 14 and 19). Among

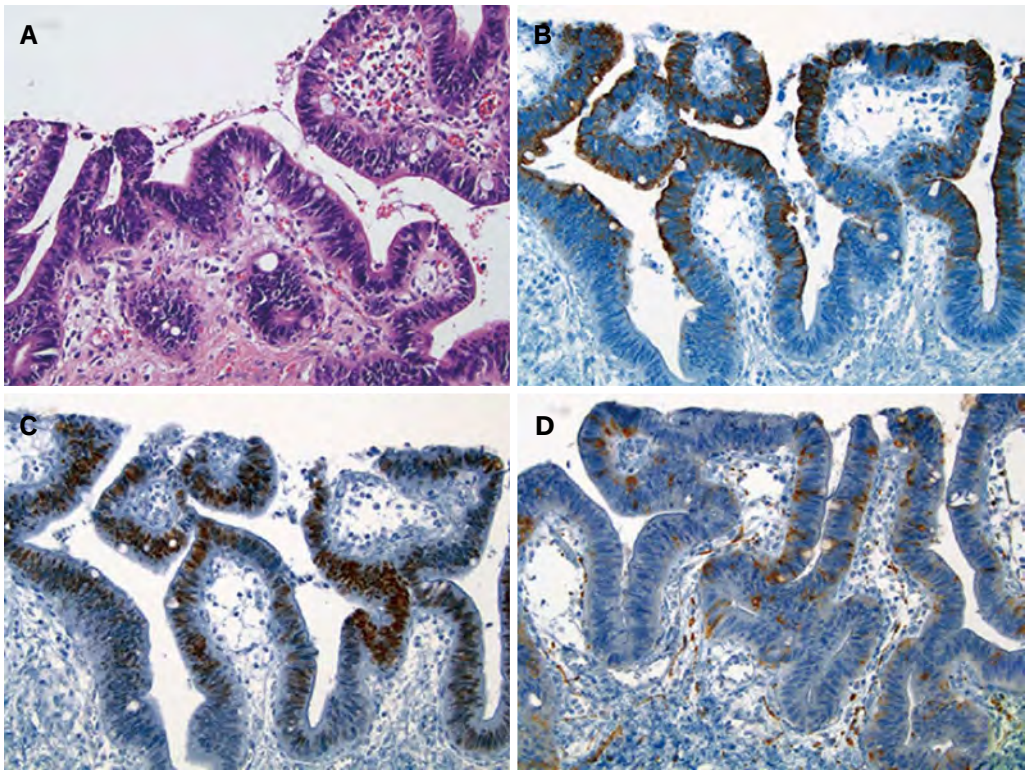

Figure 3 Histologic features of the dysplastic epithelium found in a medium-sized perihilar bile duct located within the invasive neoplasm. A: The dysplastic epithelium contained some goblet cells [Hematoxylin and eosin (HE), × 200]; B, C: The dysplastic epithelial cells were immunoreactive for CK20 (B, × 200) and CDX2 (C, × 200); D: Some of the dysplastic epithelial cells were positive for synaptophysin with less extensive and weak immunoreactivity compared to the invasive neoplasm (× 200).

the seven patients who survived at least 12 mo, five were treated with multidisciplinary treatment, including surgical resection, adjuvant or neoadjuvant chemotherapy, and radiation. The longest survival was 45 mo in a patient who was treated with surgical treatment alone (Table 1, Case 19). According to Edakuni *et al*[20], that tumor was a composite adenocarcinoma (-40%) and SCNEC (-60%). They speculated that the reason for the long survival may have been the low proliferative fraction (9.6% Ki-67-positive tumor cells) of the SCNEC. Recently, most neuroendocrine neoplasm grading systems rely extensively on the proliferation rate, which has been shown to provide significant prognostic information[31]. Based on the current WHO grading system, the NEC component of the case reported by Edakuni *et al*[20] may be best classified as intermediate-grade NET rather than SCNEC, and this appears to at least in part explain the long survival time. According to Iype *et al*[35], LCNECs appear to have a worse prognosis than SCNEC in the gallbladder. Although only two cases of LCNEC of the bile duct have been previously reported, both patients died within 12 mo of surgery despite postoperative chemotherapy (Table 1, cases 21 and 22). In our case, the patient died 21 d after the operation with radiographic evidence of rapid progression of metastatic disease. Thus, the survival for patients with LCNEC of the extrahepatic bile duct appears to be equally poor as for those with SCNEC. Multidisciplinary management appears to be effective and provide longer survival time for SCNEC of the bile duct (Table 1, cases 13 and 14). Recently, a long surviving case of LCNEC of the gallbladder was reported by Shimono *et al*[28]. That patient received multimodal treatment consisting of chemotherapy, radiation therapy, surgical resection, and γ-knife irradiation for brain metastases, which resulted in 69 mo of survival. This case suggests that multimodal treatment is potentially effective in treating LCNEC patients. The effectiveness of chemotherapy and radiotherapy in both SCNEC and LCNEC of the biliary tract needs to be further investigated in a larger number of cases to confirm this observation.

In summary, we reported a case of high-grade neuroendocrine neoplasm arising in the perihilar bile ducts that was best classified as LCNEC. The coexistent dysplasia with intestinal and neuroendocrine differentiation may represent a LCNEC precursor. We feel that histologic subtyping of NECs into SCNEC and LCNEC (or even non-small cell NEC), rather than grouping all types of high-grade neuroendocrine neoplasms together as NECs, is necessary because biologic characteristics of each subtype need to be more clearly defined for better prognostication and selection of therapy.

Abstract

A retroperitoneal hemangioma is a rare disease. We report on the diagnosis and treatment of a retroperitoneal hemangioma which had uncommonly invaded into both the pancreas and duodenum, thus requiring a pylorus preserving pancreaticoduodenectomy (PpPD). A 36-year-old man presented to our hospital with abdominal pain. An enhanced computed tomography scan without contrast enhancement revealed a 12 cm × 9 cm mass between the pancreas head and right kidney. Given the high rate of malignancy associated with retroperitoneal tumors, surgical resection was performed. Intraoperatively, the tumor was inseparable from both the duodenum and pancreas and PpPD was performed due to the invasive behavior. Although malignancy was suspected, pathological diagnosis identified the tumor as a retroperitoneal cavernous hemangioma for which surgical resection was the proper diagnostic and therapeutic procedure. Reteoperitoneal cavernous hemangioma is unique in that it is typically separated from the surrounding organs. However, clinicians need to be aware of the possibility of a case, such as this, which has invaded into the surrounding organs despite its benign etiology. From this case, we recommend that combined resection of inseparable organs should be performed if the mass has invaded into other tissues due to the hazardous nature of local recurrence. In summary, this report is the first to describe a case of retroperitoneal hemangioma that had uniquely invaded into surrounding organs and was treated with PpPD.

Key words: Retroperitoneal tumor; Retroperitoneal cavernous hemangioma; Cavernous hemangioma; Pancreaticoduodenectomy; Pylorus preserving pancreaticoduodenectomy

Core tip: A retroperitoneal cavernous hemangioma is a rare disease. This case of retroperitoneal hemangioma had uniquely invaded into the duodenum and pancreas head, and thus required treatment with pylorus preserving pancreaticoduodenectomy. Although hemangiomas are typically benign, clinicians should be aware of the possibility of invasion into the surrounding organs such as with this case. In the event of invasion, we recommend a combined resection of both the tumor and affected organs to reduce the chance of local recurrence that may be associated with inadequate resection.

Hanaoka M, Hashimoto M, Sasaki K, Matsuda M, Fujii T, Ohashi K, Watanabe G. Retroperitoneal cavernous hemangioma resected by a pylorus preserving pancreaticoduodenectomy. *World J Gastroenterol* 2013; 19(28): 4624-4629 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4624.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4624

INTRODUCTION

A retroperitoneal hemangioma is an uncommon disease in adulthood[1-3]. Only 23 cases of adult retroperitoneal hemangioma have been reported in the literature since 1950. Among those, five cases, including the case detailed in this report, needed combined resection of surrounding organs because of adhesion of the tumor. In this report, we describe the diagnosis and treatment of a retroperitoneal hemangioma that had uniquely invaded into the pancreas and duodenum and required a pylorus preserving pancreaticoduodenectomy (PpPD).

CASE REPORT

A 36-year-old man came to a local hospital with right upper quadrant pain since the day before admission. He had no specific medical history or family history. A screening-enhanced computed tomography (CT) scan revealed a bulky tumor between the dorsal side of the pancreatic head and the right kidney. The tumor was diagnosed as a retroperitoneal sarcoma and the patient was referred to Toranomon Hospital for the operation. On physical examination, the patient was found to have no palpable mass. The results of urine, blood, and adrenal cortex functional tests were within normal limits. An abdominal enhanced CT scan showed a 12 cm × 9 cm tumor without marked contrast enhancement, pushing the pancreas to ventral side (Figure 1A). The mass was distinct from the surrounding organs, including the duodenum, pancreas, kidney and retroperitoneal spaces as observed from the CT scan and therefore appeared to be resectable. An abdominal ultrasound showed an uneven echoic lesion in the same area as observed by CT. T1-weighted image of magnetic resonance imaging (MRI) showed low and a few part of relatively high intensity area inside the tumor (Figure 1B). On fat suppression examination of the MRI image, the tumor was not suppressed to any degree. T2-weighted image also showed heterogeneous finding; there were high intensity area with a few part of intermediate signal intensity area. However, there were no typical findings which suggest the type of retroperitoneal tumor on diagnostic images (Figure 1C). Based on the qualitative assessments, the tumor was diagnosed as a retroperitoneal mesenchymal tumor. Because of the high rate of malignancy associated with retroperitoneal tumors, surgical resection was performed.

Intraoperatively, the mass measured 12 cm × 9 cm in diameter. We initially tried to perform a tumor excision without combined resection of surrounding organs. However, the intraoperative findings revealed that the mass encroached on the head of the pancreas and duodenum (Figure 2). As such, we performed Kocher's mobilization of the duodenum and tried to separate the tumor from the duodenum and pancreas; however, the tumor could not be successfully separated from these organs. After the tumor was lifted from the retroperitoneal space, we tried again to separate the tumor from the pancreas head and duodenum. The tumor adhered strongly to both tissues and could only be removed completely by PpPD. The duration of surgery was 4 h and 16 min and the total blood loss was 561 mL. The patient was discharged from the hospital on postoperative day 24 and was in good health without recurrence over two and a half years after the operation.

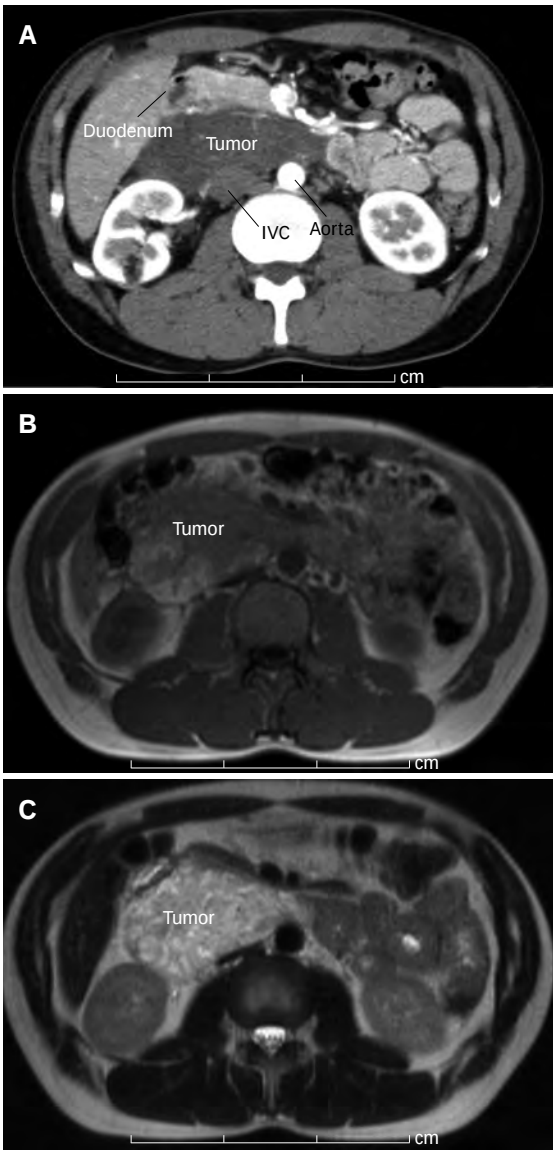

Figure 1 12 cm × 9 cm tumor was detected by computed tomography and magnetic resonance imaging. A: Abdominal enhanced computed tomography in early phase showed tumor without marked contrast. The tumor had pushed the pancreas to the ventral side; B: T1-weighted image of magnetic resonance imaging showed low and relatively high intensity area inside the tumor; C: T2-weighted image showed high intensity area with a few part of intermediate signal intensity area. IVC: Inferior vena cava.

Gross pathologic examination revealed a 120 mm × 95 mm × 50 mm hemangioma composed of multioculated cysts containing intra-cystic hemorrhages (Figure 3). The diagnosis on pathological examination was a cavernous hemangioma with a few focal areas of venous hemangioma (Figure 4A). As defined by the pathologist, the lesion had invaded into the muscle layer of the

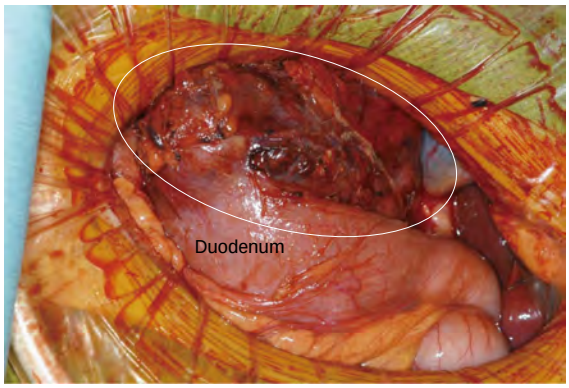

Figure 2 Macroscopic view of intraoperative findings. The mass was attached to both the duodenum and the pancreas head and required surgical resection by pylorus preserving pancreaticoduodenectomy. The circle denotes the tumor.

duodenum and the pancreas head (Figure 4B-D). Immunohistochemical analysis of tissue sections revealed that the lumina were positive for CD31 and CD34, markers of endothelial cells (Figure 4E), and partially weak positive for podoplanin/D2-40 (Figure 4F), a marker of lymphatic endothelial cells. Less angiogenic invasion was observed toward the retroperitoneal side of the tumor than toward the pancreas and duodenum. Interestingly, both macroscopically and microscopically, the tumor extended into both the pancreas and duodenum and not into the retroperitoneal space.

DISCUSSION

In this report, we describe a patient with retroperitoneal hemangioma that required PpPD. A retroperitoneal tumor is a very rare tumor that accounts for less than 0.2% of all tumor types[1]. Among malignant tumors located in the retroperitoneal space, liposarcomas and leiomyosarcomas are the most frequent, while teratomas, cysts and neurinomas are common benign masses. In the current case, the tumor was diagnosed initially as a retroperitoneal sarcoma; retroperitoneal liposarcomas are the most common malignant tumors of the retroperitoneal soft tissue[2]. Indeed, accurate diagnosis of a retroperitoneal hemangioma is classically difficult preoperatively and prior to pathological examination of the tissue.

An analysis of other retroperitoneal tumor types reveals subtle, yet distinct, differences in symptom presentation, localization, and radiographic features. Among retroperitoneal tumors, imaging studies of leiomyosarcomas demonstrate a non-specific mass but are helpful in delineating the relationship to adjacent structures[3]. Angiosarcomas classically present with cutaneous involvement of the head and neck region in elderly patients[4]. The solid growth pattern and epithelioid cytology can be easily confused with poorly differentiated carcinoma[5]. Most patients with lymphanginoleiomyomatosis (LAM), characterized by proliferation of smooth muscle cells, present with pulmonary symptoms, whereas extrapulmonary LAM is rare and typically presents in premenopausal females[6]. Cystic lymphangioma is a well-known benign tumor and its cystic abnormalities of the lymphatic vessels are predominantly congenital. By CT scan, the tumor is typically well-circumscribed and polycystic with thin septa similar in appearance to the cystadenomas[7]. Kaposiform hemangioendothelioma mainly occurs during childhood. MRI of the affected region is accepted as the

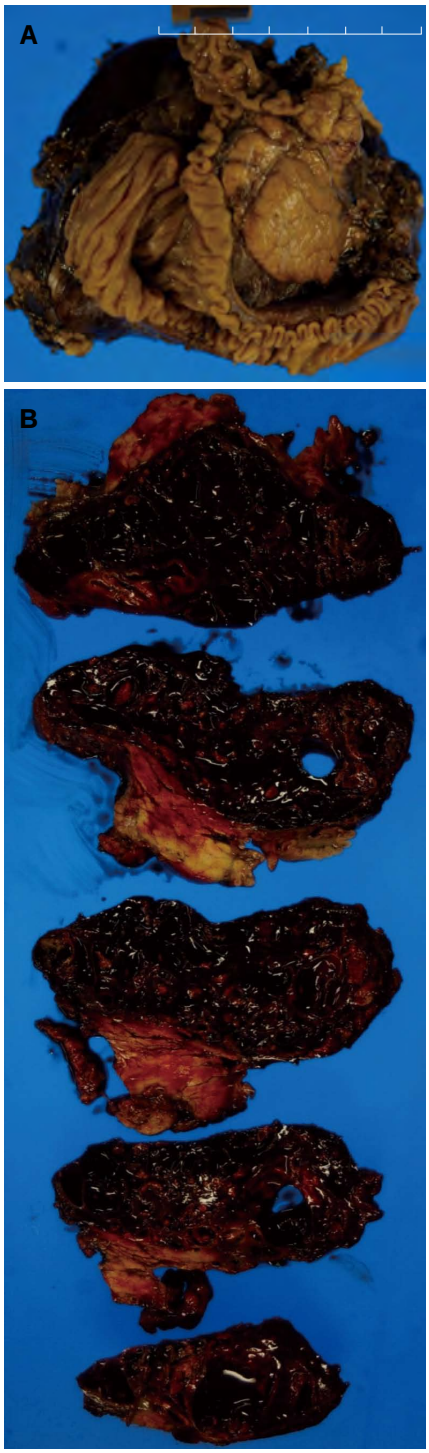

Figure 3 Macroscopic findings of the resected specimen. A: A 120 mm × 95 mm × 50 mm tumor was resected. Scale bar, 70 mm; B: The tumor contained multi-oculated cysts containing intra-cystic hemorrhages.

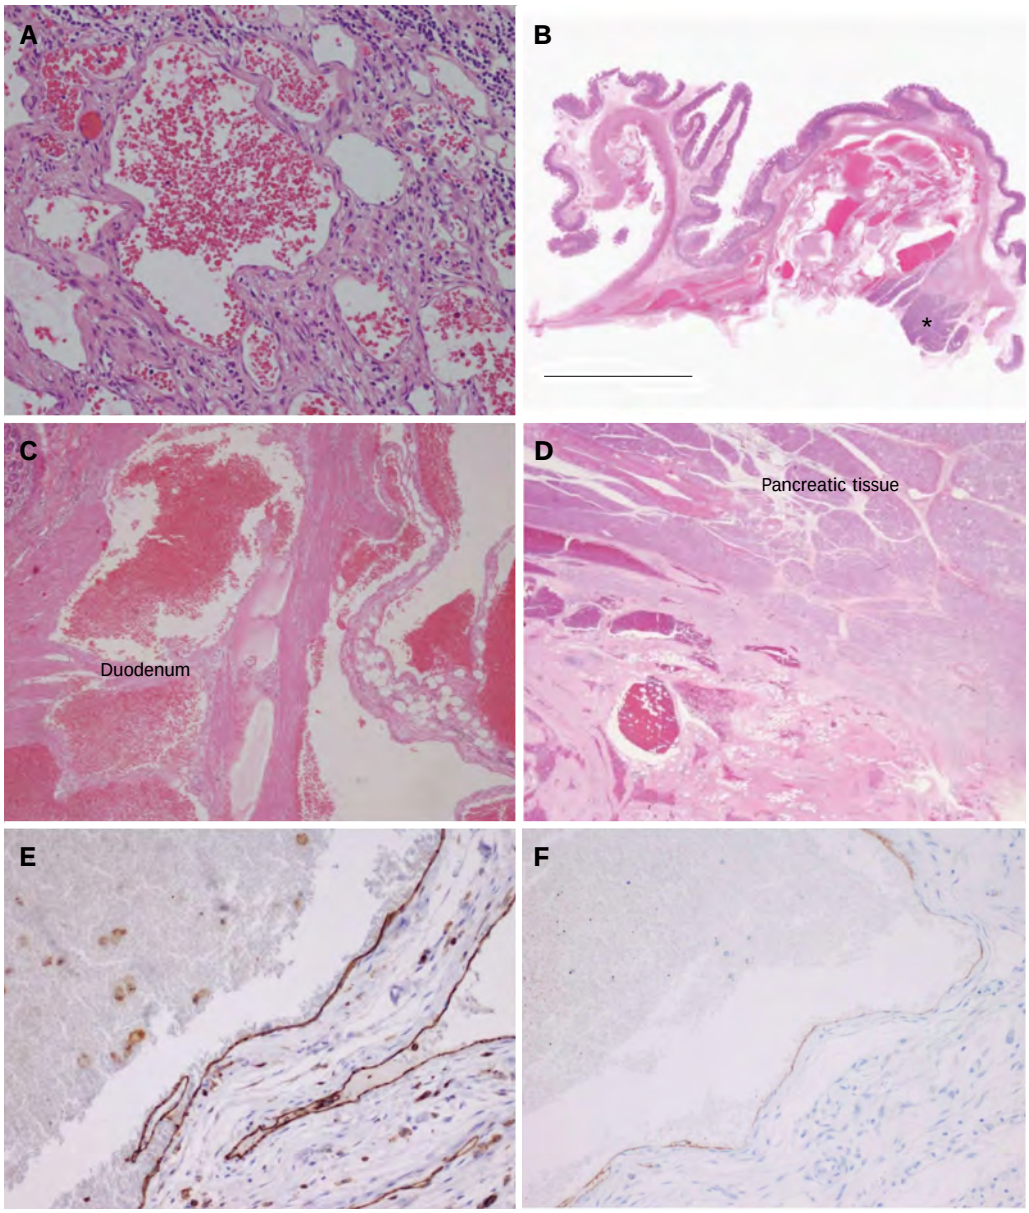

Figure 4 Pathological analysis by hematoxylin and eosin staining and immunohistochemistry. A: A representative tissue section from the main region of the cavernous hemangioma [hematoxylin and eosin (HE), magnification × 200]; B: The loupe view demonstrates a portion of cavernous hemangioma infiltrating the pancreatic head (asterisk) and duodenal wall (HE). The scale represents 10 mm; C: Tumor invasion into the muscle layer of the duodenum (HE, magnification × 4); D: Tumor invasion into the pancreas head (HE, magnification × 1); E: Positive immunostaining for CD31 supports the diagnosis of hemangioma (magnification × 20); F: The lumen showed partial and weakly positive staining for podoplanin/D2-40 (magnification × 20).

diagnostic imaging technique of choice[8]. Concerning hemangiomas arising from other tissues, pancreatic and mesenteric hemangiomas have been reported[9,10], which are extremely rare. MRI shows a common characteristic of pancreatic hemangiomas[9]. Mesenteric hemangiomas shows heterogeneous enhancement by enhanced CT and changes its shape during intestinal peristalsis[10].

As for pathological findings, gross pathological findings showed the tumor included multi-oculated cysts filled with blood. This cyst is suggested to be a pseudocyst which is a result of repeats of hemorrhage[11]. D2-40, reliable podoplanin antibody clone, has been described in a variety of lymphovascular neoplasms including lymphangioma, Kaposi sarcoma, and hemangioendothelioma[12]. Because lymphatic endothelial cells express high levels of podoplanin[13], we suggest that the weakly positive findings of D2-40 in the current case do not support a diagnosis of lymphangima. In addition to macroscopic and immunohystological findings, microscopic finding of almost all of lumen are filled with red blood cells supported the diagnosis as hemangioma.

Retroperitoneal hemangioma in the adult is extremely rare and confirmed in only 1%-3% of all retroperitoneal tumors[14]. Only 23 cases of adult retroperitoneal hemangioma have been reported in literature since 1950.

Retroperitoneal tumors are difficult to diagnose preoperatively[15] because there are usually no initial symptoms until tumors have grown large enough to produce

Table 1 Reported cases of retroperitoneal hemangioma with combined resection of surrounding organs

Ref.	Age (yr)	Sex	Tumor size (cm^3)	Hyper-vascularity	Curative resection	Pathological diagnosis	Organ(s) of combined resection

Hanaoka *et al*, 2013	36	M	12 × 19 × 5	-	+	Cavernous and Venous	Duodenum, pancreas head

Five cases, including this, needed combined resection of surrounding organs. In four cases, a complete combined resection of surrounding organs was performed, while in one case a subtotal resection was performed (Tseng *et al*[18]). NA: Not available.

patient discomfort[11]. Furthermore, retroperitoneal cavernous hemangiomas have features similar to ischemic tumors, but differ from hemangiomas arising from other tissues such as the skin or liver[11].

As for imaging studies of retroperitoneal cavernous hemangiomas, because they are usually only discovered when large enough to develop thrombi and organization at the center[16], these tumors often show slight to no enhancement in normal enhanced CT[11,14,15]. In the present case, the CT scan revealed a cystic mass with minor contrast enhancement, similar to cases reported previously[17,18]. In addition, retroperitoneal cavernous hemangiomas typically lack the complete fill-in or cotton-wool appearance in enhanced CT or high echoic areas with the same density as the abdominal echo, which is usually only seen in cavernous hemangiomas of the liver[11]. On T1-weighted image of MRI, relatively high intensity area inside the tumor is suggested to be hemorrhage and hyalinization of the tissue. A part of high intensity area of T2-weighted image suggests blood contain and relatively high signal intensity area shows hyalinization and fibrillization. However, these findings were suggested to be secondary change of structure, which don't indicate any typical tumors. With few clues for diagnosis, very few cases of retroperitoneal hemangiomas have been diagnosed preoperatively. Therefore, surgical resection is a choice for both diagnostic and therapeutic procedures.

One feature of a cavernous hemangioma is that it may be locally destructive by virtue of the pressure exerted on neighboring tissues[19]. In the present case, the pressure of the tumor affected the duodenum and pancreas, leading to invasion and destruction of these organs. Among the 23 reported retroperitoneal hemangiomas, five cases, including ours, needed combined resection of surrounding organs because of an adhesion (Table 1)[18,20-22]. Among the five cases, four cases performed complete combined resection of surrounding organs. In one case, subtotal resection was performed due to technical difficulties caused by firm adherence to the adjacent organs and the major blood vessels[22]. Like this case, which did not demonstrate findings typical of hemangioma from the contrast-enhanced CT, three cases including ours showed hypovascularity, while two cases showed hypervascularity. Pathologically, four cases, including this, were diagnosed as cavernous hemangiomas and one was diagnosed as a venous hemangioma. Hence, we conclude that vascularity from CT analysis and pathological diagnosis are not always directly correlated with adhesion to other organs.

The recommended treatment for retroperitoneal hemangioma has been surgical resection[11,15,23]. Hemangiomas are non-malignant, but patients run the risk of rupture and bleeding[24]. Therefore, surgical treatment is recommended for high-risk tumors, such as with those of large masses[25]. Although hemangiomas are benign, local recurrence has been reported with inadequate resection[26]. In this case, the decision was made to combine the tumor resection with resection of the surrounding organs to avoid local recurrence in the pancreas and duodenum from residual tumor tissue. Therefore, the PpPD procedure for this case was appropriate. From a treatment standpoint, we support a combined resection of both the tumor and the compromised organs if the tumor is invasive and cannot be removed cleanly because of adhesion.

In conclusion, a retroperitoneal cavernous hemangioma is an uncommon disease. Clinicians need to be aware of the possibility of a case that has invaded into surrounding organs despite its benign pathology. This case of a retroperitoneal hemangioma had uniquely invaded into the duodenum and pancreas and this is the first report of treatment using PpPD.

Abstract

This case report describes an unusual case of upper gastrointestinal (UGI) bleeding caused by a ruptured superior mesenteric artery (SMA) aneurysm in the duodenum in a patient with rheumatoid arthritis. The patient presented with UGI bleeding and hemorrhagic shock. Emergency UGI endoscopy could not identify the source of the bleeding because of excessive blood clots under the second portion of the duodenum. An SMA aneurysm with active contrast extravasation was diagnosed by computed tomography. The aneurysm, together with the fourth portion of the duodenum and the proximal portion of the jejunum, was surgically resected, and the SMA was skeletonized. On postoperative day 15, the patient was discharged from hospital under satisfactory conditions. Rheumatoid arthritis has been known to cause a wide spectrum of manifestations, and an SMA aneurysm is an unusual extra-articular manifestation. An SMA aneurysm rupture presenting as upper gastrointestinal bleeding is a rare complication with a high mortality rate. The clinician must be alert to this potential issue to achieve rapid diagnostic confirmation, and immediate surgical or radiological intervention.

Key words: Gastrointestinal bleeding; Aneurysm; Rheumatoid arthritis; Endoscopy; Duodenum

Core tip: Gastrointestinal bleeding is a common medical emergency. Ruptured superior mesenteric artery aneurysm is an uncommon cause of gastrointestinal bleeding, with few cases reported previously. Diagnosis is difficult before surgery. We reported the successful diagnosis and treatment of such a case.

INTRODUCTION

Upper gastrointestinal (UGI) bleeding is a common medical emergency. Patients usually present with hematemesis or melena, and are diagnosed after endoscopic evaluation. Peptic ulcers and esophagogastric varices account for most causes of UGI bleeding. A visceral aneurysm is an uncommon cause of gastrointestinal bleeding, and diagnosis is usually made after surgery. Here, we report an interesting case with pre-operative diagnosis of a ruptured superior mesenteric artery (SMA) aneurysm in the duodenum of a patient with rheumatoid arthritis.

CASE REPORT

A 27-year-old man with a history of rheumatoid arthritis was brought to the emergency department because of an episode of coffee ground vomitus and dizziness. He suffered from melena for 2 d. His blood pressure was 89/52 mmHg and his heart rate was 106/min. He presented with alert consciousness in the emergency department. A nasogastric tube lavage revealed coffee ground material, and further investigation revealed hemoglobin

levels of 8.1 g/dL. Emergency UGI endoscopy was performed after his hemodynamic status was stabilized with fluid hydration and blood transfusion. UGI endoscopy found excessive blood clots below the second portion of the duodenum. To identify the source of the bleeding, abdominal contrast-enhanced computed tomography (CT) was performed. The CT scan revealed an aneurysm about 3.9 cm in diameter at the jejunal mesentery; with active contrast extravasation into the fourth portion of the duodenum (Figure 1). The aneurysm, together with the fourth portion of the duodenum and the proximal portion of the jejunum, was surgically resected, and the SMA was skeletonized. Pathology revealed an aneurysm measuring 3.8 cm × 3.5 cm × 2.0 cm at the mesenteric side, with blood clots within the cystic space, as well as a focal rupture into the lumen of the small intestine.

The patient was subsequently able to eat on postoperative day 7, and his condition was satisfactory. He was discharged from the hospital on postoperative day 15.

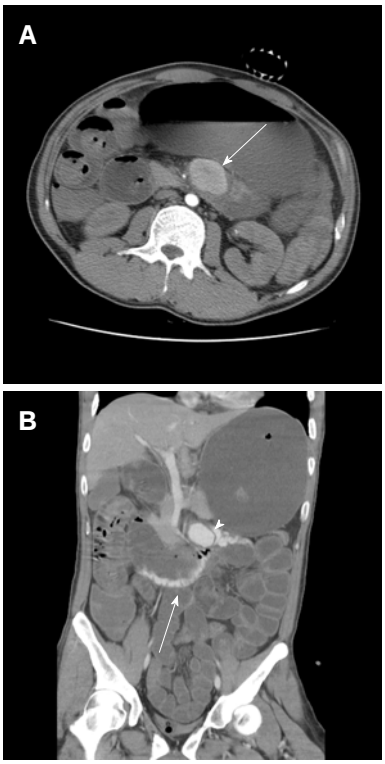

Figure 1 Computed tomography scans. A: Computed tomography (CT) scanning revealed a superior mesentery artery aneurysm about 3.9 cm in diameter at the jejunal mesentery (white arrow); B: CT scan showing a superior mesentery artery aneurysm (arrow head) with active contrast extravasation into the fourth portion of the duodenum (white arrow).

DISCUSSION

UGI bleeding is a common medical condition that results in high patient morbidity. UGI bleeding commonly presents with hematemesis or melena. It is important to take a careful history and perform a thorough physical examination to identify the possible source and etiology of the bleeding. Common causes of UGI bleeding include peptic ulcers, esophagogastric varices, erosive gastritis, Mallory-Weiss syndrome, angiodysplasia or Dieulafoy's lesion. Peptic ulcers are responsible for approximately half of UGI bleedings[1].

Our patient with an SMA aneurysm rupture in the duodenum presenting as UGI bleeding was extremely rare; there have been only a few reported cases[2-4]. Overall, only 0.2% of the general population is found to have an aneurysm of the visceral arteries, and SMA aneurysms represent only 5.5% of all visceral aneurysms[5]. Unlike other splanchnic artery aneurysms, which are mostly asymptomatic, more than 90.0% of SMA aneurysms are symptomatic, manifesting primarily as nonspecific abdominal pain[6]. Rarely, an abdominal mobile pulsatile mass or abdominal bruit maybe found on physical examination. Common causes of SMA aneurysms include septic emboli, atherosclerosis, pancreatitis and trauma. Septic emboli account for about one-third of SMA aneurysms. Other uncommon causes are collagen vascular disease, connective tissue disease and neurofibromatosis[7]. Abdominal ultrasonography and CT are useful in identifying the type of aneurysm. However, up to 50.0% of SMA aneurysms present with a rupture, where hypovolemic shock, hemoperitoneum or acute abdomen are the first manifestations. Once an SMA aneurysm ruptures, a high intra-operative mortality rate of more than 30.0% has been reported in previous studies[8]. Therefore, in patients diagnosed with an SMA aneurysm, surgical resection or radiological intervention should be recommended before the aneurysm ruptures.

An SMA aneurysm is an unusual extra-articular manifestation of rheumatoid arthritis, and our patient had no other history contributing to the formation of an aneurysm, including septic embolic, trauma or atherosclerosis. Rheumatoid arthritis can cause a wide spectrum of manifestations, from clinically insignificant to life-threatening. In postmortem examinations, rheumatoid vasculitis occurred in approximately 25.0% of all patients with rheumatoid arthritis, whereas less than 1% of rheumatoid arthritis patients developed clinical signs of vasculitis[9]. Among these patients, 10%-38% will have gastrointestinal manifestations of vasculitis and this may be the first manifestation[10,11]. Cases of abdominal aneurysm rupture with syncope and hemorrhage, bowel infarction, and intestinal perforation have been described [10-13].

Therefore, in patients with rheumatoid arthritis who have UGI bleeding, diagnosis of a ruptured SMA aneurysm in the duodenum should be considered, and the clinician should be alert to this issue to achieve rapid confirmation and to save lives.

Abstract

Sedation practices vary according to countries with different health system regulations, the procedures done, and local circumstances. Interestingly, differences in the setting in which the practice of gastroenterology and endoscopy takes place (university-based *vs* academic practice) as well as other systematic practice differences influence the attitude of endoscopists concerning sedation practices. Conscious sedation using midazolam and opioids is the current standard method of sedation in diagnostic and therapeutic endoscopy. Interestingly, propofol is a commonly preferred sedation method by endoscopists due to higher satisfaction rates along with its short half-life and thus lower risk of hepatic encephalopathy. On the other hand, midazolam is the benzodiazepine of choice because of its shorter duration of action and better pharmacokinetic profile compared with diazepam. The administration of sedation under the supervision of a properly trained endoscopist could become the standard practice and the urgent development of an updated international consensus regarding the use of sedative agents like propofol is needed.

Key words: Sedation; Conscious; Endoscopy; Propofol; Fentanyl; Meperidine

Core tip: Even though the most recent "Multisociety sedation curriculum for gastrointestinal endoscopy" guidelines addressed the upper-limit range of Midazolam for proper sedation in prolonged endoscopic procedures, there are no clear-cut guidelines on the upper limit of Fentanyl dosing, especially with the risk of rigid chest syndrome and drug accumulation in skeletal muscle at high doses. Additionally, we also raised the question of whether Propofol or other agents used for deep sedation should be a routine indication for patients with chronic opioid use.

Manickam P, Kanaan Z, Zakaria K. Conscious sedation: A dying practice? *World J Gastroenterol* 2013; 19(28): 4633-4634 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i28/4633.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i28.4633

TO THE EDITOR

While the controversy regarding the administration of sedation during gastrointestinal (GI) endoscopy continues, Triantafillidis *et al*[1] in their recent article in January 2013, provided a concise and thorough overview of the current knowledge regarding this topic. In summary, the authors concluded that the administration of sedation under the supervision of a properly trained endoscopist could become the standard practice and stressed urgent development of an updated international consensus regarding the use of sedative agents, especially propofol[1]. We would like to share some comments with the authors.

In a short survey of about sedative use in GI endoscopies conducted among thirty endoscopists at our large community-based hospital setting, Fentanyl/Midazolam and Meperidine/Midazolam are the most commonly used

sedatives for elective outpatient procedures in 63% and 36% of instances respectively. Usually, patients do not require more than 6 mg of Midazolam and 200 μg of Fentanyl to achieve moderate sedation. In a minority of patients who require more than usual dose of sedatives, 73% of the surveyed endoscopists are hesitant to go beyond the above-mentioned limits for the fear of side effects, leading to either inadequate evaluation or premature termination of the procedure. According to the recent "Multisociety sedation curriculum for gastrointestinal endoscopy" guidelines[2], the dose of Midazolam could be increased up to 6 mg and even more for prolonged endoscopic procedures[2]. However, there are no clear-cut guidelines on the upper limit of Fentanyl dosing and the risk of rigid chest syndrome[3]. During regular outpatient colonoscopies, few patients would not achieve moderate sedation despite receiving more than doses mentioned above. In such situations, 57% of the physicians responded that they would terminate the procedure and reschedule it again and 43% noted that they would proceed with increasing doses of sedatives to achieve moderate sedation. As Fentanyl can cause delayed side effects through accumulation in skeletal muscle, increasing the dose might be a concern in high-risk patients.

The second issue is with people who are chronic narcotic users. Ninety percent of the surveyed endoscopists responded that they would prefer Propofol administration in patients with chronic opioid use due to high tolerance observed in these patients. Propofol administration is usually by the anesthesia service thus adding to the patient's costs. This leads to a clinical question whether Propofol or other agents used for deep sedation should be a routine indication for patients with chronic opioid use.

Overall, this study provided a concise overview of the current knowledge and issues concerning sedation during digestive endoscopy and the authors are to be commended on their work.

AIMS AND SCOPE

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

INDEXING/ABSTRACTING

World Journal of Gastroenterology is now indexed in Current Contents®/Clinical Medicine, Science Citation Index Expanded (also known as SciSearch®), Journal Citation Reports®, Index Medicus, MEDLINE, PubMed, PubMed Central, Digital Object Identifier, and Directory of Open Access Journals. ISI, Journal Citation Reports®, Gastroenterology and Hepatology, 2012 Impact Factor: 2.547 (34/74); Total Cites: 19145 (6/74); Current Articles: 944 (1/74); and Eigenfactor® Score: 0.06035 (6/74).

Abstract

Fecal enemas were first reported to successfully treat life threatening enterocolitis in 1958, but fecal therapy to treat *Clostridium difficile* (*C. difficile*) infection has remained esoteric and not well investigated until recently. In the past few years, systematic reviews of case series and case reports of fecal microbiota transplant for recurrent *C. difficile* infection have become available and validate use of fecal transplant for *C. difficile* enterocolitis. Methods of fecal transplant reported in the literature include: nasogastric tube, gastroscope, duodenal tube, colonoscopy, rectal tube, and fecal enemas administered at home; no method has been shown to be superior. A recent randomized study published in *New England Journal of Medicine* found fecal transplant to be superior to oral vancomycin alone in treatment of recurrent *C. difficile* enterocolitis. The significance of this trial cannot be underestimated as it lends credibility to the idea of intentionally using microbes to combat disease, providing an alternative to the older paradigm of disease eradication through use of antimicrobials.

Key words: *Clostridium difficile*; Enterocolitis; Pseudomembranous; Fecal transplantation; Vancomycin

Core tip: Recurrent *Clostridium difficile* has been a challenge for patients, clinicians and hospital alike. Drug therapy for this epidemic is still not very effective. A more traditional method of fecal transplant has been discussed in this article, but it has been an uphill task to execute. We are discussing this first randomized control study, showing overarching benefits of stool transplant over traditional drug treatment. More studies needed with similar results, before making a strong recommendation in favor of it.

Vyas D, L'Esperance HE, Vyas A. Stool therapy may become a preferred treatment of recurrent *Clostridium difficile*? *World J Gastroenterol* 2013; 19(29): 4635-4637 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i29/4635.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i29.4635

COMMENTARY ON HOT TOPICS

Recurrent *Clostridium difficile* (*C. difficile*) is a growing epidemic with high rate of recurrence despite use of antibiotics. Fecal therapy to treat enterocolitis has been discussed in the literature since the late 1950's; despite anecdotal evidence suggesting its safety and efficacy, fecal therapy has remained an esoteric treatment. We read the recent article by van Nood *et al*[1] describing the results of the European randomized study investigating fecal therapy *vs* oral vancomycin for treatment of recurrent *C. difficile* infection with great interest. This is first randomized study investigating and validating use of fecal transplant for treatment of recurrent *C. difficile* infection.

C. difficile infection is identified as the cause of 25%-55.4% cases of antibiotic-associated diarrhea[2,3],

costs over $1 billion dollars annually in the United States to treat[4], and is a growing epidemic with twice as many cases reported in 2003 as in 1996 in part due to emergence of the more virulent, flouroquinolone-resistant NAP1/BI/027 strain[4,5]. *C. difficile* infection has a risk of initial recurrence rate following treatment with antibiotics of 20%-35%[6,7]; risk of recurrence is increased by use of antibiotics for other infections, being female, having initial infection in the spring, and having number of previous *C. difficile* infection recurrences[8]. Up to 65% of patients with recurrent disease ultimately develop pattern of recurrent *C. difficile* infection[6,8]. Patients with recurrent *C. difficile* infection are at risk of developing antibiotic resistance, and complications from *C. difficile* infection including: colitis, pseudomembranous colitis, toxic megacolon, and death[7,9]. Current therapies to treat recurrent *C. difficile* infection include tapered or pulsed dose oral vancomycin or metronidazole; these therapies are associated with high recurrence rates making it important that an effective treatment option for recurrent *C. difficile* infection become available[6].

Regardless of the method, fecal transplant for recurrent *C. difficile* infection appears to resolve symptoms in 83%-96% patients with most patients having durable response following single treatment[2,5,6,9]. Of patients requiring retreatment, 87.5% of patients experience symptom resolution[6]. Fecal transplant for pseudomembranous colitis appears promising with 72%-88% patients reporting improvement in symptoms[9]. Additionally, a case series found fecal transplant to be effective at treating the more pathogenic NAP1/BI/027 *C. difficile* strain in 89% patients[10]. Fecal transplant was associated with few and infrequent adverse events related to the procedure in all available case series and reports[2,6].

However promising the data from the systematic reviews of the case studies and case reports, it is not a substitute for data from prospective randomized controlled clinical trial data, as case reports and series are subject to bias from retrospective review of the data, subject selection and possible underreporting of adverse events. Results from a 3 arm randomized controlled clinical trial was recently reported by van Nood *et al*[1] in the *New England Journal of Medicine* comparing fecal transplant to vancomycin ± bowel lavage. More than 50% of patients enrolled in the trial had experienced multiple episodes of recurrent *C. difficile* infection and had been previously exposed to tapered vancomycin. The trial was stopped after an interim analysis showing superiority of fecal transplant arm to the other arms; 94% patients on the fecal transplant arm experienced symptom resolution - 81% (13/16) following initial infusion, and 66% (2/3) having symptom resolution following second infusion from another donor, *vs* 31% (4/13) patients with symptom resolution on the vancomycin alone arm and 23% (3/13) patients with symptom resolution on the vancomycin and bowel lavage. Adverse events from this trial confirm fecal transplant to be well tolerated with most common events experienced to be diarrhea (94% patients), abdominal cramping (31%), and belching (19%) immediately following fecal transplant and resolving within 3 h; and constipation (19%) as major adverse event reported during follow-up[1]. This study is far from perfect as it enrolled a small number of participants (16 on fecal transplant arm, 13 each on vancomycin and vancomycin and bowel lavage arms), was not blinded, patients on vancomycin ± bowel lavage arms frequently crossed-over following recurrence of *C. difficile* infection (non-protocol directed) and received fecal transplant, and although it enrolled primarily elderly patients it excluded many patients at higher risk of recurrent *C. difficile* infection including: patients with prolonged immunodeficiency, critically ill intensive care unit patients, and patients requiring antibiotics to treat another infection. Despite the studies limitations, it appears to favor fecal transplant for treatment of recurrent *C. difficile* infection with results similar to previous systematic reviews of case reports and case series available in the literature.

Data from the randomized trial by van Nood *et al*[1] provides further evidence that the efficacy of fecal transplant is not likely due to bowel preparation as it included a vancomycin and bowel lavage arm, but appears to be due to reconstitution of microbes in the gastrointestinal tract. As noted by observations the early 1980's, *C. difficile* growth can inhibit growth of certain strains of *Peptococcus, Peptostreptococcus,* and *Bacteroides* and its growth can also be inhibited by certain strains of *Staphylococcus, Pseudomonas, Bacteroides* and *Lactobacillus*, and recurrent *C. difficile* infection is likely due to germination of spores before balance of large bowel flora restored[11], or reinfection with a new strain of *C. difficile* due to the lack of protective bacteria in the colon[5]. Fecal transplant likely works by repopulating normal gut flora and preventing colonization with pathogenic *C. difficile* bacteria[5].

Fecal microbiota transplant has had empiric evidence demonstrating effectiveness and safety in treating recurrent *C. difficile* infection and pseudomembranous colitis enduring for over 50 years and is relatively less cost than other treatment options, so why has it remained an esoteric treatment for these disorders and not been investigated in randomized controlled trials until recently? Some possibilities include concerns of transmitting infections from donors to recipients *via* fecal material, no clear fecal transplant protocol as several methods have been described in the literature, and the idea of transplanting fecal material from one individual to another is aesthetically unappealing[9,11,12]. It should be noted that patients are reportedly receptive to the idea of fecal transplant following frustration at repeated antibiotic failure[13] and high out of pocket medical expenses to treat recurrent *C. difficile* infection[14].

Given the growing epidemic of *C. difficile* infection, cost and complications of treating recurrent disease, increasing antibiotic resistance, and growing body of evidence to support fecal microbiota transplant as a cost-effective and widely available therapy to treat recurrent *C. difficile* infection it is important that further research on fecal transplant be performed to identify methods and

indications for its use. The significance of the randomized study by van Nood *et al*[11] cannot be underestimated as it lends credibility to the idea of intentionally using microbes to combat disease, providing an alternative to the older paradigm of disease eradication through use of antimicrobials.

Abstract

The shortage of donor livers has led to an increased use of organs from expanded criteria donors. Included are livers with steatosis, a metabolic abnormality that increases the likelihood of graft complications post-transplantation. After a brief introduction on the etiology, pathophysiology, categories and experimental models of hepatic steatosis, we herein review the methods to rescue steatotic donor livers before transplantation applied in clinical and experimental studies. The methods span the spectrum of encouraging donor weight loss, employing drug therapy, heat shock preconditioning, ischemia preconditioning and selective anesthesia on donors, and the treatment on isolated grafts during preservation. These methods work at different stages of transplantation process, although share similar molecular mechanisms including lipid metabolism stimulation through enzymes or nuclear receptor *e.g.*, peroxisomal proliferator-activated receptor, or anti-inflammation through suppressing cytokines *e.g.*, tumor necrosis factor-α, or antioxidant therapies to alleviate oxidative stress. This similarity of molecular mechanisms implies possible future attempts to reinforce each approach by repeating the same treatment approach at several stages of procurement and preservation, as well as utilizing these alternative approaches in tandem.

Strategies to rescue steatotic livers before transplantation in clinical and experimental studies. *World J Gastroenterol* 2013; 19(29): 4638-4650 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i29/4638.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i29.4638

INTRODUCTION

Liver transplantation (LTx) is a successful therapy for end-stage liver disease, but it is severely restricted by the donor organ shortage[1-4]. In an effort to increase the size of the donor pool, livers from expanded criteria donors (ECD), including steatotic livers, are increasingly being used[3]. The current contribution of steatotic livers is marginal however, since the majority has an increased risk of ischemia-reperfusion injury (IRI) after LTx[3]. Here we review the clinical and experimental attempts to minimize this risk by modifying the quality of livers at different stages, on donors and isolated liver grafts during preservation, before LTx. We begin by briefly introducing the etiology, pathophysiology, categories and experimental models of hepatic steatosis, provide a summary of the techniques applied on donors and liver grafts, and con-

clude by providing future perspectives for these experimental approaches.

ETIOLOGY OF HEPATIC STEATOSIS

Livers are defined as steatotic or fatty when they have excessive (above 5% of wet liver weight) accumulation of lipids, mainly triglycerides. Steatosis occurs when lipid ingestion and synthesis exceed export and consumption in livers[5]. Based on the patient's alcohol consumption[5,6] fatty liver disease is classified as either alcoholic or non-alcoholic in origin (AFLD and NAFLD). Alcohol can decrease fatty acid oxidation and lipoprotein excretion, and increases the esterification of fatty acid to triglycerides *via* alpha-glycerophosphate[6]. Several factors contribute to NAFLD including dietary lipid overload; insulin resistance, which results in abnormal lipid metabolism; and ingestion of drugs or toxins such as carbon tetrachloride, which induces a decrease in apoprotein synthesis and lipid export[5-8].

PATHOPHYSIOLOGY OF HEPATIC STEATOSIS

A complicated pathophysiology has been exposed although the exact pathways have not been completely elucidated. Briefly, a "two-hit" theory is the current consensus, with the first "hit" being the initial abnormal fat accumulation and the second "hit" being the consequent inflammation ("steatohepatitis") leading to fibrosis and cirrhosis[6]. In the first "hit", excessive fat accumulates in vacuoles within hepatocytes, increasing cell volume and narrowing sinusoidal lumens[5,9]. This impairs microcirculation and decreases nutrient, oxygen and waste exchange. Excessive non-esterified fatty acids in hepatocytes inhibit β-oxidation thereby reduce acetyl-coenzyme A production[10]. Mitochondria uncoupling protein-2 is upregulated and associated with a dysfunction of adenosine triphosphate (ATP) synthesis[11-13]. Fat-induced hyperactivity of cytochrome P-450 enzymes increases the production of reactive oxygen species (ROS)[6,14]. ROS in turn lead to lipid peroxidation, phospholipid depletion and membrane dysfunction[6,14,15] as well as the release of inflammatory cytokines such as tumor necrosis factor (TNF)-α[14,16,17]. Inflammation occurs gradually and marks a significant downturn in disease progression as the second "hit"[18,19]. Alcohol can exacerbate oxidative injury and Kupffer cell activation[20], though alcoholic and non-alcoholic steatohepatitis (ASH and NASH) are thought to progress similarly[18].

Steatotic livers have reduced tolerance to ischemia due to low ATP stores, and are thus prone to early onset of acidosis and cellular edema during standard liver preservation method, static cold storage (SCS)[21]. Edema significantly impairs hepatic microcirculation further than the preceded impairment induced by excessive fat. Moreover, steatosis-induced inflammation is not addressed in the present liver SCS preservation solutions (Table 1).

Upon reperfusion, a complex inflammatory response involving Kupffer cells, lymphocytes, neutrophils, numerous cytokines[22] and nuclear factor kappa-B (NFκB)[23], is inevitably worse in steatotic livers compared to non-steatotic livers. Oxidative stress is also exacerbated *e.g.*, through xanthine oxidase[24,25]. The microcirculation is deteriorated further due to adherence of platelets in the sinusoids[22]. Strategies to minimize fat content and ameliorate the inflammatory and oxidative injury of steatotic livers are essential for improving these organs for transplantation.

CATEGORIES OF HEPATIC STEATOSIS

Besides AFLD and NAFLD in etiology, steatosis is also classified as "macro-" or "micro-" in histology based on the size and number of the fat vacuoles and on the location of the nucleus in the hepatocytes[5,26]. Macrosteatosis has a single fat vacuole larger than the nucleus filling the majority of the cell and pushing the nucleus to the periphery. Microsteatosis has many small fat vacuoles surrounding the nucleus in the central zone of the hepatocytes, and has more LTx success than macrosteatosis[3,27]. Steatosis can also be classified based on the proportion of hepatocytes affected, being mild (< 30%), moderate (30%-60%), or severe (> 60%), with incremental risk of graft dysfunction after LTx[5,26].

CLINICALLY APPLIED STRATEGIES

Approaches to improve steatotic livers before LTx have been tested in a handful of pilot clinical studies on living donors or donors after brain death (DBD) (Table 2). The interventions focused on reducing excessive fat (the first "hit") through limiting lipid intake and increasing lipolysis, or stimulating factors likely to be protective against inflammation and oxidative stress (the second "hit") of steatohepatitis. Living donors, though a minority in western countries[1,2], are used extensively in Asia[28] and are theoretically amenable to therapies before procurement after ethical concern is taken into account[29]. DBD livers, which comprise the majority of donor organs for LTx in western countries, could be treated between brain death declaration and organ procurement since circulation is maintained until procurement. Livers from donors after cardiac death (DCD) are seldom utilized when they have steatosis because they experience a period of warm ischemia (WI) before procurement[3] and thus were normally considered as unacceptable with two defects (steatosis and WI). Currently there are no attempts to rescue steatotic DCD livers.

Physical exercise and dietary intervention

Physical exercise and dietary restriction are general therapies for NAFLD patients, independent of whether or not they are organ donors[30,31]. But this treatment normally needs several months and might be risky to increase the mortality of recipients during the waiting time for treat-

ing donors[32]. An intensive protocol might be a solution, which was already reported to successfully reduce macrosteatosis on obese human living donors in 2-8 wk, through exercise burning 600 kcal/d, a protein-rich diet of 1000 kcal/d, and bezafibrate, an anti-hyperlipidaemia drug, at 400 mg/d[33]. However, supplementary glucose to donors a few hours before living donor liver transplantation was recommended to supply additional energy reserves, since fasting before procurement can induce glycogen depletion, decrease glycolytic ATP generation, and compromise graft transplantability[34].

The lack of omega-3 polyunsaturated fatty acids (PUFA) has been recognized in the development of NAFLD because they can activate peroxisomal proliferator-activated receptor (PPAR)-α, suppress sterol regulatory element-binding protein-1, improve microcirculation, and reduce Kupffer cell activity and inflammation[35-43]. The mechanism on microcirculation might work through reducing TXA2 synthesis after manipulating the composition of hepatic lipid (omega-3: omega-6 PUFA ratio)[43]. Based on experimental success on rodents[35-43], omega-3 PUFA was shown to be effective on NAFLD clinically after treatment at 1-2 g/d for 6-12 mo[44-46]. This has not been applied specifically on living donors but is expected to be a safe and promising approach.

Pharmacological preconditioning

Many drugs are being used clinically to treat NAFLD by decreasing lipid intake[47-49], stimulating lipid metabolism[50-53], or improving insulin sensitivity[54-57]. Ursodeoxycholic acid, a natural bile acid, was used as a non-specific hepato-protector to treat NAFLD in a pilot clinical study[58], but afterward was revealed to be controversial[59]. Pentoxifylline was used against NASH and ASH in patients[60,61] due to the effect of reducing TNF-α by inhibiting phosphodiesterase[62] and lessening oxidative stress by increasing glutathione[63]. But to date, only bezafibrate was used to treat human living donors for LTx[33]. This drug works through activating PPAR-α and β/δ to stimulate lipid metabolism and decrease fat content in livers[64,65]. While there are other candidate drugs that could potentially be taken by living donors, concerns of significant side effects are limiting their use[66,67].

Ischemic preconditioning

Though extended ischemia is deleterious to organs, it has been recognized since the 1980s that a short period of ischemia with subsequent reperfusion triggers natural de-

fense mechanisms against future ischemic insults and protects the organ against IRI[68]. Ischemic preconditioning (IP) was first observed in kidneys and hearts[69,70], and then employed for clinical liver resections and transplantation[68]. It can be applied intermittently[71], or as a single short period (5-10 min) of ischemia followed by 10-15 min reperfusion before cold flush during liver procurement[72,73]. Franchello *et al*[73] have used the technique clinically on marginal DBD livers including steatotic livers, and observed a reduction of hepatocyte swelling and enzyme release in recipients after LTx.

IP is protective because ATP consumption during the short ischemic period increases endogenous adenosine and nitric oxide[74]. Adenosine protects sinusoidal endothelial cells through adenosine A2 receptor[75]. Cyclic adenosine monophosphate (cAMP) worked as the second messenger, but whether increasing or blocking cAMP would be beneficial was still controversial[75,76]. Nitric oxide is a vasodilator, and further it attenuates the release of TNF-α, decreases the injurious interleukin (IL)-1β and increases the anti-inflammatory IL-10[77]. Another effect of the intermittent ATP consumption is to increase the level of adenosine monophosphate (AMP), which stimulates AMP-activated protein kinase (AMPK). AMPK can regulate an energy-conserving state, decrease inflammation through inhibiting NFκB, and induce the synthesis of nitric oxide as well[78-80]. Overall, the advantages of IP were an improved microcirculation[81,82], mitochondrial permeability transition and mitochondrial function[83], cytochrome oxidase C activity and tissue oxygenation[82,84], and the reduction of oxidative stress such as the xanthine accumulation and xanthine oxidase activity[85,86].

Interestingly, IP can work remotely, *e.g.*, liver IP decreased lung IRI[25,87] and limb IP decreased liver IRI[88-90]. This possibly works through some protective agents, *e.g.*, heme oxygenase-1, endothelial nitric oxide synthase, and nuclear protein High Mobility Group-Box 1[88-90]. But foreseeable ethical concerns exist with the logistics of implementing this technique in human donors.

Anesthesia selection

During clinical liver resection, Beck-Schimmer *et al*[91] observed the superiority of volatile anesthesia using sevoflurane in the prevention of hepatic injury after reperfusion compared to intravenous anesthesia with propofol. The mechanism was suggested to be the increased synthesis of nitric oxide with sevoflurane, which alleviates some of the effects of IRI as discussed above. Moreover they observed that patients with steatosis did benefit more[91]. This method could be easily applied during the procurement of steatotic livers from both DBD and living donors.

EXPERIMENTAL STRATEGIES

Induction of steatosis in animal models

Steatosis in animal models are established with or without alcohol and classified also as micro- *vs* macro- or as mild, moderate, *vs* severe. The timeline to develop the different classifications largely depends on strain and method used (Table 3).

A common rodent NAFLD model induces cerebral deficiency of the leptin receptor through a genetic mutation that causes the animals to become obese through overeating[92-98]. The methods inducing lipid overload with high fat or cholesterol diets are also quite common. A high fat diet (50% dextrose, 18% casein, 25% lipids, 4% minerals, 1% cholesterol, 0.5% sodium cholate, 0.2% choline, and 1% vitamins) for 7 d induces severe steatosis in rats[99]. A high-cholesterol (2%) diet for 12 wk in rats[82] and 8 wk in rabbits results in moderate steatosis[84]. A cafeteria diet (65% of fat) for 4-15 wk was also used to create NAFLD on rats[100,101]. Recent studies suggested it reflects human metabolic syndrome better than high-fat diet[100,101]. A choline/methionine-deficient diet (CMDD) was another rather common method to develop steatosis, for 4-6 wk or short as 7 d in rodents[5,27,102,103]. Choline is essential for the formation of phosphatidyl-choline and very low density lipoprotein needed for lipid export, while methionine is a good source of methyl groups for the endogenous synthesis of choline. This model could be criticized for not being clinically accurate because NAFLD patients due to CMDD are rather unrealistic. The most rapid induction of NAFLD in rats was with a high-starch, fat-free diet [saccharose (40%), starch (40%), casein (16%), and a mineral and vitamin mix (4%)] administered for 2 d after fasting for 2 d, which can lead to mild to moderate steatosis[104-106]. While none of these models are unanimously agreed to be ideal in replicating clinical NAFLD, the high fat or cholesterol diet model was the most widely used to mimic steatosis in humans.

There are fewer large animal NAFLD models, which usually combine more than one method described above to achieve steatosis. Takahashi *et al*[107] established a dog model using a diet rich in fat and deficient in choline, which produced moderate to severe macrosteatosis after 8-12 wk feeding. Lee *et al*[108] used a high fat and high cholesterol diet (20% kcal from fructose, 46% kcal from fat,

Table 3 Animal models of hepatic steatosis for liver transplantation

Disease	Approaches	Description	Animals	Treatment time
NAFLD	Genetic	Cerebral leptin receptor deficiency	Rodent	
	Dietary	High fat	Rodent	7 d
		High cholesterol	Rodent, rabbits	8-12 wk
		Cafeteria diet	Rodent	4-15 wk
		Choline/methionine-deficient	Rodent	7 d-6 wk
		High starch and fat free after fasting	Rodent	4 d
		High fat and choline deficiency	Dog	8-12 wk
		High fat and high cholesterol, plus choline deficiency or not	Miniature pig	24 wk

AFLD	Dietary	Ethanol in liquid diet, intragastric infusion or gavage	Rodent	20 h-9 wk
		Ethanol and high fat diet	Rodent	6 wk
		Ethanol and deficient folate diet	Micropig	12 wk

NAFLD: Non-alcoholic fatty liver disease; AFLD: Alcoholic fatty liver disease.

2% cholesterol and 0.7% cholate by weight) for 24 wk to develop microsteatosis on miniature pigs. When using lowered choline content simultaneously, severe steatosis with fibrosis was observed with increased TNF-α and oxidative stress. A recent study on Landrace pigs used a diet rich in fat (20% in volume) for 5 wk together with intravenous streptozotocin (125 mg/kg) to induce a diabetic state in the last 2 wk; but this treatment led only to mild steatosis[109].

In rodent AFLD models, ethanol was provided in a liquid diet[110-114] or *via* intragastric infusion[115,116]. Different degrees of alcohol exposure have been reported: 5%-8% in the concentration of liquid diet; 35%-40% of total energy consumption; 8-16 g/kg per day; or 150-300 mg/dL of blood ethanol[110-116]. Normally several days are needed for the animals to adapt to the alcoholic diet, and an additional 4-9 wk to observe steatosis. Acute responses to ethanol have also been reported as early as 20 h after feeding 6 g/kg ethanol by gavage on rats[117]. Combined ethanol with high-fat diet to develop steatosis on rats was also reported[118]. Large animal AFLD models are uncommon though micropigs have been fed a diet with ethanol and a deficiency of folate, as a substrate for methionine synthase, with some efficacy[119,120].

Experimental strategies applied to donors

Pharmacological preconditioning: Reduction of oxidative and inflammatory activity with heme oxygenase-1, a microsomal enzyme[121-123], was used intravenously or intraperitoneally on AFLD and NAFLD rats 24 h before liver procurement. It decreased macrophage infiltration, improved portal venous blood flow, bile production, and survival rate after LTx[121-123]. Bortezomib, a NFκB inhibitor, was used intravenously on obese donor rats and reduced IRI after LTx[23]. N-acetylcysteine, a precursor of glutathione, was injected through the mesenteric vein of CMDD rats 15 min before liver procurement and showed a protective effect on IRI in an isolated reperfusion system[124]. The subcutaneous injection of IL-6 for 10 d was observed to be protective against IRI after *in situ* partial ischemia-reperfusion on NAFLD and ALFD mice[92]. The mechanism might be the prevention of cell death and the reduction of TNF-α[125], in addition to stimulating PPAR-α, β-oxidation of fatty acids, and the export of triglycerides and cholesterol[92,125]. Theaflavin, a polyphenol substance extracted from black tea, was tested on CMDD mice and observed to have antioxidant, anti-inflammatory, and anti-apoptotic effect[126]. A multi-drug approach was reported by von Heesen *et al*[127] including N-acetylcysteine as an antioxidant, pentoxifylline for anti-inflammation, glycine to stabilize Kupffer cells, deferoxamine as an iron chelator to reduce ROS, and erythropoietin, melatonin and simvastatin to protect against IRI. In the treated rats they observed no inflammatory response with significantly reduced parenchymal dysfunction and injury compared to the untreated rats.

Heat shock preconditioning: An intriguing experimental method to improve the quality of steatotic donor livers has been to induce protective heat shock proteins (HSPs) endogenously by exposure to heat. Termed "heat shock preconditioning" and applied at 3-48 h before organ procurement by exposing anesthetized donor animals to warm (42 ℃) bath water for 10-15 min[128-132], obese and CMDD rats showed an increased expression of HSP-32 (heme oxygenase-1), -72 and -90[128,129]. These HSPs can decrease TNF-α production[129], improve microcirculation through producing carbon monoxide, and inhibit platelet aggregation[62,64]. Our group has also reported the inhibition of CD4+ T lymphocytes in CMDD rats after LTx with heat shock preconditioning[130]. Other factors might be involved in the treatment since studies on normal and WI rat livers showed IL-6, inter-cellular adhesion molecule-1, and some neutrophil chemo-attractants were also impacted[131,132].

Strategies applied on liver grafts during ex vivo preservation

Obviously, strategies to improve steatotic liver quality during preservation are more desirable than those on donors, as they have no effect on the donor's other organs, and are practical when it's not possible to work on the donor. The clinical standard for liver graft preservation has been SCS with University of Wisconsin (UW)

solution for more than 20 years[3,21]. In the past decade, histidine-trypotphan-ketoglutarate (HTK) solution[133-135] and Celsior solution[136,137] were recognized as having similar efficacy and safety as UW solution; Institut Georges Lopez-1 (IGL-1) was reported to be comparable to UW for healthy human livers[138], and better for steatotic rat livers[139]. Besides the arising new solutions, many adaptations have been suggested through enriching the intrinsic composition of the solutions with additives, or replacing SCS by machine perfusion (MP) preservation in experimental studies to rescue steatotic livers.

Pharmacological additives during SCS preservation: Liver preservation solutions normally comprise electrolytes, pH buffers, antioxidants, metabolic substrates, impermeants with or without colloid, insulin, dexamethasone, and antibiotics (Table 1)[139-143]. The additives for improving steatotic liver preservation were intended to ameliorate metabolism or suppress oxidative injury and inflammation. They were reported to be effective during SCS, despite the reduced metabolic rate of liver grafts during hypothermic preservation.

Addition of IL-6 into UW solution for donor liver flushing and SCS was tested by Sun *et al*[144], leading to improvement in microcirculation and reduced IRI after LTx of NAFLD and AFLD rats. Arnault *et al*[99] added pentoxifylline into UW solution and also observed a benefit to the microcirculation, but the exact mechanism is yet to be identified.

Tolba *et al*[106] added L-carnitine into HTK solution for SCS preservation of steatotic rat livers and observed a reduction of IRI in an isolated reperfusion system. L-carnitine is a nonessential amino acid but is essential for transporting fatty acids through the inner mitochondrial membrane and for β-oxidation[106]. It has also been reported to function as an antioxidant and to stabilize the membrane fluidity and stability *in vitro* and *in vivo*[145].

Ben Mosbah *et al*[146] added carvedilol, a cardiologic drug to block α- and β-adrenergic receptor, into UW solution for SCS of obese rat livers, and reduced oxidative stress and mitochondrial damage after isolated reperfusion. The mechanism might be an enhanced release of nitric oxide that facilitates vasodilatation and ROS scavenging[147]. AMPK activators, trimetazidine and aminoimidazole-4-carboxamide ribonucleoside (AICAR) were also tested as UW additives on obese rat livers by this group. Increased bile production, decreased enzyme release and vascular resistance, and reduced oxidative stress after isolated reperfusion were observed. It was noted that combination of trimetazidine and AICAR was not necessary[95].

Zaouali *et al*[148] tested the use of epidermal growth factor and insulin-like growth factor-I as UW additives and observed that each additive resulted in the improvement of fatty rat liver function after LTx. The mechanisms are suggested to be upregulation of Akt, a cytoprotector[149], and the subsequent over-expression of PPAR-γ. They also tested melatonin as additive in IGL solution and reported its protective role through generating nitric oxide and decreasing oxidative stress and inflammation[150].

Venous systemic oxygen persufflation during SCS preservation: In 1990s, Minor *et al*[151] developed a new method, called venous systemic oxygen persufflation (VSOP) to supply gaseous oxygen to livers during SCS preservation. The oxygen was introduced into hepatic vasculature *via* the suprahepatic vena cava and allowed to exit *via* several small pin pricks on the liver capsule made using an acupuncture needle. This technique was employed on steatotic rat livers for 24 h, and resulted in improved preservation of mitochondria and sinusoidal endothelial linings, less Kupffer cell activation and reduced hepatocellular enzyme release compared to SCS preservation[105]. Recently, by assessing the enzyme release, energy storage, bile production, and cell death during isolated reperfusion, it was demonstrated that application of VSOP for 90 min may rescue steatotic livers after extended (18 h) SCS preservation[152].

MP preservation: MP is an alternative preservation method to SCS[153], which can be further categorized based on the temperature employed[154]. Hypothermic (4 ℃) machine perfusion (HMP) preservation has proven to be superior to SCS for human kidneys[155], and feasible for normal human livers[156]. Normothermic (32 ℃-37 ℃) and sub-normothermic (20 ℃-30 ℃) machine perfusion (NMP and subNMP) preservation have been reported in experimental studies on livers, but mostly on their advantages for DCD models[143,157-162]. MP preservation of steatotic livers is limited, but also reported to be beneficial on preserving energy content and liver function experimentally[109,143,163,164]. The advantages of MP preservation result from continuously supplying nutrients, removing waste products, and maintaining microcirculation[154]. Because MP, especially NMP, provides a physiologically-relevant environment to the isolated donor organ, the quality of liver grafts can be manipulated more efficiently than those simply stored in an ice-box during SCS. Another advantage of MP is the considerable convenience for non-invasively evaluating liver viability, a key issue when ECD livers are used[153].

Bessems *et al*[163] employed HMP preservation with UW-gluconate solution on steatotic rat livers for 24 h and alleviated IRI compared to SCS. Vairetti *et al*[143] preserved steatotic rat livers by subNMP (20 ℃) with Kreb-Henseleit solution for 6 h and obtained similar results. The longest preservation of steatotic livers was the NMP preservation for 48 h in a pig model by Jamieson *et al*[109], who employed blood containing additional insulin and vasodilators as perfusate, and observed a mild reduction of steatosis from 28% to 15%. This NMP setting provided the most physiological environment to liver grafts and lead to an activated function of the isolated organs with sufficient oxygen and nutritional support. This is expected to be the best preservation method in spite of the

highest logistic restriction.

Recently our group has combined NMP and pharmacological preconditioning for decreasing steatosis[96]. A "defatting cocktail" was developed with 6 compounds to activate nuclear receptors such as PPARs, pregnane X receptor, and constitutive androstane receptor, to exert an insulin mimetic effect and to stimulate intracellular cAMP. This cocktail was added into Minimum Essential cell culture medium as a perfusate to stimulate lipid metabolism of obese rat liver grafts preserved at NMP. A significant decrease (50%) in steatosis was observed after 3 h NMP[96].

Other experimental approaches

The solution used for SCS preservation needs to be flushed out of the donor organ prior to implantation to remove possible air bubbles, and preservative components such as high potassium, which are deleterious to the recipient. This provides an opportunity for treatment of ischemic injury, although it has been very little explored. In one study, polyphenols, an antioxidant extracted from Camellia sinensis (green tea), was added to the flushing solution and improved the hepatic injury and survival rate after LTx in a steatotic rat model[117].

Another option is applying preconditioning at several phases. While it appears little explored, in one study Ye *et al*[118] injected glutathione intraperitoneally in rats with hepatic steatosis 2 d before procurement and preserved the livers by SCS with VSOP and additional glutathione. Remarkable improvement on survival rate, liver function, and oxidative stress in liver tissues after transplantation was observed.

SUMMARY AND FUTURE PERSPECTIVES

Based on the understanding on pathophysiology, current strategies to rescue steatotic donor livers work through ameliorating the abnormal lipid metabolism (the first "hit"), and the oxidative stress and inflammation (the second "hit"). Each approach employs various methods at different phases of organ recovery and preservation but generally targets similar molecular mechanisms. Notably, it may be possible to attack the same mechanism but reinforce the effects by applying the treatment at multiple points of organ recovery and preservation process, thereby producing a stacking effect. The use of glutathione on donors and in SCS solution by Ye *et al*[118] is a good example in this direction that demonstrates the therapeutic effects may stack. Stacking other medications, *e.g.*, IL-6 and pentoxifylline could also be promising as these could be given to the donors prior to recovery or readily added into preservation solutions to treat liver grafts. Whether the stacking approach works for different targets in lipid metabolism, oxidative stress or inflammation remain to be elucidated.

Similar to stacking the same/similar pharmacological agents at different stages, it is a reasonable idea to attack the two "hits" simultaneously by stacking medications targeting different pathways. Development of such combinations is usually shunned because it exponentially increases the complexity of development and clinical testing, but given that the disease itself is a very complex phenomenon spanning multiple pathways, it may be unavoidable, and a single silver bullet to treat steatosis simply nonexistent.

An intriguing alternative in development is the efforts to use MP for liver preservation. Especially in near normothermic conditions, MP provides a combined opportunity to improve energy storage, maintain microcirculation, and support pharmacological approaches to decrease fat content and treat IRI. While machine perfusion by definition is more complex than simple storage on ice, it is a very promising approach available in the near future and could be the ultimate solution to rescue steatotic as well as ischemic livers.

Both steatotic livers and DCD livers are highly susceptible to IRI. Therefore, potentially, a method to rescue DCD livers could be also applicable to steatotic livers even with the fat content intact. For instance, MP preservation was able to rescue DCD livers and steatotic livers[143,157-164]. Similarly, perfluorocarbon as an artificial oxygen carrier to improve SCS preservation of DCD livers[165] could also be tested on steatotic livers. If successful, we would then secure both DCD and fatty livers for transplantation, which would boost the organ availability dramatically and resolve donor liver shortage for a decade or more.

ACKNOWLEDGMENTS

We thank the support of the Shriners Hospitals for Children.

Abstract

Mutation of the *p53* gene is a key event in the carcinogenesis of many different types of tumours. These can occur throughout the length of the *p53* gene. Anti-*p53* auto-antibodies are commonly produced in response to these *p53* mutations. This review firstly describes the various mechanisms of *p53* dysfunction and their association with subsequent carcinogenesis. Following this, the mechanisms of induction of anti-*p53* auto-antibody production are shown, with various hypotheses for the discrepancies between the presence of *p53* mutation and the presence/absence of anti-*p53* auto-antibodies. A systematic review was performed with a descriptive summary of key findings of each anti-*p53* auto-antibody study in all cancers published in the last 30 years. Using this, the cumulative frequency of anti-*p53* auto-antibody in each cancer type is calculated and then compared with the incidence of *p53* mutation in each cancer to provide the largest sample calculation and correlation between mutation and anti-*p53* auto-antibody published to date. Finally, the review focuses on the data of anti-*p53* auto-antibody in colorectal cancer studies, and discusses future strategies including the potentially promising role using anti-*p53* auto-antibody presence in screening and surveillance.

Key words: *p53* gene; *p53* mutation; Anti-*p53* auto-antibody; Cancer; Colorectal cancer

Core tip: Anti-*p53* auto-antibodies are commonly produced in response to *p53* mutations. Anti-*p53* auto-antibody titres generally increase with tumour load, but not all patients who are initially sero-negative develop an auto-antibody response despite disease progression and metastases. Conversely, sero-positive patients do not lose their anti-*p53* auto-antibodies despite the cancer being completely excised. In general, cancers with the highest *p53* mutation rate, *e.g.*, oesophageal and ovarian, demonstrate the highest anti-*p53* auto-antibody rates; conversely, melanoma and testicular carcinoma with the lowest mutation rate have the lowest serum auto-antibody levels. Measurement of anti-*p53* auto-antibodies may be useful in screening or monitoring for tumour recurrence.

INTRODUCTION

The *p53* gene is located on the distal band of the short arm of chromosome 17p13[1,2]. It consists of approximately 20000 base pairs spread over 11 exons[2-5]. *p53* was initially discovered in 1979 as a protein binding to a viral

oncogene, Simian Vacuolating 40 (SV40) large T-antigen, and hence was thought to be an oncogene itself[6-8]. It has since been established that it has a critical role as a tumour-suppressor gene[9-11]. *p53* inactivation predisposes cells to malignant transformation in rodent models and in human clinical diseases such as Li-Fraumeni syndrome; the latter being characterized by germline mutations of *p53*[12-14]. The tumour suppressive role of *p53* is so crucial that it is referred to as "the guardian of the genome"[15,16]. It is the most common mutation found in cancers and is present in half of all solid tumours thus emphasising its importance in protecting cells from carcinogenesis[3]. The frequency of mutation varies in individual cancers ranging from 5%-12% in cervical and haemopoietic malignancies to 40%-50% in colorectal and ovarian cancer[1,5]. Additionally, the remaining cancers with no detectable *p53* mutation are still thought to have dysfunctional *p53* caused by mechanisms other than mutation[9,17-20]. The most recent advances in colorectal cancer (CRC) treatment have been in the field of immunology with the use of antibodies against potent growth factors including epidermal growth factor receptor (EGFR) and vascular endothelial growth factors (VEGF)[21,22]. As such, *p53*, with its diverse immuno-regulatory role maintains a vital role in future of management of cancer and benign diseases. This review begins with the description of the normal *p53* gene function and mechanisms of *p53* inactivation in cancer, followed by a systematic review of the association between the anti-*p53* auto-antibody response and underlying *p53* mutations, and finally a clinical focus on the current evidence and potential future role of anti-*p53* auto-antibody in colorectal cancer.

p53 GENE AND GENE FUNCTION

p53 acts as a tumour suppressor by preventing propagation of defective cells. It is up-regulated by various upstream factors in response to cellular stress or damage such as DNA damage, hypoxia, telomere shortening and oncogenic stimulation or radiation[2,11]. Activated *p53* modifies downstream gene expression and co-factor transcription, which in conjunction with *p53*, lead to growth arrest (*e.g.*, *via* $p21^{WAF1}$) or apoptosis (*e.g.*, *p53*-upregulated modulator of apoptosis, PUMA)[19,23,24].

The *p53* gene encodes for a 393 amino-acid, 53 kDa, phospho-protein which is divided into 3 domains-an amino (-NH_2) terminal region (approximately amino acids 1-100), a central "core" domain (amino acids 100-300) and a terminal carboxyl (-COOH) region (amino acids 320-360)[25-27]. Almost all mutations are harboured in the central "core" which contains the DNA-binding regions. Thus *p53* dysfunction is most likely caused by mutations that alter DNA binding behaviour. However, most anti-*p53* auto-antibodies do not recognise central core mutations but rather recognise epitopes in the 2 terminal regions. An interesting observation is that these terminal regions which contain the least mutations are also found on the wild-type and the mutant p53 protein[25,27,28]. This suggests anti-*p53* is not only produced in response to mutation but also elevated levels of normal *p53*. This is discussed later (see Anti-*p53* Auto-antibody).

Wild-type p53 protein expression is intra-nuclear with a half-life of 5-30 min and is subject to complex regulation[29]. The most important regulator is thought to be Murine Double Minute 2 (Mdm2)[29,30]. Mdm2 is an ubiquitin-dependant E3 ligase which targets wild-type p53 protein for nuclear and cytoplasmic proteasome-mediated degradation[31,32]. When up-regulated *p53* binds to the Mdm2 promoter leading to increased levels of mdm-2 transcription; the *Mdm2* gene product then inhibits *p53* thus creating a negative feedback loop. This feedback process is complex and regulated by multitude of factors. Mdm-2 in itself is subject to modifications mainly self-degradation by (1) auto-ubiquitination[33,34]; (2) small Ubiquitin-like Modifier (SUMO)-ylation[35]; (3) acetylation[36]; (4) post-translational upstream kinases (*e.g.*, ATM kinase phosphorylation of Mdm2 and Mdm-X)[37-39]; (5) Mdm-2 in conjunction with Mdm-X (also known as Mdm-4) can form a Mdm2-MdmX-p53 complex which represses *p53* activity; and (6) Mdm-X can furthermore act independently of Mdm-2 and repress *p53*-bound chromatin, without Mdm2, most likely by direct binding. The combinations of these mechanisms, regulate *p53* accumulation in response to various cellular stresses (Figure 1).

p53 increases in response to cellular stress caused by a variety of insults including DNA damage, oncogene activation, ribosomal stress and hypoxia[11] by several mechanisms: (1) increased transcription; (2) increased intra-nuclear accumulation of active *p53*; (3) increased extra-nuclear export of Mdm-2[40,41]; (4) down-regulation of Mdm2-Mdmx which usually represses chromatin-bound-*p53*[24]; (5) various downstream post-translational modifications of both *p53* and its regulators *e.g.*, Mdm2[17]; and (6) raised cytosolic *p53*[42-45].

Active *p53* has tumour suppressive activity by causing cell cycle arrest, apoptosis and autophagy. Cell cycle arrest initially provides additional time for the cell to repair damaged DNA. However, cells unable to repair damage are directed towards apoptosis by shifts in the balance between pro-arrest, pro-autophagy and pro-apoptotic factors severe cellular damage, the cell pushed directly towards apoptosis by the relative increase in pro-apoptotic markers relative to cell-cycle arrest promoters[19].

Autophagy is an evolutionary catabolic process of mass lysosomal self-degradation of cytosol/proteins/organelles which are sequestered into a double membrane vesicle which is then fused with lysosomes for bulk degradation[42,43]. *p53* plays a dual role in activating and/or inhibiting autophagy by transactivating numerous autophagy regulators including mammalian target of rapamycin (mTOR)[46], activated protein kinase (AMPK) and tuberous sclerosis protein (TSC2)[43,47]. *p53* is also able to influence the decision between apoptosis and autophagy by selectively activating pro-autophagy proteins such as AMPK, death-associated protein kinase 1 (DAPK-1) and damage-regulated autophagy modulator (DRAM)[48]. Alternatively, *p53* also promotes apoptosis by activating pro-apoptotic markers such as B-cell Lymphoma 2

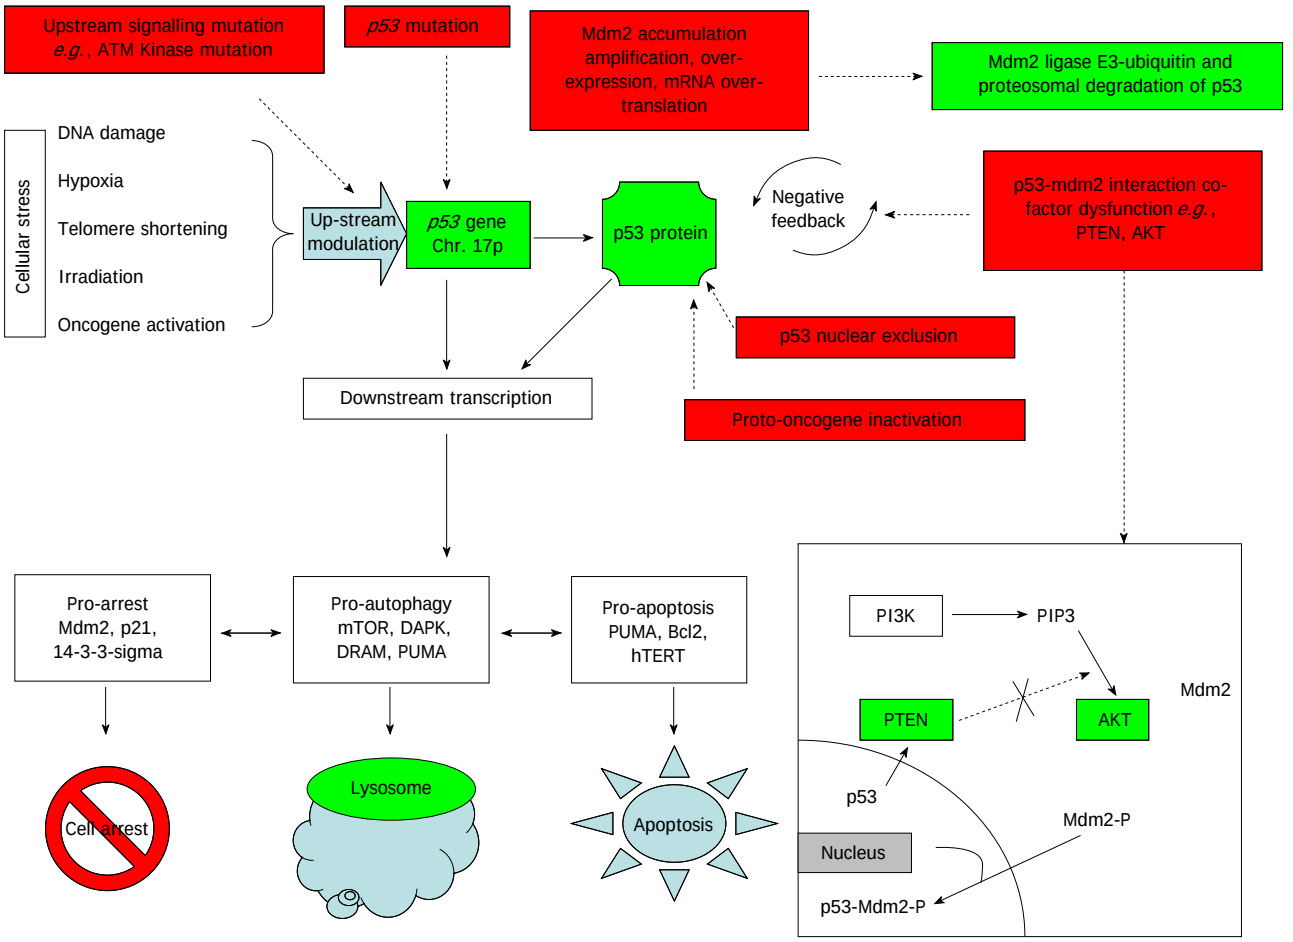

Figure 1 Normal *p53* function highlighted in green boxes and blue figures as described. Red boxes show mechanisms for inactivation; Normal *p53* function highlighted in green and blue figures. PI3K: Phosphatidylinositol-3-kinase; PTEN: Phosphatase and tensin homolog; AKT: Protein kinase B; ATM: Ataxia telangiectasia mutated kinase; mTOR: Mammalian target of rapamycin; DAPK: Death-associated protein kinase; DRAM: Damage-regulated autophagy modulator; PUMA: p53-upregulated modulator of apoptosis; hTERT: Human telomerase reverse transcriptase.

(Bcl-2), Bcl-2 associated death protein (BAD), Bcl-2 associated X-protein (BAX), *p53*-upregulated modulator of apoptosis (PUMA)[49] and autophagy inhibitors such as TP-53 induced glycolysis and apoptosis regulator proteins (TIGAR)[42].

Disruption of *p53* gene transcription function and subsequent production of an inactive mutant p53 protein allows cells to escape the cellular arrest/apoptosis controls. This allows unregulated propagation of abnormal cells and a predisposition to malignant transformation. It is important to be aware that *in vivo p53* behaviour can be different from *in vitro* response. This could be due to different stress types[50,51], cell types[52] and immune responses[24,53,54].

MECHANISMS OF *p53* INACTIVATION

The most common cause of *p53* inactivation is mutation which most frequently occurs within the *p53* core, and furthermore 70% occur at "hot spots"-amino acids 132-142, 151-159, 172-179, 237-249 and 272-286[26,55]. The International Agency for Research on Cancer (IARC) TP53 database similarly reports the most frequent *p53* mutations at codons 175, 245, 248, 249, 273 and 282; which is further corroborated by the UMD-TP53 mutation database, another international database that spans over 25 years[1,3,56]. The most common type of mutation is mis-sense (73%) followed by frame shift (9%), non-sense (8%), silent (4%) and others (6%)[1,3,57].

p53 is also inactivated by mechanisms other than *p53* gene mutation and are described below (Figure 1).

Proto-oncogene activation

Proto-oncogenes are normal proteins that become oncogenic with relatively minor modifications[6]. These proto-oncogenes are usually important cell cycle regulators (*e.g.*, $p14^{ARF}$)[58]. Human papilloma virus (HPV) 16/18 E6 protein which causes cervical cancer is able to inactivate *p53* without mutation. This explains the relatively low incidence of *p53* mutation in cervical cancer[59,60]. The SV40 large-T-antigen is another viral oncogene which is able to inactivate wild-type *p53*[61].

Mdm2 over-expression

Mdm2 is a negative regulator of *p53* and reduces the cell's ability to trigger the pro-arrest/apoptotic pathway in the event of cellular damage[62,63]. Mdm2 over-expression can occur by gene amplification, gene over-expression or

mRNA over-transcription[20,56]. Mdm2 over-expression is classically observed in soft tissue sarcomas[64,65]. Interestingly, instead of a decrease in p53 expression, the levels of both Mdm2 and p53 expression are increased. This suggests Mdm2 may have an additional *p53*-independent oncogenic mechanism (in addition to *p53* suppression by negative feedback) which can promote tumour growth.

Dysfunction of regulators of the p53-Mdm2 loop

Mutations of in the *p53*-Mdm-2 feedback loop such as AKT Kinase, Phosphatidylinositol-3-kinase (PI3K), Phosphatase and Tensin Homolog (PTEN) and Ataxia Telangiectasia Mutated (ATM)-Kinase can inappropriately influence levels of *p53* (see detailed description below). *p53* disruption has also been associated with inactivation of other tumour suppressors *e.g.*, BRCA1, Bcl-2, transforming growth factor (TGF)-β. AKT-kinase not only influences p53 levels but forms an apoptotic pathway with mTOR, an autophagy marker, in the PI3K/AKT/mTOR pathway demonstrating the complex interplay between *p53* and the relative levels of its regulators in deciding cell fate[19,42,43]: (1) AKT-kinase phosphorylates Mdm2 and induces migration of phosphorylated-Mdm2 into the nucleus where it inactivates *p53*. AKT over-expression has been shown to occur in cancer cells[66,67]; (2) PTEN is tumour-suppressive and activated in response to stress leading to *p53* up-regulation. Wild-type PTEN inhibits AKT-kinase phosphorylation of Mdm-2 and thus, intra-nuclear Mdm2 migration which suppresses *p53* activity[29,68,69]. In contrast mutated PTEN is unable to inhibit AKT-kinase which leads to continuous Mdm2- phosphorylation and Mdm-2 intra-nuclear migration leading to reduced *p53* tumour suppressive ability[69,70]; and (3) Cell stress (*e.g.*, irradiation) activates factors up-stream of *p53* such as ATM kinase and checkpoint Kinase-2[54,65]. Mutated ATM-kinase is unable to activate *p53* in response to radiation-induced stress.

Nuclear exclusion and cytoplasmic p53

Extrusion of *p53* into cytoplasm has been observed in certain tumours such as breast[71], colon[72], neuroblastoma[73] and malignant melanoma[74]. Nuclear extrusion prevents *p53* from performing its intra-nuclear interactions.

Gain of oncogenic function

Mutant *p53* has an impaired ability to regulate cell cycle which is referred to as "loss of function"[3,6,75]. In addition to this, mutated *p53* can also exhibit conformational changes which result in acquisition of new pro-oncogenic abilities; this is known as "gain of function". Such functions include increased transcription of tumour-promoting factors such as MYC and VEGF[76] and disruption of protective pro-apoptotic factors such as p73[7,77].

ANTI-*p53* AUTO-ANTIBODY

An anti-*p53* auto-antibody response was first reported by Crawford *et al*[78] in 1982 in 9% (14/155) of patients with breast cancer. Further interest in this anti-*p53* auto-antibody response declined due to the lack of accurate quantification methods and no observable clinical relevance. Research into the auto-antibody was invigorated in the 1990s when the critical role of *p53* gene in carcinogenesis was recognized. The exact cause of induction of anti-*p53* auto-antibody production is unknown but is thought to be associated with the presence of *p53* mutation and p53 protein over-expression.

An anti-*p53* auto-antibody is not normally produced wild-type p53 protein induces tolerance of the host[32,79]. In abnormal cells, mutant p53 protein is stabilised as discussed above which cause relatively high intra-nuclear p53 protein accumulation which then escapes into the cytoplasm. The resulting high cytoplasmic p53 levels increase the likelihood of p53 protein being degraded by proteasomes and presented on cell surfaces to be recognised by T-cells in a MHC I response[16]. Auto-antibodies recognises epitopes on the terminal regions of the protein, and hence auto-antibody production can theoretically be triggered by either the wild-type or the mutant *p53*, provided sufficiently high levels of these immunodominant epitopes are present at the cell surface[80]. Another probable antigen presentation mechanism is where cancer cells containing high cytoplasmic concentrations of *p53* undergo necrosis and release *p53* into the blood and lymphatic system where appropriate B-cells can interact. These antigens are also captured by Antigen Presenting Cells (APC) in their normal scavenging role and are presented in association with MHC class Ⅱ response causing a Th2-like cell response[16] (Figure 2).

P53 mutation alone is insufficient to trigger anti-*p53* auto-antibody production as evidenced by several observations. Firstly, only 20%-50% of patients with detectable *p53* mutations produce detectable auto-antibodies[81,82]. This is attributed to the type of mutation, *e.g.,* mis-sense mutations are associated with higher auto-antibody production compared with other mutations[5,56,57,83]. This is probably because mis-sense mutations are more likely to produce a stable mutant p53 protein which is more likely to accumulate to sufficient levels to increase the likelihood of antigen presentation. Other mutations such as non-sense, frameshift and deletions often lead to truncated mRNA and unstable protein sequences which are less likely to accumulate, and thus less likely to induce auto-antibody production[84]. Secondly, anti-*p53* auto-antibodies most frequently recognise terminal epitopes but not the central domain with the majority of mutations[25,27,28,81]. Thirdly, large SV40 T-antigen stabilises p53 protein leading to accumulation of the wild-type protein which also induces auto-antibody production. Together these observations suggest that humoral response is triggered by elevated p53 protein levels *per se* (mutated and/or wild-type) rather than specifically directed at a mutated sequence.

Discrepancy between anti-p53 auto-antibody and p53 mutation

There are discrepancies between the presence of *p53* mutation, p53 protein product expression and anti-*p53*

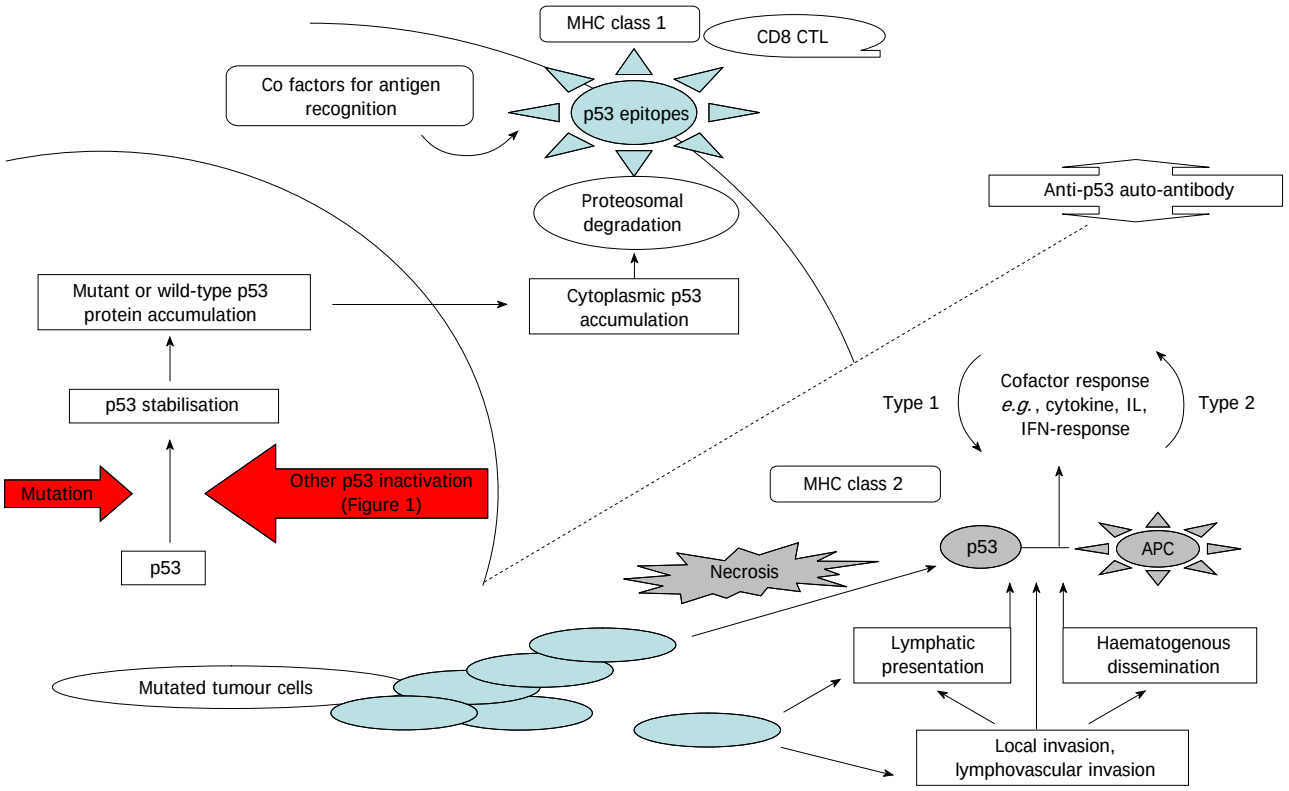

Figure 2 Proposed mechanisms of anti-*p53* auto-antibody induction. MHC: Major histocompatibility complex; CD8: Cluster of 8 differentiation; CTL: Cytotoxic T-cell; IL: Interleukin; APC: Antigen presenting cell.

auto-antibody production. This is largely attributed to the methodological differences of detection. Initial gene screening studies reported that most *p53* mutations were localised to exons 5-8 and to a lesser extent 4, 9, 10. Subsequent studies then only tended to screen these regions leading to substantial screening bias. It is now known that at least 10% of *p53* mutations occur outside these areas[84,85]. Another source of methodological difference is p53 protein detection which is inherently subject to tissue sampling and biopsy errors. Older studies (pre-1999) had different immuno-histochemical, fixation, paraffinization, antigen and antibody retrieval and observer scoring techniques. Finally, the antibody used to detect the mutant p53 protein affects sensitivity of p53 protein detection in IHC and also the detection of anti-*p53* auto-antibody in ELISA as described below.

Historically, the auto-antibody was initially detected using immunoblots or in-house enzyme linked immunosorbent assay (ELISA). These ELISA used different cut-off values leading to a vast range of reported frequencies of anti-*p53* auto-antibody within individual cancers in many older studies. Although standardised commercial ELISA are now widely available leading to an increase in anti-*p53* ELISA studies (2000 onward), auto-antibody detection can still vary depending on different manufacturers' product[86]. Most importantly, these ELISAs only measure an antibody response against those *p53* epitopes, which are expressed by the recombinant proteins used as the coating antigen. This may account for the reason that there are minor variations in commercial ELISA studies in different populations but when the same ELISA is used in the same population, inter and intra-coefficient of variations of 0.3%-2.7% are extremely reliable[82].

Finally, the differences in individual's immune systems cannot be ignored. The humoral response is dependent on an individual's unique MHC presentation as shown by several observations. Firstly, patients with similar cancers containing the same *p53* mutations do not necessarily mount the same immune response[81]. Secondly, whilst anti-*p53* auto-antibody titres increase in response to tumour load, all patients who are initially sero-negative do not develop an auto-antibody response despite disease progression and metastases. Conversely, patients who are sero-positive at diagnosis do not sero-convert to a negative anti-*p53* auto-antibody status even after the cancer is completely excised. It seems that once the patient's immune system has been primed, there is sufficient *p53* antigen available to maintain a long-term anti-*p53* humoral response[28,87,88].

MATERIALS AND METHODS: SYSTEMATIC REVIEW

Literature searches were performed using Medline and PubMed up to January 2012. Keywords used were "*p53*", "anti-*p53*", "antibody", "auto-antibody", "cancer" and combinations. No language or time restrictions were applied. All abstracts were reviewed and the relevant articles retrieved. The results of all published anti-*p53* auto-antibody cancer studies were accumulated and compiled in Table 1 with relevant key findings. The anti-*p53* auto-

Table 1 Cumulative reported frequencies of anti-*p53* auto-antibody (anti-*p53*) in controls and individual cancers *n* (%)

Melanoma	Soussi[90]	0/58 (0)	Literature review of anti-*p53* in various cancers (1979-1999)
Total		3419/18595 (18.4)	All cancers (1979-2012)

Cancer types are listed in order of decreasing anti-*p53* auto-antibody frequency. The reported studies within each cancer type are listed in reverse chronology. Squamous cell carcinoma (SCC); basal cell carcinoma (BCC), hepatocellular carcinoma (HCC), carcino-embryonic antigen (CEA). Tissue polypeptide antigen (TPA), CYFRA21-1, Neurone-specific enolase (NSE), Oestrogen receptor (ER), c-erb-2. [1]Cirrhosis; [2]Benign disease; [3]Oral pre-malignant lesions-excluded from calculation; [4]Primary carcinoma; [5]Secondary/recurrent carcinoma; [6]Ascitic titre, not included in calculation of serum titres; [7]Colon; [8]Rectum; [9]Upper renal tract tumours, excluded from anti-*p53* titres in bladder carcinoma; [10]Malignant mesothelioma (MM); [11]Lung carcinoma (LC); [12]Small cell lung carcinoma (SCLC); [13]Non-small cell lung carcinoma (NSCLC); [14]Myeloma; [15]Leukaemia; [16]Tumour type not specified; [17]Excluded as is preliminary report of the same cohort (duplicate) reported in Charuruks *et al*.

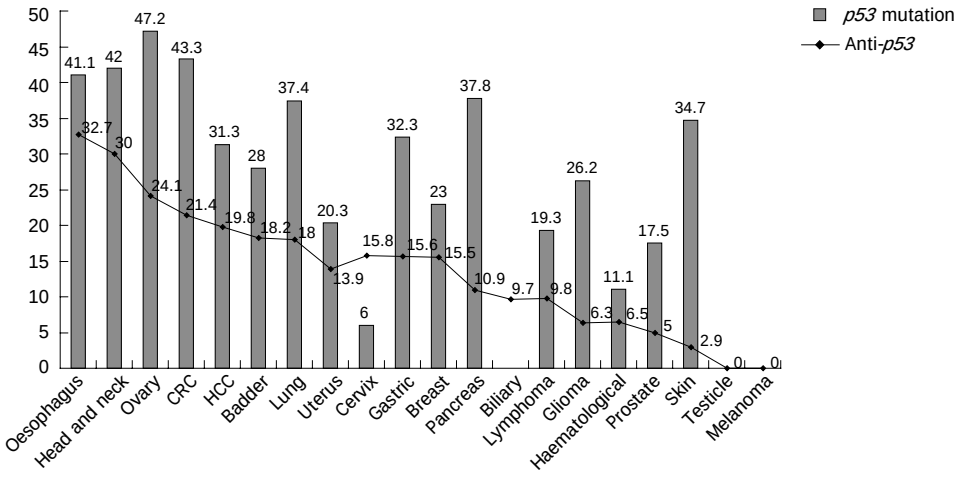

Figure 3 Percent *p53* mutations (International Agency for Research on Cancer, 2008) and percent anti-*p53* auto-antibody incidence calculated in this review. $r^2 = 0.45$, Correlation = 0.59. CRC: Colorectal cancer; HCC: Hepatocellular carcinoma.

antibody frequency from all published studies in each cancer type was calculated in this review. This calculated anti-*p53* auto-antibody frequency was then correlated with reported *p53* mutation rates to determine the associated between anti-*p53* auto-antibody presence and mutation in each cancer (Figure 3).

Methodological quality of anti-p53 and CRC publications

All published studies on anti-*p53* auto-antibody (1979-2012) were retrospective or cross-sectional case

control series with relatively small sample size (27-220 subjects tested) with a heterogeneous mix of cancer stages. The largest single study was published by Tang *et al*[89] that included a cohort of 998 CRC patients with anti-*p53* present in only small numbers (n = 130) for stage-specific analysis. An earlier non-systematic review by Soussi in 2000 recruited large numbers from various anti-*p53* studies but was study quality was limited by different cancers at various stages and different auto-antibody detection methods[90]. The primary outcome was not stated in most studies, and none was powered appropriately for survival outcomes.

ANTI-*p53* AUTO-ANTIBODY IN ALL CANCER TYPES

The reported frequency of anti-*p53* auto-antibody in individual cancer studies vary significantly due to small sample sizes, stage bias (usually a greater proportion of advanced stage tumours were included and different detection methods used. Anti-*p53* auto-antibody is usually measured in patients' sera but has also been measured in ascitic fluid of patients with ovarian cancer[68], saliva of patients with oral cancer[91] and in pleural effusions (12.5%) associated with lung, colon and pancreatic cancer[92]. In a landmark review, Soussi compiled results of 80 anti-*p53* auto-antibody studies in 18 cancer types over a 20 year (1979-1999) period[90]. The mean serum sero-positivity across all cancer types was 16.9% (1600/9489 patients, range 0%-31%) compared with 1.45% (35/2404) in controls thus demonstrating remarkable specificity (98%) but poor sensitivity. The specificity would be even higher as half the false positive subjects (17 out of 35) were from a single study reporting an extra-ordinarily high sero-positivity (24%, 17/70)[93](Table 1). When this study was excluded anti-*p53* auto-antibody specificity is near 100% for any cancer, which is confirmed by most recent reports.

Relationship between anti-p53 auto-antibody and p53 mutation

The 30-year cumulative sera anti-*p53* auto-antibody frequencies in individual cancers were calculated in this review to provide the most comprehensive anti-*p53* auto-antibody frequency in each cancer to date (Table 1). The auto-antibody frequencies are plotted (point) against the *p53* mutation rate (bars) as reported by the IARC TP53 Mutation Database to ascertain a relationship between anti-*p53* auto-antibody and *p53* mutation rates in each cancer.

The graph shows moderate correlation (r^2 = 0.45, correlation 0.59) between anti-*p53* auto-antibody and *p53* mutation (Figure 3). In general, cancers with the highest *p53* mutation rate such as oesophageal, head and neck, and colorectal demonstrate highest anti-*p53* auto-antibody rates[82,90]. Conversely, melanoma and testicular carcinoma with the lowest mutation rate have the lowest serum anti-*p53* auto-antibody rates (< 1%)[90]. The two exceptions are gliomas and skin cancers which have moderate *p53* mutation rate and low anti-*p53* auto-antibody rate (Figure 3). Proposed reasons for the low anti-*p53* auto-antibody production are poor brain antigenicity, poor *p53* antigen-presentation across the blood-brain barrier, and use of immuno-suppressive steroids (dexamethasone) in the majority of glioma cases[90,94,95]. Similar arguments about poor antigen presentation across an epithelial barrier are made for the majority superficial skin cancer. In summary, anti-*p53* auto-antibody has up to 35% sensitivity, depending on cancer type, nearly 100% specific for any malignancy but varies in individual cancer types; and demonstrates moderate correlation with *p53* mutation rate of each cancer.

ANTI-*p53* AUTO-ANTIBODY AND COLORECTAL CANCER VARIATIONS

CRC has the second highest anti-*p53* auto-antibody sero-positivity rates due in part to the high frequency of *p53* mutation. Pre-1999, eight studies used an "in-house" developed ELISA, 1 used Western blotting (WB), 1 used immuno-precipitation (IP) and another used all 3 detection methods (ELISA, WB, IP)[90]. Despite these methodological differences, most studies, 10 out of 11, reported a sero-positivity rate between 12.5% and 32%. The only study to report a discrepant and much higher sero-positivity rate (68%) used WB thus demonstrating the potential bias caused by non-standardised detection methodology[96]. New standardised commercial ELISA kits have since been developed with less variation in sero-positivity (13%-27%) with intra- and inter-assay coefficient of variation of 1.85%-2.37% and 0.3%-3.32% respectively (MESACUP anti-*p53* Test; Medical and Biological Laboratories, MBL, Nagoya, Japan)[82].

The mean sero-positivity from ELISA-only CRC studies calculated in this review was 19.9% (479/2409) with individual studies reporting of 13%-27% (Table 2). Only two studies reported inconsistently high rates of 47% and 63% in patients, and also in controls (2.6%), which suggests a lower cut-off value was used[97,98]. The same authors then reported an unusually high (40%) sero-positivity in superficial oesophageal carcinoma in another series, compared with 20%-30% in the majority of other studies. These studies used the same ELISA (Pharmacell, France)[99]. Interestingly, when the same authors later used a different ELISA (anti-*p53* EIA Kit Ⅱ, MESACUP) in a similar population, they reported a much lower sero-positivity of 30% (oesophageal cancer) and 24% (CRC) which was more consistent with other published ELISA studies[82]. This highlights potential methodological biases with anti-*p53* auto-antibody quantification even with commercially standardised ELISA kits.

Anti-p53 auto-antibody in diagnosis and screening

Cancer screening is used when early detection and intervention can lead to improved outcome for example CRC where 5 year survival in Dukes' A is 95%-100% com-

Table 2 Anti-*p53* auto-antibody in all published colorectal cancer studies and key findings *n* (%)

Ref.	Method and manufacturer	Samples	Follow-up	Key findings
Suppiah *et al*[130]	ELISA (*p53* ELISAPLUS, Calbiochem, Darmstadt, Germany)	20/92 (21.7); 0/20 (0)[1] 0/8 (0)[2]	Median 97 mo	No correlation with tumour stage, differentiation or location. Multivariate analysis show only Stage (Dukes' and TNM) to be independent prognostic factors
Nozoe *et al*[97]	ELISA (Pharmacell, France)	17/36 (47.2)	Not stated	Anti-*p53*-ab (+) associated with greater lymphatic invasion (94.1%; 16/17 *vs* 68.4%; 13/19), nodal involvement (70/6%; 12/17 *vs* 17.6%; 3/17) and advanced stage (P = 0.02). Anti-*p53* frequency higher in *p53* protein expressing tumours (74%; 14/19 *vs* 18%; 3/17). Only 3 patients with Dukes' A CRC, all sero-negative
Muller *et al*[123]	Immunoblot	Colon 63/197 (32); Rectum 7/46 (15.2); 0/57 (0)[1] 0/379 (0)[2]	CRC patients enrolled into trial with 5 year follow-up	No correlation with clinico-pathological parameters or prognosis. Trend toward higher anti-*p53* sero-positivity in N2/3 disease, poor differentiation and metastases. There were no patients with Dukes' A in this study. Anti-*p53* independent of CEA and CA19-9 with 16% information gain. This is the only study to report negative to positive sero-conversion (3.6%, 11/303)
Chang *et al*[85]	ELISA (*p53*-AK, Dianova, Hamburg, Germany)	47/167 (28.1); 0/40 (0)[1]	Median 36.3 mo (4-58)	Anti-*p53* correlates with *p53* mutation (43% *vs* 18%) but not tumour *p53* expression, clinico-pathological features or prognosis. *p53* mutations, advanced stage and pre-operative CEA > 5 ng/mL were independent prognostic factors (in that order). *p53* mutation strongly associated with advanced stage and poor differentiation
Lechpammer *et al*[88]	ELISA (ELISAPLUS Oncogene Research Products, Cambridge, United States)	40/220 (18.2); 0/42 (0)[1]	40 patients up to 20 wk; 8 patients up to 48 wk	Anti-*p53* had higher tumour *p53* expression (70% *vs* 52%). Anti-*p53* frequency shows highest increase in Dukes' A (0%, 0/28) → Dukes' B: (24%, 21/87) but no increase in progression to Dukes' C (18%,19/105). No correlation with overall tumour grade or metastases. Anti-*p53* reflects tumour load following surgery, during chemotherapy and with disease recurrence
Shimada *et al*[82]	ELISA (Anti-*p53* EIA Kit II, MESACUP anti-*p53* Test; MBL; Nagoya, Japan)	46/192 (23.9); 10/205 (4.9)[1]; 13/189 (6.9)[2]	Not reported	Validation study for MESACUP ELISA using prevalence of anti-*p53* in various cancers. Good intra- and inter-assay coefficient of variation of 1.85-2.37% and 0.3-3.2% respectively. Demonstrates stability of anti-*p53* titres at room temperature for 7 d and following 10 freeze-thaw cycles. No comment on correlation with clinico-pathological parameters or prognosis
Forslund *et al*[84]	ELISA (Dianova, Hamburg, Germany)	24/88 (27)	Not reported	Cross-sectional study on relationship between *p53* mutations and anti-*p53* presence. Frequency of *p53* mutation higher in anti-*p53* sero-positive group (92%, 22/64 *vs* 34%, 22/64) Correlation with clinico-pathological and survival parameters not reported
Tang *et al*[89]	ELISA (Calbiochem-Novabiochem, Darmstadt, Germany)	130/998 (13); 2/211 (1)[3]	Not reported	Anti-*p53* sero-positivity increases in progression from N2→ N3 (2.9%-10.6%); but not N0→N1 (11.7%-12.3%), N1→N2 (12.3%-10.6%) or M0→M1 (12%-17%). No correlation with CEA, overall TNM stage or metastases. Anti-*p53* associated with shorter survival in uni- but not multi-variate analysis. Largest study on anti-*p53* in CRC
Broll *et al*[152]	ELISA (*p53*-autoantikorpfer ELISA, Dianova, Hamburg, Germany)	20/130 (15); 0/44 (0)[1]	Median 25.5 mo	Anti-*p53* positive predictive value of 100%, but accuracy 37% and negative predictive value 29% due to poor sensitivity (15%). Anti-*p53* correlated with *p53* expression (P < 0.05), but not TNM stage, grade or location (exact numbers not shown). Approximately 70% of series Stage Ⅰ/Ⅱ CRC
Takeda *et al*[98]	Anti-*p53* EIA (PharmaCell, Paris, France)	17/27 (63); 1/38 (2.6)[3]	Up to 2 years Median not reported	Anti-*p53* correlates with *p53* protein expression and independent of CEA and CA-19-9. Sero-conversion in 94% (16/17) within 3 wk of endoscopic resection. No correlation with clinico-pathological parameters or prognosis/recurrence as all patients had early superficial CRC (23 mucosal, 4 submucosal invasion). This study reports exceptionally high anti-*p53*, especially considering very early CRC
Takeda *et al*[174]	ELISA (anti-*p53*-EIA kit, Pharmacell, Paris, France)	40 patients with anti-*p53* ab from previous studies	Up to 29 mo	No correlation between post-operative anti-*p53* sero-positivity and histological (depth, lymphatic or venous invasion) or clinico-pathological features of lymph node or liver metastases. High (96%; 27/28) sero-conversion in patients with complete tumour resection. No sero-conversion in patients with residual disease.
Shiota *et al*[112]	ELISA (GIF, Munster, Germany)	18/71 (25); 1/18 (6)[3]	Not stated, median survival 56 mo anti *p53* ab negative	Anti-*p53* correlates with TNM stage (Stage Ⅰ-Ⅲb: 9%, 4/45 *vs* Ⅳ: 56%, 14/25), Dukes' stage (A-C: 9%, 4/45 *vs* D: 56%, 14/25), CEA, CA19-9 and tumour p53 protein expression. Anti-*p53* associated with shorted survival (56 mo *vs* 20 mo) and is weak poor prognostic indicator. Anti-*p53* prognostic significance secondary to other factors, including weak factors *e.g.*, CEA and CA19-9. Only small number of Stage Ⅰ-Ⅲb patients

Bielicki *et al*[111]	ELISA (Dianova, Hamburg, Germany)	30/145 (21); 0/20 (0)[2]; 0/8 (0)[3]	Not stated. Cross sectional study	No correlation with Dukes' Stage (A/B: 22%, 16/73 *vs* C/D 19% 14/72), size, location, CEA. Highest increase in anti-*p53* frequency from Dukes' A (0%, 0/6) to Dukes B1 (28%, 5/18) but no further difference in progression to Dukes' C (19%, 7/36). Only 6 Dukes' A patients in study, all sero-negative
Soussi[90]	ELISA/WB/IP	307/1244 (24.7)	ELISA/ WB/IP	Review combining all studies with different methodologies from 1979-1999. Range of sero-positivity (12.5%-68% in 11 studies)
Total (1999-2009)		479/2409 (19.9)		All modern studies (1999 onwards) using commercial ELISA only, with one exception using Immunoblot (Muller *et al*, 2006)
Review Total (1979-2009)		786/3653 (21.5)		All studies on anti-*p53* in CRC (1979-2009)

Studies prior to 1999 used different methodology and not included (see above). Enzyme-linked immunosorbent assay (ELISA); Western blotting (WB); Immunoprecipitation (IP) [1]healthy, [2]benign disease, [3]adenoma. The study by Muller *et al* was included despite using immunoblot technique as it was a recent study with relatively large sample size. CRC: Colorectal cancer; CEA: Carcino-embryonic antigen.

pared with 5% in Dukes' D. Colonoscopy is the current gold-standard diagnostic tool but is painful, expensive and is associated with life-threatening complications such as colonic perforation (0.01%-0.3%) and haemorrhage (0.6%)[100,101]. The United Kingdom Flexible Sigmoidoscopy Screening Trial has provided evidence that one-off screening flexible sigmoidoscopy between age 55 and 64 was beneficial in reducing CRC incidence by 23%-33% and reducing mortality by 31%-43%[102,103]. Similar mortality reduction has been reproduced in other screening trials such as Norwegian Colorectal Cancer Prevention (NORCCAP)[104]. A recent meta-analysis similarly confirmed benefits of screening (endoscopy or stool-based screening) over an unscreened population in increasing detection and prognosis[105].

There are intuitive benefits of screening with serum anti-*p53* auto-antibody compared to CT, barium enemas and colonoscopy. The titre is not subject to tumour sampling error, is quicker, cheaper, easier and less traumatic, thus making it more repeatable in the general population. The auto-antibody titre itself is remarkably stable, showing no significant change when stored at room temperature for up to 7 d, or when stored at -80 ℃ for 3 years[81]. Repeated freeze-thaw cycles (up to 10 cycles) have minimal or no effect on serum levels as immunoglobulins are generally robust proteins[82]. Also, anti-*p53* auto-antibody appears to be independent of other conventional CRC tumour markers such as carcino-embryonic antigen (CEA) which means it could detect CRC in CEA-negative patients. The combined advantages of serum testing and the characteristics of anti-*p53* auto-antibody (serum stability, 95%-100% specificity, independent of current tumour markers), makes anti-*p53* auto-antibody a potentially valuable screening modality.

The role of *p53* in screening is promising its specificity for cancer, but this enthusiasm is tempered by a low sensitivity (20%-30%). It would thus be required as part of a panel of tumour markers. This panel could then be used to guide more invasive investigations such as colonoscopy. Combined serum immuno-testing for 6 markers (CEA, anti-*p53* auto-antibody, CYFRA 21-1, osteopontin, separase and ferritin) has been reported to have comparable sensitivity (> 80%) to faecal immuno-testing[106]. A similar tumour marker panel using CYFRA-21, CEA and anti-*p53* has been used in lung cancer also with 80% sensitivity[107]. Combined biomolecular and endoscopic strategies[108] are being investigated, and in conjunction with other new diagnostic non-invasive modalities (*e.g.*, CT-colonography)[109] may be able to further broaden the screening programmes for CRC and other cancers in the general population.

Anti-p53 auto-antibody and clinico-pathological parameters of CRC

p53 mutation is usually a late event in the adenoma-carcinoma sequence and hence anti-*p53* auto-antibody is unlikely to be present in early pre-invasive lesions where *p53* mutations have not occurred[110]. The largest study reports 1% (2/211) sero-positivity in adenomas which increased to 6% in carcinoma *in-situ*[89]. This 1% could be due to undetected microfoci of invasive cancer within adenoma or changes that predate microscopic detection. The increase prevalence of anti-*p53* auto-antibody to 6% in carcinoma *in situ* can be expected in these tumours which are at the end of the adenoma-carcinoma sequence with greater proportion of *p53* mutation. This would then suggest that anti-*p53* auto-antibody should increase with further growth (CRC stage) but this is not seen. Almost all studies reported no association between anti-*p53* auto-antibody and CRC stage (Tables 1 and 2). This was reported in the largest cross-sectional series, and confirmed by other long-term follow-up studies[89] (Table 2). Only a handful of studies have suggested an association between anti-*p53* and T-stage[88,111], selected nodal disease[89] and metastases[112]

Tumour depth

Two studies reported increased anti-*p53* in progression from Dukes' A to B, but not with progression from Dukes' B to C[88,111]. Lechpammer *et al*[88] reported 0% (0/28) anti-*p53* in Dukes' A which increased significantly to 9.6% (21/87) in Dukes' B, but did not increase further with Dukes C (8.6%, 19/105). Bielicki *et al*[111] similarly reported increased anti-*p53* auto-antibody from Dukes' A (0%) to Dukes' B (28% Dukes' B1, 22% Dukes' B2); but no increase in progression to Dukes C (19%). This suggests auto-antibody production is stimulated by early (Tis to T2) local invasion such as microvascular basement membrane invasion leading to antigen presentation; but not further progression. Further studies are required to

Table 3 Prevalence of anti-*p53* auto-antibody and carcino-embryonic antigen in studies reporting the presence of both tumour markers in colorectal cancer *n* (%)

	CEA	Anti-*p53*
Tang *et al*[89]	408/943 (43.3)	130/998 (13.0)
Shibata *et al*[96]	23/47 (48.9)	32/47 (68.0)
Bielicki *et al*[111]	46/148 (31.1)	29/148 (19.6)
Hammel *et al*[175]	20/54 (37.0)	14/54 (25.9)
Overall	497/1192 (41.7)	204/1247 (16.4)

CEA: Carcino-embryonic antigen.

understand the precise series of events in anti-*p53* auto-antibody production.

Nodal involvement

Anti-*p53* auto-antibody is produced in part due to response to *p53*-antigen presentation. Thus nodal involvement should also increase anti-*p53* auto-antibody production by increasing probabilities of antigen presentation to the humoral system. However, there is no correlation between anti-*p53* auto-antibody and nodal involvement in any of the studies (Table 2). Tang *et al*[89] suggested increased anti-*p53* with "advanced" nodal disease (N3: > 10 regional nodes or systemic nodal metastases) compared to N0-2 CRC in selected analysis. We re-classified the data into node "positive" and "negative" disease and found no difference in sero-positivity of 12% *vs* 14% with nodal involvement (calculation not shown).

Metastases

It would be expected that haematogenous cancer cell dissemination should invoke a further immune response but there has been no association between anti-*p53* auto-antibody status and metastatic disease except one study[112]. In this study, anti-*p53* auto-antibody had extremely high prevalence (56%, 14/25) in Stage Ⅳ disease, and unusually low prevalence in Stage Ⅰ-Ⅲ (9%, 4/45) leading to strong anti-*p53* bias towards Stage Ⅳ disease. This is the only study to report anti-*p53* auto-antibody association with stage and adverse prognosis which is discussed later (anti-*p53* auto-antibody in prognosis in CRC).

Summary of anti-p53 auto-antibody and CRC Stage

Anti-*p53* auto-antibody production is initially most likely to be produced in the final stages the adenoma-carcinoma sequence (in keeping with *p53* mutation being a relatively late event. It is likely that anti-*p53* auto-antibody production is no longer dependant on antigen-presentation, but rather now dependant on immune-recognition by (1) tumour factors *e.g.*, *p53* mutation type and conformation, presence of co-factors; and (2) patients' immune-specific factors such as MHC expression required for recognition. This response is not sufficiently consistent to justify a separate clinico-pathological parameter of its own. In the future, anti-*p53* auto-antibody may have some benefit in refining CRC stage if there is influence on prognosis or treatment, similar to k-RAS status in anti-EGFR and anti-VEGF therapy for CRC and liver metastases, or oestrogen- or progesterone-status in breast cancer.

Anti-p53 auto-antibody and carcino-embryonic antigen

CEA is the most common serum tumour marker used in CRC. It is a 180 kDa serum glycoprotein which is present at low levels in normal cells but over-expressed in adenocarcinoma, especially of the colon, rectum, breast and lung[113]. Pre-operative CEA presence has been associated with aggressive CRC and poor prognosis[114,115]. CEA has also been used as an adjunct in CRC screening, monitoring for disease recurrence following resection, or as part of tumour marker panel for metastases of unknown primary origin. CEA has high specificity (80%) with false elevations in smokers, inflammatory diseases, cirrhosis, obstructive jaundice, gastric ulcers, emphysema, diabetes and collagen vascular diseases[116-118].

CEA in isolation is not recommended for screening or detection of recurrence due to its variable sensitivity (30%-80%)[114,119]. CEA sensitivity can be modulated by changing the cut-off values for "positivity" but sensitivity has still remained low despite variations in the cut-off value used[120,121]. Despite this, The American Society of Surgical Oncology (ASCO) guidelines suggest serial CEA measurements every 3 mo in Stage Ⅱ/Ⅲ CRC for at least 3 years following diagnosis, and during treatment of metastatic disease[122].

Tumour markers used in conjunction with CEA could increase the efficacy of CRC screening in selected populations. Such tumour markers should be independent of CEA as to detect the CEA-negative CRC population and thus increase sensitivity of the tumour marker panel. The majority of studies have shown that anti-*p53* auto-antibody is independent of CEA (Table 3). The two studies which report a positive correlation had results inconsistent with other studies, with the first study having an unusually strong association between anti-*p53* auto-antibody and Stage Ⅳ disease (as discussed earlier)[112] and the second reporting the highest anti-*p53* auto-antibody frequency (68%) and used WB, not ELISA[96]. Methodological difference and sample bias are most likely responsible for the results observed.

In this review, information is compiled from all studies reporting CEA and anti-*p53* in Table 4. This shows that when used in isolation, anti-*p53* auto-antibody can CEA can detect CRC in 17% and 42% respectively. If both tumour markers are used, the sensitivity increases to 51% (as both markers are absent in 48.9%). This results in information/sensitivity gain of +9% (compared with CEA alone); and +34% (compared with anti-*p53* auto-antibody alone). The only other study to report "information gain" using anti-*p53* auto-antibody in CRC confirmed reported mean increased sensitivity of 16% with individual increased sensitivity from 55% to 71% in colon cancer and 78% to 83% in rectal cancer[123]. This report is consistent with our calculation using data from all other published anti-*p53* auto-antibody and CEA studies in CRC (Tables 3 and 4).

Table 4 Combined carcino-embryonic antigen and anti-*p53* auto-antibody rates from all studies reporting the presence of both markers (*n* = 1192) *n* (%)

	CEA normal	CEA elevated
Anti-*p53* ab present	112 (9.4)	90 (7.6)
Anti-*p53* ab absent	584 (48.9)	406 (34.1)

CEA: Carcino-embryonic antigen.

The clinical utility of this "information gain" requires examination. CRC has low prevalence in the general population and thus pick-up rates would remain low despite the use of both tumour markers. Both markers also have preponderance towards later stage CRC (as opposed to Stage I) which reduces impact of earlier detection and thus screening efficacy. It is thus likely that these 2 markers alone are insufficient and additional markers would be required, i.e panel of 6 tumour markers was used to form a panel with sensitivity similar to faecal occult testing in population screening[108]. In post-operative surveillance, small studies have demonstrated overall 4 tumour markers (CEA, TPA, CA19-9, CA72.4) panel sensitivity of 81% compared with 9%-45% using individual markers[124]. Hence, the optimal strategy would be to use other markers in addition anti-*p53* and CEA to select patients for investigations. The cost-effectiveness of these immunological-targeted strategies for general population screening, high risk population screening or post-operative surveillance requires further evaluation.

Anti-p53 Auto-antibody and monitoring for recurrence or metastases

Anti-*p53* auto-antibody may have its most promising role in post-operative monitoring for disease recurrence or distant metastases. Several, but not all, studies have demonstrated that anti-*p53* reflects tumour load, with increasing serum titres corresponding with disease recurrence/progression and decreased titres following surgery/chemotherapy[81,88,120]. Lechpammer *et al*[88] produced the most convincing series demonstrating clear decreases with post-surgery and during chemotherapy. More importantly, increases, especially during chemotherapy, predated clinical diagnosis of recurrence. Smaller subset analysis in other studies has also demonstrated fluctuations in serum titres with disease load. Similar fluctuations with resection and radiotherapy have been reported in oral, oesophageal, lung, ovarian and breast cancer[125-127].

In almost all cases, the anti-*p53* auto-antibody persists but at a much lower level. Only one study has reported complete absence of the anti-*p53* auto-antibody in a series of patients with superficial (mucosal and submucosal) CRC treated with endoscopic resection[98]. This may be because the early stage CRC had a smaller mutant *p53* load which may not have adequately stimulated the humoral system to produce a prolonged immune response following CRC removal. The other studies had more advanced CRC where there would have been prolonged antigen exposure to the humoral system[81,88,98,128].

This cost efficacy of serial anti-*p53* auto-antibody for surveillance must be considered in the light of only 20%-30% prevalence at presentation and subsequent sero-conversion (Table 5). Assuming 1% future sero-conversion and 3-monthly serum measurements for 3 years as per ASCO recommendations, this would result in 20-30 initial positives at diagnosis; and an additional 1 positive over the subsequent 3 years. This results in an initial yield 20-30 positives followed by only 1 positive out of 960 samples over next 3 years (remaining 80 patients × 4 samples per year × 3 years). We then consider this 1 positive sero-conversions out of 960 samples may not alter treatment as serum measurements may predate clinical evidence of disease, and treatment cannot be offered based anti-*p53* auto-antibody titres alone.

An alternative more cost-effective strategy of screening would be to screen all patients for anti-*p53* auto-antibody at diagnosis with further serial measurements only in patients sero-positive at diagnosis. Post-operative patients with rising titres could be selected for expedited investigations and thus increase diagnostic yield, compared to current blanket strategy of routine investigations for surveillance at fixed time intervals. Preliminary studies in small groups using tumour marker panel (CEA, TPA, CA19-9 and CA72.4) demonstrated 81% sensitivity for recurrence with mean lead times of 5.3 mo prior to radiological confirmation of recurrence[124]. A cost efficacy study would be required to ascertain the ability of anti-*p53* auto-antibody as part of a tumour marker panel to guide post-operative surveillance, improve resource allocation and prolong survival.

Anti-p53 auto-antibody and prognosis in CRC

p53 mutations have been associated with poor prognosis, possibly in part due to chemo-resistance against *p53*-dependant chemotherapy (*e.g.,* 5-fluorouracil) but reports of its prognostic significance are inconsistent[90,129]. As the anti-*p53* auto-antibody response has been associated with *p53* mutations and serum testing is easier than DNA sequencing, studies have focused on using anti-*p53* auto-antibody to predict prognosis. The majority of studies report that anti-*p53* auto-antibody response has no independent prognostic value. This was confirmed in the study with the longest follow-up which reported CRC stage, but not anti-*p53* auto-antibody, to be an independent prognostic marker in multivariate analysis[130], and also by the study with the second longest follow-up but larger sample size[85] (Table 6).

Four studies report an adverse prognostic significance but in 3 of these, the prognostic significance was in selective univariate analysis where anti-*p53* was associated with advanced stage, and prognostic significance was lost when stage was incorporated in multivariate analysis[112,131,132]. The fourth, and only study, to report anti-*p53* auto-antibody as an independent prognostic indicator in multivariate analysis strongly associated anti-*p53* auto-antibody with Dukes' D to an extent that median survival of anti-*p53* positive patients was extremely low (20 mo) compared to other studies reporting median survival up

Table 5 Anti-*p53* auto-antibody and sero-conversion in colorectal cancer

Ref.	Patients, method	Follow-up	Findings
Müller *et al*[123]	303 patients, 197 colon, 46 rectal	Median 6 mo	All cancers: 3.6% (11/303) sero(-)→ (+); 3.6% (11/303) sero(+)→ (-); Total 7.2% (22/303) sero-conversion. Colon cancer: 3% (4/137) sero(-)→ (+); 3.6% (5/137) sero(+)→ (-); Total 6.6% (9/137) sero-conversion. Rectal cancer: 6.5% (2/31) sero(-)→ (+); 3.2% (2/31) sero(+)→ (-); Total 12.9% (4/31) sero-conversion
Lechpammer *et al*[88]	Immunoblot 32 , ELISA (Oncogene, Research Products, Cambridge, United States)	Up to 20 wk; 8 patients-48 wk	Non-significant decrease at 4 wk (pre-first cycle chemo) and significant decrease at 12 wk post-surgery Significant decreases during chemotherapy and 2 patients with anti-*p53* increase at 12 wk (during chemotherapy) developed recurrence 8 patients with extended follow-up: 7/8 had decreased anti-*p53* with no recurrence. 1/8 anti-*p53* decrease post-surgery/chemotherapy but increased at 12 wk corresponding with liver metastases. Anti-*p53* fluctuates in response to tumour load but does not disappear. Anti-*p53* levels reflects tumour load even during chemotherapy
Takeda *et al*[174]	30 CUR A, 5 CUR B, 5 CUR C, anti-*p53* EIA, Pharmacell	Median 26 mo (13-144)	CUR A (n = 30): 28/30 sero(+)→(-) in 6 mo; 2 no sero-conversion: 1 recurrence CUR B (n = 5): 2 sero(+)→(-) no recurrence. 3 no sero-conversion, 2 had metastases CUR C: No sero-conversion Correlation between post-operative negative conversion and operative curability
Takeda *et al*[98]	17 mucosal/submucosal, ELISA (anti-*p53* EIA, Pharmacell, France)	Up to 2 years	94%, 16/17 sero(+)→(-) within 3 wk post-surgery No recurrences as early stage tumours and hence not able to comment on anti-*p53* and recurrence rates
Polge *et al*[128]	10, ELISA (Dianova, Hamburg, Germany)	Up to 6 mo	8 followed-up: 5/8 remained sero(+) post-operatively. All developed metastases 3/8 decreased anti-*p53* titres. No metastases or recurrence. Anti-*p53* titres decreased within 1 mo of surgery/chemotherapy but no sero-conversion to anti-*p53*(-)
Angelopoulou *et al*[81]	6, "In house" immunofluorometric assay	Up to 17 mo	Anti *p53* decreases with surgery/chemotherapy but persists at low levels Anti-*p53* increases with recurrence Anti-*p53* reflects tumour load more sensitively than CEA (n = 5) and in non-CEA producing tumour (n = 1)
Hammel *et al*[175]	12, "In house" ELISA	Up to 20 mo	Anti-*p53* in 5/8 patients decrease by > 25% within 1 mo. At 1 year, 3 with normal anti-*p53* levels and 3 with substantial decrease in anti-*p53* remain disease-free 2 patients with post-operative increased anti-*p53*: 1 developed recurrence and 1 developed metastases Anti-*p53* decreased again following surgery in both patients. CEA and CA19-9 were normal in both cases

Sero(-): Sero-negative; Sero(+): Sero-positive; CUR A: No residual tumour macroscopically; CUR B: No residual tumour but not as evaluable as CUR A; CUR C: Definite residual tumour; CEA: Carcino-embryonic antigen.

to 60 mo and 5-year survival > 50%[89,123,130]. Remarkably, anti-*p53* auto-antibody prognostic significance was even weaker than CA19-9, a pancreatic tumour marker considered unsuitable for pancreatic cancer screening by ASCO[112,122]. The results of this study are hard to credit. As such, anti-*p53* auto-antibody has no independent prognostic value.

CONCLUSION

The anti-*p53* auto-antibody response is the end-point of a complex multi-factorial humoral response to the accumulation of p53 protein which is a product mainly of *p53* gene mutation, but also mutation of *p53* regulators and non-mutative pathways. Anti-*p53* auto-antibody has low (13%-32%) sensitivity in CRC but is nearly 100% specific for malignancy. The auto-antibody frequency may increase with early local invasion or late nodal progression but is not sufficiently consistent to form a separate stage classification. There may be a promising future role of anti-*p53* auto-antibody in screening and monitoring for disease recurrence. The characteristics of the immunoglobulin and the benefits of serum testing provide a promising role in guiding the radiological and endoscopic screening of high risk populations in conjunction with other current tumour markers. The most promising future focus of anti-*p53* auto-antibody lies in being part of a bio-molecular panel of tumour markers to guide endoscopic and radiological screening in general population and high-risk population screening; and in post-operative

Table 6 Anti-p53 auto-antibody and prognosis in colorectal cancer

Ref.	*n* (%)	Follow-up	Findings
Suppiah *et al*[130]	20/92 (21.7)	Median 97 mo	No difference in overall survival (62 mo *vs* 60 mo) or disease-free survival (73 mo *vs* 82 mo)
Müller *et al*[123]	70/243 (28.8)	5-year trial protocol	No survival difference with anti-*p53* in CRC and other cancers. Trend towards decreased survival in anti-*p53* positive patients with HCC and breast carcinoma
Tang *et al*[89]	130/998 (13)	Recruitment 1995-2000	Anti-*p53* associated with decreased survival in univariate analysis but not multivariate analysis. Anti-*p53* associated with advanced nodal disease (Stage N2→N3) and metastases (M1)
Chang *et al*[85]	147/167 (28)	Median 36.3 mo (22-85)	*p53* mutation associated with poor differentiation and advanced stage. Multivariate analysis shows *p53* mutation most significant survival predictor, followed by CRC stage. No prognostic significance of p53 protein expression or anti-*p53*
Shiota *et al*[112]	18/71 (25)	Not stated	Anti-*p53* associated with shorter overall survival (20 mo *vs* 56 mo) but highly significant association with metastases (M1). Cox regression showed prognostic significance with liver metastases, TNM stage, Dukes stage, Ca19-9 and anti-*p53* (in that order)
Kressner *et al*[131]	59/184 (32.1)	Median 6 years	Anti-*p53* associated with decreased survival in univariate, but not multivariate analysis. Anti-*p53* is independent prognostic indicator in Dukes' A-C with curative surgery (*i.e.*, when metastases excluded)
Houbiers *et al*[132]	65/255 (25.5)	36 mo	Anti-*p53* associated with reduced overall (75% *vs* 88%) and disease-free survival (56% *vs* 64%) at 3 years in subgroup analysis of Dukes' A and B1. No difference in overall survival (61% *vs* 68%) or disease-free survival (51% *vs* 58%) when all stages included

CRC: Colorectal cancer; HCC: Hepatocellular carcinoma.

cancer surveillance to guide earlier detection of cancer and cancer-recurrence; and finally with more significant impact on cost-efficacy and survival.

Abstract

Among somatic stem cells, those residing in the intestine represent a fascinating and poorly explored research field. Particularly, somatic stem cells reside in the small intestine at the level of the crypt base, in a constant balance between self-renewal and differentiation. Aim of the present review is to delve into the mechanisms that regulate the delicate equilibrium through which intestinal stem cells orchestrate intestinal architecture. To this aim, special focus will be addressed to identify the integrating signals from the surrounding niche, supporting a model whereby distinct cell populations facilitate homeostatic *vs* injury-induced regeneration.

Key words: Intestinal stem cells; Organoids; Intestinal regeneration; Lgr5; Niche

Core tip: Among somatic stem cells, those residing in the intestine represent a fascinating and poorly explored research field. INTRODUCTION

In an adult organism, stem cells are characterized by their ability to generate multiple differentiated cell types while maintaining their capacity for long-term self-renewal[1,2]. These are generally known as "adult" or "somatic" stem cells, including all stem cells residing in adult organs, regardless of the age of the individual. These include mesenchymal stem cells[3-7], residing in the connective stroma of most organs, and haematopoietic stem cells[8,9] among the best known and characterized, that are already being tested in clinical trials[10-14].

The amazing renewal capacity of the intestinal epithelium[1] has made this organ an attractive site to study stem-cell regulation. The intestinal tract is anatomically subdivided into the small intestine and large intestine. The inner mucosal surface, composed by an absorptive and secretory epithelium, is folded into repeated units comprising finger-like invaginations (called crypts of Lieberkühn) associated with numerous protrusions (villi), which increase the surface area, allowing efficient absorption of nutrients from the bowel lumen[2].

In normal homeostasis, the specialized differentiated cell types that orchestrate the uptake of nutrients into the body, are routinely and rapidly turned over. In fact, the intestinal epithelium is the most rapidly self-renewing tissue in the human body, with a 3-5 d turnover rate[2]. It is widely accepted that this complex process is regulated, *via* a highly regulated process of self-renewal, by a population of multipotent stem cells, residing within the bottom of the crypt namely the intestinal stem cells (ISCs)[15-19].

The number and location of these cells are still debated. Clonal analysis has demonstrated the existence of multiple stem cells in each crypt[20], with an estimated number in the 4-6 cells per crypt range[21]. ISCs have the properties of self-renewing and generating rapidly dividing transit-amplifying (TA) daughter cells, *via* asymmetric cell division[22]. TA cells undergo rapid cell division and migrate upwards into the villus. During their migration, TA cells start differentiating and finally localize at the surface of the villus epithelium as either mature absorptive enterocytes, which represent the main cell type, or mucous secreting goblet cells, or hormone-producing enteroendocrine cells[22]. Upon completing their life cycle, TA die and are discarded into the lumen[23,24].

A distinct cell type, the Paneth cell, evades this upward migration program, completing the differentiation at the base of the crypt, where it start producing lysozyme, maintaining the sterile environment of the crypt, and regulating the stem cell compartment[25-27].

Converging evidence suggests the existence of two distinct populations of intestinal stem cells: one that remains quiescent for a long time and one that actively proliferate[28]. The actively dividing ISCs provide to the baseline regeneration, whereas quiescent stem cells represent a reserve subpopulation that copes to injuries. These two subpopulations are located in adjacent sites within the crypt and are probably maintained by specific signals from the surrounding niche. Nonetheless, the precise identity of the ISCs is still a matter of debate. Two alternative models are currently proposed in the literature: the label-retaining cells (LRC) + 4 model, which identifies the quiescent stem cells, and the crypt base columnar (CBC) cells model, which identifies the actively cycling stem cells.

According to the LRC+4 model, the ISCs should be located specifically at the +4 position from the bottom of the intestinal crypt region, precisely at the origin of the migratory epithelial cell column[29]. This prediction was supported by Potten *et al*[30], who showed that cells most commonly found in this position, are characteristically label-retaining and extremely sensitive to X- and γ-radiation, two features ascribed to stem cells. Furthermore, the expression of Bmi1, a gene thought to be involved in stem cell maintenance, was shown to be elevated in the +4 cells[31]. Alternatively, the CBC cell model is based on a series of electron microscopy studies on the crypts of the small intestine, showing slender, immature, cycling cells interspersed between Paneth cells at positions 1-4, hence termed crypt base columnar cells. To support the hypothesis of CBC as the ISCs, mutagenesis studies demonstrated that 90% of the crypts, that contained a mixed population of mutant cells of different epithelial lineages, also contained mutant CBC cells, indicating the CBC cells as the common source of these different lineages[32]. Further studies, based on targeted lineage tracing strategies, have definitively identified the CBC as the intestinal stem cells, and have revealed the strategy by which the balance between proliferation and differentiation is maintained[33]. Taken together, these studies suggested that ISCs operate within a complex and dynamic environment, in which stochastic cell loss is compensated by the proliferation of neighboring stem cells.

INTESTINAL STEM CELLS MARKERS

The crypt stem cells responsible for the renewal capacity of the intestinal epithelium, represent a minority of the whole intestinal population, therefore, their identification is extremely troublesome[14]. Indeed, until relatively recently, ISCs could be identified only by indirect measurements. The recent discovery of specific ISC markers has allowed their isolation and paved the way towards a clearer understanding of their biology and role in tissue homeostasis, repair, and cancer[14].

Among the various ISCs markers, the best characterized one is the leucine rich-repeat containing G-protein coupled receptor (Lgr5), a Wnt-target gene that expressed by the cycling crypt base columnar cells, interspersed between Paneth cells[22]. *Lgr5* encodes an orphan G-protein-coupled receptor, characterized by a large leucine-rich extracellular domain[34].

Barker and co-workers demonstrated that CBC cells are capable of long-term maintenance and support the epithelium self-renewal, using the lineage tracing technique (*i.e.*, introducing permanent genetic marker into candidate stem cell genes *in situ*, thus allowing the visualization of the modified stem cells and their progeny over time)[34]. One of the major advantages of *in vivo* lineage tracing, compared to transplantation-based methods, is the lack of a physical manipulation of the candidate stem cell, so that ISCs are studied in their physiological niche[34]. In particular, the visualization and isolation of putative ISCs was obtained by targeting the *Lgr5/Gpr49* gene locus by knock-in of a dual expression cassette encoding enhanced green fluorescent protein (EGFP) and CreERT2. This resulted in the tamoxifen-induced expression of EGFP in the Lgr5+ fraction, which allowed the *in vivo* lineage tracing when combined with inducible reporter strains such as R26RLacZ[34]. This study hence showed that Lgr5 expression was confined to CBCs, and that these cells give rise to the variety of epithelial cells present in crypts, proving that CBCs function as ISCs as well[34].

In addition, it has been demonstrated that Lgr5+ cells form self-renewing epithelial organoids in *ex vivo* culture assays, resembling the *in vivo* structure and composition

of crypt/villus epithelial units. It is also worth noticing that cells expressing low, if any, Lgr5 were unable to produce organoids[35]. Gene expression analysis of purified Lgr5+ stem cells, indicated that they express additional specific markers, such as *Olfm4* and the Achaete scutelike 2 (*Ascl2*)[36]. Ascl2 is a basic helix-loop-helix transcription factor[19]; its expression in the intestinal epithelium is regulated by the Wnt pathway and is restricted to Lgr5+ stem cells. Ascl2 deletion results in the complete loss of Lgr5+ ISCs, whereas transgenic *Ascl2* expression induces crypt hyperplasia[36].

Moreover, several lines of evidence have demonstrated the existence of another putative intestinal stem cells marker, the Polycomb family member Bmi1[31]. The Polycomb family plays a key role in the development and in the regulation of progenitor self-renewal in several tissues, including the nervous system[37], the retina[38] and hematopoietic organs[39]. *In vivo* lineage tracing technique, showed that Bmi1+ cells are mainly located at the +4 position in the crypts of the small intestine, contributing to the long-term maintenance of all its epithelial cell types[31]. In addition, the selective ablation of the Bmi1+ population led to a disorganization of the intestinal mucosa, resulting in the absence of the crypts[31]. Unexpectedly, Bmi1 transgenic expression was restricted only to a minority of the crypts in the proximal small intestine, while being completely absent in the distal tract[31]. This could be possibly due to the existence of Bmi1-negative ISC populations in other regions of the intestine, or, perhaps, to an inaccurate reporting of endogenous Bmi1 expression, as a result of the variegated transgene activity, frequently observed in the intestine. Interestingly, microarray analysis showed that sorted Lgr5+ cells express Bmi1, raising the question whether the two markers really characterize independent stem cells populations. Yan *et al*[40] clarified this issue by demonstrating that Bmi1 and Lgr5 mark two functionally distinct ISCs *in vivo*. Lgr5 identifies actively cycling ISCs that are sensitive to Wnt modulation, involved in homeostatic regeneration and markedly ablated by irradiation, *i.e.*, the CBC cells. Conversely, Bmi1 is expressed by quiescent ISCs insensitive to Wnt modulations, that contribute partly to homeostatic regeneration, and are resistant to radiation injury, namely the LRC stem cells[40].

Another interesting molecule in the scenario of ISCs putative markers, is the CD133/Prominin 1(Prom1), originally discovered as novel glycoprotein expressed on neural[41] and hematopoietic stem cells[42,43]. More recently, CD133 has been described as marker of epithelial stem/progenitor cells in human kidney tubules[44] and in the prostate[45]. In the study by Zhu *et al*[46], a knock-in allele was used that integrated a CreERT2-IRES-nLacZ cassette at the first ATG codon of Prom1 (Prom1C-L). This allowed demonstrating a wide expression pattern for Prom1 in the colon; on the other hand, the expression in the small intestine, appeared to be restricted to the crypt base, overlapping with the Lgr5+ CBC cells[46] The Prom1+ cells were self-renewing, multipotent adult stem cells. By contrast with these findings, Snippert *et al*[47] reported that Prom 1 expression occurred in Lgr5+ stem cells as well as in their TA progenitors. A possible explanation for this discrepancy may reside in the different sensitivity of detection methods used in the two studies.

The RNA-binding protein Musashi 1 (Msi1), a regulator of asymmetric cell division[48], is also involved in stem cell maintenance[49,50]. Particularly, in neural stem cells Msi1 is able to maintain stemness properties through Notch pathway activation[51]. Independent immunoistochemical and *in situ* hybridization analyses, demonstrated that, Msi1 is expressed in the CBC cells immediately above the Paneth cells[52-54].

Moreover, Msi1 overexpression in the intestine increases both Wnt and Notch pathways, and induces the upregulation of Lgr5 and Bmi1[55]. Interestingly, although Msi1 is expressed in putative ISCs, in knockout mice lacking this marker, no defects in the development of the intestine are detected[56]. Taken together, these observations demonstrated that Msi1 is not a specific ISCs marker, but is expressed in both ISCs and in their early progeny[57].

To sum up, different markers point to distinct stem cells within the crypt: the marker Lgr5 points to the crypt base columnar cells located in between the Paneth cells at the crypt bottom[22], whereas the markers BMI1 identify the +4 position in the crypt, just above the Paneth cells[31]. The existence and interdependency of these different types of ISCs remain a matter of debate.

STEM CELL NICHE: HOMEOSTASIS AND MORPHOGENESIS SIGNALS

A key role in the dynamics of ISCs is ascribed to the niche, a complex and dynamic setting, that adapts in response to environmental stimuli and provides the cells essential signals, including the morphogenetic pathways, such as Wnt, Notch, bone morphogenetic proteins (BMPs) and Hedgehog[21,58-63]. The microenvironment of the niche surrounding ISCs features extracellular matrix, neural cells, lymphocytes, macrophages, endothelial cells, fibroblasts, smooth muscle cells, and myofibroblasts, that generate signals able to regulate stem cells properties and behavior[64-67].

A wide range of evidence indicates that the Wnt pathway has a crucial role in intestinal proliferation and ISC maintenance[68-74].

The Wnt pathway molecules are evolutionary conserved intracellular signaling molecules which regulate cellular fate in the crypt-villus axis in normal gut epithelium, and are implicated in stem cells self-renewal[75]. Indeed, loss of Wnt signaling *in vivo* effectively blocks cell proliferation in the intestinal crypts, destroying the epithelium[76]. Moreover, when the Wnt secretion inhibitor (IWP1) was added to organoids, the LacZ signal derived from Lgr5+ cells, was completely lost, and the proliferation was inhibited; this inhibition could be overcome administrating exogenous Wnt3A[76]. Recent evidences have

also demonstrated that Paneth cells residing next to ISCs are crucial for their maintenance and serve as the stem cell niche[77]. Paneth cells are known to secrete a variety of bactericidal products, such as cryptidins/defensins and lysozyme, epidermal growth factor (EGF), transforming growth factor β (TGF-β), and represent the main sources of Wnt3a. Indeed, the ablation of Paneth cells, decreases the number of ISCs in the crypt[78] confirming that an active Wnt signal is crucial for ISC maintenance[79].

A Wnt signaling gradient exists along the crypt-villus axis. When cells migrate away from the Wnt source at the base of the crypt, they progressively lose their proliferative capacity and differentiate. The activity of the Wnt pathway, in conjunction with other pathways such as Notch and bone morphogenetic protein (BMP), is vital for the proper organization of the colic epithelium.

In the small intestine, Notch activity determines lineage differentiation between enterocytes and secretory cell differentiation; indeed, Notch inhibition results in an increase of goblet cells, while its activation results in goblet cells depletion[78]. Recent data support the idea that Notch promotes proliferation when Wnt activity is high, while induces enterocyte differentiation when Wnt activity decreases at the top of the crypt[29]. Given that Notch receptors are membrane-bound, it would appear that only the neighboring Paneth cells can maintain active Notch signaling in Lgr5 stem cells.

BMP belongs to a family of ligands which comprises BMP and TGF-β family members, acting through the SMAD intracellular signaling cascade[80-82].

In the intestine, BMP2 and BMP3, are expressed by mesenchymal cells and are able to arrest proliferation at the crypt-villus edge, rather than promoting differentiation[29].

In fact, both mice lacking the BMP receptor (Bmpr1a), and mice overexpressing the BMP inhibitor noggin, present hyperproliferation and crypt fission[80].

Under physiological conditions, the amount of stem cells within the niche remains constant, thus these processes need to be highly regulated, probably through negative feedback mechanisms[40]. In fact, stem cells may divide: (1) asymmetrically, giving rise to another stem cell, which remains in the niche, and to a daughter cell which form a progenitor cell, that migrates upwards in the crypt and differentiate into a mature element; and (2) symmetrically, giving rise to two daughter stem cells, or two daughter non-stem progenitor cells, the latter phenomenon leading to stem cells exhaustion[75].

Overall, the current scenario indicates a niche organized into a complex network of morphogenetic signals, each crucial for ISCs and crypt maintenance[28].

STEM CELLS DERIVED ORGANOIDS: THERAPEUTIC APPLICATIONS FOR GASTROINTESTINAL DISEASES

Rapid progress in the field of intestinal stem cell biology now lends promise to the application of adult stem cell therapy in gastroenterology. The apparently unlimited scale at which these stem cells can be expanded *in vitro* offers particularly exciting therapeutic possibilities[83-85].

In particular, organoids, derived from *in vitro* expansion of a single adult colonic stem cell, can be used to repair damaged colon tissue.

Indeed, as discussed above, intestinal organoid cultures, with a gut like structure, and containing all epithelial cell types, can be derived from single Lgr5+ sorted stem cells[86]; the resulting organoids can be expanded efficiently and over long periods of time, without losing tissue identity. To date, protocols for the efficient generation of organoids from stomach, human small bowel and colon have been developed[87-90].

Interestingly, the growth factors used to supplement the culture medium are the natural growth factors to which the stem cells are exposed *in vivo*, suggesting a high clinical-grade biocompatibility of this approach[87]. Moreover, no genetic manipulation required, making the entire procedure extremely safe.

As a first step toward the development of stem cell transplantation, it has been shown that, using the colonic organoids culture system, significant amounts of tissue can be grown *in vitro* from a single adult colon stem cell[91,92].

Colon organoids were reintroduced into superficially damaged recipient colons of immunocompromised ($rag2^{-/-}$) mice, pretreated with dextran sulphate sodium (DSS), which induces superficial mucosal lesions. The engrafted organoids RFP+, were able to readily integrate into the existing epithelium (RFP-), and generated histologically and functionally normal crypts containing all differentiated cell types, covering the area that lacked epithelium in recipient mice. At 4 wk after transplantation, the donor-derived cells constituted a single-layered epithelium, which formed self-renewing crypts that were functionally and histologically normal. In long term studies, carried out at 25 wk after transplantation, the grafts still contributed to the epithelium without any sign of adenomatous or dysplastic transformation[91,93].

Moreover, transplanted mice displayed a significant lower weight loss than control mice[91]. These data showed the feasibility of colon stem-cell therapy based on the *in vitro* expansion of a single adult colonic stem cell; graft rejection can be managed by standard approaches, *i.e.*, by leukocyte antigens matching of donor and acceptor and by immunosuppressive therapy, as currently used for organ transplantation.

Protocols have also been developed to expand human small intestine and colon organoids from small biopsies[94]. As a first application, Cleavers and his collaborators have transplanted the organoid-derived small intestinal epithelium into the bowel of patients affected by the microvillus inclusion disease[48]. This is a rare hereditary defect of the enterocyte brush border resulting in insufficient nutrients' assimilation[95-97], requiring colon transplantation as the unique therapeutic strategy. Intes-

tinal organoids technology may allow a novel venue into gene therapy approaches, that involves the introduction of DNA sequences into the genomes of cells of the pertinent patient. The achievement of a safe gene transfer represents the major hurdle, which has largely hampered the introduction of gene therapy into the clinic despite three decades of intensive efforts. On this regard, retrovirus- and lentivirus-mediated gene transfer has already been proven to be feasible in organoids systems[98,99].

These viral vectors are though associated to documented risk for insertional mutagenesis. As organoids can be grown from single sorted stem cells, one could envisage an approach in which individual stem cells are analyzed after integration of the recombinant DNA sequences. Only stem cells with safe integrations could then be expanded clonally for subsequent transplantation.

Overall, adult stem-cell therapy holds promise for the treatment of gastrointestinal diseases, using tissues "harvested" from a single living donor, overcoming the difficulties of the organ transplantation, that is still limited by the availability of donor.

Clinical application of this protocol still waits the translation of the technical procedures to the good clinical practice standards, to generate the adequate amounts of tissue to treat human subjects, and the development of efficient transplantation approaches.

CONCLUSION

ISCs could be reasonably considered the key players that orchestrate the high-rate regenerative capacity of the intestinal epithelium. The understanding of the interplay between the ISCs and their niche, led by a complex molecular network, will pave the way for the future development ISCs based therapy especially to the application in gastroenterology.

Abstract

AIM: To evaluate the prognostic factors and efficacy of hepatic arterial infusion chemotherapy in hepatocellular carcinoma with portal vein tumor thrombosis.

METHODS: Fifty hepatocellular carcinoma (HCC) patients with portal vein tumor thrombosis (PVTT) were treated using hepatic arterial infusion chemotherapy (HAIC) *via* a subcutaneously implanted port. The epirubicin-cisplatin-5-fluorouracil (ECF) chemotherapeutic regimen consisted of 35 mg/m^2 epirubicin on day 1, 60 mg/m^2 cisplatin for 2 h on day 2, and 500 mg/m^2 5-fluorouracil for 5 h on days 1-3. The treatments were repeated every 3 or 4 wk.

RESULTS: Three (6%) of the 50 patients achieved a complete response (CR), 13 (26%) showed partial responses (PR), and 22 (44%) had stable disease (SD). The median survival and time to progression were 7 and 2 mo, respectively. After 2 cycles of HAIC, CR was achieved in 1 patient (2%), PR in 10 patients (20%) and SD in 26 patients (52%). Significant pre-treatment prognostic factors were a tumor volume of < 400 cm^3 (P = 0.01) and normal levels of protein induced by vitamin K absence or antagonist (PIVKA)-Ⅱ (P = 0.022). After 2 cycles of treatment, disease control (CR + PR + SD) (P = 0.001), PVTT response (P = 0.003) and α-fetoprotein reduction of over 50% (P = 0.02) were independent factors for survival. Objective response (CR + PR), disease control, PVTT response, and combination therapy during the HAIC were also significant prognostic factors. Adverse events were tolerable and successfully managed.

CONCLUSION: HAIC may be an effective treatment modality for advanced HCC with PVTT in patients with tumors < 400 cm^3 and good prognostic factors.

Key words: Hepatocellular carcinoma; Hepatic arterial infusion chemotherapy; Portal vein tumor thrombosis

Core tip: The aim of this study was to investigate the prognostic factors of hepatic arterial infusion chemotherapy in advanced hepatocellular carcinoma patients with portal vein tumor thrombosis. The primary findings of this study were as follows: (1) The median survival and time to progression were 7 and 2 mo, respectively; (2) A tumor volume of < 400 cm^3 and protein induced by vitamin K absence or antagonist-Ⅱ were independent pre-treatment prognostic factors; (3) Disease control and ⩾ 50% tumor marker reduction were significant prognostic factors after the second cycle of hepatic arterial infusion chemotherapy (HAIC); and (4) Objective tumor response, disease control and portal vein tumor thrombosis response were independent post-treatment prognostic factors at the end of the HAIC.

Hepatic arterial infusion chemotherapy in hepatocellular carcinoma with portal vein tumor thrombosis. *World J Gastroenterol* 2013; 19(29): 4679-4688 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i29/4679.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i29.4679

INTRODUCTION

Hepatocellular carcinoma (HCC) is the sixth most common cancer globally and the third most common cause of cancer mortality[1]. Surveillance of high-risk patients facilitates the early diagnosis of HCC[2]. However, because many patients are diagnosed at intermediate or advanced stages, only 30% of patients benefit from curative therapies such as resection, transplantation, or percutaneous ablation[3]. For patients with vascular invasion and/or extrahepatic spread, *i.e.,* whose tumors were classified as advanced stage according to the Barcelona Clinic Liver Cancer (BCLC) staging system, the multi-kinase inhibitor sorafenib is recommended[4]. In recent randomized controlled trials, sorafenib significantly increased patient survival[5,6]. However, contrary to our expectations, the survival and therapeutic advantages of sorafenib are modest, and the current cost of the drug precludes sorafenib from becoming a more generalized treatment tool for advanced HCC[7]. Systemic chemotherapy also has limited utility in treating HCC due to frequent toxicity and is not associated with improved survival[8,9]. Therefore, alternatives to sorafenib and systemic chemotherapy are often required for the treatment of advanced HCC, and hepatic arterial infusion chemotherapy (HAIC) could be an alternative modality.

HAIC using an implantable port system is theoretically more effective against HCC than systemic chemotherapy. HAIC enables anti-cancer agents to be delivered locally at high concentrations to hypervascular tumors, thereby keeping systemic concentrations of chemotherapeutic agents low due to the first-pass effect[10]. Many studies using HAIC have reported that it is a useful modality for patients with advanced HCC[10-14]. However, there are limited data defining the clinical factors predicting its efficacy. In this study, we investigated the efficacy and predictive factors of HAIC in patients with advanced HCC with portal vein tumor thrombus (PVTT) using the HAIC regimen, which was composed of epirubicin, cisplatin, and 5-fluorouracil.

MATERIALS AND METHODS

Patients

Between March 2009 and January 2012, 68 consecutive patients with advanced HCC underwent HAIC *via* an implantable port system with epirubicin, cisplatin and 5-fluorouracil (5-FU) in Seoul St. Mary Hospital, Seoul, South Korea. The patients were refractory to previous treatments or not amenable to surgery or locoregional therapies such as ethanol injection, radiofrequency ablation, or transcatheter arterial chemoembolization due to metastasis or PVTT. HCC was diagnosed either histologically or using typical radiologic findings of HCC on two dynamic imaging examinations or one dynamic technique with an elevated serum α-fetoprotein (AFP) level ≥ 200 ng/mL[15,16]. Among these 68 patients, 50 patients who had PVTT and received more than two cycles of HAIC were enrolled in this study. All tumor thromboses were radiologically confirmed in the main trunk or in the first or second branch of the portal vein. Additional inclusion criteria were a white blood cell count ≥ 3000 cells/mm^3 or an absolute neutrophil count ≥ 1000 cells/mm^3 and a platelet count ≥ 50000 cells/mm^3. Other eligibility criteria included the following: ages 18-75 years, Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 1, and a Child-Pugh score ≤ 7. Patients with extrahepatic metastasis were also included in this study because extrahepatic metastasis is common in HCC patients with a large tumor and PVTT due to high AFP levels and large tumor volumes. Exclusion criteria included another concurrent malignancy or other underlying serious medical condition such as renal or cardiopulmonary insufficiency. HCC was staged using the BCLC, modified Union for International Cancer Control (UICC) and American Joint Committee on Cancer (AJCC) staging systems. Tumor volume was measured by a single radiologist using commercially available imaging software (Pinnacle^3 with AcQSim^3 v. 8.0, Philips, Fitchburg, WI, United States) and the summation-of-areas technique with a 5-mm reconstruction thickness.

Implantation of the arterial port system

After skin preparation and local anesthetic injection, the right common femoral artery was punctured using the Seldinger technique. The superior mesenteric and celiac arteries were selected under fluoroscopic guidance. After the selective angiographies were performed, the right gastric and gastroduodenal arteries were embolized with multiple microcoils to prevent reflux of the cytotoxic drug to the stomach and duodenum. After performing a follow-up celiac arteriography, a catheter was inserted and localized to the proper hepatic artery. The skin and right inguinal region was incised, and the subcutaneous pocket was prepared *via* dissection. The peripheral end of the catheter was connected to the infusion port, and the port device was implanted in a subcutaneous pocket in the right or left iliac fossa. To prevent the occlusion of the catheter, 10 mL of saline mixed with 10000 units of heparin were locked into the port after each cycle of chemotherapy. Hepatic angiography *via* the port system was performed every two cycles of treatment.

Chemotherapeutic regimen and additional therapy

The Epirubicin-Cisplatin-5-fluorouracil (ECF) chemotherapeutic regimen included 35 mg/m^2 epirubicin on day 1, 60 mg/m^2 cisplatin for 2 h on day 2, and 500 mg/m^2 5-FU for 5 h on days 1-3. Intravenous hydration was

performed prior to cisplatin infusion to prevent nephrotoxicity, and all patients were given prophylactic antiemetic treatment comprised of 5-hydroxytryptamine-3 antagonists. The treatment cycles were repeated every 3 or 4 wk until disease progression, unacceptable toxicity, or patient refusal to continue. The doses of chemotherapeutic agents or treatment intervals were adjusted at every treatment cycle depending on hepatic dysfunction or significant toxicity. The dose of subsequent treatment was reduced by 25% when repeated grade 2 or grade 3/4 toxicity occurred during the preceding cycle[14].

During or after the HAIC treatment, additional therapies were performed as necessary, depending on the tumor responses to HAIC, performance status, and hepatic function. Additional treatment included targeted therapy with sorafenib, external radiation therapy, transarterial chemolipiodolization (TACL), systemic chemotherapy, local therapies such as radiofrequency ablation (RFA) or percutaneous ethanol injection (PEI), or surgical treatment.

Study assessment

The primary endpoints were an objective response rate [complete response (CR) + partial response (PR)] and disease control rate [objective response rate + stable disease (SD)]. Response evaluations were performed after two cycles and at the end of the HAIC treatment. The overall survival (OS) and time to progression (TTP) were evaluated secondarily. The treatment response was classified according to the modified Response Evaluation Criteria In Solid Tumors (mRECIST). The pretreatment evaluation included medical history, physical examination, laboratory tests [complete blood count, blood chemistry, virologic marker, serum AFP and proteins induced by vitamin K absence or antagonist (PIVKA)-Ⅱ], and imaging studies such as a computed tomography (CT) scan, magnetic resonance imaging (MRI) or positron emission tomography (PET) scan. During the treatment, toxicity assessment, laboratory tests, as well as chest and abdominal X-rays were repeated prior to each treatment cycle. CT scans were performed every two cycles or as needed to evaluate the tumor response or to confirm the disease progression. OS was defined as the time from the first treatment to death or the last follow-up visit, and TTP was the time from the first treatment to the radiologic progression. The patient's liver function was classified according to the scheme of Child-Pugh. AFP and PIVKA-Ⅱ reduction were calculated according to the formula [(baseline level-level after the second cycle)/(baseline level) × 100] in patients whose AFP was elevated above 20 ng/mL[17] and PIVKA-Ⅱ was elevated above 40 mAU/mL[18]. The treatment toxicity was assessed using the Common Terminology Criteria for Adverse Events (CTCAE) v. 4.0[19]. The PVTT response was evaluated using dynamic imaging. Response was defined as complete disappearance or at least a 30% decrease in the diameter of PVTT, and non-response was defined as any case that did not qualify for response.

Statistical analysis

The Kaplan-Meier methods and log-rank tests were used in the analysis of time-to-event variables, and a 95%CI for the median time to event were computed. Cox-proportional hazard regression models were used to determine the hazard ratios (HRs) of pre-treatment and post-treatment prognostic factors for survival. The variables with P values < 0.05 at univariate analysis were used as input variables in the multivariate model using the enter methods. In the multivariate analysis of post-treatment prognostic factors, hazard ratios were adjusted for the significant variables in the multivariate analysis of pre-treatment variables. For each covariate, the proportional hazard assumption was verified using a log minus log survival plot, and Cox-Snell residuals were used to evaluate the fit of the model. A plot of the estimated cumulative hazard rate versus Cox-Snell residuals followed a 45° line.

The χ^2-test or Fisher's exact test were used for the analysis of clinical characteristics and prognostic factors between the disease control group (CR + PR + SD) and the disease progression group [progressive disease (PD)]. Statistical significance was defined as a P value < 0.05. All data were analyzed using the SPSS v. 14.0 software (SPSS, Chicago, IL, United States).

RESULTS

Patients characteristics

The characteristics of the 50 study patients are shown in Table 1. The median age was 54 years (range, 37-74), and 78% of the patients were male. The most common etiology of underlying liver disease was chronic hepatitis B (78%), and 84% had a Child-Pugh classification of A. All patients were BCLC stage C due to PVTT and extrahepatic metastasis, and 30 patients (60%) had main PVTT (Vp4). Sixteen patients (32%) had extrahepatic metastasis at the initiation of HAIC. Twenty-four patients (48%) received previous treatment, and the most common previous treatment was TACL.

Treatment efficacy

The patients received a total of 289 cycles of HAIC with a median of five cycles (range 2-25 cycles). The response rates are shown in Table 2. After two cycles of HAIC, 11 patients (22%) showed an objective response, and 37 patients (74%) achieved successful disease control. Based on the best response during HAIC, the objective response rate was 32% and disease control rate was 76%.

In total, the median OS was 7 mo (95%CI: 5.5-8.5) and TTP was 2 mo (95%CI: 1.3-2.7), as shown in Figure 1. We assessed the OS according to the presence of objective response and disease control (Figure 2). The treatment responses were evaluated after the second cycle of HAIC and at the end of the HAIC treatment. Based on the best response during HAIC, the median OS was 24 mo (95%CI: 12.9-35.1) in the objective responder group, 5 mo (95%CI: 3.6-6.4) in the non-responder group (P < 0.001), 8 mo (95%CI: 2.6-13.4) in the disease control

group and 4 mo (95%CI: 2.9-5.1) in the progressive disease group ($P < 0.001$). Based on response after the second cycle of HAIC, the median OS was 17 mo (95%CI: 14.6-19.4) in the responder group and 7 mo (95%CI: 5.0-9.0) in the non-responder group ($P = 0.034$), 11 mo (95%CI: 6.7-15.3) in the disease control group and 5 mo (95%CI: 2.9-5.1) in the progressive disease group ($P < 0.001$).

Prognostic factors of survival

The prognostic factors affecting patient survival were analyzed by examining the pre-treatment and post-treatment parameters shown in Tables 3 and 4. Univariate analysis revealed that four pre-treatment prognostic factors were significantly associated with survival: tumor volume (< 400 cm^3), Child-Pugh score, pre-treatment PIVKA-Ⅱ level, and AJCC stage. Based on multivariate analysis, a tumor volume of < 400 cm^3 [$P = 0.01$, HR = 2.520 (95%CI: 1.252-5.072)] and PIVKA-Ⅱ [$P = 0.022$, HR = 3.121 (95%CI: 1.177-8.274)] were independent prognostic factors among the pre-treatment parameters. There was no significant difference in overall survival according to the presence of extrahepatic metastasis; the median OS was 8 mo (95%CI: 5.192-10.808) in the patients without extrahepatic metastasis and 5 mo (95%CI: 2.387-7.613) in the patients with extrahepatic metastasis ($P = 0.201$) (Figure 3).

The post-treatment parameters were analyzed after the second cycle and at the end of HAIC. Univariate analysis after the second cycle of HAIC determined that objective response, disease control, portal vein tumor thrombosis response, and ≥ 50% reduction of AFP and PIVKA-Ⅱ level were significant post-treatment prognostic factors. Multivariate analysis after the second cycle of HAIC determined that disease control [$P = 0.001$, HR = 3.850 (95%CI: 1.768-8.381)], PVTT response [$P = 0.003$, HR = 3.398 (95%CI: 1.529-7.552)] and ≥ 50% AFP reduction [$P = 0.02$, HR = 3.031 (95%CI: 1.194-7.691)] were significant predictors for longer survival. [1]Those variables with $P < 0.05$ in univariate analysis were included. AFP: Alpha-fetoprotein; AJCC: American Joint Committee on Cancer; HAIC: Hepatic arterial infusion chemotherapy; PIVKA: Protein induced by vitamin K absence or antagonist; mUICC: Modified Union for International Cancer Control.

end of the HAIC treatment, univariate analysis was performed with combination therapy and factors related to tumor response. Six factors were significant: the overall tumor response (including objective response and disease control), intrahepatic tumor response (including objective response and disease control), PVTT response, and combination therapy. A multivariate analysis at the end of HAIC treatment determined that objective tumor response [$P = 0.001$, HR = 4.445 (95%CI: 1.893-10.439)], disease control [$P = 0.003$, HR = 3.137 (95%CI: 1.494-6.591)], objective intrahepatic tumor response [$P = 0.001$, HR = 4.445 (95%CI: 1.893-10.439)], intrahepatic tumor control [$P = 0.01$, HR = 3.009 (95%CI: 1.302-6.958)], PVTT response [$P = 0.001$, HR = 8.188 (95%CI: 2.403-27.898)], and combination therapy [$P = 0.029$, HR = 2.164 (95%CI: 1.082-4.328)] were independent predictors for longer survival.

Toxicity

The toxicities observed in this study are summarized in Table 5. No treatment-related mortality was detected. The most common toxicities were anemia and aspartate aminotransferase (AST) elevation, and all patients showed a toxicity grade of at least 1. The most common grade 3/4 toxicities were thrombocytopenia and AST elevation (22 patients, 44%). The toxicities were transient, tolerable,

[1]Adjusted for tumor volume and pre-treatment PIVKA-Ⅱ level; [2]*P* value for adjusted hazard ratio. AFP: Alpha-fetoprotein; HAIC: Hepatic arterial infusion chemotherapy; PIVKA: Protein induced by vitamin K absence or antagonist; PVTT: Portal vein tumor thrombosis.

and successfully managed using a conservative treatment; there were no discontinuation of the treatment due to toxicity. Hepatic arterial thrombosis developed in 4 of the 50 patients. However, thrombolysis by urokinase was effectively performed, and port removal was required in only 1 patient. Overall, 37 (74%) of the 50 patients in the treatment group died during the follow-up. The causes of death are listed in Table 6. The most common cause of death was tumor progression (57%), and six patients (16%) died from deteriorating hepatic function without any evidence of tumor progression, sepsis, or gastrointestinal bleeding. Five patients (14%) died from variceal bleeding, and three (8%) died from infection. Ten patients (20%) were still alive when the final analysis was performed, and three patients (6%) were lost to follow-up.

DISCUSSION

Portal vein tumor invasion is a common complication in HCC, reportedly observed in 64.7% of cases at autopsy[20]. PVTT often leads to extensive spreading of the tumor and can increase portal venous blood pressure, resulting in the fatal rupture of esophageal varices. PVTT can also decrease portal flow that may lead to ascites, jaundice, hepatic encephalopathy, or liver failure. Therefore, the presence of PVTT is one of the most significant prognostic factors of poor prognosis[21,22], and it has been reported that these patients survive only 2.7-4 mo if left untreated[22,23]. In advanced HCC patients with PVTT, standard treatments have not been established, especially in the Asia-Pacific region. Though the BCLC staging system recommends sorafenib in these patients, its efficacy is limited. Thus, HAIC is considered an alternative treatment modality, especially in Japan and South Korea.

In this study, we analyzed the response rate and overall survival of HAIC using the ECF regimen. In previous reports, the response rate and disease control rate of HAIC in advanced HCC patients with PVTT[11,24-26] were 33%-52% and 47%-77%, respectively. The median OS was 7-10 mo in those studies. The objective response

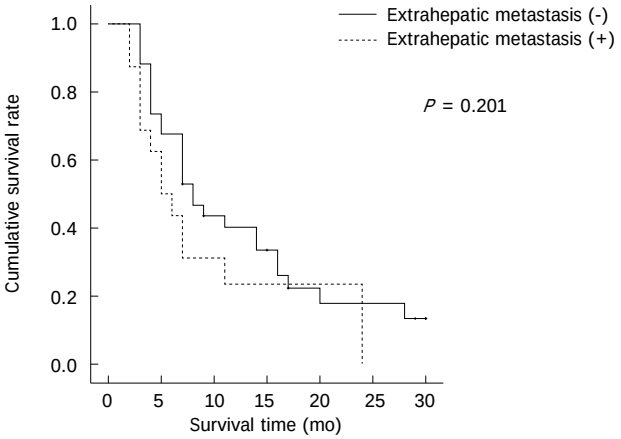

Figure 3 Cumulative survival rate according to the presence of extrahepatic metastasis.

Table 5 Adverse events related to treatment

	Grade 1	Grade 2	Grade 3	Grade 4
Hematological				
Leukopenia	26%	38%	8%	0%
Neutropenia	10%	26%	30%	12%
Anemia	26%	48%	26%	0%
Thrombocytopenia	30%	18%	44%	0%
Non-hematological				
Total bilirubin	30%	28%	10%	0%
AST	20%	36%	38%	6%
ALT	48%	12%	16%	2%

ALT: Alanine aminotransferase; AST: Aspartate aminotransferase.

	Patient number (n = 37)
Disease progression	21
Hepatic dysfunction	6
Variceal bleeding	5
Infection	3
Unknown	2

rate and disease control rate of our study, which are 32% and 76%, respectively, are in accordance with the above results. In addition, the median OS of 7 mo was similar to the results of previous reports. However, our study included patients with extrahepatic metastasis at the beginning of HAIC, whereas the previous studies excluded those patients. HAIC treatment is primarily used for the local control of liver tumors in patients with minimal extrahepatic spread[7]. Extrahepatic tumors would not respond well to HAIC. However, our data support the use of HAIC in HCC patients with extrahepatic metastasis because extrahepatic metastasis was not a significant factor in survival (Figure 3). The mortality in advanced HCC is related to intrahepatic tumors, and the leading cause of death in these patients is intrahepatic tumor progression[27,28]. In this study, all patients had advanced intrahepatic HCC with vascular invasion. Because the survival of these patients was influenced by intrahepatic tumor progression, extrahepatic metastasis may not influence overall survival. If the treatment response evaluation is confined to intrahepatic tumor lesions, the disease control rate was as high as 84%. These response and disease control rates are significantly higher than those with sorafenib treatment[5,29].

Several studies reported that the therapeutic effectiveness of HAIC was an important prognostic factor[10,11,30], which is consistent with our results. In the present study, the median OS of the disease control group after two cycles of HAIC was significantly longer than patients showing PD. In addition, patients with an objective response to HAIC treatment also had significantly longer survival than non-responders. These results indicate that the responses to HAIC were independent prognostic factors. In addition, this study showed that the response after the second cycle of HAIC also significantly influences survival; thus, patients with CR, PR or SD after the second cycle of HAIC could continue HAIC treatment and expect favorable results.

PIVKA-Ⅱ, also known as a des-gamma carboxy prothrombin (DCP), is an alternative tumor marker of AFP in diagnosing HCC. It is associated with aggressive features such as tumor size, vascular invasion, tumor stage and survival, and patients with high serum PIVKA-Ⅱ levels have a poor prognosis[31,32]. In the present study, the median OS in patients with a PIVKA-Ⅱ level ⩾ 40 and < 40 mAU/mL were 7 and 16 mo, respectively (Figure 4). Thus, patients with high serum PIVKA-Ⅱ levels prior to HAIC treatment would be expected to have a poorer prognosis. Some reports state that, independent of pre-treatment level, tumor marker response to treatment was associated with survival. Park *et al*[18] reported that AFP and DCP response were independent factors associated with survival. Personeni *et al*[17] reported that AFP response is an independent surrogate end point for survival in patients treated with sorafenib. Similarly, a ⩾ 50% decline in AFP and PIVKA-Ⅱ after the second cycle of HAIC treatment was associated with better outcomes among the patients with elevated AFP and PIVKA-Ⅱ levels prior to the initiation of HAIC treatment (though PIVKA-Ⅱ reduction is not statistically significant by multivariate analysis) (Figure 4). Therefore, tumor marker response (AFP and PIVKA-Ⅱ) after the second cycle may be a useful surrogate endpoint for good outcomes in those receiving HAIC treatment for large HCC with PVTT.

Many studies have shown that tumor size is a major determinant of survival[33,34]. However, few studies (with the exception of Hsu *et al*) have analyzed survival according to tumor volume[35]. In the current study, multivariate analysis of the pre-treatment parameters showed that a tumor volume < 400 cm^3 was an independent pre-treatment prognostic factor, while the maximal tumor diameter was not. Along with tumor volume, we evaluated the Child-Pugh score as a predictive factor of survival. Though not a significant multivariate variable, a Child-Pugh score of 5 was an important factor predicting good outcome (median OS of Child class A5, A6 and B were 16, 7 and 3 mo, respectively). This result is consistent

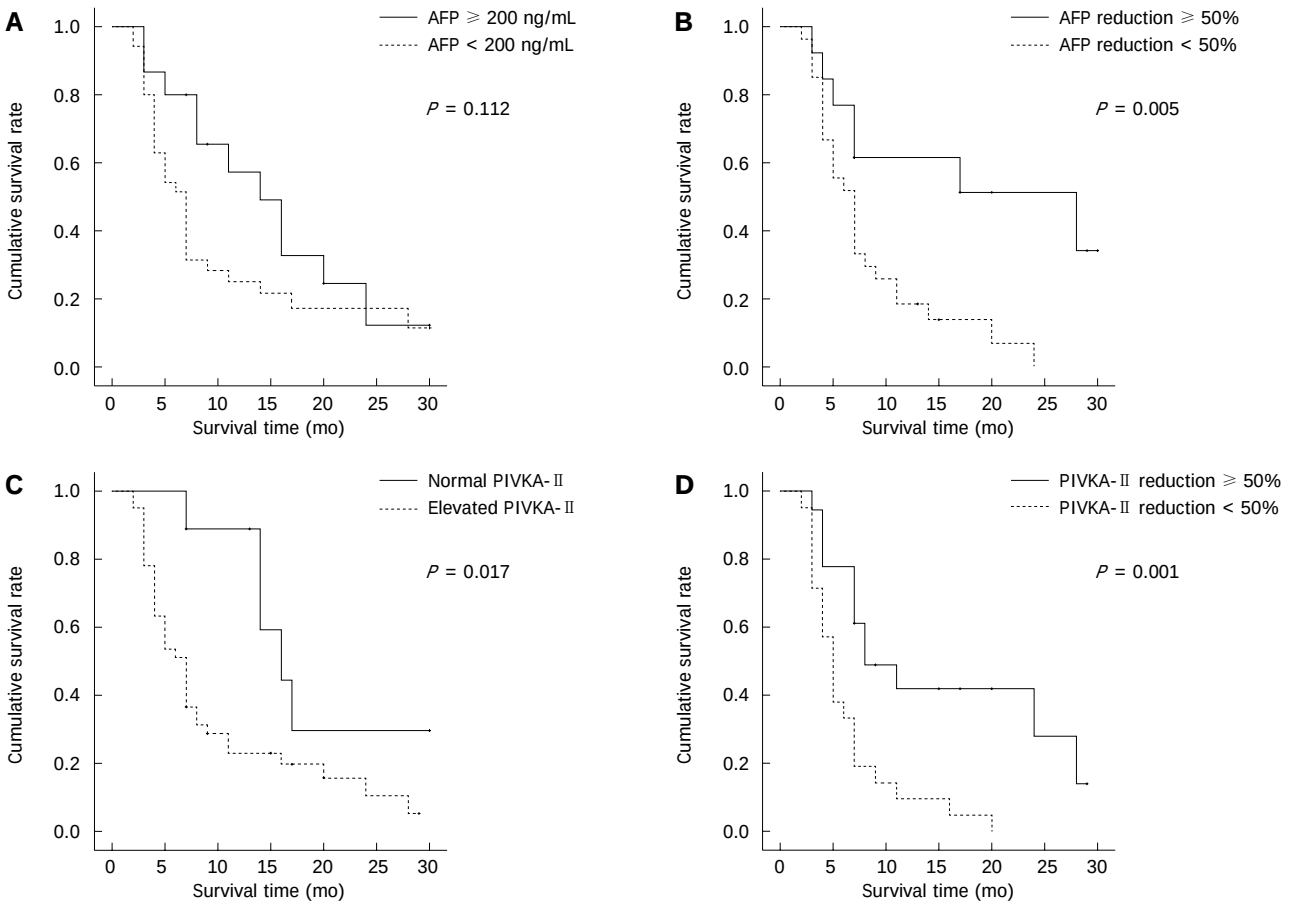

Figure 4 Cumulative survival rates. A: According to the pre-treatment α-fetoprotein (AFP) level; B: According to the AFP reduction after two cycles of hepatic arterial infusion chemotherapy (HAIC); C: According to the pre-treatment protein induced by vitamin K absence or antagonist (PIVKA)-Ⅱ level; D: According to the PIVKA-Ⅱ reduction after two cycles of HAIC.

with the results of HAIC studies showing that the Child-Pugh score was an independent survival factor[30,36]. Thus, HAIC using ECF could be indicated in selected patients with tumor volumes < 400 cm^3, good hepatic reserve function, and low PIVKA-Ⅱ levels.

Although many studies using HAIC have been performed over the last decade, the therapeutic regimen of this treatment has not been standardized. Ando *et al*[11] reported that HAIC using low-dose cisplatin and 5-FU demonstrated a good response rate and survival time in 48 patients with PVTT. Park *et al*[10] showed that repetitive HAIC with high-dose 5-FU and cisplatin given for 3 d was effective and safe. In Japan, interferon-combined HAIC is also commonly used. The ECF chemotherapeutic regimen in this study consisted of high dose cisplatin and 5-FU in combination with epirubicin. Woo *et al*[14] compared high-dose HAIC with low-dose HAIC and reported that high-dose HAIC was safe and achieved better tumor response compared with that of low-dose HAIC. The addition of epirubicin to the high-dose HAIC regimen resulted in more effective control of the intrahepatic tumor in our study.

However, the ECF regimen appears to be more toxic than in previous reports of high-dose HAIC[10,14]. While grade 3 hematologic or non-hematologic toxicities comprised less than 5% in previous studies, grade 3 leukopenia, anemia, and thrombocytopenia in this study comprised 8%, 26% and 44% of the toxicities, respectively, and hepatic toxicity was higher. In addition, hematologic toxicities tended to be more common in this study than in the trials using sorafenib such as the SHARP trial or an Asia-Pacific trial[5,29]. The more frequent grade 3/4 toxicities in this study may be due to our use of different inclusion criteria. The hematologic inclusion criteria were lower than those used in the previous study, and there were no inclusion criteria related to hepatic function such as AST, ALT and bilirubin. As a result, our study included more patients with lower blood cell counts or higher liver enzyme levels, which could lead to more toxic adverse events. However, all hematologic and hepatic toxicity returned to baseline levels within several days.

This study has some limitations. First, we included patients with extrahepatic metastasis even though HAIC is only considered effective for the treatment of intrahepatic tumors[7]. However, extrahepatic metastasis was not independently associated with survival, and the results were as good as those of previous studies despite the inclusion of patients with extrahepatic metastasis. Second, because most tumors were of the infiltrative type and margins were obscure, there was difficulty in accurately measuring tumor volume. Third, the retrospective nature of this study is underpowered due to a single arm regis-

try without a control group. In addition, this study may have inherent bias associated with a small sample size and heterogeneous treatments. Thus, large prospective studies are necessary to establish the efficacy of HAIC using the ECF regimen in patients with large tumors and PVTT.

In conclusion, HAIC with the ECF regimen may be a good option for advanced HCC with tumor volumes < 400 cm^3 and a normal PIVKA-Ⅱ level. In addition, this study suggests that response to chemotherapy after two cycles of HAIC, including radiologic tumor control and tumor marker reduction, is an independent predictor of longer survival. Therefore, HAIC treatment could be indicated in selected patients with favorable pre-treatment or post-treatment prognostic factors.

COMMENTS

Background

Hepatocellular carcinoma (HCC) is a major health problem, accounting for more than 626000 new cases per year worldwide. Most HCC patients are diagnosed at an inoperable (intermediate or advanced) stage. The prognosis for advanced HCC is dismal. Sorafenib is the only approved drug for target therapy, and this drug is recommended for advanced HCC patients according to Barcelona Clinic Liver Cancer staging system. However, sorafenib shows only modest improvements in survival and tumor response.

Research frontiers

Hepatic arterial infusion chemotherapy (HAIC) has been used as a treatment modality for advanced HCC. Although sorafenib is regarded as the standard treatment of advanced HCC, HAIC can be an alternative treatment modality. The research hotspot in the area of HAIC treatment involves patients who will have good responses to HAIC.

Innovations and breakthroughs

Until now, the HAIC therapeutic regimen has not been standardized. This study is the first to use the epirubicin-cisplatin-5-fluorouracil (ECF) regimen, which consists of epirubicin, cisplatin, and 5-fluorouracil. HAIC treatment using the ECF regimen showed a good response, and its toxicity was tolerable. While previous studies on HAIC attempted to investigate the prognostic factors among the pre-treatment variables and the best response during treatment, this study revealed that the response after the second cycle of treatment, including radiologic response and tumor marker reduction, is also an important prognostic factor. The authors measured the actual tumor volume using imaging software and suggested a cut-off volume that could indicate a good response to HAIC.

Applications

Because the response after the second cycle is an important prognostic factor, those who showed a good response after the second cycle can continue the HAIC treatment and can expect favorable results.

Terminology

HAIC: HAIC is one type of arterial chemotherapy used in advanced hepatocellular carcinoma. HAIC requires an implantable port system for which a catheter is inserted and localized to the proper hepatic artery. HAIC enables the local delivery of high concentrations of anti-cancer agents to tumors, thereby maintaining a low systemic concentration of chemotherapeutic agent.

Peer review

This is a good article about the use of HAIC in the treatment of advanced HCC with portal vein tumor thrombosis. HAIC is shown to be an effective treatment modality.

Abstract

AIM: To investigate long-term effects of *Garcinia Cambogia* (GC), weight-loss supplement, on adiposity and non-alcoholic fatty liver disease in obese mice.

METHODS: Obesity-prone C57BL/6J mice were fed a high-fat diet (HFD, 45 kcal% fat) with or without GC (1%, w/w) for 16 wk. The HFD contained 45 kcal% fat, 20 kcal% protein and 35 kcal% carbohydrate. They were given free access to food and distilled water, and food consumption and body weight were measured daily and weekly, respectively. Data were expressed as the mean ± SE. Statistical analyses were performed using the statistical package for the social science software program. Student's *t* test was used to assess the differences between the groups. Statistical significance was considered at $P < 0.05$.

RESULTS: There were no significant changes in body weight and food intake between the groups. However, the supplementation of GC significantly lowered visceral fat accumulation and adipocyte size *via* inhibition of fatty acid synthase activity and its mRNA expression in visceral adipose tissue, along with enhanced enzymatic activity and gene expression involved in adipose fatty acid β-oxidation. Moreover, GC supplementation resulted in significant reductions in glucose intolerance and the plasma resistin level in the HFD-fed mice. However, we first demonstrated that it increased hepatic collagen accumulation, lipid peroxidation and mRNA levels of genes related to oxidative stress (superoxide dismutase and glutathione peroxidase) and inflammatory responses (tumor necrosis factor-α and monocyte chemoattractant protein-1) as well as plasma alanine transaminase and aspartate transaminase levels, although HFD-induced hepatic steatosis was not altered.

CONCLUSION: GC protects against HFD-induced obesity by modulating adipose fatty acid synthesis and β-oxidation but induces hepatic fibrosis, inflammation and oxidative stress.

Key words: *Garcinia Cambogia*; Anti-adiposity; Metabolic changes; Hepatic collagen accumulation; Hepatic inflammation; Hepatic oxidative stress

Core tip: *Garcinia Cambogia* (GC) is a popular dietary supplement for weight loss. However, little is known about the efficacy and hepatotoxicity of long-term GC supplementation in mice fed a high-fat diet (HFD). We observed that GC ameliorated HFD-induced adiposity by modulating enzymatic activity and gene expression involved in fatty acid metabolism. GC also reduced the plasma resistin level and glucose intolerance. However, GC caused hepatic collagen accumulation, inflammation and oxidative stress without affecting hepatic steatosis.

Kim YJ, Choi MS, Park YB, Kim SR, Lee MK, Jung UJ. *Garcinia Cambogia* attenuates diet-induced adiposity but exacerbates hepatic collagen accumulation and inflammation. *World J Gastroenterol* 2013; 19(29): 4689-4701 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i29/4689.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i29.4689

INTRODUCTION

Obesity is one of the global public health problems commonly associated with metabolic diseases including insulin resistance, type 2 diabetes, non-alcoholic fatty liver disease (NAFLD) and dyslipidemia[1]. According to the World Health Organization global estimates from 2008, more than 1.4 billion adults are overweight and at least 500 million adults are obese[2]. Although the use of dietary supplements for weight loss becomes common[3], the optimal dose and safety profiles of many dietary supplements are poorly studied. The United States Food and Drug Administration (FDA) do not regulate dietary supplements in the same manner as pharmacological agents[4,5]. While pharmaceutical companies are required to obtain FDA approval, which involves assessing the risks and benefits prior to their entry into the market, dietary supplements are not subject to the same scientific scrutiny and are not required to demonstrate any scientific safety and efficacy pertaining to the claims made by manufacturers.

Several studies have shown that *Garcinia Cambogia* (GC), a fruit native to southeastern Asia and Western Africa, has beneficial effects on body weight and fat loss in both experimental animals and human[6-10]. Its main component hydroxycitric acid (HCA) not only inhibits ATP-citrate lyase, the enzyme response for *de novo* fatty acid synthesis, but also increases hepatic glycogen synthesis, reduces food intake by suppressing appetite and decreases body weight gain[6-9]. Although extensive experiments reported the weight loss and body fat-lowering effects of GC, some animal and clinical studies have shown controversial findings[6,10-13] and no studies have shown whether these effects persist beyond 13 wk of GC treatment. Furthermore, some studies have reported the potential for hepatotoxicity of hydroxycut, a formulation that contains GC among other ingredients[14,15].

The present study was therefore done to investigate the effect of long-term GC supplementation on adipogenesis and obesity-related metabolic changes, such as glucose intolerance and hepatic steatosis, in mice fed a high fat diet (HFD). We also examined the effect of GC on liver dysfunction, collagen accumulation, inflammation and oxidative stress.

MATERIALS AND METHODS

Animals and diets

Male C57BL/6J mice (4-wk-old) were purchased from Jackson Laboratories (Bar Harbor, ME, United States). The mice were individually housed in polycarbonate cages, which were kept in a room maintained at a constant temperature (24 ℃) with a 12-h light/dark cycle. The mice were fed a normal chow diet for acclimation for 1 wk after delivery. At 5 wk of age, they were randomly divided into two groups of 10 mice each and fed a HFD (D12451, Research Diets, New Brunswick, NJ, United States) with or without GC (1%, w/w, 60% hydroxyl citric acid; Newtree Inc., United States) for 16 wk. The HFD contained 45 kcal% fat, 20 kcal% protein and 35 kcal% carbohydrate. They were given free access to food and distilled water, and food consumption and body weight were measured daily and weekly, respectively. At the end of the experimental period, all the mice were anesthetized with isoflurane (5 mg/kg body weight, Baxter, United States) after a 12-h fast, and blood samples were collected from the inferior vena cava into heparin-coated tube for the measurement of plasma parameters. The blood was centrifuged at 1000 *g* for 15 min at 4 ℃, and the plasma was separated.

Fasting blood glucose, intraperitoneal glucose tolerance test and homeostatic index of insulin resistance

The blood glucose concentration was measured with whole blood obtained from the tail veins after withholding food for 12 h using a glucose analyzer (OneTouch Ultra, Lifescan Inc., United States) based on the glucose oxidase method. The intraperitoneal glucose tolerance test was performed on the 15th week. After a 12-h fast, the mice were injected intraperitoneally with glucose (0.5 g/kg body weight). The blood glucose level was measured from the tail vein at 0, 30, 60 and 120 min after glucose injection. Area under the curve (AUC) was calculated for all glucose levels as an index of glucose tolerance. Homeostatic index of insulin resistance (HOMA-IR) was calculated according to the homeostasis of the assessment as follows: HOMA-IR = [fasting glucose (mmol/L) × fasting insulin (μL U/mL)]/22.51.

Plasma biomarkers

Plasma adipokines were measured with a multiplex detection kit (171-F7001M, Bio-Rad, Hercules, CA, United States). Capture antibodies directed against the adipokines (resistin, leptin) were covalently coupled to the beads, and the coupled beads reacted with plasma. After a series of washes to remove unbound protein,

a biotinylated detection antibody was added to create a sandwich complex. The final detection complex was formed with the addition of streptavidin-phycoerythrin conjugate. Phycoerythrin served as a fluorescent indicator, or reporter. All samples were assayed in duplicate and analyzed with a Luminex 200 Labmap system (Luminex, Austin, TX, United States). Data analyses were done with Bio-Plex Manager software version 4.1.1 (Bio-Rad, Hercules, CA, United States).

Plasma cytokines were measured with a multiplex detection kit (M60-009RDPD, Bio-Rad, Hercules, CA, United States). Capture antibodies directed against the cytokines [insulin, tumor necrosis factor-α (TNF-α) and monocyte chemoattractant protein-1 (MCP-1)] were covalently coupled to the beads, and the same procedure for plasma adipokine analysis as described above was used to determine the plasma cytokines levels.

Plasma lipid and apolipoprotein concentrations were determined with commercially available kits: Plasma free fatty acid (01120301.HE98), phospholipid (01120251), apolipoprotein A (14535014) and apolipoprotein B (14537014) levels were measured using the Nittobo enzymatic kit (Nittobo medical Co., Tokyo, Japan), and triglyceride (AM157S-K), total cholesterol (AM202-K) and high-density lipoprotein (HDL)-cholesterol (AM203-K) levels were determined using Asan enzymatic kits (Asan, Seoul, South Korea).

Plasma aspartate aminotransferase (AST) and alanine aminotransferase (ALT) were determined using enzymatic kits (AM101-K, Asan, Seoul, South Korea).

Hepatic lipids contents

Hepatic lipids were extracted[16], and then the dried lipid residues were dissolved in 1 mL of ethanol for triglyceride and cholesterol assays. Triton X-100 and a sodium cholate solution in distilled water were added to 200 μL of the dissolved lipid solution for emulsification. The hepatic triglyceride and cholesterol contents were analyzed with the same enzymatic kit used for the plasma analysis.

Lipid-regulating enzyme activity

To measure the lipid-regulating enzymes activities in the epididymal white adipose tissue (WAT) and liver, samples were prepared and analyzed as previously described[17]. Briefly, fatty acid synthase (FAS) activity was determined with a spectrophotometric assay according to the method by Carl *et al*[18]; one unit of FAS activity represented the oxidation of 1 nmol of NADPH per minute at 30 ℃. Carnitine palmitoyltransferase (CPT) activity was determined according to the method by Markwell *et al*[19] and the results were expressed as nmol/min per milligram protein. Fatty acid β-oxidation was measured spectrophotometrically by monitoring the reduction of NAD to NADH in the presence of palmitoyl-CoA as described by Lazarow[20], with slight modification. Protein concentration was measured by the Bradford method using BSA as the standard[21].

Lipid peroxidation assay

The hepatic thiobarbituric acid-reactive substances (TBARS) concentration, as a marker of lipid peroxide production, was measured spectrophotometrically by the method of Ohkawa *et al*[22]. Hepatic homogenates containing 8.1% sodium dodecyl sulfate were mixed with 20% (w/v) acetic acid (pH 3.5), distilled water and 0.8% (w/v) TBA. The reaction mixture was heated at 95 ℃ for 60 min. After cooling the mixture, n-butanol: pyridine (15:1, v/v) was added and centrifuged at 3000 rpm for 15 min. The resulting colored layer was measured at 535 nm.

Analysis of gene expression

Epididymal WAT and liver were homogenized in TRIzol reagent (15596-026, Invitrogen Life Technologies, Grand Island, NY, United States) and total RNA was isolated according to the manufacturer's instructions. The total RNA was converted to cDNA using the QuantiTect Reverse Transcription Kit (205313, QIAGEN Gmbh, Hilden, Germany). The RNA expression was quantified by quantitative real-time PCR using the QuantiTect SYBR green PCR kit (204143, QIAGEN Gmbh, Hilden, Germany) and the SDS7000 sequence-detection system (Applied Biosystems, CA, United States). Each cDNA sample was amplified using primers labeled with SYBR Green dye for glyceraldehyde-3-phosphate dehydrogenase (GAPDH). The amplification was performed as follows: 10 min at 90 ℃, 15 s at 95 ℃ and 60 s at 60 ℃ for a total of 40 cycles. The cycle threshold values obtained were those cycles at which a statistically significant increase in the SYBR green emission intensity occurred. Ct data were normalized using GAPDH, which was stably expressed in mice. Relative gene expression was calculated with the $2^{-\Delta\Delta Ct}$ method[23]. The following gene-specific primers were used: for catalase (CAT), 5'-GCGTCCGTCCCTGCTGTC-3' (forward), 5'-TGCTCCTTCCACTGCTTCATCTG-3' (reverse); for cell death-inducing DNA fragmentation factor-α-like effector A (CIDEA), 5'-TTTCAAACCATGACCGAAGTAGCC-3' (forward), 5'-CCTCCAGCACCAGCGTAACC-3' (reverse); for CPT, 5'-ATCTGGATGGCTATGGTCAAGGTC-3' (forward), 5'-GTGCTGTCATGCGTTGGAAGTC-3' (reverse); for FAS, 5'-CGCTCCTCGCTTGTCGTCTG-3' (forward), 5'-AGCCTTCCATCTCCTGTCATCATC-3' (reverse); for fatty acid translocase/cluster of differentiation 36 (FAT/CD36), 5'-ATTGGTCAAGCCAGCT-3' (forward), 5'-TGTAGGCTCATCCACTAC-3' (reverse); for glyceraldehyde-3-phosphate dehydrogenase (GAPDH), 5'-ACAATGAATACGGCTACAGCAACAG-3' (forward), 5'-GGTGGTCCAGGGTTTCTTACTCC-3' (reverse); for glutathione peroxidase (GHS-Px), 5'-TCGCAATGAGCCAAAACTGACG-3' (forward), 5'-GCCAGGATTCGTAAACCACACTC-3' (reverse); for MCP-1, 5'-TTCCTCCACCACCATGCAG-3' (forward), 5'-CCAGCCGGCAACTGTGA-3' (reverse); for peroxisome proliferator-activated receptors (PPAR)α, 5'-CCTGAACATCGAGTGTCGAATAT (forward), 5'-GGTCTTCTTCTGAATCTTGCAGCT-3'

Histological analysis

Epididymal WAT and liver were fixed in a buffer solution of 10% formalin and embedded in paraffin for staining with hematoxylin and eosin (HE) and Masson's trichrome**.** Stained areas were viewed using an optical microscope (Nikon, Tokyo, Japan) with a magnifying power of × 200.

Ethics

After blood collection, epididymal WAT, perirenal WAT, retroperitoneal WAT, mesentery WAT, subcutaneous WAT and liver were promptly removed, rinsed with physiological saline and weighed. Among them, epididymal WAT and liver were snap-frozen in liquid nitrogen and stored at -70 ℃ until enzyme activity and RNA analyses. All experimental procedures were performed in accordance with the protocols for animal studies approved by the Kyungpook National University Ethics Committee (Approval No. KNU-2011-49).

Statistical analysis

Data were expressed as the mean ± SE. Statistical analyses were performed using the statistical package for the social science software (SPSS) program. Student's t test was used to assess the differences between the groups. Statistical significance was considered at $P < 0.05$.

RESULTS

Long-term GC supplementation did not alter body weight but significantly lowered body fat weight in HFD-induced obese mice

To investigate the effects of long-term GC supplementation in diet-induced obese mice, we provided 5-wk-old male C57BL/6J mice with HFD or 1% (w/w) GC supplemented HFD for 16 wk. During the experimental period, there was no significant difference in daily food intake between the groups (HFD, 3.96 ± 0.14 g; GC, 3.87 ± 0.07 g). The body weight gain was slightly lower in the GC-supplemented mice compared to the HFD control mice but the effects of GC were not significant (Figure 1A and B). Thus, the food efficiency ratio was not significantly different between the groups (Figure 1C). However, the weight of the visceral WAT including

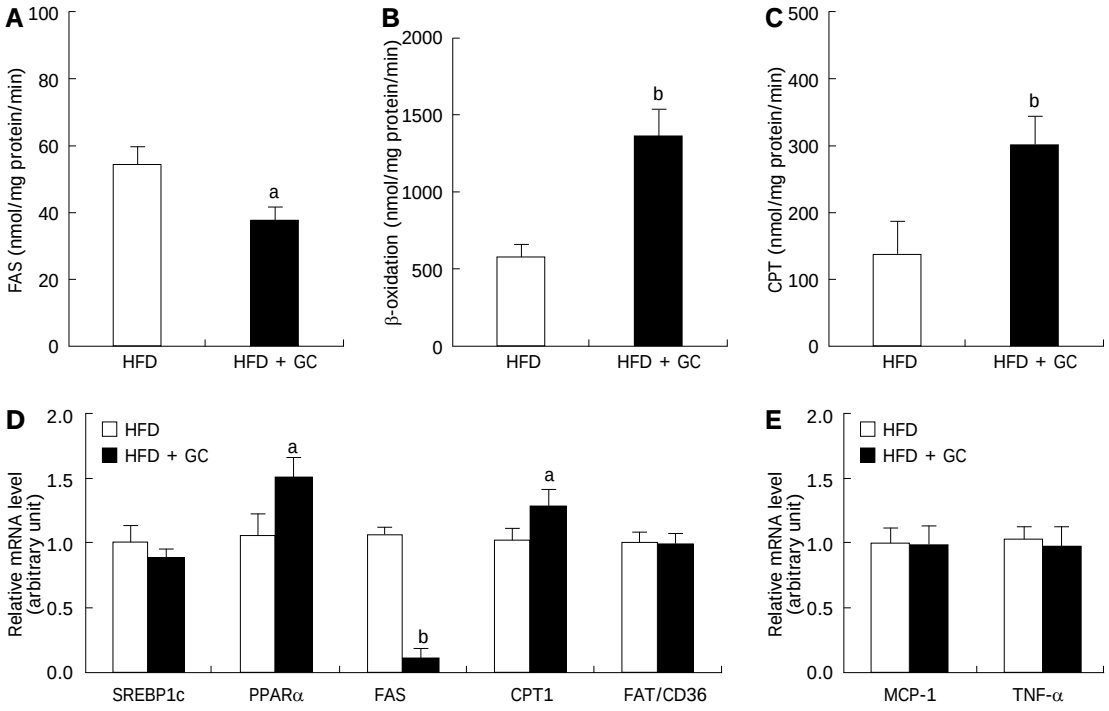

Figure 2 Effects of *Garcinia Cambogia* supplementation on fatty acid-regulating enzyme activity and gene expression in epididymal white adipose tissue of mice fed a high-fat diet for 16 wk. Data are expressed as the mean ± SE (n = 10). A: Fatty acid synthase (FAS); B: β-oxidation; C: Carnitine palmitoyltransferase (CPT); D, E: Relative mRNA level. High-fat diet (HFD), mice fed a high-fat diet alone; HFD + *Garcinia Cambogia* (GC), mice fed a high-fat diet containing GC (1%, w/w). $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* control group. WAT: White adipose tissue; PPARα: Peroxisome proliferator-activated receptor α.

the epididymal, perirenal, retroperitoneal and mesentery WAT was significantly lower in the GC-supplemented mice than in the HFD control mice (Figure 1D). The GC supplementation also tended to lower the subcutaneous WAT weight compared to the HFD control group by 17% although it was not significantly different. Hence, the weight of the total WAT (visceral and subcutaneous WAT) was significantly lower in mice fed a GC supplemented HFD. Morphological observations also indicated the epididymal adipocyte size was smaller in the GC-supplemented mice than in the HFD control mice (Figure 1E). However, GC supplementation did not alter the extent and degree of fibrosis in the epididymal WAT of HFD-fed mice (data not shown).

Long-term GC supplementation alters the activity of enzymes and expression of genes related to fatty acid synthesis and fatty acid oxidation in visceral WAT

To examine the mechanism through which GC supplementation reduces the visceral WAT weight, we measured the activity of enzymes that regulate lipid accumulation in visceral WAT. The GC supplementation resulted in a significant decrease in the activity of FAS in the epididymal WAT of mice fed a HFD (Figure 2A). Furthermore, GC-supplemented mice showed a significant increase in the activity of CPT and β-oxidation in the epididymal WAT (Figure 2B and C).

We also examined the expression of genes that regulate adipogenesis and inflammation. Consistent with the activity of adipose enzymes, GC supplementation significantly down-regulated FAS mRNA expression, whereas it markedly up-regulated CPT mRNA expression in the epididymal WAT of HFD-fed mice (Figure 2D). Moreover, GC-supplemented mice showed a significant increase in the mRNA expression of transcription factor PPARα in the epididymal WAT compared to the control mice. However, there were no significant differences in the mRNA expression of SREBP1c, FAT/CD36, MCP-1 and TNF-α between the two groups (Figure 2D and E).

Long-term GC supplementation improved HFD-induced glucose intolerance but did not alter plasma lipid, apolipoprotein and pro-inflammatory cytokine levels

We next determined whether GC influenced HFD-induced glucose intolerance. The fasting blood glucose, plasma insulin and HOMA-IR levels were not significantly altered by GC supplementation (data not shown). However, GC supplementation significantly lowered the blood glucose level compared to the control group at 120 min after glucose loading (Figure 3A). The level of AUC was also markedly decreased in the GC-supplemented mice compared to the control obese mice.

No significant differences were observed in the levels of plasma lipids (triglycerides, total cholesterol, HDL-cholesterol, phospholipids and free fatty acids) and apolipoproteins (apolipoproteins A and B) between the two groups (Table 1). GC supplementation also did not affect the plasma leptin, TNF-α and MCP-1 levels in the HFD-fed mice; however, it significantly lowered the plasma resistin level (Figure 3B and C).

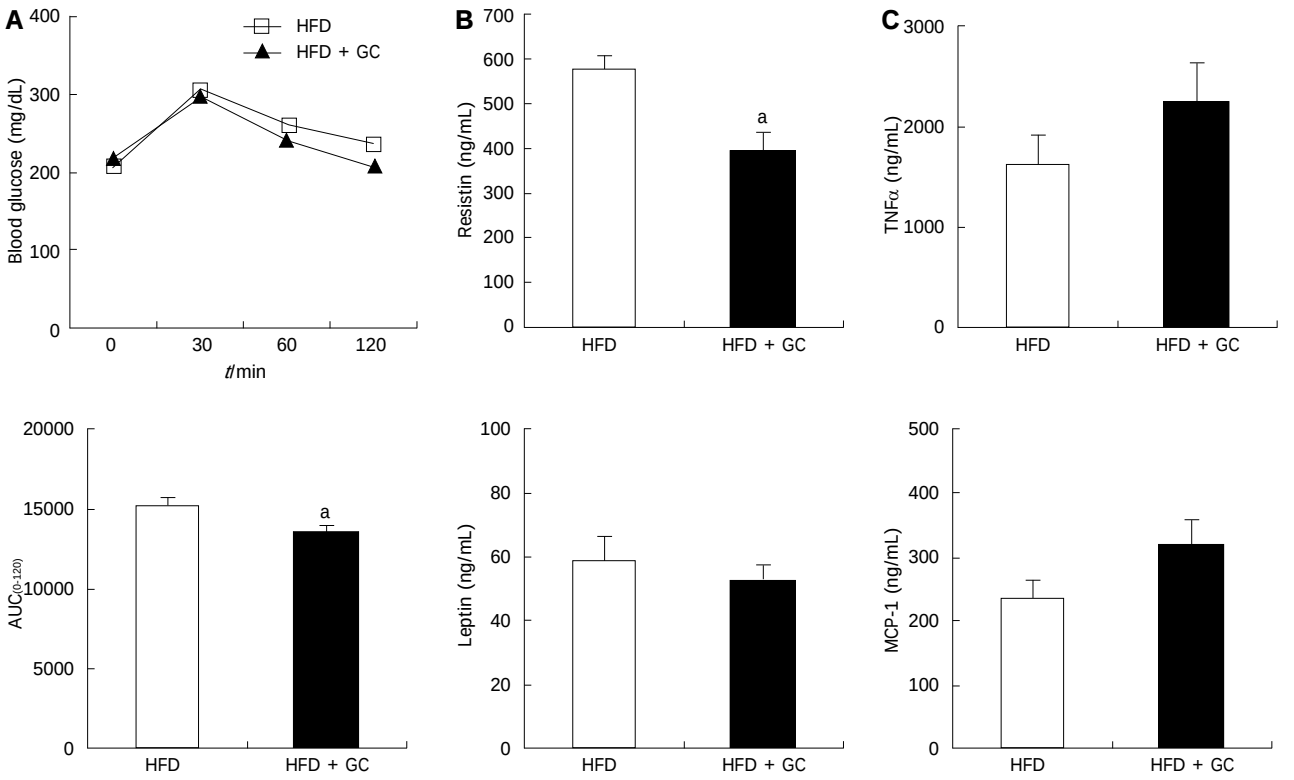

Figure 3 Effects of *Garcinia Cambogia* supplementation on glucose tolerance and plasma adipocytokine levels in mice fed a high-fat diet for 16 wk. Data are expressed as the mean ± SE (n = 10). A: The intraperitoneal glucose tolerance test was performed on the 15th week of *Garcinia Cambogia* (GC) supplementation in high-fat diet (HFD)-fed mice. Following a 12-h fast, the mice were injected intraperitoneally with glucose (0.5 g/kg body weight). Blood glucose was then measured *via* the tail vein at the indicated time [above: Blood glucose values; below: Areas under the curves (AUC)]; B, C: Plasma levels of leptin, resistin, monocyte chemoattractant protein-1 (MCP-1) and tumor necrosis factor-α (TNF-α) were assayed after 16 wk of GC supplementation in HFD-fed mice. HFD, mice fed a high-fat diet alone; HFD + GC, mice fed a high-fat diet containing GC (1%, w/w). $^aP < 0.05$ *vs* control group.

Table 1 Effects of *Garcinia Cambogia* supplementation on plasma lipids and apolipoproteins levels in mice fed a high-fat diet for 16 wk

	HFD	HFD + GC
Triglyceride (mg/dL)	97.47 ± 5.62	83.56 ± 4.51
Total cholesterol (mg/dL)	162.65 ± 10.16	167.73 ± 14.40
HDL-cholesterol (mg/dL)	76.27 ± 6.05	76.06 ± 6.37
Phospholipid (mmol/L)	2.35 ± 0.15	2.05 ± 0.15
Free fatty acid (mmol/L)	0.95 ± 0.08	1.02 ± 0.17
Apolipoprotein B (mmol/L)	5.32 ± 0.59	5.97 ± 0.39
Apolipoprotein A (mmol/L)	50.87 ± 1.24	45.22 ± 1.35

Data are expressed as the mean ± SE (n = 10). HFD: High-fat diet; GC: *Garcinia Cambogia*; HDL: High-density lipoprotein.

Long-term GC supplementation did not affect HFD-induced hepatic steatosis but increased hepatic collagen accumulation, inflammation and oxidative stress

Next, we examined the effect of GC supplementation on NAFLD induced by HFD. GC supplementation did not alter the hepatic triglyceride and cholesterol contents as well as the accumulation of hepatic lipid droplets in HFD-fed mice (Figure 4A and B). There were also no significant changes in the activities of hepatic FAS and β-oxidation and in the mRNA levels of the genes involved in lipogenesis and fatty acid oxidation, including FAS, SCD1, CPT, CIDEA, SREBP1c and PPARα, between the two groups (Figure 4C and D). However, trichrome staining of the liver revealed GC supplementation increased collagen deposition (blue staining) compared to the control mice (Figure 4E). Furthermore, Plasma ALT and AST levels were significantly increased in the GC group compared to the control mice (Figure 4F). The mRNA levels of TNF-α and MCP-1, pro-inflammatory markers, were significantly increased in the liver of GC-supplemented mice compared to the control mice (Figure 4G). GC supplementation also caused significant increases of hepatic SOD and glutathione peroxidase (GSH-Px) mRNA levels as well as TBARS level compared to the control mice, although there was no significant difference in hepatic CAT mRNA level between the two groups (Figure 4H and I).

DISCUSSION

Since unhealthy eating habits combined with limited activity are a major contributor to obesity and its related metabolic disease, lifestyle changes may present a cost-effective first-line of intervention for obesity[24-26]. Dietary supplements seemed to be an inefficient agent for dietary intervention in obese subjects[26]. Such supplements are not recommended by the position papers/guidelines for management of NAFLD[27-32], and have been associated

with increased mortality in some studies[33]. However, there are a number of natural dietary supplements for weight management, including GC, guar gum and chitosan[34]. Among them, HCA-containing GC has been shown to be efficacious in lowering body weight and body fat[6,10-13]. But, some clinical trials and animal studies have shown conflicting results[6,12], and a case series on hepatotoxicity has been reported in patients taking GC-containing hydroxycut, although the individual chemical component underling liver injury remains poorly understood[14,15]. Therefore, the aim of this study was first to determine the effects from long-term GC supplementation on obesity and related metabolic diseases as well as the hepatotoxicity in mice fed a HFD.

In the present study, GC supplementation (1%, w/w) in a HFD for 16 wk did not lead to significant changes in body weight and food intake in mice. However, it resulted in significant decreases in visceral WAT weight and adipocyte size in HFD-induced obese mice. The anti-adiposity effect of GC was partly associated with marked decreases in FAS activity and its gene expression in the epididymal WAT. FAS is a key enzyme involved in *de novo* fatty acid synthesis and WAT is a major site of fatty acid synthesis and storage. We also found that the activity of CPT as well as fatty acid oxidation in epididymal WAT was elevated by GC supplementation. Furthermore, the enhanced adipose fatty acid oxidation in GC-supplemented mice was accompanied by the up-regulated mRNA expression of genes involved in fatty acid oxidation such as CPT and PPARα in the epididymal WAT. The CPT is a major rate-limiting enzyme for fatty acid oxidation, and its gene expression is regulated by PPARα in adipocytes[35]. The PPARα mRNA expression was decreased in the WAT of both genetic and HFD-induced obese mice, and the down-regulation of PPARα in obese WAT was involved in obesity-induced mitochondrial dysfunction and metabolic disorders[36]. Taken together, our findings suggest that in HFD-fed mice, a significant reduction in visceral fat accumulation by GC supplementation could be partly due to decreased fatty acid synthesis as well as increased fatty acid oxidation in adipose tissue. The results of this study are supported by the findings of a previous study which suggested GC supplementation significantly lowered body fat mass, but not body weight and food intake, by inhibiting adipose ATP-citrate lyase (ACL) activity in Zucker obese rats[12]. The ACL is another lipogenic enzyme catalyzing the cleavage of citrate to oxaloacetate and acetyl-CoA for *de novo* fatty acid synthesis[37]. The inhibitory action of HCA on ACL reduces the acetyl-CoA pool, which can lead to a decreased concentration of malonyl-CoA, a physiological inhibitor of CPT[38], and thus results in the suppression of body

fat accumulation through stimulation of fatty acid oxidation[39]. Kim *et al*[11] also reported that HCA-containing GC (1%, w/w) supplementation in HFD-fed mice for 12 wk significantly lowered body fat accumulation by modulating multiple genes associated with adipogenesis in mice fed a HFD.

Along with the anti-obesity effects of HCA, previous studies have reported on the beneficial effects of HCA on insulin resistance[40,41]. HCA increases the cellular pool of citrate by inhibiting ACL, which in turn can increase glycogen production[42]. Recently, HCA supplementation enhanced the glycogen synthesis rate in skeletal muscles and improved post-meal insulin sensitivity[41]. Although we did not measure the level of glycogen in the liver, HCA-containing GC supplementation improved glucose tolerance in HFD-induced obese mice. Furthermore, the plasma resistin level was significantly lowered by GC supplementation in the current study. Resistin is one of the adipokines proposed to link obesity with insulin resistance. Circulating resistin level was elevated in obesity and insulin resistance[43], and HFD significantly increased plasma resistin levels in mice compared to a standard low-fat/high-carbohydrate diet[44]. Resistin deficiency ameliorated glucose homeostasis in mice[45], whereas administration of resistin impaired glucose tolerance and insulin action[43,46]. Thus, the beneficial effect of GC on glucose intolerance might be associated with the decreased resistin level in plasma. Another mechanism in which GC could contribute to improve glucose tolerance is the lowered body fat mass because excess adiposity, especially in visceral WAT, is considered to promote insulin resistance[47]. However, there was no significant difference in HOMA-IR which estimates insulin sensitivity from fasting glucose and insulin concentrations. Tripathy *et al*[48] reported a significant relationship between hepatic insulin sensitivity and HOMA-IR regardless of the stage of glucose tolerance, suggesting that the HOMA-IR is dependent upon hepatic insulin sensitivity rather than peripheral insulin sensitivity. Another clinical study also demonstrated that HOMA-IR did not accurately predict insulin sensitivity[49].

Increased adiposity with the consequences of inflammation and insulin resistance has been linked to the development of NAFLD, which refers to a wide spectrum of liver damage, ranging from simple steatosis to steatohepatitis and cirrhosis. Steatosis represents the accumulation of fat within the liver through multiple mechanisms including an altered balance in fatty acid uptake and triglycerides secretion, increased *de novo* lipogenesis, and decreased fatty acid oxidation[50,51]. Steatohepatitis is the combination of steatosis with hepatic inflammation and fibrosis. Liver fibrosis is excess synthesis and deposition of extracellular matrix proteins including collagen[52], and pro-inflammatory factors including MCP-1 and TNF-α that contribute to the second hit in the pathogenesis of steatohepatitis. Among the inflammatory mediators, MCP-1 is a pro-inflammatory chemokine which coordinates leukocyte recruitment to the liver by activation of the CC chemokine receptor 2 (CCR2) on inflammatory cells including monocytes and macrophages promoting the inflammatory response[53]. Several studies indicate that MCP-1 is an important mediator of liver fibrosis[54-56]. MCP-1 mRNA expression was markedly increased in the livers of patients with steatohepatitis and in murine models of steatohepatitis such as mice fed a HFD or methionin-cholin deficient diet[57-63]. CCR2 inhibitor suppressed the early and late features of steatohepatitis including fibrosis[64], and chronic exposure of HFD induced hepatic MCP-1 mRNA expression in mice before induction of other pro-inflammatory cytokine mRNAs including TNF-α and prior to the onset of steatohepatitis, suggesting that MCP-1 plays a major role in initiating the inflammatory process in steatohepatitis[65]. Moreover, MCP-1 deficiency reduced liver fibrosis (collagen deposition) and pro-fibrogenic gene expression in mice fed a methionine-choline deficient diet although it did not affect liver steatosis in this model[66].

Similarly, we found that GC supplementation did not affect hepatic lipogenesis and lipid droplet formation, but it markedly increased collagen deposition as well as pro-inflammatory MCP-1 and TNF-α mRNA expression in the liver of HFD-fed mice. Furthermore, GC-supplemented mice exhibited impaired liver function indicated by the elevations of plasma ALT and AST, suggesting that GC possibly promotes liver injury in HFD-fed mice. Several case reports have suggested HCA-containing hydroxycut has potential hepatotoxicity but the underlying mechanism remains unknown[14,15,67,68]. Our experiments provide new information regarding hepatotoxicity after long-term GC supplementation in HFD-induced obese mice. Accordingly, GC supplementation contributes to steatohepatitis by increasing hepatic collagen accumulation and hepatic MCP-1 and TNF-α expression in mice fed a HFD, which are independent of its effects on HFD-induced hepatic steatosis.

On the other hand, oxidative stress is considered to play an important role in progression of nonalcoholic steatohepatitis and hepatocellular injury[69]. Reactive oxygen species (ROS) can damage DNA, lipids and proteins, induce necrosis and apoptosis of hepatocytes and amplifie the inflammatory response. The ROS also stimulate the production of pro-fibrogenic mediators from Kupffer cells and inflammatory cells and directly induce hepatic stellate cells proliferation, resulting in the initiation of fibrosis[70]. Antioxidant enzymes such as SOD and GSH-Px ameliorate the damaging effects of ROS. SOD converts superoxide radicals into hydrogen peroxide, which is then further metabolized by GSH-Px, where it catalyzes the destruction of hydrogen peroxide and lipid hydroperoxide. We observed that the supplementation of GC significantly up-regulated hepatic SOD and GSH-Px mRNA expression with concomitant increase in lipid peroxidation in the liver, suggesting that the increases in antioxidant gene expression by GC seems to be a compensatory response of the liver to cope with oxidative stress.

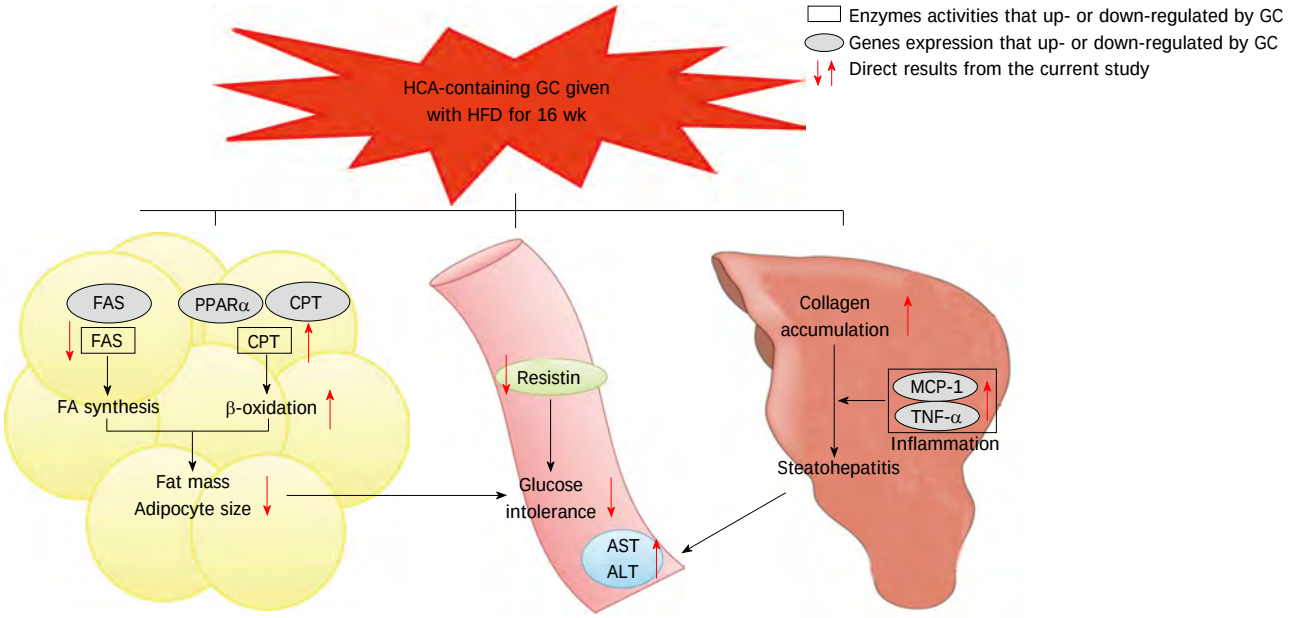

Figure 5 Summary of the long-term *Garcinia Cambogia* supplementation effects on adiposity, glucose tolerance and steatohepatitis in high-fat diet-induced obese mice. The *Garcinia Cambogia* (GC) supplementation decreased fatty acid synthase (FAS) mRNA expression and its activity, while peroxisome proliferator-activated receptor α (PPARα) and carnitine palmitoyltransferase (CPT) mRNA expression along with the activities of CPT and β-oxidation were increased in the visceral adipose tissue, indicating that these changes may be potential mechanisms for reducing body fat accumulation and glucose intolerance induced by high-fat diet (HFD). Furthermore, GC supplementation decreased the plasma resistin level, which may be also related to improved glucose tolerance. There were no significant changes in hepatic lipid accumulation as well as in hepatic gene expression and enzymatic activity involved in fatty acid synthesis, oxidation and storage. However, GC increased pro-inflammatory monocyte chemoattractant protein-1 (MCP-1) and tumor necrosis factor-α (TNF-α) mRNA expression, lipid peroxidation and collagen accumulation in the liver. Plasma alanine aminotransferase (ALT) and aspartate aminotransferase (AST) levels were also increased by GC supplementation in HFD-induced obese mice, thus suggesting that GC may negatively affect liver function by increasing hepatic fibrosis, inflammation and oxidative stress without affecting hepatic fat accumulation. FA: Fatty acid; HCA: Hydroxycitric acid. Open square means enzymes activities that up- or down-regulated by GC. Solid circle means genes expression that up- or down-regulated by GC.

In conclusion, this study demonstrated that long-term GC supplementation ameliorated adipogenesis in mice fed a HFD by promoting fatty acid oxidation with a simultaneous decrease in fatty acid synthesis in visceral WAT. Furthermore, GC exhibited a protective role against glucose intolerance induced by HFD. Moreover, this study provides the first evidence that long-term GC supplementation significantly increased hepatic collagen accumulation, lipid peroxidation and MCP-1 and TNF-α mRNA expression as well as plasma AST and ALT levels, thereby contributing partly to the exacerbation of steatohepatitis in HFD-induced obese mice at the doses given. The observations described above are summarized in Figure 5. Although further research is required to elucidate the efficacy and safety of long-term use of GC in humans, caution is needed when using GC supplements for weight management.

COMMENTS

Background

Garcinia Cambogia (GC) is a popular dietary supplement for weight loss, but the efficacy and hepatotoxicity of long-term GC supplementation remain poorly understood. Thus, authors investigated the long-term supplementation effects of GC on adiposity and non-alcoholic fatty liver disease (NAFLD) in mice fed a high-fat diet (HFD).

Research frontiers

A number of experiments reported GC has beneficial effects on weight loss and body fat in some animals and human. However, there are controversial findings and little studies have reported whether these effects persist beyond 13 wk of GC supplementation.

Innovations and breakthroughs

This is first report which shows the supplementation of GC increased hepatic collagen accumulation, inflammatory genes expression and lipid peroxidation as well as plasma alanine aminotransferase and aspartate aminotransferase levels, although HFD-induced hepatic steatosis did not change. Thus their findings suggest that long-term supplementation of GC induces hepatic fibrosis and inflammation, although it protects against HFD-induced adiposity and glucose intolerance in mice fed a high fat diet.

Applications

Extensive dietary supplements are popular and widely used for weight management. However, the optimal dose and safety profiles of many dietary supplements are poorly studied and they are not regulated by the Food and Drug Administration in a manner observed for pharmacological agents. The authors suggest that caution is needed when using GC supplements for weight management, although further research is required to elucidate the efficacy and safety of long-term use of GC in humans.

Peer review

The authors investigated long-term supplementation effects of GC on adiposity and NAFLD in diet-induced obese mice. They reported that long-term GC supplementation improved adipogenesis by promoting fatty acid oxidation along with a decrease in fatty acid synthesis in visceral white adipose tissue. They also reported a protective role of GC against glucose intolerance induced by HFD. However, they also showed that long-term GC supplementation increased hepatic collagen accumulation and cytokine expression, thereby exacerbating steatohepatitis. The manuscript has no structural flaws. The hypothesis is relevant and methods to test the hypothesis were uptodate.

Abstract

AIM: To investigate the potential therapeutic effects of mesenchymal stem cells (MSCs) in inflammatory bowel disease (IBD), we transplanted MSCs into an experimental model of IBD.

METHODS: A rectal enema of trinitrobenzene sulfonic acid (TNBS) (100 mg/kg body weight) was administered to female BALB/c mice. Bone marrow mesenchymal stem cells (BMSCs) were derived from male green fluorescent protein (GFP) transgenic mice and were transplanted intravenously into the experimental animals after disease onset. Clinical activity scores and histological changes were evaluated. GFP and Sex determining region Y gene (*SRY*) expression were used for cell tracking. Ki67 positive cells and Lgr5-expressing cells were determined to measure proliferative activity. Inflammatory response was determined by measuring the levels of different inflammatory mediators in the colon and serum. The inflammatory cytokines included tumor necrosis factor-α (TNF-α), interferon-γ (IFN-γ), interleukin-2 (IL-2), IL-6, IL-17, IL-4, IL-10, and transforming growth factor (TGF-β). Master regulators of Th1 cells (T-box expressed in T cells, T-bet), Th17 cells (retinoid related orphan receptor gamma(t), RORγt), Th2 cells (GATA family of transcription factors 3, GATA3) and regulatory T cells (forkhead box P3, Foxp3) were also determined.

RESULTS: Systemic infusion of GFP-BMSCs ameliorated the clinical and histopathologic severity of colitis, including body weight loss, diarrhea and inflammation, and increased survival ($P < 0.05$). The cell tracking study showed that MSCs homed to the injured colon. MSCs promoted proliferation of intestinal epithelial cells and differentiation of intestinal stem cells ($P < 0.01$). This therapeutic effect was mainly mediated by down-regulation of both Th1-Th17-driven autoimmune and inflammatory responses (IL-2, TNF-α, IFN-γ, T-bet; IL-6, IL-17, RORγt), and by up-regulation of Th2 activities (IL-4, IL-10, GATA-3) ($P < 0.05$). MSCs also induced activated $CD4^+CD25^+Foxp3^+$ regulatory T cells (TGF-β, IL-10, Foxp3) with a suppressive capacity on Th1-Th17 effecter responses and promoted Th2 differentiation *in vivo* ($P < 0.05$).

CONCLUSION: MSCs are key regulators of immune and inflammatory responses and may be an attractive candidate for cell-based therapy of IBD.
