Abstract

Anorectal malformations (ARM) are common anomalies in neonates. Diagnostic and therapeutic delays in the management of ARM may lead to colonic perforation, and even death. Physical examination of the perineum is often sufficient to diagnose ARM in neonates. Notwithstanding, delayed diagnosis of ARM has become increasingly familiar to surgeons, as evidenced by the number of recent publications on this topic in the literature. In this commentary, we discuss spontaneous colonic perforation due to delayed diagnosis of ARM in neonates, and highlight the importance of early diagnosis in assuring good outcomes with surgical management. At this point, a thorough examination of the perineum during the initial newborn assessment is mandatory, particularly in those patients presenting with abdominal signs or symptoms.

Key words: Anorectal malformation; Imperforate anus; Bowel perforation; Colon

Core tip: Anorectal malformations (ARM) are common anomalies observed in neonates. The delay in diagnosing a neonate with ARM results in significant complications, occasionally life-threatening morbidity, such as colon perforations. However, delayed diagnosis of ARM seems not the unique factor leading to colonic perforation, deficiency of musculature in the gut wall may also contribute. Colonic perforation due to ARM may not be avoided completely; however, early diagnosis is essential in assuring better outcomes with surgical management.

Tong WD, Ludwig KA. Neonatal colon perforation due to anorectal malformations: Can it be avoided? *World J Gastroenterol* 2013; 19(25): 3915-3917 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/3915.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.3915

COMMENTARY ON HOT TOPICS

We have read with great interest the recent article by Kapadnis *et al* describing a 2.5 kg neonate presenting after 72 h with sigmoid colon perforation due to anorectal malformation (ARM). Delayed diagnosis of ARM has become increasingly familiar to surgeons, as evidenced by the number of recent publications on this topic in the literature[1,2]. Despite the recommendations for peri-natal assessment[3], the overall incidence of a delayed diagnosis has recently been reported to be as high as 21.2%[2]. The delay in diagnosing a neonate with ARM results in significant complications, occasionally life-threatening morbidity, such as colon perforations. Spontaneous perforation of the colon is estimated to occur in 2% of neonates

Table 1 Classification of intestinal perforations complicated with anorectal malformations (n = 25)

Type of perforation	Frequency[1]	Description	Recommended management
Type 1		Perforation occurring before relief of obstruction	
Type 1a	16%	Involving cecum or proximal ascending colon	Cecostomy + distal colostomy
Type 1b	8%	Involving transverse colon including the 2 flexures	Exteriorization of perforation (as colostomy)
Type 1c	60%	Involving distal sigmoid or rectum	Closure of perforation + proximal colostomy
Type 1d	4%	Other sites such as vagina in cloaca	Closure of perforation + proximal colostomy
Type 2	12%	Perforation occurring in the postoperative period	Exteriorization of the perforation site

[1]Calculated by combining the 17 cases reported in the literature and the authors' series.

with ARM, and the incidence rises to 9.5% when the diagnosis is delayed[2]. Thus, it seems crucial to diagnose and treat ARM early to avoid colon perforation.

ARMs are common anomalies observed in neonates[4]. The reported incidence ranges between 1:3300 and 1:5000 live births. In Western countries , there is a male preponderance with 55%-70% of the patients in larger series being males[6]. They vary in severity from mild anal stenosis to complete caudal regression. These disorders usually require surgical intervention in the neonatal period and postoperative follow-up to obtain and maintain fecal and urinary continence. Diagnostic and therapeutic delays in the management of ARM may lead to complications such as sepsis, aspiration, abdominal distension, colonic perforation, respiratory embarrassment, electrolyte imbalance, and even death. The diagnosis of ARM is usually made at birth or shortly thereafter physical examination. Standardized national and international guidelines recommend a routine physical examination of all newborns within the first 48 h of life[3,5]. It has been reported that the median age at diagnosis of perforation in ARM cases was 48 h[6]. Generally, delayed diagnosis of ARM is defined as a diagnosis made after the first 48 h[2]. Undoubtedly, the necessity to diagnose ARM in a timely manner is reliant on a comprehensive neonatal examination performed by a pediatrician or pediatric trainee with sufficient experience. Furthermore, neonatal examination of all newborns should be made within the first 48 h of life. Increasing the awareness among pediatricians of the challenges and complications due to delayed ARM diagnosis may be the important first step. Additional training to adequately diagnose ARM, or change current guidelines to explicitly rule out ARM is also required. Some researchers believe that a higher incidence of associated anomalies may promote earlier diagnosis of the ARM[2], whereas others failed to confirm this hypothesis[7]. Wilson *et al*[7] believed that the only significant predictor of delayed diagnosis of ARM was a failure to receive a comprehensive neonatal examination within 48 h, reiterating that timely diagnosis of ARM is best achieved by adequate clinical examination.

However, colonic perforations cannot be simply attributed to the delayed diagnosis or treatment of ARM, because there are a few case reports of bowel rupture occurring during intrauterine life[8]. Based on their research and review of the literature, Raveenthiran[6] summarized two distinct patterns of perforations involving four different sites and recommended management (Table 1). Approximately 88% of perforations are of type 1, whereas only 12% are of type 2. Among the type 1 perforations, 60% occur in the rectum and sigmoid colon[6]. This difference suggests that the mechanism of perforation could be different for the two types. A higher ratio of rectosigmoid perforation in ARM implies an embryologic origin. As ARM is a developmental field defect, the tail end of the gut can be expected to have deficiency of musculature. The downstream obstruction leads to increased intraluminal pressure, and this, along with the muscular deficiency, is probably responsible for more frequent rupture of the rectum in ARM. Mathur *et al*[9] reported five perforations (6.5%) among 77 cases of ARM with congenital pouch colon (CPC). A high incidence of bowel perforation in CPC also favors the muscular deficiency theory. At this point, delayed diagnosis of ARM seems not the unique factor leading to colonic perforation.

Despite the fact that not all colonic perforations are the result of delayed diagnosis of ARM, the majority are, and early diagnosis is essential so that surgical management can commence to achieve better outcomes. At this point, a thorough examination of the perineum during the initial newborn assessment is mandatory, particularly in those patients presenting with abdominal signs or symptoms.

Abstract

Prevention has a paramount role in reducing the incidence of corrosive ingestion especially in children, yet this goal is far from being reached in developing countries, where such injuries are largely unreported and their true prevalence simply cannot be extrapolated from random articles or personal experience. The specific pathophysiologic mechanisms are becoming better understood and may have a role in the future management and prevention of long-term consequences, such as esophageal strictures. Whereas the mainstay of diagnosis is considered upper gastrointestinal endoscopy, computed tomography and ultrasound are gaining a more significant role, especially in addressing the need for emergency surgery, whose morbidity and mortality remains high even in the best hands. The need to perform emergency surgery has a persistent long-term negative impact both on survival and functional outcome. Medical or endoscopic prevention of stricture is debatable, yet esophageal stents, absorbable or not, show promising data. Dilatation is the first therapeutic option for strictures and bougies should be considered especially for long, multiple and tortuous narrowing. It is crucial to avoid malnutrition, especially in developing countries where management strategies are influenced by malnutrition and poor clinical conditions. Late reconstructive surgery, mainly using colon transposition, offers the best results in referral centers, either in children or adults, but such a difficult surgical procedure is often unavailable in developing countries. Possible late development of esophageal cancer, though probably overemphasized, entails careful and long-term endoscopic screening.

Key words: Caustic ingestion; Corrosive stricture; Developing countries; Surgical management; Endoscopic management

Core tip: The incidence of corrosive ingestion is high and largely unreported in developing countries, where prevention is lacking. Computed tomography and endoscopic ultrasound are gaining a more meaningful role in addressing the need for emergency surgery. The need to perform emergency surgery has a persistent long-term negative impact both on survival and functional outcome. Prevention of stricture is still a debatable issue, yet esophageal stents may offer promising outcomes. It is crucial to avoid malnutrition, especially in developing countries where management strategies are conditioned by poor clinical conditions. Late reconstructive surgery is often unavailable in developing countries.

INTRODUCTION

Ingestion of corrosive substances remain an important

public health issue in Western countries despite education and regulatory efforts to reduce its occurrence. These injuries are still increasing in developing countries[1,2], related to the social, economic, and educational variables and mainly to a lack of prevention[3,4]. The problem is largely unreported in these settings and its true prevalence simply cannot be extrapolated from the scarce papers or personal experience. Data available are heavily skewed towards well-resourced centers and do not mirror the full reality of the condition. Moreover, in industrialized and developing countries, the therapeutic approach and management strategies appear to be different, likely because of technology and endoscopic expertise.

Two independent MEDLINE and EMBASE searches from 1990-2012 were performed to identify relevant articles. The following medical subject headings terms were used in the searches: caustic ingestion, caustic lesions, corrosive injuries, esophagus, esophageal dilatation. Bibliographies of retrieved studies were reviewed and general medical and major gastroenterology journals manually searched over the previous 5 years.

Table 1 Most commonly ingested caustic substances

Caustic substance	Type	Commercially available form
Acids	Sulfuric	Batteries
		Industrial cleaning agents
		Metal plating
	Oxalic	Paint thinners, strippers
		Metal cleaners
	Hydrochloric	Solvents
		Metal cleaners
		Toilet and drain cleaners
		Antirust compounds
	Phosphoric	Toilet cleaners
Alkali	Sodium hydroxide	Drain cleaners
		Home soap manufacturing
	Potassium hydroxide	Oven cleaners
		Washing powders
	Sodium carbonate	Soap manufacturing
		Fruit drying on farms
Ammonia	Commercial ammonia	Household cleaners
	Ammonium hydroxide	Household cleaners
Detergents, bleach	Sodium hypochlorite	Household bleach, cleaners
	Sodium polyphosphate	Industrial detergents
Condy's crystals	Potassium permanganate	Disinfectants, hair dyes

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Worldwide, children represent 80% of the ingestion injury population globally[5], primarily due to accidental ingestion[6]. In contrast, ingestion in adults is more often suicidal in intent, and is frequently life-threatening.

Traditionally, ingested corrosive substances are either alkalis or acids (Table 1). Alkaline material accounts for most caustic ingestions in Western countries whereas injuries from acid are more common in some developing countries, like India, where hydrochloric acid and sulfuric acid are easily accessible[7]. Acids and alkalis produce different types of tissue damage. Acids cause coagulation necrosis, with eschar formation that may limit substance penetration and injury depth[8]. Conversely, alkalis combine with tissue proteins and cause liquefactive necrosis and saponification, and penetrate deeper into tissues, helped by a higher viscosity and a longer contact time through the esophagus. Additionally, alkali absorption leads to thrombosis in blood vessels, impeding blood flow to already damaged tissue[9]. Injury occurs quickly, depending on the agent's concentration and time of exposure (Figure 1)[10], with a 30% solution of sodium hydroxide being able to produce full thickness injury in 1 s[11]. Accordingly, alkali ingestion may lead to more serious injury and complications, but this distinction is probably not clinically relevant in the setting of strong acid or base ingestion, both being able to penetrate tissues rapidly, potentially leading to full-thickness damage of the esophageal/gastric wall. The conventional acceptance that acids preferentially damage the stomach, due to the protective esophageal eschar, has recently been questioned, with observation of extensive esophageal damage and perforations after acid ingestion[12]. Likewise, compared with alkali, ingestion of a strong acid may be associated with a higher incidence of systemic complications, such as renal failure, liver dysfunction, disseminated intravascular coagulation and hemolysis[13].

Esophageal injury begins within minutes and may persist for hours. Initially, tissue injury is marked by eosinophilic necrosis with swelling and hemorrhagic congestion[9]. Experimental findings suggest that arteriolar and venular thrombosis with consequent ischemia may be more important than inflammation in the pathogenesis of acute corrosive injury[10]. Four to 7 d after ingestion, mucosal sloughing and bacterial invasion are the main findings. At this time granulation tissue appears, and ulcers become covered by fibrin. Perforation may occur during this period if ulceration exceeds the muscle plane. Fibroblasts appear at the injury site around day 4, and around day 5, an "esophageal mold" is formed, consisting of dead cells and secretions. Esophageal repair usually begins on the 10th day after ingestion, whereas esophageal ulcerations begin to epithelialize approximately 1 mo after exposure. The tensile strength of the healing tissue is low during the first 3 wk since collagen deposition may not begin until the second week. Hence, endoscopy (and of course dilatation) is preferably avoided 5-15 d after ingestion[14]. Scar retraction begins by the third week and may continue for several months, resulting in stricture formation and shortening of the involved segment of the gastrointestinal tract. Additionally, lower esophageal sphincter pressure becomes impaired, leading to increased gastroesophageal reflux (GER), which in turn accelerates stricture formation[15]. GER is indeed a likely significant factor in persistent strictures not responding to sequential esophageal dilatations. Esophageal motility studies report low amplitude and nonperistaltic contractions, with a significantly higher exposure to pH below 4, compared with control groups[16]. Therefore, all caustic esophageal burn patients should be screened for GER

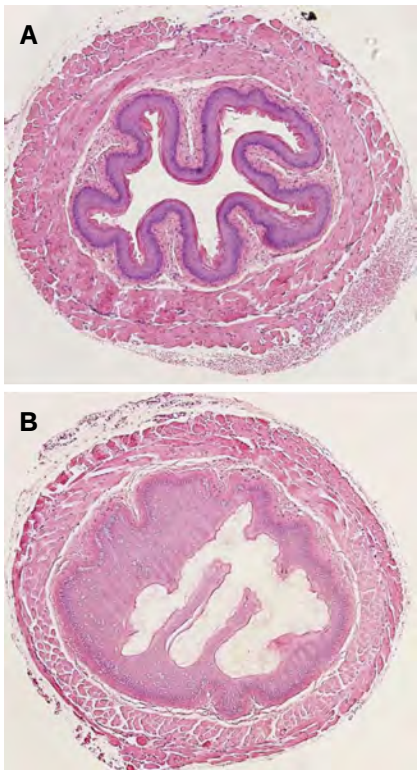

Figure 1 Murine esophagus exposed for 10 min to control (A) and 10% NaOH (B). Reproduced from Osman *et al*[10].

periodically, and GER should be controlled aggressively.

Reactive oxygen species generation with subsequent lipid peroxidation may contribute either to the initial esophageal injury, or to the subsequent stricture formation. Malondialdehyde, an end-product of lipid peroxidation, was found at significantly higher levels than normal in esophageal tissue exposed to sodium hydroxide, signifying the presence of reactive oxygen species at 24 h post exposure. These concentrations remained high for 72 h after exposure compared with no injured controls. Furthermore, significantly lower glutathione concentrations, a known endogenous free-radical scavenger, were found in the same tissues compared with controls, further supporting the presence of reactive oxygen species and free-radical damage[17].

CLINICAL PRESENTATION

Clinical features depend on the type of the substance, amount, physical form and time of presentation (early or delayed). Crystals or solid particles may adhere to the mucosa of the mouth, making them difficult to swallow and thereby diminishing the injury produced to the esophagus, but potentially increasing the damage to the upper airway and pharynx. Conversely, liquids are easily swallowed and are most likely to damage the esophagus and stomach, the extent of injury correlating directly with mortality and late sequelae[18,19]. Patients with oropharyngeal burns do not have significant damage to the esophagus in up to 70%, hence their presence is not a reliable index of esophageal damage[20]. Hoarseness and stridor suggest laryngeal or epiglottic involvement; dysphagia and odynophagia imply esophageal damage while epigastric pain and bleeding are more common in stomach involvement. The absence of pain does not preclude significant gastrointestinal damage. Later changes, such as appearance or worsening of abdominal or chest pain, should be carefully monitored and promptly investigated, since esophageal or gastric perforations can occur at any time during the first 2 wk after ingestion[5].

The relationship between symptoms and severity of injury is uncertain[21]. Stridor and drooling were considered 100% specific for significant esophageal injury[22,23], but no single symptom or symptom cluster can predict the degree of esophageal damage[20,24,25].

The incidence of coexistent gastric injury in the literature ranges from 20.0% to as high as 62.5%[26,27], extending from simple hyperemia/erosions to diffuse transmural necrosis. Delayed gastric emptying with consequent accumulation of food in the stomach (likely due to the contraction of the antropyloric region) may affect the severity of injuries. The most common presentation of an acute corrosive gastric burn is abdominal pain, vomiting, and hematemesis. Rarely, a full thickness burn can cause an immediate gastric perforation, which tends to present a few days after ingestion. Gastric perforation, early or delayed, carries a significant mortality[28], and is more rarely reported in children. Clinical examination and a careful follow-up with a computed tomography (CT) scan are likely more useful than endoscopy in assessing threatened or existing perforation[29]. Bleeding following corrosive ingestion is usually self-limiting: though massive hemorrhage from the stomach or duodenum has been reported a short time after corrosive ingestion[30], severe bleeding typically occurs at 2 wk after ingestion[29].

Respiratory complications from caustic ingestion may result in laryngeal injury and upper airway edema, which ultimately may require tracheotomy[31] and is usually coupled with extensive esophageal damage. Laryngeal injuries were diagnosed by flexible fiberoptic or rigid laryngoscopy in 38% of patients after caustic ingestion, but only few (8%) required immediate intubation and mechanical ventilation for respiratory distress on admission[11]. This low rate of lower airway and pulmonary complications suggests that the protective pharyngeal-glottic mechanism is highly efficient in preventing the caustic substance to reach the lower airway.

EVALUATION AND ASSESSMENT

Laboratory studies

Correlation between laboratory values and the severity/outcome of injury is poor. A high white blood cell count (> 20000 cells/mm^3), elevated serum C-reactive protein, age and the presence of an esophageal ulcer have been considered predictors of mortality in adults[32]; an arterial pH less than 7.22 or a base excess lower than -12 have been considered indication of severe esophageal injury

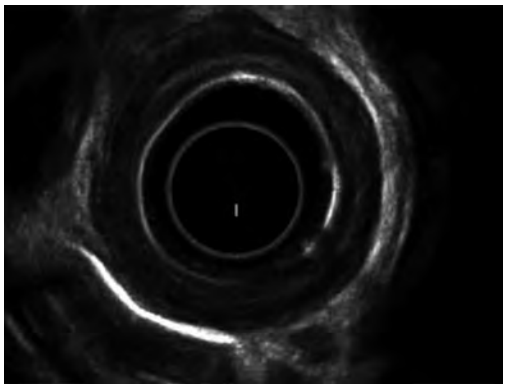

Figure 2 Endoscopic ultrasound showing involvement of the muscularis propria of esophageal wall. Reproduced from Kamijo *et al*[37].

and of emergency surgery[33]. Essentially, laboratory studies are more useful in monitoring and guiding patient management than in predicting morbidity or mortality[34].

Traditional radiology

Shortly after ingestion, a plain chest radiograph may reveal air in the mediastinum suggesting esophageal perforation, as well as free air under the diaphragm, indicating gastric perforation. If it is felt necessary to confirm a clinically suspected perforation, a water-soluble agent, such as Hypaque™ or Gastrografin™, and less irritant than barium sulphate, should probably be used, though both can be equally irritant[35]. Conversely, barium sulfate should be the preferred contrast agent in late barium swallowing, providing greater radiographic details than water-soluble contrast agents[22].

Ultrasounds

Evaluation of esophageal wall caustic damage by endoscopic ultrasound (EUS) using a miniprobe seems safe, though prolongs examination time without showing any difference with endoscopy in predicting early complications[36]. The destruction of the muscular layers of the esophagus observed at EUS seems a reliable sign of future stricture formation[37]; furthermore, ultrasound examination with a radial probe may predict the response to dilatation, which usually requires more sessions when the *muscolaris propria* is involved at EUS, as in Figure 2[38]. In spite of these encouraging reports, the role of US examination in caustic injuries is still under evaluation.

CT scan

A CT scan likely offers a more detailed evaluation than early endoscopy about the transmural damage of esophageal and gastric walls and the extent of necrosis[39]. It is more valuable than endoscopy in assessing threatened or established stomach perforation[29], and a CT grading system (Table 2 and Figure 3) has been proposed to predict esophageal stricture[40,41]. With the advantage of not being invasive, CT scan has a promising role in the early evaluation of caustic injury damage.

Table 2 Computed tomography grading system for caustic lesions

Grade	Features
Grade 1	No definite swelling of esophageal wall
Grade 2	Edematous wall thickening without periesophageal soft tissue involvement
Grade 3	Edematous wall thickening with periesophageal soft tissue infiltration plus well-demarcated tissue interface
Grade 4	Edematous wall thickening with periesophageal soft tissue infiltration plus blurring of tissue interface or localized fluid collection around the esophagus or descending aorta

Reproduced from Ryu *et al*[40].

Endoscopy

Esophagogastroduodenoscopy is considered crucial and usually recommended in the first 12-48 h after caustic ingestion, though it is safe and reliable up to 96 h after the injury[13,42]; gentle insufflation and great caution are mandatory during the procedure. Endoscopy and even dilatation have been performed without consequences from 5 to 15 d after corrosive ingestion[43], though potentially hazardous due to tissue softening and friability during the healing period. Adequate sedation (general anesthesia in children) is compulsory, yet endotracheal intubation is strictly required only for patients in respiratory distress. The constraint to stop the endoscope in the presence of a circumferential second or third degree esophageal burn is not mandatory[44,45].

When lip and oropharyngeal injuries are the main clinical findings, esophageal or gastric injuries are generally no greater than grade 1[46]. Although severe esophageal injuries have been reported in 12.0%[47] and 19.3%[48] of asymptomatic children, significant lesions at endoscopy are not usually observed when symptoms are absent after unintentional ingestion of less aggressive substances[24,49], thus making routine post-ingestion endoscopy questionable in this group of patients. All adult patients must undergo endoscopy after suicidal ingestion, because of the larger amount of more corrosive agents swallowed compared with unintentional injuries, where early esophagoscopy has been questioned[50]. Ultimately, though endoscopy is considered by most a cornerstone in the diagnosis of corrosive ingestions, which patients would clearly benefit from it is still debated. Considering that 10%-30% of caustic ingestions globally do not show any upper gastrointestinal injury[22,51], the indication for early endoscopy should be made on a case-by-case basis, with consideration of symptoms, otorhinolaryngeal injuries, and the amount and nature of the ingested substance.

Contraindications to endoscopy are a radiologic suspicion of perforation or supraglottic or epiglottic burns with edema, which may be a harbinger of airway obstruction, therefore indicating endotracheal intubation or tracheostomy. A third degree burn of the hypopharynx is a further contraindication for endoscopy[22].

Endoscopic classification[8] is important for prognosis and management (Table 3). Generally, grade 0 and 1 le-

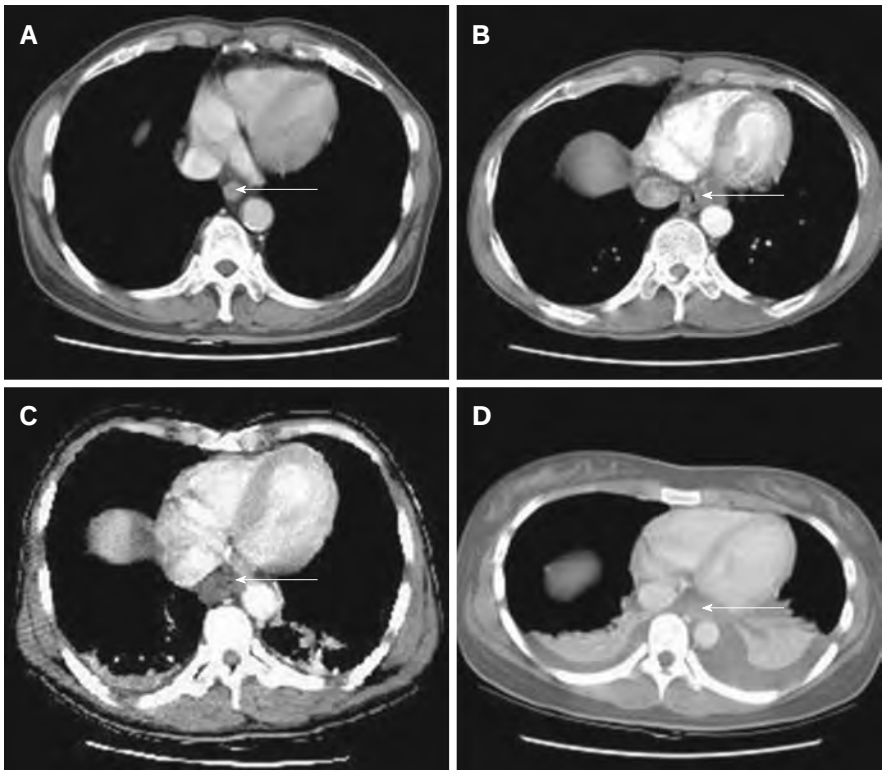

Figure 3 Computed tomography grading of esophageal caustic injuries. A: Grade 1; B: Grade 2; C: Grade 3; D: Grade 4. Reproduced from Ryu *et al*[40]. Arrows show the esophageal wall.

Table 3 Endoscopic classification of caustic injuries

Grade	Features
Grade 0	Normal
Grade 1	Superficial mucosal edema and erythema
Grade 2	Mucosal and submucosal ulcerations
Grade 2A	Superficial ulcerations, erosions, exudates
Grade 2B	Deep discrete or circumferential ulcerations
Grade 3	Transmural ulcerations with necrosis
Grade 3A	Focal necrosis
Grade 3B	Extensive necrosis
Grade 4	Perforations

Reproduced from Zargar *et al*[14].

sions do not develop delayed sequels, such as esophageal strictures or gastric outlet obstruction, whose incidence increases with the severity of the lesion. Additionally, the degree of esophageal injury at endoscopy is an accurate predictor of systemic complications and death, with each increased injury grade correlated with a 9-fold increase in morbidity and mortality[14]. Emergency surgery can be planned according to the endoscopic degree of burn, though an isolated black eschar does not always indicate full-thickness injury and the need for immediate surgical treatment: such patients may deserve further evaluation and careful observation. Recently, some concerns have been raised about the correlation between endoscopic findings and the extent of necrosis[39]: gastrectomy was considered unnecessary at laparotomy in 12% of patients with gastric injuries staged 3b at endoscopy, while the decision to perform esophagectomy based exclusively on endoscopic findings led to unnecessary esophagectomy in 15% of cases[52], suggesting the need for better criteria to improve patient selection for emergency surgery.

MANAGEMENT

Acute management

Immediate treatment is usually conservative, as the definitive extent of the injury is determined within minutes after ingestion. Hemodynamic stabilization and adequacy of the patient's airway are priorities. If the airway is unstable, fiberoptic laryngoscopy allows intubation under direct visualization, avoiding "blind" intubation with the risk of bleeding and additional injuries. In challenging patients, a surgical airway may be required. Gastric lavage and induced emesis are contraindicated for the risk of re-exposure to the corrosive agent and additional injury to the esophagus. The effectiveness of milk and water either as antidotes or to dilute the corrosive agents has never been proven. pH neutralization, with either a weak acid or base, is not recommended for fear of an exothermic reaction, which may increase the damage. Milk and activated charcoal are contraindicated because may obscure subsequent endoscopy. Nasogastric tubes may be applied to prevent vomiting and as stent in severe circumferential burns, but their validity has never be proven. In any case they should not be placed blindly because of the risk of esophageal perforation[53].

To date, the efficacy of proton-pump inhibitors and H_2 blockers in minimizing esophageal injury by suppressing acid reflux has not been proven, though an impressive endoscopic healing after *iv* omeprazole infusion has been observed in a small prospective study[54].

The utility of corticosteroid is controversial. A meta-analysis of studies between 1991 and 2004, and an ad-

ditional analysis of the literature over a longer period from 1956 to 2006 did not find any benefit of steroid administration in terms of stricture prevention. Steroids are usually reserved for patients with symptoms involving the airway[55,56].

The administration of broad-spectrum antibiotics is usually advised mainly if corticosteroids are initiated, as well as if lung involvement is identified[53,57].

Patients whose injuries are graded 1 and 2A are permitted oral intake and discharged within days with antacid therapy. In more severe cases (grade 2 or 3), observation in an intensive care unit and adequate nutritional support is required.

Early surgery

Patients with clinical or radiological evidence of perforation require immediate laparotomy, usually followed by esophagectomy, cervical esophagostomy, frequently concomitant gastrectomy and even more extensive resections, and jejunostomy feeding[58-60]. Some patients without features of perforation at admission may later develop necrosis, perforation and massive bleeding with disastrous results. Indications for emergency surgery rely more often on clinical grounds than on radiological findings; in the presence of doubtful clinical features a decision to perform laparotomy is likely more advantageous for patients than a conservative attitude especially in patients who ingested large amounts of corrosive substances[60].

Laboratory and endoscopic criteria for emergency surgery have been suggested, including disseminated intravascular coagulation, renal failure, acidosis and third degree esophageal burns[58,61]. Unfortunately, these are often late findings and surgery may improve mortality and morbidity in grade 3A injuries only[14].

Severe injuries of the stomach at endoscopy require careful monitoring with a low threshold for laparotomy. At surgery, a gastrotomy allows an accurate evaluation of the extent of damage, since mucosal (and transmural) necrosis may be more extensive than what is apparent from the serosal side. There is no role for procedures such as closure of a perforation. Conservative management of severe gastric injuries at laparotomy, with partial or total conservation of the stomach, has been recently advocated by some in the absence of clinical and biological signs of severity[62].

The need to perform surgery for caustic injuries has a persistent long-term negative impact both on survival and functional outcome. Moreover, esophageal resection *per se*, is an independent negative predictor of survival after emergency surgery[52].

Laparoscopy has been proposed when gastric perforation is highly suspected[63], but the mini-invasive approach has two caveats: unless in very expert hands, it is not a substitute for a comprehensive abdominal exploration, particularly in the posterior aspects of the stomach and duodenum, and it can extend the operative time excessively in a situation where time is a major determinant of outcome. However, it might be considered a useful tool when the stomach cannot be evaluated by endoscopy. Some authors have proposed routine laparoscopic examination in all injuries of second degree or greater[63,64] but the experience is still limited and laparoscopy may be neither feasible nor helpful in such dramatic circumstances.

All injured organs must be resected, if possible, during the first operation. Minimal resection followed by a planned second-look procedure is not recommended. However, secondary extension of caustic burns is unpredictable and re-exploration is indicated when in doubt. An extended resection to adjacent abdominal organs, even the pancreas, does not necessarily carry a prohibitive risk of death in referral centers[60], but an extensive colon resection may compromise future reconstruction and require vascular surgery for atypical transplants. A massive intestinal necrotic injury represents a reasonable limit for resection.

Emergency surgery may be required in the case of severe, uncontrolled late gastric bleeding, usually 1-2 wk after ingestion. Total gastrectomy may be necessary. In duodenal hemorrhages, under-running of the bleeding vessel through a duodenotomy is advised[29].

Acute surgery is quite exceptional in the pediatric population and most authors recommend exhausting all resources to try to preserve the child's native esophagus[25].

Late sequelae

Following a grade 2B and a grade 3 esophageal burn, stricture incidence may be 71%[14] and 100%, respectively[45,53]. Strictures usually develop within 8 wk after the ingestion in 80% of patients, but it can happen as early as after 3 wk or as late as after 1 year. Obviously, ingestion of powerful caustic substances (*e.g.*, sodium hydroxide) is followed by severe, long-standing strictures and dramatically altered esophageal motility[65].

Late sequelae of corrosive gastric injury include intractable pain, gastric outlet obstruction, late achlorhydria, protein-losing gastroenteropathy, mucosal metaplasia and development of carcinoma[66]. Gastric outlet obstruction has an incidence of 5%[67], mainly in the prepyloric area, where prolonged contact with the antral mucosa due to pyloric spasms and to resulting pooling of the caustic agent in this region[55] usually results in stricture in more than 60% of patients[68]. When the volume of the corrosive substance ingested is large, the entire stomach is scarred leading to a diffusely contracted stomach.

Stricture prevention

Steroids: Systemic administration of steroids seems ineffective in preventing strictures[55,56], especially in patients with 3rd degree esophageal burns. Intralesional triamcinolone injections have been proposed to prevent strictures[69], but optimal dose, frequency, and best application techniques are still to be defined[70].

Antibiotics: Though an old study reports a marked decrease in stricture formation with the use of antibiotics[71],

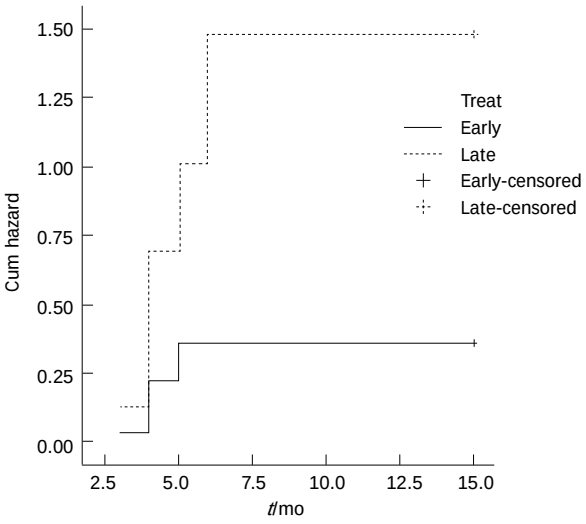

Figure 4 Significantly higher hazard of re-dilatation in patients submitted to late dilatation. $P = 0.0008$. Reproduced from Contini *et al*[97].

no prospective trial evaluated their utility, and their value in the setting of caustic ingestion, in the absence of concomitant infection, is unknown[18]. There is a consensus that patients treated with steroids should also be treated with antibiotics, but prophylactic antibiotics to prevent strictures, in the absence of steroid therapy, has not been advocated[72].

Nasogastric tube: Though a nasogastric tube may be helpful to ensure patency of the esophageal lumen, the tube itself can contribute to the development of long strictures and routine use is not uniformly recommended[22]. Any esophageal catheterization may be a nidus for infection and nasogastric placement may worsen gastroesophageal reflux in this patient population, with a consequent delay in mucosal healing. However, enteral nutrition through a nasogastric tube has been demonstrated to be as effective as jejunostomy feeding in maintaining nutrition in such patients, with a similar rate of stricture development[73]. Moreover, positioning a nasogastric tube has the advantage of providing a lumen for dilatation should a tight stricture develops. Therefore, after caustic injuries the placement of a nasogastric tube may be considered, but the decision should be made with caution and done on a case-by-case basis.

Mitomycin C: Mitomycin C, a chemotherapeutic agent with DNA crosslinking activity, when injected or applied topically to the esophageal mucosa, may be valuable in preventing strictures, but this drug has deleterious adverse effects, especially if systemic absorption occurs across the intact mucosa[74]. A recent systematic review indicated encouraging results in the long term[75], but prospective studies are clearly mandatory to determine the most effective concentration, duration and frequency of application[76]. The theoretical risk of secondary long-term malignancy should also be taken into account[77].

Intraluminal stent: Specially designed silicone rubber[78] or, more recently, polyflex stents[79] have been found helpful in preventing stricture formation but the efficacy is less than 50%, with a high migration rate (25%). Patient selection remains a challenge and the development of hyperplastic tissue is a concern. Home-made polytetrafluoroethylene stents have shown promising results with a 72% efficacy[80] at 9-14 mo, similar to home-made silicone stents positioned by endoscopy[81] or through laparotomy[82] for 4-6 mo. Biodegradable stents (poly-*L*-lactide or polydioxanone) are under evaluation for benign strictures[83,84], with a 45% success rate at 53 mo in a patient population with only two caustic strictures, a migration rate of around 10%, and a significant hyperplastic tissue response. Experimentally, biodegradable stents were not able to prevent strictures in pigs after circumferential submucosal resection[85]. Moreover, cost and minimal experience in caustic strictures make the use of biodegradable devices questionable, especially in developing countries.

Other modalities for stricture prevention under evaluation: Intraperitoneal injection of 5-fluorouracil has been effective in preventing strictures experimentally[86]. Anti-oxidant treatment (vitamin E, H_1 blocker, mast cell stabilizer, methylprednisolone) and phosphatidylcoline[87,88] inhibit collagen production and stricture formation by decreasing tissue hydroxyproline, the ultimate product of collagen degradation, but no human study is available. Octreotide and interferon-alfa-2b have been shown in animals to depress the fibrotic activity in the second phase of wound healing of the esophageal wall after a corrosive burn[89]. Cytokines have also been used experimentally with success to prevent stricture formation[90]. Until now, none of the above approaches, albeit appealing, has been tested in humans.

Stricture management

Endoscopic dilatation: Timely evaluation and dilatation of the stricture play a central role in achieving a good outcome[91]. Late management is usually associated with marked esophageal wall fibrosis and collagen deposition[5], which makes dilatation more complex. Maximal esophageal wall thickness, observed at CT scan, was associated with a higher number of sessions required for adequate dilatation[92], and recurrent strictures were significantly more frequent after delayed dilatation (Figure 4)[93-95]. Moreover, delayed presentation and treatment have been found to be strong predictors of future esophageal replacement[96]. This issue, which may entail different management strategies[3] for early or late patients, may be crucial in developing countries, where late presentations are more than 50%[2,97,98].

Dilatation can be carried out with balloon or bougies (usually Savary) without a clear advantage for each method[70]. However, the failure rate after pneumatic dilatation is higher in caustic ingestion-related strictures than in other benign strictures[99]; Savary bougies are considered more reliable than balloon dilators in consoli-

dated and fibrotic strictures such as old caustic stenosis or in long, tortuous strictures[100,101], and may offer the operator the advantage of feeling the dilatation occurring under his hands[102]. Dilatation should be avoided from 7 to 21 d after ingestion for the risk of perforation, though early, prophylactic dilatation with bougienage has been reported to be safe and effective even in this period[43]. The perforation rate after dilatation of benign esophageal strictures varies between 0.1% and 0.4%[70], but for caustic strictures it fluctuates from 0.4% to 32.0%, dropping from 17.6% to 4.5% with increased experience[103]. The 5%-8% perforation rate after balloon dilatation[104] may be as high as 32% in caustic strictures[105]. Indeed, radiological intramural and well-contained transmural esophageal ruptures were observed in 30% of balloon dilatation procedures[106]. In addition, balloon inflation may cause either extrinsic mechanical compression of the trachea or obstruction at the endotracheal tube tip[107]. Therefore, the use of the balloon catheter in children entails careful intraoperative monitoring and likely requires greater endoscopic skill and experience than for Savary bougies. If these requirements are not met, as is often the case in developing countries, pneumatic dilatations will carry a considerable risk and then require extra caution, so that bougie dilatation is preferred.

The interval between dilatations varies from less than 1 to 2-3 wk and usually 3-4 sessions are considered sufficient for durable results, although the number of dilatations required may be unpredictable and quite high[103]. In challenging strictures, a nylon thread left between the nose and the gastrostomy maintains luminal access and facilitates further dilatations when an expert endoscopist is not available[108,109]. A cut-off value for unsuccessful dilatation treatment may be difficult to define, especially in developing countries, where alternative surgical options are not widely available.

A good nutritional state is crucial for a successful outcome, especially in children, and both an improvement in nutritional status and sustained esophageal patency should be considered reference points for a successful dilatation[3]. Changes in feeding practices may be required in order to maintain an adequate nutritional status[110]. In developing countries, delayed presentation and severity of strictures due to the more corrosive substances usually ingested, together with poor nursing and surgical care make this target quite challenging. In such a scenario, feeding by nasogastric tube for long periods may be tolerated with difficulty and a gastrostomy is more effective and often necessary to attain an acceptable nutritional state. Moreover, gastrostomy allows a retrograde approach for dilatation, which is usually easier and safer[111,112].

RISK OF CANCER

Esophageal neoplasms (both adenocarcinoma and squamous cell carcinoma) may develop as a late complication of caustic injury at a rate 1000-3000 times higher than expected in patients of a similar age[113] and have actually been reported only 1 year after ingestion[114]. The reported incidence ranges from 2% to 30%, with an interval from 1 to 3 decades after ingestion[53]. Cancer is most commonly observed at the areas of anatomic narrowing, and may be related to increased exposure to the caustic substance. Esophageal bypass surgery does not prevent the development of esophageal cancer following caustic ingestion[53]. The problem may be overestimated, in accordance with the low number of esophageal cancer reported in a large series with long-term follow-up[9,115,116], yet endoscopic screening is still recommended for patients following caustic ingestion. Moreover, the role of other confounding factors, such as alcohol abuse or smoking habit, should be considered[39].

DISMOTILITY

Orocecal transit time is prolonged mainly in patients with lower third esophageal involvement of the burn[65], probably related to autovagotomy due to vagal entrapment in the cicatrization process involving the lower third of the esophagus. Moreover, impaired vagal cholinergic transmission, possibly due to the same mechanism[117] can explain the increased fasting gallbladder volume and decreased gallbladder emptying found in patients after lower esophageal damage.

Gastric emptying time of liquids after caustic ingestion, was found to be significantly prolonged in patients with lower esophageal strictures, but not in upper-middle esophageal strictures, even in the absence of symptoms suggestive of gastric outlet obstruction or gastroparesis[118].

Late surgery

Surgery for non-responding esophageal strictures: When esophageal dilatation is not possible or fails to provide an adequate esophageal caliber in the long-term, esophageal replacement by retrosternal stomach or, preferably, right colonic interposition should be considered. Mortality and morbidity are low in expert hands[119,120]. The more demanding pharyngoesophageal strictures may be treated with acceptable results, provided considerable expertise is available[121]. The native esophagus can be left or removed. Though resection of the scarred esophagus may be performed without a substantial increase in morbidity and mortality compared to by-pass[120], a 13% incidence of esophageal cancer after by-pass[93], the risk of infected esophageal mucocele in 50% of the patients after 5 years[94], and the impossibility of endoscopic follow-up for cancer are all arguments favoring esophageal resection. Removal of the native esophagus seems advisable in children because of the risk of cancer in a long life period. Conversely, the doubled mortality rate (11.0% *vs* 5.9%) of resection *vs* by-pass[122], the possible damage to the trachea and laryngeal nerve, and the low reported incidence (3.2%) of esophageal malignancy, could support a conservative strategy. In children, reconstruction with gastroplasty seems easier, and more functional failures can be expected with coloplasty[123-125]. In developing

countries, experienced pediatric surgical centers are not widely available and this should be considered before abandoning the conservative approach of dilatation.

Surgery for stomach injuries: The timing and type of elective surgery for gastric outlet obstruction is still controversial. Early surgery has been advised to decrease mortality and morbidity[67,126]. Conversely, elective surgery earlier than 3 mo has been considered risky because of poor nutritional state and the presence of adhesions and the edematous gastric wall[27]. Moreover, assessment of the limits of the gastric resection may be difficult, due to ongoing fibrosis. Endoscopic balloon dilatation and/or intralesional steroid injection have been proposed as alternatives[127,128]. However, endoscopic gastric dilatation should be considered a temporary substitute for surgical resection because gastric wall fibrosis usually diminishes the long-term functional result[129,130]. Moreover, although dilatation averts surgery in less than 50% of patients[127], perforation can occur in strictures longer than 15 mm[131]. Pyloroplasty has been recommended for moderate strictures[67], but progressive fibrosis causing recurrent stricture occurs frequently. Gastrojejunostomy is a safer alternative to gastric resection in the presence of extensive perigastric adhesion, an unhealthy duodenum, and poor general condition; marginal ulceration is rarely reported[27,132] possibly due to physiologic antrectomy resulting from mucosal damage[66]. Partial gastric resection is preferred by many[133,134] for the long-term risk of malignant transformation, though the need for gastric resection as prophylaxis against future malignancy has been overstated in the literature[29]. Previous reports of gastric carcinomas after acid ingestion are usually old and limited[135,136]. Regular follow-up and surveillance endoscopy is a more reliable approach.

Late reconstructive surgery after emergency esophagectomy: When the stomach has been removed or shows chronic injuries, the use of a gastric tube for esophageal reconstruction is obviously precluded. Reconstruction is probably advisable at the end of the evolving scarring process, usually after 6 mo, although the optimal timing of reconstruction has been reported from 2 mo to years[94,137,138]. The functional success rate after colon reconstruction at 5 years is 77% and the severity of the initial insult or a delay more than 6 mo, may strongly influence the outcome[119]. Coloplasty dysfunction is responsible for half of the failures, with an overall 70% success rate after revision surgery in expert hands. An emergency tracheostomy may have an adverse impact on the outcome of a colopharyngoplasty[139]. Secondary esophagocoloplasty should be considered with good results if intraoperative colon necrosis occurs at the time of primary reconstruction[140].

CONCLUSION

Ingestion of corrosive substances is increasingly reported in developing countries, due to lack of education and prevention. The relationship between symptoms and severity of injury may be vague, and patients should be carefully monitored, since esophageal or gastric perforations can occur at any time during the first 2 wk after ingestion. Endoscopy is considered a cornerstone in the diagnosis of corrosive ingestions, yet the indication for early endoscopy should likely be made on a case-by-case basis. Reported discrepancies between endoscopic findings and the extent of necrosis found at surgery suggest the need for better criteria to improve patient selection for emergency surgery. A CT scan may offer a promising role in assessing the evolution of the injury and impending perforations. In suicide attempts, mortality is still high and the need to perform emergency surgery for caustic injuries has a persistent long-term negative impact both on survival and functional outcome. However, timely and early surgery may be the only hope for patients with severe injuries, and a rather aggressive attitude should be considered in such patients.

Main late sequelae include esophageal strictures, often accompanied by undernourishment, especially in developing countries. The likelihood of a gastric outlet obstruction should always be kept in mind. The presence of severe GER and of esophageal dysmotility may worsen the prognosis. Stricture prevention by stents seems promising but the experience is still limited. Systemic corticosteroids offer no role. Endoscopic dilatation is usually successful in achieving a patent esophageal lumen, but in complex strictures several attempts must be carried out, and in such patients bougies may be preferred to balloon dilatation. A cut-off value for unsuccessful dilatation treatment may be difficult to define, especially in developing countries, where alternative surgical options are not widely available. Both an improvement in nutritional status and a sustained esophageal patency should be considered reference points for a successful dilatation. Gastrostomy may be lifesaving in this perspective. Mortality and morbidity of esophageal replacement in patients not responding to dilatation are low in expert hands. The preservation of the native esophagus is still debated. When late reconstructive surgery is carried out after early emergency surgical treatment, the outcome is strongly influenced by coloplasty dysfunction, responsible for half of the failures. Risk of esophageal cancer after caustic ingestion might be overestimated, yet endoscopic screening is still recommended.

Abstract

Inflammatory bowel diseases (IBD) such as Crohn's disease (CD) or ulcerative colitis are chronic intestinal disorders, which are on the increase in "Westernised" countries. IBD can be caused by both genetic and environmental factors. Interleukin-10 (IL-10) is an immunoregulatory cytokine that has been identified as being involved in several diseases including IBD. Studies have shown that polymorphisms in the promoter region reduce serum levels of IL-10 and this reduction has been associated with some forms of IBD. Mouse models have shown promising results with IL-10 supplementation, as such IL-10 supplementation has been touted as being a possible alternative treatment for CD in humans. Clinical trials have shown that recombinant human IL-10 is safe and well tolerated up to a dose of 8 μg/kg. However, to date, the results of the clinical trials have been disappointing. Although CD activity was reduced as measured by the CD activity index, IL-10 supplementation did not result in significantly reduced remission rates or clinical improvements when compared to placebo. This review discusses why IL-10 supplementation is not effective in CD patients currently and what can be addressed to potentially make IL-10 supplementation a more viable treatment option in the future. Based on the current research we conclude that IL-10 supplementation is not a one size fits all treatment and if the correct population of patients is chosen then IL-10 supplementation could be of benefit.

Key words: Inflammatory bowel disease; Crohn's disease; Interleukin-10; Recombinant human interleukin-10

Core tip: Inflammatory bowel disease (IBD) is a chronic condition with no known cure. This review addresses the current available treatments for IBD before discussing a potential new treatment strategy using the immunoregulatory cytokine interleukin-10 (IL-10). To date clinical trial results have been disappointing. We highlight the limitations of current IL-10 supplementation treatment and suggest how, with changes to IL-10 delivery and the correct choice of patient, IL-10 supplementation could become a viable treatment option.

Marlow GJ, van Gent D, Ferguson LR. Why interleukin-10 supplementation does not work in Crohn's disease patients. *World J Gastroenterol* 2013; 19(25): 3931-3941 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/3931.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.3931

INTRODUCTION

Inflammatory bowel diseases (IBD) are chronic intestinal disorders that are typified by ulcerative colitis (UC) and Crohn's disease (CD). They are considered to be caused by an aberrant intestinal immune response to commensal microbiota in genetically susceptible individuals[1-3]. IBD

affects over 1.4 million people in the United States and over 2.2 million in Europe and is on the increase[4-7]. In New Zealand CD affects 16 per 100000 and UC 7 per 100000. Clinical symptoms include pain, diarrhoea, rectal bleeding and weight loss, which can have a debilitating effect on sufferers[8]. There are both environmental and genetic factors that have a role in the development and progression of IBD. IBD is more prevalent in "Westernised" countries, believed to be a result of diet and lifestyle and also an effect of improved sanitation[9-11].

Genome-wide association studies (GWAS) have highlighted the complexity of IBD. To date, 163 IBD susceptibility loci have been identified[12], 30 associated with CD, 23 with UC and 110 with both[10,12-14]. Some susceptibility genes have been identified, covering genes involved in autophagy (*ATG16L1* and *IRGM*), pattern recognition receptors, intestinal epithelium maintenance and immune response[4].

The anti-inflammatory cytokine interleukin-10 (IL-10) has been identified as being involved in IBD[15]. Studies[16-18] have shown that polymorphisms in the *IL-10* promoter alter IL-10 serum levels and have been linked to IBD. IL-10 supplementation has been tested as a potential therapy for CD[19-28]. This review will focus on the use of IL-10 supplementation explaining why it is currently ineffective at treating patients with CD and showing how that effectiveness could be improved.

IL-10

Functions of IL-10

IL-10 was first identified as a cytokine secreted by $CD4^+$ Th2-cells that inhibits cytokine production in antigen presenting cells[29], and was described as a cytokine synthesis inhibitory factor. The gene for human *IL-10* is located in the 1q32 band on chromosome 1 and encodes for 5 exons. The encoded protein is a homodimer with a mass of 37 kDa consisting of 160 amino acid monomers[16,19,30]. The structure of IL-10 resembles interferon gamma (IFN-γ) and both IL-10 receptor (IL-10R) subunits are members of the interferon receptor family[31,32].

IL-10 is a pluripotent cytokine and could be considered the most important anti-inflammatory cytokine found in the human immune response[4,19]. IL-10 is produced by different cell types including B- and T-lymphocytes, macrophages, monocytes, dendritic cells and mast cells[16,33]. IL-10 has the ability to differentially affect the function of different subsets of immune cells, affecting both the innate immune system and the adaptive immune system, and is therefore considered to have a broad effect in immunoregulation and host defense[34]. Broadly speaking, IL-10 inhibits pro-inflammatory mediator production while increasing the production of anti-inflammatory mediators[19,34].

Many of the pro-inflammatory cytokines suppressed by IL-10 are known to be regulated by nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB). Dysregulation of NF-κB has been implicated in the pathogenesis of chronic inflammatory disease including IBD[35,36]. It has been shown that IL-10 can block IKK activation and directly inhibit the nuclear localisation ofthe NF-κB p65/p50 heterodimer[37,38]. It has also been shown that IL-10 can selectively induce nuclear translocation and DNA-binding of p50 homodimer, which has been shown to inhibit transcription[39].

IL-10 down-regulates major histocompatibility complex Ⅱ (MHC class Ⅱ) expression[40] and the expression of the co-stimulatory ligands CD80/CD86 (B7-1, B7-2) in monocytes[41], macrophages[42,43] and dendritic cells[44,45]. While both MHC class Ⅱ and co-stimulatory ligands are needed to effectively activate $CD4^+$ Th2 cells by antigen presentation, this results in decreased macrophage and T cell derived cytokine synthesis, *e.g.*, IL-1, IL-6, IL-8, IFN-α, tumor necrosis factor-α[25,46-48]. However IL-10 also has immunostimulatory effects, by up-regulating MHC class Ⅱ expression on B lymphocytes[49] and increasing the synthesis of several antibody isotypes *e.g.,* immunoglobulins (IgM, IgA and IgG)[50].

Despite unanswered questions, our current knowledge credits IL-10 with having a significant critical role in regulating intestinal immune homeostasis, this is highlighted by the fact that impaired IL-10 signalling contributes to IBD[4,51,52]. Rare homozygous mutations in *IL10RA* and *IL10RB*, resulting in defective IL-10 signalling were identified in children with early-onset IBD[52] thereby confirming IL-10's critical role in maintaining intestinal homeostasis.

IL-10 signalling

During IL-10 signalling the IL-10 homodimer binds to the tetrameric receptor IL-10R complex, consisting of 2 molecules of IL-10R α-chain (IL-10R1) and two molecules of the IL-10R β-chain (IL-10R2)[53-55]. This binding activates Janus Kinase 1 (JAK1) and tyrosine kinase 2 (Tyk2), which self-phosphorylate and subsequently phosphorylate IL-10R1 at tyrosine residues, 446 and 496, which recruits signal transducer and activator of transcription 3 (STAT3) *via* its SH2-domain. STAT3 is phosphorylated by JAK1 and Tyk2, causing dimerisation and translocation to the nucleus, where target genes are induced[2,4,20,53] (Figure 1).

There is contradictory evidence regarding the role of STAT3 in IBD[56], with studies showing that it can play both a pathogenic[57-60] or a regulatory[61-64] role in IBD depending on the specific activator and cell type[65]. STAT3 mediates mucosa-protective functions in epithelial and myeloid cells but can also contribute to inflammation if active in other cell types[66]. It has been shown that STAT3 is essential for all known functions of IL-10 and that STAT3 acts as a transcription factor for other genes within the anti-inflammatory response[67,68]. STAT3 is primarily recruited and activated in macrophages, and this activation is transient[69], which avoids the inflammation associated with an increase of activated STAT3 in IBD[70-72].

Genetic variants in *IL-10*, the IL-10 receptor and *STAT3* genes are associated with IBD, highlighting the

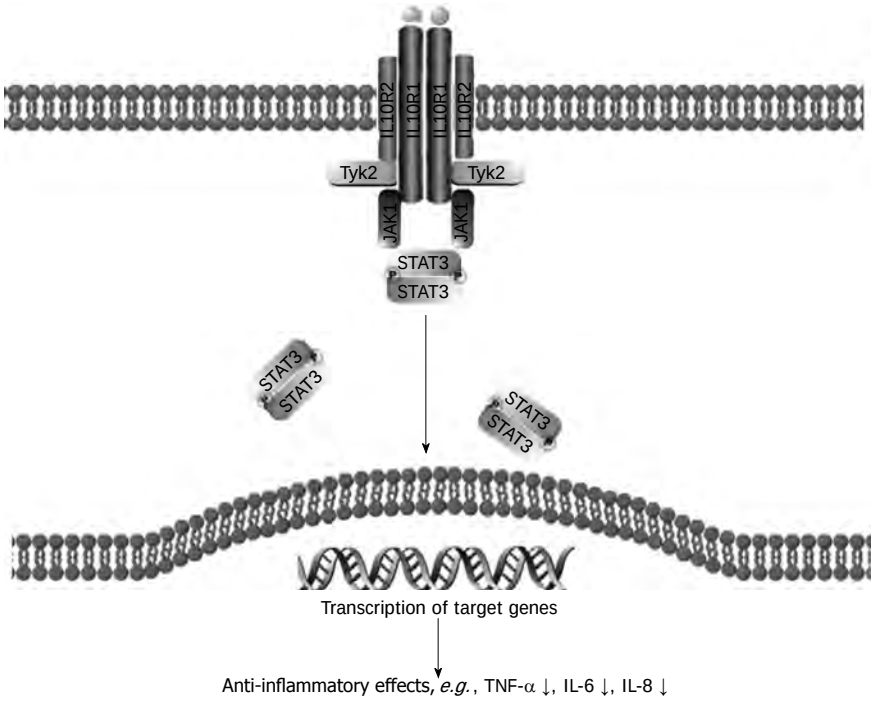

Figure 1 Interleukin-10 signalling pathway. Interleukin-10 (IL-10) binds to the tetrameric receptor IL-10 receptor (IL-10R) complex, this activates Janus kinase 1 (JAK1) and tyrosine kinase 2 (Tyk2), which self-phosphorylate resulting in the binding and phosphorylation of signal transducer and activator of transcription 3 (STAT3). STAT3 dimerises and translocates to the nucleus, inducing target genes. TNF-α: Tumor necrosis factor-α.

involvement of the IL-10 signalling cascade in the pathogenesis of CD and UC, further supporting the hypothesis that defective anti-inflammatory mechanisms may be key to IBD development[2,11,15,52,73-75].

IL-10 AND IBD

How IL-10 relates to IBD

The first evidence of a role of IL-10 in IBD, came from a GWAS study by Franke *et al*[15] that showed a significant ($P = 1.35 \times 10^{-12}$) association between a single nucleotide polymorphism (SNP) rs3024505 near the three-prime untranslated regions of the *IL-10* gene and UC, there was modest association with CD.

IL-10 knockout mice develop chronic enterocolitis, which is similar to human CD, if they are not kept in germ-free conditions. Administration of IL-10 ameliorates inflammation in both animal and *in vitro* models[76], indicating a potential role for IL-10 in the down-regulation of Th1-mediated mucosal inflammation[16,77].

Because IL-10 mediated immune responses are so important in maintaining intestinal homeostasis and commensal flora tolerance, it has been hypothesized that a defect in IL-10 production may be involved in the pathogenesis of CD[78]. In fact impaired IL-10 production has been found in severe cases of both UC[79] and CD[78]. Studies show that CD patients have normal[80,81] or high IL-10 levels[18,82]. However, low IL-10 production in intestinal mucosa has been shown to be associated with increased postoperative recurrence[22,83] and it has been shown that administration of recombinant human IL-10 in low IL-10 producers significantly reduced recurrence after surgery[22].

IL-10 mucosal levels

It has been shown that intestinal epithelial cells from healthy and inflamed colonic tissue express IL-10 mRNA and protein to the same extent. However during inflammation and also in patients with CD, there are significantly increased numbers of mononuclear cells producing IL-10[20,25]. Circulating levels of IL-10, as determined by serum levels of IL-10[82] and mRNA levels[84], have been shown to correlate with disease activity.

IL-10 serum levels

It is believed that circulating levels of IL-10 are critical in immune regulation. Basal levels of IL-10 modulate production of other cytokines and thus minor changes can affect the cytokine network, which in turn affects inflammation.

Studies have been inconsistent regarding serum levels of IL-10 in IBD, as stated earlier some studies show higher IL-10 levels in CD, Wang *et al*[18] found that CD patients had significantly higher levels of IL-10 compared to controls. Kucharzik *et al*[82] reported increased serum IL-10 concentrations in patients with active CD or UC compared to controls. Mitsuyama *et al*[85] showed an increase in serum IL-10 in active UC patients but not CD. In contrast, Nielsen *et al*[81] reported that serum IL-10 concentrations did not differ among UC, CD and healthy control subjects. These inconsistencies could be the result of variations, *e.g.,* age, severity of disease and ethnicity in the studied populations or in different methodological designs.

As IL-10 is an anti-inflammatory cytokine, we expect that high serum levels of IL-10 are likely to be good for patients with chronic inflammatory disease. In fact low IL-10 levels are known to increase disease severity in CD patients compared to high IL-10 levels[85,86]. From steroid treatment it has been shown that steroid non-responders have low IL-10 levels while steroid responders have sus-

tainable high IL-10 levels during and after treatment[87]. Sufficient IL-10 levels seem to be required for recovery but do not offer a cure.

We can hypothesize that IL-10 has an optimal level to be beneficial to reduce chronic inflammatory diseases, and may prove detrimental at too high or too low levels. Diseases associated with IL-10 SNPs such as psoriasis and rheumatoid arthritis are known to have high IL-10 serum levels[18,88,89], while in other diseases like UC, IL-10 levels vary between individuals and studies, with a trend toward increased IL-10 production, though the big studies are lacking[90-92].

IL-10 serum level and disease severity is not restricted to IBD, other diseases including autoimmune diseases, such as systemic lupus erythematosis, Behçets, type 1 diabetes mellitus[14], psoriasis[93], atherosclerosis[94] and rheumatoid arthritis[89] have all been shown to be associated with *IL-10* SNPs. Susceptibility to several cancers including prostate[95], breast[96], cervical[97] and more recently gastric[98,99] have been associated with *IL-10* promoter polymorphisms.

IL-10 promoter polymorphisms

SNPs are the most common form of genetic variation in humans. A SNP occurs at a location where more than one possible nucleotide occurs naturally within a population at a frequency >1%[100]. SNPs can be in both coding and non-coding regions of DNA. Due to the degeneracy of the genetic code. Even if the SNP is in a gene it may not change the amino acid and so has no effect on the protein (synonymous SNP), however non-synonymous SNPs do change the protein and are more commonly associated with disease. It is these variations that are most interesting to researchers as these can account for whether/how a person develops a disease, the severity of disease and how they respond to treatment.

Important variability in IL-10 secretion has been reported and is associated with SNPs in the *IL-10* promoter at 3 locations -592, -819, -1082[78,101,102]. The *IL-10* promoter polymorphisms C-592A (rs1800872), C-819T (rs1800871) and G-1082A (rs1800896) have been extensively studied. The most recent studies of Franke *et al*[15], Amre *et al*[17], Wang *et al*[18], Andersen *et al*[73], Fowler *et al*[103], Fernandez *et al*[104] and Tedde *et al*[105] reported a significant association between IL-10 rs1800896 and IBD.

The "A" allele of rs1800896 was found to be more common in IBD patients, especially in UC patients, individuals with the A/A genotype have lower IL-10 production than the G/G genotype[106], Koss *et al*[107] found that the -1082 AA is associated with decreased IL-10 production in both CD patients and controls. Wildtype -1082 (rs1800896) "G" and -592 (rs1800872) "C" are known to be associated with increased IL-10 levels; therefore we expect the GCC haplotype to show the highest IL-10 expression and ATA the lowest. This hypothesis was studied by Reuss *et al*[108] who showed in THP-1 monocyte cells that IL-10 expression was highest in the GCC haplotype compared to ACC and ATA (P = 0.042 and P = 0.0026). In the twin-study which followed, the haplotype showed no correlation with IL-10 serum levels. Wang *et al*[18] showed a significant (P = 0.001) increase in IL-10 production for TAT haplotype in healthy controls. The -592A allele was also shown to be associated with reduced transcription and decreased IL-10 secretion[16,102,109].

CURRENT IBD TREATMENTS

The current treatment options available for IBD, include: surgery, aminosalicylates, *e.g.,* 5-aminosalicylic acid, corticosteroids, *e.g.,* prednisone, immunosuppressants, *e.g.,* azathioprine, cyclosporine or biologicals, *e.g.,* infliximab[110,111]. The choice of treatment is dependent on phenotype, disease activity, characteristics of the drug and the patient. The choice should look to balance effectiveness with side effects and long term complications. As with any drug treatment there are side effects, these range from the usually well-tolerated upset stomach, nausea and headache to the more severe bone marrow and liver problems. As well as the associated side effects these treatments only work for some cases and can also result in a loss of response. Thus stronger treatments are required which have more severe side effects and long term consequences, and so alternative therapies are being investigated.

ALTERNATIVE TREATMENTS

Environmental and dietary factors are thought to play a role in the development of CD[112,113] and so changes to diet and lifestyle can have beneficial effects. Studies[114-118] have shown that specific foods are associated with IBD and that avoiding certain foods can reduce both the severity and frequency of symptoms. There are several classes of new drugs being developed: monoclonal antibodies, small molecules, fusion proteins and recombinant growth factors, as well as stem cell based therapies; one of these new therapies is IL-10 supplementation.

IL-10 supplementation for CD

Studies have suggested that IL-10 has huge therapeutic potential in intestinal inflammation, and that it should inhibit the up-regulated pro-inflammatory cytokines in CD and UC[25]. In most studies to date, Tenovil (Schering-Plough, Kenilworth, NJ, United States), has been used, which is the brand name of rhuIL-10. It is produced by a genetically engineered *Escherichia coli* strain, that expresses a 161 amino acid protein identical to human IL-10 with an additional amino-terminal methionine residue[119,120].

Why doesn't it work?

Based on the success of animal models[121-126] of intestinal inflammation, IL-10 therapy was heralded as a potential anti-inflammatory treatment in CD and several human trials have been undertaken. The first trial conducted by van Deventer *et al*[28] showed that IL-10 supplementation

Table 1 Summary of key findings from interleukin-10 trials in human and animal studies

Ref.	Model	Intervention	Outcome
	Human		
Colombel *et al*[22]	65 patients having recently undergone intestinal resection surgery	4 μg/kg daily or 8 μg/kg twice weekly for 12 wk	No clear evidence of effect
Fedorak *et al*[23]	95 mild to moderately active CD (CDAI 200-350)	1, 5, 10 or 20 μg/kg of daily for 4, 20 wk follow up	Improved clinical response (based on CDAI score) and improved endoscopic appearance
Schreiber *et al*[26]	329 therapy-refractory chronic active CD (CDAI 200-400)	1, 4, 8 or 20 μg/kg of Tenovil subcutaneously for 28 d	Non-significant clinical improvements
van Deventer *et al*[28]	46 patients with active steroid-resistant CD (CDAI 200-350)	0.5, 1, 5, 10 or 25 μg/kg daily for 1, 3 wk follow up	Reduction in the average score of CDAI
Braat *et al*[128]	10 patients with moderate to severe CD	10 enteric-coated capsules containing 10^{10} cfu of LL-Thy12 twice daily for 7 d	Clinical benefit observed in 8 of 10 patients, including 5 showing complete remission
	Animal		
Barbara *et al*[121]	DNB induced colitis Spf Sprague-Dawley rats	Ad5IL-10 (5×10^8-1×10^{10} pfu)	Improved colitis macroscopically and histologically and decreased MPO activity and LTB4 levels
Grool *et al*[123]	40 male NZ white rabbits formalin-immune complex induced colitis	100 or 500 μg/kg single IV infusion of rIL-10	Anti-inflammatory response as measured by decreased mucosal damage, leukocyte recruitment, MPO and LTB4
Ribbons *et al*[124]	TNBS induced colitis in 74 Sprague-Dawley rats	0.5, 5, 50, 500 μg/kg rIL-10 subcutaneous injection twice daily for 5 d	Mild anti-inflammatory effects Significant reduction in MPO
Sasaki *et al*[125]	3% DSS induced C57B6 mice	Intra-peritoneal administration of adIL-10	Significantly reduced disease activity and weight loss and completely prevented histopathologic injury to the colon
Tomoyose *et al*[126]	4% DSS induced colitis BALB/c mice	Recombinant mouse rIL-10 (1, 100, 1000 unit/mL)	Marked improvement in intestinal inflammation Inhibition of tissue damage and production of pro-inflammatory cytokines
Steidler *et al*[127]	DSS induced and spontaneous IL10$^{-/-}$ mouse models of colitis	Daily intragastric inocula of 2×10^7 or 10^9 LL-mIL10	Reduced histological score by 50% in DSS and prevented onset of colitis in IL-10$^{-/-}$ mice

CD: Crohn's disease; CDAI: Crohn's disease activity index; cfu: Colony forming units; MPO: Myeloperoxidase; LTB4: Leukotriene B4; TNBS: 2, 4, 6 trinitrobenzenesulfonic acid; DSS: Dextran sodium sulphate; adIL-10: Adenoviral IL-10; DNB: Dinitrobenzene sulphonic acid; Spf: Specific pathogen free; Ad5IL-10: Human type 5 adenovirus + murine IL-10; pfu: Plaque forming units; LL-mIL10: *Lactococcus lactis* secreting murine IL-10.

was safe and well tolerated. This was confirmed by subsequent studies[22,23,26]. van Deventer *et al*[28] showed a reduction in the average score of CD activity index (CDAI), but this was not significant. Fedorak *et al*[23] showed that 5 μg/kg of Tenovil given subcutaneously for 28 d to patients with mild to moderate CD activity resulted in improved clinical response (based on CDAI score) and improved endoscopic appearance of the disease. Schreiber *et al*[26] showed that 8 μg/kg of Tenovil given subcutaneously for 28 d to patients with mild to moderate CD activity resulted in a non-significant clinical improvement. However, Colombel *et al*[22] found no evidence that treatment with Tenovil for 12 wk in CD patients after intestinal resection prevented recurrence of CD. The key findings of these studies are summarised in Table 1.

These data show that IL-10 treatment did not result in significantly reduced remission rates or clinical improvements when compared to placebo[21,24]. In fact a Cochrane review in 2010[21] concluded that "Interleukin 10 does not appear to provide any treatment of active Crohn's disease. ...interleukin 10 does not increase the number of remissions (complete or clinical), but increases the rate of withdrawal due to adverse events relative to placebo." This review only included three of the studies mentioned above[23,26,28] and although more patients receiving IL-10 withdrew from studies there was no significant difference in the number of patients reporting adverse reactions between treatment and control.

However this is not the whole story, as other studies not included in the Cochrane analysis have shown that patients respond differently to IL-10 supplementation. Colombel *et al*[22] reported that endoscopic recurrence in patients with low IL-10 levels at time of surgery reduced to 47% with Tenovil treatment compared to 80% in the placebo group. Schreiber *et al*[26] found that patients responded differently to IL-10 treatment, with patients suffering from high disease activity having a greater rate of clinical improvement. These data suggest that IL-10 levels and disease activity are factors in how a patient responds to IL-10 supplementation. Also, as previously stated, some CD patients already have raised levels of IL-10[18,82]. These patients will not benefit from IL-10 supplementation and may suffer detrimental effects as high doses of systemically administered IL-10 induce the pro-inflammatory cytokine IFN-γ[27].

The different response to IL-10 supplementation is not surprising given the heterogenous nature of CD. A therapy that targets one step within a complex immunological pathway may only benefit a small proportion of patients but if you select the correct sub-population of patients who under-produce IL-10, for example those that have a penetrating phenotype who have a greater deficiency in IL-10[78], you may see a significant beneficial response to IL-10 therapy[25].

There are five potential explanations as to why IL-10 treatment has not been effective as a therapeutic strategy: (1) the administered dose of IL-10 results in an intestinal concentration of IL-10 that is too low to elicit a response; (2) there are differences among individuals depending upon disease phenotype/severity; (3) IL-10 is only successful at preventing and not treating an established disease; (4) IL-10 alone fails to suppress all the pro-inflammatory mediators involved in chronic inflammation; or (5) IL-10's immunostimulatory effects counterbalance its immunosuppressive properties.

Can IL-10 supplementation work?

Most of the potential explanations as to why IL-10 supplementation currently doesn't work can be overcome.

The modest therapeutic benefits[23,26] and adverse effects can potentially be attributed to limited mucosal bioavailability of IL-10 and the fact that the trials so far have not separated patients by genotype or disease phenotype/severity. To address the low bioavailability of mucosal IL-10 without resorting to the detrimental high levels of IL-10 systemic administration, *Lactococcus lactis* (*L. lactis*) was engineered to secrete IL-10, and this was used to successfully prevent the onset of colitis in the IL-10 KO model and caused a 50% reduction in inflammation in the DSS mouse model[127]. This study was followed up with a small phase 1 human trial using *L. lactis* modified to contain the human IL-10 sequence (LL-Thy12)[128]. 10 capsules containing 1×10^{10} cfu of LL-Thy12 were given to 10 patients with moderate to severe CD twice daily for 7 d. The results showed this approach is both safe and biologically contained, avoiding the side effects associated with high systemic doses while still retaining the ability to reduce disease activity. This was a small trial in a controlled environment without a control comparison and so further studies are needed to confirm the effectiveness of this treatment. However based on these initial results this form of IL-10 supplementation is showing promise as a treatment for patients with chronic intestinal inflammation.

Alternative ways to improve local delivery of IL-10 include gene therapy using replication-deficient adenoviral vectors delivered directly to the gastrointestinal epithelial cells. This approach has proven successful in two mouse studies[121,129] showing an effect on colitis without the associated side-effects of systemic administration. Gelatine microspheres containing IL-10 (GM-IL-10) were developed by Nakase *et al*[130] to deliver sustained IL-10 release locally without losing bioactivity. Colonic inflammation in mice treated with GM-IL-10 was reduced compared to mice treated with IL-10 alone.

The second point of selecting patients based on disease phenotype and/or severity can be easily addressed based on clinical diagnosis. Selecting patients based on genotype is slightly more complicated and would require that potential candidates for treatment be screened. Genotyping has become relatively quick and easy to perform and the cost is reducing as the technology advances. However who actually performs the genotyping service, who pays for the service and gaining patient consent may be problematic. This could potentially be overcome by having the patients enrol onto a research study. However IL-10 serum levels are determined 50% by genetics and 50% by environment[108] and so just because a person has the low IL-10 producing SNP doesn't necessarily mean they will have low IL-10 levels. Therefore a better measure to determine potential benefit of IL-10 supplementation would be to measure the serum level of IL-10, which can be done using commercially available ELISA kits. This should prove to be easier to conduct and in gaining patient consent.

As mouse models proved[121,131] IL-10 administration was only successful when administered prior to initiation of colitis and was unable to treat any established inflammation. Therefore IL-10 supplementation could be used to prevent relapses rather than to treat active inflammation.

If locally delivered IL-10 fails to have an effect, then it may be due to the fact IL-10 alone is unable to suppress all the pro-inflammatory mediators involved in chronic inflammation.Therefore it would be necessary to develop a combination treatment containing IL-10. However the evidence suggests IL-10 alone should have an effect and so it may be that IL-10 supplementation is not a suitable treatment for that disease phenotype.

CONCLUSION

Based on this knowledge, it is our opinion that a subpopulation of CD patients, who have lower expression of IL-10, and who have active disease could benefit from targeted IL-10 supplementation therapy. However further studies are needed to determine the exact population of patients who would benefit the most from this treatment and to determine if there are any long term detrimental effects of this treatment. Given that current treatments of IBD may not be beneficial to a patient or have severe side effects, we believe it is worth exploring this potential treatment avenue.

Abstract

At present, the treatment of choice for uncomplicated acute appendicitis in adults continues to be surgical. The inflammation in acute appendicitis may sometimes be enclosed by the patient's own defense mechanisms, by the formation of an inflammatory phlegmon or a circumscribed abscess. The management of these patients is controversial. Immediate appendectomy may be technically demanding. The exploration often ends up in an ileocecal resection or a right-sided hemicolectomy. Recently, the conditions for conservative management of these patients have changed due to the development of computed tomography and ultrasound, which has improved the diagnosis of enclosed inflammation and made drainage of intra-abdominal abscesses easier. New efficient antibiotics have also given new opportunities for nonsurgical treatment of complicated appendicitis. The traditional management of these patients is nonsurgical treatment followed by interval appendectomy to prevent recurrence. The need for interval appendectomy after successful nonsurgical treatment has recently been questioned because the risk of recurrence is relatively small. After successful nonsurgical treatment of an appendiceal mass, the true diagnosis is uncertain in some cases and an underlying diagnosis of cancer or Crohn's disease may be delayed. This report aims at reviewing the treatment options of patients with enclosed appendiceal inflammation, with emphasis on the success rate of nonsurgical treatment, the need for drainage of abscesses, the risk of undetected serious disease, and the need for interval appendectomy to prevent recurrence.

Key words: Appendicitis; Phlegmon; Abscess; Computed tomography; Antibiotics; Percutaneous drainage; Surgery

Core tip: The management of adult patients with inflammatory appendiceal masses is controversial. This report aims at reviewing the treatment options of these patients, with emphasis on the success rate of nonsurgical treatment, the need for drainage of abscesses, the risk of undetected serious disease, and the need for interval appendectomy to prevent recurrence. The debate arises over the importance of the complication rate of interval appendicectomy. Moreover, if appendicectomy is not performed, consideration needs to be given to what investigations should be undertaken and in which patients. It is also worth recalling that the appendix is used in reconstructive surgery.

INTRODUCTION

Acute appendicitis is one of the most common causes of acute abdomen and can be classified into uncomplicated

and complicated. The life-time risk of appendicitis is 7%-8%, with the highest incidence in the second decade. The inflammation in acute appendicitis may sometimes be enclosed by the patients own defense mechanisms, by the formation of an inflammatory phlegmon or a circumscribed abscess. The management of these patients is controversial. Immediate appendectomy may be technically demanding because of the distorted anatomy and the difficulties to close the appendiceal stump because of the inflamed tissues. The exploration often ends in ileocecal resection or a right-sided hemicolectomy due to the technical problems or a suspicion of malignancy because of the distorted tissues[1-9]. Recently, the conditions for conservative management of these patients has changed due to the development of computed tomography (CT) and ultrasound (US), which has improved the diagnosis of enclosed inflammation and made drainage of intra-abdominal abscesses easier[10-15]. New efficient antibiotics have also given new opportunities for nonsurgical treatment of appendicitis[16-21]. The traditional management of these patients is nonsurgical treatment followed by interval appendectomy to prevent recurrence. The need for interval appendectomy after successful nonsurgical treatment has recently been questioned because the risk of recurrence is relatively small[22-27]. After successful nonsurgical treatment of an appendiceal mass, the true diagnosis is uncertain in some cases and an underlying diagnosis of cancer or Crohn's disease (CD) may be delayed[27].

This report reviews the treatment options of patients with enclosed appendiceal inflammation, with emphasis on the success rate of nonsurgical treatment, the need for drainage of abscesses, the risk of undetected serious disease, and the need for interval appendectomy to prevent recurrence. The debate arises over the importance and level of the complication rate of interval appendicectomy. Moreover, if appendicectomy is not performed, consideration needs to be given to what investigations should be undertaken and in which patients. It is also worth recalling that the appendix is occasionally used in reconstructive surgery[26,28].

DEFINITIONS

Acute appendicitis is inflammation of the vermiform appendix and remains the most common cause of the acute abdomen in young adults. The term complicated appendicitis is often used to describe a palpable appendiceal mass, an appendiceal phlegmon, or a localized abscess without distinction. A phlegmon is an inflammatory tumor consisting of the inflamed appendix, its adjacent viscera and the greater omentum, whereas an abscess is a pus-containing appendiceal mass[27-31]. The diagnosis of enclosed inflammation is made by finding a palpable mass at clinical examination before or after anesthesia, or by finding an inflammatory mass or a circumscribed abscess by CT, US or at surgical exploration of the abdomen. We consider that nonsurgical treatment has failed when the patient undergoes appendectomy during the same hospital stay after attempted nonsurgical treatment. The patients treated with drainage are those who had drainage (without appendectomy) of an abscess either percutaneously or by surgical exploration. Morbidity includes postoperative infectious complications, intestinal fistula, small bowel obstruction, and recurrence after initially successful nonsurgical management[27].

TREATMENT OPTIONS OF NONCOMPLICATED ACUTE APPENDICITIS

Although the etiology of acute appendicitis is poorly understood, it is probably caused by luminal obstruction in the majority of cases. Luminal obstruction can be caused by fecaliths, lymphoid hyperplasia, foreign bodies, parasites and both primary (carcinoid, adenocarcinoma, Kaposi sarcoma and lymphoma) and metastatic (breast and colon) tumors. Once appendiceal obstruction occurs, the continued secretion of mucus results in elevated intraluminal pressure and luminal distention. This eventually exceeds capillary perfusion pressure, which leads to venous engorgement, arterial compression, and tissue ischemia. As the epithelial mucosal barrier becomes compromised, luminal bacteria multiply and invade the appendiceal wall, which causes transluminal inflammation. The most common bacteria that can cause acute appendicitis are intestinal bacteria including *Escherichia coli* and bacteria belonging to the *Bacteroides fragilis* group. Continued ischemia results in appendiceal infarction and perforation[29-31]. However, the observation of spontaneous resolution of acute appendicitis cases and some reports of a good outcome in patients treated with antibiotics suggest that not all cases of acute appendicitis are caused by mechanical obstruction and progression to complicated disease. Some researchers have suggested that uncomplicated and complicated forms of appendicitis are two distinct diseases, with different etiologies. As in other intra-abdominal infections, such as salpingitis, diverticulitis and enterocolitis, which are often treated only with antibiotics, the infectious etiology of acute appendicitis is advocated by some scholars. Conservative treatment is most effective when administered within 12 h of symptom onset, ideally within the first 6 h[16-21,29-33]. Antibiotic therapy is associated with a 68%-84% success rate and a trend toward decreased risk of complications without prolonging hospital stay. The authors have described a low morbidity and mortality rate, and a recurrence rate between 5% and 15%[25-33].

At present, the treatment of choice for uncomplicated acute appendicitis in adults continues to be surgical (open or laparoscopy) and it is the gold standard. The most common operative complications are wound infection, intra-abdominal abscess, and ileus caused by intra-abdominal adhesions (Dindo *et al*[34] classification), which vary in frequency between open and laparoscopic appendectomy. The overall complication rates for open and laparoscopic appendectomy are respectively 11.1% and 8.7%, with a mortality rate < 0.5%[35-41]. The exclusive treatment with antibiotics cannot be routinely recommended in current

medical practice and should only be considered in selected patients or conditions in which surgery is contraindicated or in the context of clinical studies[18,19,31,32].

PROPORTION OF PATIENTS WITH APPENDICITIS WHO DEVELOP ENCLOSED APPENDICEAL INFLAMMATION AND CLINICAL PRESENTATION

Circumscribed appendiceal inflammation is common and often undiagnosed preoperatively. The proportion of all patients with appendicitis treated for enclosed inflammation is 3.8%-5.0%. The risk of perforation is negligible within the first 12 h of untreated symptoms, but then increases to 8.0% within the first 24 h. It then decreases to 1.3%-2.0% during 36-48 h, and subsequently increases again to 5.8%-7.6% for each ensuing 24-h period[42-47].

The diagnosis is suspected in patients with a palpable mass or with symptom duration > 3 d and is more common in children, especially in those aged < 5 years. Delay in presentation, age > 55 years, and elevated temperature (> 38.8 ℃) on admission are predictors of perforated appendicitis. Additionally, patients older than 55 years of age have a 29% prevalence of perforated appendicitis in the first 36 h from symptom onset. Patients with hyperbilirubinemia and clinical symptoms of appendicitis should be identified as having a higher probability of appendiceal perforation than those with normal bilirubin levels[48,49].

Enclosed inflammation is found more often in studies in which the diagnosis is based on CT or US than in those based on clinical diagnosis (14.2% *vs* 5.1%). It is also more common in children than in adults as shown by the trend of 8.8% in children, 6.5% in patients of all ages, and 4.8% in adults. There is an early risk of perforation even within the first 36 h of symptom onset, which may be higher in men than women. This suggests that diagnostic imaging should be used more frequently in children, in patients with a long duration of symptoms, and in patients with a palpable mass. Appendectomy should be performed without delay in adults, especially men and those aged > 55 years once diagnosis is confirmed[42-47].

RADIOLOGICAL DIAGNOSIS

There is continued debate about the relative merits of US and CT[10-15,50-59]; the latest meta-analysis has concluded that CT[60-69] is significantly more sensitive than US for the diagnosis of appendicitis, but that US should be considered in children. Sonography has high sensitivity (86%-100%), specificity (88%-95%), and accuracy (91%-92%) in diagnosing acute appendicitis. CT is comparable to sonography with respect to sensitivity, specificity, and accuracy for adults (90%-97%, 93%-100%, and 94%-99%, respectively) and children (95%-97%, 91%-99%, and 96%, respectively) with appendiceal diameter > 6 mm, although some studies have revealed lower diagnostic rates in children than in adults. The major area of debate is regarding which patients suspected of having acute appendicitis should have a CT scan before appendectomy. There are several articles in the literature that argue against routine preoperative imaging of patients with suspected acute appendicitis. In these articles, the routine use of imaging has not been shown to decrease the rate of negative appendectomy, and may actually delay the diagnosis and appropriate intervention in cases of acute appendicitis. Other studies have shown a benefit from preoperative imaging in suspected acute appendicitis, and the development of guidelines for CT in patients with an equivocal presentation has decreased the rate of negative appendectomy from 25% to 6%. A review of a large, prospectively gathered database of general surgical procedures in Washington state has found the negative appendectomy rate to be 9.8% in patients with no preoperative imaging and only 4.5% in those who had a preoperative CT scan. This difference was statistically significant. Based on these findings, CT scans seem to have significant benefit in the evaluation of patients with suspected acute appendicitis, to exclude other pathology, in selected patients such as elderly people[52,70].

Various CT techniques have been described for diagnosing acute appendicitis, including enhanced CT with rectally administered colon contrast medium, enhanced focused CT with thin collimation (3-5 mm), nonfocused technique with oral and intravenous contrast material, focused technique with oral contrast medium, and focused helical CT with colonic contrast medium, and have a high diagnostic accuracy. CT provides a rapid complete diagnostic evaluation of the right lower quadrant, with reported accuracy rates in the diagnosis of appendicitis of up to 95%-100%[11,52,66]. The obvious disadvantages of CT include exposure to ionizing radiation and the potential for contrast medium reactions. Those who benefit most from preoperative imaging are those with an atypical presentation and women of childbearing age. However, it is recognized that this is not without increased cost, radiation exposure and a potential delay in diagnosis. The use of US is particularly important in children and can be of use in premenopausal women[50-52,58]. Institution of a clinical pathway using CT can lead to a substantial decrease in the number of negative appendectomies from 16% to 4%. CT has greater potential than US to reveal alternative diagnoses and complications, such as perforation and abscess formation. US has lower sensitivity than CT in the setting of appendiceal perforation. The appendix is significantly larger in diameter in perforated appendicitis than in appendicitis with no perforation (15 mm *vs* 11 mm). Direct CT signs (*i.e.*, phlegmon, abscess, and extraluminal air) are more specific for perforated appendicitis. Indirect signs (bowel wall thickening, ascites, ileal wall enhancement, intraluminal air, and combined intraluminal air and appendicolith) are also found with higher incidence in appendiceal perforation[13,53,54,61,63]. Intraluminal appendiceal air in the setting of acute appendicitis is a marker of perforated or necrotic appendicitis.

Recognition of this finding in otherwise uncomplicated appendicitis at imaging should raise suspicion for image-occult perforation or necrosis[56]. Defect in the enhancing appendiceal wall allows excellent sensitivity (94.9%) and specificity (94.5%) for the diagnosis of perforated appendicitis when evaluated in a group of patients with known appendicitis. A defect in the enhancing appendiceal wall has the highest sensitivity (64.3%) of any individual finding[53]. Detecting a defect in the enhancing appendiceal wall by using cine mode display of transverse thin-section CT images allows 96.1% accuracy for diagnosing appendiceal perforation[55]. In one series, appendicolith, free fluid, a focal defect in the enhancing appendiceal wall, and enlarged abdominal lymph nodes were not sensitive or specific for the presence of perforation. That study has concluded that unless abscess or extraluminal gas is present multidetector CT cannot establish the diagnosis of perforation[63].

The range of diagnoses that can mimic appendicitis is wide and includes right ureteric calculus, epiploic appendagitis, torsion of Meckel's diverticulum, mesenteric adenitis, inflammatory bowel disease, colitis, gynecological disorders, and right-sided diverticulitis. CT is useful in differentiating between these disorders[63].

Magnetic resonance imaging (MRI) has had little role in the evaluation of acute abdominal pain. However, increasing concerns over the potentially hazardous effects of ionizing radiation associated with CT have made MRI the study of choice to evaluate pregnant women and children with symptoms of appendicitis and equivocal US findings. MRI is highly accurate with a sensitivity of 100%, specificity of 98%, positive predictive value of 98%, and negative predictive value of 100%. Although MRI may be used in any patient with suspected acute appendicitis, there is a special role for MRI in pregnant women with new-onset abdominal pain. MRI has many advantages. It is valuable in the imaging of pregnant women and children because there is no exposure to ionizing radiation. Although MRI is safe during pregnancy, no intravenous contrast should be used during pregnancy because gadolinium is a category C drug and potentially teratogenic. However, noncontrast MRI provides detailed images, which usually provide the correct diagnosis. MRI is operator independent and the results are highly reproducible. MRI is more useful than US in obese patients and in patients with a retrocecal appendix, which is difficult to visualize on US. Drawbacks of MRI are that it is more expensive than other imaging modalities and not as widely available. The examination itself takes longer to perform and may be degraded by motion artifact. There are concerns that, with the exception of trained radiologists, other health care providers are not comfortable interpreting MRI findings[52,70-73].

IMMEDIATE SURGICAL TREATMENT *VS* NONSURGICAL TREATMENT

Emergency appendectomies are still considered the primary means of treating acute appendicitis, with mortality rates of 0.5%-2.4% and 0.07%-0.7% for patients with and without perforation, respectively. Overall, post-appendectomy complication rates are typically 10%-19% for acute appendicitis without perforation and reach 12%-30% for perforated acute appendicitis[19]. Perforation increases the mortality rate of acute appendicitis from 0.0002% to 3% and increases the morbidity from 3% to 47%[52]. Perforated appendicitis may be treated first by conservative treatment or percutaneous abscess drainage with great improvement of the clinical symptoms[74-80]. This is in contrast to nonperforated appendicitis, which requires operation as early as possible in order to reduce morbidity. Immediate surgical treatment of enclosed appendiceal inflammation is associated with a > 3-fold increase in morbidity compared with conservative management, and may result in an unnecessary ileocecal resection or right-sided hemicolectomy for technical reasons or suspicion of malignancy in about 3% of patients[9,27]. Nonsurgical treatment is successful in about 93% of patients, but may need percutaneous drainage of abscesses in about 20%. Most perforated appendicitis give way to generalized peritonitis and cannot be drained. Indications of drainage are absence of generalized peritonitis and presence of percutaneously or surgically drainable abscess[75-78]. Nonsurgical treatment is associated with lower morbidity and shorter hospital stay compared with immediate appendectomy. The results of immediate surgery compared with those of nonsurgical treatment, eventually followed by interval appendectomy, have been reported in 19 retrospective studies[27]. Right-sided hemicolectomy for suspicion of a malignant disease or for technical reasons, but where only inflammatory changes could be found at histopathological examination, has been reported in 17 of 493 adult patients. In all but three of the studies, the authors have concluded that nonsurgical treatment is to be recommended. Conservative treatment is associated with significantly fewer overall complications, wound infection, abdominal/pelvic abscess, ileus/bowel obstruction, and reoperation. No significant difference has been found in the duration of first hospitalization, overall duration of hospital stay, and duration of intravenous antibiotics[79]. Immediate surgery is associated with morbidity in 35.6% of patients compared with 13.5% in nonsurgical treatment and an additional 11.0% after interval appendectomy. The majority of the studies have practiced elective interval appendectomy after successful nonsurgical treatment.

PRIMARY NONSURGICAL TREATMENT FOLLOWED BY DELAYED OR INTERVAL APPENDECTOMY OR WITHOUT APPENDECTOMY

The results of primary nonsurgical treatment followed by delayed appendectomy during the same hospital stay have been compared with those of interval appendec-

tomy and with or without surgical intervention 6-12 wk later (interval appendectomy)[80-88]. Delayed appendectomy[89-93] is associated with morbidity in 18.2% compared with 12.4% after interval appendectomy. The return to work takes longer for patients treated with interval appendectomy, mainly because the patients want to have the planned interval appendectomy done before they are willing to return to work. One prospective study[7] has randomized patients to primary nonsurgical treatment followed by delayed or interval or no appendectomy. The group with nonsurgical treatment without appendectomy had the lowest morbidity and the shortest length of stay. In patients with an appendiceal mass, the authors have concluded that conservative treatment without interval appendicectomy is the best treatment.

FAILURE RATE OF NONSURGICAL TREATMENT AND NEED FOR ABSCESS DRAINAGE

All studies have reported a low failure rate for nonsurgical treatment without appendectomy; some of them even without giving antibiotics[75-80]. The failure rate for all the studies was 7.2%. Failure was associated generally with abscess diameter > 4-5 cm[77-79]. The proportion of patients in need of abscess drainage is strongly related to how the diagnosis is made, with 100% in studies of patients selected because of a drained abscess, 47.5% in patients with a palpable mass or preoperatively found abscess, 27.6% in patients with an abscess or phlegmon diagnosed by CT or US, 9.5% in patients with a palpable mass, and no need for drainage in studies of patients with a phlegmon diagnosed by CT or US. There is no association between the need for drainage and patient age.

COMPLICATIONS FOLLOWING INTERVAL APPENDICECTOMY

The morbidity of interval appendectomy has been reported in a few studies with a pooled value of 11.0%[94-97]. The age of the included patients had no influence on the results. The complication rate following interval appendicectomy is a consideration to be balanced against the recurrence rate. The complication rate varies from 8% to 23%. True surgical complications include wound infection (15.0%), pelvic abscess (5.0%), and aspiration pneumonia (1.5%). Another retrospective study reported a complication rate of 13%, but a prolonged fever, which others may not have cited as a true complication, accounted for almost half of these complications and only one wound infection occurred in 38 interval appendicectomies. An 8% complication rate was reported in a review of 50 interval appendicectomies, but about 25% of these were prolonged fever, about 50% cecal damage, and the remainder subcutaneous abscesses. Laparoscopic interval appendicectomy may decrease the complication rate and length of hospital stay[36,92]. A small retrospective study of 10 patients undergoing laparoscopic interval appendicectomy reported no complications and all patients were discharged on the day after surgery. A prospective study of open and laparoscopic appendicectomy for acute appendicitis in 65 patients showed a significantly lower wound infection rate in the laparoscopic group; however, it is not possible to extrapolate directly this finding to interval appendicectomy, even though one would expect a lower wound infection rate. In one study, the morbidity rates, particularly for intra-abdominal abscesses and wound infection, were lower for laparoscopic appendectomy in complicated appendicitis than those reported in the literature for open appendectomy, whereas operating times and hospital stays were similar[88].

RISK OF RECURRENCE

The recurrence rate of appendiceal pathology if appendicectomy is not performed is central to the debate over the use of routine interval appendicectomy. For some authors, the risk of recurrence after successful nonsurgical treatment was about 10% (3%-25% in the literature) and was often associated with an appendicolith. The majority of recurrences occur within 6 mo after initial hospital stay. Recurrence is characterized by a milder course than the primary attack in most cases. Elective interval appendectomy is associated with morbidity in about 11% (0%-23%) of patients. These results do not motivate routine elective interval appendectomy after successful nonsurgical treatment[16,20,27,98]. The literature review shows that at least 75%-90% of routine interval appendicectomies in adults are unnecessary. It would be reasonable and perhaps safer, as malignancy can be missed at appendicectomy, to replace routine interval appendicectomy with adequate follow-up of symptoms, performing appendicectomy only if symptoms recur or persist. Appropriate investigation should be done if the appendix is not removed, provided the patient has access to surgical care should symptoms recur[27].

HISTOLOGY

Several studies have examined the microscopic changes in the interval appendicectomy specimen. Many specimens show chronic inflammatory changes (52%)[5] and acute inflammation (50%)[3,8]. However, this may be of little clinical importance in the asymptomatic patient. The real concern is whether leaving the appendix *in situ* will prevent the detection of a cecal carcinoma or an ileal or appendicular malignancy[27].

RISK OF MISSING OTHER DIAGNOSES

Nonsurgical treatment is associated with a risk of missing or delaying an underlying cancer diagnosis or CD in about 2% of patients. The concern of failing to diagnose a rare case of appendiceal malignancy without interval appendicectomy may persist even with colonic investi-

gation, although it is likely that these patients will have recurrent symptoms[99-101]. Most of the cancer cases occur in patients aged > 40 years. The risk of missing an important alternative diagnosis is probably lower if imaging is used for the diagnosis of enclosed appendiceal inflammation. This underlines the need of follow-up after nonsurgical treatment, especially in patients aged > 40 years. By tradition, this follow-up consists of colonoscopy or a barium study of the colon, but a virtual colonoscopy, CT scan, or US is probably more accurate to detect malignant conditions outside the colon or CD. Malignant disease was detected during follow-up in 1.2% of patients. This risk was related to age at diagnosis with 0.2% in children, 1.8% in studies of all ages, and 1.4% in adults. There was no difference in relation to how the diagnosis was done. CD was detected in 0.7% during follow-up after nonsurgical treatment. This risk was related to age with 0.1% in children, 0.8% in all ages, and 1.5% in adults. There was no difference in relation to how the diagnosis was done. Appendicular malignancy is rare and may be missed if appendicectomy is not performed; however, it is likely that such patients will have either a nonresolving mass or early recurrence. Colonic malignancy is a more common concern, but interval appendicectomy is not a reliable method of detecting a cecal tumor. Imaging is needed when cecal malignancy is possible. Colonic investigation should be a consideration regardless of whether interval appendicectomy is performed[27].

CONCLUSION

In patients with suspicion of contained appendiceal inflammation, based on a palpable mass or long duration of symptoms, the diagnosis should be confirmed by imaging techniques, especially CT scan. The patient should receive primary nonsurgical treatment with antibiotics and abscess drainage as needed. After successful nonsurgical treatment, no interval appendectomy is indicated in some cases, but the patient should be informed about the risk of recurrence especially in the presence of appendicolith. The risk of missing another underlying condition (cancer or CD) is low, but motivates a follow-up with a colon examination and/or a CT scan or US, especially in patients above the age of 40 years.

Abstract

The present study was designed to alert the public opinion and policy makers on the supposed enhancing effects of exposure to ambient air particulate matter with aerodynamic diameters < 2.5 mm ($PM_{2.5}$) on non-alcoholic fatty liver disease (NAFLD), the most common chronic liver disease in Western countries. For far too long literature data have been fixated on pulmonary diseases and/or cardiovascular disease, as consequence of particulate exposure, ignoring the link between the explosion of obesity with related syndromes such as NAFLD and air pollution, the worst characteristics of nowadays civilization. In order to delineate a clear picture of this major health problem, further studies should investigate whether and at what extent cigarette smoking and exposure to ambient air $PM_{2.5}$ impact the natural history of patients with obesity-related NAFLD, *i.e.*, development of non alcoholic steatohepatitis, disease characterized by a worse prognosis due its progression towards fibrosis and hepatocarcinoma.

Key words: Non-alcoholic fatty liver disease; Particulate matter with aerodynamic diameters < 2.5 μm; Cytochrome P-450; Reactive oxygen species

Core tip: Important arguments Diesel exhaust particles are known to be major constituents of atmospheric particulate matter (PM) in metropolitan areas. Exposure to PM is positively associated with increases in the morbidity and daily mortality. Obesity-related health complications include cardiovascular disease, type 2 diabetes, hyperlipidemia, hypertension and non-alcoholic fatty liver disease (NAFLD). Exposure to ambient air PM may induce/worsen NAFLD.

Tarantino G, Capone D, Finelli C. Exposure to ambient air particulate matter and non-alcoholic fatty liver disease. *World J Gastroenterol* 2013; 19(25): 3951-3956 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/3951.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.3951

INTRODUCTION

The rising incidence of obesity in today's environment is associated with many obesity-related health complications, including cardiovascular disease, type 2 diabetes, hyperlipidemia, hypertension, and non-alcoholic fatty liver disease (NAFLD)[1-4]. This constellation is also recognized as the metabolic syndrome and is characterized by underlying insulin resistance. NAFLD or generally speaking hepatic steatosis is defined as the accumulation of lipid, primarily in the form of triacylglycerols in individuals who do not consume significant amounts of alcohol

(< 20 g ethanol/d) and in whom other known causes of steatosis, such as certain drugs and toxins, have been excluded[5]. The spectrum of NAFLD includes simple fatty liver, non alcoholic steatohepatitis (NASH) characterized by inflammation, apoptosis, ballooning degeneration, Mallory hyaline, fibrosis, cirrhosis post NASH, hepatocellular carcinoma and advanced liver disease, which leads to liver-related death[5-10].

Some epidemiological studies, deeply informed and full of insights, have demonstrated that exposure to ambient particulate matter (PM) is positively associated with increases in the morbidity and daily mortality caused by diseases, including ischemic heart disease[11,12] and chronic obstructive pulmonary disease[13,14], which are closely related to life habits. Diabetes mellitus and its complications are the other typical diseases related to life habits. Over the past several decades, prevalence of type 2 diabetes mellitus has reached epidemic levels in Western countries[15], which is a significant public health interest. The prognosis of patients with diabetes mellitus is worsened generally by a variety of complications including macro- or micro-angiopathy[16], fatty liver[17-20], nephropathy and infection in the presence or absence of overweight/obesity. Some epidemiological studies have reported a positive association between mortality in patients with diabetes mellitus and ambient levels of PM[21,22].

Air pollutants expelled from diesel engine-powered automobiles include diesel exhaust particles (DEP), which are known to be major constituents of atmospheric PM in metropolitan areas. DEP generate reactive oxygen species (ROS)[23], through a non enzymatic process[24], or enzymatic reactions catalyzed by cytochrome P-450 (Cyp)[25]. Furthermore, DEP enhance the gene expression for Cyp enzymes[25]. DEP induce a variety of biological damage at least partly through oxidative stress[25].

The present study was designed to alert the public opinion, international media and policy makers on the negative effects of exposure to ambient air particulate matter with aerodynamic diameters < 2.5 mm on NAFLD, a most common chronic liver disease in Western countries, which represents the first indication of liver transplantation.

SMOKING AND NAFLD

A growing body of evidence supports the potential effects of exposure to some environmental factors on liver diseases. Environmental exposure related to toxic waste sites was associated with an increased prevalence of autoimmune liver disease[26,27]. Therefore, increasing attention is being given to the effects of environmental factors on liver diseases, including NAFLD. Several recent studies have too reported the association of smoking with the incidence of and acceleration of disease progression in NAFLD, as well as with advanced fibrosis in this process[28-32].

Cigarette smoke exposure, whether passive or active, carries a high disease burden worldwide[33] and is considered a worldwide major cause of preventable morbidity and mortality[34].

Yuan *et al*[35] provide novel evidence demonstrating that tobacco smoke exposure may accelerate the development of experimental NAFLD. The study extends an earlier report from the group showing that in apo B transgenic mice, chronic environmental (second-hand) smoke exposure is associated to features of atherosclerotic plaque initiation[36]. Using the same model, the former authors now show that exposure to second-hand smoke potentiates steatogenesis elicited by a high-fat diet, as assessed by red oil staining and hepatic triglyceride quantification[35]. Since increased hepatic lipogenesis has been shown to account for about 30% of triglyceride accumulation in steatotic livers[37], the investigators subsequently review the impact of second-hand smoke on liver lipogenic pathways. Interestingly, cultured hepatocyte cell lines exposed to second-hand smoke display enhanced accumulation of triglycerides and increased expression of acetyl CoA carboxylase (ACC) and fatty acid synthase (FAS), two key enzymes governing hepatic synthesis of fatty acids. These data therefore indicate that the steatogenic properties of tobacco smoke are at least partly explained by a direct effect on hepatocytes.

In deciphering molecular determinants underlying tobacco-dependent activation of lipogenesis, the research focus on two key regulators of lipid metabolism, Sterol regulatory element binding protein-1c (SREBP-1c) and AMP-activated protein kinase (AMP kinase). SREBPs are a family of basic-helix-loop-helix-leucine zipper transcription factors synthesized as inactive precursors embedded in the endoplasmic reticulum[38]. Activation of SREBPs requires proteolytic cleavage, thereby allowing nuclear translocation and transcriptional activation of target lipogenic genes[39]. Whereas SREBP-2 governs synthesis of cholesterol, SREBP-1c promotes biosynthesis of fatty acids by upregulating enzymes such as ACC and FAS. The serine/threonine protein kinase AMP kinase is an energy sensor that acts as a metabolic master switch[40]. The phosphorylated active form of the enzyme simultaneously inhibits energy-consuming biosynthetic pathways such as lipogenesis and activates ATP-producing catabolic pathways such as fatty acid oxidation[40]. It has been shown that AMP kinase inhibits fatty acid synthesis both by phosphorylating target lipogenic enzymes and downregulating expression of transcription factors such as SREBP-1c[41-43]. In accordance with these data, Yuan *et al*[35] demonstrated that second-hand smoke exposure inhibits phosphorylation and activation of AMP kinase, thereby resulting in increased SREBP-1 activity and enhancement of fatty acid synthesis. Zein *et al*[44] showed that cigarette smoking were associated with increased fibrosis severity in human NALFD, suggesting it may accelerate disease progression.

Moreover, Yuan *et al*[35] extends this assumption to NAFLD and provides compelling evidence indicating that tobacco smoke might alter the regulatory effect of AMP kinase on lipid metabolism. Future studies should

closely investigate the clinical relevance of these findings. Nevertheless, in the meantime, tobacco cessation might be considered in the management of patients with NAFLD.

NAFLD AND AIR POLLUTION

The harmful effects of air pollutants on atherosclerotic cardiovascular diseases are well-documented[31]. These effects might be mediated through oxidative stress and insulin resistance[45], which are also known to have pivotal roles in the pathogenesis of fatty liver[46]. Therefore, it can be assumed that such environmental factors might be too associated with NAFLD. It is well-documented that DEP, which are major constituents of atmospheric PM in urban areas, generate ROS[47]. The ROS are generated *via* enzymatic reactions catalyzed by Cyp[48], or by a non-enzymatic route[49].

Folkmann *et al*[50] assessed the effects of oxidative stress elicited by DEP in the aorta, liver, and lungs of dyslipidemic ApoE(-/-) mice, at the age when visual plaques appeared in the aorta. Vascular effects secondary to pulmonary inflammation were omitted by injecting DEP into the peritoneum. Six hours later, the expression of inducible nitric oxide synthase mRNA increased in the liver. Injection of DEP did not induce inflammation or oxidative damage to DNA in the lungs and aorta. Therefore, the study proposed a direct effect of DEP on inflammation and oxidative damage to DNA in the liver of dyslipidemic mice[50].

Another study[51] evaluated the effects of following exposure of male C57BL/6 mice fed high fat chow to concentrated air particulate matter or filtered air for 6 wk, progression of NAFLD was evaluated by standardized histological assessment of hepatic inflammation and fibrosis. Progression of NAFLD was evaluated by histology cal examination of hepatic inflammation and fibrosis. Tan *et al*[51] indicated that ambient PM that reaches the liver has the potential to induce Kupffer cell cytokine secretion. Circulating fine PM may then accumulate in both atherosclerotic plaques and hepatic Kupffer cells[51]. The activation of cytokine release by Kupffer cells may then trigger inflammation and hepatic stellate cell collagen synthesis[51]. It is extraordinary that interleukin-6, the concentration of which increased up to 7-fold in the above-mentioned study, is too significantly abundant in cases of human NAFLD[52]. Some human studies confirmed the harmful effects of environmental toxins on liver diseases.

Cave *et al*[53] has showed that non-obese chemical workers highly exposed to vinyl chloride may develop insulin resistance and toxicant-associated steatohepatitis. Limited data exists on the potential role of environmental pollution on liver disease in the general population. Another study was conducted, by Cave *et al*[54] always, on 4582 adult participants without viral hepatitis, hemochromatosis, or alcoholic liver disease, from the National Health and Nutrition Examination Survey in 2003-2004, to investigate whether environmental pollutants are associated with an elevation in serum alanine aminotransferase (ALT) and suspected NAFLD. The ORs for ALT elevation were estabilished across exposure quartiles for 17 pollutants, after adjustments for age, race/ethnicity, sex, body mass index, poverty income ratio, and insulin resistance[54]. It showed that exposure to polychlorinated biphenyls in addition heavy metals, evident lead and mercury, was correlated with unexplained ALT elevation, and increased adjusted ORs for ALT elevation in a dose-dependent form[54].

Therefore, a growing number of studies suggest that air pollution can aggravate the adverse effects of obesity and insulin resistance[29,55,56]. Similarly, some other studies have documented the association of exposure to air pollutants with metabolic syndrome, as well as predisposition to diabetes mellitus and aggravation of its complications[57-59]. Given the inflammatory and oxidative properties of air pollutants, in addition their association with insulin resistance and metabolic syndrome, and considering the interaction of the latter conditions with fatty changes in liver, more studies about the effects of environmental factors, notably air pollution, on NAFLD are warranted. The high susceptibility of the young age group to the harmful effects of air pollutants, especially pertaining to early stages of chronic diseases[13,60-64], further stresses that more attention should be given to preventing late-onset effects of air pollutants.

FUTURE DIRECTIONS

It has been reported that ambient PM containing elementary carbon, sulfate, heavy metals, and organic compounds can cause and enhance cardiopulmonary diseases[65,66]. DEP form a large constituent of ambient urban PM. Inhalation or intratracheal instillation of DEP or the components of DEP has been shown to enhance lung inflammation and asthma[67,68], and to deteriorate biological cardiovascular functions[69]. On the other hand, cardiovascular disorders are critical participants in life habit diseases. Diabetes mellitus is another typical life habit disease and is characterized by complicated cardiovascular risk factors[70-72]. In epidemiological studies, individuals with diabetes mellitus have higher risk for death from exposure to polluted ambient air[73,74]. However, few experimental studies have elucidated the association between ambient air pollution and NAFLD.

In fact, Zein *et al*[44] showed that smoking may accelerate the progression of human NALFD and these observations may support a recommendation of smoking cessation in patients with NAFLD. This recommendation is added to the general recommendations of dietetic or lifestyle approach right for NAFLD patients[75].

As reported by Tan *et al*[51], exposure to ambient air particulate matter with aerodynamic diameters < 2.5 μm ($PM_{2.5}$) may be a significant risk factor for NAFLD progression. In other words, could air pollution be the so-called "second hit", according to the well-known theory?

A better understanding of the impact of ambient PM

exposure on NAFLD progression may require studies utilizing a variety of ambient PM sources[51].

CONCLUSION

So far it has been known that $PM_{2.5}$ result from fuel combustion (motor vehicles, power generation, industrial facilities), residential fireplaces and wood stoves. $PM_{2.5}$ are usually selected as indicators of air pollution since those particles cause morbidity[76]. In fact, $PM_{2.5}$ alone exposure could cause inflammation *via* tumor necrosis factor alpha[77], endothelial function and autonomic nervous system injuries, ozone potentiating these effects[78].

Further studies should investigate the effects of long-lasting exposures to cigarette smoking and to ambient air $PM_{2.5}$ on specific pathways of the hepatic metabolism, better delineating the cellular and molecular mechanisms involved. Importantly, very informative reports should clarify whether cigarette smoking, habit started at very young age, and early exposure to ambient air $PM_{2.5}$ impact the obesity, also the adolescents' one, and the obesity-related NAFLD, favouring development of NASH, disease characterized by a worse prognosis due its progression towards fibrosis, liver cirrhosis and hepatocarcinoma.

By modifying the natural history of patients with NAFLD, air pollution adds a new argument in the debate of regulating the toxic emissions.

Abstract

AIM: To investigate mucin expression profiles in colorectal carcinoma (CRC) histological subtypes with regard to clinicopathologic variables and prognosis.

METHODS: Mucin (MUC)2 and MUC5AC expressions were assessed by immunohistochemistry for a total of 250 CRC cases that underwent surgical resection. CRCs included 63 well-to-moderately differentiated adenocarcinomas (WMDAs), 91 poorly differentiated adenocarcinomas (PDAs), 81 mucinous adenocarcinoma (MUAs), and 15 signet-ring cell carcinomas (SRCCs). MUC2 and MUC5AC were scored as positive when $\geqslant$ 25% and $\geqslant$ 1% of cancer cells were stained positive, respectively. The human mutL homolog 1 and human mutS homolog 2 expressions were assessed by immunohistochemistry in PDAs to investigate mismatch-repair (MMR) status. Tumors that did not express either of these two were considered MMR-deficient. Results were analyzed for associations with clinicopathologic variables and the prognosis in individual histological CRC subtypes.

RESULTS: MUC2-positive and MUC5AC-positive WMDA percentages were 49.2% and 30.2%, respectively. In contrast, MUC2-positive and MUC5AC-positive PDA percentages were 9.5% and 51.6%, respectively. MUC2 levels tended to decrease and MUC5AC levels tended to increase from WMDA to PDA. In 21 tumors comprising both adenoma and adenocarcinoma components in a single tumor (4 WMDAs, 7 PDAs, and 10 MUAs), MUC2 was significantly downregulated in PDA and MUC5AC was downregulated in PDA and MUA in the adenoma-carcinoma sequence. These results suggested that MUC2 levels might be associated with malignant potential and that MUC5AC expression was an early event in tumorigenesis. Despite worse prognoses than WMDA, high MUC2 expression levels were maintained in MUA (95.1%) and SRCC (71.5%), which suggested a pathogenesis for these subtypes distinct from that of WMDA. No significant associations were found between MUC2 expression and any clinicopathologic variables in any histological subtype. MUC5AC expression in PDA was closely associated with right-sided location (P = 0.017), absence of nodal metastasis (P = 0.010), low tumor node metastasis stage (P = 0.010), and MMR deficiency (P = 0.003). MUC2 expression in WMDA was a marginal prognostic factor for recurrence/metastasis-free survival (RFS) by univariate Cox analysis (P = 0.077) but not by multivariate Cox analysis (P = 0.161). MUC5AC expression in PDA was a significant prognostic factor for RFS by univariate Cox analysis (P = 0.007) but not by multivariate Cox analysis (P = 0.104). Kaplan-Meier curves and log-rank tests revealed that MUC2 expression was marginally associated with a better WMDA prognosis [P = 0.064 for RFS and P = 0.172 for overall survival (OS)] but not for PDA. In contrast, MUC5AC expression was significantly and marginally associated with a better PDA prognosis in terms of RFS and OS, respectively

(P = 0.004 for RFS and P = 0.100 for OS), but not for WMDA and MUA.

CONCLUSION: Mucin core protein expression profiles and clinical significance differ according to histological CRC subtypes. This may reflect different pathogeneses for these tumors.

Key words: Mucin 2; Mucin 5AC; Microsatellite instability; Mismatch repair; Colorectal carcinoma; Poorly differentiated adenocarcinoma; Pathogenesis; Adenoma-carcinoma sequence; Prognosis

Core tip: Altered mucin expression may be correlated with biological behavior and possibly with the prognosis of colorectal carcinoma (CRC). However, many contradictory results make it difficult to interpret its clinical significance, possibly because of CRC variations. Therefore, we examined mucin (MUC)2 and MUC5AC expressions in different pathological CRC subtypes by immunohistochemistry to determine their true clinical significance. Our results suggest that the expression profiles and the clinical significance of these mucin core proteins are different according to histological subtypes. This may reflect different pathogeneses for these tumors.

INTRODUCTION

Mucins are a diverse family of high-molecular-weight glycoproteins that are widely expressed in epithelial tissues and are characterized by the presence of tandem repeat sequences that are rich in highly *O*-glycosylated serine and threonine residues[1]. Mucins can be classified as either membrane-associated or secretory glycoproteins. To date, a total of 20 human mucins have been identified. Secreted mucins can be gel-forming or non-gel-forming and include mucin (MUC)2, MUC5AC, MUC5B, MUC6, MUC7, MUC8, MUC9, and MUC19. Transmembrane mucins include MUC1, MUC3A, MUC3B, MUC4, MUC11, MUC12, MUC13, MUC15, MUC16, MUC17, MUC20, and MUC21; these are anchored to the plasma membranes of various cells through a transmembrane domain. These mucin proteins are encoded by various *MUC* genes[2]. The genes for gel-forming mucins MUC2 and MUC5AC are found in a cluster on chromosome 11p15.5[3]. The *MUC2* gene codes for a typical secretory mucin, which is predominantly found in colorectal goblet cells, and the *MUC5AC* gene is mainly expressed in gastric and tracheal-bronchial mucosa.

Altered expressions of MUC2 and MUC5AC may be significantly correlated with the biological behavior of and, possibly, the prognosis for colorectal carcinoma (CRC). However, many contradictory results make it difficult to interpret their clinical significance. For example, MUC2 expression is significantly decreased according to CRC disease progression[4-6]. MUC2-positive CRC shows a relatively good prognosis or a low incidence of liver and nodal metastasis[7,8]. Suppressing the *MUC2* gene expression in colon carcinoma cell lines in vitro was associated with methylation of its promoter region[7]. In contrast, other studies reported that MUC2 expression was not a significant marker of tumor invasion depth, liver metastasis, or overall survival[9,10]. However, the absence of MUC5AC expression can be a prognostic indicator of a more aggressive colorectal tumor. Highly villous adenoma with severe dysplasia expressed a less MUC5AC than larger adenomas of moderate villous histology and dysplasia[11]. Carcinomas with low grade atypia exhibited a higher incidence of MUC5AC expression as compared with carcinomas showing high grade atypia[6]. Consistently, MUC5AC expression analysis combined with survival analysis has demonstrated that those patients with MUC5AC-negative CRC had lower rates for disease-free status and of overall survival[12].

Most studies analyzed CRC without detailed classifications. However, in the World Health Organization (WHO) classification, CRC consists of various histological subtypes, such as conventional adenocarcinoma, mucinous adenocarcinoma (MUA), signet-ring cell carcinoma (SRCC), squamous cell carcinoma, adenosquamous carcinoma, medullary carcinoma, undifferentiated carcinoma, and other very rare variants[13]. Conventional adenocarcinoma is further sub-classified into well-to-moderately differentiated adenocarcinoma (WMDA) and poorly differentiated adenocarcinoma (PDA) based on the percentage of the area showing a gland-like structure[13]. Most CRCs encountered in the clinic are WMDA and poorly differentiated/undifferentiated carcinomas are rare, accounting for up to 16% of all CRCs in the United States[14,15]. The purpose of this study was to assess MUC2 and MUC5AC expressions in different pathological CRC subtypes by immunohistochemistry and to determine their true clinical significance.

MATERIALS AND METHODS

Patients and tumor samples

For this study, WMDA included all consecutive cases that were surgically resected in Tokyo Kosei Nenkin Hospital from April 1998 to March 2000, but excluded 10 other histological CRC subtypes. These cases included 63 tumors from 63 patients. In addition, a total of 187 histological CRC subtypes other than WMDA were collected from all CRC cases resected in Dokkyo Medical University Koshigaya Hospital between 1990 and 2011 and Tokyo Kosei Nenkin Hospital between 1991 and 2010.

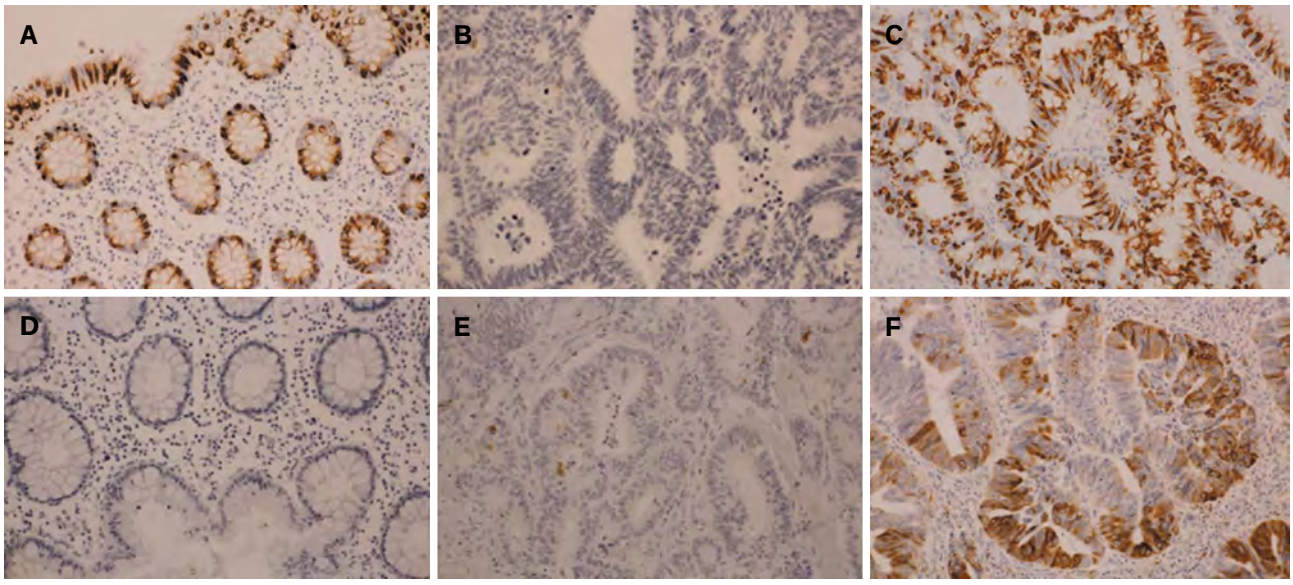

Figure 1 Expression of mucin 2 and mucin 5AC in colorectal carcinomas. A: Mucin (MUC)2 expression in normal colonic mucosa; B: MUC2 expression in cancer: level 0; C: MUC2 expression in cancer: level 4; D: MUC5AC expression in normal colonic mucosa; E: MUC5AC expression in cancer: level 1; F: MUC5AC expression in cancer: level 4 (immunohistochemical staining, × 10).

Formalin-fixed, paraffin-embedded tissue blocks were obtained from the archival material stored in the pathology departments of the both hospitals. A sufficient number of samples to provide for complete investigations were available for all these cases. Patients whose medical records were sufficiently complete were included in survival analysis. Patients with invasive cancers originating from other sites were excluded from the analysis. Clinicopathologic classifications and stage groupings were based on the WHO classification of colorectal tumors and the tumor node metastasis (TNM) staging by the American Joint Committee on Cancer[13,16]. Our study protocol was approved by the ethical review boards of the participating hospitals.

Immunohistochemistry

Tumor specimens were fixed in 10% neutral-buffered formalin for 48 h, embedded in paraffin, and cut into 4-μm-thick sections, and then mounted on silane-coated glass slides. Antigen-retrieval was done by autoclaving (121 ℃) for 5 min in pH 9 Antigen Retrieval Liquid (Nichirei, Tokyo, Japan) for MUC2, MUC5AC, and hMSH2, and by microwave irradiation for 10 min in pH 9 Antigen Retrieval Liquid for human mutL homolog 1 (hMLH1). Primary antibodies used were the mouse monoclonal antibody for MUC2 (1:100 dilution; clone Ccp58, Novocastra, Newcastle Upon Tyne, United Kingdom), the mouse monoclonal antibody for MUC5AC (1:100 dilution; CLH2, Novocastra), the rabbit anti-MLH1 monoclonal antibody (1:400 dilution; EPR3894, GeneTex, San Antonio, TX, United States), and the rabbit anti-MSH2 polyclonal antibody (1:200 dilution; 15520-1-AP, Proteintec, Chicago, IL, United States). Samples were treated overnight with each primary antibody at 4 ℃. Immunostaining was performed blindly by an investigator (Fukuda K) who was unaware of the clinical information using an N-Histofine Simple Stain MAX-PO kit (Nichirei).

The immunostaining results for mucin core proteins were assessed semi-quantitatively: 0, no staining; 1, < 5% of cells; 2, 5% to < 25% of cells; 3, 25% to < 50% of cells; 4, ≥ 50% of cells (Figure 1). The immunostaining results for mismatch repair (MMR) proteins were either completely negative (negative) or nearly 100% positive (positive). Immunoreactivity was independently evaluated by two investigators (Fukuda K and Imai Y), and discrepancies were resolved by discussion.

In light of their expression levels in normal colonic mucosa, levels 3-4 for MUC2 and levels 1-4 for MUC5AC were evaluated as positive.

Statistical analysis

Comparisons of two cohorts with or without a specific clinicopathologic variable were made by a χ^2 test with/without a Yates' correction or Fisher's exact probability test based on the expected values in a contingency table. Age was compared with Mann-Whitney *U* test. Comparisons of the mucin expression levels between adenoma and adenocarcinoma components in a single tumor were made by Wilcoxon signed-rank test for sample numbers of ≥ 6. Univariate analysis by Cox regression analysis was used to identify possible prognostic predictors. Variables for which *P* values were < 0.10 were entered into multivariate regression analysis (forced entry method). Survival curves were generated using the Kaplan-Meier method, and curves were compared by log-rank test. *P* value < 0.05 was considered significant. Statistical analysis was performed using IBM SPSS Statistics 20 (IBM, Armonk, NY, United States).

CRC: Colorectal carcinoma; WMDA: Well-to-moderately differentiated adenocarcinoma; PDA: Poorly differentiated adenocarcinoma; MUA: Mucinous adenocarcinoma; SRCC: Signet-ring cell carcinoma; MP: Muscularis propria; TNM: Tumor node metastasis.

RESULTS

Clinicopathologic characteristics

WMDA cases included 63 tumors from 63 patients. Five of these patients (5 tumors) had a family history of CRC. Additional chemotherapy and irradiation were administered for 17 tumors in 17 patients and 4 tumors in 4 patients, respectively. CRCs other than WMDA included a total of 187 tumors: 91 PDAs (90 patients); 81 MUAs (81 patients); and 15 SRCCs (15 patients). One patient had triple cancers (No. 148: two PDAs and one MUA) and one patient had double cancers (No. 170: one PDA and one MUA). Ten of these patients (12 tumors) had a family history of CRC, one of which was proven to be a hereditary non-polyposis colorectal cancer pedigree (No. 148). Predominant occurrence in females, right-sided location, depth of tumors beyond muscularis propria, lymphatic invasion, nodal involvement (except for MUA), TNM stage Ⅲ/Ⅳ (except for MUA) were more frequent in CRCs other than WMDA as compared with WMDA (Table 1). In addition to surgery, chemotherapy and irradiation were administered for 80 tumors in 80 patients and 6 tumors in 6 patients, respectively.

The clinicopathologic characteristics of each CRC subtype are summarized in Table 1. CRC patient prognosis was significantly associated with these histological subtypes (Figure 2).

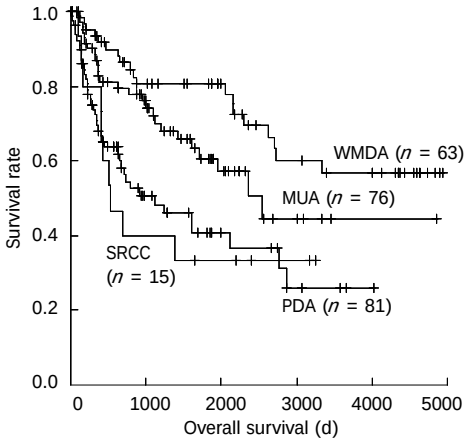

Figure 2 Colorectal carcinoma overall survival curves generated by the Kaplan-Meier method. WMDA: Well-to-moderately differentiated adeno-carcinoma; PDA: Poorly differentiated adenocarcinoma; MUA: Mucinous adenocarcinoma; SRCC: Signet-ring cell carcinoma.

Expression of MUC2 and MUC5AC in CRCs

Expression of the mucin core proteins was assessed individually in different pathological subtypes. MUC2 was expressed in the perinuclear cytoplasm of goblet cells in normal colonic mucosa and diffusely in the cytoplasm of cancer cells. MUC5AC was not expressed in normal colonic mucosa but was occasionally expressed in pericancerous normally appearing colonic mucosa. About half of WMDA cases (49.2%) were positive for MUC2 (levels 3-4), and 30.2% of these cases were positive for MUC5AC (levels 1-4). In contrast, only one tenth of PDA cases (9.5%) were positive for MUC2 and 51.6% of these cases were positive for MUC5AC. PDA was more frequently negative for MUC2 and positive for MUC 5AC than was WMDA. Nearly all MUA cases (95.1%) were positive for MUC2, and over half of these cases (54.3%) aberrantly expressed MUC5AC. Although small in number, 71.5% of SRCC cases were positive for MUC2 and nearly half (46.7%) expressed MUC5AC. These results are summarized in Figure 3.

Expression of the mucin core proteins in the adenoma-carcinoma sequence

Among our study subjects, 21 tumors in 20 patients had an adenoma component indicative of originating from the adenoma-carcinoma sequence. We investigated the sequential expression status of the mucin core proteins. MUC2 expression was found in the adenoma component in all cases, except for one PDA case. MUC2 expression was relatively well maintained in the carcinoma component of WMDA and mildly decreased in some MUA cases. MUC2 expression significantly decreased in the carcinoma component of PDA. MUC5AC was aberrantly expressed in the tubular/tubulovillous adenoma components in all but three cases, and there was a signifi-

cant decrease in MUC5AC expression in the carcinoma components as compared with the adenoma components in PDA and MUA (Table 2).

Expression of the mucin core proteins and clinicopathologic variables

Expression status of the mucin core proteins was analyzed in association with clinicopathologic variables in each histological CRC subtype that had sufficient numbers for statistical analysis. In a contingency table analysis, no statistically significant associations were found between MUC2 expression and any clinicopathologic variables in any of the histological subtypes. In contrast, MUC5AC expression was significantly associated with right-

sided location, absence of nodal metastasis, and lower TNM stage in PDA, and right-sided location in MUA. Furthermore, MUC5AC expression tended to be associated with older age in WMDA, PDA, and MUA, although the difference was not statistically significant. MUC5AC expression was not associated with any clinicopathologic variables in SRCC. These results are summarized in Table 3 (partly not shown).

Expression of the MMR proteins and the mucin core proteins in PDA

In PDA cases, MUC5AC positivity was significantly associated with right-sided location and lower TNM stage, and marginally associated with older age. Survival curve analysis also suggested a better prognosis for MUC5AC-positive PDA cases than for negative ones as described below. These are clinical features associated with high levels of microsatellite instability (MSI; MSI-H)[17-19]. A subset of sporadic CRC cases (approximately 10%-15%) is MSI-H; this is caused by inactivation of the DNA MMR system. Identifying MSI previously required molecular testing, although immunostaining for hMLH1 and hMSH2 has come to be accepted as a practical test to detect MSI[20,21]. Therefore, we investigated MMR status in PDA cases using immunohistochemistry. Tumors that did not express either of these two were considered MMR deficiency (dMMR).

dMMR was found in 19 PDA cases, 16 of 47 MUC5AC-positive cases and 3 of 44 MUC5AC-negative cases ($P = 0.003$). In contrast, there was no significant association between MUC2 expression and dMMR. Thus, dMMR showed statistically significant association with MUC5AC positivity, although it should be noted that dMMR was found in only one third of MUC5AC-positive tumors and dMMR was also found in one tenth of MUC5AC-negative tumors (Table 3).

Expression of the mucin core proteins and prognosis

The effects of clinicopathologic variables on recurrence/metastasis-free survival (RFS) and overall survival (OS) were investigated using Cox regression analysis for each CRC subtype. For WMDA, TNM stage was the only significant prognostic factor for RFS by univariate and multivariate analysis, but no significant predictor for OS was identified. Next, we included dMMR in the survival analysis for PDA. Univariate Cox regression analysis showed that TNM stage, MUC5AC expression, and dMMR were significant prognostic factors for RFS; however none of

WMDA: Well-to-moderately differentiated adenocarcinoma; PDA: Poorly differentiated adenocarcinoma; dMMR: Mismatch-repair deficiency; TNM: Tumor node metastasis; MUC: Mucin.

these was significant by multivariate analysis. TNM stage and dMMR were also significant predictors for OS by univariate analysis but were not significant by multivariate analysis (Table 4).

For MUA, MUC2 expression was excluded from the analysis because there were very few MUC2-negative MUA cases (n = 4 out of 81). The TNM stage was the only significant predictor for RFS, and no variable was a significant predictor for OS (data not shown).

Thus, no significant associations were found between mucin expression and the prognosis of each CRC subtype by multivariate Cox analysis. However, as the data suggested marginal associations between mucin expression and prognosis, and from the need for subsequent discussion, Kaplan-Meier survival curves for associations with mucin expression were generated and assessed by log-rank test for each CRC subtype.

For this analysis of WMDA, marginally better RFS and OS with MUC2-positive tumors were found as compared with negative tumors. The prognosis of MUC5AC-positive WMDA cases tended to be worse as compared to those that were negative, although this difference was not significant (Figure 4A-D). There was also no difference with respect to MUC2 status in PDA. However, MUC5AC expression in PDA was significantly and marginally associated with a better prognosis in terms of RFS and OS, respectively (Figure 4E-H). Because MUC2 positivity was very high in MUA (77 of 81 tumors), its clinical significance in these settings was not investigated. MUC5AC expression in MUA did not affect its prognosis (Figure 4I and J).

DISCUSSION

MUC2 is normally expressed in the perinuclear cytoplasm of goblet cells in normal colonic mucosa. MUC2 is also expressed in adenomas and mucinous carcinomas[4]. MUC2 downregulation occurs in non-mucinous adenocar-cinomas that arise within adenomas, whereas cancers that are considered to develop de novo do not express MUC2[4]. Thus, MUC2 levels have been thought to be a predictor of malignant potential. However, despite a poor prognosis, higher levels of MUC2 expression were maintained in MUA and SRCC than in WMDA. This suggests the difficulty with using MUC2 levels as a differentiation marker in these subtypes.

Some investigators reported MUC2 expression in CRC in association with clinical significance, although the association between MUC2 expression and prognosis has been controversial. For example, Matsuda *et al*[9] analyzed 86 CRCs that included 82 WMDA tumors and 4 other variants and reported that the MUC2 expression level was not associated with advanced Dukes' stage and liver metastasis. Baldus *et al*[10] investigated 243 CRCs that included 213 grade Ⅰ-Ⅱ tumors and 30 grade Ⅲ tumors, which also included 22 MUA tumors, and reported that

MUC2 reactivity was not a marker for worse survival. In contrast, Kang *et al*[8] investigated 301 patients with stage Ⅱ-Ⅲ CRCs, including 200 well-to-moderately differentiated and 101 poorly differentiated cancers (also 266 nonmucinous and 35 mucinous) and reported that a loss of MUC2 expression was associated with a worse overall survival with CRC of stages Ⅱ and Ⅲ. Hanski *et al*[7] showed that a loss of MUC2 expression in CRC owing to promoter methylation was associated with liver and nodal metastasis. On the other hand, a loss of MUC2 expression in CRCs was associated with peritumoral lymphocyte infiltration[22]. Host responses, such as peritumoral lymphocyte infiltration, are known to be associated with a favorable CRC prognosis[23]. MUC2 mucin harbors the sialosyl-Tn antigen that mediates the inhibition of natural killer cell cytotoxicity[24].

However, MUC5AC expression is usually absent in normal colonic mucosa and is only occasionally found in pericancerous normally appearing colonic mucosa. Aberrant MUC5AC expression can be observed in a subset of adenomas and adenocarcinomas[11,25-27]. Microscopically, MUC5AC was detected primarily as focal staining in the cytoplasm and mucous droplets in goblet cells in the normally appearing colonic mucosa but was diffuse in the cytoplasm of cancer cells. MUC5AC expression levels are highest in adenoma but decrease with increasing degrees of dysplasia, and the positive rates for MUC5AC expression were lower in CRC than in adenoma[11,25-27]. These results suggest that MUC5AC may play a role in early carcinogenesis and its expression status can be used to classify CRC from the viewpoint of pathogenesis.

Biemer-Hüttmann *et al*[28] and Losi *et al*[29] reported associations between MUC5AC expression and MSI-H, which is linked with histological subtypes like PDA and MUA. Kocer *et al*[12] analyzed MUC5AC expression in 41 CRCs that included 33 adenocarcinomas, 5 mucinous carcinomas, and 3 neuroendocrine carcinomas. They reported that MUC5AC-negative CRCs had lower rates of disease-free status and of overall survival, but thy did not investigate associations between MSI and MUC5AC expression.

It has come to be well recognized that CRC comprises various carcinomas that originate from distinct pathogenetic pathways. Owing to this CRC heterogeneity, the significance of mucin core protein expression in CRC remains controversial. Thus, we performed these analyses for each histological CRC subtype.

In the present study, the expression profiles of MUC2 and MUC5AC in conventional adenocarcinoma (WMDA and PDA), MUA, and SRCC were similar to those in previous reports. High MUC2 expression levels in MUA and SRCC suggested distinct histogenetic pathways for these cancer cells, which maintained the feature of mucin-producing goblet cells, from conventional adenocarcinoma. In addition, the expression of the both mucin core proteins tended to decrease during the course of disease progression, from adenoma to carcinoma or from WMDA to PDA. Disease progression is usually accompanied by a decrease in cells of the goblet lineage.

These results are consistent with the hypothesis that the levels of the mucin core proteins may be a marker of malignancy potential in the adenoma-carcinoma sequence in both non-mucinous and mucinous carcinomas. We found that the prognostic significance of the mucin core proteins was different between MUC2 and MUC5AC. In our survival curve analysis, a tendency for better prognosis with MUC2-positive cases than for negative cases was observed in WMDA. A difference in prognosis was not evident from the MUC2 status in PDA.

However, MUC5AC expression in PDA was significantly associated with a better RFS and marginally associated with a better OS. MUC5AC was a significant factor for RFS by univariate Cox regression analysis. Although no significant effects of MUC5AC expression on RFS or OS were found by multivariate analysis, these results may have been because of the limited number of cases

or other unknown factors associated with this patient population. A larger study will be needed to clarify these points.

In comparison, MUC5AC expression was not a factor associated with better prognosis in WMDA and MUA. Aberrant MUC5AC expression is considered to be an early event in carcinogenesis. In addition, MUC5AC expression was significantly associated with right-sided location, absence of nodal metastasis, and a lower TNM stage and was marginally associated with older age in our PDA series. These clinical features as well as poor differentiation are characteristic of MSI-high tumors. MUC5AC expression in PDA was significantly associated with dMMR as shown by a loss of MMR protein expression (16 of 47 MUC5AC-positive cases *vs* 3 of 44 negative cases; $P = 0.003$). Unlike the report by Biemer-Hüttmann *et al*[28] stating that MUC2 expression was also associated with MSI-H, our PDA cases did not exhibit an association between the two. These results suggest that PDA also consists of heterogenous groups of cancers and that MUC5AC expression status may be one of the classification hallmarks.

To date, the mechanisms underlining aberrant MUC5AC expression in the colon have not been determined. During colon carcinogenesis, MUC5AC expression may be regarded as the re-expression of this fetal mucin. MUC5AC mucin is detected from the fourth month of gestation and is maximum during the sixth month[30]. On the other hand, the MUC5AC promoter was shown to be activated by various inflammation mediators[31]. It was also reported that tumor necrosis factor-α stimulated colon cancer HT-29 cells, which are a goblet cell line, to secrete MUC5AC mucin in a dose-dependent manner[32]. Forgue-Lafitte *et al*[33] reported that MUC5AC mucin was detectable in the mucus of ulcerative colitis patients who underwent surgery. In their series, 10 patients suffering from ulcerative colitis tested were positive for MUC5AC, which suggested that long-term chronic inflammation may induce the production of this mucin in the colonic epithelium. In addition, MUC5AC expression in the regenerating areas close to ulcerations in Crohn's disease suggests its involvement in tissue repair mechanisms[34]. CRC with MUC5AC expression may originate from precancerous lesions owing to long-standing inflammation caused by bacterial infection, inflammatory bowel disease, or other reasons.

In our study, we sometimes observed aberrant MUC5AC expression in normally-looking colonic mucosa at the interface between non-tumor and tumor tissue, where a strong anti-tumor inflammatory reaction had been observed. We speculate that this may be suggestive of the origin of a neoplasm with aberrant MUC5AC expression. Furthermore, it was previously reported that long-standing inflammation due to ulcerative colitis resulted in CRC with dMMR[35,36]. Taken together, a hypothesis of inflammation-related carcinogenesis may explain the pathogenesis of CRC from MUC5AC-positive precancerous lesions and an association between dMMR and MUC5AC expression.

In conclusion, we investigated MUC2 and MUC5AC expression status in each of the histological CRC subtypes. MUC2 levels were decreased and MUC5AC levels were increased from WMDA to PDA. MUA and SRCC maintained high MUC2 levels. The expressions of these mucins in PDA and MUA decreased during disease progression in the adenoma-carcinoma sequence. MUC5AC expression was closely associated with MMR deficiency in PDA. MUC2 and MUC5AC expression tended to be associated with a better prognosis in WMDA and PDA, respectively, although these were not statistically significant. Thus, the mucin proteins show distinct clinical significance according to the histological subtypes, and this may also suggest different pathogeneses for these tumors.

We greatly appreciate the staff members of the Department of Pathology, Dokkyo Medical University Koshigaya Hospital and the Department of Pathology, Tokyo Kosei Nenkin Hospital for their technical and clerical assistance.

COMMENTS

Background

Mucin (MUC)2 mucin is predominantly found in colorectal goblet cells and MUC5AC mucin is primarily expressed in gastric mucosa. Altered mucin expression may be correlated with the biological behavior of and, possibly, the prognosis for colorectal carcinoma (CRC).

Research frontiers

To date, MUC2 and MUC5AC expressions in CRC have been investigated for their association with clinicopathologic characteristics and prognosis. However, many contradictory results make it difficult to interpret the clinical significance of altered mucin expression, possibly owing to various CRC subtypes. The authors investigated mucin expression by immunohistochemistry in each of the histological CRC subtypes individually and assessed its significance.

Innovations and breakthroughs

MUC2 levels may be associated with malignant potential in conventional adenocarcinoma, whereas mucinous adenocarcinoma and signet-ring cell carcinoma retain high MUC2 levels, which suggests distinct pathogenesis. In comparison, MUC5AC expression may be an early event in tumorigenesis. MUC5AC expression in poorly differentiated adenocarcinoma (PDA) was closely associated with mismatch repair deficiency. MUC2 and MUC5AC expression tended to be associated with a better prognosis in well-to-moderately differentiated adenocarcinoma and PDA, respectively. Thus, the mucin proteins show different clinical significance according to the histological subtypes, and this may also suggest different pathogeneses of these tumors.

Applications

These results could be the basis for further studies to understand the pathogenesis of CRC. Immunohistochemical detection of MUC5AC may be useful for further subclassifications and for predicting a favorable prognosis for PDA.

Terminology

MUC2 and MUC5AC are the backbone proteins of secreted mucins. MUC2 is synthesized in goblet cells in the gastrointestinal tract and MUC5AC is normally expressed in gastric foveolar epithelium. The *MUC2* and *MUC5AC* genes encode gel-forming mucins and are located in a cluster on chromosome 11p15.5.

Peer review

This study is important and interesting. Although there are a large number of publications on the roles of MUC2 and MUC5AC expression in CRC, the results are conflicting. This study adds some refinements to these issues, such as MUC2 and MUC5AC expressions in terms of CRC patient survival, adenoma-

carcinoma sequence, and expression of MMR proteins, with regard to associations with clinicopathologic variables by offering its own evidence.

Abstract

AIM: To determine the effects of BN52021 on platelet-activating factor receptor (PAFR) signaling molecules under lipopolysaccharide (LPS)-induced inflammatory conditions in MS1 cells.

METHODS: MS1 cells (a mouse pancreatic islet endothelial cell line) were grown in Dulbecco's modified Eagle's medium supplemented with 10% fetal bovine serum, 2 mmol/L glutamine and 100 μg/mL penicillin/streptomycin in 5% CO_2 at 37 ℃. After growth to confluency in media, the cells were processed for subsequent studies. The MS1 cells received 0, 0.1, 1 and 10 μg/mL LPS in this experiment. The viability/proliferation of the cells induced by LPS was observed using a 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide colorimetric assay. Apoptosis and necrosis of the cells under the inflammatory condition described previously were observed using Hoechst 33342-propidium iodide staining. Adenylate cyclase (AC), phospholipase A_2 (PLA_2), phospholipase Cβ (PLCβ), protein tyrosine kinase (PTK), G protein-coupled receptor kinases (GRK) and p38-mitogen-activated protein kinase (p38 MAPK) mRNA in the PAFR signaling pathway were measured by real-time polymerase chain reaction. The protein expression level of phosphorylated AC (p-AC), phosphorylated PLA_2 (p-PLA_2), phosphorylated PTK (p-PTK), phosphorylated p38 MAPK (p-p38 MAPK), PLCβ and GRK was measured using Western blotting analysis.

RESULTS: The activity of MS1 cells incubated with different concentrations of LPS for 6 h decreased significantly in the 1 μg/mL LPS group (0.49 ± 0.10 *vs* 0.67 ± 0.13, $P < 0.05$) and 10 μg/mL LPS group (0.44 ± 0.10 *vs* 0.67 ± 0.13, $P < 0.001$), but not in 0.1 μg/mL group. When the incubation time was extended to 12 h (0.33 ± 0.05, 0.32 ± 0.03 and 0.25 ± 0.03 *vs* 0.69 ± 0.01) and 24 h (0.31 ± 0.01, 0.29 ± 0.03 and 0.25 ± 0.01 *vs* 0.63 ± 0.01), MS1 cell activity decreased in all LPS concentration groups compared with the blank control ($P < 0.001$). BN52021 significantly improved the cell activity when its concentration reached 50 μmol/L compared with the group that received LPS treatment alone, which was consistent with the results obtained from fluorescence staining. The mRNAs levels of AC (4.02 ± 0.14 *vs* 1.00 ± 0.13), GRK (2.63 ± 0.03 *vs* 1.00 ± 0.12), p38 MAPK (3.87 ± 0.07 *vs* 1.00 ± 0.17), PLA_2 (3.31 ± 0.12 *vs* 1.00 ± 0.12), PLCβ (2.09 ± 0.08 *vs* 1.00 ± 0.06) and PTK (1.85 ± 0.07 *vs* 1.00 ± 0.11) were up-regulated after LPS stimulation as compared with the blank control ($P < 0.05$). The up-regulated mRNAs including AC (2.35 ± 0.13 *vs* 3.87 ± 0.08), GRK (1.17 ± 0.14 *vs* 2.65 ± 0.12), p38 MAPK (1.48 ± 0.18 *vs* 4.30 ± 0.07), PLCβ (1.69 ± 0.10 *vs* 2.41 ± 0.13) and PLA_2 (1.87 ± 0.11 *vs* 2.96 ± 0.08)

were significantly suppressed by BN52021 except for that of PTK. The level of p-AC (1.11 ± 0.12 *vs* 0.65 ± 0.08), GRK (0.83 ± 0.07 *vs* 0.50 ± 0.03), PLCβ (0.83 ± 0.16 *vs* 0.50 ± 0.10) and p-p38 MAPK (0.74 ± 0.10 *vs* 0.38 ± 0.05) was up-regulated after LPS stimulation as compared with the blank control ($P < 0.05$). The up-regulated proteins, including p-AC (0.65 ± 0.15 *vs* 1.06 ± 0.14), GRK (0.47 ± 0.10 *vs* 0.80 ± 0.06), PLCβ (0.47 ± 0.04 *vs* 0.80 ± 0.19) and p-p38 MAPK (0.30 ± 0.10 *vs* 0.97 ± 0.05), was significantly suppressed by BN52021, but p-PLA_2 and p-PTK protein level were not suppressed.

CONCLUSION: BN52021 could effectively inhibit LPS-induced inflammation by down-regulating the mRNA and protein levels of AC, GRK, p38 MAPK, PLA_2 and PLCβ in the PAFR signaling pathway.

Key words: BN52021; Platelet-activating factor receptor; Signaling pathway; Inflammation; Pancreatitis

Core tip: Microcirculatory disorder is considered to be one of the possible mechanisms of pathogenesis of severe acute pancreatitis (SAP). Platelet-activating factor (PAF) is known to mediate microcirculatory disturbance and inflammation. Although BN52021, a PAF receptor antagonist, has demonstrated significant treatment effects on SAP, its mechanism has not been elucidated in detail. In this study, we examined the signaling molecules of the PAF receptor pathway to evaluate whether BN52021 has any influence on the inflammatory effects induced by lipopolysaccharide in MS1 cells, hoping to elucidate the mechanism underlying microcirculatory disturbances in the pathogenesis of SAP *in vitro*.

INTRODUCTION

Acute pancreatitis (AP) is an inflammatory disease that can develop into severe AP (SAP)[1]. SAP refers to AP associated with organ failure and/or local complications such as necrosis, pseudocyst or abscess, which is a disease of high morbidity and mortality with an unpredictable clinical course[2,3]. There is no clinically effective therapeutic strategy for SAP, because the pathogenesis of the disease remains largely unclarified. The possible explanations for the pathogenesis of SAP include theories of self-digestion, leukocyte overactivation, microcirculatory disorder, bacterial shifting, and secondary infection, which is a second attack by immune functional change, cell apoptosis, oxygen-free radicals, and others from different aspects[4]. Accumulated evidence has proven that microcirculatory disorders are the key pathogenesis of AP. Many complications of SAP are due to the amplifying effects of microcirculatory disruption[5-10]. The inflammation of pancreatic microvascular endothelial cells induced by lipopolysaccharide is a suitable pancreatitis model to simulate the microcirculatory disturbances *in vitro*.

Platelet-activating factor (PAF), a bioactive phospholipid synthesized and secreted by a variety of cells including pancreatic acini and microvascular endothelium cells[11], is known to mediate many physiological responses such as microcirculatory disturbance and inflammation. AP causes the release of PAF, which induces systemic effects that contribute to circulatory disturbance and multiple organ failure[1]. PAF can significantly potentiate pancreatic tissue damage, increase serum amylase and lipase levels, cause scattered hemorrhages and may serve as a primary mediator of inflammation in the pathological progress of SAP[1,7,12]. A single injection of PAF into the superior pancreaticoduodenal artery of rabbits induces dose-dependent morphologic alterations of the pancreatic tissue and increased serum amylase levels[13]. Our previous research revealed that PAF was stably expressed in the rat pancreas tissue and played an important role in inflammatory response during the procession of SAP[4,14]. PAF could produce physiological and pathological effects by binding to its cell surface receptor, PAF receptor (PAFR). Flickinger *et al*[15] revealed specific localization of PAFR in the pancreatic vascular endothelium but not in other pancreatic cell types. Recent studies have demonstrated that bacterial lipopolysaccharide (LPS) can induce an increase in the surface expression of PAF receptors[16]. Our recent study demonstrated that BN52021 exerted biological effects through inhibiting the increased PAF level and binding potential with PAFR rather than through decreasing PAFR expression in the pancreatic tissue[17]. Through binding with PAFR, PAF may, through G-protein transduction, activate phospholipase C, phospholipase A2, adenylate cyclase and tyrosine protein kinase, leading to the occurrence and development of SAP[18].

PAFR antagonists can block a series of inflammatory injuries caused by PAF, thereby improving the AP prognosis as a preventive treatment[19]. Research on such a potential therapy has helped elucidate the role of PAF in AP[20]. It was observed that BN52021 extracted from Ginkgo biloba leaves could act as a potent antagonist of PAFR[21], and BN52021 can inhibit the PAF-induced cascade effect in inflammatory reactions, exhibiting an anti-shock effect by reducing the portal vein pressure of liver cirrhosis[22,23]. In experimental pancreatitis models and clinical trials, the administration of several PAF antagonists significantly reduced the level of serum amylase, leukocyte infiltration, and improved capillary blood flow in the pancreas and distant organs, as well as the renal and respiratory functions and the survival rate. BN52021 could significantly reduce vascular permeability, pancreatic edema, hyperamylasemia, diminute superoxide dismutase activity, and inhibit lipid peroxidation in the

pancreatic tissue. These changes were accompanied by a significant reduction of acinar cell vacuolization and a remarkable inhibition of inflammatory cell infiltration in the interacinar space[24,25]. Our recent studies have also shown a therapeutic effect of BN52021 on experimental SAP[26-28], but its mechanism is not yet fully understood.

In this study, we examined signaling molecules of the PAFR pathway to evaluate whether a PAF receptor antagonist (BN52021) had any influence on the inflammatory effects induced by lipopolysaccharide in MS1 cells, hoping to elucidate the mechanism underlying the microcirculatory disturbances in the pathogenesis of SAP *in vitro*.

MATERIALS AND METHODS

Chemicals and reagents

Chemicals and reagents used in this study included BN52021, 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) and LPS (Sigma-Aldrich, St. Louis, MO, United States); Dulbecco's modified Eagle's medium (DMEM, Gibco/Invitrogen, Carlsbad, CA, United States); the mouse primers for the *Adcy1* [adenylate cyclase (AC)], *Pla2g4a* [phospholipase A_2 (PLA_2)], *Plcb3* [phospholipase Cβ (PLCβ)], *Ptk7* [protein tyrosine kinase (PTK)], *Adrbk1* [G protein-coupled receptor kinases (GRK)], *Mapk14* [p38-mitogen-activated protein kinase (p38 MAPK)] and *Gapdh* (glyceraldehyde 3-phosphate dehydrogenase) genes (Beijing AuGCT DNA-SYN Biotechnology Co., Ltd., Beijing, China); rabbit polyclonal antibodies of phosphorylated PTK (p-PTK) and phosphorylated AC (p-AC) (Abcam, Cambridge, MA, United States); rabbit polyclonal antibodies for GRK_2 and phosphorylated p38 MAPK (p-p38 MAPK) (Epitomics, Burlingame, CA, United States); rabbit polyclonal antibody for phosphorylated PLA_2 (p-PLA_2) (Cell Signaling Technology, Beverly, MA, United States); rabbit polyclonal antibody for PLCβ (Santa Cruz, Dallas, TX, United States); rabbit polyclonal antibody for β-actin (Abmart, Arlington, MA, United States); protein molecular weight markers, reverse transcription-polymerase chain reaction (RT-PCR) kit and quantitative PCR kit (Beijing TransGen Biotech Co., Ltd, Beijing, China); and polyvinylidene fluoride (PVDF) membranes (BD Biosciences, BD Corporation, MA, United States).

Cell culture

MS1 cell line (a mouse pancreatic islet endothelial cell line firstly established in 1994) was purchased from Shanghai Institute of Cell Biology of the Chinese Academy of Sciences (Shanghai, China). Cells were grown in DMEM supplemented with 10% fetal bovine serum (FBS), 2 mmol/L glutamine and 100 μg/mL penicillin/streptomycin in 5% CO_2 at 37 ℃. After grown to confluency in media, the cells were processed for subsequent studies.

MTT colorimetric assay

The viability/proliferation of the cells induced by LPS was observed using a MTT colorimetric assay as previously described[29]. MS1 cells received 0, 0.1, 1 and 10 μg/mL LPS in this experiment. Briefly, the cells were trypsinized with trypsin-ethylenediaminetetraacetic acid (EDTA), followed by incubation with DMEM in the presence of 10% FBS to inhibit trypsin activity. The cell pellets were then resuspended in DMEM with 10% FBS to a concentration of 1×10^4 cells/mL. Two hundred microliters of the cell suspension containing approximately 2000 cells was inoculated into selected wells of the 96-well plate. After the cells grew to 75% confluence, 20 μL of MTT solution was added to each well, and cultured for 4 h. Next, the medium was removed by inverting and tapping the plates, and 150 μL of dimethyl sulfoxide (DMSO) was added to each well. The spectrophotometric absorbance at 490 nm was measured by a Titertek Multiscan enzyme-linked immunosorbent assay reader. Each experiment was repeated at least three times. Every experimental condition was repeated at least in triplicate wells for each experiment.

Hoechst 33342/propidium iodide staining

The apoptosis and necrosis of the cells under the conditions described previously were observed by Hoechst 33342-propidium iodide (PI) staining[30]. MS1 cells were plated in a 6-well plate and co-incubated with media, LPS, LPS + DMSO and LPS + BN52021 when the cells achieved 90% confluence. The cells were washed twice with PBS. After the addition of 5 μL of Hoechst 33342 staining solution, the cells were stained with PI in the dark for 20-30 min at 4 ℃ and washed twice with PBS. Cells with blue and red fluorescence were examined under a fluorescence microscope.

Real-time quantitative RT-PCR

The mRNAs levels of AC, PLA_2, PLCβ, PTK, GRK and p38 MAPK were measured by real-time PCR. In detail, MS1 cells were plated in a 6-well plate and co-incubated with media, LPS, LPS + DMSO and LPS + BN52021 when the cells achieved 90% confluence. The cells were collected, and the total RNA was extracted with a Trizol RNA reagent kit according to the manufacturer's instructions. In addition, 2 μL (1 μg) of total RNA was added to the reverse transcription kit MIX system, and reverse-transcribed PCR was performed by random priming. The resulting complementary DNA amount was measured by quantitative PCR analysis using the GeneAmp 5700 Sequence Detection System and Step One Plus Real-Time PCR System (Applied Biosystems). The qPCR primer sequences are available online as indicated in Table 1. All expression data were normalized to the data for *Gapdh*. A no-template, double-distilled water control was included for each template. All samples were amplified simultaneously in triplicate in a single run. The relative quantitative gene expression was calculated as previously described and expressed as the percentage of the control level[31].

p-p38 MAPK, PLCβ and GRK was measured using Western blotting analysis. In detail, MS1 cells were plated in a 6-well plate and co-incubated with media, LPS, LPS + DMSO and LPS + BN52021 for 24 h when the cells achieved 90% confluence. The cells were washed twice with 0.1 mol/L PBS and then lysed in RIPA lysis buffer (Tris-HCl 10 mmol/L, pH 7.4; NaCl 0.15 mmol/L; EDTA 0.5 mmol/L; phenylmethylsulfonyl fluoride 10 mmol/L; Tritonx-100 1%; dithiothreitol 40 mmol/L). The protein concentration of the lysate was determined using a BCA protein assay kit (Beyotime Institute of Biotechnology, Beijing, China). Cell lysates containing 60 mg of protein were subjected to sodium dodecyl sulfate polyacrylamide gel electrophoresis using 12% polyacrylamide resolving gels. After electrophoresis, the proteins were transferred onto PVDF membranes, which were then blocked with 5% nonfat dry milk in TBS-0.05% Tween 20 (TBST) for 1 h at room temperature, washed in TBST for 10 min × 3, and incubated at 4 ℃ with gentle shaking overnight with rabbit primary antibodies against the protein of interest at corresponding dilutions, followed by incubation with horseradish peroxidase conjugated to goat anti-rabbit immunoglobulin G at 1:2000 dilution, incubation with 1 mL of enhanced chemiluminescence reagent for 3 min, and exposure to the film. The optical density of the protein of interest relative to that of β-actin was analyzed using Quantity One 4.6.2.

Statistical analysis

The data are expressed as the mean ± SE. The dose and time effects of LPS on the activity of MS1 cells were evaluated with a two-way analysis of variance (ANOVA). The differences between three or more groups were evaluated by one-way ANOVA. A P value less than 0.05 (2-tailed) was considered statistically significant. All tests were performed using the statistical software package GraphPad 5.0 (GraphPad Software Inc., San Diego, CA, United States).

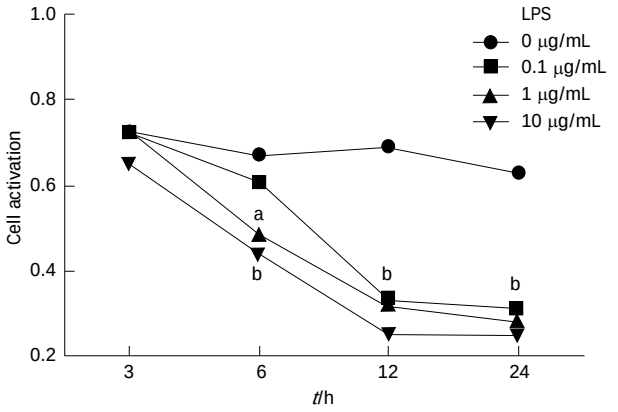

Figure 1 The optimal dose and duration of lipopolysaccharide stimulation were determined using the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide method. The cell survival rate was determined after incubation with 0 (saline) and 0.1, 1 and 10 μg/mL lipopolysaccharide (LPS) for 3, 6, 12 and 24 h. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* the saline group.

RESULTS

Dose and time effect of LPS on MS1 cell activity

MS1 cells received 0, 0.1, 1 and 10 μg/mL LPS to mimic the inflammation condition of AP *in vitro*. The optimal dose and duration of LPS stimulation were determined using the MTT method. As shown in Figure 1, there was no significant difference in MS1 cell activity between cells co-incubated with the different concentrations of LPS and control cells 3 h after culture ($P > 0.05$), but when the incubation time was extended to 6 h, MS1 cell activity decreased significantly in the 1 μg/mL LPS group (0.49 ± 0.10 *vs* 0.67 ± 0.13, $P < 0.05$) and 10 μg/mL LPS group (0.44 ± 0.10 *vs* 0.67 ± 0.13, $P < 0.001$), but not in the 0.1 μg/mL group ($P > 0.05$) compared with the control group. When the incubation time was extended to 12 h (0.33 ± 0.05, 0.32 ± 0.03 and 0.25 ± 0.03 *vs* 0.69 ± 0.01) and 24 h (0.31 ± 0.01, 0.29 ± 0.03 and 0.25 ± 0.01 *vs* 0.63 ± 0.01), MS1 cell activity decreased in all LPS concentration groups compared with the blank control ($P < 0.001$). Therefore, we chose the concentration 10 μg/mL LPS for the 24 h stimulation as the optimal protocol in the following experiments.

Dose effect of BN52021 on LPS-induced inflammation

The dose effect of BN52021 on LPS-induced inflammation was determined using the MTT method and Hoechst 33342/PI staining. The MS1 cell activity was significantly decreased 24 h after administration of 10 μg/mL LPS compared with the control group ($P < 0.01$). Pretreat-

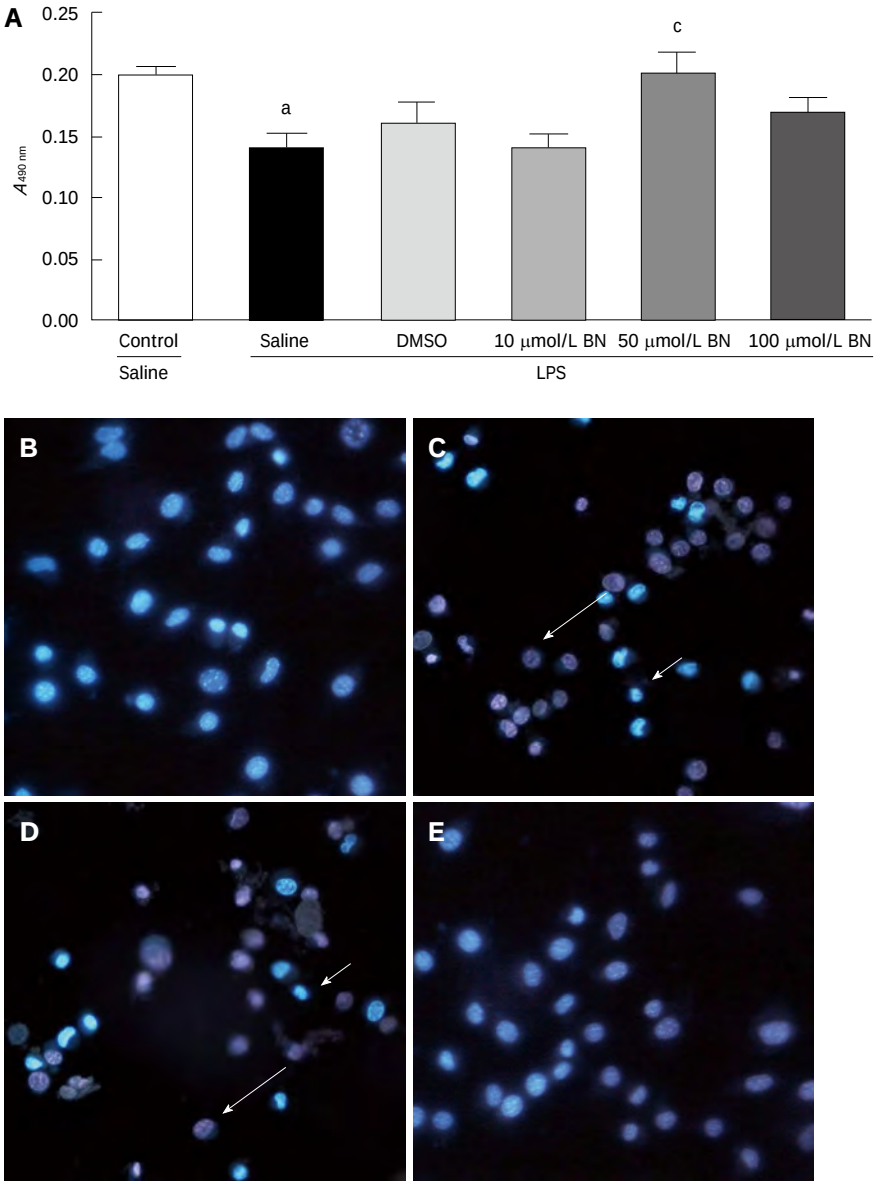

Figure 2 The dose effect of BN52021 on lipopolysaccharide-induced inflammation was determined by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide method and Hoechst 33342/propidium iodide staining. MS1 cell activity at $A_{490\ nm}$ was significantly decreased 24 h after administration of 10 μg/mL lipopolysaccharide (LPS) *vs* the control group ($^aP < 0.05$). Pretreatment with BN52021 for 20 min before incubation with LPS significantly improved the MS1 cell activity at $A_{490\ nm}$ *vs* the group that received LPS treatment only when its concentration reached 50 μmol/L ($^cP < 0.05$) (A). Pretreatment with 50 μmol/L BN52021 for 20 min before incubation with LPS significantly improved MS1 cell activity *vs* the LPS + saline group, and the LPS + dimethyl sulfoxide (DMSO) group as determined Hoechst 33342/propidium iodide staining (B, C, D and E). The arrows indicate the apoptosis (short) and necrosis (long) of the cells.

ment with BN52021 20 min before incubation with LPS significantly improved the cell activity compared with the group receiving LPS only when its concentration reached 50 μmol/L, which was consistent with the results obtained by Hoechst 33342/PI staining ($P < 0.05$) (Figure 2). Therefore, the concentration of 50 μmol/L BN52021 was used for pretreatment in the following experiments.

Effect of BN52021 on PAFR signaling molecules at the mRNA level in LPS-induced inflammation

The mRNAs levels of AC (to 4.02 ± 0.14 folds), GRK (to 2.63 ± 0.03 folds), p38 MAPK (to 3.87 ± 0.07 folds), PLA_2 (to 3.31 ± 0.12 folds), PLCβ (to 2.09 ± 0.08 folds) and PTK (to 1.85 ± 0.07 folds) were up-regulated after LPS stimulation compared with the blank control ($P < 0.05$). The up-regulated mRNAs were significantly suppressed by BN52021, except for that of PTK (fold-change relative to control, 1.83 ± 0.13, $P > 0.05$), including that of AC (fold-change relative to control, down to 2.35 ± 0.13), GRK (down to 1.17 ± 0.14), p38 MAPK (down to 1.49 ± 0.18), PLCβ (down to 2.09 ± 0.08) and PLA_2 (down to 1.87 ± 0.11), as shown in Figure 3.

Effect of BN52021 on PAFR signaling molecules at the protein level in LPS-induced inflammation

The level of p-AC (fold-change relative to control, increase from 0.65 ± 0.08 to 1.11 ± 0.12), GRK (increase from 0.50 ± 0.03 to 0.83 ± 0.07), PLCβ (increase from 0.50 ± 0.10 to 0.83 ± 0.16) and p-P38 MAPK (increase from 0.38 ± 0.05 to 0.74 ± 0.10) was up-regulated after LPS stimulation compared with the blank control ($P < 0.05$). The up-regulated protein level was significantly suppressed by BN52021 for p-AC (decrease from 1.11 ± 0.12 to 0.65 ± 0.15), GRK (decrease from 0.83 ± 0.07 to 0.47 ± 0.10), PLCβ (decrease from 0.83 ± 0.16 to 0.47 ± 0.04) and p-p38 MAPK (decrease from 0.74 ± 0.10 to 0.30 ± 0.10). However, the level of p-PLA_2 and p-PTK was not significantly up-regulated after LPS stimulation and was not significantly altered by BN52021, as shown in Figure 4.

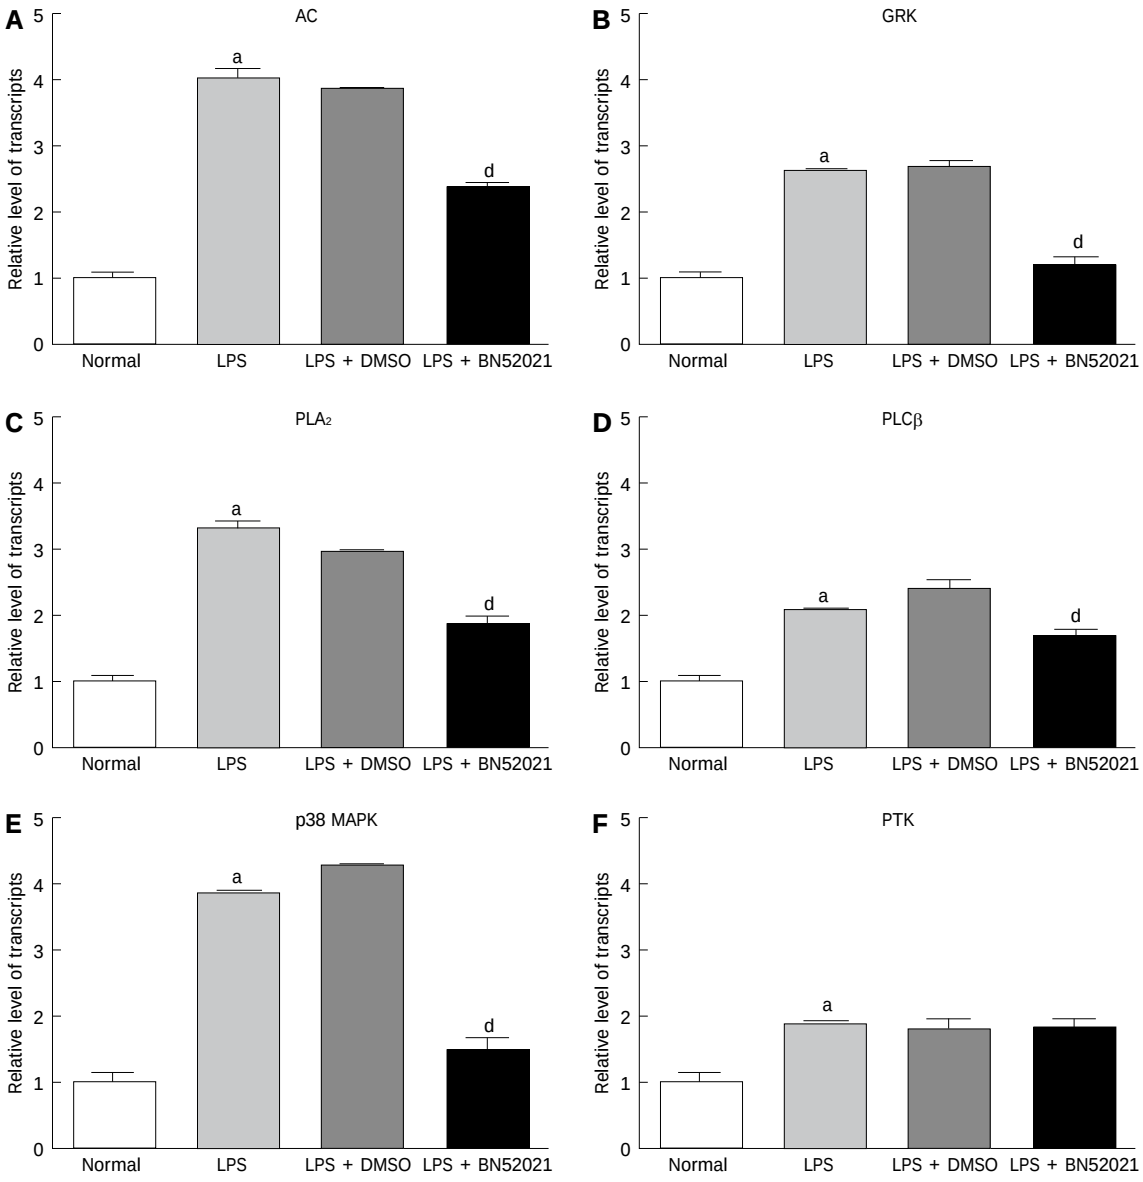

Figure 3 The effect of BN52021 on platelet-activating factor receptor signaling molecules at the mRNA level under lipopolysaccharide-induced inflammation. The mRNA level of adenylate cyclase (AC) (A), G protein-coupled receptor kinases (GRK) (B), phospholipase A_2 (PLA_2) (C), phospholipase Cβ (PLCβ) (D), p38-mitogen-activated protein kinase (p38 MAPK) (E) and protein tyrosine kinase (PTK) (F) was up-regulated after lipopolysaccharide (LPS) stimulation. The up-regulation of AC, GRK, p38 MAPK, PLCβ and PLA_2 mRNA was significantly suppressed by BN52021 except for that of PTK. $^aP < 0.05$ *vs* control; $^dP < 0.01$ *vs* the LPS + dimethyl sulfoxide (DMSO) groups.

DISCUSSION

In this study, we examined the signaling molecules of the PAFR pathway to evaluate whether the PAFR antagonist BN52021 had any influence on LPS-induced inflammation in MS1 cells. It was observed that BN52021 could sufficiently inhibit the inflammation, apoptosis and necrosis induced by LPS in pancreatic vascular endothelial cells. BN52021 could inhibit the up-regulation of signaling molecules in the PAFR pathway, which may help to explaining the mechanism underlying microcirculatory disturbance in the pathogenesis of AP.

PAF-induced microcirculatory disruption plays a key role in the pathogenesis of AP

Platelet-activating factor is a proinflammatory lipid mediator that plays a key role in many pathophysiological conditions, including asthma, ischemia, gastrointestinal ulceration, pancreatitis and multiple organ failure[32]. A number of experimental studies suggest that the pathogenesis of AP correlates with microcirculatory disorders. An experiment that constricted interlobular pancreatic arteries 2 min after intraductal infusion of sodium taurocholate indicated that microcirculatory changes are closely related to the process of AP[6]. Many complications of SAP are due to the amplifying effect of microcirculatory disruption[7]. PAF is one of the most important vasoactive mediators activated during the inflammatory response to pancreatic injury that can cause microcirculatory disorders in AP. Recent data suggest that PAF can directly modulate microvascular permeability and increase venular permeability[10]. Increased microvessel permeability

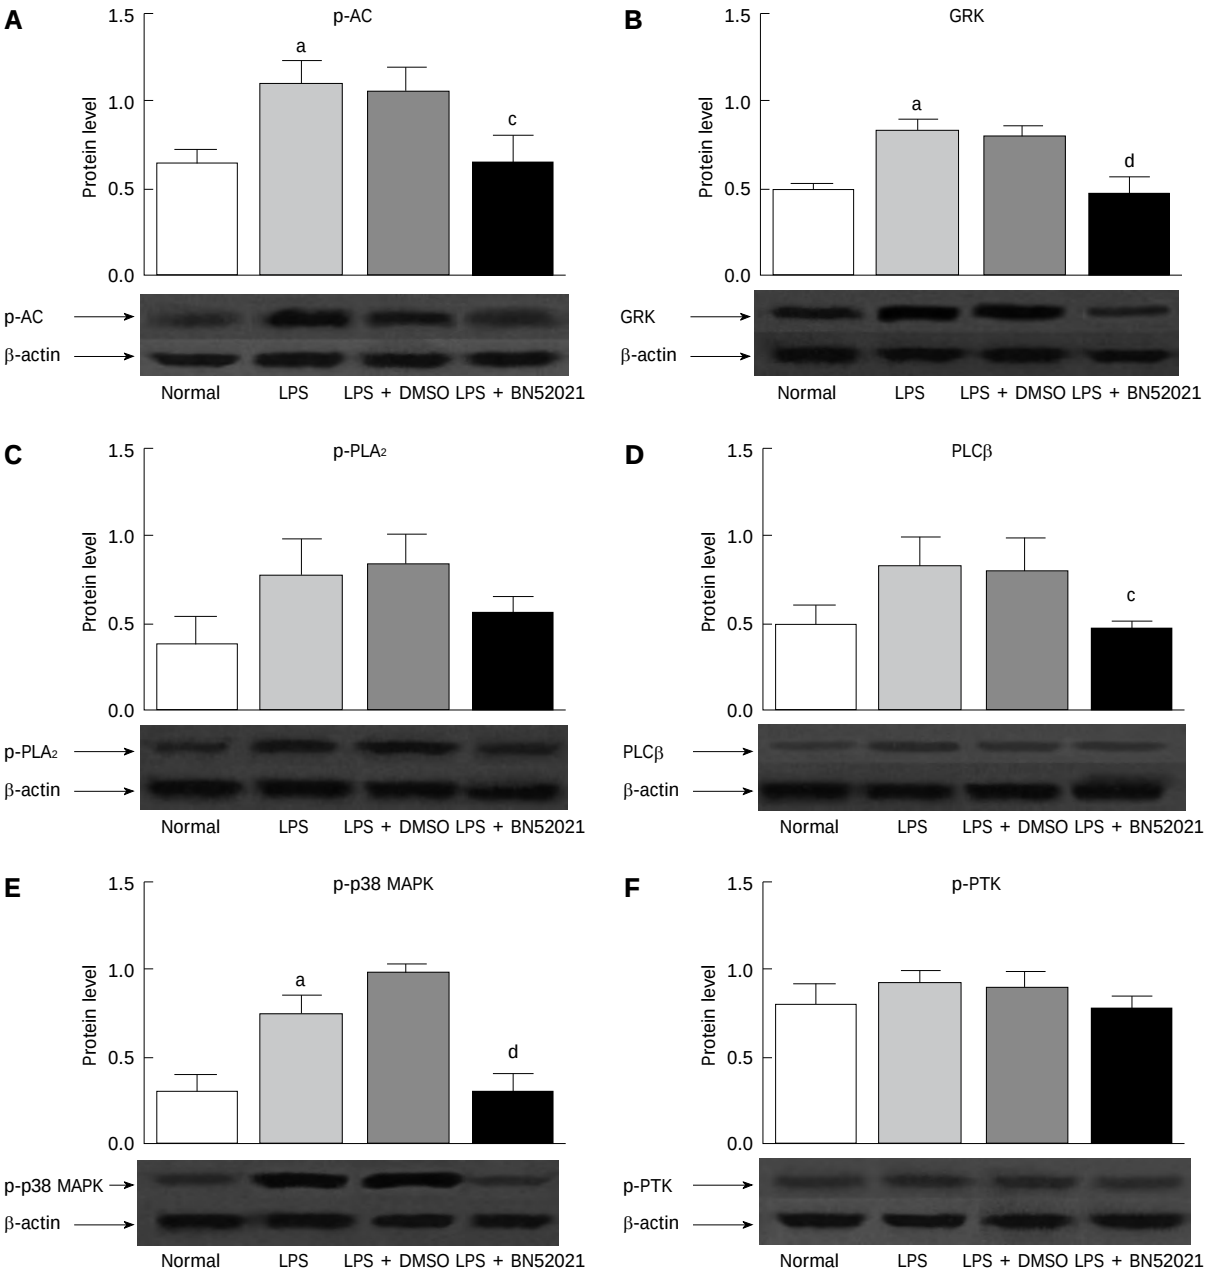

Figure 4 The effect of BN52021 on platelet-activating factor receptor signaling molecules at the protein level under lipopolysaccharide-induced inflammation. The protein level of p-adenylate cyclase (p-AC) (A), G protein-coupled receptor kinases (GRK) (B), p-phospholipase A_2 (p-PLA_2) (C), phospholipase Cβ (PLCβ) (D) and p-p38-mitogen-activated protein kinase (p-p38 MAPK) (E) was up-regulated after lipopolysaccharide (LPS) stimulation *vs* the blank control ($^aP < 0.05$). The up-regulation of p-AC, p-p38 MAPK, GRK and PLCβ protein levels was significantly suppressed by BN52021. However, p-PLA_2 and phosphorylated protein tyrosine kinase (p-PTK) protein levels were insignificantly up-regulated after LPS stimulation and were not significantly changed by BN52021 (F). $^cP < 0.05$, $^dP < 0.01$ *vs* LPS + dimethyl sulfoxide (DMSO) groups.

induced by PAF may be related directly to endothelial cell activation, adhesion molecule expression, and leukocyte activation[7,8]. Increased capillary permeability permits the sequestration of macromolecules and fluid, causing deficiency of circulating blood volume and microcirculatory disorders[7]. In addition, vasospasm and microthrombus formation due to hypercoagulability can also lead to the deterioration of pancreatic microcirculation and pancreatic necrosis[7]. The treatment of AP with PAF antagonists can significantly improve capillary blood flow in the pancreas and colon, renal and respiratory function, and the survival rate and can stabilize capillary permeability and decrease fluid loss into the third space[33,34]. As a preventive treatment, PAFR antagonists such as BN52021 can block a series of PAF-mediated inflammatory injuries, thus improving the prognosis of AP[1]. This protective effect of PAF antagonists further supports the role of PAF in microcirculatory disorders.

LPS-induced inflammation of pancreatic microvascular endothelial cells is a suitable pancreatitis model to simulate microcirculatory disturbance *in vitro*. The MS1 cell line is a mouse pancreatic islet endothelial cell line

first established in 1994. It can represent the pancreatic microvascular endothelium because previous studies[35] have verified that the pancreatic lobule is a structured and functional basic unit of pancreatic microcirculation, and insulo-acinar portal circulation represents the basic feature of the pancreatic microcirculation. Therefore, in this study, we examined the signaling molecules of the PAFR pathway in MS1 cells to evaluate whether the PAF receptor antagonist BN52021 had any influence on the LPS-induced inflammatory effect, hoping that it could help elucidate the mechanism underlying microcirculatory disturbance in the pathogenesis of SAP *in vitro*. Our results indicated that pretreatment with BN52021 for 20 min before incubation with LPS could significantly improve the MS1 cell activity compared with the group that received LPS treatment only.

PAFR signaling pathway plays a pivotal role in pancreatic proinflammatory response

In recent years, researchers have become concerned with the significance of the signal transduction pathway of PAF in the pathogenesis of AP[4,22,28], because it has been reported to induce morbidity and unacceptably high mortality[18]. However, the impact of a PAF receptor antagonist (BN52021) on the signaling molecules of the PAFR signaling pathway in pancreatic microvascular endothelial cells under the LPS-induced inflammatory condition remains unclear.

PAFR is almost ubiquitous in diverse type cells and acts not only on the local pancreas cells, including the pancreatic vascular endothelium, but also on distant organs, inducing systemic inflammatory response and multiple organ injury[15]. PAFR belongs to the G protein-coupled receptor subfamily[36]. By binding to its receptor, PAF activates the associated G protein, which, in turn, activates phosphoinositide hydrolysis by phosphoinositide specific phospholipase C, arachidonic acid release by phospholipase A_2, increases in intracellular Ca^{2+} concentration, activation of protein kinase C and PTK[37]. PAF has also been shown to activate MAPKs, including extracellular signal-regulated kinase[38-42], p38 MAPK[38,40,41], and c-Jun N-terminal kinase[43]. Deo *et al*[44] reported that PAF activated pertussis toxin-insensitive Gαq protein upon binding to its seven transmembrane receptors and adenylate cyclase, elevating cAMP levels, and thus activating protein kinase A in human umbilical vein endothelial cells. GRK plays a key role in the homologous desensitization of G protein-coupled receptor (GPCR) and GRK phosphorylate activated receptors, promoting high affinity binding of arrestins, thus precluding G protein coupling. Direct binding to active GPCRs activates GRKs so that they selectively phosphorylate only the activated form of the receptor regardless of the accessibility of the substrate peptides within it and their Ser/Thr-containing sequence[45]. Most GPCRs display a rapid loss of responsiveness in the continuing presence of chemoattractants in a process of desensitization that involves the phosphorylation of agonist-occupied GPCR by GRK[46]. The inflammation in pancreatic vascular endothelial cells induced by LPS was suppressed by BN52021. This finding might contribute to an understanding of the mechanism underlying the microcirculatory disturbances in the pathogenesis of SAP.

According to our results, the mRNA and protein levels of AC, GRK, p38 MAPK, PLA_2 and PTK were up-regulated after LPS stimulation compared with the blank control. The up-regulated AC, GRK, p38 MAPK and PLA_2 mRNA and protein levels were significantly suppressed by BN52021, suggesting that BN52021 could effectively inhibit the apoptosis and necrosis of MS1 cells under the LPS-induced inflammatory condition. The mechanism underlying the inhibition might relate to the suppression effect of BN52021 on the up-regulation of AC, GRK, p38 MAPK and PLA_2 mRNA and protein levels in the PAFR signaling pathway.

Other potential mechanisms of PAFR antagonism in AP treatment

It is known that PAFR is also able to interact with components of the bacterial wall, such as lipopolysaccharides[47] and phosphorylcholine[48]. The cell wall components exit the vasculature into the heart and brain, accumulating within endothelial cells, cardiomyocytes, and neurons in a PAFR-dependent way. The physiological consequences of the cell wall/PAFR interaction are cell specific, being noninflammatory in endothelial cells and neurons but causing a rapid loss of cardiomyocyte contractility that contributes to death. Thus, PAFR shepherds phosphorylcholine-containing bacterial components such as the cell wall into host cells from where the response ranges from quiescence to severe pathophysiology[48]. The explanation for the protective effect of BN-52021 cannot simply be attributed to the antagonism of LPS binding to PAFR or the prevention of PAF binding to its receptor. Therefore other potential mechanisms of PAFR antagonism in AP treatment must exist.

Bacterial translocation from the gastrointestinal tract to mesenteric lymph nodes and other extra intestinal organs is an important source of infection in AP. Preventing bacterial dissemination in early AP may have beneficial effects on the evolution of this disease[26,49]. PAF antagonist treatment decreases the bacterial spread to distant sites, suppresses elevation of interleukin (IL)-6 level, and has a significant effect on serum pancreatic enzymes and the histologic score of pancreatitis without reducing serum amylase and tumor necrosis factor alpha levels or ameliorating pancreatic damage in rats with AP[7,50]. In addition, BN52021 has been shown to have protective effect on slow mesenterioangial small arteriolar and venular blood flow velocity and dilated mesenterioangial small venular diameter in the early phase of AP[51]. Pretreatment with lexipafant could reduce the pancreatic endothelial barrier dysfunction and severity of pancreatitis-associated intestinal dysfunction as well as systemic concentrations of IL-1 and local leukocyte recruitment in experimental AP rats[52-54]. PAFR antagonism appears

to be involved in the maintenance of intestinal barrier integrity and the inhibition of cytokines release, such as IL-1 and IL-6[32]. Moreover, PAFR antagonists can also exert their effects by inhibiting the activity of neutrophils and depressing pulp peroxidase, competing for targets with PAF and inhibiting the activity of PAF, inhibiting increases in PAF in AP, and reducing plasma cytokines and inflammatory mediators, enzyme activity and the role of self-digestion of pancreatic tissue[1]. The involvement of the PAFR signaling pathway in these mechanisms needs to be further investigated.

The PAFR antagonist BN52021 could effectively inhibit LPS-induced inflammation, apoptosis and necrosis in pancreatic vascular endothelial cells. The mechanisms underlying the inhibition might be related to the suppression effect of BN52021 on the up-regulation of AC, GRK, p38 MAPK and PLCβ mRNA and protein levels in the PAFR signaling pathway, which may help to explain the mechanism underlying the microcirculatory disturbance in the pathogenesis of AP.

COMMENTS

Background

Microcirculatory disorder is considered to be one of the possible mechanisms of severe acute pancreatitis (SAP) pathogenesis. Platelet-activating factor (PAF), a bioactive phospholipid synthesized and secreted by a variety of cells including pancreatic acini and microvascular endothelium cells, is known to mediate many physiological responses, including microcirculatory disturbance and inflammation.

Research frontiers

Recent studies have demonstrated that PAF plays an important role in the pathological progress of SAP. Although BN52021, a PAF receptor antagonist, has demonstrated significant treatment effects against SAP, its effects on PAF receptor (PAFR) signaling molecules have not been elucidated in detail.

Innovations and breakthroughs

The authors found that BN52021 could effectively inhibit the apoptosis and necrosis of MS1 cells under lipopolysaccharide (LPS)-induced inflammatory conditions. The mechanism underlying the inhibitory effect may relate to the inhibitory effect of BN52021 on the up-regulation of adenylate cyclase, G protein-coupled receptor kinases, p38-mitogen-activated protein kinase, phospholipase A_2 and phospholipase Cβ mRNA and protein levels in the PAFR signaling pathway.

Applications

This study may contribute to a future strategy involving SAP treatment with BN52021 by investigating how PAF is induced and blocking its expression.

Terminology

PAF is a biologically active phospholipid mediator that plays its role by binding to PAFR, which is a unique G-protein-coupled seven transmembrane receptor, and the binding activates multiple intracellular signaling pathways. Ginkgolide B (code: BN52021) is one of the four Ginkgolide constituents (Ginkgolide A, B, C and J) that are present in the whole extract of Ginkgo biloba leaves.

Peer review

This article attempts to elucidate the protective role of BN-52021 against LPS-induced apoptosis and necrosis in a pancreatic islet endothelial cell line. PAF is a crucial mediator of acute pancreatitis. Therefore the inhibition of its actions by BN-52021 is interesting from a pharmaceutical point of view. Because BN-52021 is a well-established antagonist of PAFR, the authors investigated its effect on certain members of the signal transduction pathways initiated by PAFR activation. The results are novel and interesting.

Abstract

AIM: To investigate the effect of polydatin (PD), a resveratrol glucoside, on mast cell degranulation and anti-allergic activity.

METHODS: After the rats were orally sensitized with ovalbumin (OVA) for 48 d and underwent PD treatment for 4 d, all the rats were stimulated by 100 mg/mL OVA for 24 h and then sacrificed for the following experiments. The small intestines from all the groups were prepared for morphology examination by hematoxylin and eosin staining. We also used a smooth muscle organ bath to evaluate the motility of the small intestines. The OVA-specific immunoglobulin E (IgE) production and interleukin-4 (IL-4) levels in serum or supernatant of intestinal mucosa homogenates were analyzed by enzyme-linked immunosorbent assay (ELISA). Using toluidine blue stain, the activation and degranulation of isolated rat peritoneal mast cells (RPMCs) were analyzed. Release of histamine from RPMCs was measured by ELISA, and regulation of PD on intracellular Ca^{2+} mobilization was investigated by probing intracellular Ca^{2+} with fluo-4 fluorescent dye, with the signal recorded and analyzed.

RESULTS: We found that intragastric treatment with PD significantly reduced loss of mucosal barrier integrity in the small intestine. However, OVA-sensitization caused significant hyperactivity in the small intestine of allergic rats, which was attenuated by PD administration by 42% (1.26 ± 0.13 g *vs* OVA 2.18 ± 0.21 g, $P < 0.01$). PD therapy also inhibited IgE production (3.95 ± 0.53 ng/mL *vs* OVA 4.53 ± 0.52 ng/mL, $P < 0.05$) by suppressing the secretion of Th2-type cytokine, IL-4, by 34% (38.58 ± 4.41 pg/mL *vs* OVA 58.15 ± 6.24 pg/mL, $P < 0.01$). The ratio of degranulated mast cells, as indicated by vehicles (at least five) around the cells, dramatically increased in the OVA group by 5.5 fold (63.50% ± 15.51% *vs* phosphate-buffered saline 11.15% ± 8.26%, $P < 0.001$) and fell by 65% after PD treatment (21.95% ± 4.37% *vs* OVA 63.50% ± 15.51%, $P < 0.001$). PD mediated attenuation of mast cell degranulation was further confirmed by decreased histamine levels in both serum (5.98 ± 0.17 *vs* OVA 6.67 ± 0.12, $P < 0.05$) and intestinal mucosa homogenates (5.83 ± 0.91 *vs* OVA 7.35 ± 0.97, $P < 0.05$). Furthermore, we demonstrated that administration with PD significantly decreased mast cell degranulation due to reduced Ca^{2+} influx through store-operated calcium channels (SOCs) (2.35 ± 0.39 *vs* OVA 3.51 ± 0.38, $P < 0.01$).

CONCLUSION: Taken together, our data indicate that PD stabilizes mast cells by suppressing intracellular Ca^{2+} mobilization, mainly through inhibiting Ca^{2+} entry *via* SOCs, thus exerting a protective role against OVA-sensitized food allergy.

Key words: Polydatin; Food allergy; Mast cells; Store-operated calcium channels; Ca^{2+}

Core tip: In the present study, we have demonstrated for the first time that polydatin has the capacity for preventing pathogenesis of food allergy, which is dependent on regulation of Ca^{2+} mobilization *via* store-operated calcium channels in mast cells.

Polydatin attenuated food allergy *via* store-operated calcium channels in mast cell. *World J Gastroenterol* 2013; 19(25): 3980-3989 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/3980.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.3980

INTRODUCTION

Food allergy (FA) is an adverse reaction mediated by immunoglobulin E (IgE) or non-IgE antibodies[1], which involves an abnormal response by the immune system to specific proteins in foods[2]. FA has been recognized as a worldwide health problem, especially in western countries, which is due to the severity of the reactions and its dramatic increase over the past three decades[3-5]. The majority of food allergies worldwide are caused by "eight main food allergens", including peanuts, tree nuts, eggs, milk, fish, crustacean shellfish, wheat, and soy[6]. It has been suggested that 25% of infants[7], 8% of children[3-5], and 2%-5% of adults[8] suffer from FA. However, the current understanding about the etiology of food allergies remains poor, and no effective treatment is available except the preventative measure of avoiding the offending food in the diet.

Mast cells play an essential role in the development of intestinal inflammatory disorders during food allergy. Cross-linking of the high-affinity IgE receptor (FcεRI) on mast cells by allergens results in degranulation, leukotriene generation, and cytokine synthesis. Degranulated mast cells release inflammatory mediators, including histamine and Th2 cytokines[9], which cause abnormal gut contractions and intestinal mucosa damage, which in term then result in abdominal pain, cramps, vomiting, and/or diarrhea[10]. It has been known that IgE-dependent mast cell degranulation relies on intracellular Ca^{2+} signaling[11,12]. Cytoplasmic Ca^{2+} mainly comes from the stored Ca^{2+} in the endoplasmic reticulum (ER) and extracellular Ca^{2+} through store-operated calcium channels (SOCs)[13]. Therefore, modulation of Ca^{2+} mobilization is a potential therapeutic strategy for stabilizing mast cells upon FcεRI activation and potentially offering a novel treatment method for allergic diseases.

Polydatin (PD), also known as polygoni cuspidati radix, is a natural component isolated from *Polygonum cuspidatum*. It has been determined as a resveratrol glucoside with a 3,4,5-trihydroxystilben-3-*D*-mono-*D*-glucoside molecular structure. Previous studies have demonstrated that PD has a therapeutic effect on the treatment of allergic diseases. Using the passive cutaneous anaphylaxis (PCA) model in mice, Lim *et al*[14] showed that PD reduced mast cell degranulation by suppressing phosphorylation of Syk and mitogen-activated protein kinases. On the other hand, Yuan *et al*[15] found that PD alleviated PCA in mice by stabilizing mast cells *via* the inhibition of Ca^{2+} release-activated Ca^{2+} channels. However, the therapeutic effect of PD on food allergies has not yet been determined.

In this study, we established ovalbumin (OVA)-induced food allergic models and evaluated the therapeutic effect of PD on food allergy. Furthermore, we explored the effect of PD on mast cell degranulation and found that the underlying mechanism was related to Ca^{2+} mobilization. Our research presented here is the first to reveal that PD can inhibit food allergy by suppressing mast cell degranulation *via* regulation of SOCs.

MATERIALS AND METHODS

Animals

Four-week old female Brown-Norway (BN) rats were purchased from Vital River Laboratories (Beijing, China) and housed in groups of four per cage in a controlled environment with a photoperiod of 12 h light to 12 h dark and a temperature of 20 ± 2 ℃. Sanitary controls were performed for all major rodent pathogens, with the results of these tests being uniformly negative. All the animal experimental procedures were approved by the Animal Care and Use Committee of Shenzhen University and carried out in accordance with the Guide for the Care and Use of Laboratory Animals published by the United States National Institutes of Health (publication No. 85-23, revised 1996).

Forty-eight Brown-Norway rats were randomly divided into four groups: control group (n = 12), OVA group (n = 12), OVA + PD group (n = 12), and PD group (n = 12). Each group received phosphate-buffered saline (PBS), OVA, or PD, as shown in Figure 1[16]. The control group received 1 mL PBS (0.1 mol/L) daily by gavage administration for 52 d, while the OVA group was orally treated with 1 mg OVA (1 mg/mL) for the first 48 d and 1 mL PBS (0.1 mol/L) from days 48 to 52. The OVA + PD group received PD (150 mg/mL × 1 mL daily per rat) oral treatment daily from days 49 to 52 after OVA sensitization. The PD group was not challenged by OVA. All the groups of rats were stimulated by 100 mg/mL OVA for 24 h at the end of day 52 and then sacrificed for the following experiments.

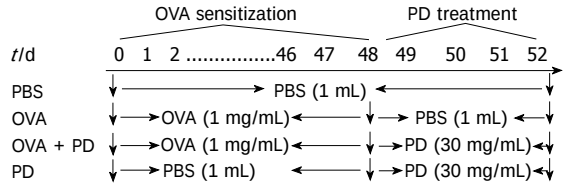

Figure 1 Protocol of ovalbumin sensitization/challenge and Formula-3 treatment. Rats were sensitized with ovalbumin (OVA) (1 mg/mL × 1 mL daily per rat) intragastrically for 48 d. For the polydatin (PD) treatment group, the rats were orally treated with PD (30 mg/mL × 1 mL daily per rat) from days 49 to 52 after OVA sensitization. All the rat groups were challenged by 100 mg/mL OVA for 24 h at the end of day 52 and then sacrificed. PBS: Phosphate-buffered saline.

Hematoxylin and eosin staining in small intestine tissues

The jejunal parts of the small intestine were isolated from the rats and embedded with paraffin. Sections (7 μm) were prepared and subjected to hematoxylin and eosin (HE) staining as previously reported[17].

Measurements of smooth muscle contractility

The tension of smooth muscle contractility was measured as previously reported[18]. Briefly, 2 cm long segments of the small intestine from the upper part of the jejunum to the lower part of the ileum were cut and mounted by hanging from triangle hooks. The hooks were connected to transducers from the upper end, and were inserted through the gut lumen from the lower end, allowing the circular muscle to contract. The tissue segments were incubated in chambers containing 20 mL Tyrode's solution (136 mmol/L NaCl, 5.4 mmol/L KCl, 1.0 mmol/L $MgCl_2$, 0.33 mmol/L NaH_2PO_4, 1.8 mmol/L NaCl, 10.0 mmol/L glucose and 5.0 mmol/L HEPES), which was kept at 37 ℃ and constantly aerated with a mixture of 95% oxygen and 5% carbon dioxide. The initial tension load was set at 1.0 g, from which the segments spontaneously relaxed over time. The segments were allowed to stabilize for 30 min before they were stimulated with 1 mg/mL OVA for 3 min. *R0* was defined as the mean basal tension, when the segments were under rest conditions. ΔR denotes (*R1-R0*), where *R1* is the contract tension when the segments were stimulated with OVA.

Toluidine blue stain

Typical mast cells in rat small intestine tissue or peritoneal lavage solution (RPLS) were stained with toluidine blue stain as previously described[19]. Briefly, 200 L RPLS was air dried on cromolyn sodium pretreated slides and then covered with several drops of staining solution (toluidine blue stain dissolved in 70% ethanol). After 90 s, the staining solutions were washed away quickly with running tap water and the stained cells were examined and counted under a light microscope (Olympus, Japan).

Enzyme-linked immunosorbent assay

The contents of interleukin-4 (IL-4) (eBioscience Inc., CA, United States) and histamine (R & D Inc., MN, United States) in RPLS and serum were assayed by commercial enzyme-linked immunosorbent assay (ELISA) kits using paired antibodies according to the manufacturer's instructions. Serum IgE levels were also checked using a commercial ELISA kit (BD Pharmingen, CA, United States), following the manufacturer's instructions.

Rat peritoneal mast cell isolation

The BN rats were sacrificed after being anaesthetized by ether inhalation in air. Rat peritoneal mast cells (RPMCs) were obtained by peritoneal lavage and purified by density gradient fractionation as described previously[20,21]. Isolated RPMCs preparations contained > 98% mast cells and at least 98% of these cells were viable, as checked by metachromatic staining in 0.05% toluidine blue.

Ca^{2+} imaging by confocal microscope

Intracellular Ca^{2+} signal was measured as described previously with minor modification[22]. RPMCs or RBL-2H3 cells were incubated with 5 μmol/L Ca^{2+} fluorescent probe fluo-4 AM (Invitrogen, CA, United States) for 30 min at room temperature. After washing with Tyrode's solution three times, the dye inside the cells was allowed to de-esterify for 30 min at 37 ℃. It has been determined that nearly 95% of the fluorescent dye was retained in the cytoplasm. Fluorescent images of Ca^{2+} were obtained using an Olympus 1000 confocal microscope with a 40 × oil immersion lens (NA 1.3) (Olympus, Japan). The fluo-4 signal was excited at 488-nm and emitted at > 505 nm. Frame-scan images were acquired at a sampling rate of 15 ms per frame and 20 s per interval.

Image data were analyzed off-line using fv10-asw.2.1 software. A selected image from each image set was used as a template for designating the region of interest (ROI) within each cell. The integrated intracellular Ca^{2+} concentration was determined by calculating $\Delta F/F0$. *F0* was defined as the mean basal fluorescence intensity of the dye recorded during the first 5-10 scanning frames, when the cells were under rest conditions. ΔF denotes (F-*F0*), where F is the temporal fluorescence intensity. The $\Delta F/F0$ values within each ROI were plotted as a function of time (typical time-courses of Ca^{2+} response to thapsigargin or DNP-BSA stimulation in single RBL-2H3 cells). The amplitude of the Ca^{2+} response within each cell was quantified as the highest $\Delta F/F0$ level reached during the measurement period, which was averaged over all cells within each group.

Statistical analysis

Data are presented as mean ± SE. When two comparisons were obtained, Student's unpaired two tailed t test was used. When multiple comparisons were obtained, the analyses consisted of one-way analysis of variance for repeated measures and Student-Newman-Keuls multiple comparison test. A value of $P < 0.05$ was considered to be statistically significant.

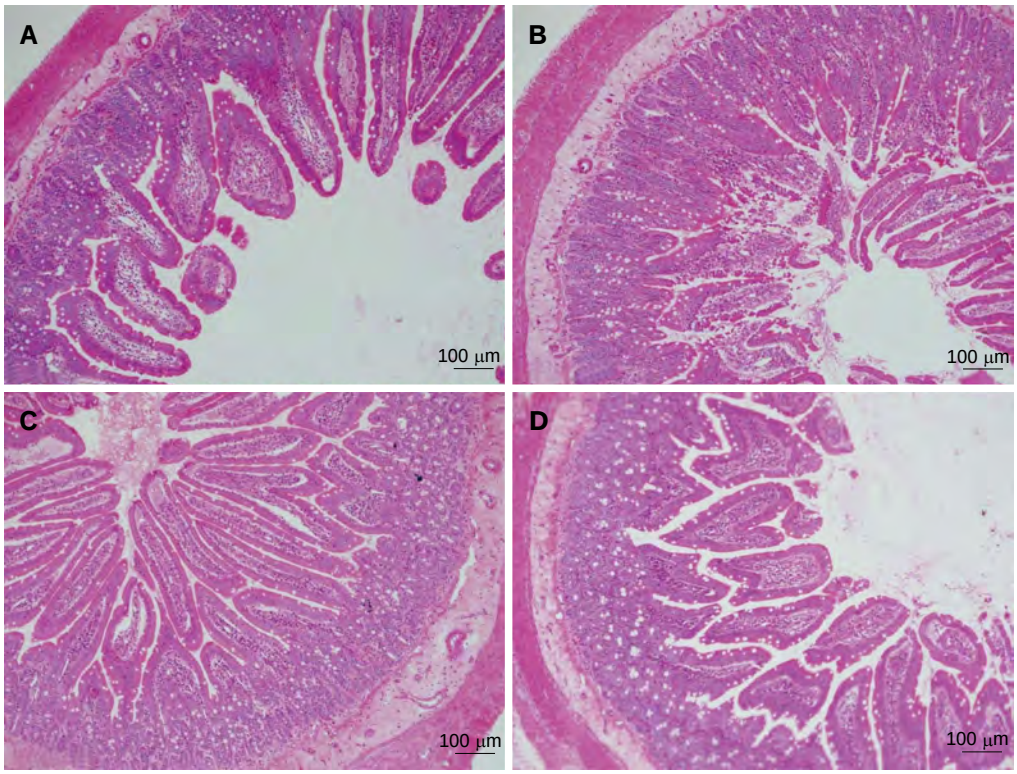

Figure 2 Polydatin attenuated tissue injury in small intestine caused by ovalbumin sensitization. A: Phosphate-buffered saline group; B: Ovalbumin (OVA) group; C: OVA + polydatin (PD) group; D: PD group. Morphology of intestinal jejunum was analyzed by hematoxylin and eosin staining. Representative images from three independent experiments are shown (magnification, × 63).

RESULTS

PD attenuated OVA-challenge caused small intestine abnormality in rats

In the present study, 1 mg OVA was used to sensitize BN rats orally and establish a food allergy model as previously described[16,23]. Loss of mucosal barrier integrity is a leading cause of food allergy[24]. Thus, we isolated jejunal fractions from the small intestine and checked tissue damage by HE staining. As shown in Figure 2, the results revealed that the intestinal mucosae were severely injured in the OVA group: the intestinal villi were eroded, and the swelling, shedding, and numbers of intestinal villi were significantly reduced. The morphological abnormality of the small intestine caused by OVA-sensitization was significantly attenuated by PD treatment.

The correlation between intestinal allergy and smooth muscle motility has been indicated by the fact that exposure to luminal allergen induces a state of proximal small intestinal hyperreactivity[25,26]. In order to evaluate the effects of PD on intestine motility, 2 cm intestine segments from each group were prepared, and the intestinal contraction tension was detected by smooth muscle organ bath. In response to 1 mg/mL OVA, intestinal segments isolated from OVA-allergic rats had a significant higher tension than the PBS group. The elevation of tissue tension caused by OVA sensitization was significantly attenuated by PD treatment by approximately 42% (Figure 3).

Treatment with PD decreased IL-4 levels and attenuated IgE production in OVA-sensitized group

The body weight of all rats in each group was monitored on days 0, 48 and 52. We found that basal body weight levels on day 0 were similar in all four groups. Compared to the PBS group, OVA sensitization significantly reduced body weight on day 48 (Figure 4A, left panel). After being treated with PD for 4 d, there was no significant difference between the PBS and OVA + PD groups (Figure 4A, left panel), which indicates that PD administration could maintain the body weight of an allergic rat at a normal level. The cytokine levels in the supernatant of the intestine mucosa were measured by ELISA. The results showed that the concentration of IL-4 in the OVA-challenged group was significantly higher than in the control group (58.15 ± 6.24 pg/mL *vs* 35.51 ± 5.48 pg/mL) (Figure 4B). Treatment with PD reduced the enhancement of IL-4 by 34%. Meanwhile, ELISA analysis showed that the concentration of OVA-specific IgE in serum was enhanced by 1.2 fold in the OVA group and PD therapy returned it to a normal level (Figure 4C).

PD reduced mast cell activation and degranulation in small intestine

Mast cell degranulation and histamine release are major factors in food allergy. The number and morphology of the mast cells in rat small intestine tissues (data not shown) or RPLS were examined by toluidine blue stain. In the OVA group, the number of mast cells was significantly increased and the cell size was much bigger, with more shrink on the cell membrane, bubbles in the cytoplasm, and degranulation vehicles around the cells (Figure 5A-D). *In vivo* administration with PD for 4 d reversed OVA-challenge-induced damage in mast cells. The ratio of degranulated mast cell, as indicated by vehicles (at least five) around the cells, dramatically increased in the OVA group by 5.5 fold and fell by 65% after PD treatment

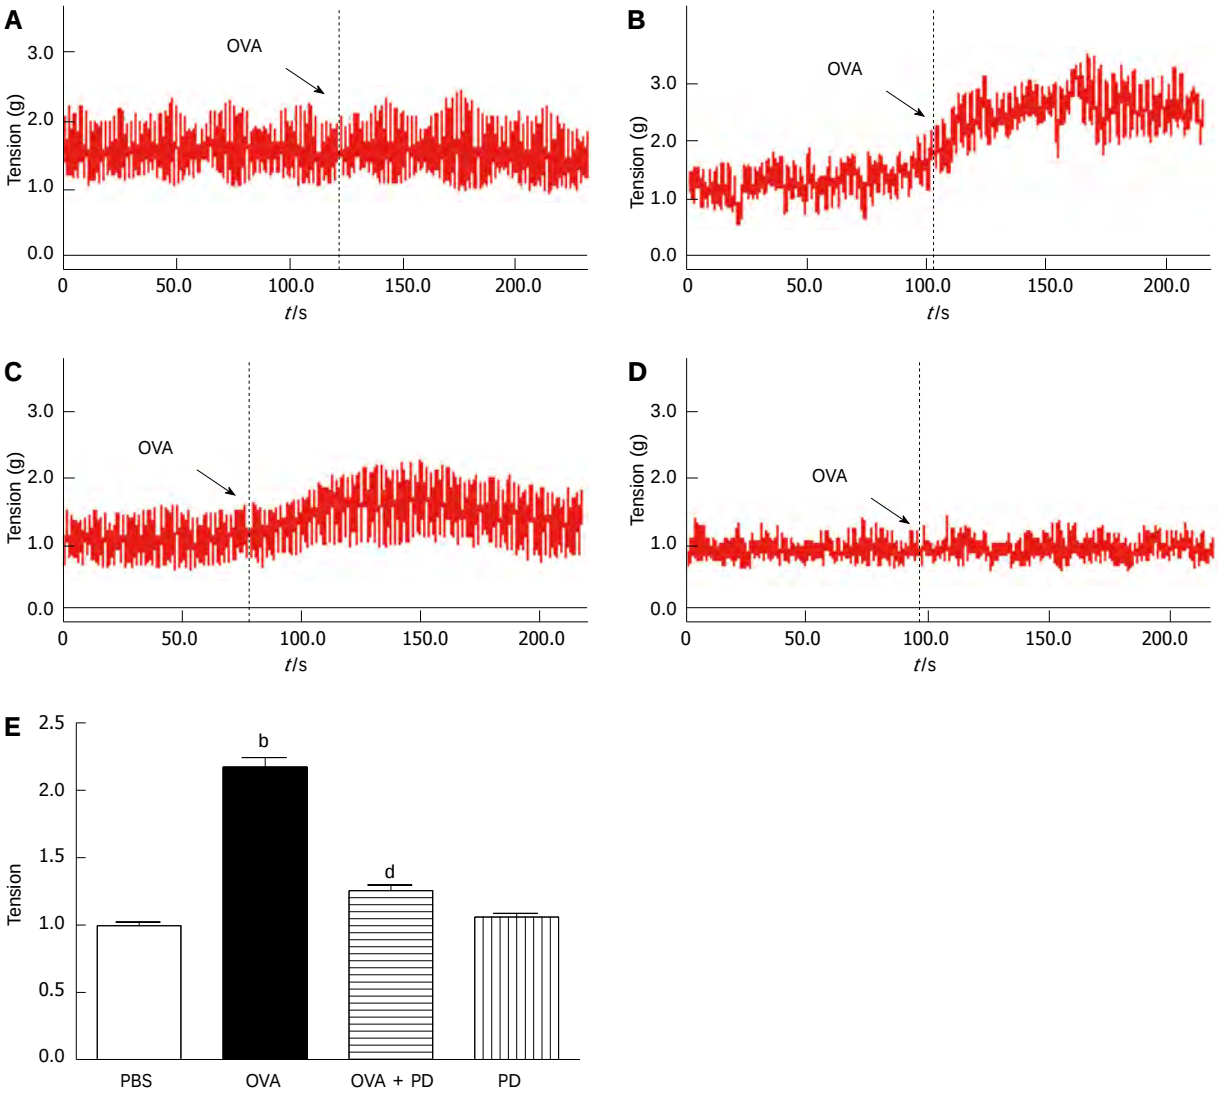

Figure 3 Polydatin attenuated small intestinal hyperreactivity in ovalbumin-allergic rats. A: Phosphate-buffered saline (PBS) group; B: Ovalbumin (OVA) group; C: OVA + polydatin (PD) group; D: PD group. n = 8, $^{b}P < 0.01$ *vs* PBS group; $^{d}P < 0.01$ *vs* OVA group. The tension of intestinal mobility was measured by smooth muscle organ bath, typical contraction curves (A-D), and the peak tension of each group (E).

(Figure 5E). PD mediated attenuation of mast cell degranulation was further confirmed by decreased histamine levels. It was found that histamine release in both serum and RPLS was significantly increased in the OVA-induced food allergic group, which was attenuated by PD therapy by approximately 11% and 20% respectively (Figure 5F).

PD inhibited mast cell degranulation by modulating Ca^{2+} mobilization through SOC channels

Rapid translocation of Ca^{2+} has been well-known to be essential for mast cell degranulation[27]. In a food allergic model, we also found that mast cell activation is related to stimulation of Ca^{2+} mobilization (data not published). To explore the underlying mechanism for the inhibitory effect of PD on mast cell degranulation, we isolated RPMCs and monitored intracellular Ca^{2+} with fluo-4 (5 mol/L). Using a standard Ca^{2+} add-back assay, in which intracellular Ca^{2+} stores were depleted by thapsigargin (TG), a sarcoplasmic/endoplasmic reticulum calcium ATPase (Ca^{2+} pump) blocker, in Ca^{2+}-free extracellular solution, after which the extracellular Ca^{2+} concentration was returned to 2 mmol/L[28]. Using this protocol, TG elicited two Ca^{2+} peaks, where the first one represented the ER Ca^{2+} release, and the second represented Ca^{2+} entry through activated SOCs. As shown in the first peaks in Figure 6A-D, when the cells were in Ca^{2+}-free solution, the TG-evoked Ca^{2+} amplitude was similar in all the groups, suggesting the amounts of Ca^{2+} released from ER are nearly the same. In the presence of 2 mmol/L extracellular Ca^{2+}, the TG-evoked Ca^{2+} influx was dramatically enhanced in OVA-sensitized RPMC by 1.5 fold, while PD treatment reduced the Ca^{2+} entry to normal level. The results indicate that PD attenuated OVA-induced Ca^{2+} influx elevation through SOCs.

DISCUSSION

The effect of resveratrol, a structural and functional

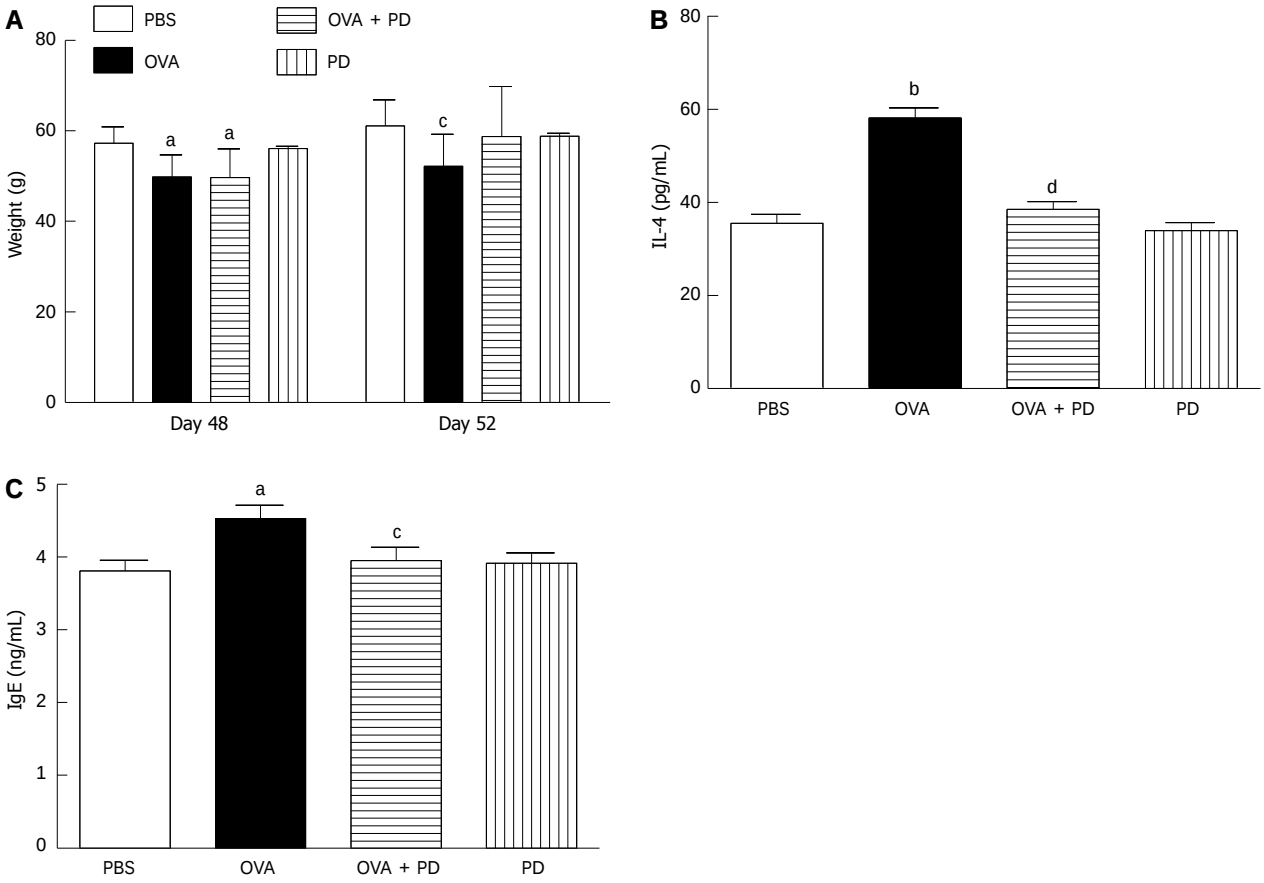

Figure 4 Polydatin suppressed interleukin-4 release and immunoglobulin E production in ovalbumin-allergic rats. A: Body weight of rats on day 48 [left panel, before polydatin (PD) treatment] or day 52 (right panel, after PD treatment) are shown; B: The cytokine levels in rat small intestine tissue or peritoneal lavage solution were analyzed by enzyme-linked immunosorbent assay; C: Statistical analysis of ovalbumin (OVA)-specific immunoglobulin E (IgE) in serum, which were collected from allergic rats administered with or without PD. $n = 8$. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* phosphate-buffered saline (PBS) group; $^{c}P < 0.05$, $^{d}P < 0.01$ *vs* OVA group.

analog of PD, on the regulation of intracellular Ca^{2+} signaling has been reported by several groups, although the results vary in different cell types[29,30]. Furthermore, a previous study in our lab identified PD as a novel mast cell stabilizer in passive cutaneous anaphylaxis mice[15]. There are two major findings in the present study. Firstly, using an *in vivo* food allergic model, we demonstrated that PD has therapeutic effects against food allergy by decreasing antigen-stimulated mast cell degranulation. Secondly, it was showed that PD suppressed Ca^{2+} mobilization by inhibiting Ca^{2+} entry through SOCs, which were the major contributors to PD-induced mast cell stabilization.

Food allergy is an immunological adverse reaction caused by food, which encompasses a range of disorders including IgE-mediated anaphylaxis, food protein-induced enterocolitis syndrome, and food-induced eosinophilic gastrointestinal disorders. Allergens from eggs seem to be one of the most frequent causes of food allergic reaction reported[31]. Thus, in this study, we used OVA to sensitize rats and establish a food allergic model. The allergic animal exhibited abnormal intestinal morphology and increased smooth muscle contractility, enhanced Th2 cytokine levels (IL-4), and OVA-specific IgE concentration. Our results are in line with other published data, as IL-4 has been reported to be the hallmark Th2-type cytokine with multiple immunological functions, including directing Th2 cell differentiation, triggering Ig class switching to IgE in B cells, driving mast cell expansion in intestines[32], and inducing an exaggerated contractile response in intestinal smooth muscle[33]. Furthermore, mast cell activation and degranulation, which was due to Ca^{2+} mobilization *via* SOCs, was also demonstrated.

Mast cells are the main effector cells in the pathogenesis of multiple allergic diseases, including asthma, allergic rhinitis, gastrointestinal allergy, and cutaneous anaphylaxis. The majority of mast cell studies have addressed their predominant role in acute allergic reactions (immediate hypersensitivity) and more recently, their roles in late-phase allergic reactions[34,35]. Therefore, developing new drugs capable of stabilizing mast cells would be valuable for treating diseases attributable to type I hypersensitivity reactions. Using the RBL-2H3 mast cell line, intensive research have been focused on looking for promising drugs to inhibit mast cell activation and degranulation, among which PD showed some latent effects[15]. In the present study, following administration with PD, the mast cell-dependent food allergic rats did not have apparent anaphylactic symptoms (data not shown) and had a marked decrease in Th2 responsiveness after oral challenge with OVA. We have found that PD significantly reduced IgE

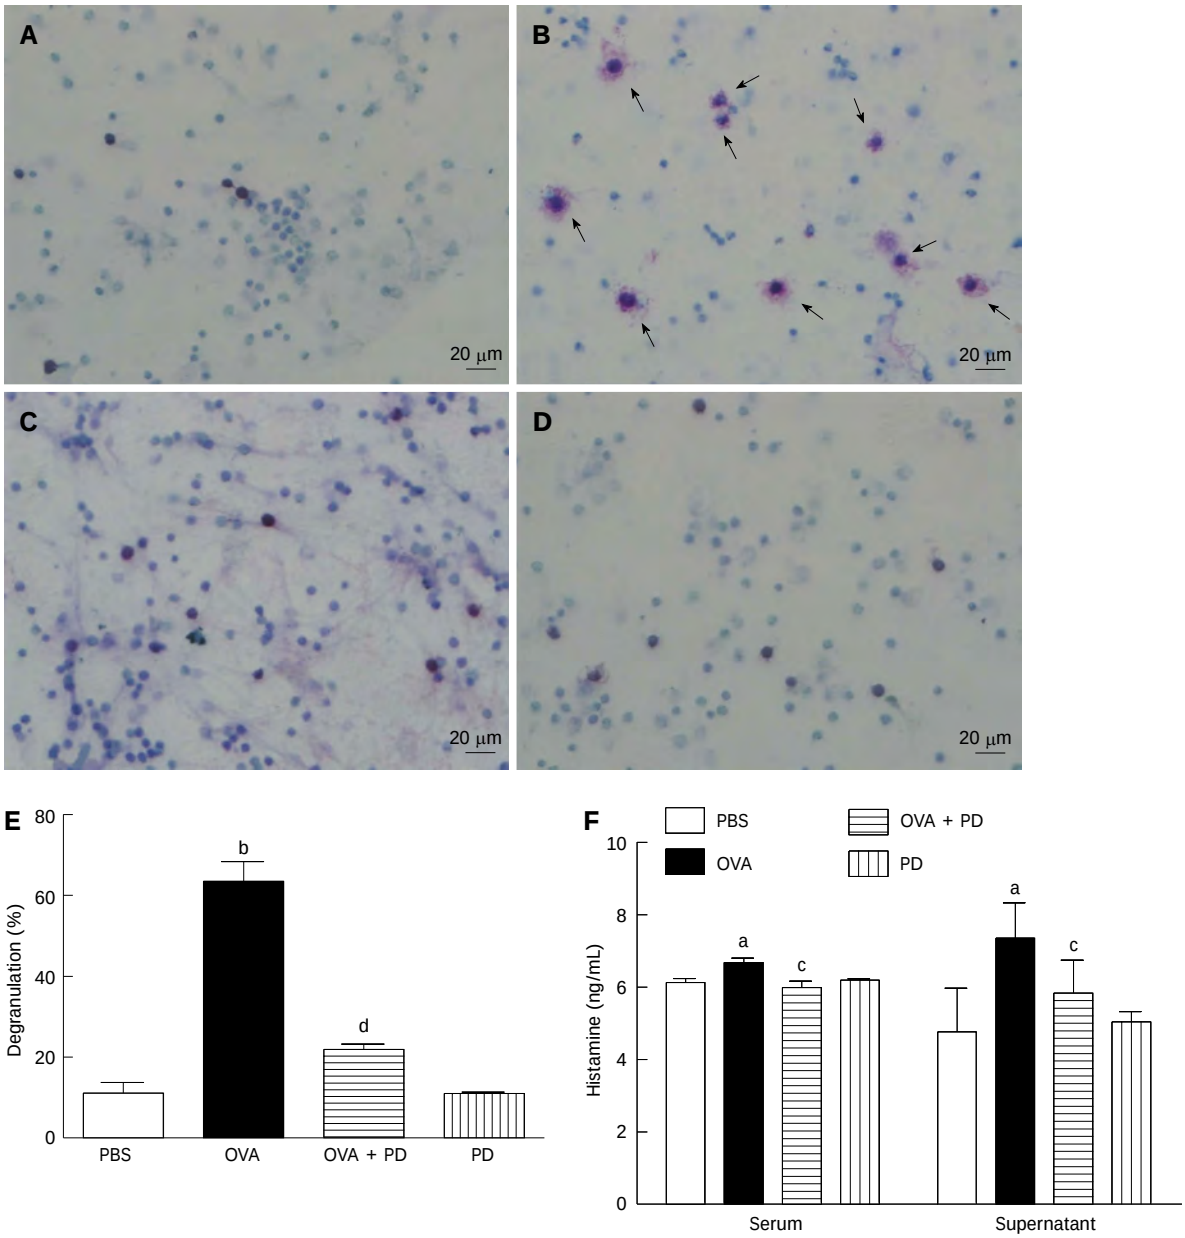

Figure 5 Polydatin therapy reduced mast cell degranulation and activation. A: Phosphate-buffered saline (PBS) group; B: Ovalbumin (OVA) group; C: OVA + polydatin (PD) group; D: PD group; E: Degranulated mast cells were counted from at least 500 total cells and the percentage of degranulation was calculated as degranulated cells against total cells; F: The release of histamine in serum (left panel), rat small intestine tissue, or peritoneal lavage solution (right panel) was measured by enzyme-linked immunosorbent assay. n = 8, $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* PBS group; $^{c}P < 0.05$, $^{d}P < 0.01$ *vs* OVA group. The mast cells in rat small intestine tissue or peritoneal lavage solution were identified by toluidine blue stain. Mast cells were considered degranulated if at least 5 granules appeared outside the cell body. Arrows indicate degranulated mast cells (magnification, × 250).

production by inhibiting Th2 cytokines release. On the other hand, PD showed the potential to block mast cell degranulation by decreasing Ca^{2+} influx *via* SOCs.

The importance of calcium influx in mast cell activation and degranulation has been well recognized[36]. The degranulation of mast cells is Ca^{2+} dependent, and an increase in intracellular Ca^{2+} characterized by Ca^{2+} entry through SOCs is essential for granules release[13,27,37]. In this study, we found that PD treatment significantly attenuated FcεRI-elicited intracellular Ca^{2+} increase, indicating that PD stabilized mast cells by suppressing Ca^{2+} mobilization. Furthermore, we found that PD inhibited Ca^{2+} entry through SOCs. Multiple mechanisms are involved in the regulation of SOC activity. It has recently been discovered that two subunits, STIM1 and Orai1, play a vital role in both the signaling and the permeation mechanisms for Ca^{2+} influx through SOCs. Overexpression of STIM1 together with Orai1 caused a dramatic increase in store-operated Ca^{2+} entry in RBL cells[38]. The mechanism underlying PD-mediated inhibition of SOCs activity remains unclear.

In summary, the present study established PD as a novel mast cell stabilizer, with the capacity for preventing pathogenesis of food allergy and perhaps other mast cell-

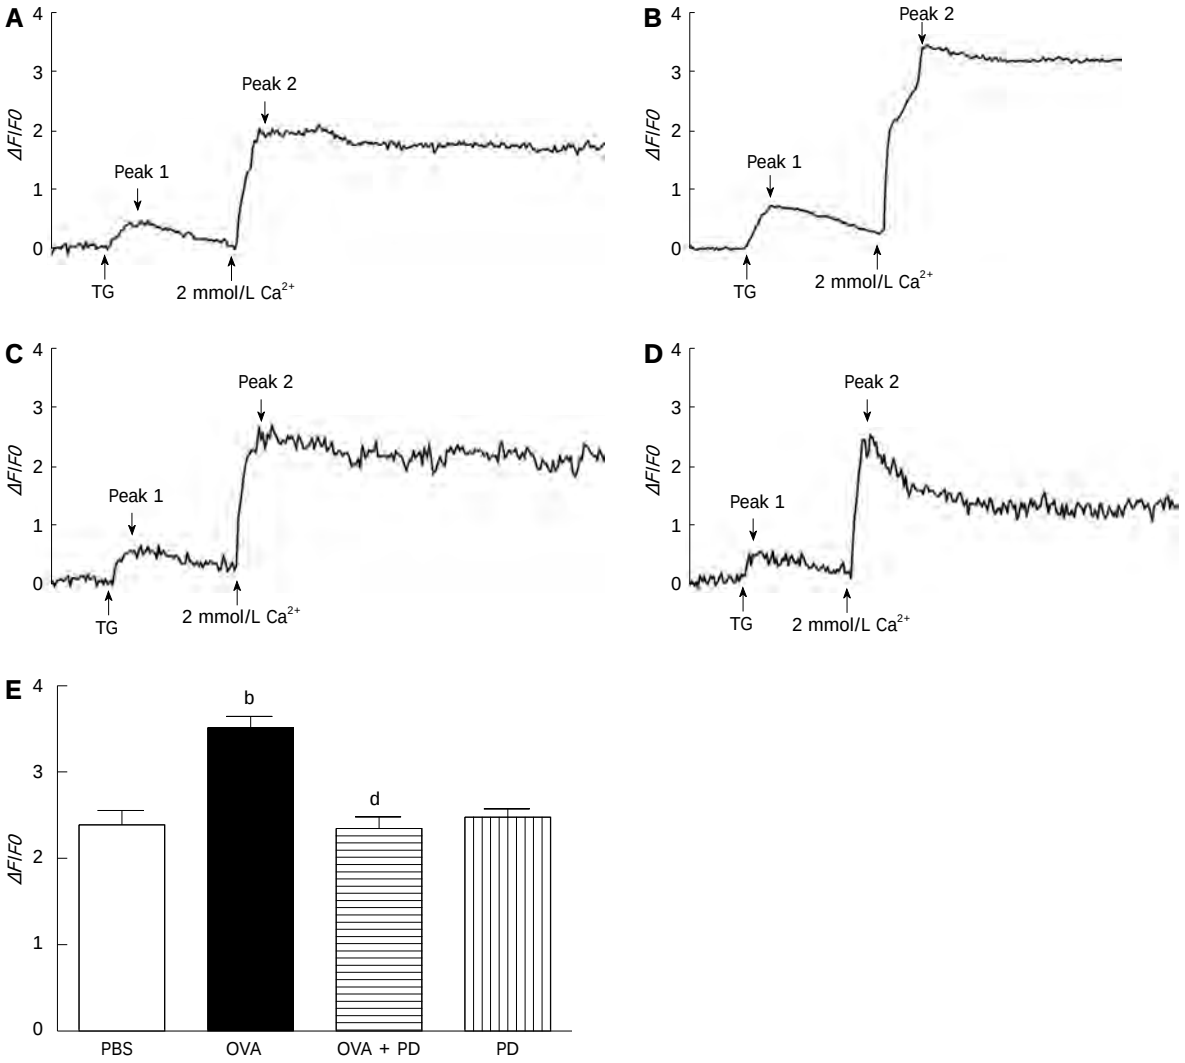

Figure 6 Polydatin reduced Ca^{2+} entry through store-operated calcium channels in food allergic mast cells. Typical responses of thapsigargin (TG)-evoked Ca^{2+} entry through store-operated calcium channels in rat peritoneal mast cells (RPMCs). A: Phosphate-buffered saline (PBS) group; B: Ovalbumin (OVA) group; C: OVA + polydatin (PD) group; D: PD group; E: Averaged peak amplitude of Ca^{2+} entry (second peak) as recorded in each group. $^{b}P < 0.01$ *vs* PBS group; $^{d}P < 0.01$ *vs* OVA group. RPMCs were isolated from Brown-Norway rat treated with or without PD. Intracellular Ca^{2+} was indicated by a fluo-4 fluorescent probe. Total cell numbers are 40-50 for each group, and the cells were from four independent experiments.

dependent allergic diseases through stabilizing mast cells. The underlying mechanism for PD-induced stabilization of mast cells is related to the inhibition of Ca^{2+} mobilization upon FcεRI activation.

COMMENTS

Background

The prevalence of food allergy has increased dramatically during the last three decades, but currently there is no satisfactory therapy except avoidance of the allergen in the diet. However, the offending foods causing an allergic effect are usually essential nutrients to human health. Therefore, to develop a new drug for food allergies is extremely important. Polydatin is a natural component isolated from *Polygonum cuspidatum*, and has been demonstrated to be effective in the treatment of allergic diseases.

Research frontiers

Polydatin is a sort of natural biological material and has been used as a medicine for many diseases. In the area of treatment of allergic diseases with polydatin, the research hotspot is how this product could stabilize mast cells and reduce allergic reactions in passive cutaneous anaphylaxis animals. The therapeutic effect of polydatin on food allergy has not yet been determined.

Innovations and breakthroughs

In previous studies in other laboratories and author's group, the extract of polydatin has been identified as a novel mast cell stabilizer in passive cutaneous anaphylaxis mice, in addition to its other new therapeutic effects, such as anticancer activity. Using an ovalbumin-sensitization mouse model, the authors are the first group to demonstrate that polydatin could attenuate food allergy by reducing mast cell degranulation. Furthermore, it was shown that polydatin suppressed Ca^{2+} mobilization by inhibiting Ca^{2+} entry through store-operated calcium channels, which were the major contributors to polydatin -induced mast cell stabilization.

Applications

The current results suggest that polydatin is a potential therapeutic drug that could be used in food allergy therapy.

Terminology

Food allergy mediated by immunoglobulin E (IgE) or non-IgE reaction, is an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food. It encompasses a range of disorders including IgE-mediated anaphylaxis, food protein-induced enterocolitis syndrome, and food-induced eosinophilic gastrointestinal disorders; Polydatin, also known as polygoni cuspidate radix, is a natural component isolated from *Po-*

lygonum cuspidatum. It has been determined as a resveratrol glucoside with a 3,4,5-trihydroxystilben-3-*D*-mono-*D*-glucoside molecular structure. It is traditionally used in South Korea, China, and Japan as a folk remedy for menoxenia, skin burns, gallstones, hepatitis, inflammation, and osteomyelitis.

Peer review

The authors investigated the effect of polydatin, a resveratrol glucoside, on mast cell degranulation and anti-allergic activity. This is a paper with some interesting value.

Abstract

AIM: To investigate the prevalence of psychiatric illness in association with functional gastrointestinal disorders using defecating proctography (DP) and validated questionnaires.

METHODS: We prospectively evaluated 45 subjects referred for DP using hospital anxiety and depression scale (HADS), state trait anxiety inventory (STAI), patient health questionnaire 15-item somatic symptom severity scale (PHQ-15), validated questionnaires for sexual or physical abuse; post-traumatic stress disorder questionnaire (PTSD) and ROME-Ⅲ questionnaires for gastrointestinal complaints. DP results were considered negative if levator ani function was normal, rectoceles (if any) were < 4 cm and there was no evidence of intussusception, rectal prolapse, or other anatomic abnormality demonstrated. Subjects were subsequently divided into those with structural defects seen on DP (DP positive group) and those with a normal defecography study (DP negative group).

RESULTS: Forty five subjects were included in the study of which 20 subjects were classified as DP negative (44.4%). There was a striking prevalence of a history of sexual abuse in DP negative group compared to the DP positive group (n = 9, 5 respectively; P = 0.036). Further, subjects in the DP negative group scored significantly higher on the HADS anxiety (6.60 ± 1.00 *vs* 4.72 ± 0.40, P = 0.04) and depression scales (5.72 ± 1.00 *vs* 3.25 ± 0.46, P = 0.01). This correlated well with significantly higher scores on the STAI state anxiety scale (42.75 ± 3.16 *vs* 35.6 ± 2.00, P = 0.027), PHQ-15 questionnaire (13.15 ± 0.82 *vs* 10.76 ± 0.97, P = 0.038) and prevalence of PTSD (20% *vs* 4%, P = 0.045) among DP negative subjects. There was no difference between the groups in terms of STAI trait anxiety.

CONCLUSION: The findings of this prospective study demonstrate a significantly high degree of psychiatric ailments in patients with negative findings on DP who should be appropriately screened for a history of sexual abuse and symptoms of psychosocial distress.

Key words: Functional gastrointestinal disorders; Sexual abuse; Defecating proctography; Post-traumatic stress disorder questionnaire

Core tip: In this study, we used validated questionnaires in consort with defecating proctography and demonstrated that subjects undergoing defecating proctography who met ROME Ⅲ criteria for functional constipation have a high prevalence of psychiatric disorders and a significant history of sexual abuse. We also found an association between post-traumatic stress

disorder questionnaire, anxiety, history of sexual abuse and functional constipation. Taken together, these findings suggest that a very detailed history about psychiatric co-morbidities and traumatic experiences must be taken in selected patients complaining of constipation.

Kashyap AS, Kohli DR, Raizon A, Olden KW. A prospective study evaluating emotional disturbance in subjects undergoing defecating proctography. *World J Gastroenterol* 2013; 19(25): 3990-3995 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/3990.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.3990

INTRODUCTION

Patients with chronic gastrointestinal symptoms such as abdominal pain and constipation often display features suggestive of concomitant emotional disturbance[1]. Conversely, patients with a history of sexual or physical abuse have a high prevalence of gastrointestinal and genitourinary complaints[2].

There is evidence suggesting that patients with history of abuse and functional gastrointestinal disorders have a higher incidence of surgeries, lower quality of life and greater disability[3]. Given the lack of a surgically correctable etiology, surgical intervention may be inappropriate in these patients. In this context, we decided to evaluate patients with constipation, studying both anatomic and psychosocial variables using a variety of instruments.

We sought to assess the prevalence of abuse and psychiatric diagnoses in patients referred for defecating proctography (DP). Specifically, we sought to ascertain the prevalence of sexual abuse, physical abuse, anxiety, depression, somatization and post-traumatic stress disorder (PTSD) in subjects meeting criteria for functional constipation and without radiographic evidence of structural explanation for symptoms. We hypothesized that patients with no anatomic disorder of the pelvic floor evidenced by radiological parameters are likely to have a history of abuse and/or psychiatric diagnosis.

The purpose of the study was to use DP and a variety of validated questionnaires to assess the prevalence of psychiatric ailments in subjects with chronic constipation.

MATERIALS AND METHODS

Study design and setting

This prospective cohort study was undertaken at the Washington Hospital Center, a 926 bed tertiary care hospital in Washington DC. All subjects undergoing DP for the evaluation of lower gastrointestinal complaints were prospectively enrolled over 18 mo starting October 2010. Patients with obvious anatomical anomalies such as rectal prolapse, solitary rectal ulcers, fissures and fistulae were excluded.

At the time of enrollment, demographic information was recorded and each subject was assigned a unique identifying number. All other subject identifiers were removed. The study was approved by the institutional review board of Washington Hospital Center and all subjects gave written informed consent.

Immediately prior to undergoing the DP, all subjects were asked to complete a set of self-administered questionnaires.

Questionnaires

All subjects answered a total of 7 self-administered validated questionnaires that assessed a history of sexual or physical abuse, generalized anxiety disorder (state and trait anxiety), PTSD, depression and somatoform disorders. Gastrointestinal symptoms were assessed using the ROME Ⅲ criteria questionnaires that included the constipation module and irritable bowel syndrome module. All questionnaires were self-administered and met appropriate reliability and validity criteria. Further, each questionnaire was easily readable and understandable.

State-trait anxiety inventory: The state-trait anxiety inventory (STAI) is a self-administered test for evaluation of state and trait anxiety and has been used extensively in research and clinical practice. It has been translated into 30 languages and has since been extensively used and validated in the research literature[4]. For the purpose of our study the revised version of the test; "Form-Y" was used[5]. The STAI-Y is a self-administered test and takes 6-15 min to complete, depending on the subject's level of education. The S-anxiety scale (STAI Form Y-1) consists of 20 statements that evaluate how the respondent feels "right now, at this moment" using a 4 point Likert scale. The T-anxiety scale (STAI Form Y-2) consists of 20 statements that evaluate how individuals "generally feel". A score of over 40 on the STAI Form Y-1 and STAI Form Y-2 was considered diagnostic of state of anxiety and trait anxiety respectively.

Screening questionnaire for sexual and physical abuse history: This is a self-report questionnaire developed by Drossman *et al*[6] and has been validated against a detailed psychological interview[7]. The questionnaire has two sections to identify sexual abuse and physical abuse as a child or adult respectively. For the purpose of our study, no distinction was made between abuse as an adult or child.

Hospital anxiety and depression scale: The hospital anxiety and depression scale (HADS) is a self-administered questionnaire to assess generalized anxiety or depression[8] and takes approximately 2-5 min to complete. It has been extensively validated in patients with gastrointestinal disorders[9] in the in-patient[5] as well as the outpatient setting[10]. Each item is answered by the patient on a four point scale (0-3) with possible scores ranging from 0-21 for anxiety and 0-21 for depression. Any score above 11 is indicative of abnormal levels of anxiety or depres-

sion, thus a positive screen for the appropriate disorder.

Screening for somatoform disorders: We used the patient health questionnaire (PHQ-15) to screen for somatoform disorders in our subjects. The PHQ-15 is a 15 item scale addressing somatic symptoms during a 2 wk period on a scale of 0-2 with a maximum score of 30[11] and has been validated among patients with gastrointestinal complaints[12]. We compared the scores of the subjects based on the findings of the DP.

PTSD: We used the 4 item screen for PTSD in primary care developed by Prins *et al*[13]. This validated screening questionnaire[14] uses a binary yes/no response to a specific experience and a score of 3 or greater on the scale was defined as a positive case of PTSD.

ROME Ⅲ constipation module and ROME Ⅲ irritable bowel syndrome module: The ROME Ⅲ criteria were used to screen for irritable bowel syndrome (IBS) and constipation[15]. The ROME Ⅲ criteria are a system used to classify functional gastrointestinal disorders and we used validated self-administered questionnaires that are freely available for download[16]. The ROME Ⅲ criteria were used to rule out constipation predominant IBS as a cause of the patients symptoms and also to diagnose patients with true functional constipation.

Notably, all the questionnaires inquired about information which may have been potentially distressing to the subjects. Hence, one of the authors (Olden KW) who is a board-certified psychiatrist was available to the subjects in case emotional and mental distress was caused or detected by the protocol related questions. After completing the questionnaires, subjects underwent DP.

Single contrast DP

Defecating proctography was used to evaluate for anatomical defects that could explain the gastrointestinal symptoms in the subjects. Briefly, the study involved rectal administration of a radio-opaque semi-solid paste with the consistency of soft stool. The subject was then seated on a commode and made to excrete the material in a manner similar to defecation[17]. The radiological images taken during the evacuation process were interpreted by a radiologist who specialized in DP. The radiologist was blinded to the results of the psychosocial evaluation and did not interact with the subjects.

DP has been used extensively in patients with defecatory dysfunction, pelvic prolapse or puborectalis dysfunction[18-20] to visualize anatomic defects like internal or complete rectal prolapse, enterocele or rectocele. The quantification of the rectal evacuation is especially helpful in patients with pelvic floor dysfunction or dyssynergia and is recommended as a physiological means of assessing rectal dysfunction[21]. DP was considered "negative" for anatomical abnormalities if levator ani function was normal, rectoceles (if any) were < 4 cm[22] and there was no evidence of intussusception, rectal prolapse, or other anatomic abnormality demonstrated. Subjects were subsequently divided into those with structural defects seen on DP (DP positive group) and those with a normal defecography study (DP negative group). Responses to the questions were subsequently compared between the DP positive and the DP negative group.

Table 1 Demographic profile and psycho-social factors of subjects

Variables	DP positive group (n = 25)	DP negative group (n = 20)	P value
Demographics			
Males	3	5	> 0.050
Age (yr)	61.8 ± 2.8	58.1 ± 2.9	> 0.050
Assessment of psycho-social factors			
Sexual abuse	5	9	0.036
Physical abuse	1	2	> 0.050
Post traumatic stress disorder	1	4	0.045
STAI state anxiety	35.60 ± 2.00	42.75 ± 3.16	0.027
STAI trait anxiety	35.08 ± 1.76	38.06 ± 2.42	> 0.050
HADS anxiety	4.72 ± 0.40	6.60 ± 1.00	0.040
HADS depression	3.25 ± 0.46	5.72 ± 1.00	0.014
PHQ-15	10.76 ± 0.97	13.15 ± 0.82	0.038

All data are presented as mean ± SE. DP: Defecating proctography; HADS: Hospital anxiety and depression scale; STAI: State trait anxiety inventory; PHQ-15: Patient health questionnaire 15-item somatic symptom severity scale.

Statistical analysis

Unpaired Student's t test was used for analyzing demographic differences in demographic variables with continuous distribution while χ^2 test was used for analyzing categorical variables using GraphPad Prism software (v 5.0a, GraphPad Prism Inc., San Diego, CA, United States). A P value of < 0.05 was considered significant. All data are presented as mean ± SE.

RESULTS

A total of 45 patients were included in the study and completed the psychosocial evaluation prior to undergoing the DP. Thirty seven (82%) of the total subjects were females (Table 1). Forty four subjects (97.7%) were referred for DP for evaluation of constipation. One subject was referred for possible anismus (pelvic floor dyssynergia).

In 20 (44.4%) of the 45 subjects, the DP did not show any anatomical anomaly and these subjects were classified as DP negative (*i.e.*, negative for anatomical abnormalities on DP). The remaining 25 patients were classified as DP positive (*i.e.,* DP demonstrated anatomical abnormalities that could contribute to symptoms).

Anxiety and depression

Subjects in the DP negative group had strikingly high scores on the HADS anxiety and depression questionnaires (P = 0.04 and P = 0.01) compared to subjects in the DP positive group (Figure 1A and B). This correlated well with the significantly higher score on the STAI state

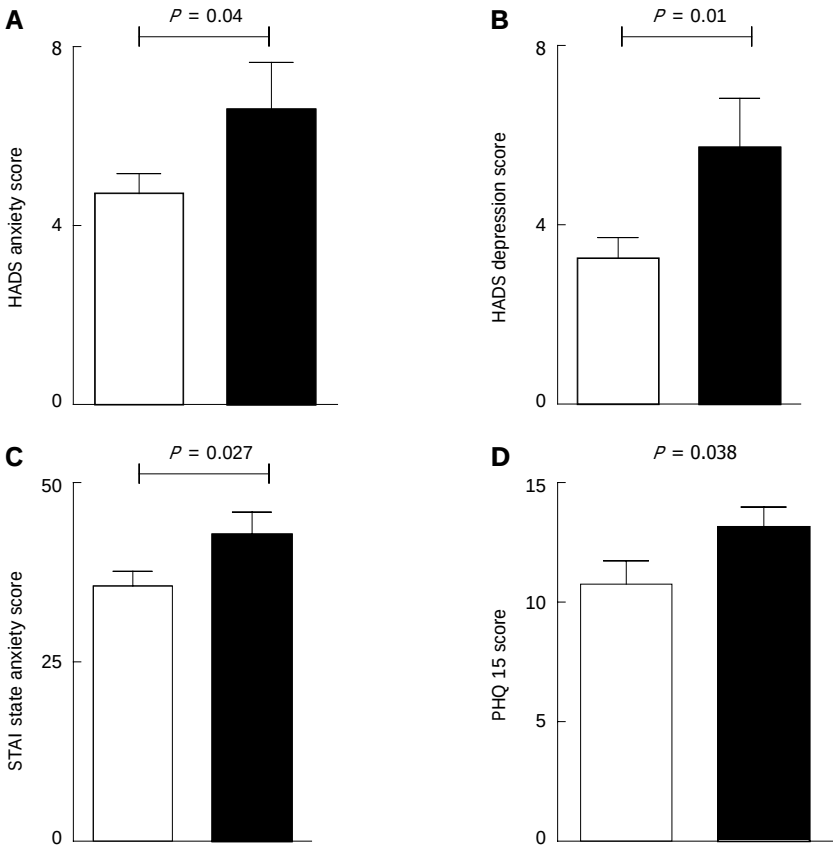

Figure 1 Subjects with no anatomical abnormalities seen on defecating proctography. Defecating proctography (DP negative; black column) have a significantly greater degree of psychiatric disorders as compared to the subjects with anatomical abnormalities on defecating proctography (DP positive; white column). A: Comparison of hospital anxiety and depression scale (HADS) anxiety; B: HADS depression; C: State trait anxiety inventory (STAI) state anxiety; D: Patient health questionnaire 15-item somatic symptom severity scale (PHQ-15) scores among DP positive and DP negative subjects using unpaired *t*-test is shown. All data are shown as mean ± SE.

anxiety questionnaire among subjects in the DP negative (P = 0.027) compared to the DP positive group (Figure 1C). Further, subjects in the DP negative group reported significantly worse PHQ-15 scores compared to the DP positive group (P = 0.038, Figure 1D).

Sexual abuse and PTSD

Notably, we found that a fair proportion of the subjects reported a history of sexual abuse. Nine of the 20 (45%) subjects in the DP negative group and 5 of the 25 (20%) subjects in the DP positive group reported a history of sexual abuse (P = 0.036, Figure 2A). This correlated well with a higher prevalence of PTSD among subjects in DP negative group (4 of 20 subjects, 20%) than the DP positive group (1 of 25 subjects, 4%; P = 0.04, Figure 2B).

Trait anxiety and physical abuse

There was no significant difference among the DP positive and DP negative groups in terms of STAI trait anxiety and prevalence of physical abuse. Further, there was no significant difference in the 2 groups in terms of prevalence of IBS or constipation assessed using the ROME Ⅲ questionnaires. Of note, all subjects included in the study had complaints of constipation and the results of the prevalence confirm the presenting complaints.

DISCUSSION

In this study, we demonstrated that subjects undergoing DP who met ROME Ⅲ criteria for functional constipation have a high prevalence of psychiatric disorders. Greater levels of state anxiety as well depression were found in the above mentioned population. We also found an association between PTSD, history of sexual abuse and functional constipation. Taken together, these findings suggest that a very detailed history about psychiatric co-morbidities and traumatic experiences must be taken in selected patients complaining of constipation.

We included subjects who were referred for DP as part of further work-up of constipation that was refractory to conservative management. It is pertinent to note that a majority of the referrals were from colo-rectal surgeons for pre-operative assessment. As the results of the study show, 44% of the patients (DP negative) did not have any surgically correctable cause and hence would not be appropriate candidates for surgical interventions.

Sexual abuse is very common among patients with functional disorders of the lower gastrointestinal tract[1] with one study showing prevalence of 40%. Further, abused patients were found to have constipation as the most common gastrointestinal complaint[23]. In our study,

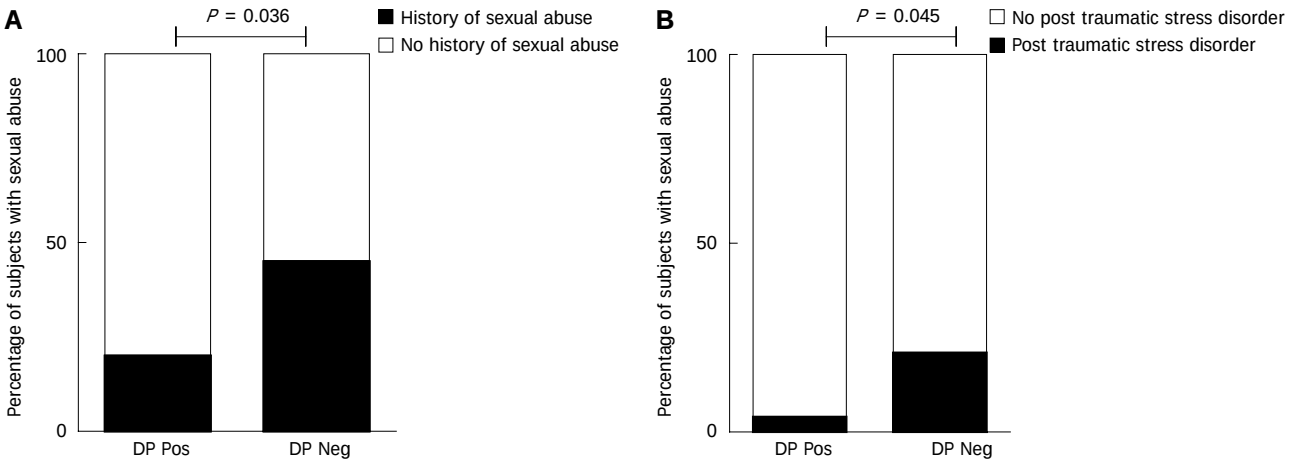

Figure 2 Subjects with no anatomical abnormalities seen on defecating proctography have a significantly greater prevalence of sexual abuse (A) and post-traumatic stress disorder (B) as compared to the subjects with anatomical abnormalities on defecating proctography. DP: Defecating proctography; Pos: Positive; Neg: Negative.

14 subjects had a history of sexual abuse of which a majority had constipation without any anatomical explanation. The difference in the prevalence of sexual abuse between the 2 groups was statistically significant. Notably, patients in the DP negative group had a significantly higher prevalence of PTSD, a condition closely associated with sexual abuse. Since a history of sexual abuse is a strong predictor of multiple surgeries and poor surgical outcomes for slow-transit constipation[24], a careful history is essential in this patient population.

There is a strong association between psychological dysfunction and gastro-intestinal disorders for which various therapeutic paradigms have been found to be effective. Cognitive behavior therapy, psychodynamic psychotherapy and pharmacological agents including anti-depressants been shown to be efficacious in managing the gastrointestinal symptoms in selected patients[1]. However, there needs to be a greater emphasis on the detection of psychological disturbance and eliciting a detailed history in these patients.

A novel aspect of our study was the use of DP for the evaluation of constipation and classifying subjects with organic (DP positive) *vs* functional (DP negative) gastrointestinal disorders. DP has been used extensively for evaluation of patients with evacuatory dysfunction[25] and is often considered the gold standard for imaging in patients with defecation disorders, most notably rectocele, enterocele, anismus and perineal descent[26]. Patients in the DP negative group would likely not benefit from surgical interventions given the functional nature of the symptoms detected by DP.

The findings of this prospective study demonstrate a significantly high degree of anxiety, depression, somatization, PTSD and sexual abuse in subjects with negative findings on DP. Our study confirms that psychological ailments can impact the lower gastrointestinal tract and is especially associated with constipation. We recommend that patients with refractory constipation and features suggestive of psychological ailment/abuse[3] should be appropriately screened for the aforementioned disorders.

COMMENTS

Background

Functional constipation is a common gastrointestinal ailment and is often associated with emotional disturbance. Defecating proctography (DP) is a radiological tool to visualize anatomical causes leading to gastrointestinal symptoms. This study assessed the prevalence of psychiatric ailments in patients with gastrointestinal symptoms who had been referred for defecating proctography.

Research frontiers

This study uses a novel approach of combining a radiological tool (DP) and multiple validated psychiatric instruments to assess the prevalence of psychiatric ailments causing gastrointestinal manifestations.

Innovations and breakthroughs

The study demonstrates that a significant proportion of subjects undergoing DP and met ROME Ⅲ criteria for functional constipation have psychiatric ailments. Further, there is an association between functional constipation and a history of sexual abuse.

Applications

It is suggested that a very detailed history about psychiatric co-morbidities and traumatic experiences must be taken in selected patients complaining of constipation. Further large scale studies are warranted to explore these associations.

Terminology

Defecating proctography is a radiological study that requires a subject to excrete a rectally administered contrast to visualize anatomical defects pertinent to rectal evacuation.

Peer review

The authors demonstrated a prospective study evaluating emotional disturbance in subjects undergoing defecating proctography. In my opinion, such a prospective study will give us more important information in this field.

Abstract

AIM: To evaluate need for and efficacy of a structured gastroenterology didactic session in expanding awareness and understanding of digestive disorders.

METHODS: A four-day symposium was developed with didactic sessions (days 1, 2) and practical endoscopy (days 3, 4). Didactic sessions included case presentations highlighting pathophysiology and management. One nurse and four practicing gastroenterologists from the United Kingdom led lectures and supervised workshops with audience participation. Practical endoscopy focused on diagnostic and therapeutic procedures and their application to diagnosis and treatment of ailments of the gastrointestinal tract. Pre- and post-workshop questionnaires were distributed to participants during didactic sessions. A pre-workshop questionnaire gauged expectations and identified objectives to be met at the symposium. Post-workshop questionnaires were administered to assess efficacy of each session. Participants graded sessions from 1 (poor) to 5 (excellent) on quality of case presentations, knowledge, clarity and mode of presentation. We assessed if time allotted to each topic was sufficient, value of sessions, impact on practice and interest in future symposiums.

RESULTS: There were 46 attendees on day 1: 41% undergraduates, 41% residents, 11% consultants and 4% unspecified. Day 2 (a Saturday) had 24 participants: 17% undergraduates, 71% residents, 9% consultants, 4% unspecified. Primary pre-workshop symposium expectation was to gain knowledge in: general gastroenterology (55.5%), practical endoscopy (13.8%), pediatric gastroenterology (5%), epidemiology of gastrointestinal disorders specific to Zambia (6%), and interaction with international speakers (6%). The post-symposium questionnaire was answered by 19 participants, of whom 95% felt specific aims were met; all would attend future conferences and recommend to others.

CONCLUSION: The beneficial effect of a structured symposium in developing countries warrants further attention as a mechanism to improve disease awareness in areas where resources are limited.

Key words: Gastroenterology training; Resource-limited country; Zambia; Specialist training; Postgraduate training; Hepatology

Core tip: The global burden of digestive diseases is increasing, yet formal training in gastroenterology is lacking in traditionally underserved areas such as the African continent. In this study we designed, implemented, and evaluated the effectiveness of a structured 4 d symposium focusing on general topics in the diagnosis and management of digestive disease. This

symposium was geared towards health care professionals and attendees reported improvement in their knowledgebase in gastrointestinal disorders. Structured symposiums are an effective and viable adjunct to medical education and their utility may be highest in regions where traditional academic medical resources are limited.

Asombang AW, Turner-Moss E, Seetharam A, Kelly P. Gastroenterology training in a resource-limited setting: Zambia, Southern Africa. *World J Gastroenterol* 2013; 19(25): 3996-4000 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/3996.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.3996

INTRODUCTION

Zambia is a Southern African nation with a population of approximately 13 million people[1,2]. The University Teaching Hospital (UTH) in Lusaka has a capacity of approximately 1600 adult and 300 pediatric beds and is the main medical training institution in Zambia. UTH houses an endoscopy unit which serves as both an inpatient and ambulatory care facility providing both emergency and routine endoscopies. The unit is equipped with a Pentax video endoscopy suite which includes gastroscopes (including pediatric scope) and colonoscopes. The unit performs approximately 1000 gastrointestinal endoscopic procedures per year. Instrument cleaning and disinfection follows international guidelines (British Society of Gastroenterology)[3]. Continuing medical education is encouraged as staff regularly attend the South African Gastroenterology conference to maintain up to date proficiency. For a combination of epidemiologic (relatively lower prevalence of biliary disease compared with industrialized nations) and economic (lack of available funding) the unit does not currently carry out endoscopic retrograde cholangiopancreatography. However, there is a significant public health burden of luminal gastrointestinal and hepatology disease, and recent attention has turned to increasing the health care communities' awareness of these disorders[4-7]. Our objective was to develop and host a formal gastrointestinal/hepatology workshop to educate the healthcare sector and also evaluate its place as a mechanism to address the growing interest in this field. We review our experience in the development of the workshop and its impact on the health professionals working in a resource-limited setting.

MATERIALS AND METHODS

We hosted a course to improve understanding of gastrointestinal disorders. The specific aims of the conference were to promote a greater understanding of: (1) the pathophysiology and management of common gastrointestinal/hepatological disorders; (2) principles of endoscopy (upper and lower) including indication, risks and benefits; (3) clinical skills in endoscopy with emphasis on management and evaluation of varices, non-portal hypertensive related gastrointestinal bleeding and colonic polyp recognition and removal; and (4) maintenance of endoscopic efficiency and patient safety.

Lectures

Didactic sessions over the first two days introduced participants to essential pathophysiology and management of prevalent disorders emphasizing a multidisciplinary approach to patient care. The sessions were open to all participants and led by a panel of experts from the United Kingdom in conjunction with staff physicians at UTH. These lectures were focused on pertinent topics including: diarrheal disease, gastrointestinal emergencies, malnutrition, esophageal disease, abdominal pain and hepatology. Sessions were conducted in a case presentation format in which clinical findings and course were reviewed to illustrate key points in pathophysiology and management.

To illustrate, a case of cholera was used as an opportunity to review the physiology of secretory (toxin-mediated) diarrhea, which in turn served as a platform to discuss the rationale of oral rehydration therapy. As another example, a session was centered on gastrointestinal bleeding using cases of peptic ulcer bleeding and variceal bleeding due to schistosomiasis to illustrate principles of emergency management and differing endoscopic approaches to both non-portal hypertensive and portal hypertensive related bleeding. We ran focused hepatology sessions which included cases that fostered discussion on the applicability of gold-standard management with limited resources (for example, availability of vaccinations and access to ultrasound). Guidelines on the management of ascites, hepatitis B and encephalopathy were developed in break-out sessions. On day 2, patients with specific gastrointestinal and hepatology ailments were interviewed in front of the audience to elaborate points for discussion. Audience participation was actively encouraged throughout and sessions were designed to facilitate interaction and comparison of management strategies.

Prior to the workshop, we administered a questionnaire to gauge attendees' expectations and identify weak areas in their knowledge base. Post-workshop questionnaires on the quality of each session asked participants to grade sessions from 1 (poor) to 5 (excellent) on the following criteria: quality of the case presentations, knowledge, clarity and mode of presentation. We also assessed if the time allotted for each topic was considered sufficient, if participants felt presented information was applicable to their stage of training, if they felt there was a need for specific guidelines for the management of presented disorder in Zambia and finally if information learned at the presented session would change their personal management approach.

Practical endoscopy

Our practical sessions complemented lecture-based dis-

cussion on management in the first two days. Participants were instructed on endoscope instruments and accessories, set-up of endoscopy equipment and preparation for endoscopy including patient safety and informed consent. The nurses were involved in the hands-on experience, and obtained additional training related to the patient preparation, aftercare and maintenance of equipment in the endoscopy unit.

There were 15 participants for the live cases. The first endoscopy day was a combination of adult and pediatric cases: esophageal variceal banding, duodenal polypectomy with hemoclip application for hemostasis and appropriate biopsies in a case of gastric ulcer. The colonoscopies included hematochezia and ulcerative colitis. All cases were followed by a case and management discussion.

RESULTS

Forty-six attendees answered our questionnaires on day 1: 41% undergraduates, 41% residents, 11% consultants and 4% unspecified. Day 2 had 24 participants: 17% undergraduates, 71% residents, 9% consultants, 4% unspecified. Attendees from neighboring countries included 3 physicians from Zimbabwe, 1 from Malawi and 1 from the Democratic Republic of Congo. The organizing committee included five visiting experts in gastroenterology from the United Kingdom, who led several of the didactic sessions. Table 1 describes the demographics.

Mode of presentation	0 (0)	0 (0)	1 (5)	7 (33)	13 (62)

Participants graded sessions from 1 (poor) to 5 (excellent) on quality of case presentations, knowledge, clarity and mode of presentation.

Primary pre-workshop symposium expectations were to gain knowledge in: general gastroenterology (55.5%), practical endoscopy (13.8%), pediatric gastrointestinal (GI) disorders (5%), epidemiology of GI disorders specific to Zambia (6%), and interaction with international speakers (6%) (Table 2). The most common areas that participants thought their knowledge was weak were: hepatology (19%), inflammatory bowel disease (17%), gastrointestinal bleeds-including peptic ulcer disease (15%) and infectious gastroenterology-including human immunodeficiency virus (HIV) (13%) and gastrointestinal malignancy (8%) (Table 2). Sessions already planned by the time these responses were received covered the majority of these areas.

The sessions were on diarrheal disease, gastrointestinal emergencies, malnutrition, esophageal diseases, abdominal pain and hepatology (Table 3). The cumulative average percentage of respondents who scored sessions either good (4/5) or excellent (5/5) for the following

criteria: case presentation 97%, knowledge 96%, clarity 93%, mode of presentation 97%. The percentage of respondents who answered "Yes" to the following questions on each topic: was time allotted to this topic sufficient? 81%; did you find this session valuable for your stage of training? 98%; do we need to develop specific management guidelines? 95%; will this session change your management? 94%.

There were some variations between sessions although the overall quality was considered high. Significant numbers of respondents said that the time allocated was insufficient for diarrhoeal disease (33%), malnutrition (24%) and esophageal disease (25%). This demonstrates an interest and need for further training in these areas. The large majority (95%) who felt specific management guidelines should be developed on these topics is also indicative of the need for further work. The post-symposium questionnaire was answered by 19 participants, of whom 95% felt specific aims were met; 90% would pay for future conferences, all would attend future conferences and recommend to others.

DISCUSSION

There is a recognized shortage of general and specialized medical doctors in Zambia and Sub-Saharan African countries[8-10]. The detailed reasons for such shortages are beyond the scope for this paper, however one of the identified strategies to curtail this problem includes training opportunities and continued medical education[9,10]. Based on 2010 statistics, the health life expectancy at birth in Zambia is 49 years[11]. The dominant gastrointestinal and hepatological clinical problems are variceal bleeding due to schistosomiasis, esophageal strictures due to caustic substance ingestion, infectious diarrhea (often HIV related), peptic ulceration, hepatitis B, and gastrointestinal cancer (Kaposi sarcoma, esophageal, gastric and colon cancer)[12,13]. There is also a considerable burden of neurogastroenterological problems including achalasia, functional dyspepsia and irritable bowel syndrome. The most common cause of esophageal bleeding in patients presenting to our endoscopy unit is esophageal varices (25%), other etiologies are duodenal ulcer (17%) and gastric ulcers (21%); less frequent but significant causes are Kaposi's sarcoma (2%) and Mallory Weiss tear (1%)[12]. It has been estimated that more than 90% of schistosomiasis cases occur within Sub-Saharan Africa[14]. The prevalence in Zambia is 77% and the two predominant forms are *Schistosoma hematobium* and *Schistosoma mansoni*[15,16]. *Schistosoma mansoni* has been implicated in intestinal and liver disarray resulting in portal hypertension, esophageal varices, gastrointestinal bleed and rarely liver failure[17-19].

The estimated prevalence of HIV infection in Zambian adults aged 15-49 years is estimated between 10.3%-19.7%, leading to an increased burden of HIV enteropathy[20,21]. With this HIV burden there is also concern for the increasing trend of hepatitis B and hepatitis C[22]. There are no Zambian liver disease management guidelines, thus current practice follows guidelines of the World Health Organization[23], American Association for the Study of Liver disease[24] and European Society for the Study of Liver[25], which are not suitable in resource-limited settings and in an area where etiopathogenesis is different.

The incidence of gastric and esophageal cancer in adults younger than 45 years is higher than in United States or United Kingdom[12]. Gastric cancer in patients under 45 years accounts for 33% of cases, whilst esophageal cancer represented 16% of endoscopically diagnosed cases[12]. Survival from digestive disease is lower in developing countries, in those within the African continent[26], thus raising awareness and developing prevention programs are important and can be enhanced through educational symposia such as described in this paper. Caustic injuries, either suicidal or accidental, are another area of concern; with patients presenting late in the course with resultant gastric outlet obstruction (55%), esophageal strictures (30%), gastric ulcerations (21%)[27].

One of the aims of the workshop was to draw in other health care workers interested in gastroenterology and hepatology but working outside UTH so as to facilitate networking and optimize standards of care for GI diseases throughout the country, and positively impact the African continent. We successfully included physicians from neighbouring countries: 3 from Zimbabwe, 1 Malawi, 1 Congo. These surrounding nations benefited from this course because they share a similar disease burden as Zambia. Continued training in the field of gastroenterology in Zambia and other resource-limited areas, is necessary to enhance understanding of pathophysiology and management, thus improving overall patient care.

ACKNOWLEDGMENTS

We thank the British Society of Gastroenterology for their sponsorship of the event.

COMMENTS

Background

Formal training in gastroenterology is lacking despite the huge burden of digestive disease across Africa. Given the disparity in the supply of formally-trained gastroenterologists and the ever increasing demand of citizens, the authors organized a structured four-day symposium focusing on gastrointestinal/hepatological case based presentations and introduction to endoscopy.

Research frontiers

Promotion of such educational activities should be encouraged not only to help physicians develop new perspectives on disease, but also to improve overall patient care.

Innovations and breakthroughs

In this work the authors organized the first gastroenterology symposium in Zambia, attracting students and physicians from neighbouring countries. The authors have set a foundation for similar activities in the future.

Applications

This could be replicated in other developing countries that face similar disease burdens and require improvements in undergraduate and postgraduate training.

Terminology

The symposium was an opportunity to teach, increase awareness of gastroin-

testinal and hepatological diseases whilst creating an environment for networking. This symposium addressed current knowledge and recent advances in gastrointestinal/hepatological disease.

Peer review

This article provides information and guidelines for setting up a structured symposium in a resource-limited setting. Equally important, this highlights the need for structured clinical gastroenterology/hepatology training programmes with adequate curricula that emphasize knowledge, skills, and scientific productivity.

Abstract

AIM: To measure a broad profile of pro- and anti-inflammatory cytokines in patients with clinically proven chronic pancreatitis (CP) taking either antioxidant therapy or placebo as part of the larger ANTICIPATE study.

METHODS: Patients with chronic pancreatitis were recruited to the ANTICIPATE study following informed consent and were randomised to intervention with either antox version 1.2-based antioxidant therapy or placebo. After a separate ethics committee amendment a subgroup of 7 patients from either arm of the study were selected for additional analysis of cytokines. Cytokines were measured at baseline and after 6 mo of either antox therapy or placebo by biochip array and enzyme-linked immunosorbent assay.

RESULTS: Antioxidant therapy and placebo groups were well-matched in terms of age, gender, aetiology of CP, opiate use and disease duration. Baseline antioxidant levels were similar in patients allocated to the antioxidant group as compared to the group allocated to placebo. After 6 mo of antioxidant therapy there was significant elevation in vitamin C levels in the intervention group: 17.6 μg/mL (12.8-29.3 μg/mL) compared to 4.8 μg/mL (1.6-9.1 μg/mL) in placebo ($P < 0.001$; 95%CI: 9.0-20.2) with similar trends in selenium levels. There was no elevation in a broad array of pro- and anti-inflammatory cytokines in the antioxidant group compared to placebo [interleukin (IL)-1B, IL-4, IL-6, IL-10, tumor necrosis factor-α] either at baseline or after 6 mo of antioxidant therapy.

CONCLUSION: Cytokine levels were low at baseline and at 6 mo despite a significant elevation in plasma antioxidants. In patients with CP, with opiate-dependent abdominal pain, circulating cytokine levels are low suggesting that pain in this disease is not simply a manifestation of inflammation.

Key words: Chronic pancreatitis; Antioxidant therapy; Cytokine

Core tip: This study examines cytokine levels in a subset of patients recruited from within the ANTICIPATE randomized controlled trial of antox for painful chronic pancreatitis. At baseline, pro- and anti-inflammatory cytokine levels were within the laboratory reference range in patients allocated to the antioxidant arm and those allocated to placebo. After 6 mo of intervention with antox, there was a significant elevation in antioxidant levels in patients in the active treatment arm. This was not associated with any change in either pro- or anti-inflammatory cytokine levels. In patients with chronic pancreatitis, with opiate-dependent abdominal pain, circulating cytokine levels are low suggesting that pain in this disease is not simply a manifestation of inflammation.

INTRODUCTION

The oxidative stress hypothesis proposed that cell injury in chronic pancreatitis (CP) was mediated at the acinar level by short-lived oxygen free radicals produced as a result of imbalance in the physiological processes producing these agents and those pathways involved in deactivating them[1]. A key component of this theory was that the methionine transsulfuration pathway which yields glutathione (important in the quenching of antioxidants) is overwhelmed in patients with CP as the detoxification of xenobiotics by cytochrome P450 led to overproduction of oxygen-derived free radicals[1]. There was evidence that the dietary intake of some patients with CP was deficient in selenium, methionine and vitamin C, key cofactors in these transsulfuration pathways[2]. This finding was supported by evidence showing that plasma/blood levels of circulating antioxidants were low in CP compared to control[3]. The logical completion of this paradigm was the development of antioxidant therapy - a pharmacological preparation containing methionine, vitamin C, vitamin E and selenium and designed to restore these critical co-factors to patients with CP[1]. Early clinical trials of antioxidant therapy failed to establish evidence of clinical efficacy and thus the treatment was not widely accepted. To address this issue, we conducted and reported the largest randomized controlled trial of antox for treatment of pain in chronic pancreatitis - the ANTICIPATE study[4]. In this, 356 patients with CP were screened for eligibility, 92 randomised and 70 completed intervention with 6 mo of antioxidant therapy or matched placebo. At the end of this period there was no difference between treatment and placebo in the primary endpoint of abdominal pain as assessed by a numerical rating scale or in secondary endpoints of pain assessed by pain diaries and quality of life assessed by validated questionnaire[4]. However, blood and plasma antioxidant levels were significantly elevated in patients in the treatment group[4]. In keeping with other clinical studies of antioxidant therapy in chronic pancreatitis with clinical endpoints there is little information on the effects of intervention on inflammatory markers.

The present study does provide unique data on cytokine profiles in patients with chronic advanced pancreatitis at their end disease stage receiving antioxidant therapy and in a matched cohort receiving placebo and provides negative results which should be regarded as important pilot data. Thus, although the principal findings were negative, the ANTICIPATE study provided a unique vehicle with which to assess the potential interaction between antioxidant therapy and cytokine markers of inflammation and fibrosis in chronic pancreatitis. To the best of our knowledge, this interaction has never previously been studied.

In chronic pancreatitis there is evidence that levels of platelet-derived growth factor-BB and transforming growth factor (TGF)-β1 are elevated and that these cytokines play an important role in pancreatic fibrosis[5]. Pancreatic stellate cells are activated by alcohol in CP and are key mediators of subsequent inflammatory changes and fibrosis with these changes being modulated by cytokines including epidermal growth factor[6,7]. Pancreatic ductal epithelium produces TGF-β which also mediates fibrosis[8]. Thus cytokines are known to be key mediators of inflammatory and fibrotic change in CP.

The aim of the present study was to examine circulating cytokine levels in a cohort of patients within the ANTICIPATE study. The principal endpoint was to assess whether there were differences between patients receiving antioxidant therapy and those receiving matched placebo.

MATERIALS AND METHODS

Study design

This is a case-control analysis of a sub-group of patients recruited from both arms of the ANTICIPATE double-blind, placebo-controlled, randomised trial of Antox version 1.2 (Pharma Nord, Morpeth, United Kingdom) in patients with painful chronic pancreatitis[4].

Setting

Tertiary care academic medical centre was eventually chosen as setting in which to implement the requirment.

Inclusion/exclusion criteria

The inclusion criteria were as for the main ANTICIPATE study and can be summarised as follows: patients with evidence of chronic pancreatitis on cross-sectional imaging together with evidence of impairment of pancreatic exocrine function as assessed by assay of faecal elastase. Patients who did not meet these criteria were excluded as were patients with evidence of malignancy. The inclusion/criteria for the main study are provided in detail elsewhere[4].

Identification and selection of study sub-group

Recruitment to ANTICIPATE commenced in February 2008 and a protocol amendment to permit additional enrolment to the present study was approved 6 mo later. Patients recruited to ANTICIPATE were allocated to receive either 6 mo intervention with antox or matched placebo in a randomised, double-blind, placebo-controlled fashion. Those patients selected to participate in this study signed an additional consent form. No additional inclusion or exclusion criteria were used. Allocation arm was unknown during the conduct of ANTICIPATE and patients were stratified at enrolment to this study by whether or not they had undergone prior pancreatic intervention (either surgical or endoscopic). Blood samples were drawn from 22 patients in the "prior intervention" stratification arm and from 15 in the "no prior intervention" stratification arm. Following the code break at the end of the clinical ANTICIPATE study, investigators were notified which patients had been allocated to active drug and which had

been allocated to placebo. At this point, a study population of 10 consecutive patients from each arm of the study was identified (total 20 patients). Allowing for loss to follow-up in 6 patients in whom blood samples for cytokine analysis were not taken after the original baseline assays a final study population of 7 patients treated with antox for 6 mo and 7 patients treated with placebo was obtained.

Assays

Full blood count (haemoglobin and white cell count) was measured at baseline and at 2, 4 and 6 mo. C-reactive protein (CRP) levels were also measured at these time points. Antioxidant levels comprising the following: selenium, vitamins C and E, β-carotene and glutathione were measured at baseline, study mid-point and at 6 mo. A range of cytokines were measured at baseline and at 6 mo as follows: pro-inflammatory cytokines interleukin (IL)-1β, IL-6, tumor necrosis factor alpha; anti-inflammatory cytokines: IL-4, IL-10; chemokines: IL-8, IL-18, monocyte chemotactic protein 1; the T cell regulatory cytokine IL-2; the angiogenic signalling protein vascular endothelial growth factor (VEGF) and epidermal growth factor an important regulator of cellular proliferation, differentiation and survival[7].

Methods of measurement

Full blood count was measured by the haematology department of the Manchester Royal Infirmary with CRP being measured in the clinical biochemistry service and these results were available to clinicians to guide on-going management during the study. Antioxidant levels were measured by the pancreatic laboratory of the Manchester Royal Infirmary. The results of these assays were available during the study. Cytokine assays were undertaken by Bio-chip Arrays and enzyme-linked immunosorbent assay by Randox laboratories, Crumlin, Northern Ireland. These were analysed as a batch at the end of the study.

Sample collection

Non haemolysed and non-lipaemic serum and plasma were used for the Biochip array. Samples were collected into leak-proof, non-absorbent plastic containers. After collection, samples were aliquoted into containers and stored at -70 ℃. Repeated freeze/thaw cycles were avoided. Samples were labelled prior to transportation on dry ice to Randox laboratory, Crumlin, Northern Ireland *via* a secure, approved courier.

Interference

The effect of bilirubin, haemoglobin, triglycerides and lipids were assessed to establish the level at which the interference caused a significant increase or decrease in assay performance. The criterion set for this was that analyte recovery (all cytokines) should not vary from base recovery by more than 10%.

Ethics committee approvals

The original full study protocol was approved by the North West Regional Ethics Committee (MREC, 07/MRE08/13) and the United Kingdom Medicines and Health products Regulatory Agency (MHRA, 2006-006958-10). This cytokine subgroup study was approved by the North West Regional Ethics Committee as a separate amendment. The master study ANTICPATE from within which these patients were recruited was registered with the International Registry of Randomized Controlled trials and allocated the number ISRCTN-21047731.

Statistical analysis

Two by two tables were analysed by Fisher's exact test and non-parametric data by Mann-Whitney *U* test using the Statsdirect software package (version 2.6.5. www statsdirect.com).

RESULTS

Demographic and biochemical profiles

As in the parent study, the two groups were well-matched in terms of age and gender distribution. Alcohol was the dominant etiologic agent and a majority in both groups were cigarette smokers (Table 1).

Antioxidant profiles at baseline and at 6 mo

Baseline levels of vitamin C, vitamin A, whole blood glutathione transferase and red cell glutathione transferase were similar between groups and were also within the reference range for population normal as reported by the Pancreatic laboratory of the Manchester Royal Infirmary (Table 2). Levels were towards the lower range of normal. Although median vitamin E, β-carotene and selenium levels were below the range for population normal in the placebo group, this difference was not significant compared to the antioxidant group at baseline.

Haemoglobin, white cell count and CRP were within normal levels in both groups.

At 6 mo (Table 3) there was significant elevation of vitamin C and selenium levels in the antioxidant group compared to baseline and also compared to placebo at 6 mo. Vitamin A and E levels were also significantly elevated in patients receiving antioxidant therapy compared to those receiving placebo at 6 mo. A similar pattern was seen for β-carotene although these values did not attain significance.

There was no difference in haemoglobin, white cell count or CRP at 6 mo between antioxidant therapy and placebo or between antioxidant therapy and baseline.

There were also no differences in opiate usage.

Cytokine profiles

There was no difference between the antioxidant group and placebo at baseline in any of the cytokines measured in this study (Table 4). Similarly, there was no difference between antioxidant and placebo at 6 mo and no difference in the antioxidant group at 6 mo compared to the same group at baseline. IL-1B, IL-2, IL-4 and IL-10 me-

Table 1 Demographic profiles

Variables	Antioxidant (n = 7)	Placebo (n = 7)	P value
Age (yr), median (range)	46 (34-79)	46 (37-60)	0.92 (Mann-Whitney U)
Gender (male:female)	5:2	4:3	0.90 (Fisher's exact)
Aetiology	Alcohol 6; idiopathic 1	Alcohol 4; idiopathic 3	0.55 (Fisher's exact)
Disease duration (yr)	4 (1-5)	3 (2-13)	0.92 (Mann-Whitney U)
Body mass index (kg/m^2)	24.2 (18.8-36.7)	22.5 (22.9-32.8)	0.62 (Mann-Whitney U)
Alcohol (g/d), median (range)	175.5 (0-396)	138.6 (0-252)	0.43 (Mann-Whitney U)
Cigarette smoker (Y:N)	6:1	5:2	0.59 (Fisher's exact)
Diabetes mellitus (Y:N)	2:5	1:6	0.62 (Fisher's exact)
Faecal elastase (μg/g)	68 (15-500)	27 (15-500)	0.27 (Mann-Whitney U)
Opiate use (mg/d)	40 (30-300)	85 (0-120)	0.30 (Mann-Whitney U)

Laboratory reference range for faecal elastase report values < 200 μg/g as representing end-stage exocrine failure. All opiate intakes are reported as morphine equivalent.

Table 2 Baseline antioxidant profiles

Variables	Antioxidant (n = 7)	Placebo (n = 7)	Laboratory reference range	Median difference	P value (MWU)	95%CI
Vitamin C (μg/mL)	7.7 (0.7-13)	5.8 (2.4-9.9)	4-20	1.6	0.53	-3-6.1

WCC (10^9/L)	6.7 (4.9-10.8)	7.4 (6-10.8)	0.330	-1.3-3.2	0.600	-3.3-1.9
Hb (g/dL)	14.2 (13.5-16.0)	12.7 (12.3-16.0)	0.510	-1-1.6	0.150	-1.3-2.6
CRP (mg/L)	3 (3-4)	6 (3-10)	0.190	0-3	0.070	-7-0
Opiate usage	20	55	0.210	-40-79	0.630	-56-60

WGSH: Whole blood glutathione; WGSH/Hb: Glutathione corrected for haemoglobin concentration; WCC: White cell count; Hb: Haemoglobin; CRP: C-reactive protein.

dian values were below the lower limit of the laboratory reference range at all sample points although individual patient sample values registered within the reference range. IL-6 and IL-8 values were within the reference range but towards the lower end at all sample points. VEGF showed higher values in the placebo group at both baseline and at 6 mo although this difference was not significant.

DISCUSSION

To the best of our knowledge, this study is the first to examine circulating cytokine levels in patients with chronic pancreatitis receiving antioxidant therapy and to compare these values to controls (also with CP) receiving matched placebo. When interpreting these findings, several important methodological sources of error should be emphasised. First, this is a small study with only 7 patients in each group. Thus it should be borne in mind that negative findings could represent a type Ⅱ error. A second source of error is the possibility of technical compromise in assay methodology as samples were transferred for analysis. As the majority of readings were low, could deterioration in sample quality have affected the assays?

Table 4 Cytokine levels in patients receiving antioxidant therapy compared to placebo

Cytokine	Laboratory range	Antioxidant therapy baseline (pg/mL)	Placebo baseline (pg/mL)	*P* value	95%CI	Antioxidant therapy at 6 mo (pg/mL)	Placebo at 6 mo (pg/mL)	*P* value	95%CI
IL-1β[1]	1.6-250	< 1.6	< 1.6			< 1.6	< 1.6

[1]All patients had interleukin (IL)-1β levels below the lower threshold of detection. IL-2: Antioxidant group at 6 mo *vs* antioxidant group at baseline, *P* = 0.64 (95%CI: -1.5-2.5); IL-4: Antioxidant group at 6 mo *vs* antioxidant group at baseline, *P* = 0.89 (95%CI: -3.7-3.7); IL-6: Antioxidant group at 6 mo *vs* antioxidant group at baseline, *P* = 0.25 (95%CI: -0.4-1.7); IL-8: Antioxidant group at 6 mo *vs* antioxidant group at baseline, *P* = 0.69 (95%CI: -17.8-4.9); [2]All patients had interleukin 10 below the lower threshold of detection. Transforming growth factor type β1 (TGFβ1): Antioxidant group at 6 mo *vs* antioxidant group at baseline, *P* = 0.46 (95%CI: -39-74); tumor necrosis factor α (TNFα): Antioxidant group at 6 mo *vs* antioxidant group at baseline, *P* = 0.97 (95%CI: -1.0-1.4); vascular endothelial growth factor (VEGF): Antioxidant group at 6 mo *vs* antioxidant group at baseline, *P* = 0.54 (95%CI: -43.8- 81.0); epidermal growth factor (EGF): Antioxidant group at 6 mo *vs* antioxidant group at baseline, *P* = 0.05 (95%CI: -0.22-59.8); monocyte chemotactic protein-1 (MCP-1): Antioxidant group at 6 mo *vs* antioxidant group at baseline, *P* = 0.05 (95%CI: -50.1-100.9).

Whilst this possibility cannot definitively be excluded, the commercial laboratory which undertook these assays works closely with the clinical biochemistry department of the Manchester Royal Infirmary and regularly undertakes analysis of externally drawn samples. Sample extraction, storage and transfer were in full compliance with established protocols. Further, laboratory markers of the inflammatory response measured in-hospital such as the white cell count and CRP were also normal providing indirect support. A third caveat is that cytokine levels measured in blood may not necessarily reflect their activity at the pancreatic parenchymal level. For example, Noh and colleagues demonstrated that IL-8 concentrations are elevated (compared to non-disease controls) in pancreatic juice collected by duodenoscopy[9].

Accepting these limitations, the present study does provide unique data on cytokine profiles in patients with chronic pancreatitis receiving antioxidant therapy and in a matched cohort receiving placebo and provides negative results which should be regarded as important pilot data. The first finding of interest is that at baseline, despite having radiological evidence of chronic pancreatitis, impairment of pancreatic exocrine function and a substantial requirement for opiate analgesia there was no elevation of circulatory pro- or anti-inflammatory cytokine levels. This is finding sits well with current paradigms of chronic pancreatitis which suggest that pain is not simply a product of inflammation and that it involves a complex interaction between inflammatory mediators and neural structures with alterations in nociception[10,11]. For example, fractalkine is a cell surface membrane-spanning adhesion molecule that can be cleaved to produce a soluble neuromodulatory chemokine which increases neuropathic pain through glial activation with expression correlating with the severity of pancreatic neuritis, fibrosis, intrapancreatic nerve fibre density and pain in chronic pancreatitis[12]. Fractalkine may be a better disease-specific chemokine in chronic pancreatitis although its relation to disease stage and response to therapy have yet to be elucidated[13].

In relation to cytokine profiles in chronic pancreatitis reported in other studies, the levels of IL-18 in our study are similar to those reported by Schneider and colleagues[14]. In terms of genotype, patients with alcohol-aetiology dominant, sporadic chronic pancreatitis do not have an increased frequency of functional polymorphisms in the *TGF-β1* gene, in the *IL-10* gene or in the intron 1 of the interferon-gamma gene[15].

In this study there was no relation between antioxidant therapy and cytokine levels. Thus, the significant elevations in plasma levels of antioxidants seen in the treatment group (and also in the main ANTICIPATE study and in other studies of antioxidant therapy) do not appear to interact with circulating cytokines. The low levels of cytokines probably reflect the results of sampling of an out-patient based population with clinically quiescent disease and in particular without evidence of a systemic inflammatory response.

In conclusion, this study has measured antioxidant profiles in patients with chronic pancreatitis receiving antioxidant therapy and compared these to patients receiving matched placebo. Cytokine levels were low at baseline and at 6 mo despite a significant elevation in plasma antioxidants. The study also demonstrates that circulating cytokine levels are low suggesting that pain in this disease is not simply a manifestation of ongoing inflammation. It could be the result of the inflammation tissue damage caused long time ago.

ACKNOWLEDGMENTS

We are indebted to the staff of the Clinical Biochemistry and Pancreatic Laboratories of the Manchester Royal Infirmary for their skilful assistance with the conduct of the study and to adrian holt in particular for his thorough

review of the final manuscript.

COMMENTS

Background

This study undertakes a subgroup analysis comparing pro- and anti-inflammatory cytokine levels in a sub-group of patients receiving either antioxidant therapy for chronic pancreatitis in the form of Antox (Pharmanord, Morpeth, United Kingdom) or matched placebo.

Research frontiers

The novel aspect of this study is that it is believed to be the first to examine pro- and anti-inflammatory cytokine levels in patients receiving antioxidant therapy for chronic pancreatitis and to compare these levels to those in patients receiving matched placebo.

Innovations and breakthroughs

The results show that pro-inflammatory cytokine levels were not elevated. This is potentially an important finding in that it shows that in patients with chronic pancreatitis, with established pain, inflammatory cytokine levels are not elevated.

Applications

The findings are preliminary and need to be reproduced in a larger validation dataset before more general acceptance.

Peer review

It is a very interesting paper. Considering that this paper employs patients from the ANTICIPATE study, it is desirable that the authors give the registration number of the main trial.

Abstract

AIM: To investigate bone mineral density (BMD) in obese children with and without nonalcoholic fatty liver disease (NAFLD); and the association between BMD and serum adipokines, and high-sensitivity C-reactive protein (HSCRP).

METHODS: A case-control study was performed. Cases were 44 obese children with NAFLD. The diagnosis of NAFLD was based on magnetic resonance imaging (MRI) with high hepatic fat fraction (≥ 5%). Other causes of chronic liver disease were ruled out. Controls were selected from obese children with normal levels of aminotransferases, and without MRI evidence of fatty liver as well as of other causes of chronic liver diseases. Controls were matched (1- to 1-basis) with the cases on age, gender, pubertal stage and as closely as possible on body mass index-SD score. All participants underwent clinical examination, laboratory tests, and whole body (WB) and lumbar spine (LS) BMD by dual energy X-ray absorptiometry. BMD *Z*-scores were calculated using race and gender specific LMS curves.

RESULTS: Obese children with NAFLD had a significantly lower LS BMD *Z*-score than those without NAFLD [mean, 0.55 (95%CI: 0.23-0.86) *vs* 1.29 (95%CI: 0.95-1.63); $P < 0.01$]. WB BMD *Z*-score was also decreased in obese children with NAFLD compared to obese children with no NAFLD, though borderline significance was observed [1.55 (95%CI: 1.23-1.87) *vs* 1.95 (95%CI: 1.67-2.10); $P = 0.06$]. Children with NAFLD had significantly higher HSCRP, lower adiponectin, but similar leptin levels. Thirty five of the 44 children with MRI-diagnosed NAFLD underwent liver biopsy. Among the children with biopsy-proven NAFLD, 20 (57%) had nonalcoholic steatohepatitis (NASH), while 15 (43%) no NASH. Compared to children without NASH, those with NASH had a significantly lower LS BMD *Z*-score [mean, 0.27 (95%CI: -0.17-0.71) *vs* 0.75 (95%CI: 0.13-1.39); $P < 0.05$] as well as a significantly lower WB BMD *Z*-score [1.38 (95%CI: 0.89-1.17) *vs* 1.93 (95%CI: 1.32-2.36); $P < 0.05$]. In multiple regression analysis, NASH (standardized β coefficient, -0.272; $P < 0.01$) and HSCRP (standardized β coefficient, -0.192; $P < 0.05$) were significantly and independently associated with LS BMD *Z*-score. Similar results were obtained when NAFLD (instead of NASH) was included in the model. WB BMD *Z*-scores were significantly and independently associated with NASH (standardized β coefficient, -0.248; $P < 0.05$) and fat mass (standardized β coefficient, -0.224; $P < 0.05$).

CONCLUSION: This study reveals that NAFLD is associated with low BMD in obese children, and that systemic, low-grade inflammation may accelerate loss of bone mass in patients with NAFLD.

Key words: Bone mineralization; Dual energy X-ray absorptiometry; Adipokines; C-reactive protein; Nonalcoholic fatty liver disease; Children

Core tip: Understanding the mechanisms underlying the relationship between nonalcoholic fatty liver disease (NAFLD) and low bone mineral density (BMD) is important to prevent poor bone mineralization in obese children. We showed that obese children with NAFLD have decreased BMD compared to obese children without liver involvement independently of adiposity, and that children with more severe histology have worse mineral status than children with more mild abnormalities. We also found a significant independent association of high sensitivity C-reactive protein with BMD scores, supporting the role of an inflammatory state which may accelerate loss of bone mass in patients with NAFLD.

Adipokines and C-reactive protein in relation to bone mineralization in pediatric nonalcoholic fatty liver disease. *World J Gastroenterol* 2013; 19(25): 4007-4014 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4007.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4007

INTRODUCTION

Concurrent with the increasing rates of childhood obesity, nonalcoholic fatty liver disease (NAFLD) has emerged as the leading cause of chronic liver disease in pediatric populations worldwide[1,2]. NAFLD comprises a disease spectrum ranging from simple steatosis to nonalcoholic steatohepatitis (NASH), with varying degrees of inflammation and fibrosis, progressing to end-stage liver disease with cirrhosis and hepatocellular carcinoma[3]. NAFLD is strongly associated with obesity, insulin resistance, hypertension, and dyslipidemia, and is now regarded as the liver manifestation of the metabolic syndrome (MetS)[4]. Recently it has been suggested that NAFLD can be a cause of low bone mineral density (BMD) in obese children and adolescents[5-7]. However, the mechanisms explaining this relationship are not completely understood[8]. Obesity-induced low-grade systemic inflammation, a key component in the pathogenesis of insulin resistance and NAFLD, may negatively influence bone health[9,10]. Expanded and inflamed visceral adipose tissue releases a wide array of molecules potentially involved in the development of insulin resistance, including free fatty acids, tumor necrosis factor (TNF)-α, and other proinflammatory cytokines[11-14]. In the presence of increased free fatty acid flux and chronic, low-grade inflammation, the liver is both the target of and a contributor to systemic inflammatory changes[15]. Indeed, in a number of case-control studies, circulating levels of several inflammatory markers [*i.e.*, C-reactive protein (CRP), interleukin (IL)-6, monocyte chemotactic protein 1 and TNF-α], procoagulant factors, and oxidative stress markers were found to be highest in patients with NASH, intermediate in those with simple steatosis, and lowest in control subjects without steatosis, and the differences were independent of obesity and other potentially confounding factors[16].

Adipose tissue also produces adipokines, which are pleiotropic molecules that not only regulate food intake and energy metabolism but also are implicated in the complex interactions between fat and bone[17,18]. Leptin, produced in bone marrow adipocytes and osteoblastic cells, regulates appetite and weight, osteoblast proliferation and differentiation *in vitro*[19-21], and osteoclasts[19,22,23]. Its receptor is expressed in osteoblasts[19,24]. Adiponectin, exclusively expressed by adipocytes, is inversely related to visceral fat mass and body mass index (BMI)[25] and regulates metabolism and inflammatory pathways[26]. Adiponectin affects osteoblast directly and osteoclast indirectly. It stimulates the proliferation and differentiation of human osteoblasts *via* the p38 mitogen-activated protein kinase signaling pathway[27]. In contrast, adiponectin indirectly influences osteoclasts by stimulating the receptor activator of nuclear factor-κB ligand (RANKL) and inhibiting osteoprotegerin production in osteoblasts[28]. Some studies have shown a negative association between adiponectin and BMD, independent of fat mass or BMI[29].

The aims of this study were to evaluate: (1) BMD in obese children with and without NAFLD; and (2) the association between BMD and the serum adipokines, leptin and adiponectin, and a circulating marker of systemic inflammation, high-sensitivity C-reactive protein (HSCRP), using multiple regression.

MATERIALS AND METHODS

Study design and patients

A case-control study was performed. Cases were Caucasian obese children (BMI above the 95th percentile for age and gender) seen at the Hepatology outpatient Clinic of the Department of Pediatrics, Sapienza University of Rome, Italy. The diagnosis of NAFLD was based on magnetic resonance imaging (MRI) with high hepatic fat fraction (HFF $\geqslant$ 5%). Other causes of chronic liver disease, including hepatic virus infections (hepatitis A-E and G, cytomegalovirus, and Epstein-Barr virus), autoimmune hepatitis, metabolic liver disease, α-1-antitrypsin deficiency, cystic fibrosis, Wilson's disease, hemochromatosis, and celiac disease were ruled out with appropriate tests. Exclusion criteria were also smoking habits, and history of type 1 or 2 diabetes, renal disease, total parenteral nutrition, use of hepatotoxic medications, and chronic alcohol intake. Finally, children were excluded for conditions that could have adversely influenced BMD including glucocorticoid therapy, hypothyroidism, Cushing's disease; history of long bone fractures; indwelling hardware; and abnormality of the skeleton or spine[30,31].

Controls were selected from Caucasian obese children with normal levels of aminotransferases, and without

MRI evidence of fatty liver (HFF < 5%) as well as of other causes of chronic liver diseases (see above). Controls were also excluded if they had smoking habits, history of type 1 or 2 diabetes, renal disease, chronic alcohol intake, and any condition known to influence BMD[30,31]. Controls were then matched (1- to 1-basis) with the cases on age, gender, pubertal stage and as closely as possible on BMI-SD score (SDS).

The research protocol was approved by the Hospital Ethics Committee, and informed consent was obtained from subjects' parents before assessment.

Clinical and laboratory data

All participants underwent physical examination including measurements of weight, standing height, BMI and determination of the stage of puberty, and laboratory tests. The pubertal stage was categorized into two groups (prepubertal: boys with pubic hair and gonadal stage I , and girls with pubic hair stage and breast stage I ; pubertal: boys with pubic hair and gonadal stage ≥ II and girls with pubic hair stage and breast stage ≥ II). The degree of obesity was quantified using Cole's least mean-square method, which normalizes the skewed distribution of BMI and expresses BMI as SDS[32]. Blood samples were taken, after an overnight fast, for estimation of glucose, insulin, alanine aminotransferase (ALT), aspartate aminotransferase (AST), HSCRP, leptin, and adiponectin.

Analyses of glucose, insulin, ALT, AST, and HSCRP were conducted by COBAS 6000 (Roche Diagnostics). Insulin concentrations were measured on cobas e 601 module (Electrochemiluminescence Technology, Roche Diagnostics), while the remaining analytes on cobas e 501 clinical chemistry module (Photometric Technology), according to the instructions of the manufacturer. The degree of insulin resistance was determined by a homeostasis model assessment of insulin resistance (HOMA-IR)[33]. Scores were calculated as the product of the fasting serum insulin level (μU/mL) and the fasting serum glucose level (mmol/L), divided by 22.5. A RIA was used to measure human (total) leptin (DRG Diagnostica, Marburg, Germany; detection limit, 0.5 ng/mL; inter- and intra-assay CVs, 3.0%-6.2% and 3.4%-8.3%, respectively), and adiponectin (DRG Diagnostica, Marburg, Germany; detection limit, 1 ng/mL; inter- and intra-assay CVs, 6.9%-9.2% and 1.8%-6.2%, respectively).

MRI for liver fat quantification

The amount of hepatic fat content (% HFF) was measured by MRI using the two-point Dixon method as modified by Fishbein[34], as previously described and validated[35]. MRI results were interpreted by an experienced radiologist who was blinded to clinical and laboratory findings.

Lumbar spine and whole body dual energy X-ray absorptiometry scans

Anteroposterior lumbar spine (L_1-L_4), and whole body scans were obtained from all cases and controls using a Hologic QDR-4500W (Waltham, MA, United States) in the fan beam mode with a multidetector system. All subjects were measured on the same machine. The measurements were performed by using standard positioning techniques. Quality control was performed daily using the Hologic anthropomorphic spine, and weekly with the whole body phantom. In our department, the precision error for BMD measurements is less than 1% for the spine phantom, and less than 2.5% for the whole body phantom. The data were analyzed using the software version 11.2. Spine scans were analyzed with low-density software[36]. BMD *Z*-scores for whole body (WB) and for lumbar spine (LS) were calculated using race and gender specific LMS curves[37]. Whole body DXA results (BMD, fat mass and lean mass) shown in this study represent values excluding the skull[38].

Liver biopsy

The clinical indication for biopsy was either to assess the presence of NASH and degree of fibrosis or other likely independent or competing liver diseases. Percutaneous needle liver biopsy was performed as previously described[35]. The main histologic features of NAFLD were scored according to the scoring system developed by the NASH Clinical Research Network (CRN)[39]. Features of steatosis, lobular inflammation, and hepatocyte ballooning were combined to obtain the NAFLD activity score. As recommended by a recent NASH CRN article[40], a microscopic diagnosis, based on overall injury pattern (*i.e.*, steatosis, hepatocyte ballooning, and inflammation), as well as the presence of additional lesions (*e.g.*, zonality of lesions, portal inflammation, and fibrosis), has been assigned to each case[41]. Accordingly, biopsies were subdivided into not-NASH and definite NASH subcategories[41].

Statistical analysis

Statistical analyses were performed using the SPSS package. The data are expressed either as frequencies or as means with 95%CI. Insulin, leptin and adiponectin levels were distributed with a long tail to the right (positive skew), but their logarithms were approximately normally distributed. Mean differences in anthropometric, laboratory and body composition variables between subjects were assessed by using the *t* test. Linear regression analysis was used to identify variables associated with BMD. Then, a stepwise multiple linear regression analysis (including all variables significantly associated with BMD) was used to determine the independent variables associated with BMD. A *P* value of less than 0.05 was considered to be statistically significant.

RESULTS

Study subjects

Forty four obese children with MRI-diagnosed NAFLD were matched to 44 obese children without evidence of liver disease. By study design cases and controls were matched for age, gender, pubertal stage and BMI-SDS. The mean age of cases and controls was 12.5 (SD 1.8) years. Both cases and controls included 20 girls and 24

Table 1 Characteristics of obese children by liver status

Variables	NAFLD (n = 44)	Non-NAFLD (n = 44)	P value
Lean mass, kg	25.8 (24.0-30.0)	26.5 (24.0-29.0)	NS
Fat mass, kg	18.7 (17.0-21.0)	16.8 (15.1-19.0)	NS
Percentage body fat	40.2% (39.0%-41.0%)	38.0% (36.0%-40.0%)	NS
Aspartate amino-transferase, U/L	34 (30-38)	24 (22-26)	< 0.0010
Alanine amino-transferase, U/L	45 (35-55)	20 (18-22)	< 0.0001
Glucose, mmol/L	4.89 (4.69-5.10)	4.88 (4.77-5.02)	NS
Insulin, μU/mL	31.2 (21.9-40.6)	20.1 (16.2-24.1)	< 0.0100
HOMA-IR values	4.27 (3.40-5.10)	3.45 (2.97-4.01)	< 0.0100
Leptin, μg/L	19.5 (15.8-23.1)	20.8 (18.2-23.4)	NS
Adiponectin, μg/L	9.0 (7.3–11.0)	12.9 (10.6–15.4)	< 0.0500
HSCRP, μg/L	3310 (2785-3836)	2165 (1710-2620)	< 0.0100
Hepatic fat fraction (%)	17.0 (11.8-22.3)	1.6 (1.0-3.1)	< 0.0001

Results are expressed as n (%), mean (95%CI), or geometric mean (95%CI) for log-transformed variables. NS: Not significant; HOMA-IR: Homeostasis model assessment of insulin resistance; HSCRP: High-sensitivity C-reactive protein; NAFLD: Nonalcoholic fatty liver disease.

boys, and five prepubertal children. The mean BMI-SDS of cases and controls was 2.19 (SD 0.16) and 2.17 (SD 0.16), respectively. The clinical and laboratory characteristics for cases and controls are shown in Table 1. There were no differences between children with and without NAFLD with respect to lean and fat mass. Compared to the non-NAFLD group, children with NAFLD had significantly higher ALT, AST, insulin concentrations, HOMA-IR values, and HSCRP levels, but lower adiponectin concentrations. There were no significant differences between the two groups with respect to glucose as well as leptin.

Histological findings in children with NAFLD

Liver biopsy was obtained in 35 of the 44 children with MRI-diagnosed NAFLD, with parental refusal in 9 cases. The 35 children did not differ from those having only liver MRI with respect to age, gender, body composition, metabolic parameters, and bone measures.

Among patients with biopsy-proven NAFLD, 20 (57%) had definite NASH, while 15 (43%) no NASH. No statistically significant differences in body composition as well as in laboratory parameters such as glucose, insulin, leptin, adiponectin levels, and HOMA-IR values were found between children with NASH and those with simple steatosis. AST [mean, 41 U/L (95%CI: 34-48) *vs* 26 U/L (95%CI: 22-29); $P < 0.001$)], ALT [mean, 58 U/L (95%CI: 41-75) *vs* 30 U/L (95%CI: 20-45); $P < 0.001$)] as well as HFF [mean, 24.8% (95%CI: 19.5-30.2) *vs* 15.7% (95%CI: 5.6-28.8); $P < 0.001$)] were significantly higher in patients with NASH compared to children without NASH. HSCRP was also higher [mean, 4055 μg/L (95%CI: 2690-5419) *vs* 2870 μg/L (95%CI: 1794-3936); $P = 0.07$], although did not reach statistically significance.

Bone measures

Obese children with NAFLD had a significantly lower LS BMD Z-score than those without NAFLD [mean, 0.55 (95%CI: 0.23-0.86) *vs* 1.29 (95%CI: 0.95-1.63); $P < 0.01$] (Figure 1A). WB BMD Z-score was also decreased in obese children with NAFLD compared to obese children with no NAFLD, though borderline significance was observed [1.55 (95%CI: 1.23-1.87) *vs* 1.95 (95%CI: 1.67-2.10); $P = 0.06$] (Figure 1B). Among children with biopsy-proven NAFLD, those with NASH had a significantly lower LS BMD Z-score than children without NASH [mean, 0.27 (95%CI: -0.17-0.71) *vs* 0.75 (95%CI: 0.13-1.39); $P < 0.05$] (Figure 1C). Moreover, children with NASH had a significantly lower WB BMD Z-score than children without NASH [1.38 (95%CI: 0.89-1.17) *vs* 1.93 (95%CI: 1.32-2.36); $P < 0.05$] (Figure 1D).

Table 2 Multivariate analysis of the variables associated with lumbar spine and whole body bone mineral density Z-score in obese children

Variables	Standardized coefficient[1]	P value
LS BMD Z-score		
NAFLD	-0.230	< 0.01
HSCRP, μg/L	-0.195	< 0.05
WB BMD Z-score		
NAFLD	-0.218	< 0.05
Fat mass, kg	-0.225	< 0.05

[1]Included in the model were age, gender, pubertal stage, nonalcoholic fatty liver disease (NAFLD), and all variables significantly associated with lumbar spine or whole body bone mineral density (BMD) Z-score in univariate analysis [*i.e.*, high-sensitivity C-reactive protein (HSCRP) and leptin levels or fat mass].

In univariate analysis, LS BMD Z-score correlated negatively with NAFLD (standardized β coefficient, -0.202; $P < 0.01$) and HSCRP (standardized β coefficient, -0.212; $P < 0.05$). In contrast, leptin was positively associated with lumbar BMD (standardized β coefficient, -0.204; $P < 0.05$). No correlation was found between LS BMD Z-score and insulin as well as HOMA-IR. Likewise, neither BMI-SDS nor lean mass nor fat mass were correlated with LS BMD Z-score. After including in the model all the significant variables as well as age, gender, pubertal status, NAFLD (standardized β coefficient, -0.230; $P < 0.01$) and HSCRP (standardized β coefficient, -0.195; $P < 0.05$) remained significantly and independently associated with LS BMD Z-score (Table 2).

WB BMD Z-score was negatively associated with NAFLD (standardized β coefficient, -0.207; $P < 0.05$), fat mass (standardized β coefficient, -0.222; $P < 0.05$), and HSCRP (standardized β coefficient, -0.216; $P < 0.05$). No correlation was found between WB BMD Z-score and insulin as well as HOMA-IR. Likewise, neither BMI-SDS nor lean mass were correlated with WB BMD Z-score. After including in the model all the significant variables as well as age, gender, pubertal status, NAFLD (standardized β coefficient, -0.218; $P < 0.05$) and fat mass (standardized β coefficient, -0.225; $P < 0.05$) remained significantly and independently associated with WB BMD Z-score (Table 2).

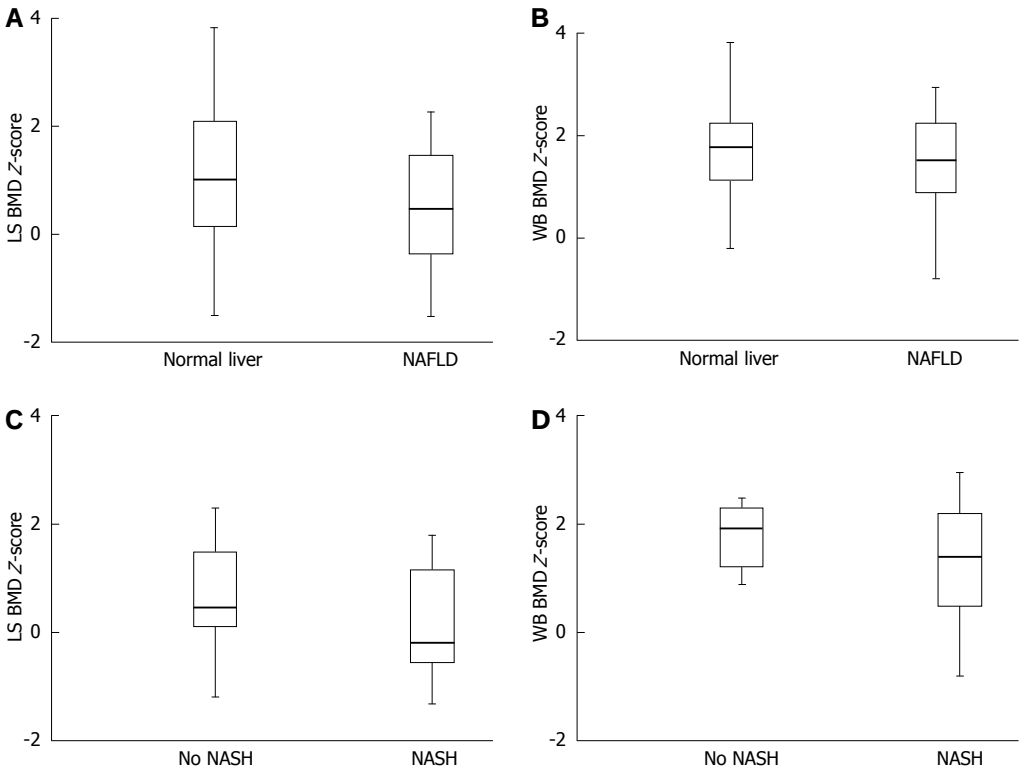

Figure 1 Bone measures. A: Lumbar spine bone mineral density *Z*-score (LS BMD *Z*-score) for obese children with and without nonalcoholic fatty liver disease (NAFLD). Box-plots give the median value (bold), 25th and 75th percentiles (lower and upper limits of the box), and lower and upper adjacent values (whiskers); B: Whole body bone mineral density *Z*-score (WB BMD *Z*-score) for obese children with and without NAFLD. Box-plots give the median value (bold), 25th and 75th percentiles (lower and upper limits of the box), and lower and upper adjacent values (whiskers); C: LS BMD *Z*-score for obese children with biopsy-proven NAFLD subdivided into those with and without nonalcoholic steatohepatitis (NASH). Box-plots give the median value (bold), 25th and 75th percentiles (lower and upper limits of the box), and lower and upper adjacent values (whiskers); D: WB BMD *Z*-score for obese children with biopsy-proven NAFLD subdivided into those with and without NASH. Box-plots give the median value (bold), 25th and 75th percentiles (lower and upper limits of the box), and lower and upper adjacent values (whiskers).

DISCUSSION

In this study, we showed that obese children with NAFLD had decreased LS BMD and WB BMD compared to obese children without liver involvement independently of adiposity, and that children with more severe histology had worse bone mineral status than children with more mild abnormalities. Furthermore, we found a significant independent association of HSCRP with BMD scores, supporting the role of an inflammatory state which may accelerate loss of bone mass in patients with NAFLD.

Growing evidence suggests the presence of a complex interplay between the skeleton and numerous homeostatic processes, including energy balance, insulin resistance, obesity and MetS[8]. Recent years have also witnessed an increased awareness of the clinical and epidemiological association between NAFLD and bone health, both in terms of reduced BMD and an increased risk of osteoporosis[8]. To our knowledge, such an association has been so far independently reported by five studies in both children and adults[5-7,42,43].

With respect to studies in adults, Moon *et al*[42] showed that in postmenopausal women ultrasound-diagnosed NAFLD was significantly associated with low lumbar BMD and this significance was maintained after adjusting for the concerned variables including age, BMI, ALT, smoking status, and alcohol consumption, and even after taking the presence of MetS into account. However, in premenopausal women, there was no such relationship. Yet, in the study by Purnak *et al*[43] involving 102 adult patients with ultrasound-diagnosed NAFLD and 54 healthy controls, there were no statistically significant differences in BMD measurements between the two groups. However, in a subgroup of patients with NAFLD, the presence of elevated serum ALT and HSCRP levels, which were suggestive of NASH, was associated with lower BMD.

With respect to studies in children, Pirgon *et al*[5] reported a negative association between BMD and insulin resistance in obese adolescents both with (n = 42) and without (n = 40) ultrasound-diagnosed NAFLD, although the obese adolescents with NAFLD had lower spine BMD *Z*-scores than their non-NAFLD counterparts. The Authors suggested that NAFLD could exert a negative impact on BMD in obese adolescents, probably *via* an increased insulin resistance. In the study by Pardee *et al*[6], poor bone mineralization was common among the 38 obese children with biopsy-proven NAFLD, but not among the 38 obese children without evidence of liver disease. Cases and controls were matched for age, gender, race, ethnicity, height and weight. Among children with NAFLD, 17 (45%) had BMD *Z*-scores $\leqslant$ -2.0, compared to none of the

controls ($P < 0.0001$). Importantly, among those children with NAFLD, children with NASH had a significantly ($P < 0.05$) lower BMD *Z*-score (-2.37) than children with NAFLD who did not have NASH (-1.58)[6]. These differences persisted after controlling for total per cent body fat. In the study by Campos *et al*[7], a 1-year interdisciplinary weight loss therapy was able to promote changes in the metabolic profile of 40 obese adolescents with ($n = 18$) or without ($n = 22$) ultrasound-diagnosed NAFLD, including a decrease in the BMI, body fat, visceral and subcutaneous fat, insulin concentration, HOMA-IR, and an increase in lean mass. At baseline, NAFLD group presented statistically lower values of bone mineral content (BMC); however, after one year of interdisciplinary therapy, there was an increase of BMC, reaching similar values of non-NAFLD group. Campos *et al*[7] suggest the importance of this kind of intervention to regulate bone mineral metabolism as result of an increased BMC and improved inflammatory state. Together, these studies indicate that NAFLD, in particular NASH, is associated with poor bone health.

Obesity and bone mineralization in children remains a topic of great interest, as data are conflicting regarding whether obesity in this age group is detrimental or protective to bone. Previous studies have suggested that body weight might improve bone mineralization in overweight adolescents by increasing the mechanical load on weight-bearing bones[44,45]. In terms of which component(s) of body weight underlie this association, the association between bone and lean mass has been found to be strongest[46]. Some studies have also suggested that fat mass may stimulate bone accrual in growing children, but these results have remained inconsistent showing both positive[47,48] and negative associations[49-51]. In multiple regression analysis, we found that fat mass had a negative association with WB BMD *Z*-score, while none of the anthropometric variables had an effect on LS BMD *Z*-scores. The basis for the negative effect of fat on WB BMD *Z*-score observed in the present study is unknown. We found that serum adipokines such as leptin and adiponectin were not significantly correlated with BMD *Z*-scores. In that vein, a recent systematic review of the literature concerning the influence of adipokines on BMD, rarely identified leptin as an independent predictor of BMD when BMI or fat mass parameters were included in the multivariate regression models[29]. Yet, in that systematic review, results were discordant for adiponectin[29]. Some studies showed a negative association between adiponectin and BMD, independent of fat mass or BMI[29]. Nevertheless, other studies did not find such associations[29]. There are possible explanations for this apparent discrepancy. Many variables, such as estrogen levels, proinflammatory cytokines, and preanalytical variability of adipokine dosage may interfere with adiponectin and bone.

Systemic inflammation is well known to contribute to low BMD in several diseases states[52-54]. CRP is a sensitive systemic marker of inflammation and tissue damage[55]. It is only produced by hepatocytes, predominantly under transcriptional control by IL-6, although other sites of local CRP synthesis and possible secretion have been suggested. Raised CRP levels are associated with many features of insulin resistance or MetS[56]. This may reflect, in part, the fact that adipocytes are the source of a substantial portion of IL-6 production[57]. On the other hand, inflammatory cytokines up-regulate the RANKL, leading to increased bone resorption and reduced BMD[58]. Some studies have suggested that an elevated CRP is associated with osteoporosis and non-traumatic fractures[9,10]. Our study suggests that HSCRP level is independently associated with LS BMD *Z*-scores in obese children with NAFLD. This finding is consistent with the hypothesis of a tight interplay between low-grade inflammation and bone turnover, even in patients with NAFLD.

COMMENTS

Background

In parallel with epidemic obesity, nonalcoholic fatty liver disease (NAFLD) has emerged as the leading cause of chronic liver disease in both pediatric and adult patients worldwide. Liver disease can be cause of low bone mineral density (BMD). However, the mechanisms explaining this relationship are still not completely understood.

Research frontiers

A better understanding of the factors that may influence bone mineral status in NAFLD may open a new frontier to fight two highly prevalent conditions like NAFLD and osteoporosis.

Innovations and breakthroughs

Recent years have witnessed an increased awareness of the clinical and epidemiological association between NAFLD and bone health, both in terms of reduced BMD and an increased risk of osteoporosis. Given the high prevalence of NAFLD and the adverse consequences of low BMD in childhood, understanding the mechanisms underlying the relationship between NAFLD and low BMD is important to prevent poor bone mineralization in this potentially vulnerable population. In this study, authors showed that obese children with NAFLD have decreased BMD compared to obese children without liver involvement independently of adiposity, and that children with more severe histology have worse mineral status than children with more mild abnormalities. They also found a significant independent association of high sensitivity C-reactive protein with BMD scores, supporting the role of an inflammatory state which may accelerate loss of bone mass in patients with NAFLD.

Applications

The presence of systemic inflammation may have important implications for the long-term skeletal health of children with NAFLD, and particularly those with nonalcoholic steatohepatitis (NASH).

Terminology

NAFLD comprises a disease spectrum ranging from simple fatty liver to NASH, with varying degrees of inflammation and fibrosis, progressing to end-stage liver disease with cirrhosis and hepatocellular carcinoma. Bone density (or BMD) is a medical term normally referring to the amount of mineral matter per square centimeter of bones. Bone density (or BMD) is used in clinical medicine as an indirect indicator of osteoporosis and fracture risk.

Peer review

In this paper, authors compared lumbar spine (LS) and whole body (WB) BMD measured by dual energy X-ray absorptiometry scans between 44 pediatric patients with magnetic resonance imaging diagnosed NAFLD and controls matched 1:1 for age, gender, and pubertal stage and body mass. They found that LS-BMD *Z* score was lower in NAFLD than in controls; Thirty three NAFLD patients were biopsied; LS and WB BMD *Z* score were lower in NASH than in non-NASH children. At multivariate analysis LS-BMD was independently associated with NASH and C-reactive protein levels. They conclude that NAFLD is associated with low BMD in obese children, and systemic low grade inflammation may play a role in such a relationship.

Abstract

AIM: To investigate the prevalence and implications of unusual histopathological findings in appendectomy specimens from patients with suspected acute appendicitis.

METHODS: The demographic and histopathological data of 1621 patients (≥ 16 years-old) who underwent appendectomy to treat an initial diagnosis of acute appendicitis between January 1999 and November 2011 were retrospectively assessed. Microscopic findings were used to classify the patients under six categories: appendix vermiformis, phlegmonous appendicitis, gangrenous appendicitis, perforated appendicitis, supurative appendicitis, and unusual histopathologic findings. The demographic and clinicopathologic characteristics of patients with unusual histopathologic findings were evaluated in detail, and re-analysis of archived resected appendix specimens was carried out.

RESULTS: A total of 912 males and 709 females, from 16 to 94 years old, were included in the study and comprised 789 cases of suppurative appendicitis, 370 cases of appendix vermiformis, 243 cases of perforated gangrenous appendicitis, 53 cases of flegmaneous appendicitis, 32 cases of gangrenous appendicitis, and 134 (8.3%) cases of unusual histopathological findings. The unusual histopathological findings included fibrous obliteration (n = 62), enterobius vermicularis (n = 31), eosinophilic infiltration (n = 10), mucinous cystadenoma (n = 8), carcinoid tumor (n = 6), granulomatous inflammation (n = 5), adenocarcinoma (n = 4; one of them mucinous), and mucocele (n = 3), adenomatous polyp (n = 1), taenia sup (n = 1), ascaris lumbricoides (n = 1), appendiceal diverticula (n = 1), and B cell non-hodgkin lymphoma (n = 1). None of the 11 patients with subsequent diagnosis of tumor were suspected of cancer prior to the appendectomy.

CONCLUSION: Even when the macroscopic appearance of appendectomy specimens is normal, histopathological assessment will allow early diagnosis of many unusual diseases.

Key words: Appendicitis; Appendectomy specimens; Histopathology; Unusual findings; Appendiceal malignancy

Core tip: Appendectomy is one of the most frequently performed surgical procedures worldwide. Although most of the resected appendectomy specimens show typical histopathologic findings, some (< 2%) show unusual histopathologic findings. The most common of these unusual features are primary or secondary appendiceal malignancies, mucocele, enterobisis, schistosomiasis, ascariasis, tuberculosis, amobiasis, and entometriosis. While some of the patients with unusual histopatholic findings require close follow-up and/or additional surgical treatment, others also necessitate antimicrobial therapy. Infectious appendicitis is respon-

sible for a significant majority of the most commonly observed unusual features, especially in cases from developing nations in geographic regions with tropical and sub-tropical climates. Therefore, regardless of the underlying etiology, the results from histopathological examination of the resected appendectomy specimen may help guide the subsequent management of cases to prevent serious appendicular diseases.

Unusual histopathological findings in appendectomy specimens from patients with suspected acute appendicitis. *World J Gastroenterol* 2013; 19(25): 4015-4022 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4015.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4015

INTRODUCTION

Appendicitis remains one of the most common acute conditions of the abdomen, and suspected cases are frequently treated with emergency appendectomy[1]. The complete organ excision not only allows for definitive diagnosis but also significantly reduces the risk of life-threatening complications, such as perforation, plastron and sepsis. However, the surgical procedure itself is very invasive, representing additional risks to the patient's morbidity and mortality as well as remarkable costs to the healthcare providers. Epidemiologic studies have revealed that the incidence of acute appendicitis roughly parallels that of lymphoid development, with the peak incidence occurring between the ages of 10 and 30 years old. The most important causative factor of acute appendicitis appears to be development of luminal obstruction. In addition, several factors have been implicated as causative etiologies of this underlying feature, and show an age-related trend[1-5]. For example, lymphoid hyperplasia is the most common factor identified in patients under 20 years old, while fecalith plugs are the most common factor identified in the elderly. Apart from these usual factors, numerous other less frequent (and thus "unusual") factors have been identified as having caused the clinical symptoms that indicated the suspicion of acute appendicitis with or without histopathologic evidence for acute appendicitis[1,3,4]. The primary objective of this study was to assess the incidence and implications of unusual histopathological findings detected in appendectomy specimens from patients who received surgery to address an initial diagnosis of acute appendicitis.

MATERIALS AND METHODS

In this retrospective study, the electronic records of the Inonu University Medical Faculty Department of Surgery were searched to identify all patients who underwent appendectomy to treat an initial diagnosis of acute appendicitis between January 1999 and November 2011. The recorded demographic and histopathological data extracted for each patient included age, sex, appendectomy surgery date, and macroscopic and microscopic properties of appendix vermicularis. Patients who had received the appendectomy incidental to other surgeries, such as colorectal or gynecological cancer surgery or trauma surgery, were excluded from study enrollment. In addition, pediatric patients younger than 16 years old were also excluded from study enrollment. Four researchers working independently collected the demographic and pathologic data of all patients fitting the inclusion criteria in excel spreadsheets, which were then adjudicated and analyzed by the group.

Using the microscopic findings of each patient's appendectomy specimen that were recorded in the pathology report, the patients were classified into one of six categories: (1) appendix vermiformis; (2) phlegmonous appendicitis; (3) gangrenous appendicitis; (4) perforated appendicitis; (5) suppurative appendicitis; and (6) unusual histopathologic findings. The archived appendectomy specimens (pathology blocks and microscopic slides) were retrieved for the 134 patients in group 6 and were re-evaluated by two experienced pathologists. The patient data for each demographic or histopathologic characteristic were summarized as mean ± SD, and incidence of a characteristic within a particular group was calculated as percentage of the entire study population.

RESULTS

General characteristics of patients undergoing appendectomy for suspected acute appendicitis

A total of 1621 patients underwent appendectomy to treat an initial diagnosis of acute appendicitis. The mean age of these patients was 36.7 ± 17.4 years (range: 16-94 years) and the male-to-female ratio was nearly equal (912: 709) but with a slight male bias (56.3% males). According to the histopathological findings, 789 patients had suppurative appendicitis, 370 had appendix vermiformis, 243 had perforated gangrenous appendicitis, 134 had unusual histopathological findings, 53 had flegmaneous appendicitis, and 32 had gangrenous appendicitis. Overall, the majorities (67.3%) of the patients were ≤ 40 years old, and 13.5% were ≥ 61 years old. There was also an age bias towards patients ≤ 40 years old for those in the negative appendicitis group (64.6% of the 370 patients), with only 17.5% in that group being ≥ 61 years old. Clinicopathologic characteristics of the 1621 patients who underwent appendectomy for clinical signs of acute appendicitis are summarized in Table 1.

Characteristics of patients who showed unusual histopathologic findings in appendectomy specimens

One-hundred-and-thirty-four (8.3%) of the patients who received appendectomy to treat the initial diagnosis of acute appendicitis had unusual histopathological findings in their appendectomy specimens. This group of patients had a mean age of 48.4 ± 19.5 years old, and the male-to-

female ratio was relatively equal (60:74) but with a slight female bias (55.2% females). The mean age of the males (50.9 ± 19.3 years old; range: 16-87 years) was slightly higher than that of the females (46.4 ± 19.5 years old; range: 16-94 years). Unlike any of the five other pathology groups, the group with unusual histopathological findings had a majority (60.4%) of patients > 40 years old.

The histopathologic findings of these 134 patients with unusual histopathological findings included fibrous obliteration (*n* = 62; Figure 1A), enterobius vermicularis (*n* = 31; Figure 1B), eosinophilic infiltration (*n* = 10), mucinous cystadenoma (*n* = 8; Figure 1C), carcinoid tumor (*n* = 6; Figure 1D), granulomatous infiltration (*n* = 5; Figure 1E), adenocarcinoma (*n* = 4; Figure 1F-G), mucocele (*n* = 3; Figure 1H), adenomatous polyp (*n* = 1), taenia sup (*n* = 1; Figure 1I), ascaris lumbricoides (*n* = 1), appendiceal diverticula (*n* = 1), and B cell non-Hodgkins lymphoma (NHL) (*n* = 1; Figure 1J).

Ninety-six of the 134 total patients with unusual histopathologic findings showed no evidence of inflammatory cell infiltration. However, 21 of these 96 cases had additional inflammation-related findings, including lymphoid hyperplasia (*n* = 18) and ovarian cyst rupture (*n* = 3). The remaining 38 of the 134 total patients did show evidence of inflammatory cell infiltration to varying degrees. Among those patients, five were histologically confirmed as having perforated appendicitis and three as having gangrenous appendicitis. Five of 134 patients showed evidence of classical granulomas and multinucleated giant cells formed by epitheloid histiocytes. Staining with erlich ziehl-nielsen and periodic acid-schiff revealed a complete absence of microorganisms; thus all cases were reported as granulomatous appendicitis. Taenia sup eggs were detected in one specimen, although the adult form of the parasite was not detected and the case was not specified as *Taenia saginata* or *Taenia solium*. Clinicopathologic features of the 134 appendectomized patients with unusual histopathological findings are summarized in Table 2.

Malignancy was detected in the appendectomy specimens of 11 of the 134 patients of this group. The mean age of these patients was 49.1 ± 16.7 years old (range: 21-74 years), and the majority was female (4:7). There was no suspicion of cancer prior to the appendectomy surgery for any of these patients. Histopathological findings, however, indicated carcinoid tumor (*n* = 6), adenocarcinoma (*n* = 4) and B cell NHL (*n* = 1). Standard appendectomy was carried out in five of the six patients with carcinoid tumor, and the tumor diameters of these cases ranged from 5-25 mm; only the sixth case underwent subsequent right hemicolectomy procedure following the cancer diagnosis. Detailed tumor data could be retrieved for only one of the four patients with adenocarcinoma (age range: 51-74 years) but all of these patients underwent subsequent right hemicolectomy following the cancer diagnosis. The one patient diagnosed with B cell NHL was referred to the Medical Oncology Department following the appendectomy surgery, and medical records indicate that the patient was in remission at the 1-year follow-up. Detailed characteristics of the 11 appendectomized patients with histologically-diagnosed appendicular malignancy are summarized in Table 3.

DISCUSSION

Acute appendicitis manifests upon inflammation of the inner lining of the appendix vermiformis, which can spread to other parts of the organ. This condition may be brought on by several different physiopathological processes, but luminal obstruction is considered the most important triggering factor of the underlying inflammation[1-5]. Although lymphoid hyperplasia and fecaliths are the most frequently observed etiologies of luminal obstruction, other, less frequent factors have been observed in patients with symptoms of acute appendicitis. According to the literature, the most common of these unusual factors are mucinous cystadenoma or mucocele[6-9], carcinoid tumor[9-12], granulomatous diseases[13-15], enterobiasis[1,5,16,17], taeniasis[3,18-20], ascariasis[4,21], diverticulitis[22-25], primary or secondary adenocarcinoma[26-30], lymphoma[26,31,32], and neurogenic appendicopathy[33,34]. In addition, the study by Akbulut *et al*[1] reported cases associated with eosinophilic granuloma, amebiasis, actinomycosis, schistosomiasis, balantidiasis, tuberculosis,

adenovirus, melanosis, neurofibroma, endometriosis, adenomatous or hyperplastic polyps, villous or tubulovillous adenoma, gastrointestinal stromal tumor, leukemia, and foreign body reactions.

Appendiceal tumors, which have been reported in < 3% of all appendectomy specimens, are rarely associated with manifestation of clinical symptomology. Thus, this condition is most often recognized incidentally, either during an abdominal operation or general pathological examination of a resected appendix specimen. The most frequently diagnosed type of appendiceal primary malignant lesion is the carcinoid tumor. Although it accounts for about 60% of all appendiceal tumors, its incidence in patients undergoing appendectomy is only 0.30%-2.27%. Most of the carcinoid tumors are located at the tip of the appendix and are < 1 cm in diameter. Fortunately, malignancy and metastasis of these tumors are very rare, and usually only involve tumors that exceed 1 cm. Therefore, simple appendectomy is considered sufficient management for these tumors. The risk of metastasis jumps up to 85%, however, once the tumor size reaches 2 cm or larger, in which case a formal right hemicolectomy is recommended[10-12]. In our patient series, the incidence of appendiceal carcinoid (0.37%) was similar to that in the overall literature.

Primary adenocarcinoma of the appendix is an extraordinarily rare tumor, with overall incidence in the literature between 0.01% and 0.20%. However, this tumor is most likely to occur in persons between 50 and 55 years old. Adenocarcinomas generally show aggressive behavior, the pattern of which has been likened to colonic adenocarcinomas. Therefore, appendicular adenocarcinomas are often treated by oncologic resection with right hemicolectomy[10,26,29]. In our patient series, only four patients presented with this tumor type, giving an incidence of 0.25% that is similar to that in the overall literature. In addition, these patients were within the age range of 51 and 74 years old (mean ± SD, 64.0 ± 8.3 years).

Appendiceal mucinous adenocarcinoma, also known as mucinous cystadenocarcinoma, is another rare condition of the appendix. This tumor type, however, is most often associated with a second malignancy of the gastrointestinal tract and the most common manifestation is symptoms of acute appendicitis. Like the other appendix-related cancers, diagnosis of mucinous adenocarcinoma is usually only made upon the subsequent pathological evaluation of a resected appendiceal specimen[27,28].

Mucocele is a condition in which mucoid material accumulates in the intraluminal region of the appendix, eventually causing obstructive dilatation of the organ. However, the occlusion of the appendiceal lumen may also be caused by endometriosis or carcinoid tumors[8,9]. The overall incidence of this condition in the literature ranges from 0.2% to 0.7%. Currently, four histologic types of appendiceal mucocele are recognized, and these include (in order of incidence): Mucinous cystadenoma, mucosal hyperplasia, mucinous cystadenocarcinoma, and retention cyst[1,6,7]. Up to one-half of mucocele cases are asymptomatic and the condition is incidentally diagnosed by histological examination of tissues from appendectomy, or sometimes during a laparotomy surgery. Appendectomy is the standard of care for mucinous cystadenoma, whereas a cystadenocarcinoma requires a right hemicolectomy[1,6,7].

The gastrointestinal tract is the most common site for extranodal lymphomas, accounting for 30%-45% of all extranodal cases. The incidence of primary appendiceal lymphoma is extremely low, and has been estimated at between 0.015% and 0.05%[26,31,32]. Cases of appendiceal lymphoma most often occur in young adults, between the ages of 20 and 40 years old. The usual manifestation of symptoms of acute appendicitis explain its diagnosis most frequently occurring following appendectomy and upon histopathologic analysis of the resected organ. Unfortunately, the rarity of the disease has impeded establishment of evidence-based guidelines for treatment.

The incidence of neurogenic appendicopathy is estimated to be about 30%. Although this process is often described as fibrous obliteration, recent studies have demonstrated that the occlusive proliferation is predominantly neurogenic in some cases. As of yet, the pathogenesis of this condition remains to be fully elucidated, but some studies have indicated that it may actually be secondary to hyperplasia of neuroendocrine cells. Differential diagnosis between appendiceal neuroma and acute

Table 3 Detailed characteristics of the 11 patients with appendicular malignancy

appendicitis is relatively subjective and depends upon a patient's clinical history, symptomology, and findings from laboratory and physical examination. Accordingly, most appendiceal neuromas are incidentally indicated by histological evidence of fibrous obliteration in appendix specimens of otherwise asymptomatic patients[1,33,34]. In the current patient series, the incidence of fibrous obliteration was only 3.7%, which is lower than in the overall literature.

Enterobius vermicularis, commonly known as the pinworm, is a widespread parasitic infection that is estimated to affect up to 200 million people worldwide. The association of pinworm infection and appendicitis was first made in the late 19th century. While the reported incidence of pinworm infections in appendectomy specimens from patients with presumed appendicitis has ranged from 0.2% to 41.8%, inflammation is often associated with pinworm infection in the appendix[1,5,16,17]. In the current patient series, the incidence of pinworms in the appendectomy specimens was 1.9%, which is similar to the overall literature.

Taeniasis manifests upon intestinal infection with helminths. The first sign of infection is usually a segment of the parasite that appears in the stool. Taenia sup infection of the appendix, in particular, is so rare that the situation invites a case report. In general, cases of taeniasis do not necessitate identification of the specific species in order to initiate appropriate treatment, and a single dose of praziquantel can efficiently clear the infection[3,18-20].

Ascaris lumbricoides is one of the most common human helminthic pathogens infecting humans worldwide; however, epidemiologic studies have revealed that the highest prevalence of ascariasis occurs in tropical and semitropical countries. In the human host, the worm can establish residence in the gastrointestinal region from the stomach to the ileocecal valve, but up to 99% of the cases reported have worms localized to the jejunum and proximal ileum. Infections involving the appendix are only rarely seen. The ability of a roundworm to migrate to the appendix, thereby causing appendicitis, is controversial. The physical and physiological effects of such a migration may indeed simulate other physiopathogenic processes that promote appendicitis, but are believed less likely to be the direct cause of it[1,4,21].

Granulomatous appendicitis is another rare condition that may be discovered incidentally in a patient with a clinical presentation of acute appendicitis. The reported incidence in Western countries has ranged from 0.14% to 0.30%, and is higher (1.3%-2.3%) in underdeveloped countries[13,14]. The criteria for diagnosis are similar to those of other diseases of the gastrointestinal tract, and include granulomatous inflamation, transmural lymphoid aggregates, and fissuring-type ulcers. Various infectious agents (such as *Yersinia* spp., *Mycobacterium tuberculosis*, and *Schistosoma* spp.) and non-infectious factors (such as Crohn's disease and sarcoidosis) have been implicated as causative factors of this condition[1,14-16]. In the current series of patients, granulomatous inflammation was observed in only 0.3%. As tuberculosis is endemic in the region where our hospital is located, all of the patients had been tested accordingly; yet, no findings related to tuberculosis were encountered.

Appendiceal diverticulum is another very rare clinical entity, and the incidence is reported between 0.004% and 2.1%. The diverticula may occur as singlets or in multiples, but generally involve the distal third of the appendix, on its mesenteric side, and their size is usually < 0.5 cm. Cases of appendiceal diverticula are routinely classified as either congenital or acquired. While the congenital form (considered a true diverticulum) is extremely rare, the acquired form (a pseudodiverticulum consisting of mucosa and submucosa herniated through vascular clefts in the muscular layer) are encountered much more often. Four clinical variations of either form of this condition have been described, and include the appendiceal diverticula without inflammation, acute appendicitis with diverticula, acute appendiceal diverticulitis with acute appendicitis, and isolated acute diverticulitis. However, all

four forms are generally asymptomatic, with the related complications of perforation and inflammation causing the abdominal pain that mimics acute appendicitis[22-25].

Considering the overall case reports in the literature and the case series presented herein, it is clear that even when the macroscopic appearance of a resected appendix is normal, histopathological assessment of specimens will allow early diagnosis of malign and infectious appendiceal diseases.

COMMENTS

Background

Appendicitis is one of the most common acute surgical conditions of the abdominal cavity. While this clinicopathologic condition may manifest from several underlying etiologies, luminal obstruction is the essential triggering factor for development of the inflammatory process. Although lymphoid hyperplasia and fecaliths are the most common cause of luminal obstruction, other less commonly observed factors, such as infectious and malignant appendiceal diseases, may also underlie this pathogenic condition.

Research frontiers

According to the literature, the most common of unusual histopathologic findings are mucinous cystadenoma or mucocele, carcinoid tumor, granulomatous diseases, enterobiasis, taeniasis, ascariasis, diverticulitis, primary or secondary adenocarcinoma, lymphoma, and neurogenic appendicopathy, eosinophilic granuloma, amebiasis, actinomycosis, schistosomiasis, balantidiasis, tuberculosis, adenovirus, melanosis, neurofibroma, endometriosis, adenomatous or hyperplastic polyps, villous or tubulovillous adenoma, gastrointestinal stromal tumor, leukemia, and foreign body reactions. In this study, the authors conducted and investigation of the incidence and implications of unusual histopathological findings detected in resected appendectomy specimens obtained from patients who underwent surgery for suspected acute appendicitis.

Innovations and breakthroughs

The authors emphasize and strongly recommend that all appendectomy specimens be examined by histopathological analysis, even if specimens have a normal gross appearance.

Peer review

This is a quite well-done manuscript of appropriate interest and with images of reasonable quality.

Abstract

AIM: To investigate the role of functional genetic polymorphisms of metabolic enzymes of tobacco carcinogens in the development of colorectal adenomas.

METHODS: The study subjects were 455 patients with colorectal adenomas and 1052 controls with no polyps who underwent total colonoscopy in a preretirement health examination at two Self Defense Forces hospitals. The genetic polymorphisms studied were *CYP1A1*2A* (rs 4646903), *CYP1A1*2C* (rs 1048943), *GSTM1* (null or non-null genotype), *GSTT1* (null or non-null genotype) and *NQO1* C609T (rs 1800566). Genotypes were determined by the polymerase chain reaction (PCR)-restriction fragment length polymorphism or PCR method using genomic DNA extracted from the buffy coat. Cigarette smoking and other lifestyle factors were ascertained by a self-administered questionnaire. The associations of the polymorphisms with colorectal adenomas were examined by means of OR and 95%CI, which were derived from logistic regression analysis. Statistical adjustment was made for smoking, alcohol use, body mass index and other factors. The gene-gene interaction and effect modification of smoking were evaluated by the likelihood ratio test.

RESULTS: None of the five polymorphisms showed a significant association with colorectal adenomas, nor was the combination of *GSTM1* and *GSTT1*. A borderline significant interaction was observed for the combination of *CYP1A1*2C* and *NQO1* (P = 0.051). The OR associated with *CYP1A1*2C* was significantly lower than unity among individuals with the *NQO1* 609CC genotype. The adjusted OR for the combination of the *CYP1A1*2C* allele and *NQO1* 609CC genotype was 0.61 (95%CI: 0.42-0.91). Although the interaction was not statistically significant (P = 0.24), the OR for individuals carrying the *CYP1A1*2C* allele and *GSTT1* null genotype decreased significantly compared with those who had neither *CYP1A1*2C* allele nor *GSTT1* null genotype (adjusted OR: 0.69, 95%CI: 0.49-0.97). Smoking did not modify the associations of the individual polymorphisms with colorectal adenomas. There was no measurable effect modification of smoking even regarding the combination of the genetic polymorphisms of the phase Ⅰ and phase Ⅱ enzymes.

CONCLUSION: Combination of the *CYP1A1*2C* and *NQO1* 609CC genotypes was associated with a decreased risk of colorectal adenomas regardless of smoking status.

Key words: Colorectal adenoma; Smoking; Polymorphism; *CYP1A1*; *GSTM1*; *GSTT1*; *NQO1*

Core tip: The study investigated the associations of *CYP1A1*2A*, *CYP1A1*2C*, *GSTM1*, *GSTT1* and *NQO1* C609T polymorphisms with colorectal adenomas among 455 cases of colorectal adenomas and 1052 controls with no polyps. None of the five polymorphisms showed a significant association with colorectal adenomas, nor was the combination of *GSTM1* and *GSTT1*. A borderline significant interaction was observed for the combination of *CYP1A1*2C* and *NQO1*. Combination of the *CYP1A1*2C* and *NQO1* 609CC genotypes was associated with a decreased risk of colorectal adenomas regardless of smoking status.

INTRODUCTION

Colorectal cancer is one of the most common cancers, accounting for approximately 10% of incident cancer cases worldwide[1]. Colorectal adenoma is a well-established precursor lesion of colorectal cancer[2,3]. Cigarette smoking has been related to increased risk of colorectal adenomas, whereas the association between smoking and colorectal cancer risk is rather inconsistent and much weaker[4-6]. Despite the consistent association between smoking and colorectal adenomas, biological mechanisms for the association remain unknown. Tobacco smoke contains various types of carcinogens such as polycyclic aromatic hydrocarbons, heterocyclic amines, aromatic amines and *N*-nitrosamines, which are activated by phase I enzymes and/or detoxified by phase II enzymes, and thus functional genetic polymorphisms of the metabolic enzymes are of interest in colorectal carcinogenesis[7].

CYP1A1 is a phase I enzyme responsible for bioactivation of tobacco carcinogens. Two functional polymorphisms are known in the *CYP1A1* gene[8,9]. One is the 3698T>C substitution (*CYP1A1*2A*, rs 4646903) that creates an *Msp*I restriction site in the 3'-flanking region, and the other is the 2454A>G substitution (*CYP1A1*2C*, rs 1048943) that results in an amino acid change (Ile462Val) in exon 7. The *CYP1A1*2A* and *CYP1A1*2C* alleles are linked to higher inducibility of the enzyme, and have been associated with an increased risk of lung cancer and less consistently of other tobacco-related cancers[8,9]. Several studies reported an increased risk of colorectal cancer associated with *CYP1A1*2A*[10] and *CYP1A1*2C*[11], while others showed no association of either *CYP1A1*2A* or *CYP1A1*2C* with colorectal cancer[12-15] or adenomas[16]. Isoforms of the glutathione S-transferase (GST) are involved in detoxification of chemical carcinogens and environmental toxic compounds[17,18]. *GSTM1* and *GSTT1* polymorphisms have been studied most intensively in relation to tobacco-related cancers. The *GSTM1* and *GSTT1* null genotypes result in a complete loss of enzyme function[17,18]. A meta-analysis suggested an increased risk of colorectal cancer associated with the null genotype of *GSTT1*, but not of *GSTM1*[19], while another meta-analysis showed no association of either the *GSTM1* or *GSTT1* null genotype with colorectal cancer or adenomas[20]. Some recent studies have shown an increased risk of colorectal cancer associated with the *GSTM1* and *GSTT1* null genotypes in combination[21,22], but others failed to show such an increase in the risk of colorectal cancer[14,15] or adenomas[23].

NAD(P)H-quinone oxidoreductase 1 (NQO1) is involved in detoxification through two electron reductions of quinones to hydroquinones, while NQO1 can also activate procarcinogens in tobacco smoke[24]. The 609C>T polymorphism (rs 1800566) that causes an amino acid substitution (Pro187Ser) results in loss of NQO1 activity[24]. A meta-analysis reported that *NQO1* 609C>T was associated with a small increase in the risk of colorectal cancer in Caucasians[25], but a recent large Japanese study failed to corroborate such an association[15]. Homozygosity of the *NQO1* 609T allele was shown to be positively associated with colorectal adenomas[26]. Heavy smokers carrying both the *CYP1A1*2C* and *NQO1* 609T variant alleles showed a substantial increase in the risk of adenomas[26].

To clarify the role of *CYP1A1*, *GSTM1*, *GSTT1* and *NQO1* polymorphisms in colorectal carcinogenesis with reference to smoking, we examined the associations of these polymorphisms with colorectal adenomas and the effect of smoking on the associations between the polymorphisms and colorectal adenomas. A particular emphasis was placed on the combination of genetic polymorphisms of phase I and phase II enzymes, because the literature is sparse on the influence of gene-gene interactions on the risk of colorectal cancer and adenomas.

MATERIALS AND METHODS

Subjects

Study subjects were male officials in the Self Defense Forces who received a preretirement health examination at the Self Defense Forces Fukuoka Hospital or Kumamoto Hospital during the period from January 1997 to March 2001. The preretirement health examination is a nationwide program that offers a comprehensive medical examination including colonoscopy to persons retiring from the Self Defense Forces. Details of the preretirement health examination have been described elsewhere[27,28]. The subjects were Japanese in ethnicity. A 7-mL fasting venous blood sample was donated for the purpose of medical research with written informed consent. The study was approved by the Ethics Committee of Kyushu University Faculty of Medical Sciences.

The present study included 455 cases of histologically confirmed colorectal adenoma and 1052 controls with no

polyps who underwent total colonoscopy. In a consecutive series of 2454 men, five refused to participate in the study and we excluded 77 who did not undergo colonoscopy. Further exclusions were 242 men with a history of colectomy (n = 17), colorectal polypectomy (n = 212), malignant neoplasm (n = 27) or inflammatory bowel disease (n = 1). For the remaining 2135 men, colonoscopic findings were classified as polyp (n = 938, 43.9%), colorectal cancer (n = 1, 0.0%), non-polyp benign lesion (n = 123, 5.8%) and normal (n = 1073, 50.3%). Of the 938 men with colorectal polyps, 461 were found to have adenoma without *in situ* or invasive carcinoma. The controls comprised 1067 men who underwent a complete colonoscopy among the 1196 men with normal colonoscopy or non-polyp benign lesions. DNA was not available for 21 men (6 cases and 15 controls), and 455 cases and 1052 controls remained in the analysis.

Lifestyle questionnaire

Smoking habits, alcohol consumption, physical activity and other lifestyle factors were ascertained by a self-administered questionnaire, with a supplemental interview for unanswered questions given prior to colonoscopy. Details of the lifestyle questions have been described elsewhere[27,28]. Lifetime exposure to cigarette smoking was expressed by cigarette-years, which were calculated as the product of total years of smoking and the average number of cigarettes per day. Cigarette smoking was classified into 0, 1-399, 400-799 and ≥ 800 cigarette-years. Daily intake of ethanol was estimated for current alcohol drinkers based on consumption frequencies and amounts of five types of alcoholic beverages on average in the past year. Alcohol use was categorized into never, past and current use with a consumption of < 30, 30-59 or ≥ 60 mL of ethanol per day. Body mass index was categorized into four levels (< 22.5, 22.5-24.9, 25.0-27.4 and ≥ 27.5 kg/m^2). The categories for alcohol use and body mass index were arbitrary, but in accordance with those used in the previous studies[27,28]. Leisure-time physical activity was expressed as the sum of products of intensity score (metabolic equivalent) and amount of time for at most three types of regular exercise, and was categorized by quartiles in the control group.

Genotyping

DNA was extracted from the buffy coat by use of a commercial kit (Qiagen GmbH, Hilden, Germany). Genotyping was carried out by the polymerase chain reaction (PCR)-restriction fragment length polymorphism or PCR method, with agarose-gel electrophoresis and visualization by ethidium bromide. The PCR was performed in a mixture of 10 μL containing 1 μL template DNA with a concentration of 50-150 ng/μL. The PCR for *CYP1A1*2A* polymorphism was done using the primers described by Sivaraman *et al*[10], and the 340-bp PCR product was digested with *Msp*I, which resulted in fragments of 200 and 140 bp for the *CYP1A1*2A* allele. The *CYP1A1*2C* polymorphism was genotyped using the primers previously specified[29], with digestion by restriction enzyme *Hin*cII. The 187-bp product was cleaved into three fragments (120, 48 and 19 bp) in the presence of the *CYP1A1*2C* allele, and otherwise into two fragments (139 and 48 bp). *GSTM1* and *GSTT1* polymorphisms were determined by the multiplex PCR using the primers for *GSTM1*, *GSTT1* and albumin as described previously[30]. Genotyping for *NQO1* 609C>T was performed as described previously[31]. The 230-bp PCR product was digested with *Hin*fI, resulting in fragments of 195 and 35 bp for the 609C allele and fragments of 151, 44 and 35 bp for the 609T allele. The assay was repeated at most three times when the PCR was unsuccessful or when the migration pattern on the gel was aberrant.

Statistical analysis

Deviation of genotype frequency from the Hardy-Weinberg equilibrium was tested by χ^2 test with one degree of freedom using the Stata version 10 (Stata Corporation, College Station, TX, United States). The associations between the polymorphisms and colorectal adenomas were assessed by means of OR and 95%CI, which were derived from logistic regression analysis. Statistical adjustment was made for age (continuous variable), hospital (dichotomous variable), rank in the Self Defense Forces (low, middle and high), cigarette smoking, alcohol use, body mass index, physical activity and parental colorectal cancer. The gene-gene interaction and effect modification of smoking were evaluated by the likelihood ratio test. In the analysis of the effect modification of smoking, smoking status was categorized into < 400 and ≥ 400 cigarette-years, *i.e.*, < 20 and ≥ 20 pack-years, because an increased risk of adenomas associated with smoking was discernible only in the latter categories (see below). Statistical significance was declared if two-sided P was < 0.05. Statistical analysis was performed with SAS version 9.2 (SAS Institute, Cary, NC, United States).

RESULTS

Selected characteristics of the cases and controls are summarized in Table 1. The age range was 50-57 years for the cases and 47-59 years for the controls. The cases had a greater body mass index and a lower physical activity in leisure time than the controls. Heavy smoking and high alcohol consumption were more frequent in the cases than in the controls.

Among the controls, the frequencies of the *CYP1A1*2A*, *CYP1A1*2C* and *NQO1 609T* alleles were 0.39, 0.23 and 0.38, respectively, and genotype frequencies of the three polymorphisms were all in agreement with the Hardy-Weinberg equilibrium (P = 0.62 for *CYP1A1*2A*; P = 0.32 for *CYP1A1*2C*; and P = 0.76 for *NQO1* C609T). The *CYP1A1*2A* and *CYP1A1*2C* polymorphisms were in complete linkage disequilibrium except for two cases; the deviation of these two was probably due to error in genotyping.

None of the five polymorphisms showed a significant association with colorectal adenomas, nor was the combination of *GSTM1* and *GSTT1* (Table 2). The gene-gene interaction was examined for the combina-

Table 1 Selected characteristics of the study subjects

Characteristics	Cases (n = 455)	Controls (n = 1052)
Age (yr), mean ± SD	52.4 ± 0.8	52.4 ± 0.9

[1]Number of variant alleles; [2]Number of null genotypes; [3]Adjusted for age, hospital, rank in the Self-Defense Forces, body mass index, cigarette smoking, alcohol use, leisure-time physical activity and parental history of colorectal cancer.

tions of the *CYP1A1* polymorphisms and the *GST* or *NQO1* polymorphism (Table 3). As regards *CYP1A1*2A*, *CYP1A1*2C* and *NQO1*, the homozygous variant genotype was combined with the heterozygous genotype because variant homozygotes were relatively few. A borderline significant interaction was observed for the combination of *CYP1A1*2C* and *NQO1* (P = 0.051). The OR associated with *CYP1A1*2C* was significantly lower than unity among individuals with the *NQO1* 609CC genotype. Although the interaction was far from statistical significance, the OR for individuals carrying the *CYP1A1*2C* allele and *GSTT1* null genotype significantly decreased compared with those who had neither the *CYP1A1*2C* allele nor the *GSTT1* null genotype.

Smoking was positively associated with colorectal adenomas; the multivariate-adjusted ORs for the smoking categories of 0, 1-399, 400-799 and ⩾ 800 cigarette-years were 1.00 (referent), 1.18 (95%CI: 0.82-1.71), 2.11 (95%CI: 1.58-2.82) and 2.11 (95%CI: 1.47-3.03), respectively. However, smoking did not modify the associations of the *CYP1A1*, *GSTM1*, *GSTT1* and *NQO1* polymorphisms with colorectal adenomas (Table 4). The ORs associated with heavy smoking were consistently increased,

regardless of genotype of the polymorphism. There was no measurable effect modification of smoking even regarding the combination of the genetic polymorphisms of the phase I and phase II enzymes (Table 5). The OR was lowest for the combination of the *CYP1A1*2C* and *NQO1* 609CC genotypes among the four composite genotypes in each stratum of smoking. The OR varied according to the combination of *CYP1A1*2C* and the composite genotypes of *GSTM1* and *GSTT1* within each stratum of smoking. The OR for the combination of the *CYP1A1*2C* allele and the non-null genotypes of both *GSTM1* and *GSTT1* was significantly lower than unity in the category of < 20 pack-years, and the OR increased significantly among heavy smokers without the *CYP1A1*2C* allele who had null genotypes for both *GSTM1* and *GSTT1*.

DISCUSSION

According to recent meta-analyses[32,33], the *CYP1A1*2C* polymorphism, but not *CYP1A1*2A* polymorphism, was significantly associated with a modest increase in the risk of colorectal cancer. Neither *CYP1A1*2A* nor *CYP1A1*2C* polymorphism was related to colorectal adenomas individually in the present study. The findings are consistent with the previous observation regarding colorectal adenomas[16,26]. Further investigation is needed to clarify whether the associations with the *CYP1A1*2C* polymorphism is differential for colorectal cancer and adenomas.

The null effects of the *GSTM1* and *GSTT1* polymorphisms in the present study are in agreement with previous observations regarding colorectal adenomas[23,34]. Some of the previous studies showed an increased risk of colorectal cancer among individuals with the *GSTM1* null genotype[11,21,22], the *GSTT1* null genotype[21], or both the *GSTM1* and *GSTT1* null genotypes[21,22]. However, these findings were not replicated in other studies on colorectal cancer[14,15,35]. Previous studies found no effect of smoking on the association with *GSTM1* and *GSTT1*, either singly or in combination, in relation to colorectal adenomas[23] and cancer[15,22,33]. The *GSTM1* and *GSTT1* non-null genotypes as determined by gel electrophoresis include heterozygous genotypes (*i.e.*, one active and one inactive allele). One study differentiated the heterozygous genotype from the homozygous non-null genotype for *GSTM1* and *GSTT1* by TaqMan assay[36]. Both heterozygous and homozygous null genotypes of *GSTM1* were associated with a decreased risk of colorectal adenomas irrespective of smoking status, while adenoma risk was increased in association with both heterozygous and homozygous null genotypes of *GSTT1* among ever-smokers, but not among never-smokers[36]. However, it is unclear whether heterozygosity in either *GSTM1* or *GSTT1* affects enzyme activity[18].

Few studies have addressed the combined effect of the *CYP1A1* polymorphisms and the *GSTM1* and/or *GSTT1* null genotype in relation to colorectal adenomas and cancer. The combination of *CYP1A1*2A* and *GSTM1* null genotype was shown to be unrelated to colorectal adenomas[16]. There was no interaction between the two *CYP1A1* polymorphisms and either *GSTM1* or *GSTT1* null genotype on the risk of colorectal cancer[14]. A Japanese study showed a decreased risk of colorectal cancer for the combination of *CYP1A*2C* and *GSTT1* non-null genotype[15]. The present study indicated a decreased risk of colorectal adenomas for the combination

[1]Number of cases/controls; [2]Adjusted for age, hospital, rank in the Self-Defense Forces, body mass index, cigarette smoking, alcohol use, leisure-time physical activity and parental history of colorectal cancer; [3]Number of variant alleles; [4]Number of null genotypes.

of *CYP1A1*2C* and *GSTT1* null genotype, although the interaction was not significant. Inconsistent findings regarding the combination of *CYP1A1*2C* and *GSTT1* are probably ascribed to random fluctuation, although further studies are needed.

The risk of adenomas was lowest for the combination of *CYP1A1*2C* and the *GSTM1* and *GSTT1* non-null genotypes among never-smokers or light smokers, and an increased risk associated with heavy smoking was most evident among men without *CYP1A1*2C* who had the *GSTM1* and *GSTT1* null genotypes. Caution is required in interpreting the findings because of the small number of each combination of the three polymorphisms when stratified by smoking. Nonetheless, further investigation is warranted because the association of the three-polymorphism combination with colorectal cancer or adenomas has not been investigated previously.

The present study did not corroborate an increased risk of colorectal adenomas associated with the combination of *CYP1A1*2C* and *NQO1 609T* alleles reported among non-Hispanic whites[26], but showed a decreased risk among men harboring the *CYP1A1*2C* allele and the *NQO1* 609CC genotype. In that study[26], however, there were only a few subjects with both the *CYP1A1*2C* and *NQO1 609T* alleles (12 cases and 26 controls), accounting for only 4.0% of the cases and 1.8% of the controls,

because these variant alleles are much less frequent in Caucasians than in Asians[10,31]. In a study of Caucasians[26], the OR for the combination of *CYP1A1*2C* allele and *NQO1* 609CC genotype was 0.6 (95%CI: 0.3-1.2), as compared with the same referent combination as used in the present study. This finding is thus compatible with the present observation. It should be noted that the borderline significant interaction between *CYP1A1*2C* and *NQO1* C609T resulted from the eight statistical tests (Table 3). The probability of detecting at least one statistically significant result is 0.34, even when none of the eight interactions are present. The combined effect of these two polymorphisms requires careful interpretation, but requires further studies for mechanistic plausibility. Exposure to activated carcinogens may be lowered in individuals with both the *CYP1A1*2C* allele and the *NQO1* 609CC genotype for faster activation and detoxification.

The advantages of our study were that colonoscopy was done non-selectively in a defined population and that the absence of polyp lesions was confirmed in the control subjects by complete colonoscopy. Ethnic homogeneity was another advantage. There were several limitations. Statistical adjustment was not made for dietary factors because such data were not available. Only men were included, and the findings may not be applicable to women. Smoking is much less prevalent in women than in men in Japan[15]. The study subjects were not representative of Japanese men in the general population, but selection was unlikely to have occurred with regard to the genetic polymorphisms under study. The allele and genotype frequencies in the present study population were almost the same as those observed among Japanese individuals elsewhere. Among community controls (n = 778) in a Japanese case-control study of colorectal cancer[15], the frequencies of the *CYP1A1*2A*, *CYP1A1*2C* and *NQO1* 609T alleles were 37%, 23% and 38%, respectively, and the *GSTM1* and *GSTT1* null genotypes accounted for 54% and 44%, respectively. In a random sample of approximately 300 Japanese adults[37], the frequencies of the *CYP1A1*2C* and *NQO1* 609T alleles were 21% and 38%, respectively. Finally, the study size was not sufficiently large to detect a moderately increased risk for the variant homozygote. With two-sided a = 0.05, the power of detecting a 1.5-fold increase in the risk for the variant homozygote in the additive model was 0.66 for *CYP1A1*2A*, 0.39 for *CYP1A1*2C* and 0.65 for *NQO1* C609T.

In conclusion, the combination of *CYP1A1*2C* and *NQO1* 609CC genotype was associated with a decreased risk of colorectal adenomas, regardless of smoking status, in Japanese men. Future studies are needed to clarify the biological mechanisms involved.

COMMENTS

Background

Cigarette smoking has consistently been related to an increased risk of colorectal adenomas, and possibly of colorectal cancer, but the biological mechanisms remain unknown.

Research frontiers

Tobacco smoke contains various types of carcinogens, which are activated by phase Ⅰ enzymes and/or detoxified by phase Ⅱ enzymes. It is a matter of interest whether or not functional genetic polymorphisms of the metabolic enzymes are related to colorectal adenomas and cancer.

Innovations and breakthroughs

Few studies have examined the association of genetic polymorphisms of phase Ⅰ and phase Ⅱ enzymes in combination with colorectal adenomas or cancer. Adenoma risk differed by the combination of genetic polymorphisms of CYP1A1 (phase Ⅰ enzyme) and NAD(P)H-quinone oxidoreductase 1 (NQO1) (phase Ⅱ enzyme), and the association was not modified by smoking.

Applications

The findings confer clues to understanding the biological mechanisms of the association between smoking and colorectal adenomas and cancer.

Terminology

CYP1A1 is responsible for bioactivation of tobacco carcinogens. *CYP1A1*2A* and *CYP1A1*2C* polymorphisms are putatively functional, and have been related to increased risk of tobacco-related cancers; Glutathione *S*-transferases are involved in detoxification of chemical carcinogens, and individuals with the *GSTM1* and/or *GSTT1* null genotype may be susceptible to increased risk of cancer; NQO1 also acts as a phase Ⅱ enzyme, and the 609C>T polymorphism results in loss of NQO1 activity.

Peer review

This was a good study. The study subjects were all male officials in the Self-Defense Forces. Besides smoking, they may have risk factors, such as alcohol drinking and dietary habits, similar to those in the general population.

Abstract

AIM: To identify clinical and pathological differences between serum immunoglobulin G4 (IgG4)-positive (SIP) and IgG4-negative (SIN) type 1 autoimmune pancreatitis (AIP) in South Korea.

METHODS: AIP was diagnosed by the international consensus diagnostic criteria. The medical records and pathology were retrospectively reviewed and IgG4-positive cells were counted in a high power field (HPF). Type I AIP was defined as a high serum level of IgG4 or histological finding. SIN type 1 AIP was defined as a histological evidence of type 1 AIP and a normal serum IgG4 level. The clinical and pathological findings were compared between the two groups. The analysis was performed using Student's *t* test, Fischer's exact test and Mann-Whitney's *U* test. A *P* value of < 0.05 was considered statistically significant. As repeated comparison was made, *P* values of less than 5% ($P < 0.05$) were considered significant.

RESULTS: Twenty five patients with definite type 1 AIP (19 histologically and six serologically diagnosed cases) were enrolled. The mean tissue IgG4 concentrations were significantly higher in SIP than SIN group (40 cells per HPF *vs* 18 cells per HPF, $P = 0.02$). Among eight SIN patients, the tissue IgG4 concentrations were less than 15 cells per HPF in most of cases, except one. The sensitivity of serum IgG4 was 68% (17 SIP and eight SIN AIP). Other organ involvement was more frequently associated with SIP than SIN AIP (59% *vs* 26%, $P = 0.016$). However, the relapse rate and diffuse swelling of the pancreas were not associated with serum IgG4 level. The concentrations of IgG4-positive cells per HPF were higher in SIP than SIN AIP (40 *vs* 18, $P = 0.02$).

CONCLUSION: The sensitivity of serum IgG4 was 68% in type 1 AIP. High serum IgG4 level was associated with other organ involvement and tissue IgG4 concentration but did not affect the relapse rate in type 1 AIP.

Key words: Autoimmunity; Chronic pancreatitis; Immunoglobulin G4-related systemic disease; Lymphoplasmacytic sclerosing pancreatitis; Immunoglobulin G4

Core tip: Type 1 autoimmune pancreatitis (AIP) is one

of the immunoglobulin G4 (IgG4)-related diseases and serum IgG4 is known as a useful diagnostic marker. However, the sensitivity of serum IgG4 is variable. The sensitivity of serum IgG4 was not sufficient (68%) in definite type 1 AIP. The demographic findings were not different between SIP and SIN type 1 AIP, but other organ involvement was significantly more common in SIP than in SIN type 1 AIP. High serum IgG4 level was associated with other organ involvement and tissue IgG4 concentration, but did not affect the relapse rate in type 1 AIP.

INTRODUCTION

Autoimmune pancreatitis (AIP) is a type of chronic pancreatitis with irregular narrowing of the pancreatic duct and systemic fibroinflammatory disease. AIP is characterized by a remarkable response to steroid therapy. According to a multicenter nationwide study in Korea, the prevalence of AIP was 2.0% among 814 patients with chronic pancreatitis[1]. An early report from Japan that proposed the term lymphoplasmacytic sclerosing pancreatitis (LPSP) described some specific morphological features of AIP, such as diffuse lymphoplasmacytic infiltration with marked interstitial fibrosis and obliterative phlebitis[2].

The Japan Pancreas Society proposed diagnostic criteria for the first time in 2002, and the characteristic features of AIP were defined as the elevation of serum immunoglobulin G4 (IgG4) and LPSP on pathology[3]. However, emerging evidence suggests the presence of two AIP types that have different clinical profiles and outcomes. In 2003, a Mayo clinic group found two distinct histological patterns, which were designated LPSP and idiopathic duct-centric chronic pancreatitis (IDCP)[4]. IDCP was characterized by inflammatory infiltrates that were denser in the lobules than in interlobular fibrotic areas.

Recently, the expert panel in the international consensus study has agreed that there are two distinct histopathological types of AIP[5]. Type 1 AIP has dense periductal lymphoplasmacytic infiltrate with storiform fibrosis and obliterative phlebitis, whereas type 2 is distinguished from type 1 by granulocyte epithelial lesions, less prominent lymphoplasmacytic infiltrate, and less prominent storiform fibrosis. Recently, international consensus diagnostic criteria (ICDC) for AIP were developed based on the agreement of an international panel of experts and ICDC include both types 1 and 2 AIP[6].

According to the ICDC, the radiological imaging and the response to steroids are common features of both types 1 and 2 AIP. However, typical serological abnormalities, such as serum IgG4 elevation and other organ involvement, can be seen only in type 1. Thus, for a definitive diagnosis of type 2 AIP, histological confirmation is always necessary. Type 2 AIP is associated with inflammatory bowel disease and affects younger patients without a gender predilection[7]. Both types of AIP respond to steroid very well, but type 2 AIP has a lower relapse rate than type 1 AIP[7].

Although elevation of serum IgG4 is the one of the characteristic features in type 1 AIP, the sensitivity of serum IgG4 is variable. The initial Japanese study reported that the sensitivities of IgG4 were 90.9%[8]. However, other studies reported the sensitivity of IgG4 as approximately 70.0%[9-12]. The problem of the previous studies was that there was no clear classification of AIP type because the study was performed before the concept of type 2 AIP was established. If the study population had included more type 2 AIP, the sensitivity of IgG4 would have been low. However, a recent multicenter study also showed that the sensitivity was only 63.0% among histologically proven type 1 AIP[13]. Type 1 AIP is considered as the pancreatic manifestation of IgG4-related systemic disease in which tissue infiltration of IgG4-positive plasma cells is a characteristic feature[14-16]. However, the reason for the variable level of serum IgG4, the relation between serum level and tissue concentration of IgG4, and clinical significance of serum IgG4 level in type 1 AIP is unknown and remains an interesting issue.

The aim of this study was to find clinical and pathological differences between serum IgG4-positive (SIP) and serum IGg4-negative (SIN) type 1 AIP in Korea.

MATERIALS AND METHODS

Patients

From January 2005 to May 2011, all patients with AIP were retrospectively reviewed at the Seoul National University Hospital. The diagnosis of AIP was based on the ICDC[6] and patients without available serum IgG4 level were excluded. Patients with definite AIP were enrolled. The institutional review board of Seoul National University Hospital approved the study.

Definition of AIP type

The histology was obtained before steroid therapy in all cases. If the histology was available, type 1 AIP was defined as LPSP and type 2 as IDCP. The serum IgG4 level was obtained before steroid therapy and tissue acquisition. If tissue was not obtained, type 1 AIP was also defined if the serum IgG4 level was higher than upper limit of normal value (134 mg/dL). If the patients had no or unclear pathological findings and serum IgG4 level was normal, the patients were classified as indeterminate type and excluded in this study.

Radiological analysis

Pancreatic imaging was categorized as diffuse or segmen-

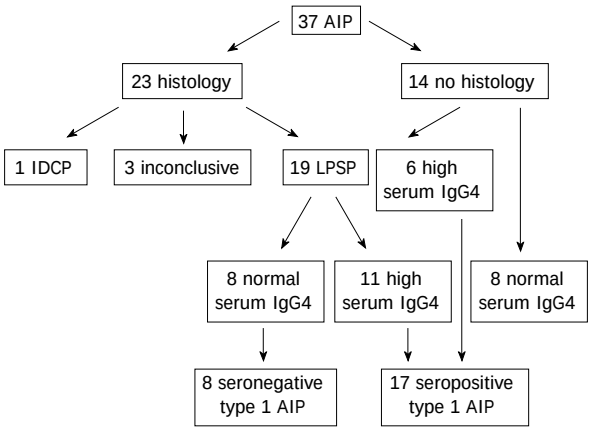

Figure 1 Enrolled patients and classification of autoimmune pancreatitis. Among 37 patients with autoimmune pancreatitis (AIP), one case was type 2 AIP and 19 patients were type 1 AIP by histology. The pathological diagnosis was inconclusive in three cases among 23 tissue samples. Among 14 patients without histology, eight patients were excluded because of normal serum immunoglobulin G4 (IgG4) levels. Ultimately, 25 patients with definite type 1 AIP (19 histologically and six serologically diagnosed cases) were enrolled in this study. LPSP: Lymphoplasmacytic sclerosing pancreatitis; IDCP: Idiopathic duct-centric chronic pancreatitis.

tal swelling by computed tomography (CT) scan. The presence of extrapancreatic lesions included sclerosing cholangitis, sclerosing sialoadenitis, lymphadenopathy, retroperitoneal fibrosis, and ulcerative colitis. Sclerosing cholangitis was defined as the presence of benign stricture of the bile duct on cholangiography. The stricture of only lower bile duct was not included in sclerosing cholangitis. The presence of sialoadenitis, lymphadenopathy and retroperitoneal fibrosis was determined based on CT findings.

Steroid therapy and relapse

Steroid therapy was done at 0.6 mg/kg per day of prednisolone for one month and gradually tapered to a maintenance dose over three months. Steroid maintenance therapy (5 mg/d) was administered for 6 mo to prevent relapse. Relapse was defined as a recurrence of symptoms with the development of pancreatic or extrapancreatic abnormal findings on imaging studies.

Histological examination

Surgically resected or core biopsied specimens were reviewed by a specialist pathologist without any clinical information. Fine needle aspiration specimens were not considered as available histology and not reviewed. All specimens were stained with anti-IgG4 antibody for immunohistochemical examination. The number of IgG4-positive plasma cells was counted in a high power field (HPF). In surgical specimens, LPSP was defined with at least three of the four characteristic features which are (1) dense infiltration of plasma cells and lymphocytes, particularly periductal; (2) peculiar storiform fibrosis; (3) venulitis with lymphocytes and plasma cells often leading to obliteration of the affected veins; and (4) abundant (> 10 cells per HPF) IgG4-positive plasma cells. In biopsy specimens, AIP was considered with lymphoplasmacytic infiltration with fibrosis and abundant (> 10 cells per HPF) IgG4-positive plasma cells.

Statistical analysis

Statistical analysis was done with statistical software (SPSS version 19.0 for Windows, SPSS Inc, Chicago, IL, United States; MedCalc version 11.5.0.0, MedCalc Software, Mariakerke, Belgium). The data were compared between two groups. The analysis was performed using Student's *t* test, Fischer's exact test and Mann-Whitney's *U* test. A *P* value of < 0.05 was considered statistically significant. As repeated comparisons were made, *P* values of less than 5% ($P < 0.05$) were considered significant.

RESULTS

Enrolled patients and classification of AIP

Thirty seven patients with AIP were enrolled and histology was available for 23 patients (Figure 1). Among 23 patients with histology, 19 patients showed typical finding of type 1 AIP and were confirmed as type 1 AIP. Only one patient was histologically confirmed as a type 2 AIP and had a history of ulcerative colitis. The pathological diagnosis was inconclusive in three cases among eight core biopsies. One type 2 and three SIN AIP patients with inconclusive pathology were excluded from this study. Among 19 patients with type 1 AIP, 11 patients had high serum IgG4 level and eight patients had normal levels. Among 14 patients without histology, six patients had elevated serum IgG4 levels (146, 213, 250, 279, 300 and 4000 mg/dL) and were included in type 1 AIP. Another eight patients with normal serum IgG4 levels were classified as indeterminate AIP and excluded from this study. Ultimately, 17 patients with SIP type 1 AIP and eight patients with SIN type 1 AIP were enrolled in this study. The median age was 61 years (range, 33-84 years) and males were predominant (72%). The sensitivity of serum IgG4 was 68.0%.

Comparison of SIP and SIN type 1 AIP

The mean age of the two groups was similar (62 years *vs* 60 years in SIP and SIN type 1 AIP) and there was no difference in sex between two groups (Table 1). The diffuse type of AIP seemed to be more common in the SIP than in the SIN group (47% *vs* 31%) but the difference was not significant ($P = 0.39$). The median serum IgG4 level was 312 mg/dL (normal range, 145-4000 mg/dL) in the SIP group and was 33 mg/dL (normal range, 6-75 mg/dL) in the SIN group and the difference was significant ($P = 0.03$). The patients of the SIP group were more likely to have other organ involvement than those of the SIN group (59% *vs* 26%, $P = 0.016$). Among the SIP group, sclerosing cholangitis was the most common (four cases) and sialoadenitis was also common (three cases) as other organ involvement. Retroperitoneal fibrosis, mediastinal lymphadenitis and lacrimal gland also represented other organ involvements. Among the SIN group, one patient

SIP: Serum immunoglobulin G4 (IgG4)-positive; SIN: Serum IgG4-negative; F: Female; M: Male.

had retroperitoneal fibrosis. Only one patient with sclerosing cholangitis was pathologically confirmed as an other organ involvement and other patients were diagnosed with only image and steroid responsiveness. The surgical resection rate was higher in the SIN than in the SIP group (75% *vs* 26%, $P = 0.018$). The mean follow up duration was not different between the two groups (30 mo *vs* 16 mo in SIP and SIN groups, $P = 0.075$). All patients, except those who received surgical resection, received steroid treatment and the response rate was 100% in both SIP and SIN groups. The relapse rate was not different between the two groups (36% *vs* 25% in SIP and SIN group, $P = 0.80$). The mean interval from steroid treatment and relapse was not different between the two groups (14 mo *vs* 11 mo in SIP and SIN groups, $P = 0.82$).

Correlation between serum and tissue IgG4 concentrations

Among the 25 patients with type 1 AIP, 19 patients had tissue specimens, which included 11 SIP and 8 SIN groups. The mean tissue IgG4 concentrations were significantly higher in the SIP than the SIN group (40 cells per HPF *vs* 18 cells per HPF, $P = 0.02$). Among eight SIN patients, the tissue IgG4 concentrations were less than 15 cells per HPF in most of cases, except one (Figure 2). Among 11 SIP patients, the tissue IgG4 concentrations were more than 25 cells per HPF, except for one case (15 cells per HPF). However, there was no linear correlation between serum and tissue IgG4 concentration among the 11 SIP patients.

Clinical features of eight patients with SIN type 1 AIP

The clinical features of eight patients with SIN type 1 AIP are summarized in Table 2. Three cases were typical diffuse type AIP. However, surgical resection was done in two cases because serum IgG4 was normal and the possibility of malignancy could not be excluded in the early period (2005). For four cases with segmental type, surgical resections were performed because the possibility of malignancy could not be excluded by imaging at that time. Only one patient had retroperitoneal fibrosis and experienced disease relapse. Six patients who received surgical resection could be confirmed as type 1 AIP with LPSP (level 1 criterion) and level 1/2 parenchymal imaging. One patient (case 3) had level 1 parenchymal imaging and level 2 histology. The other patient (case 4) could be diagnosed as type 1 AIP with level 1 ductal imaging, level 2 histology and response to steroids.

Table 2 Clinical features of eight patients with serum immunoglobulin G4-negative type 1 autoimmune pancreatitis

Patients	Age/ sex	Tissue	Image	OOI	Serum IgG4 (mg/dL)	Tissue IgG4 in HPF	Relapse

Case 8	53/F	Resection	Body	No	11	12	No

OOI: Other organ involvement; RF: Retroperitoneal fibrosis; HPF: High power field; F: Female; M: Male; IgG4: Immunoglobulin G4.

One patient had a relatively high tissue IgG4 concentration (80 cells per HPF) despite a low serum IgG4 level (43 mg/dL). He was 61-year-old male and a mass was detected incidentally at the body of the pancreas. Magnetic resonance image (MRI) findings also showed a slightly exophytic mass of iso-attenuation at the body of the pancreas with distal parenchymal atrophy and an abrupt cutting of the pancreatic duct was noticed with upstream ductal dilatation (Figure 3). Image findings were compatible with pancreatic cancer and a distal pancreatectomy was performed. Gross pathological finding showed a 1.3 cm × 1.2 cm × 3 cm sized white solid mass with uncertain margins. Microscopy showed dense periductal lymphoplasmacytic infiltration, storiform fibrosis and obliterative phlebitis (Figure 4A). The IgG4 immunohistochemistry also showed dense infiltration (80 cells per HPF) (Figure 4B). After the operation, he did not develop any symptoms or signs of recurrence for 3 years of follow-up.

DISCUSSION

IgG4-related disease was recognized as a systemic disease since 2003[17] and AIP was proposed as one of the IgG4-related sclerosing diseases in 2006[18]. Since then, two histopathological subtypes, LPSP and IDCP, have been recognized[19]. Type 1 AIP is now considered as the pancreatic manifestation of an IgG4-related systemic fibroinflammatory diseases involving the salivary gland, bile duct, and retroperitoneum. Thus, serum IgG4 is a useful marker for the diagnosis of type 1 AIP and most diagnostic criteria of AIP include serum IgG4 elevation as one of the criteria[6,9,20]. However, the sensitivity of serum IgG4 is variable and different among countries. If the

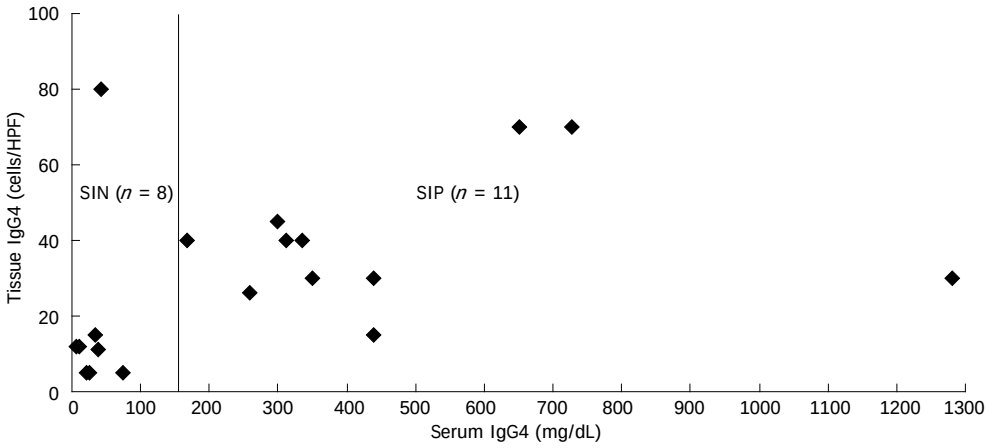

Figure 2 Correlation between serum and tissue immunoglobulin G4 concentrations. Among eight serum immunoglobulin G4 (IgG4)-negative (SIN) patients, the tissue IgG4 concentrations were less than 15 cells per high power filed (HPF) in most of cases, except one. Among 11 serum IgG4-positive (SIP) patients, the tissue IgG4 concentrations were more than 25 cells per HPF, except one case (15 cells per HPF). There was no linear correlation between serum and tissue IgG4 concentration among the 11 SIP patients.

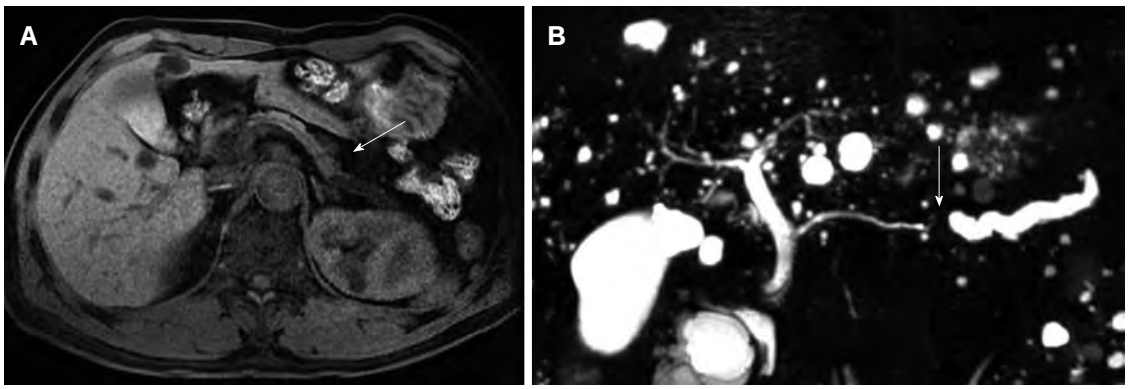

Figure 3 Magnetic resonance image of 61-year-old male patient with normal serum immunoglobulin G4. A: Magnetic resonance image shows slightly exophytic mass of iso-attenuation at the body of pancreas; B: Distal parenchymal atrophy and abrupt cutting of pancreatic duct with upstream ductal dilatation.

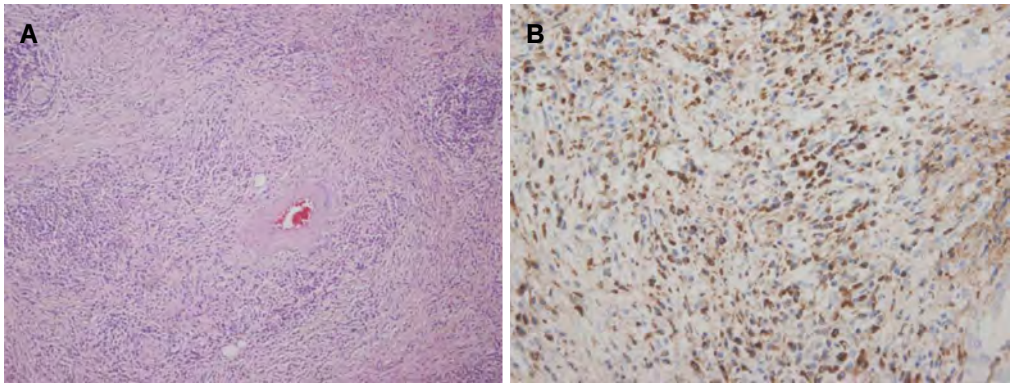

Figure 4 Histology and immunoglobulin G4 immunohistochemical staining. A: Hematoxylin and eosin staining shows typical finding of lymphoplasmacytic sclerosing pancreatitis (× 200); B: Immunoglobulin G4 (IgG4) staining shows dense infiltration of IgG4 positive cells (× 400).

study population includes more type 2 AIP, the sensitivity of IgG4 may be low because serum IgG4 is not usually elevated in type 2 AIP. A recent international multicenter study, which enrolled 713 patients with AIP from eight countries, reported that sensitivity of serum IgG4 was only 63% among 204 patients with histologically proven type 1 AIP[13]. The relatively low sensitivity of serum IgG4 can make the diagnosis of AIP in the clinical setting confusing. In our study, four patients with segmental type AIP underwent unnecessary surgical resection.

We questioned why the serum IgG4 test was not sufficiently sensitive if type 1 AIP is a type of IgG4-related

systemic disease. Therefore, we conducted our study to analyze the clinical and pathological differences between SIP and SIN type 1 AIP. Unfortunately, there have been few studies concerning the normal serum IgG4 AIP[21,22]. One study included 58 AIP patients including 13 normal serum IgG4 AIP[21] but histology was available in only 14 cases (six cases among 13 SIN AIP). Another study included 27 patients with AIP, including seven SIN AIP[22]. Histology was not available in any cases because endoscopic ultrasonography guided fine needle aspiration was performed in 26 cases using 22 gauge needle, not to diagnose AIP, but to exclude pancreatic malignancy. Thus, it could not be determined that all of the enrolled patients were really type 1 AIP in both studies. To exclude possible type 2 AIP, our study enrolled 19 patients with histologically proven type 1 AIP and six patients who were clinically diagnosed as type 1 AIP with elevated serum IgG4 levels. Of course, there is the possibility of type 2 AIP despite the elevated serum IgG4 level among six patients, because serum IgG4 elevation was detected in 23% among 47 patients with histologically proven type 2 AIP according to a recent study[13]. However, the possibility might be very low, because the serum IgG4 level was relatively high (213, 250, 279, 300, 4000 mg/dL), except in one case (146 mg/dL) and type 2 AIP was reported to be relatively rare in Asian countries, including South Korea[13]. In addition, five patients had other organ involvement, which is rarely be seen in type 2 AIP[7].

The surgical resection rate was higher in the SIN than the SIP group. One reason could be a difficult diagnosis of AIP. If the lesion is in the body/tail and serum IgG4 is normal, the clinicians would not suspect the possibility of AIP and would not hesitate to perform a surgical resection. Another reason might be selection bias of this study, because we excluded eight patients with normal serum IgG4 and no histology. The eight patients received steroid treatment and their steroid responsiveness was 100%. One patient experienced a relapse.

In this study, the clinical profiles of type 1 AIP were similar to another recent multicenter study including 327 Asian patients[12]. The higher mean age (over 60 year), male predominance, common other organ involvement, especially sclerosing cholangitis and frequent relapse, are common features of Asian patients of AIP that are similar to our study. Interestingly, the important clinical difference between SIP and SIN type 1 AIP was the frequency of other organ involvement. Other organ involvement was significantly more common in SIP than SIN type 1 AIP (59% *vs* 26%). Only one patient among the SIN group had retroperitoneal fibrosis. This result implies that other organ involvement can affect the serum IgG4 level. Mikulicz's disease refers to idiopathic symmetrical swelling of the lacrimal, submandibular gland and is an IgG4-related systemic disease. A recent study reported that the serum IgG4 level is very high (894 mg/dL) in Mikulicz's disease and significantly higher in patients with extrasalivary gland involvement[23]. More frequent other organ involvement in our SIP type 1 AIP is similar to the results of previous studies[21,22,24].

Another reason for variable serum IgG4 levels may be the number of IgG4-positive plasma cells in the tissue. As expected, the mean tissue IgG4 concentration was significantly low in SIN compared with SIP type 1 AIP. All patients in the SIP group had high IgG4 concentrations (over 25 cells per HPF), except one case (15 cells per HPF). However, the patients in the SIN group had very low IgG4 concentrations (below 15 cells per HPF), except one case (80 cells per HPF). The data might lead us to conclude that the IgG4 concentration of pancreatic tissue can influence the sensitivity of serum IgG4 in type 1 AIP. However, the serum level of IgG4 had no correlation with tissue IgG4 concentration in SIP type 1 AIP. Thus the serum level may be influenced by not only tissue concentration, but also other factors, such as the size of the involved pancreas and other organ involvement. We think that this is the first study to investigate the correlation between serum and tissue IgG4 concentration in type 1 AIP.

Other possible clinical roles of serum IgG4, other than as a diagnostic marker, are uncertain and are a interesting issue in type 1 AIP. The clinical use of serum IgG4 may be relevant in three settings: monitoring of therapy, monitoring for disease relapse and prediction of relapse. The large multicenter study in Japan reported that IgG4 levels failed to normalize in 115/182 (63%) of the patients treated with steroids[25]. The study suggested that serial IgG4 levels are helpful in identifying early relapse. However, only 30% of patients with persistent IgG4 elevation relapsed, whereas relapse was also seen in 10% of patients with normal IgG4 levels. The results regarding the value of initial serum IgG4 levels in predicting relapse vary among studies, some reporting higher relapse rate in patients with elevated serum IgG4 levels[22,26], whereas others failed to observe any association[7,27-29]. To clarify the role of serum IgG4 in predicting relapse, type 2 AIP should be excluded in the normal serum IgG4 group, because type 2 AIP is known for rare relapse[7]. The positive study might include some patients with type 2 AIP. In our study, the relapse rate was similar between the two groups of type 1 AIP. Thus, our data supports the view that initial serum IgG4 levels cannot predict relapse in type 1 AIP.

In conclusion, the sensitivity of serum IgG4 was not sufficient (68%) for definite diagnosis of type 1 AIP. The demographic findings were similar between SIP and SIN type 1 AIP, but other organ involvement was significantly more common in SIP than SIN type 1 AIP. High serum IgG4 level was associated with other organ involvement and tissue IgG4 concentration, but did not affect the relapse rate in type 1 AIP.

COMMENTS

Background

Type 1 autoimmune pancreatitis (AIP) is one of the immunoglobulin G4 (IgG4)-related diseases and serum IgG4 is known as a useful diagnostic marker.

However, the sensitivity of serum IgG4 is variable. AIP is a type of chronic pancreatitis with irregular narrowing of the pancreatic duct and systemic fibro-inflammatory disease and is characterized by a remarkable response to steroid therapy.

Research frontiers

IgG4-related disease was recognized as a systemic disease in 2003 and AIP was proposed as one of the IgG4-related sclerosing diseases in 2006. Two histopathological subtypes, lymphoplasmacytic sclerosing pancreatitis and idiopathic duct-centric chronic pancreatitis, have been recognized, and type 1 AIP is now considered as the pancreatic manifestation of an IgG4-related systemic fibroinflammatory diseases involving the salivary gland, bile duct, and retroperitoneum. Thus, serum IgG4 is a useful marker for the diagnosis of type 1 AIP and most diagnostic criteria of AIP include serum IgG4 elevation as one of the criteria. However, the sensitivity of serum IgG4 is variable and different among countries.

Innovations and breakthroughs

The sensitivity of serum IgG4 was not sufficient (68%) for defining type 1 AIP. The demographic findings were similar between serum IgG4-positive (SIP) and serum IgG4-negative (SIN) type 1 AIP, but other organ involvement was significantly more common in SIP than SIN type 1 AIP. High serum IgG4 level was associated with other organ involvement and tissue IgG4 concentration, but did not affect the relapse rate in type 1 AIP.

Peer review

The authors compared the clinical and pathological differences between serum IgG4-positive and IgG4-negative type 1 autoimmune pancreatitis and demonstrated that the sensitivity of serum IgG4 was 68% in type 1 AIP. The high serum IgG4 level was associated with other organ involvement and tissue IgG4 concentration, but did not affect the relapse rate in type 1 AIP.

Abstract

AIM: To investigate control of two different types of massive presacral bleeding according to the anatomy of the presacral venous system.

METHODS: A retrospective review was performed in 1628 patients with middle or low rectal carcinoma who were treated surgically in the Department of Colorectal Surgery, Changhai Hospital, Shanghai, China from January 2008 to December 2012. In four of these patients, the presacral venous plexus (n = 2) or basivertebral veins (n = 2) were injured with massive presacral bleeding during mobilization of the rectum. The first two patients with low rectal carcinoma were operated upon by a junior associate professor and the source of bleeding was the presacral venous plexus. The other two patients with recurrent rectal carcinoma were both women and the source of bleeding was the basivertebral veins.

RESULTS: Two different techniques were used to control the bleeding. In the first two patients with massive bleeding from the presacral venous plexus, we used suture ligation around the venous plexus in the area with intact presacral fascia that communicated with the site of bleeding (surrounding suture ligation). In the second two patients with massive bleeding from the basivertebral veins, the pelvis was packed with gauze, which resulted in recurrent bleeding as soon as it was removed. Following this, we used electrocautery applied through one epiploic appendix pressed with a long Kelly clamp over the bleeding sacral neural foramen where was felt like a pit Electrocautery adjusted to the highest setting was then applied to the clamp to "weld" closed the bleeding point. Postoperatively, the blood loss was minimal and the drain tube was removed on days 4-7.

CONCLUSION: Surrounding suture ligation and epiploic appendices welding are effective techniques for controlling massive presacral bleeding from presacral venous plexus and sacral neural foramen, respectively.

Key words: Massive presacral bleeding; Rectal surgery; Suture ligation; Welding

Core tip: Massive presacral bleeding is an uncommon but potentially life-threatening complication of rectal surgery. It is difficult to control the bleeding and several alternative techniques for hemostasis have been proposed. We described the use of two simple and effective techniques for controlling two different types of massive presacral bleeding, classified according to the anatomy of the presacral venous system.

Lou Z, Zhang W, Meng RG, Fu CG. Massive presacral bleeding during rectal surgery: From anatomy to clinical practice. *World J Gastroenterol* 2013; 19(25): 4039-4044 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4039.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4039

INTRODUCTION

Massive presacral bleeding is a potentially life-threatening complication of rectal surgery and remains one of the most challenging intraoperative emergencies to colorectal surgeons[1,2]. The incidence and the mortality have been reported as high as 9.4% and 4.3%, respectively[3,4]. Total mesorectal excision was introduced in 1982 and is considered the gold standard with an acceptable intraoperative risk for rectal carcinoma[5]. However, massive presacral bleeding remains inevitable, especially in recurrent rectal carcinoma or in operations performed by junior colorectal surgeons. Several hemostatic techniques for controlling this intraoperative emergency have been proposed, such as the use of thumbtacks, bone wax, balloon tamponade, and endoscopic stapling[6-8]. However, some techniques fail to arrest the bleeding[9], resulting in shock and even death.

Based on the anatomy of presacral venous system, massive presacral bleeding can be divided into two different types. In our opinion, the key feature in controlling massive presacral bleeding is correct judgment of the bleeding type. Here, we report our experience with massive presacral bleeding and describe the use of two simple and effective techniques (surrounding suture ligation and epiploic appendices welding) for controlling two different types of massive presacral bleeding according to the anatomy of the presacral venous system. To the best of our knowledge, there are no reports of this hemostatic strategy in the literature.

MATERIALS AND METHODS

This was a retrospective review of 1628 patients with middle or low rectal carcinoma who were treated surgically in the Department of Colorectal Surgery, Changhai Hospital, Shanghai, China from January 2008 to December 2012 (Table 1). All the patients who sustained massive presacral bleeding during mobilization of the rectum were recorded.

In four of these patients, the presacral venous plexus (n = 2) or basivertebral veins (n = 2) were injured. The first two patients (a 63-year-old woman and a 58-year-old man) with low rectal carcinoma were operated upon by a junior associate professor and the source of bleeding was the presacral venous plexus. The other two patients with recurrent rectal carcinoma were both women (aged 69 and 72 years, respectively). The rectal stumps were found to be densely adherent to the surrounding structures and the source of bleeding was the basivertebral veins. Two different techniques were used to control the bleeding.

Table 1 Adjuvant therapy for low rectal dissection in 1628 patients n (%)

Adjuvant therapy	Patients	Patients with bleeding
Rectal carcinoma	1606	2 (0.12)
Without neoadjuvant therapy	1463	2 (0.14)
With neoadjuvant radiotherapy	89	0 (0.00)
With neoadjuvant chemotherapy	29	0 (0.00)
With neoadjuvant radiochemotherapy	25	0 (0.00)
Recurrent rectal carcinoma	22	2 (9.00)
With preoperative radiotherapy	6	0 (0.00)
With preoperative chemotherapy	1	0 (0.00)
With preoperative radiochemotherapy	3	0 (0.00)
Without preoperative radiotherapy	12	2 (16.7)

RESULTS

In the first patient with massive bleeding from the presacral venous plexus, suture ligation was used initially to control the bleeding, which exacerbated the bleeding. As an alternative, the pelvis was packed with gauze, which resulted in recurrent bleeding as soon as the packing was removed. Following this, we tried to perform suture ligation around the venous plexus in the area with intact presacral fascia that communicated with the bleeding site (surrounding suture ligation). The bleeding stopped after 11 attempts at suture ligation. The patient underwent a super-low anterior resection with protective ileostomy. The estimated blood loss was 2000 mL. In the second patient with massive bleeding from the presacral venous plexus, we used the same technique to control bleeding with eight attempts at surrounding suture ligation. The estimated blood loss was 800 mL.

In the following two patients with massive bleeding from the basivertebral veins, the pelvis was packed with gauze, which resulted in recurrent bleeding as soon as it was removed. In the first of these patients, we tried to control bleeding by surrounding suture ligation initially. However, this technique was unsuccessful. Following this, we used electrocautery applied through one epiploic appendix pressed with a long Kelly clamp over the bleeding sacral neural foramen where was felt like a pit. First, fingertip pressure was applied directly to the sacral neural foramen to control the bleeding. Then, one epiploic appendix, 1-2 cm in diameter, was excised and mounted on a long Kelly clamp. The finger was rapidly withdrawn and the epiploic appendices pressed directly over the sacral neural foramen. Electrocautery adjusted to the highest setting was applied to the clamp to "weld" closed the bleeding point. The bleeding stopped after 3 min. In this patient, blood loss was 6000 mL. In the last patient with massive bleeding from the basivertebral veins, we used the same technique to control bleeding within 10 min. The estimated blood loss was 600 mL. Intraoperative data are shown in Table 2.

Postoperatively, the blood loss was minimal and the drain tube was removed on days 4-7. Patients were discharged on day 8 and they all returned for ileostomy reversal 3 mo later.

DISCUSSION

Massive presacral bleeding is considered to be an intraoperative emergency during rectal surgery. The anatomy of the presacral venous system makes it vulnerable to serious bleeding that can often be difficult to control[10]. The

Table 2 Patients with massive presacral bleeding

Patient	Sex	Age (yr)	TNM stage	Surgical procedure	Blood loss (mL)	Procedures used to control bleeding	Postoperative complication
1	Female	63	T4N0M0	AR + ileostomy	2000	Surrounding suture ligation	None
2	Male	58	T4N1M0	AR + ileostomy	800	Surrounding suture ligation	None
3	Female	69	Recurrent	AR + ileostomy	6000	Epiploic appendices welding	None
4	Female	72	Recurrent	APR	600	Epiploic appendices welding	None

TNM: Tumor-node-metastasis; AR: Anterior resection; APR: Abdominoperineal resection.

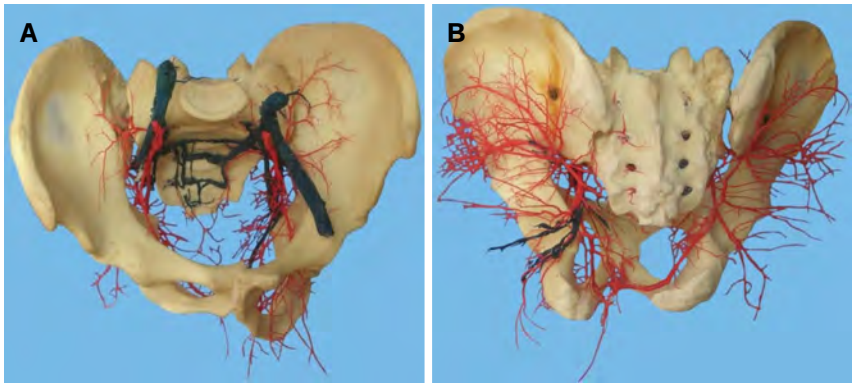

Figure 1 Presacral vascular cast. A: Front view; B: Dorsal view.

presacral venous plexus runs into the pelvic fascia that covers the anterior aspect of the sacrum. It is formed by the two lateral sacral veins, the middle sacral vein, and the in-between communicating veins. These veins are avalvular and communicate *via* the basivertebral veins with the internal vertebral venous system (Figure 1)[11]. Massive presacral bleeding can be divided into two different types according to the anatomy. The first type of bleeding arises from the presacral venous plexus. It may be massive, but can be stopped by suture ligation. The other type is massive, high-pressure bleeding that can be controlled only by pressing the sacrum with the finger or gauze. This type of bleeding originates from the sacral neural foramen where the basivertebral vein is injured[12]. When the patient is in the lithotomy position, the hydrostatic pressure is increased 2-3 times above the pressure in the inferior vena cava[13]. This avalvular system communicates with the vertebral veins, which explains why it is difficult to stop the bleeding.

Intraoperative massive bleeding may be more common during difficult operations in patients with large and fixed tumors, neoadjuvant radiotherapy, and recurrent rectal carcinoma[14]. The rate of massive presacral bleeding was higher in patients with recurrent rectal carcinoma than in those with rectal carcinoma (9.0% *vs* 0.12%, $P = 0.001$). The higher incidence of this emergency in patients with recurrent rectal carcinoma might be related to the more difficult dissection that results from fibrosis and anatomical disruption in this area. The expectation that resection of locally advanced tumors carries a higher risk of presacral vessel lesions was not confirmed in our study because we studied a small number of cases in a single institution.

Incorrect pelvic contraction or inappropriate manipulation is the most common cause of injury to the presacral venous plexus in patients without the above common contributing factors. In this series, two operations with massive presacral bleeding were performed by a junior associate professor. Initial suture ligation was performed incorrectly, which caused more massive bleeding and blood loss was estimated at 2000 mL. Massive bleeding was eventually controlled using or surrounding suture ligation technique. Blood loss was likely related to the extent and site of intraoperative vessel injury, the specific management of the bleeding, and the expertise of the surgeon[1].

The main clinical characteristics of massive presacral bleeding include: (1) bleeding that occurs suddenly during mobilization of the rectum, which can quickly lead to hemorrhagic shock and even result in death; (2) gushing of blood from the pelvic floor, which makes the bleeding site undetectable; (3) ligation of the internal iliac vessel is futile; and (4) bleeding does not stop, even in hemorrhagic shock. According to previous reports, blood loss in presacral bleeding ranges between 300 and 7800 mL[12]. Most of these patients need blood transfusion. In our study, blood loss ranged between 600 and 6000 mL (mean, 2350 mL), and three patients needed blood transfusions. In patients with colorectal carcinoma undergoing surgery, blood transfusion is associated with adverse clinical outcomes, including increased mortality[15]. Therefore, it is important to use a simple and effective procedure to control massive presacral bleeding in rectal surgery.

In our experience, whenever massive presacral bleeding occurs, the first step is direct pressure with the finger at the bleeding point. At the same time, surgeons should inform an anesthetist to prepare sufficient blood. When the bleeding point cannot be exposed clearly, gauze should be pressed directly over the presacral area and the pressure maintained for 15-20 min. The blood surround-

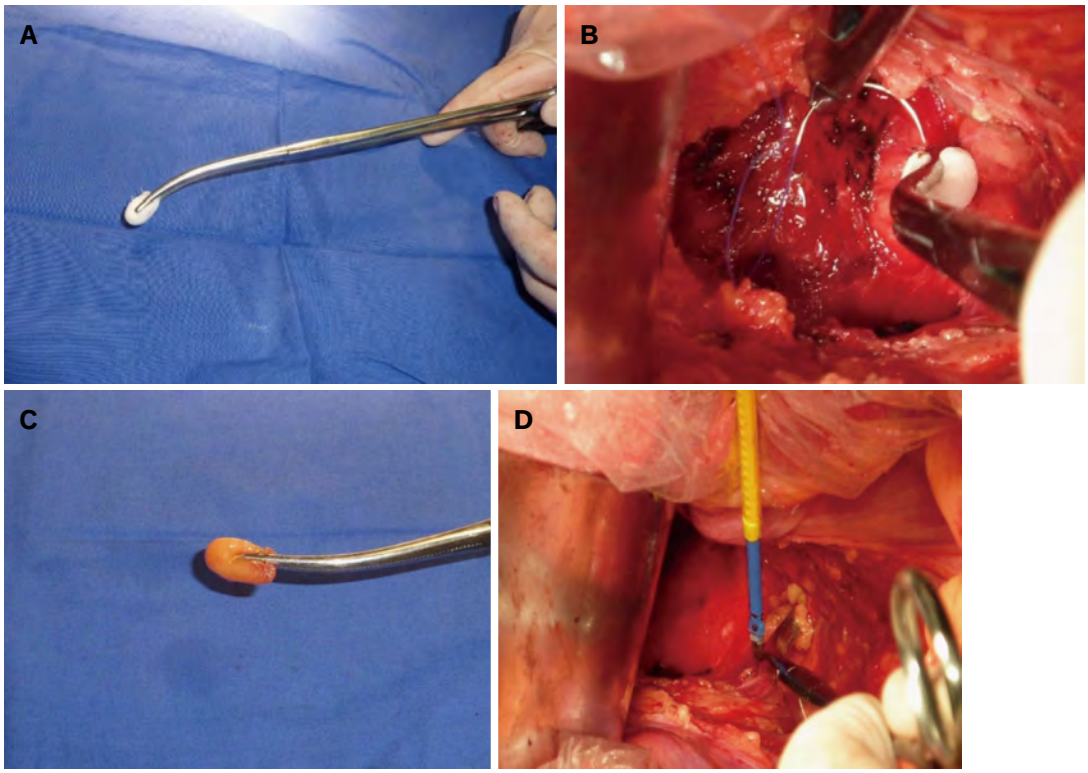

Figure 2 Bleeding point originated from the presacral venous plexus and a sacral neural foramen where the basivertebral veins were injured. A: Continuous pressure over the bleeding site using a gauze nut at the tip of a long Kelly clamp; B: Venous branches surrounding the gauze nut could be identified, and were suture ligated one by one with 3-0 suture thread; C: Continuous pressure over the bleeding site using the epiploic appendices at the tip of a long Kelly clamp; D: Electrocautery applied through the epiploic appendices pressed with a long Kelly clamp over the bleeding vessel.

ing the gauze should be removed by suction. If possible, the specimen should be removed to achieve better exposure. Next, the surgeon should remove the packing gauze, slowly exposing the bleeding point. The bleeding type should been distinguished as soon as possible and an appropriate hemostatic technique can be deployed.

In the first type of massive presacral bleeding, the bleeding point originates from the presacral venous plexus. In our experience, appropriate suture ligation remains an effective method to control this type of bleeding. It should be performed by an experienced surgeon, maintaining continuous pressure over the bleeding site using a gauze nut at the tip of a long Kelly clamp. Surgeons should continue to mobilize the rectum to achieve better exposure if possible. In cases in which the venous branches surrounding the gauze nut can be identified, they are suture ligated one by one with suture thread (VCP772D; Ethicon). Importantly, the suture-ligated tissues should include the presacral fascia, presacral veins, and deep connective tissues. Suture ligation should be performed where the presacral fascia is intact. Jiang *et al*[16] have reported that circular suture ligation of the venous plexus in the area with intact presacral fascia that surrounds the bleeding site is an effective and simple technique to control presacral venous bleeding. In the present study, this type of bleeding was successfully controlled in two patients by the surrounding suture ligation technique (Figure 2A and B).

However, there are several limitations to the surrounding suture ligation technique. First, it can be difficult for bleeding occurring at the bottom of a narrow pelvis, which is typical in patients with obesity[16]. Second, previous rectal surgery can lead to fibrosis of the presacral area, which increases the difficulty in identification of presacral vein distribution and suture ligation. Assessment of the vein locations according to the typical pattern of vein distribution could be wrong, leading to failure of bleeding control. We performed surgery for recurrent rectal carcinoma in two cases. Surrounding suture ligation technique was ineffective because vessel distribution was difficult to identify. Lastly, for bleeding coming from a retracted vein inside the sacrum, other techniques may be used to control the massive bleeding.

In the second type of massive presacral bleeding, the bleeding point originates from a sacral neural foramen where the basivertebral veins are injured.

Harrison *et al*[17] have reported a technique of muscle fragment welding to control presacral bleeding during rectal mobilization. We performed this technique in two cases whose bleeding points originated from a sacral neural foramen during surgery for recurrent rectal carcinoma. This type of bleeding was effectively controlled using electrocautery applied through the epiploic appendices pressed with a long Kelly clamp over the bleeding vessel (Figure 2C and D). Compared with the technique of muscle fragment welding, it is easier to excise one epiploic appendix than a muscle fragment. Because of the round shape of the epiploic appendices, it is easier to fill

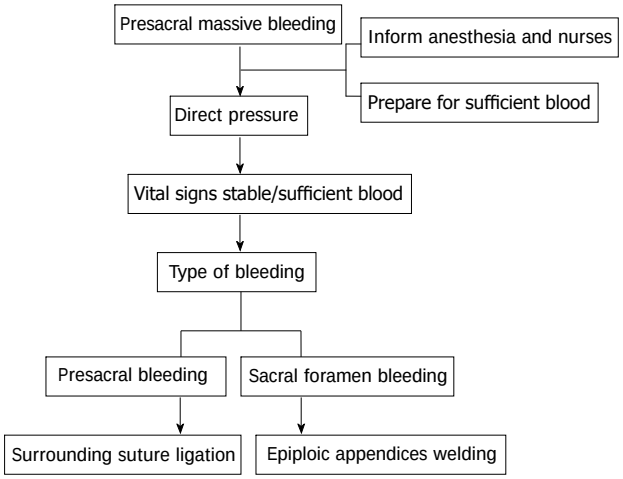

Figure 3 Process in the management of massive presacral bleeding.

the sacral neural foramen. The cauterized epiploic appendices usually adhere to the presacral tissue as a charred coagulum. Hemostasis was immediate and permanent, and no major complications were noted. This technique is intended to deliver heat energy through the forceps to the epiploic appendices. The epiploic appendices act primarily as a fluid-containing electrode that allows conduction of energy and heat to the basivertebral veins. The temperature increases gradually and coagulation is achieved. As in a previous study, necrosis and subsequent abscess development were not seen in our patients, and this may be related to the hypervascular nature of the presacral area and revascularization of the small segment of the epiploic appendices[18].

Alternative methods have been described in the literature. Pelvic packing effectively controls massive presacral bleeding. Intra-abdominal packing should be familiar to colorectal surgeons because when other attempts to provide hemostasis fail, it can be the last resort to control life-threatening bleeding[19]. Packing gauze must be carefully removed at a planned second laparotomy when the patient has stabilized hemodynamically. However, there is a risk of infection or secondary complication from foreign bodies.

Nowadays hemostatic agents are readily available. Some authors have reported that they are effective in stopping bleeding from presacral veins[20-30]. However, in our experience, they are ineffective in stopping massive presacral bleeding. Hemostatic agents may be considered in cases of little bleeding when other techniques have failed.

In conclusion, surrounding suture ligation and epiploic appendices welding are safe, readily available, and highly effective techniques for controlling massive presacral bleeding from the presacral venous plexus and sacral neural foramen, respectively (Figure 3).

COMMENTS

Background

Massive presacral bleeding is a potentially life-threatening complication of rectal surgery and remains one of the most challenging intraoperative emergencies. The incidence and mortality have been reported to be as high as 9.4% and 4.3%, respectively. Total mesorectal excision was introduced in 1982 and is considered a gold standard with an acceptable intraoperative risk during surgery for rectal carcinoma. However, massive presacral bleeding remains inevitable, especially in surgery for recurrent rectal carcinoma or during operations performed by junior colorectal surgeons.

Research frontiers

Several hemostatic techniques for controlling this intraoperative emergency have been proposed, such as the use of thumbtacks, bone wax, balloon tamponade, and endoscopic stapling. However, some techniques fail to arrest the bleeding, resulting in shock and even death.

Innovations and breakthroughs

Based on the anatomy of the presacral venous system, massive presacral bleeding can be divided into two different types. The key factor in controlling massive presacral bleeding is correct assessment of the bleeding type. This article reports two simple and effective techniques for controlling two different types of massive presacral bleeding, classified according to the anatomy of the presacral venous system. According to the authors, there are no reports of this hemostatic strategy in the literature.

Applications

Surrounding suture ligation and epiploic appendices welding are safe, readily available, and highly effective techniques for controlling massive presacral bleeding from the presacral venous plexus and sacral neural foramen, respectively.

Terminology

Presacral bleeding is considered to be an intraoperative emergency in rectal surgery. The anatomy of the presacral venous system makes it vulnerable to serious bleeding that can often be difficult to control.

Peer review

The literature review indicates a large body of work on presacral bleeding already. Often a greater number of techniques described equates to a lack of a gold standard of care, which can be problematic in whatever field. This article outlines two useful and effective techniques to deal with this severe, although not frequent, complication of rectal surgery. The results are interesting and suggest that surrounding suture ligation and epiploic appendices welding for controlling two different types of massive presacral bleeding are simple and effective techniques.

Abstract

AIM: To evaluate the clinical outcome of re-operation for recurrent abdominal liposarcoma following multidisciplinary team cooperation.

METHODS: Nineteen consecutive patients who had recurrent abdominal liposarcoma underwent re-operation by the retroperitoneal sarcoma team at our institution from May 2009 to January 2012. Patient demographic and clinical data were reviewed retrospectively. Multidisciplinary team discussions were held prior to treatment, and re-operation was deemed the best treatment. The categories of the extent of resection were as follows: gross total resection (GTR), palliative resection and partial resection. Surgical techniques were divided into discrete lesion resection and combined contiguous multivisceral resection (CMR). Tumor size was determined as the largest diameter of the specimen. Patients were followed up at approximately 3-monthly intervals. For survival analysis, a univariate analysis was performed using the Kaplan-Meier method, and a multivariate analysis was performed using the Cox proportional hazards model.

RESULTS: Nineteen patients with recurrent abdominal liposarcoma (RAL) underwent 32 re-operations at our institute. A total of 51 operations were reviewed with a total follow-up time ranging from 4 to 120 (47.4 ± 34.2) mo. The GTR rate in the CMR group was higher than that in the non-CMR group (P = 0.034). CMR was positively correlated with intra-operative bleeding (correlation coefficient = 0.514, P = 0.010). Six cases with severe postoperative complications were recorded. Patients with tumor sizes greater than 20 cm carried a significant risk of profuse intra-operative bleeding (P = 0.009). The ratio of a highly malignant subtype (de-differentiated or pleomorphic) in recurrent cases was higher compared to primary cases (P = 0.027). Both single-factor survival using the Kaplan-Meier model and multivariate analysis using the Cox proportional hazards model showed that overall survival was correlated with resection extent and pathological subtype (P < 0.001 and P = 0.02), however, relapse-free interval (RFI) was only correlated with resection extent (P = 0.002).

CONCLUSION: Close follow-up should be conducted in patients with RAL. Early re-operation for relapse is preferred and gross resection most likely prolongs the RFI.

Key words: Overall survival; Recurrent abdominal liposarcoma; Relapse-free interval

Core tip: Recurrent abdominal liposarcoma (RAL) is an intractable disease encountered by both general surgeons and surgical oncologists. RAL commonly affects multiple organs, and re-operation for RAL is often difficult and is associated with significant risk, even when debulking is imminent. The high likelihood of postoperative complications and a lower survival outcome are

detractors for repeat operations. A multidisciplinary team approach, realistic risk stratification, and careful management may help increase the success rate of gross total resection, lower these complication rates, improve survival, and increase the quality of life of these patients. Overall survival, relapse-free interval and other clinical follow-up data are also presented in detail in this study.

Recurrent abdominal liposarcoma: Analysis of 19 cases and prognostic factors. *World J Gastroenterol* 2013; 19(25): 4045-4052 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4045.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4045

INTRODUCTION

Liposarcoma is the most common retroperitoneal sarcoma[1,2]. It accounts for more than 20% of all sarcomas in adults and up to 41% of all retroperitoneal sarcomas[3,4]. Liposarcomas also originate from the mesentery, gastrointestinal wall, and even from solitary organs, which has been reported sporadically[4-11]. Complete surgical resection is the only effective treatment method for retroperitoneal liposarcomas[3,12,13].

However, liposarcomas are associated with a high local recurrence rate[14-16]. Re-operation is the only effective treatment for recurrent abdominal liposarcoma (RAL)[17]. For those who are not amenable to complete radical resection, debulking resection should be performed to relieve symptoms, reduce complications, and increase the life span[18]. However, there is no consensus concerning the utility of repeat debulking resections. RAL commonly affects multiple organs, and re-operation for RAL is often difficult and is associated with significant risk, even when debulking is imminent. The high likelihood of postoperative complications and a lower survival outcome are detractors for repeat operations.

A multidisciplinary team approach, realistic risk stratification, and careful management may help lower these complication rates, improve survival, and increase the quality of life of these patients. We have treated 19 RAL patients over the past 3 years using a multidisciplinary team approach. The clinical and follow-up data of these patients were retrospectively analyzed and summarized.

MATERIALS AND METHODS

Patient enrollment and operation selection

Between May 2009 and Jan 2012, 19 consecutive patients with RAL were treated by the retroperitoneal sarcoma team at our institution. Patients were identified by reviewing a database that accrued data prospectively. Histology was reviewed and classified according to the World Health Organization classification[19,20]. The multidisciplinary team were involved in case discussions which were held prior to treatment, and repeat resection was deemed the best treatment. The multidisciplinary team members included general surgeons, a pathologist, radiologist, oncologist, radiologist, urologist and gynecologist. Multivisceral resection was recommended only in cases of expected gross tumor resection. The operative plan was explained to the patient in detail, and informed consent was obtained before surgery.

Extent of resection

The categories of the extent of resection were as follows: gross total resection (GTR), whether the margin was histologically free or not; palliative resection; and partial resection. Palliative resections were performed when the gross disease could not be completely removed and less than a 1 cm rim of tumor remained. Partial resections were defined as visually more than a 1 cm rim of remaining tumor. Surgical techniques were divided into discrete lesion resection (DLR) and combined contiguous multivisceral resection (CMR). Tumor size was determined as the largest diameter of the specimen.

Clinical data

Patients' demographic and clinical data were reviewed retrospectively and included age, gender, disease onset date, combined resected organ, pathology subtype, tumor size, intra-operative bleeding, post-operative complications, disease relapse date and survival time in order to analyze prognostic factors.

Follow up

Patients were followed-up at approximately 3-mo intervals. The relapse-free interval (RFI) was defined as the time between initial surgery and confirmation of clinical recurrence.

Statistical analysis

The median and standard error were used to present continuous variables. Fisher's test or a crosstab analysis was performed to compare variables between groups. For survival analysis, a univariate analysis was performed using the Kaplan-Meier method, and a multivariate analysis was performed using the Cox proportional hazards model. $P < 0.05$ was considered statistically significant.

RESULTS

Patient clinical characteristics

Nineteen patients with RAL underwent 32 re-operations at our institute. The patient demographic, surgical, and pathological data are summarized in Table 1. A total of 51 operations were reviewed. The recurrences were tracked from Mar 2002 to Aug 2011, with a total follow-up time ranging from 4 to 120 (47.4 ± 34.2) mo.

Surgical treatment

The surgical methods and resection extent are summarized in Table 2. Five of the nineteen patients underwent the primary operation at our institute. The resected or-

DLR: Discrete lesion resection; CMR: Contiguous multivisceral resection; GTR: Gross total resection.

gans included the small intestine (n = 14), colon (n = 11), kidney (n = 8), spleen (n = 7), pancreas (n = 5), stomach, appendix, ovary (n = 3 each), and liver, bladder, testicle, and abdominal wall (n = 1 each). The GTR rate in the CMR group was higher than that in the non-CMR group (P = 0.034). Only one CMR case underwent partial resection. This patient had a spontaneous enterobrosis and therefore required an emergency operation. He lived for 3 mo after this salvage treatment. The median intra-operative blood loss was 500 mL. Thirteen cases had bleeding ranging from 500-4000 (1300 ± 1100) mL; bleeding in 12 of these 13 cases occurred during CMR. CMR was positively correlated with intra-operative bleeding (correlation coefficient = 0.514, P = 0.010). Six cases with severe postoperative complications were recorded. Two cases experienced anastomotic leakage, and the other four experienced either pleural effusion, subdiaphragmatic effusion, abdominal abscess, or an abdominal wall wound infection.

Pathology data

The primary tumor size was recorded in nine patients, including one patient with multiple lesions; the other eight tumors ranged in size from 13-38 (22.6 ± 9.9) cm. A total of 24 relapse cases were observed who had measurable specimens with tumor sizes ranging from 4-46 (27.2 ± 14.5) cm, and 8 cases had multiple lesions. The median size was 20 cm for all specimens. The resection extent, surgical approach, and operative blood loss were compared according to tumor size. The relapse cases were subgrouped by median tumor size when comparing the clinical data with the number of cases. Patients with tumor sizes greater than 20 cm carried a significant risk of profuse intra-operative bleeding (P = 0.009), as detailed in Table 3.

Table 3 Comparison of clinical data according to recurrent tumor size

Tumor size	< 20 cm	> 20 cm	Total
GTR	4	10	14
Palliative resection	3	5	8
Partial resection	2	0	2
DLR	4	2	6
CMR	6	12	18
Bleeding (< 500 mL)	4	6	10
Profuse bleeding (≥ 500 mL)[1]	1	13	14

[1]P = 0.009 between different recurrent tumor size group. DLR: Discrete lesion resection; CMR: Contiguous multivisceral resection; GTR: Gross total resection.

The pathological subtypes were significantly different between recurrent and primary tumors. The subtype frequently changed with each recurrence within the same patient. In this series, well-differentiated and myxoid liposarcomas were more commonly found within the primary tumor; however, dedifferentiated liposarcomas were more common in recurrent tumors. The ratio of a highly malignant subtype (dedifferentiated or pleomorphic) in the recurrent cases was higher compared to the primary cases (5/9 *vs* 23/9, P = 0.027).

Follow-up and survival analysis

Survival was tracked during the follow-up period. Six patients died of their disease after an overall survival (OS) of 8-90 (33.7 ± 29.7) mo. Single-factor survival was analyzed according to surgical method, resection extent, tumor location, tumor size, and pathological subtype of the primary disease. Patients with a GTR of the primary tumor had a longer survival than those with a palliative or partial resection (P = 0.001, Figure 1A). Patients who underwent a CMR at first operation had a slightly longer survival (P = 0.081, Figure 1B). Patients with a primary retroperitoneal liposarcoma had a worse survival than liposarcoma at any other site (mesentery, omentum and small intestine, P = 0.054, Figure 1C). Patients with a less malignant subtype of primary liposarcoma (well differentiated and myxoid cell type) tended to live longer than those with a more highly malignant subtype (dedifferentiated and pleomorphic cell type, P = 0.002, Figure 1D). Multivariate analysis using the Cox proportional hazards model showed that OS correlated with resection extent and pathological subtype (P < 0.001 and P = 0.02).

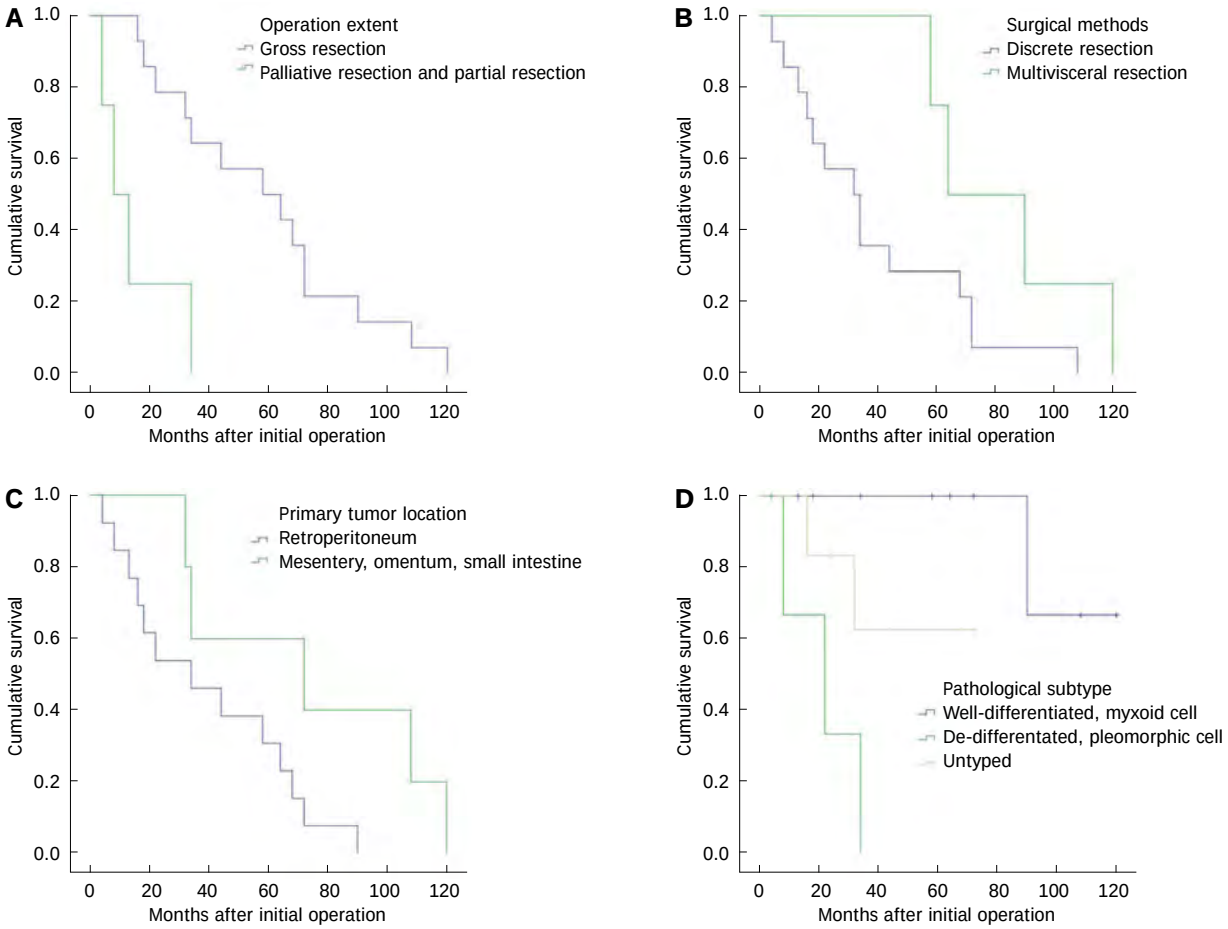

Figure 1 Relationship between overall survival and operation extent (A), surgical methods (B), tumor origin (C), and pathological subtype (D) in patients who underwent resection of a primary abdominal liposarcoma.

The RFI of the primary surgical treatment ranged from 2-84 (22.0 ± 21.2) mo. The RFI differed between GTR patients (6-84/27.0 ± 21.2 mo) and patients who underwent partial or palliative resections (2-4/3.3 ± 1.0 mo, $P = 0.001$). Eighteen recurrences were observed after a gross or palliative resection for recurrent tumor, and the RFI was 1-28 (8.3 ± 7.4) mo. Of these, 11 were post-GTR (RFI = 4-28/12.5 ± 7.4 mo) and seven were post-palliative resection (RFI = 3-6/4 ± 1.3 mo). Eight post-GTR cases had a follow-up of 3-30 (10.3 ± 10.1) mo with no relapse. Patients who underwent GTR had a longer RFI than those who underwent palliative resection ($P = 0.01$).

The RFI was compared according to the revision operation time, surgical method, resection extent, primary tumor location, tumor size, simultaneous tumor number, and pathological subtype. The RFI was shorter in patients who underwent more than 2 operations ($P = 0.035$, Figure 2A). No significant differences in RFI were found between CMR and DLR ($P = 0.599$, Figure 2B). However, there was a significant difference between GTR cases and non-GTR cases ($P < 0.001$, Figure 2C). Patients with well-differentiated liposarcomas had a longer RFI compared to those with other liposarcoma subtypes ($P = 0.007$, Figure 2D). When grouped by median tumor size (20 cm) or simultaneous tumor number (solitary or multiple), no significant difference was observed ($P = 0.54$, Figure 2E and $P = 0.33$, Figure 2F). A multivariate analysis using a Cox proportional hazards model showed that the RFI only correlated with resection extent ($P = 0.002$).

DISCUSSION

Liposarcoma is the most common mesenchymal tumor in the abdomen. To date, surgical resection is the only effective treatment for liposarcoma. Unfortunately, these tumors are almost always very large at the time of diagnosis due to their slow growth and often vague symptoms[11], which make GTR difficult. These tumors are known for their frequent local recurrence and expansive growth with contiguous organ infiltration, which are the main causes of death from this disease. There is no strong evidence that chemotherapy or radiotherapy is curative[21,22]. Re-operation is still the mainstay of treatment, but is associated with significant risk. Using a multidisciplinary team approach, the surgical management of RAL has been improved at our institute. Very few studies have focused on the re-operative treatment of RAL.

In this series, we reviewed 19 patients with RAL who

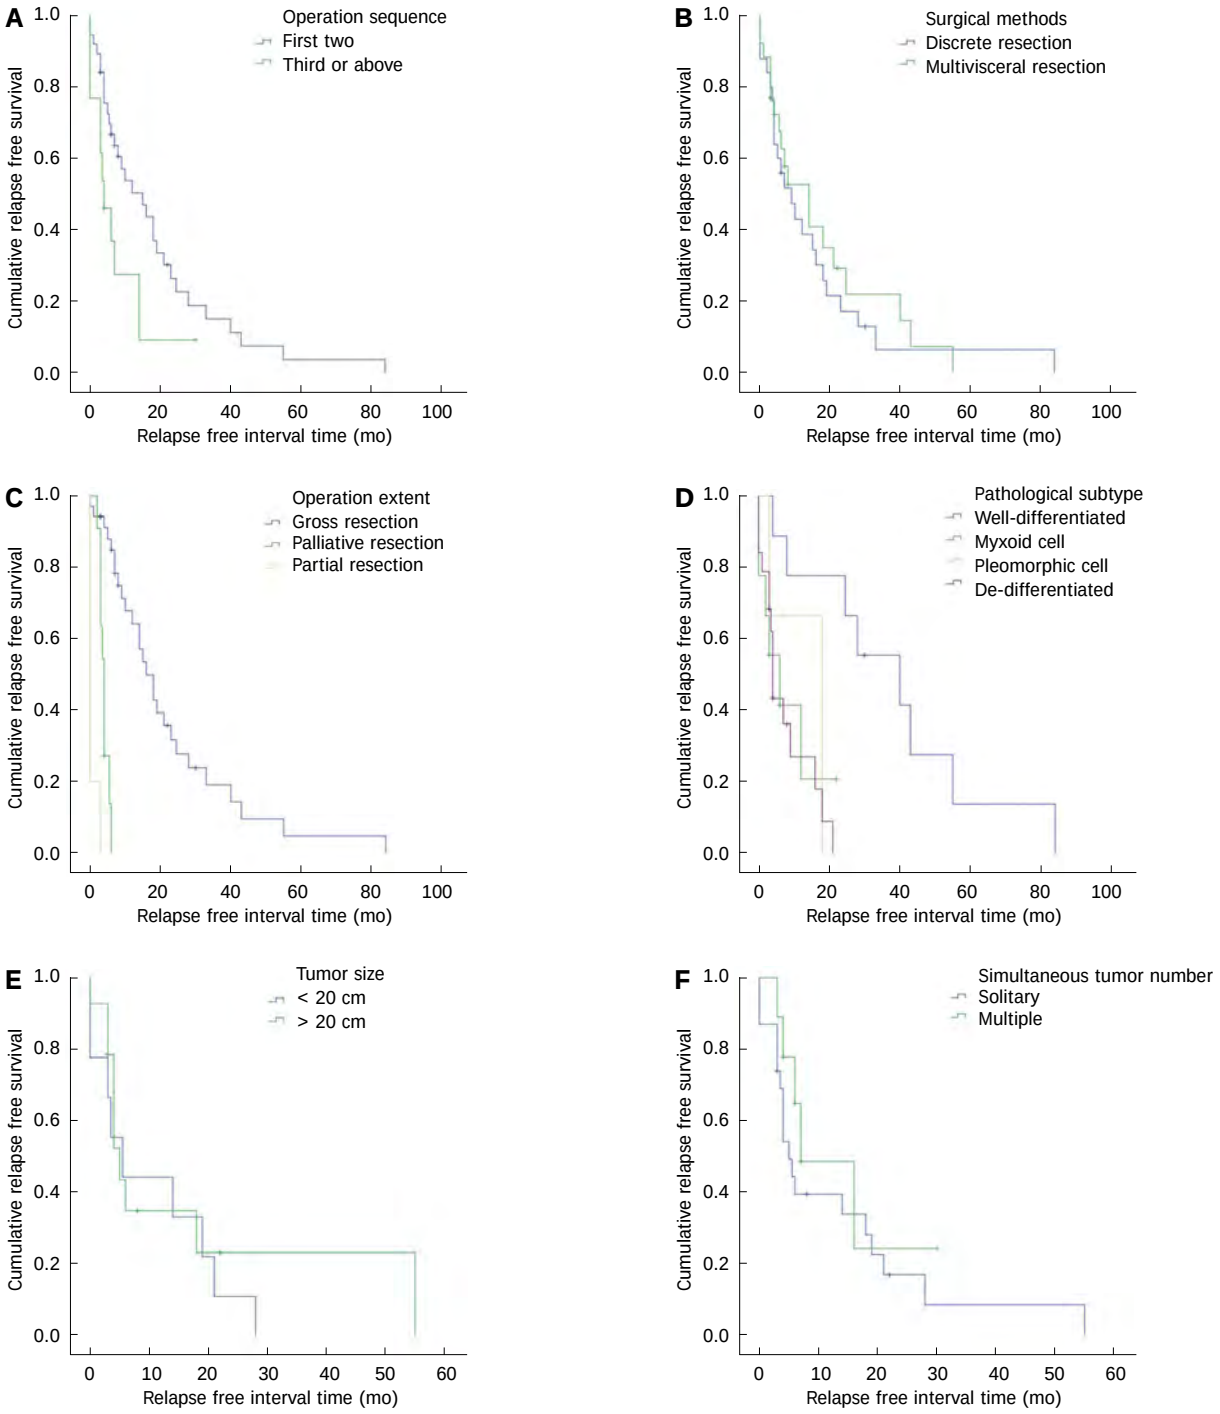

Figure 2 Relationship between the relapse-free interval and operation sequence (A), surgical method (B), operation extent (C), pathological subtype (D), tumor size (E), and simultaneous tumor number (F) in patients who underwent resection of an abdominal liposarcoma.

underwent 32 re-operations. All 19 patients had a successful re-operation with no intra-operative mortalities. However, the surgical treatment of RAL was associated with intra-operative bleeding and postoperative complications. These were most notable in cases where CMR was anticipated. The most common postoperative complications were anastomotic leak and effusion/infection.

There is no consensus in the literature regarding the guiding principles of surgical treatment for RAL. A large series of 177 primary retroperitoneal liposarcoma patients demonstrated that the pathological subtype on gross resection was the most significant prognostic factor[16]. In our multi-disciplinary team, the benefits and risks of re-operation were evaluated, and plans were formulated for all the RALs we encountered. GTR is the preferred approach for patients with RAL when CMR is necessary. If there was no possibility of gross resection, palliative resection was performed without multivisceral resection. Partial resections for RAL should only be performed in patients with intolerable symptoms (*e.g.*, extreme increas-

ing intra-abdominal pressure, grave complications, and in some emergency conditions). CMR should be avoided in patients who have undergone partial resection because this does not result in cure and incurs greater morbidity. One partial resection included an enterectomy due to spontaneous perforation caused by the RAL.

In this study, 75% (15/20) of patients who underwent GTR involved CMR. There is no similar study from our institute or similar data in the literature. It is unknown whether CMRs increase the GTR rate for RAL. However, the GTR rate was higher in CMR cases than in non-CMR cases for RALs. In operations for the primary tumor, there were more non-combined resections in GTR patients (57.9% *vs* 21.1%). The tumor size was 4-46 (median 20) cm, which is similar to that in another retrospective study of 21 cases of primary retroperitoneal liposarcoma[25]. The most frequently combined resected organ was the small intestine, which is in contrast to another study reporting the kidney[24]. In our study, the small intestine was associated with a risk of anastomotic leak. Tumor size was also correlated with intra-operative profuse bleeding (> 20 cm, $P = 0.009$). Additionally, a pathologic subtype change was observed in the RALs compared to the primary tumors or previous relapsed tumors. A pathologic subtype change predicted deterioration in repeat relapse cases[25]. Dedifferentiated liposarcomas were more commonly found as recurrent tumors[14,26-28].

There have been no studies that have focused on recurrent abdominal liposarcomas or retroperitoneal liposarcomas. Most reported studies are single cases or include less than 3 cases in a report. However, several studies have described primary and recurrent retroperitoneal liposarcoma, with more than 10 cases reported since 1991[23,25,29-32], but no primary mesentery or omental liposarcomas have been described. In our study, patients with primary retroperitoneal liposarcoma had a poorer survival, however, this was not statistically significant ($P = 0.054$). It is generally recognized that complete or gross total resection at the initial operation is very important, resulting in a more favorable prognosis[33]. In our study, patients who underwent gross resection of the primary tumor had a longer survival than those who underwent a palliative or partial resection. CMR for retroperitoneal sarcoma was recommended for the initial operation in a study of 77 patients due to an infiltrative tumor pattern[34]. Dedifferentiated tumors tend to present more often as a recurrence[35,36], frequently require multi-organ resection, and carry a shorter disease-free interval when compared to well-differentiated subtypes[25]; a similar result was observed for well-differentiated tumors in this study. OS was correlated with the resection extent and pathological subtype ($P < 0.001$ and $P = 0.02$). CMRs may increase the chance of complete resection.

Macroscopic complete resection for recurrent retroperitoneal liposarcoma has been recommended[37]. It is believed that palliative resection is worthwhile for treating the troublesome symptoms of recurrence in patients who have little chance of gross resection[32]. Repeat operations were performed in our study, and the RFI was shorter in patients who underwent more than two operations. GTR was a significant prognostic factor for the RFI ($P < 0.001$). Tumor subtype in a well-differentiated liposarcoma resulted in a significantly longer RFI compared to other types, according to the Kaplan-Meier analysis. The surgical extent was the only significant prognostic factor, as demonstrated by the Cox regression model. This showed that GTR was the major factor affecting the relapse time regardless of whether the tumor was a primary or recurrent tumor. Our results show that surgical management is the key factor in the successful treatment of abdominal liposarcoma. Multidisciplinary team cooperation has the advantage of a well-designed surgical management plan. Whether tumor size affects OS in addition to the relapse-free interval is controversial. Some authors have reported that large tumor size is negatively associated with prognosis[23,29] as large tumors require more difficult operations. However, other reports have shown no obvious difference in OS or relapse-free interval according to tumor size[25,37]. Tumor size did not affect the RFI in our study. However, it was one of the factors associated with the GTR rate, which indirectly affected OS. Multidisciplinary team approaches and multivisceral resections used in the surgical management of these cases reduced the risk of tumor residue when operating on larger abdominal liposarcomas.

Most abdominal liposarcomas are asymptomatic in the early stages. As the tumor grows patients may experience abdominal distention or other symptoms related to the tumor compressing contiguous organs, vessels, or even the ureter. Some tumors were large when the patients presented to the hospital, and it was difficult to completely resect these tumors at the time of surgery. The abdominal liposarcomas were often recurrent, particularly those with a highly malignant subtype. It is important that such patients have appropriate follow-up. However, to date, follow-up has not been standardized. The relapse time after the initial operation has been reported to vary due to the surgical extent and pathologic subtype. Postoperative adjuvant chemotherapy or radiotherapy was also not recommended as there is little evidence of benefit[38,39]. Proactive re-operation for RAL is strongly recommended. In such cases, close follow-up is necessary to identify relapse early.

RAL is a difficult disease to treat. The surgical treatment of RALs can be particularly challenging for surgical oncologists. GTR is the most important positive prognostic factor for these patients, and proactive surgical treatment is recommended. A multidisciplinary team approach most likely increases the chance of GTR, and CMR is frequently required to achieve gross tumor clearance. Palliative or partial resections are indicated in patients with recurrent disease and insufferable symptoms.

COMMENTS

Background

Abdominal liposarcomas are associated with a high local recurrence rate. Re-operation is the only effective treatment for recurrent abdominal liposarcoma

(RAL). For those who are not amenable to complete radical resection, debulking resection may relieve symptoms, reduce complications, and increase the life span. However, RAL commonly affects multiple organs, and re-operation for RAL is often difficult and is associated with significant risk, even when debulking is imminent, There is no consensus concerning the utility of repeat debulking resections. The high likelihood of post-operative complications and a lower survival outcome are detractors for repeat surgery.

Research frontiers

Re-operation is widely accepted as the treatment for recurrent abdominal liposarcoma. However, repeat re-operation for RAL is associated with high risk and a high complication rate. There are no recommended general criteria regarding when or how the re-operation should be performed. A multidisciplinary team approach, realistic risk stratification, and careful management may help lower the complication rate and improve survival.

Innovations and breakthroughs

Recurrent abdominal liposarcoma is an intractable disease encountered by general surgeons or surgical oncologists. It is generally believed that chemotherapy or radiotherapy provide minor help for patients with abdominal liposarcoma. Macroscopic complete resection or gross total resection is still the only treatment that correlates with overall survival or disease-free survival. However, recurrent lesions involve several adjacent organs in most cases. Multiple contiguous organ resections should be carried out under such conditions, however, this is associated with significant risks of failing to resect the lesion completely, multiple complications and even intra- or post-operative death. With the advantage of a multidisciplinary approach, the surgical oncologist can prepare for the treatment of this difficult disease, enhance the successful rate of gross resection and lower the morbidity and mortality related to the operation. This preliminary study summarized the outcome of multidisciplinary team cooperation in the treatment of abdominal liposarcoma which can be subsequently improved.

Applications

The study results suggest that repeat re-operation for recurrent abdominal liposarcoma with multidisciplinary team cooperation may help lower the complication rates, improve survival, and increase the quality of life of these patients.

Terminology

Recurrent abdominal liposarcoma: Recurrent abdominal liposarcoma is a disease where the liposarcoma relapses mainly in the peritoneal cavity, whether the liposarcoma originated from the retroperitoneal area or another region. Gross total resection: is the same as macroscopic complete resection, and means that the tumor is totally resected whether the pathological margin is negative or positive.

Peer review

This is a good retrospective study in which authors analyze the clinical outcome of repeated re-operation on recurrent abdominal liposarcoma. The results are interesting and suggest that repeated re-operation on recurrent abdominal liposarcoma under multidisciplinary team cooperation gain satisfactory clinical outcome.

Abstract

AIM: To investigate the benefits of probiotics treatment in septic rats.

METHODS: The septic rats were induced by cecal ligation and puncture. The animals of control, septic model and probiotics treated groups were treated with vehicle and mixed probiotics, respectively. The mixture of probiotics included *Bifidobacterium longum*, *Lactobacillus bulgaricus* and *Streptococcus thermophilus*. We observed the survival of septic rats using different amounts of mixed probiotics. We also detected the bacterial population in ascites and blood of experimental sepsis using cultivation and real-time polymerase chain reaction. The severity of mucosal inflammation in colonic tissues was determined.

RESULTS: Probiotics treatment improved survival of the rats significantly and this effect was dose dependent. The survival rate was 30% for vehicle-treated septic model group. However, 1 and 1/4 doses of probiotics treatment increased survival rate significantly compared with septic model group (80% and 55% *vs* 30%, $P < 0.05$). The total viable counts of bacteria in ascites decreased significantly in probiotics treated group compared with septic model group (5.20 ± 0.57 *vs* 9.81 ± 0.67, $P < 0.05$). The total positive rate of hemoculture decreased significantly in probiotics treated group compared with septic model group (33.3% *vs* 100.0%, $P < 0.05$). The population of *Escherichia coli* and *Staphylococcus aureus* in ascites of probiotics treated group were decreased significantly compared with that of septic model group (3.93 ± 0.73 *vs* 8.80 ± 0.83, $P < 0.05$; 2.80 ± 1.04 *vs* 5.39 ± 1.21, $P < 0.05$). With probiotics treatment, there was a decrease in the scores of inflammatory cell infiltration into the intestinal mucosa in septic animals (1.50 ± 0.25 *vs* 2.88 ± 0.14, $P < 0.01$).

CONCLUSION: *Escherichia coli* and *Staphylococcus aureus* may be primary pathogens in septic rats. Probiotics improve survival of septic rats by suppressing these conditioned pathogens.

Key words: Sepsis; Probiotics; Pathogens; *Escherichia coli*; *Staphylococcus aureus*

Core tip: We observed the survival of septic rats treated with different amounts of mixed probiotics. The data indicated that conditioned pathogens such as *Escherichia coli* and *Staphylococcus aureus* may be primary pathogens of septic rats in our study. Probiotics improve the survival of septic rats by suppressing the conditioned pathogens.

Probiotics improve survival of septic rats by suppressing conditioned pathogens in ascites. *World J Gastroenterol* 2013; 19(25): 4053-4059 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4053.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4053

INTRODUCTION

Sepsis is the systemic inflammatory response to infection and one of the most common causes of death in critically-illed patients[1]. Each year, more than 750000 clinical cases of death occur due to sepsis, and the mortalities from severe sepsis were 20%-30% in the period of 1979-2000 in the United States[2,3]. Microbial infection initiates and promotes systemic inflammatory responses by increasing cytokines release and neutrophils recruitment in target organs and inducing systemic inflammatory response syndrome and multiple organ dysfunction syndrome[4]. It has been demonstrated that intestinal microbes play an important role in sepsis[5]. Cecum is a pouch of large intestines connecting the terminal ileum to the ascending colon and home to a large number of anaerobic and aerobic microbes[6]. Cecal ligation and puncture (CLP) of rats produce cecal ischemia and polymicrobial infection[7]. The bacteria of colonic contents will spill into the abdomen, and produce severe peritonitis and bacteremia[8]. So the CLP has been used as a classic animal model of sepsis[9-11].

There is a complex microbial population in intestinal tract, some of which are probiotics. When administered in adequate amounts, probiotics confer a health benefit to the host[12]. The products of probiotics include mucin, organic acids, branched chain fatty acids, H_2, CO_2, ammonia, amines and vitamins. These products regulate host health through different pathways such as regulating energy, gene expression and cell differentiation, producing anti-inflammatory agents and keeping gut homeostasis[13,14]. The probiotics include *Bifidobacteria, Lactobacilli, Enterococci, Streptococci, Propionibacteria, Bacillus,* and yeasts. A variety of species of probiotics have been shown to benefit human gastrointestinal health[15-17]. However, the mechanisms of probiotics in improving survival in sepsis are unclear. In this study, we sought to address this question in a septic model of Wistar rats.

MATERIALS AND METHODS

Animal experiments

Male Wistar rats (8-10 wk old, Animal Center of Academy of Malitary Medical Sciences, China) were housed on a 12:12 h light-dark cycle under pathogen-free conditions with free access to food and water. We performed CLP, a clinically relevant animal model for human sepsis[18,19]. The animals were anesthetized by 10% chloral hydrate (3 mL/kg *via* intraperitoneal injection). After a midline incision was made in the abdomen, we isolated the cecum gently and placed a ligature 2.0 cm from the cecal tip using 2-0 silk suture. Ligated cecal stump was punctured by a 12-gauge needle. Colonic contents were extruded into abdominal cavity. We put back the cecum into its normal position and closed the abdomen by suturing muscle and skin, respectively. For control animals, the cecum was isolated without ligating and puncturing. The probiotic mixture consisted of three different viable strains. One dose of the probiotic mixture contained 1×10^7 CFU *Bifidobacterium longum* (ATCC 15697), 1×10^6 CFU *Lactobacillus bulgaricus* (ATCC 11842) and 1×10^6 CFU *Streptococcus thermophilus* (ATCC 19987). Before administration, the probiotic mixture was reconstituted in sterile water for 10 min at 37 ℃. We gave probiotics to animals of treated groups through intragastric administration. The animals of control and septic model groups were treated with vehicle (sterile water). The first administration of probiotics or vehicle was started 6 h after surgery. Thereafter, it was administered once a day for 3 d.

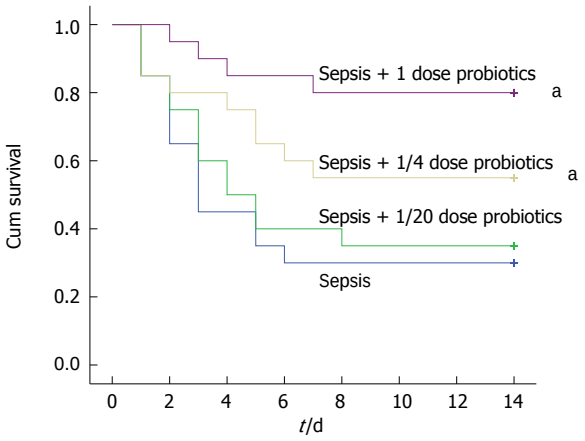

Figure 1 Survival in experimental sepsis. Survival was analysed in Wistar rats subjected to cecal ligation and puncture. Probiotics (1, 1/4 or 1/20 doses) or vehicle treatment started 6 h later and thereafter administered once a day for 3 d. All animals were observed for two weeks to compare their survival rates (n = 20; $^aP < 0.05$ *vs* septic model group).

Samples collection

All surviving animals were anaesthetised by 10% chloral hydrate (3 mL/kg, *via* intraperitoneal injection) after a 72 h period of CLP. Samples of blood and ascites were harvested for both anaerobic and aerobic microbial analysis immediately. Another portion of ascites was stored at -80 ℃ for DNA extraction. Then rats were killed by cervical dislocation, and colonic tissues were collected in neutral buffered formalin for histological analysis.

Microbial analysis of blood and ascites

Serial 10-fold dilutions were made in 0.9% sterile saline. We spread 20 μL of 10^0-10^{-7} dilutions on the nonselective blood-agar (Jinzhang Co, Ltd., Tianjin, China) surface. For anaerobic incubation, the anaerobic blood-agar dishes (Jinzhang Co, Ltd., Tianjin, China) were placed in anaerobic bags (bioMérieux, France) immediately. The time of aerobic incubation was shorter (24 h) than anaerobic (48 h) at 37 ℃. The colonies were determined in appropriate dilution, and total viable counts of original samples were calculated. Different colonies were separated and isolated for 2-3 times. We identified bacterial species using colony morphology and Gram's stain. Microstation microbe analysis system (Biolog, Winooski, VT, United States) was used for advanced identification.

Table 1 Comparison of bacterial spectrum and total viable count in ascites between septic model group and probiotics treated group

Group	Bacterial spectrums in ascites	Total viable counts (Log_{10} cells/mL ascites)
Septic model group	*Escherichia coli, Enterococcus faecalis, Staphylococcus aureus, Enterococcus avium, Streptococcus viridans, Streptococcus agalactiae, Micrococcus luteus, Enterococcus gallinarum, Enterococcus durans, Enterococcus malodoratus, Streptococcus ferus, Morganella morganii ss morganii, Acinetobacter radioresistens, Streptococcus criceti, Lactobacillus reuteri, Veillonella criceti\ratti, Desulfovibrio fructosivorans, Clostridium oroticum, Lactobacillus bifermentans*	9.81 ± 0.67
Probiotics treated group	*Escherichia coli, Enterococcus faecalis, Staphylococcus aureus, Enterococcus malodoratus, Morganella morganii ss morganii, Enterococcus durans, Streptococcus viridans, Prevotella dentioola, Desulfovibrio fructosivorcms, Bacterorides ovatus, Prevotella nigrescens*	5.20 ± 0.57[a]

Probiotics (1 dose) or vehicle treatment started 6 h later and thereafter administered once a day for 3 d. Samples of ascites were harvested for both anaerobic and aerobic culture. The bacterial spectrum of ascites was lower in probiotics treated group than in septic model group. The total viable counts of bacteria in ascites decreased significantly in probiotics treated group compared with septic model group (n = 18; [a]P < 0.05 *vs* septic model group).

Quantitative real-time polymerase chain reaction

Bacterial genomic DNA was extracted from ascites of rats using the QIAamp DNA mini kit (Qiagen, Hilden, United States) according to the manufacturer's protocol. We obtained 16S rRNA sequences of bacteria from the Ribosomal Database: (http://rdp.cme.msu.edu/), and designed primers for the specific bacterial strain using Primer 5.0 software package. The genomic DNA was used as template for the amplification of specimen and control standard bacterial strain through real-time polymerase chain reaction (PCR). PCR cycles were as follows: initial denaturation at 94 ℃ for 4 min, followed by 40 cycles of 94 ℃ for 30 s, 55 ℃ for 30 s, 72 ℃ for 40 s. PCR primers were: *Escherichia coli* forward: 5'-CATGCCGCGTGTATGAAGAA-3' and reverse: 5'-CGGGTAACGTCAATGAGCAAA-3'; *Enterococcus faecalis* forward: 5'-CAGCAGTAGGGAATCTTCGGCAATG-3' and reverse: 5'-AGCCTCAGCGTCAGTTACAGACCAG 3'; *Staphylococcus aureus* forward: 5'-CGTCAGCTCGTGTCGTGAGATGTTG-3' and reverse: 5'-GCGGTTTCGCTACCCTTTGTATTGT-3'. The real-time PCR was performed using FastStart SYBR Green Master (Roche, Basel, Switzerland) and IQ5 PCR system (BIO-RAD, Hercules, CA, United States).

Table 2 Comparison of bacterial spectrum and total positive rate of hemoculture between septic model group and probiotics treated group

Group	Bacterial spectrums of hemoculture	Total positive rate of hemoculture
Septic model group	*Escherichia coli, Staphylococcus aureus, Curtobacterium pusillum, CDC group II-E subgroup A*	100%
Probiotics treated group	*Escherichia coli, Staphylococcus aureus*	33.3%[a]

Probiotics (1 dose) or vehicle treatment started 6 h later and thereafter administered once a day for 3 d. Samples of blood were harvested for both anaerobic and aerobic culture. The bacterial spectrum of hemoculture was lower in probiotics treated group than in septic model group. The total positive rate of hemoculture decreased significantly in probiotics treated group compared with septic model group (n = 18; [a]P < 0.05 *vs* septic model group).

Histological examination of intestinal inflammation

The colonic tissues of at least four rats in each group were fixed in neutral buffered formalin, and processed for histological analysis. The sections of colonic tissues were stained by haematoxylin-eosin. Colonic sections were assessed for the severity of mucosal inflammation based on the following: infiltration of neutrophils and mononuclear cells into the intestinal mucosa (0, scant to normal; 1, minimal to mild; 2, mild to moderate; 3, moderate to severe; 4, severe inflammation)[20,21], and four fields of each sample were assessed. Moreover, epithelial thickness was measured under microscope (Leica, Frankfurt, Germany).

Statistical analysis

Data were expressed as the mean ± SD. All statistical analyses were performed using SPSS 17.0 software package. Survival analysis was shown in Kaplan-Meier survival curves. Survival comparisons between two subgroups were performed by the log-rank test. Differences between two groups were analysed using unpaired t test for continuous variables and the χ^2 test for nominal variables. A P value of less than 0.05 was considered statistically significant.

RESULTS

Probiotics improve the survival of rats with experimental sepsis

One hundred male Wistar rats were divided into five groups (control group, septic model group and three sepsis plus treatment groups) for survival analysis. We gave probiotic mixture (1, 1/4 or 1/20 doses) to animals in three treated groups by intragastric administration (once a day for 3 d). The animals of control and septic model

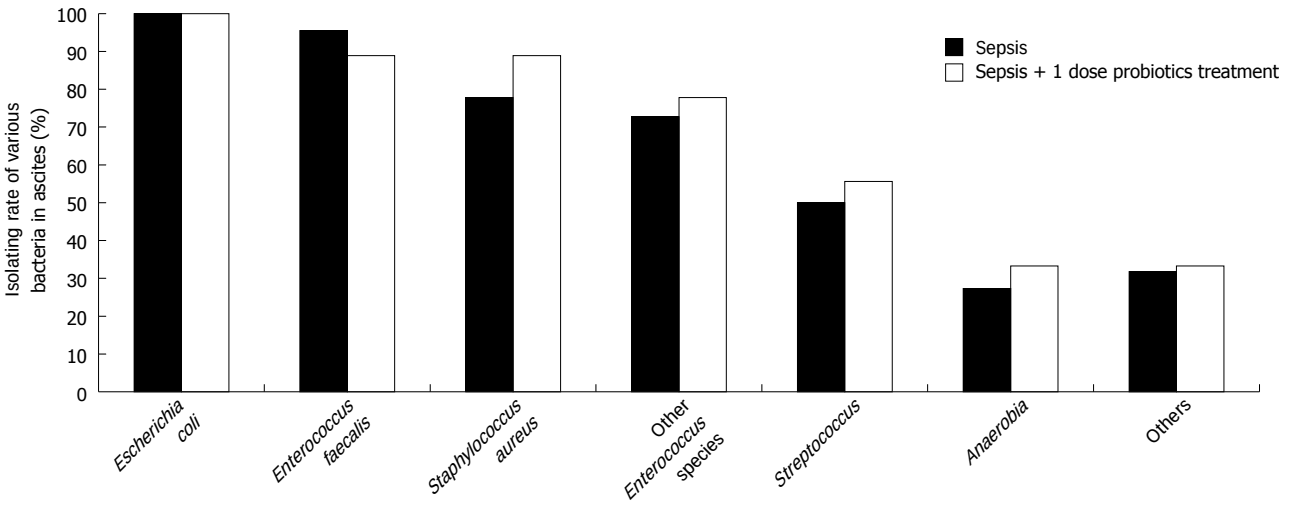

Figure 2 Comparison of isolating rate of various bacteria in ascites between sepsis and probiotics treated group. Probiotics (1 dose) or vehicle treatment started 6 h later and thereafter administered once a day for 3 d. Samples of ascites were harvested for both anaerobic and aerobic culture. There was no statistical significance in isolating rates between two groups for all bacterial species ($P > 0.05$). In addition, "other *Entertrococcus* species" include *Enterococcus avium, Enterococcus gallinarum, Enterococcus durans* and *Enterococcus malodoratus*. "Anaerobia" include *Lactobacillus reuteri, Veillonella cricetiratti, Desulfovibrio fructosivorans, Clostridium oroticum, Lactobacillus bifermentans, Prevotella dentioola, Bacterorides ovatus* and *Prevotella nigrescens*. "Others" include *Micrococcus luteus, Morganella morganii ss morganii* and *Acinetobacter radioresistens*.

groups were treated with vehicle only. We observed all animals for two weeks. The animals in control group survived normally. The majority of rats who had CLP showed clear signs of sepsis such as piloerection, lethargy, malaise and forming ascites. Probiotics attenuated the clinical manifestations of sepsis. Probiotics treatment also improved survival significantly and this effect was dose dependent. The survival rate was the lowest (30%, 6/20 rats) in the vehicle-treated septic model group. There was no protective effect using 1/20 dose probiotics (survival rate was 35%, 7/20 rats). However, 1 and 1/4 doses of probiotics treatment increased survival rate significantly (80%, 16/20 rats and 55%, 11/20 rats) compared with vehicle treated septic model group ($P < 0.05$) (Figure 1).

Probiotics inhibit bacteria in blood and ascites of rat experimental sepsis

The consequence of survival analysis indicated that 1 dose probiotics treatment was more effective than other doses. Therefore, we divided 80 male Wistar rats into three groups (control group, 8 rats; septic model group, 50 rats; and sepsis plus 1 dose probiotics treated group, 22 rats). Probiotics or vehicle were given to the animals through intragastric administration (once a day for 3 d), respectively. All animals (8 rats) in the control group survived normally. Forty-four percent of animals (22 rats) were alive in septic model group, and 81.8% of animals (18 rats) were alive in probiotics treated group. We harvested samples after a 72 h period of CLP. The microbial composition of blood and ascites were analysed. No bacteria were determined in blood and ascites of control group. The bacterial spectrum of ascites (Table 1) and blood (Table 2) was lower in probiotics treated group than in septic model group. There was no statistical significance in isolating rates between two groups for all bacterial species ($P > 0.05$, Figure 2). However, the total viable counts of bacteria in ascites decreased significantly in probiotics treated group compared with septic model group ($P < 0.05$, Table 1). Similarly, the total positive rate of hemoculture decreased significantly in probiotics treated group compared with septic model group ($P < 0.05$, Table 2).

The consequence of bacterial cultivation indicated that *Escherichia coli, Enterococcus faecalis* and *Staphylococcus aureus* were predominant microbial population in ascites of sepsis. For this reason, we detected the population of these bacteria in ascites using quantitative real-time PCR. The data indicated that all population of these bacteria decreased significantly in probiotics treated group compared with septic model group ($P < 0.05$, Figure 3).

Probiotics improve colonic mucosal inflammation of experimental sepsis

With probiotics treatment, there was a decrease in the infiltration of neutrophils and mononuclear cells into the intestinal mucosa in septic animals ($P < 0.05$, Figure 4). No apparent differences of epithelial cell hyperplasia were found between the rats in probiotics treated group and septic model group (data not shown).

DISCUSSION

Despite the development of antibiotics and other intensive care treatment, sepsis has a high mortality. CLP of rats is one of animal models of human sepsis. Because colonic contents are extruded into abdominal cavity, various microbes proliferate in ascites immediately. Therefore, the bacteria from feces cause polymicrobial infection, bacteremia and lethal peritonitis[22,23]. In this study, we treated the experimental septic rats with mixture of

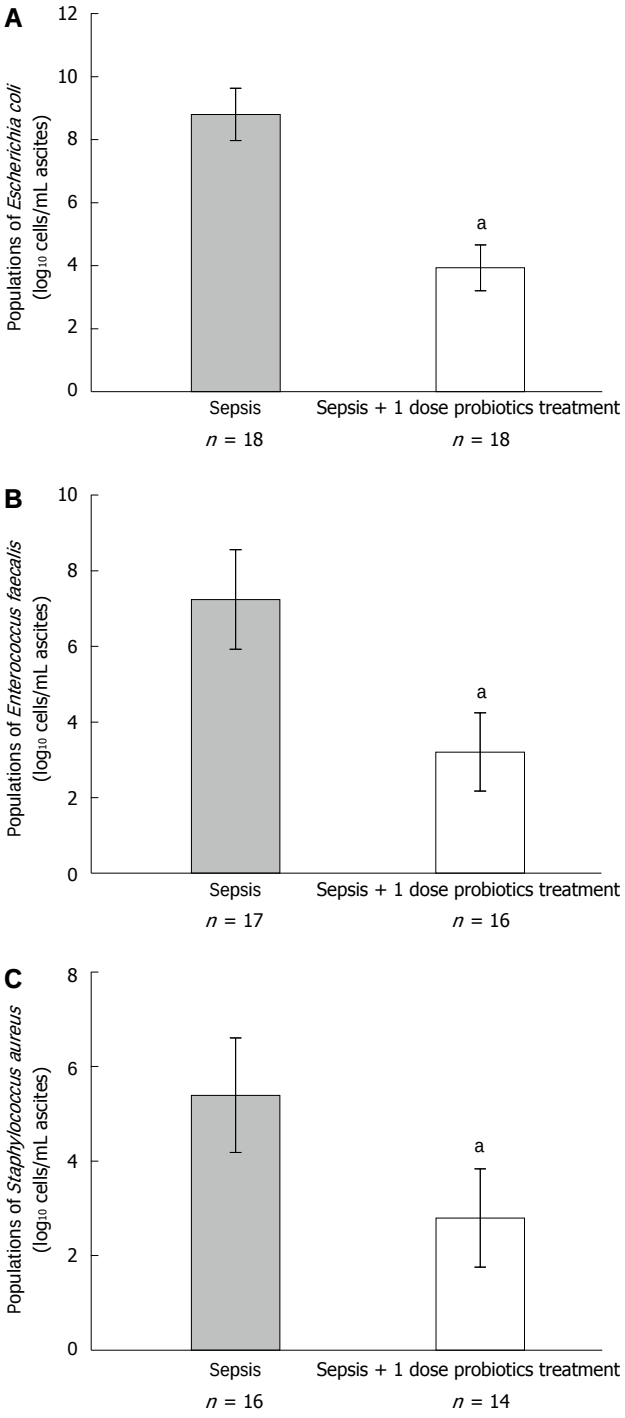

Figure 3 Comparison of predominant bacterial populations in ascites between sepsis and probiotics treated groups. Probiotics (1 dose) or vehicle treatment started 6 h later and thereafter administered once a day for 3 d. Bacterial genomic DNA was extracted and analysed by quantitative real-time PCR as described previously. The population of *Escherichia coli* (A), *Enterococcus faecalis* (B) and *Staphylococcus aureus* (C) were compared between two groups ($^{a}P < 0.05$ *vs* septic model group).

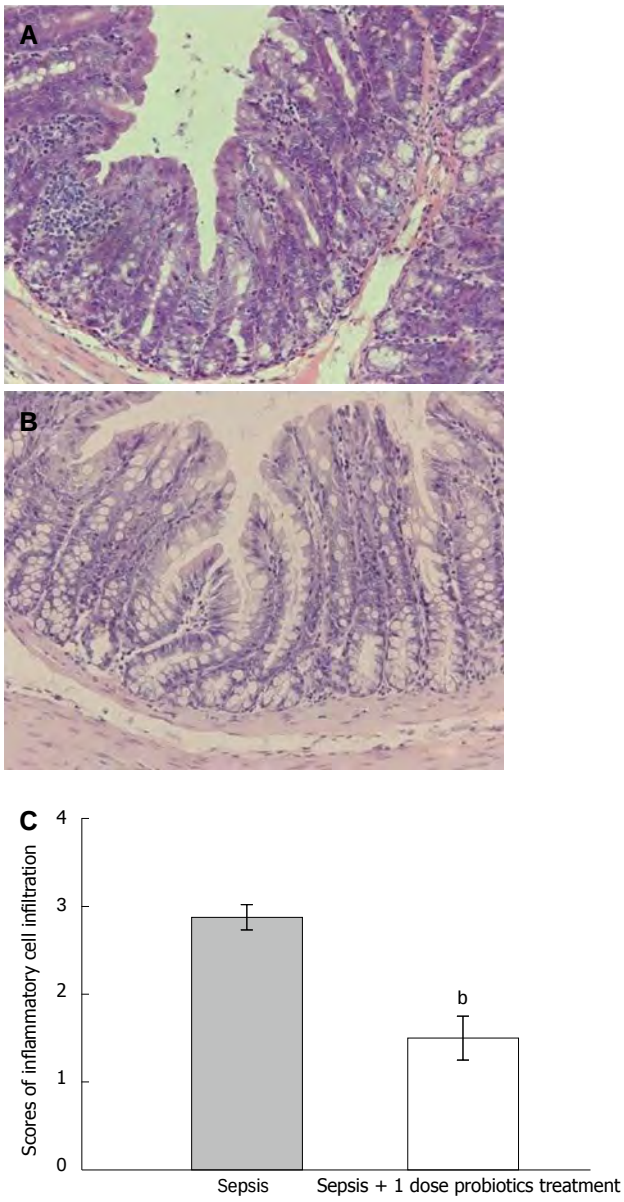

Figure 4 Colonic mucosal inflammation of experimental sepsis. Probiotics (1 dose) or vehicle treatment started 6 h later and thereafter administered once a day for 3 d. We harvested colonic tissues after a 72 h period of cecal ligation and puncture. The sections of colonic tissues were stained by haematoxylin-eosin (× 400). Four fields of each sample were assessed. More neutrophils and mononuclear cells infiltrated into the intestinal mucosa in septic model group (A) than probiotics treatment group (B). We also compared scores of inflammatory cell infiltration between two groups (C) ($^{b}P < 0.01$ *vs* septic model group).

three live probiotics. We also analysed the survival of probiotics treated septic animals. It was demonstrated that probiotics improved the survival of rats with experimental sepsis and this effect was dose dependent. No protective effect was observed using the lowest concentration of probiotics (1/20 dose). However, 1 and 1/4 doses of probiotics treatment increased survival significantly compared with septic model group. Therefore, we treated septic animals in subsequent experiments using 1 dose of probiotics all the time.

Ascites culture data indicates that more pathogens grew in septic model group (10^{9}-10^{10} cells/mL) than in probiotic treated group (10^{4}-10^{5} cells/mL). Both aerobes and anaerobes were detected in ascitic samples, although the majority of microbes were aerobes. Cecum contained anaerobes, facultative aerobes and aerobes. Furthermore, the amounts of anaerobes were greater than those of aerobes[24,25]. However, in our study, aerobes had been

isolated frequently from septic ascitic samples such as *Escherichia coli* (isolating rate was 100%), *Enterococcus faecalis* (95.5%) and *Staphylococcus aureus* (77.8%). The total isolating rate of anaerobes was less than 30%. The main reason for this phenomenon was "oxygen". When the operation of CLP was performed in experimental sepsis, the anaerobes were exposed to oxygen directly. Furthermore, some oxygen was stored in abdominal cavity of animal after operation. For these reasons, the majority of anaerobes were killed by oxygen. Thereafter, the aerobes which were minority in original colonic contents proliferated immediately. When we gave probiotics to septic rats, the bacterial spectrum of ascites and blood was lower than in the septic model group. Meanwhile, probiotics decreased total viable counts of pathogens in septic ascites significantly. In addition, the data of hemoculture showed that *Escherichia coli* and *Staphylococcus aureus* usually were detected in septic model group. Probiotics decreased the positive rate of hemoculture in septic rats.

It seemed that *Escherichia coli* and *Staphylococcus aureus* are the primary pathogens of CLP rats in septic model in our study. On one hand, we detected the population of these bacteria in ascites by quantitative real-time PCR. All population of these bacteria decreased significantly in probiotics treated group compared with septic model group. On the other hand, inflammatory response of intestinal mucosa was lessened in probiotics treated group compared with septic model group. All these data indicated that the mixture of probiotics improved the survival in a murine model of polymicrobial sepsis by suppressing the conditioned pathogens. However, the reasons for this suppression are not clear. There are two potential reasons: first, the decreased bacterial number may result from the inhibition of bacterial proliferation; second, a less bacteria infiltration or promoted bacterial killing[26-30].

Based on what had been mentioned above, we draw a conclusion that conditioned pathogens (*Escherichia coli* and *Staphylococcus aureus*) may be primary pathogens of CLP rats in septic model in our study. Probiotics (*Bifidobacterium longum*, *Lactobacillus bulgaricus* and *Streptococcus thermophilus*) contribute to improving the survival in an animal sepsis model by suppressing the conditioned pathogens.

COMMENTS

Background

Sepsis is the systemic inflammatory response to infection. Microbial infection initiates and promotes systemic inflammatory responses. A variety of species of probiotics have been shown to benefit human gastrointestinal health. However, the mechanisms of probiotics in improving sepsis are unclear. In this study, the authors sought to address this question in the septic model of Wistar rats.

Research frontiers

Recently, more and more gastrointestinal diseases have been treated using probiotics. The probiotics and their products keep gastrointestinal tract homeostasis and regulate immune responses. For example, probiotics can regulate IgE production level and maturation of T cell in the gut.

Innovations and breakthroughs

To study the benefits of probiotics for sepsis, the authors observed the survival of cecal ligation and puncture (CLP) rats using different amounts mixed probiotics. The mixture of probiotics included *Bifidobacterium longum*, *Lactobacillus bulgaricus* and *Streptococcus thermophilus*. They also detected bacterial populations in ascites and blood of CLP rats using cultivation and real-time polymerase chain reaction. The data suggested that *Escherichia coli* and *Staphylococcus aureu* may be primary pathogens in the septic model. Probiotics improve survival in the septic model by suppressing the conditioned pathogens.

Applications

The results of this study suggest that probiotics improve survival in the septic model by suppressing the conditioned pathogens. This study helps to know whether probiotics can improve the clinical course of sepsis.

Terminology

CLP of rats produces cecal ischemia and polymicrobial infection. The bacteria of fecal contents will spill into the abdomen, and produce severe peritonitis and bacteremia. So CLP has been used as a classic animal model of sepsis. There are complex microbial populations in intestinal tract. Some of them are probiotics. When administered in adequate amounts, probiotics confer a health benefit to the host. The products of probiotics include mucin, organic acids, branched chain fatty acids, H_2, CO_2, ammonia, amines and vitamins. These products regulate host health through different pathways such as regulating energy, gene expression and cell differentiation, producing anti-inflammatory agents and keeping gut homeostasis.

Peer review

This study investigated the potential benefit of probiotic supplement in preventing septic death by studying the survival rates in rats treated with different doses of a probiotic mixture and then further investigated the effects of probiotics administration on the bacteria proliferation in blood and ascites in a cecal ligation and puncture sepsis model. This study shows the importance of knowing whether probiotics can improve the survival of experimental sepsis.

BRIEF ARTICLE

Impact of postoperative complications on long-term survival after radical resection for gastric cancer

Abstract

AIM: To investigate the potential impact of complications in gastric cancer patients who survive the initial postoperative period.

METHODS: Between January 1, 2005 and December 31, 2006, 432 patients who received curative gastrectomy with D2 lymph node dissection for gastric cancer at our department were studied. Associations between clinicopathological factors [age, sex, American Society of Anesthesiologists grade, body mass index, tumor-node-metastases (TNM) stage and tumor grade], including postoperative complications (defined as any deviation from an uneventful postoperative course within 30 d of the operation and survival rates) and treatment-specific factors (blood transfusion, neoadjuvant therapy and duration of surgery). Patients were divided into 2 groups: with (n = 54) or without (n = 378) complications. Survival curves were compared between the groups, and univariate and multivariate models were conducted to identify independent prognostic factors.

RESULTS: Among the 432 patients evaluated, 61 complications occurred affecting 54 patients (12.50%). Complications included anastomotic leakages, gastric motility disorders, anastomotic block, wound infections, intra-abdominal abscesses, infectious diarrhea, bleeding, bowel obstructions, arrhythmias, angina pectoris, pneumonia, atelectasis, thrombosis, unexplained fever, delirium, ocular fungal infection and multiple organ failure. American Society of Anesthesiologists grade, body mass index, combined organ resection and median duration of operation were associated with higher postoperative complications. The 1-, 3- and 5-year survival rates were 83.3%, 53.2% and 37.5%, respectively. In the univariate analysis, the size of lesions, TNM stage, blood transfusion, lymphovascular invasion, perineural invasion, neoadjuvant chemotherapy, and postoperative complications were significant predictors of overall survival. In the multivariate analysis, only TNM stage and the presence of complications remained significant predictors of reduced survival.

CONCLUSION: The occurrence of in-hospital postoperative complications was an independent predictor of worse 5-year overall survival rate after radical resection of gastric cancer.

Key words: Gastric cancer; Perioperative complication; Surgical resection; Complications

Core tip: The concept of perioperative complications as a risk factor for survival is well known in gastric cancer, however, the potential impact of complications for patients who survive the initial postoperative period has not been determined. We showed that the occurrence of in-hospital postoperative complications is an independent predictor of worse 5-year overall survival after radical resection of gastric cancer. In 432 patients evaluated, 61 complications occurred affecting 54 patients (12.50%). American Society of Anesthesiologists grade, body mass index, combined organ resection and median duration of operation were associated with higher post-

operative complications. The 1-, 3- and 5-year survival rates were 83.3%, 53.2% and 37.5%, respectively.

Impact of postoperative complications on long-term survival after radical resection for gastric cancer. *World J Gastroenterol* 2013; 19(25): 4060-4065 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4060.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4060

INTRODUCTION

Globally, gastric cancer ranks fourth and fifth in males and females, respectively, in terms of incidence, and ranks third and fifth in males and females, respectively, in terms of mortality[1]. China is classified as a high incidence area for gastric cancer. Stomach cancer has the third highest incidence and is the second leading cause of death among all cancers[2]. Surgery is the cornerstone in the treatment of gastric cancer. Although postoperative complications after surgical resection of gastric cancer are common, the potential long-term impact of these complications for patients who survive the initial postoperative period is not well understood. Western countries have published complication rates ranging from 35% to 46%, and mortality rates from 4% to 16% after D2 lymph node dissection[3-5]. Major complications include anastomotic leakage, intra-abdominal bleeding, intra-abdominal abscess, intestinal obstruction and wound infection. Previous investigations focused on the immediate effect of postoperative complications and their impact on acute perioperative course and length of hospital stay. The concept of perioperative complications as a risk factor for survival is well known in other cancer surgery, such as esophageal, colorectal cancer liver metastases, hilar cholangiocarcinoma and colorectal cancer[6-9]. To date, few studies have determined the potential impact of early surgical complications on long-term survival for patients with gastric cancer. The aim of this study was to assess the impact of prognostic factors, in particular perioperative complications, on the long-term survival of patients undergoing radical resection for gastric cancer.

MATERIALS AND METHODS

Patients

Patients' medical records and clinicopathological data during the period from January 1, 2005 to December 31, 2006 were studied retrospectively at the Department of Gastrointestinal Surgery, First Clinic Medical School of Yangzhou University, Yangzhou, China. Patients' inclusion criteria were: (1) All patients in the study had histologically confirmed gastric adenocarcinoma and received curative gastrectomy with D2 lymph node dissection; (2) Information regarding postoperative complications and mortality was available for each patient studied. As a result, 432 patients were eligible for analysis. All these patients were followed up for a minimum of 60 mo after gastric resection. These 432 patients comprised 263 men (60.88%) and 169 women (39.12%). Their median age was 64 years (range, 28-83 years). The follow-up of patients after surgery was 5 years. Numbers of subtotal and total gastric resection were 186 and 246, respectively, and gastrointestinal reconstruction comprised 82 Billroth Ⅰ, 68 Billroth Ⅱ and 282 Roux-en-Y anastomoses. This research was in compliance with the Helsinki Declaration and was approved by the ethics committee of the First Clinic Medical School of Yangzhou University. The main characteristics of 432 people included study are summarized in Table 1.

Assessment of complications

Complications were defined as any deviation from an uneventful postoperative course within 30 d of the operation. A recently published standardized complication classification system (Clavien-Dindo classification) was used to grade postoperative complications[10]. Briefly, grade I complications include any deviation from the normal postoperative course not needing specific treatment, as well as wound infections treated topically at the bedside. Grade Ⅱ complications can be treated solely by drugs, blood transfusion, physiotherapy and nutritional support. Grade Ⅲ complications require interventional or surgical treatment, without (Ⅲa) or with (Ⅲb) general anesthesia. Grade Ⅳ complications are life-threatening complications requiring intensive-care unit management (Ⅳa, single organ dysfunction; Ⅳb, multiple organ dysfunction). Grade Ⅴ represents death of the patient. In the present study, if a patient had more than 1 complication, the grade used for analysis was defined by the highest-ranked complication.

Follow-up

Complete follow-up was available for all study patients. Follow-up was calculated from the date of surgery. Follow-up data were obtained by phone, letter, and the outpatient clinical database. The end of the follow-up period was 5 years after surgery.

Statistical analysis

The impact of clinicopathological and therapy-related variables with a potential influence on a postoperative complication were investigated. For this purpose, patients with postoperative complications were compared with those who recovered normally. The two groups were compared by univariate analysis with respect to clinicopathological factors [age, sex, American Society of Anesthesiologists (ASA) grade, body mass index (BMI), tumor-node-metastases (TNM) stage and tumor grade] and treatment-specific (blood transfusion, neoadjuvant therapy and duration of surgery) variables. For the outcome analysis, the patients were divided into two groups: those with complications and those with no postoperative complications. To investigate the impact of such complications on postoperative

outcome, the two groups were compared using Kaplan-Meier survival curves. Postoperative complications are listed in Table 2. Assessment of the oncological relevance of the complication was based on an analysis of the two groups of patients. The 5-year survival rates were first subjected to univariate analysis, followed by multivariate analysis. Three patients who died within 30 d after surgery were excluded from the survival analysis.

RESULTS

Complications

Sixty-one complications occurred, affecting 54 patients (12.50%). Complications were graded into seven categories according to their severity. The details are given in Table 2. Ten patients suffered from gastric resection-related complications. Thirteen patients experienced infectious complications. Eight patients had bleeding complications and six had bowel obstructions. Five patients developed cardiac complications. Eleven patients had pulmonary complications. Two had thrombosis and six patients had other complications. Three patients died during hospitalization within 5 to 26 d after the initial gastrectomy, representing an in-hospital mortality of 0.69%. Two patients died as a result of postoperative sepsis and multiple organ failure. One died from acute respiratory distress syndrome.

Table 2 Post-operative complication types, frequencies and severities

Variables	Number

Ⅴ	3

Risk factors for post-operative complication

The variables age, sex, ASA grade, BMI, TNM stage, mean tumor size, combined organ resection, neoadjuvant therapy and median duration of operation were investigated by Pearson χ^2 test or by t test. Only ASA grade, BMI, combined organ resection and median duration of operation had an independent impact on the occurrence of complications ($P < 0.05$).

Survival

The 1-, 3- and 5-year survival rates were 83.3%, 53.2% and 37.5%, respectively. In the univariate analysis, survival was not influenced by gender, age or BMI. In contrast, the size of the lesions, TNM stage, blood transfusion, lymphovascular invasion, perineural invasion, neoadjuvant chemotherapy and postoperative complications were significant predictors of overall survival (Table 3). In the multivariate analysis, perineural invasion, the size of the lesions, blood transfusion, lymphovascular invasion and neoadjuvant chemotherapy were no longer predictive factors for reduced survival. However, the TNM stage and the presence of complications remained significant predictors of reduced survival (Table 4).

Perineural invasion	0.7 (0.4-1.0)	0.107
Neoadjuvant chemotherapy	1.5 (0.8-2.5)	0.134
Post-operative complications	2.5 (1.8-3.6)	0.000

Cox regression analysis of patient survival. TNM: Tumor-node-metastases.

DISCUSSION

In the surgical approach for early and selective advanced gastric cancer, gastrectomy with D2 lymphadenectomy is justified[11,12]. Local tumor control and long-term oncological survival are dependent on the quality of the surgical treatment and the surgeon's case-load[13]. The occurrence of postoperative complications is higher in inexperienced hands, and there is a considerable difference in early surgical outcomes among centers[14,15]. Overall survival rate is higher at specialized centers. Therefore, it may be stated that gastric cancer surgery is safe at specialized centers. The postoperative complications at our institution were in the acceptable range: most patients had a smooth recovery and postoperative mortality was not high.

In this study, ASA grade, BMI, combined organ resection and duration of operation were greater in the postoperative complications group than in the no complications group. These findings are in agreement with recent reports showing similar predictors of postoperative complications. ASA grade was reported to affect surgical complications[1], but this was not consistent with prior studies reported by Kawamura *et al*[16]. A negative effect of BMI on perioperative complications of gastrectomy has also been reported[17,18]; elevated BMI was significantly associated with increased weight of the stomach extirpated *en bloc* with omentum and perigastric lymph nodes, which was found to increase operative times. Additional organ resection in surgical therapy for gastric cancer has been associated with increased complications and perioperative mortality in pursuit of a D2 lymphadenectomy[19,20]. A large retrospective study from Japan found no survival difference when patients undergoing gastrectomy alone were compared to patients with additional organ resection, however, the complication rate was greater[21]. The duration of operation was greater in the postoperative complications group than in the no complications group. Patients with advanced TNM stage, combined organ resection and elevated BMI always require a longer operation time than others.

Although this is the first study to identify the independent impact of postoperative complications among patients undergoing surgery for gastric cancer, other investigators have explored the potential relationship between postoperative complications and long-term survival beyond the initial perioperative period in other malignancies. In an analysis of 197 colorectal cancer liver metastases patients, Schiesser *et al*[22] reported 30% perioperative complications, and the median survival time of patients with perioperative complications was 3.2 years, compared to 4.4 years in those patients without complications. Similar results were reported for hilar cholangiocarcinoma[8]. Given these findings, it is logical to fully explore the potential impact of in-hospital, postoperative complications on long-term cancer survival. Mechanisms currently under discussion include more serious immunosuppression and more obvious inflammation associated with postoperative complications. Generally, postoperative complications have been suggested to lead to an extended period of immunosuppression, which permits residual tumor cells to proliferate and survive in the host. One example supporting this hypothesis is based, in part, on the finding that in several other malignancies, perioperative blood transfusions correlated with negative immunomodulatory effects and earlier cancer recurrence[23,24]. Our findings could be explained in a similar manner. Infective complications are the most common complications, including intra-abdominal abscesses, wound infections, pneumonia, infectious diarrhea and anastomotic leakage, which can also cause abdominal infection. Several studies have demonstrated a correlation

between long-term outcomes after curative resections of solid tumors and postoperative infection and sepsis[7,25-27]. Infection and sepsis potentiate proinflammatory cytokine cascades, including tumor necrosis factor-alpha and interleukins 1, 6 and 8. These immune modulators can affect the function and regulation of natural killer cells, cytotoxic T-lymphocytes and antigen-presenting cells[28-30]. Hypothetically, micrometastases may progress rapidly during brief and prolonged periods of relative immunosuppression resulting from postoperative complications. Besides, both sepsis and blood transfusion may stimulate vascular endothelial growth factor release, which is one of the most potent stimulators of metastatic growth[31,32]. This combination of transfusion and sepsis may stimulate cancer recurrence[33].

Our results show a clear association between postoperative complications and long-term survival for patients undergoing resection for gastric cancer. The study highlights the significance not only of appropriate patient selection and surgical technique, but also serves to emphasize the potential impact that postoperative monitoring and hospital care can have on long-term outcomes. Performance of a safe operation with minimal blood loss, careful lymphadenectomy and gastrointestinal reconstruction are important for reducing post-operative complications. Avoidance of complications improves long-term survival.

In summary, our study aimed to evaluate the impact of complications on survival for patients who received radical surgery for gastric cancer. We found that the occurrence of in-hospital postoperative complications was an independent predictor of worse 5-year overall survival rate after radical resection of gastric cancer.

ACKNOWLEDGMENTS

We thank Dr. Jing Li, Department of Medical Oncology, Second Clinic Medical School of Yangzhou University, Yangzhou, China for technical help with setting up the gastric database.

COMMENTS

Background

The concept of perioperative complications as a risk factor for survival is well known in gastric cancer, however, the potential impact of complications for patients who survive the initial postoperative period has not been determined. This article studies the potential impact of complications on patients who survive the initial postoperative period.

Research frontiers

Perioperative complications are an important factor after surgery. Currently, many experts have focused on lymphatic metastasis for survival; however, perioperative complications have not been unequivocally addressed. In this study, the authors demonstrate that the occurrence of in-hospital postoperative complications was an independent predictor of worse 5-year overall survival rate after radical resection of gastric cancer.

Innovations and breakthroughs

Between January 1, 2005 and December 31, 2006, 432 patients who received curative gastrectomy with D2 lymph node dissection were studied. Associations between clinicopathological factors, including postoperative complications and survival, were studied using univariate and multivariate models.

Applications

To understand survival during the initial postoperative period of gastric cancer, this article studied the potential impact of complications for patients who survive the initial postoperative period. In the univariate analysis, size of lesions, tumor-node-metastases (TNM) stage, blood transfusion, lymphovascular invasion, perineural invasion, neoadjuvant chemotherapy and postoperative complications were significant predictors of overall survival. In the multivariate analysis, only TNM stage and the presence of complications remained significant predictors of reduced survival.

Peer review

The article provides a detailed description of the survival impact of postoperative complications. This data is valuable for the treatment of gastric malignancy.

Abstract

AIM: To assess the value of plasma melatonin in predicting acute pancreatitis when combined with the acute physiology and chronic health evaluation Ⅱ (APACHE Ⅱ) and bedside index for severity in acute pancreatitis (BISAP) scoring systems.

METHODS: APACHE Ⅱ and BISAP scores were calculated for 55 patients with acute physiology (AP) in the first 24 h of admission to the hospital. Additionally, morning (6:00 AM) serum melatonin concentrations were measured on the first day after admission. According to the diagnosis and treatment guidelines for acute pancreatitis in China, 42 patients suffered mild AP (MAP). The other 13 patients developed severe AP (SAP). A total of 45 healthy volunteers were used in this study as controls. The ability of melatonin and the APACHE Ⅱ and BISAP scoring systems to predict SAP was evaluated using a receiver operating characteristic (ROC) curve. The optimal melatonin cutoff concentration for SAP patients, based on the ROC curve, was used to classify the patients into either a high concentration group (34 cases) or a low concentration group (21 cases). Differences in the incidence of high scores, according to the APACHE Ⅱ and BISAP scoring systems, were compared between the two groups.

RESULTS: The MAP patients had increased melatonin levels compared to the SAP (38.34 ng/L *vs* 26.77 ng/L) (P = 0.021) and control patients (38.34 ng/L *vs* 30.73 ng/L) (P = 0.003). There was no significant difference inmelatoninconcentrations between the SAP group and the control group. The accuracy of determining SAP based on the melatonin level, the APACHE Ⅱ score and the BISAP score was 0.758, 0.872, and 0.906, respectively, according to the ROC curve. A melatonin concentration ⩽ 28.74 ng/L was associated with an increased risk of developing SAP. The incidence of high scores (⩾ 3) using the BISAP system was significantly higher in patients with low melatonin concentration (⩽ 28.74 ng/L) compared to patients with high melatonin concentration (> 28.74 ng/L) (42.9% *vs* 14.7%, P = 0.02). The incidence of high APACHE Ⅱ scores (⩾ 10) between the two groups was not significantly different.

CONCLUSION: The melatonin concentration is closely related to the severity of AP and the BISAP score. Therefore, we can evaluate the severity of disease by measuring the levels of serum melatonin.

Key words: Pancreatitis; Melatonin concentrations; Predict; Cutoff; Bedside index for severity in acute pancreatitis; Acute physiology and chronic health evaluation Ⅱ

Core tip: It is important to assess the severity and changes in a patient's condition in a timely and accurate manner. Thus, a comprehensive treatment plan for acute pancreatitis patients is critical. Melatonin plays a protective role in the early course of human acute pancreatitis, and melatonin concentration variations

are closely related to the severity of acute pancreatitis and the bedside index for severity in acute pancreatitis score. We can determine the severity of disease in the clinic more objectively, accurately and rapidly by measuring the levels of serum melatonin than by using the standard scoring systems. When the serum concentration of melatonin is below 28.74 ng/L, it is possible that acute pancreatitis patients will develop severe acute pancreatitis.

Clinical significance of melatonin concentrations in predicting the severity of acute pancreatitis. *World J Gastroenterol* 2013; 19(25): 4066-4071 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4066.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4066

INTRODUCTION

Most patients with acute pancreatitis have a favorable prognosis. However, the mortality rate of acute pancreatitis (AP) has been reported as 6%-23%[1]. Effectively treating the disease becomes more difficult as it develops into severe AP (SAP). Therefore, it is important to assess the disease severity in a timely and accurate manner to provide comprehensive treatment to AP patients. Accurate treatment can improve the prognosis and reduce mortality[2]. As a result, there is an urgent need for an objective, accurate, fast and simple method of monitoring changes in AP patients.

Melatonin is best known as the activator of antioxidant enzymes such as superoxide dismutase (SOD), catalase (CAT), glutathione peroxydase, or glutathione reductase[3-6]. Melatonin is also well-known as a scavenger of radical oxygen and nitrogen species[7-9]. Melatonin, together with reduced glutathione, vitamins C and E, uric acid, selenium, and creatinine, belongs to the category of nonenzymatic scavengers[6,10,11]. A number of studies have shown that melatonin (MT) plays a protective role in AP. In acute pancreatitis, melatonin was demonstrated to inhibit nuclear binding of nuclear factor kappa B (NF-κB). NF-κB is a transcription factor that controls the expression of genes involved in immunity and inflammation and the production of prostaglandins, cytokines, cell adhesion molecules, nitricoxide (NO), and inhibitors of apoptosis[12,13]. Melatonin has been demonstrated to reduce gene expression and synthesis of proinflammatory cytokines such as tumor necrosis factor α (TNFα) and proinflammatory interleukins such as interleukin (IL)-1β, IL-6, IL-8, and prostaglandins[1,14,15]. In addition, melatonin was also reported to modulate the processes of apoptosis and necrosis by stimulating the production of vascular endothelial growth factor to activate angiogenesis[16-18]. Furthermore, MT plays a protective role in AP-associated organ injuries in animal models[19-21]. For example, Huai *et al*[22] found that melatonin protects rats against acute pancreatitis-associated lung injury through the upregulation of IL-22 and Th22. The upregulation of IL-22 increases innate immunity in tissues and enhances regeneration.

Data on the relationship between the levels of MT in patients with AP and the severity and prognosis of this disease have not been reported. The aims of this study were to assess the value of plasma MT in determining the severity of AP and in predicting SAP. Additionally, we analyzed changes in plasma MT levels and the use of two scoring systems in AP patients.

MATERIALS AND METHODS

Patients

This study enrolled 55 consecutive patients with AP (35 men and 20 women) admitted to department of gastroenterology of our hospital between July 2010 and March 2011 (median age 51 years, range 17-82 years). The diagnosis and classification of AP were based on the diagnosis and treatment guidelines for acute pancreatitis in China (2009)[23]. SAP was diagnosed by the presence of organ failure and (or) local complications. Organ failure included shock (systolic blood pressure < 90 mmHg), pulmonary insufficiency (arterial PO_2 < 60 mmHg at room air or the need for mechanical ventilation), or renal failure (serum creatinine level > 2 mg/dL after rehydration or hemodialysis). Examples of localcomplications included pancreatic necrosis, a pseudocyst, or a pancreatic abscess. According to the diagnosis and treatment guidelines for acute pancreatitis in China, 42 cases were defined as mild AP (MAP), and 13 cases were classified as SAP. Within the population of SAP patients, there were 11 patients (84.6%) with pseudocysts and 2 patients (15.4%) with pancreatic necrosis. There were also 2 patients (15.4%) with acute renal failure. The disease etiology was biliary in 19 cases (34.5%), hyperlipidemic in 14 cases (25.5%), and idiopathic in 14 cases (25.5%). The causes of the remaining 8 cases (14.5%) were hyperlipidemic and biliary, alcoholic and biliary, or alcoholic and pancreatic (duct obstruction). There were no patient deaths during the study period (Table 1). We also analyzed 45 healthy individuals as controls for the study. There were 27 men and 18 women in the control group. The median age of the controls was 44 years (range of 24-64 years).

Monitoring

The study protocol was reviewed and approved by the local ethics committee. The study patients and healthy volunteers were enrolled after providing written informed consent. The patient-acute physiology and chronic health evaluation Ⅱ (APACHE Ⅱ) and bedside index for severity in acute pancreatitis (BISAP) scores were calculated within the first 24 h after admission in all patients with AP. The APACHE Ⅱ score is the most commonly used scoring system for determining the severity and prognosis of AP. This scoring system contains 12 monitoring indicators, and the final score is composed of an acute

APACHE Ⅱ: Acute physiology and chronic health evaluation Ⅱ; BISAP: Bedside index for severity in acute pancreatitis.

physiology score, an age index and a chronic health index[24]. The BISAP scoring standard consists of five elements: blood urea nitrogen, disturbance of consciousness, systemic inflammatory response syndrome, age and pleural effusion[25]. A 3 mL sample of fasting peripheral venous blood was obtained from all patients on the first morning (6:00 AM) after admission. A blood sample was also collected from the control participants.

Laboratory methods

The blood samples from patients with AP and healthy controls were immediately centrifuged at 2500 *g* for 5 min. The sample supernatants were then stored at -80 ℃ until further investigation. The melatonin levels in serum were measured using an enzyme-linked immunosorbent assay (Changfeng Chemical Company, Shanghai, China).

Statistical analysis

The statistical analysis was performed using the SPSS 13.0 statistical program. The measurement data are expressed as the mean ± SE. Differences in MT between the mean values of various groups of experiments were compared using one-way analysis of variance and SNK post hoc analysis. The incidences of high scores for the APACHE Ⅱ and BISAP scoring systems in the high MT concentration group and the low MT concentration group were compared with a χ^2 test. A difference with a P value of < 0.05 was considered statistically significant. An receiver operating characteristic (ROC) curve was generated to analyze the ability of melatonin and the APACHE Ⅱ and BISAP scoring systems to predict SAP.

RESULTS

There was no significant difference in the age ($P = 0.751$) or sex ratio ($P = 1.000$) between patients with mild pancreatitis and severe pancreatitis. Biliary problems were the main factor in the MAP group. Conversely, most cases of SAP were caused by hyperlipidemia (46.2%). Both the APACHE Ⅱ scores and the BISAP scores in severe pancreatitis were significantly higher than in the mild cases at admission. The APACHE Ⅱ scores in the severe and mild AP cases were 12 points *vs* 6 points ($P < 0.001$), while the BISAP scores were 3 points *vs* 1 point ($P < 0.001$).

Table 2 Comparison of the capability to predict severe acute pancreatitis

Variables	Sensitivity	Specificity	Youden index	Accuracy
MT ⩽ 28.74 ng/L	73.80%	76.90%	0.507	0.758
APACHE Ⅱ score ⩾ 9.5	76.90%	83.30%	0.602	0.872
BISAP score ⩾ 2.5	76.90%	90.50%	0.674	0.906

MT: Melatonin; APACHE Ⅱ: Acute physiology and chronic health evaluation Ⅱ; BISAP: Bedside index for severity in acute pancreatitis.

The median value of melatonin levels in the MAP group, the SAP group and the control group was 38.34, 26.77 and 30.73 ng/L, respectively. The melatonin level was significantly higher in patients with mild AP compared to patients with severe pancreatitis (38.34 ± 13.76 ng/L *vs* 26.77 ± 11.88 ng/L, $P = 0.021$). A similar trend was also observed in patients with mild disease compared to controls ($P = 0.003$). There was no significant difference in melatonin levels between MAP patients and healthy individuals (38.34 ± 13.76 ng/L *vs* 30.73 ± 2.96 ng/L, $P > 0.05$)

The Youden index of MT, the APACHE Ⅱ score and the BISAP score for predicting severe acute pancreatitis was 0.507, 0.602 and 0.674, respectively. The optimal cut-off value, sensitivity, specificity, Youden index and accuracy of the respective parameters in predicting SAP are shown in Table 2. The ROC curves of MT and the APACHE Ⅱ and BISAP scoring systems are presented in Figure 1.

The optimal cutoff concentration of 28.74 ng/L for SAP, as determined from the ROC curve, was used to classify the patients into a high concentration group (34 cases) and a low concentration group (21 cases). The incidence of a high BISAP score (⩾ 3) was significantly greater in patients with alow melatonin concentration (⩽ 28.74 ng/L) compared to patients with a high melatonin concentration (> 28.74 ng/L). The incidence of a high BISAP score was 42.9% in patients with low melatonin compared to 14.7% in patients with high melatonin ($P = 0.02$). There was no significant difference in the incidence of high scores (⩾ 10) according to the APACHE Ⅱ scoring system between patients with high and low melatonin levels ($P > 0.05$) (Table 3).

DISCUSSION

In the clinic, 10%-20% of AP patients will develop severe acute pancreatitis, characterized by longer duration of disease, organ failure, systemic inflammatory response syndrome, and pancreatic necrosis. As a result, the disease pathogenesis is serious and complex. It has been reported

Table 3 Relationship between melatonin concentration and patient scores

Group[1]		APACHE Ⅱ score[2]				BISAP score[3]			
	Total cases	High score cases	Incidence	χ^2 value	*P* value	High score cases	Incidence	χ^2 value	*P* value
Low concentrations	21	8	8/21	0.821	> 0.05	9	9/21	5.422	0.02
High concentrations	34	9	9/34			5	5/34		

[1]≤ 28.74 ng/L is defined as a low concentration, > 28.74 ng/L is defined as a high concentration; [2]APACHE Ⅱ score ≥ 10 is defined as a high score, the two groups, $P > 0.05$; [3]BISAP ≥ 3 is defined as a high score. BISAP ≥ 3, low melatonin concentration compared to high concentration, $P = 0.02$. APACHE Ⅱ: Acute physiology and chronic health evaluation Ⅱ; BISAP: Bedside index for severity in acute pancreatitis.

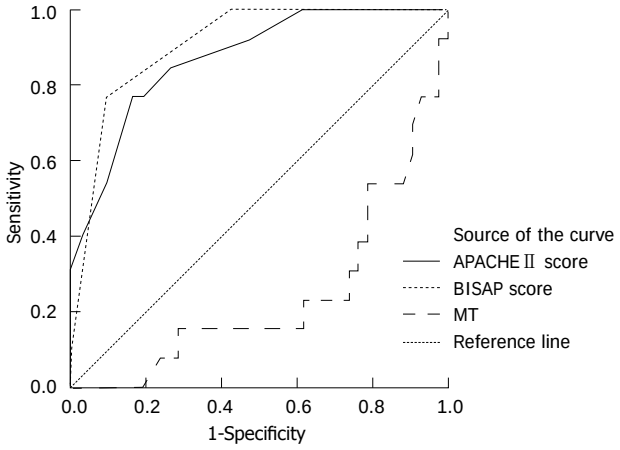

Figure 1 Receiver operating characteristic curves of melatonin, acute physiology and chronic health evaluation Ⅱ score and bedside index for severity in acute pancreatitis score to predict severe acute pancreatitis. that oxidative stress and lipid peroxidation caused by oxygen free radicals cause the destruction of acinar cells and abnormal expression of cytokines during AP pathogenesis[26]. Studies published in the literature concerning MT have demonstrated that it can stabilize cell membranes and protect the cells from oxidative damage. Moreover, MT can also penetrate all of the morphophysiological barriers in the human body and restore acinar cells with their lipophilic and hydrophilic characteristics[27]. Not only is melatonin itself an antioxidant; its metabolites can also reduce oxygen radicals. Additionally, melatonin can strengthen the activity of many antioxidants, such as SOD, Glutathione and CAT, and scavenges both oxygen free radicals and nitrogen free radicals[28,29]. MT has also been reported to have powerful anti-inflammatory and immunomodulatory effects by regulating the production of cytokines[30]. Furthermore, MT was found to promote the spontaneous regeneration process of pancreatic tissue through the activation of stellate cells[31]. MT is potentially capable of limiting pancreatic and associated organ damage produced during AP.

In our study, MT levels in the MAP group were significantly higher than the controls on the first day after admission. This result highlights the importance of the human endocrine system in AP development. The inflammatory response occurs in the early stage of AP prior to the activation of trypsinogen. The organism defense against inflammation occurs primarily through the action of the hypothalamus-pituitary-adrenal axis to increase the secretion of endogenous cortisol. However, the adrenal glands of patients with AP are in a state of relative insufficiency at the onset of disease[32]. Therefore, they may be protected by other mechanisms such as the recruitment of MT to reduce pancreatic damage; thus, an increase in MT will promote a mild disease course. It is well known that inflammation in acute pancreatitis is caused by the imbalance of pro-inflammatory factors and anti-inflammatory factors. This imbalance is more severe in patients with SAP. Perras *et al*[33] showed a clear negative correlation between disease severity and MT levels in patients suffering from severe inflammation. The pineal secretions from patients with profound systemic inflammatory responses were inhibited. This finding could explain why MT concentrations in the SAP group were significantly lower than those in the MAP group in this study. Our results indicate that the MT level is closely related to AP severity. Thus, a lower MT concentration is associated with more severe disease. Conversely, higher MT concentrations are associated with less severe disease. Our data are consistent with the view supported by Belyaev *et al*[32], who indicated that endogenous high levels of serum MT play a protective role in the early course of AP. Our findings have raised the hope that we may be able to control disease severity by using early detection of serum MT concentrations.

The ROC curve is used to compare the accuracy of two or more diagnostic tests. The ROC is considered the most reliable method of evaluating patient prognosis. In this study, we used the ROC curve to assess the relationship between MT and SAP by combining MT values with the APACHE Ⅱ and BISAP scoring systems. As shown in the results, the accuracy of the two scores for SAP were 0.872 and 0.906, respectively. This result indicates that both scoring systems can predict SAP accurately. However, these scoring systems are clinically cumbersome and difficult to remember for clinicians. In addition, it is time-consuming to monitor changes in condition accurately and rapidly using these systems[34,35]. The accuracy of SAP detection using MT was 0.758, and the optimal cut-off concentration was 28.74 ng/L in this study. Our data show that MT levels can predict SAP. Our results further demonstrate that the severity of disease can be determined objectively and accurately by early measurement of serum MT levels. Patients with AP may develop SAP when their MT concentration is below 28.74 ng/L.

Singh *et al*[36] reported that a BISAP score ≥ 3 was associated with an increased risk of developing organ failure. Thus, a BISAP score of 3 was used to divide the patients into the high score and low score groups. A key result of this study was the observation that MT levels were closely related to the BISAP score. The incidence of high score (≥ 3) was significantly increased in patients with low melatonin concentration (≤ 28.74 ng/L) compared to patients with high melatonin concentration (> 28.74 ng/L). Our results clearly demonstrate that a high BISAP score reflects a more severe AP condition and is associated with reduced MT concentration. Conversely, patients with higher MT concentrations had fewer incidences of a high BISAP score. Thus, our results agree with previously published data[36].

Chatzicostas *et al*[37] reported that SAP and its complications could be predicted accurately when the patient had an APACHE Ⅱ score ≥ 10. Therefore, patients were classified into high score and low score groups, with a dividing score of 10 between the groups. However, in our study there was no significant difference in the high score incidence between the low MT concentration group and the high MT concentration group. The reasons for this result include the following: (1) the APACHE Ⅱ score requires knowledge of the patient history, which may not be available if the patient is unconscious, intubated, or transferred from an outside hospital lacking detailed records, thus resulting in an incorrect number of points; and (2) the APACHE Ⅱ score includes a chronic health index, which is not directly correlated with AP. Thus, the relationship between MT levels and the APACHE Ⅱ score will require further studies.

In conclusion, the results of the present study reveal that exogenous melatonin may prevent the damage caused during acute pancreatitis due to its antioxidant, anti-inflammatory, and immunomodulatory properties. The variations of MT concentration might reflect the degree of AP severity to some extent. As a result, we can determine the severity of disease more objectively, accurately and rapidly by measuring the levels of serum melatonin. In addition, a melatonin concentration ≤ 28.74 ng/L was associated with an increased risk of developing SAP. The current clinical study was performed in a single center, and this research had some limitations. Therefore, large sample investigations will be needed to explore the value of serum melatonin in determining the severity of AP.

COMMENTS

Background

Acute pancreatitis (AP) includes both severe AP (SAP) and mild AP (MAP). SAP has a high reported mortality rate. It is important to assess the severity and changes in a patient's condition in a timely and accurate manner to provide comprehensive treatment. This approach could improve the prognosis and reduce mortality. Therefore, authors assessed the predictive value of plasma melatonin in identifying acute pancreatitis in combination with the acute physiology and chronic health evaluation Ⅱ (APACHE Ⅱ) and bedside index for severity in acute pancreatitis (BISAP) scoring systems.

Research frontiers

A number of studies have showed that melatonin (MT) plays a protective role in AP and its associated organ injuries using animal models. The research objective herein was to assess the value of plasma MT in determining the severity of AP. Additionally, authors predicted SAP and analyzed the changes of plasma MT levels and the use of two scoring systems.

Innovations and breakthroughs

The authors have evaluated the ability of melatonin and the APACHE Ⅱ and BISAP scoring systems to predict SAP by using a receiver operating characteristic (ROC) curve. The optimal cutoff concentration for SAP from the ROC curve was used to classify the patients into a high concentration group and a low concentration group. The differences in the incidence of high scores for the APACHE and BISAP scores scoring systems were compared between the two groups. In the present study, melatonin was shown to play a protective role in the early course of human acute pancreatitis, and concentration variations were closely related to the severity of AP and the BISAP score. The authors can determine the severity of AP more objectively, accurately and rapidly by measuring the levels of serum melatonin. When the melatonin concentration is at or below 28.74 ng/L, AP patients may develop SAP.

Applications

The study results suggest that exogenous melatonin may prevent the damage caused by AP due to its antioxidant, anti-inflammatory, and immunomodulatory properties. Variations of MT concentration might reflect the degree of severity of AP to some extent.

Terminology

The APACHE Ⅱ score contains 12 monitoring indicators, and the final score is composed of an acute physiology score, an age index and a chronic health index. The APACHE Ⅱ scoring system is the most commonly used scoring system for determining the severity and prognosis of AP. The BISAP scoring standard consists of five elements: blood urea nitrogen, disturbance of consciousness, systemic inflammatory response syndrome, age and pleural effusion.

Peer review

The authors focus on the clinical significance of melatonin concentrations in predicting the severity of AP. The results suggest that melatonin concentration variations are closely related to the severity of AP and the BISAP score. The serum melatonin level can be used to evaluate the severity of disease objectively, accurately and rapidly.

Abstract

AIM: To compare single incision laparoscopic surgery for an appendectomy (SILS-A) with conventional laparoscopic appendectomy (C-LA) when implemented by experienced surgeons.

METHODS: Studies and relevant literature regarding the performance of single-incision laparoscopic surgery *vs* conventional laparoscopic surgery for appendectomy were searched for in the Cochrane Central Register of Controlled Clinical Trials, MEDLINE, EMBASE and World Health Organization international trial register. The operation time (OR time), complications, wound infection and postoperative day using SILS-A or C-LA were pooled and compared using a meta-analysis. The risk ratios and mean differences were calculated with 95%CIs to evaluate the effect of SILS-A.

RESULTS: Sixteen recent studies including 1624 patients were included in this meta-analysis. These studies demonstrated that, compared with C-LA, SILS-A has a similar OR time in adults but needs a longer OR time in children. SILS-A has similar complications, wound infection and length of the postoperative day in adults and children, and required similar doses of narcotics in children, the pooled mean different of -0.14 [95%CI: -2.73-(-2.45), $P > 0.05$], the pooled mean different of 11.47 (95%CI: 10.84-12.09, $P < 0.001$), a pooled RR of 1.15 (95%CI: 0.72-1.83, $P > 0.05$), a pooled RR of 1.9 (95%CI: 0.92-3.91, $P > 0.05$), a pooled RR of 1.01 (95%CI: 0.51-2.0, $P > 0.05$) a pooled RR of 1.86 (95%CI: 0.77-4.48, $P > 0.05$), the pooled mean different of -0.25 (95%CI: -0.50-0, $P = 0.05$) the pooled mean different of -0.01 (95%CI: -0.05-0.04, $P > 0.05$) the pooled mean different of -0.13 (95%CI: -0.49-0.23, $P > 0.05$) respectively.

CONCLUSION: SILS-A is a technically feasible and reliable approach with short-term results similar to those obtained with the C-LA procedure.

Key words: Single incision; Laparoscopy; Appendicitis; Children; Adult

Core tip: Single incision laparoscopic surgery for an appendectomy (SILS-A) is widely accepted and has become the best option for treatment of appendicitis. Compared with conventional laparoscopic appendectomy, the safety and efficacy of SILS-A is not known. This study clarified that SILS-A has a similar operation time in adults but needs more time in children, has similar complications, wound infection and length of the postoperative day in adults and children, and needs similar doses of narcotics in children.

Safety and efficacy of single-incision laparoscopic surgery for appendectomies: A meta-analysis. *World J Gastroenterol* 2013; 19(25): 4072-4082 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4072.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4072

INTRODUCTION

Today, approximately 8% of the population will undergo appendectomy for acute appendicitis over their lifetime in Europe. An appendectomy comprises the surgical resection of the appendix and is frequently performed as an emergency process in the management of a patient suffering from acute appendicitis, a condition in which the appendix becomes inflamed and putrescent. The operation can be performed with minimally invasive surgery or as an open procedure.

Laparoscopic surgery was first used about 100 years ago, and the concept of minimally invasive surgery has significantly affected the field of traditional surgery. The first laparoscopic appendectomy was performed by the gynecologist Semm[1]. In a classic laparoscopic appendectomy, three to four incisions are required for the placement of multiple trocars. Driven by a quest toward less abdominal trauma in surgery, improved cosmesis, the potential reduction in postoperative pain, and a shorter hospital stay, specialty cameras, ports, and instruments have been developed, and minimal access surgery has undergone an accelerated process of evolution. A recent development in appendectomy has been the introduction of less invasive methods.

Single incision laparoscopic surgery applies a single multi-luminal port, or multiple mono-luminal ports, through a single skin incision. With the appearance of natural orifice translumenal endoscopic surgery, single incision laparoscopic surgery for an appendectomy (SILS-A) can be used to perform advanced[2-10], as well as preliminary procedures[11-24]. While this technique has been embraced by surgeons worldwide, the procedures and instruments used are still in the basic stages of investigation. Currently, two different methods exist for single-incision access. One involves the application of traditional, low profile laparoscopic ports that are clustered within a single skin incision, but penetration the peritoneal cavity through separate fascial incisions. The other involves the adoption of specialized ports created to provide multiple channels through a single port for one larger fascial incision. Both of methods have a good cosmetic effect. Despite its ameliorating effects, conventional laparoscopic appendectomy (C-LA) still requires three to four abdominal incisions for completion of the procedure. Each incision adds to potential morbidity risks, including bleeding, hernia, or internal organ damage[25,26]. There is little published data on the feasibility, safety, and clinical advantage of the procedure. Therefore, this study will analyze and compare the short-term surgical results of SILS-A and C-LA. The primary aim of this meta-analysis was to evaluate SILS-A *vs* C-LA; the secondary aims were to determine the difficulties, limitations or advantages of SILS-A.

MATERIALS AND METHODS

Publication search

Four bibliographic databases (Cochrane Central Register of Controlled Clinical Trials, MEDLINE, EMBASE and the World Health Organization international trial register) were searched for all relevant literature, including articles referenced in the publications. The medical subject headings (MeSH) and keywords searched for individually and in combination were as follows: "single-incision laparoscopic surgery" "multiport laparoscopic surgery" or "conventional laparoscopic" and "appendectomies". The last search was done on January 20, 2013.

Inclusion and exclusion criteria

The inclusion criteria were as follows: (1) patients should be at least 1 year of age; (2) suspected acute appendicitis on clinical and radiographic (computed tomography) grounds; (3) male or female (excluding pregnant females); (4) patients with American Society of Anesthesiology score < 3; (5) patients informed about the study, and will have read, understood and signed the patient informed; and (6) studies that provided information on at least one of the outcome measures. When a study reporting the same patient cohort was included in several publications, only the most recent or complete study was selected.

The exclusion criteria were as follows: (1) prior open laparotomy with incision through the umbilicus; (2) mental illness, dementia, or inability to provide informed consent; (3) chronic pain requiring daily medication (including opiates and NSAIDs); (4) pregnancy; (5) case reports; (6) articles that were not full text, or non-comparative studies; and (7) open operations.

Data extraction

For identified eligible studies, two reviewers using a standard form containing pre-specified outcomes would have undertaken data extraction independently. Clarification was sought where there was potential data collection but not reported. Any differences of opinion were resolved among the reviewers, and where necessary referred to a fourth party for arbitration.

Statistical analysis

Statistical analysis was performed using Review Manager (RevMan) software version 5.0.0 (The Nordic Cochrane Centre, The Cochrane Collaboration, Copenhagen, Denmark). A pooled RR and a pooled Mean Different with 95%CI were used to assess outcomes of the studies; statistical heterogeneity was tested by the χ^2 test. According to the Forest plot, heterogeneity was limited, so we used the Mantel-Haenszel fixed effect model. The significance of the pooled RR was determined by the *Z* test and statis-

SILS-A: Single-incision laparoscopic surgery for appendectomy; C-LA: Conventional laparoscopic appendectomy; M: Male; F: Female.

tical significance was considered at $P < 0.05$. Publication bias was estimated using a funnel plot with an Egger's linear regression test, and funnel plot asymmetry on the natural logarithm scale of the RR was measured by a linear regression approach.

RESULTS

Study characteristics

In total, 16 studies were included in the meta-analysis[27-42]. All of these studies were published after 2009 and comprised 751 adult patients, of whom 332 were operated on using SILS-A and 419 were operated on using C-LA. The sample size of the trials ranged from 15 to 108. Eight hundred and seventy three of the patients were children, of whom 428 were operated on using SILS-A and 445 were operated on using C-LA. The sample size of the trials ranged from 8 to 180. Moreover, some studies reported single-incision laparoscopic surgery for appendicitis, but did not report information regarding C-LA and were therefore not compared in this meta-analysis. Other studies did not provide any information about SILS-A *vs* C-LA, and were excluded in present meta-analysis (Figure 1). Tables 1-4 list the main characteristics of the 16 studies included in this analysis.

Meta-analysis results

The present meta-analysis demonstrated the pooled mean different of [-0.14, 95%CI: -2.73-(-2.45), $P > 0.05$, Figure 2A], the pooled RR of 1.15 (95%CI: 0.72-1.83), $P > 0.05$, Figure 3A) a pooled RR of 1.01 (95%CI: 0.51-2.0), $P > 0.05$, Figure 4A, a pooled mean different of -0.25 (95%CI: -0.5-0.0), $P = 0.05$, Figure 5A, a pooled mean different of 11.47 (95%CI: 10.84-12.09), $P < 0.001$, Figure 2B, a pooled RR of 1.9 (95%CI: 0.92-3.91), $P > 0.05$, Figure 3B, the pooled RR of 1.86 (95%CI: 0.77-4.48), $P > 0.05$, Figure 4B, the pooled mean different of -0.01 (95%CI: -0.05-0.04), $P > 0.05$, Figure 5B, the pooled mean different of -0.13 (95%CI: -0.49-0.23), $P > 0.05$, Figure 6, respectively. It revealed that SILS-A is feasible, and appears to have results similar to C-LA in our comparisons. But, in children, SILS-A needs more operative time than C-LA.

Operation time (min): Nine studies (701 patients) provided data on operation time for adults. The pooled results indicated that SILS-A has similar results to C-LA [weighted mean differences (WMD), -0.14 (95%CI: -2.73-2.45), $P > 0.05$]. The $\chi^2$and I^2 were 21.57 ($P = 0.0006$) and 63%, respectively, indicating heterogeneity among the studies (Figure 2A). Six studies (873 patients)

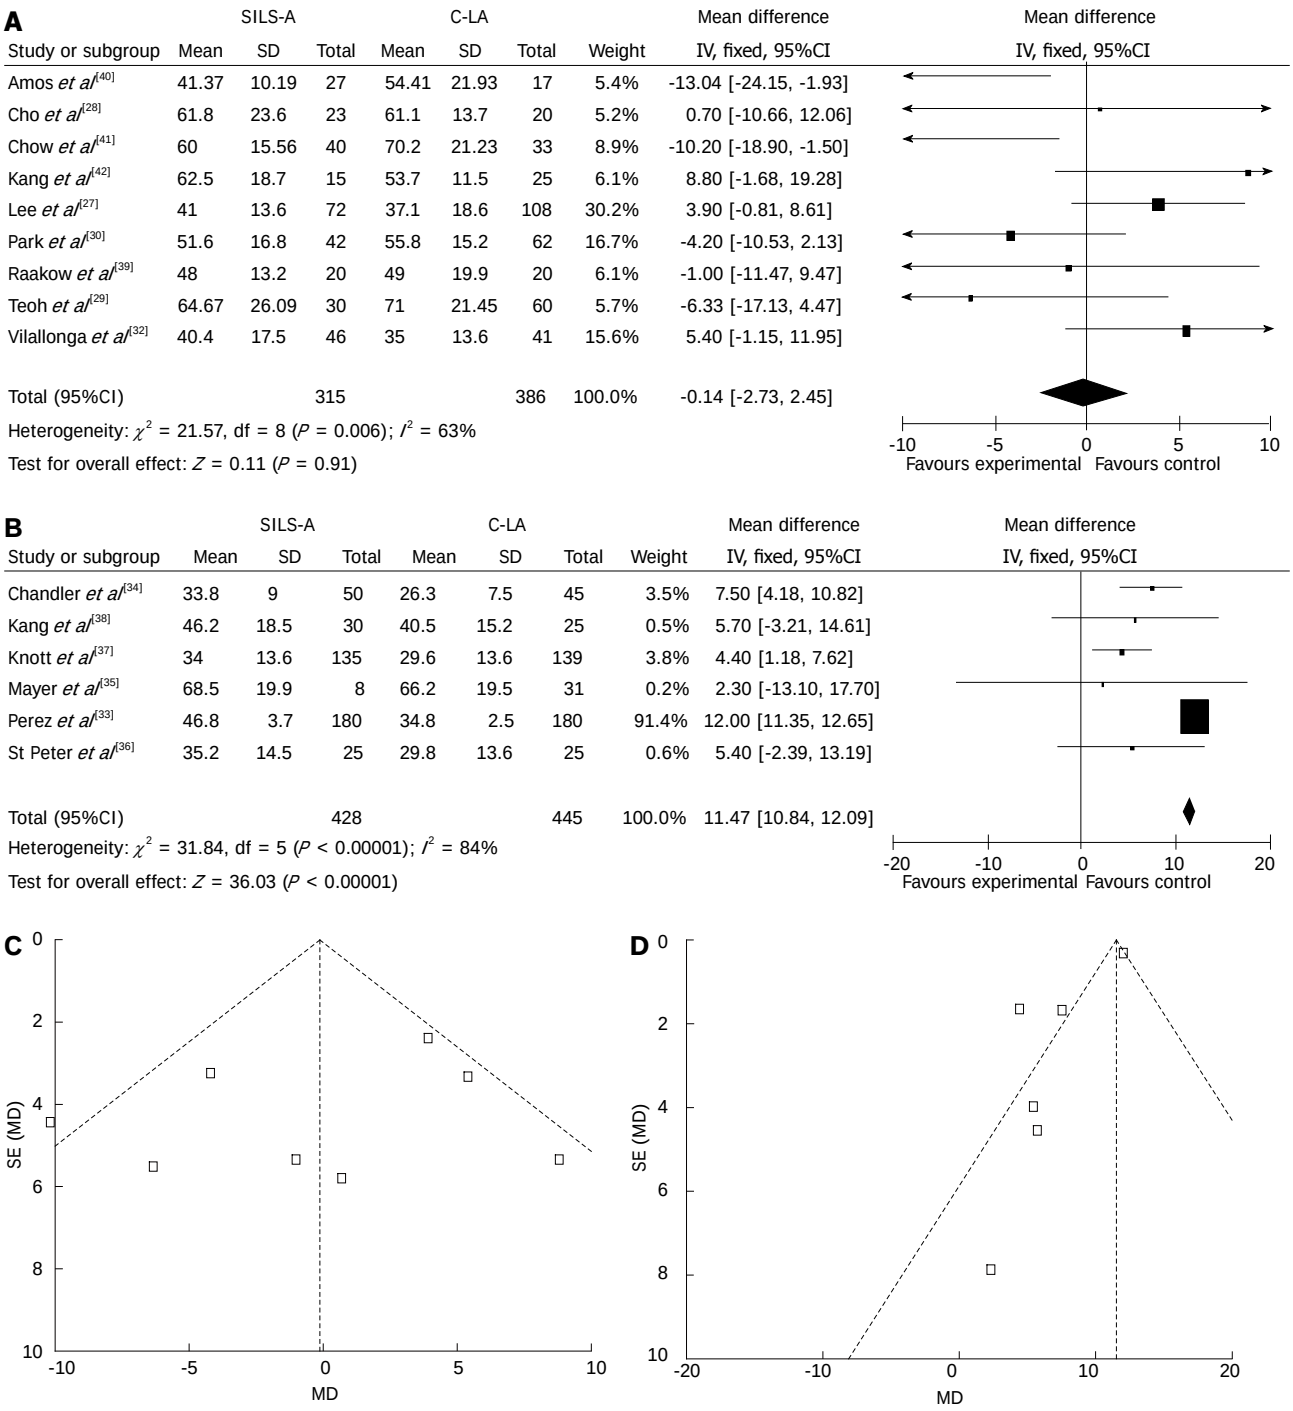

Figure 2 Forest plot of the comparison of single-incision laparoscopic surgery for appendectomies *vs* conventional laparoscopic appendectomy in terms of short-term results, outcome: operation time (min). A: Single-incision laparoscopic surgery for appendectomies (SILS-A) *vs* conventional laparoscopic appendectomy (C-LA) in terms of short-term results for adult; B: SILS-A *vs* C-LA in terms of short-term results for children; C: SILS-A *vs* C-LA in terms of short-term results for adult, mean differences (MDs); D: SILS-A *vs* C-LA in terms of short-term results for children, MDs. provided data on operation time for children. The pooled the indicated that SILS-A requires more time than C-LA [WMD, 11.47 (95%CI: 10.84-12.09), $P < 0.001$]. The χ^2 and I^2 were 31.84 ($P < 0.001$) and 84%, respectively, indicating heterogeneity among the studies (Figure 2B).

Complications: Ten studies (751 patients) provided data on complications in adults. Complications occurred in 27 of 332 (8.1%) patients after SILS-A and in 33 of 419 (7.8%) after C-LA. Pooling the results indicated that SILS-A had slightly, but not significantly, more complications than C-LA [WMD 1.15 (95%CI: 0.72-1.83), $P > 0.05$]. The χ^2 and I^2 were 6.16 ($P = 0.72$) and 0%, which excluded heterogeneity in the studies (Figure 3A). Six studies (873 patients) provided data on complications in children. Complications occurred in 18 of 428 (4.2%) patients after SILS-A and in 11 of 445 (2.4%) patients after C-LA. Pooling the results indicated that SILS-A and C-LA

data on wound infections in adults. Wound infections occurred in 13 of 236 (5.5%) patients after SILS-A and in 19 of 341 (5.6%) patients after C-LA. Pooling the results indicated that SILS-A and C-LA have the similar levels of wound infection [WMD 1.01 (95%CI: 0.51-2.0), $P > 0.05$]. The χ^2 and I^2 were 1.44 ($P = 0.96$) and 0%, which excludes heterogeneity in the studies (Figure 4A). Five studies (784 patients) provided data on wound infections in children. Wound infections occurred in 14 of 395 (3.5%) patients after SILS-A and in 7 of 398 (1.7%) patients after C-LA. The results indicated that SILS-A has more wound infections, but at an acceptable level. Pooling the results of wound infection [WMD 1.86 (95%CI: 0.77-4.48), $P > 0.05$]. The χ^2 and I^2 were 2.23 ($P = 0.53$) and 0%, which excluded heterogeneity in the studies (Figure 4B).

Postoperative days (d): Six studies (481 patients) provided data on postoperative days for adult. Pooling the results indicated that SILS-A has the slightly better results than C-LA [WMD -0.25 (95%CI: -0.50-0), $P > 0.05$]. The χ^2 and I^2 were 6.48 ($P = 0.26$) and 23%, respectively, indicating heterogeneity among the studies (Figure 5A). Five studies (822 patients) provided data on postoperative days for children. Pooling the results indicated that SILS-A has the same results as C-LA [WMD, -0.01 (95%CI: -0.05-0.04), $P > 0.05$]. The χ^2 and I^2 were 2.08 ($P = 0.72$) and 23%, respectively, which excluded heterogeneity in the studies (Figure 5B).

Doses of narcotics: Four studies (768 patients) provided data on doses of narcotics for children. Pooling the results indicated that SILS-A had similar results to C-LA, [WMD -0.25 (95%CI: -0.50-0), $P > 0.05$]. The χ^2 and I^2 were 14.25 ($P = 0.0003$) and 79%, respectively, indicating

heterogeneity among the studies (Figure 6).

Publication bias

A funnel plot was created to access the publication bias of the literature. The shapes of the funnel plots did not reveal any evidence of obvious asymmetry (Figures 2C, 2D, 3C, 3D, 4C, 4D, 5C, 5D and 6B).

DISCUSSION

The straightforward conclusion from the 16 included studies is that compared with C-LA, SILS-A has acceptable complications, similar recovery, and the same OR times for patients.

Arguments against the use SILS-A cite the lack of evidence regarding patient benefit over open surgery or CL-A. The potential requirement for advanced instrumentation may also translate into increased costs. In addition, the lack of pneumoperitoneum leaks, triangulation, and instrument "clashing" are perceived as real disadvantages of this procedure, thereby increasing its difficulty. From our study, the umbilical incision permitted only

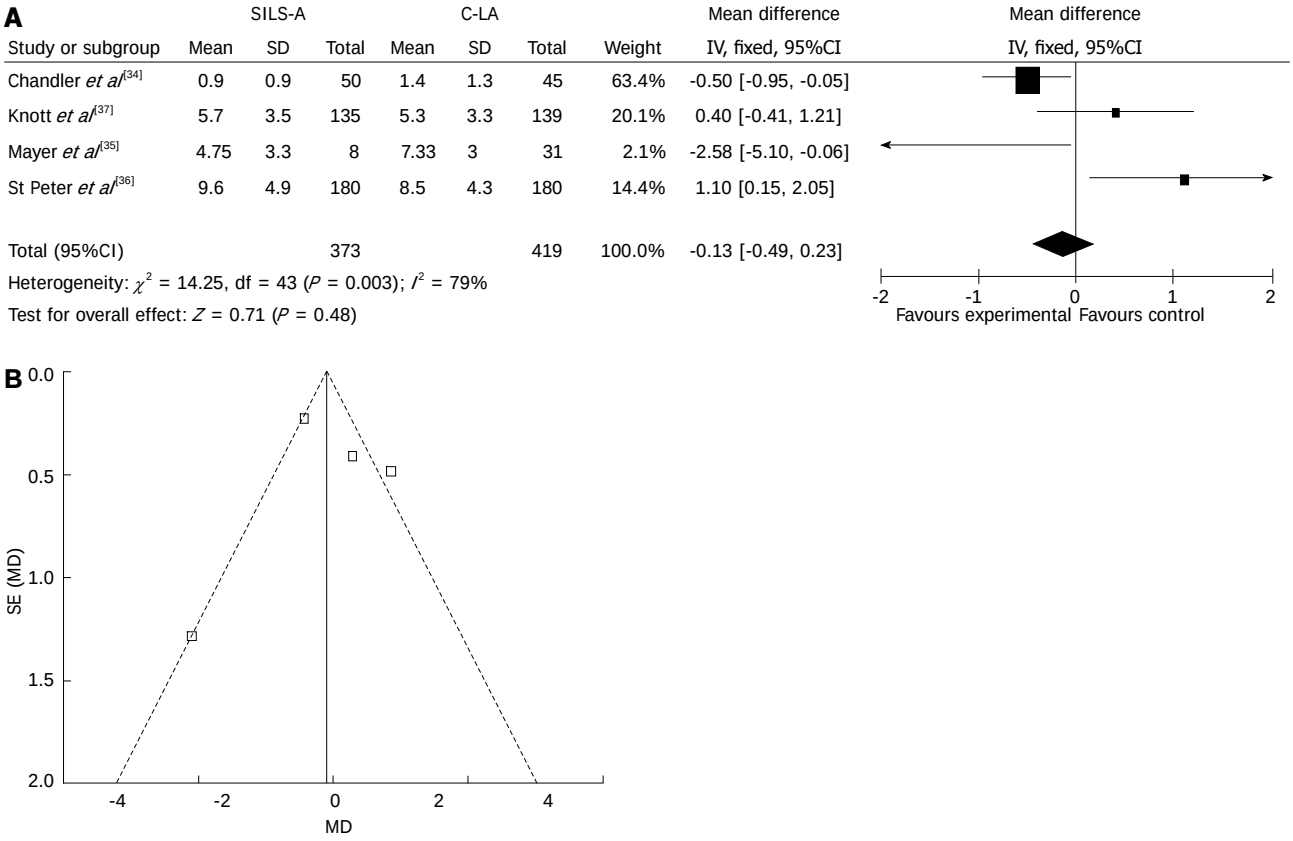

Figure 6 Forest plot of comparison: Single-incision laparoscopic surgery for appendectomies *vs* conventional laparoscopic appendectomy in terms of short-term results, outcome: doses of narcotics. A: Single-incision laparoscopic surgery for appendectomies (SILS-A) *vs* conventional laparoscopic appendectomy (C-LA) in terms of short-term results for children; B: SILS-A *vs* C-LA in terms of short-term results for children, mean differences (MDs). MDs are shown with 95%CI.

one laparoscope and one instrument into the abdominal cavity concomitantly, which ensured less trauma than the C-LA. Coaxiality was not a significant problem, except for a few of patients in whom we adopted flexible and rotating instruments. Moreover, tilting the operating table enabled us to achieve adequate exposure and dissection for the majority of patients. However, ligation of the appendix was a restricted phase of the procedure. In children, the surgery space is smaller and the lack of ancillary equipment increasing the difficulty. This is why SILS-A requires a longer time than C-LA in children at present. However, future research could be oriented toward the development of a 5-mm-diameter clip applier or sealing of the appendiceal base using energy sources, which would resolve this difficulty.

With the emergence of natural orifice translumenal endoscopic surgery, the new transumbilical approach seems to reduce the trauma of surgical access, improving postoperative pain and patient cosmesis compared to the conventional laparoscopic approach. The cosmetic outcomes of SILS-A are expected to be better if the operation is performed through the umbilicus. This is because the surgical wound is hidden within the umbilicus, leaving no visible abdominal scars. From our study, SILS-A has the same of OR times, recovery and complications as C-LA; however, SILS-A has more advantages than C-LA.

The total complication rate of 8% after SILS-A in our series was close to the 9%-14% published in the current literature for C-LA[43,44]. Extraction of the appendix through the abdominal wall is generally performed with a protected method. In our series, the risk of surgical-site infection was similar to C-LA. Although more wound infections occurred in the SILS-A group, this difference did not reach statistical significance. To answer the question of whether the wound infection rate is indeed higher for single-incision compared to C-LA, a larger number of patients are needed.

There are conflicting results regarding doses of narcotics required comparing SILS-A with C-LA, with some studies reporting higher doses of narcotics required after SILS-A[34-37] and others showing no difference. Some scholars reported that in SILS-A, early pain was more severe than in a C-LA. This might be caused by the skin incision. Although the skin incision in the umbilical area is small, the actual length of the fascia incision is much longer, and through the small incision region, all the laparoscopic equipment is used together, which stimulates the incision. From our study, there is no different between SILS-A and C-LA in children.

Postsurgical complications in patients who underwent SILS-A were treated without special side effects or complications, except for wound problems. Thus, SILS-A appears to be safe. Implementation in the identified RCT's showed a fairly low rate of complications in the SILS-A group.

However, major complications were not reduced. More large studies, with more stringent quality criteria, may improve the statistical power and provide proof of reduced morbidities. There is a common perception that although patients are released earlier after SILS-A, there are more readmissions. With a a 90 d follow up period, this is unlikely, especially in children. Although not statistically significant, it seems that SILS-A does decrease morbidities. However, the available data does not provide proof that SILS-A is superior to the conventional technique and more evidence should be provided. In addition, the quality of future trials should be higher to adequately advocate using SILS-A as the gold standard.

There are limitations to this meta-analysis. First, the sample size of some of the studies was quite low, as was the number of studies included in our meta-analysis; this may have biased the results. Second, not all of the included trials were randomized, which caused a lack of the required details. Third, we did not compare improvements in other comorbidities following SILS-A and C-LA, and these factors may be important in assessing and recommending the procedure. SILS-A is a comparatively new procedure that has become popular in recent years; therefore, there is also concern about the long-term results. The follow-up periods in most reports were 3 or 6 mo, and the studies analyzed here provided relatively short-term findings. However, we believe that, with greater awareness and the increasing popularity of SILS-A, studies comparing the two approaches in large volumes with long-term follow-up will be published.

In conclusion, this meta-analysis demonstrated that the SILS-A procedure is associated with significantly less bleeding, while providing an improved cosmetic outcome despite a modest increase the ratio of conversion. SILS-A is a technically feasible and reliable approach with short-term results similar to those obtained with C-LA. Prospective randomized studies comparing the two approaches in large patient cohorts with long-term follow-up will be needed to confirm the results reported.

COMMENTS

Background

Single incision laparoscopic surgery for an appendectomy (SILS-A) is widely accepted and has become the best option for treatment of appendicitis. Compared with conventional laparoscopic appendectomy (C-LA), the safety and efficacy of SILS-A is not known.

Research frontiers

Over the past three decades, many studies have assessed the performance of SILS-A. However, comparisons of SILS-A and C-LA for adults and children have not been published.

Innovations and breakthroughs

Based on this meta-analysis, single incision laparoscopic surgery does not increase the risk for an appendectomy. Similar associations were indicated in subgroup analyses of East Asian, Western, cohort, and high-quality studies. These findings were not presented clearly in previous systematic reviews.

Applications

Single incision laparoscopic surgery appears to be neither directly nor indirectly associated with the risk and pain of appendectomy. Further studies should seek to clarify this conclusion.

Peer review

SILS-A is rapidly becoming the focal point of attraction for specialists worldwide. This article shows the advantages of the procedure for adults and children. This analysis has great practical value for clinicians.

Abstract

Underdiagnosis of drug-induced fever leads to extensive investigation and prolongation of hospitalization, and may lead to multiple unnecessary invasive procedures and a wrong diagnosis. Azathioprine is a widely used immunosuppressive drug. We report a case of a 53-year-old female patient diagnosed with autoimmune hepatitis treated with azathioprine, who presented to the emergency room with a 6-wk history of fever and chills without other associated symptoms. Since the patient's fever was of unknown origin, she was hospitalized. All treatment was stopped and an extensive workup to explore the source of fever and chills was performed. Results of chest X-ray, viral, urine, and blood cultures, autoimmune serology, transthoracic and transesophageal echocardiography, and abdominal ultrasound revealed no source of infection. A rechallenge test of azathioprine was performed and the fever and chills returned within a few hours. Azathioprine was established as the definite cause following rechallenge. Fever as an adverse drug reaction is often unrecognized. Azathioprine has been reported to cause drug-induced fever in patients with inflammatory bowel disease, rheumatoid arthritis, and sarcoidosis. To the best of our knowledge there have been no previous reports documenting azathioprine-induced fever in patients with autoimmune hepatitis. The occurrence of fever following the readministration of azathioprine suggests the diagnosis of drug-induced fever, particularly after the exclusion of other causes. A careful rechallenge is recommended to confirm the diagnosis.

Key words: Autoimmune hepatitis; Adverse drug reactions; Azathioprine; Drug fever

Core tip: Azathioprine is widely used in inflammatory disease such as rheumatoid arthritis, inflammatory bowel disease and post solid organ transplant such as kidney transplantation. Azathioprine is an immune modulator drug that can expose patients to various infections and clinical fever. Azathioprine needs to be remembered as a potential fever provoker in the differential diagnosis of fever origin.

INTRODUCTION

Drug reaction is an underestimated cause of fever. Drug-induced fever may be defined as a disorder characterized by the appearance of elevated body temperature 7-10 d following the administration of a specific medication, with resolution of the fever upon discontinuation of the suspected agent. Less often, the fever can appear after a long period of treatment. Drug-induced fever is estimated to account for about 10% of elevated body temperature evaluations[1,2] and fever as the sole symptom of a drug's side effect has been reported in about 3%-5%[3].

The diagnosis of drug-induced fever is usually challenging, especially in medically complicated patients with multiple treatment regimens. There are no clear guidelines for the diagnosis, which is usually made by exclusion of the responsible drug. Underdiagnosis of drug-induced fever may lead to extensive investigations, unnecessary antibiotic treatment, and prolonged hospitalization[4].

Azathioprine-induced fever is a relatively rare disorder. It has been reported in only a few patients with inflammatory bowel disease, rheumatoid arthritis, and sarcoidosis[5-7]. In several other reported cases, it was associated with accompanying manifestations such as pruritus and cutaneous rash[8,9].

We report the case of a patient with autoimmune hepatitis who developed fever and chills induced by azathioprine. Rechallenge confirmed the diagnosis. To the best of our knowledge, this is the first described case of azathioprine-induced fever in autoimmune hepatitis.

CASE REPORT

A 53-year-old female of Arab descent was diagnosed in 2009 with autoimmune hepatitis by liver biopsy, which showed moderate inflammatory activity with infiltrating plasma cells suggestive of autoimmune hepatitis. Serological tests for anti-nuclear antibody (ANA), anti-double-stranded antibodies, and anti-parietal antibodies were positive, and serum immunoglobulins IgM 329 mg/dL (normal range 65-280 mg/dL), IgA 786 mg/dL (90-450 mg/dL), IgG 3120 mg/dL (800-1700 mg/dL) were elevated (Table 1). The patient had been treated with budesonide until 6 wk before admission, when azathioprine 100 mg/d was added to the treatment regimen.

Her medical history was notable for valvular heart disease, paroxysmal atrial fibrillation, hypertension, hypothyroidism, diabetes mellitus, and microcytic anemia. Her medications included warfarin 22.5 mg once daily, metformin 850 mg 3 times daily, omeprazole 20 mg once daily, losartan 80 mg twice daily, insulin detemir 20 units once daily, insulin aspart 10 units 3 times daily, metoprolol 25 mg twice daily, spironolactone 100 mg once daily, aspirin 100 mg daily, furosemide 40 mg once daily, azathioprine 50 mg once daily, and thyroxine 50 mg once daily. She presented to the emergency room due to fever and chills of several weeks duration, without other associated symptoms. On admission, the patient was stable; blood pressure was 155/69 mmHg, pulse rate 62 beats/min, and temperature 38.4 ℃. Her physical examination was unremarkable except for small skin erosion with surrounding erythema in her anterior abdominal wall. Blood tests showed a white blood cell count of 7.700 per cubic millimeter (4-10 thousand per cubic millimeter) with 90% neutrophils (40%-70%), 5.5% lymphocytes (15%-41%) and 3.5% monocytes (1%-7%). Hemoglobin was 9.3 g (12-16 g). Results of blood chemistry, including electrolytes and kidney function, were normal except for mild elevation of liver function tests. Urinalysis showed a few leukocytes but otherwise was normal. Nasal viral cultures were negative. C-reactive protein and erythrocyte sedimentation rate were normal. Computed tomography was performed to exclude an intra-abdominal cause of fever and revealed a small area of subcutaneous inflammation adjacent to the skin erosion. Chest X-ray showed no changes suggestive of infection.

ALP: Alkaline phosphatase; AST: Aspertate aminotransferase; AIH: Autoimmune hepatitis; ANA: Anti-nuclear antibody; SMA: Soluble ribonucleic acid; LKM: Liver-kidney microsomal; IgG: Immunoglobulin G.

The patient was admitted to the Department of Internal Medicine with an initial diagnosis of fever, most likely secondary to the localized skin infection in the abdominal wall. Azathioprine was withheld and the patient was treated with antibiotics. Within several hours the fever subsided and the patient remained afebrile throughout 5 d of hospitalization.

Following recovery and resolution of the cellulitis, the patient was discharged and azathioprine was re-administered. Within a few hours, fever and chills recurred and the patient was re-admitted to the hospital. An extensive work-up for fever of unknown origin was done including blood and urine cultures and nasal viral cultures, which were all negative. Serological tests for human immuno-

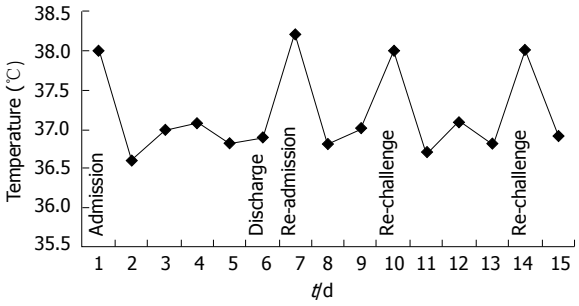

Figure 1 Patient fever scale during hospitalization and rechallenge test.

deficiency virus, hepatitis viruses, brucella, Q fever and toxoplasma were negative. Autoimmune serology showed ANA 2 of 4, anti-parietal cell antibodies 4 of 4; anti-smooth muscle, anti-mitochondrial and immunoglobulins were negative. In addition, ultrasonography of the abdomen revealed no evidence of ascites or infection. Transthoracic and transesophageal echocardiography did not show vegetation or abscess. Purified protein derivative test was negative. Again azathioprine was withheld and the fever resolved within a few hours.

With the patient's informed consent, a rechallenge with one tablet of 50 mg azathioprine was performed twice under observation. Chills appeared within 3 h and there was a gradual increase in temperature up to 38 ℃ within 7 h. Fever and chills resolved completely within 6 h after discontinuation of azathioprine.

DISCUSSION

Drug-induced fever is an underdiagnosed condition, particularly in patients treated with a large number of medications. It is described as a febrile response that coincides temporally with the administration of a drug and disappears after discontinuation of the offending agent. It is usually suspected when no other cause for fever can be explained, leaving drug fever as the diagnosis of exclusion.

Several mechanisms have been implied in the pathogenesis of drug-induced fever, most importantly hypersensitivity reaction involving the formation of antigen-antibody complexes. Common agents associated with hypersensitivity type reaction include penicillins, cephalosporins, phenytoin, methyldopa, procainamide, and antitubercular agents[2,3,10]. Other mechanisms include idiosyncratic reactions, drug effects on the thermoregulatory center, reactions to drug administration, and the extension of drug pharmacological effects as seen in patients who developed cell lysis and release of variable pyrogenic substances following chemotherapy treatment[1,11-13].

Azathioprine suppresses the immune system by inhibiting the activity of T cell lymphocytes. It is a prodrug which, following oral ingestion, is metabolized into active mercaptopurine, a purine synthesis inhibitor that impedes DNA synthesis and inhibits cell proliferation[14]. Azathioprine is known to cause multiple adverse effects, including fever, gastrointestinal symptoms, nervous system symptoms, bone marrow suppression, hepatic symptoms, myalgia, and arthralgia. Discontinuation of azathioprine is seen in about 10%-15% of patients due to side effects[5].

Several cases of azathioprine-induced fever in association with other symptoms have been reported; fever and chills were the only reported symptoms when azathioprine was administered to patients with sarcoidosis and inflammatory bowel disease, and after kidney transplantation[5,7,15,16].

In an observational study, three of 25 patients with RA developed symptoms of fever, chills, skin rash, hepatotoxicity, nausea, and diarrhea 2 wk after starting treatment with azathioprine. One patient developed only fever and chills. Rechallenge was performed in two patients with the appearance of more severe reactions[6]. In these patients, the febrile reaction appeared several days up to several weeks after beginning treatment with azathioprine. In our case the fever appeared within a few hours after restarting the offending agents. Thus the lag period between the initiation of the offending agent and the appearance of fever is highly variable.

In our patient, the sequence of events and the lack of objective evidence of infection are both highly suggestive of azathioprine-induced fever. In addition, previous reports of azathioprine causing drug fever in other disease states support the likelihood of a similar event in this patient[5-7]. With the patient's permission, two rechallenge tests were done in which 50 mg azathioprine was administered. Fever of 38 ℃ was measured about 7 h after administration, without other associated symptoms or objective findings on blood analysis, and without recurrence of the fever upon discontinuation of azathioprine (Figure 1). Thus, fever and chills in our case are the only manifestations of azathioprine and were likely caused by the administration of azathioprine.

In conclusion, drug reaction is an underestimated cause of fever. Clinicians should be aware of the fact that an immunomodulatory drug such as azathioprine, commonly used to treat various autoimmune conditions and to suppress the inflammatory response, can cause fever and chills. It is thus essential to withdraw a suspected medication and perform a rechallenge when fever fails to regress in patients already treated with antibiotics.

Abstract

Gastrointestinal arterio-venous malformations are a known cause of gastrointestinal bleeding. We present a rare case of persistent rectal bleeding due to a rectal arterio-portal venous fistula in the setting of portal hypertension secondary to portal vein thrombosis. The portal hypertension was initially surgically treated with splenectomy and a proximal splenorenal shunt. However, rectal bleeding persisted even after surgery, presenting us with a diagnostic dilemma. The patient was re-evaluated with a computed tomography mesenteric angiogram which revealed a rectal arterio-portal fistula. Arterio-portal fistulas are a known but rare cause of portal hypertension, and possibly the underlying cause of continued rectal bleeding in this case. This was successfully treated using angiographic localization and super-selective embolization of the rectal arterio-portal venous fistula *via* the right internal iliac artery. The patient subsequently went on to have a full term pregnancy. Through this case report, we hope to highlight awareness of this unusual condition, discuss the diagnostic workup and our management approach.

Key words: Portal hypertension; Esophageal varices; Splenorenal shunt; Arteriovenous malformations; Portal vein thrombosis

Core tip: We present a rare case of persistent rectal bleeding due to a rectal arterio-portal venous fistula, in the setting of portal hypertension. Through this case report, we hope to highlight awareness of this unusual condition, and discuss the diagnostic workup and our subsequent management. We believe that this is the first of such cases reported in the literature.

Yap HY, Lee SY, Chung YFA, Tay KH, Low ASC, Thng CH, Madhavan K. Rectal arterio-portal fistula: An unusual cause of persistent bleeding per rectum following a proximal spleno-renal shunt. *World J Gastroenterol* 2013; 19(25): 4087-4090 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4087.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4087

INTRODUCTION

Arterio-venous malformations occurring in the gastrointestinal tract are a known cause of gastro-intestinal bleeding and can often be missed especially in the presence of other pathology. They can lead to persistent symptoms if left undiagnosed and untreated. We present a patient who had portal vein thrombosis, portal hypertension and continued to have rectal bleeding in spite of a patent spleno renal

shunt to highlight awareness of this unusual condition.

CASE REPORT

A 33-year-old Chinese lady presented with multiple episodes of haematemesis when she was nine years old.She was seen in a secondary hospital and diagnosed to have portal hypertension secondary to portal vein thrombosis (PVT), a possible sequelae of a neonatal umbilical infection. The portal hypertension resulted in her having episodes of bleeding esophageal varices that were treated endoscopically during her childhood years. On clinical examination, she had splenomegaly but no stigmata of chronic liver disease. Investigations revealed that she did not have any liver cirrhosis or prothrombotic disorders. Liver function tests were normal. Radiological investigations confirmed the PVT and splenomegaly. More than twenty years after her initial diagnosis, she started to develop intermittent episodes of rectal bleeding which was attributed to rectal varices. She was anaemic (haemoglobin level 7.0 g/dL) and required intermittent blood transfusions for her symptoms. Her splenomegaly led to consumption thrombocytopenia (platelet levels ranged from 74-103 $\times$ 10^9 g/L) and she subsequently sought a second opinion at a tertiary centre, after much investigation including a contrast enhanced computed tomography scan, upper gastrointestinal endoscopy and a colonoscopy.

Pre-operative investigations were reviewed and showed PVT, splenomegaly and a dilated inferior mesenteric vein all the way down to the pelvis. Colonoscopy reported that there were large rectal varices. Based on these investigations, we presumed that the rectal varices were a result of left sided portal hypertension with the pressure transmitted down the inferior mesenteric vein, and thus performed a splenectomy and an end-to-side proximal splenorenal shunt for portal decompression.

After surgery, the patient continued to have rectal bleeding during her follow-up. A flexible sigmoidoscopy was performed and this revealed almost circumferentially dilated pulsatile submucosal vessels at the lower rectum. These were not reported in the colonoscopy that the patient underwent previously in the secondary hospital. A multiphasic computed tomography mesenteric angiogram confirmed a rectal arterio-venous fistula. On the arterial phase of the scan, there was evidence of arterio-venous shunting as evidenced by the dilated superior rectal vein draining into the superior mesenteric vein, with arterial feeders from the internal iliac arteries (Figure 1). A diagnostic catheter angiogram was performed to confirm the complexity of the feeder vessels and assess the potential collateral damage to rectal mucosa that could occur with angioembolisation. This revealed that there were two major arterial feeders arising from the anterior division of the internal iliac arteries on both sides which were supplying the arterio-portal fistula. There was a single tortuous drainage vein into the inferior mesenteric vein (Figure 2).

A super selective angioembolisation of the arterio-portal fistula was performed *via* a left common femoral artery access. The EV3 Apollo microcatheter (ev3 Endovascular Inc., Plymouth, MA, United States) was introduced and advanced into the arterio-portal fistula nidus and embolisation performed using 2cc of Onyx 18 embolic agent (ev3 Endovascular Inc., Plymouth, MA, United States). Completion angiograms *via* both internal iliac arteries showed successful obliteration of the arterio-portal fistula with cessation of arterio-portal shunting (Figure 3).

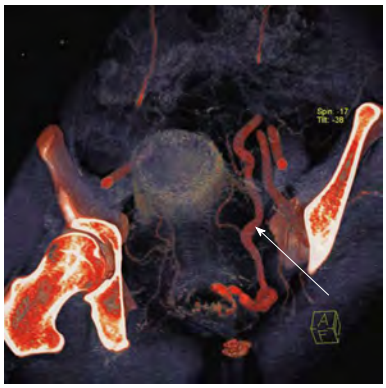

Figure 1 Computed tomography angiography image (post processed with **volume rendering technique) showing rectal arterio-portal fistula draining** into dilated superior rectal vein (arrow).

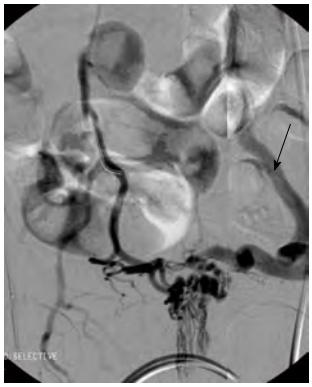

Figure 2 Pelvic angiography image showing the rectal arterio-portal fistula draining into the dilated superior rectal vein (arrow).

Figure 3 Post embolization angiogram from the anterior branch of the **right internal iliac artery (arrow) showing obliteration of blood flow in the arterioportal fistula.**

Post procedure, clinical examination and a repeat flexible sigmoidoscopy confirmed that there was no rectal ischemia. However, the patient complained of anal pain and further rectal bleeding, although the quantity of bleeding was much reduced. On clinical examination, she was found to have an anal fissure at 3 o'clock position, possibly as a result of the embolisation. This was initially treated with topical methods but did not resolve her symptoms and thus she underwent a lateral anal sphincterotomy. Since surgery, she has successfully delivered a child after a full-term pregnancy and her haemoglobin (12.0 g/dL) and platelet levels have returned to normal.

DISCUSSION

Arteriovenous malformations (AVMs) in the gastrointestinal tract are a known cause of gastrointestinal bleeding, and are usually difficult to diagnose. In the literature, it has been reported that the highest frequency of gastrointestinal AVMs occur in the right sided colon[1]. Arteriovenous malformations in the rectum are rare and it is often difficult to distinguish between bleeding from the AVM and bleeding from haemorrhoids, leading to diagnostic delays and even unnecessary procedures being performed for haemorroids[2].

Arterio-portal fistulas are a type of arteriovenous malformations defined as abnormal communications between the systemic arteries and the portal circulation[3]. They can be congenital or acquired. Congenital causes include arteriovenous malformations, ruptured aneurysms and hereditary telangiectatic diseases where there might be multiple arterio-portal fistulas present[4-7]. The majority of them are a result of penetrating or blunt trauma to the vessels which can be iatrogenic[8]. Most commonly, arterio-portal fistulas originate from the celiac or splanchnic circulation in particular the hepatic artery or splenic artery due to their close proximity to the portal and splenic veins. Rarely, they can be found to arise from the superior mesenteric or inferior mesenteric arteries[3]. In our patient, the arterio-portal fistula arose from the internal iliac arteries and this is believed to be the first such case reported in the literature.

Portal vein thrombosis is a known cause of extrahepatic presinusoidal portal hypertension. In neonates, this can be caused by umbilical infection, often as a result of umbilical vein catheterisation. The infection spreads along the left portal vein to the main portal vein causing thrombosis[8]. Due to the increase in portal resistance, collaterals arise from the high pressure veins in the portal system to the low pressure veins in the systemic circulation. The reversal of blood flow towards the systemic venous circulation leads to formation of varices at the oesophago-gastric region, along the falciform ligament at the umbilicus, in the retroperitoneum *via* the veins of Retzius and at the anorectal region where the superior haemorrhoidal veins decompress into the middle and inferior haemorroidal veins of the systemic circulation. Our patient presented with bleeding esophageal varices at an early age and this lead to her diagnosis of PVT. The leading cause of mortality in portal hypertension is bleeding esophageal varices[9]. Anorectal varices rarely bleed, likely due to the rich plexus of veins around the rectum which shunts away most of the blood.

In our patient, we offer two possibilities to account for her condition. The first is that she has a congenital pre-existing arterio-portal fistula between the rectal artery and the haemorrhoidal veins. However, when the patient first presented with rectal bleeding in the setting of portal hypertension, the most likely diagnosis of bleeding ano-rectal varices was made and she was treated with the aim of reducing her portal pressures, which was the presumed cause of the ano-rectal varices. In retrospect, this was a wrong postulation. The rectal bleeding did not resolve despite the splenorenal shunt and only on further investigations did we discover the arterio-portal fistula which had initially masqueraded as bleeding ano-rectal varices. Awareness of this entity as a possible differential diagnosis for bleeding ano-rectal varices is important. Initial investigation with a dynamic computed tomography scan with arterial and portal venous phase would have brought the diagnosis to light.

The second possibility is that the arterio-portal fistula was formed due to unintended or unnoticed trauma to the rectal wall. The left sided portal hypertension led to the formation of dilated portal vasculature in the rectum. These rectal varices are in close proximity to the branches of the arteries supplying the rectum, like the middle rectal artery in this case. An episode of unsuspecting trauma to the rectal wall possibly during defecation, led to the formation of the abnormal vascular communication between the middle rectal artery and the rectal varices, propagating the formation of an arterio-portal fistula

Multiphasic contrast enhanced computed tomography scan of the abdomen and pelvis helped to clinch the diagnosis of the arterio-portal fistula in this case, as contrast was seen on the draining dilated superior rectal vein in the arterial phase of the scan. This distinguishes it from a simple rectal bleeding secondary to rectal varices. In the setting of portal hypertension, awareness of the possible diagnoses is critical.

In the era prior to interventional radiology, arterio-portal fistulas were usually treated by open surgical excision. With the advent of super-selective angiographic catheterisation, embolisation is now the definitive treatment of choice for patients if the expertise is available[3]. Inadequate imaging especially in the setting of presumed portal hypertension has led to the delayed diagnosis of this arterio-portal fistula and local transanal treatment could have been catastrophic. Endoscopic ablation of the nidus of dilated collaterals in the rectum using sclerosant or banding could have led to massive haemorrhage from high pressure arterial bleeding if it was simply treated as for rectal varices following portal decompression.

In conclusion, arterio-portal fistulas are a known cause of portal hypertension and can also cause a diagnostic dilemma in the setting of portal hypertension. An-

giographic embolisation is the treatment of choice and this can be achieved with minimal morbidity.

Abstract

Foreign body ingestion is a common emergency situation in children with one or a few objects having been ingested. Here we report our experience using endoscopic retrieval in a female centenarian with dyspnea and foreign bodies in the esophagus. She attempted suicide by swallowing 26 coins and two other foreign bodies. A gastroscope was used to remove all foreign bodies in the lower esophagus. In total, 26 coins, one ferrous ring and one cylindrical plastic object were retrieved. To our knowledge, this is the first clinical report on retrieval of so many foreign bodies in a single case.

Key words: Foreign body; Esophagus; Endoscopy; Coin; Gastroscope; Retrieval basket

Core tip: Foreign body ingestion is typically a childhood phenomenon, and generally involves one or a few objects. Here, we report our experience using emergency endoscopy in a centenarian with dyspnea who had swallowed 26 coins and other foreign bodies. Rescue measures were applied to maintain stable vital signs and airway patency, while an alligator forceps or basket was inserted through a flexible gastroscope to remove all foreign bodies. The objects removed from the patient included 26 coins, a ferrous ring, and a cylindrical plastic object.

INTRODUCTION

Ingestion of foreign bodies that lodge in the upper gastrointestinal (GI) tract is common. Most objects pass through the GI tract spontaneously, but some need endoscopic or surgical removal. Here, we report the first case of a centenarian who had swallowed several foreign bodies, which were safely removed by endoscopy.

CASE REPORT

Foreign body ingestion is a commonly encountered clinical problem in pediatric emergency cases, but generally it involves only one or a few objects. Here, we report a case of ingestion of foreign bodies in a centenarian.

A 100-year-old woman complaining of retrosternal pain and tachypnea visited the emergency room. She had swallowed several foreign bodies in a suicide attempt due to intolerable pain induced by a fracture she suffered 3 mo previously. She was bedridden and had a depressed mood, which caused her to attempt suicide. She was admitted to hospital and a routine chest roentgenogram showed the incidental finding of suspicious foreign bodies, which were located in the lower esophagus (Figure 1). Blood

Figure 1 A roentgenogram showing foreign bodies in the lower esophagus (arrow).

Figure 3 **Foreign bodies after removal.** These included 26 coins, a ferrous ring, and a cylindrical plastic object.

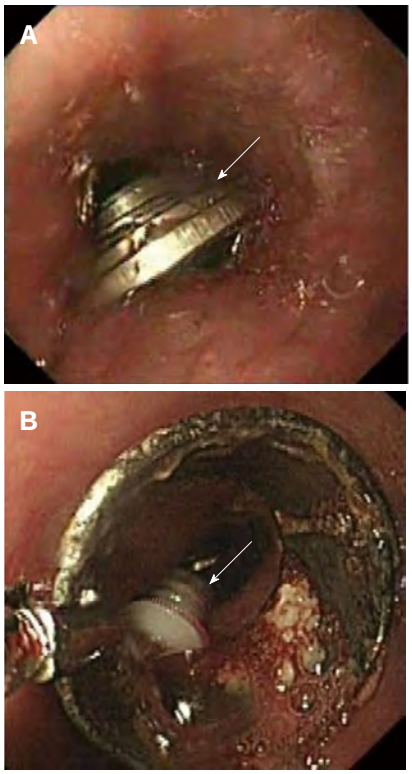

Figure 2 **Gastroscope examination.** A: Gastroscopy displayed several coins (arrow) in the lower esophagus; B: A cylindrical plastic foreign body impacted in the esophageal wall (arrow).

tests were normal, and an electrocardiogram showed premature ventricular extrasystole. Further gastroscopy examination using a flexible endoscope under a conscious state showed that several coins were located in the lower esophagus (Figure 2A). Endoscopic removal of these coins was performed, but failed because of their smooth edges. Therefore, an alligator clamp was employed to secure the coins, and more than 10 coins were successfully removed. Additionally, a cylindrical plastic foreign body was difficult to extract using the alligator clamp (Figure 2B). After several attempts, this foreign body was taken out via a stone retrieval net. Subsequently, additional foreign bodies were found and taken out using the alligator forceps. The foreign bodies removed from the patients included 26 coins, a ferrous ring, and a cylindrical plastic object (Figure 3). The procedure took about half an hour. When we reviewed the gastroscopy procedure, there was no block and no active bleeding in the esophagus.

DISCUSSION

Ingestion of foreign bodies is common in clinical practice. Most foreign body ingestion is accidental, and often occurs in the pediatric population, with a peak incidence between 6 mo and 6 years of age[1]. In contrast to the high frequency of foreign body ingestion in children, the occurrence rate of foreign body ingestion is relatively low in adults. The situation in adults occurs more commonly in patients with psychiatric disorders, mental retardation, or impairment caused by alcohol[2]. This is the first report of a centenarian ingesting foreign bodies in a suicide attempt due to intolerable pain. Additionally, the location of the foreign bodies in this case was in the lower esophagus, which was different from previous reports in which the majority of foreign bodies were located in the upper esophagus[3,4]. Foreign bodies in the upper esophagus may cause mechanical compression of the airway while in the lower esophagus may cause functional narrowing of the cardia. In this case, the patient's dyspnea was caused by both mechanical compression of the airway and functional narrowing of the cardia because of the irritation of so many foreign bodies.

The type of foreign body may influence the risk of complications. The types of foreign objects are different for different ages and cultures. In children, coins are a common type of foreign body[5]. In Asian countries, bone foreign bodies have been regarded as the most common type due to traditional habits of swallowing fish bones or eating soup from which fish bones are not removed[6,7]. The current case was rare in that a centenarian swallowed the coins.

Endoscopic removal of foreign bodies and impacted food boluses is a reliable and safe procedure in the hands of a skilled endoscopists, and it has a high success rate and low level of significant complications[8]. However,

the effectiveness of endoscopic removal of the foreign bodies was challenged by the smooth edges of the coins in the current case. Therefore, an alligator clamp was utilized. Additionally, a stone retrieval net was also employed to extract a cylindrical plastic foreign body in the present case. Many foreign bodies were removed, which is another important point in this case.

According to our experience, the key factor in shortening the procedure time was to catch and remove the foreign bodies in a short time using a powerful retrieval device. If the surface of the foreign body is smooth, it may be much more difficult. Each object is a challenge to the endoscopist. This was the reason why it took us 0.5 h to remove all the foreign bodies using a common stone extraction device. Fortunately, a novel retrieval basket is being developed by Detian Medical (Changzhou, China). Based on our animal and *in vitro* experiments, it is much easier for an endoscopist to catch foreign bodies and polyps and hold them stably in this basket device compared with traditional retrieval devices.

In conclusion, we reported our experience with retrieval of 26 coins and another two foreign bodies from the esophagus of a 100-year-old suicidal patient with dyspnea. To our knowledge, this is the first clinical report of retrieval of so many foreign bodies in a single case.

Abstract

Primary hepatic leiomyoma is a neoplasm of mesenchymal origin and occurs only rarely. Secondary to benign smooth muscle proliferation, it is usually found in adult women and is associated with Epstein-Barr virus (EBV) infection. Here, we report the 29th case of primary hepatic leiomyoma with its unique features related to diagnosis, treatment and developmental biology. A 48-year-old man, with an immunocompromised status, complained of pain in the upper quadrant of the abdomen. Serological analysis indicated no presence of hepatitis virus, no human immunodeficiency virus, and no EBV infection. The levels of α-fetoprotein and carcinoembryonic antigen were normal. A mass was detected in segment Ⅲ of the hepatic lobe by ultrasonography and an abdominal computed tomography scan. Endoscopy had negative findings. Exploratory laparotomy found no existing extrahepatic tumor and left lateral lobectomy was performed. Pathological examination showed the mass to be a typical leiomyoma. The cells were positive for α-smooth muscle actin and desmin, and negative for the makers of gastrointestinal stromal tumor (GIST), including CD117, CD34 and DOG1 (discovered on GIST1). *In situ* hybridization revealed negative status for EBV-encoded small RNA. After left lateral lobectomy, the patient was not given chemotherapy or radiotherapy. During a 2-year follow-up, no sign of local recurrence or distant metastasis was observed. In conclusion, we report a rare case of primary hepatic leiomyoma in a male patient without EBV infection. Hepatic resection was curative. This case presents data to expand our knowledge concerning the complex and heterogeneous nature of primary liver leiomyoma, indicating that EBV infection is important but neither necessary nor sufficient for the development of primary liver leiomyoma.

Key words: Epstein-Barr virus; Primary hepatic leiomyoma; Cancer diagnosis; Tumor resection; Developmental biology

Core tip: Primary hepatic leiomyoma is usually found in adult women and is associated with Epstein-Barr virus (EBV) infection. We report the 29th case worldwide in a 48-year-old kidney allograft recipient without EBV infection and extrahepatic tumor. He achieved clinical cure by mass resection. The leiomyoma was positive for α-smooth muscle actin and desmin, and negative for gastrointestinal stromal tumor markers, including CD117, CD34 and DOG1 (discovered on gastrointestinal stromal tumor 1). The tumor was negative for EBV-encoded small RNA. The data indicate that EBV infec-

tion is important but neither necessary nor sufficient for development of primary liver leiomyoma.

Luo XZ, Ming CS, Chen XP, Gong NQ. Epstein-Barr virus negative primary hepatic leiomyoma: Case report and literature review. *World J Gastroenterol* 2013; 19(25): 4094-4098 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i25/4094.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i25.4094

INTRODUCTION

Primary hepatic leiomyoma occurs rarely. The first case was described by Demel[1] in a 42-year-old woman. To date, only 28 cases have been reported worldwide in the literature (Table 1). Secondary to benign smooth muscle proliferation, primary hepatic leiomyoma is usually found in adult women, and is associated with Epstein-Barr virus (EBV) infection. Due to its low prevalence, the diagnosis, treatment and biological behavior remain elusive and require further investigation[2-5]. More data to provide essential information concerning this disease are keenly awaited.

CASE REPORT

We report a 48-year-old man who complained of pain in the upper quadrant of the abdomen for 1 year and was admitted 2 years ago. He had received a renal graft 9 years before with the immunosuppressive regimens of cyclosporine A, mycophenolate mofetil and prednisone. Due to the calcineurin inhibitor nephrotoxicity found by fine-needle aspiration biopsy 3 years ago, cyclosporine was changed to tacrolimus. Two years ago, mycophenolate mofetil was replaced by azathioprine due to persistent diarrhea. On the day of admission, he was receiving tacrolimus (4.1 ng/dL), azathioprine (50 mg/d), and prednisone (5 mg/d). Routine blood analysis showed a white blood cell count of 7.2×10^9/L and lymphocyte count of 2.4×10^9/L. His liver function was normal and graded as A (score: 6) by Child-Turcotte-Pugh classification. There was no evidence of hepatitis B or hepatitis C virus infection. Human immunodeficiency virus (HIV) testing was negative. Serological testing for EBV was also negative. α-fetoprotein was 5.27 ng/mL (range: 1.09-8.04 ng/mL), and carcinoembryonic antigen was 2.55 ng/mL (normal range: 0-5 ng/mL). Ultrasonography revealed a mass in the left region of the liver, and an abdominal computed tomography (CT) scan showed a tumor of 3.7 cm × 4.9 cm in segment Ⅲ of the hepatic lobe (Figure 1). No tumor was found by esophagogastroduodenscopy and colonoscopy.

After diagnosis with a liver tumor, the patient underwent exploratory laparotomy. A solitary tumor was found in segment Ⅲ of the liver (Figure 2A). No tumors were present at extrahepatic sites; particularly in the pelvis. Left lateral hepatectomy was performed. The patient recovered with an uneventful postoperative course and abdominal pain disappeared.

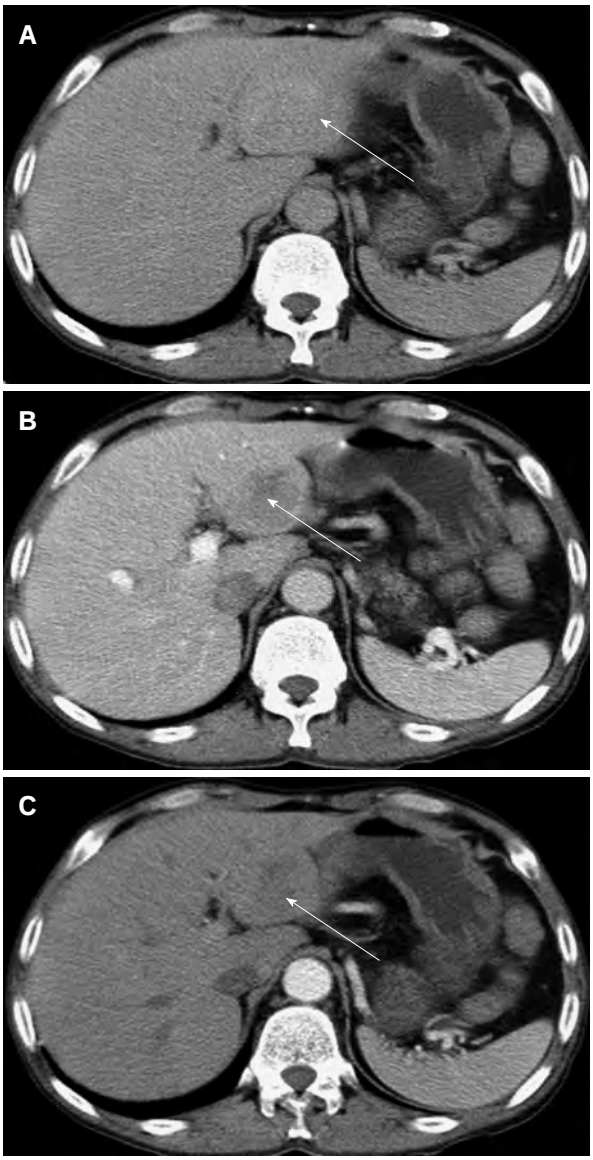

Figure 1 Abdominal computed tomography scan shows a mass in segment Ⅲ of the liver. A: Hepatic equilibrium phase; B: Portal venous phase; C: Hepatic arterial phase. The arrows indicate the tumor in the liver.

Histopathological examination of the resected specimen showed that the tumor consisted of spindle cells with scarce mitotic figures. The cells had elongated nuclei and eosinophilic cytoplasm forming a fabric-like structure, and neither giant cells nor anaplasia were present (Figure 2B). Immunohistochemical staining showed that the cells were positive for α-smooth muscle actin and desmin (Figure 2C and D), and negative for the gastrointestinal stromal tumor (GIST) markers, including CD117, CD34 and DOG1 (discovered on GIST1). *In situ* hybridization revealed that the nuclei of the tumor cells were negative for EBV-encoded small RNA (EBER) (Figure 3).

Diagnosis of primary hepatic leiomyoma was then made. As a benign tumor, neither chemotherapy nor radiotherapy was administered to the patient. During a

Table 1 Summary of the published cases of primary liver leiomyoma

Author	Age/sex	EBV infection	Symptoms	Location/size (cm)	Immunosuppression	Treatment

LL: Left lateral; NS: Not stated; RL: Right lobe; RUQ: Right upper quadrant; S: Segment; LH: Left hepatic lobe; EBV: Epstein-Barr virus.

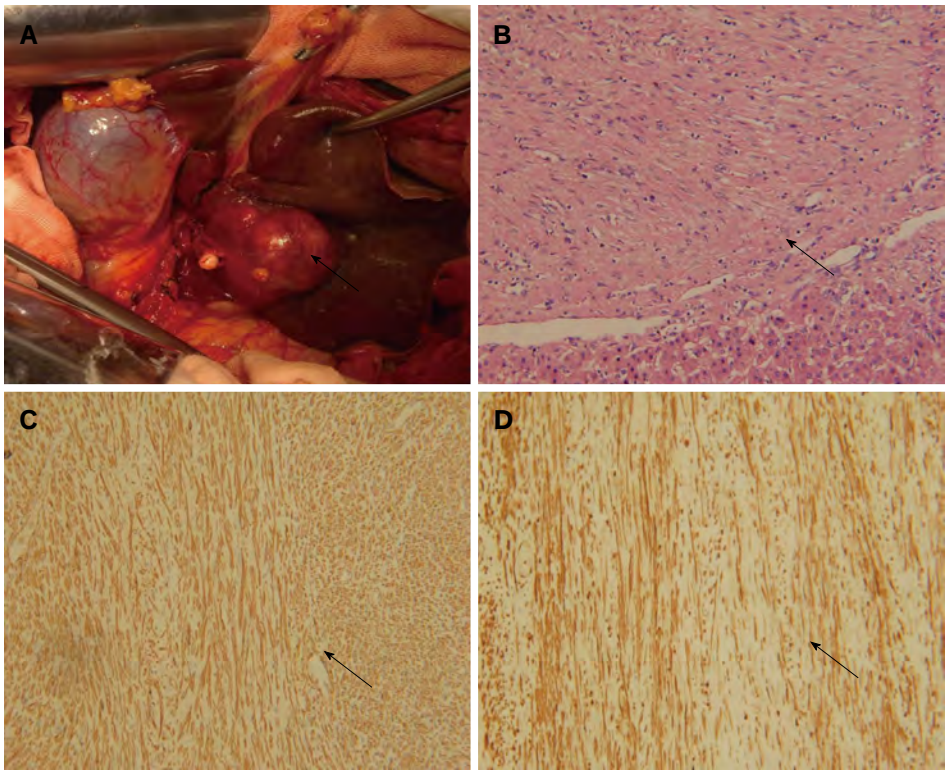

Figure 2 Pathological characteristics of the primary liver leiomyoma. A: Tumor (arrow) located in segment Ⅲ of the liver; B: Tumor (arrow) and normal liver tissue, hematoxylin and eosin staining, × 200; C: α-smooth muscle actin staining (arrow) of tumor tissues, immunohistochemical staining, × 200; D: Desmin staining (arrow) of tumor tissues, immunohistochemical staining, × 200.

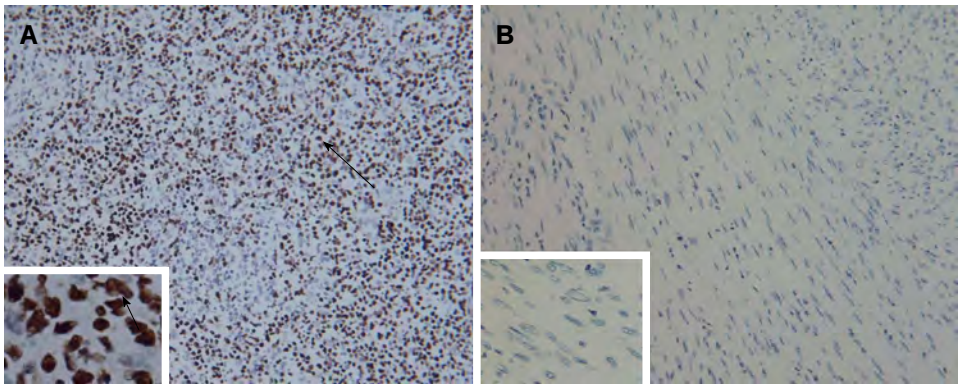

Figure 3 Tumor cells stained negative by *in situ* hybridization with Epstein-Barr virus-encoded small RNA. A: Positive control staining × 200, × 1000; B: Tumor cell staining × 200, × 1000. Arrows indicate positive staining of the nuclei.

24-mo postoperative follow-up, no sign of local recurrence or distant metastasis was observed, indicating a clinical cure in this case.

DISCUSSION

Primary hepatic leiomyoma occurs rarely. The first case was described by Demel[1] in a 42-year-old woman. To date, only 28 cases have been reported worldwide (Table 1). Secondary to benign smooth muscle proliferation, primary hepatic leiomyoma is usually found in adult women, and is associated with EBV infection. Due to its low prevalence, diagnosis, treatment and biological behavior remain elusive and require further investigation.

Leiomyoma is relatively common and tends to originate from the muscularis of the gut or the media of the blood vessels, and usually develops in the urogenital and gastrointestinal tracts. Primary hepatic leiomyoma is rare and has its own particular clinical and biological features.

To diagnose primary hepatic leiomyoma, Hawkins *et al*[2] has proposed the following criteria: (1) the tumor is composed of leiomyocytes; and (2) the presence of a leiomyomatous tumor at other sites can be excluded. Moreover, this liver tumor must be distinguished from GIST[3,4]. In the present case, we excluded the presence of hepatocellular carcinoma, and laboratory tests and histopathological examination were the first step in this process. Then, the diagnosis of leiomyoma was established on the basis of its pathological features. GIST makers (CD117, CD34 and DOG1) were also negative. Combining the findings of ultrasonography, abdominal CT scan, esophagogastroduodenscopy, colonoscopy and exploratory laparotomy, the final diagnosis of primary hepatic leiomyoma was made.

Although no standard therapy is available at present, consistent with the existing reports (Table 1), the tumor was successfully excised and neither chemotherapy nor radiotherapy was applied. Our experience supports that hepatic resection is both diagnostic and curative for primary hepatic leiomyoma.

Some unique characteristics should be noted in this case. First, the patient was male, and primary hepatic leiomyoma is more likely to be found in adult women (18 out of the total 28 cases were female) (Table 1). The relevance of sex may partly be due to the activity of the smooth muscle cells in female urogenital tissue in tumorigenesis and progenesis. The cellular origin of primary hepatic leiomyoma remains unclear and may arise from vessels or the biliary tree[6-8]. In this report, the patient had negative findings in the pelvis and for detection of GIST markers. More observations are required to explore the cellular source of primary hepatic leiomyoma. Second, this case was an adult patient. To date, a total of four pediatric cases (< 18 years) have been identified with primary hepatic leiomyoma (Table 1). Whether or not the developmental mechanisms are different between children and adults requires further investigation. Third, it could be deduced that EBV infection plays a critical role in development of primary hepatic leiomyoma[9,10]. Based on the reported literature, five patients were examined for EBV infection and all of them were positive[11-14]. The relationship between development of primary hepatic and EBV infection and immunocompromised status is also interesting. Seven out of the 28 patients (25%) were immunocompromised (6 transplanted and 1 HIV infection), and five of the seven cases (71.4%) were EBV-positive (4 transplanted and 1 HIV infection). However, in the present case, EBER *in situ* hybridization, which is the gold standard for detection and localization of latent EBV in tissues, showed that the patient did not have EBV infection, which was different from the status of other patients currently being studied.

Our data indicate that EBV infection is important but neither necessary nor sufficient for the development of primary liver leiomyoma. This observation highlights the complex and heterogeneous nature of the disease and raises the question whether EBV is a passenger rather than a causative agent for this tumor. Due to the rare occurrence of the tumor, an international primary hepatic leiomyoma sample bank, which needs worldwide cooperation of the involved institutions, will contribute to untangling the complex pathogenesis using omics- and system-based methodologies, and therefore to clarify the underlying mechanism behind this interesting tumor.

In conclusion, this report of the 29th case of primary hepatic leiomyoma with its unique features related to diagnosis, treatment and developmental biology contributes to our knowledge of the tumor.

World J Gastroenterol 2013 July 7; 19(25): I-VI
ISSN 1007-9327 (print) ISSN 2219-2840 (online)

GENERAL INFORMATION

World Journal of Gastroenterology (*World J Gastroenterol*, *WJG*, print ISSN 1007-9327, online ISSN 2219-2840, DOI: 10.3748) is a peer-reviewed open access (OA) journal. *WJG* was established on October 1, 1995. It is published weekly on the 7th, 14th, 21st, and 28th each month. The *WJG* Editorial Board consists of 1352 experts in gastroenterology and hepatology from 64 countries.

Aims and scope

The primary task of *WJG* is to rapidly publish high-quality original articles, reviews, and commentaries in the fields of gastroenterology, hepatology, gastrointestinal endoscopy, gastrointestinal surgery, hepatobiliary surgery, gastrointestinal oncology, gastrointestinal radiation oncology, gastrointestinal imaging, gastrointestinal interventional therapy, gastrointestinal infectious diseases, gastrointestinal pharmacology, gastrointestinal pathophysiology, gastrointestinal pathology, evidence-based medicine in gastroenterology, pancreatology, gastrointestinal laboratory medicine, gastrointestinal molecular biology, gastrointestinal immunology, gastrointestinal microbiology, gastrointestinal genetics, gastrointestinal translational medicine, gastrointestinal diagnostics, and gastrointestinal therapeutics. *WJG* is dedicated to become an influential and prestigious journal in gastroenterology and hepatology, to promote the development of above disciplines, and to improve the diagnostic and therapeutic skill and expertise of clinicians.

WJG is published by Baishideng Publishing Group (BPG) in both electronic and online forms. All *WJG* articles are published in *WJG* website and PubMed Central. The major advantages of OA journals are faster release and delivery, no page or graph restrictions, and increased visibility, usage and impact. Full-text PDF articles and electronic/online versions are freely available to global readers. After the paper is published, the author(s) can obtain high-quality PDF files, which contain the journal cover, a list of editorial board members, table of contents, text, and back cover of the journal. BPG has a strong professional editorial team composed of editorial board members, editors-in-chief, science editors, language editors, and electronic editors. BPG currently publishes 42 OA clinical medical journals, including 41 in English, has a total of 15471 editorial board members or peer reviewers, and is a world first-class publisher.

Columns

The columns in the issues of *WJG* will include: (1) Editorial: The editorial board members are invited to make comments on an important topic in their field in terms of its current research status and future directions to lead the development of this discipline; (2) Frontier: The editorial board members are invited to select a highly cited cutting-edge original paper of his/her own to summarize major findings, the problems that have been resolved and remain to be resolved, and future research directions to help readers understand his/her important academic point of view and future research directions in the field; (3) Diagnostic Advances: The editorial board members are invited to write high-quality diagnostic advances in their field to improve the diagnostic skills of readers. The topic covers general clinical diagnosis, differential diagnosis, pathological diagnosis, laboratory diagnosis, imaging diagnosis, endoscopic diagnosis, biotechnological diagnosis, functional diagnosis, and physical diagnosis; (4) Therapeutics Advances: The editorial board members are invited to write high-quality therapeutic advances in their field to help improve the therapeutic skills of readers. The topic covers medication therapy, psychotherapy, physical therapy, replacement therapy, interventional therapy, minimally invasive therapy, endoscopic therapy, transplantation therapy, and surgical therapy; (5) Field of Vision: The editorial board members are invited to write commentaries on classic articles, hot topic articles, or latest articles to keep readers at the forefront of research and increase their levels of clinical research. Classic articles refer to papers that are included in Web of Knowledge and have received a large number of citations (ranking in the top 1%) after being published for more than years, reflecting the quality and impact of papers. Hot topic articles refer to papers that are included in Web of Knowledge and have received a large number of citations after being published for no more than 2 years, reflecting cutting-edge trends in scientific research. Latest articles refer to the latest published high-quality papers that are included in PubMed, reflecting the latest research trends. These commentary articles should focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions. Basic information about the article to be commented (including authors, article title, journal name, year, volume, and inclusive page numbers; (6) Minireviews: The editorial board members are invited to write short reviews on recent advances and trends in research of molecular biology, genomics, and related cutting-edge technologies to provide readers with the latest knowledge and help improve their diagnostic and therapeutic skills; (7) Review: To make a systematic review to focus on the status quo of research, the most important research topics, the problems that have now been resolved and remain to be resolved, and future research directions; (8) Topic Highlight: The editorial board members are invited to write a series of articles (7-10 articles) to comment and discuss a hot topic to help improve the diagnostic and therapeutic skills of readers; (9) Medical Ethics: The editorial board members are invited to write articles about medical ethics to increase readers' knowledge of medical ethics. The topic covers international ethics guidelines, animal studies, clinical trials, organ transplantation, *etc.*; (10) Clinical Case Conference or Clinicopathological Conference: The editorial board members are invited to contribute high-quality clinical case conference; (11) Original Articles: To report innovative and original findings in gastroenterology and hepatology; (12) Brief Articles: To briefly report the novel

and innovative findings in gastroenterology and hepatology; (13) Meta-Analysis: Covers the systematic review, mixed treatment comparison, meta-regression, and overview of reviews, in order to summarize a given quantitative effect, *e.g.*, the clinical effectiveness and safety of clinical treatments by combining data from two or more randomized controlled trials, thereby providing more precise and externally valid estimates than those which would stem from each individual dataset if analyzed separately from the others; (14) Case Report: To report a rare or typical case; (15) Letters to the Editor: To discuss and make reply to the contributions published in *WJG*, or to introduce and comment on a controversial issue of general interest; (16) Book Reviews: To introduce and comment on quality monographs of gastroenterology and hepatology; and (17) Autobiography: The editorial board members are invited to write their autobiography to provide readers with stories of success or failure in their scientific research career. The topic covers their basic personal information and information about when they started doing research work, where and how they did research work, what they have achieved, and their lessons from success or failure.

SPECIAL STATEMENT

All articles published in this journal represent the viewpoints of the authors except where indicated otherwise.

Biostatistical editing
Statistical review is performed after peer review. We invite an expert in Biomedical Statistics to evaluate the statistical method used in the paper, including *t* test (group or paired comparisons), chi-squared test, ridit, probit, logit, regression (linear, curvilinear, or stepwise), correlation, analysis of variance, analysis of covariance, *etc.* The reviewing points include: (1) Statistical methods should be described when they are used to verify the results; (2) Whether the statistical techniques are suitable or correct; (3) Only homogeneous data can be averaged. Standard deviations are preferred to standard errors. Give the number of observations and subjects (*n*). Losses in observations, such as drop-outs from the study should be reported; (4) Values such as ED50, LD50, IC50 should have their 95% confidence limits calculated and compared by weighted probit analysis (Bliss and Finney); and (5) The word "significantly" should be replaced by its synonyms (if it indicates extent) or the *P* value (if it indicates statistical significance).

Conflict-of-interest statement

In the interests of transparency and to help reviewers assess any potential bias, *WJG* requires authors of all papers to declare any competing commercial, personal, political, intellectual, or religious interests in relation to the submitted work. Referees are also asked to indicate any potential conflict they might have reviewing a particular paper. Before submitting, authors are suggested to read "Uniform Requirements for Manuscripts Submitted to Biomedical Journals: Ethical Considerations in the Conduct and Reporting of Research: Conflicts of Interest" from International Committee of Medical Journal Editors (ICMJE), which is available at: http://www.icmje.org/ethical_4conflicts.html.

Statement of informed consent

Manuscripts should contain a statement to the effect that all human studies have been reviewed by the appropriate ethics committee or it should be stated clearly in the text that all persons gave their informed consent prior to their inclusion in the study. Details that might disclose the identity of the subjects under study should be omitted. Authors should also draw attention to the Code of Ethics of the World Medical Association (Declaration of Helsinki, 1964, as revised in 2004).

Sample wording: [Name of individual] has received fees for serving as a speaker, a consultant and an advisory board member for [names of organizations], and has received research funding from [names of organization]. [Name of individual] is an employee of [name of organization]. [Name of individual] owns stocks and shares in [name of organization]. [Name of individual] owns patent [patent identification and brief description].

Statement of human and animal rights

When reporting the results from experiments, authors should follow the highest standards and the trial should conform to Good Clinical Practice (for example, US Food and Drug Administration Good Clinical Practice in FDA-Regulated Clinical Trials; UK Medicines Research Council Guidelines for Good Clinical Practice in Clinical Trials) and/or the World Medical Association Declaration of Helsinki. Generally, we suggest authors follow the lead investigator's national standard. If doubt exists whether the research was conducted in accordance with the above standards, the authors must explain the rationale for their approach and demonstrate that the institutional review body explicitly approved the doubtful aspects of the study.

Before submitting, authors should make their study approved by the relevant research ethics committee or institutional review board. If human participants were involved, manuscripts must be accompanied by a statement that the experiments were undertaken with the understanding and appropriate informed consent of each. Any personal item or information will not be published without explicit consents from the involved patients. If experimental animals were used, the materials and methods (experimental procedures) section must clearly indicate that appropriate measures were taken to minimize pain or discomfort, and details of animal care should be provided.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Number all pages consecutively, and start each of the following sections on a new page: Title Page, Abstract, Introduction, Materials and Methods, Results, Discussion, Acknowledgements, References, Tables, Figures, and Figure Legends. Neither the editors nor the publisher are responsible for the opinions expressed by contributors. Manuscripts formally accepted for publication become the permanent property of Baishideng Publishing Group Co., Limited, and may not be reproduced by any means, in whole or in part, without the written permission of both the authors and the publisher. We reserve the right to copy-edit and put onto our website accepted manuscripts. Authors should follow the relevant guidelines for the care and use of laboratory animals of their institution or national animal welfare committee. For the sake of transparency in regard to the performance and reporting of clinical trials, we endorse the policy of the ICMJE to refuse to publish papers on clinical trial results if the trial was not recorded in a publicly-accessible registry at its outset. The only register now available, to our knowledge, is http://www.clinicaltrials.gov sponsored by the United States National Library of Medicine and we encourage all potential contributors to register with it. However, in the case that other registers become available you will be duly notified. A letter of recommendation from each author's organization should be provided with the contributed article to ensure the privacy and secrecy of research is protected.

Authors should retain one copy of the text, tables, photographs and illustrations because rejected manuscripts will not be returned to the author(s) and the editors will not be responsible for loss or damage to photographs and illustrations sustained during mailing.

Online submissions

Manuscripts should be submitted through the Online Submission System at: http://www.wjgnet.com/esps/. Authors are highly recommended to consult the ONLINE INSTRUCTIONS TO AUTHORS (http://www.wjgnet.com/1007-9327/g_info_20100315215714.htm) before attempting to submit online. For assistance, authors encountering problems with the Online Submission System may send an email describing the problem to wjg@wjgnet.com, or by telephone: +86-10-5908-0039. If you submit your manuscript online, do not make a postal contribution. Repeated online submission for the same manuscript is strictly prohibited.

MANUSCRIPT PREPARATION

All contributions should be written in English. All articles must be submitted using word-processing software. All submissions must be typed in 1.5 line spacing and 12 pt. Book Antiqua with ample margins. Style should conform to our house format. Required information for each of the manuscript sections is as follows:

Title page

Title: Title should be less than 12 words.

Running title: A short running title of less than 6 words should be provided.

Authorship: Authorship credit should be in accordance with the standard proposed by ICMJE, based on (1) substantial contributions to conception and design, acquisition of data, or analysis and interpretation of data; (2) drafting the article or revising it critically for important intellectual content; and (3) final approval of the version to be published. Authors should meet conditions 1, 2, and 3.

Institution: Author names should be given first, then the complete name of institution, city, province and postcode. For example, Xu-Chen Zhang, Li-Xin Mei, Department of Pathology, Chengde Medical College, Chengde 067000, Hebei Province, China. One author may be represented from two institutions, for example, George Sgourakis, Department of General, Viscer-

al, and Transplantation Surgery, Essen 45122, Germany; George Sgourakis, 2nd Surgical Department, Korgialenio-Benakio Red Cross Hospital, Athens 15451, Greece.

Author contributions: The format of this section should be: Author contributions: Wang CL and Liang L contributed equally to this work; Wang CL, Liang L, Fu JF, Zou CC, Hong F and Wu XM designed the research; Wang CL, Zou CC, Hong F and Wu XM performed the research; Xue JZ and Lu JR contributed new reagents/analytic tools; Wang CL, Liang L and Fu JF analyzed the data; and Wang CL, Liang L and Fu JF wrote the paper.

Supportive foundations: The complete name and number of supportive foundations should be provided, e.g. Supported by National Natural Science Foundation of China, No. 30224801

Correspondence to: Only one corresponding address should be provided. Author names should be given first, then author title, affiliation, the complete name of institution, city, postcode, province, country, and email. All the letters in the email should be in lower case. A space interval should be inserted between country name and email address. For example, Montgomery Bissell, MD, Professor of Medicine, Chief, Liver Center, Gastroenterology Division, University of California, Box 0538, San Francisco, CA 94143, United States. montgomery.bissell@ucsf.edu

Telephone and fax: Telephone and fax should consist of +, country number, district number and telephone or fax number, *e.g.*, Telephone: +86-10-59080039 Fax: +86-10-85381893

Peer reviewers: All articles received are subject to peer review. Normally, three experts are invited for each article. Decision on acceptance is made only when at least two experts recommend publication of an article. All peer-reviewers are acknowledged on Express Submission and Peer-review System website.

Abstract

There are unstructured abstracts (no less than 200 words) and structured abstracts. The specific requirements for structured abstracts are as follows:

An informative, structured abstract should accompany each manuscript. Abstracts of original contributions should be structured into the following sections: AIM (no more than 20 words; Only the purpose of the study should be included. Please write the Aim in the form of "To investigate/study/…"), METHODS (no less than 140 words for Original Articles; and no less than 80 words for Brief Articles), RESULTS (no less than 150 words for Original Articles and no less than 120 words for Brief Articles; You should present *P* values where appropriate and must provide relevant data to illustrate how they were obtained, *e.g.*, 6.92 ± 3.86 *vs* 3.61 ± 1.67, $P < 0.001$), and CONCLUSION (no more than 26 words).

Key words

Please list 5-10 key words, selected mainly from *Index Medicus*, which reflect the content of the study.

Core tip

Please write a summary of less than 100 words to outline the most innovative and important arguments and core contents in your paper to attract readers.

Text

For articles of these sections, original articles and brief articles, the main text should be structured into the following sections: INTRODUCTION, MATERIALS AND METHODS, RESULTS and DISCUSSION, and should include appropriate Figures and Tables. Data should be presented in the main text or in Figures and Tables, but not in both.

Illustrations

Figures should be numbered as 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each figure on a separate page. Detailed legends should not be provided under the figures. This part should be added into the text where the figures are applicable. Keeping all elements compiled is necessary in line-art image. Scale bars should be used rather than magnification factors, with the length of the bar defined in the legend rather than on the bar itself. File names should identify the figure and panel. Avoid layering type directly over shaded or textured areas. Please use uniform legends for the same subjects. For example: Figure 1 Pathological changes in atrophic gastritis after treatment. A:...; B:...; C:...; D:...; E:...; F:...; G: …*etc.* It is our principle to publish high resolution-figures for the E-versions.

Tables

Three-line tables should be numbered 1, 2, 3, *etc.*, and mentioned clearly in the main text. Provide a brief title for each table. Detailed legends should not be included under tables, but rather added into the text where applicable. The information should complement, but not duplicate the text. Use one horizontal line under the title, a second under column heads, and a third below the Table, above any footnotes. Vertical and italic lines should be omitted.

Notes in tables and illustrations

Data that are not statistically significant should not be noted. $^{a}P < 0.05$, $^{b}P < 0.01$ should be noted ($P > 0.05$ should not be noted). If there are other series of *P* values, $^{c}P < 0.05$ and $^{d}P < 0.01$ are used. A third series of *P* values can be expressed as $^{e}P < 0.05$ and $^{f}P < 0.01$. Other notes in tables or under illustrations should be expressed as ^{1}F, ^{2}F, ^{3}F; or sometimes as other symbols with a superscript (Arabic numerals) in the upper left corner. In a multi-curve illustration, each curve should be labeled with ●, ○, ■, □, ▲, △, *etc.*, in a certain sequence.

Acknowledgments

Brief acknowledgments of persons who have made genuine contributions to the manuscript and who endorse the data and conclusions should be included. Authors are responsible for obtaining written permission to use any copyrighted text and/or illustrations.

REFERENCES

Coding system

The author should number the references in Arabic numerals according to the citation order in the text. Put reference numbers in square brackets in superscript at the end of citation content or after the cited author's name. For citation content which is part of the narration, the coding number and square brackets should be typeset normally. For example, "Crohn's disease (CD) is associated with increased intestinal permeability[1,2]". If references are cited directly in the text, they should be put together within the text, for example, "From references[19,22-24], we know that...".

When the authors write the references, please ensure that the order in text is the same as in the references section, and also ensure the spelling accuracy of the first author's name. Do not list the same citation twice.

PMID and DOI

Pleased provide PubMed citation numbers to the reference list, *e.g.*, PMID and DOI, which can be found at http://www.ncbi.nlm.nihgov/sites/entrez?db=pubmed and http://www.crossref.org/SimpleTextQuery/, respectively. The numbers will be used in E-version of this journal.

Style for journal references

Authors: the name of the first author should be typed in boldfaced letters. The family name of all authors should be typed with the initial letter capitalized, followed by their abbreviated first and middle initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR). The title of the cited article and italicized journal title (journal title should be in its abbreviated form as shown in PubMed), publication date, volume number (in black), start page, and end page [PMID: 11819634 DOI: 10.3748/wjg.13.5396].

Style for book references

Authors: the name of the first author should be typed in boldfaced letters. The surname of all authors should be typed with the initial letter capitalized, followed by their abbreviated middle and first initials. (For example, Lian-Sheng Ma is abbreviated as Ma LS, Bo-Rong Pan as Pan BR) Book title. Publication number. Publication place: Publication press, Year: start page and end page.

Statistical data

Write as mean ± SD or mean ± SE.

Statistical expression

Express *t* test as *t* (in italics), *F* test as *F* (in italics), chi square test as χ^2 (in Greek), related coefficient as *r* (in italics), degree of freedom as υ (in Greek), sample number as *n* (in italics), and probability as *P* (in italics).

Units

Use SI units. For example: body mass, m (B) = 78 kg; blood pressure, p (B) = 16.2/12.3 kPa; incubation time, t (incubation) = 96 h, blood glucose concentration, c (glucose) 6.4 ± 2.1 mmol/L; blood CEA mass concentration, p (CEA) = 8.6

24.5 μg/L; CO_2 volume fraction, 50 mL/L CO_2, not 5% CO_2; likewise for 40 g/L formaldehyde, not 10% formalin; and mass fraction, 8 ng/g, *etc.* Arabic numerals such as 23, 243, 641 should be read 23243641.

The format for how to accurately write common units and quantums can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315223018.htm.

Abbreviations

Standard abbreviations should be defined in the abstract and on first mention in the text. In general, terms should not be abbreviated unless they are used repeatedly and the abbreviation is helpful to the reader. Permissible abbreviations are listed in Units, Symbols and Abbreviations: A Guide for Biological and Medical Editors and Authors (Ed. Baron DN, 1988) published by The Royal Society of Medicine, London. Certain commonly used abbreviations, such as DNA, RNA, HIV, LD50, PCR, HBV, ECG, WBC, RBC, CT, ESR, CSF, IgG, ELISA, PBS, ATP, EDTA, mAb, can be used directly without further explanation.

Italics

Quantities: *t* time or temperature, *c* concentration, *A* area, *l* length, *m* mass, *V* volume.
Genotypes: *gyrA*, *arg* 1, *c myc*, *c fos*, *etc.*
Restriction enzymes: *Eco*RI, *Hin*dI, *Bam*HI, *Kbo* I, *Kpn* I, *etc.*
Biology: *H. pylori*, *E coli*, *etc.*

Examples for paper writing

All types of articles' writing style and requirement will be found in the link: http://www.wjgnet.com/esps/NavigationInfo.aspx?id=15.

RESUBMISSION OF THE REVISED MANUSCRIPTS

Authors must revise their manuscript carefully according to the revision policies of Baishideng Publishing Group Co., Limited. The revised version, along with the signed copyright transfer agreement, responses to the reviewers, and English language Grade A certificate (for non-native speakers of English), should be submitted to the online system *via* the link contained in the e-mail sent by the editor. If you have any questions about the revision, please send e-mail to esps@wjgnet.com.

Language evaluation

The language of a manuscript will be graded before it is sent for revision. (1) Grade A: priority publishing; (2) Grade B: minor language polishing; (3) Grade C: a great deal of language polishing needed; and (4) Grade D: rejected. Revised articles should reach Grade A.

Copyright assignment form

Please download a Copyright assignment form from http://www.wjgnet.com/1007-9327/g_info_20100315222818.htm.

Responses to reviewers

Please revise your article according to the comments/suggestions provided by the reviewers. The format for responses to the reviewers' comments can be found at: http://www.wjgnet.com/1007-9327/g_info_20100315222607.htm

Proof of financial support

For papers supported by a foundation, authors should provide a copy of the approval document and serial number of the foundation.

STATEMENT ABOUT ANONYMOUS PUBLICATION OF THE PEER REVIEWERS' COMMENTS

In order to increase the quality of peer review, push authors to carefully revise their manuscripts based on the peer reviewers' comments, and promote academic interactions among peer reviewers, authors and readers, we decide to anonymously publish the reviewers' comments and author's responses at the same time the manuscript is published online.

PUBLICATION FEE

WJG is an international, peer-reviewed, open access, online journal. Articles published by this journal are distributed under the terms of the Creative Commons Attribution Non-commercial License, which permits use, distribution, and reproduction in any medium, provided the original work is properly cited, the use is non commercial and is otherwise in compliance with the license. Authors of accepted articles must pay a publication fee. Publication fee: 1365 USD per article. All invited articles are published free of charge.

Abstract

In recent years, the improvement of technology and the increase in knowledge have shifted several strongly held paradigms. This is particularly true in gastroenterology, and specifically in the field of the so-called "functional" or "idiopathic" disease, where conditions thought for decades to be based mainly on alterations of visceral perception or aberrant psychosomatic mechanisms have, in fact, be reconducted to an organic basis (or, at the very least, have shown one or more demonstrable abnormalities). This is particularly true, for instance, for irritable bowel syndrome, the prototype entity of "functional" gastrointestinal disorders, where low-grade inflammation of both mucosa and myenteric plexus has been repeatedly demonstrated. Thus, researchers have also investigated other functional/idiopathic gastrointestinal disorders, and found that some organic ground is present, such as abnormal neurotransmission and myenteric plexitis in esophageal achalasia and mucosal immune activation and mild eosinophilia in functional dyspepsia. Here we show evidence, based on our own and other authors' work, that chronic constipation has several abnormalities reconductable to alterations in the enteric nervous system, abnormalities mainly characterized by a constant decrease of enteric glial cells and interstitial cells of Cajal (and, sometimes, of enteric neurons). Thus, we feel that (at least some forms of) chronic constipation should no more be considered as a functional/idiopathic gastrointestinal disorder, but instead as a true enteric neuropathic abnormality.

Key words: Constipation; Enteric glia; Enteric nervous system; Enteric neurons; Interstitial cells of Cajap; Neurogastroenterology

Core tip: Concerning gut motility, in the last years the basic/clinical interplay between gastroenterology and neurology has become stricter, and many pathologic conditions, among which constipation, related to abnormal gastrointestinal motility are now considered and studied by a neurogastroenterological point of view. However, the fact that these conditions are still labelled as "functional" or "idiopathic" is puzzling. We examined the evidence for taking these labels out from constipation, that should be considered as a true neurenteric dysfunction.

G. Cellular and molecular basis of chronic constipation: Taking the functional/idiopathic label out. *World J Gastroenterol* 2013; 19(26): 4099-4105 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i26/4099.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i26.4099

INTRODUCTION

The field of gastrointestinal motor activity has always attracted the researchers' interest; however, in the time course it became apparent that most gut motor disorders are attributable to disordered neural control mechanisms. Thus, by the encounter of gastroenterologists and neurologists a common branch emerged, *i.e.*, neurogastroenterology[1], in which an equal partnership had been recognized concerning gut motility. Recently, ultrastructural morphologists joined and try to bring innovative perceptions on control mechanisms of digestive motility. This had led to interesting and exciting new perspectives in the pathophysiology of some frequent disorders, such as constipation.

Chronic constipation is a frequent symptom in the general population, where is present in 2%-30% of subjects[2]. However, apart from secondary forms, associated to an underlying disease (*e.g.,* neurological[3,4]), commonly used (at least for scientific purposes) classifications still label most cases of constipation as "idiopathic" or "functional"[5-9].

It is worth noting that the concept of functional diseases has been somewhat questioned in the last years[10], since several studies conducted on prototypic functional entities, such as irritable bowel syndrome (IBS) and functional dyspepsia (FD) have revealed that these condition may actually harbor an organic basis[11,12]. In fact, inflammation and neuronal degeneration have been reported in IBS patients[13] and duodenal mastocytosis, eosinophilia and intraepithelial lymphocytosis have been described in both IBS and FD patients[14].

Chronic constipation may be subdivided in two main subtypes, obstructed defecation (OD) and slow transit constipation (STC), that may also co-exist in the same patient[15,16], and it is generally thought (by data originating from both experimental animal models and humans) that colonic sensorimotor dysfunction and abnormal motility play a pivotal pathogenetic role[17-19]. Thus, abnormal colonic and anorectal function had been repeatedly demonstrated in these patients[20-22], and pharmacologic stimulation may help in addressing more targeted therapeutic approaches[23,24]. However, etiological factors are still poorly known[25].

This article will deal with the available evidence for neurobiological abnormalities in chronic constipation, that suggests how this symptom often underlie a true organic enteric disorder.

NEUROENTERIC ABNORMALITIES IN CONSTIPATION

To date, there is mounting evidence that colonic neuromuscular abnormalities may be of paramount importance in this setting[26,27], and there are numerous studies showing that (at least) severely constipated patients may have one or more abnormal features mainly (although not exclusively) linked to elements of the enteric nervous system (ENS)[28].

The ENS, considered as the brain of the gut, integrates secretion and motility into homeostatic patterns of behavior susceptible to disorder[29]. Thus, it is not surprising that some of the enteric circuitries responsible for these activities may be involved in the dysfunction of their basic control mechanisms. The resulting abnormalities are summarized below.

Abnormal colonic neurochemistry

This has been repeatedly shown in constipated patients: several studies showed a decreased content of vasoactive intestinal peptide (VIP) and substance P in tissues obtained from these subjects[30-34]. Moreover, *in vitro* studies confirmed that the diminished contractile response to these substances plays an important role in the impaired motility observed in the colon of constipated patients[35,36]. Of note, these abnormalities seem not to be related to chronic laxative use, since anthranoids cause a reduction in the levels of inhibitory neurotransmitters (VIP, somatostatin), but not of substance P, in the rat colon[37]. Other studies showed that excitatory nerve fibres are present in the circular muscle in STC but they are deficient in tachykinins and enkephalin[38-40]. In addition, investigations conducted on colonic strips showed that a decrease of cholinergic innervation and an increase of non-adrenergic non-cholinergic (NANC) inhibitory innervation play an important role in the impaired motility observed in the colon of patients with slow transit constipation[41]; these effects are mediated by an increase of nitric oxide and a decrease of neurotensin[42-44], as also confirmed by immunohistochemical methods in surgically resected specimens[45].

Enteric nervous system

Earlier studies addressing the ENS have shown the presence of several heterogeneous abnormalities in patients with severe constipation (especially those with STC), including reduced number of argyrophilic neurons[46] and of intraganglionic neurofilaments[47], myenteric plexus hypoganglionosis[48]. More recent studies, with the increasing use of immunohistochemical techniques[49,50], have demonstrated more consistent findings on the main elements of the ENS, such as the decrease of interstitial cells of Cajal (ICC)[51,52] (up to their complete absence in colonic inertia[53]), often associated to a reduced number of enteric neurons[54,55] and/or of enteric glial cells (EGC)[56,57]. Of interest, the expression of c-kit mRNA and c-kit protein was also found to be significantly decreased in the colon of severely constipated patients, suggesting that the c-kit signal pathway may play an important role in ICC reduction in these patients[58].

Colonic smooth muscle

Only a few studies have addressed this issue, often with

discordant findings, probably due to the heterogeneous cohorts of patients evaluated. Some authors reported that the ratio of the thickness of circular to longitudinal muscle was significantly lower in the left colon in constipated subjects[59], whereas other authors described a decreased circular muscle layer thickness in constipated patients[60], but no abnormalities of the colonic muscular layers were described in both studies. Another investigation showed the presence of amphophilic inclusion bodies in the muscularis externa of STC patients[61], even though these findings were found in about half of the patients. Normal actin expression was found in both adults and children with severe constipation[56,62], whereas the use of novel and nonconventional smooth muscle markers may reveal abnormalities linked to the smooth muscle contractile apparatus unnoticed by both routine stainings and alpha-actin, suggesting specific defects of smooth muscle cells involved in the pathogenesis of gastrointestinal motility disorders[63].

SIGNIFICANCE OF NEUROENTERIC ABNORMALITIES IN CONSTIPATION

There are few doubts that the ENS abnormalities repeatedly found in constipated patients play a pivotal role in the genesis of symptoms. In fact, the consistent finding of a significant decrease of ICC, enteric neurons, and (especially) EGC, variously associated each other, justifies the abnormal motor behavior of the large bowel in these patients.

In fact, looking at the physiological properties of these cell populations, it is obvious that the disruption of their number/connections/relationship leads to an impairment of the complex regulation of the well-coordinated colonic motor patterns[64], thus affecting the viscus' motility, due to the strict interplay between ICC, enteric neurons and EGC, with the latter acting as a physiologic bridge (not only by a simple mechanic point of view, but also by means of their neurotransmitter, immunologic, and trophic properties[65]) between the other two cell types.

Unfortunately, to date data are lacking on the possible factors causing neurenteric abnormalities in constipated patients. The current hypothesized mechanisms (often originating from experimental animal models) imply abnormalities in glial trophic factors leading to neural degeneration, and enteric localization of infective agents (bacteria, virus, prions) causing more or less selective degeneration of specific neurenteric cell populations (particularly EGC)[66], whereas genetic factors[67] or neurodegenerative changes due to aging seem to play a lesser role[68].

NEW CELLULAR PLAYERS IN NEUROMOTILITY DISORDERS

In biological sciences, interstitial tissue is seen as the connective tissue that surrounds the cells of a certain tissue while the extracellular matrix elements are known for its great capacity to retain water. However, except for a few described interstitial diseases (*e.g.,* inflammatory bowel disease, interstitial cystitis, tubulointerstitial nephropathy, interstitial lung disease) its role is easily overlooked, as well as the significance of its cellular elements. Recent studies related to biological and histological data revealed, among the known resident (fibroblasts/fibrocytes, adipose cells) and non-resident cells (mast cells, plasma cells, eosinophils, macrophages, *etc.*) of interstitial space, a novel cell type-the telocyte[69,70].

Morphologically, telocytes represent interstitial cells with telopodes-the longest cellular extensions described besides the axons of neurons[71]. This rather unique cell type, difficult to visualize by routine microscopy, displays a particular morphology by electron microscopy: (1) a small cell body (9-15 μm) with scarce cytoplasmic organelles surrounding a moderately euchromatic nucleus; and (2) telopodes are usually tortuous and organized in a 3D network by overlapping and/or by homocellular interactions[72,73]. Telopodes are very long (10-1000 μm), thin (0.1 ± 0.5 μm) and moniliform cytoplasmic extensions; the moniliform aspect is created by the alternation of thin segments-podomers with dilated segments-podoms; the latter accomodate functional units consisting of caveolae, mitocondria and endoplasmic reticulum[74] and occupy a strategic position in relation to stem cell niches, blood capillaries, and/or nerve bundles[75,76]. Telopodes also establish stromal contacts with other cells, such as mast cells, basophils, lymphocytes, eosinophils, plasma cells, or macrophages[77] and non-cellular elements (*e.g.*, collagen and elastic fibers)[78,79].

Telocytes have been described in human and mammalian cavitary and parenchymatous organs, as well as in serous membranes and other tissues (for details see www.telocytes.com). In the last two years telocytes were also described in the gut[77,80,81].

In modern times the significance of the information that could be achieved by signaling molecules found in intercellular fluids is overlooked. There is scarce information on the usefulness of the extracellular organelles (exosomes and shedding microvesicles) released in the extracellular space as mediators of cell-to-cell communication[82]. Such vesicles were recently demonstrated in the proximity of telopodes and even emerging from them in heart[83], lungs[76], skeletal muscle[76], pancreas[73], parotid gland[84] and human uterus[74].

Telocytes are supposed to be involved: (1) in intercellular signaling[72,74,77]; (2) as stem cell adjutants involved in tissue renewal[79,85]; (3) as sensors for steroid hormones[86]; (4) in the guidance of immune cells[77]; (5) as stretch sensors[87]; and (6) as contractility modulators[88]. Even though telocytes seem to be implicated in many important physiological and pathological processes[89,90], their exact functions still remain controversial. Although telocytes have not yet been described at colonic level, their possible involvement in pathophysiological mechanisms

of chronic constipation cannot be overlooked. In favor of this hypothesis there is a possible correlation between the fact that telocytes express receptors for estrogen and progesterone[91,92] and the fact that chronic constipation is linked to sex hormones[93] and is higher in women of reproductive age[94].

CONCLUSION

The improvement of scientific knowledge and the constant, increasing ability to recognize previously unknown pathophysiologic mechanisms is of paramount importance. Thus, labels such as "idiopathic" or "functional", that basically conceal the fact that too little is known of a specific pathologic entity[10], should be hopefully replaced when more knowledge is available, as pointed out several years ago[95]. As such, the recent recognition of neurenteric abnormalities in many patients complaining of constipation should point to reconsidering at least some of these forms (especially STC) as true enteric neuropathies, and to drop the "idiopathic"/"functional" label.

Besides semantic considerations, we feel that a better understanding of possible basic abnormalities in these patients is important, and may have therapeutic implications, addressing the researchers' interest for new options toward more targeted approaches[16].

Abstract

Hepatocellular carcinoma (HCC) represents one of the most common neoplasms worldwide. Surgical resection and local ablative therapies represent the most frequent first lines therapies adopted when liver transplantation can not be offered or is not immediately accessible. Hepatic resection (HR) is currently considered the most curative strategy, but in the last decade local ablative therapies have started to obtain satisfactory results in term of efficacy and, of them, radiofrequency ablation (RFA) is considered the reference standard. An extensive literature review, from the year 2000, was performed, focusing on results coming from studies that directly compared HR and RFA. Qualities of the studies, characteristics of patients included, and patient survival and recurrence rates were analyzed. Except for three randomized controlled trials (RCT), most studies are affected by uncertain methodological approaches since surgical and ablated patients represent different populations as regards clinical and tumor features that are known to affect prognosis. Unfortunately, even the available RCTs report conflicting results. Until further evidences become available, it seems reasonable to offer RFA to very small HCC (< 2 cm) with no technical contraindications, since in this instance complete necrosis is most likely to be achieved. In larger nodules, namely > 2 cm and especially if > 3 cm, and/or in tumor locations in which ablation is not expected to be effective or safe, surgical removal is to be preferred.

Key words: Hepatocellular carcinoma; Hepatic resection; Surgical therapy; Ablation techniques; Survival; Liver failure

Core tip: The present review shows the lights and shadows of the comparative literature regarding hepatic resection and radiofrequency ablation for hepatocellular carcinoma. Nineteen studies that directly compared these two therapies were found through an extensive literature review; of them, three randomized controlled trial were available for comparison whereas the remaining studies were represented by retrospective observational studies. Results are often conflicting and further randomized controlled trial are warranted; otherwise, retrospective observational studies should include in their analyses statistical approaches aimed at reduce possible confounding sources at a minimum.

INTRODUCTION

Hepatocellular carcinoma (HCC) represents one of the most common primary malignancies of the liver worldwide, with an incidence that varies in the different geographic areas as a consequence of the regional variations in exposure to risk factors for this tumor[1,2]. The increasing use of surveillance in clinical practice, and the advancements in diagnostic and therapeutic abilities achieved in the last decades have greatly improved patient survival[3-5]. Liver resection and radiofrequency ablation represent the most common first-line therapies adopted when HCC is diagnosed at early stages[6]. Liver resection still remains a mainstay of HCC treatment, and thanks to the considerable improvements in surgical techniques and peri-operative care, the rates of death and complications after liver resection have remarkably decreased over time, giving the procedure added value[7,8]. However, surgery can negatively impact on the already compromised function of cirrhotic livers and, on the other hand, radiofrequency ablation seems safer but its ability to achieve complete and sustained tumor necrosis can be less predictable, and technical feasibility may be sub-optimal. For these reasons, the choice between hepatic resection and radiofrequency ablation for HCC is still a matter of debate. The aim of the present review is to examine the available literature that directly compares these two therapeutic strategies. The qualities and flaws of each included study were highlighted in the attempt to reach conclusions regarding the effectiveness of one treatment with respect to the other and to make suggestions for future research on this debated topic.

LITERATURE STRATEGY SEARCH

A systematic search within the Medline and Embase databases, in the period between 1 January 2000 and 1 December 2012, was performed with the MeSH terms "hepatocellular carcinoma" and ("hepatectomy" or "surgical therapy") and "ablation techniques". The keywords "hepatocellular carcinoma", "partial hepatectomy", "hepatic resection", "radiofrequency ablation" or "percutaneous ablation" and "survival" were used to supplement the literature search. The reference lists of retrieved publications were reviewed for other relevant papers. Only articles involving human subjects and that directly compared radiofrequency ablation *vs* hepatic resection for HCC were considered for the present review. The quality of the selected articles was attributed on the basis of their level of evidence and by means of the Newcastle-Ottawa quality assessment scale for observational studies[9]. The Newcastle-Ottawa Scale (NOS) is a score system that was developed to assess the quality of non-randomized studies, in which a study is judged on three broad perspectives: (1) the selection of the study groups; (2) the comparability of the groups; and (3) the ascertainment of either the exposure or outcome of interest for case-control or cohort studies, respectively.

WHAT GUIDELINES RECOMMEND

Clinical practice guidelines should be evidence-based and should represent the consensus of expert committees. However, it is often very difficult to reach a consensus in the field of HCC, especially as regards the therapeutic approach, given the extremely limited availability of high quality trials. Table 1 reports a summary of the levels of evidence and the strength of recommendations from three published guidelines, namely, the European Association for the Study of the Liver (EASL-EORTC), updated in 2012[10], the American Association for the Study of Liver Diseases (AASLD), updated in 2010[11], and the Asian Pacific Association for the Study of the Liver (APASL), updated in 2010[12]. The EASL and AASLD guidelines are mainly based on the Barcelona Clinic Liver Cancer (BCLC) algorithm for staging and treatment of HCC and represent the most popular treatment algorithms in Western countries[13], however, the BCLC algorithm is not very popular in Asia. There are two important aspects of these guidelines that deserve attention and that are strictly related to each other. The first is represented by the role of the "alternative strategy" of ablation, with respect to resection, and the second is the recommended selection criteria for surgery. It can be immediately noted that radiofrequency ablation is always considered as a strategy alternative, and not competitive, to resection: the EASL recommends ablative therapies "for patients with BCLC 0-A tumours not suitable for surgery", the AASLD suggests that ablative therapy is "effective for patients who cannot undergo resection" and the APASL recommends local ablation as "an acceptable alternative to resection". These recommendations mainly derive from indirect comparisons of the results from the two treatments. In brief, modern standards of HCC resection in cirrhotic patients call for a peri-operative mortality < 3% and an expected 5-year survival rate above 60%[10,14-18], whereas, on the other hand, mortality after RFA has been reported to range between 0.9% and 7.9% and the 5-year survival rate to range between 40% and 70%[19-25]. Most of the uncertainties are related to the efficacy of ablation techniques, since response to ablative therapies is strongly influenced by tumor size and location[19,26-29]. In addition, patients allocated to ablation tend to suffer from a more advanced degree of liver dysfunction in comparison to those undergoing surgery, and this feature can negatively impact the observed results. On the other hand, strict selection criteria for hepatic resection can ameliorate patient survival after surgery and this is especially true as regards liver reserve. These two features are obviously related to each other, since at varying criteria for resection, different patients will be shifted to ablation techniques and this represents the second aspect that deserves attention. For example, a selection of candidates for hepatic resection strictly based on the hepatic vein pressure gradient (HVPG), as recommended by the EASL[10], could exclude several patients from surgery, shifting them to RFA. Specifically, HVPG should be <

Table 1 Proposed evidences and recommendations from international guidelines

Guidelines	Hepatic resection	Radiofrequency ablation
EASL	Resection is the first-line treatment option for patients with solitary tumors and very well-preserved liver function, defined as normal bilirubin with either hepatic venous pressure gradient ⩽ 10 mmHg or platelet count ⩾ 100000 (evidence 2A; recommendation 1B)	Local ablation with radiofrequency or percutaneous ethanol injection is considered the standard of care for patients with BCLC 0-A tumors not suitable for surgery (evidence 2A; recommendation 1B)
EORTC[9]	Additional indications for patients with multifocal tumors meeting Milan criteria (⩽ 3 nodules ⩽ 3 cm) or with mild portal hypertension not suitable for liver transplantation require prospective comparisons with loco-regional treatments. (evidence 3A; recommendation 2C)	In tumors < 2 cm, BCLC 0, Ethanol injection and radio-frequency ablation achieve complete responses in more than 90% of cases with good long-term outcome [evidence 1(i)A; recommendation 1C]
AASLD[10]	Patients who have a single lesion can be offered surgical resection if they are non-cirrhotic or have cirrhosis but still have well preserved liver function, normal bilirubin and hepatic vein pressure gradient < 10 mmHg (recommendation 2)	Local ablation is safe and effective therapy for patients who cannot undergo resection, or as a bridge to transplantation (recommendation 2); Alcohol injection and radiofrequency are equally effective for tumors < 2 cm. However, the necrotic effect of radiofrequency ablation is more predictable in all tumor sizes and its efficacy is clearly superior to that of alcohol injection in larger tumors (recommendation 1)
APASL[11]	Liver resection is a first-line curative treatment of solitary or multifocal HCC confined to the liver, anatomically resectable, and with satisfactory liver function reserve (evidence 2B, recommendation B)	Local ablation is an acceptable alternative to resection for small HCC (< 3 cm) in Child-Pugh A cirrhosis (evidence 2B, recommendation B); Local ablation is a first-line treatment of unresectable, small HCC with 3 or fewer nodules in Child-Pugh A or B cirrhosis (evidence 2B, recommendation B)

Strength of evidence according to study design: Level 1, Randomized controlled clinical trials or meta-analyses of randomized studies; Level 2, Non-randomized controlled clinical trials; Level 3, Case series. Strength of evidence according to end-points: A, Total mortality; B, Cause-specific mortality; C, Carefully assessed quality of life; D, Indirect surrogates. Grading of recommendation: 1, Strong recommendation warranted; 2, Weaker recommendation. Grading of recommendation: A, Further research is very unlikely to change out confidence in the estimate of effect; B, Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate; C, Further research is very likely to have an important impact on our confidence in the estimate of effect. BCLC: Barcelona Clinic Liver Cancer; HCC: Hepatocellular carcinoma; EASL: European Association for the Study of the Liver; EORTC: European Organisation For Research And Treatment Of Cancer; AASLD: American Association for the Study of Liver Diseases; APASL: Asian Pacific Association for the Study of the Liver.

10 mmHg to allow a safe resection[13], but the evidence for this recommendation is not very strong since it was based on data obtained in a very small cohort studied in the 1990s[30] and surgical techniques have substantially improved since then. Only one recent external validation was conducted on only 39 patients[31], whereas other studies could not confirm the influence of portal hypertension[32]. HVPG measurement can probably help to select surgical candidates, with a very low or null probability of post-operative liver failure, but it probably also excludes patients that can still benefit from surgery and that will be submitted to RFA with a lower chance of cure[32]. Thus, more restrictive criteria for resection result in a better outcome after surgery and a worse outcome after ablation that represents the alternative therapy to be adopted. It can be concluded that such discrepancies, evident even in international guidelines, are attributable to the relatively low level of evidence that can be obtained from the literature, as is pointed out in the following paragraphs.

COMPARATIVE STUDIES ON RESECTION *VS* ABLATION

The literature review retrieved 19 studies that directly compared resection and radiofrequency ablation; of them, three RCTs were available for comparison whereas the remaining studies were represented by retrospective observational studies. Randomized controlled studies were reviewed separately from observational studies. As can be noted from Table 2, the NOS scale of observational studies ranged from 5 to 8, none of them reached the maximum quality assessment of 9 and most of them had a quality scale below 8. In fact, the review of these studies showed that for the two treatment arms patients often have significant differences regarding most clinical and tumor variables, that are able to confound results. Thus, stratification for tumor size was attempted in order to reduce to a minimum potential biases resulting from covariate distribution. Differences observed between the two treatment arms were also highlighted. Characteristics of RCTs are reported in Table 3 and of observational studies in Table 4.

Randomized controlled studies

At December 2012, three RCTs were available for review and all were from Eastern countries[33-35] (Table 3). The first RCT was published by Chen *et al*[33]. Tumor recurrence rate at 2 years after treatment was used as the primary outcome measure to estimate the sample size of the study. After post-randomization exclusion, the study involved 71 patients submitted to ablation and 90 submitted to resection. The results showed that the 3-year overall survival was 71.4% after ablation and 73.4% after surgery. The corresponding disease-free survival rates were 64.1% and 69.0%, respectively. No statistical difference was observed and no differences were observed when patients were stratified by tumor size (*P*-values not provided). The authors concluded that the overall and

The Newcastle-Ottawa Score (NOS) scale can range from 5 to 9. RCT: Randomized controlled trials.

disease-free survivals were the same for patients with a single tumor ⩽ 5 cm treated with either ablation or resection; however, ablation showed an advantage over surgical resection in causing less post-treatment complications, less pain, and a shorter in-hospital stay[33].

The second RCT was published by Huang *et al*[34]. The 5-year overall survival rate after treatment was used as the primary outcome measure to estimate the sample size of the study. After post-randomization exclusion, the study involved 115 patients submitted to ablation and 115 submitted to resection. Results showed that the 5-year overall survival rates was 54.8% after ablation and 75.7% after surgery ($P = 0.001$). The corresponding recurrence-free survival rates were 28.7% and 51.3%, respectively ($P = 0.017$). The benefit of resection was maintained when patients were stratified by tumor size and number. The authors concluded that surgical resection may provide better survival and lower tumor recurrence rates than ablation for HCC within Milan criteria[34].

The third, and last, RCT was published by Feng *et al*[35]. The 3-year overall survival rate after treatment was used as the outcome measure to estimate the sample size of the study. After post-randomization exclusion, the study involved 84 patients submitted to ablation and 84 submitted to resection. Results showed that the 3-year overall survival rates was 67.2% after ablation and 74.8% after surgery ($P = 0.342$). The corresponding recurrence-free survival rates were 49.6% and 61.1%, respectively ($P = 0.122$). No stratification for tumor stage was provided. The authors concluded that percutaneous radiofrequency ablation may provide therapeutic effects similar to those of hepatic resection[35].

Thus, the available RCTs report different results and only Huang demonstrated a superiority of hepatic resection over ablation. Even if higher survival rates after resection were also observed in the analyses of Chen and Feng, they did not find a statistically significant superiority of surgery over ablation, leaving the question regarding the best therapeutic approach to be adopted unsolved. It should be noted, however, that the different proportions of HCC beyond the very early stage can, at least in part, explain the conflicting results, since it is known that ablation beyond this stage is less able to achieve complete tumor necrosis, thus biasing the final results[19,28,29]. Hence, a further review of the available observational studies is necessary to obtain more clinical, useful information.

Single tumors less or equal to 2 cm

Four observational retrospective studies analyzed outcomes of resection and ablation in single tumors ⩽ 2 cm[36-39] (Table 4) while none of the previous reported RCTs analyzed this specific tumor stage. None of the observational studies reported a convincing comparability between the two treatment arms, and the most frequent differences observed between ablated and surgical patients were that RFA patients were older than surgical patients, had a lower platelet count, belonged more frequently to Child-Pugh class B and were affected by smaller tumors ($P < 0.050$). Thus, results in terms of both patient survival and recurrence rate can be biased by covariate distribution. Three articles deserve some discussion for different reasons. The first article derives from a multi-institutional database of the Liver Cancer Study Group of Japan involving 2550 patients[39]. In this report, disease-free survival (DFS) was significantly better ($P = 0.001$) after resection ($n = 1235$) than after RFA ($n = 1315$), but patient survival was similar ($P = 0.280$). Ablated patients were more frequently in Child-Pugh class B, had higher ICG-R15 and smaller tumor size in comparison to resected patients ($P = 0.001$ in all cases). Therapy and Child-Pugh class were independent prognostic factors of DFS at Cox regression analysis but regression on patient survival was not performed. This report represents the largest series published in the literature that analyzed this specific tumor stage. It can be speculated that patient survival after RFA could be under-estimated, because of more advanced hepatic dysfunction, and, on the contrary, recurrence rate over-estimated because of smaller tumor size. These observations support the hypothesis that patient survival after ablation can be similar to that of surgery for tumors < 2 cm; unfortunately the choice of a composite end-point, as DFS is (in which the event is death or recurrence), does not allow a similar conclusion for just recurrence rate.

In a more recent report by Wang *et al*[37], the authors tried to handle the different covariate distribution by means of propensity score one-to-one match. In their sub-analysis of 104 matched patients with single tumor < 2 cm (52 patients for each arm), the authors reported that resection and RFA provide similar patient survival ($P = 0.296$), but that DFS of surgical patients was significantly better than that of RFA patients ($P = 0.031$). Unfortu-

Table 3 Characteristics of randomized controlled studies that compared hepatic resection *vs* radiofrequency ablation

Ref.	Liver function	Tumor features	Treatment	Study characteristics and main findings
Chen *et al*[33]	Child-Pugh class A ICG-R15 < 30% PLT > 40000/mm^3	Single < 5 cm	HR: 90 RFA: 71	21% of patients randomized to RFA withdrew their consent. The 1-, 3-, and 4-year overall survival rates after RFA and surgery were 95.8%, 71.4%, 67.9% and 93.3%, 73.4%, 64.0%, respectively. The corresponding DFS rates were 85.9%, 64.1%, 46.4% and 86.6%, 69%, 51.6%, respectively. Statistically, there was no difference. The 5-year rates were not reported
		Single tumor ⩽ 3 cm	HR: 42 RFA: 37	Authors stated that patient survival and DFS did not change in tumors < 3 cm but survival rates and *P*-values were not provided (only Kaplan-Meier curves were reported)
		Single 3.1-5.0 cm	HR: 48 RFA: 34	Authors stated that patient survival and DFS did not change in tumors between 3.1 and 5.0 cm but survival rates and *P*-values were not provided (only Kaplan-Meier curves were reported)
Huang *et al*[34]	Child-Pugh class A/B ICG-R15 < 20% PLT > 50000/mm^3	Single ⩽ 5 cm or up to 3 nodules < 3 cm	HR: 115 RFA: 115	Despite randomization, RFA patients had higher prevalence of nodules ⩽ 3 cm (P = 0.021). The 3- and 5-year survival rates for the RFA group and the HR group were 69.6%, 54.8% and 92.2%, 75.7%, respectively (P = 0.001). The corresponding RFS rates were 46.1%, 28.7% and 60.9%, 51.3%, respectively (P = 0.017)
		Single tumor ⩽ 3 cm	HR: 45 RFA: 57	The 3- and 5-year survival rates for the RFA group and the HR group were 77.2%, 61.4% and 95.6%, 82.2%, respectively (P = 0.030). Neither DFS nor RFS for this subgroup were provided
		Single 3.1-5.0 cm	HR: 44 RFA: 27	The 3- and 5-year survival rates for the RFA group and the HR group were 66.7%, 51.5% and 95.5%, 72.3%, respectively (P = 0.046). Neither DFS nor RFS for this subgroup were provided
		Multifocal < 3 cm	HR: 26 RFA: 31	The 3- and 5-year survival rates for the RFA group and the HR group were 58.1%, 45.2% and 80.8%, 69.2%, respectively (P = 0.042). Neither DFS nor RFS for this subgroup were provided
Feng *et al*[35]	Child-Pugh class A/B ICG-R15 < 30% PLT > 50000/mm^3	Up to 2 nodules < 4 cm	HR: 84 RFA: 84	The 1- and 3-year survival rates for HR and RFA groups were 96.0%, 74.8% and 93.1%, 67.2%, respectively (P = 0.342). The corresponding RFS rates were 90.6%, 61.1% and 86.2%, 49.6%, respectively (P = 0.122). Results at 5-year not reported (or not reached). On the basis of this lack of evidence, the authors did not include treatment as a variable in multivariate analysis

Other inclusion criteria common to all randomized controlled trials (RCTs): no radiological evidence of invasion into the portal/hepatic vein branches, no extra-hepatic metastases, no previous treatment of hepatocellular carcinoma (HCC), patient should be suitable to be treated by surgical resection and radiofrequency ablation. HR: Hepatic resection; RFA: Radiofrequency ablation; DFS: Disease-free survival; PLT: Platelet.

nately, the match was unconvincing and the inaccuracy of the match procedure is reinforced by the match provided in the same manuscript for patients with tumors < 3 cm, where covariates were still significantly different, after matching, among the two treatment arms (P < 0.001 in some cases)[37]. This work highlights the need for a rigorous statistical approach in the presence of significant covariate differences; without such an approach, the results can remain difficult to interpret with some degree of certainty.

The third report was published by Peng[36] in 2012, and involved 145 patients, submitted to resection, or ablation, for single tumor ⩽ 2 cm. The authors found that overall survival was better after RFA (P = 0.048) but that recurrence-free survival (RFS) was unaffected (P = 0.548). The results are intriguing since, when looking at the baseline characteristics, the two groups were quite similar as regards clinical and demographical covariates, except for lower prothrombin time and platelet count in the RFA arm. Thus, supposing an effect of worse liver function on survival, this would have to be shown in patients undergoing RFA, returning to an under-estimation of survival after ablation. Multivariate regression analyses showed that treatment allocation was the only significant prognostic factor for overall survival (P = 0.046). If a conclusion, regarding comparative analyses in this HCC stage, is to be drawn, it can be said that there is some evidence that for single nodules, not larger than 2 cm, RFA can provide survival similar to that of resection[24]. An increased recurrence rate, however, has to be expected after RFA even if the tumor is small but this could theoretically be the subject of re-treatment, justifying comparable survivals. For very early HCC, dedicated RCTs are warranted.

Single tumors less than or equal to 3 cm

There is greater experience published in the literature when this size threshold was selected as an inclusion criterion. Overall, seven studies were found to analyze ablation *vs* resection in single tumors ⩽ 3 cm, or that included a sub-analysis in this specific tumor stage (Tables 3, 4)[33,34,40-44]. Two of these studies were the previously cited RCTs by Chen *et al*[33] and Huang *et al*[34], which contained a sub-analysis for this specific tumor stage. In the RCT by Chen *et al*[33], the authors stated that both patient survival and DFS did not change in single tumors < 3 cm, but, unfortunately, both survival rates and *P*-values were not provided. The RCT by Huang *et al*[34] reported a survival advantage of surgery: in the subgroups of 45 resected patients *vs* 57 ablated patients with a solitary nod-

Table 4 Characteristics of observational studies that compared hepatic resection *vs* radiofrequency ablation

Ref.	Liver function	Tumor features	Treatment	Study characteristics and main findings
Peng *et al*[36]	Child-Pugh class A	Single tumor ≤ 2 cm	HR: 74 RFA: 71	RFA patients showed lower prothrombin activity (P = 0.001) and lower platelet count (P = 0.010). Other features were similar between the two groups The 3-, and 5-year survival rates were 87.7% and 71.9%, respectively, after RFA and 70.9% and 62.1% after HR (P = 0.048). The corresponding RFS rates were 65.2% and 59.8% with RFA and 56.1%, and 51.3% after HR (P = 0.548)
Wang *et al*[37]	Child-Pugh class A and B	BCLC early stage	HR: 208 RFA: 254	Patient characteristics were considerably different between the two treatments. RFA patients were significantly older, anti-HCV+, in Child-Pugh class B, with lower platelet count, with smaller and multifocal tumors than HR patients (P = 0.001 in all cases) The 3- and 5-year survival rates were 87.8% and 77.2% for HR, and 73.5% and 57.4% for RFA (P = 0.001). The 3- and 5-year DFS rates were 59.9% and 50.8% for HR and 28.3% and 14.1% for RFA, respectively (P < 0.001)
		BCLC early stage after PS match	HR: 208 RFA: 208	Patient characteristics were different between the two treatment arms. RFA patients were significantly older, anti-HCV+, in Child-Pugh class B, with lower platelet count, with smaller and multifocal tumors than HR patients (P = 0.001 in all cases). Patient and DFS rates not provided for this subgroup
		Single tumor < 2 cm	HR: 52 RFA: 91	Patient characteristics were different between the two treatment arms. RFA patients were significantly older, anti-HCV+, with lower platelet count than HR patients (P < 0.050). No Child-Pugh stratification was provided The 3- and 5-year survival rates were 98% and 91.5% for HR, and 80.3% and 72% for RFA (P = 0.073). The 3- and 5-year DFS rates were 62.1% and 40.7% for HR and 39.8% and 29.3% for RFA, respectively (P = 0.006)
		Single tumor < 2 cm after PS match	HR: 52 RFA: 52	Patient characteristics seem similar between the two treatments. The 3- and 5-year survival rates were 98% and 91.5% for HR, and 82.8% and 82.8% for RFA, respectively (P = 0.269). The 3- and 5-year DFS rates were 62.1% and 40.7% for HR and 46.8% and 38.0% for RFA (P = 0.031)
Ruzzenente *et al*[47]	Child-Pugh class A and B	Up to 3 tumors ≤ 6 cm after PS match	HR: 88 RFA: 88	Patient characteristics seem similar between the two treatments. The 3- and 5-year survival rates were 68.7% and 59.3% for HR, and 50.1% and 27.7% for RFA (P = 0.012). The 3- and 5-year DFS rates were 50.4% and 27.1% for HR and 30.2% and 18.6% for RFA, respectively (P = 0.001)
	Child-Pugh class A and B	Single tumor < 5 cm	HR: 45 RFA: 40	The 3- and 5-year survival rates were 66.1% and 54.5% for HR, and 63.7% and 43.8% for RFA (P = 0.633). The 3- and 5-year DFS rates were 42.4% and 22.6% for HR and 30.7% and 23.0% for RFA, respectively (P = 0.644). Patient and disease-free survival after HR were significantly superior to RFA, in patients with tumors ≥ 5 cm Further stratifications lead to very small groups (n < 10)
Nishikawa *et al*[42]	Child-Pugh class A and B	Single tumor ≤ 3 cm	HR: 78 RFA: 92	RFA patients had smaller tumors (P = 0.001) and lower platelet count (P = 0.004) in comparison to HR patients The 5-year overall survival rates after RFA and HR were 63.1% and 74.6%, respectively (P = 0.259). The corresponding RFS rates were 18.0% and 26.0%, respectively (P = 0.324). In the multivariate analysis treatment was not an independent risk factor for overall and RFS
Hung *et al*[38]	Child-Pugh class A and B	Up to 3 tumors ≤ 5 cm	HR: 229 RFA: 190	RFA patients were significantly older, anti-HCV+, with lower albumin and platelet count (P < 0.050) in comparison to HR patients The 3- and 5-year survival rates were 88.2% and 79.3% for HR, and 77.3% and 67.4% for RFA, respectively (P = 0.009). The 3- and 5-year RFS rates were 56.1% and 40.9% for HR and 29.0% and 20.5% for RFA (P = 0.001)
		Up to 3 tumors ≤ 5 cm after PS match	HR: 84 RFA: 84	Patient characteristics seem similar between the two treatments Patient and DFS rates not provided but only reported in Kaplan-Meier graphs. For patient survival no difference was found (P = 0.519); RFS was significantly worse after RFA (P < 0.001)
		Single tumor < 2 cm	HR: 50 RFA: 66	RFA patients were significantly older, anti-HCV+, with lower albumin and platelet count, higher bilirubin, AST and ICG-R15 and with smaller tumors (P = 0.001) in comparison to HR patients The 3- and 5-year survival rates were 91.1% and 84.6% for HR, and 86.5% and 77.8% for RFA, respectively (P = 0.358). The 3- and 5-year RFS rates were 42.6% and 21.8% for HR and 59.5% and 45.2% for RFA (P = 0.104)
Takayama *et al*[39]	Child-Pugh class A and B	Single tumor ≤ 2 cm	HR: 1235 RFA: 1315	Data from the Liver Cancer Study Group of Japan database. Results were reported in the form of brief communication. RFA patients were significantly more frequently in Child-Pugh class B, had higher ICG-R15 and smaller tumor size (P = 0.001 in all cases) in comparison to HR patients The 1- and 2-year survival rates were 98% and 94% for HR, and 99% and 95% for RFA, respectively (P = 0.280). The 1- and 2-year DFS rates were 91% and 70% for HR and 84% and 58% for RFA, respectively (P = 0.001) Multivariate analysis on DFS confirmed alpha-fetoprotein, therapy and Child-Pugh class as independent factors

Ueno *et al*[41]	Child-Pugh class A and B	BCLC early stage	HR: 123 RFA: 155	RFA patients were significantly more frequently in Liver Damage class B or C, had higher ICG-R15, MELD score and smaller tumor size (P = 0.001 in all cases) in comparison to HR patients The 3- and 5-year survival rates were 92% and 80% for HR, and 92% and 63% for RFA, respectively (P = 0.06). The 3- and 5-year DFS rates were 47% and 38% for HR and 36% and 20% for RFA (P = 0.02)
		Single tumor ⩽ 3 cm	HR: 78 RFA: 92	The 3- and 5-year survival rates were 95% and 95% for HR, and 90% and 60% for RFA, respectively (P = 0.01). The 3- and 5-year DFS rates were 56% and 44% for HR and 37% and 11% for RFA (P = 0.02)
		Single tumor 3.1-5.0 cm	HR: 32 RFA: 9	The 3- and 5-year survival rates were 92% and 72% for HR, and 73% and 73% for RFA, respectively (P = 0.15). The 3- and 5-year DFS rates were 33% and 25% for HR and 14% and 14% for RFA (P = 0.12)
		2 or 3 nodules ⩽ 3 cm	HR: 13 RFA: 54	The 3- and 5-year survival rates were 67% and not reached for HR, and 93% and 63% for RFA, respectively (P = 0.002). The 3- and 5-year DFS rates were 29% and not reached for HR and 35% and 22% for RFA (P = 0.59)
Abu-Hilal *et al*[48]	Child-Pugh class A and B	Single tumor ⩽ 5 cm	HR: 34 RFA: 34	This was a matched analysis for age, sex, tumor size, and Child-Pugh grade The 5-year survival was 56% for HR, and 57% for RFA (P = 0.302). The 5-year DFS was 28% for HR and 21% for RFA (P = 0.028)
Guglielmi *et al*[43]	Child-Pugh class A and B	Up to 3 tumors ⩽ 6 cm	HR: 91 RFA: 109	RFA patients were significantly older, belonged more frequently to Child-Pugh class B and more frequently had multinodular tumors (P = 0.010) in comparison to HR patients The 3- and 5-year survival rates were 64% and 48% for HR, and 42% and 20% for RFA, respectively (P = 0.010). The 3- and 5-year DFS rates were 56% and 27% for HR and 22% and 22% for RFA (P = 0.001) Superiority of HR was confined to patients in Child-Pugh class A. Further stratifications resulted in groups of patients not large enough (n < 10) to obtain realistic comparisons Type of treatment was significantly related to survival and DFS at multivariate analyses
	Child-Pugh class A	Single tumor ⩽ 3 cm	HR: 20 RFA: 11	The 3- and 5-year survival rates were 93% and 71% for HR, and 50% and not reached for RFA, respectively (P = 0.060)
	Child-Pugh class A	Single tumor > 3 cm	HR: 33 RFA: 23	The 3- and 5-year survival rates were 64% and 55% for HR, and 63% and 45% for RFA, respectively (P = 0.700)
Hiraoka *et al*[40]	Child-Pugh class A and B	Single tumor ⩽ 3 cm	HR: 59 RFA: 105	RFA patients belonged more frequently to Child-Pugh class B (P = 0.011), more frequently had tumors < 2 cm (P = 0.001), and had worse ICG-R15 (P = 0.026) in comparison to HR patients The 3- and 5-year survival rates were 91.4% and 59.4% for HR, and 87.8% and 59.3% for RFA, respectively (P = NS). The 3- and 5-year DFS rates were 64.3% and 22.4% for HR and 58.7% and 24.6% for RFA (P = NS) No multivariate analysis provided
Hasegawa *et al*[46]	Child-Pugh class A and B	Up to 3 tumors ⩽ 3 cm	HR: 2857 RFA: 3022	Data were analyzed together with a population of 1306 patients submitted to percutaneous ethanol injection. RFA patients were significantly older, belonged more frequently to Child-Pugh class B, had lower serum albumin, higher bilirubin, worse ICG-R15 and more frequently had multinodular and smaller tumors (P < 0.001 in all cases) in comparison to HR patients Results were limited to 24 mo. The 1- and 2-year survival rates were 98.3% and 94.5% for HR, and 98.5% and 93.0% for RFA, respectively (P = 0.640) The 1- and 2-year recurrence rates were 17.0% and 35.5% for HR and 26.0% and 55.4% for RFA (P < 0.001) At multivariate analysis, type of treatment did not affect overall survival but affected recurrence rate
Lupo *et al*[45]	Child-Pugh class A and B	Single tumor 3-5 cm	HR: 42 RFA: 60	The groups were similar in terms of median age, Child-Pugh score and tumor size The 3- and 5-year survival rates were 57% and 43% for HR, and 53% and 32% for RFA, respectively (P = 0.824). The 3- and 5-year DFS rates were 35% and 14% for HR and 18% and 0% for RFA (P = 0.283) No multivariate analyses were performed
Ogihara *et al*[49]	Child-Pugh class A and B	Single tumor without size limit	HR: 47 RFA: 40	RFA patients were significantly older, belonged more frequently to Child-Pugh class B and had smaller tumors (P < 0.001 in all cases) in comparison to HR patients The 3- and 5-year survival rates were 65% and 31% for HR, and 58% and 39% for RFA, respectively (P = NS). DFS not provided. No multivariate analysis was provided
	Child-Pugh class A and B	Single tumor ⩽ 5 cm	HR: 18 RFA: 26	In these subgroups, RFA patients were still significantly older and belonged more frequently to Child-Pugh class B (P < 0.050) in comparison to HR patients The 3- and 5-year survival rates were 64% and 21% for HR, and 53% and 32% for RFA, respectively (P = NS). The 3- and 5-year DFS rates were 37% and 37% for HR and 31% and 23% for RFA (P = NS) Results did not change in single tumors > 5 cm
Montorsi *et al*[50]	Child-Pugh class A and B	Single tumor ⩽ 5 cm	HR: 40 RFA: 58	All RFA were performed with laparoscopic approach. RFA patients had significantly worse INR and higher AST (P < 0.050). A trend toward higher bilirubin, lower platelet count and higher ALT was also reported (P < 0.10)

				The 3- and 4-year survival rates were 73% and 61% for HR, and 61% and 42% for RFA, respectively (P = 0.139). The RFS rates were not reported and only plotted in a Kaplan-Meier curve reporting a P = 0.024. Five-year rates not reported. Multivariate analysis on survival did not include the primary exposure variable (HR *vs* RFA)
Hong *et al*[51]	Child-Pugh class A	Single tumor ⩽ 4 cm	HR: 93 RFA: 55	RFA patients were significantly older (P < 0.001) but the other characteristics reported were not statistically different between the two groups The 1- and 3-year survival rates were 97.9% and 83.9% for HR, and 100% and 72.7% for RFA, respectively (P = 0.24). The 1- and 3-year RFS rates were 75.9% and 54.7% for HR and 74.1% and 40.2% for RFA (P = 0.54). Five-year rates not reported. Results did not change when patients were stratified by AJCC or CLIP stages No multivariate analyses were performed
Vivarelli *et al*[44]	Child-Pugh class A and B	No inclusion criteria specified	HR: 79 RFA: 79	RFA patients belonged more frequently to Child-Pugh class B and more frequently had multinodular tumors (P < 0.001 in both cases) The 1- and 3-year survival rates were 83% and 65% for HR, and 78% and 33% for RFA, respectively (P = 0.002). The 1- and 3-year DFS rates were 79% and 50% for HR and 60% and 20% for RFA (P = 0.001). Five-year rates not reported. No multivariate analyses were performed
	Child-Pugh class A and B	Single tumor ⩽ 3 cm	HR: 21 RFA: 22	The 1- and 3-year survival rates were 89% and 79% for HR, and 89% and 50% for RFA, respectively (P = NS). The 1- and 3-year DFS rates were 84% and 67% for HR and 70% and 34% for RFA (P = NS). Five-year rates not reported
	Child-Pugh class A and B	Single tumor > 3 cm	HR: 58 RFA: 57	The 1- and 3-year survival rates were 81% and 59% for HR, and 74% and 24% for RFA, respectively (P = 0.007). The 1- and 3-year DFS rates were 77% and 43% for HR and 56% and 12% for RFA (P = 0.003). Five-year rates not reported. These differences were confirmed when the analyses were confined to Child-Pugh class A patients

HR: Hepatic resection; RFA: Radiofrequency ablation; RFS: Recurrence-free survival; DFS: disease-free survival; PS: Propensity score; AST: Aspartate aminotransferase; NS: Not significant; BCLC: Barcelona Clinic Liver Cancer; HCV: Hepatitis C virus; AJCC: American Joint Committee on Cancer; CLIP: Cancer of the Liver Italian Program; MELD: Model for end-stage liver disease.

ule ⩽ 3 cm, the 5-year survival after surgery was 82.2%, significantly higher than the 61.4% after RFA of (P = 0.030). Disease-free or recurrence-free survivals were not analyzed. One limitation is represented by the fact that covariate distribution among the two treatment arms was not provided for these specific subgroups of patients; however, since in the whole study population tumor size was the only variable that proved to be slightly different among the two groups, this sub-analysis seems quite realistic and is, at present, the most robust evidence of the superiority of one treatment (surgery) over the competing one (ablation)[34].

Similar comments regarding covariate distribution, made for single tumors < 2 cm, can be repeated for analyses on single tumors < 3 cm. Of the five retrospective studies found, two series deserve particular discussion. In 2008, Hiraoka published results from a population of 59 surgical and 105 RFA patients: no significant differences were found in terms of both patient survival and DFS[40]. However, the magnitude of the differences observed between the two treatment arms, in terms of Child-Pugh class, ICG-R15, serum albumin, bilirubin, and tumor size that were all in favor of resection, was so large that the comparison was evidently unrealistic. Furthermore, the authors did not provide an inferential analysis, leaving the doubt unsolved[40]. In 2009, Ueno *et al*[41] published a report from the Kagoshima Liver Cancer Study Group reporting that patients with a single nodule ⩽ 3 cm achieved a 5-year survival of 95% after resection (n = 78), significantly higher than that of 60% after RFA (n = 92; P = 0.010), but 75.6% of the resected patients had a Liver damage A whereas 66.3% of ablated patients had a Liver damage B or C (P = 0.001). Stratification of survival for Liver damage returned to non-significant differences in terms of both patient and disease-free survivals and these results did not help clarify, with a convincing degree of evidence, the real superiority of resection over ablation[41]. The remaining studies report results on very small subgroups, often less than 10 patients[42-44], or suffered from wrongful comparison[37], making it hard to consider findings to provide enough degree of evidence.

Single tumors 3-5 cm

Four articles were identified that analyzed comparative results of surgery and ablation in single nodules between 3 and 5 cm or that included a sub-analysis in this specific tumor stage (Tables 3 and 4)[33,34,41,45]. Two of these studies were, again, the RCT by Chen *et al*[33] and the one by Huang *et al*[34], which contained a sub-analysis for this specific tumor stage. In the RCT by Chen *et al*[33], the authors stated that both patient survival and DFS did not change between treatment arms but survival rates and p-values were again not provided. Huang's results reported a 5-year survival after surgery of 72.3% *vs* 51.5% after ablation (P = 0.046); neither DFS nor RFS were provided (Table 3)[34]. Thus, with the limitations of subgroup analyses, the available RCTs reported a limited difference between surgery and ablation for single nodules between 3 and 5 cm. When observational studies were analyzed, the findings became very difficult to interpret. In a subgroup analysis by Ueno *et al*[41] (resection: 32 patients; RFA: 9 patients), no differences were found in terms of either patient survival (5-year rate after resection: 72%; ablation: 73%; P = 0.15) or DFS (5-year rate after resec-

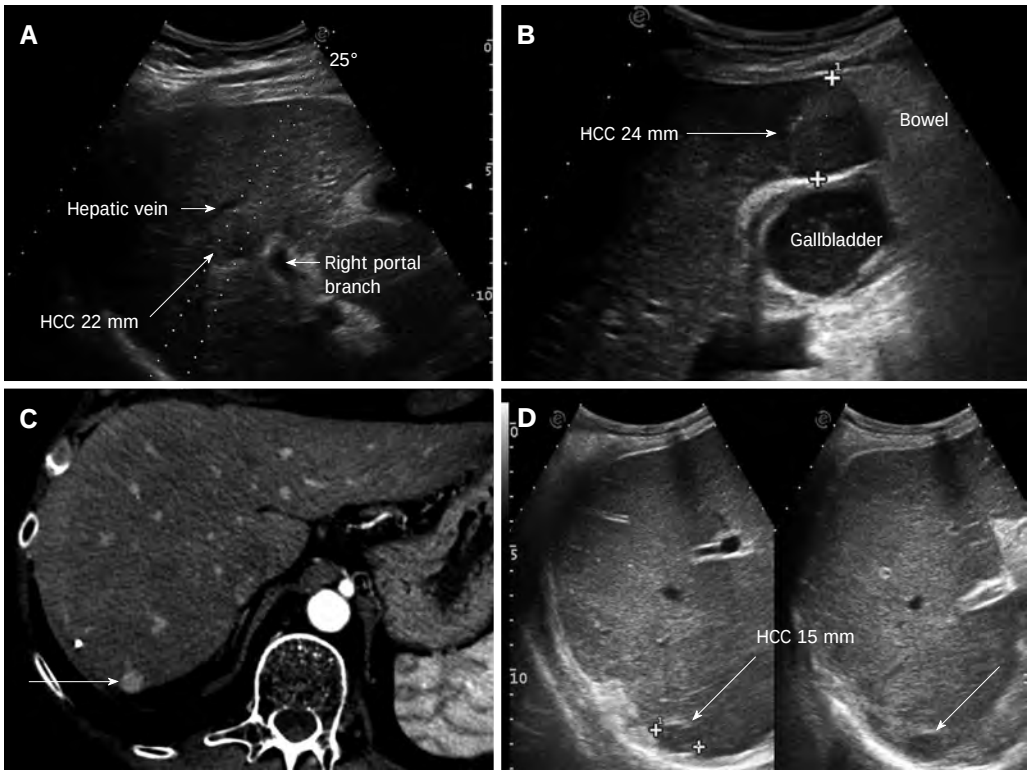

Figure 1 Clinical cases in which performing hepatic resection or radiofrequency ablation had to be decided. A: Small hepatocellular carcinoma (HCC), 22 mm in diameter, located centrally in the right liver lobe in a patient with MELD 10 and clinical signs of portal hypertension. Surgery would have required a right hepatectomy, thus, radiofrequency ablation was preferred even if a reduced rate of complete necrosis could be expected due to the possible heat sink effect of the nearby large vessels; B: The tumor is located sub-capsular, close to the bowel loops and in strict contact with the gallbladder, implying various technical contraindications to percutaneous ablation. Open surgery was the strategy adopted; C: The tumor (long arrow), shown in the arterial phase of contrast enhancement at computed tomography scan, is located sub-capsular at the liver dome; D: Ultrasonography confirms the tumor (long arrow) to lie very deep and without a safe needle track; in fact, these images are taken in deep inspiration, the lesion being hardly visible during normal breathing. The location was considered to contraindicate percutaneous ablation and surgery was performed.

tion: 25%; ablation: 14%; $P = 0.15$) but, as can be immediately noted, the sample size was very small. Another retrospective study published by Lupo *et al*[45] reported that resection and ablation provide very similar results. In particular, the 5-year survival was 43% after resection ($n = 42$) and 32% after ablation ($n = 60$; $P = 0.824$), and the corresponding DFS rates were 14% and 0% ($P = 0.283$). Thus, it must be noted that resection repeatedly leads to better patient survival and recurrence-rate, but the inability to detect a statistical difference between the two treatments leaves the question of the superiority of surgery unsolved. It could be speculated that it is paradoxical for ablation to be inferior to resection for nodules < 3 cm and equivalent for larger tumors, since the ability of RFA to achieve tumor necrosis decreases with the increase in tumor size[19,28,29,46]. Thus, for this single HCC 3-5 cm, it can be said that the literature consistently reports higher patient and disease-free survival rates that do not achieve statistical significance likely only for the small sample size of study populations. This specific tumor stage also probably deserves dedicated studies.

Multiple tumors

The presence of multiple tumors, at diagnostic evaluation prior to treatment, represents the most frequent indication for radiofrequency ablation. Except for the three RCTs and the studies conducted on solitary tumors, multifocal tumor prevalence was almost always higher in ablated patients in comparison to surgical ones[37,43,44,46]. Only two studies reported a subgroup analysis on two or three nodules less than 3 cm, thus within BCLC early stage, excluding single nodules[34,41]. The RCT by Huang reported a survival advantage of surgery ($P = 0.042$): in the subgroups of 26 resected patients *vs* 31 ablated patients with a solitary nodule ⩽ 3 cm, the 5-year survival after surgery was 69.2%, significantly higher than the 45.2% after RFA of[34]. Disease-free or recurrence-free survivals were not analyzed. In the report by Ueno *et al*[41], the 5-year survival was not reached for surgical patients ($n = 13$) and the 3-year survival was in favor of RFA ($n = 54$; $P = 0.002$), while DFS was similar ($P = 0.590$). The difficulty to obtain a comparison within this stage was highlighted by the sub-analysis by Guglielmi *et al*[43] who tried to stratify for Child-Pugh class 11 ablated patients (6 in Child-Pugh class A) *vs* 7 resected patients (all belonging to Child-Pugh class A) without obtaining any reliable result. For multiple tumors, the current comparative literature leaves the impression that the prognosis will be relatively lower despite the treatment adopted.

Other studies

Five studies remain to be briefly discussed[47-51]. The re-

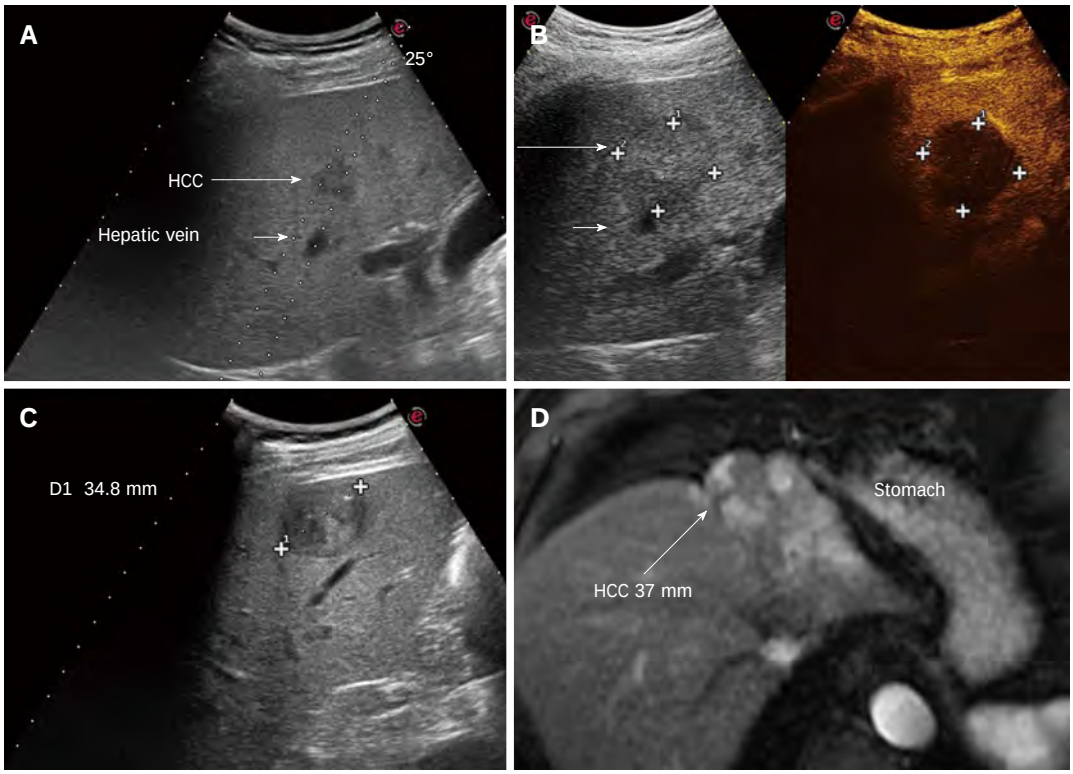

Figure 2 Clinical cases in which performing hepatic resection or radiofrequency ablation had to be decided. A: Ultrasonography through a right inter-costal scan shows a very early hepatocellular carcinoma (HCC) in segment 5 that can be reached with a safe needle track for thermal ablation. Given the small size and easy access, radiofrequency ablation was carried out; B: Post treatment assessment with contrast enhanced ultrasound shows a necrotic devascularized area (34 mm × 35 mm) that includes the tumor with a safety margin > 5 mm; C: Superficial HCC of 35 mm in hepatitis B virus related cirrhosis with preserved liver function. This lesion could be treated by either ablation or resection, but resection is preferable given the superficial location in segment 5 and the size > 3 cm; D: Tumor lesion partially treated by a previous trans-catheter arterial chemoembolization performed in another hospital, in a sub-capsular location close to the stomach. The theoretical path for radiofrequency ablation would lead the needle to puncture the tumor directly and thermal ablation would imply a risk of heat damage to the stomach wall. Laparoscopic resection was the strategy adopted. The long arrow indicates the HCC after treatment.

ports from Ruzzenente *et al*[47], in 2012, and from Abu-Hilal *et al*[48], in 2008, are examples of the attempt to account for confounding variables through matching. The first study used a propensity score match to select patients, submitted to surgery or RFA, having similar covariate distributions[47], and the second used an "a-priori" match based on age, sex, tumor size and Child-Pugh grade[48]. Both studies included tumors larger than 2 cm in both arms and reported an advantage of surgery in determining DFS over ablation but not in terms of patient survival that was similar for single tumors < 5 cm. Of note, the study by Abu-Hilal included only 34 patients for each arm and of the one by Ruzzenente included Child-Pugh B patients. The remaining articles reported results from comparative analyses without tumor size limit[49], or with large (up to 5 cm) size limit, but unfortunately they lack inference analyses[50,51].

DISCUSSION

The present review shows the lights and shadows of the comparative literature regarding hepatic resection and radiofrequency ablation for HCC. It is evident that most studies are affected by questionable methodological approaches since surgical patients and ablated patients represent patient populations that appear quite different as regards clinical and tumor features that are known to affect prognosis. Despite the inconclusive results and the interest in understanding which treatment strategy is best, it is worthwhile pointing out that the situations in which surgery and ablation would be both really equally feasible, and in which they could thus truly compete, occur in less than half of the cases seen in daily clinical practice. In fact, most studies did not report how many patients were excluded from either surgery or ablation, because of the presence of absolute or relative contraindications to one or the other treatment, which might differ in the case of one or the other therapy (thus these patients were most likely offered the alternative therapy). Patients might not be considered suitable for surgery because of liver dysfunction and/or portal hypertension, according to the individual center's strategy, as well as the presence of comorbidities or advanced age contraindicating general anesthesia. Some clinical examples can be found in Figures 1 and 2. In some cases, surgery might not be considered because of the hepatic location of the tumor, which would require very extensive parenchymal sacrifice. Conversely, a subcapsular anterior location exposes the patient to a higher risk of bleeding and/or peritoneal seeding[52], unless a direct puncture of the tumor could be

avoided[53], which is however not always possible. Moreover, complete necrosis of lesions close to the gallbladder is less often possible to achieved because of the potential risk of gallbladder wall damage[26]. Similarly, complete necrosis of lesions abutting the diaphragm may not be possible[27]. Finally, patients with compromised prothrombin time (prolonged International Normalized Radio) are invariably excluded from surgery because this alteration indicates liver dysfunction; similarly, a very low platelet count (< 50.000) is often also considered a contraindication to surgery since it indicates portal hypertension. Such patients should therefore be treated with ablation, as the first alternative therapy, but a clotting impairment might also contraindicate percutaneous ablation or at least increase the risk of adverse events, despite the possibility of preliminary transfusions. All these different variables affecting the choice between resection and ablation most likely justify the difference in the clinical covariates found in the various non randomized studies, as commented above, leading to rather heterogeneous patient populations. This is in keeping with the hypothesis that patients were not randomly allocated to one or the other treatment, but following clear preferences, so that in each case either surgery or ablation was specifically preferred on the basis of clinical variables. Only in rather a few remaining cases of early HCC within the Milan criteria might hepatic resection and radiofrequency ablation be considered truly competitive, and no definitive evidence exists strongly favoring one or the other technique.

However, based on the results reported and commented on above, we can conclude that, until further studies become available, it seems reasonable to offer radiofrequency ablation to very small HCC (< 2 cm) which present an easy access, with no technical contraindications, since in this instance complete necrosis, including the desired safety margin, is most likely to be achieved. At variance, in larger nodules, namely > 2 cm and especially if > 3 cm, and/or in tumor locations in which ablation is not expected to be effective or safe (which often correspond to subcapsular locations, which instead make atypical resections possible), surgical removal is to be preferred in our opinion. For future explorative research, it can be suggested that: (1) intention-to-treat analysis should be included in the studies; (2) further RCTs are warranted, especially for single tumors < 2 cm in which ablation can achieve a sustained pathological response; (3) retrospective observational studies should include in their analyses an inference approach that includes the primary exposure variable (that is resection *vs* ablation) regardless of its statistical difference at univariate analysis; and (4) retrospective observational studies should include stratification for tumor size and liver degree dysfunction together with an attempt at matching, as propensity score can provide.

Abstract

Toll-like receptors (TLRs) recognize specific motifs which are frequently present in bacteria, fungi, prokaryotes and viruses. Amongst TLRs, TLR9 can be activated by such bacterial or viral DNA fragments, immunoglobulin-DNA complexes or synthetic oligonucleotides, which all contain unmethylated cytosine-guanine nucleotide sequences (CpGs). Emerging data indicate that TLR9 signaling has a role in, and may influence, colorectal carcinogenesis and colonic inflammation. CpGs are classified into three groups according to their influence on both the antigen-specific humoral- and cellular immunity, and the production of type 1 interferons and proinflammatory cytokines. TLR9 activation *via* CpGs may serve as a new therapeutic target for several cancerous and various inflammatory conditions. Due to its probable anti-cancer effects, the application possibilities of TLR9-signaling modulation may be extremely diverse even in colorectal tumors. In this review we aimed to summarize the current knowledge about TLR-signaling in the pathogenesis and therapy of inflammatory bowel diseases and colorectal cancer. Due to the species-specific differences in TLR9 expression, however, one must be careful in translating the animal model data into the human system, because of the differences between CpG-oligodeoxynucleotide-responsive cells. TLR9 agonist DNA-based immunomodulatory sequences could also represent a promising therapeutic alternative in systemic inflammatory conditions and chronic colonic inflammations as their side effects are not significant.

Key words: Toll-like receptor 9; Synthetic oligodeoxynucleotide sequences; DNA-based immunomodulatory sequences; Colorectal cancer; Inflammatory bowel diseases

Core tip: Toll-like receptor 9 mediated signaling influences and regulates the severity of mucosal inflammation, and seems to have a protective role against malignant transformation. The modulation of toll-like receptor 9 signaling by synthetic oligodeoxynucleotide agonists or antagonists seems to have beneficial therapeutic effect in inflammatory and cancerous colonic disorders.

INTRODUCTION

The immunostimulatory effect of DNA was discovered by William Coley, a surgeon from New York[1]. He used living and heat-treated bacteria as a therapeutic option for different kinds of tumors. It has long been known that

microbes contain many immunostimulatory ingredients. In 1980, Tokunaga *et al*[2] identified the bacterial DNA as a main ingredient of the Coley-lysate. Later, they also showed that the same immunostimulatory effect could be achieved by using short synthetic oligodeoxynucleotide sequences (ODNs)[3,4]. In 2000, it was proven that DNA sequences are mainly recognized by the members of the Toll-like receptor (TLR) superfamily[5]. It has also been proven that in TLR9 knock out mice, microbial DNA fragments cannot result in an immune response[5]. It was also shown that the immunomodulating effect of natural and synthetic ODNs is mainly transmitted by TLR9[6].

Peyer's patches (PPs) and isolated lymphoid follicles (ILFs) are immunologic and regenerative organizers of the gut mucosa, and they also represent a unique switch point between colonic inflammation and cancer[7]. Microfold (M) cells are located in the follicle associated epithelium (FAE) of PPs and ILFs, where they mediate the uptake and transcytosis of luminal antigens to the underlying lymphoid tissue. TLR9 was found to be preferentially expressed in M cells[8]. Some TLR polymorphisms are known to be associated with the susceptibility of inflammatory bowel diseases (IBD)[9-11] and sporadic colorectal cancer (CRC) development[12,13], but the current and concrete pathogenic role of TLRs, including TLR9, remains uncertain in these conditions.

In this review we aimed to summarize the current knowledge about TLR-signaling in the pathogenesis of IBD and CRC, focusing especially on TLR9. Recent data indicate that targeting TLR9-signaling may yield new and promising therapeutic approaches to these conditions.

LIGANDS AND SIGNALING OF TOLL-LIKE RECEPTORS

TLRs belong to the type 1 transmembrane glycoproteins, which contain extracellular leucin-reach repeated sequences and Toll/interleukin-1 receptor signaling domains. TLR4 was the first to be identified, and currently 10 TLRs have been identified in humans, while 13 have been identified in mice[14]. TLRs are mainly expressed in the cells of the innate and adaptive immunity (*i.e.*, monocytes, macrophages, lymphocytes, mast cells, dendritic cells), however, some (TLR4, -5 and -9) may be expressed by modified epithelial cells as well[15]. Apical epithelial TLR9 activation by bacterial DNA fragments has been reported to maintain colonic homeostasis[16].

TLRs usually recognize microbial wall components, DNA and ribonucleic acid (RNA) fragments. TLR1, -2, -4, -5, and -6 are localized to the cell surface, while TLR3, -7, -8, and -9 are present in the intracellular compartment[17-20]. TLRs bind specific motifs, which frequently appear in bacteria, fungi, protozoa, and viruses[21,22]. These motifs can be lipids and lipopeptides (TLR1, -2, -4, -6), bacterial flagelline (TLR5), and fragments of nucleic acids (TLR3, - 7, -8, -9). TLR3 binds double stranded RNA from viruses, while TLR7 and -8 can recognize single stranded RNAs. Moreover, TLR7 recognizes immunoglobuline-self-RNA complexes in autoimmune disease conditions. Imiquimod is a specific ligand for TLR7. TLR9 could be activated by bacterial and viral DNA, immunoglobuline-DNA complexes, and synthetic ODNs, which contain unmethylated CpG sequences[21,22].

The signals transmitted by TLRs activate both innate and adaptive immunity. Due to the immune evasion nature of tumor cells, the dysregulated activation of adaptive and innate immune systems could result in cytotoxic effects. This could in turn eradicate the diseased cells or even control the tumorous progression. TLRs recognize pathogen-associated molecular patterns (PAMPs) originating from microbiota and could also bind endogenous ligands, such as danger-associated molecular patterns (DAMPs)[23]. Both bacterial DNA and synthetic ODNs activate the innate and adaptive immune system *via* plasmacytoid dendritic cells (pDCs) and macrophages[24].

TOLL-LIKE RECEPTOR 9 SIGNALING

Due to TLR9-associated activation, pDCs produce interferon-α which influences the cytokine production of B cells[24] resulting in pro- (*e.g.*, interleukin 6, tumor-necrosis factor-α) and anti-inflammatory (*e.g.*, interleukin 10) cytokine release and co-expression of MHC Ⅱ type surface antigens.

The activation of TLR9 is a complex pathway. The uptake of DNA sequences is the most unclear process, which is influenced by the structure of the DNA fragments. Many cell types can easily take up single stranded DNA, but the uptake of double stranded DNA may be more effective if a cationic lipid is used for packing it in, because TLR9 is located in the intracellular compartment of endosomes[24,25]. It was shown that fluorescein isothiocyanate labelled CpG DNA is transferred to the intracellular compartment by non-specific endocytosis[25]. This transport is non-specific, because DNA sequences lacking CpG dinucleotides may also be recognized by TLR9, and this way of immune activation can be competitively inhibited by non-CpG sequences[25]. After transportation to the intracellular compartment, endosomal acidic maturation occurs. This process may be inhibited by pH raising agents (*e.g.*, chloroquine, bafilomycin A)[25]. Finally pro- and anti-inflammatory cytokines may be released and B cell proliferation may be enhanced[25]. The main steps of TLR9-signaling are summarized in Figure 1.

The signal molecules of this pathway [*e.g.*, myeloid differentiation primary response gene 88 (Myd88), tumor necrosis factor receptor-associated factor 6 (TRAF6), interleukin receptor associated kinase (IRAK)-1, -4; p50/p65 heterodimer of nuclear factor (NF)-κB] are non-specific and are also involved in the signaling of other TLRs. Interferons may also be released by a mitogen activated protein kinase (MAPK)-associated pathway, which is also intensively being investigated[26].

CPG OLIGODEOXYNUCLEOTIDE CLASSES

The immunostimulatory effect of unmethylated CpG

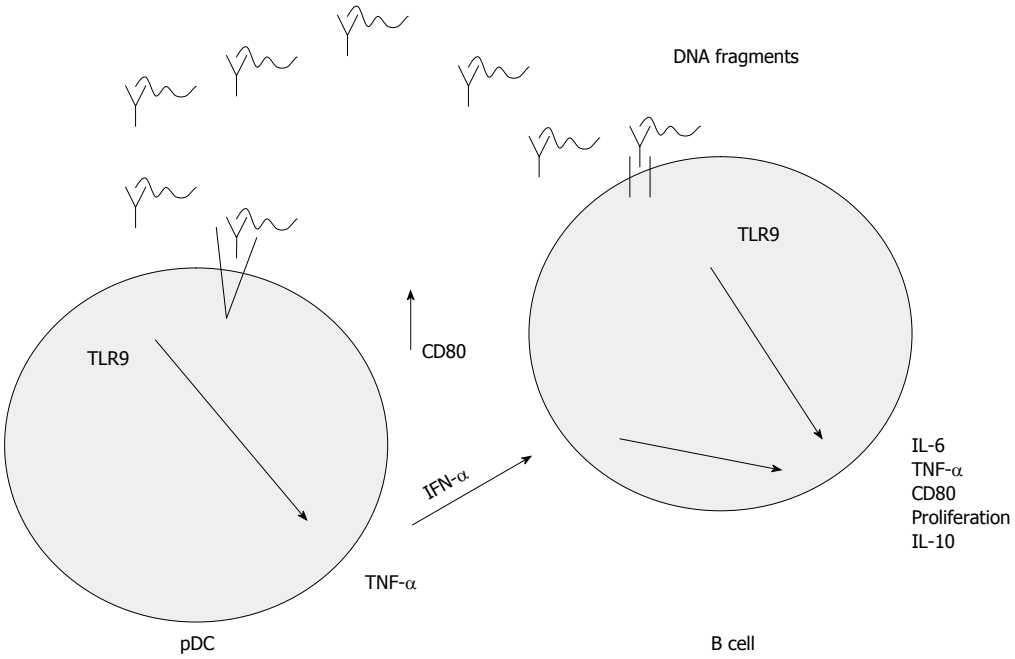

Figure 1 Toll-like receptors 9-mediated cytokine release in the colonic mucosa. Binding DNA fragments by toll-like receptors (TLRs) of plasmacytoid dendritic cells (pDCs) results in pro-inflammatory cytokine release and subsequent B cell activation together with both CD80 overexpression and B cell proliferation. CD80 provides a costimulatory signal necessary for T cell activation and survival. IFN: Interferon; TNF: Tumor necrosis factor; IL: Interleukin.

sequences has been proven in mice and in other species, as well as in *in vitro* human cell line experiments[27,28]. The CpG DNA sequences can be classified into three classes based on the different immune cell-mediated immune responses and their chemical structure. It has already been documented how these differences in the chemical structure may determine the immunostimulatory effect of these sequences on immune cells[29]. Liu *et al*[29] demonstrated in mice that three CpG-ODN classes can differentially affect antigen-specific humoral and cellular immune responses. Specifically, the B- and C-class CpG-ODNs induced a potent Th1-mediated immunity with comparable antibody levels as well as CD4+ and CD8+ T cell responses. In contrast, although the A-class CpG-ODNs weakly enhanced antibody titers and CD8+ T cell response regarding cytotoxic activity, they were not able to change the IgG1/IgG2a ratio or elicit antigen-specific, interferon γ-secreting CD4+ and CD8+ T cells. Consistent with this, three CpG-ODN classes provided differential antigen-specific protection against an intracellular bacterial infection (*i.e.*, Listeria monocytogenes). These three classes of CpG-ODNs did not show significant differences regarding the interleukin 12 producing effect[30,31]. These results may provide not only better understanding of the adjuvant activities of three CpG-ODN classes, but also of implications for the rational design of CpG-ODN adjuvants.

CONTRIBUTION OF TOLL-LIKE RECEPTOR 9 POLYMORPHISM TO DISEASE DEVELOPMENT

Components of Gram-negative bacterial cell walls alert the host to invading bacteria and activate innate immunity. These responses are usually effective in combating infection and restoring normal host function. However, in individuals susceptible to IBD, they may become excessive and lead to mucosal damage.

In genes for all the contributing proteins, single nucleotide polymorphisms (SNPs) have been identified that may increase IBD susceptibility[32]. There are several lines of sensing bacterial components (described earlier), all of which result in activation of NF-κB, and thereby stimulate the innate immune response. In genes of TLR9 signaling, SNPs have been found that may increase IBD susceptibility[9,33]. Török *et al*[9] reported that a SNP in the promoter region of the TLR9 gene was associated with increased risk of Crohn's disease in a German cohort. These genetic findings confirm an important role for innate immunity, pro- and anti-inflammatory immune responses for both gut homeostasis and the development of chronic inflammation in IBD.

Regarding the connection between polymorphisms in TLR9 genes and the risk of colorectal cancer no data are currently available.

ROLE OF TOLL-LIKE RECEPTOR 9 SIGNALING IN COLONIC INFLAMMATION AND CARCINOGENESIS

The commensal microbiota of the intestinal tract confer multiple health benefits to the host, including amelioration of IBD. It was recently identified that TLR9-induced type 1 interferons mediate the anti-inflammatory effects in experimental colitis[34]. The addition of neutralization antibodies to type 1 interferons abolished the anti-inflam-

matory effects, whereas the administration of recombinant interferon-β mimicked the anti-inflammatory effects induced by TLR9 agonists.

The relapse of IBD may occur following an infection with *Campylobacter jejuni* (*C. jejuni*). In a murine model of dextran sulfate sodium (DSS) induced colitis, the infection of the animals by *C. jejuni* disrupted TLR9-induced reinforcement of the intestinal epithelial barrier and colonization by *C. jejuni* increased the severity of DSS-induced colitis[35].

In humans, the gene expression and protein expression level of not just TLR2, -4, and -8, but also TLR9 increased in the biopsy samples of active ulcerative colitis patients. Furthermore, the levels of these TLRs positively correlated with the severity of intestinal inflammation as well as with inflammatory cytokine production[36]. Based on these results, it is plausible that TLR9 mediated signaling influences and regulates the severity of the mucosal inflammation.

In colonic carcinogenesis the role of TLR9 signaling is not well studied. It was recently published that ODNs targeting TLR9 oppositely modulate DNA repair genes in tumor versus immune cells and enhance the biologic effects of chemotherapy[37]. The first publication about the relation of TLR9 expression to colonic carcinogenesis was also published nowadays[38]. Eiró *et al*[38] found TLR9 expression to be higher in hyperplastic or adenomatous polyps compared to other polyp types. TLR9 expression was decreased in hyperplastic and villous polyps from patients who developed colorectal cancer. Their findings suggest a possible protective role of TLR9 expression against malignant transformation in the colorectal mucosa.

THERAPEUTIC POTENTIAL OF TOLL-LIKE RECEPTOR AGONISTS

The therapeutic targeting of TLRs may be useful in diseases such as tumors, allergies or viral infections. In these disorders, TLR agonists and antagonists result in a different immune response. In allergic diseases, like asthma or inflammatory conditions, such as IBD, these agents have an important effect on T cells. For a wider spectrum of anti-tumoral immune response TLR agonists in tumorous diseases require the involvement of the innate immunity, pDCs, monocytes and macrophages, as well as the activation of Th1-dependent immunity and induction of apoptosis[28].

Toll-like receptor agonists in colorectal cancer

In 2011, Rosa *et al*[39] demonstarted that an immunomodulatory oligonucleotide sequence (IMO) in combination with cetuximab has an antitumorous effect on a K-ras mutated colorectal carcinoma model. This is probably based on the alteration of MAPK phosphorylation and results in structural and functional changes in the relationship between epidermal growth factor receptor (EGFR) and TLR9[39]. They used a synthetic IMO having free 5' end. The CpG DNA sequence had dimer structure, where the 3-3' ends were connected by glycerin or 2'-deoxy-7-deazaguanosine modification. Mutation of the K-ras gene has a critical role in colon, lung and pancreatic cancers, and may cause a resistance to anti-EGFR therapy[40,41]. This is the reason why panitumumab and cetuximab therapy do not show a positive effect on the control of proliferation and metastasis of K-ras mutated colon cancer. This kind of biologic therapy could be only useful in the case of patients carrying the wild type K-ras gene[40].

It was shown in an *in vivo* murine xenograft model and *in vitro* human cancer cell lines (GEO, SW48 and LS174T) that IMOs can restore the therapy sensitivity for K-ras mutant colon and pancreatic cancers[40]. These cell lines, except GEO, were resistant for EGFR inhibition therapy, if they had a K-ras mutation. A small number of GEO cells carrying K-ras mutations showed sensitivity to anti-EGFR antibodies. This demonstrates that cells could carry a different K-ras mutation and could respond to EGFR inhibition therapy in a different way based on their K-ras status[39-41].

TLR9 agonists were also tested on a breast cancer cell line which was estrogen receptor positive[42]. After estrogen-TLR9 agonist combination the test showed significant reduction of transactivation *via* the estrogen receptor. Estrogen receptors may also take part in colorectal carcinogenesis[43,44], therefore, this interaction may have further therapeutic importance in colorectal cancer as well.

Currently, TLR9 agonist therapy has been tested clinically on colon, pancreatic and breast cancers[45-48], and experiments are running on oesophageal squamous cell cancer[49], melanomas[50], lymphomas[51,52], non-small cell lung carcinomas[53], renal tumors[47] and androgen resistant prostate cancers[54].

Toll-like receptor agonists in inflammatory bowel disease

It has long been known that in IBD patients, antibodies against own or microbial antigens can be detected. Antibodies against Saccharomyces cerevisiae, outer membrane porin, Pseudomonas fluorescens, pancreas, bacterial flagelline as well as anti-chitobioside-, anti-laminaribioside-, and anti-mannobioside antibodies[55] have all been identified. These antibodies are recognized by PAMP and DAMP receptors. The most important members of these receptor families are the nucleotide oligomerization domain (NOD) - caspase recruitment domain (CARD) system (mainly NOD2 receptor in Crohn's disease) and TLRs. These receptors are localized in the intestinal mucosa, and by increased activation and genetic polymorphisms these receptors create an excessive immune response. At the end of the pathway pro-inflammatory cytokines are released, regulatory T cells are thought to loose their control function and the Th1/Th17 cell subpopulation becomes over-expressed[55,56-58].

Rachmilewitz *et al*[56] used IMOs in a DSS-induced

colitis mouse model and found decreased IL-6, IL-12 and interferon mRNA levels. The levels of matrix metalloproteinases were found to be proportionally decreased. The immunological, clinical, biochemical and histological results showed decreased activity index of the inflammation. From these data one could suggest that the continuous presence of bacteria and bacterial DNA, which densely contain non-methylated CpG sequences, may act as a physiological factor. Furthermore, they could influence the release of inflammatory cytokines in IBD and thus may serve as a therapeutic tool[57].

A newly developed therapeutic agent is a synthetic DNA-based immunomodulatory sequence (DIMS0150), which acts through TLR9 signaling[57]. Based on the results of clinical trials, DIMS0150 seems to restore the steroid sensitivity of the mucosa in steroid-resistant ulcerative colitis patients. In the third phase of clinical trials, 71% of patients achieved remission after 12 weeks of administration of this drug[57]. Although it has no notable side effects, the mode of its administration, namely it has to be spread over the inflamed mucosa with the help of a spray catheter during colonoscopy, makes its use widely intolerable for patients. New ways of drug administration (*i.e.*, colon solvent capsules) must be developed in the near future.

Based on the results of clinical trials[45-54], TLR9 agonists are therapeutically safe *in vivo*. Only some minor side effects, mainly a dose-dependent local inflammation of the connective tissue were observed.

THERAPEUTIC POTENTIAL OF TOLL-LIKE RECEPTOR 9 ANTAGONISTS

Due to complex signaling of oligodeoxynucleotide binding TLRs (including TLR9) a dynamic regulation of pro- and anti-inflammatory cytokines is present[59]. Therefore, TLR9 antagonists and inhibitory oligodeoxynucleotides (inh-ODNs) also may represent new therapeutic options[60] in the treatment of autoimmune diseases. The mechanism of their action is by controlling and blocking the dangerous immune response activated by the self-antigen recognizing receptors. Interestingly, inh-ODNs have TLR9 (and TLR7) antagonist activity, but this effect is sequence dependent. These inhibitory oligonucleotides competitively inhibit TLR9 activation in a manner that competitively antagonizes the binding of ligands to the active, proteolytically cleaved TLR9 sequence. Their therapeutic use shows promise in systemic autoimmune diseases, DNA-mediated sepsis, and chronic inflammatory conditions (*e.g.*, IBD) in which TLR9 plays an important role[60].

SPECIES-SPECIFIC DIFFERENCE IN TOLL-LIKE RECEPTOR 9 EXPRESSION

In the majority of *in vivo* studies mice were used as animal models for showing that CpG-ODNs are effective both as adjuvants and for therapeutic intervention in infectious and tumour model systems. However, one must be careful in translating the murine data into the human system, because of the differences between CpG-ODN-responsive cells in mice and humans. One major and important difference between mice and humans refers to the expression pattern of TLR9. In humans, only pDC and B cells express TLR9 and respond directly to TLR9 activation. All other effects of TLR9 ligands on human immune cells seem to be indirect and depend on factors produced by pDCs and B cells[61].

The situation in mice is different because not only pDCs and B cells, but other dendritic cell subsets and macrophages express TLR9 and thus respond directly to TLR9 activation[61]. Given this important species-specific difference in TLR9 expression, mice are not ideal animal models for establishing TLR9-based therapeutic strategies. The natural ligands for TLR9 can be mimicked by special CpG-ODNs[62].

Besides rodent models, a few studies have analysed the immune response of CpG-ODNs in other animals[62]. Guzylack-Piriou *et al*[63] demonstrated that pig pDCs are the main producers of interferon-α in response to certain CpG-ODNs. Importantly, they additionally showed that myeloid DCs and monocytes/macrophages are refractory to CpG-ODNs. Thus, the CpG-ODN responsiveness in pigs seems to mimic the situation in humans, and therefore recommends the pig as an animal model for preclinical studies with CpG-ODN.

CONCLUSION

Since the immunomodulatory effects of TLRs are known, they are the center of biological, immunological and therapeutic research. Most of the research teams are dealing with the potential therapeutic use of TLR9 agonists and antagonists because their use is not restricted to a specific group of patients. They can be widely applied in almost all diseases where dysregulated immunity plays a central role *via* antibody production or phagocytosis by macrophages.

TLR9 plays a central role in both innate and adaptive immunity. The signalling cascade mediated by CpG ODNs is a complicated pathway and contains many steps, including the synthesis of proinflamatory cytokines and the production of interferons, and thus significant activation of pDCs and T-lymphocytes. The activation of TLR9 acts as a new therapeutic modality in bacterial, viral, inflammatory and neoplastic diseases. In inflammatory circumstances, TLR9 agonists act by both decreasing the enormous immune activation, especially in IBD, and setting the balance of the Th1/Th2 immune response. They may have an effect on the suppression of Th1/Th17 overexpression as well. In tumorous conditions, especially in colorectal cancer, these agents were able to restore anti-EGFR therapy sensitivity caused by a K-ras mutation. They also seem to be effective therapeutic agents in estrogen receptor positive breast

cancers, androgen-resistant prostate tumors, melanomas, lymphomas, large cell lung cancers and renal tumors. The side effects of TLR9 agonists are not significant. Further investigations of these new therapeutic modalities may have promising results in the near future.

Abstract

AIM: To determine whether the human giant larvae homolog 1 gene (Hugl-1/Llg1/Lgl1) exerts tumor suppressor effects in esophageal cancer.

METHODS: We constructed a Hugl-1 expression plasmid, pEZ-M29-Hugl1, for gene transfection. We transfected the pEZ-M29-Hugl1 plasmid into Eca109 esophageal cancer cell lines with Lipofectamine 2000 to overexpress Hugl-1. Real-time reverse transcription-polymerase chain reaction (RT-PCR) and Western blotting were performed to determine the effects of the plasmid on Hugl-1 expression. *In vitro* cell proliferation and apoptosis were examined separately by cell counting Kit-8 (CCK-8) assay, flow cytometry, and Western blotting before and after the transfection of the plasmid into Eca109 cells. Cell cycle distribution was assessed with flow cytometry. The effect of Hugl-1 overexpressing on tumor growth *in vivo* was performed with a xenograft tumor model in nude mice. Expression of Hugl-1 in xenograft tumor was analyzed by immunohistochemistry. The transferase-mediated dUTP nick end-labeling (TUNEL) technique was performed to detect and quantitate apoptotic cell.

RESULTS: The transfection efficiency was confirmed with real-time RT-PCR and Western blotting. Our results show that compared with control groups the mRNA levels and protein levels of Hugl-1 in pEZ-M29-Hugl1-treated group were remarkably increased ($P < 0.05$). The CCK-8 assay demonstrated that the growth of cells overexpressing Hugl-1 was significantly lower than control cells. Cell cycle distribution showed there was a G_0/G_1 cell cycle arrest in cells overexpressing Hugl-1 (64.09% ± 3.14% *vs* 50.32% ± 4.60%, 64.09% ± 3.14% *vs* 49.13% ± 2.24%). Annexin V-fluorescein isothiocyanate revealed that apoptosis was significantly increased in cells overexpressing Hugl-1 compared with control group (17.33% ± 4.76% *vs* 6.90% ± 1.61%, 17.33% ± 4.76% *vs* 6.27% ± 0.38%). Moreover, we found that Hugl-1 changes the level of the anti-apoptotic protein Bcl-2 and the pro-apoptotic protein Bax and the activation of both caspase-3 and caspase-9. With a TUNEL assay, we found that Hugl-1 markedly increased the apoptosis rate of Eca109 cells *in vivo* (60.50% ± 9.11% *vs* 25.00% ± 12.25%). It was shown that Hugl-1 represents a significantly more effective tumor suppressor gene alone in a xenograft tumor mouse model. This data suggest that Hugl-1 inhibited tumor growth and induced cell apoptosis *in vivo*.

CONCLUSION: These results suggest that Hugl-1 induces growth suppression and apoptosis in a human esophageal squamous cell carcinoma cell line both *in vitro* and *in vivo*.

Key words: Esophageal squamous cell carcinoma; Human giant larvae homolog 1; Proliferation; Apoptosis

Core tip: In this paper, we constructed a plasmid to express Hugl-1 which has significant homology to the Drosophila tumor suppressor gene lethal giant larvae. The human esophageal squamous cell carcinoma cell line Eca109 was used as the object of study. We found a positive correlation between Hugl-1 expression and cell apoptosis in Eca109 cells both *in vitro* and *in vivo*. These data suggest that Hugl-1 is a tumor suppressor gene in esophageal cancer and may provide a novel target for the treatment of esophageal cancer patients.

INTRODUCTION

Esophageal cancer has two major histological types: squamous cell carcinoma (ESCC) and adenocarcinoma (EAC)[1,2]. ESCC is one of the most frequently diagnosed cancers in China[3]. It has been well established that surgical treatment can prolong the survival time of cancer patients, yet the 5-year survival rate for ESCC after surgery is still low (ranging 14%-22%)[4]. Most esophageal cancers are diagnosed in the advanced stages[5]. Thus, detecting gene alternations that promote the carcinogenesis process leading to esophageal cancer will have a profound impact on the diagnosis and treatment of the disease.

Lethal giant larvae (lgl), an evolutionarily conserved and widely expressed cytoskeletal protein, is indispensable for the establishment and maintenance of cell polarity and is a regulator of cell proliferation[6,7]. In Drosophila, mutations in three neoplastic tumor suppressor genes, discs large (dlg), scribble (scrib) and lgl, have revealed a link between the regulation of cell polarity and cell proliferation[8-13]. The human homologs of lgl are Hugl-1 (Llgl1) and Llgl2. The Hugl-1 protein shares 62.5% similarity with Lgl[14]. Several studies have shown that Hugl-1 transcripts are reduced or absent in a high proportion of breast cancers, lung cancers, prostate cancers, ovarian cancers, colorectal cancers, melanomas, endometrial cancers and hepatocellular carcinomas[15-19]. These studies have also shown that Hugl-1 may function as a tumor suppressor gene in various cancer types. In ESCC tissue samples, Hugl-1 is notably lower than in normal tissues[20]; however, the effect of Hugl-1 on tumor progression and prognosis in ESCC is not clear.

In the present study, we analyzed Hugl-1 expression in the esophageal carcinoma cell line Eca109 as well as in tissue samples. By using a forced overexpression technique, we explored the biological activity of Hugl-1 and the underlying mechanism *in vitro* and *in vivo*. We demonstrated that Hugl-1 inhibits proliferation in the esophageal carcinoma cell line as well as in ESCC tissue samples and that it promotes apoptosis in esophageal carcinoma cells and xenograft tumors through a mitochondria-related pathway.

MATERIALS AND METHODS

Cells, cell culture

The human ESCC cell line, Eca109, purchased from the China Center for Type Culture Collection (Wuhan Province, China) and cultured in RPMI-1640 medium (Gibco, United States) containing 10% fetal bovine serum (Gibco, United States), in a humidified atmosphere of 5% CO_2 at 37 ℃.

Plasmid construction and purification of cultured Eca109 cells

Hugl-1 expression plasmids were constructed with pEZ-M29 as the vector, Hugl-1 as the expression gene and ampicillin resistance for antibiotic selection (GeneCopoeia, United States). An empty expression plasmid of the same type was used as a control. Eca109 cells were seeded into a 6 cm dish at a density of 5×10^5 cells per well and incubated overnight with 5% CO_2 at 37 ℃. For each transfection, 9 μL of lipofectamine 2000 (Invitrogen, United States) and 3 μg of the Hugl-1 expression plasmid were added to 1 mL of Opti-MEM (Invitrogen, United States) and incubated for 5 min at room temperature. The diluted plasmid and lipofectamine were mixed together and incubated for 30 min before adding them directly to the cells. Eca109 cells overexpressing Hugl-1 were grown in RPMI-1640 medium with 200 μg/mL of G418 for stable clone selection.

Real-time RT-PCR

Total RNA was prepared from the Eca109 cells with TRIzol reagent (Invitrogen, United States) according to the manufacturer's protocol. First-strand cDNA was synthesized using the PrimeScript™ RT reagent kit (Takara, Japan). The isolated RNA (1 μg) was used as template to perform one-step RT-PCR according to the protocol, and glyceraldehyde 3-phosphate dehydrogenase (GAPDH) was used as an internal control. All reactions were conducted in a 25 μL volume.

Real-time RT-PCR was conducted on the resulting cDNA with the SYBR Green method and the AB7500 Real-time RT-PCR system. The sequences of the primer sets used were as follows: forward 5'-AGAAGGCTGGGGCTCATTTG-3' and reverse 5'-AGGGGCCATCCACAGTCTTC-3' for GAPDH (258 bp); forward 5'-GCTGCTTCGATCCCTACAGTGAC-3' and reverse 5'-CGGCACATCCTAAGCTCCAG-3' for Hugl-1 (131 bp). PCR was performed by initial denaturation at 95 ℃ for 30 s followed by 40 cycles of 5 s at 95 ℃, 30 s at 60 ℃ and 1 min at 72 ℃. The threshold cycle (Ct) values of each sample were used in the $2^{-\Delta\Delta CT}$ data analysis method.

Western blotting

Cells were harvested from 6-well culture plates, and

aliquots of cell extracts were separated on an 8%-12% SDS-polyacrylamide gel. The proteins were then transferred to a polyvinylidene difluoride membrane (Millipore, United States) and incubated overnight at 4 ℃ with the following rabbit polyclonal antibodies: anti-Hugl1 (ab39292, Abcam), anti-Bcl2 (SC-492, Santa Cruzc), anti-Bax (5023, Cell Signaling), anti-p21 (2947, Cell Signaling), anti-cyclin D1 (2978, Cell Signaling), anti-survivin (2808, Cell Signaling), anti-caspase9 (9502, Cell Signaling), anti-caspase3 (9662, Cell Signaling), anti-p65 (3037, Cell Signaling), anti-p-p65 (3033, Cell Signaling) or anti-GAPDH (2118, Cell Signaling).

The blots were rinsed three times in TBST and incubated with a 1:10000 diluted goat-anti-rabbit secondary antibody (LICOR, United States) conjugated to horseradish peroxidase for 1 h at room temperature before they were washed extensively with TBST. Finally, the membranes were scanned with a two-color infrared imaging system (Odyssey, LICOR, United States). Membranes were also probed for GAPDH as an additional loading control.

Cell proliferation analysis

Cells were seeded into 96-well plates at a density of 3000 cells per well 48 h after transfection. The effects of let-7a on cell proliferation were examined with CCK-8 (Dojindo, Japan) according to the manufacturer's instruction 0, 24, 48, 72 and 96 h after seeding.

Cell cycle analysis

Cell cycle analysis was performed with flow cytometry (BD FACS Aria Ⅲ, United States). Cultured cells were harvested 48 h after transfection with pEZ-M29-eGFP and pEZ-M29-Hugl1, respectively, washed with ice-cold phosphate buffered solution (PBS), and fixed in 70% ethanol overnight at 4 ℃. After centrifugation at 500 × *g* for 5 min at 4 ℃, the cell pellets were stained with 10 μg/mL propidium iodide (PI) and 10 μg/mL RNase A in phosphate buffered saline (PBS) buffer for 20 min at room temperature in the dark. Cell cycle analysis was performed with three independent experiments.

Flow cytometric analysis of apoptotic cells using Annexin V-fluorescein isothiocyanate kit

The cultured cells were harvested after treatment with pEZ-M29-eGFP and pEZ-M29-Hugl1, respectively, washed with ice-cold PBS and centrifuged for 5 min at 500 × *g* at 4 ℃. The supernatants were discarded, and the cell pellets were resuspended in ice-cold binding buffer. Double staining with Annexin V-fluorescein isothiocyanate (FITC) and PI was performed using the Annexin V-FITC kit (Beyotime, China) according to the manufacturer's recommendations, and the cells were then analyzed by FACS (BD FACS Aria Ⅲ, United States).

Nude mice xenograft experiments

BALB/c nude mice (5-6 week old) were obtained from the Beijing HFK Experimental Animal Center and were quarantined for one week before tumor implantation. Animal welfare and experimental procedures were performed in strict accordance with guidelines. Mice were randomly divided into two groups (six mice per group). A xenograft tumor model was established by subcutaneously injecting either Hugl1-overexpressing cells or PBS-treated cells (2×10^6) suspended in 0.1 mL of PBS into the right flank of mice, and the tumor volume was measured every week until the mice were sacrificed. At the end of the experiment (day 21), tumors were harvested for additional analyses. Differences in tumor growth were tested for statistical significance.

Immunohistochemistry analysis

The xenograft tumors were embedded in paraffin, cut into 4 μm sections, and either stained with hematoxylin and eosin or treated with Hugl-1 antibody for immunohistochemical evaluation. The results were captured by microscopy (Olympus, Japan).

Transferase-mediated dUTP nick end-labeling assay

The transferase-mediated dUTP nick end-labeling (TUNEL) technique was performed to detect and quantitate apoptotic cell death using the in situ Cell Death Detection Kit (Roche, United States) according to the manufacturer's instructions. Chamber slides were fixed with 4% paraformaldehyde and permeabilized in 0.1% Triton X-100. The slides were then incubated with the TUNEL reaction mixture for 1 h at 37 ℃. After the slides were washed with PBS, they were incubated with peroxidase-conjugated antibody for 30 min at 37 ℃ and were developed with the DAB system. A minimum of 3 fields were randomly selected, and the total cells were counted in each field to achieve a minimum number of 100 total cells. Apoptotic rates (the number of apoptotic cells/total cells) were expressed as mean ± SD from different fields.

Statistical analysis

The statistical analysis was performed using SPSS software (version 17.0 for Windows). Data were presented as means ± SD and comparisons were made using Student's *t* test. A probability of 0.05 or less was considered statistically significant.

RESULTS

Overexpression of Hugl-1 in vitro

The eGFP was used as an marker to detect whether the pEZ-M29-Hugl1 plasmid vectors were successfully transduced *in vitro*. The transfection efficiency is shown in Figure 1A, *in vitro* approach to 60%.

To analyze the effect of pEZ-M29-Hugl1 on the expression of cancer genes, we assessed the mRNA levels of Hugl-1 in the treated cells by Real-time RT-PCR. Our results demonstrated that, compared with group 1 (PBS-

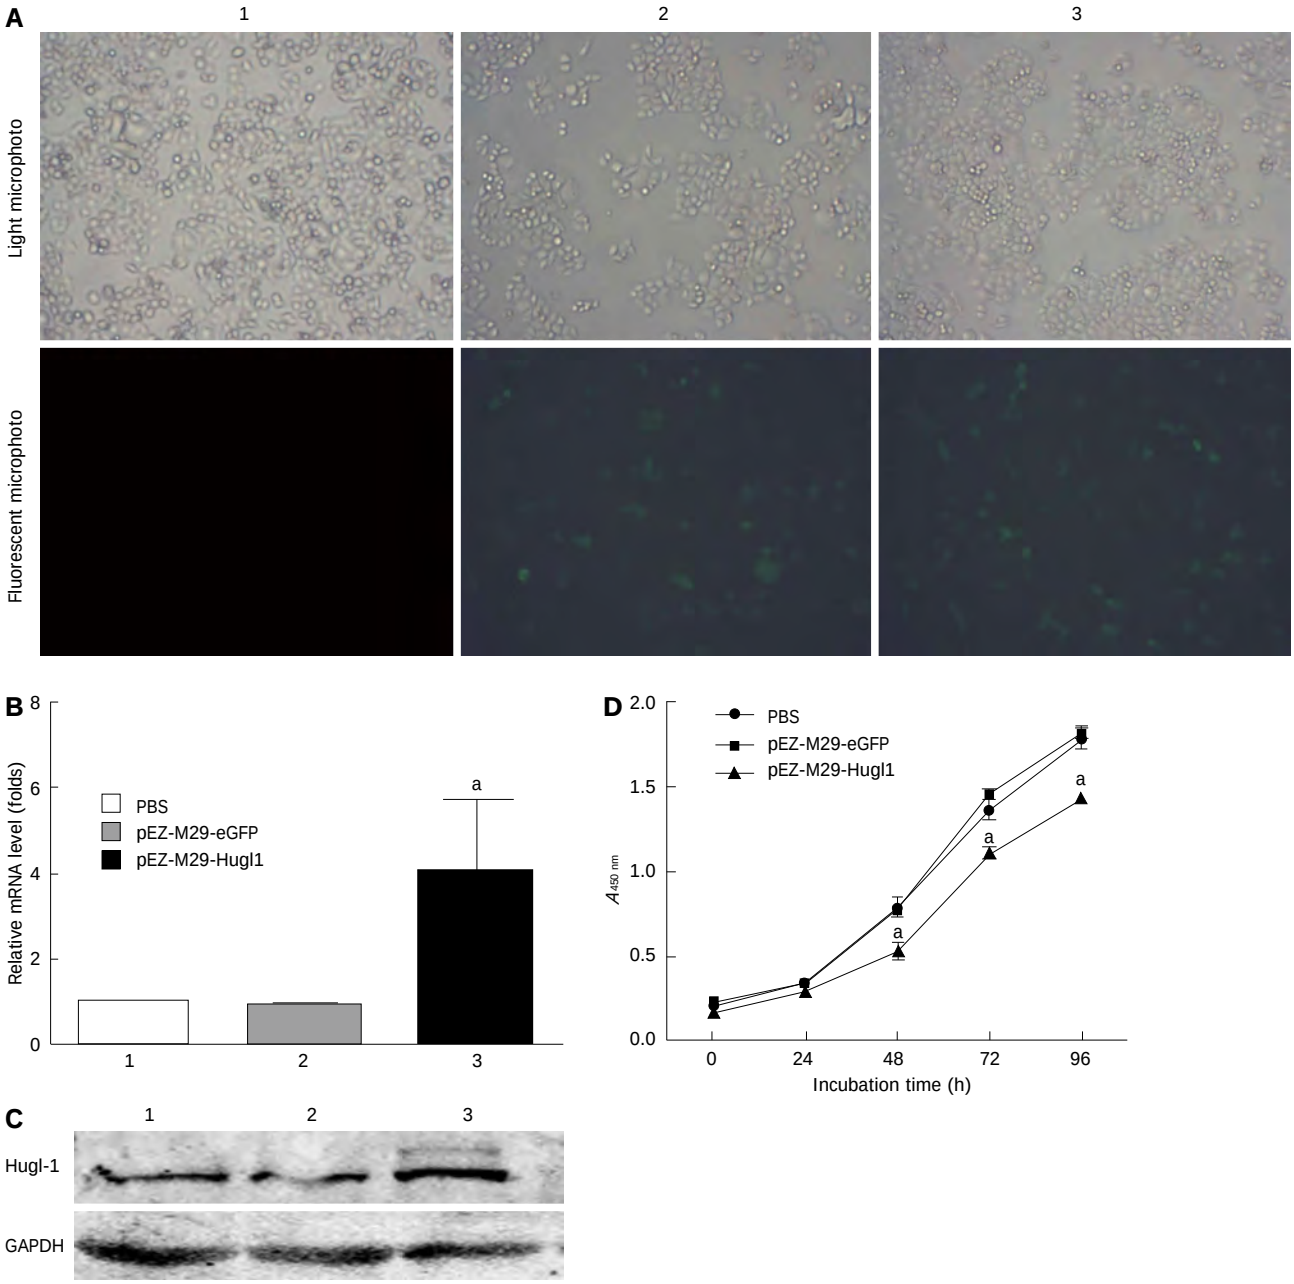

Figure 1 Transfection with pEZ-M29-Hugl1 increased Hugl-1 expression and inhibited the proliferation in Eca109 cells. A: Fluorescent expression in Eca109 cells (× 200); B: Real-time reverse transcription-polymerase chain reaction data of Hugl-1 mRNA levels following transfection with pEZ-M29-Hugl1 plasmids (group 3), pEZ-M29-eGFP (group 2), or treatment with phosphate buffered saline (PBS) (group 1); C: Western blotting data showing Hugl-1 protein expression levels following pEZ-M29-Hugl1 transfection compared with control groups; D: The effect of Hugl-1 on cell proliferation was assessed by cell counting Kit-8. Results represent mean values of three experiments and are indicated as mean ± SD. $^{a}P < 0.05$ *vs* the pEZ-M29-eGFP-treated and PBS-treated groups. GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

treated), the mRNA levels of Hugl-1 in group 3 (pEZ-M29-Hugl1-treated) were remarkably increased ($P < 0.05$), but the mRNA levels in group 2 (pEZ-M29-eGFP-treated) were not noticeably different (Figure 1B).

We next assessed the expression of Hugl-1 protein by Western blotting. The expression of Hugl-1 was consistent with results from real-time RT-PCR, and compared with group 1, the protein level of group 3 was increased (Figure 1C).

Effect of Hugl-1expression on the proliferation of Eca109 cells

Cell proliferation assays were performed with the cell counting Kit 8 assay 48 h after transfection. The proliferation of Eca109 cells 48 h after being transfected with pEZ-M29-Hugl1 was slower than that of the other two control groups ($P < 0.05$). Therefore, Hugl-1 inhibited the proliferation of Eca109 cells (Figure 1D).

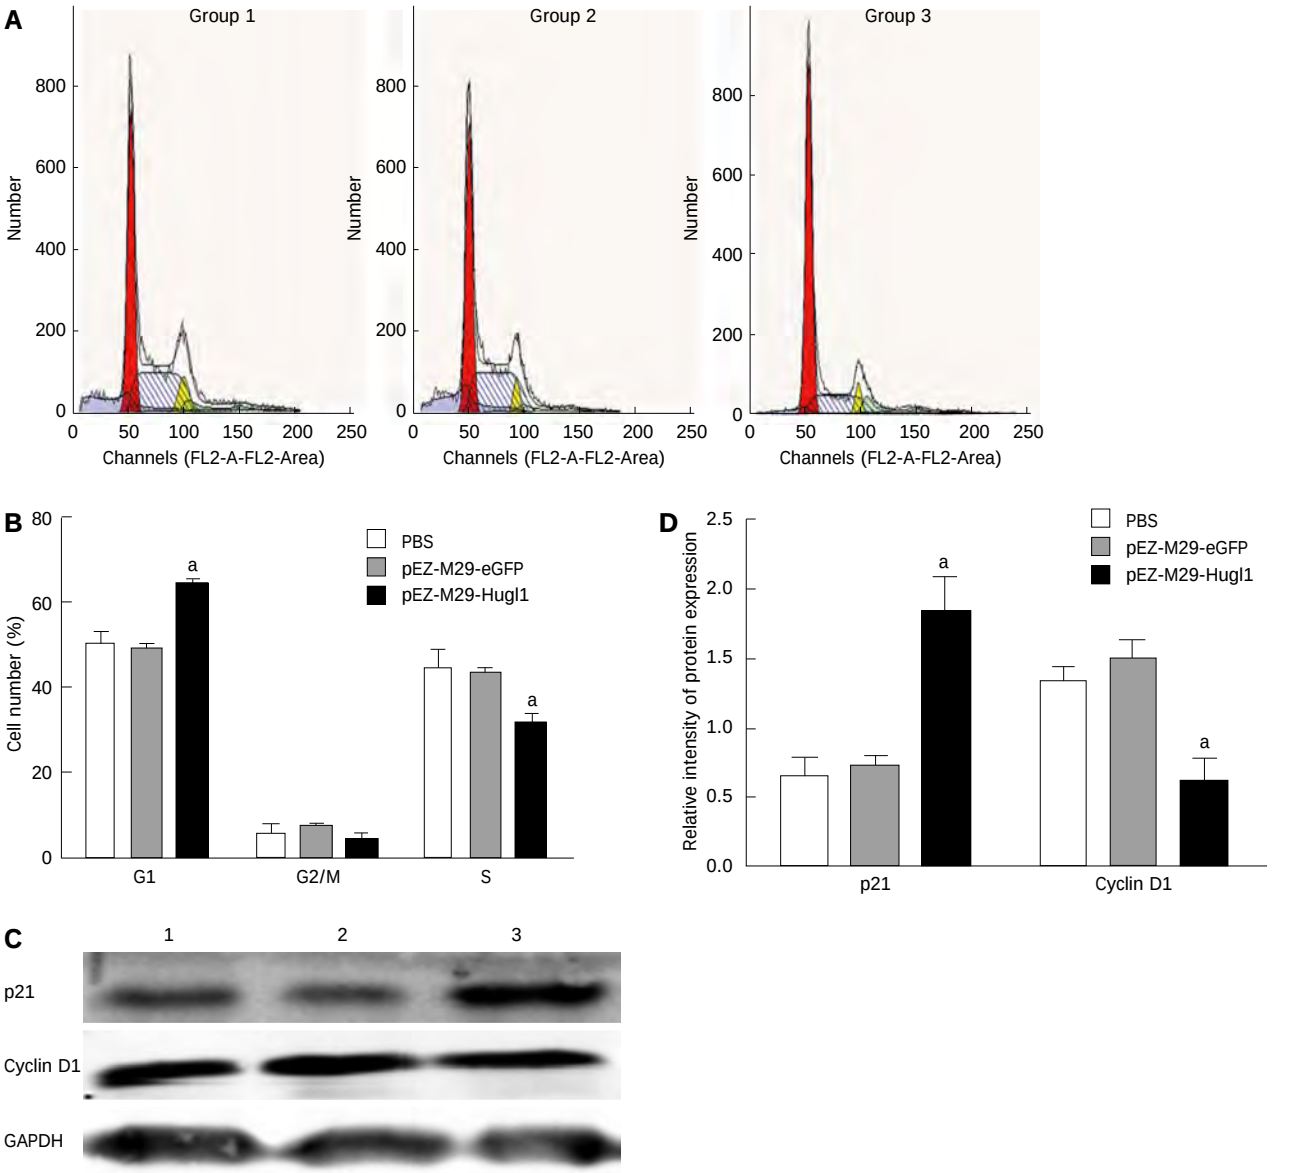

Figure 2 Effect of Hugl-1 on cell cycle distribution of Eca109 cells *in vitro*. A: Cells were treated with pEZ-M29-Hugl1, pEZ-M29-eGFP or phosphate buffered saline (PBS) for 48 h and were then prepared for fluorescence-activated cell sorting analysis; B: Data are presented as mean ± SD of three independent experiments; C: Western blotting data of p21 and cyclin D1 protein expression levels following transfection with pEZ-M29-Hugl1 or controls; D: Analysis of the expression of proteins. $^{a}P < 0.05$ *vs* the pEZ-M29-eGFP-treated and PBS-treated groups. GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

Effect of Hugl-1 protein on the cell cycle of Eca109 cells

The mechanism underlying the inhibition of cell proliferation in Eca109 cells was investigated by analyzing the cell cycle with FACS following pEZ-M29-Hugl1 transfection. It was observed that Hugl-1 overexpression arrested the cell cycle in the G_1 phase (Figure 2A). The pEZ-M29-Hugl1 transfected cells were found to contain 64.09% ± 3.14% of cells in the G_1 phase and 31.47% ± 4.90% of cells in the S phase, whereas in the PBS-treated group, 50.32% ± 4.60% of cells were in the G_1 phase and 49.30% ± 4.98% of cells were in the S phase (Figure 2B). There was no difference between the group 3 and the group 2 (49.13% ± 2.24% in the G_1 phase and 43.47% ± 2.09% in the S phase).

Figure 2C shows that cells overexpressing Hugl-1 exhibited down-regulation of cyclin D1 and up-regulation of p21; these results suggest that the G_0/G_1 cell cycle arrest induced by Hugl-1 involved a reduced level of cyclin D1 and an increased level of p21. The protein levels of p21 was upregulated (1.83 ± 0.25 *vs* 0.64 ± 0.14, 1.83 ± 0.25 *vs* 0.72 ± 0.08, $P < 0.05$) and cyclin D1 was down-regulated (0.61 ± 0.18 *vs* 1.33 ± 0.12, 0.61 ± 0.18 *vs* 1.48 ± 0.15, $P < 0.05$) in the pEZ-M29-Hugl1 transfected cells (Figure 2D).

Effect of Hugl-1 protein on Eca109 cell apoptosis

After transfection, cells were incubated with Annexin V-FITC in a buffer containing PI and were then analyzed by flow cytometry (Figure 3A). The results show that group 3 had a higher apoptosis rate (17.33% ± 4.76%)

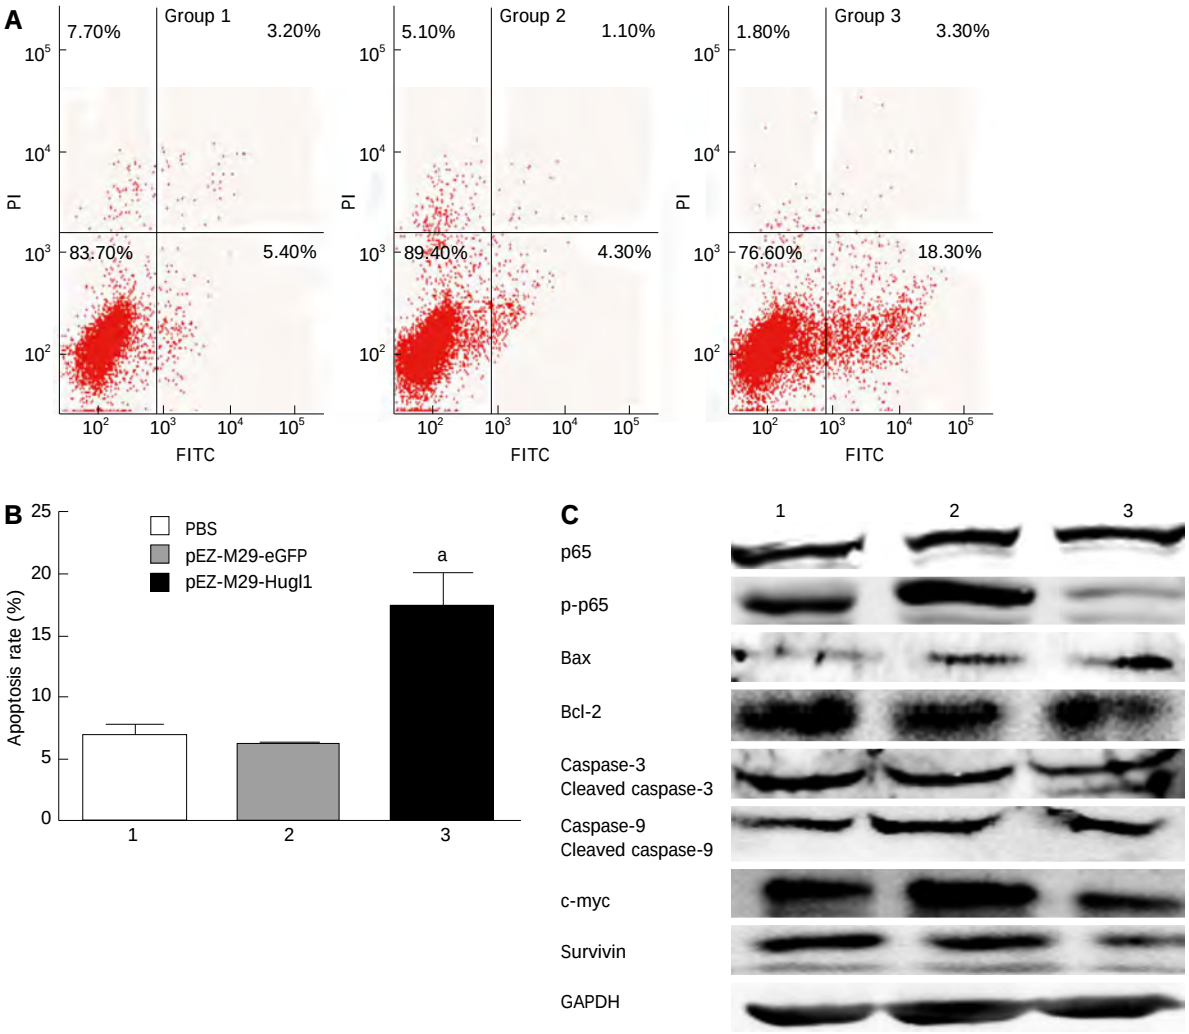

Figure 3 Effect of Hugl-1 on apoptosis of Eca109 cells *in vitro*. A: Cells were treated for 48 h and were then processed for FACS by staining with Annexin V-fluorescein isothiocyanate (FITC) and propidium iodide (PI); B: After transfection with pEZ-M29-Hugl1, a significant number of cells were in an early state of apoptosis, and a population of cells had progressed to a later stage of apoptosis; C: Up-regulation of Hugl-1 led to a change of the protein levels of p65, p-p65, Bax, Bcl-2, caspase-3 and -9, survivin and c-myc among the three cell lines. All experiments were performed three times independently. $^{a}P < 0.05$ *vs* the pEZ-M29-eGFP-treated and phosphate buffered solution (PBS)-treated groups. GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

compared with group 1 (6.90% ± 1.61%) ($P < 0.05$), and as we expected, no difference was observed between the apoptosis rates of group 1 and group 2 (6.27% ± 0.38%) ($P > 0.05$) (Figure 3B).

To identify the mechanisms that were affected by Hugl-1 expression, Eca109 cells expressing Hugl-1 were analyzed by Western blotting for changes in the levels of various cell-signaling proteins. Figure 3C shows that phospho-p65 was essentially absent in Hugl-1-overexpressing cells, but the total p65 level decreased only slightly. These results suggest that Hugl-1 down-regulated the nuclear factor kappa B (NF-κB) signaling pathway through inhibition of IKKα/β and p65 phosphorylation.

To establish that Hugl-1 induced apoptosis, we examined the activation of the classical caspases and the Bcl-2 family of proteins by Western blotting. Figure 3C shows that Hugl-1 up-regulated the expression of Bax, of cleaved caspase-3, and of cleaved caspase-9, and it down-regulated Bcl-2, survivin, and c-myc expression. These results suggest that Hugl-1 induced apoptosis in Eca109 cells through activation of the mitochondrial apoptotic pathway.

Effect of Hugl-1 expression on xenograft tumor growth

To study the effect of Hugl-1 on tumor growth, nude mice were inoculated with Hugl-1-overexpressing cells, and the resulting tumor growth was compared to that in a control group of mice injected with PBS-treated cells. The difference in tumor growth between the two groups of mice was statistically significant at $P < 0.05$. In the control group, tumors displayed rapid and continued outgrowth during the course of the experiment, and the mean tumor volume was 1126.56 ± 141.70 mm^3. In contrast, the mean tumor size for the experimental group was 606.03 ± 22.49 mm^3 (Figure 4A).

Hematoxylin and eosin staining revealed a significant level of cell death in tumor tissues treated with the pEZ-M29-Hugl1 plasmid compared to the control group (Fig-

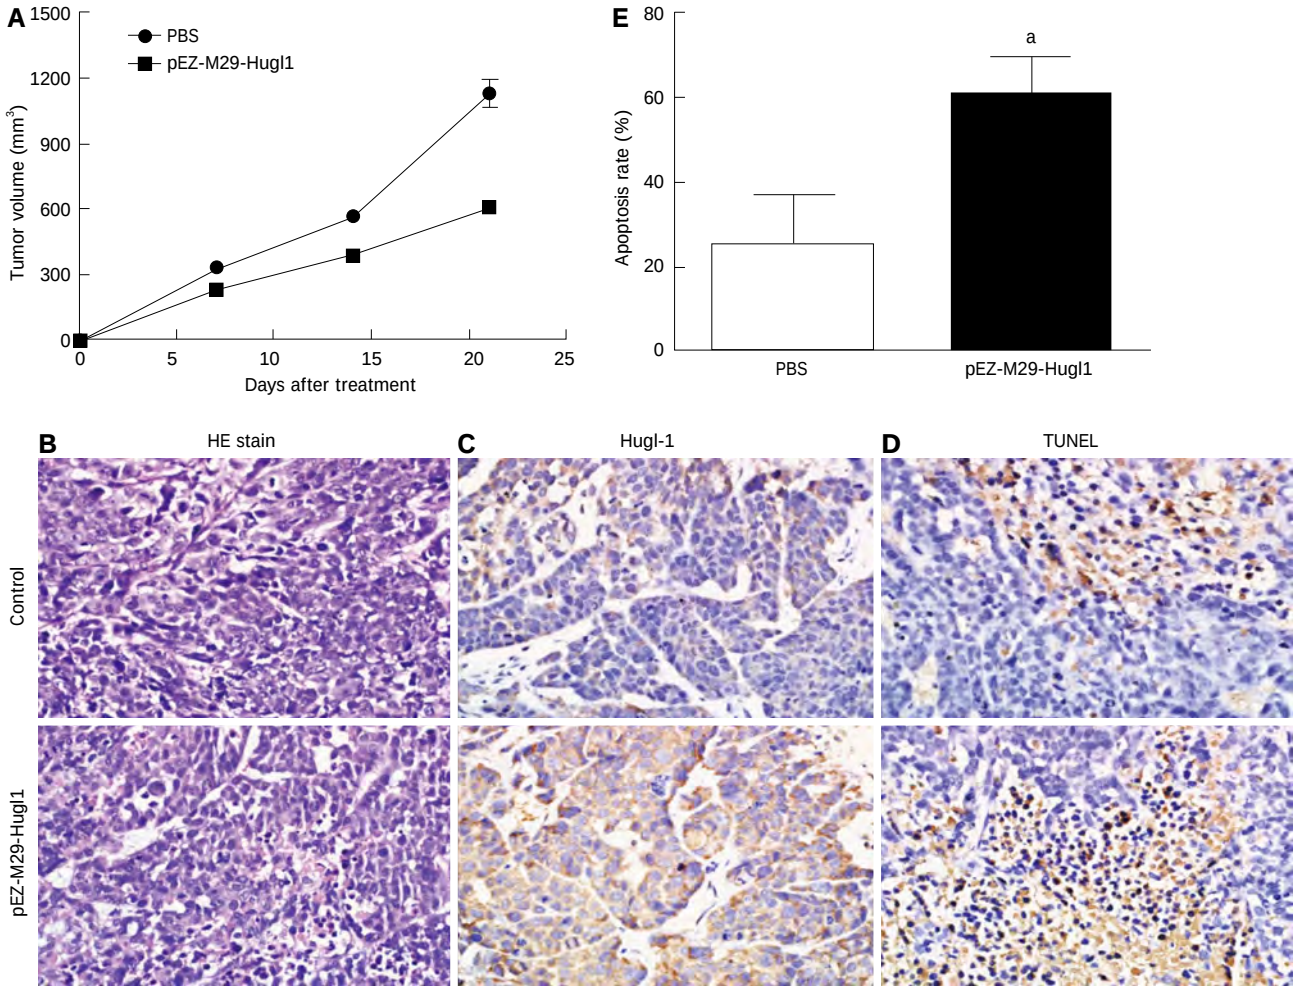

Figure 4 Effect of Hugl-1 on xenograft tumor *in vivo*. A: Cells were injected subcutaneously into nude mice, and with one group of mice receiving pEZ-M29-Hugl1-treated cells and another receiving phosphate buffered saline (PBS). Tumor volume was measured at 7-d intervals for 21 d; B: Tumor sections were observed by hematoxylin and eosin (HE) staining (× 400); C: Expression of Hugl-1 in tumor tissues was analyzed by immunohistochemistry. Many cells were strongly positive for Hugl-1 in the pEZ-M29-Hugl1-treated tumor sections (× 400); D: Representative photomicrographs showing transferase-mediated dUTP nick end-labeling (TUNEL) staining for evidence of apoptosis in transplantation tumors undergoing various treatments (× 400); E: Quantitative analysis of apoptotic cells in tumors treated with PBS or pEZ-M29-Hugl1. Apoptotic cells, shown by TUNEL, were significantly increased in tumors treated with pEZ-M29-Hugl1. Data are presented as mean ± SD (× 400). $^{a}P < 0.05$ *vs* the pEZ-M29-eGFP-treated and PBS-treated groups.

ure 4B). As shown in Figure 4C, many cells were strongly positive for Hugl-1 in the pEZ-M29-Hugl1-treated tumor sections. Apoptotic cells in the tumor sections were analyzed by TUNEL staining (Figure 4D), which showed markedly more positive cells in the pEZ-M29-Hugl1-treated group (60.50% ± 9.11%) than in the PBS-treated group (25.00% ± 12.25%) (Figure 4E).

DISCUSSION

The oncogenesis of esophageal cancer involves accumulated alternations of oncogenes, tumor suppresser genes and other epigenetic regulations[21,22]. Hugl-1 gene is one of the tumor suppresser genes involved in tumor cell proliferation. In this study, we reported that Hugl-1 was a potent anticancer gene for Eca109 cells through inducing G_0/G_1 cell cycle arrest and apoptosis. We concluded that up-regulation of Hugl-1 suppressed esophageal cancer cell proliferation by CCK-8 assay. Flow cytometry showed that overexpression of Hugl-1 reduced the number of cells in S-phase while increasing the number of cells in G_0/G_1-phase, indicating a G_0/G_1 arrest. To understand the mechanism by which Hugl-1 induces esophageal cancer apoptosis, we analyzed the expression of p65, p-p65, Bcl-2, Bax, survivin, c-myc, cyclin D1, p21, and caspase-3 and -9 between cells transfected with the Hugl-1-expressing plasmid and those transfected with the control plasmid. Immunoblotting analysis revealed that Hugl-1 overexpression significantly decreased the expression of p-p65, cyclin D1, Bcl-2, survivin, and c-myc and that it increased the expression of p21 and Bax. In addition, Hugl-1 significantly increased the expression and activity of caspase-3 and caspase-9. More importantly, Hugl-1 potently suppressed the growth of Eca109 cells xenografted in nude mice by inducing cell apoptosis.

Cell cycle arrest and apoptosis are two main ways by which cell growth can be inhibited. In higher eukaryotes, multiple cyclin-dependent kinases associate with multiple cyclins to regulate cell cycle progression[23,24]. Cyclin D1, a member of the G_1 cyclins, controls the cell cycle tran-

sit from G_1 to S phase[25]. The activities of CDKs and CDK/cyclin complexes are known to be regulated by the CIP/KIP family member p21[26]. P21 is, in turn, under transcriptional control of the tumor suppressor p53 and is required for p53-dependent cell cycle arrest[27]. In this study, we found that up-regulation of Hugl-1 in Eca109 cells resulted in a G_0/G_1 cell cycle arrest that was accompanied by down-regulation of cyclin D1 and up-regulation of p21. These data suggest that the mechanism of Hugl-1-induced cell cycle arrest involves down-regulation of cyclin D1 and up-regulation of the CDK inhibitor p21, causing inhibition of CDK activity.

Furthermore, the increase in Hugl-1 expression induced down-regulation of the anti-apoptotic gene Bcl-2 and up-regulation of the pro-apoptotic gene Bax. The central cast of players in the mitochondrial pathway of programmed cell death is the extended Bcl-2 family of proteins[28,29]. Therefore, the balance between the levels of Bcl-2 and Bax is critical in determining the fate of cells in terms of survival or death[30]. Homo-oligomerization of Bax leads to permeabilization of the mitochondrial membrane and subsequent release of cytochrome C to activate apoptosis[31]. Bcl-2 interacts with Bax, preventing its homo-oligomerization and, ultimately, apoptosis[31]. In this case, we found that Hugl-1 induced apoptosis in Eca109 cells, as evidenced by the increase in Annexin V-positive cells, the reduced cell proliferation, and the changes in caspase activation. Currently, there are two known pathways that activate the apoptotic caspase cascade, the intrinsic (mitochondrial) and extrinsic pathways[32]. Our results disclosed that the caspase-9-regulated intrinsic pathway was involved in Hugl-1-induced cell apoptosis. In Hugl-1-treated cells, we observed an increase in the cleaved caspases-9 and caspases-3. These results suggest that Hugl-1 induces apoptosis in Eca109 cells through activation of the mitochondrial pathway.

Considerable evidence indicates that NF-κB is constitutively active in esophageal cancer and that its activation is correlated with tumor progression[33]. The relationship between the NF-κB signaling pathway and tumor cell apoptosis has been extensively studied[34]. It has been presumed that the NF-κB pathway was involved in suppressing apoptosis[35]. The NF-κB family is composed of homodimers and heterodimers of the Rel family of proteins, including p65 (RelA), c-Rel, RelB, p52 and p50[36]. The most abundant form of NF-κB is a heterodimer with two subunits: p50 and p65. Our study showed that phospho-p65 was essentially absent in Hugl-1-overexpressing cells, but the total level of p65 was only slightly reduced. It has been suggested that Hugl-1 down-regulates the NF-κB signaling pathway through inhibition of the IKKα/β and p65 phosphorylation.

In addition, in the nude mice xenografted with Eca109 cells, we found that up-regulation of Hugl-1 reduced tumor growth (606.03 ± 22.49 mm^3 *vs* 1126.56 ± 141.70 mm^3). With a TUNEL assay, we found that Hugl-1 markedly increased the apoptosis rate of Eca109 cells *in vivo* (60.50% ± 9.11% *vs* 25.00% ± 12.25%). Thus, our results indicate that Hugl-1 may be a tumor suppressor of esophageal cancer.

In summary, our study has demonstrated that Hugl-1 exerts tumor suppressor effects by inducing growth suppression and apoptosis both *in vitro* and *in vivo*. G_0/G_1 cell cycle arrest induced by Hugl-1 occurs through a pathway that is mediated by p53-dependent p21 and cyclin D1 and that apoptosis induced by Hugl-1 occurs through the mitochondria pathway. The data presented here also indicate that Hugl-1 interferes with cell proliferation by affecting the NF-κB signaling pathway. The observations that Hugl-1 expression led to the loss of activated IKKα/β and p65 suggest that Hugl-1 is a negative regulator of NF-κB signaling. More importantly, Hugl-1 induced growth suppression and apoptosis in a human esophageal carcinoma cell line *in vivo*. Taken together, we show that Hugl-1 induces growth suppression and apoptosis in a human esophageal squamous cell carcinoma cell line both *in vitro* and *in vivo*. These data suggest that Hugl-1 may provide a novel target for treatment of esophageal cancer patients.

COMMENTS

Background

Esophageal squamous cell carcinoma (ESCC) is one of the most frequently diagnosed cancers in China. Most esophageal cancers are diagnosed in the advanced stages. Thus, detecting gene alternations that promote the carcinogenesis process leading to esophageal cancer will have a profound impact on the diagnosis and treatment of the disease. The human homologs of lethal giant larvae (lgl) are Hugl-1 (Llgl1) and Llgl2. The Hugl-1 protein shares 62.5% similarity with lgl. Several studies have shown that Hugl-1 transcripts are reduced or absent in a high proportion of breast cancers, lung cancers, prostate cancers, ovarian cancers, colorectal cancers and hepatocellular carcinomas. However, the effect of Hugl-1 on tumor progression and prognosis in ESCC is not clear. The authors aimed to determine whether the Hugl-1 exerts tumor suppressor effects in esophageal cancer.

Research frontiers

Targeted molecular therapy is a new effective treatment for cancer including esophageal cancer. Hugl-1 is a potential tumor suppressor in several cancers, but the role of Hugl-1 remains controversial and its exact role in ESCC remains unknown.

Innovations and breakthroughs

Authors constructed a Hugl-1 expression plasmid, pEZ-M29-Hugl1, for gene transfection. Authors transfected the pEZ-M29-Hugl1 plasmid into Eca109 esophageal cancer cell lines to overexpress Hugl-1. The results showed that overexpression of Hugl-1 could inhibit the growth of Eca109 cells and promote cell apoptosis, and modulate the expression of Bcl-2, Bax, caspase-3, caspase-9, *etc.* Hugl-1 may serve as a potential therapeutic target in ESCC. It suggested that Hugl-1 is a tumor suppressor and interact with the mitochondrial pathway in ESCC.

Applications

The results showed that Hugl-1 is a tumor suppressor and interact with the mitochondrial pathway in ESCC. It may contribute to the future research of ESCC and be a promising target for therapeutic intervention in ESCC.

Terminology

Lethal giant larvae homolog 1 (Human): This gene encodes a protein that is similar to a tumor suppressor in Drosophila.

Peer review

The function of Hugl-1 as a tumor suppressor has been studied in other cancers, but not in ESCC. Thus authors examined the effects of Hugl-1 up-regulation on cell growth and apoptosis in the ESCC cell line Eca109 and determined the conclusion. This conclusion is meaningful in the sense characterized the function of Hugl-1 in ESCC cells.

Abstract

AIM: To investigate the effects of rhein on intestinal epithelial tight junction proteins in rats with IgA nephropathy (IgAN).

METHODS: Twenty-eight female Sprague-Dawley rats were randomly divided into four groups (7 per group): Control, IgAN, Rhein-treated, and Rhein-prevented. Bovine serum albumin, lipopolysaccharide and CCl_4 were used to establish the rat model of IgA nephropathy. The Rhein-treated group was given rhein from week 7 until the rats were sacrificed. The Rhein-prevented group was given rhein from week 1. Animals were sacrificed at the end of week 10. We observed the changes in the intestinal epithelial tight junctions using transmission electron microscopy, and expression of intestinal epithelial tight junction proteins zona occludens protein (ZO)-1 and occludin by immunofluorescence using laser confocal microscopy. Changes in mRNA and protein expression of ZO-1 and occludin were measured by reverse transcriptase polymerase chain reaction and Western blotting. The ratio of urinary lactulose/mannitol was measured by high performance liquid chromatography (*HPLC*) for assessing the intestinal permeability.

RESULTS: In the control group, the tight junctions lied between epithelial cells on the top of the outer side of the cell membrane, and appeared in dense dotted crystal structures, the neighboring cells were binded tightly with no significant gap, and the tight junction protein ZO-1 and occludin were evenly distributed in the intestinal epithelial cells at the top of the junction. Compared with the control group, in the IgAN group, the structure of the tight junction became obscured and the dotted crystal structures had disappeared; the fluorescence of ZO-1 and occludin was uneven and weaker (5.37 ± 1.27 *vs* 10.03 ± 1.96, $P < 0.01$; 4.23 ± 0.85 *vs* 12.35 ± 4.17, $P < 0.01$); the mRNA expression of ZO-1 and occludin decreased (0.42 ± 0.19 *vs* 0.92 ± 0.24, $P < 0.01$; 0.40 ± 0.15 *vs* 0.97 ± 0.25, $P < 0.01$); protein expression of ZO-1 and occludin was decreased (0.85 ± 0.12 *vs* 1.98 ± 0.43, $P < 0.01$; 0.72 ± 0.15 *vs* 1.38 ± 0.31, $P < 0.01$); and the ratio of urinary lactulose/mannitol increased (3.55 ± 0.68 *vs* 2.72 ± 0.21, $P < 0.01$). In the Rhein-prevented and Rhein-treated groups, compared with the IgAN group, the intestinal epithelial tight junctions were repaired; fluorescence of ZO-1 and occludin was stronger (11.16 ± 3.52 and 8.81 ± 2.30 *vs* 5.37 ± 1.27, $P < 0.01$; 10.97 ± 3.40 and 9.46 ± 2.40 *vs* 4.23 ± 0.85, $P < 0.01$); mRNA of ZO-1 and occludin increased (0.81 ± 0.17 and 0.64 ± 0.16 *vs* 0.42 ± 0.19, $P < 0.01$; 0.82

± 0.22 and 0.76 ± 0.31 *vs* 0.40 ± 0.15, $P < 0.01$); protein expression of ZO-1 and occludin was increased (2.07 ± 0.41 and 1.57 ± 0.23 *vs* 0.85 ± 0.12, $P < 0.01$; 1.34 ± 0.21 and 1.15 ± 0.17 *vs* 0.72 ± 0.15, $P < 0.01$); and the ratio of urinary lactulose/mannitol decreased (2.83 ± 0.43 and 2.87 ± 0.18 *vs* 3.55 ± 0.68, $P < 0.01$).

CONCLUSION: Rhein can enhance the expression of ZO-1 and occludin, repair damaged tight junctions, and protect the intestinal barrier.

Key words: Intestine; Tight junction; Rhein; IgA nephropathy; Rat

Core tip: It has been reported that the incidence and aggravation of IgA nephropathy (IgAN) are often accompanied with intestinal mucosal damage. We speculate that various factors cause the destruction of the intestinal mucosal barrier, food proteins activate the mucosal immune system, and a large amount of secretory IgA is deposited in kidney and causes IgAN. Rhubarb has a protective effect on the intestine. Rhein is isolated from rhubarb and we speculate that it also has a protective effect, although this has not been reported to date. We used various biochemical approaches to confirm this.

INTRODUCTION

IgA nephropathy (IgAN) is the most common primary glomerular disease worldwide[1]. Although the etiology and pathogenesis of IgAN are still not clear, and it lacks effective treatment, the incidence and aggravation of IgAN are often accompanied with intestinal mucosal damage[2]. We speculate that various virulence factors cause destruction of the intestinal mucosal barrier, the permeability of the intestinal mucosa increases, food proteins activate the intestinal mucosal immune system, and a large amount of secretory IgA is produced and deposited in the kidney, which causes renal damage and IgAN. We suggest that the protection of the intestinal mucosal barrier can decrease the permeability of intestinal mucosa and prevent or reduce the occurrence of IgAN.

It has been reported that rhubarb has a protective effect on the intestinal mucosal barrier[3]. Rhein (1.8-dihydroxy-3-carboxy-anthraquinone, CAS number: 478-43-3) is an anthraquinone monomer isolated from rhubarb, and we speculate that it may also have a protective effect on the intestinal mucosal barrier and delay or prevent the course of IgAN. The function of the intestinal mucosal barrier mainly depends on the integrity of the tight junction proteins in the intestinal epithelial cells. A decrease in tight junction proteins increases intestinal permeability and leads to dysfunction of the intestinal mucosal barrier[4]. As far as we are aware, a protective effect of rhein on the intestinal epithelial tight junction proteins in rats with IgAN has not yet been reported. Therefore, we used various biochemical approaches to determine how rhein regulates the expression of intestinal epithelial tight junction proteins in IgAN.

MATERIALS AND METHODS

Materials

Rhein (> 95% purity) was extracted and identified by Chengdu Mansite Pharmaceutical Co. Ltd. (batch number: MUST-11032801; China). Antibodies against occludin were purchased from Abcam (Cambridge, United Kingdom). Antibodies against zonula occludens protein (ZO)-1 were purchased from Invitrogen (Carlsbad, CA). Bovine serum albumin (BSA) was purchased from Roche (Mannheim, Germany). Lipopolysaccharide (LPS), lactulose and mannitol were purchased from Sigma (St Louis, MO). Carbon tetrachloride and castor oil were purchased from Shanghai Reagents (China). Antibodies against β-actin, horseradish-peroxidase-conjugated secondary antibodies and fluorescein isothiocyanate (FITC)-conjugated secondary antibodies were purchased from Beijing Zhongshan (China). Trizol and reverse transcriptase polymerase chain reaction (RT-PCR) kit were purchased from Transgen (Beijing, China).

Animal model

Twenty-eight female Sprague-Dawley rats weighing 180-220 g were obtained from the Animal Center of Nanchang University. They were housed in the animal facilities of the Nanchang University, with free access to food and water. Animals were treated humanely by use of protocols that were approved by the Institutional Animal Use and Care Committee of Nanchang University. Rats were divided randomly into the control group, IgAN group, Rhein-prevented group, and Rhein-treated group ($n = 7$ each). The IgAN experimental animal model was established by treatment with BSA, LPS and CCl_4[5], and specific implementation was as follows: BSA (400 mg/kg, oral every other day) for 6 wk plus LPS (0.05 mg, intravenous injection at wk 6 and 8) and CCl_4 (0.1 mL dissolved in 0.5 mL castor oil, subcutaneous injection weekly for 9 wk). The Rhein-treated group was given rhein (100 mg/kg per day)[6] from week 7 until sacrifice. The Rhein-prevented group was given rhein (100 mg/kg per day) from week 1. The control and IgAN groups were given the same volume of normal saline. All the rats were sacrificed at week 10.

Transmission electron microscopy

Seven rats per group were analyzed by transmission elec-

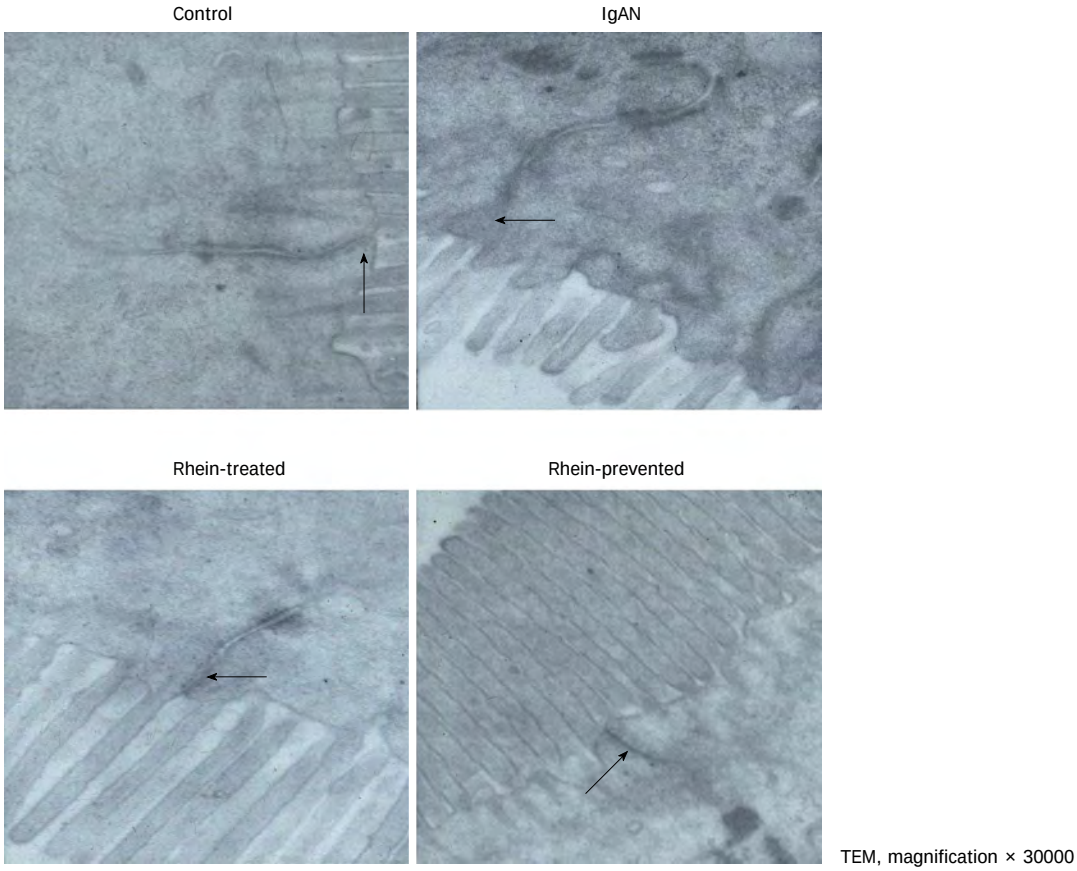

Figure 1 Electron micrograph of intestinal epithelial cells showing tight junction. A: In the control group, the tight junction appeared as an electron-dense belt at the apex of the intestinal epithelial cells (arrow), indicating an intact intestinal mucosal barrie; B: In the IgA nephropathy (IgAN) group group, the intercellular space was widened, the tight junction was indistinct, and the density was reduced (arrow); C and D: In the Rhein-treated and Rhein-prevented groups, the density of the tight junctions was increased compared with that in the IgAN group (arrows). TEM: Transmission electron microscopy.

tron microscopy (TEM) (H-600). Pieces of ileum, 2 mm × 2 mm, were fixed in 2.5% glutaraldehyde overnight at 4° C. The fixed tissues were then post-fixed in 1% osmium tetroxide for 2 h and then rinsed and stored in 0.1 mol/L sodium cacodylate buffer containing 6% sucrose for 12 h. The pieces of ileum were dehydrated through a graded acetone series and embedded in epoxy resin. Semi-thin sections (1.5 μm) were cut and stained with toluidine blue. Ultra-thin sections were stained with 4% uranyl acetate solution in 50% ethanol and lead citrate and then the intestinal epithelial tight junctions were examined by TEM.

Immunofluorescence analysis of occludin and ZO-1

Seven rats per group were analyzed by immunofluorescence. Pieces of ileum, 5 mm × 5 mm, were frozen in liquid nitrogen and 10-μm frozen sections were cut. The frozen sections were fixed with cold acetone for 10 min at 4 ℃. After extensive washing three times (5 min per wash) with cold PBS, the frozen sections were blocked with 10% normal sheep serum in PBS and then incubated with the antibodies against occludin (1:200, Abcam) and ZO-1 (1:100, Invitrogen) at 4 ℃ overnight, followed by staining with FITC-conjugated secondary antibodies. Stained frozen sections were examined with a laser confocal microscope equipped with a digital camera, identifying occludin and ZO-1 by light green color (excitation light wave length of 490 nm). Stained frozen sections were analyzed by a morphological analysis system to determine semi-quantitatively the expression of occludin and ZO-1. Five visual fields were randomly observed under high magnification, with two sections selected from each specimen. The integrated optical density of the positive material in each visual field and its area were measured by morphological analysis system; the ratio of which showed the relative content of occludin and ZO-1.

RT-PCR

Five rats per group were analyzed by RT-PCR. RT-PCR was used for mRNA detection and semi-quantitative assessment. Total RNA was extracted from the small intestine using Trizol reagent (Transgen), measured and verified with a UV spectrophotometer. cDNA was synthesized using an One-Step RT-PCR kit (Transgen) from 1 μg total RNA. Primers were designed by the Primer Premier 5.0 software (Premier Biosoft International, Palo Alto, CA) according to mRNA sequences (by GenBank) of occludin, ZO-1 and β-actin (as control). The sequences of primers were as follows: forward primer of β-actin gene was 5'-TCAGGTCATCACTATCGGCAAT-3'

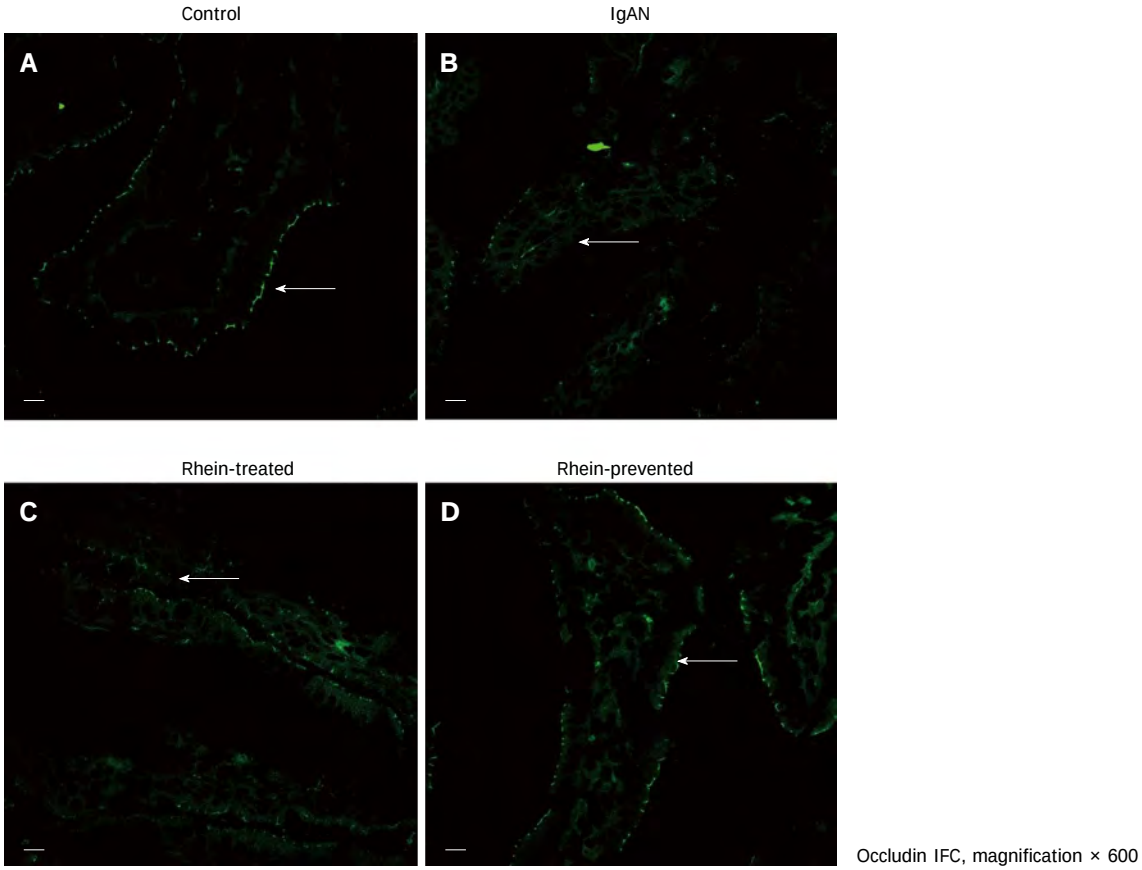

Figure 2 Location of tight junction protein occludin in rat ileum. Laser confocal microscope immunofluorescence staining of ileum from all four groups of rats. A: Cross-section of a normal intestinal villus. Immunoreactive occludin was localized at the apex of intestinal epithelial cells, consistent with the site of the intestinal mucosal barrier (arrow); B: Cross-section of an intestinal villus in the IgA nephropathy (IgAN) group. Occludin immunofluorescence staining became weak and discontinuous (arrow); C and D: Cross-section of an intestinal villus in the Rhein-treated group and cross-section of an intestinal villus in the Rhein-prevented group. Compared with the IgAN group, occludin immunofluorescence staining became stronger and continuous (arrows). Scale bars = 10 μm. IFC: Integrated fluidic circuit.

and its reverse primer was 5'-AAAGAAAGGGTGT AAAACGCA-3'. The forward primer of the occludin gene was 5'-TGCGTGGCTTCCACACTT GCT-3' and its reverse primer was 5'-TTTGCCGCTCTGGGGTCT-GT-3'. The forward primer of the ZO-1 gene was 5'-TGCCCGGCCATTTGAACGCA-3' and its reverse primer was 5'-TCAGG CGGCTGTGTGGAACT-3'. The PCR products were separated by electrophoresis on a 2% agarose gel stained with ethidium bromide to confirm that products of the expected size were detected. The electrophoretic bands were analyzed using a gel image analysis system. The results were normalized to the respective β-actin expression. RT-PCR experiments were repeated twice.

Western blotting

Five rats per group were analyzed by Western blotting. For Western blotting, the small intestines were frozen in liquid nitrogen until further use. Protein extraction was carried out using the RIPA lysate (Solarbio, Beijing, China). Protein (20-50 μg per lane) was separated by SDS-PAGE. Occludin was separated on 10% gel and ZO-1 on 8% gel. Proteins were transblotted to polyvinylidene difluoride membranes (Solarbio) in standard Tris-glycine transfer buffer, pH 8.3, containing 0.5% SDS. After transfer, membranes were blocked for 1 h at room temperature in TBST (10 mmol/L Tris-HCl, pH 8.0, 150 mmol/L NaCl, 0.2% Tween-20) containing 5% non-fat milk powder, and incubated overnight at 4 ℃ with either anti-occludin (Abcam) or anti-ZO-1 (Invitrogen) diluted 1:200 in TBST containing 1% non-fat milk powder. Membranes were then washed in TBST for 30 min, incubated with horseradish-peroxidase-conjugated goat anti-rabbit IgG, diluted 1:5000 (Beijing Zhongshan, China) in TBST, washed in TBST for 30 min, and resolved by chemiluminescence (Thermo, Waltham, MA). All membranes were stripped and reprobed with anti-β-actin antibodies (Beijing Zhongshan) as loading controls. Intensities of immunoreactive bands were quantified by densitometry, and normalized to the respective β-actin content. Western blotting experiments were repeated twice.

Measurement of intestinal permeability

Intestinal permeability was determined using two non-metabolized sugars. Three grams lactulose and 1.5 g mannitol were dissolved in 60 mL distilled water. After a fasting period of 12 h, all animals received 2 mL lactulose/mannitol solution by orogastric tube. One hour

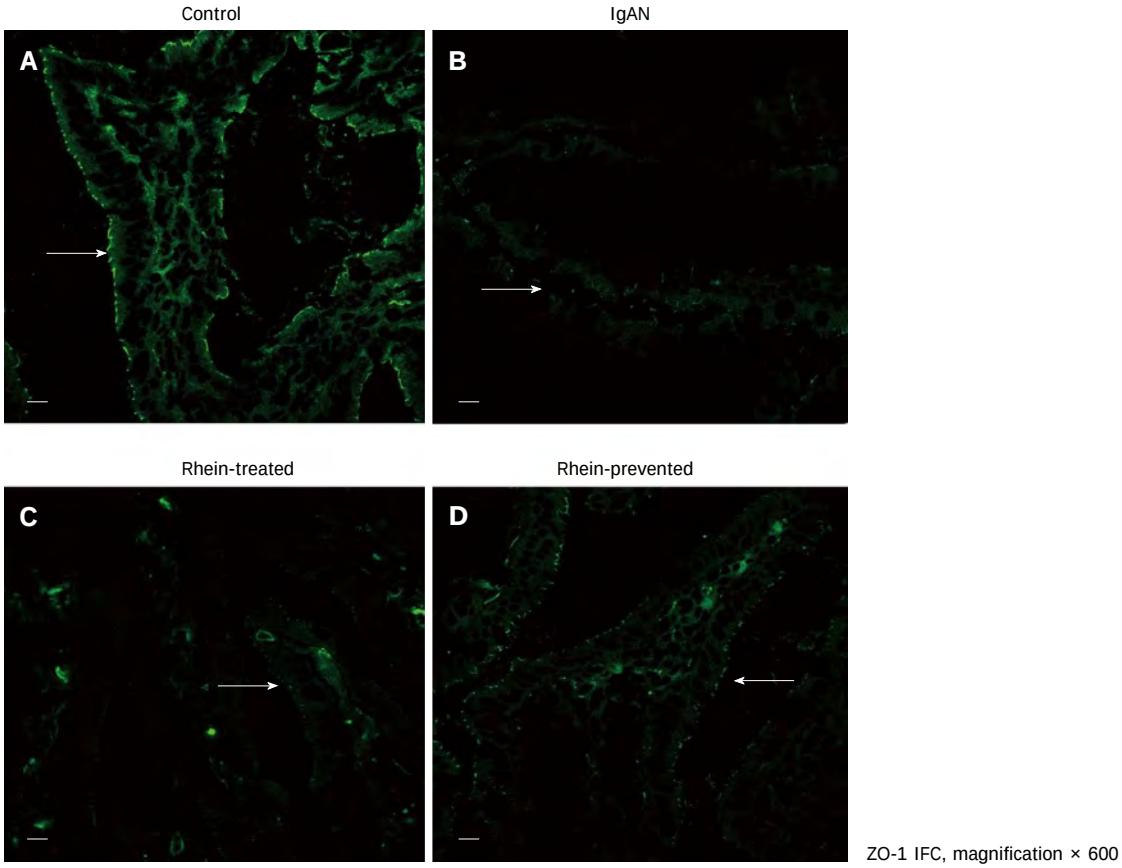

Figure 3 Location of tight junction protein zona occludens protein-1 in rat ileum. Laser confocal microscope immunofluorescence staining of ileum from all four groups of rats. A: Cross-section of a normal intestinal villus. Immunoreactive zona occludens protein (ZO)-1 was localized at the apex of intestinal epithelial cells, consistent with the site of the intestinal mucosal barrier (arrow); B: Cross-section of an intestinal villus in the IgA nephropathy (IgAN) group. ZO-1 immunofluorescence staining became weak and discontinuous (arrow); C and D: Cross-section of an intestinal villus in the Rhein-treated group and cross-section of an intestinal villus in the Rhein-prevented group. Compared with the IgAN group, ZO-1 immunofluorescence staining became stronger and continuous (arrows). Scale bars = 10 μm. IFC: Integrated fluidic circuit.

Table 1 Average optical density value of occludin and zona occludens protein-1

	Control group	IgAN group	Rhein-treated group	Rhein-prevented group
In immunofluorescence ($\times 10^{-2}$)				
Occludin	12.35 ± 4.17	4.23 ± 0.85[b]	9.46 ± 2.40[b,d]	10.97 ± 3.40[d]
ZO-1	10.03 ± 1.96	5.37 ± 1.27[b]	8.81 ± 2.30[d]	11.16 ± 3.52[d,f]
In reverse transcriptase polymerase chain reaction				
Occludin	0.97 ± 0.25	0.40 ± 0.15[b]	0.76 ± 0.31[a,d]	0.82 ± 0.22[d]
ZO-1	0.92 ± 0.24	0.42 ± 0.19[b]	0.64 ± 0.16[b,d]	0.81 ± 0.17[d,e]

The results were normalized to the respective β-actin expression. [a]$P < 0.05$, [b]$P < 0.01$ *vs* control group; [d]$P < 0.01$ *vs* IgA nephropathy (IgAN) group; [e]$P < 0.05$ *vs* Rhein-treated group; [f]$P < 0.01$ *vs* Rhein-prevented group.

after feeding, the 6-h urine was collected using metabolic cages before sacrifice. The ratio of urine concentrations of lactulose and mannitol was measured to assess the intestinal permeability.

Statistical analysis

All measurement data were expressed as mean ± SE. Statistical analysis was performed using SPSS 17.0 software. Comparison between groups was made using one-way analysis of variance followed by Student-Newman-Keuls test. $P < 0.05$ was considered to be statistically significant.

RESULTS

TEM results

ZO-1 and occludin are important components in tight junctions, so we performed a morphological analysis of the junctions (Figure 1). Tight junctions are belt-shaped and expand around the apex of epithelial cells. TEM indicated that the cell membrane was intact, and distinct junction complexes were observed in the Control Group. However, in the IgAN Group, the structure of the tight junctions became obscured and the dotted crystal structures disappeared. The microvilli were sparse with irregular length and arrangement. The situations in rhein-treated group and rhein-prevented group were improved compared with IgAN group. The intestinal epithelial tight junctions were repaired with respect to structural integration, with close intercellular connection and high electron density.

Laser confocal microscopy

Indirect immunofluorescence staining for occludin (Figure 2; intestinal epithelium by occludin immunofluorescence staining) and ZO-1 (Figure 3; intestinal epithelium

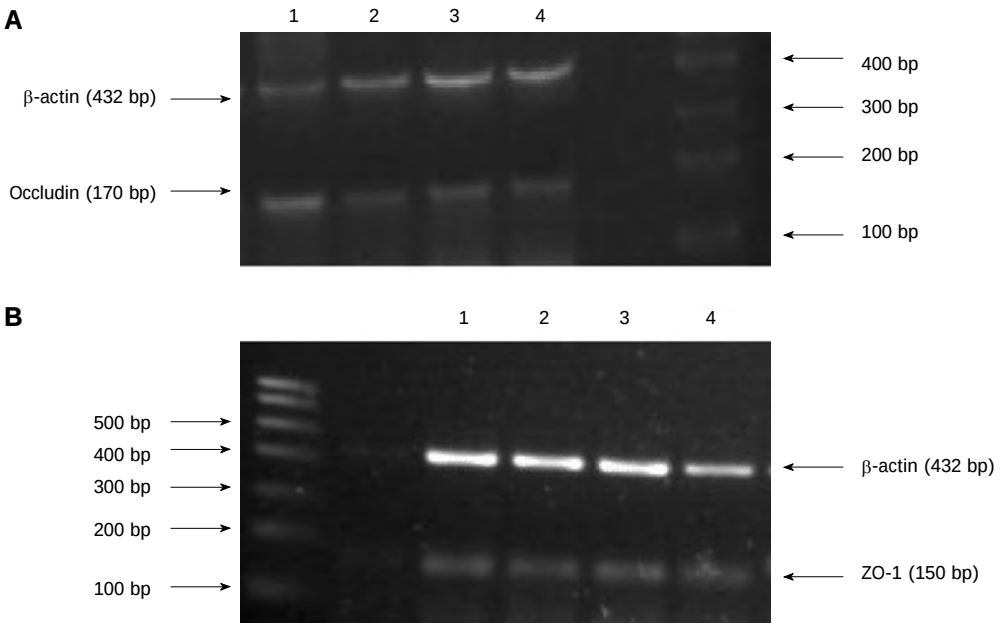

Figure 4 Reverse transcriptase polymerase chain reaction analysis for zona occludens protein-1 and occludin mRNA in rat ileum. By reverse transcriptase polymerase chain reaction, amplification products of expected size [150 bp for zona occludens protein (ZO)-1 and 170 bp for occludin] were obtained in the ileum in all four groups of rats. β-actin was the housekeeping protein. The levels of occludin and ZO-1 expression in the IgA nephropathy (IgAN) group were lower than in the control group. In the Rhein-treated and Rhein-prevented groups, the levels were higher than in the IgAN group. 1: Control; 2: IgAN; 3: Rhein-treated; 4: Rhein-prevented.

by ZO-1 immunofluorescence staining) was performed. In the control group, occludin and ZO-1 staining was found at the apical part of the lateral membranes of the polar epithelial cells and distributed continuously, similar to an intestinal mechanical barrier. In the IgAN Group, the green signals were intermittent and markedly weaker than those in the Control group ($P < 0.01$), and the integrity of the barrier was damaged. The condition of the Rhein-treated and Rhein-prevented groups was ameliorated compared with the IgAN group ($P < 0.01$). The green signals of ZO-1 in the Rhein-prevented group were stronger than in the Rhein-treated group ($P < 0.01$). In contrast, no change in the green signals of occludin was observed between these two groups (Table 1).

Rhein upregulated expression of occludin and ZO-1 mRNA in the small intestine

Occludin, ZO-1 and β-actin RNAs were 170, 150 and 432 bp long, respectively. RT-PCR semi-quantitative analyses showed that the levels of occludin and ZO-1 expression in the IgAN group were significantly lower than in the control group ($P < 0.01$). In the Rhein-treated and Rhein-prevented group, the levels were markedly higher than in the IgAN Group ($P < 0.01$). The level of ZO-1 expression in the Rhein-prevented group was higher than in the Rhein-treated group ($P < 0.05$). In contrast, no change in occludin expression was observed between these groups (Figure 4 and Table 1).

Rhein upregulated expression of occludin and ZO-1 protein in the small intestine

Western blotting analysis showed that occludin and ZO-1 protein expression decreased significantly in the IgAN group compared with the control group ($P < 0.01$). In the Rhein-treated and Rhein-prevented groups, occludin and ZO-1 protein expression was higher than in the IgAN group ($P < 0.01$). ZO-1 protein expression in the Rhein-prevented group was higher than in the Rhein-treated group ($P < 0.01$). However, no change in occludin protein expression was observed between the groups (Figure 5 and Table 2). These findings are consistent with the immunofluorescence results.

Rhein decreased intestinal permeability

The intestinal permeability was assessed by differential uptake of lactulose and mannitol in all four groups. Measurement of mannitol and lactulose by HPLC showed that the ratio of urinary lactulose/mannitol increased in the IgAN group compared with the control group ($P < 0.01$), indicating an increase of intestinal permeability. In the Rhein-treated and Rhein-prevented groups, the ratio of urinary lactulose/mannitol decreased compared with the IgAN group ($P < 0.05$), indicating decreased intestinal permeability. The decrease in intestinal permeability in the Rhein-prevented group was more obvious than that in the Rhein-treated group ($P < 0.05$) (Table 3).

DISCUSSION

IgAN is defined as the predominant deposition of IgA in the glomerular mesangium[7]. The etiology of IgAN has not been completely clarified, but one hypothesis involves the stimulation of antigen by an intestinal route causing an increase in IgA production in the intestinal

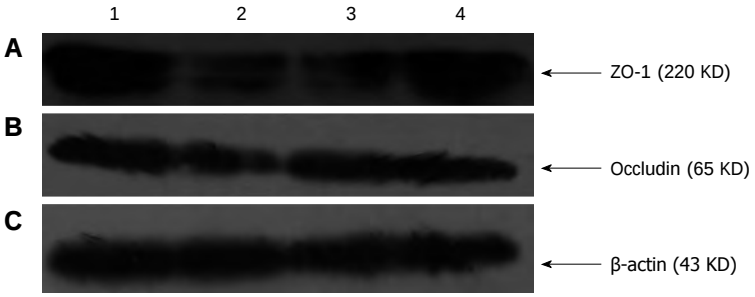

Figure 5 Western blotting analysis for zona occludens protein-1 and occludin of rat ileum. Western blotting analysis revealed zona occludens protein (ZO)-1 immunoreactivity by a band of 220 kDa in the control group and by a weaker band at the same level in the IgA nephropathy (IgAN) group. Compared with the IgAN group, there were stronger bands at the same level in the Rhein-treated and Rhein-prevented groups. Occludin immunoreactivity was revealed by a band of 65 kDa in the control group and by a weaker band at the same level in the IgAN group. Compared with the IgAN group, there were stronger bands at the same level in the Rhein-treated and Rhein-prevented groups. β-Actin was the housekeeping protein. 1: Control; 2: IgAN; 3: Rhein-treated; 4: Rhein-prevented.

Table 2 Grey level of occludin and zona occludens protein-1 in Western blotting

	Control group	IgAN group	Rhein-treated group	Rhein-prevented group
Occludin	1.38 ± 0.31	0.72 ± 0.15[b]	1.15 ± 0.17[d]	1.34 ± 0.21[d]
ZO-1	1.98 ± 0.43	0.85 ± 0.12[b]	1.57 ± 0.23[a,d]	2.07 ± 0.41[d,f]

The results were normalized to the respective β-actin expression. [a]$P < 0.05$, [b]$P < 0.01$ *vs* control group; [d]$P < 0.01$ *vs* IgA nephropathy (IgAN) group; [f]$P < 0.01$ *vs* Rhein-treated group.

Table 3 Ratio of urinary lactulose/mannitol

	Concentration of lactulose	Concentration of mannitol	Ratio of them
Control	5.73 ± 0.37	2.10 ± 0.05	2.72 ± 0.21
IgAN group	7.38 ± 1.42[b]	2.08 ± 0.11	3.55 ± 0.68[b]
Rhein-treated group	6.02 ± 0.31[d]	2.10 ± 0.05	2.87 ± 0.18[d]
Rhein-prevented group	6.06 ± 0.97[c]	2.15 ± 0.07	2.83 ± 0.43[d]

[b]$P < 0.01$ *vs* control group; [d]$P < 0.01$ *vs* IgA nephropathy (IgAN) group; [c]$P < 0.05$ *vs* Rhein-treated group.

mucosa, such as ulcerative colitis or Crohn's disease[8,9]. In recent years, an IgAN animal model induced by oral immunization has supported this hypothesis[10].

It has been reported that the permeability of the intestinal mucosa of IgAN patients is significantly higher than normal[11]. This is consistent with the experimental results, but its mechanism is not yet clear. Intestinal mucosal permeability is closely related to the integrity of the intestinal barrier. Mucosal barrier plays an important role in protecting the body from food antigens, microorganisms and their harmful metabolites[12]. The mucosal barrier includes mechanical, immune, chemical and biological barriers, among which, the mechanical barrier is essential for maintaining the integrity of the intestinal barrier. It is mainly composed of the intestinal epithelial cells and cellular junctions among them. The function of the intestinal barrier is affected by the morphology and number of epithelial cells and cellular junctions[13]. The cellular junctions include tight junctions, intermediate junctions, desmosomes, and gap junctions, and tight junctions are closely related to the mechanical barrier[14]. Tight junctions, or ZO, expand around the apex of epithelial cells and form a semipermeable barrier in the paracellular pathway in most vertebrate epithelia[15]. Disruption of the tight junctions can cause increased permeability and leakiness[16,17]. Three groups of macromolecules are considered as integral components of the tight junctions: occludins, claudins and junction adhesion molecules[18]. ZO-1 is the major tight junction protein that binds to the intracellular domain of occludins[19]. The interaction between occludin and ZO-1 plays a crucial role in maintaining the structure of tight junctions and epithelial barrier function[20,21]. Therefore, detection of occludin and ZO-1 reflects the condition of the tight junctions and intestinal mucosa barrier.

Our results showed that expression of intestinal epithelial tight junction proteins occludin and ZO-1 was significantly reduced in the IgAN Group. Therefore, we hypothesized that increased intestinal permeability in that group might be related to the decrease in expression of intestinal epithelial tight junction proteins. This decrease may be due to excess secretion of inflammatory cytokines, such as tumor necrosis factor (TNF)-α, interferon (IFN)-γ, NO, and oxygen free radicals, which is caused by intestinal antigen stimulation in the modeling process[22,23]. It has been reported that TNF-α affects the interaction of occludin and ZO-1 with components of the actin cytoskeleton[24]. Moreover, a series of recent reports has indicated that TNF-α disrupts tight junction assembly and decreases expression of ZO-1[25,26]. The synergy between TNF-α and IFN-γ can downregulate occludin expression of the occludin promoter[27].

Increased expression of tight junction proteins improves intestinal mucosal barrier function[28,29]. It has been reported that rhubarb can promote intestinal mucosal barrier function recovery and alleviate intestinal bacterial translocation in animal models of burns[30]. Therefore, we speculated that rhein, as the main pharmacological component of rhubarb, would also have a protective effect on the intestinal mucosal barrier and delay or prevent progression of IgAN. Western blotting showed that occludin and ZO-1 protein expression in the Rhein-treated

and Rhein-prevented Groups was higher than that in the IgAN Group, which was consistent with the immunofluorescence and RT-PCR results. The protective effect of rhein on tight junction proteins may be associated with the following aspects. First, rhein lowers the activity of macrophages and inhibits the secretion of TNF-α and other inflammatory cytokines that damage the structure and function of tight junctions[31]. Second, rhein has a positive effect on the peristaltic reflex of the small intestine[32], speeds up the excretion of intestinal bacteria and LPS, and reduces LPS-induced secretion of inflammatory cytokines. Third, reactive oxygen species destroy tight junction proteins by affecting the signal transduction pathway[33]. Rhein can remove reactive oxygen species and alleviate oxidative damage[34]. Lastly, dysfunction of the intestinal microcirculation results in structural damage of tight junctions[35]. Rhein inhibits intestinal microvascular endothelial cell secretion of NO, endothelin-1 and other vasoconstrictor substances, which improves the intestinal microcirculation[36].

In summary, rhein reduces intestinal permeability by protecting intestinal epithelial tight junction proteins ZO-1 and occludin, which alleviates the damage to the intestinal mucosa in IgAN. In this regard, rhein may be a potential therapeutic agent for protecting the intestinal mucosa in IgAN.

COMMENTS

Background

IgA nephropathy (IgAN) is the most common primary glomerular disease worldwide. The etiology and pathogenesis of IgAN are still not clear, and it lacks effective treatment. The incidence and aggravation of IgAN are often accompanied with damage to the intestinal mucosa. Rhein is an anthraquinone monomer isolated from rhubarb. It has been reported that rhubarb has a protective effect on the intestinal mucosal barrier in burns and pancreatitis, but a protective effect on the intestinal mucosal barrier in IgAN has not yet been reported.

Research frontiers

The intestinal mucosal barrier is an important area in research related to the etiology and pathogenesis of IgAN. The research hotspot is how to protect the intestinal mucosal barrier to prevent the occurrence of IgAN.

Innovations and breakthroughs

It has been reported previously that rhubarb has a protective effect on the intestinal mucosal barrier in burns and pancreatitis. Rhein is one of the anthraquinone monomers isolated from rhubarb. The protective effect of rhein on the intestinal mucosal barrier in IgAN has not yet been reported. The authors observed the protective effect of rhein on the intestinal mucosa in a rat model of IgAN; further demonstrated the pathogenesis of intestinal mucosal barrier injury in IgAN; and showed that intestinal protection and repair play an important role in the prevention and treatment of IgAN.

Applications

The results suggest that rhein is a potential therapeutic material that could be used in protecting intestinal mucosa barrier and preventing and treating IgAN.

Terminology

Rhein (1.8-dihydroxy-3-carboxy-anthraquinone, CAS number: 478-43-3) is a substance in the anthraquinone group obtained from rhubarb. Originally the rhubarb plant was used as a laxative, and it was believed that rhein along with other anthraquinone glycosides imparted this activity.

Peer review

This was a good descriptive study in which the authors analyzed the preventive effect of rhein on the intestinal mucosa barrier in rats with IgAN. The results are interesting and suggest that rhein is a potential therapeutic substance that could be used in protecting the intestinal mucosa and preventing IgAN.

Abstract

AIM: To investigate the role of T helper 17 cells (Th17) and regulatory T cells (Treg) in hepatitis B virus (HBV)-related acute-on-chronic liver failure (ACLF).

METHODS: We enrolled 79 patients with HBV infection into the study, 50 patients with HBV-related ACLF and 29 patients with chronic hepatitis B (CHB), from the First Affiliated Hospital of Medical College from January 2009 to June 2012. The ACLF patients were diagnosed according to the criteria recommended by The 19th Conference of the Asian Pacific Association for the Study of the Liver in 2009. Twenty healthy individuals with a similar gender and age structures to the two patient groups were also included as the normal controls (NC). Of the 50 ACLF patients, 28 were subsequently classified as non-survivors: 19 patients died from multi-organ failure, 3 underwent liver transplantation, and 6 discontinued therapy during follow-up because of financial reasons. The remaining 22 ACLF patients whose liver and anticoagulation function recovered to nearly normal levels within the next 6 mo were classified as survivors. The number of circulating Treg and Th17 cells was determined upon diagnosis and during the 8th week of follow-up through flow cytometry.

RESULTS: The percentage of circulating Treg cells in the ACLF group was significantly higher than that in the CHB group (5.50% ± 1.15% *vs* 3.30% ± 1.13%, $P < 0.01$). The percentages of circulating Th17 cells in the ACLF and the CHB groups were significantly higher than that in the NC group (6.32% ± 2.22% *vs* 1.56% ± 0.44%, $P < 0.01$; 3.53% ± 1.65% *vs* 1.56% ± 0.44%, $P < 0.01$). No significant difference in Treg cell to Th17 cell ratio was observed between the ACLF group and the CHB group (0.98 ± 0.44 *vs* 1.12 ± 0.64, $P = 0.991$), whereas those in the two HBV infection groups were significantly lower than that in the NC group (1.85 ± 1.22; both $P < 0.01$). The percentage of Treg cells in the survivors during the 8th week of follow-up was significantly lower than that during peak ACLF severity [total bilirubin (TBIL) peak] (3.45% ± 0.97% *vs* 5.18% ± 1.02%, $P < 0.01$). The percentage of Th17 cells in survivors during the 8th week of follow-up was significantly lower than that during the peak TBIL (2.89% ±

0.60% *vs* 5.24% ± 1.46%; $P < 0.01$). The Treg cell to Th17 cell ratio during the 8th week of follow-up was significantly higher than that during the TBIL peak (1.22 ± 0.36 *vs* 1.10 ± 0.54; $P < 0.05$).

CONCLUSION: Restoring the Treg cell to Th17 cell ratio during the follow-up phase of ACLF could maintain the immune system at a steady state, which favours good prognosis.

Key words: Hepatitis B virus; Acute-on-chronic liver failure; Regulatory T cells; T helper 17 cells; Treg cell to Th17 cell ratio

Core tip: In this study, the expression of circulating Treg and Th17 cells in hepatitis B virus-related acute-on-chronic liver failure (ACLF), chronic hepatitis B (CHB), and normal controls (NC) was measured using flow cytometric analysis. The percentages of circulating Treg and Th17 cells in ACLF group increased significantly compared with that in CHB group and NC group. Furthermore, the ratio of Treg to Th17 cells increased significantly upon recovery. Our study suggests that the reverting ratio of Treg to Th17 cells at the follow-up phase of ACLF could maintain the immune system at a steady state in favour of good prognosis.

Niu YH, Yin DL, Liu HL, Yi RT, Yang YC, Xue HA, Chen TY, Zhang SL, Lin SM, Zhao YR. Restoring the Treg cell to Th17 cell ratio may alleviate HBV-related acute-on-chronic liver failure. *World J Gastroenterol* 2013; 19(26): 4146-4154 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i26/4146.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i26.4146

INTRODUCTION

Acute-on-chronic liver failure (ACLF) is defined as an acute hepatic insult that manifests as jaundice and coagulopathy complicated by ascites and/or encephalopathy within four weeks among patients with chronic liver disease. The major aetiologic agents of ACLF are alcohol and drugs in the West and infectious agents in the East[1]. A characteristic feature of ACLF is its rapid progression and high incidence of short- and medium-term mortality, ranging from 50% to 90%[2]. Recent advances in medical therapy have only slightly decreased the mortality rate of HBV-related ACLF. Antiviral treatment improves the survival of patients with HBV-related ACLF[3,4]. Administering granulocyte-colony stimulating factor improves survival of patients with ACLF[5]. Liver transplantation can also improve outcomes, even in critically ill patients with multi-organ failure[6]. However, these advances have not significantly decreased the mortality associated with HBV-related ACLF.

In China, hepatitis B virus (HBV) infections account for 82% of all ACLF[7]. The exact mechanism of HBV-related ACLF is currently unclear. HBV is not directly cytopathic[8] and the hepatocellular injury caused by HBV infection is predominantly immune-mediated[9,10]. Wasmuth *et al*[11] demonstrated that the immunopathology of ACLF is similar to "sepsis-like" immune paralysis. Cytokines also play an important role in ACLF[12,13]. Evidence shows that circulating IL-17$^+$ T cells accumulate in large numbers in the liver of CHB patients, increasing with progression from CHB to ACLF[14,15]. By contrast, Treg cells suppress immune responses and inflammatory diseases[16,17], and they regulate chronic inflammatory responses that contribute to the pathologic events in the liver during HBV infection[18]. Several research groups have demonstrated increased Th17 cells in the peripheral blood and liver tissues, as well as changes in the balance between Th17 and Treg cells in ACLF patients[19,20].

In this study, we focus on the balance between CD4$^+$CD25$^+$FoxP3$^+$ Treg cells and CD4$^+$IL17$^+$ Th17 cells in HBV-related ACLF and examine the effects of this balance on patient responses to therapy and outcomes.

Table 1 Clinical characteristics of subjects in hepatitis B virus-related acute-on-chronic liver failure, chronic hepatitis B, and normal control groups *n* (%)

	ACLF (n = 50)	CHB (n = 29)	NC (n = 20)
Male/female	42/8	24/5	16/4
Age (yr)	40.2 ± 12.0	34.4 ± 12.0	34.5 ± 9.2
ALT (IU/L)	176.6 ± 430.0	328.4 ± 386.8	22.3 ± 6.7
TBIL (μmol/L)	566.3 ± 133.5	68.8 ± 90.9	12.2 ± 2.3
INR	1.83 ± 0.44	1.09 ± 0.10	0.99 ± 0.03
HBeAg	17 (34)	18 (62.1)	NA
Anti-HBe	30 (60)	8 (27.6)	NA
HBVDNA (Log10 IU/mL)	5.25 ± 1.30	6.11 ± 1.28	NA
MELD score	22.5 ± 4.7	4.6 ± 6.5	-2.7 ± 1.9

This table shows the mean ± SD of age, alanine aminotransferase (ALT), total bilirubin (TBIL), international normalized ratio (INR), and hepatitis B virus (HBV) DNA of all patients. Model for End-stage Liver Disease (MELD) scores are shown for the HBV-related acute-on-chronic liver failure (ACLF) group, chronic hepatitis B (CHB) group, and normal control (NC) group. The proportion of patients positive for hepatitis B e antigen (HBeAg) or hepatitis B e antibody (anti-HBe) in the ACLF and CHB groups is also displayed. NA: Not available.

MATERIALS AND METHODS

Subjects

We enrolled 79 patients with HBV infection into the study, 50 patients with HBV-related ACLF and 29 patients with CHB, from the First Affiliated Hospital of Medical College, Xi'an Jiaotong University (Xi'an, China) from January 2009 to June 2012. The ACLF patients were diagnosed according to the criteria recommended by The 19th Conference of the Asian Pacific Association for the Study of the Liver in 2009[1]. Patients were excluded if their liver disease was caused by conditions other than HBV infection. No patient received steroids or other immunosuppressive drugs within 6 mo before sampling.

Table 2 Predisposing factors of hepatitis B virus-related acute-on-chronic liver failure non-survivors and survivors *n* (%)

	Variceal bleeding	Infection			Drug	Alcohol	Indeterminant reasons
		Gastrointestinal tract	Upper respiratory tract	Ascites			
Non-survivors (n = 28)	2 (7.1)	5 (17. 8)	4 (14.3)	2 (7.1)	7 (25.0)	2 (7.1)	8 (28.6)
Survivors (n = 22)	0	7 (31.8)	5 (22.7)	0	5 (22.7)	1 (4.5)	4 (18.2)

Table 3 Clinical characteristics of non-survivors and survivors in hepatitis B virus-related acute-on-chronic liver failure group

	Non-survivors (n = 28)	Survivors (n = 22)	P value
Male/female	24/4	18/4	ND
Age (yr)	40.8 ± 11.0	39.5 ± 13.3	0.570
TBIL (μmol/L)	607.6 ± 117.5	513.7 ± 136.7	0.006
INR	2.00 ± 0.44	1.62 ± 0.33	0.088
MELD scores	23.7 ± 4.6	20.9 ± 4.4	0.021

This table shows the mean ± SD of age, total bilirubin (TBIL), international normalized ratio (INR) and Model for End-stage Liver Disease (MELD) scores for non-survivors and survivors in the hepatitis B virus (HBV)-related acute-on-chronic liver failure (ACLF) group. The P values of each parameter between groups are also displayed. ND: Not done.

The normal controls (NC) consisted of 20 healthy individuals with similar gender and age structures to the two patient groups.

Blood samples were collected from the ACLF patients 1 wk after diagnosis and again on the 2nd, 4th, 6th, 8th, and 12th week. The blood samples of the CHB patients were collected upon diagnosis and before receiving antiviral therapy. The clinical and biochemical details of ACLF patients at the time of their highest total bilirubin (TBIL), as well as those of the CHB patients are listed in Table 1. The Model for End-stage Liver Disease (MELD) score was calculated using the following formula: 3.8 × $\log_e$[bilirubin (mg/dL)] + 11.2 × $\log_e$(INR) + 9.6 × $\log_e$[creatinine (mg/dL)] + 6.4 × (aetiology: 0 if cholestatic or alcoholic, 1 otherwise)[21].

We classified 28 patients as non-survivors: 19 patients died from multi-organ failure, 3 underwent liver transplantation, and 6 discontinued therapy during follow-up because of financial reasons. The remaining 22 patients whose liver function and coagulation recovered to nearly normal within the next 6 mo were classified as survivors.

The study protocol was approved by the Ethics Committee of the First Affiliated Hospital of Medical College, Xi'an Jiaotong University, and written informed consent was obtained from each subject prior to enrolment in the study.

Cell stimulation and culture

Heparinized whole blood (200 μL) from study subjects was incubated for 4 h in phorbol 12-myristate 13-acetate (PMA) (final concentration 25 ng/mL) and ionomycin (final concentration 1 μg/mL) with monensin (end concentration 1.4 μg/mL) at 37 ℃ under a 5% CO_2 atmosphere.

Then, the whole blood was separated and incubated with anti-CD4-fluorescein isothiocyanate (FITC) and anti-CD25-phycoerythrin conjugate (PE) or anti-CD4-FITC. After simultaneous fixation and permeabilization, the cells were incubated for 30 min with anti-Foxp3-phycoerythrin-cyanine 5 conjugate (PE-Cy5) or anti-IL17A-PE. Then, the cells were washed again and were resuspended in PBS for flow cytometric analysis.

Flow cytometric analysis

To detect the expression of circulating Th17 and Treg cells, the whole blood was subjected to flow cytometry on a CyFlow® SL machine (PARTEC Company, Germany) using FloMax software.

Virologic and immunologic assessment

The levels of HBsAg, anti-HBs, HBeAg, anti-HBe, anti-HCV, anti-HDV, anti-HEV, and anti-HIV antibodies were detected *via* qualitative enzyme immunoassays. The serum HBV DNA levels were measured using a real-time polymerase chain reaction (PCR) assay with a detection limit of 1 × 10^3 IU/mL. All tests were performed in a clinical laboratory according to standardized methods.

Statistical analysis

Results are expressed as mean ± SD. Statistical comparisons between groups were performed using a Mann-Whitney non-parametric U test. A Spearman's correlation analysis was performed to evaluate the relationship between variables. The data were analyzed using SPSS version 16.0 for Windows (SPSS Inc., Chicago, IL). Differences with P values < 0.05 were considered statistically significant in all analyses.

RESULTS

Clinical characteristics of different short-term outcomes of ACLF patients

The characteristics of survivors and non-survivors in the ACLF group are listed in Table 2. The biochemical parameters and MELD scores at the time of peak TBIL level of the survivors and non-survivors are listed in Table 3.

Peripheral Th17 and Treg cells expression between groups

The percentages of $CD4^+CD25^+FoxP3^+$ (Treg) cells and $CD4^+IL\text{-}17^+$ (Th17) cells and the ratio of Treg to Th17 cells between groups are relative to $CD4^+$ T cells (Figure 1A). The percentages of circulating Treg cells in the two HBV infection groups were significantly higher than that in the NC group [2.46% ± 0.78%, P = 0.000 (*vs* ACLF),

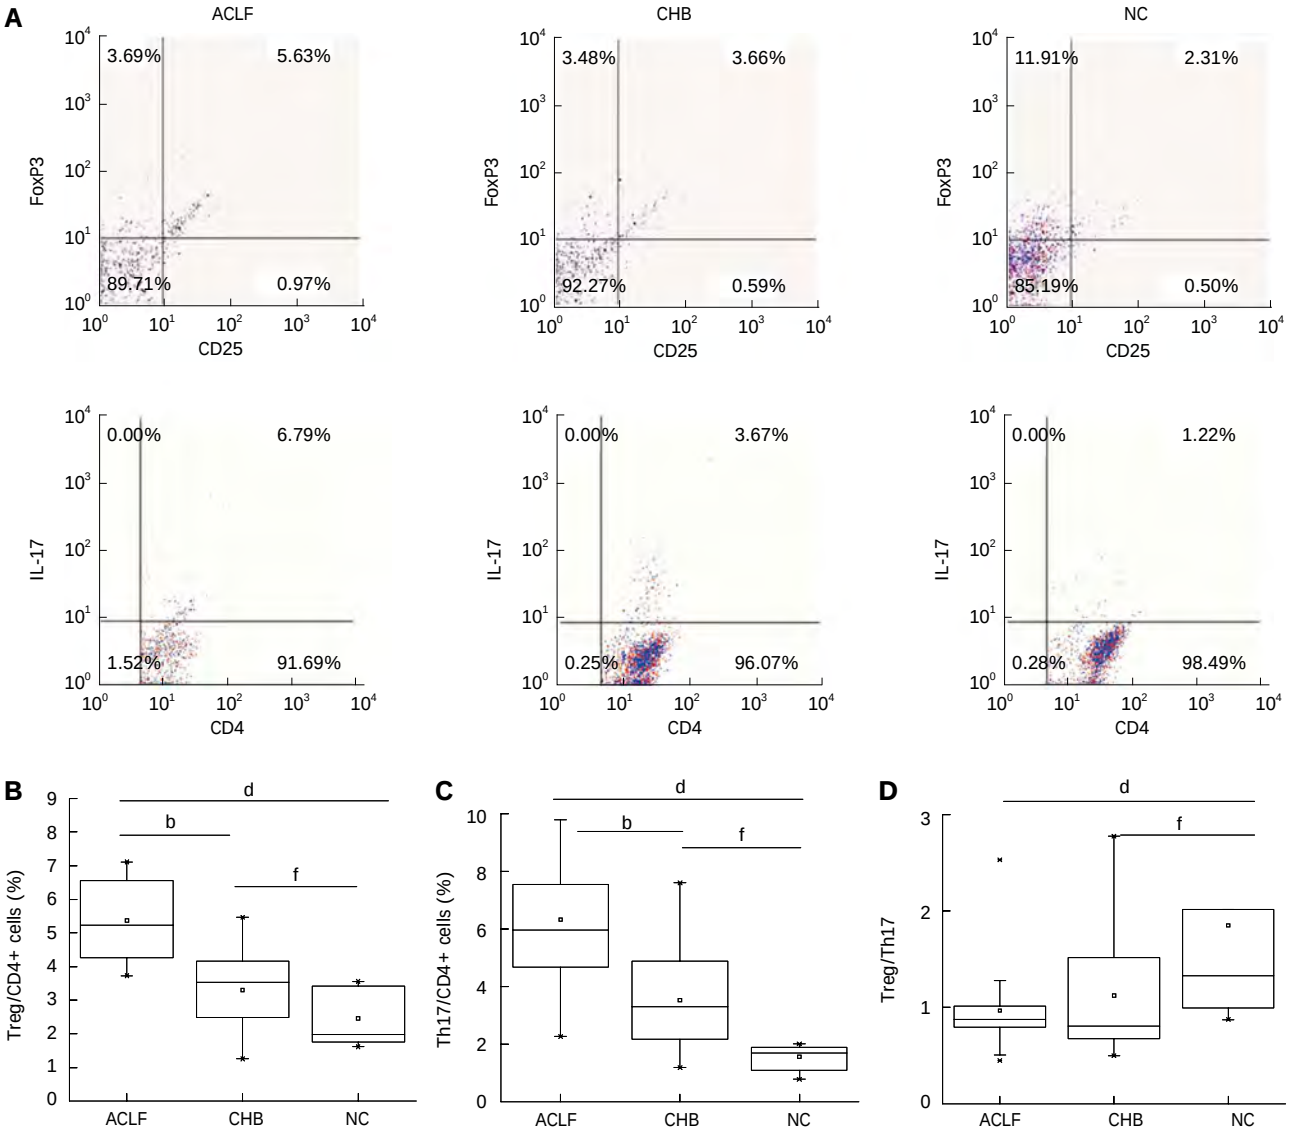

Figure 1 Percentages of T helper 17 cells and regulatory T cells, and the ratio of regulatory T cells to T helper 17 cells in hepatitis B virus-related acute-on-chronic liver failure, chronic hepatitis B, and normal control groups. Typical four-quadrant graphs of $CD25^+FoxP3^+$ cells [regulatory T (Treg)] and $IL17^+$ cells [T helper 17 (Th17)] in $CD4^+$ cells were divided into three groups (A). The proportion of Treg cells (B) and Th17 cells (C) among $CD4^+$ cells, and the Treg cell to Th17 cell ratios (D) were shown as box plot graphs. Acute-on-chronic liver failure (ACLF) *vs* chronic hepatitis B group (CHB) $^bP < 0.01$; ACLF *vs* normal control group (NC) $^dP < 0.01$; CHB *vs* NC $^fP < 0.01$.

$P = 0.008$ (*vs* CHB)]. The percentage of Treg cells in the ACLF group was also significantly higher than that in the CHB group (5.50% ± 1.15% *vs* 3.30% ± 1.13%, $P = 0.001$) (Figure 1B). Strikingly, the percentages of circulating Th17 cells in the ACLF and CHB groups were significantly higher than those in the NC group (6.32% ± 2.22% *vs* 1.56% ± 0.44%, $P = 0.000$; 3.53% ± 1.65% *vs* 1.56% ± 0.44%, $P = 0.000$) (Figure 1C). No significant difference in the Treg cell to Th17 cell ratio was observed between the ACLF group and the CHB group (0.98 ± 0.44 *vs* 1.12 ± 0.64, $P = 0.991$). However, the Treg cell to Th17 cell ratios in the two HBV infection groups were significantly lower than that in the NC group [1.85 ± 1.22; $P = 0.000$ (*vs* ACLF), $P = 0.004$ (*vs* CHB)] (Figure 1D). In summary, the percentages of Th17 and Treg cells in the peripheral blood of ACLF patients increased, whereas the ratio of Treg to Th17 cells was lower in the ACLF and CHB groups compared with that in the NC group.

Clinical correlation of Th17 and Treg expression in HBV-related ACLF

The percentage of Treg cells in the ACLF group was correlated with ALT ($r = 0.381$ $P = 0.006$), TBIL ($r = 0.378$, $P = 0.007$), and INR ($r = 0.381$, $P = 0.006$) (Figure 2A-C). The percentage of Th17 cells was positively correlated with ALT ($r = 0.360$, $P = 0.012$), TBIL($r = 0.323$, $P = 0.025$), and MELD scores (r = 0.293, $P = 0.043$) (Figure 2D-F). The percentage of Treg cells was significantly correlated with the percentage of Th17 cells ($r = 0.425$, $P = 0.003$; Figure 2G). The ratio of Treg to Th17 cells was not significantly correlated with any of the biochemical parameters. Neither the percentages of Treg

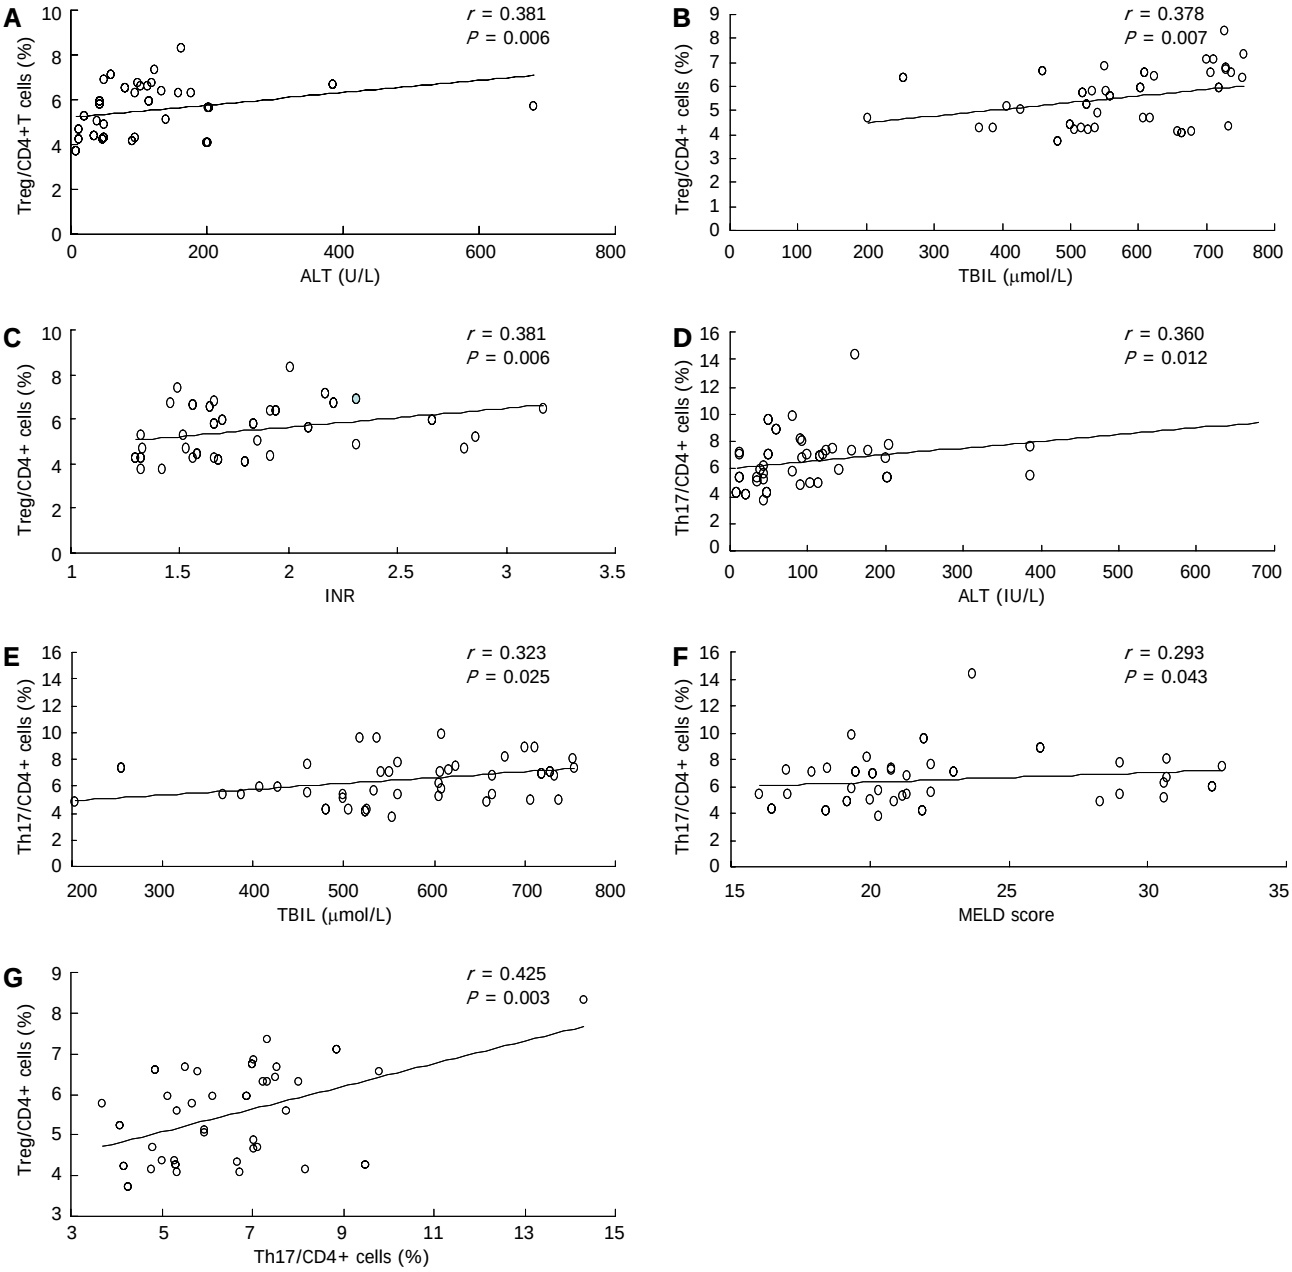

Figure 2 Correlation between T helper 17 cells and regulatory T cells counts and clinical parameters in hepatitis B virus-related acute-on-chronic liver failure group. The percentage of regulatory T (Treg) cells was significantly correlated with alanine aminotransferase (ALT) (A), total bilirubin (TBIL) (B), and international normalized ratio (INR) (C). The percentage of T helper 17 (Th17) cells was significantly correlated with ALT (D), TBIL (E), and Model for End-stage Liver Disease (MELD) scores (F).The percentage of Treg cells was significantly correlated with that of Th17 cells (G).

and Th17 cells, nor the ratio of Treg to Th17 cells, was correlated with serum HBV DNA levels.

In CHB group, the percentage of Treg cells was positively correlated with TBIL ($r = 0.431$, $P = 0.02$), whereas the percentage of Th17 cells was significantly correlated with ALT ($r = 0.367$, $P = 0.05$). Neither the percentages of Treg and Th17 cells, nor the ratio of Treg to Th17 cells, showed a relationship with serum HBV DNA levels.

Percentages of Treg and Th17 cells and the ratio of Treg to Th17 cells during follow-up phase in ACLF patients

The percentages of Treg and Th17 cells were measured serially in the ACLF group during a follow-up phase, which lasted for 8 wk. During TBIL peak, the percentage of Treg cells in non-survivors increased slightly compared with that in survivors (5.76% ± 1.21% *vs* 5.18% ± 1.02%), but the difference was not statistically significant ($P = 0.103$; Figure 3A). The percentage of Th17 cells in non-survivors was significantly higher than that in survivors (7.17% ± 2.37% *vs* 5.24% ± 1.46%; $P = 0.002$) (Figure 3B). No significant difference in Treg cell to Th17 cell ratio was observed between non-survivors and survivors (0.88 ± 0.32 *vs* 1.10 ± 0.54; $P = 0.233$; Figure 3C).

During 8th week follow-up, the percentages of Treg and Th17 cells and the Treg cell to Th17 cell ratio of the survivors were compared with those at the time of TBIL

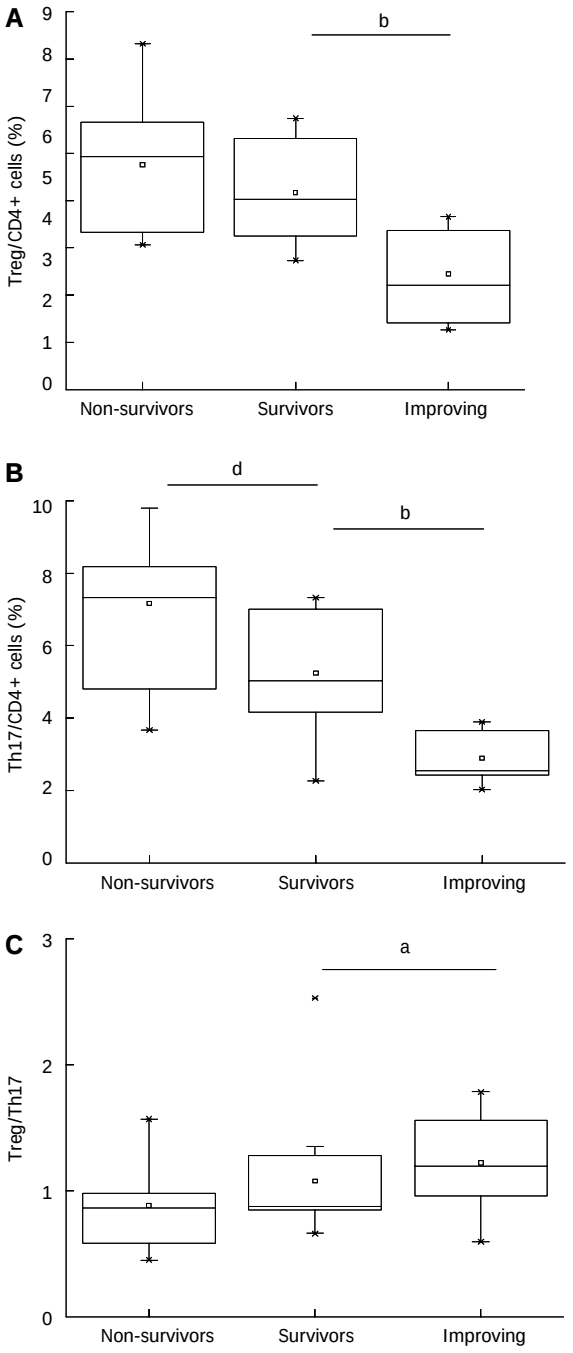

Figure 3 Comparison of regulatory T cells and T helper 17 cell counts, and the regulatory T cell to T helper 17 cell ratio between acute-on-chronic liver failure survivors and non-survivors, as well as those during the peak of acute-on-chronic liver failure severity (total bilirubin peak) and those during the 8th week of follow-up. Regulatory T (Treg) cell counts (A), T helper 17 (Th17) cell counts (B), and the Treg cell to Th17 cell ratios (C) of acute-on-chronic liver failure (ACLF) non-survivors, as well as those of ACLF survivors during the total bilirubin (TBIL) peak and during the 8th week of follow-up. $^{a}P < 0.05$, $^{b}P < 0.01$ *vs* the 8th week of follow-up in ACLF survivors, $^{d}P < 0.01$ *vs* non-survivors. Non-survivors: The non-survivors in ACLF group; Survivors: The survivors in ACLF group during the TBIL peak; Improving: The survivors in ACLF group during the 8th week of follow-up.

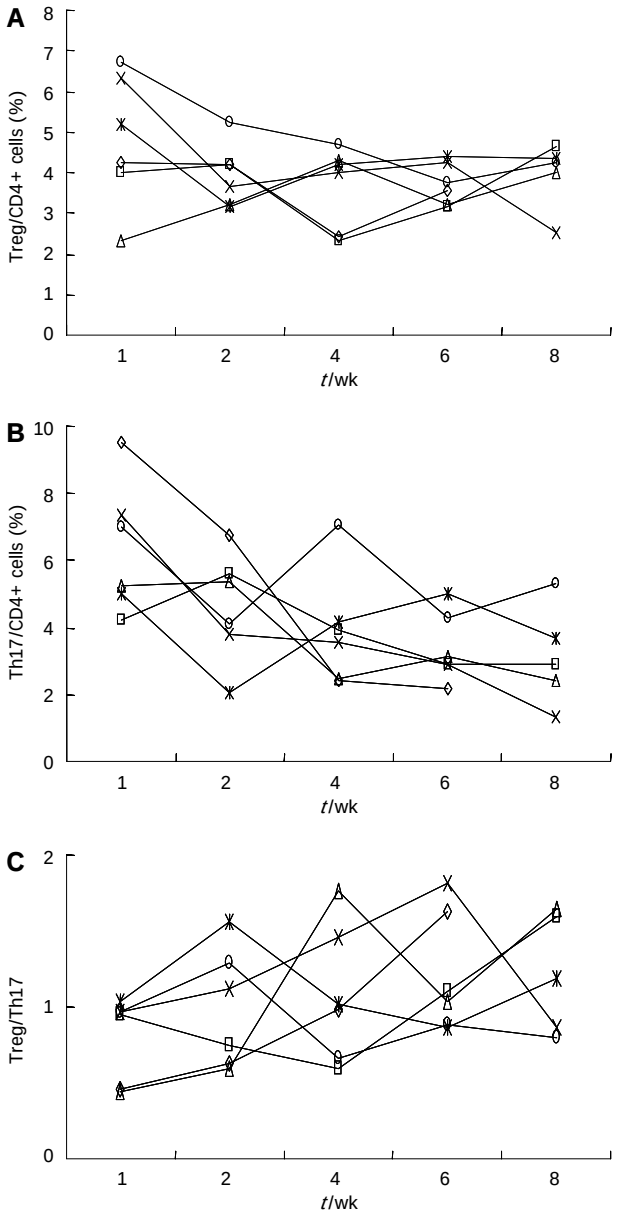

Figure 4 Changes in regulatory T cells and T helper 17 cell counts, and regulatory T cells and T helper 17 cell ratios of acute-on-chronic liver failure survivors. Changes in regulatory T (Treg) cell counts (A), T helper 17 (Th17) cell counts (B), and the Treg cell to Th17 cell ratio (C) of six acute-on-chronic liver failure survivors (5 males and 1 female).

peak. The percentage of Treg cells during the 8th week was significantly lower than that during the TBIL peak (3.45% ± 0.97% *vs* 5.18% ± 1.02%, $P = 0.000$) (Figure 3A), whereas the percentage of Th17 cells during the 8th week was significantly lower than that during the TBIL peak (2.89% ± 0.60% *vs* 5.24% ± 1.46%; $P = 0.000$) (Figure 3B). The Treg cell to Th17 cell ratio was significantly higher during the 8th week than that during the TBIL peak (1.22 ± 0.36 *vs* 1.10 ± 0.54; $P = 0.039$) (Figure 3C).

We examined changes in the percentage of Treg cells and Th17 cells, as well as the Treg cell to Th17 cell ratios, of 6 ACLF survivors (5 males and 1 female) who exhibited decreased TBIL with obvious clinical improvement. The percentage of Treg cells (Figure 4A) decreased together with the percentage of Th17 cells (Figure 4B) during the follow-up period, whereas the Treg cell to Th17

cell ratio increased gradually (Figure 4C).

DISCUSSION

Th17 and Treg cells are subsets of $CD4^+$ T helper cells with developmental pathways that contribute significantly to immune responses[22-27]. Th17 cells are implicated in host defence against a number of microorganisms[28,29]and they participate in autoimmune and chronic inflammatory diseases[30,31]. By contrast, Treg cells display suppressive and surveillance functions in immune responses and inflammatory diseases[16,17]. A study suggested that Th17 cells mediate airway inflammatory responses whereas antigen-specific Treg cells suppress Th17-mediated lung inflammation[32]. Yang *et al*[33] reported that an imbalance between Th17 and Treg cells contributes to the pathogenesis of systemic lupus erythematosus (SLE) and that regulating the balance between Treg and Th17 cells may be a promising strategy for SLE treatment. However, our aim is to determine whether an imbalance in Treg and Th17 cells contributes to the pathogenesis of acute hepatocellular injury in HBV-related ACLF and its mechanism.

Treg and Th17 cells were significantly higher in ACLF patients than in CHB patients and the normal controls. Furthermore, in ACLF patients, the percentage of Treg cells was significantly correlated with the percentage of Th17 cells, as well as with ALT and TBIL. Several recent studies demonstrated that the percentages of circulating Th17 and Treg cells increase with disease progression and are parallel to the severity of liver inflammation as CHB progresses to ACLF[14,18,19]. These results suggest that Th17 cells are a potential marker for the degree of liver injury in ACLF, whereas Treg cells may contribute to the suppression of the immune system[11].

We then analyzed the Treg and Th17 cell counts of ACLF survivors and non-survivors to determine their correlation with their clinical outcomes. The percentage of Th17 cells in ACLF non-survivors was significantly higher than that in survivors, but the percentage of Treg cells and the Treg cell to Th17 cell ratio were not significantly different between the two groups. Our findings are consistent with those of Zhai *et al*[20] who also found increased Th17 cells and Treg cells in ACLF patients. However, they found no significant difference in Th17 and Treg cell counts between ACLF survivors and non-survivors and they observed significantly lower Th17 cell to Treg cell ratios in the survivors than in non-survivors. These differences between the two studies may be attributed to differences in the severity of hepatic injury, as well as differences in the timing of sample acquisition. However, both studies found that patients with ACLF have higher Treg and Th17 cell counts and that higher Th17 cell to Treg cell ratios may predict poorer prognosis.

In China, ACLF occurs mainly in patients with CHB or HBV-related cirrhosis. Spontaneous or treatment-induced inflammatory flare ups are frequently observed in chronic hepatitis B[34]. Several researchers in Asia have demonstrated that early intervention using antiviral therapy improves the short- and long-term outcomes of HBV-related ACLF by aggressively targeting the precipitating events to prevent multi-organ failure[3,4,35]. Entecavir-induced suppression of HBV replication in nine CHB patients showed rapid increases in Th17 cells and decreases in Treg cells, which significantly reduced the Treg cell to Th17 cell ratio[36]. Thus, the effects of antiviral therapies with ACLF will affect Treg and Th17 cells.

We measured the Treg and Th17 cell counts in ACLF survivors during follow-up to determine whether antiviral therapy affects the balance between Treg and Th17 cells. The percentages of Treg and Th17 cells decreased significantly during follow-up, whereas the Treg cell to Th17 cell ratio increased significantly compared with that during the peak of illness, which coincides with the peak serum total bilirubin. Restoring the Treg cell to Th17 cell ratio could help maintain the immune system in a steady state, favouring good outcomes among patients with HBV-related ACLF.

In conclusion, Th17 cell counts may reflect the degree of liver injury, where Treg cells may regulate the protective suppression of the immune system of patients with ACLF. Treg cells and Th17 cells increased in patients with ACLF, but higher Th17 cell to Treg cell ratios may be correlated with poorer prognosis. Restoring the Treg cell to Th17 cell ratio during ACLF could help maintain the immune system in a steady state, which may improve patient prognosis.

COMMENTS

Background

Acute-on-chronic liver failure (ACLF) is an acute hepatic insult with rapid progression and high short- and medium-term mortality. In China, hepatitis B virus (HBV) infections account for 82% of all ACLF cases. Studies have demonstrated that the hepatocellular injury caused by HBV infection is predominantly immune-mediated.However, the mechanism of HBV-related ACLF is currently unclear.

Research frontiers

Several studies showed that Treg and Th17 cells may contribute to the pathologic events in the liver during HBV infection and the balance between Treg cells and Th17 cells may be disrupted during ACLF progression.

Innovations and breakthroughs

The authors found that ACLF patients have significantly increased Treg cell to Th17 cell ratios. The Treg cells and Th17 cells decreased significantly with improvement of the ACLF, but the Treg cell to Th17 cell ratio significantly increased. Thus, Th17 cells may be a marker for the degree of liver injury and poor prognosis in ACLF. Restoring the Treg cell to Th17 cell ratio during the aggravating phase of ACLF could maintain the immune system at a steady state, which favours good prognosis.

Applications

Th17 cells and Treg cells are subsets of $CD4^+$ T helper cells with related developmental pathways. The balance between Th17 cells and Treg cells is important for maintaining human immune homeostasis. The balance between Th17 cells and Treg cells should be maintained before chronic hepatitis B progresses to ACLF. Once CHB has progressed to ACLF, restoring the Treg cell to Th17 cell ratio becomes even more significant to the outcome.

Terminology

ACLF is defined as an acute hepatic insult that manifests as jaundice and coagulopathy in a patient with chronic liver disease, complicated within 4 wk by ascites and/or encephalopathy. The major aetiologic agents of ACLF are alcohol

and drugs in the West and infectious agents in the East. A characteristic feature of ACLF is its rapid progression and high short- and medium-term mortality (50% to 90%).

Peer review

The manuscript focuses on the balance between $CD4^+CD25^+FoxP3^+$ Treg cells and $CD4^+IL17^+$ Th17 cells in HBV-related ACLF. The authors examined the effects of this balance on patient responses to therapy and outcomes. This manuscript is interesting. The references used in the study are updated.

Abstract

AIM: To explore the role of CDX2 in the multi-drug resistance (MDR) process of gastric cancer *in vitro* and *in vivo*.

METHODS: A cisplatin-resistant gastric cancer cell line with stable downregulation of CDX2 was established. mRNA and protein expression levels of CDX2, survivin, cyclin D1, and c-Myc were detected by western blotting and semi-quantitative reverse-transcriptase polymerase chain reaction (RT-PCR). The influence of downregulation of CDX2 on MDR was assessed by measuring IC50 of SGC7901/DDP cells to cisplatin, doxorubicin, and 5-fluorouracil, rate of doxorubicin efflux, apoptosis, and cell cycle progression detected by flow cytometry. In addition, we determined the *in vivo* effects of CDX2 small interfering RNA (siRNA) on tumor size, and apoptotic cells in tumor tissues were detected by deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling and hematoxylin and eosin staining.

RESULTS: CDX2 siRNA led to downregulation of endogenous CDX2 mRNA (0.31 ± 0.05 *vs* 1.10 ± 0.51, 0.31 ± 0.05 *vs* 1.05 ± 0.21, $P = 0.003$) and protein (0.12 ± 0.08 *vs* 0.51 ± 0.07, 0.12 ± 0.08 *vs* 0.55 ± 0.16, $P = 2.57 \times 10^{-4}$) expression. It significantly promoted the sensitivity of SGC7901/DDP cells to cisplatin (0.12 ± 0.05 *vs* 0.33 ± 0.08, 0.12 ± 0.05 *vs* 0.39 ± 0.15, $P = 0.001$), doxorubicin (0.52 ± 0.13 *vs* 4.11 ± 1.25, 0.52 ± 0.13 *vs* 4.05 ± 1.44, $P = 2.81 \times 10^{-4}$), and 5-fluorouracil (0.82 ± 0.13 *vs* 2.81 ± 0.51, 0.82 ± 0.13 *vs* 3.28 ± 1.03, $P = 1.71 \times 10^{-4}$). Flow cytometry confirmed that the percentage of apoptotic cells increased after CDX2 downregulation (32.15% ± 2.15% *vs* 17.63% ± 3.16%, 32.15% ± 2.15% *vs* 19.3% ± 2.25%, $P = 1.73 \times 10^{-6}$). This notion was further supported by the observation that downregulation of CDX2 blocked entry into the S-phase of the cell cycle (31.53% ± 3.78% *vs* 65.05% ± 7.25%, 31.53% ± 3.78% *vs* 62.27% ± 5.02%, $P = 7.55 \times 10^{-7}$). Furthermore, downregulation of CDX2 significantly increased intracellular accumulation of doxorubicin (0.21 ± 0.06 *vs* 0.41 ± 0.11, 0.21 ± 0.06 *vs* 0.40 ± 0.08, $P = 0.003$). In molecular studies, semiquantitative RT-PCR and western blotting revealed that CDX2 downregulation could inhibit expression of c-Myc, survivin and cyclin D1.

CONCLUSION: CDX2 may be involved in regulating multiple signaling pathways in reversing MDR, suggesting that CDX2 may represent a novel target for gastric cancer therapy.

Key words: Homeobox gene CDX2; RNA interference; Gastric cancer; Drug resistance; Murine model

Core tip: Modulator of multidrug resistance (*MDR*) gene is a direct transcriptional target of CDX2. However, we still speculate whether CDX2 affects MDR through other ways. Our results showed that downregulation of CDX2 significantly promoted sensitivity of SGC7901/DDP cells to anticancer drugs, and increased the percentage of apoptotic cells. Downregulation of CDX2 potentiated G1 phase arrest of the cell cycle. Furthermore, it significantly increased intracellular accumulation of doxorubicin. We conclude that downregulation of CDX2 can efficiently reverse MDR *via* inhibition of apoptosis/cell-cycle-related gene expression (c-Myc, survivin and cyclin D1).

INTRODUCTION

The transcription factor, CDX2, is a member of the caudal-related homeobox gene family. It is expressed exclusively in the small and large intestine, playing important roles in proliferation and differentiation of intestinal epithelial cells[1]. Several investigators have reported that low levels of CDX2 are a characteristic feature of human colon and squamous esophageal cancer[2,3], but others have shown that strong and robust expression of CDX2 is found in > 80% of colorectal cancer and non-small cell lung cancer[4,5]. In addition, CDX2 enhances proliferation and has tumorigenic potential in human colon cancer cell lines LoVo and SW48[6]. These studies have suggested that CDX2 also has oncogenic activity. Together, these conflicting findings point to a complex role for CDX2 in cell regulation. In adult humans, CDX2 is associated with intestinal metaplasia in the stomach in which ectopic expression of CDX2 is speculated to cause the gastric epithelial cells to trans-differentiate and assume the intestinal phenotype[7]. In addition, CDX2 transgenic mice have been shown to have intestinal metaplasia and a high incidence of gastric carcinoma[8,9].

In a previous study[10], it has been reported that RNA interference (RNAi)-mediated inhibition of CDX2 decreases endogenous MDR1 expression. MDR1 was originally identified as an overexpressed and amplified gene in multidrug-resistant cells. Its product, P-glycoprotein (P-gp), appears to play a critical role in drug resistance, which suggests that CDX2 is associated with multidrug resistance (MDR) of gastric cancer. Previously, we have reported that CDX2 affects the cell cycle and apoptosis of gastric cancer[11], Furthermore, apoptosis is just one of the important mechanisms of reversal MDR[12]. CDX2 may play a crucial role in the control of reversal MDR.

In the present study, we constructed small interfering RNA (siRNA) sequences that targeted CDX2, transfected them into a cisplatin-resistant gastric cancer cell line SGC7901/DDP, selected stable transfectants, and explored changes in IC50, rate of doxorubicin efflux, cell cycle, and apoptosis. We also observed the effect of CDX2 siRNA on the expression of genes associated with apoptosis, including c-Myc and survivin. Moreover, we investigated the effects of CDX2 downregulation on the growth and apoptosis of SGC7901/DDP cells in nude mice.

MATERIALS AND METHODS

Reagents

5-fluorouracil, cisplatin and doxorubicin were purchased from Sigma-Aldrich (St Louis, MO, United States). Cell culture medium RPMI-1640 was purchased from Invitrogen-Gibco (Carlsbad, CA, United States). Fetal bovine serum (FBS) was from Invitrogen-Gibco. Trypsin, streptomycin and penicillin were obtained from Sunshine Biotechnology (Nanjing, China). CDX2, c-Myc, survivin, cyclin D1, glyceraldehyde 3-phosphate dehydrogenase (GAPDH), and β-actin antibody were from Santa Cruz Biotechnology (Santa Cruz, CA, United States). All other chemicals were of the highest commercial grade available.

Cell culture

The cells were cultured in RPMI 1640 supplemented with 10% FBS (Sijiqing Biotec, Co. Ltd., Hangzhou, China), antibiotics (100 U/mL penicillin and 100 mg/mL streptomycin) in a humidified 5% CO_2 atmosphere at 37.8 ℃. For SGC7901/DDP cells, 0.6 μg/mL cisplatin was supplemented in the medium to maintain the drug-resistance phenotype.

Gene transfection

Recombinant lentiviral vector for *CDX2* gene (siRNA-CDX2) and null vector (siRNA-NC) were stored in our laboratory[13]. SGC7901/DDP cells were seeded in six-well plates with antibiotic-free medium. After 24 h incubation, cells were infected with viral supernatant at a multiplicity of infection of 150 PFU per cell (MOI = 150), and the stable-transfected cell lines were obtained by culturing transfected cells in the presence of 700 mg/mL G418 (Invitrogen, Carlsbad, CA, United States) for 3-4 wk. The cells were divided into three groups: SGC7901/DDP + siRNA-CDX2, SGC7901/DDP + siRNA-NC, and SGC7901/DDP.

Measurement of cell drug sensitivity by MTT analysis

The IC50 was determined by MTT [3-(4,5-dimethylthiazol-2-yl)-2, 5-diphenyl-tetrazoliumbromide] assay. Cells were plated in 96-well plates (5000 cells/well), and after

adherence, the cells were exposed to cisplatin, doxorubicin, and 5-fluorouracil. After incubation for 48 h, the cells were incubated with 20 μL MTT (at a final concentration of 0.5 mg/mL) at 37 ℃ for 4 h. The medium was removed and the precipitated formazan was dissolved in 100 μL DMSO. The absorbance at 490 nm was detected using a microplate reader (Bio-Rad, Hercules, CA, United States). The IC50 was estimated by the relative survival curve. Each assay was performed in triplicate.

Measurement of pump rate of doxorubicin by flow cytometry

The cells were inoculated into six-well plates and 4 mg/mL doxorubicin was added, and all wells were placed at 37 ℃ for 30 min. Flow cytometry was used to measure the fluorescent intensity of doxorubicin in cells with an excitation wavelength of 488 nm and emission wavelength of 575 nm. The cells were then washed twice with fresh culture medium and incubated with the new medium at 37 ℃ for 1 h to detect the retained doxorubicin. Subtraction of the fluorescence retained from the total fluorescence was the fluorescent index of doxorubicin. The procedure was repeated three times and an average value was obtained to calculate the pump rate of doxorubicin. The pump rate of the drug from the cells = (accumulated quantity of doxorubicin-retained quantity of doxorubicin)/accumulated quantity of doxorubicin.

Cell cycle analysis by flow cytometry

SGC7901/DDP cells (1×10^6) were washed twice with ice-cold PBS, treated with trypsin, and fixed in cold 70% ethanol at 4 ℃ for 30 min. The cell pellet was incubated in a solution containing 50 ng/mL propidium iodide, 0.2 mg/mL RNase, and 0.1% Triton X-100 at room temperature for 30 min. The cells were analyzed by flow cytometry using an EPICS XL-MCL FACScan (Becton-Dickinson, Mountain View, CA, United States). The data was analyzed with the MultiCycle Software for Windows (Phoenix Flow Systems, San Diego, CA, United States).

Semiquantitative reverse-transcriptase polymerase chain reaction

Total RNA was extracted from SGC7901/DDP + siRNAi-CDX2 cells, SGC7901/DDP + siRNAi-NC cells, and SGC7901/DDP cells using TRIzol Reagent (Invitrogen). All gene segments were amplified and verified by semiquantitative reverse-transcriptase polymerase chain reaction (RT-PCR). cDNAs were reverse-transcribed from 2 μg total RNA. The PCR primer sequences (CDX2 primers were sense: 5'-CGG CAG CCA AGT GAA AAC-3' and antisense: 5'-GAT GGT GAT GTA GCG ACT GTA-3'. Survivin primers were sense: 5'-AAA TGC ACT CCA GCC TCT GT-3' and antisense: 5'-TGT CGA GGA AGC TTT CAGGT-3'. Cyclin D1 primers were sense: 5'-CCC TCG GTG TCC TAC TTC AA-3' and antisense: 5'-GGG GAT GGT CTC CTT CAT CT-3. c-Myc primers were sense: 5'-TTC TCT CCG TCC TCG GAT TC-3' and antisense: 5'-GTA GTT GTG CTG ATG TGT GG-3'. GAPDH primers were sense: 5'-ACC ACA GTC CAT GCC ATC AC-3' and antisense: 5'-TCA CCA CCC TGT TGC TGT A-3'). The products of PCR were checked by agarose gel electrophoresis, and the abundance of each mRNA was detected and normalized to that of GAPDH mRNA.

Western blotting

Cell lysates were prepared in a buffer containing 100 mmol/L NaCl, 10 mmol/L Tris-HCl (pH 7.6), 1 mmol/L EDTA (pH 8.0), 1 μg/mL aprotinin, 100 μg/mL phenylmethylsulfonyl fluoride, and 1% (v/v) NP-40. After protein quantitation using the Lowery protein assay, equal amounts of proteins were separated by SDS-PAGE and blotted onto nitrocellulose membranes by the semi-dry blotting method using a three-buffer system. The membranes were incubated with a dilution of primary antibody (anti-CDX2: 1:500, anti-c-Myc: 1:1000, anti-survivin: 1:1500, anti-cyclin D1:1:3000), overnight at 4 ℃. The membrane was washed with TBST and incubated with a peroxidase-conjugated secondary antibody (1:1000) (Santa Cruz Biotechnology) for 1 h. Specific antibody binding was detected using a chemiluminescence detection system (Pierce, Rockford, IL, United States), according to the manufacturer's recommendations. Western blot film was scanned, and the net intensities of the bands were quantified using Image-QuanT software (Molecular Dynamics, Sunnyvale, CA, United States). After development, the membrane was stripped and reprobed with antibody against GAPDH (1:1000) or β-actin (1:1500) to confirm equal sample loading.

Effect of CDX2 siRNA on reversing MDR of human gastric cancer in vivo

BALB/c 5-wk-old male nude mice (Guangxi Animal Center, Nanning, China) were kept under specific pathogen-free conditions and tended to in accordance with institutional guidelines. All experimental studies were approved by the Guangxi Medical University Animal Care and Use Committee. SGC7901/DDP cells were used for tumor implantation. Approximately 2×10^6 tumor cells were harvested, resuspended in 100 μL PBS, implanted subcutaneously into the flanks of the BALB/c nude mice, and resulting tumor was named as SGC7901/DDP tumor. After 7 d, when the SGC7901/DDP tumor measured 3-5 mm in diameter, these nude mice were randomly divided into the following three groups (6 mice/per group): SGC7901/DDP + siRNA-CDX2, SGC7901/DDP + siRNA-NC, and SGC7901/DDP. The animals were administered an intratumoral injection of LV-siRNA- CDX2 or LV-siRNA-NC at a titer of 5×10^6 TU in 100 μL PBS, and injection of an equal volume of PBS was used as a blank control. After the first injection, the animals were administered a similar injection every 2 d. DDP was administered by intraperitoneal injection at a dose of 25 mg/kg. After the first injection, the animals were administered a similar injection every 2 d. The tumors were monitored every day and measured every 2 d with a caliper, and the diameters were recorded. The tumor volume (TV) was calculated by the formula: $TV =$

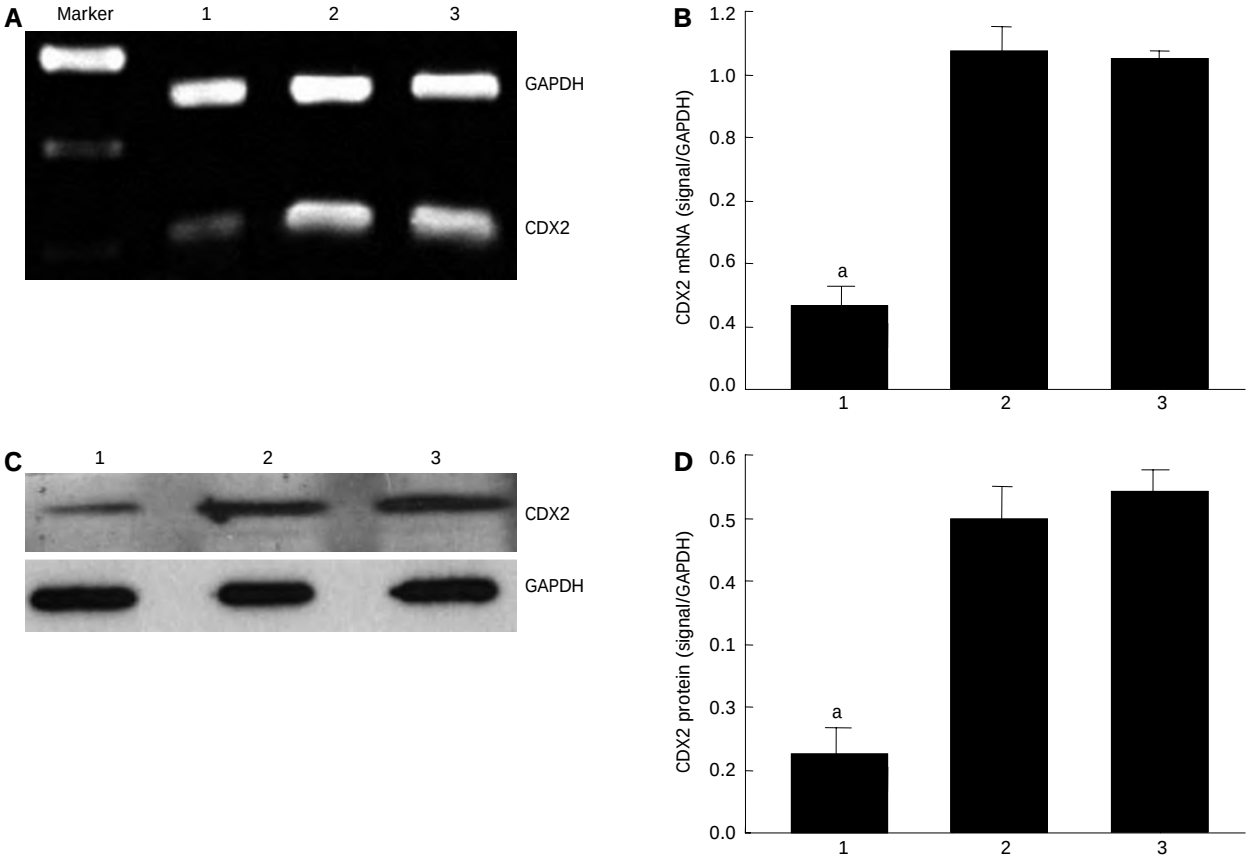

Figure 1 mRNA and protein expressions of CDX2 after RNA interference. A, B: Expression level of CDX2 mRNA was determined by semiquantitative reverse-transcriptase polymerase chain reaction; C, D: Expression level of CDX2 protein was determined by Western blotting. mRNA results were expressed as the ratio of CDX2 to glyceraldehyde 3-phosphate dehydrogenase (GAPDH). Western blotting results were expressed as the ratio of optical density of CDX2 bands to GAPDH bands. All values are mean ± SE. $^{a}P < 0.05$ for SGC7901/DDP + small interfering RNA (siRNA)-CDX2 cells *vs* SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells. Lane 1: SGC7901/DDP + siRNA-CDX2 cells; Lane 2: SGC7901/DDP + siRNA-NC cells; Lane 3: SGC7901/DDP cells.

$W^2 \times L/2$, where L is the length and W is the width of the tumor. The relative tumor volume (RTV) was calculated by the formula: $RTV = V_t/V_0$ (V_0 is the TV at the day when the chemicals were given, and V_t is the TV of subsequent measurement). The animals were sacrificed at 12 d after tumor injection and the tumors were analyzed.

Hematoxylin and eosin staining and deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling assay

For hematoxylin and eosin (HE) staining tumor tissues were fixed in 4% formaldehyde, dehydrated with gradient ethanol, and embedded in paraffin wax. Tissue sections were dewaxed and rehydrated according to a standard protocol. Sections were stained with HE. For the deoxynucleotidyl transferase-mediated dUTP-biotin nick end labeling (TUNEL) assay, apoptotic cells in sections of mouse tumor tissue were detected using an *in situ* apoptosis detection kit (KEYGEN, Nanjing, China) as instructed by the manufacturer. Cells were visualized with a light microscope (Olympus IX70, Tokyo, Japan). The apoptotic index was calculated as follows: the apoptotic index = number of apoptotic cells/total number of cells. The *in vivo* experiments strictly obeyed the ethical principles and guidelines for scientific experiments on animals.

Statistical analysis

Data are expressed as mean ± SE. Statistical significance was determined using χ^2 test, Student's t test, or one-way analysis of variance (ANOVA). Statistical analysis were carried out using SPSS version 13.0 (Chicago, IL, United States) or Origin 7.5 software programs (OriginLab, Northampton, MA, United States). A value of $P < 0.05$ was considered as statistically significant.

RESULTS

CDX2 siRNA inhibits CDX2 mRNA and protein expression

Our previous study suggested that recombinant lentiviral vector for CDX2 gene (siRNA-CDX2) successfully inhibited CDX2 mRNA and protein expression in MGC-803 cells[13]. In the present study, we further tested the hypothesis that CDX2 siRNA downregulates CDX2 mRNA and protein expression in SGC7901/DDP cells. We treated SGC7901/DDP cells with siRNA-CDX2 and siRNA-NC (negative control). Transfection of siRNA-CDX2 into SGC7901/DDP cells led to marked inhibition of CDX2 mRNA (Figure 1A) and protein expression (Figure 1C). Densitometry analysis showed that CDX2 mRNA (Figure 1B) and protein (Figure 1D) in SGC7901/DDP

Table 1 IC50 values for anticancer drugs in SGC7901/DDP cells

	Doxorubicin (μg/mL)	5-fluorouracil (μg/mL)	Cisplatin (μg/mL)
SGC7901/DDP + siRNA-CDX2	0.12 ± 0.05[a]	0.52 ± 0.13[a]	0.82 ± 0.13[a]
SGC7901/DDP + siRNA-NC	0.33 ± 0.08	4.10 ± 1.25	2.81 ± 0.50
SGC7901/DDP	0.39 ± 0.15	4.05 ± 1.44	3.28 ± 1.03

IC50 values were evaluated by MTT assay. Each experiment was conducted in triplicate. Data are expressed as means ± SD. One-way analysis of variance followed by Dunnett's multiple comparison tests revealed statistical differences. [a]$P < 0.05$ for SGC7901/DDP + small interfering RNA (siRNA)-CDX2 cells *vs* SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells.

+ siRNA-CDX2 cells were about 3.5- and 4-fold lower, respectively, than those in SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells ($P < 0.05$). There were no differences between SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells. These results suggested that CDX2 siRNA could downregulate CDX2 mRNA and protein expression in SGC7901/DDP.

CDX2 siRNA reverses MDR

Although SGC7901/DDP cells were selected with the single anticancer drug cisplatin, they also displayed multiple resistances to other anticancer drugs. We studied the regulatory effects of CDX2 siRNA on the drug sensitivity of gastric cancer cells. MTT assay was used to detect the sensitivity of cells to one P-gp-related drug (doxorubicin) and two P-gp-non-related drugs (5-fluorouracil and cisplatin). As showed in Table 1, compared with SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells, SGC7901/DDP + siRNA-CDX2 exhibited significantly decreased IC50 values for cisplatin, doxorubicin and 5-fluorouracil ($P < 0.05$).

Effects of CDX2 siRNA on pump rate of doxorubicin

Pumping out chemotherapeutic agents is the key process in MDR[14]. We proposed that downregulation of CDX2 inhibited drug efflux in gastric cancer cells. To test this hypothesis, intracellular drug accumulation and retention were evaluated using doxorubicin as a probe. As shown in Figure 2A, compared with SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells, SGC7901/DDP + siRNA-CDX2 cells exhibited significantly increased accumulation and retention as well as a lower releasing index of doxorubicin (Figure 2B) ($P < 0.05$).

Effect of CDX2 siRNA on cell cycle control

We used flow cytometry to determine whether reversal of MDR by CDX2 siRNA in SGC7901/DDP cells was mediated, at least in part, through an effect on cell cycle progression. We found that the number of cells in G1 phase markedly increased, while those in S phase decreased in SGC7901/DDP + siRNA-CDX2 cells, compared with SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells (Figure 2C) ($P < 0.05$).

CDX2 siRNA induces apoptosis

Anti-apoptosis is an important mechanism of MDR, therefore, we investigated the effect of siRNA-CDX2 on cisplatin-induced gastric cancer cell apoptosis by calculating apoptosis index. Cells were stained with annexin V PE and 7-AAD, and then subsequently analyzed by flow cytometry. The dual parameter fluorescent dot plots showed that the viable cells were in the lower left quadrant, and the apoptotic cells were in the right quadrant. As shown in Figure 2E, compared with SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells, SGC7901/DDP + siRNA-CDX2 cells exhibited significantly increased apoptosis index (Figure 2F) ($P < 0.05$).

CDX2 siRNA influenced expression of c-Myc, survivin and cyclin D1

To investigate the mechanism by which CDX2 siRNA induces reversal of MDR in SGC7901/DDP cells, we detected expression levels of some well-known regulators of apoptosis (caspase-9, caspase-3, p53, bax, bcl-2, Survivin, and c-Myc), and an important cell cycle molecule (cyclin D1) by semiquantitative RT-PCR and Western blotting (Figure 3). The mRNA and protein expression level of c-Myc, survivin and cyclin D1 in SGC7901/DDP + siRNA-CDX2 cells was lower than that in SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells ($P < 0.05$). However, no significant difference in the expression level of caspase-9, caspase-3, p53, bax and bcl-2 was found in the cell models (data not shown).

Effect of CDX2 siRNA on reversing MDR of human gastric cancer in vivo

We examined the effect of CDX2 siRNA on growth of SGC7901/DDP cells *in vivo*, by implanting LV-siRNA-CDX2 and LV-siRNA-NC subcutaneously into the flanks of BALB/c nude mice. We detected expression levels of CDX2 *in vivo* by semi-quantitative RT-PCR and Western blotting. The mRNA (Figure 4A) and protein (Figure 4B) expression level of CDX2 in SGC7901/DDP + siRNA-CDX2 group was lower than that in SGC7901/DDP + siRNA-NC group and SGC7901/DDP group. Three weeks after implantation, TV in the SGC7901/DDP + siRNA-CDX2 group was significantly less than in the SGC7901/DDP and SGC7901/DDP + siRNA-NC groups ($P < 0.05$) (Figure 4D). The percentage of apoptotic tumor cells in SGC7901/DDP + siRNA-CDX2 cells was 7.2% ± 1.3%, which was more than the 3.1% ± 1.2% in SGC7901/DDP + siRNA-NC cells and 3.1% ± 1.4% in SGC7901/DDP cells, as determined by the HE staining and TUNEL assay (Figure 4C).

DISCUSSION

The development of MDR to cancer chemotherapy is a major obstacle to the effective treatment of gastric cancer[14]. However, the mechanism of MDR remains obscure. P-gp was the first molecule identified as a modulator of MDR. After that, various other molecules were

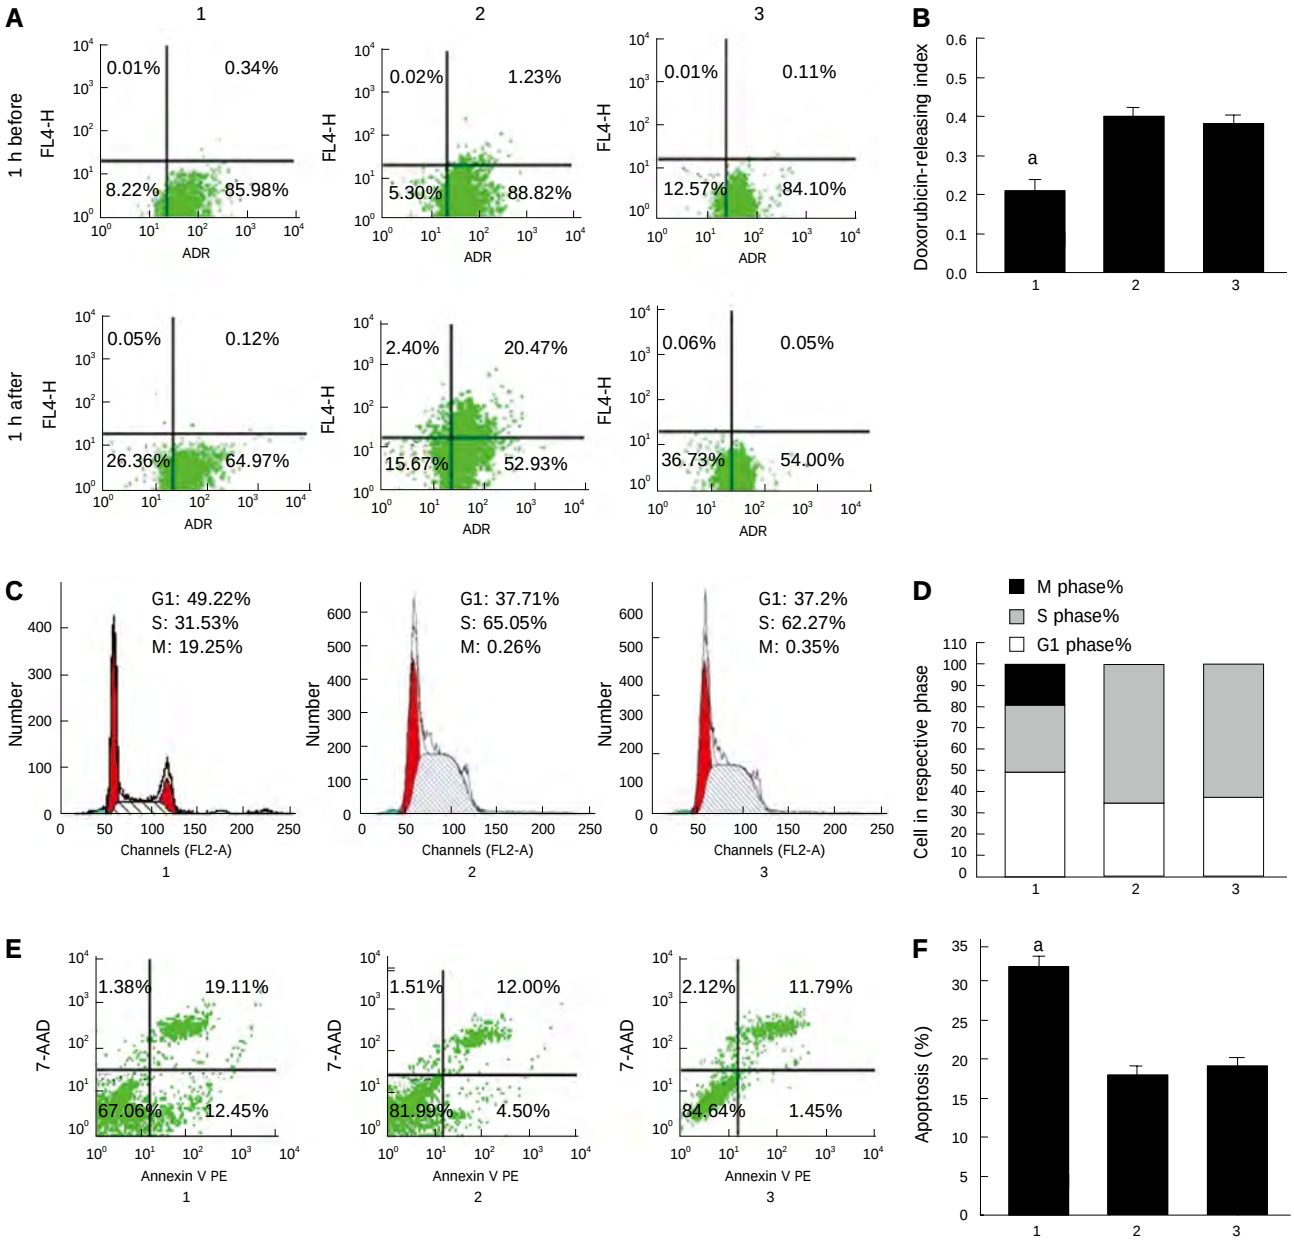

Figure 2 Effect of downregulation of CDX2 on cell pump rate of doxorubicin, cell cycle, and apoptotic rate in SGC7901/DDP cells after RNA interference. shown to be involved, including transporters that eject anticancer drugs from cells, such as MDR-associated protein (MRP)[15], genes regulating apoptosis, such as p53[16], PKC[17], and Bcl-2 family[18]. Recently, the distribution of drugs in cancer cells was also considered to play a part in MDR[19]. According to our previous report, some classic molecules are involved in MDR, including caspase-3 (apoptosis-related cysteine peptidase) and caspase-9 (an initiator caspase, has been linked to the mitochondrial death pathway)[20,21], but there may be other mechanisms that control MDR of gastric cancer cells[12].

The CDX2 homeobox gene, which is homologous to the *Drosophila* gene caudal, has an essential role during early development[2], an important study by Ma *et al*[22] demonstrated that short interfering RNA-mediated knockdown of CDX2 resulted in reduced apical sodium-dependent bile acid transporter (ASBT) mRNA expression in intestinal cells. Overexpression of CDX2 in human colon cancer cells induces a less malignant phenotype, inhibiting proliferation, invasion, and migration[23]. Furthermore, CDX2 has a crucial role in the regulation of MDR1 gene expression in drug resistance[10]. However, the precise molecular mechanism of CDX2 in reversing MDR in gastric cancer cells is still poorly characterized. The present study is believed to be the first to correlate CDX2 with MDR of gastric cancer cells, and we found

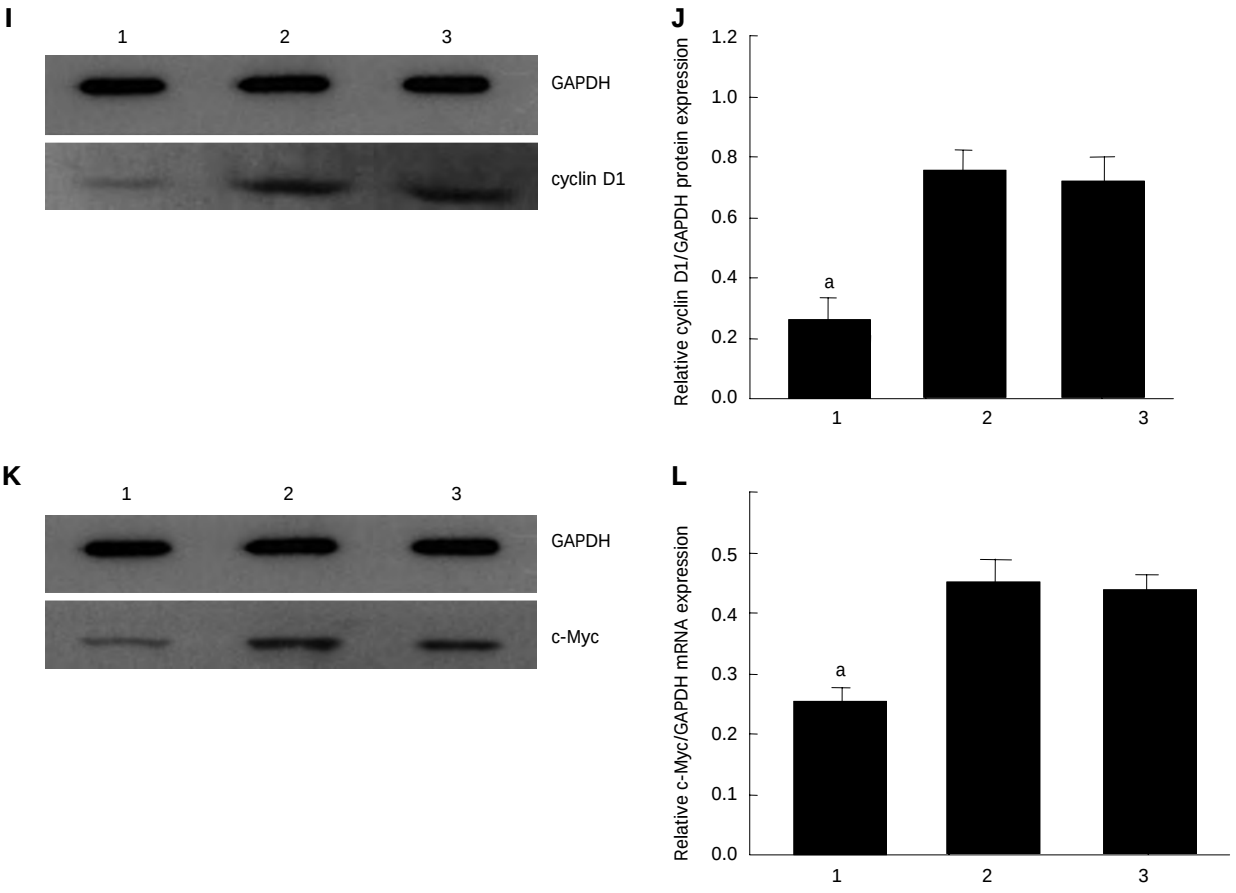

Figure 3 RNA interference-mediated inhibition of CDX2 decreased survivin, cyclin D1 and c-Myc mRNA and protein expression. mRNA expression levels of survivin (A), cyclin D1 (C), and c-Myc (E) were determined by semiquantitative reverse-transcriptase polymerase chain reaction. Protein expression levels of survivin (G), cyclin D1 (I), and c-Myc (K) were determined by western blotting. mRNA results were expressed as the ratio of survivin (B), cyclin D1 (D), and c-Myc (F) to glyceraldehyde 3-phosphate dehydrogenase (GAPDH). Western blotting results are expressed as the ratio of optical density of survivin (H), cyclin D1 (J) and c-Myc (L) bands to GAPDH bands. All values are mean ± SE. $^{a}P < 0.05$ for SGC7901/DDP + small interfering RNA (siRNA)-CDX2 cells *vs* SGC7901/DDP + siRNA-NC cells and SGC7901/DDP cells. that expression of CDX2 regulated drug efflux pumping, the cell cycle, and apoptosis. The multiple changes conferred by CDX2 on gastric cancer cells are not surprising, given the involvement of CDX2 in a wide range of biochemical reactions, and CDX2 is a homeobox transcription factor that contributes to reversing MDR.

Our study indicated that CDX2 siRNA led to marked downregulation of CDX2 mRNA and protein expression in SGC7901/DDP cells, caused cell cycle arrest in the G0/G1 phase, and induced apoptosis. Furthermore, downregulation of CDX2 in SGC7901/DDP cells enhanced sensitivity to cisplatin, 5-fluorouracil (P-gp-nonrelated drug), and doxorubicin (P-gp-related drug). The ability to pump doxorubicin was reduced significantly, moreover, a strong antitumor effect of CDX2 siRNA *in vivo* was observed, as tumor growth was suppressed and tumor apoptosis was increased in nude mice when CDX2 mRNA and protein were downregulated. These findings suggest that CDX2 siRNA reversed MDR of human gastric cancer cells.

Doxorubicin is a common substrate for P-gp, but SGC7901/DDP + siRNA-CDX2 cells also exhibited significantly decreased IC50 values for cisplatin and 5-fluorouracil. It should be noted that P-gp-mediated drug efflux was not the only mechanism involved in drug resistance. Previous studies have shown that the effect of P-gp on drug resistance is closely related to cell cycle distribution and apoptosis[24-26]. Cyclin D1 is a regulatory kinase of cell cycle distribution. Previously, overexpression of cyclin D1 in a human fibrosarcoma cell line has been shown to confer resistance to methotrexate[27], which suggests that cyclin D1 overexpression can contribute to the resistance of cancer cells to chemotherapeutic agents. Conversely, suppression of cyclin D1 levels has been shown to potentiate the response of human pancreatic cancer cells to cisplatinum, transfection and multidrug selection experiments have demonstrated that resistance to mitoxantrone can be associated with MDR1 and/or multidrug resistance-associated protein (MRP) overexpression[28]. Indeed, subsequent analysis of MDR1 and MRP expression has revealed that cyclin D1 suppression decreases MDR1 and MRP mRNA levels[24]. Besides regulation of cell cycle distribution, apoptosis is a common pathway that finally mediates the killing effects of anticancer drugs, which is an important cause of MDR. Mitochondria are known to play an active role in the apop-

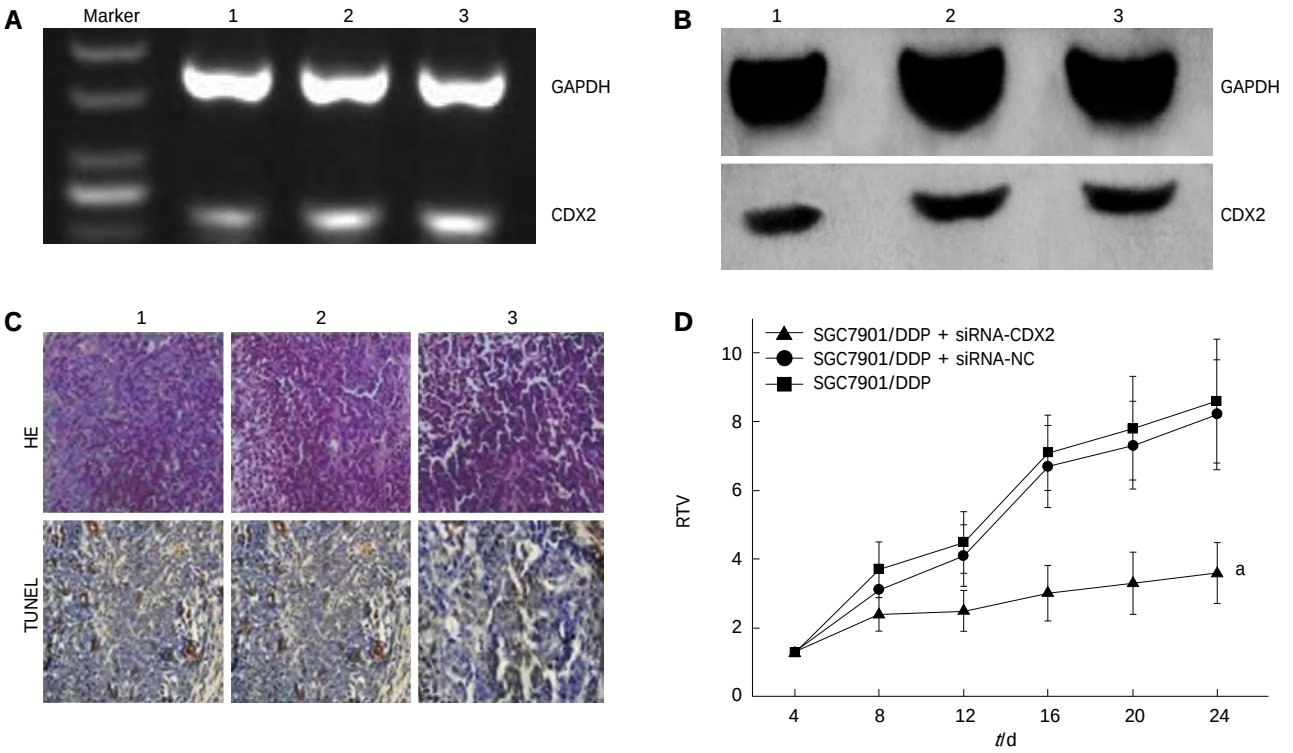

Figure 4 Effect of RNA interference-mediated inhibition of CDX2 mRNA and protein expression and downregulation of CDX2 on apoptosis *in vivo*. totic process by various mechanisms, including release of caspase activators, disruption of electron transport and energy metabolism, and production of reactive oxygen species[29]. Survivin induces mitochondrial fragmentation and reduces mitochondrial respiration[30]. These data indicate that survivin is closely related to apoptosis. Therefore, in the present study, inhibition of CDX2 expression may have decreased cyclin D1 and survivin expression directly or indirectly, which was responsible for reversal of MDR in human gastric cancer cells *in vitro* and *in vivo*. Further studies are needed to confirm our results.

The term MDR was originally coined to define a condition enabling a disease-causing organism or cancer cells to resist distinct drugs or chemicals with a wide variety of structure and function, targeted at eradicating the organism/cancer cell. Much routine chemotherapy cannot achieve good therapeutic effects because of MDR. It is important to find a new way to reverse MDR. In this study, we showed that CDX2 plays a critical role in reversing MDR. Downregulation of CDX2 using RNAi reversed the progression of MDR in gastric cancer SGC7901/DDP cells *in vitro* and *in vivo*. In conclusion, this study lays the foundation for treatment of MDR in gastric cancer through manipulation of CDX2 expression.

COMMENTS

Background

The term multidrug resistance (MDR) was originally coined to define a condition enabling a disease-causing organism or cancer cells to resist distinct drugs or chemicals with a wide variety of structure and function, targeted at eradicating the organism/cancer cell. Much routine chemotherapy cannot achieve good therapeutic effects because of MDR. It is believed that MDR is the key factor in the failure of gastric cancer chemotherapy. It is important to find a new way to reverse MDR. The caudal-type homeobox gene, CDX2, plays an important role in intestinal metaplasia, and is a precursor of intestinal-type gastric carcinoma. However, the effect of CDX2 in reversing MDR is still not clear.

Research frontiers

CDX2 has a crucial role in the regulation of *MDR1* gene expression in drug resistance, but P-glycoprotein (P-gp)-mediated drug efflux is not the only mechanism involved in drug resistance. The CDX2 research hotspot is how it affects the reversal of MDR by other pathways.

Innovations and breakthroughs

This study is believed to be the first to demonstrate that downregulation of CDX2 causes cell cycle arrest in the G0/G1 phase, and induces apoptosis. Furthermore, downregulation of CDX2 in SGC7901/DDP cells enhances the sensitivity of SGC7901/DDP cells to cisplatin, 5-fluorouracil (P-gp-non-related drug), and doxorubicin (P-gp-related drug). The ability to pump doxorubicin was reduced significantly, moreover, a strong antitumor effect of CDX2 siRNA *in vivo* was observed, as tumor growth was suppressed and tumor apoptosis was increased in nude mice when CDX2 mRNA and protein were downregulated. CDX2 siRNA also decreased c-Myc, survivin and cyclin D1 expression as determined by semiquantitative reverse-transcriptase polymerase chain reaction and Western blotting.

Applications

This study lays the foundation for treatment of MDR in gastric cancer through manipulation of CDX2 expression.

Terminology

The transcription factor, CDX2, is a member of the caudal-related homeobox gene family, and is mainly expressed in the intestine. It is also known to be a key factor in reversing MDR by manipulation of MDR1 expression.

Peer review

This is a well-written manuscript and most of the experiments were properly controlled and clearly presented.

Abstract

AIM: To assess the aetiological role of *Helicobacter pylori* (*H. pylori*) infection in adult patients with iron-refractory or iron-dependent anaemia of previously unknown origin.

METHODS: Consecutive patients with chronic iron-deficient anaemia (IDA) with *H. pylori* infection and a negative standard work-up were prospectively evaluated. All of them had either iron refractoriness or iron dependency. Response to *H. pylori* eradication was assessed at 6 and 12 mo from follow-up. *H. pylori* infection was considered to be the cause of the anaemia when a complete anaemia resolution without iron supplements was observed after eradication.

RESULTS: *H. pylori* was eradicated in 88 of the 89 patients. In the non-eradicated patient the four eradicating regimens failed. There were violations of protocol in 4 patients, for whom it was not possible to ascertain the cause of the anaemia. Thus, 84 *H. pylori* eradicated patients (10 men; 74 women) were available to assess the effect of eradication on IDA. *H. pylori* infection was considered to be the aetiology of IDA in 32 patients (38.1%; 95%CI: 28.4%-48.8%). This was more frequent in men/postmenopausal women than in premenopausal women (75% *vs* 23.3%; $P < 0.0001$) with an OR of 9.8 (95%CI: 3.3-29.6). In these patients, anaemia resolution occurred in the first follow-up visit at 6 mo, and no anaemia or iron deficiency relapse was observed after a mean follow-up of 21 ± 2 mo.

CONCLUSION: Gastric *H. pylori* infection is a frequent cause of iron-refractory or iron-dependent anaemia of previously unknown origin in adult patients.

Key words: *Helicobacter pylori*; Iron-deficiency anaemia; Iron refractoriness; Gluten-sensitive enteropathy; Menopause

Core tip: Data on the effect of *Helicobacter pylori* (*H. pylori*) eradication on adult patients with iron-refractory or iron-dependent anaemia of previously unknown origin are scarce, and thus the frequency of *H. pylori* infection as the cause of anaemia in that setting is unknown. Resolution of iron-deficient anaemia (IDA)

was observed in 32 out of the 84 *H. pylori* eradicated patients (38.1%). In all of them there was no relapse after a mean follow-up of 21 ± 2 mo. Thus, *H. pylori* infection was considered the aetiology of IDA in these cases. *H. pylori* infection as the aetiology of IDA was greater in men *plus* postmenopausal women than in premenopausal women (75.0% *vs* 23.3%, $P < 0.0001$).

INTRODUCTION

Iron-deficiency anaemia (IDA) occurs in 2%-5% of adult men and postmenopausal women in the developed world, with blood loss from the gastrointestinal tract being the most common cause[1-4]. In addition, IDA also occurs in 5%-12% of otherwise healthy premenopausal women[5]. IDA is a common cause of referral to gastroenterologists (4%-13% of referrals)[3], and for 5%-10% of patients with IDA without gastrointestinal bleeding the cause of the condition remains obscure in spite of extensive examination[6,7].

Helicobacter pylori (*H. pylori*) colonisation in gastric mucosa may impair iron uptake and increase iron loss, potentially leading to IDA. The speculative mechanisms by which *H. pylori* may produce IDA have recently been reviewed[8-10]. Four meta-analyses to assess the effect of *H. pylori* eradication combined with ferrous supplementation on the treatment of IDA have been published[11-14]. The conclusions suggest that *H. pylori* eradication therapy improves iron absorption, since *H. pylori* eradication combined with iron administration was more effective than iron administration alone for the treatment of IDA. However, there was no follow-up of patients after oral iron therapy was completed, and relapse of IDA after *H. pylori* eradication was not evaluated; thus, it was not established whether *H. pylori* infection was the cause of IDA. Most of the intervention trials have been performed in geographical areas where both IDA and *H. pylori* infection are highly prevalent, and where the aetiology of IDA may be multifactorial (malnutrition, vitamin deficiencies, chronic parasitic infections, malaria). In western countries there are only some uncontrolled intervention studies showing recovery from anaemia after *H. pylori* eradication[15,16]. In light of the above-mentioned studies, *H. pylori* infection has been considered as a risk factor for IDA. The British Society of Gastroenterology recommends eradication of *H. pylori* infection in patients with IDA and normal colonoscopy and oesophagogastroduodenoscopy (Grade of recommendation, C)[1], and the Maastricht guidelines suggest to eradicate *H. pylori* in patients with IDA (Grade of recommendation, A)[17]. However, data on the effect of *H. pylori* eradication on adult patients with iron-refractory or iron-dependent IDA of previously unknown origin are scarce, and thus the frequency of *H. pylori* infection as the cause of IDA in that setting is unknown. Therefore, the aim of the present study was to assess the aetiological role of *H. pylori* infection in such patients, in a geographical background where concomitant causes of IDA are unusual.

MATERIALS AND METHODS

Patients

Consecutive patients with unexplained chronic IDA or isolated iron deficiency (ID) referred to the Gastroenterology Department from January 2007 to December 2010 were prospectively evaluated.

Patients were included if they were older than 18 years of age with all the following: (1) chronic IDA defined as haemoglobin < 10.5 g/dL in women and < 11.5 g/dL in men, and serum ferritin < 13 μg/L or ID defined as only serum ferritin < 13 μg/L; (2) gastric *H. pylori* infection; (3) iron refractoriness or iron dependency (see below for definition); (4) negative faecal immunochemical tests for occult blood (at least three negative samples); (5) negative coeliac serology [both serum immunoglobulin A (IgA)-antiendomysial an IgA-human anti-tissue transglutaminase antibodies], although patients diagnosed with coeliac disease in whom IDA persisted in spite of being on a strict gluten-free diet with negative coeliac serology and no villous atrophy were included; (6) normal gastroscopy and full colonoscopy; (7) normal physical examination, blood analysis (including routine blood biochemistry, C reactive protein, folate and vitamin B_{12} levels), and urinalysis; and (8) normal gynaecological examination.

Patients with the following conditions were excluded from the study: (1) frequent (three times a week or more) use of non-steroidal anti-inflammatory drugs or salicylates during the previous 6 mo; (2) use of dicumarinics; (3) other conditions which cause anaemia or interfere with erythropoiesis including malignancy, haematological diseases, connective tissue disease, chronic diseases such as chronic renal failure, chronic liver disease, severe cardiac and respiratory disease, and previous gastrointestinal surgery; (4) pregnancy or lactation; (5) history of alcoholism or drug addiction; (6) heavy menstrual flow (cycles > 5 d, associated with passage of clots after the three first days) and/or metrorrhagia; (7) obvious blood loss (melena, haematochezia, haematuria, recurrent epistaxis); (8) adherence to vegetarian or iron-deficient diet; and (9) expected lack of cooperation.

Capsule endoscopy was not routinely performed since one inclusion criterion was that repeated faecal immunochemical tests for occult blood were negative. In individual cases (12 patients), it was performed by the decision of the physician at charge, yielding in all cases normal results.

All patients had received iron supplements and all of them fulfilled the criteria of either iron refractoriness or iron dependency. Iron refractoriness was defined as an inappropriate increase in haemoglobin levels (< 2 g/dL) after completion of a 5000 mg dosing cycle of ingested elemental iron over one month or longer[18]. Iron dependency was defined as the patient's requiring daily oral iron supplementation (ferrous sulphate, 100-200 mg daily of elemental iron) to maintain adequate haemoglobin levels.

Study design

The following tests were prospectively performed in all included patients: (1) two endoscopic biopsies from both gastric body and antrum, and four biopsies from distal duodenum; (2) histological examination of antral biopsies and/or ^{13}C-urea breath test to assess *H. pylori* infection; and (3) human leukocyte antigen (HLA)-DQ2 and HLA-DQ8 haplotypes of predisposition to coeliac disease.

In all patients *H. pylori* was eradicated using a standard 7-d triple regimen with omeprazole 20 mg *bid*, amoxicillin 1 g *bid*, and clarithromycin 500 mg *bid*. Two-week quadruple regimens were used as a rescue therapy for patients failing the first-line eradication therapy, and in some cases a levofloxacin-based third-line rescue therapy was used. *H. pylori* eradication was evaluated by histological examination of antral biopsies and/or ^{13}C-urea breath test. Analytical response to *H. pylori* eradication was assessed at 6 and 12 mo of follow-up. In cases with associated lymphocytic duodenitis (LD), histological follow-up was also performed at 6 and 12 mo.

Final diagnosis

H. pylori infection was considered to be the cause of IDA or ID when after eradication a complete response (*i.e.*, IDA or ID recovery, with normal serum ferritin levels), without iron supplements, was observed at 12 mo of follow-up. A diagnosis of gluten-sensitive enteropathy was performed in patients with LD and positive coeliac genetics (HLA-DQ2 and/or HLA-DQ8) without response after achieving *H. pylori* eradication, when there was a sustained (at 12 mo follow-up) complete clinical and histological response on a strict gluten-free diet[19]. The cause of either IDA or ID was considered to be unknown in patients without response to both *H. pylori* eradication and gluten-free diet (when indicated).

Histological studies

Four endoscopic biopsies from the 2nd-3rd portions of the duodenum and two biopsies from both body and antrum were obtained in the index endoscopy. *H. pylori* infection was investigated in gastric antral mucosal samples by standard histopathological assessment[20]. Duodenal samples were processed using haematoxylin/eosin staining and CD3 immunophenotyping, and these were blindly evaluated by an expert gastrointestinal pathologist (Salas A). LD was defined as 25 or more intraepithelial lymphocytes per 100 epithelial nuclei and normal villous architecture, as suggested in recent literature[21]; the cut-off value was validated in our laboratory[19]. This cut-off value was also selected to define LD due to gluten-sensitive enteropathy, which corresponds to the Marsh 1 type lesion of the coeliac disease spectrum[21].

Helicobacter pylori status

Patients were classified as having *H. pylori* infection when either histology or ^{13}C-urea breath test was positive. ^{13}C-urea breath test was performed on those patients with negative histology who either were taking proton-pump inhibitors or had antral intestinal metaplasia at the index endoscopy, as previously described[20]. In the case of proton-pump inhibitors, the breath test was performed 4 wk after discontinuation.

Ethics

The protocol was approved by the Ethics Committee of the Hospital Universitari Mútua Terrassa, and all participants provided informed consent.

Statistical analysis

Results are expressed as mean ± SE and as percentages plus their 95%CI. Chi-square statistics were used to assess significant associations between qualitative variables. The OR and 95%CI of the significant associations were computed.

RESULTS

One hundred thirty-six consecutive adult patients fulfilled the inclusion criteria during the study period. Twenty-two were excluded due to presence of exclusion criteria, 7 patients had previously unrecognised non-steroidal anti-inflammatory drug intake, and 15 had other causes of anaemia (1 infection by intestinal parasites, 2 recurrent rectal bleeding attributed to haemorrhoids, 1 chronic renal failure, 2 small bowel Crohn's disease, 1 gastrinoma, and 8 pernicious anaemia). Twenty-five additional patients (18.4%) were lost in follow-up before achieving a definite diagnosis of their anaemia. Thus, 89 patients were finally included in the study (10 men; 79 women; mean age: men, 54.0 ± 15.8 years; premenopausal women, 44.0 ± 8.6 years; postmenopausal women, 59.0 ± 9.8 years). There were no significant differences in demographic data or frequency of menopause, *H. pylori*-related chronic gastritis, associated enteropathy (LD) or coeliac genetics between included patients and those lost in follow-up (Table 1).

H. pylori was eradicated in 88 of the 89 patients. In the non-eradicated patient the four eradicating regimens failed. There were violations of protocol in 4 patients, for whom it was not possible to ascertain the cause of the anaemia. Thus, 84 *H. pylori*-eradicated patients were available to assess the effect of eradication on IDA.

Resolution of IDA or ID was observed in 32 out of the 84 *H. pylori*-eradicated patients (38.1%; 95%CI: 28.4-48.8). In all of them, IDA or ID recovery was observed at the 6-month follow-up visit after *H. pylori*-erad-

Table 1 Comparison of demographic, clinical, and biological data between included patients and those lost in follow-up

	Included patients (n = 89)	Loss of follow-up patients (n = 25)
Age (yr), mean ± SE	46.0 ± 11.8	41.0 ± 14.2
Sex (M/F)	10/79	4/21
Postmenopausal women	17.90%	16.00%
Chronic antral gastritis	81.80%	78.30%
Chronic body gastritis	83.00%	78.30%
Associated enteropathy	59.50%	60.00%
HLA-DQ2 and/or DQ8+	48.30%	40.00%

There were no significant differences in any parameter. HLA: Human leukocyte antigen; M/F: Male/female.

ication, and there was no relapse after a mean follow-up of 21 ± 2 mo. Therefore, *H. pylori* infection was considered the aetiology of IDA in these cases. Frequency of *H. pylori* infection as the aetiology of IDA was greater in men (8 of 10, 80%) *plus* postmenopausal women (10 of 14, 71.4%) than in premenopausal women (14 of 60, 23.3%) (75.0% *vs* 23.3%, $P < 0.0001$) with an OR of 9.8 (95%CI: 3.3-29.6). There were no differences in the frequency of *H. pylori* infection as the cause of IDA between patients with and those without associated enteropathy (18 of 49, 36.7%; with LD and 14 of 35, 40%, without LD).

In addition, a gluten-free diet was offered to 13 patients in whom IDA persisted after *H. pylori* eradication. Gluten-sensitive enteropathy was the aetiology of IDA in 4 (men, 1 of 10, 10%; premenopausal women, 1 of 14, 7.1%; postmenopausal women, 2 of 60, 3.3%) of the 84 *H. pylori* eradicated patients (4.8%; 95%CI: 1.8-11.6). In all of them LD was detected, and a clinical (IDA recovery without iron supplementation) and histological remission after a gluten-free diet was observed. There was no relapse of IDA or ID after the 12 mo of follow-up.

The final diagnosis of IDA in the remaining 48 patients, who were mainly premenopausal women, was unknown. Despite *H. pylori* eradication there was a need to maintain iron supplementation during follow-up, with persistent iron-dependent IDA. A relation with menstrual blood loss was observed in 30 of the premenopausal women since anaemia recovered after either entering menopause or starting hormonal contraceptive therapy. As previously mentioned, none of them had heavy menstrual blood loss at inclusion, and for all of them the gynaecologic examination had been normal.

DISCUSSION

Results of the present study suggest that *H. pylori* infection is a frequent cause of IDA in adult patients with iron refractoriness or iron dependency in whom the standard diagnostic work-up is negative. In 38% of such patients *H. pylori* eradication was associated with both IDA resolution without the need for more iron supplementation and an absence of IDA relapse after nearly two years mean follow-up. These observations argue in favour of causality of *H. pylori* infection. In addition, the efficacy of *H. pylori* eradication to recover from IDA in such patients was compared between men *plus* postmenopausal women and premenopausal women. There was IDA recovery in 75% and 23% of them, respectively, with highly significant differences. In fact, the OR of *H. pylori* infection as the cause of IDA was almost 10 times higher in the first group than the second.

We have to take into account that the *H. pylori* re-infection rate after cure in our geographical area is low, around 1% patient-year; this implies that the present results might not be extrapolated to other regions with higher re-infection rates.

Results of the present study on premenopausal women are in disagreement with previous results of Annibale *et al*[15], since they showed recovery from anaemia at 12 mo of follow-up after *H. pylori* eradication in 92% of patients, mainly premenopausal women. The discrepancies revolve around the definition of response. In our study, response to *H. pylori* eradication was defined as anaemia recovery with normalisation of serum ferritin levels. In Annibale's study, however, ferritin levels returned to normal in only 17% of the patients despite recovery from anaemia, which is a figure similar to that of the 23% obtained in our study. Taking into account the meta-analysis data mentioned in the introduction[11-14], and the results of the present study in men and postmenopausal women, *H. pylori* infection may also be a contributing factor to IDA in premenopausal women, and *H. pylori* eradication is indicated to improve iron absorption. In this sense, it would be of interest to assess whether iron requirements change after *H. pylori* eradication in these patients. Regrettably, iron requirements were not sufficiently well recorded in the present study to allow for this evaluation.

Other factors may contribute to IDA in otherwise healthy premenopausal women such as menstrual loss, increased iron demands on pregnancy and breast feeding, and dietary deficiency[22]. Hormonal contraceptive therapy may reduce menstrual blood loss by approximately 50%, even in women with average or slightly above-average blood loss[23]. In the present study, this type of therapy was effective for IDA recovery in those premenopausal women in whom increased iron requirements persisted after *H. pylori* eradication.

H. pylori infection may be a cause of LD, which may disappear after eradication of the infection[19,24]. However, whether *H. pylori*-infected patients with LD are more prone to developing IDA is unknown. The present study shows that the frequency of *H. pylori* infection as the final diagnosis of IDA is similar for patients with and without associated enteropathy. Therefore, these data argue against a pathophysiological role for this mild enteropathy in the development of IDA in *H. pylori*-infected patients.

In 4.5% of the included patients the final diagnosis was gluten-sensitive enteropathy. These results agree with

a previous study by our group showing that a subgroup of patients with IDA of previously unknown origin and positive coeliac genetics presented a gluten-sensitive mild enteropathy with negative coeliac serology[25].

In conclusion, the results of the present study show that *H. pylori* infection is a frequent cause of IDA in men and postmenopausal women with either iron refractoriness or iron dependency, in whom other causes of IDA have been previously ruled out. *H. pylori* eradication therapy produces long-term resolution of IDA in such patients. Also, *H. pylori* infection may be a contributing factor to IDA in otherwise healthy premenopausal women without heavy menstrual blood loss, and it is the aetiology of IDA in almost 25% of them.

COMMENTS

Background

Iron deficiency anaemia (IDA) is a common cause of referral to gastroenterologists (4%-13% of referrals), and for 5%-10% of patients with IDA without gastrointestinal bleeding the cause of the condition remains obscure in spite of extensive examination. Previous data suggest that *Helicobacter pylori* (*H. pylori*) eradication therapy improves iron absorption, since *H. pylori* eradication combined with iron administration was more effective than iron administration alone for the treatment of IDA. The Maastricht guidelines suggest to eradicate *H. pylori* in all patients with IDA.

Research frontiers

H. pylori eradication may improve iron absorption, but how often is gastric *H. pylori* infection the cause of IDA? Data on the effect of *H. pylori* eradication on adult patients with iron-refractory or iron-dependent anaemia of previously unknown origin are scarce, and thus, the frequency of *H. pylori* infection as the cause of IDA in that setting is unknown.

Innovations and breakthroughs

This study is performed in a large prospective series of consecutive patients using very strict inclusion criteria, with a long follow-up after *H. pylori* cure. Resolution of anaemia was defined as both haemoglobin and iron stores normalization, which was long-term maintained without requiring iron supplements. Frequency of IDA resolution was compared between men/post-menopausal women and pre-menopausal women.

Applications

Gastric *H. pylori* infection may be a frequent cause of iron-refractory or iron-dependent anaemia of previous unknown origin in adult patients, mainly in men and post-menopausal women. In these patients, *H. pylori* infection eradication produced the cure of IDA. In addition, *H. pylori* infection may be a contributing factor to IDA in otherwise healthy premenopausal women without heavy menstrual blood loss, being the aetiology of IDA in almost a 25% of them.

Peer review

The authors in this article have focused on the possible role of *H. pylori* infection in causation of IDA. They have stated that 38% of the patients may have the anaemia duo to the infection by *H. pylori*.

Abstract

AIM: To investigate whether single endoscopist-performed percutaneous endoscopic gastrostomy (PEG) is safe and to compare the complications of PEG with those reported in the literature.

METHODS: Patients who underwent PEG placement between June 2001 and August 2011 at the Baskent University Alanya Teaching and Research Center were evaluated retrospectively. Patients whose PEG was placed for the first time by a single endoscopist were enrolled in the study. PEG was performed using the pull method. All of the patients were evaluated for their indications for PEG, major and minor complications resulting from PEG, nutritional status, C-reactive protein (CRP) levels and the use of antibiotic treatment or antibiotic prophylaxis prior to PEG. Comorbidities, rates, time and reasons for mortality were also evaluated. The reasons for PEG removal and PEG duration were also investigated.

RESULTS: Sixty-two patients underwent the PEG procedure for the first time during this study. Eight patients who underwent PEG placement by 2 endoscopists were not enrolled in the study. A total of 54 patients were investigated. The patients' mean age was 69.9 years. The most common indication for PEG was cerebral infarct, which occurred in approximately two-thirds of the patients. The mean albumin level was 3.04 ± 0.7 g/dL, and 76.2% of the patients' albumin levels were below the normal values. The mean CRP level was high in 90.6% of patients prior to the procedure. Approximately two-thirds of the patients received antibiotics for either prophylaxis or treatment for infections prior to the PEG procedure. Mortality was not related to the procedure in any of the patients. Buried bumper syndrome was the only major complication, and it occurred in the third year. In such case, the PEG was removed and a new PEG tube was placed *via* surgery. Eight patients (15.1%) experienced minor complications, 6 (11.1%) of which were wound infections. All wound infections except one recovered with antibiotic treatment. Two patients had bleeding from the PEG site, one was resolved with primary suturing and the other with fresh frozen plasma transfusion.

CONCLUSION: The incidence of major and minor complications is in keeping with literature. This finding may be noteworthy, especially in developing countries.

INTRODUCTION

Percutaneous endoscopic gastrostomy (PEG) has been used widely for the enteral feeding of patients who have a functioning gastrointestinal tract but are unable to consume adequate nutrition orally. Patients with cerebro-

vascular diseases, Parkinson's disease, dementia and head injury and those suffering from head and neck cancer and upper digestive tract cancer are candidates for PEG[1,2]. A PEG tube can be placed using one of four methods: push (Sachs-Vine), pull (Ponsky), introducer (Russell) or versa (t-fastener). The pull and push techniques are preferred because they offer greater safety and efficacy[3,4]. Both minor and major complications may occur during PEG placement. Major complications associated with PEG include peritonitis, gastric perforation, esophageal perforation, gastrocolocutaneous fistula, gastric outlet obstruction, necrotizing fasciitis and buried bumper syndrome. Minor complications include pneumoperitoneum, temporary ileus, hematoma, hemorrhage, wound infection, aspiration, tube dislodgement, gastroesophageal erosion, and gastric ulcer. Other gastrointestinal problems include gas distension, nausea, emesis, constipation and diarrhea[5-7]. In general practice, a PEG is placed by two endoscopists[1,8]. The aim of this study is to evaluate whether single endoscopist-performed PEG is safe and to compare the major and minor complications of PEG with those reported in the literature.

MATERIALS AND METHODS

This study was approved by the Baskent University Institutional Review Board and Ethics Committee (Project No: KA12/150) and supported by the Baskent University Research Fund. Patients who underwent PEG placement between June 2001 and August 2011 at the Baskent University Alanya Teaching and Research Center were evaluated retrospectively. Patients whose PEG was placed for the first time by a single endoscopist were enrolled in the study. For all patients, the PEG was placed using the "pull method". All of the patients were evaluated for indications for PEG, major and minor complications of PEG, nutritional status (prealbumin and albumin levels), C-reactive protein (CRP) levels and antibiotic treatment or antibiotic prophylaxis prior to PEG placement. Comorbidities and the rates, time and reasons for mortality were also evaluated, as were the reasons for PEG removal and the duration of PEG placement. The patients' first-degree relatives were telephoned and interviewed about the complications associated with the PEG and the patients' outcomes.

In our medical center, the standard PEG procedure was performed by single endoscopist. Before the procedure, permission for PEG placement was obtained from the patients' first-degree relative. The procedure was performed in the intensive care unit. Lidocaine spray was administered to the throat for local anesthesia. Midazolam and/or propofol-based sedation were administered intravenously by an anesthesiologist. An upper endoscopy was performed at the beginning of the procedure to exclude severe gastric ulceration, varices and outlet obstruction. After the stomach was insufflated with air through scope, the best location for the PEG placement was determined by pressing a finger slightly against the abdominal wall. The best location was indicated by the clear indentation of the finger observed inside the stomach on the greater curvatures and the illumination of the abdominal wall (Figure 1). The nurse was then given the scope. The sterile-dressed endoscopist cleaned the abdominal wall using a povidone-iodine solution. A one-centimeter incision was made after local anesthetic was applied to the planned location. The nurse filled the patient's stomach with air, and then the endoscopist inserted the needle of the PEG set through abdominal wall into the fully insufflated stomach. After removing the trocar, the endoscopist passed the guide wire through the needle. The nurse then caught the guide wire by the snare which was inserted through the endoscope, the endoscopist then withdrew the guide wire and the endoscope from the patient's mouth. After the endoscopist redressed, attached the guide wire to the PEG tube and the wire was pulled out of the abdominal wall, moving the PEG tube down the esophagus. Control endoscopy was performed to optimally place the PEG tube tip. The PEG tube was turned to locate the appropriate position and was fixed with an external device, leaving a 5-mm distance between the external device and the abdominal wall. This site was cleaned with povidone-iodine solution and dressed with gauze. Enteral feeding began 24 h after the procedure and ensuring that no local wound infection was present. The patient was inspected for erythema, induration and discharge at the PEG site and was assessed using the scoring system developed by Jain *et al*[9] for PEG infection. The patient was also followed by the nutrition team for other complications and nutritional status until discharge. The patient's family was asked to inform the nutrition team about possible complications.

Figure 1 The best location was indicated by the clear indentation of the finger observed inside the stomach and the illumination of the abdominal wall.

Statistical analysis

Statistical analyses were performed using the Statistical Package for the Social Sciences software program (Version 11.0, SPSS Inc., Chicago, IL, United States).

RESULTS

Between June 2001 and August 2011, a total of 82 patients underwent PEG placement. Twenty patients un-

derwent PEG replacement and were excluded from the study. Sixty-two patients underwent the PEG procedure for the first time. Eight of these procedures were performed by 2 endoscopists and were excluded from the study. A total of 54 patients were enrolled in the study. Indications were cerebral infarct in 39 patients (72.2%), cardiac arrest and cerebral ischemia in 4 patients (7.4%), dementia in 7 patients (12.9%), head trauma in 3 patients (5.6%), and cancer in 1 patient (1.9%).

Of the patients whose PEG was placed for the first time, 24 (46.3%) were women and 30 (55.6%) were men. The mean age was 69.9 years. The comorbidities accompanying the patients' primary disease were hypertension, diabetes mellitus, cardiac arrhythmia, coronary artery disease, chronic obstructive pulmonary disease, chronic renal disease, hyperlipidemia and hydrocephaly. The mean albumin levels were 3.04 ± 0.7 g/dL, and 76.2% were below normal values. The mean CRP level was high in 90.6% of patients prior to the procedure (Table 1). In our study, 74.1% of the patients received antibiotics either for prophylaxis or for treatment for infections prior to the PEG procedure. The demographic, clinical and laboratory characteristics of the study subjects are shown in Table 1.

After hospitalization, the mean time past until PEG placement was 22 ± 15.6 d. Buried bumper syndrome was the only one major complication (1.6%), and it occurred in the third year in one patient. In that case, the PEG was removed, and a new PEG tube was placed surgically. Eight patients (15.1%) experienced minor complications, 6 (11.1%) of which were wound infections and 2 of which (3.7%) were bleeding. All wound infections except for 1, which resulted in the removal of the PEG, recovered with antibiotic treatment. Two patients experienced bleeding from the PEG site; one patient was receiving anticoagulation therapy. One case resolved with primary suture, and the other resolved with fresh frozen plasma transfusion.

The first-degree relatives of all of the patients were interviewed by phone. The family members of 6 of the 54 PEG patients could not be reached by telephone, so we do not have long-term follow-up results for these patients. In our study, 1 mo survival was 85.4%, and three-month survival was 41.7%. Twenty-nine patients died during follow-up. The PEG indications for the patients who died were as follows: 14 had cerebral infarct, 3 had head trauma, 2 had cardiac arrest and cerebral ischemia and 1 had cancer. Mortality was not related to PEG placement in any of the patients and mainly depended on the underlying medical problems. The PEG tube was withdrawn in seven patients after they regained swallowing function and in one patient with an uncontrolled local wound infection. As of this writing, eleven patients live with the PEG tube, and 6 of them underwent PEG replacement during follow-up. To date, their relatives have not mentioned any problem related to the PEG in follow-up telephone interviews.

DISCUSSION

Although PEG is usually a safe procedure, certain complications can occur that may cause mortality, especially in patients with comorbidities. In our study, no mortality was associated with the PEG procedure. Buried bumper syndrome was the only major complication, and it occurred in only one patient (1.9%) in the third year of PEG placement. Minor complications occurred in 15.1% of patients, and most of these complications were wound infections.

Survival is an important endpoint in PEG studies. One-month survival is approximately 80% to 90% in most reports[10-12]. Similar to our study, the most frequent indication for PEG insertion was a neurological condition, and several studies reported that stroke was the most common indication[12-14]. In our study, one-month survival was 85.4%, and three-month survival was 41.7%. Buried bumper syndrome is an uncommon but severe complication of the procedure. It usually occurs after four months of PEG placement; however, it has also been reported to occur as late as 7 years after placement[15-17]. Rino *et al*[5] reported this complication as early as 5 d after the procedure. Finocchiaro *et al*[10] reported that one hundred twenty-eight patients were followed long-term for more than 31 d; major complications occurred in 3% of the patients, 2 of whom had buried bumper syndrome. Other major complications included 1 case of aspiration pneumonia and 1 case of subcutaneous abscess. In our study, buried bumper syndrome was the only observed major complication, and it occurred 3 years after the procedure. In the patient with buried bumper syndrome, the PEG tube was successfully surgically removed, and a new PEG tube was placed *via* the same procedure.

As in our study, the most common complication of

PEG was infection, which sometimes results in the removal of the PEG tube[18,19]. In a prospective study in which antibiotic prophylaxis was not given, the rate of peristomal infection was 33.6%[7]. Another study reported wound infections rates of up to 18%, and antibiotic prophylaxis was shown to reduce the rate to nearly 3%[19]. In a prospective, randomized, double-blind, placebo-controlled study by Jain *et al*[9], antibiotic prophylaxis with cefazolin was associated with decreased local PEG site infection. In a meta-analysis by Jafri *et al*[20], antibiotic prophylaxis before the PEG procedure was effective in reducing postprocedure local infection rates. In our study, 74.1% of the patients received antibiotics for either prophylaxis or the treatment of infections prior to the PEG procedure. The local wound infection rate was 11.1%, which is comparable to the rates reported by other studies in the literature. Only one patient developed a PEG site infection that did not resolve with antibiotic therapy; in this case, the PEG was removed. The other minor complication in our study was bleeding from the PEG puncture site, which occurred in two patients. One patient was treated with fresh frozen plasma, and the other was treated *via* primary suture of the abdominal wall vessel. Bleeding from the puncture site occurs as a result of a puncture of the abdominal wall vessel soon after the procedure. It can also be treated by tightening the outside apparatus of the PEG tube. Singh *et al*[21] reported that gastrointestinal bleeding after PEG placement occurred in 3.3% of patients, and bleeding directly attributed to PEG was noted in 0.4%.

Many factors contribute to PEG complications. The PEG tube placement team's experience, the PEG tube size, underlying malignancy and the institution in which the PEG procedure is performed are risk factors for wound infection. Low albumin levels and high CRP levels, age over 65 years and low BMI have also been associated with increased mortality risk[7,8,22-26]. In our study, the mean age was 69.9 years. High CRP levels were found in 41.5% of the patients, and low albumin levels were found in 76.9%. Although these unfavorable parameters existed prior to the procedure, there was no evidence of mortality related to PEG.

The nonrandomized and retrospective nature of our study are its restrictions. A prospective and randomized study might better define the safety and appropriateness of the single endoscopist-performed procedure.

In conclusion, the major and minor complications of single-endoscopist PEG are consistent with those reported in the literature for PEG procedures performed by two endoscopists. This finding may be noteworthy, especially in developing countries.

COMMENTS

Background

Percutaneous endoscopic gastrostomy (PEG) is lifesaving for patients who cannot feed orally for certain reasons. PEG is routinely placed by two endoscopists and carried inherent complications, some of which are life-threatening. It is not known whether PEG placement performed by a single endoscopist is safe or appropriate.

Research frontiers

The complications of PEG are significant. No study has reported the single-endoscopist PEG procedure or its related complications.

Innovations and breakthroughs

Although this study is retrospective and lacks the advantages of prospective and randomized trials, it provides important information indicating that PEG procedures can be applied by a single endoscopist, and the complications encountered are similar to those reported in other studies of PEG performed by two endoscopists.

Applications

Single endoscopist-performed PEG may be an appropriate and safe method for performing the procedure, especially in developing countries.

Peer review

This is a well-written retrospective study about the PEG procedure, which is performed here by a single endoscopist. The results show that it may be safe and appropriate for a single endoscopist to perform PEG. This study may lead to prospective and randomized trials in this field.

Abstract

AIM: To increase satisfaction and diminish anxiety and shame during colonoscopy, we developed novel double pants (NDP) which consist of doubled fabrics with an inner hole. The aim of study was to compare satisfaction, anxiety and shame between NDP and conventional single pants (CSP).

METHODS: Total 160 consecutive examinees were randomly divided into NDP and CSP group. Before colonoscopy, questionnaires identifying state and trait anxiety were completed. After colonoscopy, questionnaires for overall satisfaction (Group Health Association of America 9) and pants-specific satisfaction (5-20), state anxiety (20-80), and shame (6-24) were interviewed.

RESULTS: Pants-specific satisfaction scores regarding willingness to repeat colonoscopy using same pants (3.3 ± 0.8 *vs* 2.1 ± 0.9, $P < 0.001$) and recommendation of same pants to other people (3.3 ± 0.7 *vs* 2.0 ± 1.0, $P < 0.001$) were significantly higher in NDP than CSP groups. State anxiety (33.0 ± 7.0 *vs* 35.4 ± 6.9, $P = 0.028$) and shame (6.6 ± 1.5 *vs* 8.1 ± 3.2, $P = 0.001$) after colonoscopy was lower in NDP group compared with CSP group.

CONCLUSION: The NDP contribute to increase satisfaction and decrease anxiety and shame after colonoscopy.

Key words: Pants; Colonoscopy; Satisfaction; Shame; Anxiety

Core tip: We developed novel double pants (NDP) those are consisted of double fabrics with an inner hole. We compared the satisfaction, anxiety and shame between NDP and conventional single pants (CSP). The examinees in NDP group responded higher pants specific satisfaction, lower state anxiety after colonoscopy and lower shame score compared to those in CSP group. NDP developed in our institute may contribute to increase satisfaction and decrease anxiety and shame after colonoscopy.

Chung SH, Park SJ, Hong JS, Hwang JY, Lee SA, Kim KR, Lee HS, Hong SP, Cheon JH, Kim TI, Kim WH. Comparison of double pants with single pants on satisfaction with colonoscopy. *World J Gastroenterol* 2013; 19(26): 4177-4184 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i26/4177.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i26.4177

INTRODUCTION

Colonoscopy has recently increased in importance worldwide due to its use in screening for colon polyps and colorectal cancer[1]. Even in institutions where conscious sedated colonoscopy is available, colonoscopy without sedation is still performed due to patient comorbidities, the economic burden of sedation, and examinee preference. There is considerable global variation in the prevalence of sedative endoscopy[2]. Most colonoscopies in the United States are performed as sedated procedures, but some countries rarely use sedation in colonoscopy[3,4].

Consideration of the factors affecting satisfaction during colonoscopy has also recently increased because satisfaction may represent an important quality indicator for colonoscopy[5,6]. Moreover, the satisfaction of examinees may be reduced by anxiety, shame, discomfort, and embarrassment[7-11]. Many factors have been identified which determine satisfaction, anxiety, and shame, including the circumstance of the endoscopy room, the clothing for the procedure, endoscopist's skill, and the unfamiliarity of the medical staff with whom examinees interact during the procedure.

During colonoscopy at our center, examinees previously wear conventional single pants (CSP), where there is no hole for insertion of the scope. Examinees remove the CSP to below the level of the buttocks and expose their buttocks area during colonoscopy. Exposing the buttocks during colonoscopy can make examinees feel shameful and anxious, which can diminish their satisfaction with the colonoscopy. To decrease the shame and anxiety induced by exposing the buttocks of examinees wearing CSP during colonoscopy, we developed novel double pants (NDP). Examinees wearing NDP can undergo colonoscopy without taking off the inner pants. The smaller area of the buttock exposed by using NDP could minimize shame and anxiety during colonoscopy. Therefore we hypothesized that NDP could decrease shame and anxiety and increase satisfaction. We aimed to assess satisfaction, anxiety, and shame of patients wearing NDP compared with patients wearing CSP during colonoscopy through a prospective randomized single-center study. We also investigated the factors associated with patient satisfaction, anxiety, and shame during colonoscopy.

MATERIALS AND METHODS

Participants and study design

The study included examinees over 20 years old who agreed to undergo colonoscopy without sedation in the endoscopy unit of Severance Hospital, Yonsei University College of Medicine, Seoul, South Korea from January 2012 and July 2012. All of included people were the patients who visited the clinic for routine health check-up or for evaluating their mild gastrointestinal symptoms. Because we tried to minimize the selection bias of tertiary referral medical center, we excluded the patients who were referred by the physicians of primary or secondary medical center and needed more special care due to their objective medical problems. Before they signed at written informed consent, the nurse in outpatient clinic explained the purpose of the study. They got the information about not only the purpose of the study, but also the study design, the types of pants, the possible adverse events of procedure, and the contents of interview. Examinees under 20 years of age, those who had undergone colonoscopy within the past three years, those who were treated with an emergent colonoscopic procedure, those with a history of bowel resection surgery, inflammatory bowel disease (IBD), cancer, colostomy, ileostomy, psychotic disease including depression, anxiety disorder, or obsessive compulsive disorder, women who were pregnant or lactating, illiterate patients, foreigners, or examinees with American Society of Anesthesiologists (ASA) Scores of ⩾ 3 were excluded. We used our preliminary survey data to perform a power calculation due to the lack of the prior published reports to guide this analysis. We calculated that a sample size of 80 participants was sufficient to detect an effect value of 0.5 (mean difference/common SD) at a significance level of 0.05% (two-sided) with 80% power and 20% drop-out rate. A total of 185 colonoscopy examinees were enrolled in this study between February 2012 and July 2012. Eight examinees were excluded because of colon cancer found during the colonoscopy, ten examinees were excluded because of psychologic disorder, three examinees were excluded because of a history of bowel resection, and four examinees were excluded because of ASA scores ⩾ 3, as shown in Figure 1. Finally a total of 160 consecutive examinees were randomly divided into NDP and CSP groups. Participants in this study were randomly assigned to a "CSP group" or a "NDP group" using a permuted four-block randomization method. Biostatistician made permuted four-block randomization table and calculated the numbers of participants. All random code was contained in a closed box. The nurse in outpatient clinic enrolled the examinees. Before colonoscopy, participants, outcome assessors, and care providers (endoscopists and nurses) were blinded to assignment to

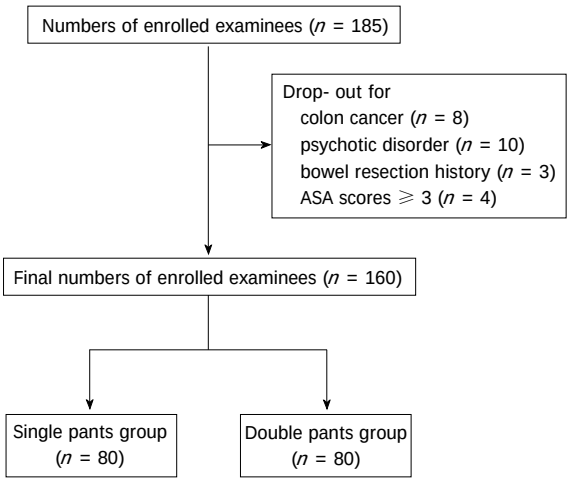

Figure 1 Consort diagram. ASA: American Society of Anesthesiologists.

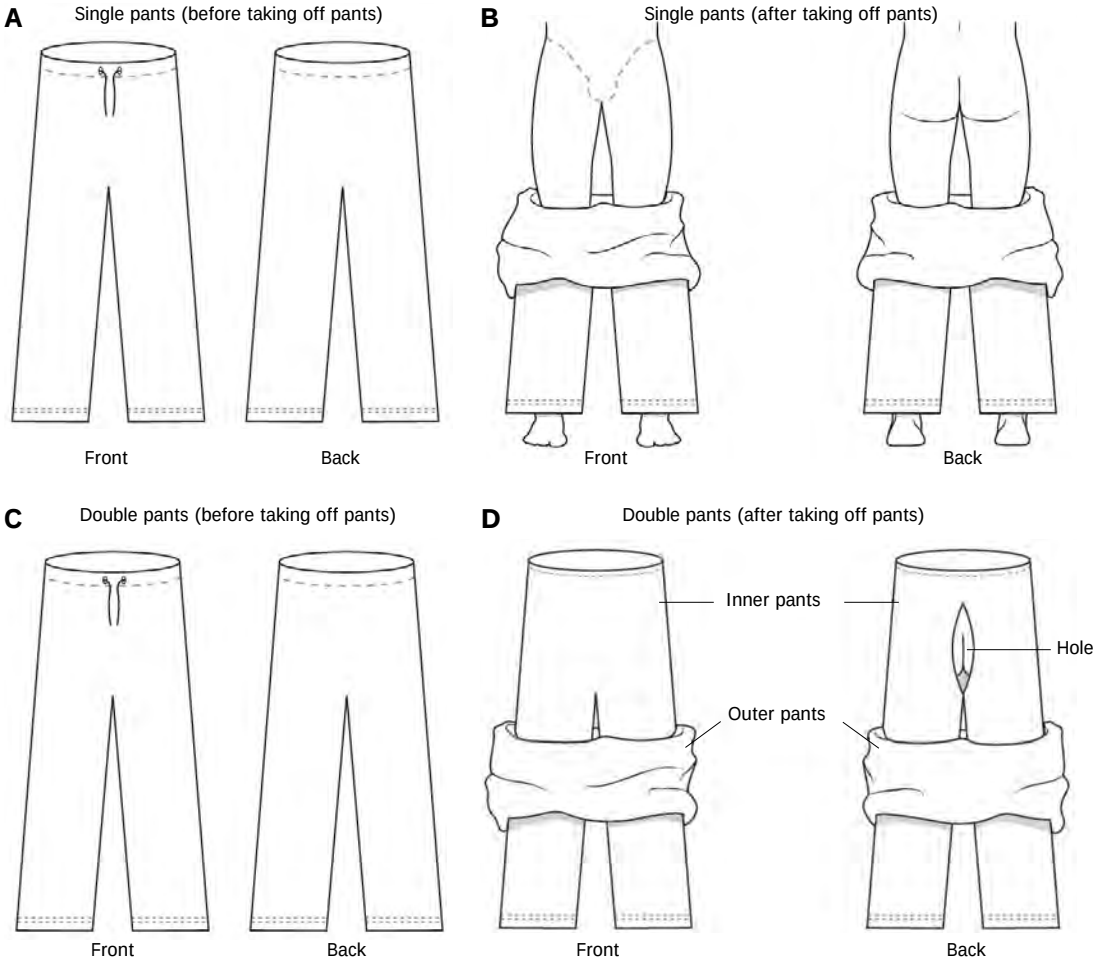

Figure 2 Drawings of the conventional single pants and novel double pants. A: The conventional single pants were composed of a single layer of fabric; B: If the examinees wearing conventional single pants dropped the outer pants below hips, the total area of the hip is exposed; C: The novel double pants were composed of a double layer of fabric from the hip to the thigh and a single layer of fabric below the thigh; D: In the inner layer of the double pants, there is a hole for insertion of scope in the back. If the examinees wearing novel double pants dropped the outer pants below hips, the only buttock area is exposed through the hole (25 cm × 15 cm) for insertion of scope.

the allocation because the third party examiner allocated the enrolled subjects regarding to the prepared permuted-block randomization table. Written informed consent was provided by all participants in the study.

Pants

In CSP, there is no hole for insertion of the scope. Examinees remove the CSP to below the level of the buttocks and expose their buttocks area during colonoscopy, as shown in Figure 2A and B. NDP consist of single fabric only below the thigh, and doubled fabric from the hip to the thigh with a hole in the inner pants at the level of the buttocks. The hole is 25 cm wide and 15 cm long. Examinees wearing NDP can undergo colonoscopy without taking off the inner pants, as shown in Figure 2C and D. We supplied the 80 NDP (Bobo trading, Seoul, South Korea) to NDP group and 80 CSP (Seodaemun uniform, Seoul, South Korea) to CSP group. All patients got the pants in the hospital just before the procedure according to the randomized allocation by the nurse in outpatient clinic. The pants had been prepared with marking "A type" (CSP) and "B type" (NDP).

Interview

In this study the only one nurse, as the third party examiner, interviewed the patients before and after the procedure to exclude interviewer's influence on the answers in this study. Before colonoscopy, examinees underwent a one-on-one interview in a quiet, separated room with a third-party examiner in which they completed questionnaires identifying state and trait anxiety, marital status, education, and residence. After colonoscopy, examinees had a similar one-on-one interview to complete the questionnaires, which included the Group Health Association of America 9 (GHAA 9) scales and questions regarding pant-specific satisfaction, state anxiety, and shame. After colonoscopy, examinees' pain during colonoscopy was assessed after the procedure and scored from 0 to 10 using a face pain scale (0-very happy, no pain, 2-hurts just a little bit, 4-hurts a little more, 6-hurts even more, 8-hurts a lot, 10-hurts as much as you can imagine; don't have to be crying to feel this much pain)[12].

Colonoscopy

Professional endoscopists who had performed more than 1000 colonoscopies performed all of the study colonoscopy procedures with a standard colonoscope (CF Q240L, CF Q240I, CF H260AI, CF Q260AI; Olympus Optical Co, Ltd, Tokyo, Japan). The indication for colonoscopy, ASA status, Ottawa quality scale, procedural time, number of polyps, number of examinees with polyps, method of polyp removal, rates of adverse events after polyp removal, rates of successful cecal approach, and gender difference between examinees and endoscopists in the NDP and CSP groups were investigated.

Outcome measurements

Satisfaction: The questionnaires measuring satisfaction included 14 questions regarding the examinees' colonoscopy experience. Nine of the questions regarding overall satisfaction were derived from a previously validated GHAA 9 satisfaction survey[13]. These questions used a 5-point scale to grade satisfaction (1: poor, 2: fair, 3: good, 4: very good, 5: excellent). A score of more than 3 was considered a favorable response. Five questions were asked to elicit pants-specific satisfaction as related to the following: difficulty of defecation wearing the pants; difficulty in position change during the colonoscopy; worriness about the exposed buttock area; willingness to try the same pants for the next exam; and recommendation of the same pants to other people. The five pants-specific satisfaction questions used a 4-point scale to grade satisfaction (1, not at all; 2, somewhat; 3, moderately so; 4, very much so). Three of the five questions were negative questions about satisfaction and thus scored in reverse. Scores on pants-specific satisfaction ranged between 5 and 20.

Anxiety: The trait anxiety questionnaire has been shown to reflect the general disposition of patients or stable tendency for anxiety, while the state questionnaire reflects a patient's anxiety related to a particular set of circumstances[9,14]. The trait and state questionnaires each consists of 20 statements, and all answers were graded using a 4-point scale (1, not at all; 2, somewhat; 3, moderately so; 4, very much so). Seven of the 20 questions from the STAI−Trait anxiety and 10 of the 20 questions from the STAI-State anxiety were negative questions and scored in reverse. The scores of the trait and state questionnaire range between 20 and 80, and higher scores reflected higher anxiety.

Shame: Among the experienced shame scale, 4 questions were used to measure body shame during colonoscopy[15]. We designed another 2 questions to measure shame following the exposure of the body during position change for the colonoscopy and exposure of the buttock area while walking to the colonoscopy room. In total, 6 different questions were used to measure shame. All answers were graded using a 4-point scale (1, not at all; 2, somewhat; 3, moderately so; 4, very much so). Scores on the body shame questionnaire ranged between 6 and 24, and higher scores reflected higher level of shame.

Ethical considerations

Informed consent was obtained from each patient included in the study. The study protocol conforms to the ethical guidelines of the 1975 Declaration of Helsinki (6th revision, 2008) as reflected in a prior approval by the institution's human research committee. The study protocol was approved by the ethical committee of Yonsei University College of Medicine. The study protocol was also approved by clinicaltrial.gov (NCT 01524042).

Statistical analysis

All differences in CSP and NDP were examined using SPSS Statistics (version 18.0.0, IBM Corp., Armonk, NY, United States). Continuous variables were compared using Student's t test, while categorical data were analyzed using the χ^2 test (Fisher's exact test) between two groups. Univariate and multivariate linear regression analysis were used to assess independent predictive factors associated with satisfaction, state anxiety after colonoscopy, and shame. For multivariate analysis, variables with $P < 0.1$ by univariate analysis were included. All statistical tests were two-tailed and considered statistically significant with a P value < 0.05.

RESULTS

Baseline characteristics and endoscopic characteristics of the study population

There was no significant difference in baseline characteristics including age, gender, marital status, education, and residence in the study population and in the NDP and CSP groups in Table 1. There were no significant differences in the endoscopic characteristics of study population including indication for colonoscopy, Ottawa quality scale, procedural time, number of polyps, number of examinees with polyps, method of polyp removal, rates of adverse events after polyp removal, rates of successful cecal approach, pain scale, and gender difference between examinees and endoscopists in the NDP and CSP groups, as shown in Table 2.

Outcomes of satisfaction, state anxiety, trait anxiety and shame

There was no significant difference in GHAA9 score (Likert scale, 0-5) between the NDP and CSP groups. There were high favorable response rates (FRRs) which were greater than 90% for waiting time, waiting on procedure day, personal manner of physician and support staff, technical skills, adequacy of explanation, overall rating of the visit, and willingness to have the procedure repeated by the same physician and at the same facility in Table 3. In terms of pants-specific satisfaction in Table 3, the CSP group worried more about exposing the buttock area during the colonoscopy than did the NDP group (3.3 ± 0.7 *vs* 2.9 ± 0.7, $P < 0.001$). The NDP group was more willing to wear same pants when they undergo their

Data are expressed as absolute numbers (percentage) or mean ± SD. [1]Examinees' pain during colonoscopy was assessed after the procedure and scored from 0 to 10 using a face pain scale (0-very happy, no pain, 2-hurts just a little bit, 4-hurts a little more, 6-hurts even more, 8-hurts a lot, 10-hurts as much as you can imagine; don't have to be crying to feel this much pain). CSP: Conventional single pants; NDP: Novel double pants.

next colonoscopy than the CSP group (3.3 ± 0.8 *vs* 2.1 ± 0.9, $P < 0.001$). The NDP group was also more willing to recommend other people wear the same pants when they undergo their own colonoscopies than the CSP group (3.3 ± 0.7 *vs* 2.0 ± 1.0, $P < 0.001$). A significantly lower shame score was estimated in the NDP group compared with CSP group (6.6 ± 1.5 *vs* 8.1 ± 3.2, $P < 0.001$), which is shown in Table 3.

Predictive factors for satisfaction, state anxiety, and shame after colonoscopy

To investigate the predictive factors related to satisfaction, state anxiety, and shame after colonoscopy, univariate and multivariate regression analysis was performed (Table 4). In the multivariate analysis of pants-specific satisfaction, unmarried examinees had less pants-specific satisfaction than married examinees [B (SE) = -1.82 (0.61), $P = 0.004$], and the NDP group had higher pants-specific satisfaction than the CSP group [B (SE) = 2.72 (0.28), $P < 0.001$]. In multivariate analysis of state anxiety after the colonoscopy, female participants had higher state anxiety score after the procedure than males [B (SE) = 3.52 (1.14), $P = 0.002$]. Unmarried examinees had higher state anxiety score after colonoscopy than married examinees [B (SE) = 4.45 (2.22), $P = 0.047$]. Urban examinees had higher state anxiety score after colonoscopy than rural examinees [B (SE) = 4.68 (1.70), $P = 0.007$]. The NDP group had a tendency of lower state anxiety score after colonoscopy than the CSP group [B (SE) = -1.80 (1.04), $P = 0.086$]. In the multivariate analysis of shame, female examinees had higher shame score than male examinees [B (SE) = 1.25 (0.37), $P = 0.001$]. Unmarried examinees also had higher shame score than married examinees [B (SE) = 2.78 (0.81), $P = 0.001$]. The NDP group had lower shame score than the CSP group [B (SE) = -1.37 (0.37), $P = 0.001$].

DISCUSSION

In this study, we compared the satisfaction, anxiety and shame between NDP and CSP with prospective randomized control trial. The examinees in NDP group responded with higher pants-specific satisfaction, lower state anxiety after colonoscopy, and lower shame scores compared to those in CSP group. Thus, the NDP developed at our institution may contribute to increased satisfaction and decreased anxiety and shame after colonoscopy.

Although there have been a wide range of studies regarding satisfaction[1,16-20] and anxiety[9,21-23] during colonoscopy, our study was unique because it specifically addressed colonoscopic pants and investigated the differences in emotional change by the type of colonoscopic pants participants wore. Colonoscopic pants were designed considering the maximization of the efficiency of colonoscopies and hygiene aspects. Various types of colonoscopic pants have been used at different institutions. In some centers, examinees wear CSP or pants with

CSP: Conventional single pants; NDP: Novel double pants.

a hole in the buttock area with a movable flap, which can potentially expose buttock area during walking. In other centers, examinees wear single pants with hole in the buttocks and outer gown to hide the hole, which is likely inferior to the NDP we describe in terms of repair and maintenance expenses.

In our study there was no significant difference in GHAA 9 patient satisfaction between NDP and CSP groups as the contents of GHAA 9 were not closely connected with satisfaction regarding colonoscopic pants. However, in the survey of pants-specific satisfaction, the NDP group showed increased satisfaction than the CSP group in terms of their willingness to wear the same pants in the next time and to recommend the same pants to other people. High patient satisfaction during colonoscopy may result in a higher rate of compliance with screening and clinical surveillance programs[1]. The American Society for Gastrointestinal Endoscopy and the American College of Gastroenterology recommends assessment of patient satisfaction during colonoscopy to evaluate the quality of colonoscopy[5,6].

The sensitivity related to the psychological aspects including anxiety and shame might partly depends on the different characteristics including age, gender, behavior, social environment and sensitivity of the society. As example lower anxiety scores was reported to be associated with older age, male sex, lower income, experience of previous colonoscopy and lower education[9]. During gastrointestinal endoscopic procedures, female examinees have been reported to have higher state and trait anxiety levels than male examinees[10,22]. In our study, female, unmarried, urban examinees and CSP group had more state anxiety after colonoscopy than that of their male, married, rural examinees and NDP group counterparts. The differences of shame and state of anxiety after colonoscopy between the two groups were moderate in most of the items. But, the difference in change of state of anxiety before and after the procedure might be clinically significant. Because all participants are healthy persons in psychological aspect at baseline, even moderate change of anxiety level after colonoscopy could result in decreased satisfaction of the procedure and reduced compliance to next examinations in clinical practice.

There were some limitations to our study. Endoscopists could not be completely blinded to the types of colonoscopic pants worn because they ultimately saw which pants they were wearing during the colonoscopic procedure. However, the outcome assessors were blinded during the total period of study. In addition, all the endoscopists who performed the colonoscopy were excluded from the outcome assessors. And there was no questionnaire for endoscopists in this study. Examinees with cancer or IBD were suspected to have higher anxiety levels during colonoscopy, and thus were excluded. Therefore understanding the satisfaction, anxiety, and satisfaction of these particular examinees would require further investigation. Most of examinees in this study were over 40 years old and more than half of examinees underwent colonoscopy for screening purposes; the number of young unmarried examinees was very small in this study, and the level of anxiety, shame and satisfaction in this group may be significantly different. For a more ideal comparision of anxiety, shame and satisfaction during colonoscopy between the NDP and CSP group, it would be better for one examinee to wear single pants and double pants during colonoscopy, but this was not logistically feasible. To compensate for this limitation in state anxiety we measured the change in state anxiety before and after colonoscopy in the same examinees.

In conclusion, the examinees in the NDP group had higher pants-specific satisfaction and lower state anxiety and lower shame after colonoscopy compared to CSP group. Therefore NDP could help to increase satisfaction and decrease anxiety and shame after colonoscopy. Future studies should continue to investigate factors for anxiety, shame and satisfaction.

ACKNOWLEDGMENTS

We thank Mr. Dong-Su Jang for help in preparing the specimens and figures.

COMMENTS

Background

Exposing buttocks during colonoscopy can make examinees feel unsatisfied, anxious, and shameful. To increase satisfaction and diminish anxiety and shame during colonoscopy, the authors developed novel double pants (NDP) which consist of doubled fabrics with an inner hole.

Research frontiers

Pants-specific satisfaction scores regarding willingness to repeat colonoscopy using same pants and recommendation of same pants to other people were significantly higher in NDP than conventional single pants (CSP) groups. State anxiety and shame after colonoscopy was lower in NDP group compared with CSP group.

Innovations and breakthroughs

Although there have been a wide range of studies regarding satisfaction and anxiety during colonoscopy, this study was unique because it specifically addressed colonoscopic pants. The authors developed NDP, which consist of single fabric only below the thigh, and doubled fabric from the hip to the thigh with a hole in the inner pants at the level of the buttocks. Examinees wearing NDP can undergo colonoscopy without taking off the inner pants.

Applications

Through these findings, the NDP developed at our institution may contribute to increased satisfaction and decrease anxiety and shame after colonoscopy.

Terminology

NDP are single fabric only below the thigh, and doubled fabric from the hip to the thigh with a hole in the inner pants at the level of the buttocks. The hole is 25 cm wide and 15 cm long.

Peer review

Satisfaction studies are important in relationship with the compliance of colorectal cancer screening programs and less so in the group of patients with specific suspicion of diseases affecting the anus, rectum or colon. This complex study is well designed and analyzed. The topic of the manuscript is interesting and the work performed is ambitious.

Abstract

AIM: To evaluate the clinicopathological features and treatment outcomes of cap polyposis in the pediatric population.

METHODS: All pediatric patients with histologically proven diagnosis of cap polyposis were identified from our endoscopy and histology database over a 12 year period from 2000-2012 at our tertiary pediatric center, KK Women's and Children's Hospital in Singapore. The case records of these patients were retrospectively reviewed. The demographics, clinical course, laboratory results, endoscopic and histopathological features, treatments, and outcomes were analyzed. The study protocol was approved by the hospital institutional review board. The histological slides were reviewed by a pediatric histopathologist to confirm the diagnosis of cap polyposis.

RESULTS: Eleven patients were diagnosed with cap polyposis. The median patient age was 13 years (range 5-17 years); the sample included 7 males and 4 females. All of the patients presented with bloody stools. Seven patients (63%) had constipation, while 4 patients (36%) had diarrhea. All of the patients underwent colonoscopy and polypectomies (excluding 1 patient who refused polypectomy). The macroscopic findings were of polypoid lesions covered by fibrinopurulent exudates with normal intervening mucosa. The rectum was the most common involvement site (n = 9, 82%), followed by the rectosigmoid colon (n = 3, 18%). Five (45%) patients had fewer than 5 polyps, and 6 patients (65%) had multiple polyps. Histological examination of these polyps showed surface ulcerations with a cap of fibrin inflammatory exudate. Four (80%) patients with fewer than 5 polyps had complete resolution of symptoms following the polypectomy. One patient who did not consent to the polypectomy had resolution of symptoms after being treated with sulphasalazine. All 6 patients with multiple polyps experienced recurrence of bloody stools on follow-up (mean = 28 mo).

CONCLUSION: Cap polyposis is a rare and under-recognised cause of rectal bleeding in children. Our study has characterized the disease phenotype and treatment outcomes in a pediatric cohort.

Key words: Cap polyposis; Polyps; Rectal bleeding; Pediatrics; Inflammatory bowel disease

Core tip: Cap polyposis is a rare and under-recognized condition with distinct clinical, endoscopic and histopathological features. All children with cap polyposis invariably present with rectal bleeding. Awareness of this diagnosis is important as its clinical and endoscopic features can mimic inflammatory bowel disease result-

ing in prolonged and inappropriate treatment. This article evaluates the clinicopathological features and treatment outcomes in a series of children with cap polyposis. Complete polypectomy should be performed where possible in combination with medical therapy. Prognosis is good for children with few polyps although recurrence rate is high in those with multiple polyps at diagnosis requiring further surgical intervention.

INTRODUCTION

Cap polyposis (CP) is a rare and under-recognized condition with distinct clinical, endoscopic and histopathological features. It was first described by Williams *et al*[1] in 1985. CP is characterized by inflammatory polyps that are usually located from the rectum to the distal descending colon. Histologically, these polyps consist of elongated, tortuous, and often distended crypts covered by a "cap" of inflammatory granulation tissues. Macroscopic findings include dark red, sessile polyps that are commonly situated on the apices of transverse mucosal folds, with normal intervening mucosa.

Characteristic symptoms in adults include mucous diarrhea, tenesmus and rectal bleeding[2]. CP may be confused with other inflammatory conditions of the large intestine, in particular inflammatory bowel disease (IBD), due to their similarities in clinical and endoscopic features. The pathogenesis of CP is unknown, and no specific treatment has yet been established.

CP has been rarely described in the pediatric population. We report a case series of 11 pediatric patients diagnosed with CP and characterized their clinical, endoscopic, and histological features.

MATERIALS AND METHODS

All pediatric patients with histologically proven diagnosis of CP were identified from our endoscopy (total number = 1905) and histology database over a 12 year period from 2000-2012 at our tertiary pediatric center, KK Women's and Children's Hospital in Singapore. The case records of these patients were retrospectively reviewed. The demographics, clinical course, laboratory results, endoscopic and histopathological features, treatments, and outcomes were analyzed. The study protocol was approved by the hospital institutional review board (Singhealth Centralised Institutional Review Board). The histological slides were reviewed by a pediatric histopathologist to confirm the diagnosis of CP.

RESULTS

Patients

There were 11 pediatric patients diagnosed with cap polyposis from 2000 and 2012. The clinical features of these patients are summarized in Table 1. There were 7 males and 4 females, with a median age of 13 years (range 5-17 years). The racial distributions included 5 Malays, 4 Chinese, and 2 Indian patients.

Clinical features

Common presenting features of these patients included per-rectal bleeding, constipation and straining, diarrhea, and abdominal pain (Table 1). All 11 patients presented with blood in the stools. Seven patients (63%) had constipation and/or straining, and 4 patients (36%) had diarrhea. Abdominal pain was a presenting complaint in 6 (54%) patients. Digital rectal examinations revealed rectal polypoid masses in 7 (63%) patients and 1 patient had perianal fissure.

The median hematological values at diagnosis were hemoglobin 10.9 (IQR 12.6-14) g/dL, white cell counts 6.7 $\times$ 10^9/L (IQR 4-11)10^9/L and platelet counts of 342 (IQR 150-400) $\times$ 1000/μL. All of the patients had normal coagulation profiles. Eight of the 11 patients had normal serum albumin measured with a median value of 38 g/L (IQR 35-45). Only 2 patients (IDs 8 and 10) had hypoalbuminemia. Inflammatory markers C-Reactive protein/Erythrocyte Sedimentation Rate were measured in 6 patients (ID 2, 5, 7, 8, 9, and 10), and they were normal.

Endoscopic features and histology

All patients underwent colonoscopy with macroscopic findings of polyps or polypoid lesions. These were mainly small, red and sessile polyps covered by a thick layer of fibrinopurulent exudates predominantly found on the apices of the mucosa folds. The intervening mucosa was normal both macroscopically and on histological examination (Figure 1A and B). The polyps were most commonly located in the rectum only (n = 9, 82%). Two patients (18%) had polyps in the rectum and sigmoid colon. The number of polyps ranged from 1 to more than 10. Five (45%) patients had fewer than 5 polyps, and 6 (65%) patients had multiple (> 5) polyps on initial colonoscopy.

On histological examination, these colonic polyps showed a variable degree of surface ulceration associated with a cap of fibrin inflammatory exudates and granulation tissue. Focally, the surface epithelium is preserved but attenuated. The crypts within the polyps showed crypt elongation and luminal epithelial serration. In some cases, the crypts were mildly distended towards the surface. The lamina propria contained a variably increased number of acute and chronic inflammatory cells (Figure 2). These histological features were consistent with inflammatory cap polyps. The mucosa surrounding these polyps was normal.

Three patients presented with abdominal pain and

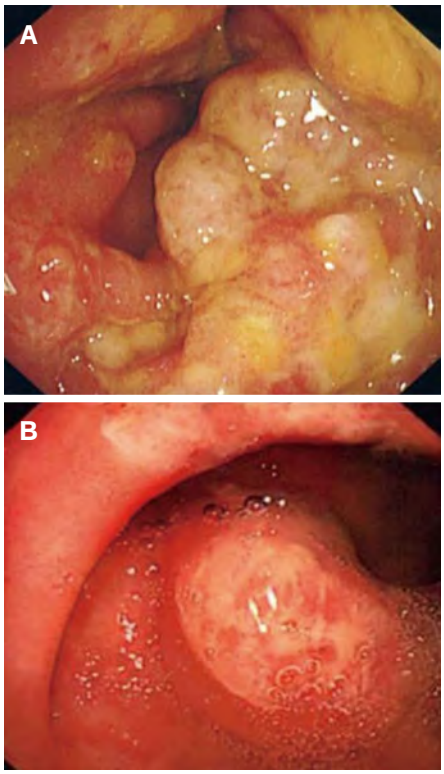

Figure 1 Colonoscopy images of 2 patients with cap polyposis. A: Colonoscopy image of a patient showing multiple small sessile polypoid lesions with mucous exudates of cap polyposis (CP) in the rectum; B: Colonoscopy image of a patient showing a single sessile red polypoid lesion located on the transverse folds with normal intervening mucosa.

underwent simultaneous upper gastrointestinal (GI) endoscopies; the histological findings showed mild gastritis but no evidence of *Helicobacter pylori* (*H. pylori*). There were no polypoid lesions noted in the stomach of these 3 patients.

Management and outcomes

All but one patient underwent polypectomies. Patients 1-5 had fewer than 5 polyps detected by the initial colonoscopy. Patients 1-4 had polypectomy performed and were subsequently treated with stool softeners. Patient 4 also received a course of metronidazole. All 4 of these patients had complete resolution of their symptoms with no further rectal bleeding at mean follow-up period of 28 mo. Patient 5 had 3 small sessile polyps and did not consent for polypectomy but had complete resolution of symptoms at 18 mo after being treated with sulphasalazine.

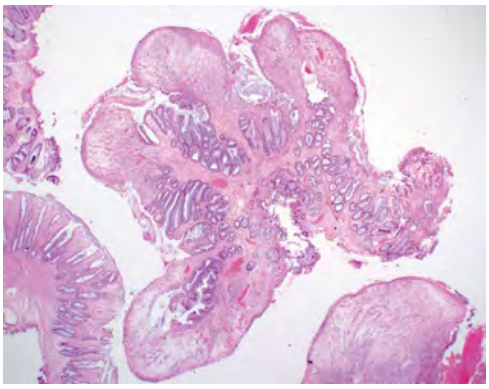

Figure 2 Histology of a sessile colonic polyp from a patient with cap polyposis. The polyp was comprised of granulation tissue and focally distended crypts with a slightly serrated luminal surface. Surface ulceration with fibrinomucoid exudates was also present.

Six patients with multiple polyps (Patients 6-11) underwent colonoscopy and polypectomies. One patient was lost to follow-up (Patient 11). The other 5 patients were given stool softeners and 3 patients were given metronidazole. All of the patients experienced a recurrence of symptoms, mainly blood in the stools at subsequent follow-up (mean follow-up period of 28 mo). These patients required repeated colonoscopies with polypectomies and continued to have intermittent per rectal bleeding. Patient 8 eventually had a resolution of his symptoms after 6 colonoscopies with multiple polypectomies at follow-up of 6 years. Patient 11, whose polyps were confined to the recto-sigmoid area, had persistent rectal bleeding that required recurrent blood transfusions and will require more extensive surgical resection in the future. All of the 5 patients with multiple polyps were otherwise well-thrived and had normal inflammatory markers at subsequent follow-up.

DISCUSSION

CP is a rare but distinct disorder with characteristic endoscopic and histological features first described by Williams[1]. Although CP was first described more than 20 years ago, this disease is still not well recognized by physicians. Only approximately 60 cases have been reported in the English language medical literature, mainly as case series or case reports. Due to its rarity, CP is often underrecognized and misdiagnosed as inflammatory bowel disease IBD, leading to prolonged and inappropriate treatment.

To our knowledge, this report is the first and largest case series describing CP in the pediatric population. Shimuzu *et al*[3] have previously described CP in a 12 year old girl. Previous adult studies have found that CP occurs more frequently in females than males[3]. In contrast, there were more boys than girls (7 males and 4 females) in our study, and their median age was 13 years old. We also noted a slightly higher proportion of Malay patients (approximately 40%) in our cohort.

Common presenting symptoms of previously described cases of CP include mucous and/or bloody diarrhea, habitual straining with defecation, chronic constipation and abdominal pain[4]. Rectal bleeding occurred universally in all 11 patients in our study. In total, 65% of our patients had chronic straining and/or constipation, while 35% of the patients had diarrhea. Almost half of our patients presented with abdominal pain, particularly those with multiple polyps. Anemia was a predominant feature in our cohort, with median Hb of 10.9 g/dL.

Protein-losing enteropathy has been reported to be associated with CP[5-9]. Shiomi *et al*[9] reported a case of CP in which protein loss from the lesions was confirmed *via* technetium 99m-labeled diethylenetriaminepentaacetic acid complexed to human serum albumin. There have also been reports of lower limb edema resulting from protein-losing enteropathy from CP[5,7-10]. In addition, laboratory investigations often reveal low total protein and serum albumin levels in CP patients. Symptoms of pre-tibial edema and low protein levels have been shown to normalize with resolution of cap polyposis[5,6-9]. None of the patients in our study presented with lower limb edema. Moreover, hypoalbuminemia was not a predominant feature in our cohort, with only 2 patients having documented low albumin levels.

Endoscopic and histological features

CP is characterized by polyps covered with fibrinopurulent exudates on the surface. The polyps range in size from several millimeters to as large as 7 cm[11,12]. The number of polyps varies from 1 to a few hundred, and the polyps are typically located at the apices of mucosal folds. These polyps have varying morphologies, including polypoid, ulcerative, and flat types[13]. The intervening mucosa has been described as normal or covered with white specks[13], although the significance of this morphology has yet to be ascertained. Initial edematous, flushed mucosa with subsequent development of polyps at the same area, has been reported with serial endoscopic studies[7,14]. The rectum and rectosigmoid colon are the most commonly affected sites, although pan-colonic and gastric involvement has been described[4,6,15]. In agreement with previous findings, all patients in our series had polyps localized to the rectum or rectosigmoid region with normal intervening mucosa.

Histologically, cap polyps consist of elongated, tortuous and hyperplastic crypts that are attenuated towards the mucosal surface. The surfaces of these polyps are ulcerated and covered by a thick layer of fibrinopurulent exudates, hence the term "cap polyps". The lamina propria also contain inflammatory cells[5]. These histological features were reported in our patients.

Role of abnormal colonic motility

The exact etiology and pathogenesis of inflammatory cap polyps are unclear. Various possible causes, including infection[6,14], mucosal ischemia[2], inflammation[16], abnormal bowel motility, and repeated trauma to the colonic mucosa caused by straining[8] have been proposed. Campbell *et al*[2] proposed that abnormal colonic motility may lead to prolapse of redundant mucosa at the apices of transverse mucosal folds. The resultant local ischemia produces characteristic histological appearances of fibromuscular obliteration of the lamina propria; superficial erosion associated with granulation tissue; and elongated, tortuous, hyperplastic glands. These histological features are also present in other conditions, such as prolapsing mucosal polyps, solitary rectal ulcers, inflammatory cloacogenic polyps, and gastric antral vascular ectasia. These findings, along with the fact that CP predominantly affects the rectosigmoid and has a circumferential involvement of the colonic mucosa, have led many researchers to attribute CP to abnormal colonic motility and repeated trauma to the colonic mucosa caused by straining during defecation. Hence, CP has been considered part of a spectrum of "mucosal prolapse syndromes"[5,17,18].

However, aberrant motility of the distal large bowel may only partially contribute to the development of cap polyposis. Although many CP patients present with a history of straining at defecation, these individuals usually lack a typical mucosal prolapse that involves the anterior wall of the lower rectum[18]. There have also been reports of CP developing in patients without evidence or history of abnormal colonic motility. Géhénot *et al*[14] and Konishi *et al*[16] reported the differentiating features between and mucosal prolapse syndrome, where there was significant thickening of the second layer on endoscopic ultrasound in cap polyposis, as opposed to smooth, diffuse thickening of the third layer and minimal thickening of the second layer in mucosal prolapse. Furthermore, avoidance of straining alone has not been reported as an effective treatment modality. In our cohort of patients, stool softeners were prescribed in 8 of 11 patients to avoid straining on defaecation but the symptoms still recurred in those with multiple polyps.

The role of inflammation and infection

In recent years, the role of infectious organisms, such as *H. pylori*[5,6,7,19,20], and inflammation[14] has been proposed. Three of our patients underwent an upper GI endoscopy, but none of them showed any evidence of *H. pylori* on in their gastric mucosa biopsies.

Konishi *et al*[21] described a patient in whom CP was noted to progress along the surgical anastomotic line after a laparoscopic sigmoid colectomy was performed, leading to the hypothesis that local inflammation plays a role in the development of cap polyposis. The effectiveness of infliximab in 2 case reports[22,23] also supports the role of inflammation in the pathogenesis of CP. However, molecular studies of the abnormal mucus in CP have proven inconclusive. Buisine *et al*[24] found a predominance of non-sulphated mucins in cap polyps, compared to both non-sulphated and sulphated mucins expressed in normal colonic mucosa. This finding has been associated with a wide range of pathological conditions, including colorectal carcinomas, ulcerative colitis, and familial polyposis, and there has been a lack of data to show a direct involvement of mucins in the initial pathogenesis of cap polyposis.

Treatment of cap polyposis

Different treatment modalities have been trialed including steroids, aminosalicylates, infliximab, *H. pylori* eradication, endoscopic and surgical resection with variable clinical outcomes. The clinical course of CP has been reported to range from spontaneous remission[19,22] to a disease course requiring surgical resection of the affected bowel segments.

Metronidazole has been used widely in the treatment of CP, often in combination with other modalities[5,7,8,25-27]. Shimizu *et al*[3] reported improvement of symptoms and stromal infiltration on colonic biopsies in a patient treated with metronidazole after failed treatment with mesalamine and levofloxacin, leading to the hypothesis that the role of metronidazole may be related to its anti-inflammatory effects rather than antibiotic action against specific pathogens. It has been postulated that by acting as a radical scavenger, metronidazole can inhibit leukocyte emigration and adherence[5]. In our series, 4 patients received a course of metronidazole together with polypectomy. Of these 4 patients, 3 patients had a recurrence of symptoms. This result suggests that metronidazole may have a limited role in the treatment of patients who have multiple cap polyps.

Limited reports of treatment with infliximab have yielded varying results[22,23,28]. Kim *et al*[26] reported a resolution of symptoms and endoscopic lesions after a single infusion of infliximab, but Maunory *et al*[27] reported a case of recurrence despite 2 infusions of infliximab.

The effective eradication of *H. pylori* has been reported to play a role in the treatment of CP. A review of the English language medical literature has identified 6 reports[6,7,15,19,20,25] in which 9 CP patients were treated with *H. pylori* eradication treatment, 8 of whom showed a complete resolution of symptoms and cap polyps (88.9%) and 1 patient experienced a partial improvement of symptoms. Interestingly, all 9 patients tested positive for *H. pylori*, and the patient who showed only a partial improvement in symptoms had persistent *H. pylori* infection despite eradication therapy.

The possible role of *H. pylori* in extragastric diseases, including idiopathic thrombocytopenic purpura, iron deficiency anemia, chronic urticaria and ischemic heart disease, has been suggested[28-30]. Various mechanisms, including the release of inflammatory mediators, molecular mimicry and a systemic immune response, have been postulated[20]. Although *H. pylori* has not been detected in the colonic mucosae of CP patients, these results suggest that *H. pylori* infection may indirectly play a part in the etiology of CP. Similar histological features between Menetrier's disease (in which *H. pylori* has been postulated to play a role) and CP, such as elongated tortuous crypts, have been highlighted by Akamatsu *et al*[7]. Testing for *H. pylori* in all CP cases and subsequent eradication therapy, if necessary, has been recommended by various authors[7,20]. In our series of pediatric patients, 3 patients underwent upper endoscopy, but none of these patients had *H. pylori* detected in their gastric mucosal biopsies. One patient received triple therapy but continued to have recurrence of symptoms. The role of *H. pylori* eradication therapy needs to be further evaluated in the pediatric population.

Steroids and aminosalicylates have been used with varying results[8,25]. Chang *et al*[25] reported a series of 7 patients, 2 of whom maintained clinical response after 2 courses of systemic steroids: Symptoms persisted in 1 patient despite 2 courses of steroids and aminosalicylates; 3 patients experienced spontaneous remission, and 1 patient showed partial improvement after *H. pylori* eradication therapy. None of our patients received steroid therapy, although one patient was successfully treated with aminosalicylic acid. All of our patients for whom inflammatory markers were measured had normal values for these markers.

Polypectomy and surgical removal of the affected colon have produced inconsistent results, with Ng *et al*[4] reporting recurrence in 2 of 5 patients receiving polypectomy and recurrence in 2 of 4 patients who underwent surgical resection of the affected colon[7,31]. In our series, 10 of 11 patients underwent polypectomies. However, only half of these patients achieved complete remission at mean follow-up of 28 mo. These were patients with fewer than 5 polyps at presentation. Those patients with persistent symptoms despite polypectomies were more likely to have multiple polyps at presentation.

Clinical course

The clinical course and long-term prognosis of CP remain largely unknown. A self-limiting course has been reported, despite whether polypectomy or surgery has been performed[32,33]. A polypectomy will, however, provide a definitive histological diagnosis and may also be war-

ranted when the patient presents with significant lower gastrointestinal bleeding. A complete polypectomy was effective in several studies[4,5], and this approach is recommended whenever possible. Our findings suggest that patients with multiple polyps at diagnosis are more likely to experience symptom recurrence.

In conclusion, CP is a rare cause of rectal bleeding in children. Awareness of this diagnosis is important as the clinical and endoscopic features of CP can mimic Inflammatory Bowel Disease[32] and a misdiagnosis can result in prolonged and inappropriate treatment. CP polyps are distinctive inflammatory polyps covered by a cap of fibrinopurulent exudates normally located at the apices of the mucosal folds with normal intervening mucosa both macroscopically and on histological examination. Although the pseudopolyps in IBD have granulation tissues, the intervening mucosa is usually associated with inflammatory changes, such as superficial ulcerations, granularity and/or friability with crypt abscesses[34]. CP is mainly localized to the rectum and sigmoid, whereas the pseudopolyps in IBD may involve the entire colon. Clinically, CP patients are also more likely to have normal inflammatory markers with no extraintestinal manifestations, such as weight loss, oral ulcers, joint pain *etc*.

The clinical course of CP has not been well described. CP may in some instances, be a self-limiting condition. A complete colonoscopy should be performed as polyps have been described throughout the colon[35,36] when possible, a total polypectomy is recommended. Patients with predominant straining/constipation symptoms can be treated with laxatives and advised to avoid straining. Medical treatment including antibiotics (*e.g.*, metronidazole) and eradication therapy for *H. pylori* has been shown to be effective in some reports. There is currently no good evidence for using aminosalicylic acid or immunosuppressive therapy for treatment of CP. Surgical resection may be indicated if symptoms persist despite medical therapy, although recurrence has been described post-operatively.

In summary, CP is a rare cause of rectal bleeding in children. Awareness of this diagnosis is important as its clinical and endoscopic features can mimic inflammatory bowel disease and a misdiagnosis can result in prolonged and inappropriate treatment. Response to medical treatment has been shown to be inconsistent and unsatisfactory. Endoscopic or surgical excision can be curative, but the recurrence rates are high, particularly if numerous polyps are present. Longer term studies are necessary to understand the natural course of this condition.

COMMENTS

Background

Cap polyposis (CP) is a rare and under-recognized condition with distinct clinical, endoscopic and histopathological features first described by Williams *et al*. Little is known of CP in the pediatric population.

Research frontiers

The pathogenesis of CP is unknown and no specific treatment has been established. CP has been rarely described in the paediatric population. The research hotspot is to better define the clinical features and course of CP in children, and identify effective treatment modalities.

Innovations and breakthroughs

The study is the first case series in available literature to characterise the disease phenotypes and treatment outcomes in a group of paediatric patients.

Applications

Cap polyposis is a rare condition especially in children. It is commonly misdiagnosed as inflammatory bowel disease subjecting patients to unnecessary immunosuppressive therapy. The clinical course and long-term prognosis of cap polyposis remain largely unknown. A case series describing the treatment modalities and clinical course of CP in children will raise the awareness of this rare condition amongst paediatricians and gastroenterologists, as well as improve treatment outcomes.

Terminology

Cap polyposis is characterised by inflammatory polyps located in the rectum to distal descending colon. Histologically, these polyps consist of elongated, tortuous crypts covered by a "cap" of inflammatory granulation tissue.

Peer review

The manuscript is interesting and the main importance of the research is represented by the help offered to clinicians and endoscopists in recognizing and treating a rare pathology that could be misdiagnosed as Inflammatory Bowel Disease. These series of children demonstrate the importance of cap polyposis in young patients. Manuscript is well presented and well written.

Abstract

AIM: To assess the technical safety and efficacy of transcatheter arterial chemoembolization (TACE) combined with immediate radiofrequency ablation (RFA) for large hepatocellular carcinomas (HCC) (maximum diameter ⩾ 5 cm).

METHODS: Individual lesions in 18 patients with HCCs (mean maximum diameter: 7.5 cm; range: 5.1-15.5 cm) were treated by TACE combined with percutaneous RFA between January 2010 and June 2012. All of the patients had previously undergone one to four cycles of TACE treatment. Regular imaging and laboratory tests were performed to evaluate the rate of technical success, technique-related complications, local-regional tumor responses, recurrence-free survival time and survival rate after treatment.

RESULTS: Technical success was achieved for all 18 visible HCCs. Complete response (CR) was observed in 17 cases, and partial response was observed in 1 case 1 mo after intervention. The CR rate was 94.4%. Local tumors were mainly characterized by coagulative necrosis. During follow-up (2-29 mo), the mean recurrence-free survival time was 16.8 ± 4.0 mo in 17 cases of CR. The estimated overall survival rate at 6, 12, and 18 mo was 100%. No major complications were observed. Levels of alanine aminotransferase (ALT) and aspartate aminotransferase (AST) in the blood of 17 patients transiently increased on the third day after treatment (ALT 200.4 ± 63.4 U/L *vs* 24.7 ± 9.3 U/L, $P < 0.05$; AST 228.1 ± 25.4 U/L *vs* 32.7 ± 6.8 U/L, $P < 0.05$). Severe pain occurred in three patients, which was controlled with morphine and fentanyl.

CONCLUSION: TACE combined with immediate RFA is a safe and effective treatment for large solitary HCCs. Severe pain is a major side effect, but can be controlled by morphine.

Key words: Large hepatocellular carcinoma; Transcatheter arterial chemoembolisation; Radiofrequency ablation; Combination therapy; Synchronism

Core tip: Transcatheter arterial chemoembolization (TACE) immediately followed by radiofrequency ablation (RFA) under digital subtraction angiography-computed tomography is used to treat large hepatocellular carcinomas. This technology can improve the synergistic treatment effects of TACE and RFA, as well as reduce the need for repeated treatments and amount of radiation exposure. Furthermore, different treatment technologies are fused into one machine, thereby simplify-

ing the operational process. TACE immediately followed by RFA enhances tumor inactivation ability, decreases recurrence rates, prolongs patient survival time and improves prognosis.

Transcatheter arterial chemoembolization followed by immediate radiofrequency ablation for large solitary hepatocellular carcinomas. *World J Gastroenterol* 2013; 19(26): 4192-4199 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i26/4192.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i26.4192

INTRODUCTION

Hepatocellular carcinoma (HCC), the sixth most malignant tumor worldwide, is the third most common tumor leading to death; unfortunately, only 10%-54% of all patients with HCC are suitable for surgery[1-3]. Transcatheter arterial chemoembolisation (TACE) is one of the modalities used to treat unresectable HCC; however, its low complete tumor necrosis rate results in tumor recurrence and metastasis and influences long-term efficacy[1,3-6]. In addition, the effect of TACE is influenced by tumor size which decreases inactivation ability, especially for HCCs with diameters larger than 5 cm[7,8]. Compared with TACE, the combination of TACE with radiofrequency ablation (RFA) shows enhanced efficacy against HCC and prolonged survival in patients[7-11]. RFA is usually performed 1-4 wk after TACE[3,11-13]. However, the combination of TACE with immediate synchronous RFA for unresectable and large HCCs has not yet been reported. We retrospectively summarized 18 patients treated between January 2010 and June 2012 to assess the technical safety and efficacy of TACE combined with immediate synchronous RFA as a treatment modality for HCC.

MATERIALS AND METHODS

Patients

This retrospective study was approved by the Ethics Committee of the People's Liberation Army (PLA) General Hospital, and all patients signed informed consent forms. A total of 18 patients were admitted to the Department of Interventional Radiology of the PLA General Hospital between January 2010 and June 2012 and were diagnosed with HCC by ultrasound, computed tomography (CT), magnetic resonance imaging (MRI) and α-fetoprotein (AFP) blood test or pathological examination according to the diagnostic criteria for HCC established by the National Association for the Study of Liver Cancer. All patients, including 16 males and 2 females, with an average age of 55 ± 8.0 years (47-63 years) underwent TACE followed immediately by synchronous RFA. The AFP level was higher than 20 ng/mL in 10 cases. On the basis of the Child-Pugh score, 13 cases were classified as Grade A and 5 cases were classified as Grade B.

Patients were allowed to receive the combination therapy if: (1) various imaging examinations (ultrasound, CT, MRI and intra-procedure imaging in TACE) showed one lesion in the liver with a maximum diameter larger than 5 cm and the patients had no surgical indications or refusal to surgery, and (2) the Child-Pugh score was Grade A or B. Patients were excluded from the treatment if they had: (1) cancer embolus in the main portal vein and its left and right portal veins, arteriovenous fistula formation, biliary invasion and extrahepatic metastases and (2) severe coagulation disorders, such as prothrombin activity < 40% and platelet concentration < 30×10^9/L. All the RFA lesions were located 1 cm away from the gall bladder, intestinal canal, bile duct and major blood vessels. All patients underwent regular physical examination and tests (routine blood test, hepatorenal function, electrolytes, blood coagulation and tumor markers), as well as other relevant examinations (liver CT, ultrasound or MRI, lung and brain CT and bone ECT). The maximum diameter of the lesion was determined on enhanced CT or MRI. TACE was performed in these 18 patients one to three times prior to the procedure.

Methods

TACE: All the interventional procedures were performed *via* INNOVA4100 IQ digital subtraction angiography (DSA) (GE Company, United States) by an interventional radiologist with 8-10 years of experience at the Department of Interventional Radiology. After the right femoral artery was punctured by Seldinger's technique, a 4F catheter (RH, Terumo Corporation, Japan) was used for celiac artery and superior mesenteric artery angiography, as well as selective hepatic arteriography if necessary. Chemoembolisation was then conducted with a 3F microcatheter (Progreat, Terumo Corporation, Japan) on the feeding arteries of the tumor. Three to four of the following drugs were administered during the procedure: epirubicin (30-50 mg), cisplatin (40-60 mg) or oxaliplatin (100-150 mg), mitomycin (10-14 mg), 5-FU (500-750 mg), calcium folinate (200-300 mg) and hydroxycamptothecine (10-14 mg). Each drug powder was mixed with lipiodol to form an emulsion and liquid chemotherapy drugs for target vessel perfusion through a microcatheter. When the branch of the portal vein had developed or blood flow had obviously slowed down after chemoembolisation induced by the lipiodol emulsion, gelatine sponge particles were used to perform embolisation. Patients with large lesions or a large number of blood vessels around the tumor were administered the same drugs, but with the addition of 500-700 μmol/L polyvinyl alcohol (Cook Medical, Bloomington, IN, United States). Collateral artery embolisation was conducted if branches such as the phrenic artery and internal thoracic artery were involved in the tumor blood supply.

Immediate synchronous RFA: Percutaneous RFA was immediately performed under general anaesthesia after TACE with the guidance of a C-arm cone beam CT

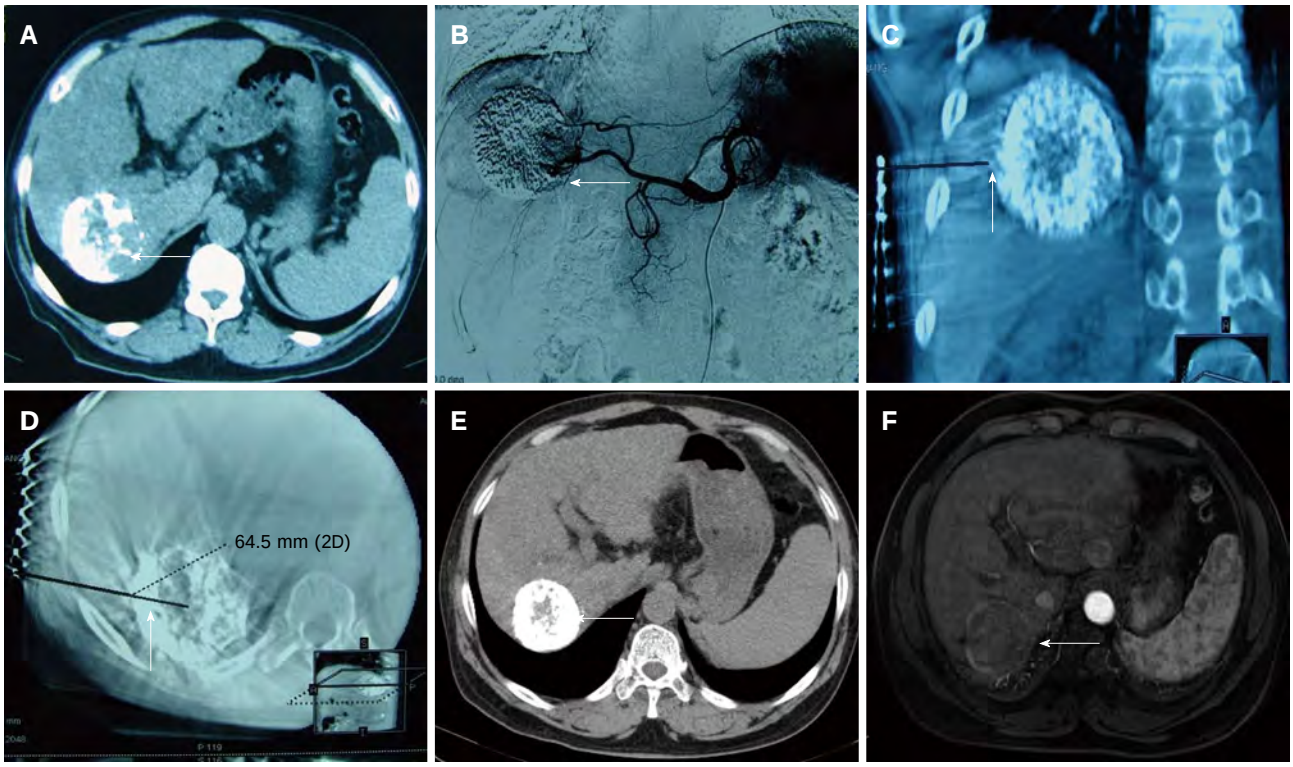

Figure 1 A male patient aged 60 years with hepatocellular carcinoma. Computed tomography (CT) scan showed a residual lesion in the liver after the first interventional therapy. Thus, transcatheter arterial chemoembolisation (TACE) immediately followed by radiofrequency ablation (RFA) was performed under the guidance of digital subtraction angiography (DSA)-CT. A: Liver CT scan showed a partial lipiodol deposit (arrow) after first interventional therapy; B: Angiogram performed before RFA showed a lipiodol deposit in the liver and staining of the delay phase around the lipiodol (arrow); C, D: INNOVA4100 IQ DSA-CT was used to obtain the coronal section and cross section of the reconstructed image to design the puncture path and angle (arrow); E, F: Liver CT scan 23 mo after combination therapy showed good lipiodol deposits without enhancement (arrow).

and DSA. Three-dimensional (3D) CT navigation with INNOVA4100 IQ DSA was used. To establish 3D CT images, the radiofrequency (RF) puncture path and its parameters, 6 × 6 square metal grid lines (diameter: 1 cm) were placed in parallel on the right side of the 8^{th}-10^{th} costal margin or below the xiphoid. Then, a 3D CT scan of the target lesion and image reconstruction (Figure 1) were conducted. The corresponding site was located on the body surface instead of the ribs, and the puncture path was identified through the surface point. The target lesion was determined to avoid important organs, such as the intestinal canal, gallbladder and lung. The puncture path was calibrated to one (*i.e.*, bull's eye configuration), and various parameters, such as the angle of the head, lateral position of the tube ball and needle depth, were determined. The device was then switched on to automatically set the system, which adjusted the tube ball to the correct position. To puncture and localize the target lesion under the perspective, the RF needle was inserted toward the target, and the bull's eye graphic converged on the target. When the puncture needle was in the correct position, the multipolar RF needle was switched on and the tube ball was rotated 70°-90° toward the right and left lateral positions to verify whether the RFA needle was located in the target lesion. For the RFA parameter setting, different RFA needles and RFA parameters were selected according to the tumor position, size and shape. A multipolar RF needle (RITA Company, Cristal Lake, IL, United States) with a maximum ablation diameter of 5 cm and needle length of 15 to 25 cm was used in all cases due to the presence of large HCCs in some patients. The following settings were used: power, 150 to 200 W; ablation time, 6 min (3 cm), 8 min (4 cm) and 15 min (5 cm) and target temperature, 105 ℃. RFA was performed twice as routine and three times if necessary. After ablation, final solidification of the puncture path and inactivation of tumor tissue were conducted to avoid bleeding and tumor implantation metastasis.

Post-procedure treatment and follow-up: Local pressure (RF puncture site and puncture site in right femoral artery) was applied after RFA. To alleviate pain, an analgesic pump was used continuously for 3 d which injected 0.2 mg/kg fentanyl with 10 mg of tropisetron hydrochloride and normal saline at a total volume of 80 mL. Electrocardiographic monitoring was performed for 24 h. The following procedures were also conducted: anti-infection, improvement of damaged liver function, nutritional support and defaecation. About 3 d to 1 wk after the procedure, routine blood examination, hepatorenal function and electrolytes were examined. Exactly 1 mo after the procedure, the patients underwent CT, ultrasound or enhanced MRI scan, and examinations for hepatorenal function and tumor markers (AFP, CA199

and carcinoembryonic antigen). If the tumor was well controlled, subsequent reviews were arranged at 2-3 mo intervals. All the images were analysed by a radiologist with over 8 years of experience. The efficacy of the combination therapy on local tumors was assessed according to the evaluation method recommended by the European Association for the Study of the Liver. Complete response (CR) was defined as the absence of signs of intensified lesions in and around the tumor. Partial response (PR) referred to a minimum of 50% reduction in size of the enhancing tumor. Progressive disease (PD) described the presence of new lesions or at least one lesion with 25% reduction in the size of the enhancing tumor. Stable disease (SD) referred to the presence of a stable lesion between PR and SD. During follow-up, the complete inactivation rate, duration and necrosis characteristics of the local tumor and survival condition of the patients were assessed. The appropriate treatment (combination therapy, close observation or single RFA or TACE) of the patients was determined on the basis of clinical conditions, such as the characteristics of new or residual lesions. Major complications were evaluated on the basis of bleeding and injuries of the intestinal canal, bile duct and gallbladder. Minor complications were assessed using several indicators, including changes in hepatorenal function after combination therapy, and changes in syndrome symptoms after embolisation, such as pain.

Statistical analysis

Quantitative data were analysed using CHISS2004 software. The *t* test was employed to compare liver function (Child-Pugh Grade) before and after intervention.

RESULTS

Technical evaluation and clinical efficacy

All patients were tolerant of the concurrent combination therapy. A total of 18 lesions were confirmed by previous images and successfully labelled with lipiodol deposit in TACE. One-off RFA puncture was successfully conducted with two to three RFA needles per lesion (Figures 2, 3). The success rate of the combination therapy was 100%. For 9 cases with lesions near the diaphragm, the puncture avoided normal lung tissue under the perspective and entered the lesions for RFA treatment.

One month after the intervention, all 18 patients underwent routine imaging (ultrasound, enhanced CT or MRI of liver) and AFP examination. Local lesions were mainly characterized by coagulative necrosis without liquefactive necrosis. Increased AFP was discovered in 10 patients before intervention, which significantly decreased 1 mo after surgery. CR was observed in 17 cases, and PR was observed in 1 case. During follow-up, the mean recurrence-free survival time of the 18 cases was 16.8 ± 4.0 mo (2-29 mo). The estimated overall survival rate at 6, 12 and 18 mo was 100%.

Complications after intervention

No TACE and percutaneous RFA-related complications, such as bleeding or necrosis of the gallbladder, bile duct, intestinal canal, pneumothorax or hepatapostema or liver/kidney failure, occurred after the intervention. Pain was completely alleviated by injection of the fentanyl mixture in 16 patients using the analgesic pump, and by 3-4 mg of morphine once every 24 h in 3 patients in addition to the analgesic pump. All patients received oral central analgesics (such as oxycodone hydrochloride) 4 d after treatment to relieve pain. Different degrees of constipation, low fever (37.3-38.4 ℃) and nausea and vomiting were observed in 5, 7 and 5 cases, respectively, and relieved with medication. The ALT (200.4 ± 63.4 U/L) and AST (228.1 U/L ± 25.4 U/L) levels in all patients transiently increased ($P = 0.00 < 0.05$) on the third day after treatment relative to levels before surgery (24.7 ± 9.3 and 32.7 ± 6.8 U/L, respectively). ALT and AST levels decreased to 29.8 ± 11.5 U/L and 36.8 ± 10.2 U/L ($P = 0.15$, $P = 0.16 > 0.05$), respectively, on the 7th day after treatment. No statistical differences in bilirubin and albumin were found before and after treatment.

DISCUSSION

Large solitary HCCs are a special type of liver cancer, the prognosis of which is better than that of the multinodular type after complete inactivation by chemoembolisation or resection[14-17]. Although surgery is still the primary treatment mode for HCC, it has several disadvantages resulting from the large size or location of the carcinoma, such as difficulty in complete resection, heavy bleeding, high incidence of complications and high recurrence rates after surgery[16,17]. Aside from surgery, many other non-surgical treatments such as TACE and RFA are used to cure solitary HCCs. However, TACE or RAF can only inactivate local carcinomas with diameters smaller than a specific value. For instance, TACE treatment requires repetition and a large dose of lipiodol, involves a high likelihood of collateral formation after multiple embolisations and has low inactivation rates after the procedure and adverse effects on long-term liver function and prognosis[17]. In our study, all the patients underwent one to three cycles of TACE before the combination therapy and were reviewed for the presence of residual or new tumors. The results indicate that a single technique cannot completely inactivate HCC and that recurrence rate of the cancer was high after the procedure.

The combination of TACE and RFA is one of the major treatments used to enhance the inactivation rate of local tumors, decreasing short- or long-term recurrence rates and extending patient survival[3-12,17-20]. However, the current combination therapy is mainly performed separately or several times and the local recurrence rate increases as tumor diameter increases[21,22]. The interval between TACE and RFA is longer than 1 or 4 wk, during which recanalization after embolisation, collateral formation and elimination of lipiodol-chemotherapeutant may occur. Therefore, this method is not strictly concurrent, and the effects of TACE and RFA are not fully synergistic.

To increase local tumor inactivation rates, prelimi-

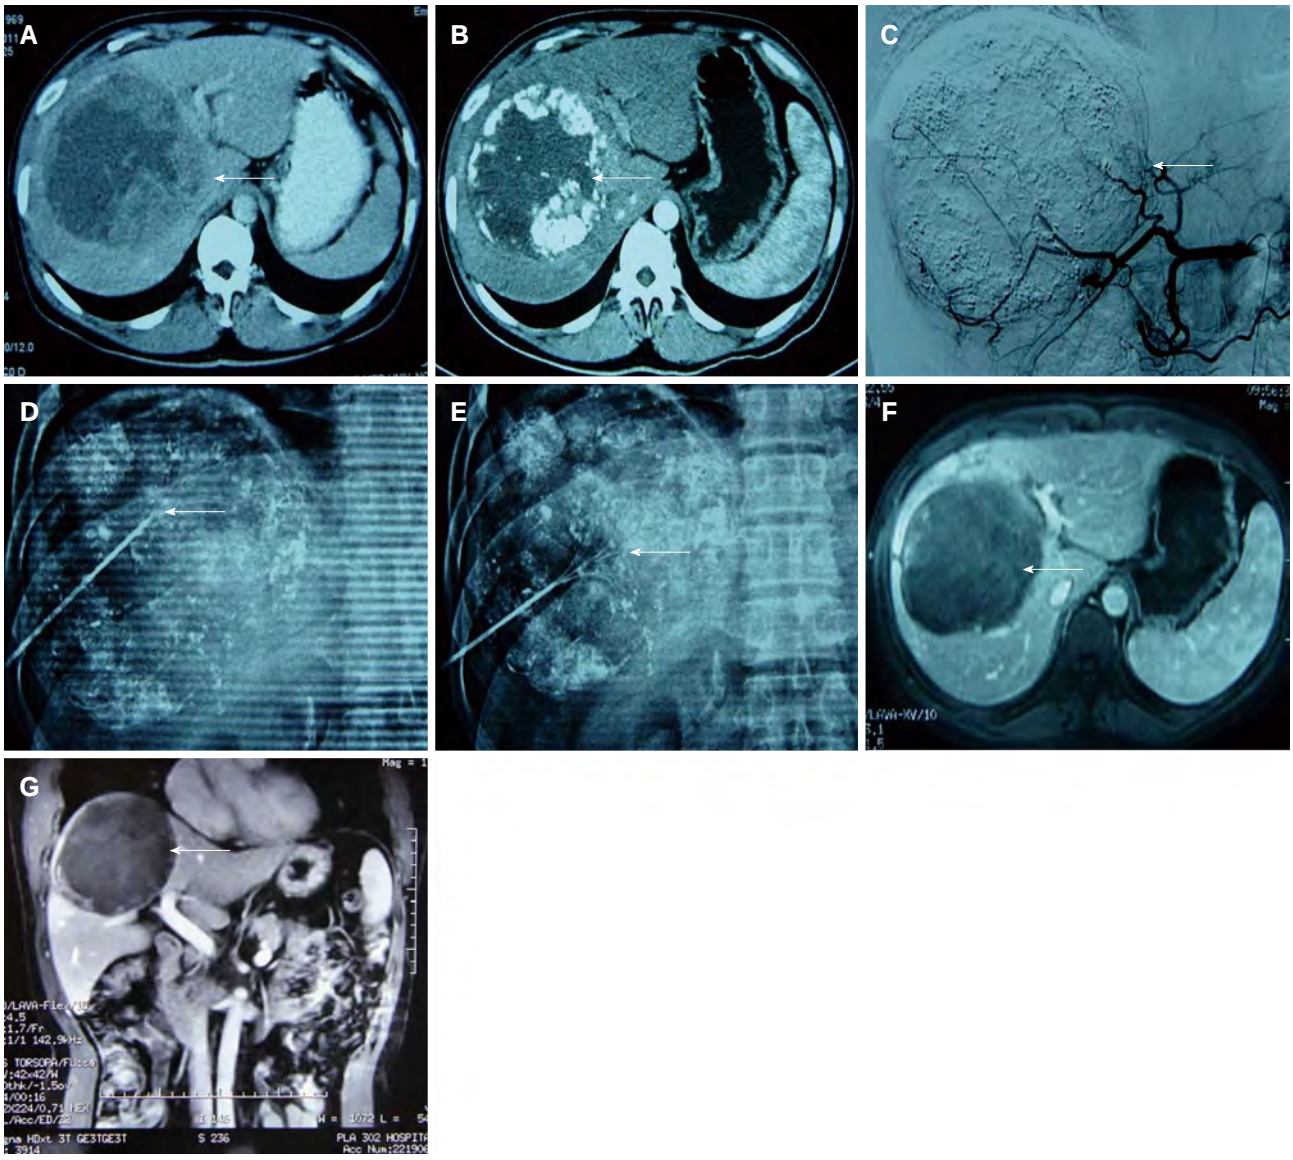

Figure 2 A male patient aged 42 years with poorly differentiated hepatocellular carcinoma. Computed tomography (CT) scan showed a residual lesion in the liver after first interventional therapy with α-fetoprotein (345 μg/mL). Thus, transcatheter arterial chemoembolisation combined with radiofrequency ablation (RFA) was performed. A: CT scan showed a large solitary tumor in the right hepatic lobe before interventional therapy (arrow); B: A lipiodol deposit appeared around the liver tumour after the first procedure. CT revealed an enhanced residual lesion in the artery phase (arrow); C: Hepatic artery angiogram before RFA showed staining of the residual lesion around the lipiodol in the liver (arrow); D, E: A multipolar probe with a maximum extended diameter of 5 cm, which could cover the residual lesion, was designed to perform RFA in the region labelled by lipiodol and the original lesion (lipiodol deposition area). A diaphragmatic dome was involved, and the puncture tunnel detoured the lung tissue under the fluoroscope (arrow); F, G: The hepatic lesion was well controlled, and no recurrence was found after 15 mo follow-up (arrow).

nary studies on the safety and effectiveness of TACE combined with immediate RFA in the treatment of liver tumors (diameter, ≤ 5 cm) have been conducted. Gadaleta *et al*[23] used immediate combination therapy to treat HCC and liver metastatic tumors of different sizes and achieved a success rate of 100% with an 88% CR. Kang *et al*[18] treated HCC (diameter, ≤ 5 cm) by TACE combined with immediate RFA. Approximately 1 mo later, the complete necrosis rate of tumors successfully labelled by TACE was 100%, and the cumulative incidence of local tumor progression at 1 year and 3 years was 1.8% and 9.4%. These results demonstrate the positive effects of immediate combination therapy. We studied the application of immediate combination therapy for large solitary HCCs (diameter, > 5 cm) and showed the favorable clinical efficacy of this method. The clinical efficiency was 100% in 18 patients, with 17 cases of CR and 1 case of PR. Compared with single TACE, combination therapy increased the local inactivation rate and prolonged recurrence-free survival. During follow-up, the estimated overall survival rate at 6, 12 and 18 mo was 100%. Based on the literature and clinical practice, as well as comparisons with conventional sequential therapy, the advantages of immediate combination therapy are as follows: (1) Single TACE or RFA cannot completely inactivate the tumor, especially the tissue on the tumor border, resulting in recurrence. In immediate combination therapy, lipiodol precipitation in the lesion wraps around

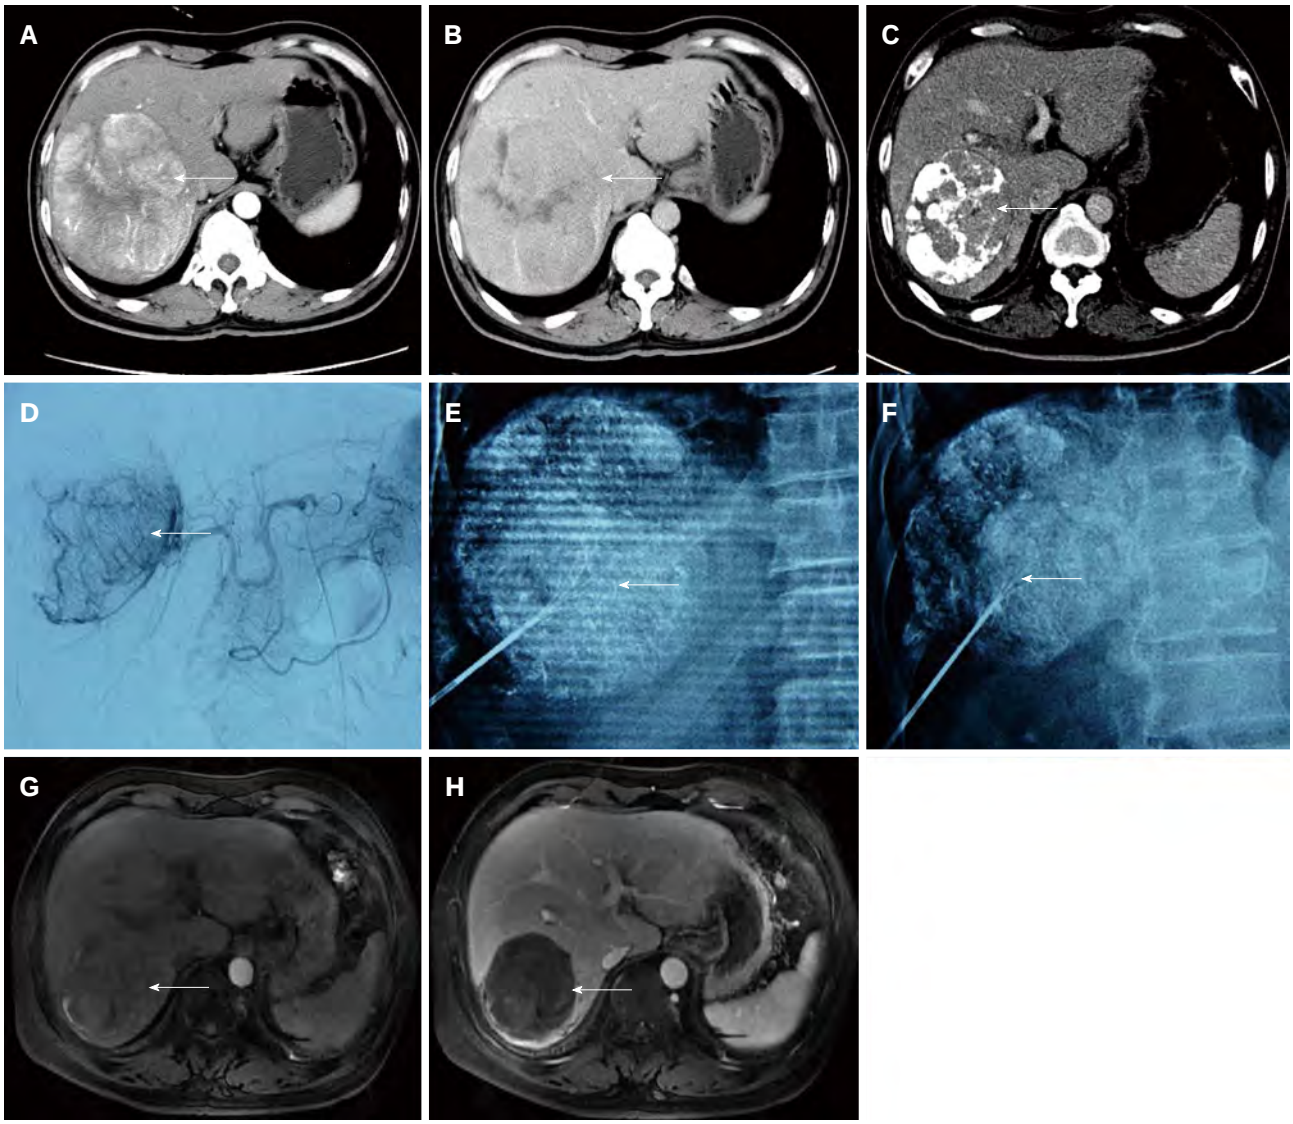

Figure 3 A male patient aged 53 years with a large lesion in the right lobe of the liver. A residual lesion was found after three cycles of transcatheter arterial chemoembolisation (TACE). TACE combined with radiofrequency ablation (RFA) was performed under the guidance of digital subtraction angiography-computed tomography. A, B: A large hypervascular hepatocellular carcinomas was observed in the right lobe (arrow); C, D: A residual lesion around the lipiodol deposit was still visible after three cycles of TACE (arrow); E, F: The lesion was successfully labelled after TACE. A multipolar needle was opened and rotated 70° to the left (E) and right (F) sides to verify whether the RF needle was in the center of the residual lesion (arrow); G, H: The large lesion was well controlled, and no recurrence was observed by magnetic resonance imaging during 13 mo follow-up after combination therapy (arrow).

and inactivates the surrounding tissue of the tumor, thereby preventing recurrence from residual tumors[3,24]; (2) Immediate combination therapy also fully enhances the synergistic effects of chemotherapeutics and thermal ablation. In TACE, lipiodol, which is the carrier of chemotherapeutics, is uncontrolled and unstable. Lipiodol cannot be released slowly with sustained high concentrations. Chemotherapeutics in lipiodol are eliminated over time if no other embolisation agents (such as sponge) are added to the drug. However, in TACE with immediate RFA, chemotherapeutics, such as adriamycin, can inhibit tumors due to their high accumulative concentration in and around the lesions[25,26]; and (3) TACE accurately locates and labels new and residual lesions, as well as lesions that cannot be observed by conventional CT and B ultrasound, through lipiodol precipitation. Thus, RFA targets are more specific. The labelling of lesions by lipiodol precipitation is more effective, especially in lesions that have become relatively complicated after several cycles of TACE because previous necrotic and new or residual lesions are labelled[27,28].

TACE combined with RFA is a safe treatment with 4%-6% incidence of various complications; severe complications are rare[3,18,23,28]. Kang *et al*[18] reported two cases of serious liver damage and one case of hemorrhage from a ruptured hepatic artery in combination therapy. Only one case of hepatic function damage without other complications, such as severe liver failure, was found in our series; this complication may have resulted from the application of a super-selective embolisation technique and bypassing of normal liver tissue by the RFA needle. Most patients only experienced post-embolisation syn-

drome (pain, low fever, *etc.*), transient liver dysfunction and constipation after surgery, all of which were relieved with medication. Constipation may be associated with the continuous application of analgesics, and low fever may be related to absorption after tumor necrosis. Transient liver dysfunction is related to combination therapy. Given that concurrent TACE with RFA increases pain in patients, RFA was performed immediately after TACE under general anaesthesia and tracheal intubation. An analgesic pump was utilized for 3 d to relieve pain. However, three patients still experienced intense local pain, which was alleviated by the addition of analgesics. Therefore, instead of the conventional combination of TACE and RFA, we recommend the application of an analgesic pump for 3 d after immediate combination therapy. Compared with the liquefactive necrosis induced by single TACE or RFA, the tumors were characterized by coagulative necrosis, which has a lower risk for local secondary hepatapostema[5].

Our study has several limitations: (1) The small sample size in this retrospective research may have influenced the results to some extent; and (2) the follow-up period was too short to accurately evaluate long-term efficacy. More patients should be included in comparative studies and further assessment of the advantages of combination therapy.

In conclusion, TACE immediately followed by RFA is a safe and effective treatment for large HCCs. To prevent pain after the procedure, an analgesic pump should be used for 3 d. The long-term efficacy of this combination therapy requires further assessment.

COMMENTS

Background

Transcatheter arterial chemoembolisation (TACE) is the main treatment method for unresectable primary hepatocellular carcinomas (HCC). However, simple TACE has low tumor inactivation and high recurrence rates. In addition, with increasing tumor size, the tumor inactivation rate significantly decreases.

Research frontiers

Combination therapy [mainly TACE combined with radiofrequency ablation (RFA)] is one of the main modalities for treating unresectable HCC. However, RFA is often performed 1 to 2 wk after TACE, which considerably reduces the synergistic effects of the combination therapy, especially for large HCCs.

Innovations and breakthroughs

The combination of TACE with immediate RFA under digital subtraction angiography-computed tomography (CT) guidance is applied to treat large single HCCs. With this technique, different treatment technologies are fused into one angiographic machine, which improves their synergistic effects (*e.g.*, heat treatment with epirubicin and embolisation with thermal ablation), thereby enhancing the inactivation rate of large HCCs and reducing the radiation dose applied to patients and the risk of repeated treatment. Preliminary results show that combination therapy has obvious advantages and can help improve the long-term survival of patients. This technique also has significance in the treatment of other metastatic and hypervascular HCCs.

Applications

TACE immediately followed by RFA is a safe and effective treatment for large HCCs. This technology can improve the synergistic treatment effects of TACE and RFA, as well as reduce the need for repeated treatments and amount of radiation exposure. Furthermore, different treatment technologies are fused into one machine, thereby simplifying the operational process. TACE immediately followed by RFA enhances tumor inactivation ability, decreases recurrence rates, prolongs patient survival time and improves prognosis.

Terminology

TACE: Transcatheter arterial chemoembolisation with lipiodol and chemical drugs. Immediate RFA: RFA procedure is performed immediately after TACE. A three-dimensional CT image, radiofrequency puncture path and parameters are first established to target the lesion and avoid non-target lesions. This combination therapeutic modality requires general anesthesia. Post-procedure pain management is required for 2 to 3 d. The combined therapeutic modality can be used for HCCs and single hypervascular metastatic tumors.

Peer review

In this manuscript, the authors summarised 18 patients treated between January 2010 and June 2012 to assess the technical safety and efficacy of TACE combined with immediate synchronous RFA as a means of treating HCC. The manuscript is very interesting. It is a very good study about the technical safety and efficacy of the combined therapy for large hepatocellular carcinomas.

Abstract

AIM: To investigate the metabolic profiles of xenograft pancreatic cancer before and after radiotherapy by high-resolution magic angle spinning proton magnetic resonance spectroscopy (HRMAS ^{1}H NMR) combined with principal components analysis (PCA) and evaluate the radiotherapeutic effect.

METHODS: The nude mouse xenograft model of human pancreatic cancer was established by injecting human pancreatic cancer cell SW1990 subcutaneously into the nude mice. When the tumors volume reached 800 mm^3, the mice received various radiation doses. Two weeks later, tumor tissue sections were prepared for running the NMR measurements. ^{1}H NMR and PCA were used to determine the changes in the metabolic profiles of tumor tissues after radiotherapy. Metabolic profiles of normal pancreas, pancreatic tumor tissues, and radiation- treated pancreatic tumor tissues were compared.

RESULTS: Compared with ^{1}H NMR spectra of the normal nude mouse pancreas, the levels of choline, taurine, alanine, isoleucine, leucine, valine, lactate, and glutamic acid of the pancreatic cancer group were increased, whereas an opposite trend for phosphocholine, glycerophosphocholine, and betaine was observed. The ratio of phosphocholine to creatine, and glycerophosphocholine to creatine showed noticeable decrease in the pancreatic cancer group. After further evaluation of the tissue metabolic profile after treatment with three different radiation doses, no significant change in metabolites was observed in the ^{1}H NMR spectra, while the inhibition of tumor growth was in proportion to the radiation doses. However, PCA results showed that the levels of choline and betaine were decreased with the increased radiation dose, and conversely, the level of acetic acid was dramatically increased.

CONCLUSION: The combined methods were demonstrated to have the potential for allowing early diagnosis and assessment of pancreatic cancer response to radiotherapy.

Key words: High-resolution magic angle spinning proton magnetic resonance spectroscopy; Principal components analysis; Pancreatic cancer; Radiotherapy

Core tip: In the present study, for the first time to our knowledge, high-resolution magic angle spinning proton magnetic resonance spectroscopy and principal components analysis were combined to highlight metabolite profiles of pancreatic cancer after radiotherapy,

by analyzing the correlation between radiotherapy effect and metabolic change, and optimizing the therapeutic scheme. The results showed that metabolic profile changes of pancreatic cancer after radiotherapy were closely correlated with therapeutic effect. The outcome of the study is both interesting and beneficial to pathological research, early diagnosis, and therapy evaluation of pancreatic diseases.

Metabonomic studies of pancreatic cancer response to radiotherapy in a mouse xenograft model using magnetic resonance spectroscopy and principal components analysis. *World J Gastroenterol* 2013; 19(26): 4200-4208 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i26/4200.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i26.4200

INTRODUCTION

Pancreatic cancer is a malignant tumor with very poor prognosis, and surgery has been considered as the only radical therapy. However, about 85% of newly diagnosed cases have developed distant metastasis, and only 5%-25% of pancreatic head cancer and less than 10% of pancreatic body cancer can be treated with surgical excision, and the postoperative recurrence rate is high. Therefore, radiation therapy has become the predominant treatment method for locally advanced pancreatic cancer[1-3]. Therapeutic evaluations of radiotherapy are mainly: remission from the symptoms of pain and jaundice, solid tumor size and its survival time, and the lack of a specific targeted method. During the last three decades, there has been ongoing magnetic resonance spectroscopy (MRS) research in malignant diseases. These studies provided valuable data on the biochemistry and metabolism of tumors, and on the effects of nutrients, hormones, and growth factors[4,5]. The mechanisms of action of anticancer drugs and the acquired resistance to these agents were delineated[6,7]. MRS was also used for monitoring the response to therapy[8,9].

High-resolution magic angle spinning proton magnetic resonance spectroscopy (HRMAS ^{1}H NMR) is a well-recognized technique in metabonomics studies *in vitro*, by which biopsy or postmortem samples of intact tissues are spun at the magic angle, resulting in a significant improvement in the resolution of the spectrum obtained for some of the line-broadening factors, such as dipole–dipole interactions and chemical shift anisotropy, and magnetic field inhomogeneities are averaged out[10,11]. This approach requires minimal sample preparation and, unlike convenient ^{1}H NMR spectroscopy of tissue extracts, both aqueous and lipid-soluble metabolites can be observed simultaneously *in situ*. In addition, information about the metabolic environment of the tumor can also be obtained. Therefore, HRMAS ^{1}H NMR has proved to be an efficient method for studying a wide variety of cancers, including breast cancer[12], cervical cancer[13], kidney cancer[14], prostate cancer[15], malignant lymph nodes[16], and liposarcoma[17] of animals and humans. However, so far, there are very few metabonomic studies in cancer therapeutics by the application of HRMAS ^{1}H NMR.

HRMAS ^{1}H NMR spectra obtained from tissues reflect the dynamic biological systems and processes that contribute to the overall metabolic status of an organism. It is not possible to isolate the effects of any single metabolite signal in a spectrum and, furthermore, the manual analysis of even a small number of such spectra is a laborious and complex task. Therefore, metabonomists utilize data reduction and multivariate analysis techniques, such as principal components analysis (PCA), to facilitate automated NMR pattern recognition[18,19]. Moreover, our previous study demonstrated that using ^{1}H NMR and PCA could discriminate pancreatic cancer from chronic pancreatitis accurately[20]. In the present study, HRMAS ^{1}H NMR and PCA were combined to highlight metabolite profiles of pancreatic cancer after radiotherapy, in order to analyze the correlation between radiotherapy effects and metabolic changes, and to optimize the therapeutic scheme. The study has an important implication for reference guides on therapeutic evaluation by nuclear magnetic resonance spectroscopy on pancreatic cancer *in vivo*.

MATERIALS AND METHODS

Animals and experiment schedule

Six- to eight-week-old female nude mice were obtained from the Planned Parenthood Research Institute, Shanghai, People's Republic of China. All animals in this study were housed under pathogen-free conditions and maintained in accordance with the guidelines of the Committee on Animals of the Second Military Medical University, Shanghai, China. Human pancreatic cancer cell line SW1990 in mid-log-growth phase was harvested by trypsinization. Single-cell suspensions (5×10^{6} cells in 0.1 mL HBSS) were injected subcutaneously into the nude mice. The tumors were measured every 4 d with a caliper, and the diameters were recorded. Tumor volume was calculated by the formula: $a^{2}b/2$, where a and b are the two maximum diameters. When tumors reached 2.0 cm × 2.0 cm, the duration of survival was recorded and the mouse euthanized.

For the radiotherapy experiment, when the tumor volume reached 800 mm^{3}, the mice were divided into four groups. Group A mice were used as untreated controls. Groups B, C, and D received 10, 20, and 30 Gy radiation doses, respectively. Tumor size was measured as described above. Two weeks later, tumor tissue sections were prepared for histological tests or for running the NMR measurements.

NMR spectroscopy

HRMAS ^{1}H NMR experiments were carried out using a DRX-500 spectrometer (1H frequency at 500.13 MHz;

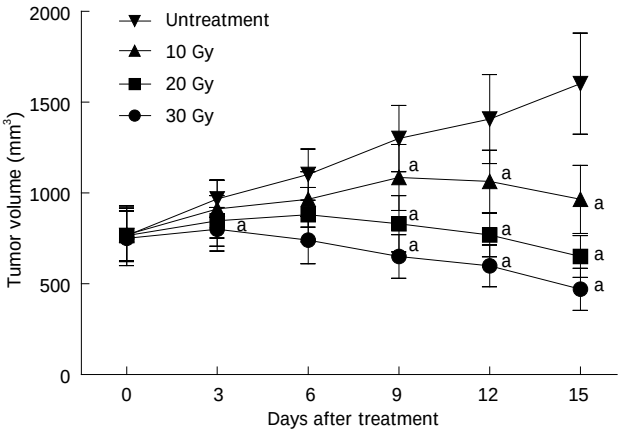

Figure 1 Effect of radiotherapy on the growth of human pancreatic tumor in nude mouse. Mice received a subcutaneous injection of SW1990 cells. When the tumor volume reached about 800 mm^3, the mice were divided into four groups. Group A mice were used as untreated controls. Groups B, C, and D received 10, 20, and 30 Gy radiation doses, respectively. Tumor size was measured for two weeks. $^{a}P < 0.05$ *vs* the untreated group.

Bruker Biospin, Rheinstetten, Germany). Tissue samples were rinsed three times with D_2O and placed into a 4-mm zirconium oxide MAS rotor with drops of D_2O (deuterium lock reference). Spectra were acquired at 300.0 K using single-pulse and CPMG pulse sequences, both with water presaturation during the relaxation delay of 2 s. CPMG pulse sequence was applied as a T2 filter to suppress signals from the molecules with short T2 values (such as macromolecules and lipids) using a total TE of 320 ms. The main parameters used for ^{1}H NMR spectra were: SW = 15 kHz; TD = 64 k; NS = 256; and MAS rate = 5 kHz. Spectral assignments were confirmed by 2-dimensional ^{1}H-^{1}H TOCSY and ^{1}H-^{1}H COSY (data not shown), together with values obtained from the literature[10,21].

The stability of tissue samples was evaluated by repeating a 1-dimensional NMR experiment after overall acquisition. No biochemical degradation was observed for any of the tissue samples.

Principal components analysis

Spectral data were phased and baseline-corrected using XWINNMR (Bruker Biospin). All FID were multiplied by an exponential function equivalent to a 0.3-Hz line broadening factor prior to Fourier transformation. Each HRMAS ^{1}H NMR spectrum was segmented into 211 regions of equal width (0.04 ppm) over the region 0.00-10.00, and the signal intensity in each region was integrated using AMIX version 3.6 (Bruker, Biospin). The region 4.50-5.00 was removed to eliminate baseline effects of imperfect water saturation. Prior to PCA, each integral region was normalized by dividing by the sum of all integral regions for each spectrum[12,14]. In order to exclude the effects of lipids and concentrate on the impacts of LMW metabolites in the CCM region, PCA was again done for ^{1}H CPMG NMR spectra over the range 0.7-4.70, each 0.04 ppm wide. PCA was used to calculate a new, smaller set of orthogonal variables from linear combinations of the intensity variables, while retaining the maximum variability present within the data. These new variables are the derived principal components, and the distribution of their values (scores) permits the simple visualization of separation or clustering between samples. The weightings (loadings) given to each integral region in calculating the principal components allows for the identification of those spectral regions of greatest influence to the separation and clustering and, hence, the deduction of biomarkers of pancreatic cancer.

Statistical analysis

Continuous variables are expressed as mean ± SD. Statistical analysis of data was done by Student's *t* test using SigmaPlot software. Differences were considered statistically significant at $P < 0.05$.

RESULTS

Radiotherapy of human pancreatic tumor-bearing nude mouse

One week after SW1990 tumor cell inoculation, tumor size was measured and tumor volume recorded weekly. All 32 nude mouse models generated tumor tissues, and the success rate of model construction was 100% (32/32). Tumor volume in the control group (untreated), and the three groups which were given 10, 20, and 30 Gy radiation are shown in Figure 1. The transplanted tumor volume before treatment was 0.8 cm^3 on average, increasing with breeding period in the control group. Compared with the control group, the tumor volume of the treatment groups reduced significantly, with the most obvious being the 30 Gy dose treatment group. These data showed that radiotherapy could effectively suppress the growth of pancreatic cancer in the nude mice. The changes in the morphological levels are expected to be accompanied with observable changes in the tissue biochemical composition which can be accessed with HRMAS ^{1}H NMR spectroscopy *ex vivo*.

Metabolic profiles of normal pancreas and pancreatic tumor tissues

Using ^{1}H NMR spectroscopy, components such as Cho, taurine (Tau), betaine (Bet), glutamic acid (Glu), glycerophosphocholine, and choline phosphate (GPC + PC), acetic acid (Ace), alanine (Ala), and lactic acid (Lac) were detected and identified in the normal pancreas and isolated transplanted tumor tissues in the nude mouse by their spectrum peaks. The literature was referred to before (18-20) and 2-D spectrum estimation (J-res, COSY, TOCSY) (Figure 2A). Score plots of PCA based on ^{1}H NMR spectra were performed on 8 normal and 8 tumor samples, in which the spectra region was δ = 0.70-4.70, and the minimal region δ = 0.04 (Figure 2B). As shown in the loading plots, the main factors that differentiated the samples were δ 0.90-0.86, δ 1.34-1.26, δ 1.50-1.46, δ 3.30-3.18, δ 3.46-3.38, and δ 3.70-3.66, which were con-

sistent with what was observed in Figure 2A, corresponding to the residual lipid, Lac, Ala, Cho compound, Tau, and unknown chemicals.

As is well-known, absolute concentration quantification for metabolites is difficult in HRMAS spectroscopy, and the metabolite ratios are commonly used for statistical analysis. Table 1 shows the relative signal integrals and signal ratios for some metabolites that contributed to the classification of normal pancreas and pancreatic tumor tissues discussed in the above sections. Compared to the normal pancreas, concentrations of Ileu, Leu, Val, Lac, Ala, Glu, Tau, Cho, and some carbohydrates (G, contained galactose β-H possibly due to characteristic twin peak at δ 4.52) increased relatively in the pancreatic tumor samples, while GPC + PC, Bet, GPC/Cre, and unknown chemicals at δ 3.66 decreased relatively. The level

Table 1 Relative integrals and their ratios from some selected metabolites contributing to the classification of normal pancreas and pancreatic tumor tissues

		Normal pancreas	Pancreatic tumor	*P*-value
Metabolites	Choline	2.75 ± 1.37	3.99 ± 0.35	0.0376
	Taurine	1.99 ± 0.55	13.63 ± 2.92	0.0001
	Betaine	2.91 ± 0.57	1.58 ± 0.47	0.0002
	Glutamic acid	0.29 ± 0.11	0.46 ± 0.13	0.0260
	Alanine	0.60 ± 0.14	1.93 ± 0.16	0.0001
	Lactate	1.93 ± 0.86	8.30 ± 1.02	0.0001
	Acetic acid	0.06 ± 0.10	0.06 ± 0.03	0.7942
	Glycerophosphocholine+ phosphocholine	19.47 ± 1.36	16.61 ± 1.31	0.0007
Metabolites ratio	Glycerophosphocholine/ Creatine	3.51 ± 0.76	2.35 ± 0.58	0.0042
	Phosphocholine/ Creatine	5.19 ± 0.96	6.22 ± 1.52	0.1284

of Ace and PC/Cre showed no significant change.

Metabolic profiles of pancreatic tumor tissues after radiotherapy

The metabolic profiles of tumor tissues after radiotherapy were also detected by ^{1}H NMR. As shown in Figure 3A, no significant metabolic changes were observed in the ^{1}H NMR spectrum. PCA analysis was further conducted on samples in each group, with the spectrum integration region δ = 0.70-4.70, and the minimal region δ = 0.04 (Figure 3B). In score plots, most of samples in the control group concentrate in the upper left, but overlap partly with samples in the 10 Gy radiation dose group. A partial overlap is shown between the 10, 20, and 30 Gy radiation dose groups, but overall it seems that the three groups have a left, upper, and lower distribution trend in terms of scores. Loading plots showed the changes of Cho-containing compounds, along with Ace and Bet content among the three dose groups.

Table 2 shows the relative signal integrals and signal ratios for some metabolites that contributed to the evaluation of pancreatic tumor tissues response radiotherapy. Cho content showed a significant difference between the control and 30 Gy dose groups, as well as the 10 and 30 Gy dose groups. The Cho content decreased with an increase of radiation dosage. Bet content also decreased with an increase of radiation dosage. In contrast, Ace content showed a positive relationship with the radiation dosage.

DISCUSSION

Although HRMAS ^{1}H NMR combined with PCA has been demonstrated as an efficient method for studying a wide variety of animal and human cancers[12-17], this combined method has not been reported to analyze the metabolic features of cancer response to therapy. Here, for the first time to our knowledge, our findings demonstrate that applying this combined method has the potential for clinical assessment of the pancreatic cancer radiotherapeutic response.

Kaplan *et al*[22] conducted ^{1}H NMR analysis on perchlorate extract (water-soluble) of heterotopic transplanted pancreatic cancer tissue in nude mice. Compared with the normal pancreas of nude mice, Tau and Lac content in transplanted tumors increased, GPC content decreased, and there was little change in Cho and PC. However, in previous studies, some important information may be missed, and human factors introduced as a destructive process in extraction will lead to a negative impact on the results, along with poor experimental repeatability results from different pH values. Therefore, in this study, ^{1}H NMR combined with PCA was applied to the metabolic study on transplanted tumor tissues in a human pancreatic tumor-bearing nude mouse model. This has avoided the error factor involved in complex processes such as tissue extraction. Moreover, due to the application of the 500 mHz high-field strength NMR instrument, the spectrum resolution obtained is significantly higher than that reported in the literature, with more metabolites being found and variation characteristics of metabolites embodied more clearly. Consequently, not only did the accuracy of spectrum peak identification improve, but statistical analysis errors were also reduced. In this study using ^{1}H NMR combined with PCA, pancreatic cancer was shown to have higher Tau, Ileu, Leu, Val, Lac, Ala, Glu, and Cho levels relative to normal pancreas, while GPC + PC, and Bet and GPC/Cre levels decreased relatively. Compared to the other metabolites, Tau, Lac, and Ala had the most noticeable differences between normal pancreas and pancreatic cancer. Ace and PC/Cre showed no significant difference between normal and pathological conditions. The results suggest that these changes in the metabolite profile might be used as metabolic markers for the early diagnosis of pancreatic cancer.

Radiotherapy is a local treatment, and its ultimate goal is to eradicate tumor cells thoroughly, while protecting normal tissues and vital organs as much as possible[23]. The application of computer tomography simulations and the three-dimensional conformal technique in radiotherapy has boosted the pancreatic target dosage and offered better protection for the gastrointestinal tract. Currently, therapeutic evaluations of radiotherapy are mainly: remission from the symptoms of pain and jaundice, solid tumor size and its survival time, and the lack of a specific targeted method[23]. By imaging examination, tumor size and contrast agent enhancement were observed to determine tumor activity, and indirectly determine therapy efficacy, although lacking strong direct evidence[24-27]. In this study, we use ^{1}H NMR and PCA to compare pancreatic cancer metabolic variation characteristics before and after radiotherapy. Although no significant metabolic changes were observed in the ^{1}H NMR spectra, PCA results showed a trend of certain changes among different dosage groups. We found that the Ace level was increased, which positively correlated with the radiation dose. In contrast, Cho and Bet levels were decreased, which in-

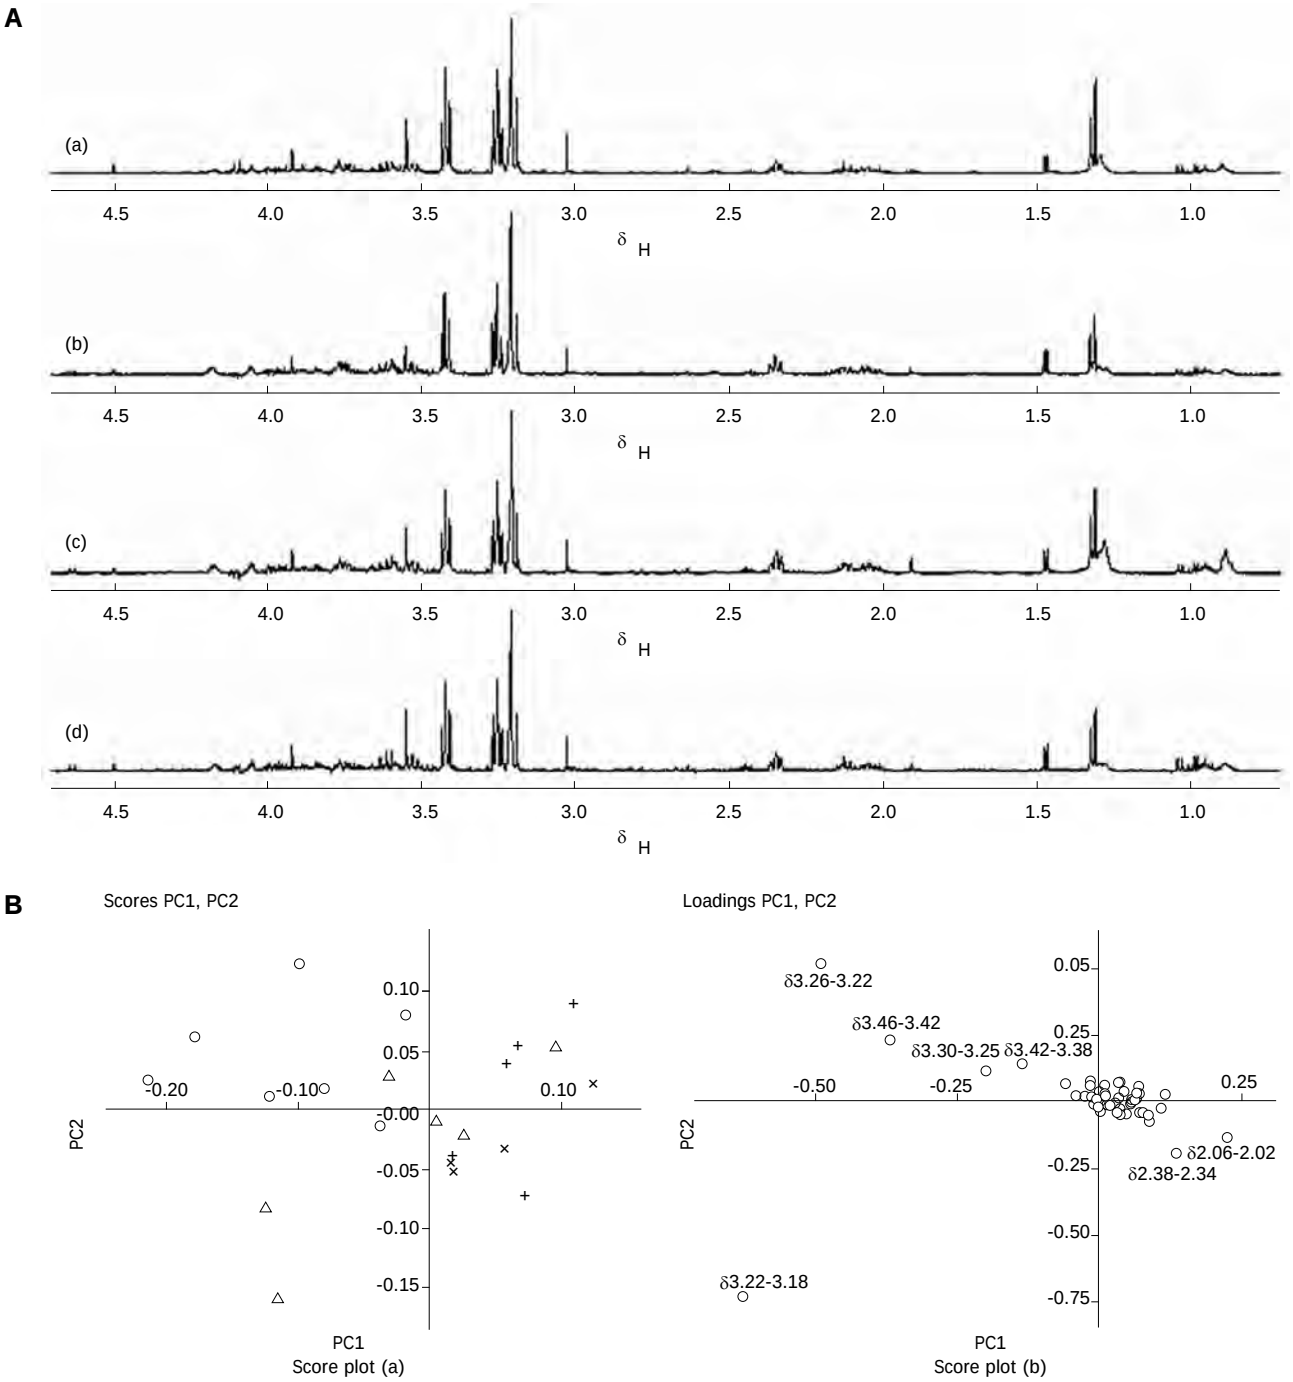

Figure 3 High-resolution magic angle spinning proton magnetic resonance spectroscopy spectra of transplanted pancreatic tumor after radiotherapy (500 mHz). A: Untreated group(a); 10 Gy treatment group (b); 20 Gy treatment group (c); 30 Gy treatment group (d); B: Principal component analysis to compare the metabolic profiles of the pancreatic tumor after radiotherapy based on the high-resolution magic angle spinning proton magnetic resonance spectroscopy spectra. versely correlated with the radiation dose. Additionally, other metabolites, including Tau, Ileu, Leu, Val, Lac, Ala, Glu, and GPC + PC showed no significant change after radiotherapy. Thus, these data suggest that the changes in these metabolite profiles might provide a reference guide on therapeutic evaluation by NMR on pancreatic cancer *in vivo*.

Choline-containing metabolites (CCM) have already been chosen as biomarkers in various carcinoma studies[28,29]; however, they have not been mentioned in cancer treatment so far. CCM levels were shown to increase in most cancer tissues, which were explained as a result of high membrane concentration during the proliferation of cancer cells. We found that Cho level was reduced in pancreatic cancer after radiotherapy, suggesting that proliferation of cancer cells was inhibited in response to radiotherapy. However, PC and GPC levels showed no significant change in tumor tissue after radiotherapy. This

might be explained by a blockage of Cho-kinase and PC transferase, or by the consumption of PC through the CDP-Cho pathway[30,31]. Thus, we may deduce that increasing Cho and unchanged PC and GPC could be used as a unique profile of pancreatic cancer response to radiotherapy. Bet donates methyl groups for the remethylation of homocysteine to methionine and dimethylglycine, which supports proper liver and pancreatic function, cellular replication, and detoxification reactions. Because Cho is the precursor of Bet, the decrease of both Bet and Cho levels in pancreatic cancer after radiation treatment must be interrelated. Interestingly, the Ace level showed no significant difference between the normal pancreas and pancreatic cancer. However, Ace level dramatically increased with the radiation dose. The underlying significance of this needs to be further investigated.

In summary, although the number of samples in our study was limited, the potential of HRMAS NMR for the *in vitro* investigation of pancreatic disease response to radiotherapy should not be ignored. The above results clearly demonstrate that the metabolic profile changes of pancreatic cancer after radiotherapy were closely correlated with therapeutic effect through HRMAS ^{1}H NMR and the PCA combined method. Because metabolite changes observed by HRMAS NMR always occur before morphological changes investigated by MRIS, HRMAS NMR will certainly be beneficial to pathological research, early diagnosis, and therapy evaluation of pancreatic diseases.

COMMENTS

Background

Therapeutic evaluations of radiotherapy are mainly: remission from the symptoms of pain and jaundice, solid tumor size and its survival time, and the lack of a specific targeted method. During the last three decades, there has been ongoing magnetic resonance spectroscopy research in malignant diseases. These studies provided valuable data on the biochemistry and metabolism of tumors, along with the effects on nutrients, hormones, and growth factors.

Research frontiers

High-resolution magic angle spinning proton magnetic resonance spectroscopy (HRMAS ^{1}H NMR) is a well-recognized technique in metabonomics studies *in vitro*, by which biopsy or postmortem samples of intact tissues are spun at the magic angle, resulting in a significant improvement in the resolution of the spectrum obtained for some of line-broadening factors such as dipole–dipole interactions and chemical shift anisotropy. Magnetic field inhomogeneities are also averaged out. This approach requires minimal sample preparation and, unlike convenient ^{1}H NMR spectroscopy of tissue extracts, both aqueous and lipid-soluble metabolites can be observed simultaneously *in situ*.

Innovations and breakthroughs

Although HRMAS ^{1}H NMR combined with principal components analysis (PCA) has demonstrated to be an efficient method for studying a wide variety of animal and human cancers, this combined method has not been reported to analyze the metabolic features of cancer response to therapy. Here, HRMAS ^{1}H NMR and PCA were combined to highlight metabolite profiles of pancreatic cancer after radiotherapy, and by which the correlation between radiotherapy effect and metabolic change was analyzed, and the therapeutic scheme optimized.

Applications

The study has important implication for a reference guide on therapeutic evaluation by nuclear magnetic resonance spectroscopy on pancreatic cancer *in vivo*.

Peer review

The authors investigated whether metabolic profile changes of pancreatic cancer after radiotherapy were closely correlated with therapeutic effect through the HRMAS ^{1}H NMR and PCA combined method. The outcome of the study is interesting and beneficial to pathological research, early diagnosis, and therapeutic evaluation of pancreatic diseases.

Abstract

AIM: To perform a large-scale retrospective comparison of laparoendoscopic single-site cholecystectomy (LESSC) and three-port laparoscopic cholecystectomy (TPLC) in a single institution.

METHODS: Data were collected from 366 patients undergoing LESSC between January 2005 and July 2008 and were compared with the data from 355 patients undergoing TPLC between August 2008 and November 2011 in our department. Patients with body mass index greater than 35 kg/m^2, a history of major upper abdominal surgery, signs of acute cholecystitis, such as fever, right upper quadrant tenderness with or without Murphy's sign, elevated white blood cell count, imaging findings suggestive of pericholecystic fluid, gallbladder wall thickening > 4 mm, and gallstones > 3 cm, were excluded to avoid bias.

RESULTS: Altogether, 298 LESSC and 315 TPLC patients met the inclusion criteria. The groups were well matched with regard to demographic data. There were no significant differences in terms of postoperative complications (contusion: 19 *vs* 25 and hematoma at incision: 11 *vs* 19), hospital stay (mean ± SD, 1.4 ± 0.2 d *vs* 1.4 ± 0.7 d) and visual analogue pain score (mean ± SD, 8 h after surgery: 2.3 ± 1.4 *vs* 2.3 ± 1.3 and at day 1: 1.2 ± 0.4 *vs* 1.3 ± 1.2) between the LESSC and TPLC patients. Four patients required the addition of extra ports and 2 patients were converted to open surgery in the LESSC group, which was not significantly different when compared with TPLC patients converted to laparotomy (2 *vs* 2). LESSC resulted in a longer operating time (mean ± SD, 54.8 ± 11.0 min *vs* 33.5 ± 9.0 min), a higher incidence of intraoperative gallbladder perforation (56 *vs* 6) and higher operating cost (mean ± SD, 1933.7 ± 64.4 USD *vs* 1874.7 ± 46.2 USD) than TPLC. No significant differences in operating time (mean ± SD, 34.3 ± 6.0 min *vs* 32.7 ± 8.7 min) and total cost (mean ± SD, 1881.3 ± 32.8 USD *vs* 1876.2 ± 33.4 USD) were found when the last 100 cases in the two groups were compared. A correlation was observed between reduced operating time of LESSC and increased experience (Spearman rank correlation coefficient, -0.28). More patients in the LESSC group expressed satisfaction with the cosmetic result (98% *vs* 85%).

CONCLUSION: LESSC is a safe and feasible procedure in selected patients with benign gallbladder diseases, with the significant advantage of cosmesis.

Key words: Cholecystectomy; Laparoscopy; Single site;

Retrospective studies

Core tip: This is a large-scale retrospective randomized study aimed to explore the safety and feasibility of laparoendoscopic single-site cholecystectomy (LESSC) for the treatment of benign gallbladder diseases, compared with three-port laparoscopic cholecystectomy in clinical outcomes. It was found that LESSC is a safe and feasible procedure in selected patients, with the significant advantage of cosmesis.

INTRODUCTION

Laparoendoscopic single-site cholecystectomy (LESSC) has increased in popularity due to its potential cosmetic benefits and faster recovery. It is predicted that this technique may become a standard approach to cholecystectomy[1-3]. The aim of this study was to report our experience in the LESSC with the aid of suture suspension by performing a retrospective comparison with conventional three-port laparoscopic cholecystectomy (TPLC).

MATERIALS AND METHODS

Between January 2005 and November 2011, 366 patients underwent LESSC and 355 underwent TPLC in the Department of Hepatobiliary Surgery, Zhujiang Hospital, Guangzhou, China. Retrospective data were collected from both case notes and the operating theater database.

As the LESSC procedure is a new technique and we have performed TPLC for nearly 15 years at this hospital, to avoid bias, the exclusion criteria for both the LESSC and TPLC groups included patients with a body mass index greater than 35 kg/m^2, history of major upper abdominal surgery, signs of acute cholecystitis, such as fever, right upper quadrant tenderness with or without Murphy's sign, elevated white blood cell count, imaging findings suggestive of pericholecystic fluid, gallbladder wall thickening > 4 mm, and gallstones > 3 cm. This study protocol was approved by the Institutional Review Board of the Second Affiliated Hospital of Southern Medical University, Guangzhou, China in November 2009 (No. ZJYY-2012-GDEK-001). Written informed consent for the procedure was obtained from all patients.

Eligible patients were assigned to the LESSC group (n = 298) and the TPLC group (n = 315). Collected data included patient demographics, intra-operative data about estimated blood loss, intra-operative complications, conversion to multi-port laparoscopic cholecystectomy (LC) or open surgery, and operating time (in all patients and in the last 100 patients in both groups), and postoperative data about length of hospital stay, visual analogue pain score, post-operative complications (contusion: an injury around the port site and bruised skin; hematoma: a localized collection of blood in the port site), total cost (for all patients and for the last 100 patients in both groups) and cosmetic results. The total costs for all procedures in the study were calculated using hospital financial records, which consisted of the cost of operating room usage and hospital ward stay during the perioperative period. Postoperative pain was assessed using a standard visual analogue scale [range, 0 (no pain) to 10 (maximum pain)] at 8 h after surgery and on postoperative day 1. The cosmetic effect was evaluated at the 2-wk follow-up visit, where patients were asked to assess the cosmetic results (satisfied or not very satisfied) by identifying the number and site of scars[4]. All operations were performed by two experienced surgeons who had performed more than 200 LC procedures before this study.

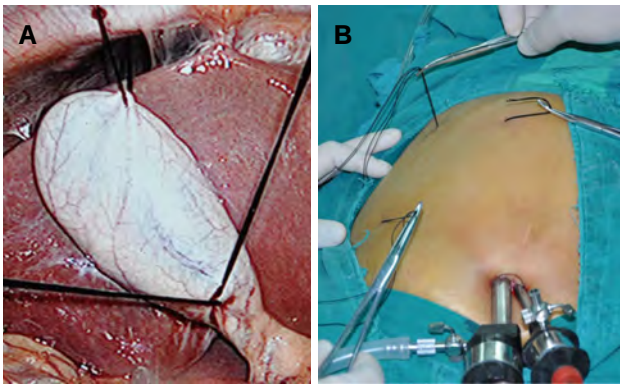

Figure 1 Suture suspension. A: The fundus and Hartmann's pouch were punctured and retracted by two sutures to expose Calot's triangle; B: Puncture spot at the superior chest wall along the costal margin in order to draw the liver up a bit more.

Surgical procedure

LESSC was performed with the help of 2 slings of sutures, and included the following steps.

Under general anesthesia, a single curved intra-umbilical 20-mm incision was made. One 10-mm trocar (Tonglu Kanger Medical Instrument Co., Ltd., Hangzhou, China) was placed to allow the insertion of a 30-degree laparoscope (Olympus, Tokyo, Japan) through the abdomen at the left side of the incision and a 5-mm trocar (Tonglu Kanger Medical Instrument Co., Ltd., Hangzhou, China) was inserted at the right side for the harmonic scalpel (Ethicon Endosurgery, 5 mm, Cincinnati, OH, United States). Tissues between the trocars were preserved to prevent air leakage. The first suture using a straight needle was inserted through the right 7th inter-costal space in the anterior axillary line, and the seromuscular layer of the gallbladder fundus was punctured and retracted toward the anterior abdominal wall. Hartmann's pouch was punctured and retracted using the second suture to expose Calot's triangle (Figure 1). A harmonic scalpel was used to dissect Calot's triangle. Once the cystic artery and duct were exposed, the cystic artery was cut using the

Figure 2 Umbilical incision was closed.

harmonic scalpel, and the cystic duct was ligated by three 5-mm titanium clips (Tonglu Kanger Medical Instrument Co., Ltd., Hangzhou, China) and divided. The harmonic scalpel was used to dissect the gallbladder from the gallbladder fossa. The specimen was placed into a specimen bag (TK Medical, Guangzhou, China), and removed through the umbilical incision. The umbilical incision was closed without a drainage tube in place (Figure 2)

In the TPLC procedure, the same instruments were used as in the LESSC procedure. A sub-umbilical incision, ultimisternal incision and right sub-costal incision were made. A 10-mm trocar was inserted into the sub-umbilical incision to allow introduction of the laparoscope, and another two trocars, a 10-mm and a 5-mm, respectively, were inserted for the grasp and harmonic scalpel. The operation was performed following the routine three-port cholecystectomy procedure[5], however, the cystic artery was divided and cut using the harmonic scalpel instead of being clipped and divided.

Statistical analysis

Statistical analysis was accomplished using the SPSS program for Windows 12.0 (SPSS, Chicago, IL, United States). The χ^2 test or t test was used as indicated. The Spearman rank correlation was used to investigate the relationship between operating time and experience. All data were presented as mean ± SD. $P < 0.05$ was considered statistically significant.

RESULTS

There were no significant differences regarding demographic variables between the two groups (Table 1). In the LESSC group, four patients required additional ports (one or two) to adequately expose Calot's triangle. There were two conversions to open surgery in each group due to abnormal anatomy. There were no major intra- or post-operative complications such as bleeding, infection and bile leakage, however, LESSC resulted in a higher incidence of intraoperative gallbladder perforation than TPLC (56 cases *vs* 6 cases, $P < 0.001$). Overall, there were no significant differences in terms of surgical complications such as contusion (19 cases *vs* 25 cases, $P = 0.4540$) and hematoma at incision (11 cases *vs* 19 cases, $P = 0.1790$), hospital stay (1.4 ± 0.2 d *vs* 1.4 ± 0.7 d, $P = 1.0000$), and visual analogue pain score (8 h after surgery: 2.3 ± 1.4 *vs* 2.3 ± 1.3, $P = 1.0000$ and at day 1: 1.2 ± 0.4 *vs* 1.3 ± 1.2, $P = 0.2042$) between the LESSC and TPLC groups. LESSC resulted in a longer operating time (54.8 ± 11.0 min *vs* 33.5 ± 9.0 min, $P < 0.0010$). However, the operating time in the last 100 cases in the two groups was the same (34.3 ± 6.0 min *vs* 32.7 ± 8.7 min, $P = 0.1589$). A correlation was observed between reduced operating time and increased experience, with a Spearman rank correlation coefficient of -0.28.

Table 1 Demographic data

	LESSC (n = 298)	TPLC (n = 315)	P value
Age (yr)	41.5 ± 14.0	42.3 ± 11.0	0.3997
Female/male	170/128	191/124	0.3670
BMI (kg/m^2)	23.1 ± 4.0	23.5 ± 3.0	0.1279
ASA	1.4 ± 0.1	1.4 ± 0.2	1.0000
Clinical diagnosis			0.4530
Cholecystolithiasis	192	212	
Cystic polyps	106	103	

ASA: American Society of Anesthesiology; LESSC: Laparoendoscopic single site cholecystectomy; TPLC: Three-port laparoscopic cholecystectomy; BMI: Body mass index.

The total cost for LESSC per patient was 1933.7 USD compared with 1874.1 USD for the TPLC procedure (1933.7 ± 64.4 USD *vs* 1874.7 ± 46.2 USD, $P < 0.001$), and the overall cost of LESSC was approximately 57.8 USD more than the TPLC technique. However, no significant difference was found when the last 100 cases in the two groups were compared (1881.3 ± 32.8 USD *vs* 1876.2 ± 33.4 USD, $P = 0.0571$), suggesting that the cost difference was mainly due to the increased operating time.

Most patients were surprised by the reduced number of sites, and more patients who underwent LESSC satisfied with the cosmetic result than those who underwent TPLC (98% *vs* 85%, $P = 0.0010$) (Table 2).

DISCUSSION

Laparoendoscopic single-site surgery has attracted wide attention due to the decreased number of incisions needed and potentially good cosmetic results[6-13]. Recently, more studies have focused on comparing LESSC with multi-port LC and have reached an agreement that LESSC may become the gold standard treatment[14,15]. However, there is still a long way to go before this approach becomes the gold standard treatment as the standardization, safety, and other outcomes of LESSC require further validation[16-19].

Standardization is a prerequisite for clinical popularization of a surgical approach. Approaches to LESSC are technically immature. For example, to expose Calot' s triangle, trials on the use of sutures, Kirschner wires and loop retractors have been reported. The devices used in surgery vary from one surgeon to another: some use common trocars[20,21], some tend to use LESSC multi-ports[22] and others favor self-designed devices such as sterile gloves[23], in addition, there are differences in ma-

Table 2 Patient outcomes

	LESSC (n = 298)	TPLC (n = 315)	P value
Conversions to open surgery	2	2	1.0000
EBL (mL)	14 ± 6.0	15 ± 4.0	0.2643
Gallbladder perforation during surgery	56	6	< 0.001
Operating time (min)	54.8 ± 11.0	33.5 ± 9.0	< 0.001
Operating time of the last 100 cases (min)	34.3 ± 6.0	32.7 ± 8.7	0.1589
VAS (1–10)			
8 h after surgery	2.3 ± 1.4	2.3 ± 1.3	1.0000
Day 1	1.2 ± 0.4	1.3 ± 1.2	0.2042
Complications			
Contusion at incision	19	25	0.4540
Hematoma at incision	11	19	0.1790

Cosmetic result	98%	85%	0.0010
Total cost (USD)	1933.7 ± 64.4	1874.7 ± 46.2	< 0.0010
Total cost of the last 100 cases (USD)	1881.3 ± 32.8	1876.2 ± 33.4	0.0571

EBL: Estimated blood loss; LESSC: Laparoendoscopic single site cholecystectomy; TPLC: Three-port laparoscopic cholecystectomy; VAS: Visual analogue score.

nipulative instruments such as routine instruments and reticulating instruments[22]. For example, to prevent air leakage, we have tried tri-ports and gel-ports at our center, but discontinued these due to high cost and longer trans-umbilical incision. We have used routine trocars because they are effective in preventing air leakage and are more cost-effective. With regard to surgical instruments, we have tried flexible forceps and laparoscopes, but have finally resorted to suture suspension assisted technology in LESSC, for which only one 30-degree laparoscope and one manipulative instrument are needed, eliminating the clashing of more instruments intra-operatively.

An appropriate method to place the sutures is essential for the operation. To achieve an ideal exposure of surgical site, we choose a puncture site at the superior chest wall along the costal margin so that the suture can draw the liver up a bit more, which is different from view of Piskun *et al*[23] that the puncture spot should be at the inferior costal margin. In addition, the use of harmonic scalpel is effective in occluding 3-mm blood vessels and dissecting tissues[24]. At our center, the cystic arteries were all cut using the harmonic scalpel, indicating the safety of this scalpel.

In this study, the groups were not randomized or operated on at the same time periods, thus inevitably increasing the risk of bias[25]. For example, TPLC was performed earlier than LESSC at our institution, suggesting a difference in operating experience between LESSC and TPLC. Many patients with signs of acute cholecystitis and other complications successfully underwent TPLC in our institution, but few patients with these complications successfully underwent LESSC during the study period. Therefore, exclusion criteria were applied, where patients with a history of major upper abdominal surgery, signs of acute cholecystitis, and gallstones > 3 cm, were excluded to minimize bias. However, despite the use of selection criteria, this study remains retrospective and was affected by the well-known bias due to this design.

Our results showed that the LESSC technique was more expensive and time-consuming than the TPLC technique. However, the comparisons in the last 100 patients between the two groups demonstrated that these differences were minimized through improvement of surgical skills. Analyses of operating time and total cost demonstrated a relationship between reduced operating time and increased experience, and a relationship between reduced total cost and increased experience. It is concluded that LESSC with the aid of suture suspension will not add a financial burden to the patient if the operator is skilled in this technique.

In conclusion, this large-scale retrospective trial demonstrated that LESSC with the aid of suture suspension is a safe and feasible procedure in selected patients. However, the limitations of the retrospective nature in this study preclude us from drawing a firm conclusion that LESSC is as safe as TPLC in terms of major complications, such as the bile duct injury, and from demonstrating its potential advantages, such as improved result, reduced postoperative pain and patient satisfaction. Therefore, more large-scale and multi-center randomized studies comparing LESSC with multi-port LC are needed to investigate the safety, potential benefits and clinical application of LESSC.

COMMENTS

Background

Recently, surgeons have begun performing laparoscopic cholecystectomy through a single umbilical incision, which is known as laparoendoscopic single-site cholecystectomy (LESSC). The potential benefits of this approach include reduced postoperative pain, improved cosmetic result and earlier return to normal life. Some investigators have predicted that LESSC may become an alternative standard approach for benign gallbladder diseases. However, there are still controversies with regard to its safety and efficiency, although increasing literatures demonstrate that single-incision laparoscopic surgery is a feasible and safe approach. This retrospective study explored the safety and efficiency of LESSC for the treatment of benign gallbladder diseases in selected patients compared with the three-port laparoscopic cholecystectomy (TPLC) in clinical outcomes.

Research frontiers

LESSC has attracted wide attention because of its potential advantages in cosmetic result and faster rehabilitation. However, whether LESSC could be an alternative to multi-port laparoscopic cholecystectomy remains unknown, and therefore it is necessary to compare the clinical outcome of LESSC and multiple-port laparoscopic cholecystectomy in a large cohort.

Innovations and breakthroughs

This is a large-scale retrospective study to explore the safety and efficiency of LESSC for the management of benign gallbladder diseases compared with the TPLC in selected patients.

Applications

LESSC is a safe and effective approach in selected patients with benign gallbladder diseases. LESSC has a better cosmetic benefit than TPLC.

Terminology

LESSC is a complementary approach to laparoscopic cholecystectomy, in which all operating procedures are completed through a single 15-25 mm incision around the navel. However, unlike the traditional multi-port laparoscopic approach, LESSC leaves only a single small scar.

Peer review

The authors have presented for an interesting manuscript in which they retrospectively compare a single incision laparoscopic cholecystectomy *vs* conventional 3 port cholecystectomy. The main strength of this study is the large simple size of considered groups of patients. The authors have compared the outcomes

of interest in a total of 613 eligible patients, 298 in the single incision group (LESSC) *vs* 315 in the three port group (TPLC). The procedures have been performed by two high experienced surgeons on laparoscopic cholecystectomy who have performed more than 200 laparoscopic cholecystectomy before this study. The authors have evaluated all necessary outcomes and they have accurately described the details of the performed surgical procedures. The study has concluded that LESSC is more expensive than TPLC, it requires longer operating time and it is a safe and feasible procedure in selected patients and in expert hands. Overall, the manuscript is well structured, clear and concise.

Abstract

AIM: To study the effects of low-dose amitriptyline (AMT) on gastrointestinal function and brain-gut peptides in healthy Chinese volunteers.

METHODS: This was a double-blind, randomised, placebo-controlled, two-period cross-over trial. Twenty-eight healthy volunteers were randomised and administered 1-wk treatments of AMT (12.5 mg *tid*) or placebo. Before and during the final two days of treatment, gastric emptying, proximal gastric accommodation and visceral sensitivity were measured by drinking-ultrasonography test; the orocecal transit time (OCTT) was measured by lactulose hydrogen breath test, and fasting blood was collected. Plasma levels of ghrelin, motilin and neuropeptide Y (NPY) were measured by enzyme-linked immunosorbent assay kits.

RESULTS: AMT slowed the OCTT (109.2 ± 29.68 min *vs* 96.61 ± 23.9 min, $P = 0.004$) but did not affect liquid gastric emptying and had no effect on proximal gastric accommodation. AMT resulted in decreases in the visual analogue scale (VAS) for difficulty in drinking 600 and 800 mL of water (3.57 ± 0.94 *vs* 2.98 ± 0.85, 5.57 ± 0.82 *vs* 4.57 ± 0.98, $P < 0.01$ for both), although it had no significant effect on the VAS for difficulty in drinking 200 mL and 400 mL of water. AMT significantly increased the plasma ghrelin level (442.87 ± 176.79 pg/mL *vs* 526.87 ± 158.44 pg/mL, $P = 0.04$) and the neuropeptide-Y level (890.15 ± 131.46 pg/mL *vs* 965.64 ± 165.63 pg/mL, $P = 0.03$), whereas it had no effect on the MTL level.

CONCLUSION: Low-dose AMT could slow OCTT, make the stomach less sensitive and increase the plasma levels of ghrelin and NPY. Thus, we recommend the use of low-dose AMT for functional gastrointestinal disorders.

Key words: Amitriptyline; Orocecal transit time; Visceral hypersensitivity; Gastric emptying; Brain-gut peptides

Core tip: Low-dose amitriptyline has been used to treat functional gastrointestinal disorders for many years, but the precise mechanism is still not clear. Brain-gut peptides, such as motilin, ghrelin and neuropeptide Y, may regulate gastrointestinal functions. However, evidence indicating the possible effects of amitriptyline on the levels of brain-gut peptides in healthy Chinese volunteers is limited. In this study, we conclude that low-dose amitriptyline can slow orocecal transit time, make the stomach less sensitive and increase the plasma levels of ghrelin and neuropeptide Y. Thus, we recommend the use of low-dose amitriptyline for functional gastrointestinal disorders.

INTRODUCTION

Functional dyspepsia (FD) and irritable bowel syndrome (IBS) are the most common functional gastrointestinal disorders (FGIDs). The aetiology of FGIDs is unclear, and treatment options are limited[1,2]. Low-dose amitriptyline (AMT) is a tricyclic antidepressant that has been used to treat FGIDs for many years[3]; however, the exact mechanism of action is not clear.

Brain-gut peptides, including motilin (MTL), ghrelin, neuropeptide Y (NPY) and so on, also known as peptide hormones, can be found in the cerebral nervous system, enteric nervous system and endocrine cells in the gastrointestinal tract. Brain-gut peptides, can be neuropeptides and neuroendocrine and paracrine substances, regulate the secretory and motor functions of the gastrointestinal tract. MTL can reportedly accelerate gastric emptying and reduce the proximal gastric volume in patients with FD[4,5]. Ghrelin, the closest family member of MTL, was reported to be abnormal in FD[6]. NPY is a 36 amino-acid peptide in the central and peripheral nervous systems that can inhibit gastric emptying and stimulate colonic transit[7]. However, as far as we know, evidence indicating the possible effects of AMT on the levels of brain-gut peptides in healthy Chinese volunteers is limited.

We hypothesised that low-dose AMT is beneficial for FGIDs because of the changes in the gastrointestinal sensor, motor function and plasma levels of brain-gut peptides. Therefore, we aimed to explore the effects of low-dose AMT on liquid gastric emptying, proximal gastric accommodation, proximal gastric sensitivity, orocecal transit time (OCTT) and the plasma levels of MTL, ghrelin and NPY in healthy Chinese volunteers.

MATERIALS AND METHODS

Methods and drugs

This study was a randomised, double-blind, placebo-controlled, two-period cross-over trial in healthy Chinese volunteers (Clinical trial number: ChiCTR-TTRCC-12001967), which was approved by the ethics committee of the hospital. Written informed consent was obtained from healthy volunteers, which conformed to the Declaration of Helsinki.

Twenty-eight healthy volunteers were randomised to the two therapies: group A was treated for 1 wk with 12.5 mg AMT *tid* and then with placebo, while group B was treated with the opposite sequence. There was a 2-wk washout phase, followed by a crossover to the alternate treatment (Figure 1). AMT hydrochloride tablets were purchased from HuNan DongTing Pharmaceutical Co. Ltd. of China (batch number: B110824). The placebo

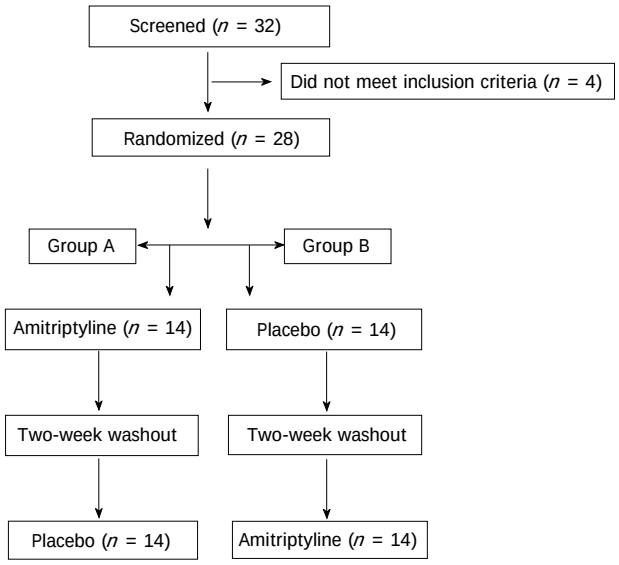

Figure 1 Consort diagram.

was supplied by ShenZhen WanHe Pharmaceutical Co. Ltd. of China. AMT and placebo tablets were similar, and the strength of each tablet was 25 mg. The investigators and patients were blinded to the treatment. The results were analysed by the investigators, and the original randomisation scheme was released after all of the analyses were performed.

Healthy volunteers

The exclusion criteria of healthy volunteers included: (1) history of FGIDs (in line with the definition of the Rome Ⅲ criteria) that may affect gastrointestinal motility; hypersensitivity or allergy to any tricyclic drug; (2) history of gastrointestinal surgery and psychiatric illness; (3) pregnancy or breast feeding; (4) use of medications that may affect gastrointestinal motor function (*e.g.*, prokinetics and anti-spasmotic agents) or the effect of AMT; (5) concomitant therapy with a monoamine oxidase inhibitor, history of urinary retention, known glaucoma, history of seizures and thyroid or liver dysfunction; and (6) participation in another clinical trial during the last two weeks.

Endpoints of the study

All healthy volunteers completed the Hamilton Anxiety and Depression Rating Scale before the treatment; a score less than 7 was defined as no anxiety or depression[8,9]. During the two days before therapy and the final two days of treatment, we assessed the following endpoints: (1) liquid gastric emptying, proximal gastric relaxation and visceral hypersensitivity by drinking- ultrasonography test; (2) OCTT by lactulose hydrogen breath test; and (3) plasma MTL, ghrelin and NPY levels by ELISA.

Drinking-ultrasonography test

The drinking-ultrasonography test was performed according to the method of Kato *et al*[10]. After an overnight

Ghrelin	460.06 ± 146.25	444.94 ± 202.43	0.82
NPY	888.88 ± 154.52	913.46 ± 139.32	0.66

Values are represented as mean ± SD. Symptom scores on 10-cm visual analogue scale. HAMD: Hamilton depression rating scale; HAMA: Hamilton anxiety rating scale; BMI: Body mass index; OCTT: Orocecal transit time; NPY: Neuropeptide Y; MTL: Motilin; VAS: Visual analogue scale.

fast, healthy volunteers ingested 200 mL of water (approximately 28 ℃) in 2 min for a total of four times with 2-min intervals. The subjects were in the supine position and ingested water through a straw. The emptying periods were calculated to be 5 and 10 min (by measuring the time) after drinking the total 800 mL of water. All of these examinations were performed by a single ultrasonography technician using a Philips IU22 ultrasound scanner (Philips Medical Systems, Bothell, Washington) and a Convex-type 5-20 MHz probe. The spleen served as an echo window, and the cross-section of the proximal stomach was measured *via* the 10th inter-costal space. The mucosal surface of the gastric lumen was traced from images acquired before the test at each 2 min interval after water consumption and 5 and 10 min after the end of the water consumption. The cross-sectional area was also calculated. Frozen images were saved on a hard disk. Before the test and every time after ingestion of water, abdominal symptoms were self-evaluated and recorded on a questionnaire using a visual analogue scale from 0 to 10 to investigate the difficulty (such as abdominal fullness) in drinking water.

Lactulose hydrogen breath test for OCTT

Subjects were placed on a low fibre diet 3 d before the test. After a 12-h overnight fast, two end-expiratory breath H_2 samples were collected as base values using a HHBT-01 breath hydrogen detector (Hydeway, China). After the subjects ingested 15 mL of lactulose syrup containing 10 g of lactulose, exhaled H_2 was recorded every 15 min for a total of three hours. OCTT was defined as the duration from the moment of lactulose administration to the moment when exhaled H_2 was increased over 12 ppm from the baseline[11].

Plasma ghrelin, MTL and NPY levels

After twelve-hours of fasting, the blood samples were collected and centrifuged at 3000 g for 10 min. Plasma samples were collected and stored at -70 ℃ until the procedure. We measured plasma levels of ghrelin, MTL and NPY using commercial ELISA kits (Shanghai Bluegene Biotech Co., Ltd., China).

Statistical analysis

Data analysis was performed using SPSS 13.0 software (SPSS Inc., Chicago IL, United States), and the measurement data are reported as the mean ± SD; baseline parameters and differences between the two treatments were compared using Student's t test. Differences between the baseline and AMT or placebo treatment were compared by paired t test. $P < 0.05$ was considered statistically significant.

RESULTS

Study participants

Thirty-two healthy volunteers were selected initially by public advertisement. After a screening visit, four subjects were not appropriate for the study by the exclusion criteria (two subjects had a history of gastrointestinal surgery and two subjects experienced abdominal pain during the last three months). Twenty-eight subjects completed the study. There were no statistically significant differences in age, gender, body mass index, Hamilton depression scale, Hamilton anxiety scale scores, proximal gastric accommodation, liquid gastric emptying, proximal gastric sensitivity, OCTT or the levels of MTL, ghrelin and NPY between group A and group B ($P > 0.05$) (Table 1).

Proximal accommodation, visceral hypersensitivity and gastric emptying using the drinking-ultrasonography test

There was no statistically significant difference in the proximal gastric accommodation between the AMT and placebo groups after consumption of 200, 400, 600 or 800 mL water ($P > 0.05$). Similarly, no differences were found in the gastric emptying rate (%) at 5 and 10 min after the completion of the drinking test (all $P > 0.05$). Moreover, there were no statistically significant differences between the two groups for the VAS test for difficulty in drinking 200 or 400 mL water (all $P > 0.05$). However, there were significant differences in VAS results for difficulty in drinking 600 and 800 mL between the two groups (all $P = 0.001$) (Table 2).

There were no significant differences between the baseline and placebo treatment in proximal accommoda-

Table 2 Effects of amitriptyline on gastrointestinal function and brain-gut peptides

MTL	471.75 ± 127.02	473.40 ± 122.75	0.75
Ghrelin	452.50 ± 173.46	442.87 ± 176.79	0.35
NPY	901.17 ± 144.91	890.15 ± 131.46	0.12

Values are represented as mean ± SD. Symptom scores on 10-cm visual analogue scale. OCTT: Orocecal transit time; MTL: Motilin; NPY: Neuropeptide Y; VAS: Visual analogue scale.

tion, gastric emptying and VAS results for difficulty in drinking 200, 400, 600 or 800 mL of water ($P > 0.05$) (Table 3).

There were no significant differences between the baseline and AMT treatment in the cross-sectional area of the proximal stomach (cm^2) after drinking 200, 400, 600 or 800 mL of water ($P > 0.05$) (Table 4). Similarly, no significant differences were found between the baseline and AMT treatment in the VAS after drinking 200 or 400 mL of water ($P > 0.05$). However, the VAS results significantly dropped from baseline in response to AMT treatment after drinking 600 and 800 mL water ($P = 0.001$) (Table 4). No differences in gastric emptying were observed between the baseline and AMT treatment ($P > 0.05$; Table 4).

OCTT with lactulose hydrogen breath test

AMT slowed the OCTT, and there was a significant difference between the AMT and placebo groups ($P = 0.004$; Table 2). OCTT was not different between the baseline and placebo treatment (Table 3), although there was a significant difference between the baseline and treatment with AMT ($P = 0.001$; Table 4).

Plasma levels of MTL, ghrelin and NPY using ELISA

The fasting plasma concentration of MTL was similar in the AMT and placebo groups ($P = 0.61$; Table 2). There were no significant differences in the MTL levels between the baseline and treatment with placebo ($P = 0.75$; Table 3) or between the baseline and treatment with AMT ($P = 0.11$; Table 4). However, in the AMT group, the fasting plasma ghrelin concentration was significantly greater than the placebo group ($P = 0.04$; Table 2). There was no difference in the ghrelin level between the baseline and treatment with placebo ($P = 0.35$; Table 3), but the ghrelin concentration was elevated following AMT treatment compared to the baseline values ($P = 0.001$; Table 4). Compared with the placebo group, the AMT group had higher fasting plasma NPY levels ($P = 0.03$; Table 2). There was no significant difference between the baseline and treatment with placebo ($P = 0.12$; Table 3), but the NPY level was significantly elevated after AMT treatment ($P = 0.001$; Table 4).

Adverse effects and safety

Table 5 shows the adverse effects that occurred during the treatment. There were no adverse effects which required emergency evaluation or hospitalisation. No subjects dropped out of the study.

DISCUSSION

In previous studies, low-dose AMT was useful for FD and IBS, especially for the improvement of abdominal pain[12-15], possibly because AMT reduces the visceral sensitivity and increases the pain threshold in FGID patients, although this is still controversial. Mertz *et al*[12] suggested that after AMT (50 mg/d) treatment for 4 wk in FD, the perception of gastric distension using the barostat test was not different from the placebo treatment. Conversely, Thoua *et al*[13] demonstrated that after 3 mo of treatment with AMT (25-50 mg/d) in IBS, the rectal hypersensitivity to electrical current stress was decreased, however the study was uncontrolled. Obviously, it is not due to the antidepressant effect of AMT as the doses were below the effective doses of the antidepressant; the benefits are in patients who are not depressive, with responses occurring before the antidepressant effect[16].

Here, we measured visceral sensitivity using the non-invasive drinking-ultrasonography test in healthy volun-

Table 4 Baseline and after treatment with amitriptyline

Variable	Baseline (n = 28)	Amitriptyline (n = 28)	P value
Cross-sectional area of the proximal stomach (cm^2)			
200 mL	17.95 ± 3.62	16.51 ± 3.78	0.22
400 mL	29.97 ± 6.35	27.14 ± 5.71	0.09
600 mL	40.78 ± 9.54	34.11 ± 6.11	0.06
800 mL	46.34 ± 9.67	39.58 ± 7.35	0.06
Difficulty in drinking water VAS			
200 mL	0.93 ± 0.59	0.93 ± 0.65	0.99
400 mL	1.82 ± 0.54	1.93 ± 0.46	0.36
600 mL	3.36 ± 0.72	2.98 ± 0.85	0.01
800 mL	5.46 ± 0.73	4.57 ± 0.98	0.001
Gastric emptying			
5 min	79.55 ± 6.35	78.40 ± 11.71	0.96
10 min	63.89 ± 8.39	66.72 ± 11.63	0.17
OCTT (min)	85.18 ± 19.60	109.29 ± 29.68	0.001
Plasma levels (pg/mL)			
MTL	471.75 ± 127.02	461.88 ± 129.66	0.11
Ghrelin	452.50 ± 173.46	526.87 ± 158.44	0.001
NPY	901.17 ± 144.91	965.64 ± 165.63	0.001

Values are represented as mean ± SD. Symptom scores on 10-cm visual analogue scale. OCTT: Orocecal transit time; MTL: Motilin; NPY: Neuropeptide Y; VAS: Visual analogue scale.

teers, which is different from previous studies. We found that low-dose AMT reduced gastric sensitivity immediately after the volunteers ingested 600 and 800 mL water, which was consistent with the result of Thoua *et al*[13]. This might contribute to the potential centrally mediated visceral analgesic properties of AMT. As Morgan *et al*[16] suggested, low-dose AMT has a central effect on pain-related cerebral activation in the anterior cingulate cortex and left posterior parietal complex in IBS patients during mental stress.

A variety of gastrointestinal motility disturbances have been implicated in FGIDs[17]. Bouras *et al*[18] demonstrated that low-dose AMT could slow solid gastric emptying in healthy individuals. Vahedi *et al*[14] observed that low-dose AMT was effective for the treatment of diarrhoea-predominant IBS; the reason might be the anti-cholinergic effect of the drug. In our research, AMT did not affect liquid gastric emptying but did significantly prolong the OCTT (which is also reflects the small bowel transit time[19]). This is consistent with previous investigations in which imipramine delayed OCTT in controls and IBS patients[20]. The reason for the differences in the current results compared to previous studies might be that liquid emptying is related to the proximal portion or fundus relaxation, but solid emptying is associated with the distal stomach[21]. In the current study, there were no effects on proximal gastric accommodation with low-dose AMT. Similar conclusions have been previously reported and showed that AMT had no effect on drinking capacity in healthy volunteers[18]. The gold standard for the measurement of proximal gastric accommodation is gastric barostat[22], although this procedure is invasive. In this study, we used the new drinking-ultrasonography test, which is non-invasiveness, safe, reproducible, better accepted by volunteers and relatively simple to administer.

Table 5 Adverse effects of amitriptyline and placebo

Adverse effect	Amitriptyline (n = 28)	Placebo (n = 28)
Sleepiness	10	2
Bitter taste	7	2
Dry mouth	6	3
Tired in early morning	2	1
Dizziness	2	0
Constipation	1	1

MTL levels were not significantly different between the placebo and AMT groups. However MTL levels have been reported to be significantly elevated in patients with constipation who are receiving tricyclic antidepressant drugs[23]. It is possible that we evaluated healthy volunteers rather than patients in this study. In healthy individuals, AMT might not have any effect on the normal levels of MTL because of intact reflex mechanisms. Ghrelin plays a role in regulating appetite[24]. Lee *et al*[6] reported that unusually low preprandial ghrelin levels occur in FD patients due to dysmotility. It is possible that FD patients with dysmotility may respond to AMT effectively. Caproni *et al*[25] found that the plasma levels of NPY were markedly increased in migraine patients receiving AMT treatment (25 mg/d) for 3 mo. The present study extends the previous finding by showing that the plasma level of NPY was significantly increased with low-dose AMT treatment. A previous study showed that NPY may help patients with stress on the gut-brain axis[26], so the increase in NPY levels might be a reason for the treatment of FD and IBS patients who are often hypersensitive to stress[27].

This study included a small sample size of healthy volunteers. Further studies consisting of larger sample sizes that are powered to find smaller differences may be required. As the duration of AMT administration in the clinic is typically 4-12 wk[12-15], it is possible that the course of medication in our study was too short. A longer trial might have different effects on gastrointestinal function and brain-gut peptides.

In summary, low-dose AMT slows OCTT, decreases gastric sensitivity and increases the plasma levels of ghrelin and neuropeptide Y in healthy Chinese individuals, which may be the cause of the beneficial effects of low-dose AMT in FGID patients.

ACKNOWLEDGMENTS

We thank Ming-Zhi Xu, Professor of the Guangdong Mental Disorder Research Institute, for his role in the application and quality control of the anxiety and depression scale.

COMMENTS

Background

Low-dose amitriptyline (AMT) has been used to study functional gastrointestinal disorders for many years, although the precise mechanism of the action is still not clear. Evidence indicating the possible effects of AMT on gastrointestinal

function and brain-gut peptides in healthy Chinese volunteers is limited.

Research frontiers

Therapeutic options for functional gastrointestinal disorders are limited. Antidepressant agents such as low dose AMT are effective in functional gastrointestinal disorders.

Innovations and breakthroughs

Based on previous data, this study first explored the possible effects of low dose AMT on gastrointestinal function and brain-gut peptides in healthy Chinese volunteers. The results of the present study revealed that low-dose AMT could slow orocecal transit time (OCTT), decrease gastric sensitivity and increase the plasma levels of ghrelin and neuropeptide Y in healthy Chinese individuals, which may be the cause of the beneficial effects of low-dose AMT in functional gastrointestinal disorders (FGID) patients.

Applications

Low dose AMT plays a role in regulating gastrointestinal function, supporting its clinical applicability for gastrointestinal disorders in China.

Terminology

The drinking-ultrasonography test is a novel method to measure proximal accommodation, visceral hypersensitivity and gastric emptying. The test is non-invasive, safe, better accepted by volunteers, reproducible and relatively simple to administer.

Peer review

This manuscript has originality so far. Low-dose AMT slows OCTT, decreases gastric sensitivity and increases the plasma levels of ghrelin and neuropeptide Y in healthy Chinese individuals, which may be the cause of the beneficial effects of low-dose AMT in FGID patients.

Abstract

AIM: To evaluate the feasibility of a new computed virtual chromoendoscopy (CVC) device (M i-scan) in the diagnosis of gastric neoplasia.

METHODS: Patients with superficial lesions no larger than 1.0 cm found during high definition endoscopy were included. Those with advanced or obviously protruded or depressed lesions, lesions larger than 1.0 cm and/or lesions which were not amenable to observation by zoom function were excluded. The endoscopist was required to give the real-time descriptions of surface pit patterns of the lesions, based on surface pattern classification of enhanced magnification endoscopy. According to previous reports, types Ⅰ-Ⅲ represent non-neoplastic lesions, and types Ⅳ-Ⅴ represent neoplastic lesions. Diagnosis with M i-scan and biopsy was performed before histopathological diagnosis. Magnified images of gastric lesions with and without enhancement were collected for further analysis. The diagnostic yield of real-time M i-scan and effects on magnification image quality by tone enhancement (TE), surface enhancement (SE) and color enhancement (CE) were calculated. The selected images were sent to another endoscopist. The endoscopist rated the image quality of each lesion at 3 levels. Ratings of image quality were based on visualization of pit pattern, vessel and demarcation line.

RESULTS: One hundred and eighty-three patients were recruited. Five patients were excluded for advanced gastric lesions, 1 patient was excluded for poor preparation and 2 patients were excluded for superficial lesions larger than 1.0 cm; 132 patients were excluded for no lesions found by high definition endoscopy. In the end, 43 patients with 43 lesions were included. Histopathology revealed 10 inflammation, 14 atrophy, 10 metaplasia, 1 low grade dysplasia (LGD), 5 high grade dysplasia (HGD) and 3 cancers. For 7 lesions classified into type Ⅰ, histopathology revealed 6 atrophy and 1 metaplasia; for 10 lesions classified into type Ⅱ, histopathology revealed 2 inflammation, 7 atrophy and 1 metaplasia; for 10 lesions classified into type Ⅲ, histopathology revealed 1 inflammation, 8 metaplasia and 1 LGD; for 9 lesions classified into type Ⅳ, histopathology revealed 4 inflammation, 1 atrophy and 4 HGD; for 7 lesions classified into type Ⅴ, histopathology revealed 3 inflammation, 1 HGD and 3 cancers. A total of 172 still images, including 43 images by white light (MWL) and 129 images by M i-scan (43 with TE, 43 with SE and 43 with CE), were selected and sent to the endoscopist who did the analysis. General image quality of M i-scan with TE and SE was significantly better than that

of MWL (TE, 4.55 ± 1.07; SE, 4.30 ± 1.02; MWL, 3.25 ± 0.99; $P < 0.001$). Visualization of pit pattern was significantly improved by M i-scan with SE (1.93 ± 0.25 *vs* 1.50 ± 0.50, $P < 0.001$). Microvessel visualization was significantly improved by M i-scan with TE (1.23 ± 0.78 *vs* 0.76 ± 0.73, $P < 0.001$). Demarcation line visualization was improved by M i-scan with both TE and SE (TE, 1.75 ± 0.52; SE, 1.56 ± 0.59; MWL, 0.98 ± 0.44; $P < 0.001$). M i-scan with CE did not show any significant improvements of image quality in general or in the 3 key parameters. Although M i-scan with TE and SE slightly increased the diagnostic yield of MWL, there was no significant difference ($P > 0.1$).

CONCLUSION: Although digital enhancement improves the image quality of magnification endoscopy, its value in improving the diagnostic yield seems to be limited.

Key words: Computed virtual chromoendoscopy; i-scan; Gastric neoplasia; Diagnosis

Core tip: In this study, the authors applied a new endoscopic device combining magnification endoscopy and virtual chromoendoscopy, equipped with surface enhancement, tone enhancement and color enhancement (M i-scan), in the diagnosis of 43 patients with small superficial gastric lesions. The results showed that real-time diagnosis of the gastric cancerous lesions by using M i-scan corresponded well with their histopathology. In comparisons between different enhancement capabilities using offline images, images with surface enhancement and tone enhancement were found to be slightly superior to those with color enhancement.

Magnified and enhanced computed virtual chromoendoscopy in gastric neoplasia: A feasibility study. *World J Gastroenterol* 2013; 19(26): 4221-4227 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i26/4221.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i26.4221

INTRODUCTION

Since conventional endoscopy has limited definition and magnification, detection and characterization of early gastric cancer are still challenging in daily practice. Recently, advanced endoscopy techniques have been introduced to improve the diagnosis of early gastric cancer, such as chromoendoscopy with dyes[1], acetic acid-enhanced endoscopy[2,3], magnification endoscopy[4] and dyeless virtual chromoendoscopy[5]. Incorporation of magnification endoscopy and chromoendoscopy[6] or enhanced endoscopy[7] into one instrument is perfect, because chromoendoscopy and enhanced endoscopy serve as the red flag in detection, while magnification endoscopy serves in characterization. Magnified virtual chromoendoscopy is more preferable than dye spraying magnification chromoendoscopy for efficiency and safety[5]. One example is magnified narrow band imaging (M-NBI)[8-16]. Clinical trials suggest that M-NBI is helpful in the diagnosis of Barrett's esophagus[17-21], small colorectal lesions[22] and early gastric cancer[8,23]. Along with NBI, multi-band imaging virtual chromoendoscopy, such as Fuji Intelligence Chromoendoscopy (FICE)[24-30] and Pentax i-scan, are also available in clinical practice.

Unlike NBI, FICE and i-scan use reflection band filtering to achieve color enhancement of the mucosa. The instrument in this study not only incorporates color enhancement but also surface enhancement and magnification (M i-scan). The principle of surface enhancement is to adjust the dark-to-light contrast of the nearby pixels in order to show sharper surface details.

The aim of this study is to assess the accuracy of a real-time M i-scan in the diagnosis of gastric neoplasia (primary outcome). A comparison between magnified virtual chromoscopy and non-magnified virtual chromoscopy was made by using post-endoscopy still images (secondary outcome).

MATERIALS AND METHODS

Patients

From January 1st to March 31st 2012, consecutive patients who underwent high definition gastroscopy in Shandong University Qilu Hospital were recruited into this study. Patients aged 18-80 years, having superficial lesions with diameter less than 1 cm were included. Those with advanced or obviously protruded or depressed lesions, lesions larger than 1.0 cm and/or lesions which were not amenable to observation by zoom function (poor preparation, difficult positions, and non-cooperation of patients) were excluded. This study was approved by the local ethics committee (Ethics Committee of Shandong University Qilu Hospital) and adhered to the Declaration of Helsinki for Medical Research involving Human Subjects-Ethical Principles for Medical Research Involving Human Subjects. All the patients who participated in this study have provided their written informed consents.

Endoscopic procedure

The instruments applied in this study were an EG-2990Zi endoscope (Pentax, Tokyo, Japan) and an EPK-i endoscopic system (Pentax, Tokyo, Japan). This high definition endoscope incorporated surface enhancement (at +2, +4 and +6 levels), color enhancement (+4, +5 and +6 levels) and tone enhancement functions. It is also equipped with an adjustable image magnification in a continuous range up to 100-fold. The diameter and the length of the insertion tube of this instrument are the same as those of a standard upper endoscope. To achieve the maximum magnification, a transparent hood was attached to the distal tip of the endoscope to fix the distance between endoscope and gastric mucosa at 2 mm.

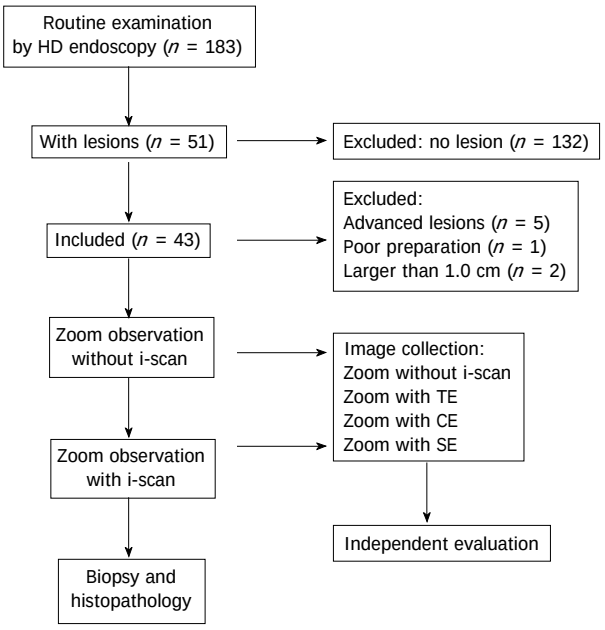

Figure 1 Study flow diagram. TE: Tone enhancement; SE: Surface enhancement; CE: Color enhancement.

All the patients underwent routine preparation before the procedure. The detected lesions were observed with magnification endoscopy in white light (MWL) mode and in enhancement (M i-scan) mode consecutively. The endoscopic procedures were performed by an experienced endoscopist who was familiar with magnification endoscopy diagnosis of early gastric cancer. The endoscopist was required to give the real-time descriptions of surface pit patterns of the lesions, based on surface pattern classification of enhanced magnification endoscopy. The surface pattern classification includes 5 types: type Ⅰ, small round pits of uniform size and shape; type Ⅱ, slit-like pits; type Ⅲ, gyrus and villous patterns; type Ⅳ, irregular arrangement and size; and type Ⅴ, destructive pattern. According to previous reports, types Ⅰ-Ⅲ represent non-neoplastic lesions, and types Ⅳ-Ⅴ represent neoplastic lesions[7]. Real-time diagnoses to determine neoplasia or non-neoplasia were not required from the endoscopist. Instead, the diagnoses were made by another investigator according to the diagnostic strategy and real-time description above. Images of MWL [without tone enhancement (TE), surface enhancement (SE) and color enhancement (CE)] and i-scan (with "g" TE, +2 SE or +4 CE) were collected and stored on USB devices during the procedures. Four best quality images per lesion were selected and sorted randomly by the investigator.

Post-endoscopy still image analysis

The selected images were sent to another endoscopist who did not participate in any of the endoscopic procedures. The endoscopist was kept blind to the clinical and endoscopic information of the patients. The endoscopist rated the image quality of each lesion at 3 levels. Ratings of image quality were based on visualization of pit pattern, vessel, and demarcation line[22], which are key parameters to detect and characterize the gastric neoplasia. Rating scales of image quality were: pit pattern, 0 for unassessable, 1 for fine, 2 for excellent; vessel, 0 for invisible, 1 for visible, 2 for clearly visible; demarcation line, 0 for unassessable, 1 for fine, 2 for clear. The endoscopist then recorded the descriptions of the still images according to the same standards as applied in the real time observation[7].

Biopsy and histopathology

The lesions were routinely biopsied, and the specimens were placed in 10% formalin solution and processed in the routine manner. The slices were examined by an experienced pathologist who had specific training in gastrointestinal pathology. The pathologist was kept blind to the clinical and endoscopic information of the patients. The histology report was based on the WHO (World Health Organization) classification of gastrointestinal tumors. The study flow diagram is illustrated in Figure 1.

Statistical analysis

Diagnostic accuracy of gastric neoplasia by using real-time M i-scan was presented with sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and likelihood ratio (LR). The agreement between real time M i-scan and histopathology was presented with kappa values (0.1-0.2 were considered slight agreement, 0.21-0.4 fair agreement, 0.41-0.6 moderate agreement, 0.61-0.8 substantial agreement and 0.81-0.99 almost perfect agreement). Parameters of still image quality were presented as mean ± SD, and differences of magnification image quality between MWL and i-scan were determined by one-way ANOVA test. A P value < 0.05 is considered to be significant. All data were analyzed by SPSS 13.0 (SPSS Inc., Chicago, IL, United States).

RESULTS

Patients

One hundred and eighty-three patients were recruited. Five patients were excluded for advanced gastric lesions, 1 patient was excluded for poor preparation and 2 patients were excluded for superficial lesions larger than 1.0 cm; 132 patients were excluded for no lesions found by high definition endoscopy. In the end, 43 patients with 43 lesions were included. The average age of the patients was 47.5 (18-74) years, of which 32 were males. Locations of the lesions were: 5 in cardia and fundus, 2 in body, 4 on angle and 32 in antrum. All the lesions could be easily identified and zoomed. Histopathology revealed 10 inflammation, 14 atrophy, 10 metaplasia, 1 low grade dysplasia (LGD), 5 high grade dysplasia (HGD) and 3 cancers.

Real-time diagnosis by M i-scan

For 7 lesions classified into type Ⅰ, histopathology revealed 6 atrophy and 1 metaplasia; for 10 lesions classified into type Ⅱ, histopathology revealed 2 inflammation, 7 atrophy and 1 metaplasia; for 10 lesions classified into type Ⅲ, histopathology revealed 1 inflammation, 8 meta-

Table 1 Histopathology and pit patterns of the lesions classified by M i-scan

Pit	Histology						Total
	Inflammation	Atrophy	Metaplasia	LGD	HGD	Cancer	
Type Ⅰ	0	6	1	0	0	0	7
Type Ⅱ	2	7	1	0	0	0	10
Type Ⅲ	1	0	8	1	0	0	10
Type Ⅳ	4	1	0	0	4	0	9
Type Ⅴ	3	0	0	0	1	3	7
Total	10	14	10	1	5	3	43

HGD: High grade dysplasia; LGD: Low grade dysplasia.

plasia and 1 LGD; for 9 lesions classified into type Ⅳ, histopathology revealed 4 inflammation, 1 atrophy and 4 HGD; for 7 lesions classified into type Ⅴ, histopathology revealed 3 inflammation, 1 HGD and 3 cancers. The real-time descriptions of pit patterns and the corresponding histopathology are shown in Table 1. Typical images representing pit patterns of types Ⅰ-Ⅴ are illustrated in Figure 2.

When the histopathology was re-classified into 2 categories (as non-cancerous lesions including inflammation, atrophy, metaplasia and LGD, or cancerous lesions including HGD and cancer) and the pit patterns re-classified into 2 categories as described above, sensitivity, specificity, PPV, NPV and likelihood ratio of M i-scan regarding gastric neoplasia were 100%, 77.1%, 50%, 100% and 4.37% respectively. Kappa value calculated from agreement between M i-scan and histopathology was 0.557 (moderate agreement). The diagnostic yield after re-classification is shown in Table 2.

Post-endoscopy still image analysis

A total of 172 still images, including 43 images by MWL and 129 images by M i-scan (43 with TE, 43 with SE and 43 with CE), were selected and sent to the endoscopist who did the analysis. General image quality of M i-scan with TE and SE was significantly better than that of MWL (TE, 4.55 ± 1.07; SE, 4.30 ± 1.02; MWL, 3.25 ± 0.99; $P < 0.001$). Regarding the 3 key parameters, visualization of pit pattern was significantly improved by M i-scan with SE (1.93 ± 0.25 *vs* 1.50 ± 0.50, $P < 0.001$). Microvessel visualization was significantly improved by M i-scan with TE (1.23 ± 0.78 *vs* 0.76 ± 0.73, $P < 0.001$). Demarcation line visualization was improved by both M i-scan with TE and SE (TE, 1.75 ± 0.52; SE, 1.56 ± 0.59; MWL, 0.98 ± 0.44; $P < 0.001$). M i-scan with CE did not show any significant improvements of image quality in general or in the 3 key parameters.

Descriptions of the still images based on lesions demonstrated that diagnosis by MWL revealed a sensitivity, specificity, PPV, NPV and LR of 87.5%, 71.4%, 41.2%, 96.2% and 3.06%, respectively. Although M i-scan with TE and SE slightly increased the diagnostic yield, there was no significant difference ($P > 0.1$). M i-scan with CE did not change the diagnostic yield by MWL. M i-scan with SE perfectly matched the results of real-time

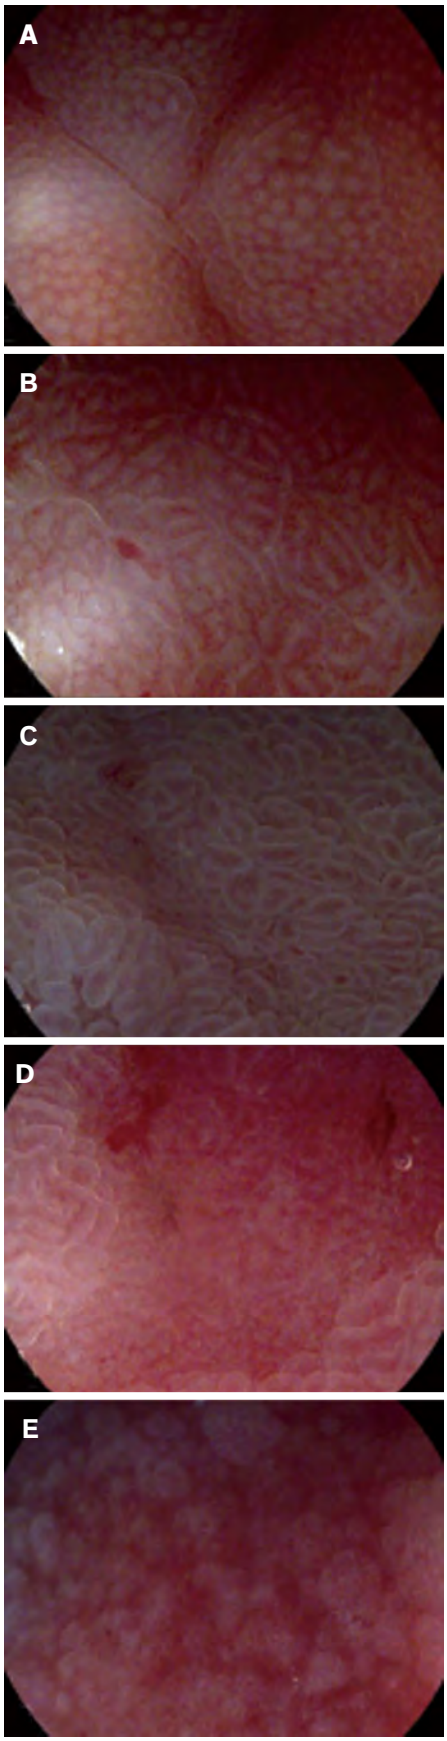

Figure 2 Images representing typical pit pattern classification by M i-scan. A: Type Ⅰ, small round pits of uniform size and shape; B: Type Ⅱ, slit-like pits; C: Type Ⅲ, gyrus and villous patterns; D: Type Ⅳ, irregular arrangement and size; E: Type Ⅴ, destructive pattern.

descriptions. Representative images showing image quality differences among different modes are illustrated in Figure 3.

DISCUSSION

Detection and characterization of early gastric cancer by dyeless virtual chromoendoscopy, such as NBI and computed virtual chromoendoscopy (CVC), are preferable for the endoscopist, because of time, labor and potential risks reduction[31,32]. Virtual chromoendoscopy with magnification is thought to be the dream team, since the former provides the detection "red flag" followed by real-time characterization by the latter. It was reported that real-time characterization of Barrett's esophagus[33,34], gastric cancer[35,36] and colorectal adenoma[37,38] can be improved by dyeless virtual chromoendoscopy, such as NBI or FICE[25-29,39]. In this pilot feasibility study, we aimed to evaluate application of M i-scan in the diagnosis of small superficial gastric lesions, both in real-time investigation and post-endoscopy still image analysis. The preliminary results showed that M i-scan is helpful for the *in vivo* prediction of small gastric superficial lesions with excellent sensitivity and NPV, acceptable specificity and LR, and poor PPV. The post-endoscopy still image analysis showed that M i-scan with TE and SE can slightly increase the image quality.

One feature of M i-scan is to mimic the surface enhancement of EME by acetic acid spraying. In this study, the still image analysis showed that SE significantly improves visualization of surface pit pattern and demarcation line compared to MWL. Although there were excellent sensitivity and NPV, and acceptable specificity results, the PPV was poor, just as the results of enhanced magnification endoscopy[7]. This is partly due to the low percentage of neoplastic lesions in the sample (18.6%, 8/43). On the other hand, erosion is sometimes difficult to be differentiated from neoplasia by surface pit pattern evaluation, as in both lesions surface pits could be lost. In these cases, evaluation of microvessel pattern in addition to surface pit pattern may be helpful. However, observation of microvessels is not satisfactory by M i-scan. Although still image analysis shows that TE significantly improves the visualization of microvessels, which only happens in cases with visible microvessels (visible to clearly visible), visualization of those cases with invisible microvessels (41.2%) remains unchanged.

This study has several limitations. Firstly, this is a feasibility study with small sample size and no sample size calculation. Secondly, the detection rate of small superficial gastric lesions was not evaluated. There has not been any report on the detection rate of small gastric lesions by CVC yet. In our own practice, CVC is not suitable for screen gastroscopy with insufficient luminous intensity. Thirdly, only one endoscopist performed the real-time and still image analysis, so there was no interobserver agreement analysis. However, the perfect match between surface classification of real-time and still image with

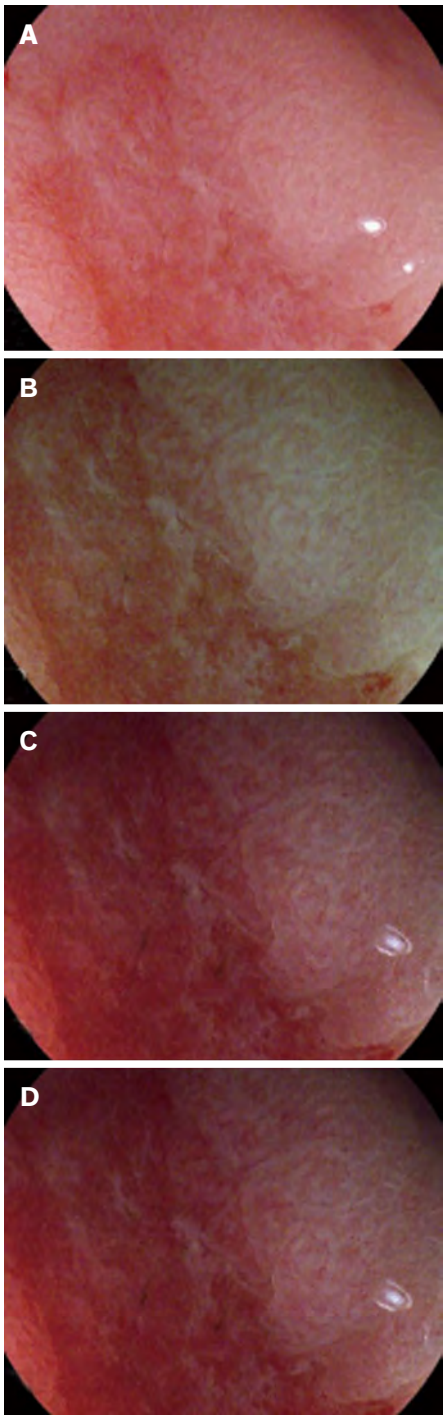

Figure 3 Representative images showing white light (A), M i-scan with tone enhancement (B), surface enhancement (C) and color enhancement (D), respectively.

SE suggests an excellent consistency, which should be validated in future studies. Fourthly, there was no comparison between M i-scan and magnification chromoendoscopy with indigo carmine or other contrast agents. And finally (the last may not be the least), gold standard histopathology was only performed by biopsy. Although we only included lesions smaller than 1.0 cm to minimize the heterogeneity, a discrepancy between biopsy and autopsy still remains.

In conclusion, real-time prediction of the histopathology of small superficial gastric lesions by M i-scan is feasible. Although digital enhancement increases image quality, its value in the diagnosis of gastric neoplasia seems to be limited.

COMMENTS

Background

Magnified chromoendoscopy is a promising tool in the surveillance and diagnosis of gastric neoplasia. Enhanced magnification endoscopy is superior to conventional endoscopy with detailed surface characterization.

Research frontiers

Dyeless virtual chromoendoscopy with magnification might be preferable for reduction of labor and health risks. The endoscope used in this study is a magnification endoscope with both color and surface enhancement.

Innovations and breakthroughs

To date, this is the first endoscopic device with surface enhancement mimicking acetic acid spraying enhanced magnification endoscopy. With the surface enhancement, the gastric pit patterns can be classified into 5 categories according to the classification from enhanced magnification endoscopy, which enables the detailed characterization of the gastric mucosa. With classification of gastric pits, different common gastric pathologies such as atrophy, intestinal metaplasia and neoplasia can be identified in real-time procedures or by still image analysis. The margin of gastric lesions can be more easily identified although the differences were not significant.

Terminology

Although digital enhancement improves the image quality of magnification endoscopy, its value in improving the diagnostic yield seems to be limited.

Peer review

This is a quite interesting study on virtual chromoscopy on gastric neoplasia. However, data are limited.

Abstract

AIM: To compare the effects of propranolol (PR) to that of PR plus isosorbide-5-mononitrate (ISMN) on variceal pressure in patients with schistosomiasis.

METHODS: Forty-eight patients with schistosomiasis who had no previous variceal bleeding were treated with PR alone or PR plus ISMN. Seven patients refused variceal pressure manometry (3 receiving PR and 4 receiving PR plus ISMN). One patient withdrew from the trial due to headache after taking ISMN. At the time of termination, twenty patients were randomly assigned to treatment with PR plus ISMN or PR alone. The dose of PR was adjusted until the resting heart rate had been reduced by 25% or was less than 55 bpm. In the PR plus ISMN group, after PR was titrated to the same target, the dose of ISMN was increased up to 20 mg orally twice a day. Variceal pressure was measured using a noninvasive endoscopic balloon technique at the end of the 6-mo treatment period.

RESULTS: In 40 patients (20 in the PR group and 20 in the PR plus ISMN group), variceal pressure was measured before treatment and at the end of the 6-mo treatment period. PR or PR plus ISMN treatment caused a significant reduction in variceal pressure (PR group: from 24.15 ± 6.05 mmHg to 22.68 ± 5.70 mmHg, P = 0.001; PR plus ISMN group: from 25.69 ± 5.26 mmHg to 20.48 ± 5.43 mmHg; P < 0.001). The percentage decrease in variceal pressure was significant after PR plus ISMN compared with that after PR alone (15.93% ± 8.37% *vs* 6.05% ± 3.67%, P = 0.01). One patient in the PR plus ISMN group and two patients in the PR group had variceal bleeding during follow-up. There were no significant differences between the two groups regarding the incidence of variceal bleeding. In the PR plus ISMN group, three patients had headache and hypotension. The headache was mild and transient and promptly disappeared after continuation of the relevant drug in two patients. Only one patient withdrew from the trial due to severe and lasting headache after taking ISMN. No side effects occurred in the PR group.

CONCLUSION: PR plus ISMN therapy may be an alternative treatment for patients with schistosomiasis who have a high risk of bleeding.

Key words: Esophageal varices; Schistosomiasis; Portal hypertension; Bleeding; Propranolol; Variceal pressure; Isosorbide-5-mononitrate

Core tip: The results of the present study suggested that the combination of propranolol and isosorbide-5-mononitrate was more effective than propranolol alone in decreasing variceal pressure. This drug combination will reduce the rate of bleeding in patients with schistosomiasis, high-risk esophageal varices and no previous history of variceal bleeding.

INTRODUCTION

Variceal bleeding is the most frequent and severe complication of portal hypertension in patients with cirrhosis. Identification of those who have a high risk of variceal hemorrhage is effective for preventive therapy in patients with a high disease predisposition[1]. Variceal size and the red color sign are considered to be the most important endoscopic parameters in predicting variceal bleeding[2]. However, endoscopic findings alone can not be used to reliably predict the risk of variceal bleeding. The formation of esophageal varices depends on an elevation in portal pressure; a hepatic venous pressure gradient (HVPG) greater than 10 mmHg is necessary for the development of and bleeding from esophageal varices[3-6]. On the other hand, a more rational approach would be to guide pharmacologic therapy based on hemodynamic response, defined as a decrease in HVPG to < 12 mmHg or a decrease of > 20% from baseline levels[7]. However, limitations to the generalized use of HVPG measurement are the lack of local expertise and poor adherence to guidelines that will ensure reliable and reproducible measurements, and its invasive nature[5]. In the majority of published studies, the dose of nonselective β-blockers was titrated to decrease the heart rate by 25% from baseline or maximal tolerated doses[5,7].

Propranolol (PR) or isosorbide-5-mononitrate (ISMN) is effective in preventing the first variceal bleeding in patients with cirrhosis[1,5]. ISMN enhances the reductive effect of PR on variceal pressure in cirrhotic patients[1,5]. In contrast to liver cirrhosis, published data regarding the effect of PR on schistosomiasis-related portal hypertension are scarce and contradictory, and the effect of ISMN plus PR treatment is unknown in these patients[8,9]. A short-term study in patients with schistosomiasis and previous variceal bleeding after PR treatment found that the portal pressure was not decreased[8]. Moreover, the required mean dose to achieve a 20%-25% reduction in heart rate from baseline was up to 400 mg/d[8]. Cohort studies indicated that PR treatment achieved a reduction in rebleeding rates and increased the survival of patients with no serious side effects[9]. Recently, a study from Brazil found that PR significantly reduced variceal pressure in schistosomiasis patients who had never bled[10]. However, it is not clear whether ISMN plus PR is better than PR alone in the treatment of schistosomiasis patients who had never bled. In this study, we will ascertain whether the combination of PR and ISMN is more effective than PR alone in decreasing variceal pressure.

MATERIALS AND METHODS

Selection of patients

From September 2007 to October 2010, patients admitted to our hospital due to schistosomiasis-related portal hypertension were assessed for inclusion in the trial. The diagnosis of schistosomiasis was established in accordance with the World Health Organization criteria[11]. The eligibility criteria were age between 18 and 65, schistosome eggs in stool specimens, the characteristic ultrasound criteria, and endoscopic evidence of esophageal varices. The exclusion criteria were previous treatment for portal hypertension (*e.g.*, beta-blockers, sclerotherapy, or endoscopic band ligation), severe hepatic disease (*e.g.*, Child-Pugh score higher than 12 points or hepatorenal syndrome), previous variceal bleeding, presence of any neoplastic disease, portal vein thrombosis, inability to attend follow-up, contraindications to beta-blockers (severe chronic pulmonary obstructive disease, asthma, severe insulin-dependent diabetes mellitus, heart failure, grade II atrioventricular block, sinus bradycardia < 50 bpm, aortic stenosis, peripheral arterial disease, arterial hypotension with systolic pressure < 85 mmHg), or long-acting nitrates (glaucoma). The study was approved by the Ethics Committee of Anhui Medical University, and all patients gave written informed consent to participate in the study. Patients were assigned to one of two treatment groups according to the sequential method of randomization.

Treatment

Patients who fulfilled the inclusion and exclusion criteria were immediately randomized into the two treatment groups using consecutively numbered envelopes that contained the treatment assignments, which were generated by a system using computer-allocated random digit numbers. PR was given orally at an initial dose of 20 mg 3 times daily. The dose was subsequently adjusted over a period of 5 d until the resting heart rate had been reduced by 25% or was less than 55 bpm. In the PR plus ISMN group, after PR was titrated to the same target in resting heart rate, the dose of ISMN was increased up to an oral dose of 20 mg twice a day.

Methods

Measurement of variceal pressure was performed after

an overnight fast during upper gastrointestinal endoscopy. Variceal pressure was assessed with a previously described noninvasive technique using an esophageal variceal manometer (EVM; Esophageal Varix Manometer; Treier Endoscopie AG, Beromünster, Switzerland) and recorded by the workstation which was developed by our group[12,13]. To minimize esophageal tonus and peristalsis, all patients received premedication with 5 mg diazepam and 20 mg *n*-butylscopolamine intravenously. The reliability of the endoscopic measurement of variceal pressure was determined in a previous study which found a good correlation with needle puncture measurement[13-15]. In the current study, endoscopic measurement of variceal pressure was used because of the unique hemodynamic pattern of pre-sinusoidal portal hypertension. The largest varix situated above the cardia was chosen for measurement of variceal pressure. The pressure in each patient was measured five times. Variceal pressure was calculated as the mean of five satisfactory measurement periods recorded.

After variceal pressure measurement, the size of the varix was estimated in the absence of peristaltic waves, by comparing the varix with the scales in the balloon variceal markers (5-mm intervals). The maximal size of the varices and the red color signs were recorded as proposed by the Japanese Research Society for portal hypertension[16].

Follow-up and endpoints

All patients were followed in the outpatient clinics at 3-month intervals and assessed for adverse events, compliance (direct questioning, prescription renewal, and reinforcement), variceal bleeding, and progression of liver disease. Variceal pressures in all patients were measured before and after 6 mo of continuous PR or PR plus ISMN therapy. The primary end point was variceal bleeding and secondary end points were treatment-related complications and mortality. Variceal bleeding was defined as hemetemesis or melena, with an associated drop in hematocrit by 10%, in the absence of any other source of gastrointestinal bleeding on endoscopy. In the case of variceal bleeding, physicians were free to choose endoscopic treatment to prevent rebleeding.

Statistical analysis

Statistical analyses were performed with SPSS (version 10; SPSS, Inc., Chicago, IL, United States). All quantitative data were tested for normal distribution. Quantitative data were expressed as mean ± SD if the data were normally distributed. Each continuous parameter was analyzed with the independent-samples t-test. The paired-samples t-test was used to examine change from baseline to follow-up. Categorical data were examined using Fisher's exact test. P-values < 0.05 were considered statistically significant.

RESULTS

Baseline data

Twenty-five patients received PR plus ISMN and 23 patients received PR alone (dosage of PR: 60 to 160 mg/d, median: 80 mg; dosage of ISMN: 20 mg/d). Seven patients refused to variceal pressure manometry (3 receiving PR and 4 receiving PR plus ISMN). One patient withdrew from the trial due to headache after taking ISMN. Therefore, there were 20 patients in each treatment group. Clinical and endoscopic data of the patients in the subsets are shown in Table 1. There were no significant differences between the two groups at baseline with regard to clinical and demographic characteristics or baseline variceal pressure (Table 1, PR group = 24.15 ± 6.05 mmHg; PR plus ISMN = 25.69 ± 5.26 mmHg).

Changes in variceal pressure

In 40 patients (20 in the PR group and 20 in the PR plus ISMN group), variceal pressure was measured again the end of a 6-mo continuous treatment period. PR or PR plus ISMN caused a significant reduction in variceal pressure (PR group: from 24.15 ± 6.05 mmHg to 22.68 ± 5.70 mmHg, P = 0.001; PR plus ISMN group: from 25.69 ± 5.26 mmHg to 20.48 ± 5.43 mmHg; P < 0.001). The percentage decrease in variceal pressure after PR plus ISMN was more significant than that after PR alone (Table 2, 15.93% ± 8.37% *vs* 6.05% ± 3.67%, P = 0.01).

Bleeding

One patient in the PR plus ISMN group and two patients in the PR alone group had variceal bleeding during the 6-mo follow-up period. There were no significant differences between the two groups regarding the incidence of variceal bleeding.

Adverse effects

In the PR plus ISMN group, three patients had headache and hypotension. The headache was mild and transient and promptly disappeared after continuation of the rel-

evant drug in two patients. One patient withdrew from the trial due to severe and lasting headache after taking ISMN. No side effects occurred in the PR group. There was no worsening of liver function or impairment of renal function in the 2 groups within the 6-mo treatment period (Table 2).

DISCUSSION

Nonselective β-blockers are the most commonly used drugs to prevent variceal bleeding in patients with cirrhosis and esophageal varices[6,14]. Although many trials have shown that variceal hemorrhage risk was reduced with β-blockers, these drugs do not protect all treated patients, probably due to an inadequate decrease in the HVPG[5,17]. Most published studies have shown that PR and ISMN have a synergistic effect on reducing portal pressure and a combination of the two could be more effective than PR alone[17,18]. Recently, PR was found to significantly reduce variceal pressure and wall tension in patients with schistosomiasis[10]. However, it is uncertain whether the combination of PR and ISMN is more effective than PR alone in decreasing variceal pressure in schistosomiasis patients who have never bled.

This study investigated the efficacy of PR compared with PR plus ISMN in schistosomiasis patients that had never bled. Our approach was to assess variceal pressure in patients with high-risk varices, using the same methodology reported for cirrhotic patients[12]. Variceal bleeding is believed to occur when the tension exerted over the thin wall of the varices increases beyond a critical value determined by the elastic limit of the vessel[5]. Variceal pressure and size are key factors determining variceal wall tension. Not only is variceal pressure the best parameter for predicting rupture of varices and consequent complications, but it is also a useful guide for studying the effect of the pharmacotherapy of portal hypertension and a measure of the effects of transjugular intrahepatic portosystemic shunting[6,19-21]. As confirmed by one study, the measurement of variceal pressure can efficiently monitor the direct effect of the prophylaxis of variceal bleeding compared with the rate of bleeding in cirrhotic patients[17].

In the present study, we observed that PR and PR plus ISMN administration caused a significant reduction in variceal pressure in patients with schistosomiasis. After a 6-mo continuous treatment period, the percentage decrease in variceal pressure was more obvious in patients receiving PR plus ISMN than PR alone (15.93% ± 8.37% *vs* 6.05% ± 3.67%, $P = 0.01$). Thus, the results of our study suggest that PR plus ISMN is superior to PR alone in reducing variceal pressure in patients with schistosomiasis. These results are consistent with the data from different randomized clinical trials which show that the effect in patients treated with combined pharmacological therapy was greater than that obtained with PR alone[17,18]. Therefore, the pharmacological therapy of choice in the prevention of variceal bleeding is probably the combination of PR and ISMN.

The mean dosage of PR used in our study was lower than that in other studies for cirrhotic patients and schistosomiasis patients[1,5]. However, the low dosage of PR in the current study was expected because it is well know that the metabolism of this drug is different between Asian and European patients[22]. In a previous study, Lay *et al*[23] found that the mean daily dosage of PR was 68.2 ± 32.8 mg, which was sufficient to reduce the heart rate by 25%. Therefore, it is possible that a lower dosage of PR to reach a target heart rate reduction of 25% would have enough power to result in a lower bleeding rate in a Chinese population.

Three patients treated with PR plus ISMN experienced side effects. Most reported side effects caused by β-blockers (hypotension, tiredness, breathlessness, poor memory, insomnia) can be easily managed by adjusting the dose of the medication, which does not affect the treatment effect. ISMN may increase vasodilatation leading to more side effects such as headache and hypotension[1,5]. In a trial performed in patients with cirrhosis and ascites which compared β-blockers with ISMN, the latter medication was associated with more side effects[24]. Furthermore, other studies also found a trend toward more side effects requiring withdrawal of the combination therapy compared with PR alone[17,18,25]. In our study, two patients experienced mild and transient headache on the first administration of ISMN, which disappeared after continuation of the relevant medication. One patient withdrew from the trial due to severe and lasting headache after taking PR plus ISMN. When the resting heart rate was reduced by 25% or was less than 55 bpm, most patients showed a significant reduction in variceal pressure (15.93% ± 8.37%) after receiving PR plus ISMN.

We are aware of the limitations of the current study. First, we found that the measurement of variceal pressure is technically difficult and time consuming in patients with small varices, which may reduce the applicability of measurements in clinical practice. However, because very large varices and red color signs indicate imminent bleeding, these patients are at high risk of bleeding and require prophylactic measures even though their variceal pressure

is not high[26,27]. On the other hand, the measurement of variceal pressure is probably not very important in patients with very small varices due to rare bleeding[28-31]. Second, patients not suitable for PR plus ISMN therapy need to be investigated in future studies. Third, future randomized controlled studies with a larger number of patients are warranted to confirm these findings and to demonstrate the long-term decrease in the frequency of bleeding episodes and mortality.

In conclusion, we found that combination treatment with PR plus ISMN compared with PR alone, more effectively decreased variceal pressure in schistosomiasis patients. Future randomized controlled studies with a larger number of patients are warranted to demonstrate the long-term decrease in variceal pressure, to determine when side effects will outweigh the benefits, and monitor the frequency of bleeding episodes and mortality.

COMMENTS

Background

Non-cirrhotic portal hypertension and gastrointestinal bleeding are complications of the infection caused by the intravascular parasitic trematode *Schistosoma mansoni*. The prophylactic treatment of variceal bleeding is therefore crucial in the management of these patients.

Research frontiers

Treatment with propranolol plus isosorbide-5-mononitrate resulted in a synergistic decrease in variceal pressure compared with propranolol alone in cirrhotic patients. However, this has not been demonstrated in non-cirrhotic portal hypertension caused by *Schistosoma mansoni* infection.

Innovations and breakthroughs

In this study, the authors found that the combination of propranolol and isosorbide-5-mononitrate was more effective than propranolol alone in decreasing variceal pressure, which is important in reducing the rate of bleeding in patients with schistosomiasis, high-risk esophageal varices and no previous history of variceal bleeding.

Applications

The results suggest that the combination of propranolol plus isosorbide-5-mononitrate should be recommended as the first prophylaxis of variceal bleeding in non-cirrhotic portal hypertension caused by *Schistosoma mansoni* infection. Additional studies with long-term follow-up are needed to confirm the results concerning mortality.

Peer review

The authors have compared the effect of propranolol alone with the combination of propranolol and isosorbide-5-mononitrate on variceal pressure in patients with portal hypertension due to schistosomiasis. The results suggested that the combination led to a more pronounced decrease of variceal pressure than propranolol did.

Abstract

AIM: To investigate if there is an association between hepatitis B virus (HBV) or hepatitis C virus (HCV) infection and the risk of pancreatic cancer.

METHODS: All relevant studies published before 11 October, 2012 were identified by a systematic search of MEDLINE, EMBASE, BIOSIS Previews and the Cochrane Library databases and with cross-referencing. The observational studies that reported RR or OR estimates with 95%CIs for the association between HBV or HCV and pancreatic cancer were included. A random-effects model was used to summarize meta-analytic estimates. The Newcastle-Ottawa quality assessment scale was applied to assess the quality of the methodology in the included studies.

RESULTS: A total of 8 eligible studies were selected for meta-analysis. Overall, chronic hepatitis B and inactive hepatitis B surface antigen (HBsAg) carrier state (HBsAg positive) had a significantly increased risk of pancreatic cancer with OR of 1.20 (95%CI: 1.01-1.39), especially in the Chinese population (OR = 1.30, 95%CI: 1.05-1.56). Past exposure to HBV (possible occult HBV infection) had an increased OR of pancreatic cancer risk (OR = 1.24, 95%CI: 1.05-1.42), especially among those patients without natural immunity [anti hepatitis B core (HBc) positive/hepatitis B surface antibody (anti HBs) negative], with OR of 1.67 (95%CI: 1.13-2.22). However, past exposure to HBV with natural immunity (anti-HBc positive/anti-HBs positive) had no association with pancreatic cancer development, with OR 0.98 (95%CI: 0.80-1.16), nor did the HBV active replication (hepatitis B e antigen positive status), with OR 0.98 (95%CI: 0.27-1.68). The risk of pancreatic cancer among anti-HBs positive patients was significantly lower than among anti-HBs negative patients (OR = 0.54, 95%CI: 0.46-0.62). Past exposure to HCV also resulted in an increased risk of pancreatic cancer (OR = 1.26, 95%CI: 1.03-1.50). Significant between-study heterogeneity was observed. Evidence of publication bias for HBV/HCV infection-pancreatic cancer association was not found.

CONCLUSION: Chronic HBV and HCV infection increases pancreatic cancer risk. Our findings underscore the need for more studies to confirm this potential relationship.

Key words: Hepatitis B; Hepatitis C; Pancreatic cancer; Observational studies; Meta-analysis

Core tip: Based on the meta-analysis, we identified that chronic hepatitis B virus (HBV) or hepatitis C virus (HCV) infection is associated with pancreatic cancer, especially among Chinese population. Patients with past exposure to HBV/HCV should be screened for hepatocellular carcinoma and other malignancies, especially pancreatic cancer.

Hepatitis B or C viral infection and risk of pancreatic cancer: A meta-analysis of observational studies. *World J Gastroenterol* 2013; 19(26): 4234-4241 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i26/4234.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i26.4234

INTRODUCTION

Pancreatic cancer is one of the most lethal and devastating human malignancies and the fourth leading cause of cancer-related fatality worldwide. Because of absence of early symptoms, lack of sensitive and specific tests to screen the cancer in the initial phases, limited therapeutic options and rapid progression, nearly all patients die of the disease within one year of diagnosis with the overall 5-year survival rate being less than 5%[1]. Therefore, it is crucial to identify the intrinsic genes as well as other risk factors, that may influence the progression of the cancer, and to develop more accurate screening programs for early monitoring and intervention strategies. Although several risk factors associated with pancreatic cancer have been explored, the causative factors for pancreatic cancer are far from being understood, one of which is chronic hepatitis infection[2,3].

The prevalence of hepatitis B virus (HBV) and hepatitis C virus (HCV) infection varies worldwide, ranging from less than 0.5% in Western countries to 7% and 25% in East Asian and African countries[4,5]. Infection with HBV is a huge global public health concern, especially in China. According to the World Health Organization, there are 2 billion people infected with HBV globally, with China accounting for 65% of the HBV infective public health burden of the world[6]. HBV/HCV have been detected not only in hepatotropic tissue but also in extrahepatic sites such as the pancreas[7,8]. Several studies reported conflicting results regarding the association between HBV infection and the risk of subsequent pancreatic cancer. Studies by Berrington de Gonzalez *et al*[9] and Hong *et al*[10] found no relationship between chronic infection with HBV and the development of pancreatic cancer, while several published studies found an association between presence of HBV infection and incidence of pancreatic cancer, not only in countries with a lower prevalence of HBV infection such as the United States but also in countries with a higher number of HBV infections such as China[11,12]. Meanwhile, little is known about the association between the presence of HCV infection and the risk of pancreatic cancer[3].

The purpose of the present study is to summarize all available evidence of observational studies in order to better define the impact of HBV and HCV infection on the risk of pancreatic cancer in patients following the meta-analysis of observational studies in epidemiological guidelines.

MATERIALS AND METHODS

Data sources and searches

A comprehensive literature search was carried out on observational studies and trials, and no language or time restriction was applied. All literature from January 1, 1980 to October 18, 2012 was searched using the following databases: Pubmed, ISI web of Science, Embase and Cochrane library. The following main keywords or corresponding MeSH terms were used: hepatitis, virus, viral, pancreas, cancer OR adenocarcinoma OR neoplasm OR tumor. A manual search was also performed for references cited in the selected articles.

Study selection

Studies were included in the meta-analysis if (1) they were the principal published reports of original data from case-control or cohort studies; (2) they were independent from other studies to avoid giving double weight to estimate the same study; (3) the exposure of interest was a history of HBV/HCV infection; (4) the outcome of interest was pancreatic cancer incidence or mortality; and (5) they had sufficient information to allow adequate estimation of OR or RR and 95%CI to estimate cancer risk under HBV/HCV exposure. Two authors (Fu JJ and Xu JH) independently evaluated all of the studies retrieved from database, then compared their results. Any disagreements were resolved by consensus.

Data extraction

The following data were extracted from each study: authors, publication year, study design, country of origin, sample size, measure of outcome, duration of follow-up, marker of hepatitis serostatus, covariates adjusted for in the analysis, and the effect estimates with corresponding 95%CIs.

Quality evaluation

The Newcastle-Ottawa quality assessment scale (NOS)[13] was applied to assess the quality of the methodology in the included studies. A star system was used to judge the data according to the selection populations, comparability of groups and exposure/outcome of interest. The NOS scale consists of 8 questions with 9 possible points. The assessment score ranged from 0 to 9. Studies with a total score of 6 or lower indicated low quality while study

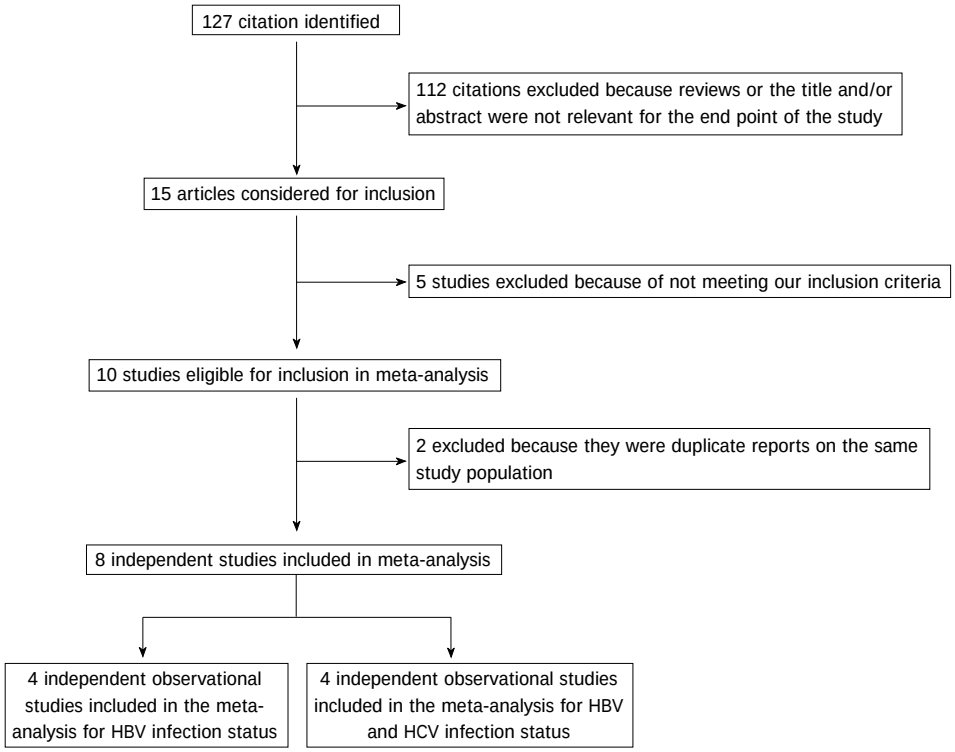

Figure 1 Flowchart of selection of studies for inclusion in meta-analysis. HBV: Hepatitis B virus; HCV: Hepatitis C virus.

NOS: Newcastle-Ottawa quality assessment Scale. For case-control studies: (1) represents cases with independent validation; (2) cases are consecutive or representative; (3) controls are community; (4) controls have no history of pancreatic cancer; (5) study controls are comparable for age and sex; (6) study controls for any additional factor(s); (7) cases and controls have the same method of ascertainment; (8) was follow-up long enough for outcomes to occur; and (9) cases and controls have complete follow-up. For cohort studies: (1) indicates the exposed cohort study representative of the population; (2) the non exposed cohort drawn from the same population; (3) the exposure ascertainment are from secure record or structured interview; (4) the pancreatic cancer was not present at start of study; (5) cohorts are comparable for age and sex; (6) cohorts are comparable for any additional factor(s); (7) assessment of pancreatic cancer is from secure record; (8) follow-up long enough for pancreatic cancer to occur; and (9) complete follow-up.

scores of 7 or higher were considered to be of high quality. Two reviewers (Xu JH and Fu JJ) independently evaluated and cross-checked the qualities of the included studies (Table 1).

Statistical analysis

Statistical analyses were completed with STATA version 10.0 (STATA, College Station, TX, United States). Summary odd ratio estimates with the corresponding 95%CIs were combined and weighted to produce pooled ORs using a random-effects model, which considers both within- and between-study variations[14]. Q and I^2 statistics were both examined to investigate the source of heterogeneity across studies. I^2 values of 25, 50 and 75% were assigned to low, moderate, and high heterogeneities, respectively[15]. The Begg's adjusted rank correlation test and the Egger's regression test (significant at $P < 0.1$) were performed to test for evidence of publication bias[16].

RESULTS

Description of the studies

The participant flow diagram for the study inclusion in the meta-analysis is shown in Figure 1. A total of 8 articles were retrieved and checked for relevance in terms of infectious status, population studied, and reporting of pancreatic cancer risk data[2,3,9-12,17,18]. Seven of other articles were not included in the meta-analysis for the following reasons: (1) two referred to the same cohort[19,20]; (2) two were editorials responding to originated studies[21,22]; (3) one reported HCV infection and pancreatic cancer incidence in the abstract but no OR (95%CI) information was found[23]; and (4) two studies were manual search cited in the selected articles, but did not meet our inclusion criteria after reading the text[24,25].

The main characteristics of the 8 studies pooled in

CC: Case-control study; HBV: Hepatitis B virus; HCV: Hepatitis C virus; HBsAg: Hepatitis B surface antigen; Anti-HBs: Anti-hepatitis B surface antigen; Anti-HBc: Anti-hepatitis B core antigen; Anti-HCV: Anti-hepatitis C virus; ICD-9: International Classification of Diseases, Ninth Revision; DM: Diabetes mellitus; BMI: Body mass index.

the present analysis are reported in Table 2. All studies except one prospective study were retrospective. Five studies were case-control, and three were cohort studies conducted between 1988 and 2010 and published between 2008 and 2012. These studies included a total of 744 120 investigated patients and 3758 cases of pancreatic cancer events. Four studies were conducted in China, two in South Korea and two in the United States.

Quantitative data synthesis

Hepatitis B surface antigen (HBsAg) was seropositive in 4492 patients across all of the groups. Meta-analysis of 6 studies in a random-effects model found that compared to individuals without a history of chronic hepatitis B, those with chronic hepatitis B and in inactive HBsAg carrier state (HBsAg positive) had a 20% greater risk of pancreatic cancer (OR = 1.20, 95%CI: 1.01-1.39), with moderate heterogeneity among studies (test for heterogeneity I^2 = 29.6%, P = 0.213). To further evaluate the HBsAg carrier state associated with pancreatic cancer in the Chinese population, a subgroup type was used to analyze the data. As shown in Figure 2, 4 studies conducted in the Chinese population revealed that the odds ratio of pancreatic cancer for HBsAg positivity was 1.30 (95%CI: 1.05-1.56). Moderate heterogeneity (I^2 = 40.2%, P = 0.171) was seen across studies.

Prior infection with hepatitis B, as determined by the presence of anti- hepatitis B core (HBc), resulted in a significantly increased risk of pancreatic cancer showing OR of 1.24 (95%CI: 1.05-1.42) (I^2 = 71.4%, $P_{heterogeneity}$ = 0.015) which is summarized in Figure 2. Furthermore, an increased risk of pancreatic cancer was observed for hepatitis B surface antibody (anti-HBs)-seronegative/anti-HBc-seropositive carriers who were previously exposed to HBV without natural immunity, with OR of 1.67 (95%CI: 1.13-2.22) (I^2 = 0.0%, $P_{heterogeneity}$ = 0.329), but not for past exposure to HBV carriers with natural immunity (anti-HBs-seropositive/anti-HBc-seropositive), with OR of 0.98 (95%CI: 0.80-1.16) (I^2 = 82.3%, $P_{heterogeneity}$ = 0.003).

We observed non-significant positive associations between markers of active viral replication and pancreatic cancer risk, as illustrated in Figure 2. The risk of developing pancreatic cancer was 0.98 (95%CI: 0.27-1.68) (I^2 = 0.0%, $P_{heterogeneity}$ = 0.399) for HBsAg-seropositive/hepatitis B e antigen (HBeAg)- seropositive subjects compared with that of HBsAg-seronegative subjects while a significant positive association between the protective markers of HBV, anti-HBs and pancreatic cancer risk was found for studies conducted in the pooled analysis with OR of 0.54 (95%CI: 0.46-0.62) (I^2 = 92.7%, $P_{heterogeneity}$ = 0.000).

As summarized in Figure 2, the incidence of pancreatic cancer risks were also significantly increased in previously HCV infected population, with OR of 1.26 (95%CI: 1.03-1.50) (I^2= 0.0%, $P_{heterogeneity}$ = 0.949).

We also carried out stratified analyses to assess the impact of confounding factors of the RRs on the chronic carriers of HBV subgroup. As shown in Table 3, when we restricted the meta-analysis to those studies adjusted for smoking, the association between chronic HBV infection and pancreatic cancer risk was positive, the pooled OR was 1.32 (95%CI: 1.08-1.56). No positive association between chronic HBV infection and pancreatic cancer risk was found in the studies that were not adjusted for smoking, the pooled OR was 0.99 (95%CI: 0.68-1.30). In the stratified analysis, the association between chronic HBV infection and pancreatic cancer risk was also similar between the studies that were adjusted for alcohol drinking (the pooled OR = 1.51, 95%CI: 1.17-1.85) and those that were not adjusted for alcohol drinking (the pooled OR = 1.05, 95%CI: 0.83-1.28). Meanwhile, there was no positive association between chronic HBV infection and pancreatic cancer risk in the studies adjusted for diabetes (the pooled OR = 1.25, 95%CI: 0.95-1.55), neither was

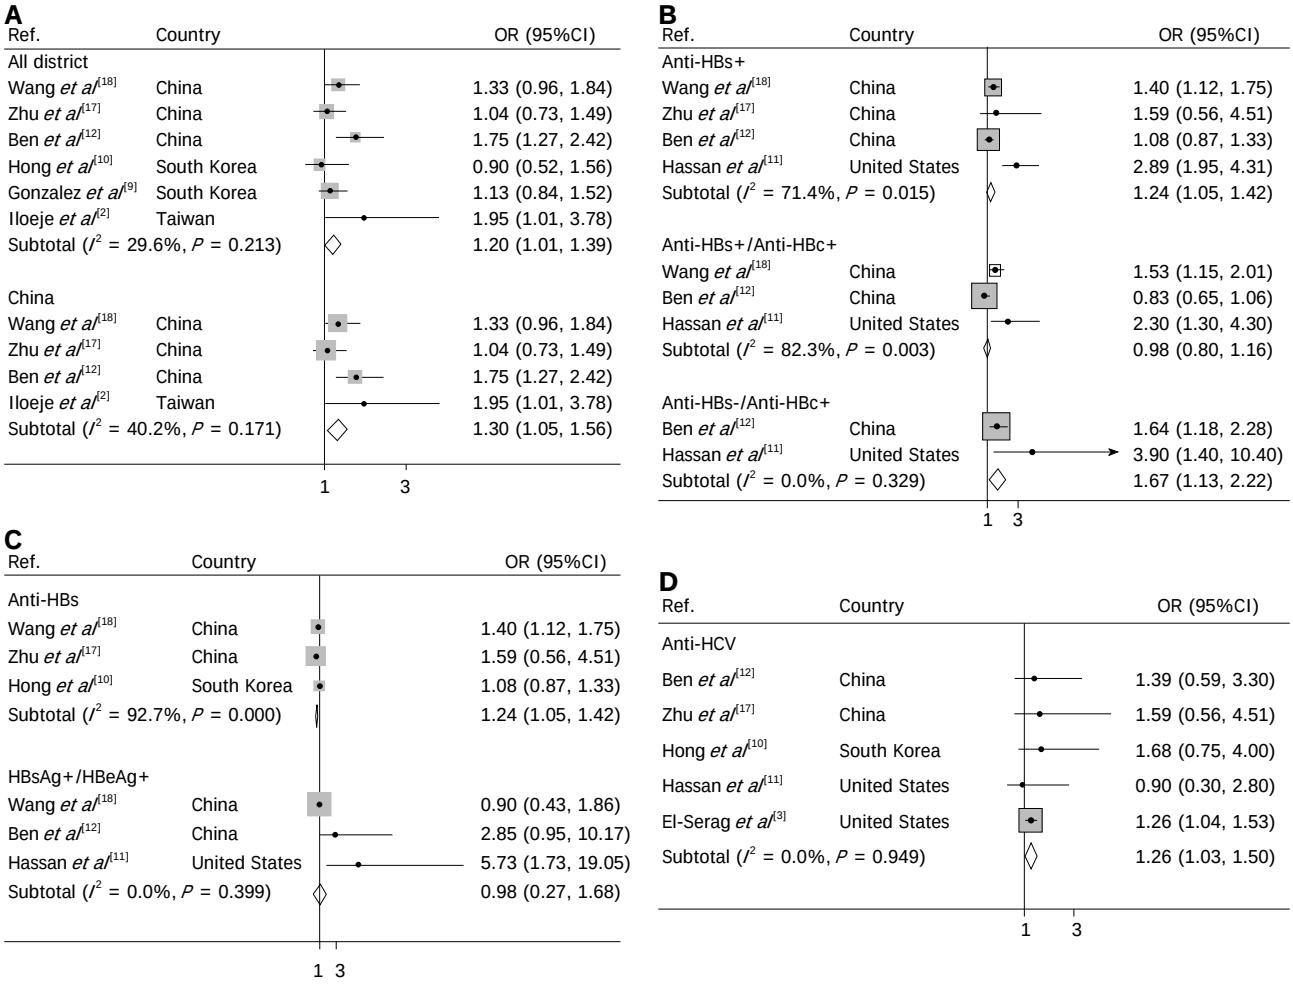

Figure 2 Forest plots of risk of pancreatic cancer. A: Associated with chronic hepatitis B (HBsAg carrier state) around the world and Chinese population; B: Associated with anti-HBc status; C: Associated with active hepatitis B virus viral replication and anti-HBs status; D: Associated with hepatitis C virus infection.

Table 3 Stratified analysis of pancreatic cancer risk by adjusted covariates

Stratifying variables	Studies (*n*)	OR (95%CI)	Tests for heterogeneity		
			χ^2	*P* value	I^2
Adjusted for smoking					
Yes	4	1.32 (1.08-1.56)	4.14	0.246	27.60%
No	2	0.99 (0.68-1.30)	0.18	0.670	0.00%
Adjusted for drinking					
Yes	3	1.51 (1.17-1.85)	1.70	0.428	0.00%
No	3	1.05 (0.83-1.28)	0.53	0.766	0.00%
Adjusted for diabetes					
Yes	4	1.25 (0.95-1.55)	5.22	0.156	42.50%
No	2	1.24 (0.50-1.98)	1.54	0.214	35.20%

in the studies that were adjusted for diabetes (the pooled OR, 1.24, 95%CI: 0.50-1.98).

Publication bias

No publication bias was apparent following an assessment by funnel plot (Figure 3, Begg's test $P = 0.711$, Egger's test $P = 0.868$).

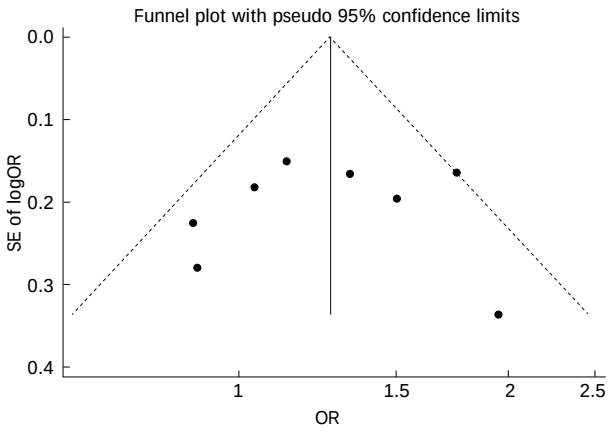

Figure 3 Begg's funnel plot with 95% confidence limits to detect publication bias. Each point represents a separate study for the indicated association.

DISCUSSION

This is the first comprehensive meta-analysis of observational studies on the association between chronic hepa-

titis viral infection and pancreatic cancer risk. We found that HBV and HCV infection is associated with 20% and 23% higher risk of pancreatic cancer, respectively. Our results reveal that prior infection with hepatitis B, especially in those without natural immunity would significantly increase the risk of pancreatic cancer. However, active hepatitis B viral replication does not increase the pancreatic cancer incidence. These observations provide evidence supporting the importance role of chronic HBV and HCV infection in the development of pancreatic cancer. In light of the fact that pancreatic cancer is a highly fatal tumor with a 5-year survival rate of less than 5% and that the number of people with HBV is 2 billion[6,26], our findings have substantial clinical and public significance on a global scale. It points to the need for further investigation on the etiological causes involved in human pancreatic carcinogenesis, the recognition of pancreatic damage mechanisms caused by chronic hepatic viral infection, and for long-term, large scale clinical studies to confirm this clinical association.

If the positive association between the chronic or inactive HBV or HCV carriers and the development of pancreatic cancer is a true, what mechanism could explain such a link? From the anatomical point of view, the proximity of the liver to the pancreas, as well as the sharing of the two organs blood vessels and ducts may make the pancreas a potential reservoir of hepatitis viruses. HBV or HCV may travel through the blood stream and be deposited in non-liver tissue[27,28]. In fact, by means of *situ* hybridization and immunohistochemical techniques, the serological markers of present or past HBV infection, HBsAg was detected in chronic inflammatory pancreatic acinar cells and in the pancreatic duct epithelia with pancreatic adenocarcinoma[29]. The same was true with HCV antigen, which was also found in pancreatic acinar cells[30]. These findings demonstrated the possibility of HBV infection and evidence of a chronic inflammatory reaction in non-hepatic tissues.

HBV and HCV replication intermediates in pancreatic cells support the assumption that the permissiveness of these extrahepatic cells for viral replication might also induce the chronic inflammatory response, thus eventually promoting tumor development. Anti-HBc-positive status, the sero biological marker of past exposure to HBV had an increased risk of developing pancreatic cancer. The observation provides some biological plausibility to the idea that long-lasting persistence of viral infection could indeed replicate in the pancreas. In fact, HBV and HCV are oncogenic viruses, and both are able to integrate the viral RNA or DNA into the genome of the infected cells[31,32]. DNA integration may play a key role in the regulation of the cell cycle, inducing carcinogenesis associated with HBV infection[33].

The third reason why our finding of a relationship between HBV infection and pancreatic cancer incidence may not be surprising is that the presence of HBV infection protection marker, seroconversion from HBsAg to anti-HBs, which is considered a sign of disease protection, leads to a significantly decreased risk of pancreatic cancer showing an OR of 0.54 in the pooled studies.

As with all meta-analyses of observational studies, our findings might have some limitations. First, because five of eight studies used a case-control design[10-12,17,18], the findings provided by this meta-analysis should be viewed with caution since more recall and selection bias might be seen in case-control studies. In addition, all the case-control studies were hospital-based and therefore may not fully represent the general population of pancreatic cancer patients, thereby introducing potential for selection bias into our meta-analysis.

Second, when investigating the association between hepatic virus infection and the risk of pancreatic cancer, the potential residual confounding and the allocation bias, with hepatic virus infection being at different stage and baseline risk of pancreatic cancer would affect the results. For example, it is difficult to understand the biological explanation for finding the cancer risk in subjects with chronic infection and not in those with current and active replication of the virus as shown by a positive HBeAg. The progression from active hepatitis virus infection to chronic inflammatory response targeted to pancreatic carcinogenesis is still unknown, for there is a lack of such data[34]. This incomplete information on HBV/HCV in the pathogenesis of progressive stages limits our knowledge on the true relationship of these oncogenic viruses with pancreatic cancer development. Although an increased risk of pancreatic cancer was observed for anti-HBs-seronegative/anti-HBc-seropositive carriers who were previously exposed to HBV without natural immunity, it is very difficult to interpret a pooled analysis of only 2 studies. Another issue is that none of the studies directly tested for the presence of markers of hepatitis virus infection in the pancreatic tissue. Therefore, a correlation between the level of the markers of HBV/HCV infection in peripheral blood and that in pancreatic tissue could not be established, which would throw some doubt into the reliability of the summary of RRs. More research is necessary to assess a dose-response association to examine the influence of viral load on the progression of pancreatic cancer to support biological plausibility.

Third, possible confounding factors and biases that may not have been fully adjusted for in this study exist. In fact, risk factors such as cigarette smoking, alcohol intake and diabetes, all of which could increase risk of pancreatic cancer associated with a history of chronic hepatitis virus infection. Only 4[2,10-12], 3[2,11], and 4[10-12,17] studies provided risk estimated adjusting for smoking, alcohol intake, and diabetes, respectively. The positive association between chronic HBV infection and pancreatic cancer risk was found after adjustment by smoking and alcohol drinking, but no positive correlation was maintained after adjustment by diabetes, suggesting that residual confounding by diabetes modified the association between chronic HBV infection and pancreatic cancer risk.

Finally, it is also important to realize that there is still a significant heterogeneity observed across studies, mostly

due to the diversity of the study designs and the varying incidence of pancreatic cancer and HBV/HCV infection rates may vary from continent to continent.

Even with these limitations, our meta-analysis supports the hypothesis that chronic HBV and HCV infection may significantly increase pancreatic cancer risk. The findings of this study raise the question of whether the early detection and provision of aggressive antiviral treatment for chronic hepatitis virus infection could prevent the development of pancreatic cancer, and whether patients with past exposure to HBV/HCV should be screened for malignancies other than HCC particularly in patients at high risk of HBV/HCV infection.

In conclusion, our meta-analysis favors the association between HBV/HCV infection and pancreatic cancer risk. However, observational studies were moderately heterogeneous and biased. Additional long-term prospective evidence for HBV/HCV infection among higher risk of pancreatic disease patients should be monitored and new evaluations on the effects of early intervention including HBV/HCV treatment, especially in occult HBV infection (anti-HBc-seropositive status), on the molecular carcinogenesis of pancreatic cancer are warranted.

COMMENTS

Background

Data from epidemiological studies related to the association of hepatitis B virus (HBV) and hepatitis C virus (HCV) and pancreatic cancer risk are inconsistent, with some studies supporting the excess pancreatic cancer with HBV/HCV infection compared to non-infected controls, and some studies showing differently. The aim of this meta-analysis was to clarify the association of chronic hepatitis viruses with the risk of pancreatic cancer.

Research frontiers

To date, several studies have assessed the association between the chronic HBV/HCV and pancreatic cancer risk in different ethics; however, the results are inconsistent and inconclusive. No quantitative summary of the evidence has ever been performed.

Innovations and breakthroughs

Based on the meta-analysis, the authors identified that chronic HBV and HCV infection is associated with pancreatic cancer, especially among Chinese population. Early intervention of HBV and HCV infection might decrease pancreatic cancer incidence.

Applications

The results support the hypothesis that chronic HBV/HCV infection significantly increases pancreatic cancer risk. Findings of this analysis are comparable with previous studies, and long-term prospective studies. Patients with past exposure to HBV/HCV should be screened for hepatocellular carcinoma and other malignancies, especially pancreatic cancer.

Terminology

Anti-hepatitis B core antigen (HBc)+/anti-hepatitis B surface antigen (HBs)± are serum biomarkers of possible occult HBV infection. Anti-HBc+/anti-HBs+ is the status of past exposure to HBV with evidence of HBV immunity or recovery, but possibly harboring persistent HBV infection. Anti-HBc+/ anti-HBs- is the status of past exposure to HBV without natural immunity.

Peer review

The meta-analysis was aimed at assessing the association between HBV/HCV chronic infection and risk of pancreatic cancer. This is an appealing issue, leading to interesting results.

Abstract

AIM: To investigate the association between *babA2* gene and peptic ulcer disease (PUD) and gastric cancer (GC) in *Helicobacter pylori*-infected populations.

METHODS: We evaluated the relationship between *babA2* and clinical outcomes (PUD and GC) using a meta-analysis. A literature search was performed using the PubMed and Web of Science databases for relevant case-control studies that met the defined inclusion criteria. The ORs and 95%CIs were calculated to estimate the association between *babA2* genotype and clinical outcomes. A fixed-effect or random-effect model was performed depending on the absence or presence of significant heterogeneity.

RESULTS: A total of 25 articles with 38 studies met the inclusion criteria and were finally included in this meta-analysis. The results showed that the *babA2* genotype was significantly associated with an increased risk of PUD (OR = 2.069, 95%CI: 1.530-2.794, $P < 0.001$) and especially in the subgroup of duodenal ulcer (OR = 1.588, 95%CI: 1.141-2.209, $P = 0.006$). Moreover, a significant association between *babA2* gene and PUD and duodenal ulcer (OR = 2.739, 95%CI: 1.860-4.032, $P < 0.001$; OR = 2.239, 95%CI: 1.468-3.415, $P < 0.001$, respectively) was observed in western countries but not in Asian countries.

CONCLUSION: We demonstrated that the presence of *babA2* may be associated with increased risks for PUD, especially duodenal ulcer, in western countries.

Key words: *Helicobacter pylori*; *babA2*; Peptic ulcer; Gastric cancer; Risk

Core tip: BabA encoded by *babA2* gene is an outer member protein of *Helicobacter pylori* (*H. pylori*), which plays a key role in facilitating bacterial colonization in the stomach. The association between *babA2* and *H. pylori*-related gastroduodenal diseases is still controversial. We summarized a total of 25 case-control articles with 38 studies in this meta-analysis and evaluated the relationship between *babA2* and clinical outcomes. The presence of *babA2* may contribute to increased risk of peptic ulcer disease (PUD), especially duodenal ulcer, in western countries. In Asians, *babA2* genotype only showed a marginal association with PUD risk, which requires further investigation.

INTRODUCTION

Helicobacter pylori (*H. pylori*) is a Gram-negative spiral bacterium that may colonize the human gastric mucosa and establish a life-long infection[1]. Although *H. pylori* infects approximately half of the population worldwide, especially in developing countries, the majority of infected people remain asymptomatic. Only 15%-20% of those infected develop severe gastroduodenal diseases, such as peptic ulcer disease (PUD), gastric cancer (GC), and mucosa-associated lymphoid tissue lymphoma[2,3]. In addition to the host and environmental factors, another important reason for the diverse clinical outcomes is the differences in virulence factors among *H. pylori* strains[3]. For example, *H. pylori* strains harboring the vacuolating toxin A (*vacA*) and the cytotoxin-associated antigen (*cagA*) have been proposed as possible risk factors for PUD and GC[4].

Successful colonization in the stomach is the most important step for the pathogenicity of *H. pylori* infection. It is generally accepted that bacterial attachment to the gastric epithelium is the first critical stage of colonization by *H. pylori*[5]. The blood group antigen binding adhesin (BabA) is a well-described outer member protein of *H. pylori* that targets fucosylated Lewis^b blood group antigens presented on gastric epithelium[6,7]. Three *bab* allelic types have been identified, including *babA1*, *babA2* and *babB*; however, only the product of the *babA2* gene is necessary for endowing the bacteria with Lewis^b binding activity[6]. In 1999, Gerhard *et al*[8] first reported a positive association between a *babA2*-gene-positive strain and duodenal ulcer (DU) and GC. Subsequently, a series of studies of the association between *babA2* gene and PUD and GC have been done, but with inconsistent or conflicting conclusions[9-11].

We proposed a hypothesis that bacterial adherence factor BabA mediating close attachment to the epithelium may contribute to pathogenesis of PUD and/or GC. So far, it has not been possible to draw any causal conclusion about the relationship between the *babA2* gene and specific diseases, partly because of the small size of individual studies. Therefore, in the present study, we conducted a meta-analysis, combining available data from published case-control studies, to obtain a more precise estimate of the association between *babA2* gene and PUD and GC in *H. pylori*-infected populations.

MATERIALS AND METHODS

Literature search strategy

A literature search was performed using the PubMed and Web of Science databases for articles estimating the association between *babA2* gene and clinical outcomes in *H. pylori*-infected populations. All enrolled studies were published from January 1997 to October 2012 and retrieved using one of the keywords "*babA*" or "*babA2*" in combination with "*Helicobacter pylori*". The search was performed without restriction on language.

Inclusion criteria

The criteria used to select studies for this meta-analysis were as follows: (1) fully published case-control studies [case group included DU, gastric ulcer (GU), PUD or GC, and the control group included gastritis or nonulcer disease (NUD)]; (2) studies described the relationship between *babA2* gene status and clinical outcomes; (3) the presence of *babA2* was examined by polymerase chain reaction (PCR); and (4) the papers were written in English.

Exclusion criteria

The exclusion criteria were as follows: (1) the results came from review articles; (2) there was no integrated raw data; (3) *in vitro* studies or animal experiments; (4) studies with abstract only; and (5) studies with children.

Data extraction

Evaluation of all potentially relevant articles and extraction of raw data were independently performed by two investigators (Chen MY and He CY). Disagreements were resolved through discussion. We collected information on the following items from each study: first author's name, year of publication, countries and areas of the study population, *babA2* status and clinical outcomes (DU, GU, PUD and GC), and the total number of cases and controls.

Statistical analysis

All statistical analyses were performed using STATA version 11.0 (College Station, TX, United States). Two-sided *P* values were evaluated in this meta-analysis and $P < 0.05$ was considered statistically significant. The strength of the association between the *babA2* gene and clinical outcomes was estimated by OR and corresponding 95%CIs. The statistical heterogeneity among the included studies was assessed by χ^2-based Q and I^2 statistics. If the heterogeneity was considered not significant (with $P > 0.1$ for Q test) among studies, a fixed-effects model based on the Mantel-Haenszel method[12] was used to calculate the pooled OR. On the contrary, a random-effects model based on the DerSimonian and Laird method[13] was used to assess the pooled OR when the P value of the Q test was < 0.1. In addition, a sensitivity analysis was performed to estimate the effects of each included study on the overall risk of clinical outcomes. ORs and 95%CIs were recalculated when any single study was excluded in turn. Begg's test[14] and Egger's test[15] were performed to estimate the publication bias.

RESULTS

Characteristics of selected studies

According to the literature search strategy, a total of 220

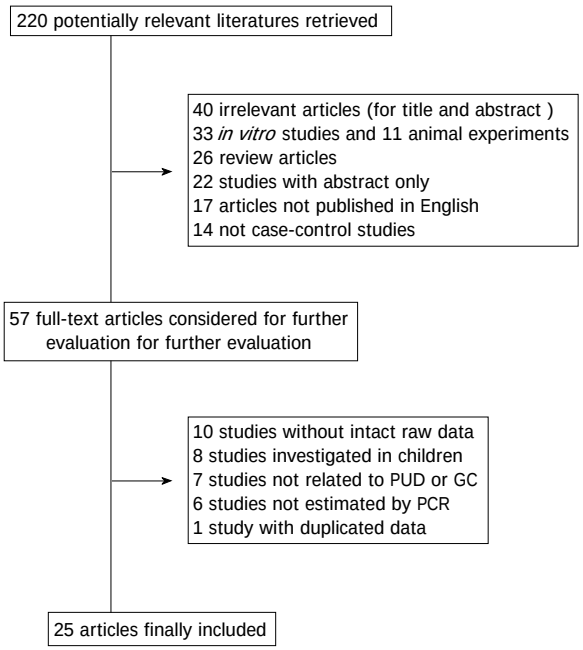

Figure 1 Flowchart of literature search and studies selection. PUD: Peptic ulcer disease; GC: Gastric cancer; PCR: Polymerase chain reaction.

possibly relevant studies were retrieved and 195 were excluded. The main reasons for exclusion were that the articles were reviews, *in vitro* studies, irrelevant to the theme of our research, or did not meet our inclusion criteria (Figure 1). Twenty-five case-control studies met the inclusion criteria[8-11,16-36]. Four of these studies[10,11,19,32] investigated the association between *babA2* gene and clinical outcomes in several different countries. Considering that these data partially evaluated the geographic variation of the influence of *babA2* gene status on the risk of *H. pylori*-related gastroduodenal diseases, data that came from different countries were treated as a separate study. Therefore, with respect to geographical location, 16 studies[11,17,19,22-26,29,33-36] were concerned with Asian populations, and 23[10,16,18,20,21,27,28,30-32] analyzed western populations. One of the latter group, which involved a study from Sweden[10], was excluded because of insufficient data. Finally, a total of 38 independent studies with 4556 patients were included in this meta-analysis (Table 1).

Association between babA2 gene and PUD

There were 36 studies[8-11,17-20,22-36] that investigated the distribution difference of *babA2* genotypes between patients with PUD and gastritis and/or NUD, which consisted of 1859 cases and 1909 controls. The overall prevalence of *babA2* gene was 73.96% (1375/1859) in PUD patients and 57.94% (1106/1909) in control subjects. Data from Oleastro *et al*[19] (Japan, South Korea, Brazil population), Sheu *et al*[26] and Lai *et al*[34] showed that the prevalence of *babA2* gene was 100% in both case and control groups, and the OR and standard error could not be estimated; thus, these studies were excluded. We found that the *babA2* gene significantly increased the risk of PUD in a random-effects model, with a pooled OR of 2.069 (95%CI: 1.532-2.794, $P < 0.001$), and moderate heterogeneity was observed ($I^2 = 62.8$, $P < 0.001$) (Figure 2).

To explore the source of heterogeneity, subgroup analysis was performed. PUD was classified into DU and GU. Among the total of 36 PUD-related studies, 19[8,9,11,17,22-24,26,27,29,31-35] could be used to evaluate risk for DU and eight[22,24,26,27,29,33-35] for GU. For DU analysis, the overall prevalence of *babA2* gene in DU and control subjects was 77.20% (813/1053) and 71.77% (811/1130), respectively. After removal of two studies with 100% prevalence of *babA2* genotype[26,27], the pooled OR based on the random-effects model was 1.588 (95%CI: 1.141-2.209, $P = 0.006$), and mild heterogeneity was observed ($I^2 = 45.8$, $P = 0.021$) (Figure 2). For GU analysis, the overall prevalence of *babA2* genotype seemed to be lower in GU (73.73%, 174/236) than in controls (80.89%, 402/497). Two studies with 100% prevalence of *babA2* genotype were also excluded because of statistical limitation[26,34]. No significant association was observed between *babA2* genotype and GU in a fixed-effects model (OR = 0.755, 95%CI: 0.496-1.150, $P = 0.191$), and there was no heterogeneity among the studies ($I^2 = 0.0\%$, $P = 0.845$) (Figure 2).

When geographical location was considered, data from different countries were subdivided into Asian and western groups. For PUD, the overall prevalence of *babA2* gene was 78.36% (822/1049) in Asian countries and 68.27% (553/810) in western countries. Furthermore, in western countries, the presence of *babA2* substantially increased PUD risk, with a pooled OR of 2.739 (95%CI: 1.860-4.032, $P < 0.001$), while in Asian countries, the *babA2* genotype was only borderline associated with PUD (OR = 1.370, 95%CI: 0.941-1.994, $P = 0.100$) (Figure 2). For DU, the *babA2* genotype significantly increased the risk of DU in western countries (OR = 2.239, 95%CI: 1.468-3.415, $P < 0.001$), but not in Asian countries (OR = 1.158, 95%CI: 0.802-1.672, $P = 0.433$) (Figure 2). The results suggested that differences in geographical distribution of *babA2* genotype may also confer heterogeneity to the studies. Only one study with a small sample size investigated the relationship of *babA2* gene and GU in a western country[27]; therefore, we did not perform subgroup analysis according to geographical area.

Sensitivity analysis was conducted to assess the influence of individual studies on the overall risk of PUD and DU by excluding any single study in turn and recalculating the pooled OR and 95%CI. A similar OR and 95%CI were generated, which indicated high stability of the results (Figure 3).

Association between babA2 and GC

A total of 16 studies[8,9,16,17,21-24,29,31-36] investigated the association between *babA2* gene and GC. The overall prevalence of *babA2* gene was 70.72% (384/534) in GC cases and 60.64% (607/1001) in gastritis or NUD controls. One study with both 100% prevalence of *babA2* in cases and controls was excluded from our meta-analysis[34]. In a random-effects model, the risk of GC increased 1.972-fold (95%CI: 1.103-3.525, $P = 0.022$) in the pres-

ence of *babA2* compared with the controls; however, high heterogeneity among studies was observed (I^2 = 76.8%, $P < 0.001$). Meta-analyses were conducted repeatedly when each study was omitted. As showed in Figure 4, two studies[9,23] showed larger differences in the risk estimates compared with other studies in the sensitivity analysis. Sensitivity analysis excluding these studies generated an OR of 1.303 (95%CI: 0.881-1.927, $P = 0.185$) among homogeneous studies (I^2 = 45.0%, $P = 0.040$), which was different from the OR of 1.972 (95%CI: 1.103-3.525, $P = 0.022$) before the removal of those studies (Figure 4). In terms of geographical area, no statistically significant findings were found among the Asian or western subpopulations, with a pooled OR of 1.132 (95%CI: 0.763-1.680, $P = 0.539$) in the former and 1.303 (95%CI: 0.881-1.927, $P = 0.349$) in the latter (Figure 4).

Publication bias analysis

Publication bias was preliminarily estimated by Begg's and Egger's tests. No significant publication bias was observed in all the comparisons based on Begg's test (all $P > 0.1$), but P value was 0.08 in Egger's test, suggesting a slight publication bias.

DISCUSSION

The Gram-negative bacterium *H. pylori* is known to have a remarkably high level of genetic diversity, and is implicated in human diseases after decades of persistence in the stomach[37-39]. A crucial virulence factor BabA, encoded by the *babA2* gene, facilitates colonization by *H. pylori* in the stomach and may be involved in the pathogenesis of different *H. pylori*-related gastroduodenal diseases, such as PUD and gastric malignancy[8]. To date, there have been numerous relevant studies published but with divergent results on the relationship between the *babA2* gene and PUD and GC[9-11]; moreover, there is no comprehensive meta-analysis on the significance

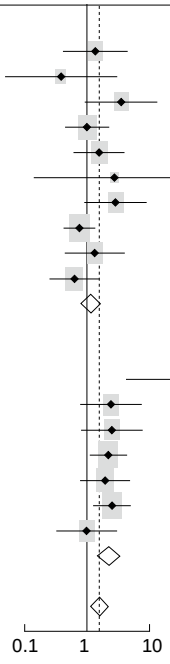

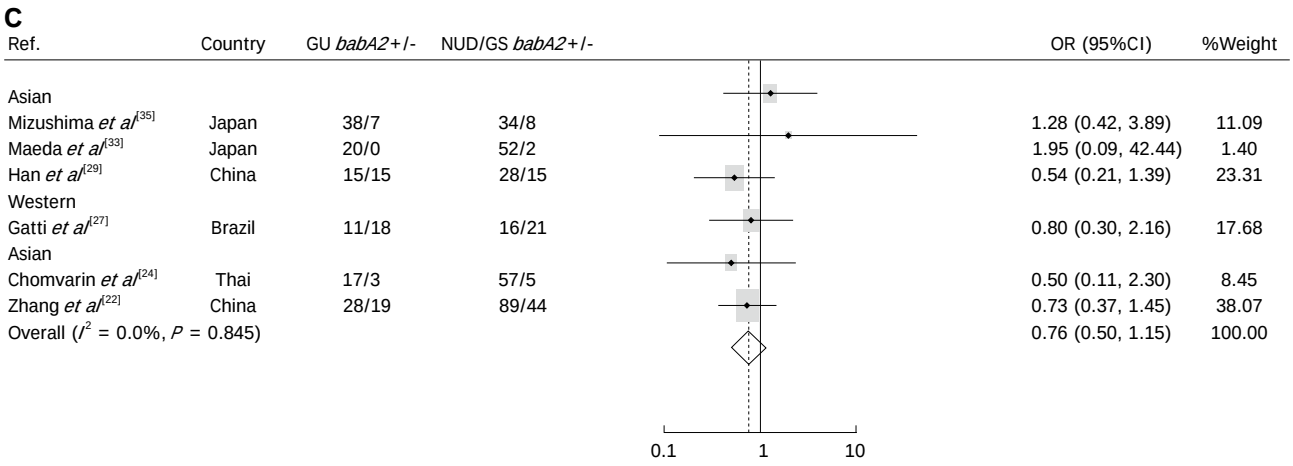

Figure 2 Results of the association between *babA2* gene and peptic ulcer disease, duodenal ulcer and gastric ulcer risk. A: Association between *babA2* and peptic ulcer disease (PUD); B: Association between *babA2* and duodenal ulcer (DU); C: Association between *babA2* and gastric ulcer (GU). ORs and 95%CIs were calculated by a random-effect (A, B) and fixed-effect (C) model. NUD: Nonulcer disease.

of *babA2*. Therefore, we performed the present meta-analysis of the available published literature to obtain a more precise conclusion. Our meta-analysis showed that *babA2* was significantly associated with increased risks of PUD, especially DU, with corresponding ORs of 2.069 and 1.588; moreover, statistically significant findings were more apparent in western populations with ORs of 2.739 for PUD and 2.239 for DU. The summary ORs for PUD and DU in Asians, however, were relatively small (1.370 and 1.158, respectively) and without statistical significance. No significant risk association was observed for GU and GC, but a decreased tendency was noted for GU with a pooled OR of 0.755.

Over the past 20 years, there has been marked progress in our understanding of the role of *H. pylori* infection in the etiology of gastroduodenal diseases. It is well known that *H. pylori* infection increases the risk of developing PUD, including both GU and DU subtypes[40]. Our meta-analysis confirmed a positive association of *H. pylori* with *babA2* genotype with PUD development. Among the major outer membrane proteins of *H. pylori*, BabA has significance not only in triggering bacterial colonization of the gastric epithelium, but also in regulating its functional interaction with host cells, which mainly acts through binding to Lewis^b and fucosylated ABO blood group antigens present in the stomach[41,42]. Gene inactivation experiments have demonstrated that only the product of *babA2* gene is essential for Lewis^b binding activity[7]. Rad *et al*[43] have reported a high density of *H. pylori* colonization in the stomach in the presence of *babA2* genotype, which increases interleukin-8 secretion and granulocytic infiltration, resulting in intense mucosal inflammation. In addition, Ishijima *et al*[41] have demonstrated that *babA2*-positive strains with Lewis^b binding activity are potentiators of the type IV secretion system (T4SS), implying a possible combined effect of *babA2* and other virulence factors related to T4SS. Although the detailed mechanism of the pathogenicity of *babA2* in PUD development has not been fully established, our meta-analysis suggests an important role of *babA2* genotype in distinguishing *H. pylori*-related PU and especially DU from NUD.

Intriguing findings in this study further suggested that individuals infected with *babA2*-positive pathogens have a unique pathogenicity in DU development; conversely, there was no significant association between *babA2* and GC. This difference may be partially due to the distinct etiologies of DU and GC development. Generally, *H. pylori*-related chronic severe gastritis could progress in two different directions[44]. One possibility is that *H. pylori*-related gastritis, predominating in the antrum as well as generating gastric acid, usually induces DU[45]. Patients with DU rarely develop atrophic gastritis of the corpus, and therefore GC risk may decrease in such cases[46]. Another possibility is that patients with extensive gastritis in the corpus and antrum, involving decreased acid output, tend to develop intestinal metaplasia, atrophic gastritis, and even GC[45]. It is speculated that *babA2* combined with other virulence factors may also lead to GC development. Studies conducted by Gerhard *et al*[8] and Erizin *et al*[47] have suggested that triple-positive *H. pylori* strains with *cagA, vacAs1* and *babA2* coexpression increase the risk of developing GC. Zambon *et al*[30] have also reported that infections with these triple-positive strains carry a higher risk of intestinal metaplasia, known as a gastric precancerous lesion. The different risk associations between GC and DU should be interpreted with caution, which should be further investigated in the future.

Our stratified analysis according to geographical areas demonstrated that *babA2* genotype is closely involved in the risk of PUD, especially DU in western populations, but not in Asian populations. This important information about geographical difference in the *babA2* gene suggests a potential biomarker distinguishing PUD, especially DU, from other NUDs in western populations, and reveals a phylogenetic difference between Asian and western *H. pylori* strains. Previous studies have also reported divergence in genes accounting for BabA and other virulence genes, such as *cagA* and *vacA*, between Asian and western strains[48-50]. The above-mentioned findings support the

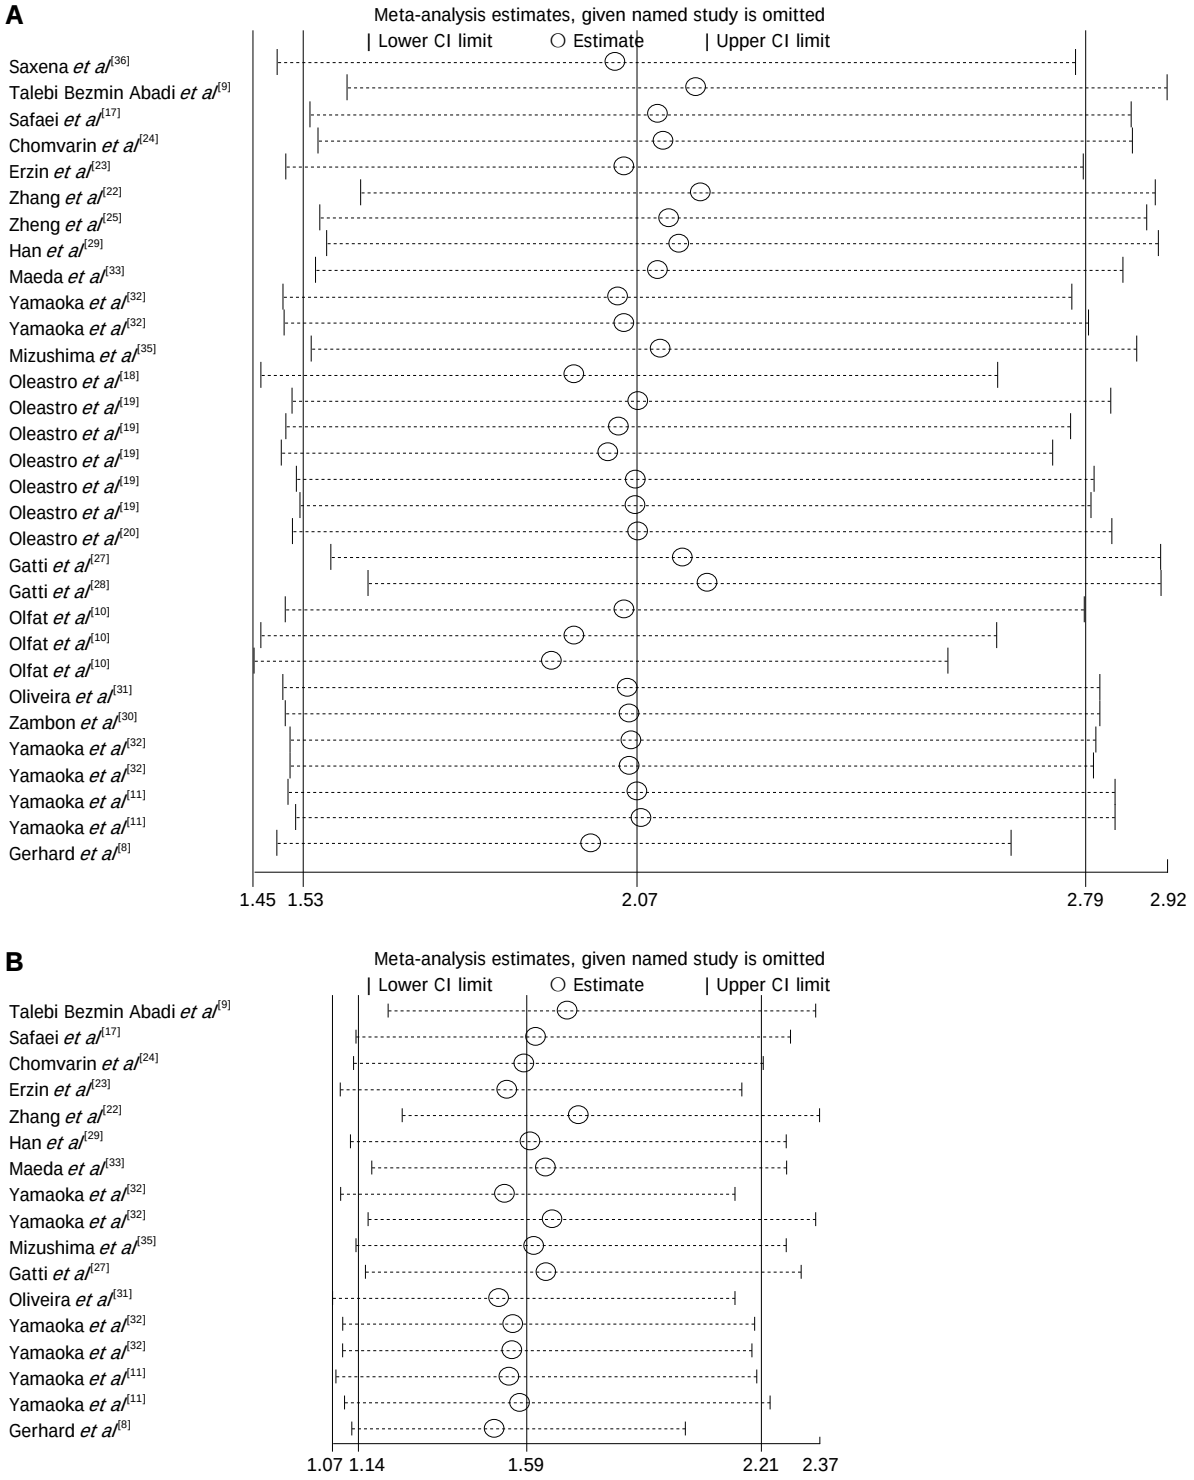

Figure 3 Influence of the summary OR coefficients on the association between *babA2* genotype and peptic ulcer disease and duodenal ulcer risk. A: *babA2* genotype and peptic ulcer disease (PUD) risk; B: *babA2* genotype and duodenal ulcer risk. Results were calculated by omitting each study (on the left) in turn. Bars, 95%CI. Meta-analysis random-effects estimates (exponential form) were used.

suggestion that genetic variability within the *H. pylori* genome, especially in probable host interaction genes, plays a critical role in its different adaptive ability and pathogenicity among different ethnicities[49].

There were several unavoidable limitations to our meta-analysis that should be considered. First, 17 studies[10,18-20,25,28,30,36] related to PUD lacked information about the distribution of DU and GU, which may have influenced the results of the stratified analysis. Second, a lack of original data on histopathological types of GC limited the subgroup analysis according to differences in these types. An unstable result was obtained according to the sensitivity analysis that assessed the relationship between *babA2* and GC, but there were insufficient data to explore

Note: Weights are from random effects analysis

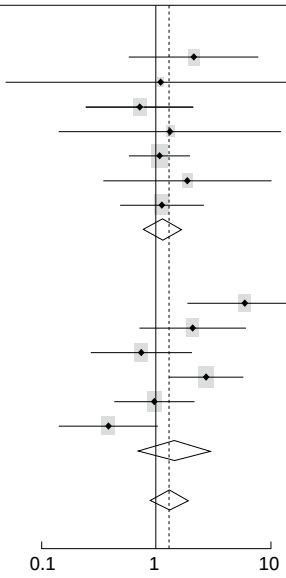

Figure 4 Influence of summary OR coefficients and results on the association between *babA2* genotype and gastric cancer risk. A: Influence analysis. Results were calculated by omitting each study (on the left) in turn. Bars, 95%CI. Meta-analysis random-effects estimates (exponential form) were used; B: Results. ORs and 95%CIs were calculated by a random-effect model.

the source of heterogeneity related to histopathological types. Third, most of the studies had a relatively small sample size.

In conclusion, our results suggest that the presence of *babA2* may contribute to increased risk of PUD, especially DU development, in western countries. In Asians, *babA2* genotype only showed a marginal association with PUD risk, which requires further investigation in the future.

COMMENTS

Background

Helicobacter pylori (*H. pylori*) is a common bacterium with a high prevalence rate and severe pathogenicity, which has been identified as a major cause of severe gastroduodenal diseases, such as peptic ulcer disease (PUD) and gastric cancer (GC). The genome of various *H. pylori* strains demonstrates significant genetic diversity. Genetic variation in specific virulence genes of *H. pylori* may participate in the pathogenic process of *H. pylori* infection in the stomach, thereby contributing to the variable risk of diverse clinical outcomes.

Research frontiers

BabA encoded by the *babA2* gene is a crucial virulence factor of *H. pylori*, which may be involved in the pathogenesis of PUD and GC. Although a few studies have focused on the association between *babA2* gene and the risks of *H. pylori*-related gastroduodenal diseases, those studies showed discrepant results. Moreover, there is no comprehensive meta-analysis integrating the currently available data on the relationship between *babA2* gene and PUD and GC.

Innovations and breakthroughs

This meta-analysis investigated the association between *babA2* gene and PUD and GC. They observed that the presence of *babA2* may contribute to increased risk of PUD, especially duodenal ulcer (DU) development, in western countries. However, in Asians, the presence of *babA2* only showed a marginal association with PUD risk, which requires further investigation. This meta-analysis achieved a relatively comprehensive conclusion on the relationship between *babA2* and clinical outcomes.

Applications

The study suggested that individuals infected with *H. pylori* harboring *babA2* gene were associated with increased risk of PUD, especially DU, in western countries. Eradication of *H. pylori*, in particular *H. pylori* harbouring *babA2*, may contribute to a lower incidence of PUD.

Terminology

babA2: Three *bab* allelic types have been identified, including *babA1*, *babA2* and *babB*, and only the product of the *babA2* gene is necessary for endowing *H. pylori* with Lewis^b antigen binding activity. *babA2* encodes the blood group antigen binding adhesion that binds to fucosylated Lewis^b blood group antigens on gastric epithelial cells.

Peer review

This was a well-performed meta-analysis of currently available studies on the association between *babA2* gene and PUD and GC, and concluded that the presence of *babA2* may be associated with increased risk of PUD, with an emphasis on DU and in western countries. This study was well designed and performed, and the results are well discussed.

Abstract

Lymphocytic and collagenous colitis are forms of microscopic colitis which typically presents in elderly patients as chronic watery diarrhea. The association between microscopic colitis and inflammatory bowel disease is weak and unclear. Lymphocytic colitis progressing to ulcerative colitis has been previously reported; however there is limited data on ulcerative colitis evolving into microscopic (lymphocytic or collagenous) colitis. We report a series of six patients with documented ulcerative colitis who subsequently were diagnosed with collagenous colitis or lymphocytic colitis suggesting microscopic colitis could be a part of the spectrum of inflammatory bowel disease. The median duration of ulcerative colitis prior to being diagnosed with microscopic colitis was 15 years. We noted complete histological and/or symptomatic remission in three out of six cases while the other three patients reverted back into ulcerative colitis suggesting lymphocytic or collagenous colitis could present as a continuum of ulcerative colitis. The exact molecular mechanism of this histological transformation or the prognostic implications is still unclear. Till then it might be prudent to follow up these patients to assess for the relapse of inflammatory bowel disease as well as for dysplasia surveillance.

Key words: Ulcerative colitis; Lymphocytic colitis; Microscopic colitis; Collagenous colitis; Inflammatory bowel disease

Core tip: Lymphocytic colitis (LC), together with collagenous colitis (CC) is a part of the spectrum of "microscopic colitis" (MC) characterized by profuse non-bloody watery diarrhea, without endoscopic or radiological lesions, but with histological abnormalities. The association between LC and inflammatory bowel disease (IBD) is weak and unclear. The case reports of CC progressing to ulcerative colitis (UC) and vice versa has been previously reported but however to our knowledge we report the first case series of six patients with chronic UC subsequently developing into CC or LC suggesting MC could be a part of the spectrum of IBD.

Microscopic colitis: Is it a spectrum of inflammatory bowel disease? *World J Gastroenterol* 2013; 19(26): 4252-4256 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i26/4252.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i26.4252

INTRODUCTION

Lymphocytic colitis (LC), together with collagenous

colitis (CC) is a part of the spectrum of "microscopic colitis" (MC) characterized by profuse non-bloody watery diarrhea, without endoscopic or radiological lesions, but with histological abnormalities. LC is characterized by increased lymphocytic infiltration of the colonic epithelium and lamina propria. CC in addition to the inflammatory infiltrate is characterized by a markedly thickened sub epithelial collagen band adjacent to the basal membrane. The association between LC and inflammatory bowel disease (IBD) is weak and unclear. The case reports of CC progressing to ulcerative colitis (UC) and vice versa has been previously reported but however to our knowledge we report the first case series of six patients with chronic UC subsequently developing into CC or LC suggesting MC could be a part of the spectrum of IBD[1-4].

We evaluated more than 1000 UC patients from a retrospectively collected UC colonoscopy database who had more than 3000 colonoscopies at our institution from 1998-2011. We identified a total of six patients with documented UC who subsequently were diagnosed with biopsy proven CC or LC from this database. All six patients were seen at our institution with the underlying UC for further management and the diagnosis of UC was reconfirmed by colonoscopic study in our institution. When these patients were followed up either for the change in symptoms or surveillance with the colonoscopic studies, colonic biopsies revealed CC or LC with no evidence of UC (Table 1).

Diagnostic criteria used by our pathologists to diagnose LC is increased intraepithelial lymphocytes (IELs > 20/100 colonic surface epithelial cells) in an architecturally normal colonic mucosa, accompanied by surface epithelial damage and a mixed mononuclear inflammatory infiltrate in the lamina propria[5]. These patients were treated for LC and on subsequent follow up three out of six patients reverted back to UC. All the slides were re-examined by a single pathologist and the diagnosis was confirmed (Liu X).

CASE REPORT

Patient 1

A 79-year-old female with a history of UC for 14 years presented with complaints of left lower quadrant abdominal pain for 1 month duration. She also had intermittent watery diarrhea and fecal urgency over the past 2 years. She denied bloody diarrhea or recent weight loss. She was on maintenance mesalamine, and UC was kept under complete remission. She was evaluated with colonoscopy for the present complaints which revealed very mild generalized redness throughout colon. Random colonic biopsies suggested marked surface epithelial lymphocytosis with collagen deposition in all areas of the colon consistent with the diagnosis of CC without any evidence of UC. She was treated with mesalamine 2400 mg/d and complete resolution of symptoms occurred within a month. She was asked to continue mesalamine and follow up if symptoms recur again. She has not had any recurrence of any symptoms.

Patient 2

A 75-year-old male with a history of UC for 25 years came for the surveillance colonoscopy to our institution. The surveillance colonoscopy with random colon biopsies revealed chronic quiescent UC involving the entire colon with no dysplasia. Subsequently, the patient developed intermittent watery diarrhea with fecal urgency. He denied nocturnal symptoms, bloody diarrhea and recent weight loss. He had a history of aspirin intake but there was no temporal relationship between aspirin intake and onset of diarrhea. Further work up with colonoscopy revealed mild erythema in left colon. The colon biopsies were consistent with LC throughout the colon with a significant increase in the number of intraepithelial lymphocytes without any evidence of UC. He was started on sulfasalazine and symptoms resolved within a month. Surveillance colonoscopy done 2 years later was macroscopically normal. Histopathological studies were negative both for UC and LC. He was asymptomatic to follow up till date.

Patient 3

A 61-year-old male with a long standing history of left-sided UC maintained on remission with sulfasalazine and 6-mercaptopurine had a surveillance colonoscopy performed for UC at our institution 20 years later and was macroscopically normal. Colonic biopsies revealed evidence of LC in the right colon. He was not treated for LC since he was asymptomatic on maintenance treatment. Four years later another surveillance colonoscopy revealed chronic quiescent UC. He was completely asymptomatic through these years.

Patient 4

A 59-year-old female was diagnosed with left-sided UC at the age of 46 and was maintained on mesalamine with complete symptomatic remission. She subsequently developed symptoms of intermittent watery diarrhea accompanied by abdominal cramps. She was treated with prednisone and mesalamine with no symptomatic improvement. She had a history of ibuprofen intake for back pain for a long time and there was no association between ibuprofen and the development of new symptoms. She was further evaluated with colonoscopy which revealed increased intraepithelial lymphocytes with collagen deposition throughout the colon consistent with CC. She was treated with bismuth and her symptoms resolved within 2 mo. The follow up colonoscopy a year later was negative for CC.

Patient 5

A 53-year-old female with a history of left-sided UC for 16 years had surveillance colonoscopy performed which revealed inactive UC in rectum and a tubular adenoma in the descending colon. She was referred to our institution for an opinion regarding UC and tubular adenoma. She

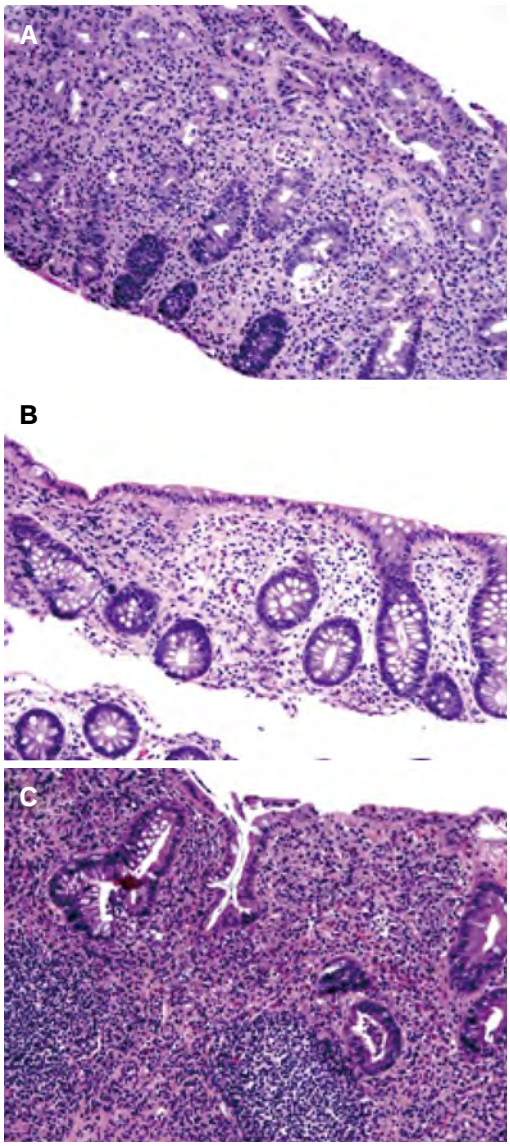

Figure 1 Histologic evolution of colitis (hematoxylin and eosin stain, × 200). A: Active colitis manifested by epithelial injury and cryptitis, in the context of clinical history of ulcerative colitis (UC) and lack of other etiologies for active colitis, this is consistent with early exacerbation of UC; B: Lymphocytic colitis (LC) (3 years after the exacerbation depicted in A). There is surface intraepithelial lymphocytosis and epithelial injury but without significant chronic information. The crypt architecture is normal; C: Reverting to active ulcerative colitis manifested by basal lympho plasmacytosis, architectural distortion, and cryptitis (3 years after an episode of LC-pattern of injury).

was treated with mesalamine for UC in the past and she was kept under complete remission. She was evaluated with a colonoscopy in our institution which suggested macroscopically normal colon with a histop anthology consistent with LC without any evidence of dysplasia. There was no change in treatment. Subsequently, surveillance colonoscopy done a year later revealed mild inactive UC in rectum and sigmoid colon without any evidence of LC and dysplasia. Two subsequent surveillance colonoscopies were positive for chronic UC in sigmoid colon and rectum without any dysplasia.

Patient 6

A 36-year-old female had a long standing history of extensive colitis for 18 years. She developed steroid dependent UC and required 6-mercaptopurine and mesalamine for symptom control (Figure 1A). She was maintained on complete remission on these medications. She had a surveillance colonoscopy performed which revealed mild erythema in distal rectum. The colonic biopsy studies were consistent with LC (Figure 1B) in all other areas of the colon. She had a follow up colonoscopy three years later which showed left-sided chronic active UC without any evidence of LC (Figure 1C). She has been asymptomatic at the time of last follow-up.

DISCUSSION

LC is characterized by chronic watery diarrhea and specific histopathological changes in a macroscopically normal colonic mucosa. The incidence has been reported to be 5.5 per 100000 and prevalence is 63.7 per 100000[6], but the incidence and prevalence appears to be increasing over time. The median age at diagnosis is 59 years with female: male ratio of 2.4:1. The most frequent symptoms at presentation are diarrhea, abdominal pain, weight loss and fecal urgency. Most patients are in remission with a limited disease duration of 6 mo; it can be chronic intermittent or chronic continuous in minority of patients. 7 However, relatively limited data has been published on the relationship between inflammatory bowel disease (IBD) and LC[7-11].

The etiology of LC is largely unknown and probably multifactorial. At present, it is thought to be caused by immunological reaction to different mucosal insults in predisposed individuals. The frequent association of LC with other autoimmune disorders (thyroid disease, diabetes mellitus, celiac disease, psoriasis, and rheumatoid arthritis), inflammation in the lamina propria with increased intraepithelial lymphocytes and the fair response to steroids support this theory. Infectious agents, drugs, or food antigen such as gluten may be precipitating factors. The importance of genetic factors in LC is still unclear but Olesen *et al*[7] suggested a family history of IBD in patients with LC. We describe six cases of UC that subsequently evolved into CC or LC. The median age at the time of UC diagnosis was 38 years in our series. The median duration of UC prior to being diagnosed with CC or LC was 15 years. The median age at the time of LC diagnosis was 51 years. We noted complete histological and/or symptomatic remission in three out of six cases while the other three patients reverted back into UC suggesting that LC could present as a continuum of UC. The triggering factor for this transformation is still unknown. The association between MC and IBD is found predominantly in patients with extensive colitis[12]. However, in our case series only 50% of patients had extensive colitis when LC or CC was diagnosed.

The relationship between LC and IBD is unclear. Sur-

Table 1 Clinical characteristic of patients

Variables	Case 1	Case 2	Case 3	Case 4	Case 5	Case 6
Age at the time of last follow-up (yr)	81	75	62	60	52	36
Gender	Female	Male	Male	Female	Female	Female
Age at diagnosis of UC	65	42	28	46	34	18
Age at diagnosis of LC/CC	79	72	48	54	45	33

NSAIDS: Non steroidal anti-inflammatory drugs; CC: Collagenous colitis; LC: Lymphocytic colitis; UC: Ulcerative colitis; IBD: Inflammatory bowel disease.

veillance colonoscopic biopsies from IBD patients with inactive disease may show a collagenous colitis pattern in UC and a focal LC-like pattern with Crohn's disease[1,12,13]. In our patients, the histopathological diagnosis of LC when UC was in complete remission further raises the question whether the observed LC pattern is an expression of healing and inactive UC disease in reality. However, the presence of symptoms in some patients and lack of IBD flare immediately prior to LC diagnosis makes this "healing" theory unlikely. A previous study had demonstrated that the transcriptional factor nuclear factor κB activation occurs in both UC and CC patients. However in CC patients, nuclear factor κB activation occurs only in epithelial cells whereas it occurs both in epithelial cells and lamina propria macrophages in UC patients[14]. Hence it is possible that the site of nuclear factor κB activation determines the pathological manifestation of the disease. Either UC or MC may precede the onset of the other. Based on these data, it seems reasonable to assume that UC and MC could represent both ends of the spectrum of the same disorder.

With the aggregate of cases we have reported along with other few case reports it seems highly reasonable to assume that LC or CC could be a part of the spectrum of IBD. Whether it is a random coincidence of MC and IBD in the same patient remains to be answered. Since there was no specific cause of LC in our patients such as an infection or drugs, along with the absence of autoimmune conditions usually associated with LC further supports our current view. The prognostic implication of this histological transformation to LC in inactive UC patients is still unknown and has to be further evaluated with prospective studies. Until then it might be prudent to consider MC as a part of the natural history of IBD, at least in some cases, and follow up these patients to assess for the relapse of IBD as well as for dysplasia surveillance.

Abstract

Human alveolar echinococcosis (AE) is a potentially deadly disease; recent studies have shown that the endemic area of *Echinococcus multilocularis*, its causative agent, is larger than previously known. This disease has low prevalence and remains underreported in Europe. Emerging clinical data show that diagnostic difficulties are still common. We report on a 76-year old patient suffering from AE lesions restricted to the left lobe of the liver who underwent a curative extended left hemihepatectomy. Prior to the resection a liver biopsy under the suspicion of an atypical malignancy was performed. After the intervention he developed a pseudoaneurysm of the hepatic artery that was successfully coiled. Surprisingly, during surgery, the macroscopic appearance of the tumour revealed a growth pattern that was rather typical for cystic echinococcosis (CE), *i.e.*, a gross tumour composed of multiple large vesicles with several centimeters in diameter. In addition, there were neither extensive adhesions nor infiltrations of the neighboring pancreas and diaphragm as was expected from previous imaging results. The unexpected diagnosis of AE was confirmed by definite histopathology, specific polymerase chain reaction and serology results. This is a rare case of unusual macroscopic presentation of AE that posed immense diagnostic challenges and had an eventful course. To our knowledge this is the first case of an autochthonous infection in this particular geographic area of Germany, the federal state of Saxony. This report may provide new hints for an expanding area of risk for AE and emphasizes the risk of complications in the scope of diagnostic procedures and the limitations of modern radiological imaging.

Key words: Alveolar echinococcosis; *Echinococcus multilocularis*; Autochthonous infection; Liver resection; Hemihepatectomy

Core tip: We describe a rare case of uncommon macroscopic presentation of autochthonous infection with *Echinococcus multilocularis* that posed immense diagnostic challenges and had an eventful course. To our knowledge this is the first case of an autochthonous infection in this geographic area. This report may deliver new hints for an expanding area of risk for alveolar

echinococcosis and emphasizes the risk of complications in the scope of diagnostic procedures and the limitations of modern imaging techniques.

INTRODUCTION

The fox-tapeworm *Echinococcus multilocularis* (*E. multilocularis*) is the causative agent of alveolar echinococcosis (AE), a potentially deadly parasitic disease. AE is prevalent in the northern hemisphere and central Europe is an endemic focus[1-3]. In the era prior to anthelmintic treatment the cumulative lethality for AE was about 90% ten years after a diagnosis has been established[4]. Imaging techniques of hepatic involvement by AE commonly reveal an ill-defined lesion of the liver parenchyma and contrast computer tomography (CT) and magnetic resonance imaging (MRI) are considered to clearly demonstrate infiltrative structure and extension of the parasitic tumour to adjacent structures[5-8]. In macroscopic sections of the human liver the larval parasite usually exhibits an alveolar (spongy) structure composed of numerous irregular vesicles with diameters between less than 1 and up to 20 mm[9]. Biologically, the lesions behave like a slow-growing liver cancer, without sharp boundaries between the parasitic tissue and the liver parenchyma.

Publications on surgical procedures and results are rare but essential, and prospective studies are not available because the incidence of the disease is low. According to current treatment guidelines, surgery should be the first choice if the parasitic mass is resectable *in toto*[10]. Complete resections of the parasitic lesion can cure the patient while available drugs are only parasitostatic[10-12].

Emerging clinical data indicate that the parasite's geographic range has widened in recent years[13,14]. Growing fox populations in Europe, especially in urban zones, have drawn attention to a potentially increased infection risk for humans with a phase lag of 10-20 years[15-17]. In addition, since AE is not adequately considered as a differential diagnosis, the disease remains thus underdiagnosed in Europe[18].

We report on a 76-year old patient with AE of the liver, who underwent a curative resection. Prior to resection the patient had an eventful course due to the development of a postinterventional pseudoaneurysm (aneurysm spurium) of the hepatic artery following a biopsy of the liver lesion. Interestingly, during surgery the parasitic mass appeared typical for cystic echinococcosis (CE) and revealed no infiltrations or extensive adhesions to adjacent structures as contrastingly expected from the preoperative imaging results of the abdomen. Nevertheless, the definite histology as well as referral evaluations [serology and polymerase chain reaction (PCR)] confirmed the diagnosis of AE. The patient has not been abroad for the last 20 years and at his farm he has been in constant contact to various animal species, including dogs and wild foxes. To our knowledge this is the first case of autochthonous AE infection in the federal state of Saxony, Germany.

CASE REPORT

In April 2010 a 76-year old farmer from Saxony was presented in the emergency department of a general district hospital with a severe abdominal pain under the suspicion of a biliary colic and pancreatitis, respectively. In the performed imaging of the abdomen a large cystic tumour in the left sided liver was detected. In the further course, suspecting a highly malignant atypical primary liver cancer, a biopsy for the presumed confirmation of the diagnosis was performed. After the intervention the patient was discharged in good clinical condition. Surprisingly, the histological findings from the tumour biopsy were consistent with the larval stage of *E. multilocularis*. Subsequent serological investigation by a referral laboratory for echinococcosis confirmed specific antibodies for AE in the patient's serum. Moreover, a pan-cestode 12S rRNA gene-PCR from the paraffin block was positive and sequencing of the amplicon revealed 100% identity with *E. multilocularis*. Therefore, an anti-infective drug treatment with albendazole was initiated.

Several days after liver biopsy the patient presented again with severe abdominal pain and jaundice. In the emergency CT scan of the abdomen the gross tumour revealed no progression. Though, a postjunctional pseudoaneurysm of a branch of the left hepatic artery in segment 4a in direct proximity to the tumour tissue was newly diagnosed. A subsequent coil-embolization of the aneurysm was successfully performed.

One month later, in May 2010, the patient was referred to our centre as a potential candidate for abdominal surgery. A thorough examination of patient data and history files revealed that the farmer has not been abroad in the last few decades. In his farm he has been in a constant contact and exposure to numerous domestic and wild animals, including dogs and foxes. The patient had neither B-symptoms nor further major ailments and was in good general condition. The blood tests revealed normal findings for alpha-1-fetoprotein, carbohydrate-antigen 19-9 and carcinoembryonic antigen. Preoperatively, due to pronounced cholestasis and hyperbilirubinaemia, an endoscopic retrograde cholangiography (ERC) with stenting of the main bile duct was performed. Clinical imaging prior to surgery revealed that the echinococcal lesion infiltrated liver segments 2 and 3 and showed a maximum diameter of 13.5 cm (Figure 1A and B). In addition, CT suggested the presence of adhesions in the

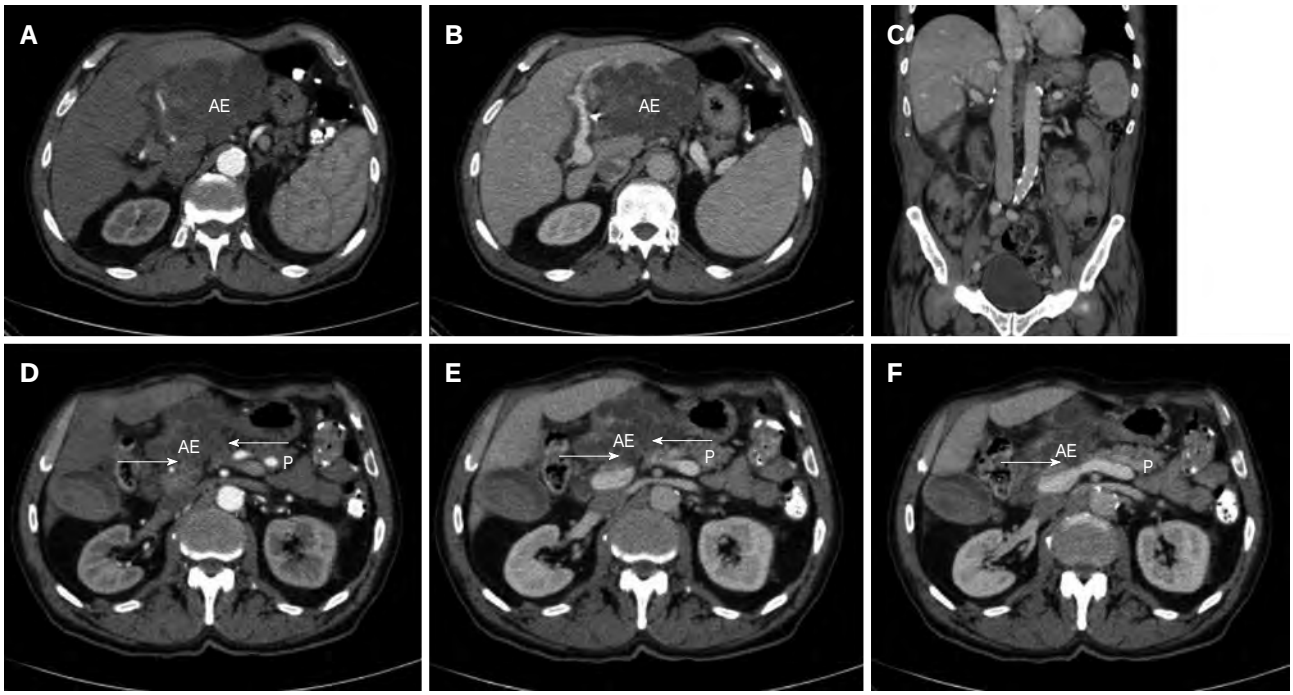

Figure 1 Radiological findings prior and after curative resection. A, B: Computed tomography of the abdomen displaying an extended tumour manifestation prior to resection; C: Computed tomography of the abdomen following extended left hemihepatectomy; D-F: Computed tomography of the abdomen prior to resection. Arrows: possible extensive adhesions to adjacent pancreatic head and corpus. AE: Alveolar echinococcus tumour; P: Pancreas.

area of the diaphragm and cystic infiltration of the pancreatic head and corpus (Figure 1 D-F). The diagnostic evaluation revealed no further extrahepatic manifestations. Hence, additionally to extended left hemihepatectomy, we considered a concomitant resection of the pencreatic head and corpus.

During surgery the tumorous manifestation in the left lobe of the liver was confirmed but, surprisingly, no infiltrative growth to neighboring structures was detectable. Basically, we observed a gross tumor with multiple large cystic structures that varied in size, *i.e.,* a growth pattern that is rather typical for CE. Further exploration revealed no cystic adhesions to the diaphragm. After exploration of the bursa omentalis, no infiltration of the pancreas was notable either. No evidence for further extrahepatic tumorous dissemination or lymph node metastases was found. As the restriction of the tumour to the left liver lobe was confirmed, we affirmed the indication for extended left hemihepatectomy with curative intent. The situs was then suffused with cloths imbued in hypertonic (10%) Sodium chloride (NaCl) solution. Subsequently the isolation of the proper hepatic artery and the selective division of the left hepatic artery followed. After isolation of the main trunk of the portal vein and the left portal vein branch, the latter was divided. Then cholecystectomy was performed. After the left hepatic vein was divided, lobus caudatus (segment 1) was mobilized. Then, a liver resection was completed without any intraoperative complications. Parenchymal transection was performed using an ultrasonic dissection device (cavitron ultrasonic surgical aspirator, CUSA®). The caudate lobe did not appear to be infiltrated but to ensure an additional safety distance it was resected as well. The parenchymal resection was performed along the level of the middle hepatic vein in direction to the gall bladder bed and then caudally to the hepatic hilum. At the hilum the liver dissection diverged to the left and then ended in the parenchymal bridge leading to the caudate lobe. In the region of the hilum the left hepatic duct was isolated and then selectively divided. After removing the left liver lobe and the caudate lobe, the situs was rinsed with hypertonic NaCl solution. A T-Drain was inserted in the main bile duct for decompression and easy access cholangiography. During the postoperative stay in the intensive care unit the patient did not develop any significant complications.

Based on the finding of multiple large cystic formations of the tumorous lesion an additional histological evaluation was performed in a referral centre for pathology. There, the original diagnosis of hepatic AE was confirmed (Figure 2). In the postoperative course no signs of insufficient liver function were notable. The conclusive pathological result showed the parasitic tumour was entirely resected (Figures 1C and 3).

After a total postoperative hospitalization of 30 d the patient was dismissed. The anti-infective drug treatment with albendazole was maintained as long-term therapy. The follow up visit 6 and 12 mo after resection revealed normal liver function and no evidence for recurrent disease.

DISCUSSION

AE, caused by the larval (metacestode) stage of *E. multilocularis*, is found in the northern hemisphere and is a

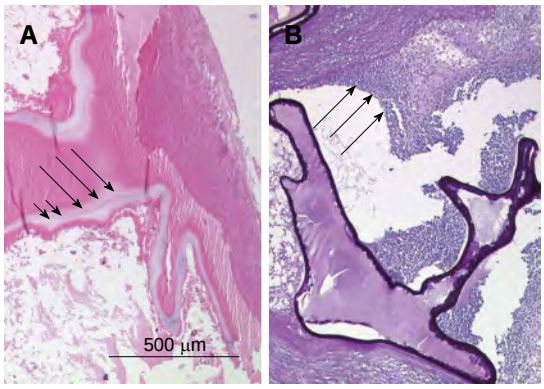

Figure 2 Referral evaluations for diagnosis of alveolar echinococcosis. A: The hematoxylin and eosin stain of paraffin sections displays the laminated layer as a narrow band (long arrows). The germinal layer is marked by short arrows; B: Periodic acid-Schiff (PAS) stain shows a strongly PAS-positive basophilic laminated layer displaying a bizarre narrow structural pattern. The long arrows indicate the typical severe inflammatory process associated with the characteristic tubular growth pattern of the parasite.

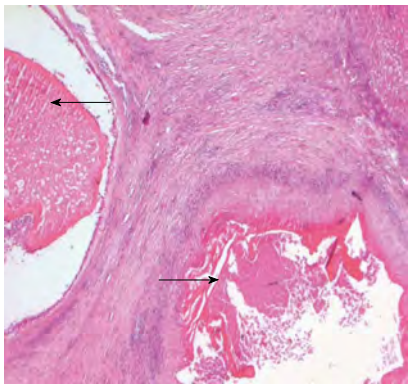

Figure 3 Histological findings after curative resection. Hematoxylin and eosin stain of paraffin sections displaying two daughter cysts containing no vital protoscoleces embedded in a larger lesion. Black arrows indicate avital protoscoleces.

potentially fatal disease. The parasite is transmitted to humans by eggs of the helminth shed into the environment by feces of foxes. Almost exclusively, the liver is affected[19]. Recent studies have shown that the endemic area of *E. multilocularis* is larger than previously known and has regionally expanded from rural to urban areas[20-22]. In addition, increasing fox populations are associated with higher infection risk in humans with a phase lag up to 20 years[15].

The macroscopic appearance of an echinococcal lesion is distinct in regard of its species and developmental stage. While parasitic masses of CE ordinarily display a typical structure of a single or multiple fluid-filled large unilocular cysts that can reach monstrous dimensions, AE preferentially exhibits metastasis and an infiltrative growth to adjacent host tissues with a spongy structure composed of numerous irregular small vesicles of several millimeters. Thus, the surgical therapy for hepatic AE conforms the operative principles established for malignant liver tumours, *i.e., in toto* removal of the tumour with additional safety distance and tumour free resection margins[4].

Chemotherapy with benzimidazoles is the backbone of the comprehensive treatment of AE and long-term anti-infective drug treatment has been established in many centres in Europe as well as in China[9]. In spite of remarkable improvement of long term patient survival after the introduction of anti-helmintic drug treatment, this therapeutic modality proved to be mainly parasitostatic. Therefore, surgical resection represents the therapy of choice for patients with operable lesions of AE.

In the present report we have described the first case of autochthonous infection with *E. multilocularis* in our federal state of Saxony, Germany. The tumour masses affected liver segments 2 and 3 and the patient received a curative extended left hemihepatectomy. Due to a suspected liver malignancy an interventional biopsy of the lesion was preoperatively performed. Usually, such a diagnostic step is considered a contraindication in cases of AE because of the risk of abdominal seeding and anaphylaxis. Fortunately, the postinterventional iatrogenic pseudoaneurysm of the left hepatic artery could be treated with success. Interestingly, the parasitic mass showed a macroscopic pattern that appeared typical for CE which is caused by the larval stage of the dog tapeworm, *Echinococcus granulosus* (*E. granulosus*). The cause of this phenomenon remains for the most part unknown but has been reported occasionally in historic reports. Dual infection with *E. granulosus* and *E. multilocularis* could have also been possible. Indeed, concomitant infections with both echinococcal species have been reported in the literature but in the present case the definite histology, PCR results, serology, and immunohistology for specific structural proteins were all clearly positive for *E. multilocularis* only[23]. Additionally, a major distinguishing factor between *E. granulosus* cysts and *E. multilocularis* is the presence of an adventitial layer around the *E. granulosus* metacestode. The histological evaluations did not detect such a structure in the present case. Furthermore, despite the expected extensive adhesions to the diaphragm and pancreas seen by preoperative imaging, no such condition or infiltration to neighboring structures could be confirmed, showing current limitations of modern imaging techniques. All together this data indicate that in the current era diagnosis as well as assessment of extent of local disease still remain a challenge for clinicians.

Recent investigations suggest that AE remains underreported and human infection can also occur in regions with low overall parasite prevalence. Case reports from regions remote from the areas of high prevalence may be strong hints of new areas at risk[18,24]. In addition to the high prevalence rates for AE in the southern geographic regions of Germany, recent data suggest growing numbers of AE cases in neighboring European countries, such as the Czech Republic. Some of these cases indicate an autochthonous character of the infection[25,26]. Thus, a possible enlargement of fox populations in the last decades as well as migration of infected animals might have

been a possible source for infection in the current case.

In conclusion, we have here described the first autochthonous infection with *E. multilocularis* in Saxony, Germany, providing the first evidence for a new geographical area at risk for the acquisition of AE. Albeit, curatively treated with an extended left hemihepatectomy the disease presented with uncommon findings and had an eventful course, constituting a challenge for clinicians.

Abstract

The endoscopic findings of gastric hyperplastic polyps (HPs) with dysplasia have not been well-defined, and the clinical significance of these lesions, including their malignant potential, is unclear. In this report, we describe a case of a white opaque substance (WOS)-positive gastric HP with dysplasia. A 76-year-old woman was referred to our hospital for endoscopic resection of a gastric HP. Upper endoscopy revealed a 25-mm whitish and reddish polypoid lesion on the greater curvature in the lower third of the stomach. The whitish part was diagnosed as a WOS using conventional and magnifying endoscopy with narrow band imaging. An examination of the biopsy specimen indicated that the lesion was a typical gastric HP. However, because of its color and the presence of a WOS, we suspected that this lesion was an atypical gastric HP. Therefore, we performed a polypectomy. Histopathologically, diffuse low- to high-grade dysplasia was found on the surface of the polyp. We performed immunohistochemical staining using a monoclonal antibody specific for adipophilin as a marker of lipid droplets (LDs). LDs were detected in approximately all of the neoplastic cells, especially in the surface epithelium of the intervening apical parts and were located in the subnuclear cytoplasm of the neoplastic cells. According to endoscopic and histopathological findings, the WOS-positive epithelium indicated dysplasia of the gastrointestinal phenotype, which could absorb lipids. The presence of a WOS in a gastric HP may be considered an endoscopic finding that is predictive of the neoplastic transformation of a gastric HP. We suggest that a WOS-positive gastric HP should be resected endoscopically to investigate its neoplastic transformation.

Key words: Gastric hyperplastic polyp with dysplasia; White opaque substance; Adipophilin; Lipid droplet; Narrow band imaging

Core tip: In this report, we present the first case of a white opaque substance (WOS)-positive gastric hyperplastic polyp (HP) with dysplasia. We performed immunohistochemical staining using a monoclonal antibody specific for adipophilin as a marker of lipid droplets. According to endoscopic and histopathological findings, the WOS-positive epithelium corresponded to the dysplasia in this lesion. The presence of a WOS in a gastric HP may be considered an endoscopic finding that is predictive of the neoplastic transformation of a gastric HP. We suggest that patients with a WOS-positive gastric HP should be treated by endoscopic resection to investigate the neoplastic transformation of the HP.

INTRODUCTION

With the widespread use of digestive endoscopy in recent years, gastric polyps are now diagnosed more frequently and can be easily studied after a biopsy or polypectomy. Gastric hyperplastic polyps (HPs) are among the most common type of benign epithelial gastric polyps[1-6]. Gastric HPs are usually considered to be benign lesions similar to adenomas; however, neoplastic transformation can occur but rarely. Moreover, endoscopic findings of gastric HPs with dysplasia have not been well-defined, and the clinical significance of these lesions, including their malignant potential, is unclear. A white opaque substance (WOS) is a finding from magnifying endoscopy (ME) with narrow band imaging (NBI), which was first reported by Yao *et al*[7-9] to be a substance in the superficial area of gastric neoplasias that obscures the subepithelial microvascular architecture. However, the presence of a WOS in gastric lesions other than adenomas and adenocarcinomas has not been reported. We report a rare case of a WOS-positive gastric HP with dysplasia.

CASE REPORT

A 76-year-old woman was referred to our hospital for further investigation and treatment of a gastric HP. Excluding the existence of the gastric HP, she had no specific symptoms and the results of the physical examination were normal. Her medical history included hyperlipidemia and diabetes mellitus, and there was no family history of gastrointestinal polyposis. She had not undergone proton pump inhibitor therapy. An assessment of Immunoglobulin G antibodies and a histological examination were negative for *Helicobacter pylori* infection. Upper endoscopy revealed a 25-mm polypoid lesion on the greater curvature in the lower third of the stomach (Figure 1A). The entire lesion was reddish with scattered whitish areas. The whitish parts were determined to be a WOS using conventional endoscopy and ME with NBI (Figure 1). The WOS in the lesion was comprised of two morphological types (Figure 1C and D). One type had a symmetrical distribution of a regular dotted pattern (Figure 1C), and the other type had an asymmetrical distribution of an irregular speckled and linear pattern (Figure 1D). An examination of the biopsy specimen revealed findings that were typical of a gastric HP without dysplasia. However, we suspected that this lesion was an atypical gastric HP because of its color and the irregular distribution of the WOS. Therefore, we performed a polypectomy, which was without complications. Histopathologically, the findings for the entire lesion were typical of

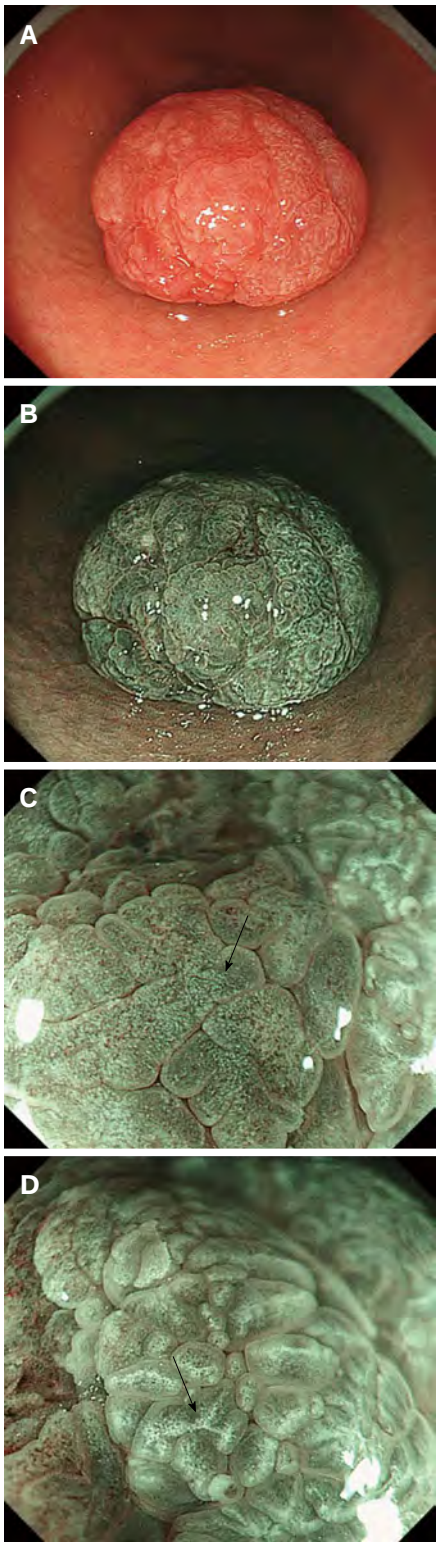

Figure 1 A white opaque substance-positive gastric hyperplastic polyp is shown on upper endoscopy. A: An endoscopic examination with a white light image revealed a 25-mm polypoid lesion on the greater curvature in the lower third of the stomach; B: A white opaque substance (WOS) was visualized on the surface of this lesion using conventional endoscopy and magnifying endoscopy (ME) with narrow band imaging (NBI); C: The ME with NBI findings. A regular dotted pattern of the WOS was distributed symmetrically (arrow); D: The ME with NBI findings. An irregular speckled and linear pattern was distributed asymmetrically (arrow).

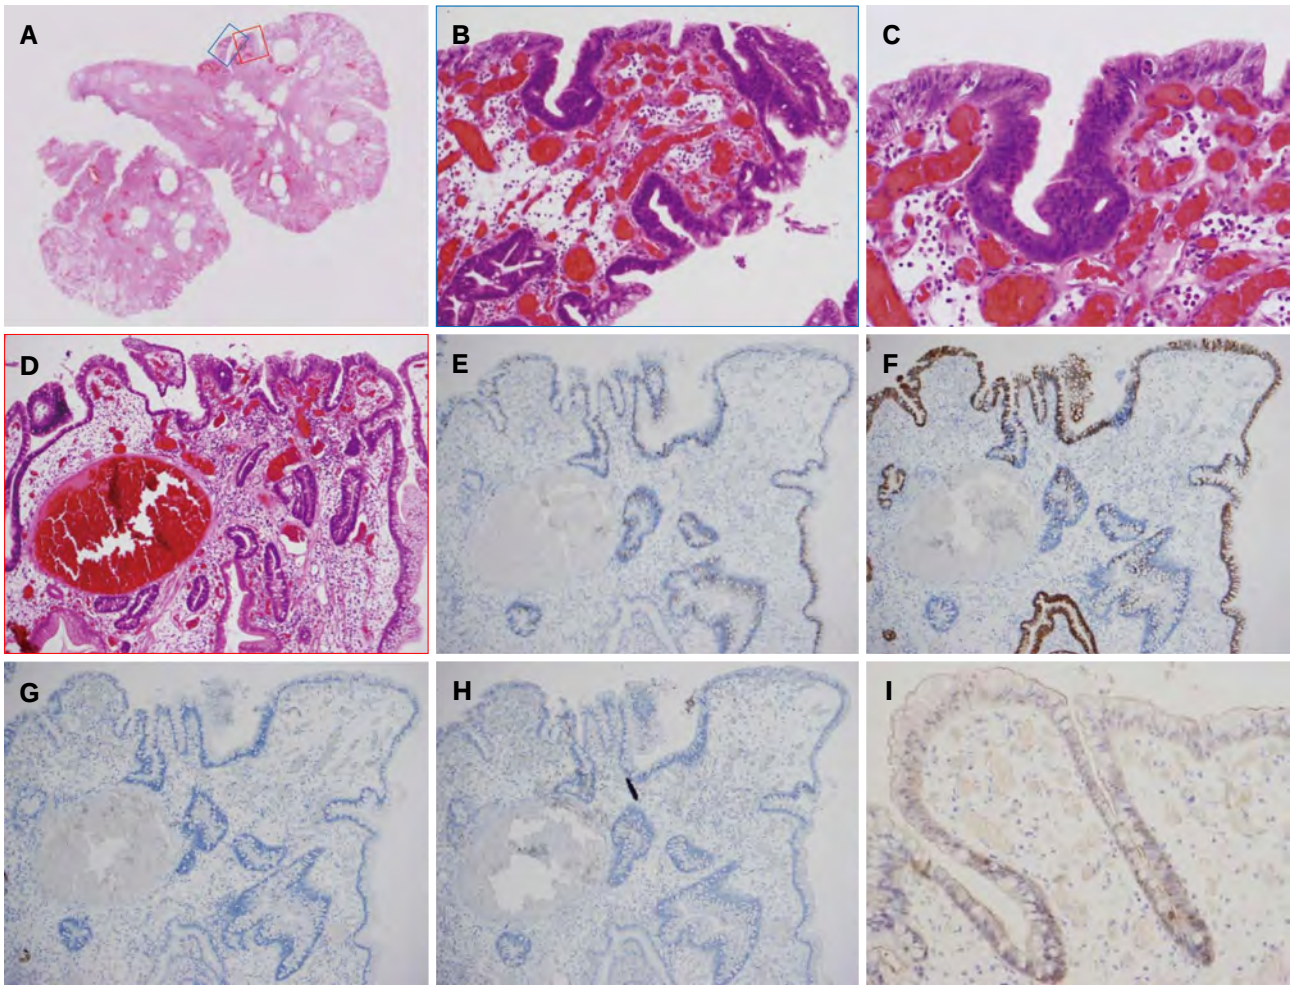

Figure 2 The resected specimen shows a gastric hyperplastic polyp with dysplasia. A-D: The histological examination of the resected specimens (hematoxylin and eosin stain). A: In the low power view, the findings for the entire lesion were typical of a gastric hyperplastic polyp; B, C: High-grade dysplasia was observed on the surface of the lesion; D: Low-grade dysplasia was observed on the surface of the lesion; E-I: The immunohistochemical examination. E: Mucin 2 (MUC2); F: MUC5AC; G: MUC6; H: CD10; I: Villin. The lesion had diffuse positivity for MUC5AC, focal positivity for MUC2 and villin, and negative staining for MUC6 and CD10.

a gastric HP, and diffuse low- to high-grade dysplasia was found on the surface of the lesion (Figure 2A-D). Immunohistochemically, the lesion had diffuse positivity for MUC5AC, focal positivity for mucin 2 (MUC2) and villin, and negative staining for MUC6 and CD10 (Figure 2E-I). This lesion was classified as having the gastrointestinal (GI) phenotype according to combinations of the expression of MUC2, MUC5AC, MUC6, CD10 and villin. The GI phenotype was detected in approximately all of the neoplastic cells, whereas an examination of the other cells indicated a gastric phenotype. The Ki-67 labeling index of dysplasia was slightly higher than that of a typical HP, and the positive cells were irregularly distributed. The overexpression of the p53 protein was not observed. In addition, adipophilin was detected in approximately all of the neoplastic cells, especially in the surface epithelium of the intervening apical parts and was located in the subnuclear cytoplasm of the neoplastic cells (Figure 3). This lesion was finally diagnosed as a WOS-positive gastric hyperplastic polyp with dysplasia. Surveillance endoscopy with biopsy specimens is planned for 6 mo after the endoscopic resection.

DISCUSSION

The endoscopic findings for gastric HP with dysplasia have not been well-defined. Typical HPs are markedly reddish polypoid lesions with a smooth surface, which occasionally has erosions. In this case, the entire lesion was reddish and was scattered with whitish areas, which differs from typical HPs. The whitish areas were determined to be a WOS using conventional and ME with NBI. Histopathologically, low- to high-grade dysplasia was diffusely present on the surface of the gastric HP. Adipophilin was detected in approximately all of the neoplastic cells, especially in the surface epithelium of the intervening apical parts. These findings suggested that the WOS-positive epithelium corresponded to the dysplasia in this lesion. Yao *et al*[10] reported that the hallmark of a WOS is the presence of lipid droplets (LDs) that accumulate in the superficial part of the epithelial neoplasia within the stomach. Using immunohistochemistry and immunoelectron microscopy, Ueo *et al*[11] found that the WOS resulted from an accumulation of LDs with adipophilin. These findings supported a relationship

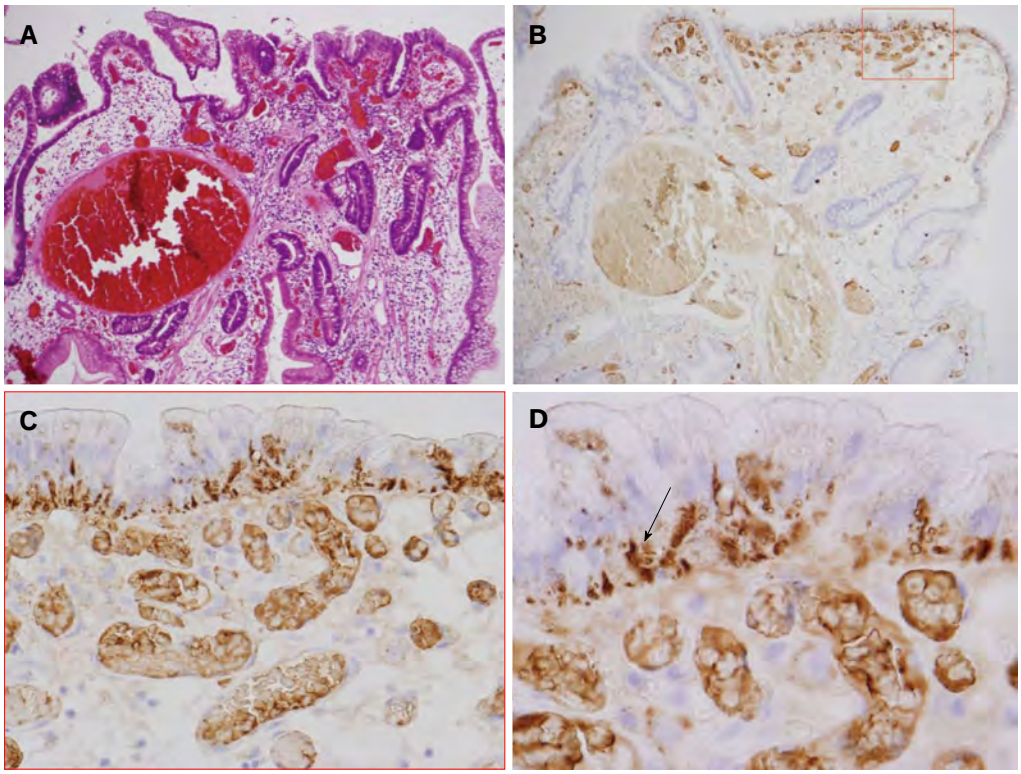

Figure 3 The immunohistochemical analysis indicates that dysplasia is positive for adipophilin. A: Low-grade dysplasia was observed on the surface of the lesion; B-D: The immunohistochemical examination of adipophilin. Adipophilin was detected in approximately all of the neoplastic cells, especially in the surface epithelium of the intervening apical parts and was located in the subnuclear cytoplasm of the neoplastic cells (arrow).

between the WOS and adipophilin in this case. In addition, the WOS in this lesion was comprised of two morphological types: one type with a symmetrical distribution of a regular dotted pattern and the other type with an asymmetrical distribution of an irregular speckled and linear pattern. We could not discriminate between these patterns pathologically. Yao *et al*[7] reported that the WOS in adenomas was regular and homogeneous, whereas the WOS in adenocarcinomas was irregular and speckled. In this case, we speculated that the findings for a WOS may be based on the differences in the shape, the intraepithelial and intracytoplasmic density and the distribution of the LDs between low-grade and high-grade dysplasia. In our case, most of the reddish area indicated low-grade dysplasia. Endoscopically, we determined that these areas were reddish because a slight accumulation of LDs may not allow these areas to be visualized as a WOS. We concluded that a WOS may be visualized only in the dysplastic areas of gastric HPs. The presence of a WOS in a gastric HP may be considered an endoscopic finding that is predictive of the neoplastic transformation of a gastric HP.

The neoplastic transformation of HPs has not been well-defined, and their clinical significance, including their malignant potential, is unclear. Kang *et al*[12] reported that the neoplastic transformation of gastric HPs was significantly associated with the postgastrectomy state and lesions that were 1 cm in diameter, pedunculated, and synchronous neoplastic lesion. Daibo *et al*[13] reported that cancer cells arose from the dysplastic area in HPs rather than directly from nondysplastic hyperplastic epithelium, which is consistent with the histogenesis of the malignant transformation of HPs. Endoscopic resection should be considered for these HPs to avoid the risk of missing HPs with neoplastic potential. In our case, the dysplasia was observed on the surface of the resected HP; however, an examination of the biopsy specimen indicated a typical HP without dysplasia. Regarding this discrepancy, we speculate that when the biopsy specimen was collected, a small sample was unintentionally taken from the part of the lesion that did not exhibit dysplasia. Using the biopsy specimen that was obtained, we could not clearly determine whether the lesion was a typical HP or an HP with low-grade dysplasia. Therefore, in gastric HPs, WOS positivity may be considered an endoscopic finding that indicates endoscopic resection.

The mechanism of the accumulation of LDs in gastric epithelium is unknown. Yao *et al*[10] proposed the following two possible mechanisms: the absorption hypothesis and the production hypothesis. In addition, they reported that the WOS in gastric neoplasms with an intestinal phenotype was caused by the accumulation of lipids and WOS-positive gastric neoplasms may be able to absorb lipids. Matsubara *et al*[14] demonstrated that the expression of adipophilin may be induced during the process of early colorectal carcinogenesis, which supports the production hypothesis that neoplastic cells synthesize LDs. In our case, the neoplastic cells that were

positive for adipophilin were of the GI phenotype. This finding suggests that the neoplastic transformation of gastric epithelium with a phenotypic change to the intestinal phenotype may require the ability to absorb lipids. However, further investigation is needed to elucidate the mechanism of LD accumulation.

In this report, we present the first case of a WOS-positive gastric HP with dysplasia. We suggest that patients with a WOS-positive gastric HP should be treated by endoscopic resection to investigate the neoplastic transformation of the HP.

Abstract

A 57-year-old man underwent endoscopy for investigation of a duodenal polyp. Endoscopy revealed a hemispheric submucosal tumor, about 5 mm in diameter, in the anterior wall of the duodenal bulb. Endoscopic biopsy disclosed a neuroendocrine tumor histologically, therefore endoscopic mucosal resection was conducted. The tumor was effectively and evenly elevated after injection of a mixture of 0.2% hyaluronic acid and glycerol at a ratio of 1:1 into the submucosal layer. A small amount of indigo-carmine dye was also added for coloration of injection fluid. The lesion was completely resected *en bloc* with a snare after submucosal fluid injection. Immediately, muscle-fiber-like tissues were identified in the marginal area of the resected defect above the blue-colored layer, which suggested perforation. The defect was completely closed with a total of 9 endoclips, and no symptoms associated with peritonitis appeared thereafter. Histologically, the horizontal and vertical margins of the resected specimen were free of tumor and muscularis propria was also seen in the resected specimen. Generally, endoscopic mucosal resection is considered to be theoretically successful if the mucosal defect is colored blue. The blue layer in this case, however, had been created by unplanned injection into the subserosal rather than the submucosal layer.

Key words: Endoscopic mucosal resection; Submucosal tumor; Neuroendocrine tumor; Hyaluronic acid; Perforation; Duodenum; Endoclip

Core tip: We herein report a case of endoscopic full-thickness resection of a duodenal neuroendocrine tumor after unplanned injection into the subserosal layer. Generally, large perforations require urgent salvage surgery and duodenal perforation is more serious than other sites of the gastrointestinal tract because of bile acid and pancreatic juice. In this case, we found the "mirror target sign" immediately, and repaired the defect endoscopically. Prompt recognition of this sign and rapid closing of the defect is important to minimize injury.

Unexpected endoscopic full-thickness resection of a duodenal neuroendocrine tumor. *World J Gastroenterol* 2013; 19(26): 4267-4270 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i26/4267.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i26.4267

INTRODUCTION

Endoscopic mucosal resection (EMR) technique has

been developed and widely performed to provide less invasive treatment for gastrointestinal tumors. However, perforation is perhaps one of the most unfavorable complications associated with EMR. The most effective way to avoid perforation is to maintain a sufficiently thick and long-lasting submucosal cushion by endoscopic fluid injection into the submucosal layer. Various solutions such as hypertonic saline, glycerin solution, and hyaluronic acid (HA) have been used, however, among those solutions, HA is preferred because of its higher viscosity[1]. Recently, EMR has been also applied for submucosal tumors, such as neuroendocrine tumors (NETs)[2-4]. We herein report a case of an endoscopic full-thickness resection of a duodenal NET after unplanned fluid injection into the subserosal layer.

CASE REPORT

An asymptomatic 57-year-old man underwent endoscopy for investigation of a duodenal polyp detected in a private full medical checkup at another hospital. Endoscopy revealed a whitish hemispheric submucosal tumor with a smooth surface, about 5 mm in diameter, in the anterior wall of the duodenal bulb (Figure 1). Endoscopic biopsy disclosed a NET histologically. Because endoscopic findings such as size, shape, and mobility of the lesion indicated the tumor existed in the submucosal layer, EMR was conducted for its removal.

The tumor was effectively and evenly elevated after endoscopic submucosal injection of a mixture of 0.2% HA and glycerol at a ratio of 1:1 with a small amount of indigo-carmine dye added for coloration. The lesion was completely resected *en bloc* with a snare after submucosal fluid injection. Immediately, muscle-fiber-like tissues were identified at the margin of the resected defect, which suggested perforation, although a blue-colored layer was detected in the resection defect (Figure 2). The defect was completely closed with a total of 9 endoclips (Figure 3). No pneumoperitoneum was detected during or after EMR and endoscopic closure. The muscle layer was involved in the underside of the resected specimen (Figure 4). Computed tomography performed after the procedure revealed a small amount of free air but no fluid collection in the retroperitoneal space. Though the patient was in the hospital for 5 d longer than planned, he was successfully treated conservatively with intravenous fluids including antibiotics for 4 d without oral intake, and no symptoms associated with peritonitis appeared. Histologically, the tumor was diagnosed as a NET grade (G) 1 limited within the submucosal layer without muscular or lymphovascular invasion. The horizontal and vertical margins of the resected specimen were free of NET and the muscularis propria (MP) was also seen in the resected specimen (Figure 5). The blue layer in the resection defect had been created by fluid injection into the subserosal layer rather than the intended submucosal layer. No local recurrence or metastasis was detected after a follow-up of 30 mo from EMR.

Figure 1 A neuroendocrine tumor, 5 mm in diameter, was detected in the duodenal bulb during endoscopy in an asymptomatic 57-year-old man.

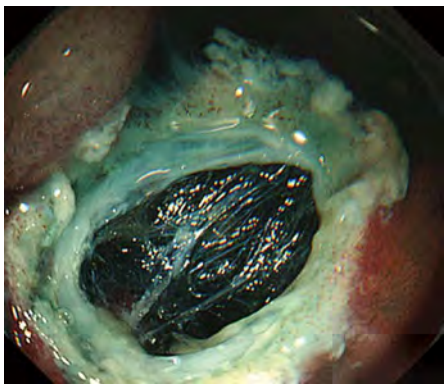

Figure 2 Although a blue-colored layer was identified in the resection defect, a small amount of a whitish layer was detected above the blue layer.

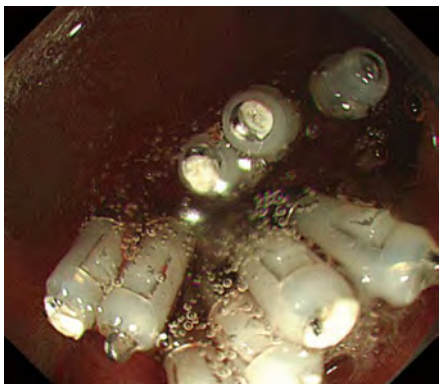

Figure 3 The defect was immediately closed with endoclips.

DISCUSSION

Duodenal NETs account for 2%-15% of gastrointestinal NETs, which are the most common type of NETs[5,6]. Some of them secret bioactive substances such as serotonin, histamine, and prostaglandin, and cause the following typical clinical presentations: cutaneous flushing, sweating, and gut hypermotility with diarrhea[7]. The metastasis rate of duodenal NETs is associated with tumor size. Duodenal NETs, which are located outside the peri-

Figure 4 The muscle layer was clearly located on the underside of the resected specimen.

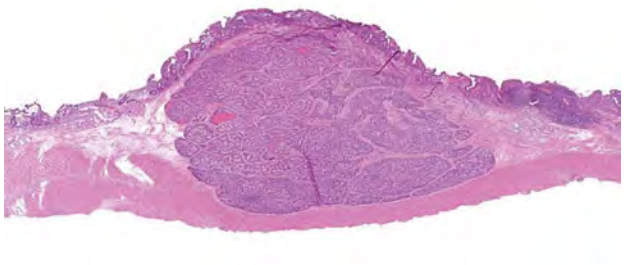

Figure 5 The muscularis propria was detected just beneath the submucosal layer (hematoxylin-eosin staining, loupe image).

ampullary region, 1 cm or smaller in size, and confined to submucosal layer, are considered to be good candidates for endoscopic resection[5,8,9]. Endoscopic resection of duodenal NETs, however, can be associated with a higher risk of perforation, as the bowel wall is thinner in the duodenum and deeper endoscopic resection is necessary because of the tumor localization.

During EMR, a sufficiently thick submucosal elevation created by appropriate fluid injection into submucosal layer is crucial for prevention of perforation, and a small amount of indigo-carmine dye is commonly added for coloration of the injected solution to help determine whether the resection defect is in the submucosal layer or muscular layer (blue or white). In the present case, the tumor was elevated easily, evenly, and sufficiently after fluid injection as if the solution was appropriately injected into the submucosal layer. In addition, as the resection defect was colored blue after resection, we initially thought that EMR was successful. After careful investigation of the defect, however, we detected a few whitish bundles suggesting the presence of MP above the blue layer, a so-called "mirror target sign". Therefore, we could recognize that the blue layer below the MP had been created by unplanned injection of fluid into the subserosal layer rather than the submucosal layer and concluded that our EMR had resulted in an unexpected full-thickness resection.

Both the "target sign" and "mirror target sign" were reported to help in identifying the endoscopic resection of the MP[10]. Surrounded by mucosa and submucosal tissue, the resected MP on the resected surface appears as the "target". In contrast, the resected defect consisted of 2 concentric rings, the inner ring seen as an area of exposed subserosal layer and the outer ring as the commonly encountered submucosal layer, which make the mirror image of the target sign. A similar case has been reported in an EMR during colonoscopy[11]. A detailed examination of the resection defect is important, but endoscopists should remember that the blue layer in the resection defect of EMR is not always the submucosal layer as unexpected subserosal injection can occur. Especially when high viscosity fluid such as HA is used during EMR, unexpected subserosal injection would raise the MP and result in an unexpected full-thickness resection. Retrospectively, the vertical approach of fluid injection in the thin duodenal wall would also explain this unexpected subserosal injection. We suggest that the injection needle could easily be misguided into the subserosal layer, as duodenal submucosal tumors occupy a significant space of the thinner submucosal layer of the duodenum. Furthermore, the thinner duodenal MP could be easily elevated by subserosal injection.

Generally, large perforations require urgent salvage surgery. Duodenal perforation related to endoscopic treatment is reported to require salvage surgery in as many as 43.6% of cases, and these perforations are more serious than those occurring at other sites of the gastrointestinal tract because of bile acid and pancreatic juice[12]. However, selected cases, especially those that can be totally repaired endoscopically, can be managed medically. In this case, prompt recognition of the potential perforation led to the successful endoscopic closure of the defect with endoclips, and moreover, subserosal fluid injection of HA also may have played some important role in sealing the defect. We believe both the clips and the subserosal fluid injection protected this patient against subsequent peritonitis and salvage surgery.

In conclusion, we herein report a case of endoscopic full-thickness resection of a duodenal NET after unplanned fluid injection into the subserosal layer. In this case, we found the "mirror target sign" immediately and repaired the defect endoscopically. A detailed examination of the resection defect regardless of its color, prompt recognition of signs of possible inappropriate resection, and immediate closure of the defect are important to minimize injury.

Abstract

Endoscopic band ligation (EBL) is the preferred endoscopic technique for the endoscopic treatment of acute esophageal variceal bleeding. EBL has also been used to treat nonvariceal bleeding. Recently, Han *et al* demonstrated that EBL can be a feasible and safe alternate technique for the management of iatrogenic gastric perforation especially in cases in which closure with endoclips is difficult. EBL is technically simpler to perform than other methods and provides a good view of the lesions under direct pressure and suction from the transparent ligation cap. EBL can be used even if the diameter of the perforation is greater than 10 mm or if there is a severe tangential angle. In this commentary, we discuss the efficacy and safety of EBL for the closure of iatrogenic gastrointestinal perforation. We also discuss the advantages and disadvantages of EBL for the treatment of nonvariceal bleeding.

Key words: Band ligation; Endoscopy; Intestinal perforation; Gastrointestinal hemorrhage

Core tip: Recently, Endoscopic band ligation (EBL) has been widely used in the treatment of nonvariceal bleeding from angiodysplasia, Dieulafoy's lesion, Mallory-Weiss tears, polypectomy bleeding and colonic diverticular bleeding. In this commentary, we describe EBL may be useful for the endoscopic closure in iatrogenic gastrointestinal perforation in which endoclip closure failed. In addition, the advantages and disadvantages of EBL for the treatment of nonvariceal bleeding are discussed.

COMMENTARY ON HOT TOPICS

Elastic band ligation was introduced in the United States in 1951[1], and has been used for decades to treat bleeding and/or prolapsed internal hemorrhoids[2]. In the late 1980s, Stiegmann *et al*[3] demonstrated that the results of an initial endoscopic band ligation (EBL) trial were equal to or superior to those obtained with endoscopic sclerotherapy for the treatment of active bleeding, the prevention of recurrences, and survival. Currently, EBL is the most useful and accepted treatment for acute esophageal variceal bleeding[4]. Recently, EBL has been widely used in the treatment of nonvariceal bleeding from angiodysplasia, Dieulafoy's lesion, Mallory-Weiss tears, polypectomy bleeding and colonic diverticular bleeding[5]. This

technique is equally as useful as the standard methods, such as endoclipping, epinephrine injections, and thermal therapy.

In a recent case report series, Han *et al*[6] have shown successful endoscopic closure using band ligation in iatrogenic gastric wall perforations in which primary endoclip closure failed. In this commentary, we describe the clinical efficacy and safety of EBL for the closure of iatrogenic gastrointestinal (GI) perforation. In addition, the advantages and disadvantages of EBL for the treatment of nonvariceal bleeding will be discussed.

Iatrogenic GI perforation

Although iatrogenic perforations occurring during endoscopic procedures are typically managed surgically, the successful endoscopic management of iatrogenic perforation has been increasingly reported. Surgery is required in patients in whom the endoscopic closure of a perforation failed or in whom the recognition of an endoscopic perforation was delayed. The endoscopic devices approved by the United States Food and Drug Administration for the closure of perforations include endoclips, stents, and endoscopic suturing devices[7]. Several case reports or series have described iatrogenic GI perforation managed by endoscopic clip placement[8-11]. Clipping is currently the standard method for closing perforations. Several through-the-scope (TTS) clips have been developed, including the QuickClip2 (Olympus Inc.), the Resolution clip (Boston Scientific Inc.), and the Tri-Clip and Instinct clip (Cook Medical). However, there still are no comparative studies evaluating one type of clip as superior to another for the closure of perforations[7]. The decision to close an iatrogenic perforation with clips is made on the basis of the duration of the procedure; the cause, location, and size of the perforation; the patient's age and general health; and the endoscopist's experience[12]. The most common causes of iatrogenic acute perforation in the GI tract are endoscopic mucosal resection (EMR) and endoscopic submucosal dissection (ESD)[9,10,13]. Perforation can also occur during the process of diagnostic endoscopy. The endoscopic closure of a perforation caused by EMR or ESD is simpler to perform than the endoscopic closure of a perforation caused by a blunt instrument because of the smaller size of the perforation caused by therapeutic endoscopy. Fujishiro *et al*[14] suggested that there are four prerequisites for a successful outcome after closing an iatrogenic perforation with endoscopic clips and using conservative management: (1) the perforation must be small (less than 1 cm); (2) the content of the GI tract must be as clean as possible and the amount of material escaping into the abdomen or mediastinum must be minimized; (3) the closure must be performed by experienced endoscopists'; and (4) there should be no deterioration in the clinical symptoms and laboratory indices, which should be closely monitored by experienced surgeons. The risk factors associated with the need for early surgery within 24 h after endoscopic closure were reported to be a large perforation, leukocytosis, severe abdominal pain, and a large amount of peritoneal free air[15].

The over-the-scope clip (OTSC; Ovesco Endoscopy AG, Tübingen, Germany) has a higher compression force and the capacity to capture a larger volume of tissue than the TTS clip[7]. In a recent prospective multicenter study the CLIPPER study group[16] showed that 32 of 36 consecutive patients with acute iatrogenic perforations (5 esophageal, 6 gastric, 12 duodenal, and 13 colonic perforations) had successful closures without adverse events. Newly developed endoscopic suturing devices for NOTES and antireflux and bariatric surgery may also be suitable for the closure of iatrogenic perforation[17].

Although clipping devices are relatively inexpensive and easy to use, endoscopic clip closure may be difficult in cases that involve large perforations, tangential angles, and/or fibrotic tissue. OTSC and endoscopic suturing devices are not readily available in many countries and require experience in their use for the closure of iatrogenic perforations. Recently several case reports or series of iatrogenic perforations treated by EBL have been described in the literature, involving the stomach, duodenum[18], and colon-rectum[19-21]. Moon *et al*[19] reported the first successful endoluminal closure of a 3 mm rectal perforation with one band following the ESD of a lateral spreading tumor. Two case reports showed that EBL was used to successfully close three iatrogenic colonic perforations in which closure with endoclips initially failed because there were two large perforations and a severe tangential angle[20,21]. Perforations occurring in the process of diagnostic endoscopy, as in these cases, are generally large because of the strong pressure of the endoscope on the wall of the gut over a large area[12]. In these cases, EBL may be applied successfully despite a large perforation. Duodenal perforations are complicated by the leakage of contaminated intestinal fluid and digestive enzymes and require early surgical repair[8]. Even when using a transparent cap on the tip of the endoscope, the application of clips to close perforations is still difficult in the posterior wall of the duodenal bulb because of the limited space and the tangential angle[22]. The deployment of band ligation is simpler than clipping, but displacement of the band poses another problem. Fan *et al*[18] reported the successful repair of a polypectomy-induced duodenal perforation with a combination of hemoclips and band ligation. The perforation was located on the posterior wall of the duodenal bulb and measured 10 mm in diameter. Although the endoscopic closure of large perforations (larger than 20 mm in diameter) is difficult, the successful endoscopic closure of a large duodenal perforation using endoloops and endoclips has been reported[23]. The perforation was located in the duodenal second portion and measured 30 mm in diameter. Two endoloop snare-endoclip sutures achieved complete closure.

In case reports by Han *et al*[6] rescue EBLs were performed in five patients in whom primary endoclip closure either failed or was technically difficult. The common causes of closure failure with clips in four of the

iatrogenic perforations were difficulties in approximating the location of the adjacent gastric mucosa due to wall tension and a tangential angle. In a case of ulcer base perforation, the fibrotic tissue on the base made clipping difficult. Successful endoscopic closure was achieved in all five patients, with no complications occurring. Based on these results, EBL may be a safe and effective alternate therapy for the closure of acute gastric perforations, especially when repairs using endoclips are problematic. Prospective clinical trials are required to demonstrate the efficacy and safety of EBL for the treatment of iatrogenic GI perforations.

Nonvariceal bleeding

The Dieulafoy lesion (DL), a rare vascular abnormality consisting of a large and tortuous artery that is located in the submucosa, can cause potentially life-threatening gastrointestinal bleeding. With advances in endoscopic techniques, endoscopic treatment has become the treatment of choice for many endoscopists because of its effectiveness in the majority of bleeding DLs. Endoscopic treatments include injection, thermal therapy, and mechanical methods such as endoscopic hemoclip placement (EHP) or EBL. These methods have been used with high rates of successful hemostasis[24-26]. Of the endoscopic treatments available, mechanical methods demonstrated good hemostatic efficacy and long-term outcomes, primarily for lesions located in the upper GI tract[27]. In a prospective study, Park *et al*[28] reported that EBL (n = 13) and EHP (n = 13) were equally effective and safe methods for the treatment of bleeding gastric DLs. In a recent large retrospective study that compared EHP with EBL, Ahn *et al*[29] showed that both EHP and EBL were effective for the treatment of bleeding DLs, although recurrent bleeding occurred in 6 of the 66 cases; 5 (15%) and 1 (3%) in the EHP and EBL groups, respectively. This result suggests that EBL may be used as an initial endoscopic treatment for bleeding DLs due to a more favorable clinical outcome than EHP and a shorter procedure time. Although DLs are usually located in the stomach, esophageal, duodenal, and rectal DLs have been successfully treated with EBL[30-32]. However, EBL entails some risks and disadvantages including recurrent bleeding due to ulcer formation, perforation, delay in overtube preparation, and technical difficulties (particularly in retroflexion)[33]. We have previous experience with six patients with acute lower gastrointestinal bleeding due to rectal DL who were treated with thermal therapy, EHP, and EBL[34]. Of the four patients who were treated with EBL, two experienced rebleeding after EBL. Using additional injections and hemoclipping to achieve hemostasis failed, and transanal suture ligations of the vessel were performed. Our cases suggest that residual vessels at the base of a necrotic ulcer may cause delayed bleeding, and it may be difficult to predict this complication on the basis of an endoscopic examination.

Some patients with Mallory-Weiss syndrome (MWS), a vomiting-induced mucosal laceration in the region of the gastroesophageal junction, may require intensive care, especially those with active bleeding, unstable vital signs, and associated comorbid diseases. Although endoscopic injection may be incomplete for a patient with a large and/or long plexuses of vessels, the results of hemostasis using epinephrine injection only are controversial. Chung *et al*[35] reported that rebleeding was more common in hemostasis with hypertonic saline-epinephrine (HSE) injection treatment than in mechanical hemostasis. However, Park *et al*[36] reported that EBL and HSE injections had the same efficacy with a primary hemostasis of 100% *vs* 94%, respectively, without recurrent bleeding or major complications in either group. In addition, Huang *et al*[37] reported that EHP and HSE were equally effective with respect to achieving hemostasis and reducing the rebleeding rate. A prospective, randomized study that compared EBL with EHP in our group showed that the two procedures were equivalent with respect to primary hemostasis (100%) and rebleeding rate (6% *vs* 10%, respectively)[38]. Recently, Lecleire *et al*[39] compared the efficacy of EBL with hemoclips plus epinephrine (H and E) in bleeding MWS. They showed that rebleeding occurred in 0% in the EBL group *vs* 18% in the H and E group and that hemostasis by H and E was an independent predictive factor of early rebleeding. Although a further large prospective study is required, this result suggests that EBL may be the first choice of endoscopic treatments for actively bleeding MWS. Although these studies have shown promising results for the treatment of nonvariceal bleeding, few of these reports were prospective controlled design, and sample sizes of randomized trials were small. Further prospective studies with a large number of patients are necessary to demonstrate the hemostatic efficacy of EBL.

Recently, EBL has been applied to the management of other types of nonvariceal bleeding, including post-polypectomy bleeding[40-43], vascular malformation[44,45], gastric antral vascular ectasia (GAVE)[46-50], blue rubber bleb nevus syndrome[51], and chronic hemorrhagic radiation proctitis[52]. Akahishi *et al*[43] showed that band ligation after endoscopic resection with an HSE injection was effective for the prevention of polypectomy-related bleeding in 20 pedunculated or semipedunculated polyps that were larger than 1 cm. Although the resection margin was histologically affected by the non-neoplastic components in 6 of 20 lesions, all 20 polyps were completely resected. In a prospective study, Junquera *et al*[45] reported that EBL achieved hemostasis in a single endoscopic session in 14 patients with angiodysplasia located in the duodenum (bulb, n = 5; 2nd portion, n = 8; 3rd portion, n = 1), and no patients had further bleeding at 40 days of follow-up. In a recent retrospective study, Sato *et al*[50] demonstrated that the recurrence rate of argon plasma coagulation (68%) was higher than that of EBL (8%) after treatment in patients with GAVE in association with liver disease.

More recently, EBL has been used in the treatment of colonic diverticular bleeding[53-57]. In a large retrospective

study, Ishii *et al*[57] reported that EBL was successful in 27 of 31 cases of colonic diverticular bleeding with the stigmata of a recent hemorrhage, except in 3 diverticula with a small orifice and a large dome and in 1 diverticulum with a large orifice. There were no perforation or penetration complications. Early rebleeding after EBL occurred in 3 cases (11%), which were managed conservatively by a repeat EBL or by a right hemicolectomy. Although the ruptured vasa recta were not identified, the histopathological examination of the surgical specimen showed that the muscularis propria was banded by an O ring. Considering that the direct placement of endoclips is difficult in cases of dome location, massive hemorrhage, or small diverticular orifice, EBL could be an alternative endoscopic treatment for colonic diverticular bleeding.

Endoscopic banding devices

Currently available EBL devices include single-band and multiband ligation devices. While the single-band ligator needs overtube for repeated intubation to place multiple bands, multiband ligator doesn't require use of an overtube. For the treatment of nonvariceal bleeding and GI perforation, single-band ligator has been usually used. For the variceal ligation, the use of multiband device was associated with a significant reduction in sedation requirement, endoscopic time, and patient discomfort compared to single-band ligator[58]. The multiband ligators include the Saeed Multi-band Ligator (Cook Endoscopy, Winston-Salem, North Carolina), the Auto-band Ligator (Scandimed International, Glostrup, Denmark), and the Speedband Superview Super 7 Multiple Band Ligator (Boston Scientific Corp, Natick, Mass)[59]. All EBL devices have a short transparent cylindrical cap that carries 1, 4, 5, 6, 7, or 10 bands, a tripwire that runs from the cap through the accessory channel to the control handle, and a control handle with a retracting spool that is fixed to the biopsy port for attachment and firing of the trip wire[59].

Safety of EBL

Stiegmann *et al*[3] showed that band ligation in the esophagus, when used for variceal bleeding, affected only the mucosa and submucosa. However, the safety of EBL in the anatomically thinner bowel (the colon and small intestine) has not been established. In an *ex vivo* study of EBL for the small bowel and colon using fresh surgical specimens, the histologic evaluation revealed the inclusion by the band ligator of the muscularis propria and serosa on the small bowel, the muscularis propria in the right colon, and the submucosa in the left colon[60]. This result suggests that EBL may not be safe in the small bowel and the right colon but is likely to be safe in the thicker left colon. Recently, Kakutani *et al*[61] showed that the full thickness of the duodenal wall after EBL was captured in the duodenum using *ex vivo* porcine models, and routine EBL is not recommended in the duodenum because of the high risk of perforation. However, Farrell *et al*[54] reported that none of the 11 band ligated colonic diverticula in surgical resected specimens contained either muscularis propria or serosal involvement, and there was no perforation in patients with actively bleeding colonic diverticula controlled by EBL. Further studies are needed to define the appropriate indications and locations for EBL.

Abstract

Despite multiple efforts aimed at early detection through screening, colon cancer remains the third leading cause of cancer-related deaths in the United States, with an estimated 51000 deaths during 2013 alone. The goal remains to identify and remove benign neoplastic polyps prior to becoming invasive cancers. Polypoid lesions of the colon vary widely from hyperplastic, hamartomatous and inflammatory to neoplastic adenomatous growths. Although these lesions are all benign, they are common, with up to one-quarter of patients over 60 years old will develop pre-malignant adenomatous polyps. Colonoscopy is the most effective screening tool to detect polyps and colon cancer, although several studies have demonstrated missed polyp rates from 6%-29%, largely due to variations in polyp size. This number can be as high as 40%, even with advanced (> 1 cm) adenomas. Other factors including sub-optimal bowel preparation, experience of the endoscopist, and patient anatomical variations all affect the detection rate. Additional challenges in decision-making exist when dealing with more advanced, and typically larger, polyps that have traditionally required formal resection. In this brief review, we will explore the recent advances in polyp detection and therapeutic options.

Key words: Polyps; Endoscopy; Colonoscopy; Endoscopic submucosal dissection; Endoscopic mucosal resection; Quality; Combined endoscopic-laparoscopic resection; Combined laparoscopic-endoscopic resection; Combined endoscopic-laparoscopic surgery

Core tip: Changes in polyp detection including chromoendoscopy and narrow band imaging, as well as reliance on quality indicators such as the 6-min withdrawal time, aim to improve adenoma detection rates. Once identified, novel approaches for large and advanced polyps such as endoscopic submucosal dissection and endoscopic mucosal resection, combined laparoscopic-endoscopic resection along with combined endoscopic-laparoscopic resection are available to surgeons that

may obviate the need for formal resection. Although technical expertise and experience is required, physicians caring for these patients should be familiar with each of these alternative procedures.

Endoscopy and polyps-diagnostic and therapeutic advances in management. *World J Gastroenterol* 2013; 19(27): 4277-4288 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4277.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4277

INTRODUCTION

Endoscopic technology has undergone dramatic improvements since Philipp Bozzini (1773-1809), a urologist from Frankfurt, Germany, developed the lichtleiter in 1806 - a light-conducting system that featured a candle and system of prisms to inspect the rectum, bladder and esophagus of patients[1]. Since then, multiple different physicians and scientists such as Nitze, Mikulicz, Waye, and Shinya have advanced this technology from a rigid device able to look into the bladder and stomach to a fully flexible endoscope capable of evaluating the entire gastrointestinal tract. Modern endoscopic equipment allows the direct visualization and treatment of many diseases ranging from colorectal polyps, carcinoma, inflammatory bowel disease, intestinal ischemia, diarrhea, diverticular disease, and lower gastrointestinal bleeding. Auxiliary devices ranging from biopsy forceps, snares, injection needles, various knives, baskets and balloon dilators have been developed to expand the ability of surgeons and gastroenterologists alike to manage complex pathology through the use of endoscopes. This update will briefly review some of the emerging advances and evolving parameters as well as their impact on clinical practice.

QUALITY PARAMETERS

Colon cancer remains the third leading cause of cancer-related deaths in the United States when each gender is considered separately and second when combined, with an estimated 50830 deaths in 2013 alone. This is despite multiple efforts aimed at early detection through screening, as well as evidence that routine screening reduces mortality[2-5]. Barriers to screening include patient fear of the exam and results, financial constraints, time off from work, transportation, and (in some regions) access to care. Multiple studies have demonstrated that when compared to flexible sigmoidoscopy and air-contrast barium enemas, colonoscopy is the most effective screening tool to detect colon cancer[6,7]. These dramatic results, in part, prompted Medicare in July 2001 to provide coverage for screening colonoscopy; which, along with technological advances, dramatically increased its overall use in the United States[8]. Despite the success of optical colonoscopy to detect and remove polyps, there remains a substantial rate of undetected polyps. In most major series this rate appears to be low, but has not improved over time, suggesting the need for further advances in the technique. Large studies that include physicians with extensive experience have demonstrated missed polyp rates from 6%-29%, with the variation depending primarily on the size of the lesion[9]. Not surprisingly, missed polyp detection rates have been significantly lower for larger lesions. Pooled analysis of tandem colonoscopies has revealed a failure to detect polyps of any size in as many as 22% of cases (95%CI: 19%-26%). In this systematic review, when further stratified by size, adenoma miss rates were 2.1% lesions for $\geqslant$ 1 cm, 13% for those 5-10 mm, and 26% for polyps 1-5 mm[10]. Others have reported similar results, with miss rates for all polyps at 28%, adenomas (20%), polyps < 5 mm (12%), > 5 mm (9%) and advanced adenomas (11%)[11]. When accounting for other factors such as the concomitant presence of a sub-optimal bowel preparation, these rates have been reported to be higher than 40% for any size polyp, and even up to 36% with advanced adenomas[12]. In order to understand how we may potentially be able to lower this missed adenoma detection rate, we will explore these factors and the data behind each of them.

Time of withdrawal

One factor that has more recently been identified to impact overall polyp detection rates is colonoscopy withdrawal time. In 2002, a United States Multi-Society Task Force on Colorectal Cancer recommended that the withdrawal time for colonoscopies should average 6-10 min. Interestingly, this was based, in part, on a single small series of only 10 consecutive colonoscopies performed by two experienced endoscopists with vastly different withdrawal practices that found different adenoma missed rates[13]. Following confirmatory studies, practice guidelines have since recommended that endoscopists spend a minimum of 6-10 min examining the colonic mucosa during the withdrawal phase of colonoscopy to optimize the diagnostic yield of polyps. In many instances, this has evolved to become a metric that is tracked by hospital administrators to assess the quality of colonoscopies[14]. The response was initially positive, and adherence to this benchmark was supported by findings in a study by Simmons *et al*[15] that included 11000 colonoscopies showing a direct association between longer withdrawal times and higher polyp detection rates (r = 0.76; P < 0.0001). Although this association was overall strong, it dropped significantly as polyp size increased (r = 0.19 for polyps 6-9 mm, r = 0.28 for polyps 10-19 mm, r = 0.02 for polyps $\geqslant$ 20 mm). Small variations on this theme were subsequently reported, with others finding overall procedure time (which included the consent and sedation periods and not just withdrawal time) correlated with increased rates of polyp detection (r = 0.64, OR = 1.4, 95%CI: 1.19-1.64 for polyps > 1 cm; OR = 1.03, 95%CI: 0.74-1.43 for polyps > 2 cm)[16]. In one of the sentinel

papers, Barclay and associates published a study in the *NEJM* with 7882 colonoscopies using 6 min as the minimum length of time to allow for "adequate inspection" during withdrawal[17]. In this study of 12 gastroenterologists, rates of polyp detection ranged widely when measured either by number (0.1-1.05 mean number per patient) or percentage with adenomas (9.4%-32.7%), as well as times of withdrawal (3.1-16.8 min for procedures with no polyps removed). When specifically using a cutoff of 6 min, those with longer withdrawal times had significantly higher rates of detection for any neoplasia (28.3% *vs* 11.8%, $P < 0.001$), as well as advanced lesions (6.4% *vs* 2.6%, $P = 0.005$). Since then, multiple authors have confirmed average withdrawal times of 6 min or longer to be correlated with increased adenoma detection rates, including a quality assurance review of 15955 patients over 49 ambulatory centers, 17 states and 315 gastroenterologists, where longer withdrawals had a 1.8-fold higher rate of polyp detection[18]. In this review, factors that were found to be the strongest predictors of withdrawal time ⩾ 6 min include the presence of carcinoma (OR = 3.7), adenoma (OR = 2), and number of polyps visualized (OR = 1.7). Whether the study is performed in a private practice or academic environment, the relationship between longer withdrawal times and higher rates of overall polyp detection, or adenomas per patient (0.09-0.82), has been consistent[19].

However, the adoption of this quality indicator has not been uniformly supported nor met with complete agreement. Several authors have demonstrated no difference in polyp detection rates, despite improving the frequency of meeting the > 6 min quality metric from 65% to near 100% of the time[14]. Others argue that colonoscopy rarely misses polyps > 1 cm (*i.e.*, the most clinically significant polyps), regardless of the time spent during the withdrawal phase. Still others have agreed that while withdrawal time is associated with higher rates of polyp detection, longer withdrawal times have not been associated with changes in rates of neoplasia discovered at subsequent follow-up colonoscopies, including a recent VA Cooperative Studies Group analysis[20]. Similarly, after a monitoring and feedback program was instituted that focused on withdrawal times and polyp detection rates, there was an increase in mean withdrawal time (6.6-8.1 min, $P < 0.0001$) and overall polyp detection rate (33.1%-38.1%, $P = 0.04$). However, this was again observed to *not* be associated with an increase in neoplasia detection rate from the initial to the post-intervention time periods (19.6%-22.7%, $P = 0.17$)[21].

Despite this, withdrawal time has evolved into a quality metric indicator in many centers for determining the adequacy of colonoscopy. As such, this has led to some changes in clinical practice - both positive and negative. Some authors have reported improved rates of longer withdrawal times to comply with these guidelines, simply knowing that this quality measure was being recorded, but without using that time to perform the corresponding evaluation. To combat this, practices such as vetting through bystander observation and video recording have been attempted, though without a significant increase in polyp detection[22]. Other authors have shifted their focus in an attempt to further clarify the reasons for variations in polyp detection rate. Factors such as number of procedures, mean patient age, percentage of women, and mean procedure time have all been evaluated (in addition to polyp size) with only procedure time being significantly associated with polyp detection rate in a study of 2665 screening colonoscopies[23]. Multiple other patient and physician-related factors have also been identified as causes for higher miss rates including experience of the endoscopist, larger colon folds, morphology of polyp, and polyp location (*i.e.*, blind spots at the flexures)[11,24].

Physician fatigue

Physician fatigue has been considered another variable that affects colonoscopy quality performance and adenoma detection rates. This was first noted in a study demonstrating that afternoon colonoscopies have higher failure rates than morning colonoscopies, with higher overall incompletion rates (6.5% *vs* 4.1%, $P = 0.013$) as well as higher rates of inadequate bowel preparation (15.4% in am *vs* 19.7% in pm)[25]. When using cecal intubation rates as the endpoint, success was again lower in the afternoon (93.5% *vs* 95%, $P = 0.02$), although gender, age and bowel preparation were felt to play a role in these differences as well[26]. Adenoma detection rates have also varied based on the time of day the colonoscopy is performed, with one study reporting rates of 29.3% in the morning *vs* 25.3% in the afternoon ($P = 0.008$), independent of factors such as poor bowel preparation, withdrawal time, or partial evaluation[27]. To further clarify this, authors have compared results of providers that perform a full day of colonoscopy with those limited to half-day blocks. Adenoma detection rates in those only working half days have showed no significant difference between early and late procedures within that time period (27.6% *vs* 26.6%, OR = 1.05, 95%CI: 0.88-1.26, $P = 0.56$), while those in the same practice with full-day blocks reporting higher detection rates in the morning (26.1% *vs* 21%, $P = 0.02$), suggesting that the additional time, and subsequent fatigue, plays a role for this difference[28]. It appears that provider fatigue culminates in lack of focus or acumen in many cases, and translates into lower rates of "successful" colonoscopies as time progresses. Interestingly, polyp detection rates have also been shown to decline as time passes during an endoscopist's schedule, regardless of time of day, or number of prior procedures. Each elapsed hour in their work schedule was associated with a 5.6% reduction in polyp detection ($P = 0.005$), suggesting that physician fatigue can progress more rapidly in certain cases[29].

Training and technique

Regardless of the metric proposed, proper training remains a major factor in becoming and remaining proficient in any endeavor. Historically, intra-procedural quality indicators for colonoscopy have focused primarily on

physician-related factors such as cecal intubation rates, terminal ileal intubation, number of polyps detected, number of polyps retrieved, size of polyps detected, time to reach the cecum, and more recently withdrawal time. Guided by principles such as the United Kingdom Department of Health Global Rating Scale for endoscopy, emphasis has shifted more on defining quality experience through patient-driven metrics including appropriateness of the intervention, proper information/consent, overall safety, patient comfort, and providing timely results[30]. Use of colonoscopy-based virtual-simulator models has been one way to supplement inadequate exposure during residency training, and improve both the trainee experience and end result. Multiple studies have demonstrated that following intervention with 3-D simulators, many of these aforementioned traditional metrics such as cecal intubation rates, overall times, and need for further medication interventions significantly improve[31]. On the other hand, it remains to be seen how these newer quality metrics will be evaluated, reported and enforced.

POLYP CLASSIFICATION

In general terms, a polyp refers to the elevation of tissue above the gastrointestinal epithelium. Colon polyp types range widely from hyperplastic, hamartomatous, and inflammatory varieties to neoplastic adenomatous lesions. Although these lesions are all "benign", up to one-quarter of patients over 60 years old will have "pre-malignant" adenomatous polyps. Traditionally, polyps have been classified most commonly by their histology (*i.e.,* villous, tubular, tubulovillous, *etc.*), location, and physical description - with pedunculated and sessile being the most common descriptive classes. Since their first description in 1985[32], flat adenomas are increasingly more common and represent one of the "high-risk" categories along with adenomas larger than 1 cm, those with high-grade dysplasia, those associated with inflammatory bowel disease, villous or tubulovillous adenomas, and patients with multiple adenomas (typically > 3). Similarly, serrated adenomas represent another high-risk group, and are believed to represent a unique pathway in the adenoma-carcinoma sequence.

Flat polyps and serrated adenomas

While there has been some controversy regarding the impact and importance of flat adenomas in the United States and Europe, they are more widely believed to be significant in Asia. The Japanese Research Society Classification (Kudo classification of adenomas) describes flat lesions as those with a height that is less than one half the diameter[33]; while the Paris classification uses protruding and non-protruding divisions[34]. Increasingly, these lesions are recognized for their role in malignancy as well as difficulty with identification[35]. Serrated polyps represent another type of lesion that has been reported to be more difficult to diagnosis. Originally described following evaluation of hyperplastic polyposis syndrome patients, these lesions have a characteristic serrated architecture and can occur either as a traditional serrated adenoma (classically seen as a polypoid lesion), or as a sessile serrated adenoma (flat, slightly raised, right-sided > left). Though historically often diagnosed as a variant of hyperplastic polyps, these lesions are found in about 7% of all colonoscopies, and are now more properly classified as their own distinct entity. They are also believed to have a higher risk of malignancy that occurs apart from the traditional adenoma to carcinoma sequence[36,37].

The traditional polyp-cancer sequence has been established since Muto *et al*[38] described it in 1975. Adenocarcinoma of the colon can arise *via* multiple different pathways, with the most common described by genetic alterations that result in micro-satellite stable carcinomas[39]. Approximately 1/3rd, however, will arise along the serrated pathway, developed from the precursor lesion known as the sessile serrated adenoma (SSA). This is caused from an extensive methylation at the CpG island promoter site, which may demonstrate microsatellite instability. While controversy exits, it has been reported that SSAs are precursor lesions to micro-satellite unstable carcinomas; though limited data on the rate of progression currently exists[40]. In their pre-malignant state, these polyps show features between those of hyperplastic polyps and adenomas. On a molecular level, they have a high proportion of the *BRAF* mutation and DNA methylation. BRAF, a member of the RAF family of serine/threonine kinases, mediates cellular responses to growth signals, and *BRAF* mutations have been strongly associated with mis-match repair-deficient colorectal cancer[41]. Methylation and inactivation of the DNA repair genes *MLH1* and *MGMT* (06 methylguanine-DNA methyltransferase) similar to that in hereditary non-polyposis colorectal cancer, are felt to be the critical steps that lead to this instability[42]. It has also previously been found that patients with micro-satellite unstable cancers demonstrate an increased serrated polyp to adenoma ratio compared to those with stable cancers. Therefore when encountering patients that have more serrated polyps than adenomas during colonoscopy, subsequent cancers in these patients may demonstrate microsatellite instability and should be considered for appropriate testing[43]. Risk factors for the development of sessile serrated adenomas include greater than 20 pack-year smoking history (OR = 7.31, 95%CI: 3.9-13.6), and, to a smaller extent, diabetes and obesity[44].

Unfortunately, there continues to be inconsistencies in the literature regarding the ultimate prognosis and malignant potential of both flat polyps and serrated adenomas. Even large series comparing flat lesions with polypoid have found that the size of the lesion confers much greater risk than the morphology for the development of malignancy. Furthermore, the incidence of high-grade dysplasia or cancer in flat neoplasms was found to be similar to that of polypoid neoplasms (5.4% *vs* 4.6%, $P = 0.36$)[45]. While still somewhat controversial, what seems increasingly clear is that while further informa-

tion is required to determine the exact malignant risk of these lesions, there is evidence to suggest that they have a higher risk profile and should be followed accordingly.

Laterally spreading tumors

Another subset of high-risk lesions includes laterally spreading tumors (LSTs). These lesions have been increasingly described over the past 20 years and are characterized by their higher likelihood to spread laterally along the lumenal wall rather than vertically[46]. By definition, LSTs applies to lesions > 10 mm in diameter[47]. Okamoto initially described two clinical and histologic subtypes, which are identified as the granular-type (LST-G) and non-granular (LST-NG)[48]. Granular types appear endoscopically as multiple even or uneven nodules with the same color with its surrounding normal mucosa, while the non-granular type (also referred to as flat) appear smooth. These lesions may also be further stratified based on their morphological appearance as LST-G-H (homogenous) and LST-G-M (nodular mixed) type or LST-NG-F (flat elevated) and LST-NG-FD (pseudodepressed)[49].

These lesions have a much higher propensity for being missed *via* standard white light colonoscopy, as well as more advanced techniques such as narrow band imaging (NBI) and chromoendoscopy[50]. More importantly, LSTs have an increased rate of submucosal invasion. Rates of invasion, particularly for the LST-NG subtype are as high as 30%-40%[46], whereas the granular subtype are significantly lower (about 5%-10%)[51]. While the risk of lymph node metastases is low for early invasion[52], the preferred management is still somewhat controversial, but mostly based on clinical and morphological appearance[53,54]. What is clear, however, is that these lesions represent a high-risk group with a substantial rate of concomitant malignancy, and endoscopists need to have an acute awareness of their potential presence and follow-up on them accordingly.

POLYP DETECTION

There is little doubt that colonoscopy is a highly specific and sensitive test for the detection of colonic lesions, and several factors play a role in the adenoma detection rate (Table 1). However, differentiating early colon cancer from polyps can be more difficult. Factors that are associated with the presence of malignancy in a colonic polyp include villous architecture, increasing size, presence of multiple polyps and sessile lesions[55]. To further help in distinguishing benign from cancerous lesions, Kudo *et al*[56] in 1994 reported on differences in mucosal pit patterns of various colorectal polyps. In this classification system, staining patterns that are often seen in hyperplastic polyps or normal mucosa differ from the unstructured surface architecture more commonly identified with malignancy. Pit patterns were classified into seven principal types: (1) normal round pit; (2) small round pit; (3) small asteroid pit; (4) large asteroid pit; (5) oval pit; (6) gyrus-like pit; and (7) non-pit. The authors found that there was a correlation between pit patterns and the histology of the cells in the gland. The authors further went on to categorize these seven principle types into 5 pit patterns: (1) normal round pit; (2) small and large asteroid pits; (3) small round pit; (4) oval pit; (5) gyrus-like pit; and (6) non-pit pattern. By using this schema, types I and Ⅱ are non-neoplastic and Ⅲ, Ⅳ and Ⅴ are neoplastic, with accuracy rates reported as high as 90%[57]. Chromoendoscopy and NBI use these differences in pit pattern to help detect and differentiate polyps.

Table 1 Factors associated with adenoma detection

Variable	Association
Withdrawal Time < 6 min	Worse
Sub-optimal bowel preparation	Worse
Patient anatomy	Variable
Experience of endoscopist	Variable (mostly worse with early)
Afternoon endoscopy	Worse
Flat adenomas	Worse
< 1 cm	Worse
Narrow band imaging	Variable data[1]
Chromoendoscopy	Variable data[1]

[1]Compared to traditional white light colonoscopy.

Chromoendoscopy

In chromoendoscopy, a dye such as indigo carmine can further enhance the surface structure of epithelial lesions with the aid of magnifying endoscopy[58]. Pit patterns become more recognizable, and outlining the borders of polyps is reported to be more accurate. Accuracy rates have been reported as high as 87%-100% and 76%-99.8% in diagnosing non-neoplastic and neoplastic polyps, respectively[59]. Furthermore, this technique has been shown to be beneficial for helping detect small lesions and decreasing the missed polyp rate, with diagnostic accuracies of 95% with magnification chromoendoscopy for lesions < 5 mm compared to 76% with traditional colonoscopy[60,61]. A recent update of the Cochrane review consisting of 5 studies compared chromoendoscopy *vs* conventional endoscopy for detection of polyps, and showed that chromoendoscopy is more apt to identify patients with at least one neoplastic lesion (OR = 1.67, 95%CI: 1.29-2.15), as well as those with ≥ 3 neoplastic lesions (OR = 2.55, 95%CI: 1.49-4.36) over "white" light endoscopy[62]. Although still not widely used, especially in the United States, chromoendoscopy has also been cited to reduce the time, cost and risk with biopsy/polypectomy, once the initial learning curve associated with dye application is complete.

NARROW BAND IMAGING

NBI is an imaging technique that also relies on better definition of capillary pattern to improve the contrast between adenomas and surrounding normal mucosa. Adenomas, like malignancy, have a characteristic angiogenesis that can be detected using various wavelengths

of light that variably penetrate the colon mucosa[63]. The theory behind it's efficacy lies in its ability to contrast the "normal" mucosa from that of adenomatous tissue to a greater degree than standard white light colonoscopy by selecting out specific wavelengths through optical filters that "narrow" the bandwidth of light. Developed by Gono *et al*[63] (and originally described on the vascular pattern and adjacent mucosa of the underside of the human tongue), it uses the reflected light to visualize the superficial structure and enhance the vasculature within the mucosal layers. Unlike chromoendoscopy, which relies on sprays and specialized equipment, NBI is readily available on many colonoscopy systems and does not require additional imaging. The data supporting its use, however, remains somewhat conflicting. In a pilot study by Machida *et al*[64], NBI had a 93.4% diagnostic accuracy, equivalent to chromoendoscopy with magnification, and higher than that of conventional colonoscopy. In one randomized trial during screening colonoscopies, patients randomized to white light (n = 108) and NBI (n = 103) had adenoma detection rates of 58.3 and 57.3 (P = 0.88), respectively. However, when the authors further evaluated only flat adenomas, a lesion believed to be best defined by NBI, the detection rates were 9.3% for traditional colonoscopy and 21.4% for NBI (P = 0.019)[65]. Other randomized data including 1256 patients comparing NBI technology to white light with associated high definition video found no difference in overall adenoma detection rates (33% *vs* 34%), total number of lesions (200 *vs* 216), or any other subgroups of adenomas to include flat lesions[66]. In this study, only hyperplastic polyps were found more commonly in NBI. Several other authors have found NBI did not improve the colorectal neoplasm miss rate compared to traditional methods[67], or even those of small and flat adenomas with the use of high-definition colonoscope[68]. A recent Cochrane review identified 11 randomized trials with 3673 patients comparing NBI to standard white light endoscopy for the detection of colorectal polyps. The authors found similar rates of overall polyp detection (6 trials, n = 2832, RR = 0.97, 95%CI: 0.91-1.04), and adenomas (8 trials, n = 3673, RR = 0.94, 95%CI: 0.87-1.02), even when stratifying by the number of patients with at least one lesion by size [< 5 mm: RR = 0.95, 95%CI: 0.84-1.08, I^2 = 56%; 6-9 mm: RR = 1.06, 95%CI: 0.81-1.39, I^2 = 0%; ≥ 10 mm: RR = 1.06, 95%CI: 0.77-1.45, I^2 = 0%][69].

On the contrary, there are studies that do report improvements in distinguishing neoplastic from non-neoplastic lesions using NBI, with accuracy rates higher than that of colonoscopy and equivalent to chromoendoscopy (80%-82% low magnification NBI; 85% low magnification chromoendoscopy; 87%-90% high magnification NBI; 82%-92% high magnification chromoendoscopy; standard colonoscopy (67%-68%)[70]. Other authors have found sensitivity of 90%-96% and specificity of 85%-89% in differentiation of neoplastic *vs* non-neoplastic lesions, comparable to that of chromoendoscopy. Furthermore, accuracy rates were even higher with the addition of magnifying endoscopy, up to 94% for neoplastic and 89% for non-neoplastic lesions[71,72]. Similar to chromoendoscopy, however, the ultimate role this will have relies on the long-term data, ability to lower costs, and proper training of endoscopists prior to incorporation into everyday and widespread use.

Endoscopic mucosal resection

Endoscopic mucosal resection (EMR) was first described in 1990 by Inoue and Endo in Japan[73], and subsequently followed by Soehendra *et al*[74] in Hamburg, Germany in 1997. In the esophagus and stomach, as well as the colon, EMR allows removal of superficial tumors of the gastrointestinal tract. Unlike polypectomy that removes the tumor at the base of the mucosa, the plane of resection during EMR occurs in the middle or deep submucosal layer. Drawbacks of piecemeal excision include difficulty with proper staging, histological diagnosis, and definitive evaluation of the margins[46,75]. Furthermore, unlike the stomach, the colonic wall is much thinner and haustrated, leading to a technically more difficult procedure. Indications for EMR currently include adenomas or small, well-differentiated carcinomas confined to the mucosa or with minimal invasion into the submucosa, those more than 1/3rd of the lumenal diameter, or flat/depressed polyps. In essence, EMR enables select lesions to be removed endoscopically that would potentially require colectomy[76]. It is important that these early carcinomas do not have lymphovascular invasion, due to the increased risk of lymph node metastases. As this technique is currently performed more commonly in Japan, the Japanese Society for Cancer of the Colon and Rectum's current criteria for curative endoscopic resection are: submucosal invasion of less than 1000 μm, moderate or well-differentiated lesion characteristics, and the absence of vascular invasion[77]. Moss and colleagues have also identified risk factors for submucosal invasion and failure of successful EMR in a prospective, multi-center cohort of 479 patients and 514 lesions[78]. In their collective experience, Paris classification 0-Ⅱa+c morphology, nongranular surface, and Kudo pit pattern type Ⅴ were all risk factors for invasion, with even higher risks (up to 55.5%) when multiple factors were present. EMR was attempted in 464 patients, being successful in 414 (89%), with a prior EMR attempt by the referring endoscopist (OR = 3.75, 95%CI: 1.77-7.94), difficult position (OR = 2.17, 95%CI: 1.14-4.12) and ileocecal valve location (OR = 3.38, 95%CI: 1.20-9.52) all predictors of initial failure.

Local recurrence has been reported in 6.9%-13.4% of cases of EMR, with higher rates reported following piecemeal excision, invasive pathology, and for lesions > 2 cm (rates up to 39%)[79]. Median times for recurrence are typically within the first 6 mo, signifying the importance of follow-up endoscopic evaluation between 3 mo and 1 year[80]. In patients with larger polyps or those with dysplasia or cancer, it is recommended that they undergo more high intensity surveillance[81,82]. Other reported risk factors for recurrence include a granulous appearance of

the lesion and distal rectal lesions. Incomplete (R1) resections and those with deep positive margins should be considered for surgery.

Outcomes for EMR are, in general, very good as most patients are highly selected. When performed by experts, less than 3% of lesions are referred for surgical resection (due to inadequate removal), 44%-60% are performed *en bloc*, and the remaining lesions undergo successful piecemeal removal[83]. In sample series, complications involve procedural (10%-13%) and late (0%-1%) bleeding, post-polypectomy syndrome (2%-3%) and perforations (1%-2%)[84]. In attempt to identify high risk polyps that contain cancer prior to EMR, several authors have shown malignancy rates are higher with sessile polyps and those > 3 cm[83,84]. Although these factors are not absolute contraindications to EMR, it is typically more difficult to remove tumors larger than 2 cm by *en bloc* resection using EMR, with reported rates of about 30%. The decision to perform EMR should be made on an individual basis[85-87].

Endoscopic submucosal dissection

Endoscopic submucosal dissection (ESD) is primarily used to help with resecting larger tumors and aid in achieving higher rates of en-bloc resection of superficial tumors in the gastrointestinal tract than EMR. While EMR is the current standard in most centers outside of Asia, ESD is a technique that should, in general, be reserved for highly selected lesions by specialized endoscopists skilled and experienced in this technique Although still primarily performed in select centers and lacking widespread use, the goals of ESD remain: (1) treating mucosal cancer; (2) achieving an R0 resection; (3) meeting quality standards; and (4) ensuring that procedures are performed by endoscopists trained in this technique and under institutional review board approval[88]. As a general guideline, ESD is more commonly indicated when a snare is unlikely to enable a successful *en bloc* resection with EMR. ESD is also indicated when tumors are diagnosed as carcinomas with intramucosal to shallow submucosal invasion, as well as lesions with submucosal fibrosis that cannot be removed by EMR, even if less than 20 mm in size. Others have proposed that this technique is suitable for all large polyps, early colorectal cancer, and those lesions that cannot be accessed transanally in patients who wish to avoid major resection.

Similar to other new technology, both EMR and ESD have learning curves that play a large role in determining outcomes. Previous reports out of Asia, where experience tends to be much greater, have demonstrated proficiency for larger lesions occurs at about 80 cases, with generalized avoidance of major complications such as perforation at about 30-40 procedures[89,90]. Yet, the learning curve of ESD and its outcome comparison to EMR in centers where endoscopists are not as familiar or experienced is less defined to date. Probst and colleagues evaluated their learning curve in a European study of 82 rectosigmoid lesions, with successful resection using ESD techniques in 76 (93%)[91]. Over the 7-year study period, the authors divided up their experience into three separate phases (1-25, 26-50 and 51-76 years). During this time, both the rates of en-bloc resection (60%, 88% and 96%, respectively) and R0 resection (80%, 86% and 88%) increased, while procedure times significantly decreased (200, 193 and 136 min).

Using different techniques, other authors have reported successful en-bloc resection occurs in up to 85%-89% of cases and piece-meal resection is possible in the remaining 10%-15%[92-96]. Clear lateral and deep margins (*i.e*, complete resections) have been reported in up to 79%-86% of cases[97,98]. As previously stated, because it is difficult to perform en-bloc resection by EMR for lesions larger than 20 mm, ESD may be more suitable for these lesions. The ability to predict depth of invasion in an attempt to decide whether to pursue EMR, ESD or formal resection remains somewhat difficult. Similar to EMR studies, predictors of submucosal *vs* mucosal invasion include poor-differentiation and the absence of background adenoma[83,84].

Briefly the technique of ESD involves an initial bowel preparation to remove residual feces. An endoscope with a single channel is used along with a high-frequency electrosurgical generator. After identification of a lesion, one of several types of solutions (including a mixture of 1% hyaluronic acid solution and 10% glycerin solution) is injected around the lesions to elevate the submucosa[99]. Specialized knives in various shapes and sizes help to perform the dissection and resection. The border of the tumor is initially marked by indigo carmine dye and with approximately 1 cm margins. Following a mucosal incision, and depending on the physician preference, a partial or circumferential incision is made along with injection of hyaluronic acid solution into the submucosa, and the dissection is carried down to the deep submucosa. This process is continued around the tumor until the entire lesion is resected en bloc, when possible.

Perforation using ESD occurs in 1.4%-10.4% of cases, with the majority of series reporting rates < 2%[100]. These rates are classically higher than reported with EMR and are most likely due to the depth of dissection, and in certain cases lesions that are associated with a significant amount of fibrosis[101]. When small perforations occur, endoscopic clips have been utilized to close the site when feasible[102]. In more severe cases or those that cannot be closed endoscopically, more definitive procedures should be performed either by laparoscopy or laparotomy. Cases of delayed perforation occur in < 1% of cases, and are thought to be a result of thermal injury[103]. Postoperative hemorrhage rates are reported between 0%-12%, comparable to that with EMR, and the majority are self-limiting[96]. Another not infrequent complication is the inability to complete the procedure secondary to patient restlessness from abdominal distension and pain (12%-32%), requiring additional conscious sedation or even general anesthesia. Additionally, the use of carbon dioxide has been shown to significantly reduce this pain and bloating when deep sedation compared to traditional

air insufflation[104]. Other more rare complications include obstruction, fever, and pain[105]. Most importantly, residual disease has been reported in 2%-3% with ESD[106]. In one of the few series comparing ESD with EMR, 145 colorectal tumors were treated by ESD and another 228 treated by EMR. ESD was associated with a longer procedure time (108 min *vs* 29 min, $P < 0.0001$), higher en bloc resection rate (84% *vs* 33%, $P < 0.0001$) and larger resected specimen size (37 mm *vs* 28 mm, $P = 0.0006$)[86]. There were three (2%) recurrences in the ESD group and 33 (14%) in the EMR group requiring additional EMR ($P < 0.0001$). Complication rates were similar (perforation 6.2% ESD *vs* 1.3% EMR, delayed bleeding 1.4% ESD *vs* 3.1% EMR; $P > 0.05$). Although both of these techniques are currently only offered in select centers, emerging literature and advances in technology may provide the impetus for more widespread training and utilization.

Combined laparoscopic-endoscopic resection/combined endoscopic-laparoscopic surgery

It is important to note that most lesions can (and should) be approached through traditional techniques. However, for select more advanced lesions, other methods are available. Combined laparoscopic-endoscopic resection (CLER) or combined endoscopic-laparoscopic surgery offers another approach for the removal of these advanced lesions that are not amenable to traditional endoscopic techniques, and would normally go on to formal resection. Lesions that are identified as being larger or more difficult to remove in the endoscopy suite are marked, and the patient is taken for a procedure under general anesthesia. In the operating room, the subcutaneous layer under the polyp is injected to lift the polyp. After laparoscopic ports are placed, the bowel is manipulated from the outside to expose the base of the lesion, and endoscopic polypectomy is performed. This enables direct evaluation for any full thickness injury, as well as the ability to imbricate or close the bowel wall using full thickness sutures should the need arise. Additionally, a sleeve resection can be performed that removes the lesion along with a full-thickness section of the surrounding wall (*i.e.*, in cecal lesions). A leak test can also be performed by submersion of the staple/suture line under water along with CO_2 or air insufflation. Any concerns regarding the applicability of the lesion for this procedure are alleviated by immediate conversion to a standard laparoscopic-assisted oncological resection[107].

Technical success rates have consistently been reported in 77%-97%, with the remaining requiring conversion to resection[108,109]. Common reasons for an inability to perform this procedure include difficult lesion location, poor visualization (which has been aided by CO_2-insufflation), and concerns for malignancy. Post-operative complications have been generally < 10%, with the majority being minor wound infections, bleeding, and ileus. Major complications are rare, with many reports citing a 0%-3% incidence. Recurrence rates are also low, reported in 10%-15% and typically are benign that may be approached *via* similar CLER, standard endoscopy or formal resection[107-109]. Final pathology ultimately will dictate the need for any subsequent segmental resection, and patients should be counseled about this ahead of time. Novel approaches for large and advanced polyps are available to surgeons that may obviate the need for formal resection. Although technical expertise and experience is required, physicians caring for these patients should be familiar with these alternative procedures.

CONCLUSION

Our goal remains to identify and intervene on lesions at the polyp stage, prior to invasion. While colonoscopy is the most effective screening tool to detect pre-cancerous polyps and colon cancer, we must focus on the quality indicators such as withdrawal time and adenoma detection rate to ultimately improve our outcomes. Advances such as NBI, chromoendoscopy, endoscopic mucosal resection, endoscopic submucosal dissection, and CLER are tools that may improve the management of benign and early malignant polyps, and physicians performing endoscopy should be well-versed in their applicability and efficacy.

Abstract

AIM: To use microarray-based miRNA profiling of colonic mucosal biopsies from patients with ulcerative colitis (UC), Crohn's disease (CD), and controls in order to identify new potential miRNA biomarkers in inflammatory bowel disease.

METHODS: Colonic mucosal pinch biopsies from the descending part were obtained endoscopically from patients with active UC or CD, quiescent UC or CD, as well as healthy controls. Total RNA was isolated and miRNA expression assessed using the miRNA microarray Geniom Biochip miRNA *Homo sapiens* (Febit GmbH, Heidelberg, Germany). Data analysis was carried out by principal component analysis and projection to latent structure-discriminant analysis using the SIMCA-P+12 software package (Umetrics, Umea, Sweden). The microarray data were subsequently validated by quantitative real-time polymerase chain reaction (qPCR) performed on colonic tissue samples from active UC patients (n = 20), patients with quiescent UC (n = 19), and healthy controls (n = 20). The qPCR results were analyzed with Mann-Whitney U test. *In silico* prediction analysis were performed to identify potential miRNA target genes and the predicted miRNA targets were then compared with all UC associated susceptibility genes reported in the literature.

RESULTS: The colonic mucosal miRNA transcriptome differs significantly between UC and controls, UC and CD, as well as between UC patients with mucosal inflammation and those without. However, no clear differences in the transcriptome of patients with CD and controls were found. The miRNAs with the strongest differential power were identified (miR-20b, miR-99a, miR-203, miR-26b, and miR-98) and found to be up-regulated more than a 10-fold in active UC as compared to quiescent UC, CD, and controls. Two miRNAs, miR-125b-1* and let-7e*, were up-regulated more than 5-fold in quiescent UC compared to active UC, CD, and controls. Four of the seven miRNAs (miR-20b, miR-98, miR-125b-1*, and let-7e*) were validated by qPCR and found to be specifically upregulated in patients with UC. Using *in silico* analysis we found several predicted pro-inflammatory target genes involved in various pathways, such as mitogen-activated protein kinase and cytokine signaling, which are both key signaling pathways in UC.

CONCLUSION: The present study provides the first evidence that miR-20b, miR-98, miR-125b-1*, and let-7e* are deregulated in patients with UC. The level of these miRNAs may serve as new potential biomarkers for this chronic disease.

Key words: Biomarker; Crohn's disease; Diagnostics; Inflammatory bowel disease; Microarray; MicroRNA; Ulcerative colitis

Core tip: This study contributes to the current knowledge on the putative role of microRNAs in inflammatory bowel disease pathogenesis, and it provides the first evidence that miR-20b, miR-98, miR-125b-1*, and let-7e* are deregulated in patients with ulcerative colitis. The level of these miRNAs may serve as new potential biomarkers for this chronic disease.

Coskun M, Bjerrum JT, Seidelin JB, Troelsen JT, Olsen J, Nielsen OH. miR-20b, miR-98, miR-125b-1*, and let-7e* as new potential diagnostic biomarkers in ulcerative colitis. *World J Gastroenterol* 2013; 19(27): 4289-4299 Available from: URL: http://www.wjgnet.com/1007-9327/full/v19/i27/4289.htm DOI: http://dx.doi.org/10.3748/wjg.v19.i27.4289

INTRODUCTION

MicroRNAs (miRNAs) are short (about 22 nucleotides in length), endogenous, non-coding single-stranded RNAs that act in concert to regulate expression of their target mRNAs[1-3]. The biogenesis of these small regulatory miRNA is a multistep process occurring in the cell nucleus and cytoplasm. Briefly, miRNAs are transcribed as long primary miRNA transcripts in the nucleus, and are then cleaved into precursor miRNA hairpin (pre-miRNA) by the Drosha-DGCR8 microprocessor complex[4-6]. Next, the pre-miRNAs are exported to the cytoplasm and further cleaved to mature miRNAs by Dicer[7-9]. It is generally believed that the mature miRNA then incorporates into the RNA-induced silencing complex, and guides this complex to the 3'-untranslated region (3'-UTR) of specific target mRNA transcripts to suppress translation or induce their degradation[1,2,10-13]. However, miRNA-binding sites in coding regions as well as in the 5'-UTRs have also been reported[14-19].

It is estimated that nearly one-third of the genes in the human genome might be regulated by the more than 2000 mature miRNAs so far identified[20]. As master regulators of post-transcription in cells, these regulatory miRNAs are involved in key functions in many physiological networks[21-23], and differentially expression miRNAs have been implicated in the pathogenesis of diverse gastrointestinal disorders, such as cancer and inflammatory diseases[24,25]. In facts, loss of intestinal miRNAs in mouse models has been shown to impair differentiation of intestinal cells and epithelial barrier function, resulting in acute inflammation[23].

Recent studies have demonstrated miRNAs to be involved in inflammatory bowel disease (IBD) susceptibility, as polymorphisms in miRNA-binding sites affect the gene expression and thus seem to play a pivotal part in the pathogenesis of this chronic disorder[17,26]. Moreover, it has been found that miRNAs are differentially expressed in ulcerative colitis (UC) and Crohn's disease (CD)[27], the two main forms of IBD. However, the pathogenesis of IBD still remains enigmatic[28], but the identification of differentially expressed miRNAs and subsequent understanding of their molecular mechanisms appear to provide new ways to reveal the pathophysiology, discover new diagnostic biomarkers, and develop new therapeutics[27].

The present study aims to analyze the miRNA expression in colonic mucosal biopsies from IBD patients and healthy individuals in order to identify new potential miRNA biomarkers in IBD using miRNA microarray profiling.

MATERIALS AND METHODS

Patients and tissue samples

Two cohorts, including both IBD individuals and controls, were analyzed in this study. In order to identify potentially deregulated miRNAs, a miRNA microarray analysis was performed on samples from cohort 1 (microarray cohort) consisting of 4 patients with UC (2 with active and 2 with quiescent disease; mean age 34 years, range 34-37 years, 2 females), 4 patients with CD (2 active and 2 quiescent; mean age 40 years, range 25-73 years, 3 females), and 2 controls (mean age 39 years, range 37-41 years, 2 females). A subsequent quantitative real-time polymerase chain reaction (qPCR) validation study was performed on samples from cohort 2 (validation cohort) including 20 patients with active UC, 19 patients with quiescent UC, and 20 healthy controls (Table 1). In both cohorts, the included subjects underwent a routine colonoscopy at the Department of Gastroenterology, Medical Section, Herlev Hospital, Denmark due to their clinical condition. They were included into the study as UC or CD patients with active disease, quiescent disease, or as controls (*i.e.*, an endoscopy was performed due to gastrointestinal symptoms but all clinical and paraclinical investigations subsequently turned out to be normal). All individuals with IBD had their diagnosis established on well-defined criteria[29] and disease activity of all UC patients were before the colonoscopy graded in accordance with the Mayo score[30]: a score $\leqslant 1$ as quiescent UC and > 1 as active UC, and CD patients were graded in accordance with the Harvey-Bradshaw score[31]: a score $\leqslant 4$ as quiescent CD and > 4 as active CD. Exclusion criteria were age above 80 or below 18 years, clinical evidence of infection, recent (within 14 d) use of antibiotics or probiotics, pregnancy, and severe mental illness.

All mucosal pinch biopsies, each of approximately

Table 1 Patients' characteristics (validation cohort)

Characteristics	Control (n = 20)	Inactive UC (n = 19)	Active UC (n = 20)
Gender (male/female)	10/10	6/13	9/11
Age (yr), mean (range)	48 (24-83)	48 (21-69)	38 (16-79)
Age at diagnosis (< 25/> 25 yr)	-	4/15	7/13
Years with disease (< 10/> 10 yr)	-	8/11	15/5
Mayo score, mean (range)	-	0 (0-1)	6 (2-12)
Extension of disease (P/PS/PC/LC/PH)	-		3/3/7/5/2
Smoking/non-smoking	5/15	6/13	3/17
EIM (present/never present)	-	3/16	0/20
Daily medications, *n* (%)			
Systemic mesalazine (1.6-3.2 mg)	-	14 (74)	17 (85)

EIM: Extraintestinal manifestations; LC: Left-sided colitis; P: Proctitis; PC: Pancolitis; PH: Proctitis hemorrhagica; PS: Proctosigmoiditis; UC: Ulcerative colitis.

15 mg, were obtained from endoscopically non-inflamed or inflamed areas of the descending colon using routine endoscopic forceps. The descending colon was preferred to avoid any intersegmental variation. Non-inflamed samples originated from CD patients with endoscopically quiescent Crohn's colitis in the descending colon, where no other segments of the colon or ileum were endoscopically inflamed. Inflamed samples originated from CD patients with endoscopically active Crohn's colitis in the descending colon. Endoscopic activity was defined as areas with mucosal oedema, hyperemia, and friability. The endoscopic diagnosis of active or inactive disease was confirmed by histopathology conducted on parallel biopsies taken within an inch of the 1st biopsy. The biopsies were immediately placed in RNA-Later solution (Ambion, Austin, TX, United States), and following 24 h in RNA-Later at 4 ℃ the biopsies were stored at -80 ℃ until RNA extraction.

The study was approved by the Scientific Ethics Committee of the Capital Region of Denmark. All patients gave their informed written consent to participate in the study.

Extraction of total RNA and miRNA microarray profiling

The *mir*Vana™ miRNA isolation kit (Applied Biosystems, Carlsbad, CA, United States) was applied to isolate total RNA according to the manufacturer's protocol, and subsequently analyzed with a Geniom Real Time Analyzer (GRTA) (Febit GmbH, Heidelberg, Germany) using the Geniom Biochip miRNA *Homo sapiens*. The total RNA quality was assayed on an Agilent BioAnalyzer 2100 (Agilent Technologies, Santa Clara, CA, United States). The quantity of total RNA was measured using a NanoDrop Spectrophotometer (NanoDrop Technologies, Wilmington, DE, United States). The 260/280 nm absorbance values were consistently above 1.9.

The array contained ten replicates of each human miRNA and miRNA star (*) sequences as annotated in the Sanger miRBase v.11.0[32]. Sample labelling with biotin was carried out using the *mir*Vana™ miRNA labeling kit (Ambion). Following hybridization for 16 h at 42 ℃ the biochip was washed as indicated by the supplier and signal enhancement was processed with the GRTA. For each array, signal intensities were calculated using the Geniom Wizard Software (Febit GmbH).

qPCR

Total RNA (10 ng) was reverse transcribed into cDNA using miRNA-specific primers (Applied Biosystems) and the TaqMan® miRNA reverse transcription kit (Applied Biosystems) according to the manufacturer's instructions. MiRNA expression levels of seven selected miRNAs identified by microarray were measured using commercially available pre-designed miRNA-specific TaqMan® miRNA assays (Applied Biosystems) according to the manufacturer's recommendations. All PCR reactions were performed using a Mx3000P thermocycler (Stratagene, La Jolla, CA, United States), and cycles were as follows: 95 ℃ for 10 min, 45 cycles of 95 ℃ for 15 s, and 60 ℃ for 1 min. The expression levels of each miRNA were normalized to endogenous RNU6B expression - a widely used internal control - and analyzed using the $2^{-\Delta\Delta CT}$ method.

miRNA target gene predictions

Target genes of miRNAs were predicted using the miRWalk database (http://www.ma.uniheidelberg.de/apps/zmf/mirwalk/) that allows simultaneous searches of several databases[33]. Four additional programs were selected: TargetScan, miRanda, miRDB, and RNA22 as target prediction programs. The search was performed on the 3'-UTR regions of target mRNAs with a P value of 0.05 defining the probability distribution of random matches set in the software with a minimum miRNA seed length of 7. When at least three programs co-identified a specific transcript, then the target(s) were selected for our list of potential targets. In addition, due to the limited ability of all algorithms to predict targets of miRNA complementary strands (*), the miRNA* targets were identified using miRWalk and miRanda and only those targets predicted by both programs were examined more closely.

Statistical analysis

miRNA data analysis: The raw microarray-data were background corrected and the ten replicate intensity values of each miRNA were summarized by their median value.

In order to reduce data complexity the unsupervised multivariate data analysis tool principal component analysis (PCA) was applied to determine if any intrinsic clustering existed within the dataset. If intrinsic clustering was found, the supervised multivariate data analysis tool projection to latent structure-discriminant analysis (PLS-DA) was employed. PLS-DA, like PCA, involves reduction of

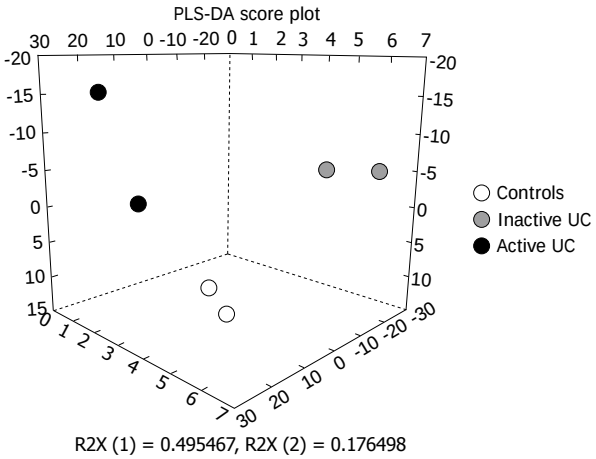

Figure 1 Projection to latent structure-discriminant analysis score-plot of the miRNA microarray expression profiles from mucosal colonic biopsies of controls, active ulcerative colitis, and inactive ulcerative colitis reveals a clear separation of these three groups. All patient with active ulcerative colitis (UC) are positioned in the left part of the space, and all patients with inactive UC are placed in the right space, whereas all control subjects are found in the middle. PLS-DA: Projection to latent structure-discriminant analysis.

data complexity and is commonly used where quantitative or qualitative relationships are sought between a matrix, X, in this case miRNA expression profiles, and another matrix, Y, in this case the class belonging of the samples. Such PLS-DA models offer the opportunity to create lists of miRNAs with the highest regression coefficients for each class, thus making it possible to identify the miRNA expression profiles responsible for the differentiation between the classes and subsequently the unique miRNAs with the strongest differential power. The multivariate data analysis was performed using SIMCA-P+ 12.0 (Umetrics, Umea, Sweden).

qPCR data analysis: Groups were compared using the Mann-Whitney *U* test, and *P* values less than 0.05 were considered significant.

RESULTS

Identification of differentially expressed miRNAs by miRNA microarray profiling

We have previously demonstrated that gene expression profiles using microarray studies can differentiate between active UC, inactive UC, and control samples[34,35]. Thus, in an initial attempt to identify new miRNAs that are differentially expressed in patients with IBD, we performed miRNA microarray profiling of colonic tissue samples from cohort 1. The PCA score-plot indicated a 3-way separation of the samples; controls, active CD, and inactive CD in one cluster, and active UC and inactive UC in two separate clusters (data not shown). The PCA model was described by 2 components explaining a total of 61% (R2X) of the variation in the dataset. The clustering of controls, active CD, and inactive CD in the PCA model indicates a similar miRNA expression profile in all three groups making further comparisons questionable. Thus, the subsequent PLS-DA model only contained the following three groups: active UC, quiescent UC, and controls. As seen in Figure 1, the PLS-DA score-plot resulted in a clear separation of these three groups. This PLS-DA model contained 2 components explaining a total of 67% (R2X) of the variation in the dataset and with a cross-validation parameter Q2Y (cum) of 0.89, indicating the predictability of the model. In order to substantiate the initial interpretation of the PCA score-plot, *i.e.*, clustering of active CD, inactive CD, and controls, an identical statistical procedure (creation of a PLS-DA model and comparison of regression coefficient lists) was performed with respect to these three groups. As expected, this resulted in an extensive number of miRNA duplicates in the regression coefficient lists, and the few miRNAs that were not duplicates had fold changes below 2 (results not shown).

In order to identify the miRNA expression profiles responsible for the differentiation between UC, CD, and controls, a list of 50 miRNA with the highest regression coefficients was generated for each group. When comparing the lists, no miRNA duplicates were found. Several of the differentially expressed miRNAs (such as miR-23a, miR-155, miR-16, miR-150, miR-346, and miR-126) reported to be associated with UC in previous studies[36-38] were also identified within our analyses (Tables 2 and 3). However, in addition to these previously reported miRNAs, we additionally identified five potential miRNAs, miR-20b, miR-99a, miR-203, miR-26b, and miR-98 to be differentially up-regulated more than a 10-fold in active UC compared to inactive UC, active CD, inactive CD, and controls (Table 2). Two miRNAs, miR-125b-1* and let-7e*, were differentially up-regulated more than a 5-fold in inactive UC compared to active UC, active CD, inactive CD, and controls (Table 3). These miRNAs have not previously been reported to be involved in IBD[27]. Thus, in the subsequent study, we focused on these seven new candidate miRNAs.

Verification of differences by qPCR

The expression levels of the seven candidate miRNAs (miR-20b, -99a, -203, -26b, -98, -125b-1*, and let-7e*) were tested in an independent validation cohort on samples from patients with active UC (n = 20), inactive UC (n = 19), and controls (n = 20) using individual miRNA-specific primers. In accordance with the microarray data, qPCR results showed significantly increased miR-20b ($P < 0.05$) expression in active UC *vs* controls. Moreover, miR-20b expression was significantly higher ($P < 0.05$) in inactive UC than in controls (Figure 2). Additionally, the qPCR analysis confirmed a significant ($P < 0.05$) higher expression of let-7e* in inactive UC *vs* controls (Figure 2).

In contrast to microarray results, miR-98 was significantly over-expressed in inactive UC ($P < 0.05$), when compared to both active UC and controls (Figure 2). Similarly, miR-125b-1* was not significantly up-regulated in inactive UC, as predicted by the microarray profiling,

but was significantly different ($P < 0.01$) between active UC and controls (Figure 2). The expression levels of the other predicted miRNAs (miR-99a, -203, and -26b) did, however, not reach a statistical significance (Figure 3).

Prediction of miRNA target genes associated with UC

Having identified significant changes in the four miRNA expression profiles (miR-20b, miR-98, miR-125b-1*, and let-7e*) between UC and controls, we next examined the biological relevance of these miRNAs by identifying their target genes. *In silico* analysis using miRWalk, which combines the output of multiple prediction algorithms, was used to identify putative targets. Among the large number of predictive targets identified by this approach,

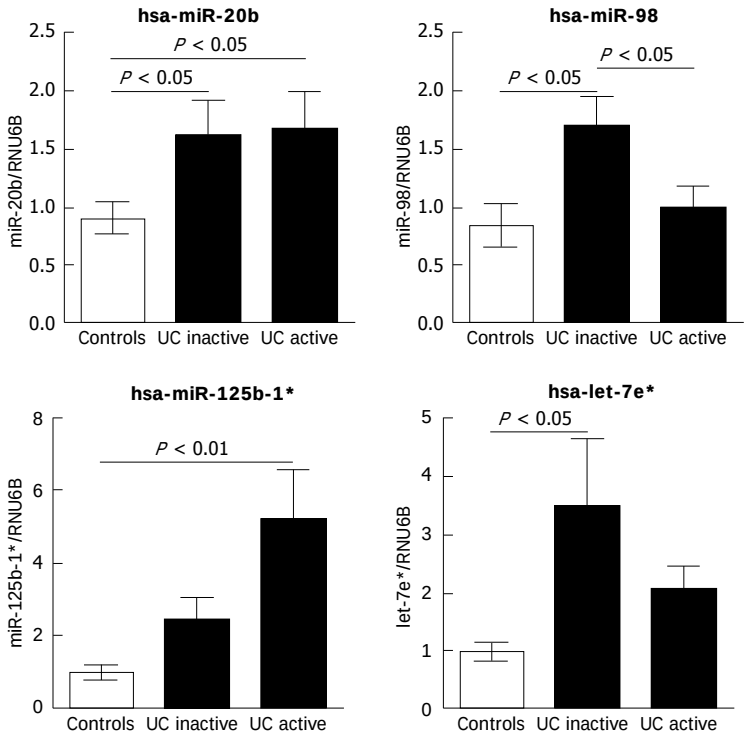

Figure 2 **Expression levels of four miRNAs in mucosal colonic biopsies were significantly up-regulated in ulcerative colitis.** Expression differences of miRNA in active ulcerative colitis (UC) (n = 20), inactive UC (n = 19), and controls (n = 20). Levels were determined using quantitative real-time polymerase chain reaction. Relative expression differences of each miRNA were normalized to endogenous RNU6B expression and calculated using the $2^{-\Delta\Delta CT}$ method. P value was calculated by Mann-Whitney U test and data are represented as medians with interquartile ranges.

several putative targets well known to be associated with the inflammatory response were revealed. For example, predicted target genes of miR-20b included interleukin-6 receptor (*IL-6R*), *IL-8, IL-10, REL* [a member of the nuclear factor (NF)-κB family], autophagy related 16-like 1 (*ATG16L1*), NOD-LRRs containing pyrin domain 3 (*NLRP3*), CASP8 and FADD-like apoptosis regulator (*CFLAR*), extracellular signal-regulated kinase 2 (*ERK2*), *p38-α* (MAP kinase), MAP kinase kinase kinase 1 (*MEKK1*), and signal transducer and activator of transcription 3 (*STAT3*). Putative target genes of miR-98 included *IL-8*, *IL-10*, toll-like receptor 4 (*TLR4*), *MEKK1, ATG16L1, CD95,* claudin-1 (*CLDN1*) and *STAT3*. Finally, miR-125b-1* and let-7e* were predicted to regulate genes such as, hepatocyte nuclear factor-1α (*HNF1α*) and *p38-α*, respectively.

The progress in gene discovery in complex disease genetics has increased with the genome-wide association studies (GWAS). Until recently, 99 IBD susceptibility loci were reported: 71 associated with CD, 47 with UC, and 28 with both CD and UC[39,40]. However, new IBD susceptibility loci were recently added bringing the total number of IBD loci to 163, most of which are associated with both CD and UC[41]. Thus, in order to identify which of the predicted miRNA targets that are actually reported as UC associated susceptibility genes, we used the web application BioVenn[42] (http://www.cmbi.ru.nl/cdd/biovenn/) to compare the list of the miRNA predicted target genes and UC associated susceptibility genes reported in the literature[40,41,43-45]. The UC associated predicted miRNA target genes have been illustrated in a Venn diagram (Figure 4). The four circles represent predicted miRNA targets found in the list of reported UC susceptibility genes. Interestingly, 25 of the miR-20b predicted targets were identified as UC associated susceptibility genes, and 14 miR-98 targets were found to be associated with UC, with 6 common target genes (Figure 4). Additionally, we found four UC associated target genes for miR-125b-1*, however, only one let-7e* target gene were predicted to be associated with UC susceptibility (Figure 4).

DISCUSSION

In recent years, miRNA profiling studies using tissue or blood samples from IBD patients have provided us with new ways to understand this otherwise enigmatic disease, and identifying differentially expressed miRNAs is a first step in the development of miRNA profile-based diagnostic tools.

Thus, in this study, using miRNA microarray profiling followed by qPCR analysis, we identified new miRNAs that were altered in patients with UC *vs* controls. Previous studies have demonstrated different mRNA expression profiles of mucosal colonic biopsies from IBD patients and healthy individuals[34,35,46,47]. Furthermore, Olsen *et al*[34] demonstrated that active and inactive UC could be distinguished from CD patients and controls. However, these studies could not differentiate between inactive CD and controls[34,48]. Similarly, in the PCA and PLS-DA scoreplots of miRNA expression profiles, we observed a clear separation of active and inactive UC patients from CD patients and controls. These results suggest that miRNA and mRNA profiles might follow the same pattern in UC patients and could be combined to differentiate between UC *vs* CD and controls in order to identify potential diagnostic biomarker panels. However, Wu *et al*[49] claimed to be able to discriminate active CD from controls using

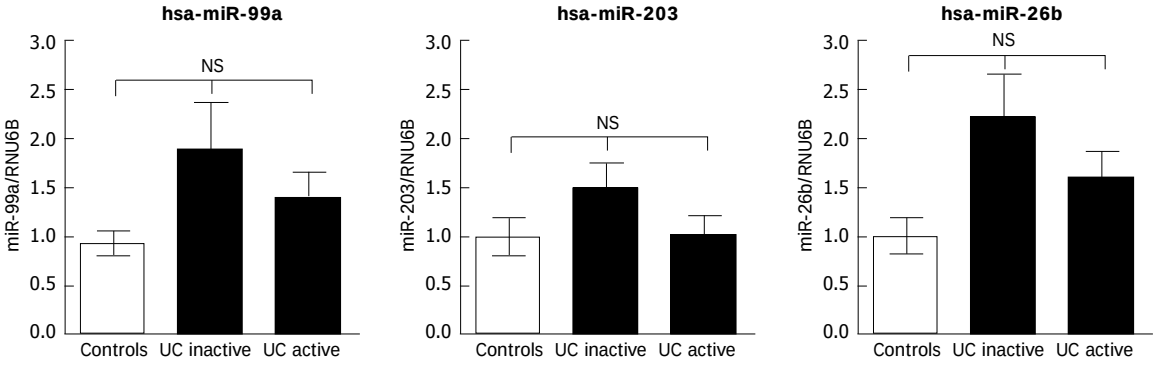

Figure 3 Expression of other miRNAs identified by microarray profiling. Expression differences of miRNA in active ulcerative colitis (UC) (n = 20), inactive UC (n = 19), and controls (n = 20). Levels were determined using quantitative real-time polymerase chain reaction. Relative expression differences of each miRNA were normalized to endogenous RNU6B expression and calculated using the $2^{-\Delta\Delta CT}$ method. NS: Not significant.

microarray analysis of intestinal biopsies, whereas other studies have mainly examined the expression of miRNAs by qRT-PCR analysis[27], which is inherently a much more sensitive technique than microarray[50]. When comparing our study with the study by Wu *et al*[49] there is, however, a striking difference in the miRNA microarray platforms used; Wu *et al*[49] used a miRNA microarray platform from NCode (Invitrogen, La Jolla, CA, United States) detecting about 470 unique human miRNAs, while we used a platform from Geniom Biochip miRNA (Febit) detecting almost 850 unique human miRNAs. Thus, the overall miRNA expression panel may possibly not follow the same pattern due to a dissimilar number of detected miRNAs in different arrays. Furthermore, the stringent significance and fold change criteria set by the current study might very well exclude subtle differences present in the expression profiles of patients with CD and controls. However, it cannot be excluded that the limited size of the microarray cohort as well as the medical therapy that each patient received also contributed to the inability to discriminate between groups.

Among the miRNAs with the strongest differential power from the microarray expression data we identified several differentially expressed miRNAs (such as miR-23a, miR-155, miR-16, miR-150, miR-346, and miR-126) previously reported to be associated with UC[36-38]. However, we also identified seven miRNAs (miR-20b, miR-99a, miR-203, miR-26b, miR-98, miR-125b-1*, and let-7e*) that were not previously reported to be involved in IBD[27]. Therefore, we focused on these seven new candidate miRNAs. The four significantly up-regulated human miRNAs (miR-20b, miR-98, miR-125b-1*, and let-7e*) identified in UC patients in the present paper contributes to the current knowledge of the roles of miRNAs in IBD. In particular, we show that miR-20b expression is increased in both active and quiescent UC as compared to controls. This could make miR-20b a potential biomarker to differentiate between controls and UC as it is not dependent on disease activity. Increased levels of miR-20b have been reported in human cancers including lung cancer, gastric cancer and leukemias where miR-20b facilitates cellular adaption to normoxia and hypoxia *in vitro* by regulating the transcription factor hypoxia-inducible factor 1-alpha[51]. Therefore, it is possible that miR-20b might be involved in the pathophysiology of colitis-associated colorectal cancer[52].

We also found miR-125b-1* to be significantly up-regulated in active UC. The miR-125 family has 2 mature isoforms: miR-125a and miR-125b (encoded by miR-125b-1 and miR-125b-2). Deregulated expression of miR-125 family members in various cancers has been reported[53-55]. Tili *et al*[56] has earlier demonstrated that miR-125b is of importance for the innate immune response, as lipopolysaccharide (LPS) stimulation of a murine macrophage cell line caused suppressed miR-125b levels. LPS is the principal component of bacteria in terms of pro-inflammatory properties as it activates the innate immune system through toll-like receptors to produce pro-inflammatory cytokines, including interferon-γ or tumor necrosis factor-α[57].

In the present study, we additionally found two let-7 miRNA family members, miR-98 and let-7e*, significantly altered in UC. MiR-98 was significantly up-regulated in

inactive UC compared to controls and active UC. Moreover, miR-98 has been reported to negatively regulate the anti-inflammatory cytokine, IL-10, production in macrophages - an important factor in the immune response that protects the host from excessive inflammation[58]. Additionally, a recent study has revealed that miR-98 targets the Fas-receptor mRNA, and decreases Fas-mediated apoptosis[59]. The increased expression of miR-98 could explain the attenuated Fas-mediated cell death response of lamina propria T-cells in IBD[60]. This resistance of mucosal T-cells to Fas-mediated apoptosis might explain the sustained mucosal inflammation seen in IBD[61].

In accordance with the microarray data, we found significantly increased let-7e* levels in inactive UC when compared to healthy individuals. The let-7 family of miRNAs is highly conserved across diverse animal species from worms to humans, and plays important roles in the regulation of cell proliferation and differentiation[62]. Humans have ten mature let-7-family sequences that are produced from 13 precursor sequences[63]. Most of the human *let-7* genes map to regions altered or deleted in human tumours[64], and are reported to be down-regulated in various cancerous conditions[65,66]. In addition to cancer, an altered expression of let-7 has been reported in inflammation. In allergic airway inflammation, administration of let-7 mimic to mice represses IL-13 production and reduces the inflammation[67]. Furthermore, other let-7 family members than let-7e* described in this study have previously been linked to IBD. Wu *et al*[36] found let-7f differentially expressed in the intestinal tissue of active UC patients when compared to controls, and Zahm *et al*[68] found higher concentrations of let-7b miRNA in sera of pediatric CD patients *vs* controls. It has been reported that there is a regulatory interaction between NF-κB activation and expression of let-7 members[69-72], which suggests a significant importance for the pathogenesis of IBD. Let-7 miRNAs has also been demonstrated to be repressed in inflammation, which result in increased expression of pro-inflammatory cytokines and enhanced inflammatory responses[72].

The miRNAs described and analyzed in the present study were initially selected based on the microarray results. The subsequent validation procedure using qPCR resulted in partial discrepancy between the microarray and qPCR results. This was, however, to be expected as correlation coefficients between microarray and qPCR assays have been found to be as low as 0.4[73], and just substantiates the microarray technology as a hypothesis generating tool and illustrates the importance of verifying microarray expression data.

Another challenge in miRNA research is the identification of genes regulated by miRNAs. One common method to address this challenge is by predicting targets by computer algorithms. Through *in silico* predictions we identified multiple potential miRNA targets in the inflammatory response well-known to be associated with UC. Interestingly, the most target genes were associated with the mitogen-activated protein kinase pathway and cytokine signaling, which are important key signaling pathways in IBD[74]. These findings further suggest that the miRNA molecules found in this study may have a pivotal influence on the clinical course of IBD.

In conclusion, this study contributes to the current knowledge on the putative role of miRNAs in IBD pathogenesis, and it provides the first evidence that miR-20b, miR-98, miR-125b-1*, and let-7e* are deregulated in patients with UC. The level of these miRNAs may serve as new potential biomarkers for this chronic disease. However, this area of research is in its infancy, and studies in the field of IBD need to identify all of the miRNAs that are consistently deregulated in IBD.

We thank Anne Hallander, Anni Petersen, Birgit Deibjerg Kristensen, Hanne Fuglsang, Vibeke Voxen Hansen, and Lotte Laustsen for excellent technical assistance.

COMMENTS

Background

MicroRNAs (miRNAs) are small, non-coding single-stranded RNA molecules that regulate the expression of target genes and are involved in many cellular and physiological mechanisms. The discovery of miRNAs in inflammatory bowel disease (IBD), particularly their role in cell signaling, offers a novel way of understanding this chronic disease and gives rise to new potential diagnostic tools and therapeutic strategies. In this paper, the authors identified new potential miRNA biomarkers in ulcerative colitis (UC).

Research frontiers

The pathogenesis of IBD remains largely unknown, but involves a complex interaction between genetic, environmental, and immunological factors. However, to date, there are still no ideal methods to asses the severity of inflammation and to differentiate between UC and Crohn's disease (CD). In this context, research on miRNAs is a promising new research, providing novel insights into the pathogenesis of IBD, biomarker identification, and treatment. Thus, there is great promise that miRNAs will aid in the early diagnosis of IBD, and in the development of more targeted, personalized therapies.

Innovations and breakthroughs

Recent reports have highlighted the importance of using miRNAs in IBD pathogenesis, diagnostics and therapeutics. Through microarray-based miRNA profiling of colonic mucosal biopsies from patients with UC, CD, and controls, the authors found that the expression of miR-20b, miR-98, miR-125b-1*, and let-7e* was upregulated in patients with UC. This is the first study to report that these four miRNAs may serve as potential biomarkers for UC.

Applications

The present study suggest that miR-20b, miR-98, miR-125b-1*, and let-7e* levels are deregulated in patients with UC. The level of these miRNAs may serve as new potential biomarkers for this chronic disease.

Peer review

The authors analyzed the miRNA expression in IBD patients and healthy individuals in order to identify new potential miRNA biomarkers in IBD using miRNA microarray profiling of colonic mucosal biopsies. Among the most differentially expressed miRNAs, the authors found that the levels of miR-20b, miR-98, miR-125b-1*, and let-7e* were specifically upregulated in patients with UC. These data are quite important and may help to clarify the complex pathogenesis of UC and further suggest that the level of these miRNAs may serve as new potential biomarkers for this disease.
