The Authors summarize problems, criticisms but also advantages and indications regarding the recent surgical proposal of associating liver partition and portal vein ligation (PVL) for staged hepatectomy (ALPPS) for the surgical management of colorectal liver metastases. Looking at published data, the technique, when compared with other traditional and well established methods such as PVL/portal vein embolisation (PVE), seems to give real advantages in terms of volumetric gain of future liver remnant. However, major concerns are raised in the literature and some questions remain unanswered, preliminary experiences seem to be promising. The method has been adopted all over the world over the last 2 years, even if oncological long-term results remain unknown, and benefit for patients is questionable. No prospective studies comparing traditional methods (PVE, PVL or classical 2 staged hepatectomy)

with ALPPS are available to date. Technical reinterpretations of the original method were also proposed in order to enhance feasibility and increase safety of the technique. More data about morbidity and mortality are also expected. The real role of ALPPS is, to date, still to be established. Large clinical studies, even if, for ethical reasons, in well selected cohorts of patients, are expected to better define the indications for this new surgical strategy.

**Key words:** Portal ligation; *In situ* split; Liver resections; Colorectal metastases; Liver metastases

**Core tip:** The recent publication by Regensburg's Group on the new technical possibility of associating liver partition and portal vein ligation for staged hepatectomy for the surgical managing of bilateral colorectal liver metastases, generated a great debate and a burst of publications about preliminary experiences from many groups all over the world. As one of the first groups in Germany to adopt this technique, in the present article we clarify some aspects of our experience in the light of published data and raised concerns.

### INTRODUCTION

The progressive enlargement of surgical indications to colo-rectal liver metastasis (CRLM) resection of the last 20 years has led to a redefinition of resectability criteria<sup>[1]</sup>. Nowadays no limits due to number of lesions and

**Figure 1** Example of strategy using a semi-automated 3D volumetry system. Hepavision® MEVIS. A: 3D volumetry before associating liver partition and portal vein ligation for staged hepatectomy (ALPPS): future liver remnant (FLR) 26%; B: Two weeks after ALPPS volumetry of FLR: 43% (increase of 65%).

location are of value as in the past<sup>[2]</sup>. The main problem for resectability criteria of CRLM is due to volume of future liver remnant<sup>[3]</sup>, in fact, postoperative liver failure is one of the biggest risk and a significant complication after extended hepatectomy<sup>[4]</sup>. Some techniques were established such as portal vein ligation (PVL) and portal vein embolisation (PVE) with well known advantages and limits. Also 2 stage combined strategies were developed to overcome resectability problems due to bilobar location of metastases and two-staged hepatectomy has been reported as an efficient strategy for oncological outcomes and has been adopted by many liver centers<sup>[5,6]</sup>. A real novelty on 2 staged surgical procedures that has recently been proposed, is the advent of associating liver partition and PVL for staged hepatectomy (ALPPS)<sup>[7]</sup>. The technique was first performed by Schlitt *et al.*<sup>[8]</sup> of Regensburg in 2007 and first presented to a German Congress in 2010. After that the technique spread all over the world<sup>[9]</sup>. This is rapidly gaining great interest from the surgical community leading to debate<sup>[10]</sup> and even proposals for a reinterpretation of methods<sup>[10-12]</sup>, and giving a new hope to a large number of patients traditionally judged unresectable<sup>[13]</sup>. Despite an “explosion” of publications and case reports in the literature during the last 2 years, a lot of questions remain concerning safety and effectiveness of this method<sup>[14]</sup>. Given the large amount of surgical experience world wide<sup>[15]</sup>, and the critical appraisals of some surgical groups, in the present article we would like to summarize the main sur-

gical aspects, open questions and express our point of view on this method in the light of our preliminary experience<sup>[16]</sup> and other published data, in the era of two-stage treatment of CRLM<sup>[17]</sup>.

## TECHNICAL ASPECTS AND DEVELOPMENT

The first aim of introducing this technique by Regensburg's group was to enhance liver hypertrophy after portal ligation increasing the ischemia effect on future liver remnant (FLR)<sup>[16]</sup>. The concept on which this technique is based seems to be an old finding<sup>[18]</sup>, but of course revisited and reinvented or recombined in the light of new problems of CRLM surgery<sup>[19]</sup>. The assumption is that any closure of the right portal branch is followed by a reactive perfusion of “deportalized” liver, from contralateral one, through the intrahepatic branches and collaterals presents between the 2 lobes<sup>[20]</sup>. This aspect was recently confirmed by a clinical study<sup>[21]</sup>.

The technique consists in an association of classical right portal branch ligation together with liver parenchyma surgical split. The split could be conducted following the falciform ligament line (splitting segment 2-3 from the rest of the liver) as originally described<sup>[7]</sup>, or even atypically adding 4b segment as previously shown in our video<sup>[22]</sup>. To split the liver avoiding manipulation and obtaining a better bleeding control, such as a clear anatomic line of parenchymal transection, we usually perform an anterior approach<sup>[23]</sup>. Between the right and left split hemilivers a plastic sheet or bag should be positioned in order to avoid cicatrization with the disappearance of the resection line. In addition some atypical resection of additional metastases (1 or 2) in the future liver remnant must be performed. We have extended the indication to ALPPS also for bilateral CRLM with little FLR (< 30%) or even < 40% with damaged liver parenchyma; and during the first step of the procedure we resect metastases on FLR. Other groups used more restricted indications reserving ALPPS only for patients without metastases on FLR<sup>[7]</sup>.

In the original description the Authors waited for about 8-10 d before performing the 2<sup>nd</sup> step of specimen removal<sup>[7]</sup>. Other Authors usually wait 7 d<sup>[24]</sup>, while our group usually performs the 2<sup>nd</sup> step after 12 d. A computed tomography (CT) scan after 1<sup>st</sup> step, in 7-10 d, is mandatory in order to evaluate volumetric gain. We routinely use 3D-reconstruction and Volumetry performed by MEVIS® system using Hepavision® software<sup>[22]</sup> (Figure 1). The key role of CT-volumetry with 3D-reconstructions for this novel method was later confirmed by another study<sup>[25]</sup>. This technique showed that the speed of hypertrophy and also the percentage of volume gain were more enhanced than with classical methods such as PVE or PVL<sup>[7]</sup>.

Some technical variants were quickly introduced by some surgeons. Some authors, in fact, proposed the laparoscopic approach<sup>[11,26]</sup>, citing some advantages of lapa-

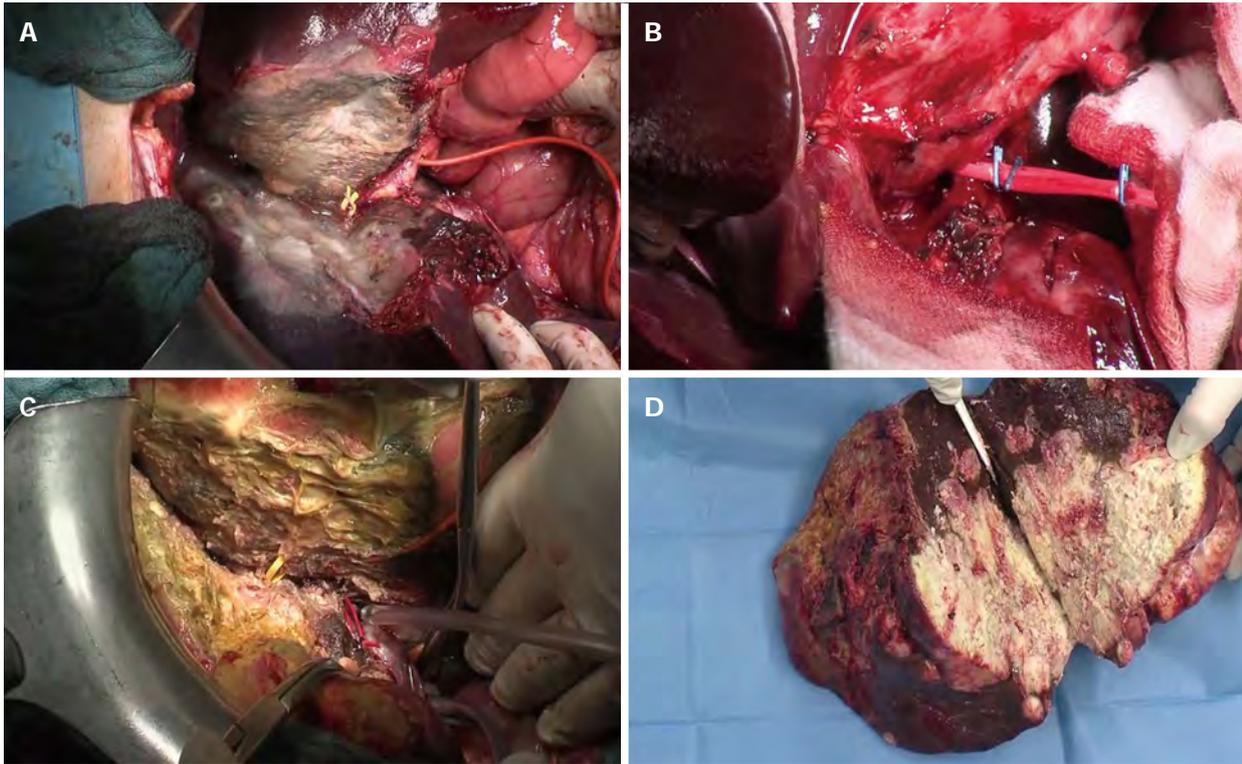

Figure 2 Intraoperative images of associating liver partition and portal vein ligation for staged hepatectomy in our center. A, B: 1<sup>st</sup> Step procedure with apposition of colored loop (red for the right hepatic artery, yellow for the right hepatic duct) and of T-drainage. C, D: Easy identification of loops during the second step and opened specimen of R0-resection of colo-rectal liver metastasis.

roscopy in avoiding adhesions thus making the 2<sup>nd</sup> step easier<sup>[27]</sup>. Even if ALPPS was developed for extended right hepatectomy, 3 main strategies were recently standardized to use ALPPS not only for right hepatectomies but even for extended left hepatectomies<sup>[28]</sup>.

We proposed the following technical modifications in addition to referred routine use of 3D-reconstruction in order to improve the safety of the procedure: (1) Do not use the plastic bag or sheet but interpose only a fibrillar mesh (Figure 2A); (2) Use of a colored plastic loop to leave *in situ* for the 2<sup>nd</sup> step (yellow for right biliary duct and red for hepatic artery) in order to find it very easily and quickly during the challenging 2<sup>nd</sup> step (Figure 2B and C); and (3) Routine use of T-drain in order to reduce the risk of biliary leak and biomass (main referred surgical complication after preliminary reports (Figure 2B and C). Additionally we enhanced the significance of complete liver mobilization (apparently in contradiction with the anterior approach!) as previously described as a preliminary maneuver of surgical step 1, that in this technique, in our opinion, is of value not only for a complete manual and ultrasonography exploration of both lobes, but also to enhance the ischemia effect, avoid collateralisation through ligaments' vessels and increase the hypertrophy effect of ALPPS. On the other hand some surgeons criticized<sup>[10,15]</sup> the technique, questioning: complexity of procedure, high risk of 2 very close big operations, additional morbidity and reported mortality, and uncertainty of long-term oncological results. If detractors have made

some logical considerations about the proposed method, also enthusiasts of ALPPS have been engaged in reporting positive results<sup>[11,16,17]</sup>. It should be underlined that some of the most talented surgeons use ALPPS<sup>[9]</sup>, testifying to the potential of this technique, trying to find the best indications (Table 1).

We have also expressed some considerations related to our preliminary data in a previous article<sup>[16]</sup>, however, the ideas and criticisms raised during this last year convinced us to introduce, in this debate, some other considerations.

## PUBLISHED EXPERIENCE

First of all it should be taken into consideration that ALPPS is mainly indicated for patients that have to undergo a right trisegmentectomy. This extended liver resection is known to be at particular risk of postoperative liver failure<sup>[4]</sup>, the combination in a 2 staged procedure is forced in these patients by a judgment of not resectability with other established 2 stage surgical strategies<sup>[29-31]</sup>. Therefore this cohort of patients is "*per se*" a group of very sick patients with advanced disease, traditionally not resectable CRLM and therefore destined for palliative treatment. The novelty of this method is the percentage gain of patients to resectability. Thus we are convinced that the questionable additional risk related to the technique could be acceptable in the light of resectability gain. Doubtless, also other one stage combined proposed

**Table 1** Associating liver partition and portal vein ligation for staged hepatectomy: an overview of worldwide experience

Author	Cases (n)	Hypertrophy (range)	Days of interval (range)	Morbidity	Mortality

<sup>1</sup>Data referred only to one case.

strategies could be taken into account in selected groups of patients<sup>[32]</sup>. However, very aggressive chemotherapeutic regimens, in many cases, are nowadays forcing surgeons to find new technical solutions, sometimes delaying radical treatment in order to achieve patients' safety. We also think that the potential of ALPPS was wrongly judged by some eminent colleagues only because it was tested on very challenging indications (duodenocephalopan-creatotomy and extended hemihepatectomy for biliary tract tumors)<sup>[15]</sup> leading to high morbidity and mortality rates. We expressed our opinion that the main indication for ALPPS seems to be for CRLM in selected patients, as stated in other papers<sup>[16]</sup>. In patients affected by bilateral CRLM, the proposed method regained resectability also in apparently not resectable patients, increasing safety of resection and lowering risk of postoperative liver failure, enhancing, in a very short time (average about 7 d), the great hypertrophy potential of liver parenchyma. Undoubtedly ALPPS, compared to traditional PVE or PVL, allows a tremendously quick FLR growth (22% *vs* 3% growth the day after the procedure)<sup>[16]</sup>. Of course our previous considerations should be considered in the light of no published long-term oncologic results. In consideration of the right moment to resect after split, this aspect should be carefully taken into account in patients submitted to several cycles of neoadjuvant chemotherapy. As we demonstrated in a previous publication, a long wait (about 4 wk) after split can allow a volumetric gain of 200%, but with the disadvantage of a more difficult second surgical step<sup>[23]</sup>. It is foreseeable that with the rapid diffusion of new neoadjuvant chemotherapeutic regimens (chemo first approach), the need for ALPPS, as a safe alternative strategy to the classic 2 stage approach, will increase; in fact, more patients are gaining, and will gain, resectability due to partial or sometimes full response to new chemotherapeutic protocols<sup>[33,34]</sup>. Thus a multidisciplinary approach of CRLM<sup>[35]</sup>, starting with aggressive neoadjuvant regimen, under indications of institutional tumor boards, will push more patients to ALPPS. On the other hand, ALPPS makes the resection safer after neoadjuvant chemothera-

py, reducing the risk of postoperative liver failure.

## OPEN QUESTIONS

Even with the big enthusiasm for this technique and surge in the number of centers adopting it over the last 2 years, even in an episodic manner, leading to a lot of case reports<sup>[36-38]</sup>, some considerations must be made. First of all we should consider that the method has not yet been tested in an evidence based manner, only preliminary experience is available, publishing dishomogeneous data. Even the technique has not yet been standardized. The big question is if oncologic long-term results are acceptable, if a gain, in terms of quality of life and time gained, could balance the big risk of complications and mortality. Whether the stimulation of liver hypertrophy could also accelerate tumor progression is also an open question still debated since the time of classic PVE, PVL techniques<sup>[39]</sup>. Recently, Van Gulik's group has shown how tumor progression could clearly be stimulated by PVE only<sup>[40]</sup>, reporting the objections about the short time-frame of ALPPS among speculations, because the same phenomenon is observed in PVE and PVL<sup>[41]</sup>. Even a study by Pamecha *et al*<sup>[42]</sup> first experimentally and then confirmed by Maggiori *et al*<sup>[43]</sup>, showed a clear tumor progression after PVE so that about one third of patients cannot undergo the second step after embolization because of tumor progression. Obviously one could speculate that if ALPPS allows a bigger and quicker liver regeneration, the same stimulation could realize an intensive and quicker tumor progression. An early recurrence was occasionally reported among disomogeneous published experiences<sup>[7]</sup>, but more data are expected in the next years and of course also results of international register.

If CRLM is to be considered the best indication in other tumours (for example Neuroendocrine tumor metastases) with slower biology and tumor progression, patients could benefit from such a method, this remains one of the main questions. Thus the great advantage of volumetric gain must be taken with the above mentioned

open questions before establishing the method in clinical practice. The method remains very challenging and not only for liver surgeons, but for extremely skilled liver centers and must be approached in a multidisciplinary manner. More effort must be made to reduce the morbidity and mortality associated with ALPPS.

Of course it must be taken into consideration that some other established methods of obtaining FLR hypertrophy are less risky and whenever possible should be the first choice in planning staged surgical strategies<sup>[44]</sup>. Nevertheless, also if PVE is, to date, the most used technique and considered the standard procedure to enhance FLR, about 30% of patients never undergo complete resection because of insufficient hypertrophy or tumor progression on FLR. Furthermore, as in a recent systematic review the two stage hepatectomy with traditional strategies has shown an certain morbidity, that appears comparable with the morbidity of ALPPS (17% after first step and 40% after the second one)<sup>[6]</sup>. Therefore, in well selected cases, in limit-cases, or when PVE failed to gain volumetric enhancement of FLR<sup>[17,45]</sup>, sometimes ALPPS seems to be the only reasonable-feasible option to achieve resectability. The additional morbidity and mortality referred in the bigger reports respectively up to 44% and 12% could be accepted as additional risks only in the light of “no other choices”, even if we need more scientific studies to confirm this. Furthermore, it should be taken into account that reported high mortality rates are referred to very initial experiences in very small groups of patients, in which also 1 death strongly influences overall mortality rates. However, also 3<sup>rd</sup> referral hepatobiliary centers need a learning curve to optimize the procedure. Some proposed technical details could reduce the “surgical risk” also shortening the time of the second procedure<sup>[15]</sup>. Due to ethical limits to clinical experimentation and the difficulty in recruiting a reasonable group of highly selected patients, an online world register was created (see international register: [www.alpps.net](http://www.alpps.net)). Some detractors of ALPPS have recently published a study comparing traditional PVE efficacy and safety compared with published data on ALPPS, concluding to be in favour of traditional and well established strategies<sup>[46]</sup>. However, despite confirming that PVE and similar techniques are still the standard of care, the referred study suffers from some BIAS in comparison, therefore conclusions are not well addressed by the study and a definitive conclusion cannot be made. The challenge of the ongoing study will be, despite the BIAS of patient collection from many different centers, to establish some kind of evidence of safety (as declared by many authors and criticized by others), usefulness (long-term oncologic results), best indications, and in our opinion also guidelines to standardize the preoperative flow-chart, surgical timing and steps. It is foreseeable that ALPPS could gain a position also among feasible surgical strategies for the complex scenario of Klatskin tumours<sup>[47,48]</sup> in order to extend the resectability rate as we stated in a previous article<sup>[16]</sup>, and as confirmed by recently reported experiences<sup>[35,49]</sup>. Despite all the potential of this technique, to

date the scientific evidence should be still considered as a phase 1 clinical trial; we believe that the method, in consideration of all the above mentioned open questions at the moment, should be adopted only by extremely well-trained and experienced Hepatobiliary Surgical Centres.

## CONCLUSION

The problems on the table are many and the technique needs to be defined, maybe first on acceptable indications and long-term results, in order to achieve the current position of ALPPS not only in the surgical management of CRLM, but also in its greater potential to treat other liver tumours. Therefore, in conclusion, we think that the ALPPS proposal should be considered the “real novelty” in the CRLM surgical landscape of the last 3 years and despite the enthusiastic view to “change the face of liver surgery” as suggested by other Authors<sup>[10]</sup>, we prefer to say that it is foreseeable that such a method will gain, after the physiological period of experimentation and publication of the first large clinical studies, an important position among the surgical strategy options for the surgeon managing bilateral colorectal liver metastases, even maybe for a restricted and well-selected subgroup of patients.

### Abstract

Perineural invasion (PNI) in pancreatic cancer is an important cause of local recurrence, but little is known about its mechanism. Pleiotrophin (PTN) is an important neurotrophic factor. It is of interest that our recent experimental data showed its involvement in PNI of pancreatic cancer. PTN strongly presents in the cytoplasm of pancreatic cancer cells, and high expression of PTN and its receptor may contribute to the high PNI of pancreatic cancer. Correspondingly, PNI is prone to happen in PTN-positive tumors. We thus hypothesize that, as a neurite growth-promoting factor, PTN may promote PNI in pancreatic cancer. PTN is released at the time of tumor cell necrosis, and binds with its high-affinity receptor, N-syndecan on pancreatic nerves, to promote neural growth in pancreatic cancer. Furthermore, neural destruction leads to a distorted neural homeostasis. Neurons and Schwann cells produce more N-syndecan in an effort to repair the pancreatic nerves.

However, the abundance of N-syndecan attracts further PTN-positive cancer cells to the site of injury, creating a vicious cycle. Ultimately, increased PTN and N-syndecan levels, due to the continuous nerve injury, may promote cancer invasion and propagation along the neural structures. Therefore, it is meaningful to discuss the relationship between PTN/N-syndecan signaling and PNI in pancreatic cancer, which may lead to a better understanding of the mechanism of PNI in pancreatic cancer.

**Key words:** Pleiotrophin; N-syndecan; Neurite outgrowth; Perineural invasion; Pancreatic cancer

**Core tip:** We discussed the important novel role of pleiotrophin (PTN) in perineural invasion (PNI) of pancreatic cancer, an important cause of local recurrence. Our recent experimental data demonstrated the involvement of PTN in PNI of pancreatic cancer. PTN strongly presents in the cytoplasm of pancreatic cancer cells, and high expression of PTN and its receptor may contribute to the high PNI of pancreatic cancer.

### INTRODUCTION

Pancreatic cancer is one of the most malicious human malignancies with the lowest 5-year survival rate<sup>[1-3]</sup>. At the time of diagnosis, most patients have locally advanced disease and/or distant metastatic lesions precluding radical operation resection<sup>[3-5]</sup>. Perineural invasion (PNI) is considered as an important factor of aggressive tumor

behavior, and it is associated with local recurrence and poor outcome of pancreatic cancer<sup>[6]</sup>. Pancreatic cancer cells frequently have intimate contact with intrapancreatic nerves and thereby alter, invade, and damage the intrapancreatic nerves<sup>[7]</sup>. PNI extending into the extrapancreatic nerve plexus is a histopathologic characteristic in pancreatic cancer, which leads to abdominal pain and retropancreatic tumor extension<sup>[8-10]</sup>. PNI is defined as presence of cancer cells within the epineural, perineural, and endoneurial spaces of the neuronal sheet and around the nerves<sup>[11,12]</sup>. It precludes curative resection, promotes local recurrence, and finally negatively influences the prognosis of the patients. However, the mechanisms of the alteration and invasion of pancreatic nerves and the spread of cancer cells along pancreatic nerves in pancreatic cancer remain poorly understood. Therefore, neurotrophic factors are of interest because recent experimental data showed their involvement in neuro-cancer interactions in pancreatic cancer<sup>[13]</sup>.

## MECHANISM OF PNI IN PANCREATIC CANCER

The mechanism of PNI in pancreatic cancer is unclear, although it can be partially explained by the anatomical proximity of the pancreatic and celiac artery neural plexus. The perineurium is believed to be deficient near the nerve ending, at the site invaded by the blood vessels in the nerves, and at the site invaded by reticular fiber<sup>[14]</sup>. Another possible explanation of PNI in pancreatic cancer is neurotropism because some advanced cancers with PNI express numerous types of neuroendocrine markers including S-100, Synaptophysin, substance P, enkephalin, and neural cell adhesion molecules<sup>[15]</sup>. Other specific factors such as nerve growth factor also enhance the cancer-nerve interaction, providing biological and physical parameters that would explain their frequent and intimate relationship<sup>[16]</sup>.

## PLEIOTROPHIN-CANCER INTERACTION

Pleiotrophin (PTN) is a neurotrophic factor, also known as the neurite growth-promoting factor. The protein is mainly expressed during early embryogenesis. In human adult tissues, it is markedly down-regulated and present only at minimal levels in very few tissues. PTN is a 136-amino-acid long secreted cytokine related to diverse biological properties, including neurite outgrowth, angiogenesis, and tumor growth<sup>[17,18]</sup>. It is strongly expressed in different human tumor cells, and expression of the PTN gene in tumor cells *in vivo* accelerates growth and stimulates tumor angiogenesis<sup>[19,20]</sup>. Experimental evidence from different laboratories also supported the potential of PTN to play an important role in promotion of human tumors. PTN transcripts are highly expressed in a high proportion of different human tumor samples, including pancreatic cancer, breast carcinoma, melanocytic tumor, carcinoma of the prostate, glioblastoma, and astrocytomas<sup>[21-25]</sup>. Cell

lines derived from these tumors have constitutive activation of the endogenous *PTN* gene, while PTN expression is not detected in non-tumor cell lines of the same origin and in the non-tumorous tissues<sup>[26]</sup>.

## ASSOCIATION BETWEEN PTN AND PANCREATIC CANCER

PTN is not expressed in normal pancreatic tissues, but it is highly expressed in pancreatic cancer tissues and correlates with pancreatic cancer progression<sup>[27]</sup>. In previous experiment, we studied PTN and its receptor N-syndecan protein levels in 38 patients with pancreatic cancer by immunohistochemistry, analyzed for its correlation with clinicopathological features, PNI, and prognosis. The results suggested that PTN was strongly present in the cytoplasm of pancreatic cancer cells; N-syndecan was intensely present in the perineurium of pancreatic nerves but not in the cancer cells. PTN combined with N-syndecan might have contributed to the high level of PNI and poor prognosis of pancreatic cancer<sup>[28]</sup>. Furthermore, tissue expression of PTN resulted in its elevated serum levels in more than 50% of the pancreatic cancer patients, and a statistically significant positive association was found between elevated serum levels of PTN at the time of surgery and its expression by tumors<sup>[27]</sup>. In both mice and humans, serum PTN levels dropped after successful tumor removal, suggesting that PTN may represent a new tumor marker in pancreatic malignancies.

## PTN-NERVE INTERACTION

PTN was initially isolated from neonatal rat brain as a neurite outgrowth-promoting protein. Previous studies have demonstrated that N-syndecan acts as a receptor in PTN-induced neurite outgrowth in perinatal rat brain neurons<sup>[29]</sup>. N-syndecan-stably-transfected N18 neuroblastoma cells showed clearly enhanced neurite outgrowth upon contact with PTN-containing substrate. PTN and N-syndecan utilize the cortactin-src pathway for the intracellular signaling in neurite outgrowth<sup>[30]</sup>.

PTN promoted neurite outgrowth from different cultured neuronal cell types, including cultures of embryonic and perinatal cortical neurons, neuroblastoma cells, and PC12 cells<sup>[31]</sup>, and anti-PTN antibodies inhibited neurite outgrowth *in vitro*<sup>[29]</sup>. The addition of PTN to donor cells resulted in better functional recovery and better survival of dopaminergic neurons, owing to the decrease of cell death after transplantation<sup>[32]</sup>. The results revealed that PTN had effects on donor cells in neural transplantation both *in vitro* and *in vivo*. In adult animals, PTN expression was lower but increased during recovery from injury, playing a major role in the cell growth and differentiation associated with tissue regeneration. A higher PTN level was noticed in sciatic nerves within a few days after crush injury when axon regrowth was induced, whereas PTN level was lowered after the axons reached their target<sup>[33]</sup>. The increased PTN protein levels during the first step of

peripheral nerve regeneration suggested time-restricted synthesis of PTN within the injured nerve. These results suggested that PTN may be involved in peripheral nerve regeneration after the nerve injury.

PTN and N-syndecan act as a ligand-receptor pair in neurite outgrowth<sup>[34]</sup>. It is possible that PTN and its receptor act synergistically to promote PNI in pancreatic cancer. Our previous experiments also showed that recombinant adenovirus-mediated PTN-shRNA successfully silenced *PTN* gene expression in pancreatic cancer cells, and the neurite outgrowth of dorsal root ganglion neurons was evidently inhibited by knocking down the PTN protein<sup>[35,36]</sup>.

## CONCLUSION

Previous studies described the importance of individual neurotrophic factor in PNI in pancreatic cancer<sup>[37]</sup>; however, the mechanism of PNI was not clarified explicitly. Former studies of PTN focused on angiogenesis, neuritis outgrowth, and tumor growth<sup>[38,39]</sup>. There was no relevant report about the association between PTN and PNI in human tumors. Interestingly, elevated PTN expression has been found to be an essential autocrine and paracrine factor for various human malignancies, including pancreatic cancer, breast carcinoma, melanocytic tumor, carcinoma of the prostate, and astrocytomas<sup>[40]</sup>. Correspondingly, PNI is also prone to happen in these PTN-positive tumors. Therefore, we hypothesize that, as a neurite growth-promoting factor, PTN and N-syndecan act synergistically to promote PNI in pancreatic cancer. PTN is an important factor of the induction of neurite outgrowth, survival of neurons, and peripheral nerve regeneration under pathological conditions<sup>[30,31,41]</sup>. PTN is released at the time of tumor cell necrosis and binds with its high-affinity receptor, N-syndecan on pancreatic nerve, to promote neurite growth in pancreatic cancer. Furthermore, in pancreatic cancer, cancer cells infiltrate and destroy the perineurium of pancreatic nerves, and the neural destruction leads to a distorted neural homeostasis. Neurons and Schwann cells produce more N-syndecan in an effort to repair the pancreatic nerves. However, the abundance of N-syndecan further attracts PTN-positive cancer cells to the site of injury, creating a vicious cycle. Ultimately, increased PTN and N-syndecan levels, due to the continuous nerve injury, may promote cancer invasion and propagation along the neural structures.

## FUTURE IMPLICATION

Pancreatic cancer is characterized by PNI, early lymph node metastasis, and poor prognosis. PNI is an important cause of local recurrence, but little is known about its mechanism. It is meaningful to discuss the relationship between PTN/N-syndecan signaling and PNI in pancreatic cancer, which will probably lead to a better understanding of the mechanism on PNI. Considering

that the production of inhibitors for PTN and N-syndecan is at the stage of laboratory trials, we believe that such study has significant translational potential. Due to the unclear mechanism, it is difficult to improve or apply gene therapy targeting the possible candidate cancer genes. Therefore, understanding the relationship between PTN/N-syndecan signaling and PNI may contribute to an improved therapy of PNI in pancreatic cancer. In further studies, we will silence the *Ptn* gene in orthotopic pancreatic cancer model in nude mice using recombinant adenovirus-mediated PTN-shRNA, and investigate the effects of PTN on PNI of pancreatic cancer.

### Abstract

**AIM:** To investigate the effects of photodynamic therapy with quantum dots-arginine-glycine-aspartic acid (RGD) probe as photosensitizer on the proliferation and apoptosis of pancreatic carcinoma cells.

**METHODS:** Construction of quantum dots-RGD probe as photosensitizer for integrin-targeted photodynamic therapy was accomplished. After cells were treated with photodynamic therapy (PDT), the proliferation of SW1990 cells were measured by methyl thiazolyl tetrazolium assay. Morphologic changes, cell cycle retardance and apoptosis were observed under fluoro-

scope and flow cytometry. The expression of myeloid cell leukemia-1 (Mcl-1), protein kinase B (Akt) and tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) mRNA were detected by reverse transcription-polymerase chain reaction. The amount of reactive oxygen species were also evaluated by fluorescence probe.

**RESULTS:** The photodynamic therapy with quantum dots-RGD probe as photosensitizer significantly inhibited cell proliferation ( $P < 0.01$ ). Apoptotic cells and morphologic changes could be found under optical microscope. The FCM revealed PDT group had more significant cell apoptosis rate compared to control cells ( $F = 130.617, P < 0.01$ ) and cell cycle  $G_0/G_1$  and S retardance ( $P < 0.05$ ) compared to control cells. The expression of Mcl-1 and Akt mRNA were down-regulated, while expression of TRAIL mRNA was up-regulated after cells treated with PDT. PDT group had more significant number of cells producing reactive oxygen species compared to control cells ( $F = 3262.559, P < 0.01$ ).

**CONCLUSION:** The photodynamic therapy with quantum dots-RGD probe as photosensitizer significantly inhibits cell proliferation and increases apoptosis in SW1990 cells.

**Key words:** Pancreatic carcinoma; Targeted probe; Photodynamic therapy; Apoptosis; Reactive oxygen species

**Core tip:** Arginine-glycine-aspartic acid (RGD), sequence of small peptide, is an integrin antagonist. Quantum dots are characterized by conjugation with antibodies, peptides, or small molecules. Therefore, the construction of RGD-coupled quantum dots fluorescence probe allows for successful combination to integrin. Photodynamic therapy with a quantum dots-RGD probe, as a photosensitizer, significantly inhibits cell proliferation and increases apoptosis in SW1990 cells.

## INTRODUCTION

Pancreatic adenocarcinoma ranks as the fourth most common cause of cancer death in the United States. Patients usually present late with advanced disease, limiting attempted curative surgery to 10% of cases. Overall prognosis is poor with one-year survival rates of less than 10% with palliative chemotherapy and/or radiotherapy<sup>[1-3]</sup>. Given these dismal results, a minimally invasive treatment capable of local destruction of tumor tissue with low morbidity may have a place in the treatment of this disease. The photodynamic therapy is a treatment that has high specificity, minimal invasiveness and good cosmetic outcome, which produces local necrosis of tissue with light after prior administration of a photosensitizing agent<sup>[4]</sup>. In the past few years, little studies have been reported in the literature about the photodynamic therapy (PDT) on pancreatic cancer treatment, especially for the targeted-PDT<sup>[5-7]</sup>. Integrins  $\alpha_v\beta_3$  plays a critical role in regulating tumor growth and metastasis as well as tumor angiogenesis<sup>[8,9]</sup>. Arginine-glycine-aspartic acid (RGD) peptides is the integrin antagonist which can link to integrin<sup>[10-12]</sup>. Therefore, it makes the RGD coupled quantum dots (QDs) probe successful to image the pancreatic cancer. In order to further discuss the possibility of PDT applied to pancreatic cancer treatment and its mechanism, we investigated the effects of photodynamic therapy with quantum dots-RGD probe as photosensitizer on the proliferation and apoptosis of pancreatic carcinoma cells to provide a new prospect for the clinical treatment of pancreatic cancer.

## MATERIALS AND METHODS

### Materials

Quantum dots-RGD probe synthesized by School of Materials Science and Engineering, Shanghai University. Pancreatic cell line SW1990 purchased from Chinese Academy of Science. DEPC, Trizol, anhydrous ethanol, DAPI, MTT, DMSO, reactive oxygen species assay kit purchased from Beyotime institute of Biotechnology. Annexin V-FITC/PI purchased from invitrogen. RPMI 1640, 0.25% trypsin, fetal bovine serum, phosphate buffered saline purchased from Gibco. Reverse transcription-polymerase chain reaction (RT-PCR) assay kit purchased from Takara.

### Methods

**Quantum dots-RGD probe targeting research on pancreatic cancer cells:** For laser confocal micros-

copy, cells grown on 35-mm two imaging dishes (Cat no. P35G-0-14-C, Ashland, MA, United States) were washed with PBS and then were incubated at 37 °C in the presence of 5 nmol/L quantum dots-RGD probe and probe with excessive RGD 1  $\mu$ mol for 1 h. Afterward, cells were washed in ice-cold PBS, fixed by 4% paraformaldehyde and examined with simultaneous 543-nm excitation for laser confocal microscopy imaging. DAPI 2  $\mu$ g/mL was utilized for the nuclear labeling localization which was incubated dark at room temperature for 15 min.

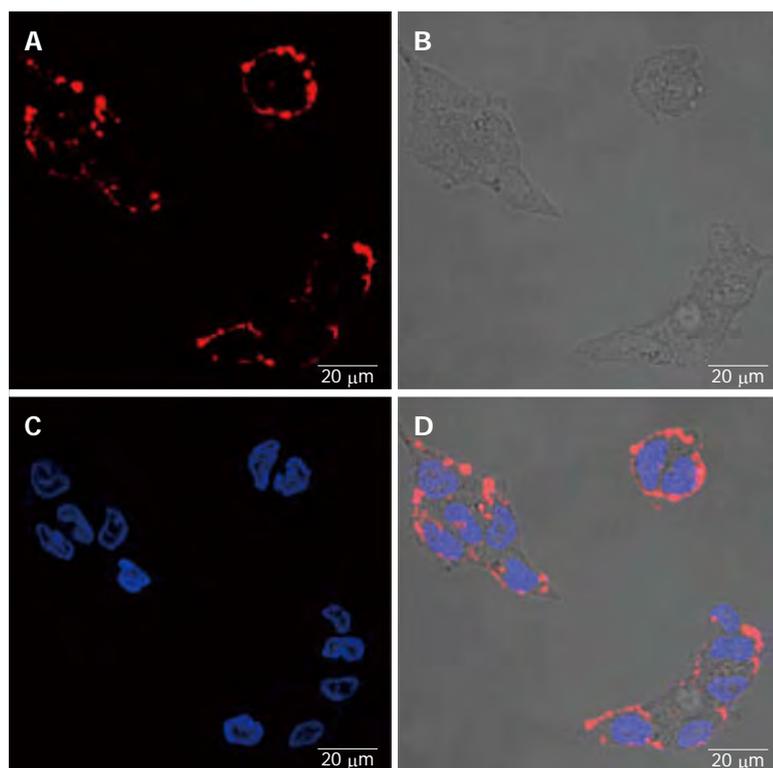

**Methyl thiazolyl tetrazolium assay test:** Cells grown on 96-well plates were divided into four groups, without QDs and light treated cells as blank control, pure light treated group, photosensitizer group, PDT group. Each group were set 10 double holes. Photosensitizer, PDT groups were incubated at 37 °C in the presence of 10 nmol/L Qds-RGD integrin-targeted probe. Pure light treated and PDT groups were treated with the wavelength of 690 nm laser, 20 J/cm<sup>2</sup> for 20 min. Absorbance (*A*) value were measured at the wavelength of 490 nm. Cells growth were observed after treated 24, 48 and 72 h. Cells relative inhibition rate (%) = (1 - the average *A* value of experimental group/the average *A* value of control group)  $\times$  100%.

**Morphologic changes in fluorescence microscopy:** After treated 48 h, cells were fixed by 4% paraformaldehyde and incubated with DAPI 2  $\mu$ g/mL. The morphological changes of cells were examined under fluorescence microscope.

**Cell cycle retardance and apoptosis observed by flow cytometry:** Each group were set 5 double holes. After treated 48 h, cells apoptosis and cell cycle retardance were observed by flow cytometry.

**Reactive oxygen species test:** Each group were set 3 double holes. After treated 48 h, DCFH-DA probe was applied to detect the expression of reactive oxygen species of four groups respectively.

**Relative gene expression by RT-PCR test:** According to the RT-PCR test kit procedure from Takara company, we observed the relative gene expression after PDT therapy. Gene primer sequences were synthesized by Shanghai Shengong. Myeloid cell leukemia-1 (Mcl-1) primer forward 5'-AAAGCCTGTCTGCCAAAT-3', reverse 5'-TATAAACCCACCACTCCC-3', product fragment 196 bp. Protein kinase B (Akt) primer: forward 5'-AAGCACCGCGTGACCATGAA-3', reverse 5'-TCT-TAATGTGCCCGTCCCTTG-3', product fragment 445 bp. Tumor necrosis factor-related apoptosis-inducing ligand (TRAIL) primer: forward 5'-TGGCTAACT-GACCTGGAA-3', reverse 5'-GGAAACCTGGAGGC-TACT-3', product fragment 415 bp. Internal reference primer glyceraldehyde 3-phosphate dehydrogenase (GAPDH) forward 5'-CATGGTCTACACGTTCCAGT-3'. Re-

**Figure 1** The fluorescence expression of SW1990 cells with the imaging of quantum dots-arginine-glycine-aspartic acid probe. A: Quantum dots-arginine-glycine-aspartic acid probe imaging; B: Original image; C: 4',6-diamidino-2-phenylindole, dihydrochloride dyeing; D: Integrated image.

verse 5'-GGCTAAGCAGTTGGTGGTGC-3', product fragment 349 bp. PCR reaction condition: 94 °C 3 min predenaturation, 94 °C 30 s, 55 °C 30 s, 72 °C 1 min ( $\times$  35 cycles) 72 °C extend for 5 min. Afterwards, grayscale scanning analysis was made by means of gel imaging analysis system. mRNA expression of the target gene = average gray value of specimens target gene/average gray value of the same specimen GAPDH.

### Statistical analysis

Quantitative data in accordance with the normal distribution were analyzed using the One-way ANOVA and Student-Neuman-Keuls, otherwise using the non-parametric tests. SPSS 17.0 statistical software was used for analysis, and the significance level  $\alpha$  was set at 0.05.

## RESULTS

### Quantum dots-RGD probe targeting research on pancreatic cancer cells

The fluorescence expression of SW1990 cells with the imaging of QDS-RGD probe: QDS-RGD probe imaging, original image, DAPI dyeing, and integrated image (Figure 1).

The fluorescence imaging of SW1990 cells with QDS-RGD probe at the block of excess RGD peptide: QDS-RGD probe imaging, original image, DAPI dyeing, and integrated image (Figure 2).

### Methyl thiazolyl tetrazolium assay test

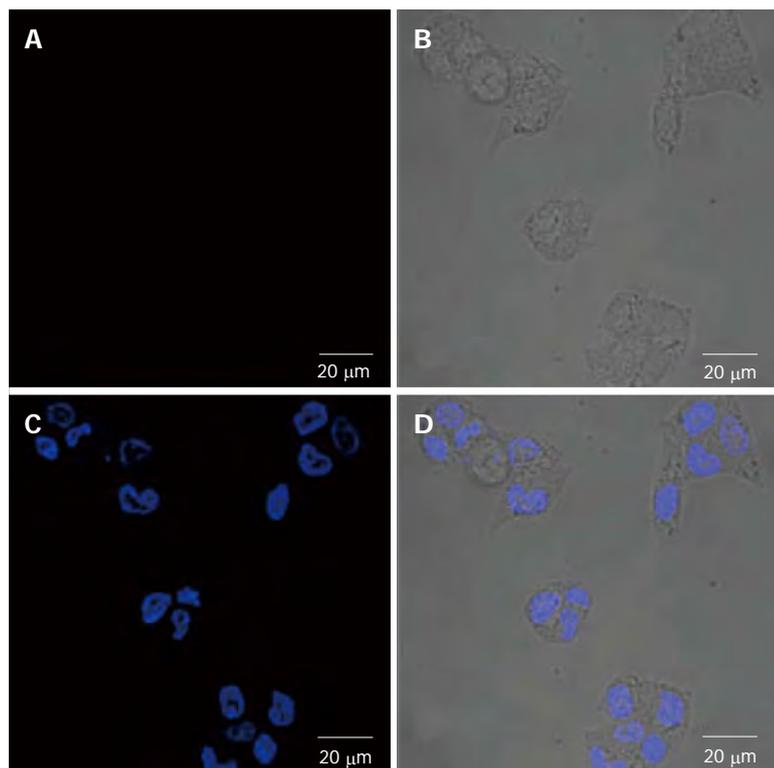

After 24, 48 or 72 h incubation, the PDT group cells growth inhibition rate was all higher than that of the control group, which makes statistically significant difference ( $F = 73.00, 85.10, 126.58, P < 0.01$ ). While compared with the control group, the cell growth inhibition rate of light group and photosensitizer group had no significant difference ( $P > 0.05$ ) (Table 1).

### Morphologic changes in fluorescence microscopy

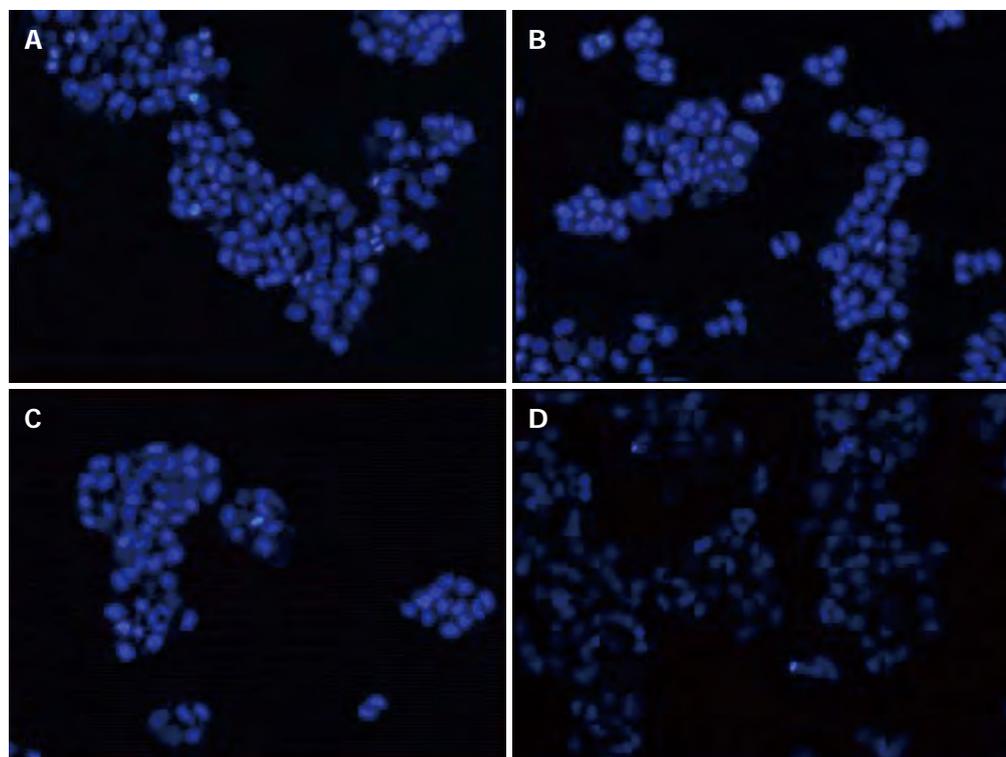

The cells nuclear morphologic changes in PDT group were corrugated under fluorescence microscopy. The nuclear of partial cells became staining deepen, bright blue, fuzzy and obviously pyknotic. With time prolonged, a large number of nuclear began to become dark, pyknotic and fragmentation. The remaining cells showed no significant change (Figure 3).

### Cell cycle retardance and apoptosis observed by flow cytometry

After treated for 48 h, the cell apoptotic rate of PDT group ( $17.86\% \pm 1.230\%$ ) was higher than the control ( $7.62\% \pm 1.219\%$ ), the light group ( $8.38\% \pm 0.277\%$ ) and the photosensitizer group ( $8.96\% \pm 0.673\%$ ), which made statistical difference ( $F = 130.617, P < 0.01$ , Figure 4). Compared to the control, PDT group had cell cycle  $G_0/G_1$  and S retardance ( $G_0/G_1$   $69.14\% \pm 2.63\%$  vs  $55.74\% \pm 2.82\%$ , S  $24.41\% \pm 2.67\%$  vs  $37.47\% \pm 0.74\%$ ,

**Figure 2** The fluorescence imaging of SW1990 cells with quantum dots-arginine-glycine-aspartic acid probe at the block of excess arginine-glycine-aspartic acid peptide. A: Quantum dots-arginine-glycine-aspartic acid probe imaging; B: Original image; C: 4',6-diamidino-2-phenylindole, dihydrochloride dyeing; D: Integrated image.

**Table 1** The inhibition, and cell cycles effects of cells by methyl thiazolyl tetrazolium assay after treated separately

Treat grouping	24 h	48 h	72 h	G <sub>0</sub> /G <sub>1</sub>	S
Control group	0.213% ± 0.079%	0.216% ± 0.071%	0.274% ± 0.065%	55.74% ± 2.82%	37.47% ± 0.74%
Light group	0.217% ± 0.053%	0.242% ± 0.057%	0.281% ± 0.042%	53.73% ± 1.37%	37.88% ± 3.60%
Photosensitizer group	0.280% ± 0.061%	0.273% ± 0.055%	0.300% ± 0.050%	57.72% ± 0.91%	33.90% ± 3.39%
PDT group	0.566% ± 0.052% <sup>b</sup>	0.600% ± 0.062% <sup>b</sup>	0.651% ± 0.045% <sup>b</sup>	69.14% ± 2.63% <sup>b</sup>	24.41% ± 2.67% <sup>b</sup>

<sup>b</sup>*P* < 0.01 vs control group. PDT: Photodynamic therapy.

**Figure 4** The cell apoptosis of cells after treated separately. A: Control group; B: Light group; C: Quantum dots-arginine-glycine-aspartic acid group; D: Photodynamic therapy (PDT) group.

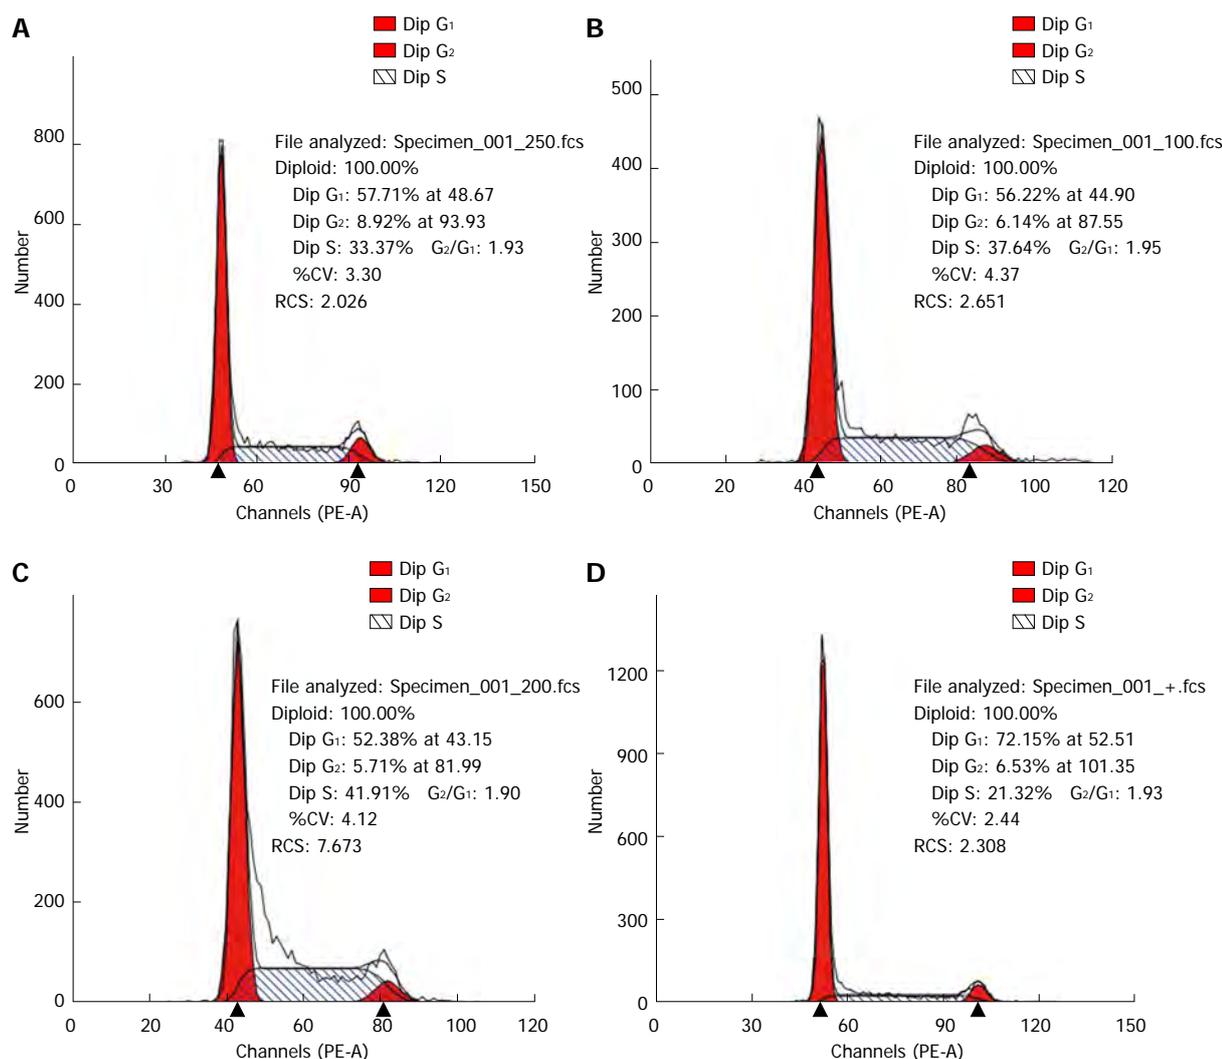

all *P* < 0.05, Figure 5 and Table 1).

### Reactive oxygen species test

Each group was observed five high fields and figured out the mean value of the cells. The cells of each HPF expressing fluorescence in PDT group ( $286 \pm 5.508$ ) were higher than the control ( $28 \pm 2.646$ ), the light group ( $34 \pm 2.082$ ) and the photosensitizer group ( $36 \pm 4.163$ ), which made statistical difference ( $F = 3262.559$ ,  $P < 0.01$ ) (Figure 6).

### Relative gene expression by RT-PCR test

The grayscale ratio of Akt mRNA and GADPH mRNA of the control, the light group, the photosensitizer group and PDT group were  $1.3319 \pm 0.0482$ ,  $1.3137 \pm 0.0100$ ,  $1.2900 \pm 0.0116$ ,  $0.6161 \pm 0.0032$ , respectively. The ratio of PDT group was lower than the others, which made statistical difference ( $F = 567.456$ ,  $P < 0.05$ ); The relative expression level of Mcl-1 was  $0.9864 \pm 0.0056$ ,  $1.0467 \pm 0.0248$ ,  $1.0187 \pm 0.0205$ ,  $0.3394 \pm 0.0451$ , respectively. The ratio of these two mRNA in PDT group were

**Figure 5** Cell cycle of cells after treated separately. A: Control group; B: Light group; C: Quantum dots-arginine-glycine-aspartic acid group; D: Photodynamic therapy group.

lower than the others, which made statistical difference ( $F = 446.817, P < 0.05$ ); the relative expression level of TRAIL was  $0.6221 \pm 0.0076, 0.6075 \pm 0.0072, 0.6189 \pm 0.0114, 0.7239 \pm 0.0017$ , respectively. The ratio of PDT group was higher than the others, which made statistical difference ( $F = 145.238, P < 0.05$ ) (Figure 7).

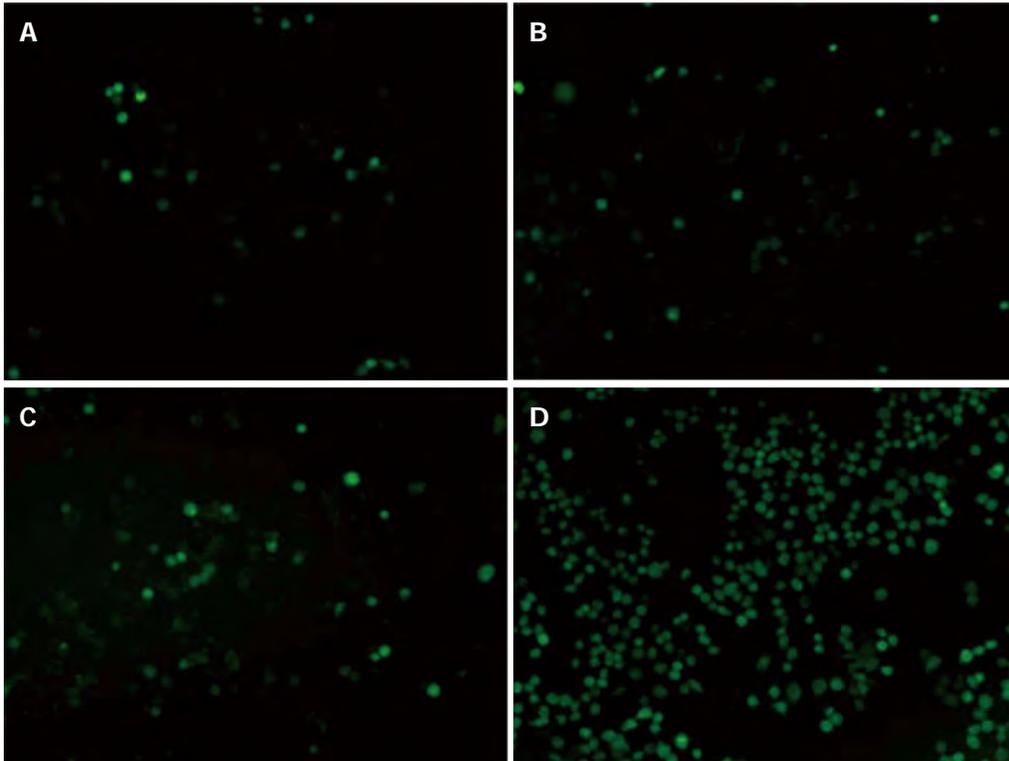

## DISCUSSION

Since its discovery in the early 1900s, photodynamic therapy has developed from an emerging cancer treatment to an Food and Drug Administration-approved therapy for different malignancies. Two major challenges of current PDT are the limited tissue penetration of excitation light and poor tumor-selectivity of the photosensitizer. To address these issues, we developed a multifunctional nano-construct consisting of Semiconductor quantum dots and RGD peptide. RGD peptide was coated on the surface of QDs to anchor the probe close to SW1990 cells, thereby facilitating tumor imaging and targeted therapy.

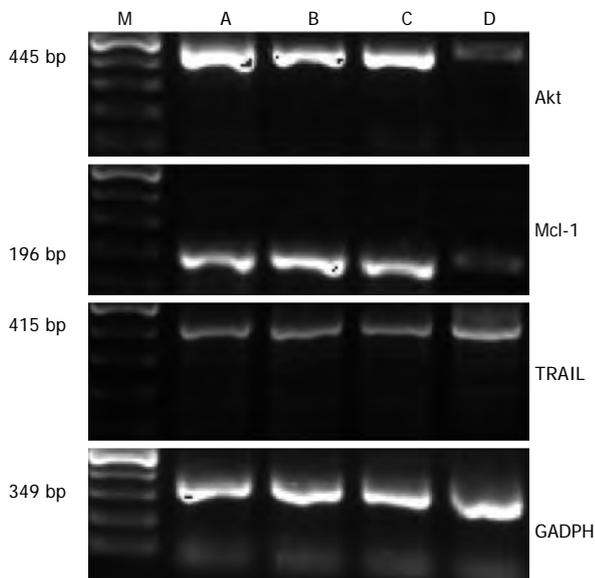

Semiconductor QDs, after surface modification to

render them water soluble and biocompatible, have a promising future in biomedical applications. QDs have size- and composition-adjustable fluorescence emission wavelengths, narrow emission bands, and very high levels of brightness and photostability. For *in vitro* studies, QDs have been used for cell labeling, fluorescence in situ hybridization, cell tracking, fluorescence resonance energy transfer, photodynamic therapy and many other applications<sup>[13-16]</sup>. QDs can serve as energy donors to conventional photosensitizers through FRET or interact directly with molecular oxygen *via* energy transfer mechanisms, to generate reactive <sup>1</sup>O<sub>2</sub> species that can be exploited for PDT<sup>[17,18]</sup>.

Members of the integrin family influence several aspects of tumor progression and metastasis, including cell survival, proliferation, and angiogenesis. The  $\alpha_v\beta_3$  integrin is the most prominent receptor class affecting tumor growth, tumor invasiveness, metastasis, tumor-induced angiogenesis, inflammation, osteoporosis, and rheumatoid arthritis. The  $\alpha_v\beta_3$  integrin is strongly expressed on tumor cells and activated endothelial cells. In contrast,

**Figure 6** Number of cells producing reactive oxygen species after treated separately. A: Control group; B: Light group; C: Quantum dots-arginine-glycine-aspartic acid group; D: Photodynamic therapy group.

**Figure 7** Expression of myeloid cell leukemia-1, protein kinase B and tumor necrosis factor-related apoptosis-inducing ligand mRNA in each group by reverse transcription-polymerase chain reaction analysis. A: Control group; B: Light group; C: Quantum dots-arginine-glycine-aspartic acid group; D: Photodynamic therapy group. Mcl-1: Myeloid cell leukemia-1; Akt: Protein kinase B; TRAIL: Tumor necrosis factor-related apoptosis-inducing ligand; GAPDH: Glyceraldehyde 3-phosphate dehydrogenase.

expression of  $\alpha_v\beta_3$  integrin is weak on resting endothelial cells and most normal tissues<sup>[8,9,19]</sup>. The  $\alpha_v\beta_3$  antagonists are being studied as anti-tumor and anti-angiogenic agents. A tripeptide sequence consisting of Arg-Gly-Asp

(RGD) has been identified as a recognition motif used by extracellular matrix proteins (vitronectin, fibrinogen, laminin, and collagen) to bind to a variety of integrins, including  $\alpha_v\beta_3$ .

Confocal microscopy demonstrated the enhanced tumor-selectivity of the nanoconstructs to cancer cells that overexpressed integrin receptor. The integrin-positive SW1990 cells were clearly visualized in fluorescence images from QDs-RGD binding. The fluorescence intensity correlated with the integrin expression level of the cell lines. This binding was blocked effectively by excessive 1  $\mu\text{mol/L}$  RGD. Unconjugated QDs showed no significant binding to the cell lines.

*In vitro*, the light-triggered PDT based on the nanoconstructs possessed remarkable therapeutic efficacy with tumor cell inhibition. The result of MTT showed that the PDT group cells growth inhibition rate was all higher than that of the control group, which made statistically significant difference ( $P < 0.01$ ). While dealt with quantum dots or light irradiation alone, the cells did not showed significant destruction ( $P > 0.05$ ). Apoptotic cells and morphologic changes could be found under optical microscope. The FCM revealed PDT group had more significant cell apoptosis rate compared to control cells ( $F = 130.617, P < 0.01$ ) and cell cycle  $G_0/G_1$  and S retardance ( $P < 0.05$ ) compared to control cells. All the results demonstrated that photodynamic therapy based on integrin targeted probe could really inhibit pancreatic cancer cell proliferation and induce apoptosis, which were similar to the results of Yu *et al*<sup>[20]</sup> and Liu *et al*<sup>[7]</sup>. Xie

*et al*<sup>[21]</sup> also reported that *in vivo* PDT combined with gemcitabine chemotherapy drugs could effectively inhibit the proliferation of pancreatic tumors and kill tumor tissue, which confirmed the inhibition and killing effect of PDT treatment in pancreatic cancer.

Akt is an important molecule involved in cell growth and invasion. *Bcl-2* gene family have close relationship with cell apoptosis, including Mcl-1 (apoptosis inhibition) and TRAIL (apoptosis promotion) among members of the family. In our study, the expression of Mcl-1 and Akt were down-regulated, while expression of TRAIL mRNA was up-regulated after SW1990 cells treated with PDT. All the changes revealed the direction to promoting apoptosis.

The literature indicated that reactive oxygen species (ROS) was the activator of mitochondrial damage and apoptosis, which is highly reactive and toxic to cell membranes, lysosomes, and mitochondria<sup>[22]</sup>. Our study showed that PDT group had more significant number of SW1990 cells producing reactive oxygen species compared to the control, which revealed that the PDT promoted pancreatic cancer cells generating large amounts of ROS resulting in apoptosis. It had been reported that cancer cells had lower ability to scavenge oxygen free radicals and were more sensitive to ROS than the normal<sup>[22]</sup>. Though pancreatic cancer cell growth inhibition could also occur with the treatment of laser or photosensitizer alone, the inhibition in PDT group was significantly enhanced. The results revealed that PDT could significantly change the redox state of the pancreatic cancer cells and enhance their level of oxidative stress, which were similar to the others. The literature indicated that the semiconductor nanoparticles were not internalized in the cell nuclei but in the cytoplasm<sup>[22]</sup>. Furthermore, the nanoparticles were internalized into the lysosomes. Lysosomes were the primary cellular targets of photodynamic therapy. The ruptured lysosomes release cathepsins B or L, which activate initiator caspases or inhibited the Bcl-2 family, which then promoted apoptosis *via* the mitochondria. The expression changes of apoptosis related genes, Bcl-2 and TRAIL, were consistent with the literature reported<sup>[22]</sup>. Therefore, with this study, we proved for the first time that the increased cell death by the integrin-targeted photodynamic therapy.

Furthermore, it had been reported that photodynamic therapy could kill the pancreatic tumor *in vitro*<sup>[20]</sup> and was also effective to improve the chemotherapy drug gemcitabine resistance<sup>[23]</sup>. *In vivo*, it had been reported that PDT and chemotherapy drugs could have synergistic effect on killing tumor. PDT was respected to be a new promising method because of broad application in pre-cancerous lesions and partial pancreas advanced lesions<sup>[24]</sup>.

In summary, these results indicate that the multifunctional nanoconstruct is a promising PDT agent for deep-seated tumor treatment and demonstrate a new paradigm for enhancing PDT efficacy. Photodynamic therapy can be an effective treatment of patients with pancreatic cancer, but more extensive preclinical and clinical trials are

needed for further improvement in the clinical application of PDT, especially in avoidance of complications during PDT.

## COMMENTS

### Background

A minimally invasive treatment capable of local destruction of tumor tissue with low morbidity may have a place in the treatment of pancreatic adenocarcinoma. The photodynamic therapy is a treatment that has high specificity, minimal invasiveness and good cosmetic outcome, which produces local necrosis of tissue with light after prior administration of a photosensitizing agent. They investigated the effects of photodynamic therapy with quantum dots-arginine-glycine-aspartic acid (RGD) probe as photosensitizer on the proliferation and apoptosis of pancreatic carcinoma cells to provide a new prospect for the clinical treatment of pancreatic cancer.

### Research frontiers

The photodynamic therapy is a treatment that has high specificity, minimal invasiveness and good cosmetic outcome, which produces local necrosis of tissue with light after prior administration of a photosensitizing agent. In the past few years, little studies have been reported in the literature about the photodynamic therapy (PDT) on pancreatic cancer treatment, especially for the targeted-PDT.

### Innovations and breakthroughs

Two major challenges of current photodynamic therapy (PDT) are the limited tissue penetration of excitation light and poor tumor-selectivity of the photosensitizer. To address these issues, authors developed a multifunctional nanoconstruct consisting of Semiconductor quantum dots and RGD peptide. RGD peptide was coated on the surface of quantum dots to anchor the probe close to SW1990 cells, thereby facilitating tumor imaging and targeted therapy.

### Applications

These results indicate that the multifunctional nanoconstruct is a promising PDT agent for deep-seated tumor treatment and demonstrate a new paradigm for enhancing PDT efficacy. Photodynamic therapy can be an effective treatment of patients with pancreatic cancer, but more extensive preclinical and clinical trials are needed for further improvement in the clinical application of PDT, especially in avoidance of complications during PDT.

### Peer review

This is a good descriptive study in which authors evaluate the effect of photodynamic therapy with quantum dots-RGD probe as photosensitizer on the proliferation and apoptosis of pancreatic carcinoma cells. The results are interesting and suggest that significantly inhibits cell proliferation and increases apoptosis in SW1990 cells, which provide a new prospect for the clinical treatment of pancreatic cancer.

### Abstract

**AIM:** To elucidate the prognostic value of age for gastric cancer and identify the optimal treatment for elderly gastric cancer patients.

**METHODS:** We enrolled 920 patients with gastric cancer who underwent gastrectomy between January 2003 and December 2007 in our center. Patients were categorized into three groups: younger group (age < 50 years), middle-aged group (50-69 years), and elderly group ( $\geq 70$  years). Clinicopathological features were compared among the three groups and potential prognostic factors were analyzed. The log-rank test was

used to assess statistical differences between curves. Independent prognostic factors were identified by the Cox proportional hazards regression model. Stratified analysis was used to investigate the impact of age on survival at each stage. Cancer-specific survival was also compared among the three groups by excluding deaths due to reasons other than gastric cancer. We analyzed the potential prognostic factors for patients aged  $\geq 70$  years. Finally, the impact of extent of lymphadenectomy and postoperative chemotherapy on survival for each age group was evaluated.

**RESULTS:** In the elderly group, there was a male predominance. At the same time, cancers of the upper third of the stomach, differentiated type, and less-invasive surgery were more common than in the younger or middle-aged groups. Elderly patients were more likely to have advanced tumor-node-metastasis (TNM) stage and larger tumors, but less likely to have distant metastasis. Although 5-year overall survival (OS) rate specific to gastric cancer was not significantly different among the three groups, elderly patients demonstrated a significantly lower 5-year OS rate than the younger and middle-aged patients (elderly vs middle-aged vs younger patients = 22.0% vs 36.6% vs 38.0%, respectively). In the TNM-stratified analysis, the differences in OS were only observed in patients with II and III tumors. In multivariate analysis, only surgical margin status, pT4, lymph node metastasis, M1 and sex were independent prognostic factors for elderly patients. The 5-year OS rate did not differ between elderly patients undergoing D1 and D2 lymph node resection, and these patients benefited little from chemotherapy.

**CONCLUSION:** Age  $\geq 70$  years was an independent prognostic factor for gastric cancer after gastrectomy. D1 resection is appropriate and postoperative chemotherapy is possibly unnecessary for elderly patients with gastric cancer.

**Key words:** Gastric carcinoma; Elderly patients; Prognosis; Lymphadenectomy; Chemotherapy

**Core tip:** Few studies have compared the characteristics and prognosis of gastric cancer among younger, middle-aged and elderly patients. Elderly patients have distinctive properties, and we have to treat them individually with particular care. We found that age  $\geq 70$  years was an independent prognostic factor for patients with gastric cancer after gastrectomy and these patients had distinctive characteristics of male predominance, larger tumor size, more histological differentiation, higher number of tumors located in the upper third of the stomach, and advanced tumor-node-metastasis stage, but less distant metastasis compared to younger and middle-aged patients.

## INTRODUCTION

The population of China is growing both larger and older. According to the National Bureau of Statistics of China (NBSC, 2011), the population of China reached 1.35 billion at the end of 2011, making it the most populous country in the world, and the number of people aged  $\geq 65$  years has risen to 118 million, or approximately 8.87% of the total population compared to 6.96% in 2000. With the aging of the population, the number of patients aged  $\geq 70$  years with gastric cancer is increasing in China. It has been reported that surgery is safe and the surgical outcome is better compared with the best supportive care in elderly gastric cancer patients<sup>[1,2]</sup>. However, it is still unclear whether surgical outcome in elderly patients differs from that in younger patients. In Japan, treatment guidelines for gastric cancer have been issued, and a standard therapeutic strategy for gastric cancer by stage has been established. Gastrectomy with D2 lymph node dissection has been increasingly regarded as the standard surgical procedure for most patients with operable gastric cancer. For elderly patients, it is not established whether these therapeutic strategies are suitable and controversy still exists. Previous studies have compared outcomes between elderly and younger patients with gastric cancer<sup>[3,4]</sup>. However, gastric cancer in younger patients also has distinctive properties.

In the present study, we compared the clinicopathological characteristics and surgical outcomes of gastric cancer among elderly patients ( $\geq 70$  years), middle-aged patients (50-69 years), and younger patients ( $< 50$  years).

Our ultimate aim was to identify the optimal treatment for elderly patients with gastric cancer.

## MATERIALS AND METHODS

### Patients

We reviewed surgical and pathological data of 920 patients with gastric cancer who had undergone gastrectomy with lymph node dissection, who were followed up between January 2003 and December 2007 at Tianjin Medical University Cancer Institute and Hospital. All the patients had histologically confirmed gastric adenocarcinoma. Patients who had previously undergone gastric surgery or had received neoadjuvant chemotherapy were excluded. There were 659 men (71.6%) and 261 women (28.4%), with a median age of 62 years (age range: 20-89 years). All the patients were categorized into the following three groups: younger group ( $< 50$  years old, 166 patients), middle-aged group (50-69 years old, 481 patients) and elderly group ( $\geq 70$  years, 273 patients).

### Surgical treatment and perioperative management

All the patients underwent gastrectomy with D1 or D2 lymph node dissection. The choice of surgical procedure of reconstruction was made according to the surgeon's preference. Resection margin was detected by histological examination. Negative resection margin was defined as microscopic complete resection, without residual cancer cells in the margin. Positive resection margin was defined as tumor cells  $< 1$  mm from the cut edge or residual cells in the margin. Postoperative adjuvant chemotherapy was implemented according to the tumor stage, physical condition and willingness of the patient. Chemotherapeutics consisted of 5-fluorouracil, leucovorin and oxaliplatin (FOLFOX-6). Radiotherapy was not used in the present study.

### Evaluation of clinicopathological variables and survival

Clinicopathological features studied included sex, age, tumor location, tumor size, Borrmann type, histology, surgical margin status, extranodal metastasis, depth of invasion, lymph node metastasis, distant metastasis, tumor-node-metastasis (TNM) stage, extent of lymphadenectomy, type of gastrectomy, and postoperative chemotherapy. The tumors were staged according to the Union for International Cancer Control TNM classification system, 7<sup>th</sup> edition, and lymphadenectomy and lymph node stations were defined according to the 3<sup>rd</sup> English Edition of the Japanese Classification of Gastric Carcinoma. Tumors were classified into two groups based on histology: differentiated type, including papillary, well or moderately differentiated adenocarcinoma; and undifferentiated type, including poorly differentiated or undifferentiated adenocarcinoma, signet ring cell carcinoma and mucinous carcinoma.

### Follow-up

All the patients were followed every 3 mo until 2 years

after surgery, then every 6 mo for up to 5 years, and then every year or until death. Physical examination, laboratory tests, imaging and endoscopy were performed at every visit. The median follow-up was 26 mo (range: 1-103 mo), and the last follow-up date was December 25, 2012. The overall survival rate was calculated from the day of surgical resection until time of death or final follow-up.

### Statistical analysis

Categorical variables were analyzed by means of the  $\chi^2$  or Fisher's exact test. Overall survival curves were calculated using the Kaplan-Meier method based on the length of time between primary surgical treatment and final follow-up or death. The log-rank test was used to assess statistical differences between curves. Independent prognostic factors were identified by Cox proportional hazards regression model.  $P < 0.050$  was considered statistically significant. The statistical analysis was performed using SPSS version 17.0 (Chicago, IL, United States).

## RESULTS

### Clinicopathological features

Of the 920 patients who underwent gastrectomy, 793 patients achieved a negative resection margin (241 elderly, 415 middle-aged and 137 younger patients), and 127 patients had a positive resection margin (32 elderly, 66 middle-aged and 29 younger patients). Of all the patients, 402 (43.7%) underwent D2 lymph nodes dissection, and 518 (56.3%) D1 dissection, including 65 (7.1%) patients who accepted palliative surgery without formal lymph node dissection because of distant metastasis. Six hundred and seventy-one (72.9%) patients accepted surgery alone and 249 (27.1%) surgery plus postoperative chemotherapy with FOLFOX-6.

All the patients were divided into three categories according to their age (Table 1). The mean age was 42.8 years in the younger group, 60.1 years in the middle-aged group, and 74.1 years in the elderly group. There were no significant differences in Borrmann type, extranodal metastasis, surgical margin status, depth of invasion, and lymph node metastasis among the three groups. In the elderly group, there was a male predominance, and cancers of the upper third of the stomach and differentiated type, and less-invasive surgery were more common than in the younger and middle-aged groups. The elderly patients were more likely to have advanced TNM stage and larger tumors, but less likely to have distant metastasis and undergo postoperative chemotherapy. The rate of distant metastasis was 10.2% in the younger group, 8.1% in the middle-aged group, and 3.3% in the elderly group. Although there were no significant differences in type of distant metastasis, elderly patients were more likely to have liver metastasis, but less likely to have peritoneal metastasis than younger or middle-aged patients.

### Prognostic value of age in gastric cancer

The results of univariate and multivariate analysis of all

920 patients are shown in Table 2. Surgical margin status, pT<sub>4</sub>, N stage, M1, extent of lymphadenectomy, postoperative chemotherapy and age  $\geq 70$  years (hazard ratio: 1.487,  $P = 0.003$ ) remained as independent prognostic factors for overall survival (OS). Patients aged  $\geq 70$  years demonstrated a significantly lower 5-year OS rate than the younger and middle-aged patients (elderly *vs* middle-aged *vs* younger patients, 22.0% *vs* 36.6% *vs* 38.0%, respectively) (Figure 1). In the TNM-stratified analysis, the differences in OS were only observed in patients with TNM stage II and III cancer (Table 3 and Figure 2). However, when deaths caused by factors other than gastric cancer were excluded, there were no significant differences in cancer-specific survival among the three groups (Figure 3).

### Survival of patients aged $\geq 70$ years

Survival analysis of the elderly patients is shown in Table 4. Sex, tumor size, histology, extranodal metastasis, surgical margin status, pT<sub>4</sub>, lymph node metastasis, M1 and type of gastrectomy were found to be prognostic factors in the univariate analysis, while only surgical margin status, pT<sub>4</sub>, lymph node metastasis, M1 and sex were independent prognostic factors in the multivariate analysis. For patients aged  $\geq 70$  years, women tended to have a significantly higher 5-year OS than men (29.3% *vs* 20.0%,  $P = 0.045$ ). Although the patients who underwent D2 resection had better survival than those with D1 resection, there was no significant difference in OS between D1 and D2 resection for the elderly patients. In the stratified analysis, chemotherapy was a prognostic factor for the younger and middle-aged patients, but not for the elderly patients (Table 5 and Figure 4).

## DISCUSSION

The number of elderly patients with gastric cancer is rapidly increasing with an aging population. With regard to elderly, no clear-cut distinction exists. Previous studies used 65, 70, 75, 80 and 85 years as thresholds<sup>[1-7]</sup>. Data from NBSC show that the average life span in China was 72.38 years for men and 77.37 years for women in 2010, and patients aged  $\geq 65$  years accounted for 8.87% of the total population. Taking into consideration that the majority of elderly patients with gastric cancer are male, we used 70 years as a threshold, which is close to the average life span of Chinese men. Many elderly patients with gastric cancer also suffer from comorbid diseases such as hypertension, diabetes mellitus, ischemic heart disease, brain infarction, or renal dysfunction. Therefore, we have to treat elderly patients individually with particular care. Gastric cancer in elderly patients actually presents a distinctive entity with specific clinicopathological characteristics.

The current study showed that the distinguishing characteristics in the elderly gastric cancer patients included male predominance, more histologically differentiated type, higher rate of tumors located in the upper third of the stomach, larger tumor size, more advanced

Table 1 Case characteristics *n* (%)

Characteristics	Age (yr)			$\chi^2$	P value
	< 50 ( <i>n</i> = 166)	50-69 ( <i>n</i> = 481)	≥ 70 ( <i>n</i> = 273)

proximately 1:1<sup>[10]</sup>. Our findings are consistent with these reports. The sexual imbalance may reflect a more frequent and prolonged exposure of elderly male patients to environmental carcinogens. We also found that the proportion of the histologically differentiated type cancer increased with aging, from 14.5% in the younger patients to 42.5% in the elderly. Some studies concluded that gastric carcinoma in elderly patients may principally develop as well-differentiated lesions that progress to poorly differentiated ones, whereas in younger patients, most gastric carcinoma emerges as poorly differentiated type

at an early phase<sup>[11,12]</sup>. This may also be attributed to the fact that younger patients are more likely to have distant metastasis. Although many studies have demonstrated that gastric cancer in elderly patients was predominantly localized in the lower third of the stomach<sup>[8,11,12]</sup>, some researchers reported that cancer involving the upper third of the stomach was more common in elderly than in younger patients<sup>[13,14]</sup>. In our study, only 28.6% of tumors were located in the lower third of the stomach in elderly patients, and the ratio of upper-third tumors increased from 12.7% in the younger patients to 38.8% in the el-

MST: Median survival time; TNM: Tumor-node-metastasis; OS: Overall survival.

**Figure 1** Overall survival curves for all patients grouped by age. Patients aged ≥ 70 years demonstrated a significantly lower 5-year OS rate than the younger and middle-aged patients (elderly vs middle-aged vs younger patients, 22.0% vs 36.6% vs 38.0%, respectively). EG: Elderly group; MG: Middle-aged group; YG: Younger group.

**Figure 3** Cancer-specific survival of each age group. When deaths caused by factors other than gastric cancer were excluded, there were no significant differences in cancer-specific survival among the three age groups. EG: Elderly group; MG: Middle-aged group; YG: Younger group.

**Figure 2** Overall survival curves for patients with tumor-node-metastasis II and III cancer. In the tumor-node-metastasis (TNM)-stratified analysis, the differences in overall survival (OS) were only observed in patients with TNM stage II and III cancer. A: Patients with II cancer; B: Patients with III cancer. EG: Elderly group; MG: Middle-aged group; YG: Younger group.

elderly patients. It is possible that the risk of developing carcinoma in the upper third of the stomach increases with advancing age. Previous reports have shown no significant difference in tumor stage between elderly and younger or middle-aged patients<sup>[15-17]</sup>. Although in the present study there were no significant differences in the depth of invasion and lymph node metastasis among the three groups, the elderly patients were more likely to have advanced TNM stage. The ratio of stage III cancer was 62.6% in the elderly patients compared to 51.2% in the younger patients. Usually the symptoms of gastric cancer are not obvious in elderly patients, which may result in delayed diagnosis. Thus, it is easier for advanced tumor stage and larger tumor size to develop in elderly than younger and middle-aged patients.

It has been reported that surgery is safe and surgical outcome is better compared with the best supportive care in elderly patients with gastric cancer<sup>[1,2]</sup>. Limited operation is predominant because total gastrectomy and D2 resection in elderly patients are associated with higher rates of postoperative morbidity and mortality compared to subtotal gastrectomy and D1 resection<sup>[15,18]</sup>. In the present study, subtotal gastrectomy and D1 resection were more frequently performed in the elderly patients. However, the long-term outcome of elderly patients is still controversial after limited operation.

Many studies have specifically compared the long-term outcome of gastric cancer in elderly patients with that in younger or middle-aged patients. Some found no significant difference in survival between them<sup>[15,19]</sup>. How-

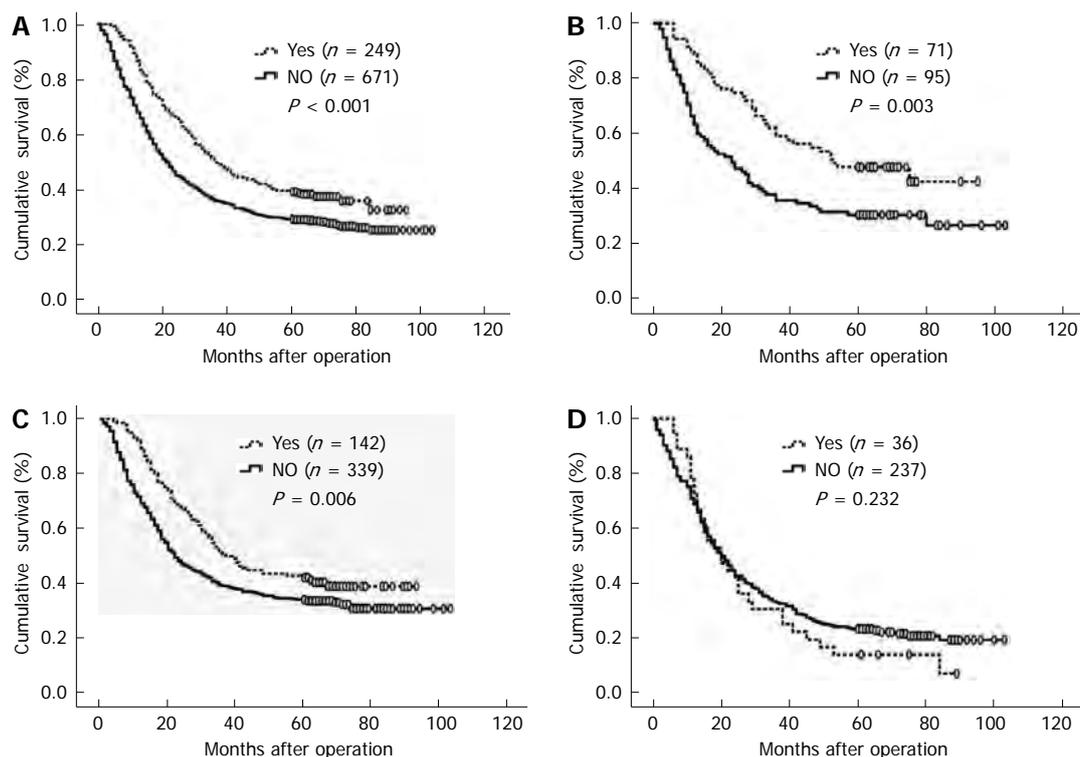

Figure 4 Overall survival curves for patients grouped by chemotherapy. In the age-stratified analysis, chemotherapy was a prognostic factor for the younger and middle-aged patients, but not for the elderly patients. A: All patients; B: Younger group; C: Middle-aged group; D: Elderly group.

ever, most studies confirmed the prognosis of elderly patients was poorer than that of younger and middle-aged patients<sup>[9,16,17]</sup>. Our results are consistent with most of those reports. Patients aged  $\geq 70$  years had a significantly lower 5-year OS rate than younger and middle-aged patients. In general, the poor prognosis of elderly patients can be attributed to the delay in diagnosis and advanced tumor stage<sup>[9,20]</sup>. However, in TNM-stratified analysis, such differences were still observed in stage II and III cancer. In multivariate analysis, age was an independent prognostic factor, as well as surgical margin status, pT<sub>4</sub>, lymph node metastasis, M1, chemotherapy and the extent of lymphadenectomy. It has been reported that as patients age, they have a reduced ability to tackle cancer growth, which may lead to poorer prognosis of elderly patients<sup>[21]</sup>. In our study, when deaths caused by other comorbid diseases and malignancies were excluded, there were no significant differences in cancer-specific survival among the three groups. This result agrees with previous studies<sup>[8,17,22,23]</sup>. According to our results, the poorer prognosis of the elderly patients with gastric cancer was due to other comorbid diseases and malignancies rather than gastric cancer itself. To improve the outcome of gastric cancer in elderly patients, we should pay attention to treating other comorbid diseases and malignancies in addition to providing adequate treatment for gastric cancer itself.

Elderly patients have distinguishing characteristics and prognosis from younger and middle-aged ones, thus, it is necessary to elucidate prognostic factors that influ-

ence OS in elderly patients. In the present study, sex, surgical margin status, pT<sub>4</sub>, lymph node metastasis and M1 disease were found to be independent prognostic factors for elderly patients with gastric cancer. Some studies have reported better prognosis for women than men<sup>[24,25]</sup>. Usually, women have a longer life-span than men. In 2005, life expectancy was 2.4 years longer for women than men in India, 3.2 years longer in China, 3.8 years longer in Indonesia, and 7.4 years longer in Japan<sup>[26]</sup>. This may account for the better prognosis of female elderly patients with gastric cancer. Depth of invasion, lymph node status and distant metastasis have been proven to be the most powerful independent prognostic factors for gastric cancer. However, few studies have specifically evaluated the prognostic value of these factors in elderly patients. Yokota *et al.*<sup>[27]</sup> reported that lymph node metastasis and depth of invasion were significantly correlated with 5-year survival in patients aged  $> 70$  years. Pisanu *et al.*<sup>[28]</sup> demonstrated that tumor stage was the only prognostic factor influencing survival for patients aged  $\geq 75$  years. Our results were consistent with these reports and strongly showed that depth of invasion, lymph node metastasis and M1 disease were independent prognostic factors for elderly patients. R0 resection represents the only treatment modality offering possible long-term survival. Positive surgical margin status has been reported to be associated with poor prognosis in patients with gastric cancer<sup>[29,30]</sup>. Our results showed that surgical margin was an independent prognostic factor for all the patients including elderly ones. To ensure a negative surgical margin

is of paramount importance in gastric cancer surgery.

Extended lymphadenectomy (D<sub>2</sub>) has been reported to yield better survival results in Asian countries, such as Japan and Korea where gastric carcinoma is very

common. Until the 15-year follow-up results of the randomized Dutch D<sub>1</sub>D<sub>2</sub> trial were published, D<sub>2</sub> was not recommended in western countries. The follow-up data showed that OS of patients who had curative resection

was 25% for D1 and 35% for D2 when postoperative deaths (4% in D1 and 10% in D2) were excluded (log-rank  $P = 0.08$ ), however, there were no significant differences in survival between D1 and D2 for patients > 70 years of age (3% for D1 and 13% for D2,  $P = 0.36$ )<sup>[31]</sup>. Also the 5-year follow-up results from the Dutch Gastric Cancer Trial showed no significant survival benefit in the D2 group (47% for D2 and 45% for D1)<sup>[32]</sup>. In elderly patients, surgeons are usually reluctant to perform D2 resection to avoid major complications in the postoperative period<sup>[18,33]</sup>. It was actually reported that none of the elderly patients had lymph node recurrence following limited lymph-node resection<sup>[21]</sup>. In our study, there were no significant differences in OS between D1 and D2 resection for patients aged  $\geq 70$  years (5-year OS: 23.1% for D1 and 19.8% for D2,  $P = 0.232$ ), although those aged < 70 years may benefit from D2 resection. The average life expectancy of elderly patients is short, which may obscure the value of D2 resection, and explain why it is of little benefit in elderly patients. Considering this rather short life expectancy and the increased risk for D2 resection in elderly patients, D1 may be an adequate procedure for elderly patients with gastric cancer.

Many studies have affirmed the survival benefit with postoperative chemotherapy or chemoradiotherapy for gastric cancer<sup>[34-36]</sup>. However, no clinical trial has demonstrated that elderly patients can benefit from postoperative chemotherapy. Although the Adjuvant Chemotherapy of TS-1 for Gastric Cancer (ACTS GC) trial in Japan showed that 3-year survival rates were 80.1% and 70.1% for patients treated with S-1 or surgery alone, respectively, the results concerning elderly patients was not statistically significant<sup>[36]</sup>. FOLFOX-6 has been widely used in gastric cancer patients and has equal efficacy to the XELOX regimen (capecitabine/oxaliplatin), which improved 3-year disease-free survival in the CLASSIC (Adjuvant capecitabine and oxaliplatin for gastric cancer after D2 gastrectomy) trial<sup>[37]</sup>. In our study, improved survival with chemotherapy was only observed in the younger and middle-aged patients, and elderly patients benefited little from chemotherapy. Only 36 (13.2%) elderly patients received postoperative chemotherapy in the present study, therefore, we could not draw any definitive conclusions. A multicenter, larger study is recommended for future investigations.

In conclusion, patients aged  $\geq 70$  years had distinctive characteristics such as male predominance, larger tumor size, more histological differentiated type, higher rate of tumors located in the upper third of the stomach, and advanced TNM stage, but less distant metastasis compared to younger and middle-aged patients. Although there was no significant difference in the prognosis specific to gastric cancer, the elderly patients demonstrated poorer prognosis than the younger and middle-aged patients. Age  $\geq 70$  years was an independent prognostic factor for patients with gastric cancer after gastrectomy. Considering short life expectancy, limited lymph node dissection (D1 resection) is appropriate and postoperative

chemotherapy is possibly unnecessary for elderly patients.

## COMMENTS

### Background

The population of China is growing both larger and older. With the aging of the population, the number of patients aged  $\geq 70$  years with gastric cancer is also increasing. However, it is still unclear whether elderly patients benefit from adjuvant chemotherapy or extended lymph-node dissection.

### Research frontiers

Gastrectomy with D2 lymph node dissection has been increasingly regarded as the standard surgical procedure for most patients with operable gastric cancer, and postoperative adjuvant chemotherapy can improve overall survival. However, it is still controversial whether these therapeutic strategies are suitable for elderly patients. In the present study, authors demonstrated that age  $\geq 70$  years is an independent prognostic factor for patients with gastric cancer after gastrectomy, D1 resection is appropriate, and postoperative chemotherapy is possibly unnecessary for elderly patients.

### Innovations and breakthroughs

Few studies have compared the characteristics and prognosis of gastric cancer among younger, middle-age and elderly patients. In this study, authors compared characteristics and prognosis among the three age groups and found that elderly patients had distinctive characteristics such as male predominance, larger tumor size, more histological differentiated type, higher rate of tumors located in the upper third of the stomach, and advanced tumor-node-metastasis stage, but less distant metastasis compared to younger and middle-aged patients. Furthermore, cancer-specific survival was almost equal between the elderly and the younger patients, but overall mortality was higher in the former group.

### Applications

By understanding the characteristics and prognostic factors of elderly gastric cancer patients, this study may provide a reference for treatment planning for elderly patients with gastric cancer in China.

### Terminology

Extranodal metastasis was defined as the presence of tumor cells in extramural soft tissue that was discontinuous with either the primary lesion or locoregional lymph nodes.

### Peer review

The authors reported the characteristics and prognosis of gastric cancer in 920 patients who were treated in the authors' hospital. The manuscript has been well designed and conducted. It revealed that for the elderly patient subset, in comparison with younger patient subsets, distant metastasis was less frequent, the efficacy of adjuvant chemotherapy was less effective, and the benefit of extended lymph-node dissection was unclear. A cancer-specific death rate was almost equal between the elderly subset and the younger subset, but overall mortality was higher in the former patient group. These data are very informative for the planning of strategy to treat the elderly patients with gastric cancer in China. The idea of the manuscript has potential instruction for clinicians.

### Abstract

**AIM:** To use more representative sample size to evaluate whether computed tomography (CT) scan evidence of the concomitant presence of pneumatosis and portomesenteric venous gas is a predictor of transmural bowel necrosis.

**METHODS:** Data from 208 patients who were referred for a diagnosis of bowel ischemia were retrospectively reviewed. Only patients who underwent a surgical intervention following a diagnosis of bowel ischemia who also had a post-operative histological confirmation of such a diagnosis were included. Patients were split into two groups according to the presence of histological evidence of transmural bowel ischemia (case group) or partial bowel ischemia (control group). CT images were reviewed for findings of ischemia, including mural thickening, pneumatosis, bowel distension, portomesenteric venous gas and arterial or venous thrombi.

**RESULTS:** A total of 248 subjects who underwent surgery for bowel ischemia were identified. Among the 208 subjects enrolled in our study, transmural bowel necrosis was identified in 121 subjects (case group), and partial bowel necrosis was identified in 87 subjects (control group). Based on CT findings, including mural thickening, bowel distension, pneumatosis, pneumatosis plus portomesenteric venous gas and presence of thrombi or emboli, there were no significant differences between the case and control groups. The concomitant presence of pneumatosis and porto-mesenteric venous gas showed an odds ratio of 1.95 (95%CI: 0.491-7.775,  $P = 0.342$ ) for the presence of transmural necrosis. The presence of pneumatosis plus porto-mesenteric venous gas exhibited good specificity (83%) but low sensitivity (17%) in the identification of transmural bowel infarction. Accordingly, the positive and negative predictive values were 60% and 17%, respectively.

**CONCLUSION:** Although pneumatosis plus porto-mesenteric venous gas is associated with bowel ischemia, we have demonstrated that their co-occurrence cannot be used as diagnostic signs of transmural necrosis.

**Key words:** Bowel ischemia; Pneumatosis; Mesenteric venous gas; Computed tomography

**Core tip:** Although the finding of pneumatosis plus porto-mesenteric venous gas is useful in verifying transmural necrosis with a specificity of 83%, the very low sensitivity of 17% indicates that the diagnosis of transmural necrosis cannot be excluded based on a normal findings. Thus, our results appear to be encouraging by indicating that neither portomesenteric venous gas nor pneumatosis were pathognomonic of bowel transmural infarction.

## INTRODUCTION

Acute bowel ischemia is an urgent, life-threatening vascular condition with a mortality rate of approximately 70%<sup>[1-3]</sup>.

The slightest suspicion of mesenteric ischemia should be ruled out through imaging diagnostics<sup>[1]</sup>. In such a case, the diagnostic tool of choice is computed tomography (CT) angiography using an early arterial contrast medium bolus injection, followed by an evaluation of the primary axial layers and a multiplanar reconstruction of the imaging technique<sup>[1]</sup>.

In recent years, CT has increasingly been used to evaluate patients with clinical signs and symptoms of ischemic bowel disease. Depending on the severity and the extent of disease, intestinal ischemia may be detectable by CT based on a spectrum of findings, including intestinal pneumatosis, bowel wall thickening, portomesenteric venous gas and arterial or venous thrombi<sup>[4-7]</sup>.

Pneumatosis plus portomesenteric venous gas have been considered signs of advanced disease that usually indicate irreversible injury and transmural necrosis<sup>[6-8]</sup>.

Although Wiesner *et al*<sup>[9]</sup> and Kernagis *et al*<sup>[6]</sup> found an association between transmural bowel infarction and the comorbid presence of pneumatosis and porto-mesenteric venous gas, these studies represented only reports and included up to seven patients.

The purpose of our study was to use a more representative sample size to evaluate whether CT scan evidence of the concomitant presence of pneumatosis and portomesenteric venous gas is a predictor of transmural bowel necrosis.

## MATERIALS AND METHODS

Data of patients referred during a 13-year period (from January 2000 to December 2012) to the University of Naples "Federico II" and to the "Fatebenefratelli" Hospital of Naples with diagnoses of bowel ischemia were retrospectively reviewed. Only patients who underwent a surgical intervention following a diagnosis of bowel ischemia and obtained a post-operative histological confirmation of the diagnosis were included.

The patients were split into two groups according to the presence of histological evidence of transmural bowel ischemia (case group) or partial bowel ischemia (control group). Medical records were reviewed to determine the demographic and clinical characteristics of the patients in both groups.

CT images were reviewed for findings that were con-

sistent with the most common signs of ischemia that had been identified in previous literature<sup>[4-9]</sup>, including mural thickening, pneumatosis, bowel distension, portomesenteric venous gas and arterial or venous thrombi.

A measurement of 2-3 mm as the upper limit of normal thickness has been used<sup>[10]</sup>, and air bubbles or continuous bands of air in the bowel wall were considered to be a sign of pneumatosis<sup>[9]</sup>. Gas in the mesenteric veins or gas in the intrahepatic branches of the portal vein were indicative of gas in the portomesenteric circulation (Figure 1)<sup>[9]</sup>, and only the emboli or thrombi in the mesenteric arteries and veins that were clearly shown on contrast-enhanced CT images were assessed<sup>[11]</sup>.

To minimise selection bias, all CT scans were analysed by an observer with 30 years of experience related to the interpretation of CT who was blinded to the surgical and pathological findings and to the eventual clinical outcomes for each patient included in the chart review.

Patients without a contrast-enhanced CT obtained with 150 mL of iodinate contrast media and 5- and 7-mm slice collimations (pitch, 1.3:1, 200-220 mAs), reconstructed with a soft-tissue algorithm, were excluded from the study.

Superficial damage of the bowel mucosa and submucosa was classified as partial bowel ischemia before the development of transmural infarction based on the histological examination<sup>[12]</sup>.

The results were then correlated with the clinical and pathological data to determine the frequency with which pneumatosis plus portomesenteric venous gas was associated with irreversible transmural infarction.

## Statistical analysis

Statistical analysis was performed with SPSS 16.0. The Yates corrected  $\chi^2$  test was used to evaluate differences in categorical variables, and the independent samples *t* test was used to analyse continuous variables. To adjust for covariates and to make predictions, linear and logistic regression models were used. Statistical significance was accepted when the *P* value was less than 0.05.

## RESULTS

A total of 248 subjects who underwent surgery for bowel ischemia were identified. Of these, 208 subjects were included in the analysis; 28 subjects were excluded because they lacked adequate CT images, and 12 subjects were excluded for lacking a properly conducted pathological differentiation of mural bowel necrosis.

Among the 208 subjects enrolled in our study, transmural bowel necrosis was identified in 121 subjects (case group), and partial bowel necrosis was identified in 87 subjects (control group).

There were no significant demographic, clinical and laboratory differences between the case and control groups (Table 1). Based on a group comparison of CT findings of mural thickening, bowel distension, pneumatosis, pneumatosis plus portomesenteric venous gas

Figure 1 A case of intra-hepatic venous gas without trans-mural necrosis.

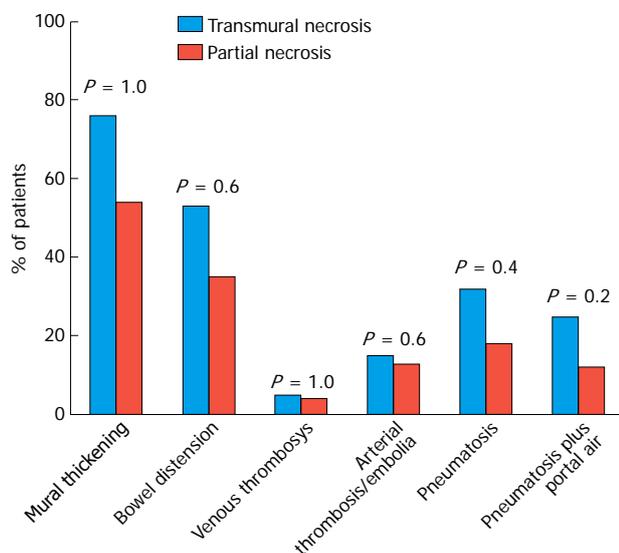

Figure 2 Association between the evaluated computed tomography findings and the presence of transmural or partial necrosis.

and the presence of thrombi or emboli, no significant differences were observed between the case and control groups (Figure 2).

A multivariate analysis indicated that after adjusting for major clinical and demographic patient characteristics, none of the CT findings were found to be predictive of transmural necrosis. Specifically, the concomitant presence of pneumatosis and porto-mesenteric venous gas showed an OR of 1.95 (95%CI: 0.491-7.775,  $P = 0.342$ ) for the presence of transmural necrosis. Similarly, the presence of isolated pneumatosis ( $P = 0.840$ ), of mural thickening ( $P = 0.974$ ) and of thrombi ( $P = 0.483$ ) did not predict the presence of transmural necrosis.

The presence of pneumatosis plus porto-mesenteric venous gas showed good specificity (83%) but low sensitivity (17%) in the identification of transmural bowel infarction. Accordingly, the positive and negative predictive values were 60% and 17%, respectively. Specifically, we registered 96 cases of transmural necrosis without pneumatosis plus porto-mesenteric venous gas (false negatives) and 12 cases of transmural necrosis with

Table 1 Demographic and clinical characteristics of the included patients in both groups  $n$  (%)

Characteristics	Transmural necrosis group	Partial necrosis group	$P$ value
Age (mean $\pm$ SD), yr	66.6 $\pm$ 8.1	66.2 $\pm$ 5.9	0.7
Sex (male)	61 (50.8)	43 (49.4)	1.0
Hypertension	57 (47.1)	43 (49.4)	0.7
Type 2 diabetes	26 (21.5)	20 (23.0)	0.8
Chronic pulmonary disease	21 (17.3)	13 (14.9)	0.7
Atrial fibrillation	10 (8.3)	14 (16.0)	0.1
Chronic renal failure	7 (5.8)	6 (6.9)	0.7
Coronary artery diseases	15 (12.4)	15 (17.2)	0.4
Pain	121 (100.0)	87 (100.0)	1.0
White blood cell count > 15000/mL	75 (62.0)	56 (64.4)	0.7
pH < 7.2 on blood gas analysis	56 (46.3)	36 (41.4)	0.5
Lactate in serum > 4 mmol/L	69 (57.0)	55 (63.2)	0.3

pneumatosis plus porto-mesenteric venous gas (false positives). In a ROC curve analysis, the evidence of pneumatosis plus porto-mesenteric venous gas was associated with an area under the curve of 0.50 (95%CI: 0.420-0.580) for predicting the presence of transmural bowel infarction.

## DISCUSSION

To our knowledge, no previous group has evaluated a large series of patients to statistically analyse whether the presence of pneumatosis intestinalis and portomesenteric venous gas facilitates the prediction of ischemic bowel wall damage severity.

Acute intestinal ischemia is pathogenetically and histologically divided into four primary clinical categories, including acute mesenteric embolus, acute mesenteric thrombus, non-occlusive disease and mesenteric vein thrombosis<sup>[3,13-15]</sup>.

Although acute intestinal ischemia is generally uncommon, as it accounts for < 1 in 1000 hospital admissions<sup>[16,17]</sup>, it is a highly complex clinical problem faced during the daily routines of surgeons, gastroenterologists, and radiologists<sup>[4]</sup> due to the difficulty of providing a diagnosis.

The severity of bowel ischemia may range from mild and transient superficial damage of the bowel mucosa to life-threatening transmural bowel infarction<sup>[18,19]</sup>.

Early diagnosis and treatment determine the overall outcome. As a result, increased awareness among physicians who have clinical patients with suspected mesenteric ischemia and a timely diagnostic workup and initiation of therapy are the keys to saving a patient's life<sup>[4,20]</sup>.

However, the absence of specific symptoms upon clinical examination may make an appropriate assessment more difficult<sup>[4,21]</sup>. Typically, the course of an ischemic condition is triphasic. During the initial stage (0-6 h), there is intense, acute abdominal pain that is often accompanied by shock and diarrhoea. These signs are normally followed by a phase with little evidence of symptoms, known as the silent phase (7-12 h), which is

characterised by dull abdominal pain, intestinal paralysis, and a rapid deterioration of the general condition. During the final phase (12–24 h), manifest ileus and bacterial peritonitis with sepsis are evident, and multi-organ failure has begun. Satisfactory treatment results are only possible in the early stage (0–12 h)<sup>[1]</sup>.

Necrosis is typically accompanied by increased serum lactate (> 4 mmol/L), increased CRP (> 10 mg/L), and leukocytosis (> 15000/mL). Furthermore, the blood gas analysis indicates an ischemic necrosis exhibiting acidosis with a pH of < 7.2 and a base excess of minus 7–8 mmol/L<sup>[1]</sup>. Despite these signs, no laboratory-chemical parameters currently exist that are specifically designed to confirm intestinal necrosis.

Currently, contrast-enhanced biphasic multidetector row helical CT of the abdomen is conducted as the primary imaging modality in many medical centres. This technique enables the imaging of the entire abdomen with high temporal and spatial resolution in the arterial and portal venous phases<sup>[4]</sup>.

In addition to high sensitivity and specificity, multidetector CT provides the following advantages: it is a rapid and non-invasive technique that is available 24 h a day in most acute-care medical centres. Due to its high sensitivity, specificity, availability, and non-invasiveness, the multidetector CT is a suitable modality for the diagnosis of acute mesenteric ischemia. Furthermore, it is extremely helpful for triage patients who require subsequent conventional angiography, surgery, or clinical surveillance<sup>[4]</sup>.

Aschoff *et al.*<sup>[5]</sup> reported a sensitivity of 93% and a specificity of 100% of CT angiography for the diagnosis of acute mesenteric ischemia. Diagnosis was based on an analysis of both vascular occlusions and the consequences of tissue damage, such as intestinal pneumatosis, bowel wall thickening, portomesenteric venous gas, or solid organ infarction<sup>[4]</sup>.

An association between pneumatosis intestinalis and portomesenteric venous gas is a strong indicator of the presence of mesenteric infarction or segmental ischemia, and it is therefore an indication for emergency exploratory surgery<sup>[9,22–26]</sup>.

Data from the literature suggest that the combination of pneumatosis intestinalis and portal venous gas is associated with the presence of bowel ischemia in approximately 70% of all cases<sup>[22,27,28]</sup>. We extended these results by evaluating the association of this CT finding with the severity of mural necrosis.

Bowel pneumatosis is an imaging phenomenon that can represent the presence of gas in the bowel wall<sup>[22]</sup>. Hepatic portal venous gas is defined radiologically as tubular areas of decreased attenuation in the liver periphery<sup>[29,30]</sup>.

Although the etiology of pneumatosis appears to be multifactorial, the exact causes are not known. Two primary theories have been proposed in the medical literature. A mechanical theory hypothesises that gas dissects into the bowel wall from either the intestinal lumen or the lungs, *via* the mediastinum, due to some mechanism

that causes increased pressure (*i.e.*, bowel obstruction or emphysema). In contrast, a bacterial theory proposes that gas-forming bacilli enter the submucosa through mucosal rents or increased mucosal permeability, thereby producing gas within the bowel wall. A combination of both theories is also plausible. Bacterial overgrowth in the gastrointestinal tract arising from a variety of causes can lead to excessive hydrogen gas production, bowel distension, and subsequently, the dissection of intraluminal hydrogen gas into the bowel wall<sup>[25]</sup>. In the case of ischemia, pneumatosis has been considered to be an ominous radiographic finding, particularly if it is associated with portomesenteric venous gas. In some articles, pneumatosis has been described as an advanced sign of ischemic bowel disease, usually indicating irreversible injury and transmural necrosis<sup>[6–8]</sup>.

Wiesner *et al.*<sup>[9]</sup> supports the hypothesis that patients with pneumatosis and portomesenteric venous gas are more likely to exhibit transmural infarction. Similarly, Kernagis *et al.*<sup>[6]</sup> determined that patients with CT findings of pneumatosis and portomesenteric venous gas were more likely to have transmural infarction than those with pneumatosis alone.

However, these studies share several limitations, as they were retrospective investigations with small sample sizes (up to seven patients), which may have magnified the effects of selection bias on the study population.

Although pneumatosis plus porto-mesenteric venous gas is associated with bowel ischemia, we have demonstrated that it cannot be used as a diagnostic sign of transmural necrosis. No statistical associations were identified between transmural infarction and the presence of pneumatosis plus porto-mesenteric venous gas, according to both univariate and multivariate analyses. Although the finding of concomitant pneumatosis plus porto-mesenteric venous gas is useful in verifying transmural necrosis with a specificity of 83%, the very low sensitivity of 17% indicates that the diagnosis of transmural necrosis cannot be excluded based on normal findings. Some limitations of our study warrant discussion. A major concern is the retrospective design of the present study, which has inherent limitations and biases. Moreover, we included only patients who underwent surgical intervention in the analyses. As a result, we are likely to have selected patients with more severe clinical presentations. Thus, further ad hoc-designed prospective studies with adequate sample sizes are needed to evaluate whether pneumatosis intestinalis and portomesenteric venous gas facilitates the prediction of ischemic bowel wall damage severity. However, our encouraging results appear to suggest that neither portomesenteric venous gas nor pneumatosis were pathognomonic of bowel trans-mural infarction.

## COMMENTS

### Background

Pneumatosis plus portomesenteric venous gas have been considered signs of

advanced disease, usually indicating irreversible injury and transmural necrosis. Although some authors have identified an association between transmural bowel infarction and the presence of concomitant pneumatosis plus portomesenteric venous gas, these studies only represented reports that included up to seven patients.

### Research frontiers

Although a strong indicator of the presence of mesenteric infarction or segmental ischemia is the association of pneumatosis intestinalis with portomesenteric venous gas, their study demonstrates that these findings are not useful in assessing the presence of transmural necrosis.

### Innovations and breakthroughs

The finding that pneumatosis plus porto-mesenteric venous gas is useful in verifying transmural necrosis with a specificity of 83%, but its very low sensitivity of 17% indicates that the diagnosis of transmural necrosis cannot be excluded based on normal findings.

### Applications

Their study emphasises that pneumatosis and portomesenteric venous gas cannot be considered signs of transmural necrosis.

### Terminology

A superficial damage of bowel mucosa and submucosa was histologically assessed as partial bowel ischemia before the development of transmural infarction. Air bubbles or continuous bands of air in the bowel walls were considered to be signs of pneumatosis, whereas gas in the mesenteric veins or gas in the intrahepatic branches of the portal vein were indicative of gas in the portomesenteric circulation at the time of computed tomography (CT) examination.

### Peer review

This is an interesting study in which authors use more representative sample size to evaluate whether CT scan evidence of the concomitant presence of pneumatosis and portomesenteric venous gas is a predictor of transmural bowel necrosis. The results are interesting and suggest that although pneumatosis plus porto-mesenteric venous gas is associated with bowel ischemia, they have demonstrated that their co-occurrence cannot be used as diagnostic signs of transmural necrosis.

common *vacA* subtype was s1a (79.6%). However, the s2 gene was found less frequently with an isolation rate of 8.2% of the *H. pylori* isolates. The genotypes *iceA2* and *vacA s1m2* were the most frequently found types in children with antral nodularity. In addition, the genotypes *iceA1*, *babA2* and *vacA s1m1* were found in similar ratios in all the *H. pylori* isolates obtained from children with peptic ulcer. The genotypes *vacA s2m1* and s1c were not observed in any of isolates studied.

**CONCLUSION:** This study showed that *vacA s1m2*, *cagA* and *iceA2* were the most common genotypes, and no association between antral nodularity and genotypes was observed.

### Abstract

**AIM:** To identify the virulence genotypes of *Helicobacter pylori* (*H. pylori*) if present in children in Eastern Turkey and if those genotypes are mostly associated with severe clinical presentations.

**METHODS:** A total of 49 *H. pylori* positive Turkish children (42 with antral nodularity and 7 with peptic ulcer) who underwent upper gastrointestinal endoscopy with abdominal symptoms during the period from March 2011 to September 2012 were enrolled in this study. Antral nodularity was diagnosed endoscopically by two of the authors. We determined for the presence of *cagA*, *vacA*, *cagE*, *iceA* and *babA2* genotypes of *H. pylori* isolates in DNA obtained directly from frozen gastric biopsy samples by polymerase chain reaction test using specific primers.

**RESULTS:** Of the 49 *H. pylori* isolates studied, 61.2%, 91.8%, 22.4%, 28.6%, 57.1% and 40.8% were positive for the *cagA*, *vacA* s1, *cagE*, *iceA1*, *iceA2* and *babA2* genes, respectively. We showed that the most

**Core tip:** In this research we have attempted to determine the prevalence of some genotypes of *Helicobacter pylori* (*H. pylori*) among children in Eastern Turkey and to investigate the relationship between these genotypes with antral nodularity. Identifying the virulence genes among *H. pylori* isolates in children would allow for the development of new treatments and eradication policies in adults. The study results suggest that there was no significant association between antral nodularity and the presence of genotypes ( $P > 0.05$ ).

### INTRODUCTION

*Helicobacter pylori* (*H. pylori*) infection is generally acquired

during childhood, persists throughout life unless treated with antibiotics, and the infection is usually associated with the development of several gastroduodenal diseases such as gastritis, peptic ulcer, gastric carcinoma and mucosa-associated lymphoid tissue lymphoma<sup>[1-3]</sup>.

The cytotoxin associated gene A (*cagA*) being a marker for the presence of the *cag* pathogenicity island (*cag* PAI) was the first recognized virulence gene in the *H. pylori* genome in both adults and children<sup>[3,4]</sup>. Cytotoxin associated gene E (*cagE*) is also a member of the *cag* PAI, and has been described as a potential virulence factor associated with duodenal ulcer in children<sup>[5]</sup>. The vacuolating cytotoxin (*vacA*) gene exists in different subtypes, varying in the signal (s1 or s2) and middle (m1 or m2) regions<sup>[6,7]</sup>. *H. pylori vacA* alleles differ in their ability to express an active toxin<sup>[7]</sup>. Inducement occurs *via* contact with the epithelium gene (*iceA*), has two allelic variants (*iceA1* and *iceA2*), and has been determined through its upregulation after adherence of *H. pylori* to the gastric epithelium<sup>[8,9]</sup>. The blood adhesion binding antigen A (*babA*) adhesion of *H. pylori*, encoded by the *babA2* gene is an outer membrane protein that binds to the fucosylated histo-blood group antigens on the surface of gastric epithelial cells<sup>[10]</sup>.

Despite a high prevalence of *H. pylori* infection among children and adults in Turkey, the published data on geographic distribution of the virulence genes in *H. pylori* strains among Turkish children are very limited, and relatively few studies have been reported on the prevalence of the *cagA* gene of *H. pylori* in Turkish children<sup>[11-13]</sup>. This study was performed to determine the prevalence of some virulence genes of *H. pylori* which were not previously reported among children in Eastern Turkey, and to investigate the association between these genotypes with clinical disease.

## MATERIALS AND METHODS

A total of 49 *H. pylori* isolates were investigated for the presence of virulence genotypes. These isolates [by polymerase chain reaction (PCR)] were recovered from 101 Turkish children (53 girls and 48 boys, ranging between 4 and 18 years old, average 12 years) who underwent upper gastrointestinal endoscopy with abdominal symptoms at the clinic of the Pediatric Gastroenterology Department at the Firat University Hospital between March 2011 and September 2012. Antral nodularity was defined as being endoscopically characterized by the irregular appearance of the mucosa as like that of a "cobblestone pavement"<sup>[14]</sup>. Also, the presence of ulcers was determined by endoscopic examination.

Our study was approved by the Medical Ethics Committee of Firat University. All patients received informed consent that was signed by their parents before endoscopic procedures.

### Isolation of *H. pylori* DNA and PCR detection of its genotypes

*H. pylori* DNA was prepared using the QIAamp DNA

mini kit (Qiagen, Germany) following the manufacturer's instructions. The extracted DNA was kept at -20 °C until tested.

PCR was carried out using oligonucleotide primers targeting the 298 bp fragment of the *cagA* gene; the fragment 259 bp or 286 bp in size for type s1 or s2; the 190, 187 and 213 bp fragments for s1a, s1b, and s1c; the 567 bp and 642 bp fragments for m1 and m2; the 508 bp fragment of the *cagE* gene; the 247-bp fragment of *iceA1*; the 229 or 334-bp fragments of *iceA2*; and the 271 bp fragment of the *babA2* gene, in order to amplify the *cagA*, *vacA*, *cagE*, *iceA* and *babA2* genes of the *H. pylori* isolates<sup>[7,15-20]</sup>. Ten µL of each PCR product was subjected to electrophoresis in a 1.5% (w/v) agarose gel.

All reactions were performed with positive controls containing the DNA of the HP 26695, HP J99, and some clinical isolates supplied by Dr. Yoshio Yamaoka, along with negative controls containing all PCR components with distilled water to substitute the DNA sample.

### Statistical analysis

Statistical analysis was performed by statistical software program SPSS for Windows version 12.00 (SPSS, Chicago, IL, United States). The correlation between *H. pylori* genotypes and antral nodularity was assessed by Fischer's exact and  $\chi^2$  tests. A *P*-value of less than 0.05 was considered statistically significant.

## RESULTS

Table 1 summarizes the prevalence of *cagA*, *vacA*, *cagE*, *iceA* and *babA2* genes with antral nodularity and peptic ulcers. The number of children with peptic ulcers in the present study was low; therefore further analysis was not carried out.

The *cagA* gene was found in 30 of the 49 isolates (61.2%). In our study, the *vacA* genes were observed in all isolates. The most predominant subtype was s1a (79.6%), followed by s1b (12.2%), then s2 (8.2%). The genotype s1m2, which was predominant in this study, was observed in 28 (57.1%) isolates. However, the genotypes s1m1 and s2m2 were detected in 17 (34.7%) and 4 (8.2%) isolates, respectively. Furthermore, the genotype *vacA* s2m1 and subtype s1c were not found in any of the isolates. The prevalence of *cagE* gene in children with antral nodularity and peptic ulcer was 8 out of 42 (19%) and 3 out of 7 (42.9%) isolates, respectively. The *iceA* gene was not observed in 4 of the 49 isolates. The *iceA2* gene was positive in 28 (57.1%) isolates, while *iceA1* was detected in 14 (28.6%) isolates. Three isolates (6.1%) were positive for both *iceA1* and *iceA2*. The prevalence of *iceA1* was higher in patients with peptic ulcers (57.1%), with no significance difference observed compared to patients with antral nodularity (23.8%). The *babA2* gene was detected in 20 (40.8%) samples. The *babA2* showed a higher proportion (57.1%) in patients with peptic ulcer compared to patients with antral nodularity (38.1%).

We emphasized no significant association between antral nodularity and the presence of the genotypes (*P* > 0.05).

**Table 1** The prevalence of the virulence factor genes of *Helicobacter pylori* from children with antral nodularity and peptic ulcer *n* (%)

Virulence factor genes	Antral nodularity ( <i>n</i> = 42)	Peptic ulcer ( <i>n</i> = 7)	Total ( <i>n</i> = 49)

## DISCUSSION

Although only one study on virulence genes of *H. pylori* has been performed in adults in the Elazig Province in Eastern Turkey<sup>[21]</sup>, there is no data related to the prevalence of *H. pylori* genotypes among children in this region. However, there are a few studies on determining the prevalence of the *cagA* gene of *H. pylori* in Turkish children<sup>[11-13]</sup>.

The prevalence of the *cagA* gene in children among European countries varies from 22.4% to 76%<sup>[2,22]</sup>. Earlier studies performed in Turkish children showed the prevalence of the *cagA* gene was 55%-74.4%<sup>[11-13]</sup>. In this study, we detected the prevalence of 61.2% of the *cagA* gene among Turkish children. The inconsistent findings may be due to adaptation of *H. pylori* to the environment in different geographic regions<sup>[23]</sup>. Some studies had confirmed a significant correlation between the severity of histological changes and the presence of the *cagA* gene in the *H. pylori* genome<sup>[23-26]</sup>, whereas others<sup>[11,27-29]</sup> have not emphasized this association.

It has been demonstrated that the geographic distribution for *vacA* alleles differs in many countries around the world<sup>[30]</sup>; *s1c* is the common strain in East Asia, while *s1a* is the prevalent strain in Northern Europe, and *s1b* in Portugal and Spain<sup>[19]</sup>. The majority of *H. pylori* isolates identified as *s1a*; however, no subtypes *s1c* and *s2* were found in this study. The *vacA* *s1m1*, *s1m2*, and *s2m2* genotypes were found in 34.7%, 57.1%, and 8.2%, respectively. No *s2m1* genotype was detected in the present study. Our data is consistent with the results reported in Poland<sup>[31]</sup> and Shanghai<sup>[32]</sup> where the *s1m2* was the most prevalent genotype. In contrast, other predominant *vacA* genotypes were reported in Brazil, Slovenia, the Midwestern United States (*s1m1*), and Spain (*s2m2*)<sup>[25,28,33,34]</sup>.

The prevalence of the *iceA1* genotype was found

to be 14% in Brazil<sup>[24]</sup>, 37% in Israel<sup>[28]</sup>, 44% in North America<sup>[27]</sup>, and 62% in Slovenia<sup>[23]</sup>. The prevalence (28.6%) of the *iceA1* gene in this study was similar to the Brazilian population (14%)<sup>[24]</sup>, but lower than in Korea (76%)<sup>[35]</sup>. Although it has been shown that the *iceA1* gene is associated with ulcer disease in adults<sup>[19]</sup>, no significant association between the *iceA1* subtype and disease severity was found which is concordant with other studies<sup>[23,27,28]</sup>. We found that the *iceA2* gene (57.1%) was the predominant genotype, supporting the findings of pediatric studies in Brazil (68.9%), Israel (52%), and the Midwestern United States (84%)<sup>[25,28,33]</sup>.

The prevalence of *cagE* was found in 24.5% of *H. pylori* isolates in Israel<sup>[28]</sup>, 59% in Canada<sup>[5]</sup>, and 41.7% in Bulgaria<sup>[26]</sup>. The *cagE* gene was detected in 11 (22.4%) out of 49 isolates, and no significant association was found between the *cagE* and peptic ulcers in children in this study, consistent with a study by Benenson *et al.*<sup>[5]</sup>. However, another study showed just such an association<sup>[5]</sup>. Furthermore, we observed that the *cagE* gene was predominantly detected in *H. pylori* isolates from children with peptic ulcers. Because of the relatively low number of children with peptic ulcers, statistical analysis was not carried out.

The prevalence of *H. pylori* *babA2* was 17.2% in Portugal, 36% in the Midwestern United States, 84.4% in Brazil, and 66.7% in Bulgaria<sup>[2,25,26,33]</sup>. In the present study, the *babA2* gene was detected in 40.8% of the *H. pylori* isolates. The low prevalence of *babA2* in children can also be explained by the fact that *H. pylori* strains exhibit different patterns of adherent to gastric mucosa cells in adults and children, pointing out the importance of host characteristics in the selection of determinants of the infecting strain<sup>[36,37]</sup>.

In conclusion, we feel that the clinical presentations observed are not correlated with the presence of the virulence genotypes because of small numbers of *H. pylori* isolates. However, the identification of virulence genotypes in this study will be important for future policies for the eradication of *H. pylori* in order to prevent severe diseases in adults.

## ACKNOWLEDGMENTS

The authors thank to Dr. Yoshio Yamaoka (Michael E. DeBakey Veterans Affairs Medical Center, Houston, TX 77030, United States) for providing the DNA of the HP 26695, HP J99, and some clinical isolates, and the management of the Elazig Veterinary Control and Research Institute for providing laboratory opportunities in this study. We also thank Dr. Alfizah Hanafiah (Department of Medical Microbiology and Immunology, Faculty of Medicine, UKM Medical Centre, Kuala Lumpur, Malaysia), Dr. Guillermo I. Perez Perez (NYU School of Medicine, Department of Medicine and Microbiology, New York, United States), and Matjaz Homan (University Children's Hospital, Bohoričeva 20, 1000 Ljubljana, Slovenia) for their critical reading of the manuscript.

## COMMENTS

**Background**

There are a few studies on the virulence genes of *Helicobacter pylori* (*H. pylori*) in Turkish children and the correlation of these genotypes with clinical outcome. The present study aimed to detect the prevalence of *cagA*, *vacA*, *cagE*, *iceA* and *babA2* genotypes of *H. pylori* in children in Eastern Turkey and to assess the association between these virulence genotypes and antral nodularity.

**Research frontiers**

In this study, the authors investigated the prevalence of *cagA*, *vacA*, *cagE*, *iceA* and *babA2* genotypes of *H. pylori* among children in Eastern Turkey and evaluated the association between these genotypes with antral nodularity. There was no significant association between virulence factor genes with antral nodularity.

**Innovations and breakthroughs**

This is the first study on the prevalence of the *vacA*, *cagA*, *cagE*, *iceA* and *babA2* genes among children in Eastern Turkey and the correlation of these virulence factor genes with antral nodularity. This research is useful not only in developing future strategies to control and eradicate *H. pylori* infection but also to contribute a better understanding of the epidemiology of *H. pylori* infection. In this study, they examined small numbers of *H. pylori* isolates. More large population and genotyping studies are needed for the development of the future policies to eradicate *H. pylori* infection.

**Applications**

The data obtained from this study will be useful in developing the future policies for the eradication of *H. pylori* in order to prevent severe diseases in adults.

**Peer review**

The authors studied the prevalence of *H. pylori* virulence genotypes among children in Eastern Turkey. This is a useful paper on a topic for which there is, as yet little information. It will certainly contribute to knowledge on the issue.

### Abstract

**AIM:** To investigate the weight loss and glycemic control status [blood glucose, hemoglobin A1c (HbA1c) and hypoglycaemic treatment].

**METHODS:** The primary risk factor for type 2 diabetes is obesity, and 90% of all patients with type 2 diabetes are overweight or obese. Although a remarkable effect of bariatric surgery is the profound and durable resolution of type 2 diabetes clinical manifestations, little is known about the difference among various weight loss surgical procedures on diabetes remission. Data from patients referred during a 3-year period (from January 2009 to December 2011) to the University of Naples "Federico II" diagnosed with obesity and diabetes were retrieved from a prospective database. The patients were split into two groups according to the surgical intervention performed [sleeve gastrectomy (SG) and mini-gastric bypass (MGB)]. Weight loss and glycemic control status (blood glucose, HbA1c and hypoglycaemic treatment) were evaluated.

mic treatment) were evaluated.

**RESULTS:** A total of 53 subjects who underwent sleeve gastrectomy or mini-gastric bypass for obesity and diabetes were screened for the inclusion in this study. Of these, 4 subjects were excluded because of surgical complications, 7 subjects were omitted because young surgeons conducted the operations and 11 subjects were removed because of the lack of follow-up. Thirty-one obese patients were recruited for this study. A total of 15 subjects underwent SG (48.4%), and 16 underwent MGB (51.6%). After adjusting for various clinical and demographic characteristics in a multivariate logistic regression analysis, high hemoglobin A1c was determined to be a negative predictor of diabetes remission at 12 mo (OR = 0.366, 95%CI: 0.152-0.884). Using the same regression model, MGB showed a clear trend toward higher diabetes remission rates relative to SG (OR = 3.780, 95%CI: 0.961-14.872).

**CONCLUSION:** Although our results are encouraging regarding the effectiveness of mini-gastric bypass on diabetes remission, further studies are needed to provide definitive conclusions in selecting the ideal procedure for diabetes remission.

© 2013 Baishideng. All rights reserved.

**Key words:** Bariatric surgery; Sleeve; Bypass; Obesity and diabetes

**Core tip:** Duodenum exclusion could suggest the potential superiority of mini-gastric bypass over sleeve gastrectomy to obtain diabetes remission. This mechanism could suggest the potential superiority of mini-gastric bypass over sleeve gastrectomy to obtain diabetes remission. Thus, although the gold standard for diabetes remission is still the Roux-en-y gastric bypass, being similar mechanisms of diabetes remission involved and being easier to be performed, the mini-gastric bypass

could become a valuable alternative.

## INTRODUCTION

Severe obesity is one of the major problems in Western Countries and is associated with several comorbidities and disabling diseases (*e.g.*, cardiovascular disease, metabolic syndrome, type 2 diabetes, fertility, certain tumor types and increased mortality)<sup>[1-6]</sup>.

One of the major comorbidities of obesity is type 2 diabetes mellitus (T2DM). In fact, the term “diabesity”<sup>[7]</sup> has been introduced to refer to obesity accompanied by T2DM.

With the exception of nutritional and some pharmacological treatments, bariatric surgery is performed more and more frequently as the treatment of choice in patients with severe obesity.

The efficacy of these surgical procedures in weight control has been widely described in several studies. Additionally, one of the most relevant corollary effects reported following bariatric surgery is T2DM remission.

A variety of surgical procedures are available and, currently, it is difficult to identify the most effective option based on patient characteristics and comorbidities. Furthermore, little is known regarding the effect of the various surgical procedures on glycemic control and on T2DM remission<sup>[8-11]</sup>.

The aim of this study is to compare the clinical efficacy of laparoscopic sleeve gastrectomy (SG) and laparoscopic mini-gastric bypass (MGB) in terms of T2DM remission.

## MATERIALS AND METHODS

Data from patients referred during a 3-year period (from January 2009 to December 2011) to the University of Naples “Federico II” diagnosed with obesity and diabetes were retrieved from a prospective database.

Only patients who underwent uneventful laparoscopic SG or MGB with a follow-up of at least 1 year were included.

The patients were split into two groups according to the surgical intervention performed (SG and MGB).

Medical records were reviewed to collect the demographic and clinical characteristics of the patients. According to standard procedures<sup>[12]</sup>, the study population was stratified based on abdominal obesity [body mass index (BMI) > 30 kg/m<sup>2</sup>], triglycerides levels (equal to or

> 150 mg/dL), HDL-cholesterol (< 40 mg/dL for men and 50 mg/dL for women with total cholesterol values > 200 mg/dL), blood pressure (systolic blood pressure equal to or > 130 and/or diastolic > 85 mmHg) and fasting glucose levels (equal to or > 110 mg/dL).

Diagnosis of T2DM was made according to the American Diabetes Association guidelines. T2DM remission was defined as a fasting plasma glucose level below 126 mg/dL in the absence of hypoglycemic drugs.

The indications for treating these patients were the same as those published in the Italian Society for Bariatric Surgery guidelines<sup>[13]</sup>. Following the failure of a non-operative weight reduction program that included diet and other interventions (*e.g.*, behavioral modification, psychotherapy, dietary counseling, or physical training), bariatric surgery plays a critical role in patient outcome when the BMI is > 40 kg/m<sup>2</sup> or is > 35 kg/m<sup>2</sup> combined with serious co-existing conditions.

Only surgical procedures performed by an expert surgeon (more than 500 laparoscopic surgical procedures) were included in the analysis.

Prevention of surgical site infection and perioperative antiplatelet drug administration were managed according to validated criteria<sup>[14,15]</sup>.

For the sleeve gastrectomy procedure, 75%-80% of the greater curvature was excised, leaving a narrow stomach tube of 38F. Single-loop gastric bypass was performed, which consisted of constructing a 40-70 mL sleeve gastric pouch with a jejunal exclusion of 200-220 cm. All procedures were performed using a laparoscopic approach<sup>[16-18]</sup>.

Following surgery, clinical controls were performed once a month for the first 3 postoperative months and every 3 mo thereafter.

At each follow-up visit, weight loss and glycemic control status [blood glucose, hemoglobin A1c (HbA1c) and hypoglycemic treatment] were evaluated. Diabetes remission was defined as HbA1c values less than 6.5 without the use of oral hypoglycemic treatment or insulin<sup>[11,19]</sup>.

Statistical analysis was performed using the SPSS 17 system (SPSS Inc., Chicago, IL, United States). Continuous data were expressed as the mean  $\pm$  SD, and categorical variables were expressed as the percent changes. To compare continuous variables, an independent and/or paired sample *t* test was performed, and correlation was assessed using the Pearson's linear correlation coefficients (*r*). Changes in BMI, glycemia and HbA1c were expressed as the percent changes *vs* baseline values. The  $\chi^2$  test was used to analyze categorical data. When the minimum expected value was < 5, the Fisher's exact test was used. To adjust for major covariates and to generate predictions, a logistic regression (stepwise) model was applied, with diabetes remission at 12 mo as the dependent variable and gender, age, hypertension, hypercholesterolemia, current hypoglycemia treatment, BMI baseline value, glycemia and HbA1c as independent variables. All of the results are presented as 2-tailed values with statistical significance defined as *P* values < 0.05.

**Table 1** Baseline clinical and demographic characteristics of the study population *n* (%)

	Sleeve ( <i>n</i> = 15)	Mini-bypass ( <i>n</i> = 16)	<i>P</i> value
Age	37.26 ± 3.7	39.3 ± 2.3	0.076
Male gender	7 (46.7)	8 (50.0)	1.000
BMI	43.6 ± 2.99	45.8 ± 5.0	0.140
Diabetes treatment			
Metformin ± insulin	7 (46.7)	9 (56.3)	0.724
Metformin	8 (53.3)	7 (43.7)	
Glycemia	161.4 ± 31.4	177.8 ± 38.6	0.207
HbA1c	8.6 ± 1.0	8.47 ± 1.1	0.782
Hypertension	8 (53.3)	10 (62.5)	0.722
Diabetes	15 (100.0)	16 (100.0)	1.000
Hypercholesterolemia	4 (26.6)	4 (25.0)	1.000

BMI: Body mass index; HbA1c: Hemoglobin A1c.

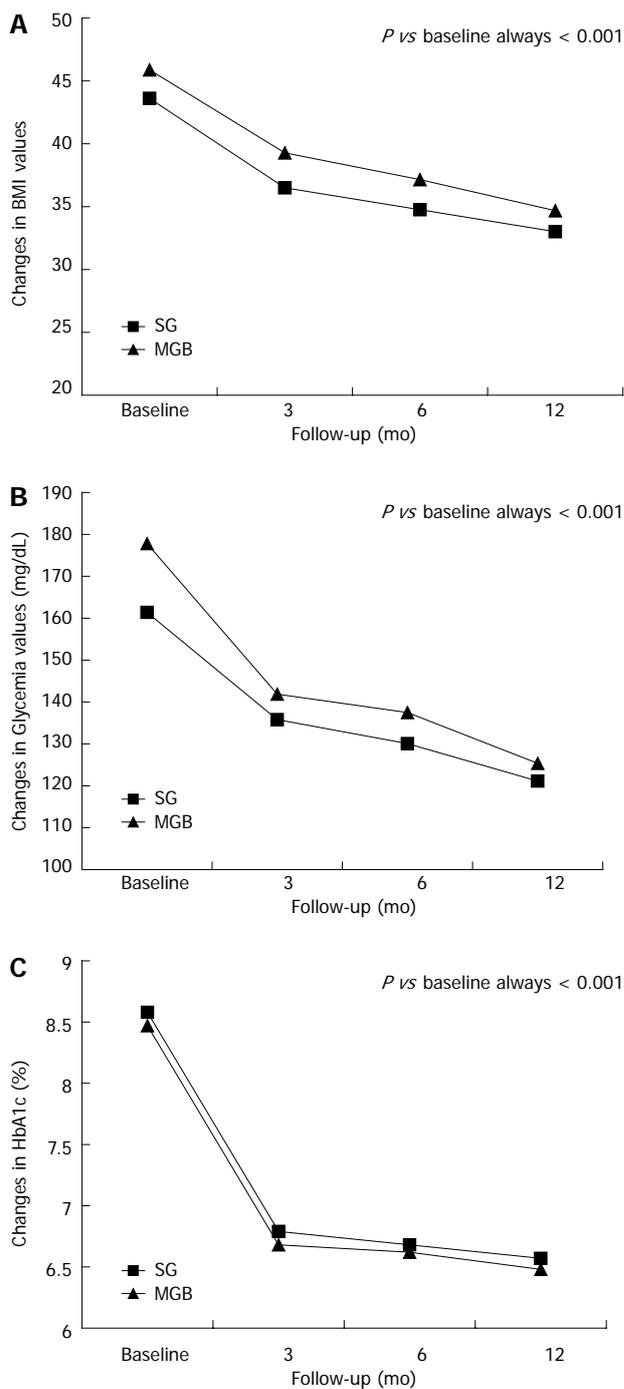

## RESULTS

A total of 53 subjects who underwent sleeve gastrectomy or mini-gastric bypass for obesity and diabetes were screened for the inclusion in this study. Of these, 4 subjects were excluded because of surgical complications, 7 subjects were omitted because young surgeons conducted the operations and 11 subjects were removed because of the lack of follow-up. Thus, a total of 31 obese patients (15 males and 16 females; mean age: 38.32 ± 3.21 years; BMI: 44.78 ± 4.25 kg/m<sup>2</sup>) were recruited for this study. All patients were diagnosed with type 2 diabetes [15 (48.4%) on metformin and 16 (51.6%) on metformin + insulin], 18 subjects (58.1%) reported hypertension and 8 presented with hypercholesterolemia. The mean glycemia value was 169.87 ± 35.76, and the mean HbA1c level was 8.5 ± 1.0. A total of 15 subjects underwent SG (48.4%), and 16 patients underwent MGB (51.6%). Major clinical and demographic characteristics of the study population stratified according to type of surgery are reported in Table 1.

After surgical intervention, a significant and consistent reduction in BMI, glycemia and HbA1c values were observed relative to the baseline values (Figure 1). Stratifying for type of surgery, SG and MGB were associated with similar percent changes in BMI (-24.33 ± 4.48 *vs* -24.19 ± 4.42, *P* = 0.931), glycemia (-24.30 ± 11.40 *vs* -28.42 ± 14.03, *P* = 0.379) and HbA1c (-22.57 ± 8.70 *vs* -22.67 ± 8.46, *P* = 0.975).

Overall, significant correlations were not detected in the percent change from baseline to 12-mo follow-up between BMI and glycemia, as well as between BMI and HbA1c (Figure 2). Additionally, the same results were confirmed after stratifying based on the type of surgery. Indeed, the percent change in BMI did not correlate with changes in glycemia (*r* = -0.119, *P* = 0.673 for SG and *r* = 0.462, *P* = 0.071 for MGB) or with changes in HbA1c (*r* = -0.349, *P* = 0.202 for SG and *r* = -0.018, *P* = 0.946 for MGB).

As shown in Figure 3, the prevalence of diabetes remission was gradually increased following surgery, regardless of the type.

**Figure 1** Changes in body mass index (A), glycemia (B) and hemoglobin A1c (C) values following surgery. HbA1c: Hemoglobin A1c; SG: Sleeve gastrectomy; MGB: Mini-gastric bypass; BMI: Body mass index.

Specifically, at 3 mo post-surgical intervention, diabetes remission was reported by 18 subjects (53.3% in SG *vs* 62.5% in MGB, *P* = 0.722). Similar results were confirmed at the 6-mo follow-up (53.3% for SG *vs* 68.8% for MGB, *P* = 0.473).

At the 12-mo follow-up, 66.7% of subjects who underwent SG achieved diabetes remission *vs* 87.5% of those who underwent MGB (*P* = 0.220).

Interestingly, the percent change in BMI was similar between patients achieving diabetes remission and

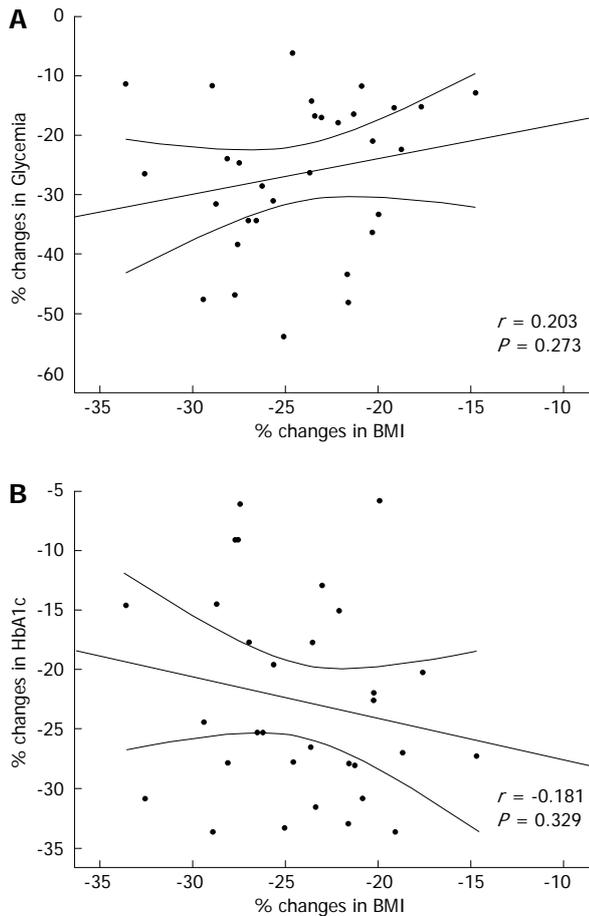

Figure 2 Scatter plot of Pearson's correlations between the percent change in glycemia and body mass index (A) and in hemoglobin A1c and body mass index (B) following surgical intervention. HbA1c: Hemoglobin A1c; BMI: Body mass index.

patients who did not ( $-24.28 \pm 4.33$  vs  $-24.15 \pm 4.53$ , respectively,  $P = 0.97$ ).

After adjusting for various clinical and demographic characteristics in a multivariate logistic regression analysis, a high HbA1c was considered a negative predictor of diabetes remission at 12 mo (OR = 0.366, 95%CI: 0.152-0.884). Using the same regression model, MGB showed a clear trend towards a higher diabetes remission rate relative to SG (OR = 3.780, 95%CI: 0.961-14.872).

## DISCUSSION

The prevalence of type 2 diabetes has markedly increased in the last decade, both in the United States<sup>[20-23]</sup> and globally<sup>[24-26]</sup>. These data are correlated with a comparably steep increase in the prevalence of obesity<sup>[27-29]</sup>. The primary risk factor for type 2 diabetes is obesity, and 90% of all patients with type 2 diabetes are either overweight or obese<sup>[30,31]</sup>. The National Health and Nutrition Examination Survey III (1988-1994) data demonstrated that the risk for chemical diabetes is approximately 50% with a BMI of greater than or equal to 30 kg/m<sup>2</sup> and over 90% with a BMI of 40 kg/m<sup>2</sup> or more<sup>[32]</sup>. The Nurses' Health Study that was conducted on 84941 women (1980-1996)

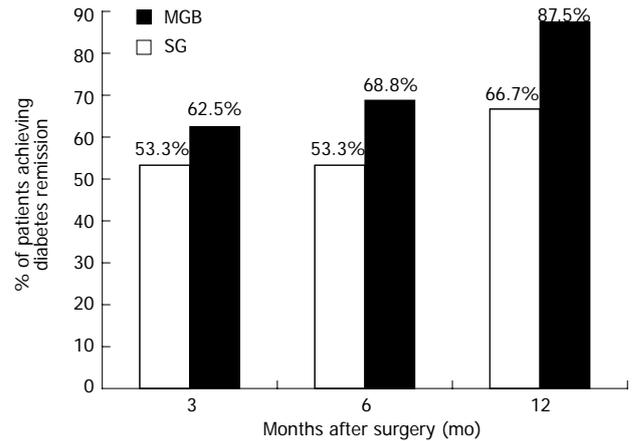

Figure 3 Prevalence of subjects achieving diabetes remission in the sleeve gastrectomy group and the mini-gastric bypass group. SG: Sleeve gastrectomy; MGB: Mini-gastric bypass.

showed that the relative risk of diabetes increased approximately 40-fold as the BMI increased from less than 23 kg/m<sup>2</sup> to more than 35 kg/m<sup>2</sup><sup>[33]</sup>.

Morbid obesity has been defined by the National Institutes of Health as a BMI of greater than or equal to 40 kg/m<sup>2</sup> or greater than or equal to 35 kg/m<sup>2</sup> in the presence of obesity comorbidities<sup>[13,19,20]</sup>.

The prevalence of people who are overweight or obese has increased dramatically in high-income countries during the past 20 years. The World Health Organization estimates that 54.3% of women and 51.7% of men in the United States will be obese (BMI 30 kg/m<sup>2</sup>) in 2015.

Obesity is notoriously difficult to manage. Diet, behavioral therapy, exercise, and pharmacologic intervention have traditionally been used but generally yield modest results. Additionally, weight regain is a common problem. In cases of failed medical therapy, bariatric surgery should be considered the treatment of choice for severe obesity<sup>[34]</sup>.

Surgical treatment of obesity is a rapidly growing area of surgical practice, reflecting the ability of bariatric surgery to achieve significant and durable weight loss, as well as the evolution of safer, less-invasive procedures<sup>[35-37]</sup>.

A remarkable effect of bariatric surgery is the profound and durable resolution of type 2 diabetes clinical manifestations. In a meta-analysis of 134 studies that reported comorbidity resolution (2738 citations), bariatric surgery followed by resolution of type 2 diabetes was observed in 48% of patients who underwent laparoscopic adjustable gastric banding, 84% of patients who underwent gastric bypass, and 98% of patients who underwent biliopancreatic diversion/duodenal switch<sup>[38]</sup>. These data were based on reports from 22094 patients from January 1, 1990 to June 5, 2003.

Roux-en-Y gastric bypass (RYGB) is considered the gold standard bariatric procedure for achieving diabetes remission.

To explain the mechanisms underlying the effective-

ness of gastric bypass procedures in normalizing glycemia, it has been suggested that removal of the gut may play a major role in diabetes remission, especially because important hormones are secreted from this region. In 2009, Cummings reviewed the existing hypotheses regarding the mechanisms underlying diabetes remission. Based on this review, the main hypotheses include the ghrelin hypothesis, the upper intestinal hypothesis and the lower intestinal hypothesis. The ghrelin hypothesis<sup>[39]</sup> maintains that ghrelin regulation may be disturbed following RYGB. Ghrelin is a hormone secreted by the stomach and proximal small bowel, particularly before meals. Its main physiological effects include increased appetite and fat mass increase<sup>[40]</sup>. In support of the ghrelin hypothesis, several studies have shown that ghrelin levels are very low following RYGB. Diminished ghrelin secretion can decrease appetite and food intake, and reduced secretion might also have a role in increasing glucose tolerance, as ghrelin can stimulate counter-regulatory hormones<sup>[41]</sup>. The lower intestinal hypothesis claims that intestinal shortcuts, created by bariatric surgery, expedite delivery of ingested nutrients and increase glucagon-like peptide-1 (GLP-1) release. GLP-1 is an incretin, defined as a peptide secreted from enteroendocrine L-cells. These cells are found throughout the small intestine and at a high density in the ileum. GLP-1 increases insulin secretion and has also been shown to increase proliferation and decrease apoptosis of beta-cells<sup>[42]</sup>. Both RYGB and BPD create gastrointestinal shortcuts, and studies have shown that postprandial GLP-1 secretion is increased post-surgery<sup>[43,44]</sup>. Therefore, it seems reasonable that, following surgery, GLP-1 secretion may be enhanced, leading to enhanced insulin secretion. This mechanism could also explain the increase in  $\beta$ -cell mass that is thought to accompany post-RYGB hyperinsulinemic hypoglycemia<sup>[45]</sup>. The upper intestinal hypothesis maintains that avoiding nutrient contacts with the duodenum is somehow key in the process through which diabetes is improved. The basis of this hypothesis is that unknown factors or processes from the duodenum influence glucose homeostasis<sup>[39]</sup>. Rubino and Marescaux<sup>[46]</sup> were the first to provide support for this hypothesis. They experimented on a variant of RYGB creating the intestinal bypass but leaving the stomach intact, which induced the same digestive discontinuation without re-anastomosis. This surgery, termed duodenal-jejunal bypass, was tested in several studies showing an improvement in T2DM without reduction in body weight<sup>[41]</sup>. These studies suggest that the exclusion of the proximal intestine may play a role in diabetes remission.

Interestingly, sleeve gastrectomy and mini-gastric bypass have emerged as new and effective weight loss procedures<sup>[8-11,16-18,47,48]</sup>.

There is increasing evidence indicating that SG causes early and significant improvements in glucose homeostasis in most morbidly obese subjects with T2DM<sup>[49-52]</sup>.

A systematic review of the existing literature showed

that SG results in T2DM resolution ranging from 80% to 96% in morbidly obese subjects<sup>[50]</sup>, a range similar to that in patients following RYGBP<sup>[38]</sup>.

Similarly, laparoscopic mini-gastric bypass is reported to be a safe alternative to LRYGB, showing comparable efficacy in weight reduction and resolution of metabolic complications, including diabetes<sup>[52-54]</sup>.

Both short-term<sup>[55-57]</sup> and long-term<sup>[58,59]</sup> follow-up confirmed the durable effect of this simplified procedure for obese or morbidly obese patients with T2DM.

Laparoscopic mini-gastric bypass in morbidly obese patients with T2DM has been shown to be effective in prospective randomized controlled trials<sup>[55]</sup>, as well as in extensive reports in the literature<sup>[54-59]</sup>.

Ghrelin regulation is disturbed following the sleeve gastrectomy procedure. SG was also reported to have a hindgut effect with increasing levels of glucagon-like peptide 1 and peptide YY due to the increased transit time after SG<sup>[60]</sup>.

Because construction of the sleeve gastric pouch is the first step of this technique, similar mechanisms are involved in mini-gastric bypass procedure.

The only region unaffected by SG was on the foregut. Specifically, the upper intestine was not in contact with ingested nutrients in the GB-treated group, while contact was made in the SG-treated group.

Recently, Lee *et al.*<sup>[9]</sup> published the first comparative study between sleeve gastrectomy and mini-gastric bypass to determine the efficacy of these treatments on diabetic control. Their results strongly support the hypothesis that duodenal exclusion may play a role in diabetes mellitus resolution following bariatric surgery in overweight patients.

Our findings extend the observations of Lee to severely obese patients. Unlike the study conducted by Lee *et al.*<sup>[9]</sup>, we only enrolled patients diagnosed with severe obesity and a clear indication to bariatric surgery. Despite this difference in the recruited patient population, our results also confirm that MGB is associated with better glycemic control and a higher rate of diabetes remission.

Although we observed a clear trend in our study, this did not achieve statistical significance. A multivariate analysis was performed to adjust for major clinical and demographic variables, but because of the relatively small sample size, our results need to be validated in larger studies. Thus, the present work could be considered a preliminary study, providing the rationale for a randomized prospective trial.

Further supporting this hypothesis, we reported that BMI changes were similar between patients achieving diabetes remission and patients not attaining remission. This finding suggests that diabetes remission may be independent from weight loss and that the type of surgery may play a more relevant role. These results combined with the evidence that weight loss is similar following the sleeve gastrectomy and mini-gastric bypass procedures may still support the theory suggested by Lee *et al.*<sup>[9]</sup>. Consequently, if we exclude the role of weight loss and

both the ghrelin and hindgut theories, the only remaining theory to explain the different results is the foregut (duodenal exclusion).

Overall, this mechanism suggests a potential superiority of the mini-gastric bypass over the sleeve gastrectomy in obtaining diabetes remission, but further data are needed to make this conclusion.

While the gold standard for diabetes remission remains the Roux-en-y gastric bypass because similar mechanisms of diabetes remission may be involved and the procedure is easier to perform, the mini-gastric bypass could become a valuable alternative.

Although our results appear to be encouraging and support mini-gastric bypass as an effective treatment strategy for diabetes remission, further studies are needed to allow for definitive conclusions regarding the ideal procedure for obtaining diabetes remission.

## COMMENTS

### Background

A remarkable effect of bariatric surgery is the profound and durable resolution of type 2 diabetes clinical manifestations. Interestingly, although both sleeve gastrectomy and mini-gastric bypass have emerged as new and effective weight loss procedures, the duodenal exclusion (involved in the mini-gastric bypass) may play a role in diabetes mellitus resolution.

### Research frontiers

The encouraging results obtained in this study with the mini-gastric bypass provide the rationale for a future randomized prospective trial to validate the effectiveness of this surgical technique.

### Innovations and breakthroughs

Their results confirm that mini-gastric bypass is associated with better glycemic control and higher diabetes remission rates relative to sleeve gastrectomy. The gold standard for diabetes remission remains Roux-en-y gastric bypass. However being similar mechanisms of diabetes remission involved and being easier to be performed, the mini-gastric bypass could become a valuable alternative.

### Applications

Mini-gastric bypass should be considered an effective weight loss procedure in diabetic patients.

### Peer review

The results are interesting and suggest that the effectiveness of mini-gastric bypass on diabetes remission, further studies are needed to provide definitive conclusions in selecting the ideal procedure for diabetes remission.

### Abstract

**AIM:** To investigate the association between human papillomavirus (HPV) and esophageal squamous cell carcinoma (ESCC) in southern Brazil.

**METHODS:** We studied 189 esophageal samples from 125 patients from three different groups: (1) 102 biopsies from 51 patients with ESCC, with one sample from the tumor and another from normal esophageal mucosa distant from the tumor; (2) 50 esophageal biopsies from 37 patients with a previous diagnosis of head and neck squamous cell carcinoma (HNSCC); and

(3) 37 biopsies from esophageal mucosa with normal appearance from 37 dyspeptic patients, not exposed to smoking or alcohol consumption. Nested-polymerase chain reaction (PCR) with the MY09/11 and GP5/6 L1 primers was used to detect HPV L1 in samples fixed in formalin and stored in paraffin blocks. All PCR reactions were performed with a positive control (cervicovaginal samples), with a negative control (Human Genomic DNA) and with a blank reaction containing all reagents except DNA. We took extreme care to prevent DNA contamination in sample collection, processing, and testing.

**RESULTS:** The histological biopsies confirmed the diagnosis of ESCC in 52 samples (51 from ESCC group and 1 from the HNSCC group) and classified as well differentiated (12/52, 23.1%), moderately differentiated (27/52, 51.9%) or poorly differentiated (7/52, 13.5%). One hundred twenty-eight esophageal biopsies were considered normal (51 from the ESCC group, 42 from the HNSCC group and 35 from dyspeptic patients). Nine had esophagitis (7 from the HNSCC and 2 from dyspeptic patients). Of a total of 189 samples, only 6 samples had insufficient material for PCR analysis: 1 from mucosa distant from the tumor in a patient with ESCC, 3 from patients with HNSCC and 2 from patients without cancer. In 183 samples (96.8%) GAPDH, G3PDH and/or  $\beta$ -globin were amplified, thus indicating the adequacy of the DNA in those samples. HPV DNA was negative in all the 183 samples tested: 52 with ESCC, 9 with esophagitis and 122 with normal esophageal mucosa.

**CONCLUSION:** There was no evidence of HPV infection in different ESCC from southern Brazil.

**Key words:** Esophageal cancer; Esophageal squamous cell carcinoma; Human papillomavirus; Head and neck cancer; Polymerase chain reactions; Nested-polymerase

chain reaction

**Core tip:** This paper gives additional evidence related to the controversy on the potential role of human papillomavirus (HPV) in the pathogenesis of esophageal squamous cell carcinoma (ESCC). Taking great care to avoid contamination by environmental HPV and using a very sensitive HPV DNA detection technique, we found no evidence of HPV neither in ESCC tumor tissue, nor in esophageal non-tumoral tissue from ESCC patients, or from head and neck squamous cell carcinoma patients or from dyspeptic controls without cancer. These data convincingly argue that when environmental contamination is carefully controlled, there is no evidence that HPV is involved in ESCC carcinogenesis in southern Brazil.

## INTRODUCTION

Worldwide, esophageal cancer is the eighth most common cancer and the sixth most common cause of death from cancer, with an estimated incidence of 482000 new cases and 407000 deaths in 2008<sup>[1]</sup>. Esophageal squamous cell carcinoma (ESCC) is still the most common type worldwide and its known risk factors are smoking and excessive alcohol consumption, poor nutritional and socio-economic status, exposure to polycyclic aromatic hydrocarbons (PAH), low consumption of fruits and vegetables, ingestion of hot beverages, genetic factors, history of caustic injury in the esophagus, and history of head and neck squamous cell carcinoma (HNSCC)<sup>[2-4]</sup>. In Brazil, the highest rates of esophageal cancer occur in the country's southernmost state, Rio Grande do Sul, where the rate of incidence is considered moderate with 18.01 cases per 100000 men and 6.60 cases per 100000 women<sup>[5]</sup>. In the south of Brazil the most important risk factors are the combination of smoking and excessive alcohol consumption<sup>[5]</sup>, however, the consumption of a hot beverage made with the infusion of *Ilex paraguayensis* (also known as *yerba mate*) is also a risk factor<sup>[6]</sup>. This beverage is often consumed at high temperatures and contains high levels of PAH<sup>[7]</sup>.

The role of human papillomavirus (HPV) in the development of ESCC remains controversial<sup>[8-12]</sup>. Two studies conducted in southern Brazil, each using a different technique, showed different results regarding the association between ESCC and HPV<sup>[13,14]</sup>. Therefore, to clarify the association between HPV infection and ESCC in southern Brazil, we looked for the presence of HPV DNA in esophageal biopsies from: (1) primary tumor

and mucosa without neoplasia from patients with ESCC; (2) Lugol stained and unstained areas in patients with HNSCC; and (3) normal appearing mucosa from patients not exposed to tobacco or alcohol.

## MATERIALS AND METHODS

### Patients and tissues

We evaluated 189 consecutive esophageal samples, collected in Santa Maria, a city in the central region of Rio Grande do Sul, the most southern state in Brazil, from 2008 to 2011. We included 51 samples from esophageal tumors and 51 samples from non-tumoral areas of the esophagus of patients with ESCC. We analyzed 50 esophageal biopsies (32 from Lugol stained areas, 17 from unstained areas and 1 from tumor) from patients diagnosed with HNSCC. Neither the patients with ESCC nor those with HNSCC had received chemotherapy or radiotherapy before the sample collection. We also collected biopsies from the normal middle esophagus of thirty-seven non-smoking and non-alcohol drinking dyspeptic patients who underwent upper GI endoscopy.

We collected demographic data (sex, age, place of birth, occupation) and information regarding smoking habits, alcohol consumption and previous history of cancer. The samples were fixed in neutral buffered formalin, embedded in paraffin, cut and stained with Hematoxylin-Eosin. For DNA extraction, one slice at least 5  $\mu$ m thick, as recommended for polymerase chain reaction (PCR) amplification, was cut from the paraffin-embedded tissues<sup>[15]</sup>. To minimize the risk of contamination, the materials used to process the sample stored in the paraffin block were completely disposable and used once per sample. In addition, the microtome sample holder was washed with absolute alcohol and the blade was replaced before each block was cut. Different rooms were used for DNA extraction, preparing the DNA solution, adding the DNA samples to the PCR solution and electrophoresis analysis. The rooms could only be accessed through antechambers with a single flow of material. All PCR reactions were performed with a positive control (cervicovaginal samples), with a negative control (Human Genomic DNA, Cat. No. G304A, Promega, Madison, WI) and with a blank reaction containing all reagents except DNA. The same method was also employed to test for the presence of HPV DNA in thirty-five samples of primary tumor from patients with HNSCC.

### DNA Extraction and PCR

Once the samples were de-waxed, the DNA was extracted using the Qiagen QIAamp DNA Mini Kit (Valencia, CA) according to manufacturer's instructions. DNA quantification and purity were determined by optical density in a spectrophotometer (Thermo Scientific NanoDrop 2000).

The DNA (25-80 ng) from each sample was amplified by PCR. The integrity of the DNA samples was observed by amplifying the human conserved genes GAP-

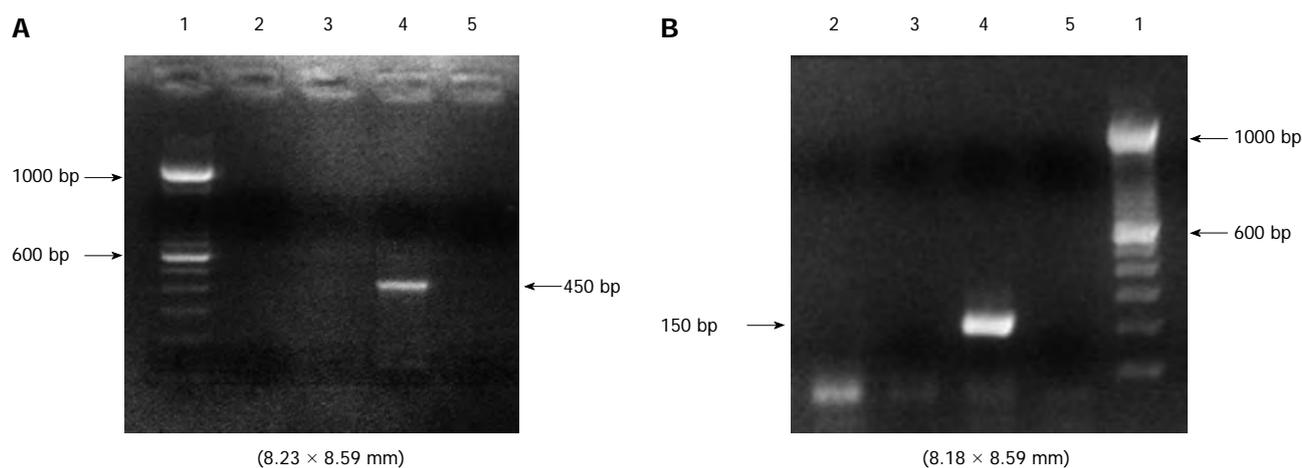

Figure 1 Analysis of DNA from esophageal tumor tissue for human papillomavirus using nested- polymerase chain reaction for human papillomavirus L1 gene. The MY09/11 primer pair was used in the first step (A) and the GP5/GP6 primer pair was used in the second step (B). 1: DNA size marker (100 bp DNA ladder); 2: Patient tumor DNA: [human papillomavirus (HPV)]-negative; 3: HPV DNA-negative control (Human Genomic DNA); 4: HPV DNA-positive control (cervicovaginal sample); 5: Negative control containing all polymerase chain reaction reagents except DNA.

DH, G3PDH and  $\beta$ -globin. The sequences of the *HPV L1* gene were amplified by nested-PCR using two general primer sets: MY09/MY11 (MY09: 5'-GTCCMARRG-GAWACTGATC-3', MY11: 5'-GCMCAGGGWCATA-AYAATGG-3') in the first amplification step to produce a 450 bp fragment; and GP5/GP6 (GP5: 5'-TTTGT-TACTGTGGTAGATAC-3', GP6: 5'-ACTAAATGT-CAAATAAAAAG-3') in the second step to produce 150 bp fragments of the PCR product. In the first step, PCR was performed with a reaction mixture containing 50  $\mu$ L, including 5.0  $\mu$ L of the genome from the extracted DNA sample, 5.0  $\mu$ L 10  $\times$  PCR buffer, 5.0  $\mu$ L of dNTP (2.5 mmol/L), 1.2  $\mu$ L of MgCl<sub>2</sub> (50 mmol/L), 0.5  $\mu$ L of Taq DNA polymerase and 0.2  $\mu$ L (500 pmol/ $\mu$ L) of the MY09 and MY11 primers. In the second step, which also had a final volume of 50  $\mu$ L, 1.0  $\mu$ L (500 pmol/ $\mu$ L) of the GP5 and GP6 primers was used. The PCR mixture was subjected to 40 amplification cycles, each consisting of an initial denaturation step at 94  $^{\circ}$ C for 30 s, annealment at 56  $^{\circ}$ C for 1 min and extension at 72  $^{\circ}$ C for 1 min. The PCR products were separated by electrophoresis on 2% agarose gel and visualized by staining with ethidium bromide by electrophoresis (Figure 1).

### Ethics

The study was approved by the Research Ethics Committee of the Federal University of Santa Maria and of the Federal University of Rio Grande do Sul, Rio Grande do Sul, Brazil. Informed consent was obtained from each participant before they underwent upper GI endoscopy.

### Statistical analysis

The variables were expressed as mean and SD or numbers and percents. Associations would have been considered statistically significant when a two-sided *P* value was  $\leq 0.05$ . All statistical analyzes were performed with the aid of SPSS 11 (Statistical Package for Social Sciences).

## RESULTS

### Patient characteristics

We included 125 individuals divided in three groups (Table 1): (1) 51 patients with ESCC, 43 male (84.3%) with a mean age of  $60.1 \pm 10.3$  years; (2) 37 patients with previous diagnosis of HNSCC, 34 males (91.9%) with a mean age of  $57.8 \pm 8.4$  years; and (3) 37 dyspeptic patients, 12 males (32.4%) with a mean age of  $56.8 \pm 17.7$  years.

### Histology

We studied 189 esophageal biopsy samples. All fifty-two biopsies from tumoral areas (51 from the ESCC group and 1 from the HNSCC group) were diagnosed as squamous cell carcinoma and classified as well differentiated (12/52, 23.1%), moderately differentiated (27/52, 51.9%) or poorly differentiated (7/52, 13.5%). None of the 51 samples of esophageal mucosa distant from the tumor in the ESCC group showed malignancy. In the patients with HNSCC, we performed 55 esophageal biopsies. Their histological analysis showed the following findings: 42 were normal (76.4%), 7 had esophagitis (12.7%), 1 contained ESCC (1.8%) and five had insufficient tissue for histological analysis (9.1%). In the biopsies of normal esophagus in the dyspeptic patients, 35 were considered normal and 2 had mild esophagitis.

### PCR analysis

The average DNA concentration in the samples was 214.68 ng/ $\mu$ L (range: 8-1313), with a mean ratio between the absorbance readings at 260 nm and 280 nm wavelengths of 2.12 (range 1.15-5.95). GAPDH, G3PDH and/or  $\beta$ -globin were amplified in 183 (96.8%) esophageal biopsies, showing that the DNA was adequate for analysis. These conserved human genes were not amplified in only six samples, all with normal esophageal mucosa (1 from mucosa distant from the tumor in a patient

**Table 1 Clinical and demographic characteristics and risk factors of the patients *n* (%)**

ESCC: Esophageal squamous cell carcinoma; HNSCC: Head and neck squamous cell carcinoma.

with ESCC, 3 from patients with HNSCC and 2 from patients without cancer). The PCR results were negative for HPV DNA in all the esophageal biopsies (52 with ESCC, 9 with esophagitis and 122 with normal esophageal mucosa), as well as in all biopsies from the primary tumor of head and neck cancer.

## DISCUSSION

The current study used a nested primer-based PCR test to identify HPV DNA in esophageal samples from individuals from a moderate risk area for ESCC in southern Brazil. Our results showed no evidence of HPV DNA in any of the samples of the ESCC and from non-tumoral areas of the esophagus, in the esophageal mucosa of patients with HNSCC, or in the esophageal mucosa from patients without risk factors for ESCC.

Some studies using a bovine model have found that the bovine papillomavirus is essential in the early stages of carcinogenesis of the upper digestive tract, but is not required for progression to the status of malignancy<sup>[8,16,17]</sup>. Considering the possibility of this “hit-and-run” mechanism to induce oncogenesis in the esophagus in humans, we included samples with and without cancer from the esophageal mucosa of patients with ESCC and esophageal mucosal samples from patients with HNSCC. In order to enhance the detection of ESCC precursor lesions, all patients with HNSCC underwent upper endoscopy with mucosal iodine staining and biopsy of stained and unstained areas<sup>[18-21]</sup>. However, all samples were negative for HPV DNA, both in the primary tumors and in the esophageal mucosa without neoplasia of patients with ESCC or HSNCC and in the group without cancer who were not exposed to tobacco or alcohol. The consistent presence of the GAPDH, G3PDH or  $\beta$ -globin genes in

the samples indicated that the specimens were suitable for DNA analysis.

We used the nested primer-based PCR system with the MY11-MY09 consensus primers in combination with another general primer pair, GP5-GP6, positioned within the former. According to Evander *et al*<sup>[22]</sup>, this two-step PCR amplification is able to detect 1 to 10 copies of the HPV 16 genome, while the use of isolated pairs of primers MY11-MY09 or GP5-GP6 detect 100 and 10 copies, respectively. Thus, we used a technique with good yield for samples with low viral load. In addition, the MY11-MY09 primer is highly capable of detecting multiple HPV types within a given sample<sup>[23]</sup>. Furthermore, the inner primer pair GP5-GP6 spans a shorter region (about 150 bp), which is useful when the DNA is isolated from paraffin-embedded tissue fixed with formalin<sup>[24-27]</sup>. More sensitive techniques can be used to detect HPV DNA, but as Ha *et al*<sup>[28]</sup> suggest, without at least one copy of the viral genome per cell, a clonal relationship cannot be established; therefore, a sufficient number of copies of HPV affecting most of the cells in the lesion is required. Hence, we believe that our technique was sufficiently sensitive to accurately detect the presence of HPV DNA in tissue samples from the aero-digestive tract.

In southern Brazil, Weston and Prolla<sup>[13]</sup> analyzed 40 ESCC samples and 10 benign esophageal biopsies from patients without cancer. Using the Hybrid Capture II test, they detected HPV DNA in only one case of ESCC and in one benign specimen. Subsequently, Souto Damin *et al*<sup>[14]</sup> reported detecting HPV in 15.75% of ESCC patients (26/165) and in none of the specimens of benign esophagus (0/26) using auto-nested PCR with the GP5+/GP6+ consensus primer pair. Some features of our study that differed from these two previous HPV studies conducted in southern Brazil are: (1) the extreme care we took to prevent DNA contamination throughout the specimen processing and testing; (2) the use of a more highly sensitive HPV detection method; and (3) the assessment of possible precursor lesions in the non-tumoral mucosa of esophagi with cancer and in the esophageal mucosa of patients with head and neck cancer.

A tissue study similar to ours was recently reported from a high-risk area of China<sup>[29]</sup>. The authors analyzed tumor samples from 272 patients with ESCC who underwent esophagectomy at the Yaocun Commune Hospital in Linxian, in north-central China. The patients came from various regions of China, with different incidence rates of ESCC and different mortality rates for cervical cancer. HPV DNA was tested on fresh frozen tumor tissue and tumor samples fixed with formalin and stored in paraffin using PCR with the PGMY L1 and SPF10 L1 consensus primers, respectively. Adopting careful measures to avoid contamination of the samples, similar to those used in the present study, these authors also found no cases with convincing evidence of carcinogenic HPV activity.

There are some limitations to the present study, such as the lack of information regarding sexual habits, socio-

economic characteristics and the consumption of the beverage *yerba mate*, but there is no reason to think that having such information would have changed the PCR results of this study.

Our results confirm previous observations in other regions that report the absence of an association between esophageal mucosa infection by HPV and ESCC, and suggest that, in southern Brazil, this virus is not an important risk factor for squamous cell carcinoma of the esophagus.

## ACKNOWLEDGMENTS

The authors thank the following individuals for their assistance: Patrícia Chaves Brites for useful suggestions in the human papillomavirus analysis, and Drs Leandro Bizarro Muller, Eduardo Buzatti Souto, Daniela Costa, Stela Maria Motta, Alexandre Rampazzo and João Carlos Cantarelli Jr for their collaboration in the upper endoscopy. Special acknowledgment is given to Dr Sanford M. Dawsey for his helpful comments on the manuscript and for his help in the English revision.

## COMMENTS

### Background

The high geographical variation in esophageal squamous cell carcinoma (ESCC) incidence observed worldwide reflects the exposure to specific environmental factors that are not completely understood. High-risk human papillomavirus (HPV) infections are present in almost all cervical cancers, beside other neoplasms in squamous epithelial-lined tissues, probably being involved in their genesis. The etiologic role of HPV in ESCC remains highly controversial.

### Research frontiers

A large number of controversial manuscripts have been published investigating the possible role of HPV in the etiology of esophageal cancer. In this study the authors used a very sensitive HPV DNA detection technique, and evaluated the HPV presence in ESCC tumor tissue and esophageal non-tumoral tissue.

### Innovations and breakthroughs

Previous studies have suggested that the HPV would have an essential role in the early stages of the ESCC. Besides ESCC tumor tissue, they also examined esophageal non-tumoral tissue from the same ESCC patients. The authors also analysed esophageal biopsies from patients with head and neck squamous cell carcinoma and from dyspeptic controls without cancer. They used a highly sensitive technique for detection of HPV with nested-polymerase chain reaction (PCR), taking the utmost care to avoid false positive results caused by samples contamination.

### Applications

This study adds more evidence that HPV is not involved in esophageal carcinogenesis, and it also suggests the high prevalence of HPV in some ESCC studies can be due to contamination. Therefore, the results of this study reinforce the need of utmost care to avoid contamination in further protocols looking for HPV in tissue samples.

### Terminology

Nested PCR uses two sequential sets of primers. The first pair of PCR primers amplifies a fragment similar to a standard PCR. The second primer set binds to sequences in the target DNA that are within the portion amplified by the first set. Thus, the second set of primers will bind and amplify target DNA within the products of the first reaction. The advantage of nested PCR is that if the wrong PCR fragment was amplified, the probability is quite low that the region would be amplified a second time by the second set of primers.

### Peer review

Overall, it is a well written and easy to follow paper that reports a hot topic about the involvement of HPV infection in the development of ESCC. The technique and the sampling procedure used are correct. The topic of the con-

tribution of HPV to ESCC is an important one since there is a vaccine for HPV that if related to squamous cell carcinoma could have a significant impact on the public health implications of this disease. This is a well prepared manuscript that reads well.

antagonists on normal gastrointestinal motor activity were analyzed.

**RESULTS:** 5-HT2B, 5-HT3 and 5-HT4 receptor antagonists had no contractile effect on the fasting canine terminal ileum. The 5-HT3 and 5-HT4 receptor antagonists inhibited phase III of the interdigestive motor complex of the antrum and significantly inhibited colonic motor activity. In the proximal colon, the inhibitory effect was dose dependent. Dose dependency, however, was not observed in the distal colon. The 5-HT2B receptor antagonist had no contractile effect on normal colonic motor activity.

**CONCLUSION:** The 5-HT3 and 5-HT4 receptor antagonists inhibited normal colonic motor activity. The 5-HT2B receptor antagonist had no contractile effect on normal colonic motor activity.

**Key words:** 5-hydroxytryptamine receptor antagonist; Colonic motility; Irritable bowel syndrome

### Abstract

**AIM:** To study the effects of 5-hydroxytryptamine (5-HT) receptor antagonists on normal colonic motor activity in conscious dogs.

**METHODS:** Colonic motor activity was recorded using a strain gauge force transducer in 5 dogs before and after 5-HT2B, 5-HT3 and 5-HT4 receptor antagonist administration. The force transducers were implanted on the serosal surfaces of the gastric antrum, terminal ileum, ileocecal sphincter and colon. Test materials or vehicle alone was administered as an intravenous bolus injection during a quiescent period of the whole colon in the interdigestive state. The effects of these receptor

**Core tip:** Previous studies have investigated the effects of 5-hydroxytryptamine (5-HT) receptor antagonists on abnormal colonic motor activity, following either the administration of 5-HT or stress induction. This study is the first to investigate the effects of 5-HT receptor antagonists on normal colonic motor activity in dogs. 5-HT3 and 5-HT4 receptor antagonists inhibited normal colonic motor activity. A 5-HT2B receptor antagonist had no contractile effect on normal colonic motor activity. 5-HT3 and 5-HT4 receptor antagonists may also be used as premedications for colonoscopy. A 5-HT2B receptor antagonist may be used for the treatment of diarrhea-predominant irritable bowel syndrome without the side effect of constipation.

Effects of 5-HT<sub>2B</sub>, 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists on gastrointestinal motor activity in dogs. *World J Gastroenterol* 2013; 19(39): 6604-6612 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i39/6604.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6604>

## INTRODUCTION

Over 95% of the 5-hydroxytryptamine (5-HT) in the body is found in the gastrointestinal tract; 90% of the gastrointestinal 5-HT is contained within enterochromaffin cells<sup>[1,2]</sup>, and the remaining 10% is contained within the enteric neurons<sup>[3,4]</sup>. Seven major types and multiple subtypes of 5-HT receptors have been identified. 5-HT receptors that are known to affect gut motor functions are those belonging to the 5-HT<sub>1</sub>, 2, 3, 4 and 7 subtypes<sup>[5]</sup>. 5-HT has a variety of actions; it can cause smooth-muscle contraction (*via* cholinergic nerve stimulation) or relaxation (*via* stimulation of inhibitory nitric oxide-releasing neurons)<sup>[6]</sup>. Mucosal release of 5-HT stimulates both intrinsic sensory neurons (most likely *via* 5-HT<sub>4</sub> receptors) and extrinsic sensory neurons (*via* 5-HT<sub>3</sub> receptors); these actions modulate sensation<sup>[7]</sup>. Previous studies have shown that 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor agonists stimulate gastrointestinal motility<sup>[8-12]</sup>. However, the effects of these antagonists are unknown.

Irritable bowel syndrome (IBS) is a common gastrointestinal disorder associated with altered motility, secretion and visceral sensation<sup>[5]</sup>. Stress is known to strongly contribute to the pathogenesis of IBS<sup>[13]</sup>. Data have shown that systemic administration of 5-HT<sub>3</sub> receptor antagonists abolishes the abnormal contractions and visceral sensations induced by stress<sup>[14-16]</sup>, leading to the use of 5-HT<sub>3</sub> receptor antagonists in the treatment of diarrhea-predominant IBS. However, the effects of 5-HT<sub>3</sub> receptor antagonists on normal colonic motor activity are controversial. Previous studies have shown that 5-HT<sub>3</sub> antagonists have no effect on colonic motor activity during the interdigestive state in dogs and humans<sup>[17-19]</sup>. By contrast, the migrating motor complex in the murine small and large bowel is abolished by 5-HT<sub>3</sub> antagonist activity<sup>[20]</sup>. Ondansetron, a 5-HT<sub>3</sub> receptor antagonist, has been shown to delay colonic transit time in healthy subjects<sup>[21-23]</sup> and tends to slow left-sided colonic transit in patients with diarrhea-predominant IBS<sup>[24]</sup>. The effect of 5-HT<sub>3</sub> receptor antagonists on normal colonic motor activity is still unknown. However, these studies suggest that 5-HT<sub>3</sub> receptor antagonists may have an inhibitory effect on colonic motor activity.

5-HT<sub>2B</sub> receptors are expressed by the smooth muscle of the adult human gut<sup>[25]</sup>, but their functions are unclear. It is known that 5-HT<sub>2B</sub> receptor antagonists inhibit visceral hypersensitivity<sup>[26]</sup>. These data suggest that 5-HT<sub>2B</sub> receptor antagonists also have a potential

therapeutic role in the treatment of IBS. The effects of 5-HT<sub>2B</sub> receptor antagonists on normal colonic motor activity *in vivo* remain unknown.

5-HT<sub>4</sub> receptors are distributed along the gut, where they may play a role in mediating smooth muscle tone, peristaltic reflex and mucosal secretion. In healthy humans, 5-HT<sub>4</sub> receptor agonists have been demonstrated to stimulate both whole gut transit and colonic transit. Clinically, 5-HT<sub>4</sub> receptor agonists are used for patients suffering from gastro-esophageal reflux disease, dyspepsia or constipation-predominant IBS<sup>[5,27,28]</sup>. As with the 5-HT<sub>3</sub> receptors, the effects of 5-HT<sub>4</sub> receptors are complex. 5-HT<sub>4</sub> receptors mediate both the relaxation and contraction of circular smooth muscle<sup>[28-31]</sup>. The effect of 5-HT<sub>4</sub> receptor antagonists on normal colonic motor activity remains unknown.

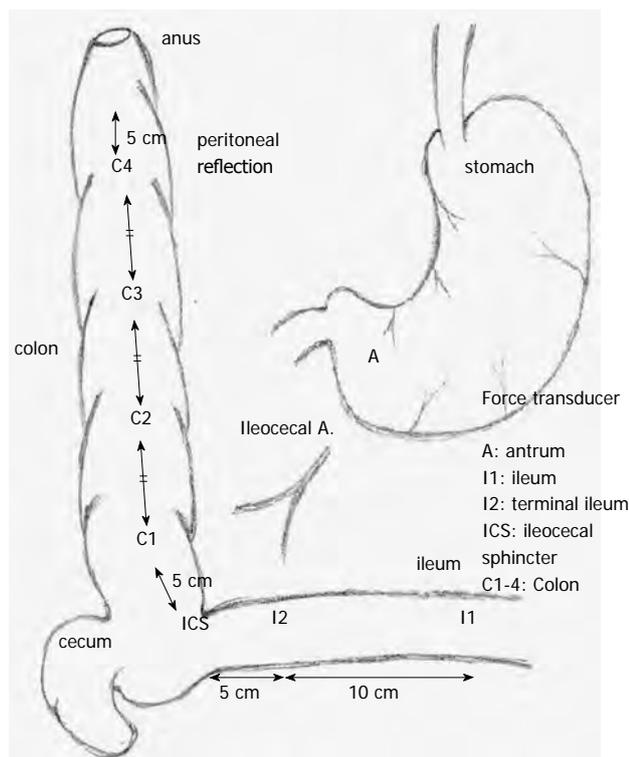

This study aimed to determine the effects of 5-HT<sub>2B</sub>, 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists on normal colonic motor activity in conscious dogs.

## MATERIALS AND METHODS

### Preparation of animals

Experiments were completed in 5 healthy conscious dogs of both sexes, each weighing 8-11 kg. The procedures were approved by the Review Committee on Animal Use of Gunma University, Maebashi, Japan. Overnight-fasted dogs were anesthetized by a single intravenous injection of thiopental sodium (Ravonal; Tanabe Pharmaceutical, Osaka, Japan) at a dose of 20 mg/kg. General anesthesia was maintained by endotracheal inhalation of halothane (Fluothane; Takeda Chemical Industries, Osaka, Japan) and oxygen. A Silastic tube (Silastic 602-205; Dow Corning, Midland, MI) was inserted into the superior vena cava through a branch of the right internal jugular vein (jugular tube). The abdominal cavity was opened, and eight force transducers<sup>[32]</sup> were implanted on the serosal surfaces of the gastric antrum, terminal ileum (5 and 15 cm proximal to ileocecal sphincter) (I1/I2), ileocecal sphincter (ICS) and colon (C1-C4); C1 was placed 5 cm distal to the ICS, and C4 was placed 5 cm proximal to the peritoneal reflection. C2 and C3 were placed at equal distances between C1 and C4 (Figure 1). The ICS was identified by inspection and palpation. Wires from each force transducer were tunneled subcutaneously to the dorsum and connected to an eight-channel telemeter (GTS-800; Star Medical, Tokyo, Japan); gastrointestinal and colonic contractile activities were thereby continuously recorded on a computer (Adif1412.dill; Star Medical).

After the operation, the dogs were housed in individual experimental cages. They were fasted for 2 d after this procedure and maintained by intravenous infusion of Lactec G (Otsuka Pharmaceutical, Tokyo, Japan) at a daily volume of 500 mL. Cefmetazole (1 g) was administered intravenously, once preoperatively and once on postoperative day 1. The dogs were allowed to recover for  $\geq 10$  d. They were fed normal dog food (20 g/kg; Funabashi Farm, Funabashi, Japan) once daily and pro-

**Figure 1** Scheme of the dog model and the locations of the force transducers implanted in the canine gastrointestinal tract. Force transducers were implanted in the colon on the serosal surfaces of the gastric antrum (A), terminal ileum [5 and 15 cm proximal to ileocecal sphincter (ICS); I1-I2], ICS and colon (C1-C4); C1 was placed 5 cm distal to the ICS and C4 5 cm proximal to the peritoneal reflection. C2 and C3 were implanted equidistantly between C1 and C4.

vided water ad libitum.

After all experiments were completed, the dogs were sacrificed by an overdose of potassium chloride. Specimens of ICS were then fixed in 10% formalin and stained with hematoxylin and eosin. Proper placement of the transducers was confirmed.

### Drugs

Ondansetron, a 5-HT<sub>3</sub> receptor antagonist, was purchased from Sigma Japan (Tokyo). GR113808, a selective 5-HT<sub>4</sub> receptor antagonist<sup>[33]</sup>, was purchased from Wako Pure Chemical Co. (Osaka, Japan). RQ-00310941, a novel, potent, and selective 5-HT<sub>2B</sub> receptor antagonist<sup>[34]</sup>, was synthesized by RaQualia Pharma Inc. (Aichi Japan). Ondansetron was dissolved in distilled water, GR113808 was dissolved in DMSO, and RQ-00310941 was dissolved in acid DMSO.

### Experimental protocol and recording of contractile activity

The dogs were fasted overnight before each experiment. After the interdigestive motor complex<sup>[35]</sup> had been recorded at the antrum,  $\geq 2$ -h of contractile activity was recorded. Test material or vehicle (5 mL of 154 mmol/L NaCl solution) alone was then administered as an intravenous bolus injection during a quiescent state of the

whole colon in the interdigestive state. The experiments were performed with the following treatment doses: ondansetron (0.01, 0.03, 0.10 and 0.30 mg/kg), GR 113808 (0.1 and 0.3 mg/kg), and RQ-00310941 (1, 3 and 10 mg/kg). Contractile activities were recorded for  $\geq 2$ -h after administration. All experiments were carried out in a random order, and the test material was given once per day.

### Data analysis

The recorded mechanical activities were analyzed using software for analysis of gastrointestinal motility (8STAR, Star Medical Co., Ltd). The analysis of colonic contractile activity (from ICS to C4) was performed for 1 h both before and after administration. The mean motility index (MI) and average MI of colonic contractile activity were recorded at each site. The MI was defined as the integrated area between baseline (zero level) and the contractile wave expressed in motor units. This parameter was expressed as the inhibition ratio: the ratio of contractile activity before and after drug administration.

### Statistical analysis

Student's *t* test was used for statistical analysis. The results are expressed as the mean  $\pm$  SD. *P* < 0.05 was considered statistically significant.

## RESULTS

### Effects of 5-HT<sub>2B</sub>, 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists on gastric and terminal ileum motility

5-HT<sub>2B</sub>, 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists had no contractile effect on the fasted canine terminal ileum (I1, I2) during the observation period (Figures 2-5). In contrast, the 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists both significantly inhibited phase III of the interdigestive motor complex of the antrum (Figures 4 and 5).

### Effects of 5-HT<sub>2B</sub>, 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists on normal colonic motor activity

The 5-HT<sub>2B</sub> receptor antagonist had no contractile effect on normal colonic motor activity (Figure 3). However, both the 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists inhibited colonic motor activity (Figures 4 and 5). At 0.3 mg/kg, the 5-HT<sub>3</sub> receptor antagonist significantly inhibited whole colonic motor activity (ICS - C4) (72%  $\pm$  9% *vs* -11%  $\pm$  6%, 70%  $\pm$  10% *vs* 6%  $\pm$  10%, 65%  $\pm$  15% *vs* 1%  $\pm$  11%, 61%  $\pm$  7% *vs* 5%  $\pm$  9% and 68%  $\pm$  7% *vs* -10%  $\pm$  3%, respectively; Figure 4). In the proximal colon, the inhibitory effects of the 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists were dose dependent. However, no dose-dependent response was observed in the distal colon. Upon administration of the 5-HT<sub>4</sub> receptor antagonist, colonic migrating motor complexes (CMMCs) corresponding to phase III of the migrating motor complex at the ileum were sometimes observed (Figure 5, see arrow). The motor complex independent of phase III of the migrating motor complex tended to be inhibited (Figure 5). These inhibited effects were observed for at least 1 h.

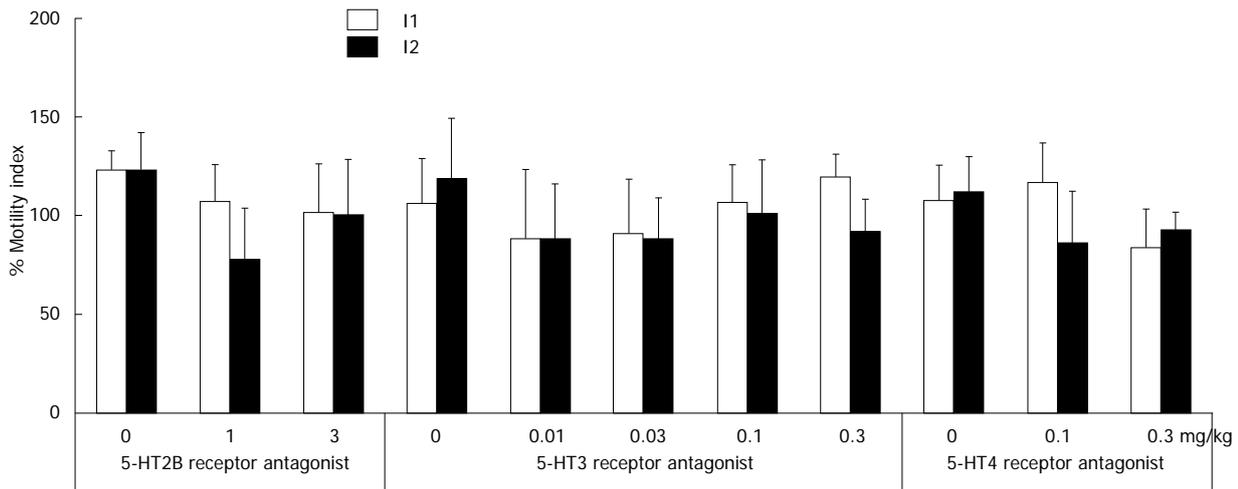

Figure 2 Inhibition ratio based on comparing the drug effects to before 5-hydroxytryptamine receptor antagonist administration in the terminal ileum (I1-I2). A systematic change was not observed. Values are mean  $\pm$  SE. 5-HT: 5-hydroxytryptamine; I1:Ileum; I2: Terminal ileum.

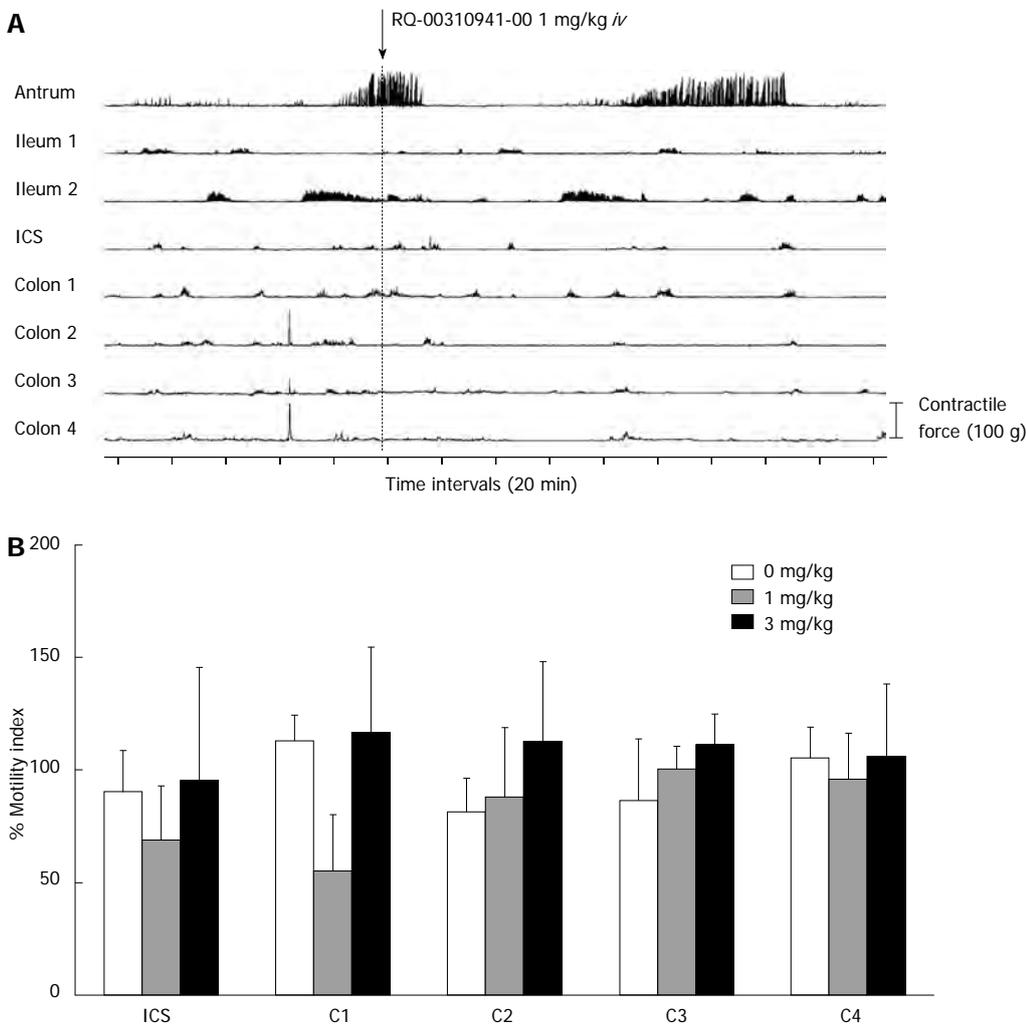

Figure 3 5-hydroxytryptamine 2B receptor antagonists on normal colonic motor activity. A: Typical effect of the 5-hydroxytryptamine (5-HT) 2B receptor antagonist. The 5-HT2B receptor antagonist had no contractile effect on the whole intestine; B: The inhibition ratio compared with before 5-HT2B receptor antagonist administration. A systematic change was not observed. Values are mean  $\pm$  SE. ICS: ileocecal sphincter; C1-4: Colon 1-4.

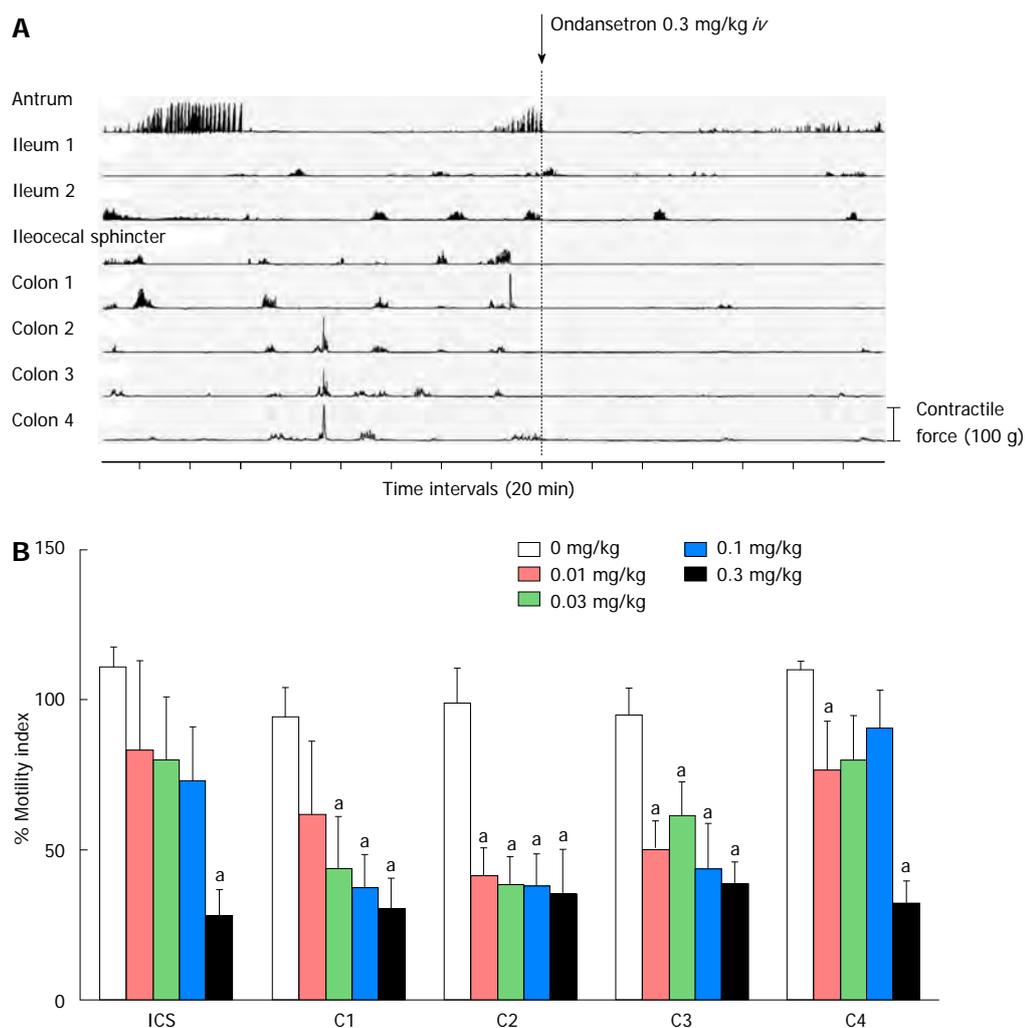

Figure 4 5-hydroxytryptamine 3 receptor antagonists on normal colonic motor activity. A: Typical effect of the 5-hydroxytryptamine (5-HT) 3 receptor antagonist. The 5-HT3 receptor antagonist inhibited phase III of the interdigestive motor complex at the antrum and whole colonic motor activity; B: The inhibition ratio compared with before 5-HT3 receptor antagonist administration. The inhibitory effect of the 5-HT3 receptor antagonist was dose dependent in the proximal colon (ICS-C2). At a dose of 0.3 mg/kg, whole colonic motor activity was inhibited significantly. Values are mean  $\pm$  SE. <sup>a</sup> $P < 0.05$  vs control (0 mg/kg). ICS: ileocecal sphincter; C1-4: Colon 1-4.

## DISCUSSION

Previous studies have investigated the effects of 5-HT receptor antagonists on abnormal colonic motor activity, following either the administration of 5-HT or the induction of stress<sup>[14,26,31,36,37]</sup>. This study is the first to investigate the effects of 5-HT receptor antagonists on normal colonic motor activity in dogs using a force transducer.

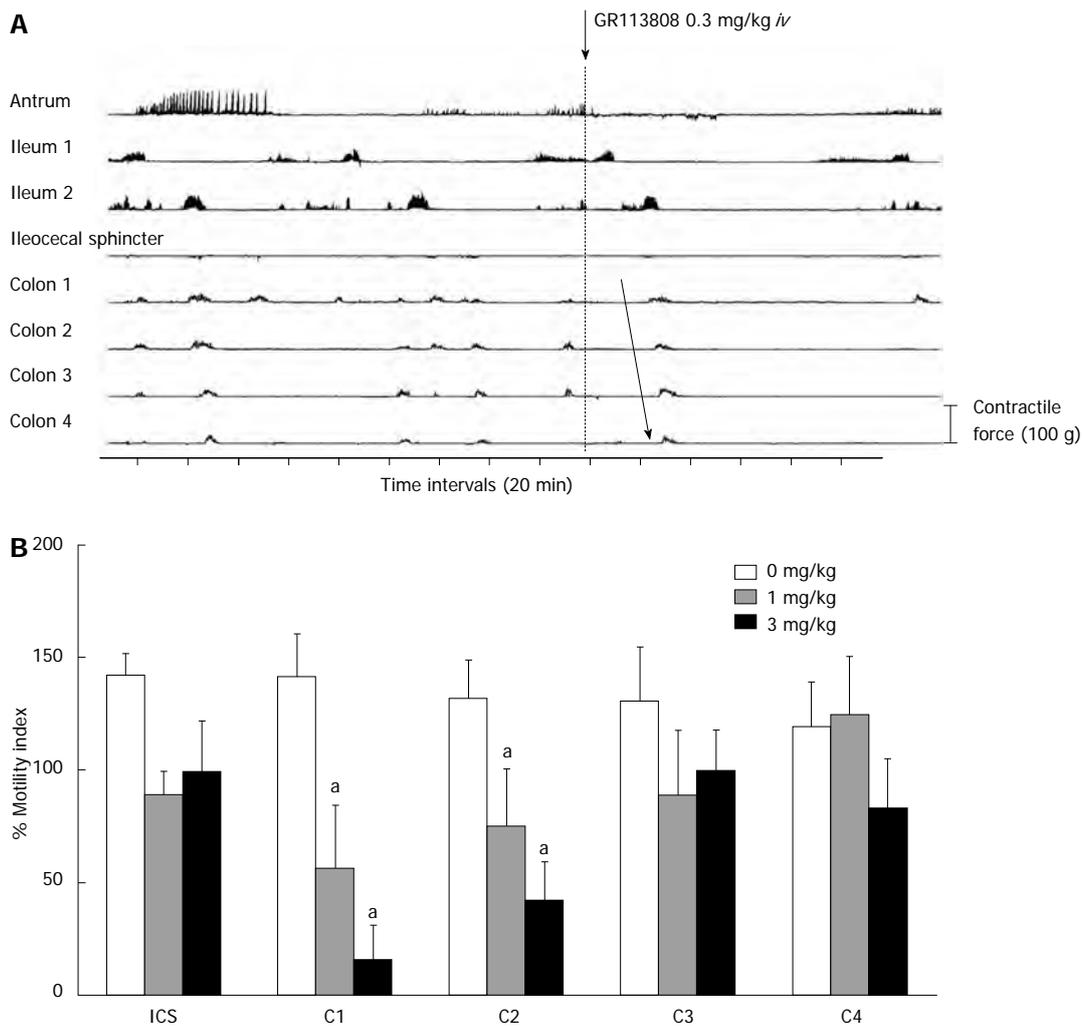

In this study, 5-HT3 and 5-HT4 receptor antagonists inhibited normal colonic motor activity. In contrast, a 5-HT2B receptor antagonist had no contractile effect on normal colonic motor activity. The 5-HT3 receptor antagonist inhibited phase III of the interdigestive motor complex of the antrum. None of the three 5-HT receptor antagonists had contractile effects on the fasted dog terminal ileum.

The effects of 5-HT3 receptor antagonists on colonic motor activity are controversial. In the present study, the 5-HT3 receptor antagonist inhibited normal colonic motor activity. However, Yoshida *et al*<sup>[17]</sup> reported that

ondansetron (GR38032F) had no contractile effect on normal colonic motor activity in the interdigestive state in dogs. In their study, the 5-HT3 receptor antagonist was administered at a high dose of 1 mg/kg. It is possible that a higher dose of the 5-HT3 receptor antagonist may paradoxically have no contractile effect on normal colonic motor activity.

Because we administered the 5-HT3 receptor antagonist systemically, we were unable to determine its mechanism of action. We did observe, however, that the inhibitory effects were exerted in the extrinsic denervation region<sup>[38]</sup> (data not shown), suggesting that it acted locally.

How colonic contractions are generated is unclear. It is known that the pacemaker of colonic contractions lies within the colon wall itself because contractions can occur in an isolated colon. The pacemaker itself, however, has not been characterized. Heredia *et al*<sup>[39]</sup> showed that the initiation of colonic contractions requires serotonin. Dickson *et al*<sup>[40]</sup> demonstrated that 5-HT initially excites

**Figure 5** 5-hydroxytryptamine 4 receptor antagonists on normal colonic motor activity. **A:** Typical effect of the 5-hydroxytryptamine (5-HT) 4 receptor antagonist. The 5-HT<sub>4</sub> receptor antagonist inhibited phase III of the interdigestive motor complex at the antrum and whole colonic motor activity, CMMCs corresponding to phase III of the migrating motor complex at the ileum were sometimes observed (see arrow); **B:** The inhibition ratio compared with before 5-HT<sub>4</sub> receptor antagonist administration. The inhibitory effect of the 5-HT<sub>4</sub> receptor antagonist was dose dependent in the proximal colon (C1-C2). Values are mean  $\pm$  SE. <sup>a</sup> $P < 0.05$  vs control (0 mg/kg). ICS: Ileocecal sphincter; C1-4: Colon 1-4.

5-HT<sub>3</sub> receptors on the mucosal endings of Dogiel type II/AH neurons and that this is coincidental with colonic contractions. It is possible that the inhibitory effects of 5-HT<sub>3</sub> receptor antagonists demonstrated in this study may act at this site. Bharucha *et al.*<sup>[41]</sup> showed that a 5-HT<sub>4</sub> receptor antagonist (SB-207266) tended to delay colonic transit. Consistent with this, in our study, the 5-HT<sub>4</sub> receptor antagonist inhibited colonic motor activity. Studies have shown that receptors on contractile nerves may be more sensitive to receptor antagonism than those on relaxation nerves<sup>[22-25]</sup>. We hypothesize that the 5-HT<sub>4</sub> receptor antagonist inhibitory effect on colonic contractile nerves may be a mechanism that results in the delay of colonic transit.

Glucagon and scopolamine butylbromide are commonly used as antispasmodic premedications for colonoscopy. In addition, 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists may also be used as premedications for colonoscopy. In this study, we used ondansetron as the 5-HT<sub>3</sub> receptor antagonist. Ondansetron has no effect on visceral sensa-

tions<sup>[28]</sup>. Visceral hypersensitivity has been proposed as a mechanism of IBS, and Kim *et al.*<sup>[42]</sup> have reported that the degree of pain perception during colonoscopy is higher in IBS patients than in non-IBS patients. Alosetron, which can abolish visceral sensations<sup>[14]</sup>, may be used as a premedication for colonoscopy without pain. However, whether alosetron is effective in controlling colonic motor activity has not been conclusively determined.

In a study by Ohashi-Doi *et al.*<sup>[26]</sup>, a 5-HT<sub>2B</sub> receptor antagonist inhibited visceral hypersensitivity and reduced restraint stress-induced defecation. It is therefore logical to hypothesize that a 5-HT<sub>2B</sub> receptor antagonist may have therapeutic potential for the treatment of non-constipation IBS. Bassil *et al.*<sup>[43]</sup> have previously shown that high-dose (10 and 30 mg/kg) 5-HT<sub>2B</sub> antagonists inhibit colonic motility and defecation in normal mice. The present study did not confirm their findings, as the 5-HT<sub>2B</sub> receptor antagonist had no contractile effect on normal colonic motor activity. However, we only evaluated doses up to 3 mg/kg. By contrast, our previous study showed

that RQ-00310941 at 3 mg/kg *p.o.* inhibited restraint stress-induced defecation in TNBS-treated rats<sup>[34]</sup>. In that preliminary study, rats were administered 3 mg/kg TNBS orally, but the plasma concentration of RQ-00310941 was greater than that in the dogs in the current study, which were also administered 3 mg/kg *iv* (data not shown). We therefore speculate that RQ-00310941 can inhibit restraint stress-induced defecation at higher doses.

In the proximal colon, the inhibitory effects of 5-HT<sub>3</sub> and 5-HT<sub>4</sub> antagonists were dose dependent. However, this inhibition was dose independent in the distal colon. Nagakura *et al.*<sup>[36]</sup> also showed that the effect of a 5-HT<sub>4</sub> receptor agonist on colonic motor activity in the proximal colon was stronger than that in the distal colon. A different distribution of 5-HT receptors in the distal colon compared with the proximal colon may explain this effect. These confounding effects may also be based on a differential sensitivity to drugs in the proximal and distal colon<sup>[44,45]</sup>. Further studies are needed to clarify this result. In conclusion, 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists inhibited phase III of the interdigestive motor complex at the antrum and colonic motor activity. The 5-HT<sub>2B</sub> receptor antagonist had no contractile effect on normal colonic motor activity.

## ACKNOWLEDGMENTS

We gratefully acknowledge the contributions of Dr. Zen Ito and Dr. Yuichi Tabe. We thank Mr. Arimitsu Bettou for making the jackets for the dogs.

## COMMENTS

### Background

Most of the body's 5-hydroxytryptamine (5-HT) is found in the intestinal tract, where it helps regulate intestinal motor activity. The 5-HT receptors that are known to affect gut motor functions are those belonging to the 5-HT<sub>1</sub>, 2, 3, 4 and 7 subtypes.

### Research frontiers

Irritable bowel syndrome (IBS) is a common gastrointestinal disorder associated with altered motility, secretion and visceral sensation. Recently, 5-HT was identified as the cause of IBS.

### Innovations and breakthroughs

Previous studies have investigated the effects of 5-HT receptor antagonists on abnormal colonic motor activity, following either the administration of 5-HT or the induction of stress. This study is the first to investigate the effects of 5-HT receptor antagonists on normal colonic motor activity in dogs.

### Applications

The study results suggest that 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists may also be used as premedications for colonoscopy. 5-HT<sub>2B</sub> receptor antagonists may be used for the treatment of diarrhea-predominant IBS without the side effect of constipation.

### Terminology

Motility index (MI): MI was defined as the integrated area between baseline (zero level) and the contractile wave expressed in motor units. MI is an index used when analyzing gastrointestinal motility. 5-HT: Over 95% of the 5-HT in the body is found in the gastrointestinal tract; 90% of the gastrointestinal 5-HT is found within enterochromaffin cells. 5-HT receptors are known to affect gut motor functions.

### Peer review

This is a good descriptive study in which the authors analyze the effects of 5-HT<sub>3</sub>, 5-HT<sub>4</sub> and 5-HT<sub>2B</sub> receptor antagonists on normal gastrointestinal mo-

tility. 5-HT<sub>3</sub> and 5-HT<sub>4</sub> receptor antagonists inhibited colonic motor activity. The 5-HT<sub>2B</sub> receptor antagonist had no contractile effect on normal colonic motor activity.

### Abstract

**AIM:** To investigate the comorbid disease could be the predictors for the elective colectomy in colonic diverticulitis.

**METHODS:** A retrospective chart review of 246 patients with colonic diverticulitis admitted between 2000 and 2008 was conducted, and 19 patients received emergent operation were identified and analyzed. Data were collected with regard to age, sex, albumin level on admission, left or right inflammation site, the history of recurrent diverticulitis, preoperative comorbidity, smoking habits, medication, treatment policy, morbidity, and mortality. Preoperative comorbid diseases included cardiovascular disease, diabetes, pulmonary disease, peptic ulcer disease, gouty arthritis, and uremia. Medications in use included non-steroidal anti-inflammatory drugs, acetylsalicylic acid (Aspirin), and corticosteroids. Univariate and multivariate logistic regression analyses

were performed to identify the relevant risk factors correlating to colectomy.

**RESULTS:** The mean age of the 246 patients was 69.5 years (range, 24-94 years). Most diverticulitis could be managed with conservative treatment ( $n = 227$ , 92.3%), and urgent colectomy was performed in 19 patients (7.7%). There were three deaths in the surgical group and four deaths in the nonsurgical group. The overall mortality rate in the study was 1.7% among patients with conservative treatment and 15.7% among patients undergoing urgent colectomy. Multiple logistic regression analysis indicated that comorbidities were risk factors for urgent colectomy for diverticulitis.

**CONCLUSION:** To avoid high mortality and morbidity related to urgent colectomy, we suggest that patients with colonic diverticulitis and comorbid diseases may require elective colectomy.

**Key words:** Colonic diverticulitis; Colectomy; Comorbid disease

**Core tip:** Colonic diverticulitis can usually be managed with conservative treatment. However, in select groups of patients with recurrent persistent infection causing life-threatening septic shock, emergent and risky surgical management may be necessary. Elective colectomy for diverticulitis has been discussed in many reports. However, the criteria for elective surgery for colonic diverticulitis still remain controversial. Our data indicate that diverticulitis with comorbid disease increases the operative risk in urgent surgery. Therefore, if a patient has diverticulitis with comorbid disease, an elective colectomy may prevent the consequences of an urgent operation.

Colonic diverticulitis with comorbid diseases may require elective colectomy. *World J Gastroenterol* 2013; 19(39): 6613-6617 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i39/6613.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6613>

## INTRODUCTION

Diverticular disease of the colon has an overall prevalence of less than 10% in individuals under 40 years old and an estimated 50%-66% prevalence in individuals 80 years old or older<sup>[1-4]</sup>. A diverticulum is the herniation of the mucosa and submucosa through the muscular layers of the colon and occurs because of increased intraluminal pressure and weakness in segments of the colonic wall<sup>[5]</sup>. Overall, 10%-25% of patients with diverticular disease will experience diverticulitis and its complications<sup>[6,7]</sup>. Diverticulitis is the inflammation of a diverticulum or diverticula and can be classified as uncomplicated or complicated. Cases involving abscesses, perforation, obstruction, fistula formation or peritonitis are defined as complicated diverticulitis<sup>[8]</sup>. They may require percutaneous drainage of an abscess or emergent surgery. On the other hand, elective colectomy is recommended if an episode of complicated diverticulitis was treated non-operatively<sup>[5,6]</sup>. Elective colectomy to prevent recurrent attacks of diverticulitis or emergent surgery was previously advised<sup>[6]</sup>. However, newer recommendations have called for a revision of the practice of aggressive surgical resection in patients with uncomplicated disease, despite recurrence or age<sup>[8]</sup>. The basis of these arguments is that a majority of patients do not appear to progress from uncomplicated to complicated disease over time<sup>[9,10]</sup>. Moreover, recurrent diverticulitis has not been demonstrated to be a risk for emergency surgery<sup>[8,9]</sup>. The aim of this study was to identify which comorbid diseases could be risk factors for urgent colectomy to aid in the management of colonic diverticulitis. Using this information, we can identify patients who may benefit from early elective colectomy.

## MATERIALS AND METHODS

The charts of 246 patients who had been admitted to the Tri-Service General Hospital, Taipei, Taiwan, between 2000 and 2008 with a diagnosis of diverticulitis were reviewed, and 19 patients who received emergent operations were identified and analyzed retrospectively.

Data were collected with regard to age, sex, albumin level on admission, left or right inflammation site, history of recurrent diverticulitis, preoperative comorbidity, smoking habits, medication, treatment policy, morbidity, and mortality. The diagnosis of colonic diverticulitis was based on the findings of computed tomography, which has a high diagnostic sensitivity of approximately Ninety-three percent to ninety-seven percent and a specificity of

approximately 100%<sup>[4]</sup>. Urgent colectomy was indicated in patients with peritonitis that could not be corrected by medical treatment or drainage. Preoperative comorbid diseases included cardiovascular disease (*e.g.*, hypertensive cardiovascular disease and coronary artery disease), diabetes, pulmonary disease (*e.g.*, chronic obstructive pulmonary disease and asthma), peptic ulcer disease (*e.g.*, gastric ulcer and duodenal ulcer), gouty arthritis, and uremia. Medications in use included non-steroidal anti-inflammatory drugs (NSAIDs), acetylsalicylic acid (aspirin), and corticosteroids.

The mean values were compared using an independent *t* test, and  $\chi^2$  or Fisher's exact test was used to compare proportions. A value of  $P < 0.05$  was considered statistically significant. Data were analyzed using SPSS version 15.0 (SPSS Inc., Chicago, IL, United States) for Windows.

## RESULTS

In total, 246 patients were admitted with a diagnosis of colonic diverticulitis. The mean age was 69.5 years (range, 24-94 years); 144 of the 246 patients were men (58.5%), and 102 were women (41.5%). Most episodes could be managed with conservative treatment consisting of antibiotics and bowel rest ( $n = 227$ , 92.3%), but urgent colectomy was performed in 19 patients (7.7%) (Table 1). All of these patients received Hartmann's operation. However, there were three deaths in the surgical group, two from postoperative lobar pneumonia complicated with septic shock and acute respiratory distress syndrome and the other from urinary tract infection. There were four deaths in the non-surgical group. Two deaths (ages 81 and 79 years; the patient's family refused surgical intervention in both cases) in the nonsurgical group were the result of uncontrolled intra-abdominal infection complicated with septic shock during hospitalization. The other two deaths were due to lobar pneumonia (Table 2). The overall mortality rate was 2.8% ( $n = 7$ ), and it was 15.7% ( $n = 3$ ) in the group that underwent urgent colectomy. Ten patients had wound infections after colectomy, and four were returned to the operating room for surgical debridement. The morbidity rate in the urgent surgery group was 52.6% ( $n = 10$ ) (Table 3).

Univariate analysis with logistic regression indicated that the factors associated with a greater likelihood of having an urgent colectomy were albumin level on admission (OR = 13.488,  $P < 0.001$ ), comorbidity with cardiovascular disease (OR = 3.203,  $P = 0.019$ ), type 2 diabetes (OR = 3.311,  $P = 0.019$ ) or gouty arthritis (OR = 9.777,  $P < 0.001$ ), and use of anticoagulants (OR = 3.200,  $P = 0.023$ ) or NSAIDs (OR = 9.603,  $P < 0.001$ ; Table 4). According to the multivariate analysis with logistic regression, only the albumin level, comorbidity with type 2 diabetes, the use of NSAIDs, and smoking remained risk factors for urgent colectomy for colonic diverticular disease (Table 5).

## DISCUSSION

Emergent surgery should be considered for diverticulitis when the patient has peritonitis from perforation or obstruction causing unstable vital signs, when the patient fails to respond to conservative treatment within the first week of hospitalization, and when the patient presents with a large abscess (> 5 cm) that is undrainable by interventional radiology<sup>[11]</sup>. Approximately 5.5% of patients who recover from an initial episode of diverticulitis require emergency surgical intervention<sup>[12]</sup>. Although the mortality and morbidity rates are low, in a previous study, as in our study, they are higher when an urgent operation was performed. The mortality and morbidity rates were high in our operated group (15.7% and 52.6%, respectively). These results are in agreement with previous reports that indicated that patients who require surgical intervention have high mortality and morbidity rates of

approximately 4.5%-16.7% and 27.2%-71.1%, respectively<sup>[1-3]</sup>. Hartmann's operation is a potential choice for the surgical intervention if the patient has diverticulitis with necrotic perforation. However, laparoscopic washout with diversion may be used if the patient has diverticulitis without necrotic perforation. In our study, all patients were subjected to Hartmann's procedure because they had diverticulitis with necrotic perforation.

To prevent a delay in treatment or consequent resource waste, elective surgery for patients with comorbidities may be recommended. In the previous practice parameters for sigmoid diverticulitis, elective surgery was recommended after two episodes of diverticulitis<sup>[6]</sup>. Richards *et al*<sup>[13]</sup> demonstrated that prophylactic colectomy is associated with increased life expectancy and quality-of-life years when performed after the third attack. However, Ricciardi *et al*<sup>[14]</sup> found that the decline in the surgical treatment for diverticulitis is not associated with an increase in complicated diverticulitis, which indicates that elective surgery has a minimal effect on preventing

emergency colectomies. The recent recommendation of the American Society of Colon and Rectum Surgeons stated that “the decision to recommend elective sigmoid colectomy after recovery from acute diverticulitis should be made on a case-by-case basis”<sup>[15]</sup>. The decision should be made based on the age and the medical condition of the patients, the frequency and severity of the attacks, whether there are persistent symptoms and the suspicion of the malignancy<sup>[15]</sup>. Furthermore, elective surgery is also recommended if an episode of complicated diverticulitis is treated nonoperatively. The predictors of diverticulitis requiring surgery have not been determined, which is still a vexing problem confronting surgeons.

Our study was a retrospective analysis of 246 patients with colonic diverticulitis treated at a single medical center over 9 years. No difference was found in the distribution of colonic diverticulitis between the sexes ( $P = 0.671$ ), and this trend was the same for cases requiring emergent surgery. The ages of patients with diverticulitis had no significant association with surgery ( $P > 0.344$ ). Patient nutritional status upon admission affected the length of hospital stay for patients with colonic diverticulosis. Serum albumin levels correlated negatively with the length of hospital stay<sup>[16,17]</sup>. Moreover, it is well known that there is a correlation between malnutrition and infection, poor wound healing, and the overgrowth of bacteria in the alimentary tract. In the present study, 57.9% of colonic diverticulitis patients in the emergent surgery group had albumin levels below 3 g/dL, whereas this was true of only 9.3% of patients in the non-surgery group. All patients with low albumin (< 3 g/dL) levels had parenteral nutrition.

Among the comorbidities, type 2 diabetes mellitus independently increased the severity of diverticulitis ( $P = 0.019$ ). It is well established that diabetes mellitus has a negative effect on immunity. Polymorphonuclear leukocyte function, leukocyte adherence, chemotaxis, and phagocytosis are all affected in patients with diabetes mellitus<sup>[18]</sup>. Gouty arthritis have also been demonstrated to be a risk factor of urgent operation ( $P < 0.001$ ). How-

**Figure 1 Management of patients with colonic diverticulitis.** NSAIDs: Non-steroidal anti-inflammatory drugs.

ever, this relation may be because of the medication used in treatment because patients with these diseases take NSAIDs for pain control. It is known that there is a correlation between NSAIDs and perforation of colonic diverticula. Several reports have indicated that patients with perforated diverticular disease are significantly more likely to be taking NSAIDs than patients without disease<sup>[19-21]</sup>. The inhibition of cyclo-oxygenase 1 (COX-1) results in deficient levels of prostaglandins, which are related to the protection of bowel mucosa. On the other hand, COX-2 inhibition leads to the failure of the immune response to localize a microperforation. In these patients, continuation of their non-steroidal anti-inflammatory treatments is highly likely to impair colonic mucosal repair<sup>[19-21]</sup>. Cardiovascular disease has also been shown to be associated with urgent colectomy in diverticulitis. In the present study, all of the patients with cardiovascular diseases were taking acetylsalicylic acid, known as aspirin, as an anti-coagulant for preventive treatment. Aspirin is also classified as an NSAID because of its inhibition of platelet COX activity and is considered to predict colonic perforation<sup>[22]</sup>. Smoking was one of the independent factors associated with emergent operation. Smoking may enhance or precipitate the inflammatory process in diverticulitis. Nicotine in cigarettes is a smooth muscle relaxant, which may counteract the colonic muscle spasm that correlates with the pathogenesis of diverticular disease<sup>[23]</sup>. Nicotine may also decrease mucosal immunity by inhibiting the synthesis of proinflammatory cytokines such as interleukin  $\alpha$  and tumor necrosis factor  $\alpha$  in colonic mucosa. Smoking could also cause systemic sepsis via the promotion of oxidative damage by generating oxygen free radicals<sup>[23]</sup>. Steroid treatment also has a negative effect on mucosal regenerative activity<sup>[24]</sup>. In our study, it did not significantly predict diverticular perforation. This

is most likely because the number of patients with steroid treatment in our series was small.

Our results indicated several comorbid diseases are risk factors to urgent colectomy. There were 7.7% of patients with colonic diverticular disease who had to receive urgent colectomy despite conservative treatment including antibiotics and bowel rest. Preoperative comorbid diseases may increase the operative risk in urgent surgery, and the outcome is poor. The mortality and morbidity rates are up to 15.7% and 52.6%, respectively. To avoid high mortality and morbidity related to urgent colectomy. We suggested that patients with colonic diverticulitis and comorbid disease may require elective colectomy (Figure 1).

## COMMENTS

### Background

Colonic diverticulitis with comorbid disease may get fatal complication after urgent surgery. Therefore, To avoid high mortality and morbidity related to urgent colectomy, the authors suggest that patients with colonic diverticulitis and comorbid diseases may require elective colectomy.

### Research frontiers

This study is designed to clarify the predictors of elective colectomy for colonic diverticulitis.

### Innovations and breakthroughs

Comorbid disease could be the predictors of elective colectomy for colonic diverticulitis.

### Applications

Provide a possible policy of surgical management for the patients with colonic diverticulitis.

### Peer review

This is an interesting paper stressing the importance of comorbidities in the treatment of diverticulitis.

group received the same volume of 0.9% isotonic saline for 2 wk. Patients underwent imaging studies and liver-function tests every week for 4 wk. The rate of spontaneous passage of CBD stones was analyzed.

**RESULTS:** The rate of spontaneous passage of CBD stones was significantly higher in the anisodamine group than that in the control group (47.0% vs 22.7%). Most (87.2%, 41/47) stone passages in the anisodamine group occurred in the first 2 wk, and passages in the control group occurred at a comparable rate each week. Factors significantly increasing the possibility of spontaneous passage by univariate logistic regression analyses were stone diameter ( $< 5$  mm vs  $\geq 5$  mm and  $\leq 10$  mm) and anisodamine therapy. Multivariate logistic regression analyses revealed that these two factors were significantly associated with spontaneous passage.

**CONCLUSION:** Two weeks of anisodamine administration can safely accelerate spontaneous passage of single and symptomatic CBD stones  $\leq 10$  mm in diameter, especially for stones  $< 5$  mm.

### Abstract

**AIM:** To investigate the rate of spontaneous passage of single and symptomatic common bile duct (CBD) stones  $\leq 10$  mm in diameter in 4 wk with or without a 2-wk course of anisodamine.

**METHODS:** A multicenter, randomized, placebo-controlled trial was undertaken. A total of 197 patients who met the inclusion criteria were enrolled. Ninety-seven patients were assigned randomly to the control group and the other 100 to the anisodamine group. The anisodamine group received intravenous infusions of anisodamine (10 mg every 8 h) for 2 wk. The control

**Key words:** Common bile duct stones; Anisodamine; Spontaneous passage; Success rate; Randomized controlled trial

**Core tip:** Common bile duct (CBD) stones are known to pass spontaneously in many patients. This phenomenon has not been given sufficient emphasis in terms of optimizing the timing of management of CBD stones. We investigated the rate of spontaneous passage of single and symptomatic CBD stones  $\leq 10$  mm in diameter in 4 wk with or without a 2-wk course of anisodamine in a multicenter, randomized, placebo-controlled trial. Anisodamine administration for 2 wk can safely accelerate spontaneous passage of single and symp-

tomatic CBD stones  $\leq$  10 mm in diameter, especially for stones < 5 mm.

Anisodamine accelerates spontaneous passage of single symptomatic bile duct stones  $\leq$  10 mm. *World J Gastroenterol* 2013; 19(39): 6618-6624 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i39/6618.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6618>

## INTRODUCTION

Gallstone disease is one of the most common digestive diseases worldwide. Common bile duct (CBD) stones may develop in 3%-14.7% of patients who undergo cholecystectomy<sup>[1-4]</sup>. The stones can present in various ways or may be asymptomatic. Common symptoms of CBD stones include biliary colic, jaundice, acute pancreatitis, acute cholangitis, or a combination of these symptoms<sup>[4]</sup>.

Management of symptomatic CBD stones has evolved over the recent two decades and continues to evolve<sup>[5,6]</sup>. Before the advent of laparoscopy, patients with CBD stones requiring surgical treatment usually underwent laparotomy with CBD exploration and T-tube placement. Alternatively, they underwent endoscopic retrograde cholangiopancreatography (ERCP)/endoscopic sphincterotomy (EST) by endoscopists<sup>[7-9]</sup> to avoid surgical CBD exploration. In recent years, laparoscopic CBD exploration has emerged as an alternative to ERCP/EST and a successor to open CBD exploration for the management of CBD stones<sup>[10-12]</sup>.

The management strategy of CBD stones has focused mainly on the choice of treatment rather than timing. A consensus on the timing of management of symptomatic CBD stones is lacking. Most physicians, surgeons and endoscopists propose that symptomatic CBD stones should be extracted promptly<sup>[5]</sup>. However, accumulating evidence has shown that CBD stones often pass spontaneously, which raises the possibility of avoiding CBD intervention altogether<sup>[1,13-16]</sup>. The reported prevalence of spontaneous passage varies considerably, mainly because of different inclusion criteria and research methods used<sup>[1,13-15]</sup>, but authors conclude that a significant portion of CBD stones may pass spontaneously with conservative treatment and do not need to be extracted by surgical or endoscopic means.

Spontaneous passage of CBD stones is dependent upon relaxation of the sphincter of Oddi. Hence, it is logical to use a medication to relax the sphincter of Oddi to accelerate the passage of CBD stones. Anisodamine, 6(s)-hydroxyhyoscyamine, is a belladonna alkaloid derived from the Chinese medicinal herb *Scopolia tangutica* Maxim of the Solanaceae family. It appears to be a non-selective M-cholinergic antagonist presumably capable of blockade at all M-choline receptor subtypes<sup>[17-23]</sup>. Little clinical information is available regarding its toxicity in humans.

Based upon animal studies, it is less toxic than atropine or scopolamine<sup>[18]</sup>. Since the late 1970s in China, anisodamine has been employed almost exclusively as an OTC anti-spasmodic agent for relieving colic pain in the treatment of CBD stones<sup>[17]</sup>.

We first attempted to use anisodamine to aid spontaneous passage of symptomatic CBD stones by prolonging its use to 2 wk in 2007, and noticed that it might accelerate their spontaneous passage. In 2009, we initiated a prospective, randomized, placebo-controlled trial to observe the rate of spontaneous passage of single and symptomatic CBD stones  $\leq$  10 mm diameter in 4 wk with or without a 2-wk course of anisodamine.

## MATERIALS AND METHODS

### Design

This study was a multicenter, randomized, placebo-controlled trial comparing the rate of spontaneous passage of single and symptomatic CBD stones  $\leq$  10 mm in diameter in 4 wk with or without a 2-wk course of anisodamine. The following hospitals in China participated in the study: Beijing Chaoyang Hospital affiliated to Capital Medical University, Beijing, China; 254 Hospital of PLA, Tianjin, China; Chaoyang Central Hospital, Liaoning, China; and Zhanhua People's Hospital, Shandong, China. Each center obtained approval from the responsible ethics committee according to the standards of the Declaration of Helsinki before the trial according to the current practice and guidelines in China. The first or primary approval of the study was obtained at the Beijing Chaoyang Hospital affiliated to Capital Medical University. All research personnel and collaborators were trained accordingly.

All patients with CBD stones were informed of the currently available therapies to extract stones from the bile duct: ERCP/EST, laparoscopic surgery, or laparotomy. All patients were informed of the potential morbidity of each endoscopic or surgical procedure. All participants provided written informed consent for inclusion in the study. Patients were recruited into the study between January 2009 and April 2013.

Patients were enrolled if they met the following three inclusion criteria: (1) clinical presentation was consistent with biliary colic, cholangitis, jaundice, or/and acute pancreatitis. Jaundice was defined as a bilirubin level of > 50  $\mu\text{mol/L}$  (normal range, 7-20  $\mu\text{mol/L}$ ). Acute pancreatitis was defined by at least two of the following criteria: characteristic abdominal pain, serum amylase and/or lipase values exceeding three times the upper limit of normal, and a computed tomography (CT) scan demonstrating the characteristic changes of acute pancreatitis<sup>[24]</sup>; (2) abnormal liver function: high serum levels of aminotransferase, alkaline phosphatase, or  $\gamma$ -glutamyl transpeptidase of more than twice the normal values; and (3) a single CBD stone  $\leq$  10 mm in diameter confirmed by conventional CT or magnetic resonance cholangiopancreatography (MRCP).

Exclusion criteria were: (1) histories of emergency ERCP/EST or other procedures for severe cholangitis or pancreatitis; (2) CBD stones > 10 mm (which rarely pass spontaneously); and (3) contraindications to the use of anisodamine, such as glaucoma or cerebral hemorrhage.

Patients were assigned to the control group or anisodamine group by a computerized randomization process, and all patients were blinded to the allocation.

### Treatment protocol

For patients with jaundice or isolated abnormal liver test results, a pharmacological strategy for protection against liver injury was adopted: vitamin E, vitamin C, glutathione and tiopronin. Patients with biliary colic were treated with non-steroidal anti-inflammatory drugs for pain relief<sup>[25]</sup>. Patients with cholangitis were treated with antibiotics. For patients with acute pancreatitis, support measures were adopted: aggressive hydroelectrolytic replacement, analgesia and nutritional support treatment.

Patients in the anisodamine group received intravenous infusions of anisodamine (10 mg every 8 h) for 2 wk in addition to the treatments mentioned above. Anisodamine was terminated within the following 2 wk. Patients in the control group received the same volume of 0.9% isotonic saline for 2 wk in addition to the treatments mentioned above.

Patients who developed severe pancreatitis<sup>[24]</sup>, severe cholangitis<sup>[26]</sup>, or aggravated jaundice during this conservative treatment period dropped out of the study.

### Data collection

All data (demographic characteristics, nature of clinical presentation, imaging reports, and laboratory results) were collected for analyses by two trained physicians. Imaging reports were completed by two radiologists who had > 10 years of experience and were blinded to the allocation.

### Study endpoints

The primary endpoint of the study was the rate of spontaneous passage of CBD stones in 4 wk. The secondary endpoints were the safety of anisodamine and the dropout rate.

All patients underwent monitoring *via* conventional CT or MRCP and liver-function tests at a 1-wk interval for 4 wk. Spontaneous passage of CBD stones was defined as no signs of CBD stones upon CT or MRCP and normal results of liver function tests after conservative treatment.

Patients who experienced successful passage of CBD stones underwent only laparoscopic cholecystectomy (LC) without CBD intervention. However, if they did not experience successful passage, LC and laparoscopic CBD exploration *via* the transcystic or transduction route were performed. Patients with a history of cholecystectomy did not receive further treatment after successful passage of CBD stones. However, if the CBD stones failed to pass spontaneously, the patients underwent ERCP/EST.

### Statistical analysis

Frossard *et al.*<sup>[13]</sup> reported that the rate of spontaneous passage of CBD stones within 1 mo was 21%. We estimated that the rate of spontaneous passage of CBD stones was 20% because the patients and research methods in the present study were similar to those of Frossard *et al.*<sup>[13]</sup>. Furthermore, the number of patients predicted to be necessary for statistical validity was based on the premise of improving the rate of spontaneous passage of CBD stones from 20% to 40%, with alpha set at 0.05 and beta set at 0.2, yielding a power of 80%. A two-tailed test was used. We calculated that 82 patients would be required in each arm of the study for a total projected study population of 164 patients. After taking a dropout rate of 20% into account, 197 patients would be required.

Continuous data are the mean  $\pm$  SD, and an independent *t* test was used to examine differences between the two groups. Categorical variables were presented as number (%) and analyzed using the  $\chi^2$  test or Fisher's exact test. A stepwise logistic regression model was used to determine the effects of multiple factors on spontaneous passage. Significance was accepted at the 5% level. All CIs were reported at the 95% level. All statistical computations were undertaken using Statistical Package for the Social Sciences ver15.0 (SPSS, Chicago, IL, United States).

## RESULTS

Of the 450 patients with CBD stones who were screened at the four participating hospitals of the study between January 2009 and April 2013, 197 met the inclusion criteria and were enrolled (Figure 1). Ninety-one (46.2%) patients were male and 106 patients were female (53.8%). Ninety-seven patients were randomized to the control group, and 100 to the anisodamine group. No difference in baseline patient characteristics was observed between control and anisodamine groups (Table 1). During the period of conservative treatment, 11 (5.6%) patients (4 in the control group and 7 in the anisodamine group) dropped out because of aggravation of cholangitis (8 patients), pancreatitis (1 patient) and jaundice (2 patients). For these patients, laparoscopic cholecystostomy was carried out in 1 patient, percutaneous transhepatic gallbladder drainage in 2 patients, and ERCP/EST in 8 patients. There was no mortality in the 11 patients.

Spontaneous passage of CBD stones occurred in 22.7% (22/97) and 47.0% (47/100) of patients in control and anisodamine groups, respectively ( $P < 0.05$ ) (Figure 2, Table 2). For subgroup patients with stones < 5 mm in diameter, this rate was significantly higher in the anisodamine group than that in the control group (71.7% *vs* 31.8%,  $P < 0.05$ ), and for those with stones of  $\geq 5$  mm and  $\leq 10$  mm, this rate was also significantly higher in the anisodamine group than that in the control group (27.3% *vs* 15.1%,  $P < 0.05$ ) (Table 2). In the control group, the rate of spontaneous passage of CBD stones in each of the 4 wk was not significantly different ( $P >$

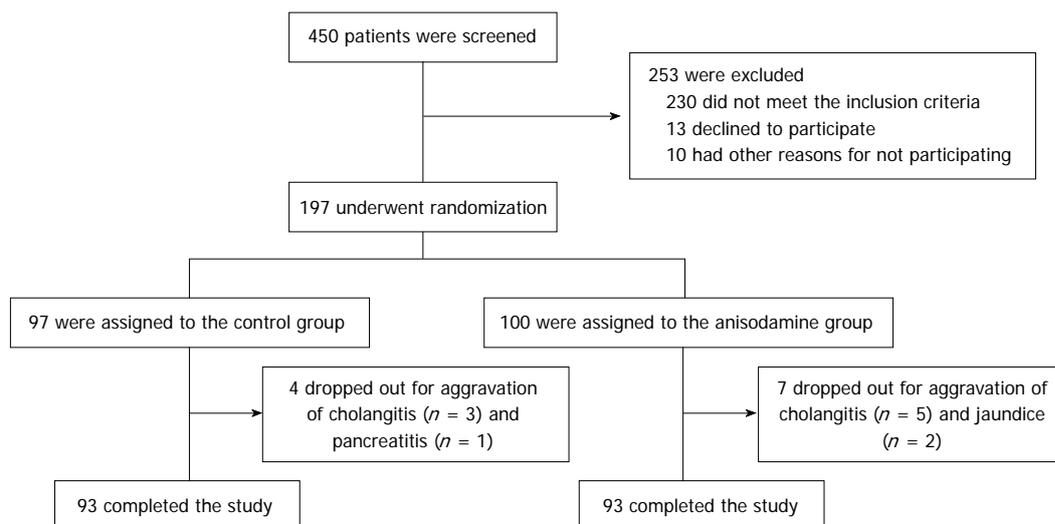

Figure 1 Enrollment and outcomes.

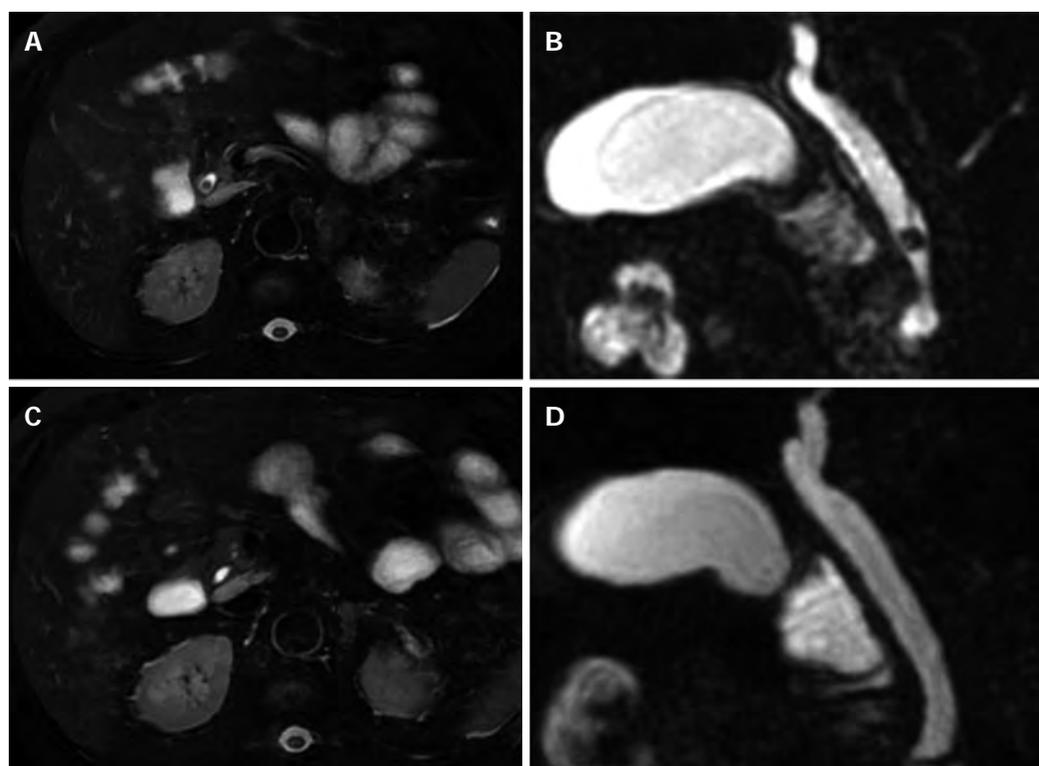

Figure 2 A 60-year-old male with gallstones and a common bile duct stone of 7.0 mm in diameter received anisodamine for 2 wk. The common bile duct (CBD) stone passed spontaneously within 2 wk after treatment. A: Magnetic resonance imaging (MRI) on cross-sectional T2-weighted imaging showing a filling defect in the CBD; B: Magnetic resonance cholangiopancreatography (MRCP) showing a 7-mm filling defect in the dilated CBD; C: Repeat MRI in the second week after conservative treatment illustrating that the CBD is clear of calculi; D: MRCP showing no signs of CBD stones.

0.05). In contrast, in the anisodamine group, the rate of spontaneous passage of CBD stones in the first 2 wk using anisodamine was significantly higher than that in the latter 2 wk without anisodamine treatment ( $P < 0.05$ ), (Table 2). All 197 patients with symptomatic CBD stones experienced 1-3 attacks of biliary colic during follow-up. It was difficult to verify whether the stone passed during the colic attack or whether it passed silently.

Table 3 lists the results of univariate and multivariate

logistic regression models constructed to identify the predictors for spontaneous passage. Factors significantly increasing the possibility of spontaneous passage by univariate logistic regression analyses were the diameter of the CBD stone and anisodamine therapy. Furthermore, multivariate logistic regression analyses also revealed that the factors associated with spontaneous passage included the diameter of the CBD stone (OR = 3.095; 95%CI: 1.927-4.970;  $P = 0.000$ ) and anisodamine therapy (OR =

3.534; 95%CI: 1.810-6.902; *P* = 0.000). Clinical presentation did not significantly influence the rate of spontaneous passage (Table 3).

Among the 69 patients whose CBD stones passed spontaneously, 50 patients with gallstones underwent LC and avoided CBD intervention, and the other 19 patients with a history of cholecystectomy did not receive additional treatment. Among the 117 patients who failed to pass CBD stones, 85 patients with gallstones underwent LC and laparoscopic CBD exploration (56 trans-ductal and 29 trans-CBD), and 32 patients with a history of cholecystectomy underwent ERCP/EST to remove CBD stones. No patient underwent conversion to open surgery. Exploration of the CBD and common hepatic duct in all of these patients found stones, which were removed using a Dormia basket or flushed into the duodenum. The CBD was closed over an appropriately sized T-tube in 29 patients by incising and opening the CBD directly with stone retrieval after the stones were removed under endoscopic visualization. T-tube cholangiography was undertaken 21 d or later postoperatively, and the T-tube was removed if abnormalities were not observed.

Tachyarrhythmia, palpitations, blurred vision and severe retention of urine were not observed in the anisodamine group. Of 100 patients in the anisodamine group, 11 patients experienced a dry mouth occasionally, which disappeared immediately after withdrawal of anisodamine.

## DISCUSSION

This study was designed to investigate the rate of spontaneous passage of single and symptomatic CBD stones with the aid of a 2-wk course of anisodamine in symptomatic patients to demonstrate the role of conservative treatment for symptomatic CBD stones. The results of the study showed that 47.0% (47/100) of CBD stones passed spontaneously in the anisodamine group, and 87.2% (41/47) of the passages occurred in the first 2 wk with anisodamine treatment. However, only 22.7% (22/97) of patients passed CBD stones spontaneously in the control group, with comparable rates of spontaneous passage each week. Multivariate analyses indicated that anisodamine therapy carried a substantial advantage for accelerating the spontaneous passage of CBD stones. Moreover, stones < 5 mm in diameter were more likely to pass spontaneously, and spontaneous passage was not related to the clinical presentation. This finding would be useful for clinicians to predict which patients might pass stones spontaneously and to make rational clinical judgments.

Most clinicians specializing in hepatobiliary medicine are familiar with spontaneous passage of CBD stones, and such passage is recognized in the literature<sup>[1,13-16]</sup>. Collins *et al*<sup>[1]</sup> reported that 12/34 of silent CBD stones confirmed by intraoperative cholangiography in selective LC passed spontaneously 6 wk after the procedure. Frossard *et al*<sup>[13]</sup> evaluated the prevalence and time-course of CBD stone passage in symptomatic patients by analyzing discrepancies between endoscopic ultrasonography and ERCP as a function of the time elapsed between these two procedures. They found that the rate of spontaneous passage of CBD stones was 21% (12/57), and that the rates of spontaneous passage in different periods (from 6 h to 3 d and from 3 to 27 d) were 21% (8/37) and 20% (4/20), respectively. They also concluded that stone diameter was the only factor that predicted passage, and that the rate of spontaneous passage of stones with a diameter of > 8 mm was only 4.3% (2/47). Tranter *et al*<sup>[14]</sup> conducted a study in 1000 patients to determine the rate of spontaneous passage of CBD stones and related it

CBD: Common bile duct.

to the various presentations of CBD stones. They found that 390/532 CBD stones passed spontaneously, but they did not specify the observation period. Lefemine *et al*<sup>[15]</sup> retrospectively investigated 108 patients presenting with jaundice due to CBD stones, and found that spontaneous passage of CBD stones occurred in 60 (55.6%) of 108 patients within approximately 4 wk. The inclusion criteria of the latter two studies<sup>[14,15]</sup> were not strict: patients with a history of jaundice, pancreatitis, abnormal results of liver function tests, or a dilated CBD were assumed to have a history of CBD stones. Therefore, the reported rates of spontaneous passage were probably overestimated.

Reported rates of spontaneous passage of CBD stones vary mainly because of different inclusion criteria and research methods used<sup>[1,13-15]</sup>. However, studies have demonstrated that a significant portion of CBD stones can pass spontaneously through the sphincter of Oddi into the duodenum with conservative treatment. However, further investigation is required to clarify the true potential of spontaneous passage of symptomatic CBD stones of different diameters because this potential is related closely to clinical decision-making for patients with symptomatic CBD stones. The present study was the first randomized study to investigate the rate of spontaneous passage in selected patients with CBD stones with the aid of a 2-wk course of anisodamine, and no studies have focused on other pharmacologic therapies for CBD stones. We showed not only the rate of spontaneous passage of CBD stones  $\leq 10$  mm in the control arm, but also confirmed that anisodamine effectively and safely accelerated the spontaneous passage of CBD stones in these patients.

Tranter *et al*<sup>[14]</sup> found that spontaneous passage of CBD stones occurred more commonly in patients with pancreatitis, biliary colic, and cholecystitis, but less commonly in jaundiced patients. They explained that patients with jaundice may be treated more quickly than other patients, allowing less time for spontaneous passage. The present study did not support this finding. We did not identify a particular characteristic of the patients who failed to pass stones spontaneously during the same observation period. Therefore, we concluded that spontane-

ous passage was not related to the presentation.

The limitation of this study was that the attending physicians were not blinded to the patient allocation. To address this, all physicians underwent strict and standardized training based on the treatment protocol. This training stressed that all patients should be treated with the same demeanor regardless of their randomized treatment arm.

In conclusion, 2 wk of anisodamine administration can safely accelerate spontaneous passage of single and symptomatic CBD stones  $\leq 10$  mm in diameter in symptomatic patients. These findings suggest that conservative treatment may be regarded as first-line management for these patients, especially for those with a stone  $< 5$  mm.

## COMMENTS

### Background

Common bile duct (CBD) stones are known to pass spontaneously in many patients. This phenomenon has not been given sufficient emphasis in terms of optimizing the timing of management of CBD stones. Anisodamine has been used as an antispasmodic agent for relieving colic pain in the treatment of CBD stones in China for more than 40 years. The authors hypothesized that anisodamine therapy can accelerate the passage of CBD stones by relaxing the sphincter of Oddi. The rate of spontaneous passage of single and symptomatic CBD stones  $\leq 10$  mm in 4 wk with or without a 2-wk course of anisodamine, was investigated.

### Research frontiers

The management of CBD stones has focused mainly on the choice of treatment rather than its timing. Consensus on the timing of management of symptomatic CBD stones is lacking. Most physicians, surgeons and endoscopists propose that symptomatic CBD stones should be extracted promptly. However, accumulating evidence has shown that CBD stones often pass spontaneously, which raises the possibility of avoiding CBD intervention.

### Innovations and breakthroughs

The results of the present study suggested that anisodamine administration for 2 wk can safely accelerate spontaneous passage of single and symptomatic CBD stones  $\leq 10$  mm in symptomatic patients. These findings indicated that conservative treatment could be the first-line management for these patients, especially for those with stones  $< 5$  mm in diameter.

### Applications

The results of the present study suggest that 2 wk of anisodamine administration can safely accelerate spontaneous passage of single and symptomatic CBD stones  $\leq 10$  mm in diameter in symptomatic patients. These findings indicated that conservative treatment could be the first-line management for these patients, especially for those with stones  $< 5$  mm.

**Peer review**

The authors undertook a randomized controlled trial investigating if anisodamine accelerated spontaneous passage of single symptomatic CBD stones  $\leq$  10 mm in diameter. The study was well conducted and the results are interesting that 47.0% of CBD stones  $\leq$  10 mm in diameter passed spontaneously with the aid of a 2-wk course of anisodamine.

### Abstract

**AIM:** To evaluate the efficacy of gracilis muscle transposition and postoperative salvage irrigation-suction in the treatment of complex rectovaginal fistulas (RVFs) and rectourethral fistulas (RUFs).

**METHODS:** Between May 2009 and March 2012, 11 female patients with complex RVFs and 8 male patients with RUFs were prospectively enrolled. Gracilis muscle transposition was undertaken in all patients and postoperative wound irrigation-suction was performed in patients with early leakage. Efficacy was assessed in terms of the success rate and surgical complications. SF-36 quality of life (QOL) scores and Wexner fecal incontinence scores were compared before and after surgery.

**RESULTS:** The fistulas healed in 14 patients after gracilis muscle transposition; the initial healing rate was 73.7%. Postoperative leakage occurred and continuous irrigation-suction of wounds was undertaken in 5 patients: 4 healed and 1 failed, and postoperative fecal diversions were performed for the patient whose treatment failed. At a median follow-up of 17 mo, the overall healing rate was 94.7%. Postoperative complications occurred in 4 cases. Significant improvement was observed in the quality outcomes framework scores ( $P < 0.001$ ) and Wexner fecal incontinence scores ( $P = 0.002$ ) after the successful healing of complex RVFs or RUFs. There was no significant difference in SF-36 QOL scores between the initial healing group and irrigation-suction-assisted healing group.

**CONCLUSION:** Gracilis muscle transposition and postoperative salvage wound irrigation-suction gained a high success rate in the treatment of complex RVFs and RUFs. QOL and fecal incontinence were significantly improved after the successful healing of RVFs and RUFs.

**Key words:** Rectovaginal fistula; Rectourethral fistula; Gracilis muscle; Quality of life; Therapeutic irrigation

**Core tip:** A prospective study of 19 patients with complex rectovaginal fistulas (RVFs) and rectourethral fistulas (RUFs) undergoing gracilis muscle transposition followed by postoperative salvage wound irrigation-suction was reported to yield an overall healing rate of 94.7%. In addition, quality of life and fecal incontinence were reported to be significantly improved after the successful healing of RVFs and RUFs.

## INTRODUCTION

Rectovaginal fistulas (RVFs) and rectourethral fistulas (RUFs) are pathological sinus tracts between the rectum and vagina or urethra. The exact incidence of RVFs/RUFs is not known. The reported frequency of RVFs following low anterior rectal resection reached 10%<sup>[1-5]</sup>, and RUFs developed in 0.53% of patients after radical prostatectomy<sup>[6]</sup>. Moreover, such fistulas have attracted appreciable attention because of their obvious influence on quality of life (QOL) and their difficulty of repair. Multiple surgical procedures to repair these fistulas have been described, but the success rates have varied dramatically, and the sample sizes reported were generally small<sup>[7]</sup>. The most popular treatments are transrectal or transvaginal flaps, direct peritoneal closure, a wide variety of abdominal procedures (including coloanal anastomosis and tissue interposition), and gracilis muscle transposition<sup>[8,9]</sup>.

Gracilis muscle transposition was first described in 1928 by Garlock<sup>[10]</sup>, who rotated the muscle subcutaneously to the fistula region. The treatment was subsequently applied in patients with vesicovaginal fistulas in 1952<sup>[11]</sup>. This method satisfies the criteria of relative safety afforded by perineal procedures while providing the healthy, well-vascularized tissue offered by abdominal procedures<sup>[12]</sup>.

After reviewing the results of various repairs (including gracilis muscle transposition for RVFs and RUFs)<sup>[13]</sup>, Wexner *et al*<sup>[11]</sup> reported that gracilis muscle transposition is associated with minimal morbidity and a high success rate, but a second repair is needed in some cases. The leakage of anastomoses in the digestive tract was found to be the predominant reason for postoperative fistulization<sup>[14]</sup>; anastomoses may be cured without surgical intervention by continued irrigation-suction<sup>[15]</sup>.

In the present study, we hypothesized the following: (1) gracilis muscle transposition to repair complex RVFs and RUFs can improve QOL; and (2) continuous wound irrigation-suction during the perioperative period can avoid the need for a second repair and can yield a high success rate.

## MATERIALS AND METHODS

### *Ethical approval of the study protocol*

The study protocol was approved by the Ethics Committee of Capital Medical University (Beijing, China). All the patients provided written informed consent before being enrolled in the study.

### *Patient characteristics and study design*

The prospectively registered data were as follows: patient demographics, etiology, clinical manifestation, diagnostic

procedures, repair history, use of fecal and/or urinary diversions, fistula type, surgical details, morbidity, and preoperative management. The Wexner score<sup>[16]</sup> and the Short-Form (SF)-36 score<sup>[17]</sup> were recorded preoperatively and 6 mo postoperatively by an independent research assistant.

Inclusion criteria and exclusion criteria were: All patients with RUFs were enrolled. However, complex RVFs had to meet one or more of the following criteria: (1) positioning in the upper-third of the rectovaginal septum; (2) size of fistula orifice  $\geq 2.5$  cm; (3) secondary to inflammatory bowel disease, radiotherapy or a tumor; and (4) having experienced a previous failed repair.

### *Surgical procedure*

The repair of complex RVFs and RUFs *via* gracilis muscle transposition was conducted as described previously<sup>[18]</sup>. At the end of surgery, two draining tubes were placed in perineal and leg wounds. All leakages were confirmed as fistula repair failures using the methylene blue test<sup>[19]</sup>. The perineal tube was routinely replaced with an irrigation-suction device (Changzhou Anker Medical Co., Ltd, Changzhou, China) as soon as leakage was observed from the vagina or from the perineal incision (Figure 1). The procedure was conducted by one surgeon, and local anesthesia was not used. Continuous irrigation with approximately 2000-3000 cm<sup>3</sup> of 0.9% saline per day and suction with a negative pressure of 0-0.01 kPa were used for all patients with leakages. The criterion for ending irrigation-suction was that suction collection was clear for  $> 3$  d.

Fecal diversions were used for 3 mo prior to gracilis interposition in 15 patients with RUFs and RVFs and were removed 3 mo after healing was confirmed. Epicystostomy was undertaken in 7 patients with RUFs before gracilis interposition and was closed 3 mo after healing was confirmed. A urinary catheter was left in place for 1 mo after the RUF procedures. The criteria for successful repair were that the fistula healed within 1 mo postoperatively or from the completion of irrigation-suction. Follow-up began 3 mo after the last hospitalization.

### *Statistical analysis*

Quantitative data were presented as the mean and standard deviation or the median and interquartile range (IQR) depending on whether an underlying normal distribution can be assumed. Numeric data were presented as percentages. Score values were compared using Student's *t* test or corresponding nonparametric methods. All the tests were two sided, and  $P < 0.05$  was considered to be of statistical significance.

## RESULTS

From May 2009 to November 2011, 18 patients (8 RUFs and 11 complex RVFs) were recruited into the study; 10 patients were excluded (6 because they had simple RVFs and 4 because they underwent procedures other than gracilis muscle transposition).

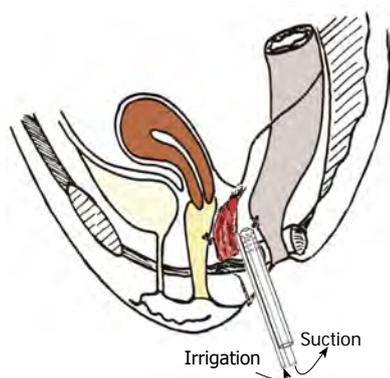

Figure 1 An irrigation-suction device was placed in the leakage site following gracilis muscle transposition.

The median age of the study cohort was 47 years (range, 16-80 years). The median value of the body mass index (BMI) was 21.9 kg/m<sup>2</sup> (range, 15.6-29.1 kg/m<sup>2</sup>). The median duration of the disease was 18 mo (range, 13-48 mo). The etiologies of the RUFs were previous surgery and pelvic irradiation of prostatic carcinoma ( $n = 5$ ), congenital imperforation ( $n = 1$ ), bulbourethral infection ( $n = 1$ ) and pelvic injury ( $n = 1$ ). The etiologies of the complex RVFs were surgery for rectal cancer ( $n = 4$ ), gynecologic surgery ( $n = 3$ ), birth trauma ( $n = 3$ ) and pelvic injury ( $n = 1$ ). The mean number of failed attempts was 1 (0-3). Fistulas associated with Crohn's disease were not observed in this cohort.

All fistulas were in the upper external sphincter and had a mean diameter of 1.6 cm (range, 0.5-3.0 cm). The median duration of surgery was 247 min (range, 120-400 min). The median postoperative hospital stay was 21 d (range, 10-39 d). The median postoperative follow-up was 17 mo (range, 6-34 mo). Postoperative short-term complications were numbness and pain in the thigh ( $n = 2$ ) and leg numbness ( $n = 2$ ), and both normalized within 6 mo without surgical intervention. No long-term complications were reported. The initial success rate of fistula healing after gracilis muscle transposition was 73.7% (14/19).

As an early sign of repair failure, postoperative leakage occurred in 5 patients (one male and 4 female). The median age was 53 years (range, 30-75 years). The median time from gracilis muscle transposition to the first leakage was 7 d (range, 6-10 d). Four patients were healed after continuous irrigation-suction, and the median duration of irrigation-suction was 8 d (range, 4-27 d). The overall success rate was 94.7% (18/19). The failed case was a 30-year-old female with RVF following 2 failed repairs. Gracilis muscle transposition was undertaken without preoperative fecal diversion; leakage occurred 6 d after surgery; irrigation-suction was conducted for 27 d and a sigmoid colon stoma was made 12 d postoperatively. However, the fistula persisted during a follow-up period of 22 mo.

The median Wexner score for successfully repaired fistulas was 15 (IQR = 18) and 0 (IQR = 0) before and

6 mo after the surgery, respectively. Fecal incontinence improved significantly after successful repair ( $P = 0.002$ ). QOL improved significantly after successful healing ( $P < 0.001$ ; Table 1). No difference was found in QOL in subjects whose fistula repair was successful ("initial success group") and those healing was successful after irrigation-suction ("secondary success group"; Table 2).

## DISCUSSION

The success rate of RUF/RVF repair after gracilis muscle transposition has been reported to be between 77% and 90%<sup>[18,20-23]</sup>. Wexner *et al*<sup>[11]</sup> reported the largest series of 53 RVFs and RUFs with gracilis muscle interposition, and the overall initial success rate was 70%; after seven repeated gracilis muscle transpositions, the final success rate was 87%. In the present study, the initial success rate was 73.7%; after continuous irrigation-suction, the success rate increased to 94.7%. Repeated gracilis muscle transposition was not performed in the present study. Continuous irrigation-suction was effective in improving the success rate of gracilis muscle transposition for complex RVFs and RUFs, and it protected patients from the potential complications associated with a second repair.

QOL is one of the most important outcomes of RVF/RUF repair. However, data related to changes in the QOL of patients with RVFs/RUFs and to the improvement of QOL after repair are lacking. This is the first prospective study to compare the preoperative and postoperative SF-36 scores in RVF/RUF patients after gracilis muscle transposition. Our data showed that the QOL improved significantly after successful RUF/RVF repair. The QOL was similar between the initial success group and secondary success group after irrigation-suction. Successful healing of RUFs/RVFs, after either surgical repair or continuous irrigation-suction, was the key factor in improvement of QOL. Correlations were found between the Wexner score and the SF36 domain scores in patients with pelvic disorders such as urinary incontinence and pelvic organ prolapse<sup>[24]</sup>. The fecal incontinence score increased significantly after successful healing of RVFs/RUFs in the current study, which may have contributed to the improvement in QOL. However, Lefèvre *et al*<sup>[25]</sup> reported that patients with recurrent RVFs have significantly lower postoperative SF-36 scores compared with the general population, while the impact of RVF/RUF repair on QOL remained unknown because the authors did not compare QOL before and after successful repair. Samplaski *et al*<sup>[26]</sup> investigated the QOL outcomes in patients undergoing transperineal repair with gracilis muscle interposition for RUF and achieved reasonable bowel and bladder function postoperatively. Further studies aimed at QOL in patients with RVFs or RUFs, especially whether QOL is improved even when fecal incontinence remains unchanged after repair, are needed to provide consensus for clinical care.

An adequate length of the bulky muscular portion of a well-vascularized gracilis to place the muscle between

the two suture lines is important for initial success. It is important to place the tip of the irrigation-suction tube close to the leakage site for successful healing. Hence, the length of the irrigation-suction tube underneath the skin should be exactly the same as that of the original tube.

The success rate of gracilis muscle transposition for RUFs is, in general, higher than that for RVFs, and the success rate is considerably higher in non-Crohn’s disease-associated RVFs than in Crohn’s disease-associated RVFs<sup>[13]</sup>. Crohn’s disease may have a negative impact on fistula healing. In the present study, Crohn’s disease-associated RVF was not encountered, which might explain why that initial success rate and final success rate were considerably higher compared with previous studies. The efficacy of gracilis muscle transposition for Crohn’s-associated RVF needs further verification.

The main limitation of the present study was the low prevalence of postoperative leakage. The number of patients in the secondary success group (only 4) seems too small to provide a meaningful comparison to the initially success group; therefore, we should accept the lack of difference in QOL between the two groups with caution. Further studies comparing postoperative leakage treated with or without perioperative irrigation-suction are necessary before this surgical method can be widely used.

According to the data, gracilis muscle transposition may be indicated in complex RVFs/RUFs resulting from pelvic irradiation, surgical injury, trauma and infection, especially they are associated with malignancy and failed

repair. Postoperative irrigation-suction should be considered as soon as a leakage is found. Gracilis muscle transposition and postoperative salvage wound irrigation-suction to treat complex RVFs and RUFs was shown to have a high success rate. QOL and fecal incontinence were improved significantly after the successful healing of RVFs and RUFs.

**COMMENTS**

**Background**

The obvious influences of complex rectovaginal fistulas (RVFs) and rectourethral fistulas (RUFs) on quality of life (QOL) and the difficulty of their repairs have attracted extensive attention. Gracilis muscle repair is associated with minimal morbidity and a high success rate, but second repair is often required in some cases.

**Research frontiers**

The success rate of RUF/RVF repair after gracilis muscle transposition has been reported to be 77%-90%. Data related to changes in the QOL of patients with RVFs/RUFs and to the improvement of QOL after repair have not been reported. This is the first prospective study comparing the preoperative and postoperative SF-36 scores in RVF/RUF patients after gracilis muscle transposition. The data showed that the QOL improved significantly after successful repair of RUF/RVF.

**Innovations and breakthroughs**

In this study, the initial success rate was 73.7% and, after continuous irrigation-suction, the success rate increased to 94.7%. Repeated gracilis muscle transposition was not carried out in the study. In addition, QOL and fecal incontinence were first reported to significantly improve after successful healing of RVFs and RUFs.

**Applications**

Postoperative irrigation-suction should be considered as soon as leakage was

found.

### Terminology

QOL referred to the general well-being of individuals and societies, which is used in a wide range of contexts, including the fields of international development, healthcare, and politics. Within the field of healthcares, QOL is often regarded in terms of how it is negatively affected, on an individual level, a debilitating weakness that is not life-threatening, life-threatening illness that is not terminal, terminal illness, the predictable, natural decline in the health of an elder, an unforeseen mental/physical decline of a beloved one, chronic, end-stage disease processes, *etc.* RVFs referred to pathological sinus tracts between the rectum and vagina. RUFs referred to pathological sinus tracts between the rectum and urethra.

### Peer review

It is an innovative paper dealing with a relevant surgical intervention in fecal incontinence. Though this is a small series it does provide useful information to the readers.

were assessed after cancer cells were incubated with cisplatin, and were divided into terciles and compared in relation to clinical outcomes.

**RESULTS:** Among groups classified by expression time of ABCG2 mRNA, no significant differences in baseline clinical characteristics and pathological findings were detected. The median overall time was 14.2 (95%CI: 9.7-18.6), 11.4 (95%CI: 6.3-16.5) and 8.1 (95%CI: 5.4-10.8) in patients with low, intermediate and high increases in ABCG2 mRNA expression times ( $P < 0.05$ ), respectively. Median survival associated with performance status and tumor node metastasis (TNM) stage showed a similar trend, with longer survival and higher risk for mortality associated with lower performance status score and TNM stage. In a multivariate analysis for survival with Cox proportional-hazards model, increased ABCG2 mRNA expression time was an independent predictor for overall survival. Overall survival was longer with increased ABCG2 mRNA expression times  $\leq 0.71$  than increased ABCG2 mRNA expression times  $> 0.71$ , with a hazard ratio for death of 0.855 (95%CI: 0.615-0.962,  $P = 0.038$ ).

**CONCLUSION:** Increased ABCG2 mRNA expression time driven by cisplatin is associated with survival of gastric cancer patients, and this may help modify the therapeutic strategies.

## INTRODUCTION

Gastric cancer is the fourth most prevalent malignant cancer worldwide, and is the second most frequent cause of cancer death<sup>[1]</sup>. Despite advances made in gastric cancer therapy, the prognosis of patients with gastric cancer remains unsatisfactory. Because of early detection in screening programs in Japan, survival is prolonged (52%), whereas survival in the United States, Europe, and China is only 20%-25% due to delayed diagnosis<sup>[2]</sup>. The 5-year survival rate for advanced or metastatic gastric cancer is nearly 5%-20%, with a median overall survival being less than 1 year<sup>[3,4]</sup>. With the development of new anticancer drugs, such as taxanes, CPT-11, oxaliplatin, gefitinib and S-1, significant improvements in the efficacy of chemotherapy against gastric cancer have been achieved<sup>[5]</sup>. However, some patients still fail on first-line chemotherapy and will relapse and eventually develop resistance to currently available treatment options due to the acquisition of multidrug resistance (MDR)<sup>[6]</sup>. Therefore, it is necessary to find markers which could accurately predict the risk of gastric cancer, and give the evidence for early prediction of the clinical outcome so as to improve the clinical management of gastric cancer patients.

Breast cancer resistance protein (BCRP/ABCG2), the second member of the ATP-binding cassette-transporter superfamily, is prominently expressed in the epithelium of small intestine and colon, liver canalicular membranes, ducts and lobules of mammary tissue and blood-brain barrier, which plays a pivotal role in the bioavailability and brain disposition of drugs<sup>[7]</sup>. A broad spectrum of anticancer drugs, sulfate and glucuronide conjugates of sterols and xenobiotics, natural compounds and toxins, fluorescent dyes, photosensitizers, and antibiotics have been identified as substrates of ABCG2<sup>[8]</sup>. As a major drug transporter, ABCG2 has been shown to play an active role in MDR in various cancers<sup>[9-11]</sup>. Increased expression of ABCG2 results in resistance to anticancer drugs, including topoisomerase inhibitors, anthracyclines, camptothecin (CPT) analogs, tyrosine kinase inhibitors (TKI), and antimetabolites<sup>[8]</sup>. The resistant phenotype is conferred through the reduction of cytoplasmic chemotherapeutic drug concentrations to levels below those required for cytotoxicity<sup>[7]</sup>. Using an immunohistochemical method, ABCG2 expression was seen in all 150 tumor samples comprising 21 types of cancer, especially

in carcinomas of the digestive tract (colon, esophagus and stomach), endometrium and lung, and in melanoma, which suggested that ABCG2 represented a common mechanism of clinical drug resistance<sup>[12]</sup>. Results from clinical studies indicate that high expression of ABCG2 in tumors is a prognostic marker of poor clinical outcome<sup>[9,13,14]</sup>. However, there are a limited number of studies on the relevance of ABCG2 expression driven by chemotherapeutic agents and its clinical significance.

In light of the above information, this study was an attempt to clarify the impact of increases in ABCG2 mRNA expression times driven by cisplatin on clinical outcome in patients with gastric cancer.

## MATERIALS AND METHODS

### Patients and samples

Tumor specimens and normal control tissues were collected from 78 patients with newly-diagnosed histologically proven gastric cancer (GC) in Shanghai Sixth People's Hospital, Renji Hospital and Shanghai Putuo Hospital, from January 2008 to December 2011. All of the tumor specimens were obtained before chemotherapy. None of the patients received preoperative radiotherapy or chemotherapy. The clinical stage of GC was determined on the basis of the tumor-node-metastasis (TNM) classification system recommended by the International Union Against Cancer. Demographic and clinicopathological details of the patients were collected from electronic patient records. The study was approved by the Institutional Review Board of Shanghai Sixth People's Hospital, Renji Hospital and Shanghai Putuo Hospital. All samples were obtained after receiving patients' written informed consent.

All patients received platinum-based first-line chemotherapy and second-line chemotherapy for GC according to the NCCN guideline of GC<sup>[6]</sup>. The platinum-based first-line were cisplatin 60-100 mg/m<sup>2</sup> plus fluoropyrimidine (750-1000 mg/m<sup>2</sup> *iv* on days 1-5 as a protracted continuous infusion, FP; *n* = 18), docetaxel (75 mg/m<sup>2</sup> *iv* on day 1, DP; *n* = 12), paclitaxel (135 mg/m<sup>2</sup> *iv* on day 1, PP; *n* = 10), capecitabine (1000 mg/m<sup>2</sup> *bid po* on days 1-14, XP; *n* = 25) or S-1 (40 mg/m<sup>2</sup> *bid po* on days 1-21, SP; *n* = 13). Chemotherapy was repeated every 3 wk (XP, DP, PP and FP) or every 5 wk (SP) according to the regimen. All the patients received 2 or more courses of chemotherapy or until the appearance of progressive disease. In second-line chemotherapy, patients were administered the following regimens: oral S-1 or capecitabine (*n* = 30); weekly paclitaxel (*n* = 18); irinotecan and cisplatin (*n* = 13); irinotecan and docetaxel (*n* = 9) and mitomycin C, etoposide and cisplatin (*n* = 8).

### Cell culture with cisplatin

Fresh tumor tissues obtained from the surgically resected specimens were tested within 6 h. The tumor tissue was cut into pieces (smaller than 1 mm<sup>3</sup>) and passed through No. 100 and No. 200 stainless steel meshes respectively

into a complete medium containing RPMI 1640 solution, 100 µg/mL penicillin, and 100 µg/mL streptomycin, and washed twice gently with the same solution. The viable cells were assessed using a trypan blue exclusion method. The cell suspension was collected into sterile 96-well flat-bottomed microtiter plates ( $1 \times 10^5$  cells per well) with or without 0.5 µg/mL cisplatin (CDDP). The plates were then incubated at 37 °C in a humidified atmosphere containing 50 mL/L CO<sub>2</sub> for 72 h. Microtiter wells containing tumor cells but no anticancer agents were used as control cells, in which the total number of tumor cells was equivalent to that in the test wells.

### Quantitative polymerase chain reaction

Treated and untreated cancer cells were suspended at  $1 \times 10^6$  cells/mL in 5 mL PBS as samples. Total RNA was then isolated using TriPure Isolation reagent (Roche Diagnostics GmbH, Germany) or RNeasy Mini Kit (Qiagen, United States) according to the manufacturer's instructions. Quantitative polymerase chain reaction (PCR) were performed using specific hydrolysis probes targeting ABCG2 on Applied Biosystems 7300S Real Time PCR systems (ABI, United States). Total RNA was isolated from cisplatin-treated GC cells using TRIzol (Tarkara, Dalian, China) and reverse-transcription was performed to synthesize cDNA using PrimeScript Reverse Transcriptase (Tarkara, Dalian, China). Subsequent PCR amplification was performed using 2 µg of cDNA under the following conditions: 95 °C for 30 s, 35 cycles of 95 °C for 5 s, 60 °C for 30 s, and 72 °C for 30 s. SYBR<sup>®</sup> Premix Ex Taq<sup>™</sup> (Tarkara, Dalian, China) was used. β-actin was used as an internal control. PCR products were run on 2% agarose gels and analyzed under ultraviolet light after ethidium bromide staining. The primer sequences of ABCG2 used in real-time RT-PCR were: sense 5'-TTTCCAAGC-GTTCATTC AAAAA-3', antisense 5'-TACGACTGT-GACA ATGATCTGAGC-3'. β-actin: sense 5'-ACC-GTG GAGAAGAGCTACGA-3', antisense 5'-GTACTT GCGCTCAGAAGGAG-3'. Each RT-PCR amplification was repeated in triplicate. The β-actin primer was included in every plate to avoid sample variations. The PCR efficiency was examined by serially diluting the template cDNA and the melting curve data were collected to check the PCR specificity. Each cDNA sample was triplicated and the corresponding no-RT mRNA sample was included as a negative control. The β-actin primer was included in every plate to avoid sample variations. The mRNA level of each sample was normalized to that of the β-actin mRNA. Relative increases in mRNA expression times of target gene against β-actin were measured as follows:  $\text{mRNA}_{\text{target}} = (\text{mRNA}_{\text{target}} / \text{mRNA}_{\beta\text{-actin}})_{\text{cisplatin treated cells}} / (\text{mRNA}_{\text{target}} / \text{mRNA}_{\beta\text{-actin}})_{\text{control cells}}$ . All data shown were the mean ± SD of three separate experiments.

### Statistical analysis

To determine the correlation between mRNA increased expression times and survival rate after chemotherapy, the  $\chi^2$  test or Fisher's exact test was used to analyze the

data with R software statistical environment (version 2.15.1; R Development Core Team, Vienna, Austria). Cumulative overall survival probability was calculated by the Kaplan-Meier method for censored failure time data, and statistical significance was calculated using the log-rank test for comparison of survival rates between the different groups. The Cox proportional-hazards model was used to calculate the hazard ratios.  $P < 0.05$  was considered statistically significant. All  $P$  values were two-tailed and unadjusted for potential multiple comparisons.

## RESULTS

### Patient characteristics

The clinical and pathological characteristics of the patients are outlined in Table 1. The median age was 59 years (range, 27-81 years). All of the patients were treated with platinum-based combination chemotherapeutic regimens. The median number of chemotherapy courses was 4 (range, 2-15). The disease progression was the most common reason for the discontinuation of the chemotherapy. The median follow-up time of the 78 patients was 12 mo (range, 3-42 mo).

ABCG2 mRNA levels were measured by quantitative PCR and increased expression times in the cancer cells incubated with cisplatin were calculated by comparing with cancer cells incubated without cisplatin. Using the method reported by Font *et al.*<sup>[15]</sup>, results from these analyses were used to categorize the patients into terciles according to their ABCG2 mRNA expression times (lowest tercile,  $\leq 0.71$ ,  $n = 40$ ; intermediate tercile, 0.71-1.80,  $n = 23$ ; and highest tercile,  $\geq 1.80$ ,  $n = 15$ ). No differences in clinical characteristics were observed according to BRCA1 mRNA expression levels. Among groups determined according to ABCG2 mRNA expression times, no significant differences in baseline clinical characteristics and pathological findings were detected (Table 1).

### ABCG2 mRNA increased expression times and clinical outcome

The median overall survival time was 14.2 mo (95%CI: 9.7-18.6), 11.4 mo (95%CI: 6.3-16.5) and 8.1 mo (95%CI: 5.4-10.8) in the patients with low, intermediate and high ABCG2 mRNA expression times (Table 2), respectively. Because survival rates were similar in patients with intermediate and high expression times, the patients in these two groups were mixed for further statistical analyses. In patients with intermediate/high ABCG2 mRNA expression times, median overall survival (OS) time was 10 mo (95%CI: 5.8-14.2), whereas in patients with low expression levels, median survival was 14.2 mo (95%CI: 9.7-18.6) ( $P = 0.025$ ) (Figure 1A). There was no statistical difference in progression-free survival (PFS) between the two groups (Figure 1B).

Univariate analysis was conducted to examine the impact of increases in ABCG2 mRNA expression times and other clinical pathological parameters on prognosis. In the univariate analysis, three parameters were found

**Table 1** Characteristics of patients according to increased expression times of ABCG2 mRNA by tertiles *n* (%)

Clinical pathological parameters	Total cohort	ABCG2 mRNA expression times			<i>P</i> value
		≤ 0.71 ( <i>n</i> = 40)	0.71-1.8 ( <i>n</i> = 23)	≥ 1.8 ( <i>n</i> = 15)

to be significantly associated with overall survival and risk for mortality statistically: performance status; TNM stage; and ABCG2 mRNA expression times (Table 2). Median survival associated with performance status and TNM stage showed a similar trend, with longer survival and higher risk for mortality associated with lower performance status score and TNM stage. In the multivariate analysis using the Cox proportional hazards model, only increased ABCG2 mRNA expression times and TNM stage were independent predictors for overall survival. The HR of TNM stage III A *vs* III B-IV for overall survival was 0.921 (95%CI: 0.656-0.983, *P* = 0.045), and

the HR of ABCG2 mRNA increased expression times ≤ 0.71 *vs* > 0.71 was 0.855 (95%CI: 0.615-0.962, *P* = 0.038).

## DISCUSSION

Platinum-containing regimens have now been clinically validated as effective advanced GC treatments. However, the relatively rapid acquired chemotherapeutic resistance to such therapies significantly limits their effects and remains a substantial obstacle to the clinical management of GCs. With the elucidation of molecular mechanisms of resistance, new strategies of predicting the formation

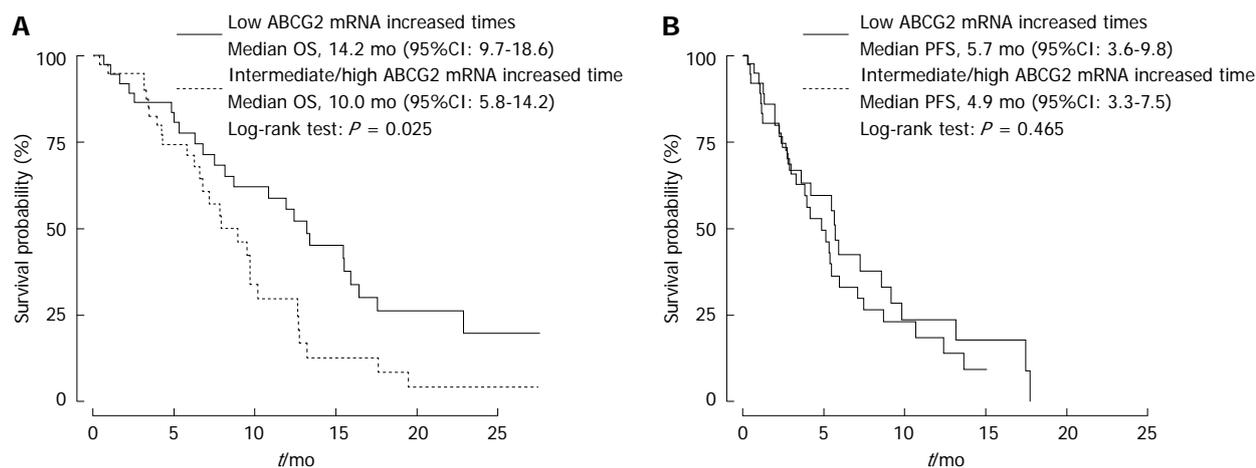

Figure 1 Overall survival (A) and progression-free survival (B) according to increased ABCG2 mRNA expression times (intermediate or high vs low tertiles). OS: Overall survival; PFS: Progression-free survival.

of resistance have become a potential area of interest. In the current study, we found that ABCG2 mRNA expression levels were increased by incubation in sub-therapeutic concentrations of cisplatin *in vitro*, which could lead to the MDR phenotype associated with ABCG2. Moreover, a significant relationship between increased ABCG2 mRNA expression times and overall survival was observed in GC patients treated with platinum-containing chemotherapy. Patients with higher ABCG2 mRNA expression times had a shorter median overall survival time. In a multivariate analysis, increased ABCG2 mRNA expression times driven by cisplatin *in vitro* might be an independent prognostic marker of overall survival, while no baseline clinical pathological parameters, except TNM stage, had a prognostic impact on overall survival. To the best of our knowledge, there has been no study examining the role of ABCG2 mRNA expression times induced by cisplatin *in vitro* in GC treatment.

ABCG2 has been found to be an important molecule involved in both innate and acquired MDR by regulating drug bioavailability. Over-expression of ABCG2 shows the potential to be an independent prognostic marker of both hematopoietic and solid malignancies. In hematopoietic malignancies, the results from several follow-up studies have validated the relationship between ABCG2 expression and the prognosis and survival of acute myeloid leukemia patients<sup>[16-18]</sup>. In esophageal squamous cell carcinoma, lung cancer, digestive tract tumors and lymphoma, the presence of ABCG2-positive cells in the tumor indicated by immunohistochemical study was associated with poorer survival<sup>[12,19-21]</sup>. These studies observed the relationship between the prognosis and the presence of chemotherapeutic resistance in tumors. However, they did not take the potential of acquisition of MDR into account. In fact, sub-therapeutic concentrations of anti-cancer agents, including cisplatin, would result in MDR in neoplastic cells<sup>[22]</sup>. The current study might provide a helpful method to assess the potential of acquisition of MDR driven by chemotherapeutic agents.

The expression of ABCG2 in normal and cancer cells appears to be regulated at different levels including gene amplification, epigenetic modifications, transcriptional and post-transcriptional regulation<sup>[8,23]</sup>. Nuclear hormone receptor proteins, including the pregnane X receptor (PXR), constitutive androstane receptor, and farnesoid X receptor have shown the ability to regulate the expression of ABC transporters<sup>[24]</sup>. In peripheral blood mononuclear cells and small intestine, PXR-selective ligands have been shown to increase the expression of various transporters like solute carrier family 21A6 (SLC21A6), ABCC2 and ABCB and significant relationships between expression of PXR and ABCB1, ABCC2 and ABCG2 have been reported<sup>[25-27]</sup>. One recent study found that IL-1 $\beta$  and TNF- $\alpha$  induced ABCG2 and PXR expression and NF- $\kappa$ B activity in some breast cancer and normal cell lines, which indicated a probable relationship between ABCG2, PXR and NF- $\kappa$ B<sup>[25]</sup>. Pradhan *et al*<sup>[28]</sup> showed that the cooperative binding of ER and p65 at adjacent response elements led to a major increase in both ABCG2 mRNA and protein expressions. Wu *et al*<sup>[29]</sup> reported that prolactin could up-regulate ABCG2 in T-47D human breast cancer epithelial cells *via* activation of JAK2/STAT5, MAPK, and PI3K signaling. However, the precise mechanism of regulating the expression of ABCG2 caused by DNA damage remains unclear.

In conclusion, ABCG2 mRNA increased expression times driven by cisplatin *in vitro* is associated with clinical outcome, which may be a novel biological marker for optimizing the treatment of GC. However, our data should be interpreted cautiously because of the limited number of patients enrolled. This is the first report to indicate a relationship between the potential for acquisition of MDR and prognosis of patients with GC. Further prospective randomized controlled trials with a larger number of patients would be worth doing to confirm these results, and the mechanism of DNA damage caused by cisplatin also should be elucidated.

## COMMENTS

**Background**

Gastric cancer (GC) ranks the fourth in morbidity among malignant tumors worldwide. Despite the advances made in diagnosis and treatment, the prognosis of GC patients remains poor. This is most probably attributed to the delayed diagnosis and resistance to currently available agents. Therefore, determining the markers which could predict the evidence for early clinical outcome and modify the therapeutic regimens is important.

**Research frontiers**

ABCG2 has been shown to represent a common mechanism of multidrug resistance in various cancers. Increasingly, it has become a hot research topic to identify the relevance of ABCG2 expression driven by chemotherapeutic agents and its clinical significance.

**Innovations and breakthroughs**

To date, there have been a limited number of studies regarding the potential for acquisition of MDR. In this study, the authors employed a method to assess the potential for acquisition of MDR driven by chemotherapeutic agents. Furthermore, the authors confirmed the significant correlation between the over-expression of ABCG2 and decreased overall survival rate.

**Applications**

By identifying the high expression of ABCG2 driven by cisplatin *in vitro* as being associated with overall survival, the authors evaluated the biological features and prognosis in GC, which could improve their understanding of GC, and provide a novel biological marker for optimizing the treatment of GC.

**Terminology**

ATP-binding cassette sub-family G member 2 is a protein that in humans is encoded by the ABCG2 gene. This protein transports various molecules across extra- and intra-cellular membranes, which may also play a role in multi-drug resistance to chemotherapeutic agents.

**Peer review**

The authors determined the expression of ABCG2 driven by cisplatin *in vitro*, and identified the high expression of this protein was associated with the prognosis of patients with GC. The result is interesting and indicates that the over-expression of ABCG2 could be used as a biomarker for prognosis in GC.

### Abstract

**AIM:** To investigate expression of stem cell marker Musashi-1 (Msi-1) in relationship to tumorigenesis and progression of intestinal-type gastric cancer (GC).

**METHODS:** Endoscopic biopsy specimens and surgical specimens were obtained, including 54 cases of intestinal-type GC, 41 high-grade intraepithelial neoplasia, 57 low-grade intraepithelial neoplasia, 31 intestinal metaplasia, and 36 normal gastric mucosa. Specimens were fixed in 10% paraformaldehyde, conventionally dehydrated, embedded in paraffin, and sliced in 4- $\mu$ m-thick

serial sections. Two-step immunohistochemical staining was used to detect Msi-1 and proliferating cell nuclear antigen (PCNA) expression. Correlation analysis was conducted between Msi-1 and PCNA expression. The relationship between Msi-1 expression and clinicopathological parameters of GC was analyzed statistically.

**RESULTS:** There were significant differences in Msi-1 and PCNA expression in different pathological tissues ( $\chi^2 = 15.37, P < 0.01$ ;  $\chi^2 = 115.36, P < 0.01$ ). Msi-1 and PCNA-positive cells were restricted to the isthmus of normal gastric glands. Expression levels of Msi-1 and PCNA in intestinal metaplasia were significantly higher than in normal mucosa ( $U = 392.0, P < 0.05$ ;  $U = 40.50, P < 0.01$ ), whereas there was no significant difference compared to low or high-grade intraepithelial neoplasia. Msi-1 and PCNA expression in intestinal-type GC was higher than in high-grade intraepithelial neoplasia ( $U = 798.0, P < 0.05$ ;  $U = 688.0, P < 0.01$ ). There was a significantly positive correlation between Msi-1 and PCNA expression ( $r_s = 0.20, P < 0.01$ ). Msi-1 expression in GC tissues was correlated with their lymph node metastasis and tumor node metastasis stage ( $\chi^2 = 12.62, P < 0.01$ ;  $\chi^2 = 11.24, P < 0.05$ ), but not with depth of invasion and the presence of distant metastasis.

**CONCLUSION:** Msi-1-positive cells may play a key role in the early events of gastric carcinogenesis and may be involved in invasion and metastasis of GC.

**Key words:** Musashi-1; Stem cells; Gastric cancer; Precancerous lesions; Immunohistochemistry.

**Core tip:** Gastric cancer (GC) is currently thought to be a disease originating in stem cells. We detected expression of stem cell marker Musashi-1 (Msi-1) and proliferating cell nuclear antigen (PCNA) in intestinal-type GC and precancerous lesions. Expression of Msi-1 and

PCNA in precancerous lesions was significantly higher than in normal mucosa, but lower than in intestinal-type GC. Msi-1 expression in GC tissues was correlated with lymph node metastasis and tumor node metastasis stage. These results suggest that expansion of Msi-1-positive cells is an early event in gastric carcinogenesis and may be involved in invasion and metastasis of GC.

Expression and significance of Musashi-1 in gastric cancer and precancerous lesions. *World J Gastroenterol* 2013; 19(39): 6637-6644 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i39/6637.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6637>

## INTRODUCTION

Gastric cancer (GC) is the fourth most common cancer and the second leading cause of cancer-related death worldwide. Intestinal-type GC is believed to arise from an intestinal metaplasia to intraepithelial neoplasia sequence in gastric epithelial cells. The cancer stem cell theory indicates that cancers contain tumor-initiating stem cells possess the capacity for self-renewal and can cause the heterogeneous lineages of cancer cells constituting the tumor<sup>[1]</sup>. There is consensus that all gastric mucosal cells originate from stem cells<sup>[2]</sup>. The classical multistep model of gastric carcinogenesis requires a cell to receive multiple "hits" before it is transformed. Stem cells are long-lived; therefore, they are more likely to acquire these multiple hits and become transformed<sup>[3]</sup>. It was proposed that tumor-initiating cancer stem cells may be derived from normal stem cells; however, the lack of useful markers has made it difficult to characterize the stem cells in the human stomach and has hindered the study of the origin of GC.

Musashi-1 (Msi-1), an RNA-binding protein isolated as a mammalian homolog of a *Drosophila* protein, is selectively expressed in murine and human neural progenitor cells, including neural stem cells, can be used as a neural stem/progenitor cell marker, and plays an important role in the asymmetric division of neural stem cells<sup>[4]</sup>. In recent years, Msi-1 was also found to be expressed in tissues outside the nervous system. It has been confirmed that Msi-1 is preferentially expressed in the predicted stem cell regions of mouse and human intestinal crypts, suggesting that it can serve as a potential marker for intestinal stem/progenitor cells<sup>[5,6]</sup>. Msi-1 has also been observed in the stomach of chickens<sup>[7]</sup>, mice<sup>[7]</sup>, rats<sup>[8]</sup> and humans<sup>[9]</sup>. Akasaka *et al*<sup>[9]</sup> reported that Msi-1 is mostly expressed in the antrum and Murata *et al*<sup>[10]</sup> found that it is expressed in both the antrum and corpus of the human stomach. For the past several years, the functional role of Msi-1 in tumors has attracted increasing interest. Msi-1 overexpression has been reported in tumor tissues

and cell lines, such as medulloblastoma<sup>[4]</sup>, astrocytoma<sup>[11]</sup>, retinoblastoma<sup>[12]</sup> and endometrial carcinoma<sup>[13]</sup>.

Recently, Wang *et al*<sup>[14]</sup> selected 10 cases of intestinal-type GC taken from the transitional area between malignancy and adjacent normal mucosa for full section analysis. They found that Msi-1 was frequently expressed in both premalignant gastric lesions and invasive GC; however, the number of patients with premalignant gastric lesions in this study was low. Proliferating cell nuclear antigen (PCNA) is the auxiliary protein of DNA polymerase  $\delta$  and can be used as a good indicator of GC cell proliferation and prognosis<sup>[15]</sup>. In the present study, to explore proliferation activity diversity of Msi-1-positive cells in the development of GC, we investigated the expression of Msi-1 and PCNA in intestinal-type GC and precancerous lesions, including 41 high-grade intraepithelial neoplasia, 57 low-grade intraepithelial neoplasia, and 31 intestinal metaplasia. The correlation between Msi-1 expression and various clinicopathological parameters was also studied. Additionally, we aimed to determine whether Msi-1 is a candidate marker of intestinal-type GC stem cells because this would be an important aspect of the function of Msi-1 in gastric carcinogenesis.

## MATERIALS AND METHODS

### *Clinical and pathological features*

Endoscopic biopsy antral specimens were obtained from September 2008 to January 2011 at Qianfoshan Hospital Affiliated to Shandong University, including: 36 cases of normal gastric mucosa (21 males and 15 females; aged 39-60 years, mean  $57 \pm 7.2$  years); 31 cases of intestinal metaplasia (17 males and 14 females; aged 43-70 years, mean  $54 \pm 8.4$  years); 57 cases of low-grade intraepithelial neoplasia (33 males and 24 females; aged 45-79 years, mean  $58 \pm 8.2$  years); and 41 cases of high-grade intraepithelial neoplasia (23 males and 18 females; aged 46-80 years, mean  $57 \pm 9.6$  years). The other 54 cases were intestinal-type GC, including 29 males and 25 females, aged 40-72 years, mean age  $57 \pm 9.5$  years. All the pathological specimens were diagnosed and reviewed by three veteran pathologists.

According to tumor node metastasis (TNM) stage of the Union for International Cancer Control in 1997, GC is divided into I a, I b, II, III a, III b and IV stage. Twenty-seven cases of I a and I b stage were considered as the early clinical GC (I stage), including 17 male and 10 female patients, with a mean age of  $56 \pm 9.4$  years. Twenty-seven cases of II-IV stage GC merged in the late stage GC (II-IV stage), including 12 male and 15 female patients, with a mean age of  $57 \pm 9.8$  years. On the basis of the depth of cancer invasion, 20 cases were limited to mucosa and submucosa ( $\leq T1$ ) and 34 cases broke through the submucosa (T2-4). In GC metastasis, there were 27 patients with lymph node metastasis and 27 without, or 14 patients with distant metastasis and 40 without. No significant difference in age and sex existed among all the groups of patients.

### Immunohistochemistry

Specimens were fixed in 10% paraformaldehyde, conventionally dehydrated, embedded in paraffin, and sliced into 4- $\mu$ m-thick serial sections. The microwave ethylene diamine tetraacetic acid (EDTA) (pH 9.0) antigen retrieval method was used to retrieve the antigen. A two-step immunohistochemical method was used to observe the antigen expression. Rabbit polyclonal anti-human Msi-1 antibody (ab52685; 1:300 dilution) and mouse anti-human PCNA monoclonal antibody (ab29; 1:1000 dilution) were purchased from Abcam Company (Cambridge, MA, United States).

### Assessment of cell staining

Cells were considered positive for Msi-1 when the cytoplasm contained evenly stained yellow or brown granules. PCNA positivity was adjudged by the appearance of brown or yellow granules in the nucleus. Tissue sections were observed microscopically at  $\times 400$  magnification. Five representative regions were selected with 200 cells each. Msi-1 staining intensity was defined as follows: no staining or  $< 10\%$  of cells stained, negative (-); 10%-30% stained cells, weakly positive (+); 31%-50% stained cells, positive (++); and  $> 50\%$  stained cells, strongly positive (+++). PCNA staining intensity was defined as follows: no staining or  $< 25\%$  of cells stained, negative (-); 25%-50% stained cells, weakly positive (+); 51%-75% stained cells, positive (++); and  $> 75\%$  stained cells, strongly positive (+++).

### Statistical analysis

All statistical analyses were performed using SPSS version 13.0. Measurement data were analyzed using Student's *t* test and categorical data were studied using the  $\chi^2$  test, Fisher's exact test or nonparametric rank sum test. The Spearman correlation test was used to determine the correlation between expression of Msi-1 and PCNA. Correlations between Msi-1 expression and clinicopathological parameters were also statistically analyzed. Statistical significance was taken as  $P < 0.05$ .

## RESULTS

### Expression of Msi-1 and PCNA in different pathological tissues

There were significant differences in Msi-1 and PCNA expression in different pathological tissues ( $\chi^2 = 15.37$ ,  $P < 0.01$ ;  $\chi^2 = 115.36$ ,  $P < 0.01$ ). Msi-1 and PCNA-positive cells were restricted to the isthmus of gastric glands in normal gastric mucosa (Figures 1A and 2A). The expression levels of Msi-1 and PCNA in intestinal metaplasia were higher than in normal mucosa ( $U = 392.0$ ,  $P < 0.05$ ;  $U = 40.50$ ,  $P < 0.01$ ) and the distribution of Msi-1 and PCNA-positive cells was more diffuse (Figures 1B and 2B). Expression of Msi-1 and PCNA showed no significant difference among intestinal metaplasia, low and high-grade intraepithelial neoplasia (Figures 1C, 1D, 2C and 2D) ( $\chi^2 = 2.72$ ,  $P > 0.05$ ;  $\chi^2 = 1.64$ ,  $P > 0.05$ ). Msi-1

expression in intestinal-type GC was higher than in high-grade intraepithelial neoplasia (Figure 1E) ( $U = 798.0$ ,  $P < 0.05$ ) and PCNA expression in GC was also higher than in high-grade intraepithelial neoplasia (Figure 2E) ( $U = 688.0$ ,  $P < 0.01$ ) (Table 1).

### Relationship between Msi-1 expression and GC invasion and metastasis

No significant difference existed in Msi-1 expression between tumor invasion depth  $\leq T1$  and T2-4 ( $\chi^2 = 7.37$ ,  $P > 0.05$ ). Msi-1 expression was higher in GC with than without lymph node metastasis ( $\chi^2 = 12.62$ ,  $P < 0.01$ ). There was no significant difference between Msi-1 expression in GC with and without distant metastasis ( $\chi^2 = 7.06$ ,  $P > 0.05$ ). Msi-1 expression was higher in GC II - IV stage group than in stage I group ( $\chi^2 = 11.24$ ,  $P < 0.05$ ) (Figure 3, Table 2).

### Correlation between expression of Msi-1 and PCNA

Spearman's bivariate correlation analysis was made between Msi-1 and PCNA expression in different pathological tissues. Msi-1 and PCNA expression showed a significant positive correlation ( $r = 0.20$ ,  $P < 0.01$ ) (Table 3).

## DISCUSSION

The epithelial stem cells of the adult stomach are thought to be present in the proliferative region of the isthmus of the gastric glands. They constantly regenerate and migrate bidirectionally, up to the mucosal surface and down to the gland base, as they differentiate into mature cells of the gastric unit<sup>[16]</sup>. In the present study, immunohistochemistry demonstrated the presence of small numbers of PCNA-positive cells concentrated in the isthmus region of normal gastric glands, suggesting that this region is the proliferative zone of the gastric glands. We found that Msi-1 expression was also limited to the isthmus region of the gastric glands where adult putative stem cells are located. The positive correlation between the distribution of Msi-1-positive cells and that of the proliferative regions in the gastric glands suggests that Msi-1-positive cells have stem cell characteristics in the human stomach. Akasaka *et al.*<sup>[9]</sup> have reported a similar expression pattern of Msi-1 in the human antrum, suggesting that Msi-1 can be useful for identifying stem cells in the human stomach.

Our observations indicate that Msi-1 expression can correlate positively with proliferative activity in the stomach, but the correlation coefficient is low. All the cells in the gastrointestinal epithelium are renewed within a short time; thus, it is possible that precursor cells, not stem cells, in the proliferative zone produce a large number of mature cells within a short time. Indeed, it has been proposed that the proliferative zone has a pyramid-like structure, consisting of various cell layers with stem cells on top, and that the number of stem cells produced is small<sup>[17]</sup>. In our study, PCNA expression showed proliferative activity in all the cells in the gastric tissue. We be-

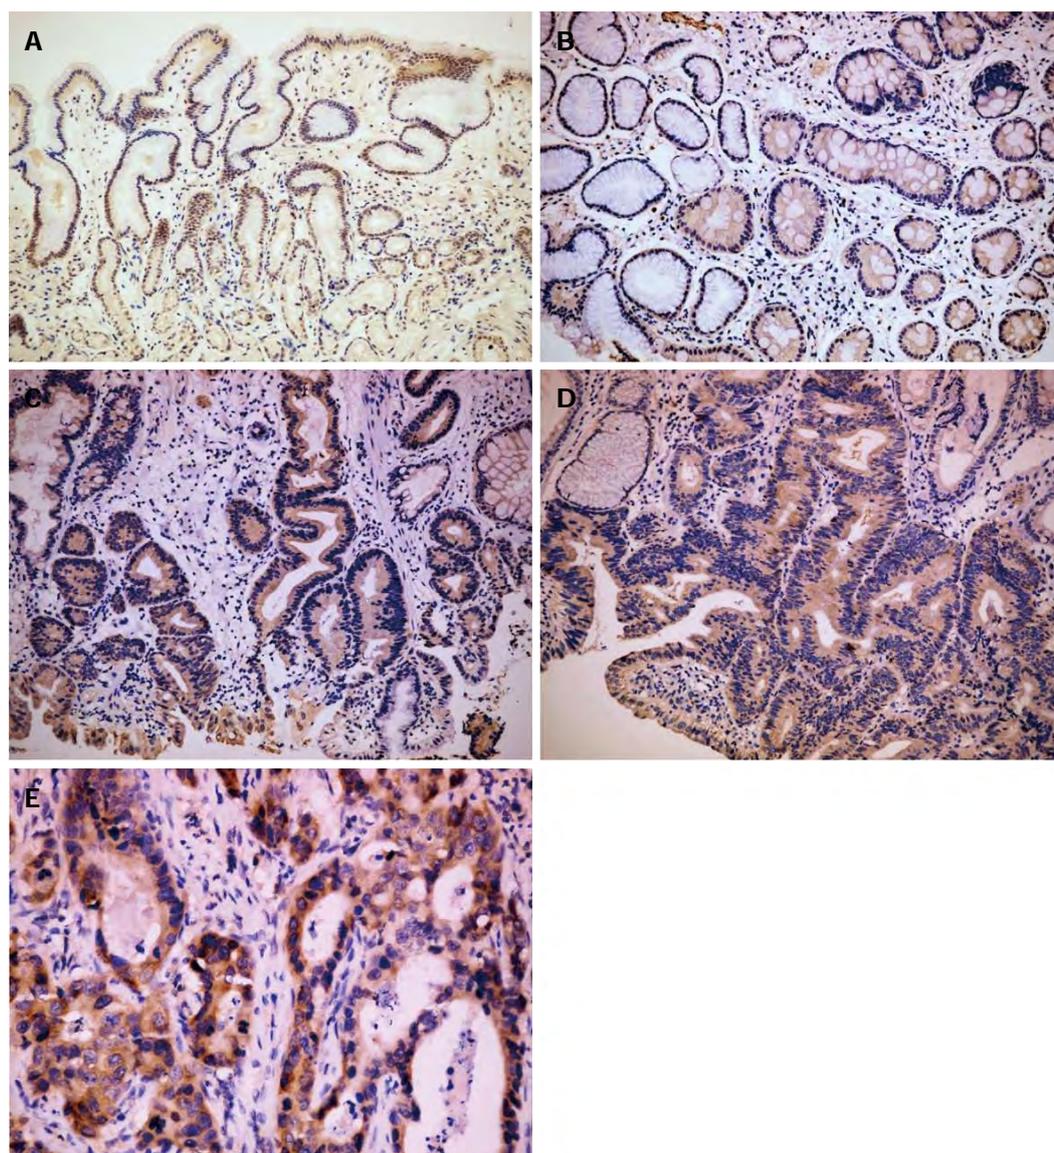

Figure 1 Immunohistochemical staining for Musashi-1 in different gastric tissues. A: A weak expression of Musashi-1 (Msi-1) was observed in the isthmus of normal gastric glands ( $\times 100$ ); B: The expression of Msi-1 was significantly increased in intestinal metaplastic mucosa ( $\times 100$ ); C: Msi-1 expression showed no significant difference between in low grade intraepithelial neoplasia ( $\times 100$ ); D: high grade intraepithelial neoplasia ( $\times 100$ ); E: The expression of Msi-1 was increased again in the intestinal type gastric cancer ( $\times 400$ ).

Table 1 Expression intensity of Musashi-1 and proliferating cell nuclear antigen in different pathological tissues

Pathological tissues	Msi-1 protein staining intensity (n)				PCNA protein staining intensity (n)			
	-	+	++	+++	-	+	++	+++
Normal gastric mucosa	17	19	0	0	27	9	0	0
Intestinal metaplasia <sup>a,b</sup>	7	21	3	0	0	9	10	12
Low grade intraepithelial neoplasia	21	32	4	0	0	9	29	19
High grade intraepithelial neoplasia	19	17	4	1	0	6	16	19
Intestinal-type GC <sup>c,d</sup>	12	29	9	4	0	0	10	44

<sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$ , significantly different *vs* normal gastric mucosa; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$ , significantly different *vs* high-grade intraepithelial neoplasia. PCNA: Proliferating cell nuclear antigen; Msi-1: Musashi-1; GC: Gastric cancer.

lieve that the expression of Msi-1 in the human stomach is associated with cell proliferation; however, because the number of stem cells is small, the correlation is not close.

Intestinal metaplasia is the precancerous lesion of

intestinal-type GC<sup>[18]</sup>. Akasaka *et al*<sup>[9]</sup> reported that Msi-1 expression was markedly decreased in intestinal metaplasia cells of the human stomach. They believe that intestinal metaplasia is a consequence of abnormal differentia-

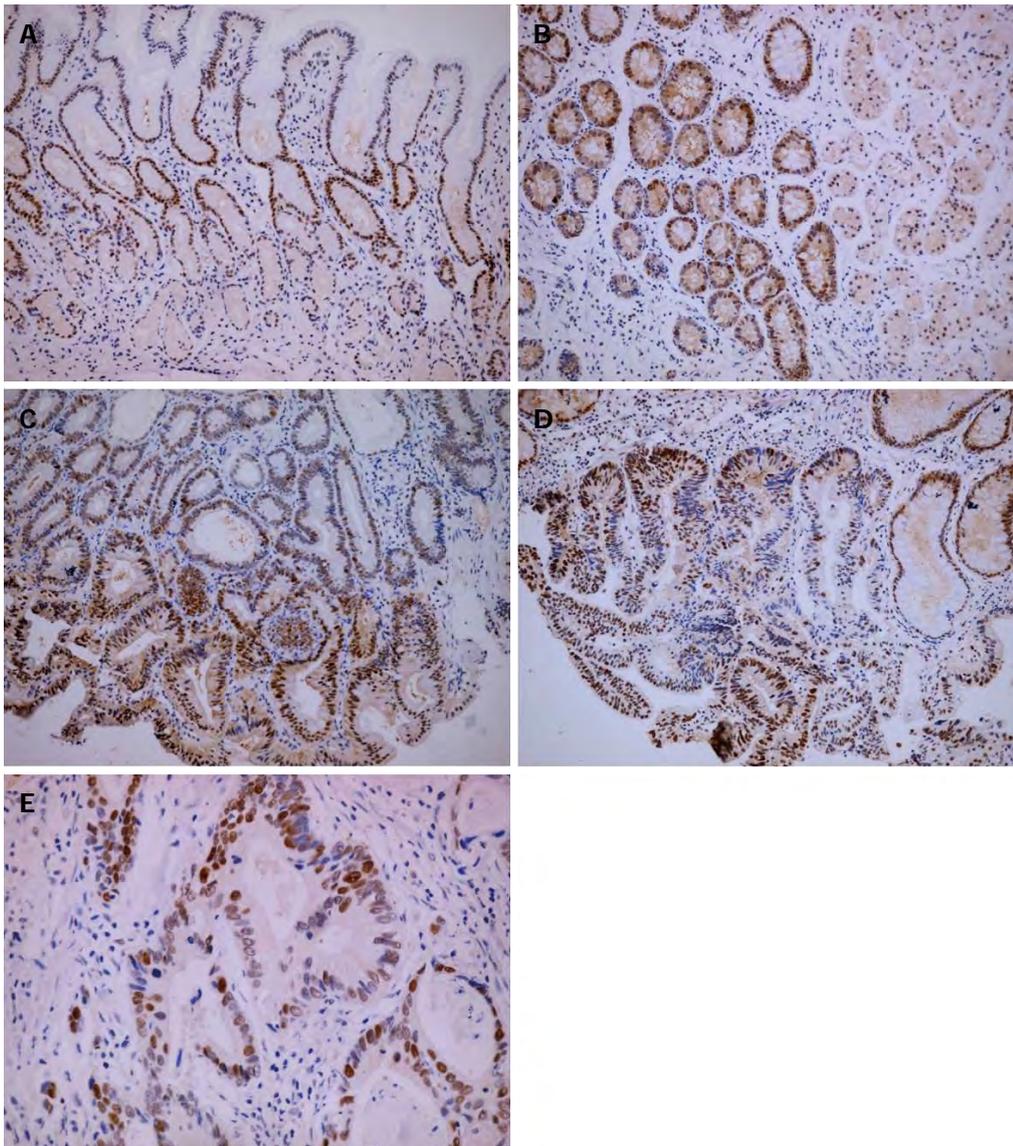

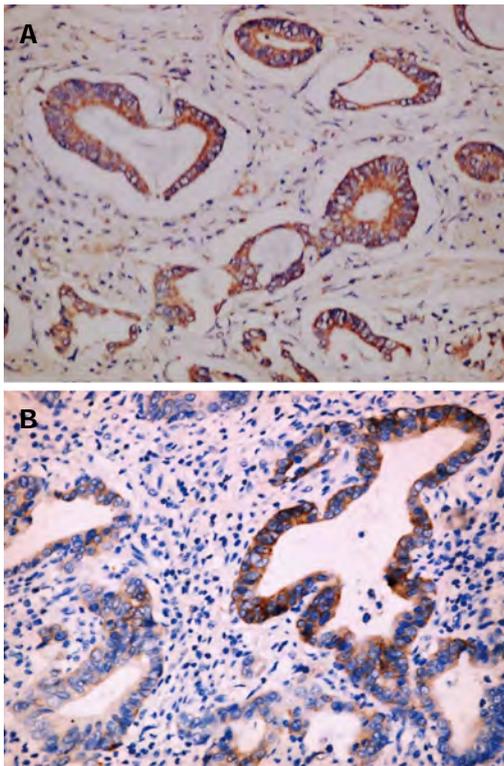

Figure 2 Immunohistochemical staining for proliferating cell nuclear antigen was increased along with the development of gastric carcinogenesis. A: The staining of proliferating cell nuclear antigen (PCNA) in the isthmus of normal gastric glands ( $\times 100$ ); B: Intestinal metaplastic mucosa ( $\times 100$ ); C: Low grade intraepithelial neoplasia ( $\times 100$ ); D: High grade intraepithelial neoplasia ( $\times 100$ ); E: Strong staining of PCNA in intestinal type gastric cancer ( $\times 400$ ).

**Table 2 Relationship between Musashi-1 expression and clinicopathological parameters**

Variable	Group	No.	Msi-1 staining intensity			
			-	+	++	+++
Infiltration depth	$\leq T1$	20	8	9	3	0
	T2-4	34	4	20	6	4
Lymph node metastasis <sup>a</sup>	NO	27	11	9	5	2
	YES	27	1	20	4	2
Distant metastasis	NO	40	12	21	5	2
	YES	14	0	8	4	2
TNM staging <sup>b</sup>	Stage I	27	11	10	4	2
	Stage II-IV	27	1	19	5	2

There was a significant difference between Musashi-1 (Msi-1) expression and clinicopathological parameters in Gastric cancer. <sup>a</sup> $P < 0.01$  and <sup>b</sup> $P < 0.05$ . TNM: Tumor node metastasis.

tion of stem cells, in which tissue-specific stem cells in the stomach may not differentiate into any of the normal intestinal epithelial phenotypes. In our study, however, more Msi-1-positive cells were observed in the intestinal metaplasia than in the normal gastric mucosa and the distribution was also more diffuse. It is known that Msi-1 is not a tissue-specific marker of epithelial stem cells. We believe that Msi-1 can be expressed in epithelial stem cells in both gastric mucosa and intestinal metaplasia, but proliferation of stem cells is different, which may be due to the mode of fission. In normally growing gastric tissues, stem cells undergo a slow but constant self-renewal by asymmetric division and give rise to all the various gastric epithelial cell types by differentiation<sup>[19]</sup>. These properties are essential to their normal role in gastric tissues because

**Figure 3** Musashi-1 expresses higher in intestinal type gastric cancer classified as stage II-IV. A: Type gastric cancer classified as stage II-IV; B: Those classified as stage I ( $\times 400$ ).

stem cells maintain tissue homeostasis by regulating cell turnover, depending on the demand at any given time. Surprisingly, experimental and mathematical modeling studies have indicated that intestinal crypt stem cells divide symmetrically and stochastically, and not with the asymmetry observed in stem cell division in some other tissues<sup>[20,21]</sup>. Similarly, symmetric division among intestinal metaplasia stem cells probably leads to accelerated division of stem cells, adapting to high proliferative activity. Murata *et al*<sup>[10]</sup> demonstrated that Msi-1 was expressed in gastric glands with intestinal metaplasia where proliferative activity was relatively high. Similar results were also obtained in the study of Wang *et al*<sup>[14]</sup>. Therefore, by influencing dividing cells, Msi-1 might regulate metaplastic changes.

We found that there was no significant difference between intestinal metaplasia and low and high-grade intraepithelial neoplasia for the expression of PCNA and Msi-1, suggesting that there was similar proliferation of epithelial stem cells in the gastric precancerous lesions. An *in vitro* study in primary cultures of intestinal epithelium showed that Msi-1 overexpression promotes the proliferation of stem cells and activates Wnt and Notch pathways. Moreover, Msi-1-overexpressing cells exhibited tumorigenic properties in xenograft experiments<sup>[22]</sup>. Using mitochondrial DNA mutations as a marker of clonal expansion, McDonald *et al*<sup>[23]</sup> investigated how mutations expand in gastric mucosa showing signs of intestinal metaplasia. They have shown that intestinal metaplastic crypts are

**Table 3** Relationship between Musashi-1 and proliferating cell nuclear antigen expression

Msi-1 protein staining intensity	PCNA protein staining intensity				Total
	Negative	Weak positive	Positive	Strong positive	
Negative	10	23	17	26	76
Weak positive	17	7	40	54	118
Positive	0	2	7	11	20
Strong positive	0	1	1	3	5
Total	27	33	65	94	219

PCNA: Proliferating cell nuclear antigen; Msi-1: Musashi-1.

clonal, possess multiple stem cells, and that fission is a mechanism by which intestinal metaplasia spreads. The expansion and spread of mutated gastric stem cells is one mechanism of carcinogenesis in the human stomach. Our findings suggest that expansion of Msi-1-positive cells in the intestinal metaplasia mucosa may be an early event in initiating the intestinal metaplasia - intraepithelial neoplasia - adenocarcinoma cascade. Stem cell amplification caused by deregulation of this self-renewal process may play a key role in the early events of gastric carcinogenesis.

We found that there were significantly more PCNA-positive and Msi-1 positive cells in intestinal-type GC than in gastric precancerous lesions, suggesting that Msi-1 could be used as a potential marker for intestinal-type GC stem cells, and that cancer stem cells have stronger proliferation compared to stem cells in precancerous lesions. Cancer stem cells are able to sustain and propagate tumors and give rise to invasive lesions and metastases<sup>[24]</sup>. In agreement with our data, Msi-1-positive cells may be involved in tumor invasion and metastasis because Msi-1 expression correlated with lymph node metastasis and TNM stage of GC. Msi-1 plays a fundamental role in maintaining stem cells in an undifferentiated state and it has been implicated in proliferative pathology in various tissues where Msi-1 may be acting to promote self-renewal of tumor cells with stem cell-like properties<sup>[25-27]</sup>. Small cell pulmonary carcinoma is usually an aggressive neoplasm with high metastatic potential and recurrence. Moreira *et al*<sup>[28]</sup> reported that small cell carcinomas demonstrate diffuse expression of Msi-1, whereas focal or isolated positivity is seen in most other types of pulmonary carcinoma. In human colorectal cancer, Msi-1 protein expression is significantly higher in tissue samples classified as stage III than stage I or II<sup>[29]</sup>. It was demonstrated that siRNA-mediated knockdown of Msi-1 in the HCT116 colon adenocarcinoma xenografts resulted in the arrest of tumor growth<sup>[30]</sup>. Knockdown of Msi-1 expression by siRNA induced apoptosis and a severe decline in cell numbers in 5637 bladder carcinoma cells<sup>[31]</sup>. These results suggest that Msi-1 plays an important role in tumorigenesis and tumor progression. We speculate that Msi-1 overexpression contributes to maintain cancer stem cells in an undifferentiated state, increasing their capacity for self-renewal or proliferation, thus promoting GC invasion and metastasis.

Shen *et al.*<sup>[32]</sup> proposed that cancer may arise from a long development process of tumor-initiating cells - precancerous stem cells - cancer stem cells - cancer, which is in parallel to histological changes of hyperplasia - precancer - carcinoma, accompanied by clonal evolutionary epigenetic and genetic alterations. In the present study, we demonstrated that expansion of Msi-1-positive cells appeared to be an early event in the process of gastric carcinogenesis and proliferation of Msi-1-positive cells was different in GC and precancerous lesions. The precancerous stem cells, representing the early stage of developing cancer stem cells, have the potential for both benign and malignant differentiation, depending on environmental cues<sup>[33]</sup>. Therefore, a broad therapeutic approach to GC may be achievable through rational targeting of precancerous stem cells. More work is needed to investigate the differentiation of Msi-1-positive cells between GC and precancerous lesions. However, Msi-1 may eventually represent a biomarker that can be used for early diagnosis of GC or to monitor cancer progression and response to therapy.

## COMMENTS

### Background

Gastric cancer (GC) remains one of the leading causes of global cancer mortality. The gastric epithelium is continuously regenerated by gastric stem cells, which give rise to various kinds of epithelial cells. GC is currently thought to be a disease originating in stem cells and it is hypothesized that cancer stem cells drive cancer growth and metastasis. However, the lack of useful markers has made it difficult to characterize the stem cells in the human gastric mucosa and has hindered study of the origin of GC. The RNA binding protein Musashi-1 (Msi-1) is a putative stem cell marker. However, the role of Msi-1 in GC and precancerous lesions is not fully understood.

### Research frontiers

Msi-1, a neural RNA-binding protein, was initially identified as a neuronal stem cell marker. In recent years, Msi-1 has been found in tissues outside the nervous system and identified as a putative intestinal and gastric stem cell marker. For the past several years, overexpression of Msi-1 has been reported in many tumor tissues and cell lines. High levels of Msi-1 expression in glioma and astrocytoma indicate a poor prognosis. Knockdown of Msi-1 in the HCT116 colon adenocarcinoma xenografts resulted in the arrest of tumor growth. These results suggest that Msi-1 plays an important role in tumorigenesis and tumor progression.

### Innovations and breakthroughs

Msi-1 has been proposed as a putative stem cell marker in the mouse intestine and human stomach but little is known about the role of such markers in the overall pathway of gastric carcinogenesis. Moreover, the results of previous studies in intestinal metaplasia are different. In this study, the authors explored proliferation diversity of Msi-1-positive cells in the development of GC and found that the expression levels of Msi-1 and proliferating cell nuclear antigen (PCNA) in intestinal metaplasia were significantly higher than in normal mucosa, while there were no significant differences compared with intraepithelial neoplasia. Msi-1 and PCNA expression in intestinal-type GC was higher than in intraepithelial neoplasia. Msi-1 expression in GC tissues correlated with their lymph node metastasis and TNM stage. There was a significantly positive relationship between Msi-1 and PCNA expression. These results suggest that Msi-1-positive cells may play a key role in the early events of gastric carcinogenesis, and may be involved in invasion and metastasis of GC.

### Applications

The study results contribute to a better understanding of the associations between putative stem cell marker expression and tumorigenesis and progression of GC. The knowledge gained by studying cancer stem cells in gastric mucosa will support the development of novel therapeutic strategies for GC. Msi-1 may

eventually represent a biomarker that can be used for early diagnosis of GC or to monitor cancer progression and response to therapy.

### Terminology

Cancer stem cells are defined as the unique subpopulation in tumors that possess the ability to initiate tumor growth and sustain self-renewal, as well as metastatic potential. Musashi is an evolutionarily conserved family of RNA-binding proteins that is preferentially expressed in the nervous system. The first member of the Musashi family was identified in *Drosophila*. Its mammalian homolog, Msi-1, is a neural RNA-binding protein that is selectively expressed in murine and human neural stem cells, can be used as a neural stem cell marker, and plays important roles in the maintenance of stem cell states, as well as in the regulation of differentiation of stem cells.

### Peer review

The study was well designed and performed. The authors detected stem cell marker Msi-1 and PCNA expression in the multistep process of gastric carcinogenesis. The results are interesting and suggest that the expansion of Msi-1-positive cells is an early event in the process of gastric carcinogenesis and may be involved in invasion and metastasis of GC.

### Abstract

**AIM:** To evaluate the influence of oral *Helicobacter pylori* (*H. pylori*) on the success of eradication therapy against gastric *H. pylori*.

**METHODS:** A total of 391 patients with dyspepsia were examined for *H. pylori* using the saliva *H. pylori* antigen test (HPS), <sup>13</sup>C-urea breath test (UBT), gastroscopy, and gastric mucosal histopathological detection. Another 40 volunteers without discomfort were subjected to HPS and <sup>13</sup>C-UBT, and served as the control group. The 233 patients who were <sup>13</sup>C-UBT+ were enrolled in this study and divided into 4 groups. Patients who were HPS- and <sup>13</sup>C-UBT+ (*n* = 53) received triple therapy alone. Those who were both HPS+ and <sup>13</sup>C-UBT+ (*n* = 180) were randomly divided into 3 groups: (1) the O+G+t group which received triple therapy alone (*n* = 53); (2) the O+G+tm group which received both triple therapy and mouthrinse treatment (*n* = 65); and (3) the O+G+tmp group which received triple therapy, mouthrinse, and periodontal treatment (*n* = 62). The HPS and <sup>13</sup>C-UBT were continued for 4 wk after completion of treatment, and the eradication rate of gastric *H. pylori* and the prevalence of oral *H. pylori* in

the 4 groups were then compared.

**RESULTS:** The eradication rates of gastric *H. pylori* in the O-G+t group, the O+G+tm group, and the O+G+tmp group were 93.3%, 90.0%, and 94.7% respectively; all of these rates were higher than that of the O+G+t group (78.4%) [O-G+t group vs O+G+t group (*P* = 0.039); O+G+tm group vs O+G+t group (*P* = 0.092); O+G+tmp group vs O+G+t group (*P* = 0.012); O+G+tm group vs O-G+t group (*P* = 0.546); O+G+tmp group vs O-G+t group (*P* = 0.765); O+G+tm group vs O+G+tmp group (*P* = 0.924)]. The eradication of gastric *H. pylori* was significantly improved using the combination of triple therapy, mouthrinse, and periodontal treatment. The eradication rates of gastric *H. pylori* in the peptic ulcer group, chronic atrophic gastritis group and control group were higher than in the duodenitis group and the superficial gastritis group. The prevalence rates of oral *H. pylori* in the O-G+t group, O+G+t group, O+G+tm group and O+G+tmp group following treatment were 0%, 76.5%, 53.3%, and 50.9%, respectively [O-G+t group vs O+G+t group (*P* < 0.0001); O+G+tm group vs O+G+t group (*P* = 0.011); O+G+tmp group vs O+G+t group (*P* = 0.006); O+G+tm group vs O-G+t group (*P* < 0.0001); O+G+tmp group vs O-G+t group (*P* < 0.0001); O+G+tm group vs the O+G+tmp group (*P* = 0.790)]. Both mouthrinse and periodontal treatment significantly reduced the prevalence of oral *H. pylori*.

**CONCLUSION:** Mouthrinse treatment alone or combined with periodontal treatment can, to some extent, reduce the prevalence of oral *H. pylori* and improve the eradication rate of gastric *H. pylori*.

**Key words:** *Helicobacter pylori*; Dental plaque; Eradication; Periodontal; Mouthrinse

**Core tip:** The average eradication rate of gastric *Helico-*

*bacter pylori* (*H. pylori*) has decreased in recent years. However, some foreign studies have shown that the eradication rate of gastric *H. pylori* may be improved by eliminating the presence of oral *H. pylori* rather than increasing the dose of antibiotics. In most studies, *H. pylori* DNA was detected and used to confirm oral *H. pylori* infection, and later determine whether professional periodontal treatments were effective in killing oral *H. pylori*. To avoid the expensive and complicated techniques involved with this approach, the current study used a cost-effective and simple method to test for and eliminate oral *H. pylori*. This method can be used to prove the elimination of gastric *H. pylori*, and is practical for use in the clinic.

Song HY, Li Y. Can eradication rate of gastric *Helicobacter pylori* be improved by killing oral *Helicobacter pylori*? *World J Gastroenterol* 2013; 19(39): 6645-6650 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i39/6645.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6645>

## INTRODUCTION

*Helicobacter pylori* (*H. pylori*) is believed to be one of the major factors responsible for chronic active gastritis, gastroduodenal ulcers, mucosa-associated lymphoid tissue lymphomas, and gastric cancers<sup>[1]</sup>. It was designated as a type I carcinogen by the World Health Organization in 1994 and approximately 50% of the world's population is infected. The isolation of *H. pylori* from dental plaque by Krajde<sup>[2]</sup> in 1989 strongly suggested that both oral and gastro-oral routes are important transmission modes of *H. pylori*, and that the oral cavity is an extra-gastric reservoir for *H. pylori*<sup>[3-6]</sup>. Several studies have suggested that oral *H. pylori* is associated with the presence of gastric *H. pylori*<sup>[6,7]</sup>; additionally, patients who are oral *H. pylori*-positive have a lower success rate of gastric *H. pylori* eradication than patients who test negative for oral *H. pylori*<sup>[6,8,9]</sup>. Also, previous studies have shown that DNA samples obtained from oral *H. pylori* are very similar to those obtained from corresponding gastric *H. pylori*<sup>[10-12]</sup>. The prevalence of oral *H. pylori* is related to an individual's quality of oral hygiene and periodontal status, such as the presence of dental plaque and periodontal pockets<sup>[13]</sup>, and the eradication rate of gastric *H. pylori* can be increased by controlling dental plaque and improving oral hygiene<sup>[14,15]</sup>. In our study, the saliva *H. pylori* antigen test (HPS) and the <sup>13</sup>C-urea breath test (<sup>13</sup>C-UBT) were used to detect oral and gastric *H. pylori* infections, respectively, and in this report, the term HPS+ signifies the presence of oral *H. pylori* infection, while <sup>13</sup>C-UBT+ signifies the presence of gastric *H. pylori* infection. <sup>13</sup>C-UBT+ patients were recruited for this study. HPS- cases were treated with triple therapy alone, while HPS+ cases were randomly distributed into 3 groups which received different treatments. The goal of this study was to evaluate the influence of oral *H. pylori* on the success of eradication

therapy against gastric *H. pylori*.

## MATERIALS AND METHODS

### Patient population

From August 2011 to July 2012, outpatients with dyspepsia seen at the Department of Gastroenterology, Shengjing Hospital of China Medical University, Shenyang, China, were recruited and selected for this study. Exclusion criteria included a past history of *H. pylori* eradication therapy; treatment with antibiotics, H<sub>2</sub> receptor blockers, bismuth or proton pump inhibitors within one month of study enrollment; the presence of severe periodontal disease; presence of an immune disease; current pregnancy; age < 18 years; and the use of immune depressant drugs. A total of 391 eligible patients were enrolled in the study and another 40 volunteers without discomfort were enrolled to serve as a control group (Table 1).

The diseases listed in Table 1 were diagnosed using the following criteria: Peptic ulcer was defined as the presence of gastric ulcer and/or duodenal ulcer. Chronic atrophic gastritis: Endoscopy showed good visualization of the submucosal vessel in the antrum and in the body. Histopathology showed the loss of appropriate glands or the presence of metaplasia. Duodenitis: During endoscopy, the duodenal bulb mucosa appeared abnormally congested, edematous, or roughened in the absence of an ulcer or scar. Histopathology showed nuclear atypia of the glandular epithelium and infiltration by neutrophils. Superficial gastritis: During endoscopy, gastric mucosa appeared abnormally congested, edematous, or roughened. Histopathology showed nuclear atypia of the glandular epithelium and infiltration by neutrophils.

### Study groups

Each subject was evaluated by HPS, <sup>13</sup>C-UBT, gastroscopy, and gastric mucosal histopathological examination. Two biopsy specimens were taken from the greater curvature of both the antrum and the body of the stomach, respectively. Another 2 biopsy specimens were taken from both the lesser curvature of the antrum and body, respectively. Patients who were HPS- and <sup>13</sup>C-UBT+ (*n* = 53) received triple therapy alone. Those who were both HPS+ and <sup>13</sup>C-UBT+ (*n* = 180) were randomly divided into 3 groups: (1) the O+G+t group which received triple therapy alone (*n* = 53); (2) the O+G+tm group which received triple therapy and mouthrinse treatment (*n* = 65); and (3) the O+G+tmp group which received triple therapy, mouthrinse, and periodontal treatment (*n* = 62). The triple therapy consisted of amoxicillin (1.0 g) and esomeprazole (20 mg), twice a day, and levofloxacin (0.5 g), once a day, given for 10 d. Mouthrinse (brand name Chlorhexidine Gargle), (Shenzhen Nanyue Pharmaceutical Co., Ltd., Shenzhen, China) was purchased from a drugstore. This mouthwash contained 0.02% tinidazole and 0.12% chlorhexidine, and a 20 mL volume was held in the mouth for 5 min and then spat out, for 10 d. Periodontal therapy consisted of plaque and calculus removal with an ultrasonic device twice a month in the Depart-

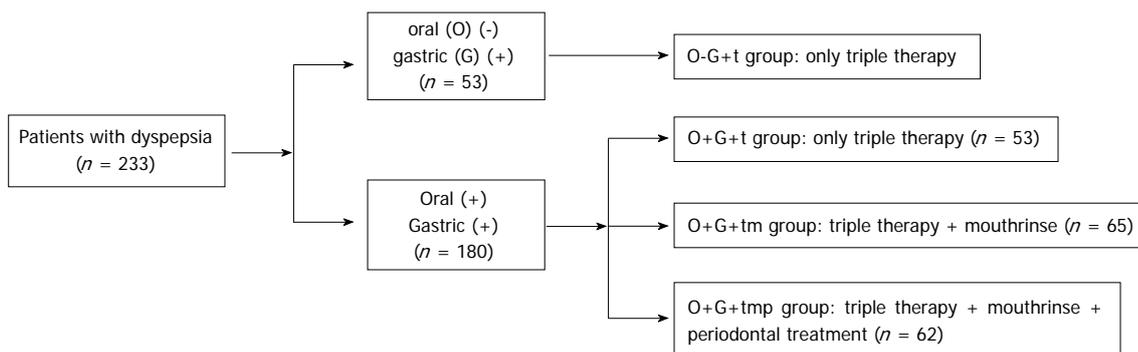

Figure 1 Study design schematic and study measures.

**Table 1 Characteristics of the 431 patients**

Diseases	Total	Male	Female	Age range (yr)	Mean age (yr)
Peptic ulcer	54	40	14	20-80	51.1
Chronic atrophic gastritis	48	32	16	46-82	58.5
Duodenitis	58	31	27	26-77	51.0
Superficial gastritis	231	95	136	18-74	49.6
Control group	40	17	23	18-67	44.0

ment of Stomatology, Shengjing Hospital of China Medical University. HPS and <sup>13</sup>C-UBT testing were conducted 4 wk after triple therapy was completed. A flow-chart of patient treatment is shown in Figure 1.

**HPS**

The saliva *H. pylori* antigen test (Meili Taige Diagnostic Reagent Co., Ltd, Jiaxing, China) is a rapid immunochromatographic assay that uses antibody-coated colloidal gold to detect the presence of specific *H. pylori* antigens in the saliva specimen. Yee *et al*<sup>[16]</sup> clarified that HPS was designed to detect two *H. pylori* antigens: flagellin and urease. In Yee’s experiment, the HPS results were compared in parallel with the UBT, serum antibody, Campylobacter-like organism test, silver stain, culture, and stool antigen test results. The test’s sensitivity was 10 ng/mL *H. pylori* flagellin and urease antigen. There was no interference or cross-reactivity with the other bacteria in the oral cavity and there was statistical correlation between oral antigen and serum antibody test results. No food or drink was allowed 1 h before the test. To perform the test, four drops of saliva were added to the sampling cup using a pipette and two drops of PBS were added. After mixing, a new pipette was used to transfer four drops of the mixture into the sample well of the test cassette. The sample flowed through a label pad containing *H. pylori* antibody coupled to red-colored colloidal gold. If the sample contained *H. pylori* antigens, the antigen would bind to the antibody coated on the colloidal gold particles to form antigen-antibody-gold complexes. The complexes then moved on a nitrocellulose membrane by capillary action toward the test zone. A second control line always appeared in the result window to indicate that the test had been correctly performed and that the test device was functioning prop-

erly. The results were observed within 5-30 min. The occurrence of two bands in the test and control zones was positive for *H. pylori*. The occurrence of one band in the control zone was negative for *H. pylori*. If there was no band in the control zone, the samples were re-tested.

**<sup>13</sup>C-UBT**

An HG-IRIS<sup>13</sup>C infrared spectrometer and diagnostic kits (Beijing Pharmaceutical Co., Ltd) were used to detect gastric *H. pylori*. The test was judged positive when the detected value in the exhalation was larger than 4.

**Statistical analysis**

Statistical analysis of data was performed with SPSS software 19.0. The  $\chi^2$  test was used to analyze the eradication rate of gastric *H. pylori* and the prevalence of oral *H. pylori* in each group. A *P* value  $\leq 0.05$  was considered statistically significant.

**RESULTS**

**Results of HPS and <sup>13</sup>C-UBT testing**

A total of 431 patients were tested using HPS and <sup>13</sup>C-UBT methods, and the results are shown in Table 2.

The prevalence of gastric and oral *H. pylori* differed among the 5 disease groups. There was a reduced trend for the prevalence of gastric *H. pylori* starting from the peptic ulcer group and continuing to the control group, but no similar trend was seen for oral *H. pylori* (Figure 2).

**Eradication rate of gastric *H. pylori* after treatment**

Four weeks after completion of treatment, 213 patients returned for evaluation, and 20 patients did not return. The gastric *H. pylori* eradication rate in the O+G+t group was significantly lower than in the O-G+t and O+G+tmp groups (O-G+t group *vs* O+G+t group, *P* = 0.039), (O+G+tmp group *vs* O+G+t group, *P* = 0.012). The gastric *H. pylori* eradication rate in the O+G+tm group was higher than in the O+G+t group, but the difference was not statistically significant (*P* = 0.092). There were no statistical differences between the O-G+t and O+G+tm groups when compared to the O+G+tmp group (O+G+tm group *vs* O-G+t group, *P* = 0.546), O+G+tmp group *vs* O-G+t group, *P* = 0.765), and

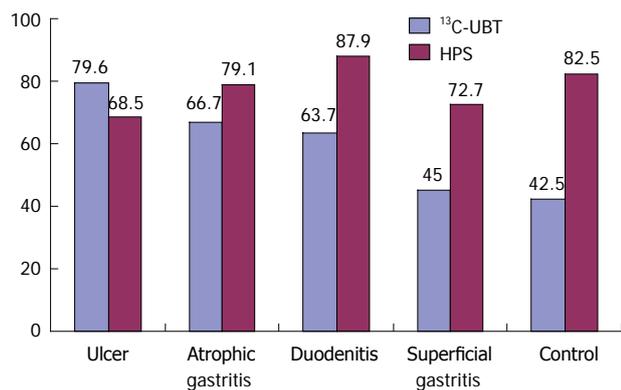

Figure 2 Percentages of positive <sup>13</sup>C-urea breath test and *Helicobacter pylori* antigen test results for gastric and oral *Helicobacter pylori* before treatment. HPS: *Helicobacter pylori* antigen test; UBT: Urea breath test.

Negative	2 (3.4)	5 (8.7)
Superficial gastritis ( <i>n</i> = 231)		
Positive	79 (34.2)	89 (38.5)
Negative	25 (10.8)	38 (16.5)
Control group ( <i>n</i> = 40)		
Positive	12 (30.0)	21 (52.5)
Negative	5 (12.5)	2 (5.0)

HPS: *Helicobacter pylori* antigen test; <sup>13</sup>C-UBT: <sup>13</sup>C-urea breath test.

O+G+tm group *vs* O+G+tmp group, *P* = 0.924) (Table 3).

There were some subtle differences in the rate of gastric *H. pylori* eradication between the different gastric disease groups. The eradication rates in the peptic ulcer and chronic atrophic gastritis groups were higher than those in the duodenitis and superficial gastritis groups, but the differences were not statistically significant (Table 4).

### Prevalence of oral *H. pylori* after treatment

After treatment, the prevalence of oral *H. pylori* in the O+G+tm group was significantly higher than those in the other 3 groups: O-G+tm group *vs* O+G+tm group (*P* < 0.0001), O+G+tm group *vs* O+G+tm group (*P* = 0.011), and O+G+tmp group *vs* O+G+tm group (*P* = 0.006). There was no significant difference between the O+G+tm and O+G+tmp groups (*P* = 0.790) (Table 3).

## DISCUSSION

The idea that *H. pylori* can be transmitted by both oral

Table 3 Eradication rate of gastric *Helicobacter pylori* and prevalence of oral *Helicobacter pylori* after treatment in all groups *n* (%)

Group	Eradication rate of gastric <i>Helicobacter pylori</i>	Prevalence of oral <i>Helicobacter pylori</i>
O-G+tm	42 (93.3) <sup>a,c</sup>	0 (0.0) <sup>a</sup>
O+G+tm	40 (78.4)	39 (76.5)
O+G+tm	54 (90.0) <sup>b</sup>	32 (53.3) <sup>a</sup>
O+G+tmp	54 (94.7) <sup>a,b,c</sup>	29 (50.9) <sup>a</sup>

<sup>a</sup>*P* < 0.05 *vs* O+G+tm group; <sup>b</sup>*P* > 0.05 *vs* O-G+tm group; <sup>c</sup>*P* > 0.05 *vs* O+G+tm group.

to oral and stomach to oral routes has been recognized since 1989 when Krajce first isolated *H. pylori* from the dental plaque of patients with gastric diseases related to *H. pylori* infection. Further studies have shown that the gastric *H. pylori* eradication rate in patients with oral *H. pylori* infection is lower than that in patients without oral *H. pylori* infection. With the increase in antibiotic resistance which has occurred during the past 10 years, the rate of gastric *H. pylori* eradication following triple therapy has significantly decreased. From 1983-1997, the average eradication rate for gastric *H. pylori* was 75%-90%<sup>[17]</sup>, but later decreased to 68.8% in the period from 1996 to 2005<sup>[18]</sup>. Improvements in the gastric *H. pylori* eradication rate produced by killing oral *H. pylori* can reduce the application of antibiotics<sup>[9,14]</sup>, which not only reduces the economic burden of treatment, but also lowers the risk of increasing the resistance of *H. pylori* to antibiotics. Oral *H. pylori* is mainly present in periodontal pockets and dental plaque<sup>[19,20]</sup>. Zaric *et al*<sup>[9]</sup> collected dental plaque and gastric tissues and examined them for *H. pylori* using nested polymerase chain reaction (PCR). In our study, for patients with both oral and gastric *H. pylori*, periodontal treatment was applied in addition to triple therapy. Ultrasonic waves were used to remove dental plaque and calculi, and root surface scaling was used to eradicate the periodontal pockets. Glucose chlorhexidine solution (0.15%) was used to lavage the periodontal pocket. After periodontal treatment, the gastric *H. pylori* eradication rate was increased from 47.6% to 77.3%, while the prevalence of oral *H. pylori* was decreased from 66.7% to 27.0%; these results indicated that periodontal treatment could kill oral *H. pylori*. The methods used by Zaric were useful, but not easy to employ, and the monetary cost was high. Conducting nested PCR requires specific instruments, and the periodontal treatment also requires experienced dentists; therefore, these methods are not practical for routine clinical application. The current study was conducted to seek a cost-effective method for diagnosing oral *H. pylori* infection and reducing its prevalence.

Currently, there are two methods (bacterial culturing and nested PCR) used to diagnose oral *H. pylori* infection. Although the bacterial culture method has high specificity, large numbers of other oral bacteria can inhibit the growth of *H. pylori*, leading to a high false negative rate<sup>[21]</sup>. The nested PCR method has high sensitivity and

**Table 4** Eradication rate of gastric *Helicobacter pylori* after treatment in all gastric disease groups *n* (%)

Group	Gastric diseases				
	Peptic ulcer	Chronic atrophic gastritis	Duodenitis	Superficial gastritis	Control group
O+G+t	10 (100.0)	6 (100.0)	2 (100.0)	19 (86.4)	5 (100.0)
O+G+t	9 (90.0)	7 (87.5)	8 (72.7)	12 (70.6)	4 (80.0)
O+G+tm	9 (100.0)	10 (100.0)	9 (75.0)	22 (88.0)	4 (100.0)
O+G+tmp	9 (100.0)	5 (100.0)	10 (91.0)	27 (93.1)	3 (100.0)

specificity, but the results have been highly variable due to the use of different primers, and it cannot differentiate between DNA from dead and living bacteria. *H. pylori* DNA can still be detected even if the bacteria are already dead<sup>[22,23]</sup>. Thus, the nested PCR method cannot monitor the therapeutic efficacy of a treatment for oral *H. pylori*.

The HPS test is a rapid immunochromatographic assay. The principle of this test kit is based on using a colloidal gold chromatography double antibody sandwich to detect *H. pylori* flagellae and urease in human saliva. There are no cross-reactions with the urease released by other oral bacteria<sup>[14]</sup>.

Our results showed that the positive rate of HPS testing was 74.9%, demonstrating that the mouth is another storage site for *H. pylori*. In this study, the gastric *H. pylori* eradication rate in patients who were HPS+ was lower than that in patients who were HPS- (78.4% *vs* 93.3%). We also noted that the test results of gastric and oral *H. pylori* were not consistent. Previous studies have shown that *H. pylori* does not colonize in the mouth of a person who practices good oral hygiene (*e.g.*, no periodontal disease, no gingival band or plaque)<sup>[24]</sup>. In this situation, the oral *H. pylori* titer is low and does not reach the threshold of gastric *H. pylori* infection. Therefore, a test to detect gastric *H. pylori* infection would give negative results. For gastric *H. pylori*-positive patients with good oral hygiene, although gastric *H. pylori* may be refluxed into the mouth, the bacterium may not survive in the mouth. In this study, the HPS test had a high sensitivity, which enabled it to detect a low titer of *H. pylori*. Therefore, the positive rate for oral *H. pylori* infection was higher than that for gastric *H. pylori* infection.

*H. pylori* in the oral cavity is covered by a special protective shell called a biofilm, and systemic eradication therapy may not be very effective when used for treatment<sup>[25,26]</sup>; this study confirmed that hypothesis. The gastric *H. pylori* eradication rate in the O+G+t group was much higher than that in the oral *H. pylori* group (78.4% *vs* 23.5%). Compared with the O+G+t group, the eradication rates of gastric *H. pylori* in the O+G+tm and O+G+tmp groups were elevated from 78.4% to 90.0% and 94.7%, respectively, while the prevalence of oral *H. pylori* was reduced from 76.5% to 53.3% and 50.9%, respectively. There was no significant difference in gastric *H. pylori* eradication rate between the O+G+tm group and the O+G+tmp group. The gastric *H. pylori* eradication rates in the peptic ulcer group, chronic atrophic gastritis group, and control group were higher than those in the duodenitis group and superficial gastritis group, but no conclusion could be drawn from this finding because the

number of patients was small. This study demonstrated that mouthrinse treatment alone or combined with periodontal treatment could effectively reduce the prevalence of oral *H. pylori*, but did not prove a mechanism for this result. One hypothesis may be that the mouthrinse treatment or periodontal treatment reduced the amount of dental plaque and improved oral hygiene, thus enabling the titer of *H. pylori* to be reduced.

This study proved that mouthrinse treatment alone or combined with periodontal treatment could reduce the prevalence of oral *H. pylori* and improve the eradication rate of gastric *H. pylori*. The HPS test is a simple and rapid method that can diagnose oral *H. pylori* infection; however, the test results cannot be analyzed quantitatively. Therefore, the therapeutic effect of various treatments could not be thoroughly analyzed.

## COMMENTS

### Background

It is well acknowledged that the stomach can serve as a reservoir for *Helicobacter pylori* (*H. pylori*) and that gastric *H. pylori* can be killed by triple or quadruple therapy. Increasing numbers of studies have suggested that the average eradication rate of gastric *H. pylori* has dropped in recent years, and it is important to find a practical way to improve the eradication rate.

### Research frontiers

Since Krajce isolated *H. pylori* from dental plaque in 1989, many studies have demonstrated that the oral cavity serves as an extra-gastric reservoir for *H. pylori*. Several studies have suggested that patients who test positive for oral *H. pylori* have a lower success rate of gastric *H. pylori* eradication than oral *H. pylori*-negative individuals. Zaric used nested polymerase chain reaction (PCR) to test for the presence of oral *H. pylori*, and improved the eradication rate of gastric *H. pylori* from 47.6% to 77.3% by removing dental plaque. However, the cost of this procedure was high and the process was complicated. There is a great need to find a simple and rapid diagnostic test that can be used to confirm the presence of oral *H. pylori* infection, and to identify a method that can increase the eradication rate of gastric *H. pylori* and is feasible for clinical application.

### Innovations and breakthroughs

<sup>13</sup>C-UBT is the gold standard for diagnosis of gastric *H. pylori* infection; however, a unified method has not been identified for diagnosing oral *H. pylori* infection. Nested PCR, which tests the DNA of *H. pylori*, is commonly used, but has a high false positive rate because it cannot distinguish between DNA from dead and living bacteria. The current study replaced the nested PCR method with a saliva *H. pylori* antigen test (HPS) to test for oral *H. pylori*. The HPS test employs a monoclonal antibody that was developed against semipurified *H. pylori* protein, and in another experiment, this test showed no interference or cross reactivity with other oral bacteria. Zaric killed oral *H. pylori* by removing dental plaque and lavaging the periodontal pocket, which required a professional dentist. In the current study, mouthwash was used to effectively kill oral *H. pylori*.

### Applications

This study used the saliva *H. pylori* antigen test to diagnose oral *H. pylori* infection. This test is simple to use and results are rapidly obtained. The eradication rate of gastric *H. pylori* improved significantly in patients who received mouth-

rinse treatment alone or combined with periodontal treatment. This innovative approach can not only reduce the economic burden of patients, but also decrease the development of resistance to antibiotics.

### Terminology

*H. pylori*: *H. pylori* is a spiral rod-shaped bacterium that mainly colonizes the epithelium of the stomach. It is considered to be the main cause of peptic ulcer, chronic active gastritis, gastroduodenal ulcer, mucosa-associated lymphoid tissue lymphoma and gastric cancer. Approximately half of the world's population is infected. Triple therapy which consists of one proton inhibitor and two antibiotics is often used to kill *H. pylori*.

### Peer review

This is an interesting study, indicating a cheap way of improving *H. pylori* eradication rate. The study was performed on 391 persons who underwent gastroscopy and histopathological examination of gastric mucosa. For evaluation of *H. pylori* in oral cavity, the authors used *H. pylori* saliva test based on detection of *H. pylori* antigen in saliva using rapid immunochromatographic assay. For evaluation of *H. pylori* in stomach mucosa, the authors used <sup>13</sup>C-urea breath test. The results showed that the eradication of *H. pylori* in the mouth cavity using mouth rinse and periodental treatment could kill the oral *H. pylori* and improve the eradication rate of gastric *H. pylori* by triple therapy. The study is set up correctly. The paper is written well. The Introduction gives a good overview of the study background and the authors raised clearly the aim of the study. The material studied is large enough to draw the conclusions. The Tables and Figure give a good overview about the results.

### Abstract

**AIM:** To investigate the use of multi-*b*-value diffusion-weighted imaging in diagnosing pancreatic cancer.

**METHODS:** We retrospectively analyzed 33 cases of pancreatic cancer and 12 cases of benign pancreatic tumors at the Second Affiliated Hospital of Kunming Medical University from December 2008 to January 2011. The demographic characteristics, clinical presentation, routine magnetic resonance imaging and diffusion weighted imaging (DWI) features with different *b* values were reviewed. Continuous data were expressed as mean  $\pm$  SD. Comparisons between pancreatic cancer and benign pancreatic tumors were performed using the Student's *t* test. A probability of  $P < 0.05$  was considered statistically significant.

**RESULTS:** Thirty-three patients with pancreatic cancer were identified. The mean age at diagnosis was  $60 \pm 5.6$  years. The male: female ratio was 21:12. Twenty

cases were confirmed by surgical resection and 13 by biopsy of metastases. T1 weighted images demonstrated a pancreatic head mass in 16 patients, a pancreatic body mass in 10 cases, and a pancreatic tail mass with pancreatic atrophy in 7 cases. Eight patients had hepatic metastases, 13 had invasion or envelopment of mesenteric vessels, 4 had bone metastases, and 8 had lymph node metastases. DWI demonstrated an irregular intense mass with unclear margins. Necrotic tissue demonstrated an uneven low signal. A *b* of 1100 s/mm<sup>2</sup> was associated with a high intensity signal with poor anatomical delineation. A *b* of 700 s/mm<sup>2</sup> was associated with apparent diffusion coefficients (ADCs) that were useful in distinguishing benign and malignant pancreatic tumors ( $P < 0.05$ ). *b* values of 50, 350, 400, 450 and 1100 s/mm<sup>2</sup> were associated with ADCs that did not differentiate the two tumors.

**CONCLUSION:** Low *b* value images demonstrated superior anatomical details when compared to high *b* value images. Tumor tissue definition was high and contrast with the surrounding tissues was good. DWI was useful in diagnosing pancreatic cancer.

**Key words:** Pancreatic cancer; Magnetic resonance imaging; *b* value; Apparent diffusion coefficient; Diffusion weighted imaging

**Core tip:** In this study, we retrospectively analyzed the conventional magnetic resonance imaging and diffusion weighted imaging (DWI) characteristics of 33 cases of pancreatic cancer using different *b* values, and assessed the value of the DWI examination in differentiating pancreatic cancer from benign pancreatic tumors.

Hao JG, Wang JP, Gu YL, Lu ML. Importance of *b* value in diffusion weighted imaging for the diagnosis of pancreatic cancer. *World J Gastroenterol* 2013; 19(39): 6651-6655 Available from:

## INTRODUCTION

Pancreatic cancer is the fourth leading cause of cancer-related deaths<sup>[1]</sup> and accounts for 80% to 90% of exocrine gland malignant tumors<sup>[2]</sup>. Most patients present without symptoms and have a median survival of approximately 6 months. There is an urgent need for early diagnosis and accurate assessment of this disease. Magnetic resonance imaging (MRI) is a sensitive and specific imaging modality. MRI has been used to assess tumor macroscopic morphology, microscopic metabolism, and functional status<sup>[3,4]</sup>. Diffusion weighted imaging (DWI) is an imaging technique that is sensitive to water diffusion in living tissues. DWI was originally used to diagnose acute stroke<sup>[5,6]</sup>. DWI has also been used to diagnose liver, kidney, breast, prostate and uterine disease. DWI is frequently used to diagnose pancreatic diseases<sup>[7-10]</sup>. We retrospectively analyzed the conventional MRI and DWI characteristics of 33 patients with pancreatic cancer and 12 with benign pancreatic tumors to evaluate the value of DWI.

## MATERIALS AND METHODS

### Study patients

Thirty-three patients with pancreatic cancer were hospitalized at the Second Affiliated Hospital of Kunming Medical University between December 2008 and January 2011. Twenty patients had their diagnosis confirmed by pathological examination of the resected specimen and 13 by biopsy of metastases. There were 21 male and 12 female patients with an average age of  $60 \pm 5.6$  years. Sixteen patients had a mass in the pancreatic head, 10 in the pancreatic body, and 7 in the pancreatic tail. Clinical symptoms included abdominal pain, abdominal discomfort, jaundice, abdominal mass, significant weight loss and loss of appetite. Control cases with benign pancreatic tumors were confirmed by histopathology.

### Imaging data

Imaging was performed using a Siemens Sonata 1.5 T superconducting scanner with a body phased-array surface coil. A T1WI-FLASH sequence (repetition time, TR 124 ms and echo time, TE 2.47 ms) and T2WI-HASTE sequence (TR 1000 ms and TE 93 ms) were used with 18-24 layers, a thickness of 4-8 mm, spacing between 0 and 1.6 mm, and a field of view (FOV) of 240-280 mm  $\times$  300-380 mm. The matrix was 320  $\times$  256. Scan time was 13-18 s.

DWI scanning was performed using a SE-EPI sequence (TR 4000 ms, TE 85-95 ms, Matrix 128  $\times$  128, FOV 230 mm  $\times$  230 mm, thickness 5 mm, spacing 0.5 mm) with fat suppression, flow compensation and chemical shift saturation. The *b* value (apparent diffusion coefficient) was varied (50, 350, 400, 450, 700 and 1100 s/mm<sup>2</sup>) to capture images. Slice selection was performed

using frequency encoding and phase encoding in 3 directions. Images were processed using MR software. Scan time was 13-18 s.

### Data analysis

The original DWI scanning data and automatically generated apparent diffusion coefficients (ADC) were transferred to the workstation. The value of the ADC was measured from the ADC image of each region of interest (ROI). Solid tumor ROIs were not less than half of the lesion and located in the center of the mass. Areas of necrosis, the main pancreatic duct, vascular branches and chemical shift artifacts were avoided. Three ADCs were measured from each ROI and averaged.

### Statistical analysis

All statistical analyses were performed using SPSS, version 17.0 for Windows. Continuous data were expressed as mean  $\pm$  SD. The differences in ADC values of pancreatic cancer and benign pancreatic tumors were evaluated using the Student's *t* test. All reported *P* values were two-sided. *P* < 0.05 was considered statistically significant.

## RESULTS

### Conventional MRI-T1WI

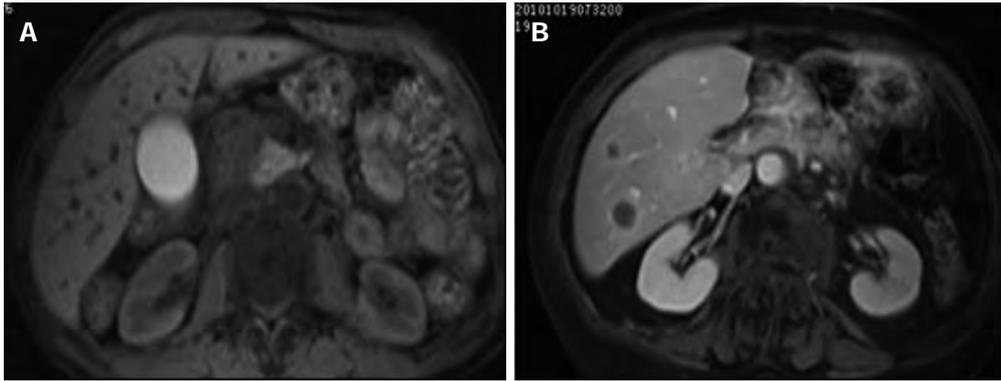

Sixteen patients had a pancreatic head mass, with a local or diffuse low intensity signal (Figure 1A). 10 had a pancreatic body mass with a low intensity signal (Figure 1B) and 7 patients had a pancreatic tail mass with pancreatic atrophy. Eight patients had liver metastases, 13 demonstrated invasion into or enveloping local mesenteric vessels, 4 had bone metastases and 8 had lymph node metastases.

### DWI

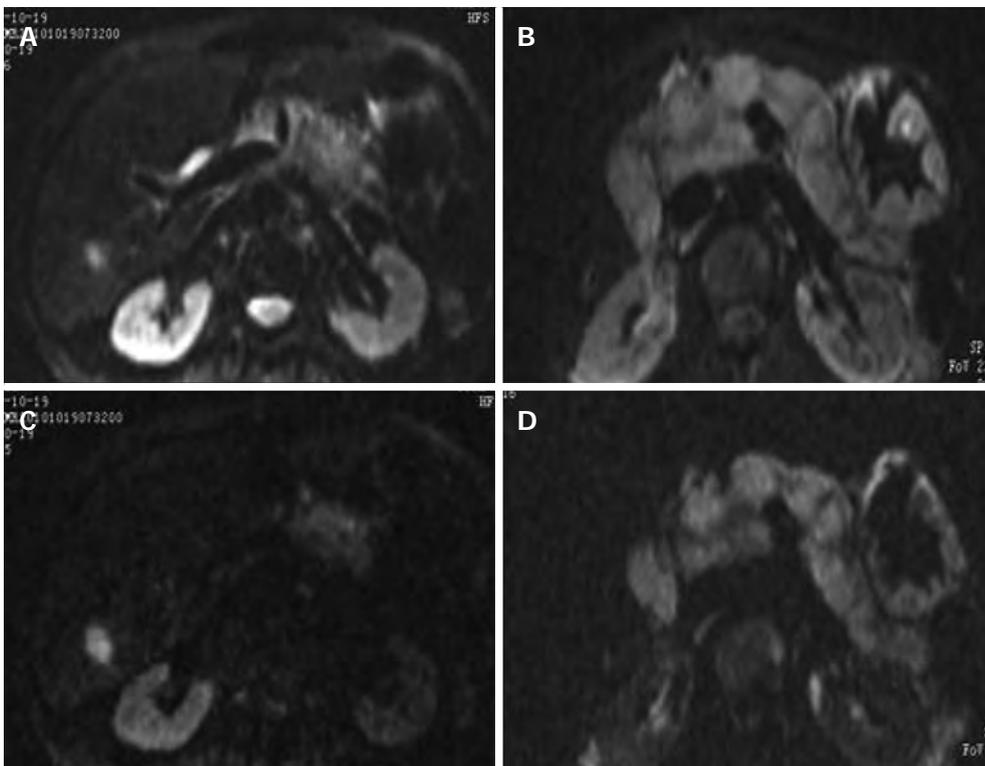

DWI demonstrated an uneven intense signal with margins that were not clearly delineated. The central necrotic tissue had an irregular low intensity signal. A low *b* value image provided better anatomical detail than a high *b* value image. Tumor tissue definition was high, and there was sharp contrast with the surrounding tissue (Figure 2). A *b* of 1100 s/mm<sup>2</sup> was associated with a high value signal and poor definition of anatomic structures. A *b* of 700 s/mm<sup>2</sup> was associated with benign pancreatic tumors and pancreatic cancer ADCs that were significantly different (*P* < 0.05). The two tumor types had similar ADCs when *b* values of 50, 350, 400, 450 and 1100 s/mm<sup>2</sup> were used for imaging (*P* > 0.05) (Table 1).

## DISCUSSION

Pancreatic cancer is one of the most common malignant tumors of the pancreas, accounting for approximately 75%-90% of tumors. It is the most common gastrointestinal malignant tumor<sup>[10]</sup>. The retroperitoneal location and lack of symptoms prevents early detection. Pancreatic cancers have a poor prognosis, with a five year survival of only 1%-3%<sup>[11]</sup>. Patients are generally male and 40-70

**Figure 1** T1 weighted image. A: T1 weighted image. The margins were not sharp; B: T1 weighted image with contrast. There was obvious enhancement. Two nodules in the right liver demonstrated ring enhancement.

**Figure 2** Tumor tissue definition was high, and there was sharp contrast with the surrounding tissue. A:  $b = 50 \text{ s/mm}^2$ ; B:  $b = 400 \text{ s/mm}^2$ ; C:  $b = 700 \text{ s/mm}^2$ ; D:  $b = 1100 \text{ s/mm}^2$ . A high intensity signal was seen.

**Table 1** Evaluation of apparent diffusion coefficients in pancreatic cancer and benign pancreatic tumors using different  $b$  values

$b \text{ (s/mm}^2\text{)}$	Apparent diffusion coefficients ( $10^{-3} \text{ s/mm}^2$ )	
	Benign pancreatic tumors	Pancreatic cancer
50	$2.273 \pm 0.298$	$2.006 \pm 0.194$
350	$1.705 \pm 0.227$	$1.489 \pm 0.306$
400	$1.590 \pm 0.553$	$1.376 \pm 0.276$
450	$1.544 \pm 0.194$	$1.333 \pm 0.218$
700	$1.519 \pm 0.125^1$	$1.118 \pm 0.102^1$
1100	$1.380 \pm 0.249$	$1.085 \pm 0.163$

<sup>1</sup>Indicates statistically significant difference,  $P < 0.05$ .

years of age. Only a minority of patients are candidates for surgery at the time of diagnosis<sup>[12]</sup>.

The majority of pancreatic cancers are adenocarcinomas. Ductal adenocarcinomas account for 85%-90% of pancreatic carcinomas and originate in the ductal epithelium. Ductal adenocarcinomas are avascular solid tumors that are locally invasive. About 70% of pancreatic cancers are located in the pancreatic head, neck and uncinate process, 20% are located in the body of the pancreas, and 5%-10% are located in the tail of the pancreas.

Abdominal imaging is used to diagnose pancreatic tumors, distinguish benign and malignant pancreatic tumors, and evaluate the resectability of pancreatic cancers

before surgery<sup>[13-15]</sup>. Endoscopic ultrasound (EUS) with zone sonography technology has been used in the diagnosis of pancreatic disease<sup>[16]</sup>. The sensitivity of EUS fine needle aspiration for pancreatic adenocarcinoma<sup>[17]</sup> in early studies was more than 85%. Further studies are needed. Egorov *et al*<sup>[18]</sup> demonstrated the utility of combined CT and EUS in the detection of arterial involvement by pancreatic cancer. Previous studies<sup>[19]</sup> have shown that DWI performed significantly better than multidetector-row CT in the detection of liver metastases in patients with pancreatic tumors. PET has also been useful as a diagnostic and predictive tool, but its efficacy in the staging of pancreatic cancer is not known<sup>[20]</sup>. A meta-analysis of pancreatic imaging<sup>[21]</sup> suggested that DWI was a potentially useful modality for differentiating malignant from benign pancreatic lesions. There are few studies on the effect of *b* value on DWI in the diagnosis of pancreatic cancer. Normal pancreatic tissue contains more water than pancreatic cancer, resulting in a high T1 weighted signal. Tumor liquefaction, necrosis and hemorrhage are associated with an irregular low intensity signal. T2 weighted images are mainly used to evaluate fluid composition, pancreatic duct dilation, and pseudocyst formation. These images are not specific for pancreatic cancer, eliciting low and high intensity signal. DWI is a noninvasive magnetic resonance imaging method, which can detect the irregular random movement of water molecules<sup>[22]</sup>. DWI can provide spatial information and evaluate the exchange rate of water molecules in tissues. ADCs have been used to describe and measure the activity of water molecules.

*b* values of 50 and 350 s/mm<sup>2</sup> were associated with clear DWIs, but the ADC value was not precise. With small *b* values, the proportion of diffusion is small and blood perfusion had a greater impact on DWI. While T2 was associated with an intense signal, DWI did not show a good margin between tumors and the surrounding tissue<sup>[23-25]</sup>. These factors affect the quality of DWI and the measurement of ADC.

DWI and ADCs with small *b* values were not useful in diagnosing pancreatic tumors. A *b* value of 1100 s/mm<sup>2</sup> was not useful in generating ADCs that could differentiate benign and malignant pancreatic tumors. This may be due to a decline in image quality seen with high *b* values. A *b* value of 700 s/mm<sup>2</sup> was useful in generating ADCs that could differentiate the two tumor types. The amount of tumor fibrosis, necrosis, cell proliferation, and changes in the nuclear/cytoplasmic ratio and membranous structure restricted the movement of water molecules in pancreatic cancers, decreasing the ADC values<sup>[26]</sup>.

The small sample size of this study increases the possibility of a type 2 error. Randomized controlled trials are needed to verify the utility of specific *b* values to aid in the differential diagnosis of pancreatic cancer.

In conclusion, low *b* value imaging demonstrated anatomical details that were superior to high *b* value images. Tumor tissue definition was high and contrast with the surrounding tissue was good. DWI was useful in diagnos-

ing pancreatic cancer.

## COMMENTS

### Background

Pancreatic cancer is the fourth leading cause of cancer-related deaths. Early detection, early diagnosis, and suitable treatment play an important role in extending patient survival. Diffusion weighted imaging (DWI) is a technically feasible measure to differentiate malignant from benign pancreatic lesions.

### Research frontiers

DWI is a magnetic resonance imaging technique that can be used to evaluate liver, kidney, breast, prostate and uterine tissue, and is especially useful in evaluating the upper abdomen.

### Innovations and breakthroughs

The authors retrospectively analyzed the DWI characteristics of 33 cases of pancreatic cancer using multiple *b* values in order to identify the optimal *b* value for differentiating malignant from benign pancreatic lesions.

### Applications

The authors found that low *b* values provided superior anatomical details, a quality image, good tumor tissue definition, and good contrast with the surrounding tissue.

### Terminology

DWI is an imaging technique sensitive to water molecule diffusion. It can non-invasively evaluate diffusion processes inside living cells.

### Peer review

This is an interesting study with great promise. DWI appears useful in diagnosing pancreatic cancer.

### Abstract

**AIM:** To investigate the association of macrophage migration inhibitory factor (MIF) promoter polymorphisms with inflammatory bowel disease (IBD) risk.

**METHODS:** One thousand and six New Zealand Caucasian cases and 540 Caucasian controls were genotyped for the *MIF* SNP -173G > C (rs755622) and the repeat polymorphism CATT<sub>5-8</sub> (rs5844572) using a pre-designed TaqMan SNP assay and capillary electrophoresis, respectively. Data were analysed for single site and haplotype association with IBD risk and phenotype. Meta-analysis was employed, to assess cumulative evidence of association of *MIF* -173G > C with IBD. All published genotype data for *MIF* -173G > C in IBD were identified using PubMed and subsequently searching the references of all PubMed-identified studies. Imputed genotypes for *MIF* -173G > C were generated from the Wellcome Trust Case Control Consortium (and National Institute of Diabetes and Digestive and Kidney Diseases). Separate meta-analyses were performed on Caucasian Crohn's disease (CD) (3863 patients, 6031 controls), Caucasian ulcerative colitis (UC) (1260 patients, 1987 controls), and East Asian UC (416 patients and 789 controls) datasets using the Mantel-Haenszel method. The New Zealand dataset had 93% power, and the meta-analyses had 100% power to detect an effect size of OR = 1.40 at  $\alpha = 0.05$ , respectively.

**RESULTS:** In our New Zealand dataset, single-site analysis found no evidence of association of MIF polymorphisms with overall risk of CD, UC, and IBD or disease phenotype (all *P* values > 0.05). Haplotype analysis found the CATT<sub>5</sub>/-173C haplotype occurred at a higher frequency in New Zealand controls compared to IBD patients (0.6 vs 0.01; *P* = 0.03, OR = 0.22; 95%CI: 0.05-0.99), but this association did not survive bonferroni correction. Meta-analysis of our New Zealand *MIF* -173G > C data with data from seven additional Caucasian datasets using a random effects model found no association of *MIF* polymorphisms with CD, UC, or overall IBD. Similarly, meta-analysis of all pub-

lished *MIF* -173G > C data from East Asian datasets (416 UC patients, 789 controls) found no association of this promoter polymorphism with UC.

**CONCLUSION:** We found no evidence of association of MIF promoter polymorphisms with IBD.

**Key words:** Crohn's disease; Ulcerative colitis; Migration inhibitory factor; rs755622; rs5844572; Genetic association study

**Core tip:** Migration inhibitory factor (MIF) is an important mediator of inflammatory bowel disease (IBD). However, whether promoter polymorphisms in MIF alter susceptibility to IBD is unclear. This study sought to clarify this, as definitively as possible, for Caucasians and East Asians. Analysis of a New Zealand Caucasian cohort found no association of the polymorphisms *MIF* -173G > C and *CATT*<sub>5-8</sub> with IBD. Subsequent meta-analysis of the New Zealand data with published MIF -173G > C data from other Caucasian cohorts found no association. A separate meta-analysis of East Asian datasets also found no evidence of association of this promoter polymorphism with IBD.

Falvey JD, Bentley RW, Merriman TR, Hampton MB, Barclay ML, Geary RB, Roberts RL. Macrophage migration inhibitory factor gene polymorphisms in inflammatory bowel disease: An association study in New Zealand Caucasians and meta-analysis. *World J Gastroenterol* 2013; 19(39): 6656-6664 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i39/6656.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6656>

## INTRODUCTION

Macrophage migration inhibitory factor (MIF) is a pro-inflammatory cytokine implicated in the pathophysiology of numerous inflammatory conditions including inflammatory bowel disease (IBD)<sup>[1]</sup>. MIF is a widely expressed component of the immune system that is released in response to diverse stimuli including lipopolysaccharide (*via* toll-like receptor-4, TLR-4), pro-inflammatory cytokines such as tumor necrosis factor- $\alpha$  and interferon-gamma, and hypoxia<sup>[2,3]</sup>. MIF in turn up-regulates the expression of TLR-4, pro-inflammatory cytokines, and acts as a co-factor for the activation of T-cells<sup>[4]</sup>. MIF is elevated in the plasma of patients with active IBD and falls following successful treatment<sup>[5,6]</sup>. In murine models, transgenic over-expression of MIF increases susceptibility to IBD while *MIF* knockout mice are protected from the development of colitis<sup>[5-8]</sup>. Moreover, the ability of neutralising anti MIF antibodies to ameliorate murine colitis indicates the potential value of MIF as a therapeutic target<sup>[5,6,8]</sup>.

A single nucleotide polymorphism (SNP) -173G > C (rs755622) and a tetra-nucleotide repeat *CATT*<sub>5-8</sub>

(rs5844572) have been identified in the *MIF* promoter<sup>[4,9]</sup>. These polymorphisms are associated with increased plasma concentrations of MIF, increased risk and severity of inflammatory disease, and reduced response to glucocorticoid medication<sup>[4,9,10]</sup>. The functional effect of *MIF*-173G > C is attributed to the creation of a binding site for the transcription factor AP4<sup>[11]</sup>, whilst the mechanism by which *CATT*<sub>5-8</sub> alters promoter activity is unknown. Despite several previous studies<sup>[12-19]</sup>, the genetic contribution of *MIF* promoter polymorphisms to IBD susceptibility and phenotype is unclear. The overall aim of this study was to clarify, as definitively as possible, the contribution of *MIF* promoter polymorphisms to IBD risk and phenotype in Caucasians and East Asians. To achieve this aim, we conducted the largest single-dataset study of *MIF* promoter polymorphisms -173G > C and *CATT*<sub>5-8</sub> in Caucasians to date, and meta-analysed these new data with previously published data to test for cumulative evidence of association with IBD risk and phenotype in Caucasians and East Asians.

## MATERIALS AND METHODS

### Ethics

All New Zealand study participants gave their informed written consent and approval for the study was obtained from the Upper and Lower South Regional Ethics Committees of New Zealand (Approval ID: CTY/03/01/011; Date: 05/06/2007). For the meta-analysis, genotype data from non-New Zealand subjects were obtained from review of published studies (Table 1).

### New Zealand controls and IBD patients

Study participants were selected from a population-based study of genetic and environmental determinants of the aetiology of IBD in the Canterbury region of New Zealand which has been described in detail elsewhere<sup>[20]</sup>. The population of Canterbury is largely of Northern European (United Kingdom and Irish) origin and participants were included in the current study if they were of self-reported European ancestry. Diagnosis of IBD was made by standard criteria<sup>[21]</sup>. Detailed phenotypic data according to the Montreal Classification system were available in addition to information regarding the presence of extra-intestinal manifestations of disease, history of immunomodulator use and the need for surgery<sup>[21]</sup>. The control group comprised 540 healthy Caucasian New Zealanders over the age of 17 years with no history of inflammatory disorders<sup>[22]</sup>.

### MIF genotyping

DNA was collected from peripheral blood samples of the IBD patients and controls using guanidinium isothiocyanate-chloroform extraction<sup>[23]</sup>. Genotyping of *MIF* -173G > C (rs755622) was performed using a pre-designed Taqman<sup>®</sup> SNP genotyping assay (assay ID: C\_2213785\_10) as per the manufacturer's instructions (Applied Biosystems, Foster City, CA, United States).

**Table 1 Characteristics of previously published association studies of MIF -173G > C in inflammatory bowel disease**

Cohort	Sample size	Demographics			Ref.

<sup>1</sup>The study of Sivaram *et al*<sup>[19]</sup> was not included in the meta-analyses as study participants were neither East Asian, nor Northern European or American Caucasians. IBD: Inflammatory bowel disease; UC: Ulcerative colitis; CD: Crohn's disease; NA: Not available.

The *MIF* CATT<sub>5-8</sub> repeat, was amplified in a total volume of 10 µL containing 2 mM dNTPs (Fisher Biotech), 2 mM MgCl<sub>2</sub>, 10% betaine (Sigma, St Louis, Missouri, United States), 0.5 µmol/L of the primers MIFrepf (5' FAM-gcctgtgatccagttgctgctgtgc3') and MIFrepr (5'ccac-taatgtaaaactcggggaccat3'), 1 U of Platinum Taq DNA Polymerase (Invitrogen, CA, United States), and 20 ng of genomic DNA. The forward primer, MIFrepf, was labelled to enable subsequent resolution on a DNA Analyzer (Applied Biosystems 3730xl DNA Analyzer). The polymerase chain reaction (PCR) conditions comprised an initial denaturation step of 2 min at 94 °C; followed by 30 cycles of 94 °C for 30 s, 65 °C for 30 s, 72 °C for 30 s; and a final extension step of 1 min at 72 °C. PCRs were diluted by the addition of 20 µL of water. Amplification of the *MIF* promoter was assessed by 3% agarose gel electrophoresis. To accurately size the PCR products and thus reliably assign CATT genotypes, 2 µL of each diluted PCR product was mixed with 1 µL of GeneScan™ 500 LIZ® Size Standard (Applied Biosystems, Foster City, CA, United States) and resolved on an ABI 3730xl DNA Analyzer. Samples containing 5, 6, 7, or 8 CATT repeats yielded PCR products of 152, 156, 160 and 164 bp, respectively. Genotyping results were then analysed using Peak Scanner™ Software version 1 (Applied Biosystems, Foster City, CA, United States). Accuracy of the TaqMan SNP and CATT assays was confirmed by repeat analysis of 10% of samples. The concordance between original and repeat genotypes was 100%.

### Association testing

The software package PLINK<sup>[24]</sup> was used to test for deviations from Hardy-Weinberg Equilibrium (HWE), and to conduct single marker and haplotype association tests. The statistical significance of the observed allele and genotype associations were determined by Pearson's  $\chi^2$ . Results were considered statistically significant if *P* was < 0.05. Bonferroni's correction was applied to adjust for multiple testing (0.05/18 tests, adjusted *P* < 0.0028). As CATT<sub>5</sub> is reported to have less promoter activity than longer repeat alleles<sup>[9,25]</sup>, tests of association were performed on full genotype and following simplification to 55, 5X or XX, where X = CATT<sub>6-8</sub>, as previously described<sup>[9,26,27]</sup>.

### Imputation and meta-analysis

All published studies of *MIF* -173G > C and *MIF* CATT<sub>5-8</sub> in IBD were identified using PubMed and subsequently searching the references of all PubMed-identified studies. Imputed genotypes for *MIF* -173G > C were generated from the Wellcome Trust Case Control Consortium (WTCCC)<sup>[28]</sup> and National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK) Crohn's disease (CD) datasets<sup>[29,30]</sup> using IMPUTE and the HapMap release [NCBI dbSNP Build 131 (Apr 2010, hg37.1)]. A quality threshold of 0.95 was set for imputation of both datasets.

Meta-analyses were conducted for the *MIF* SNP -173G > C in STATA (Stata Statistics/Data Analysis Software, version 8, Stata Corporation, Texas, United

States) using the Mantel-Haenszel (MH) method with either a random or a fixed effects model depending on the presence or absence respectively of significant heterogeneity between studies ( $P < 0.05$ ). Meta-analyses were considered significant if the pool MH  $P$  value was  $< 0.05$ . As published CATT<sub>5-8</sub> frequency data was limited to a single Japanese ulcerative colitis (UC) dataset<sup>[18]</sup>, meta-analysis was not conducted for this variant.

## RESULTS

### Single-site analysis of MIF polymorphisms

MIF-173G > C genotype was determined in 988 New Zealand patients (495 CD, 466 UC and 27 IBD-U) and 488 New Zealand controls, and CATT<sub>5-8</sub> genotype was determined in 975 New Zealand patients (476 CD, 473 UC and 26 IBD-U) and 535 New Zealand controls. The baseline characteristics of the cases are shown in Table 2. Genotype and allele frequencies are shown in Table 3 (MIF-173G > C) and Table 4 (MIF CATT<sub>5-8</sub>). No significant deviation from HWE was observed in the patients or controls. Single-site analysis found no evidence of association of MIF-173G > C or CATT<sub>5-8</sub>, and CD, UC or overall risk of IBD (Tables 3 and 4). Furthermore, neither polymorphism was significantly associated with age at first diagnosis, disease location, or disease behaviour (penetrating, stricturing or non-penetrating/non-stricturing) in our New Zealand dataset.

### Haplotype analysis

Nine hundred and fifty-seven New Zealand patients (CD 467, UC 464, IBD-U 26) and 483 New Zealand

controls were successfully genotyped for both MIF promoter polymorphisms. Haplotype analysis of these polymorphisms found the MIF CATT<sub>5</sub>/-173C haplotype occurred at a higher frequency in controls compared to IBD patients (0.6 *vs* 0.01;  $P = 0.03$ , OR = 0.22, 95%CI: 0.05-0.99). However, after bonferroni correction for multiple testing (0.05/18 tests) no association of haplotype with susceptibility to CD, UC or IBD, or with disease phenotype, behaviour or clinical course was found.

### Meta-analyses of MIF-173G > C in Caucasian and East Asian IBD datasets

Meta-analysis was undertaken in order to determine the overall influence of MIF -173G > C on IBD susceptibility in Caucasians and East Asians. Published summary genotype data were available for five Caucasian<sup>[12,14,16,17]</sup>, and three East Asian datasets<sup>[13,15,18]</sup>. In addition, MIF-173G > C genotypes were imputed from both the WTCCC and NIDDK Caucasian CD datasets. As the contribution that specific loci make to IBD susceptibility differs significantly with race, the East Asian and Caucasian datasets were meta-analysed separately. The Breslow-Day test revealed the existence of significant heterogeneity ( $P_{het} \leq 0.05$ ) among the Caucasian datasets but not among the East Asian datasets ( $P_{het} = 0.5$ ). As a result a random effects model was applied to the Caucasian meta-analysis whilst a fixed effects model was applied to the East Asian meta-analysis. No cumulative evidence of association of MIF -173G > C with UC, CD or all IBD risk was detected in either Caucasians or East Asians (Figure 1).

## DISCUSSION

### Functional effects of MIF polymorphisms

MIF is a pleiotropic pro-inflammatory cytokine implicated in the pathophysiology of numerous diseases including IBD<sup>[5,9,31-33]</sup>. Promoter polymorphisms in MIF influence both basal and disease-associated MIF expression, and MIF expression has been shown to have profound effects on disease phenotype in experimental models<sup>[5,7,34]</sup>. *In vitro* MIF -173C allele exhibits greater expression than the MIF -173G allele in T lymphoblast cells, and expression of MIF increases with increasing length of the CATT repeat in COS-7 fibroblast like cells<sup>[9]</sup>. Despite these effects on expression, previous association studies investigating these polymorphisms in IBD have given discordant results<sup>[12-19]</sup>.

### Previously reported associations of MIF-173G > C and CATT<sub>5-8</sub> polymorphisms with UC and CD

The MIF-173C allele has been significantly associated with increased UC susceptibility in Spanish and Polish datasets<sup>[16,17]</sup>, but not in German<sup>[14]</sup> or Indian<sup>[19]</sup> datasets. The MIF-173 C/C genotype was significantly associated with pan-colitis compared with left-sided or distal disease (OR = 10.78, 95%CI: 1.34-86.62.  $P = 0.0074$ ) in one Japanese UC dataset ( $n = 221$ )<sup>[15]</sup>, but not a second Japanese

<sup>a</sup>X = 6, 7, or 8 CATT repeats. IBD: Inflammatory bowel disease; UC: Ulcerative colitis; CD: Crohn's disease.

dataset<sup>[18]</sup>. With respect to the length polymorphism, *MIF* CATT<sub>5</sub>/CATT<sub>5</sub> genotype has been found to confer a

protective effect against IBD in Japanese individuals aged over 20 years (OR = 0.33, 95%CI: 0.14-0.82. *P* = 0.013)<sup>[18]</sup>,

**Figure 1 Meta-analyses of migration inhibitory factor-173G > C in Caucasian and East Asian inflammatory bowel disease datasets.** Meta-analyses of migration inhibitory factor (MIF)-173G > C were performed by the Mantel-Haenszel method using a random effects model. On each Forest plot the 95%CI of the individual datasets are represented by horizontal lines and the total number of study participants in each dataset is proportional to the size of the square. The diamond represents the pooled OR with 95%CI delineated by the diamond's width. A: The combined Caucasian ulcerative colitis (UC) dataset; B: The combined East Asian UC datasets; C: The combined Caucasian Crohn's disease dataset had 100% power to detect an effect size of OR = 1.40 at  $\alpha = 0.05$ .

whilst the CATT<sub>7</sub>/CATT<sub>7</sub> genotype was significantly associated with both a chronic continuous phenotype (OR = 5.49, 95%CI: 1.19-25.3,  $P = 0.015$ ) and distal disease location (OR = 6.10, 95%CI: 1.32-28.3,  $P = 0.0091$ ) in Japanese subjects. However, no association of CATT repeat length with UC risk was observed in two Spanish datasets<sup>[16]</sup>.

The story is similar for CD. Of the previous studies to have investigated the association between *MIF*-173G > C and CD, four found no association<sup>[12,13,16,17]</sup>, and one reported a protective effect of the minor allele, *MIF*-173C<sup>[14,16]</sup>. Furthermore, in one dataset, despite no association with overall CD susceptibility, further analysis revealed *MIF*-173C influenced CD phenotype; conferring a protective effect against the development of upper GI CD (OR = 0.31, 95%CI: 0.118-0.789,  $P = 0.01$ )<sup>[12]</sup>.

### *MIF* promoter polymorphisms in New Zealand Caucasians

Our study sought to resolve the discordance observed between previous investigations by conducting the single largest Caucasian dataset (1006 New Zealand cases, 540 New Zealand controls) study of *MIF* promoter polymorphisms, and employing meta-analysis. Single-site analysis found no evidence of association of *MIF* promoter polymorphisms with overall IBD susceptibility in New Zealand Caucasians. Haplotype analysis found preliminary evidence that a rare haplotype, CATT<sub>5</sub>-173C, which is the least active haplotype *in vitro*<sup>[9]</sup>, confers protection against IBD (OR = 0.22, 95%CI: 0.05-0.99,  $P_{unadjusted} = 0.03$ ). However, as the functional effects of *MIF* promoter polymorphisms are cell type specific and relevant experiments in monocytes, the primary cell type responsible for MIF dependent mucosal inflammation in IBD are lacking, no firm conclusions can be drawn from these observations<sup>[5]</sup>.

### Meta-analyses of *MIF*-173G > C in Caucasians and East Asians

Subsequent meta-analyses with additional Caucasian CD (3373 patients, 5543 controls), Caucasian UC (794 patients, 1499 controls), and Asian UC (416 patients, 789 controls) datasets also detected no association of *MIF*-173G > C with CD or UC in Caucasians, or with UC in East Asians (Figure 1). However, our Caucasian meta-analysis is limited by the presence of significant heterogeneity among the datasets, thus it is not possible to completely rule out the possibility that *MIF* promoter polymorphism may alter susceptibility to IBD in some Caucasian populations. In contrast, no significant heterogeneity was detected in the East Asian datasets ( $P_{het} = 0.50$ ), therefore the discordance previously observed is likely to be due to sample size rather than to differences in baseline characteristics of the study participants.

In conclusion, based on the results of our study, neither *MIF*-173G > C nor *MIF* CATT<sub>5-8</sub> are risk factors for IBD in New Zealand Caucasians, nor is *MIF*-173G > C a risk factor for UC in East Asians. The results of meta-

analysis do not support *MIF*-173G > C as a susceptibility factor for IBD in Caucasian datasets however, because significant heterogeneity exists between the populations investigated, the possibility that a significant effect exists in a subgroup of these populations cannot be excluded. Additional well-powered studies in European Caucasian datasets would be required to clarify this point.

## ACKNOWLEDGMENTS

We thank the people of Canterbury with IBD who generously gave of their time to take part in the study. We also thank Rhondda Brown and Judy Hoar for their assistance in coordinating the recruitment of patients to the Canterbury IBD dataset; Pip Shirley, Meagan Reilley, David Tan, Ramez Ailabouni and Charlotte Duncan for entering patient details into the clinical database. We are also very grateful to Dr. Michael Black for his expert review of our statistical analysis and manuscript. This study makes use of data generated by the Wellcome Trust Case-Control Consortium. A full list of the investigators who contributed to the generation of the data is available from [www.wtccc.org.uk](http://www.wtccc.org.uk). Funding for the project was provided by the Wellcome Trust under award 076113 and 085475. The NIDDK IBD Genetics Consortium CD Genome-Wide Association Study was conducted and supported by the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK). This manuscript was not prepared in collaboration with Investigators of the NIDDK IBD Genetics Consortium CD Genome-Wide Association Study and does not necessarily reflect the opinions or views of the NIDDK IBD Genetics Consortium CD Genome-Wide Association Study or the NIDDK.

## COMMENTS

### Background

Macrophage migration inhibitory factor (MIF) is a pro-inflammatory cytokine implicated in the pathophysiology of inflammatory arthritis, systemic lupus erythematosus, atherosclerosis, and cancer. Evidence from animal models and human inflammatory bowel disease (IBD) indicates that MIF is also an important mediator of IBD; however few studies have considered its mechanism of action in these diseases. In recent years, evidence regarding the role of MIF in inflammatory disease has accumulated rapidly, and efforts have subsequently turned to the development of specific anti-MIF therapies for use in human disease.

### Research frontiers

An international phase one trial of a neutralizing anti-MIF antibody is currently underway for lupus nephritis. On this background authors believe that critical appraisal of the role of MIF in IBD is needed in order for IBD patients to benefit from developments in this field. Two functional variants of the *MIF* promoter region have been identified. Despite clear association with other inflammatory diseases, the contribution of these polymorphisms to IBD risk and phenotype remains uncertain due to previous studies being under-powered.

### Innovations and breakthroughs

This paper describes the largest single cohort study of *MIF* promoter polymorphisms to date, as well as meta-analysis of all available genotype data on Caucasians and East Asians. Their population based cohort study had 93% power, and the meta-analyses 100% power, to detect an effect size of OR = 1.40 ( $\alpha = 0.05$ ). They found no evidence of association of *MIF* promoter polymorphisms with IBD.

### Applications

This study is important as it provides clear evidence that genetic variants of MIF

do not influence IBD susceptibility. Their findings are in agreement with recent research that indicates the contribution of MIF to IBD pathophysiology is not determined at the level of nuclear transcription.

### Peer review

The role of MIF in the pathogenesis of IBD has been intensively discussed during last couple of years, including the promoter polymorphism of this gene. It is also seen as one of the possible novel therapeutic targets for the management of IBD. The group has contributed to the research in this field by contributing data about the prevalence of the MIF promoter polymorphism in large population of patients and healthy controls. Furthermore, they have meta-analyzed this new data with previously published data, and concluded that there is no evidence of association of *MIF* promoter polymorphisms with IBD. Paper is well structured, comprehensive and clearly written.

### Abstract

**AIM:** To compare the effects of entecavir (ETV) and lamivudine (LAM) for the treatment of hepatitis B decompensated cirrhosis using a meta-analysis.

**METHODS:** We conducted a literature search for all eligible studies published prior to May 30, 2013 using PUBMED, MEDLINE, EMBASE, the China National Knowledge Infrastructure (CNKI), the VIP database, the Wanfang database and the Cochrane Controlled Trial Register. Randomized controlled trials (RCTs) comparing ETV with LAM for the treatment of hepatitis B decompensated cirrhosis were included. The data were analyzed with Review Manager Software 5.0.2. We used RR as an effect measure, and reported its 95%CI. The meta-analysis was performed using either a fixed-effect or random-effect model, based on the absence or presence of significant heterogeneity. Two reviewers assessed the risk of bias and extracted data independently and in duplicate. The analysis was executed using the main outcome parameters including

hepatitis B virus (HBV) DNA undetectability, HBV DNA level, hepatitis B e antigen (HBeAg) seroconversion, alanine aminotransferase (ALT) level, albumin level, total bilirubin (TBIL) level, prothrombin time activity (PTA) level, Child-Turcotte-Pugh (CTP) score, mortality, drug-resistance, and adverse reactions. Meta-analysis of the included trials and subgroup analyses were conducted to examine the association between pre-specified characteristics and the therapeutic effects of the two agents.

**RESULTS:** Thirteen eligible trials (873 patients in total) were included and evaluated for methodological quality and heterogeneity. Of these studies, all had baseline comparability, 12 of them reported baseline values of the two treatment groups in detail. Following various treatment durations (12, 24, 36, 48 and > 48 wk), both ETV and LAM significantly reduced HBV DNA level, however, reductions were greater in the ETV group (MD = -0.66, 95%CI: -0.83-0.50,  $P < 0.00001$ ), (MD = -0.93, 95%CI: -1.36-0.51,  $P < 0.00001$ ), (MD = -1.4, 95%CI: -1.78-1.01,  $P < 0.00001$ ), (MD = -1.18, 95%CI: -1.90-0.46,  $P = 0.001$ ), (MD = -0.14, 95%CI: -0.17-0.11,  $P < 0.00001$ , respectively). At 12, 24 and 48 wk of treatment, ETV had a significant effect on the rate of HBV DNA undetectability (RR = 1.55, 95%CI: 1.22-1.99,  $P = 0.0004$ ), (RR = 1.25, 95%CI: 1.13-1.38,  $P < 0.0001$ ), (RR = 1.2, 95%CI: 1.10-1.32,  $P < 0.0001$ , respectively). Although HBeAg seroconversion in the ETV group was more pronounced than that in the LAM group at 24 wk (27.90% vs 26.19%) and 48 wk (31.52% vs 25.00%) of treatment, there was no statistically significant difference between them (RR = 1.49, 95%CI: 0.98-2.28,  $P = 0.07$ ), (RR = 1.27, 95%CI: 0.98-1.65,  $P = 0.07$ , respectively). Following various treatment durations, both the ETV group and the LAM group showed significantly improved liver function (ALT, AIB, TBIL, PTA and CTP levels) and reduced mortality (ETV 6.37%, LAM 7.89%). The effects in the ETV group (0.33%) were statistically lower than those in the LAM group (14.33%) regarding the rate of drug-resistance (RR

= 0.1, 95%CI: 0.04-0.24,  $P \leq 0.00001$ ). In addition, no severe adverse reactions were observed in the two treatment groups.

**CONCLUSION:** ETV and LAM significantly improved liver function and reduced mortality. Both drugs produced similar serological responses, and were safe and well tolerated. However, ETV resulted in a better virological response and lower drug-resistance, but is more expensive.

**Key words:** Hepatitis B; Decompensated cirrhosis; Entecavir; Lamivudine; Randomized controlled trial; Meta-analysis.

**Core tip:** This meta-analysis was conducted to compare the effects of entecavir (ETV) and lamivudine (LAM) in the treatment of hepatitis B associated decompensated cirrhosis. The results suggested that ETV and LAM significantly improved liver function and reduced mortality. Both drugs produced similar serological responses, and were safe and well tolerated. However, LAM had higher drug-resistance and is therefore unsuitable for the long-term treatment of patients with hepatitis B decompensated cirrhosis. ETV can be used as the first-line drug for long-term treatment of patients with hepatitis B decompensated cirrhosis as it has stronger anti-viral activity and extremely low drug-resistance.

Ye XG, Su QM. Effects of entecavir and lamivudine for hepatitis B decompensated cirrhosis: Meta-analysis. *World J Gastroenterol* 2013; 19(39): 6665-6678 Available from: URL: <http://www.wjg-net.com/1007-9327/full/v19/i39/6665.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6665>

## INTRODUCTION

The treatment of chronic hepatitis B (CHB) is a major healthcare problem affecting over 350 million people worldwide<sup>[1]</sup>. Approximately 25%-40% of infected patients will develop various life-threatening conditions such as liver failure, liver cirrhosis (LC) and hepatocellular carcinoma (HCC). The 5-year survival rate is 84% in patients with compensated cirrhosis, but decreases to 14%-35% in individuals with decompensated cirrhosis<sup>[2]</sup>. Antiviral therapy is now considered to be the most important measure to prevent further development of this disease. Rapid and effective antiviral therapy can not only improve liver function and clinical symptoms as well as postpone progression to LC, but can also reverse the process of LC, prolong survival time and improve the quality of life. Some researchers have shown that mortality due to hepatitis B virus (HBV) and LC was positively correlated<sup>[3,4]</sup>. As interferon is prohibited for the treatment of decompensated cirrhosis, nucleosides

or nucleoside analogues have become the primary drugs for antiviral therapy. Entecavir (ETV) is currently the strongest nucleoside analogue and the first-line drug for hepatitis B. It has the advantages of low drug-resistance and high safety, thus it is suitable for long-term use. However, due to its higher cost, the long-term use of ETV results in heavy financial pressures for patients with hepatitis B decompensated cirrhosis and their families. Lamivudine (LAM) is a moderate strength nucleoside analogue, and has high resistance following long-term use, which leads to treatment failure. However, due to its lower cost, LAM has a pharmacoeconomic advantage. Although there have many studies conducted on the efficacy of ETV compared with LAM for the treatment of patients with hepatitis B decompensated cirrhosis, there are few systematic reviews on this topic<sup>[5]</sup>. The roles of the two drugs in hepatitis B decompensated cirrhosis are not yet completely clear. Therefore, we conducted a meta-analysis of randomized controlled trials (RCTs) using the Cochrane methodology and explored the efficacy of ETV compared with LAM in patients with hepatitis B decompensated cirrhosis.

## MATERIALS AND METHODS

### Literature search

We searched PUBMED, MEDLINE, EMBASE, CNKI (China National Knowledge Infrastructure), the VIP database, the Wanfang database and the Cochrane Controlled Trial Register for the relevant studies published up to May 30, 2013. The following keywords were used for the search: "hepatitis B", "decompensated cirrhosis", "entecavir", "lamivudine", and "RCTs". The reference lists of eligible studies were also searched. The language of the trials was not limited.

### Inclusion criteria

The following inclusion criteria were used: (1) RCTs; (2) Articles studying hepatitis B decompensated cirrhosis patients, who were included in Chinese articles according to the diagnostic standards of the China guidelines for HBV management (2005)<sup>[6]</sup>, in foreign articles diagnosis was based on clinical, biochemical, radiological and histological responses, and a Child-Turcotte-Pugh (CTP) score  $\geq 7$ ; (3) Studies comparing the treatment methods of ETV (0.5 mg/d) and LAM (100 mg/d). Both groups were given symptomatic treatment and conventional treatment; and (4) The main outcome parameters included the rate of HBV DNA undetectability, HBV DNA level, hepatitis B e antigen (HBeAg) seroconversion, alanine aminotransferase (ALT) levels, albumin (ALB) levels, total bilirubin (TBIL) levels, prothrombin time activity (PTA) levels, CTP score, mortality, drug-resistance, and adverse reactions.

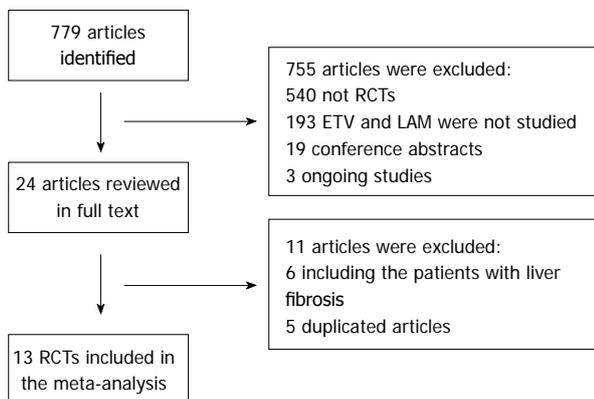

### Exclusion criteria

The following exclusion criteria were used: (1) Non-RCTs; (2) Insufficient analytical information regarding

**Table 1** Characteristics of included randomized controlled trials

Trial	Sample size (n)		mean age (yr)		Regimen		Duration (wk)	Observation time (wk)	Outcome parameters	Jadad scores

treatment schedule, follow-up, and outcomes; (3) Receiving interferon, nucleosides or nucleotides for CHB within 6 mo of the trial; (4) Coinfection with hepatitis A, C, D, E virus, cytomegalovirus, or HIV; and (5) Patients with liver failure, HCC, and liver-related complications caused by alcoholism, autoimmune disease, and cholestasis.

### Data extraction

Data extraction was assessed independently by two reviewers (Song LY and Zhang SR). Discrepancies among reviewers were resolved by discussions between the reviewers or by a third person (Ou-Yang RJ). Basic information obtained from each eligible trial included the study design (randomization, allocation concealment, blinding method, description of withdrawals and dropouts), patient characteristics, numbers in each group, related study results and treatment duration. Data were reviewed to eliminate duplicate reports of the same trial.

### Statistical analysis

We used Review Manager Software 5.0.2 (Cochrane Col-

laboration, Oxford, United Kingdom) to carry out data analysis. We used RR as an effect measure for dichotomous data, mean difference (MD) as an effect measure for continuous data, and reported their 95%CI. The meta-analysis was performed using a fixed-effect or random-effect model, based on the absence or presence of significant heterogeneity.

Statistical heterogeneity between trials was evaluated by  $\chi^2$  and  $I^2$  analysis. The fixed-effect method was used in the absence of statistically significant heterogeneity ( $P \geq 0.1$ ), the random-effect method was used when the heterogeneity test was statistically significant ( $P < 0.1$ ). A value of  $P < 0.05$  was regarded as statistically significant. We used subgroup analyses to examine the association of pre-specified characteristics (treatment duration) with treatment effect, sensitivity analysis was used to estimate the stability of the results, and funnel plots were used to assess publication bias if more than five trials were included<sup>[7]</sup>.

## RESULTS

### Characteristics and quality of studies

The process of identifying the included trials is presented in Figure 1. We initially identified 779 abstracts, and after evaluating the full texts, we included 13 trials (12 in Chinese and 1 in English) based on the pre-specified criteria. A total of 873 patients were included in the study: 423 treated with ETV and 450 treated with LAM. Table 1 shows the characteristics of the 13 trials. Of these studies, all showed baseline comparability, 12 of them reported the baseline values of the two groups in detail, 1 only referred to the two groups as having no significant differences in gender, age and duration<sup>[12]</sup>. One described the method of randomization in detail<sup>[9]</sup>, 9 referred to randomization, but did not describe the method of randomization in detail<sup>[8,11-15,18-20]</sup>. None of the trials referred to allocation concealment and blinding method. Six described the reasons for withdrawals and dropouts<sup>[8,12-14,16]</sup>. Quality

assessment of the trials was performed with Jadad scores that ranged between 1 and 5<sup>[21]</sup>. Based on these scores, 10 trials were of high quality ( $\geq 3$  scores)<sup>[8-12,14,16,18-20]</sup>, and 3 trials were of inferior quality ( $< 3$  scores)<sup>[13,15,17]</sup>.

### HBV DNA undetectability

In this analysis, 8 trials reported rates of HBV DNA undetectability. According to  $\chi^2$  and  $I^2$  analyses, heterogeneity was observed ( $\chi^2 = 40.42$ ,  $P = 0.03$ ,  $I^2 = 38\%$ ); therefore, we used the random-effect method to analyze the data. At 12, 24 and 48 wk of treatment, the rate of HBV DNA undetectability was higher in the ETV group than in the LAM group, and the difference between the two groups was statistically significant [(RR = 1.55, 95%CI: 1.22-1.99,  $P = 0.0004$ ), (RR = 1.25, 95%CI: 1.13-1.38,  $P < 0.0001$ ), (RR = 1.2, 95%CI: 1.10-1.32,  $P < 0.0001$ , respectively)], while at 36 and  $> 48$  wk, the rate of HBV DNA undetectability between the two groups was similar, and no statistically significant differences were observed [(RR = 1.21, 95%CI: 0.92-1.59,  $P = 0.18$ ), (RR = 1.27, 95%CI: 0.98-1.64,  $P = 0.07$ ), respectively] (Figure 2A).

### HBV DNA levels

In this analysis, 8 trials reported HBV DNA levels. According to  $\chi^2$  and  $I^2$  analyses, heterogeneity was observed ( $\chi^2 = 1274.13$ ,  $P < 0.00001$ ,  $I^2 = 99\%$ ); therefore, we used the random-effect method to analyze the data. At 12, 24, 36, 48, and  $> 48$  wk, HBV DNA levels were lower in the ETV group than in the LAM group, and the difference between the two groups was statistically significant [(MD = -0.66, 95%CI: -0.83-0.50,  $P < 0.00001$ ), (MD = -0.93, 95%CI: 1.36-0.51,  $P < 0.0001$ ), (MD = -1.4, 95%CI: -1.78-1.01,  $P < 0.00001$ ), (MD = -1.18, 95%CI: -1.90-0.46,  $P = 0.001$ ), (MD = -0.14, 95%CI: -0.17-0.11,  $P < 0.00001$ ), respectively] (Figure 2B).

### HBeAg seroconversion

In this analysis, 7 trials reported the rate of HBeAg seroconversion. According to  $\chi^2$  and  $I^2$  analyses, heterogeneity was not observed ( $\chi^2 = 6.88$ ,  $P = 0.87$ ,  $I^2 = 0\%$ ); therefore, we used the fixed-effect method to analyze the data. At 12 wk, the rate of HBeAg seroconversion was higher in the ETV group than in the LAM group, and the difference between the two groups was statistically significant (RR = 2.05, 95%CI: 1.06-3.98,  $P = 0.03$ ), while at 24 and 48 wk, the rate of HBeAg seroconversion in the two groups was similar, and no statistically significant differences were observed. [(RR = 1.49, 95%CI: 0.98-2.28,  $P = 0.07$ ), (RR = 1.27, 95%CI: 0.98-1.65,  $P = 0.07$ ), respectively] (Figure 2C).

### ALT levels

In this analysis, 7 trials reported ALT levels. According to  $\chi^2$  and  $I^2$  analysis, heterogeneity was observed ( $\chi^2 = 110.78$ ,  $P < 0.00001$ ,  $I^2 = 89\%$ ); therefore, we used the random-effect method to analyze the data. At 48 wk, ALT levels were lower in the ETV group than in the LAM group, and the difference was statistically significant

(MD = -9.74, 95%CI: -17.87-1.61,  $P = 0.02$ ), while at 12, 24 and  $> 48$  wk, ALT levels in the two groups were similar, and no statistically significant differences were observed [(MD = -3.72, 95%CI: -8.7-1.26,  $P = 0.14$ ), (MD = -5.73, 95%CI: -15.52-4.06,  $P = 0.25$ ), (MD = -1.07, 95%CI: -15.73-13.59,  $P = 0.89$ ), respectively] (Figure 2D).

### ALB levels

In this analysis, 5 trials reported ALB levels. According to  $\chi^2$  and  $I^2$  analysis, heterogeneity was observed ( $\chi^2 = 89.49$ ,  $P < 0.00001$ ,  $I^2 = 91\%$ ); therefore, we used the random-effect method to analyze the data. At  $> 48$  wk, ALB levels were higher in the ETV group than in the LAM group, and the difference was statistically significant (MD = 1.84, 95%CI: -0.47-4.15,  $P = 0.0001$ ), while at 12, 24 and 48 wk, ALB levels in the two groups were similar, and no statistically significant differences were observed [(MD = -3.43, 95%CI: -14.3-7.45,  $P = 0.54$ ), (MD = 0.15, 95%CI: -0.94-1.25,  $P = 0.78$ ), (MD = 3.83, 95%CI: -0.11-7.77,  $P = 0.06$ ), respectively] (Figure 2E).

### TBIL levels

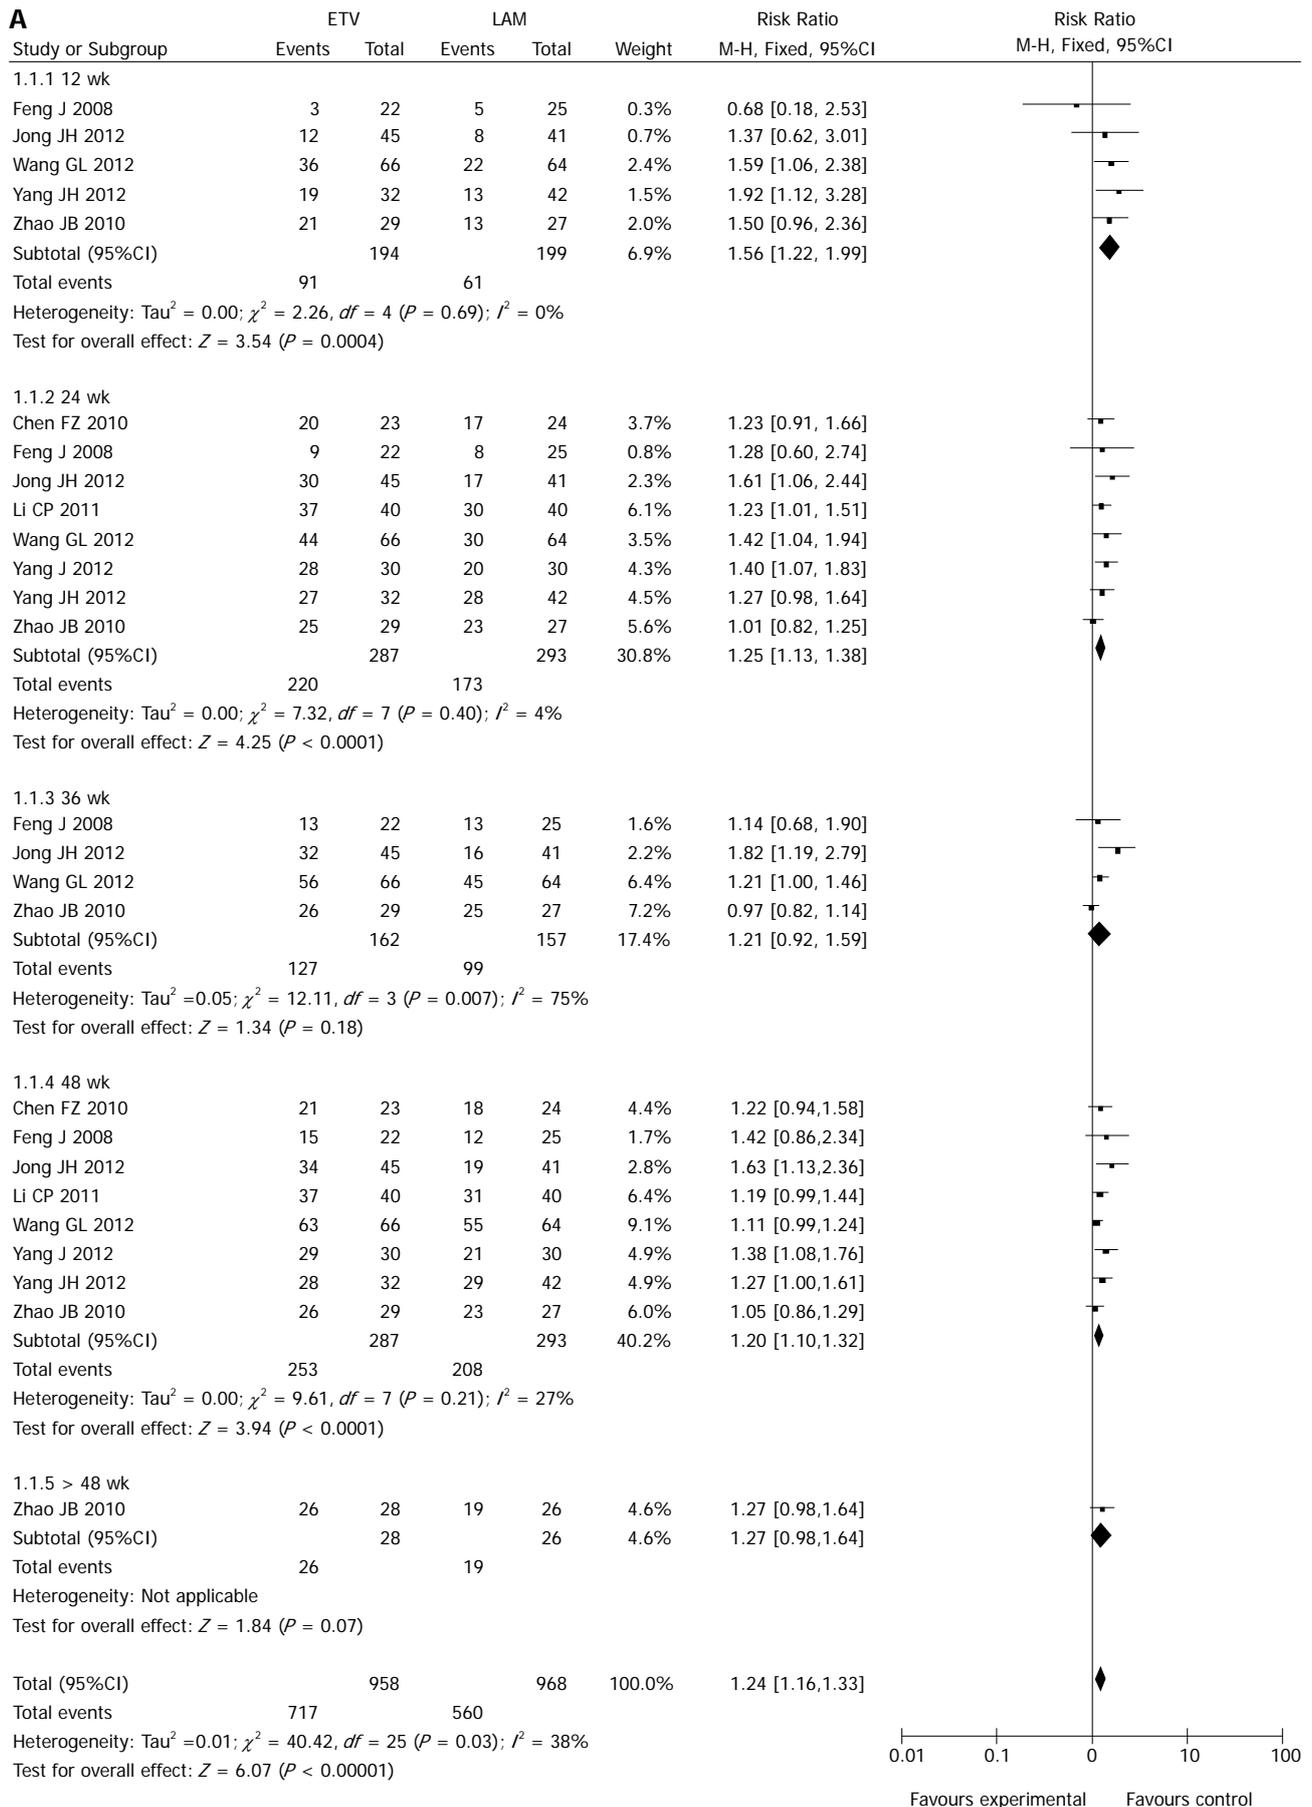

In this analysis, 5 trials reported TBIL levels. According to  $\chi^2$  and  $I^2$  analysis, heterogeneity was observed ( $\chi^2 = 29.21$ ,  $P \leq 0.00001$ ,  $I^2 = 90\%$ ); therefore, we used the random-effect method to analyze the data. At 12, 24 and 48 wk, TBIL levels were lower in the ETV group than in the LAM group, and the difference was statistically significant [(MD = -6.21, 95%CI: -8.86-3.57,  $P < 0.00001$ ), (MD = -6.61, 95%CI: -8.42-4.81,  $P < 0.00001$ ), (MD = -11.51, 95%CI: -17.18-5.84,  $P < 0.0001$ ), respectively], while at  $> 48$  wk, TBIL levels in the two groups were similar, and no statistically significant difference was observed (MD = -1.43, 95%CI: -10.52-7.66,  $P = 0.76$ ) (Figure 2F).

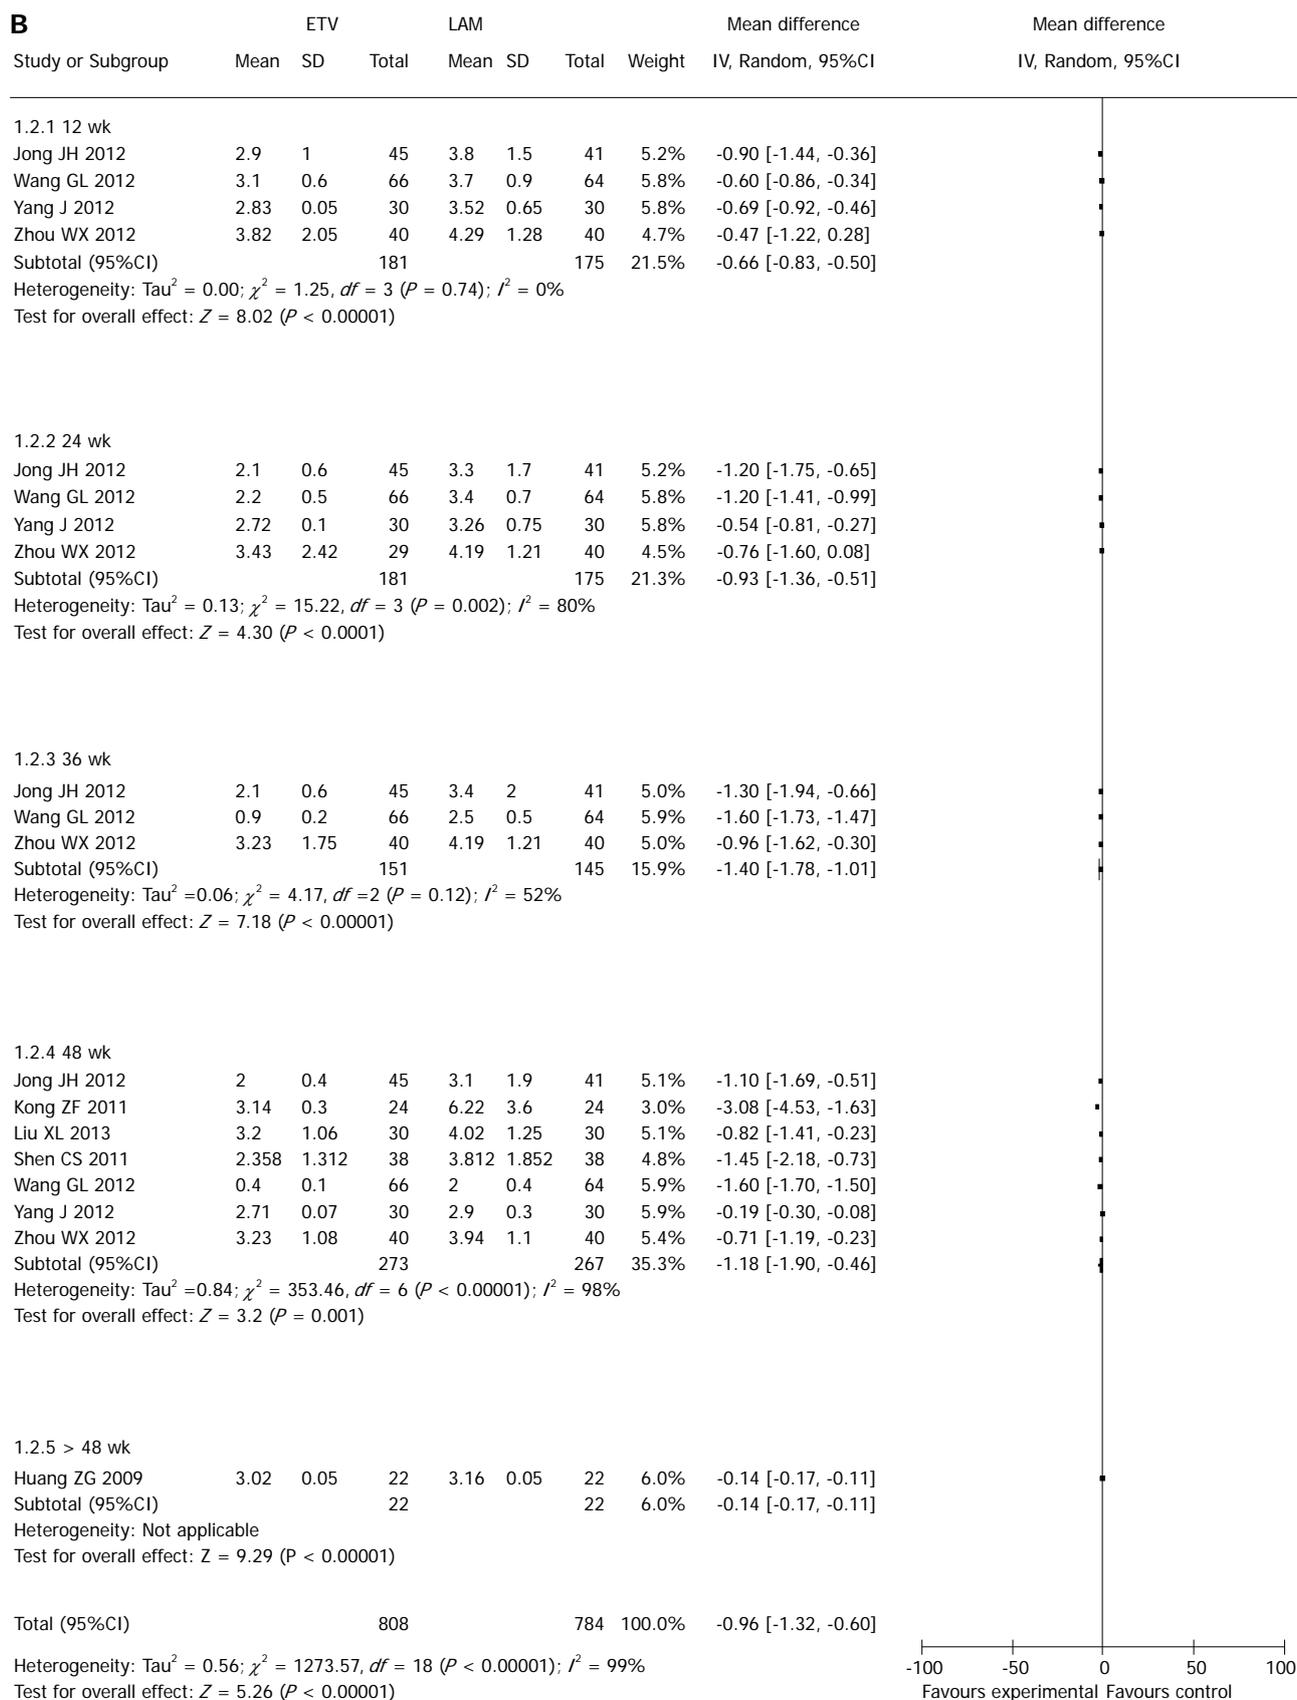

### PTA levels

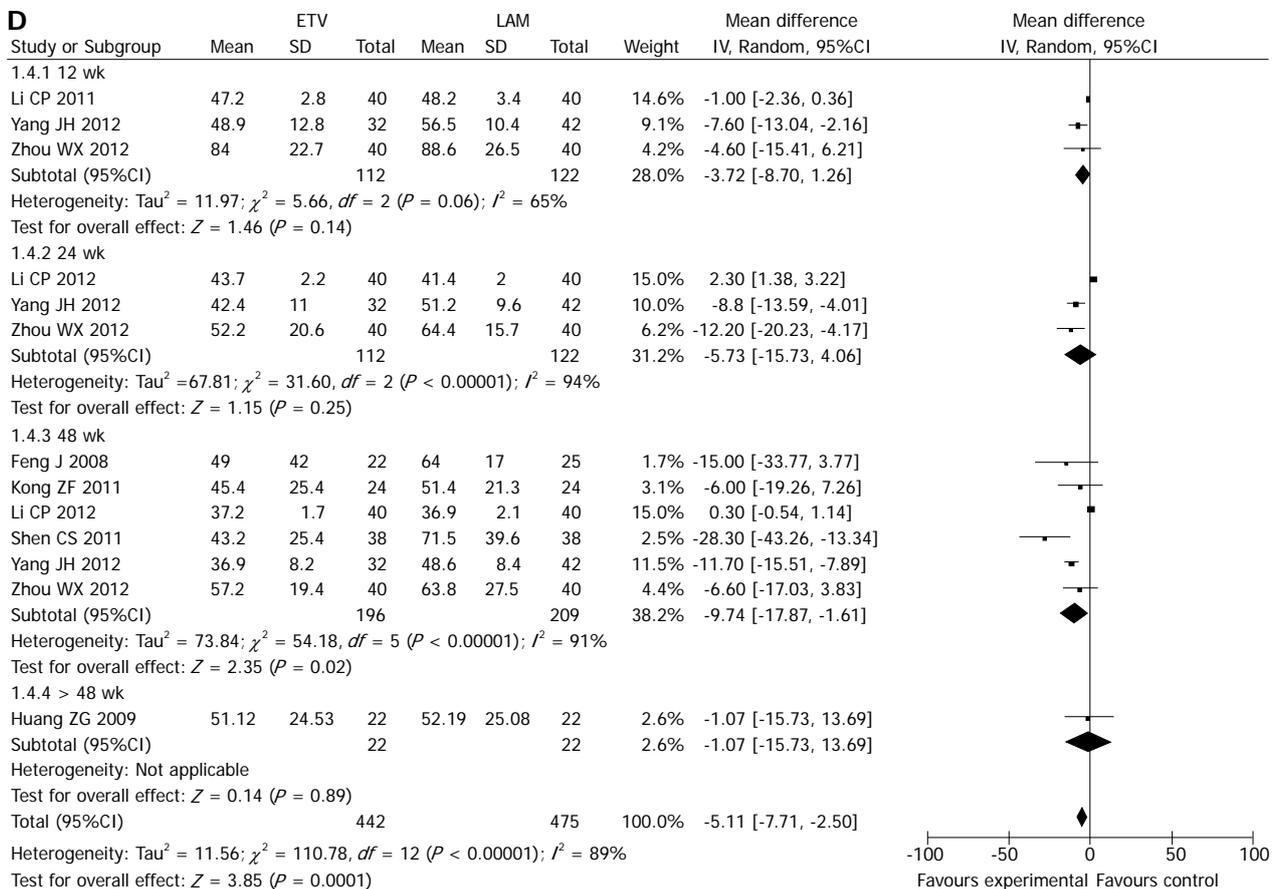

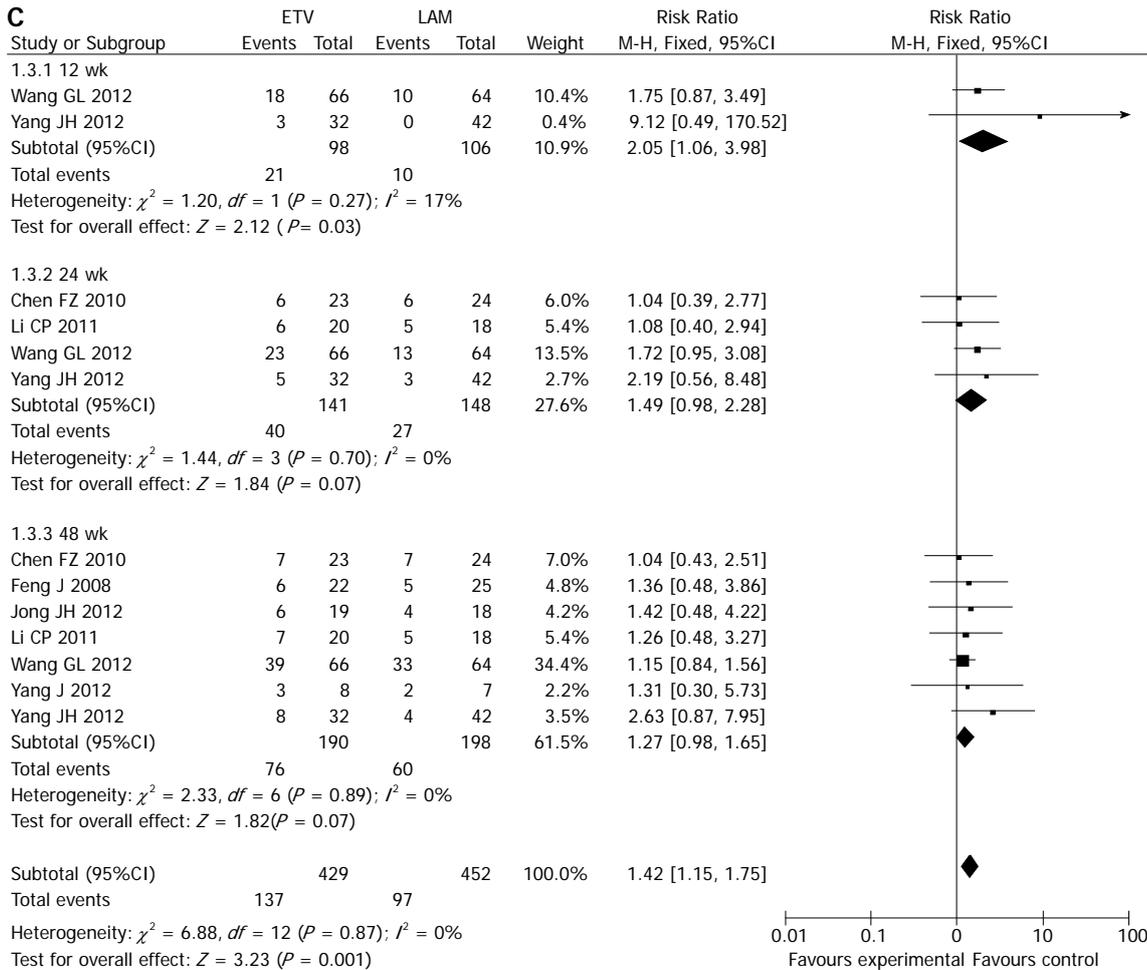

In this analysis, 4 trials reported PTA levels. According to  $\chi^2$  and  $I^2$  analysis, heterogeneity was observed ( $\chi^2 = 0.42$ ,  $P = 1.0$ ,  $I^2 = 0\%$ ); therefore, we used the fixed-effect method to analyze the data. At 12 and 24 wk, PTA levels were higher in the ETV group than in the LAM group, and the differences were statistically significant [(MD = 2, 95%CI: 0.26-3.74,  $P = 0.02$ ), (MD = 2.09, 95%CI: 0.29-3.88,  $P = 0.02$ ), respectively], while at 48 and  $> 48$  wk, PTA levels in the two groups were similar, and no statistically significant differences were observed [(MD = 1.68, 95%CI: -1.19-4.54,  $P = 0.25$ ), (MD = -0.40, 95%CI: -9.44-8.64,  $P = 0.93$ ), respectively] (Figure 2H).

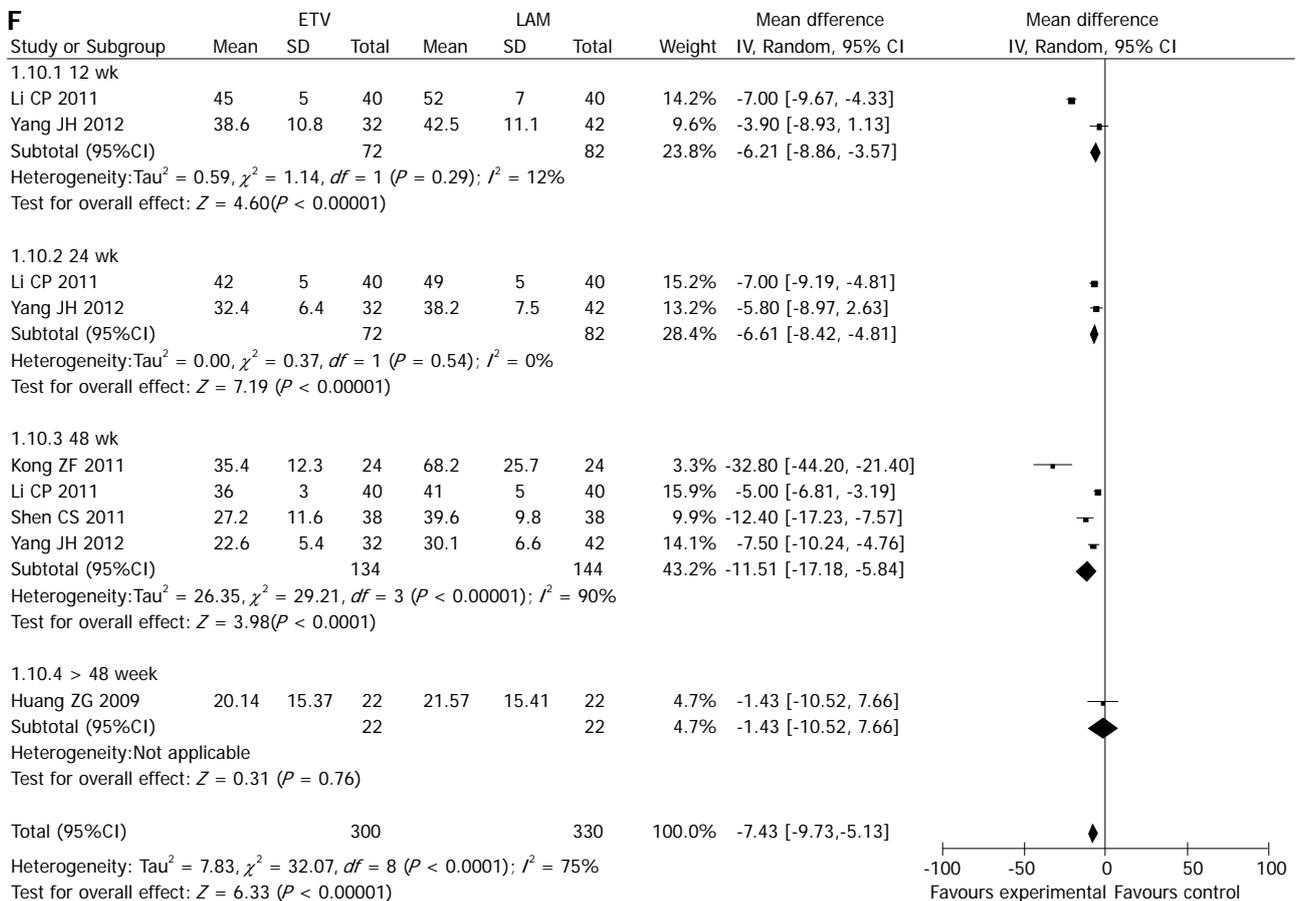

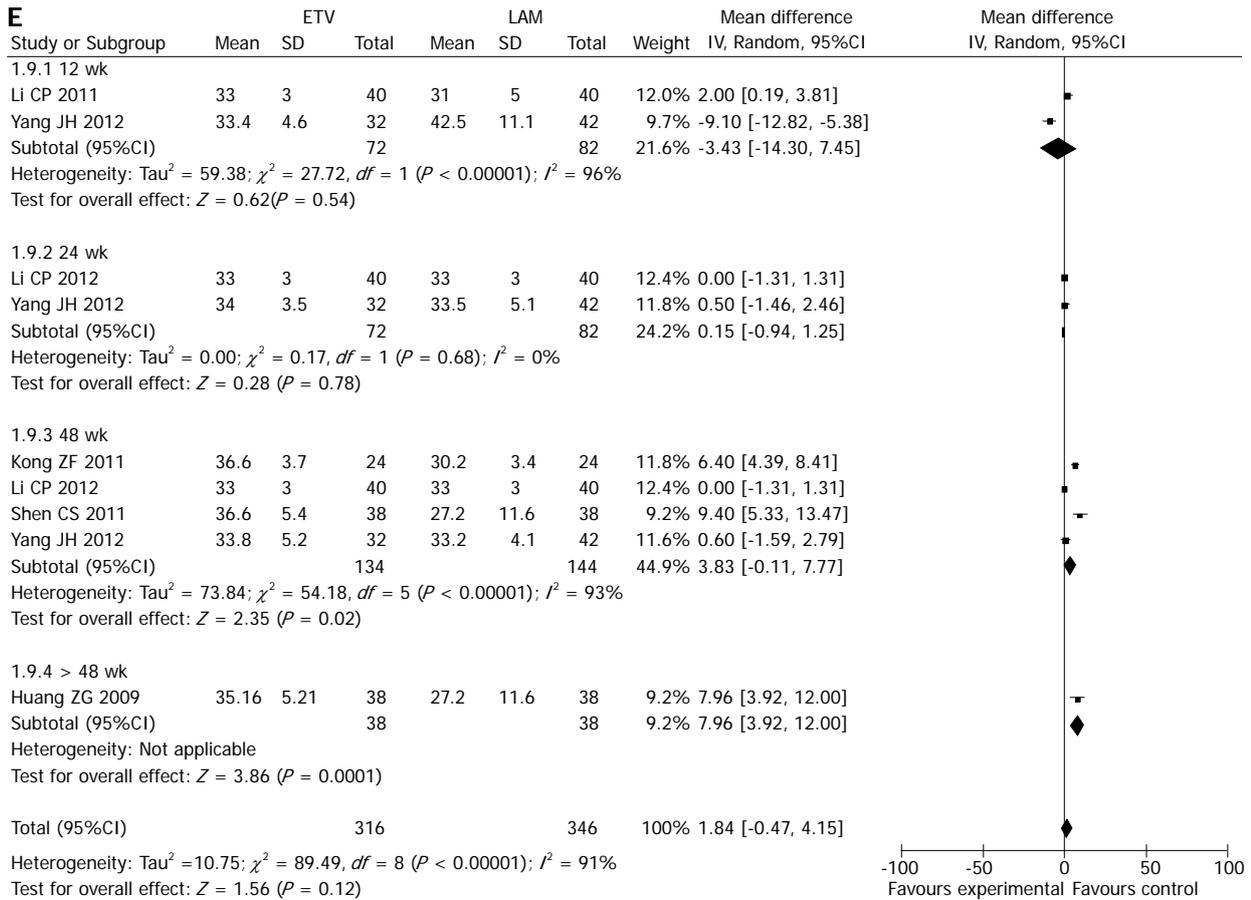

### CTP score

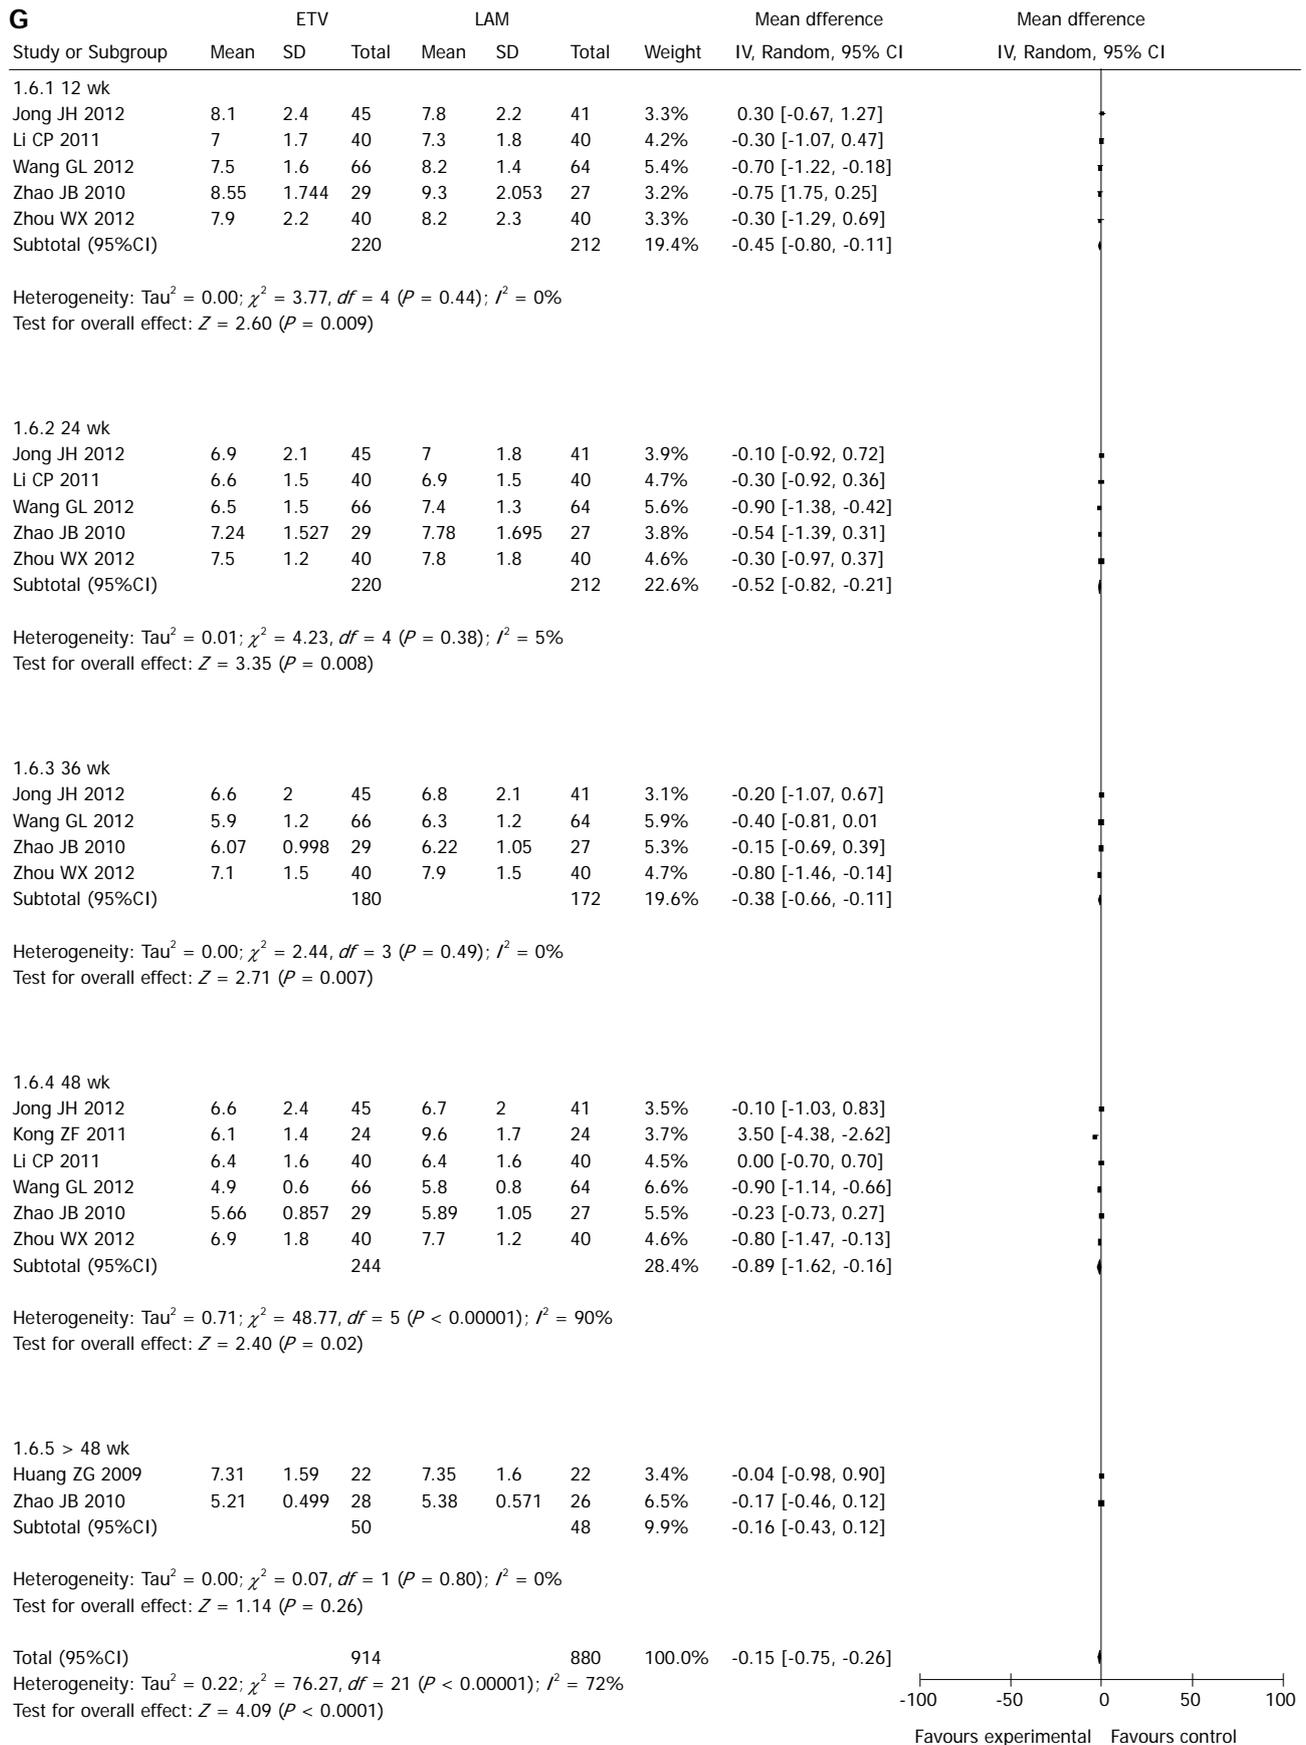

In this analysis, 7 trials reported the CTP score. According to  $\chi^2$  and  $I^2$  analysis, heterogeneity was observed ( $\chi^2 = 76.27$ ,  $P < 0.00001$ ,  $I^2 = 72\%$ ); therefore, we used the random-effect method to analyze the data. At 12, 24, 36 and 48 wk, the CTP score was lower in the ETV group than in the LAM group, and the differences were statistically significant [(MD = -0.45, 95%CI: -0.80-0.11,  $P =$

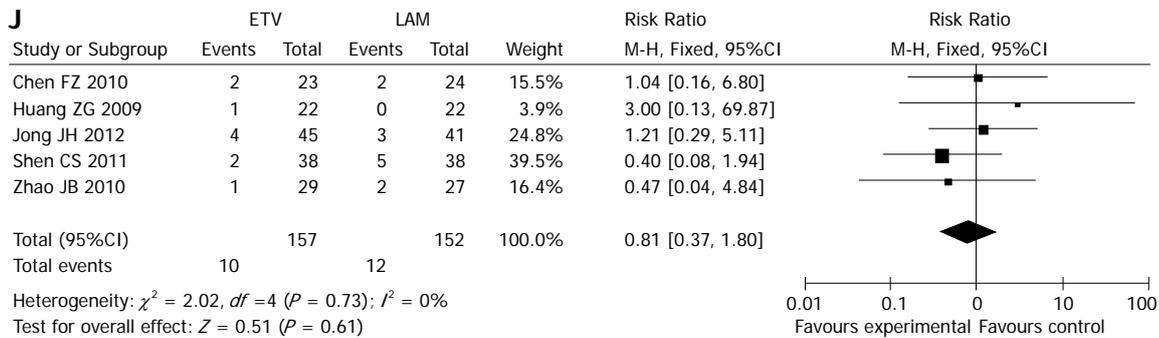

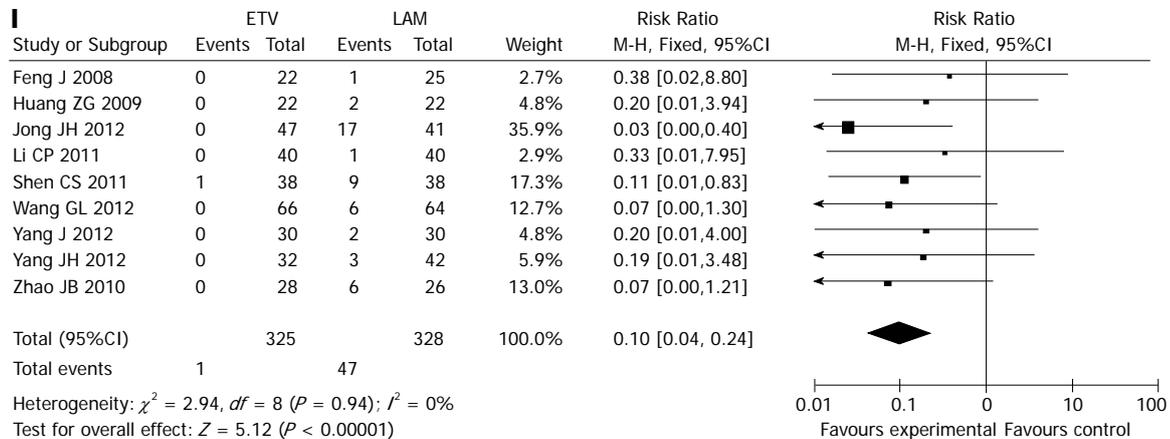

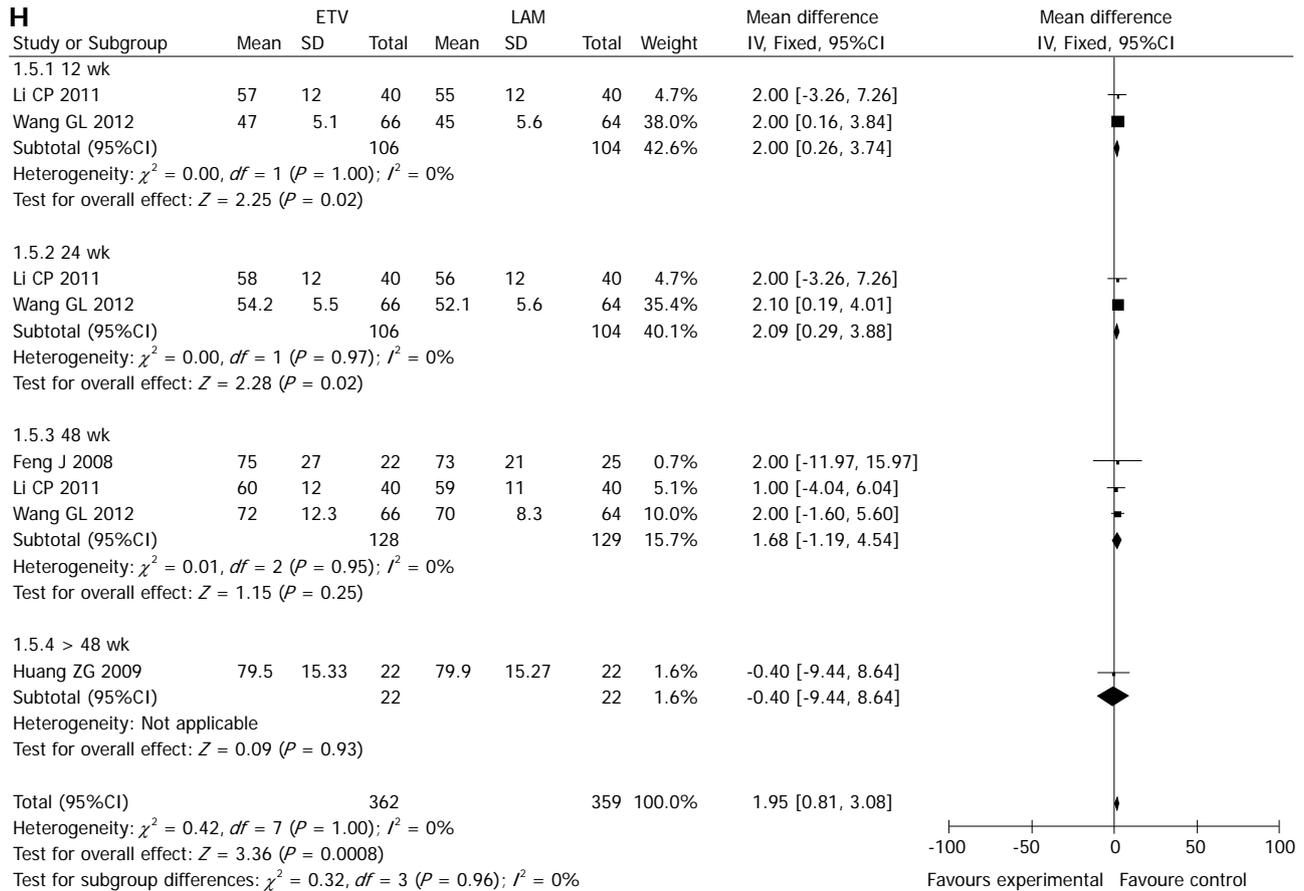

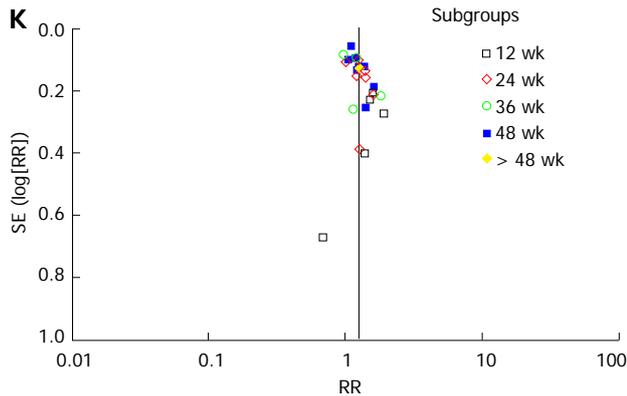

**Figure 2** Meta-analysis. A: Hepatitis B virus (HBV) DNA undetectability in the two treatment groups; B: HBV DNA levels in the two treatment groups; C: Hepatitis B e antigen (HBeAg) seroconversion in the two treatment groups; D: Alanine aminotransferase (ALT) levels in the two treatment groups; E: Albumin (ALB) levels in the two treatment groups; F: Total bilirubin (TBIL) levels in the two treatment groups; G: The child-Turcotte-Pugh (CTP) score in the two treatment groups; H: Prothrombin time activity (PTA) levels in the two treatment groups; I: Drug-resistance in the two treatment groups; J: Mortality in the two treatment groups; K: The two treatment groups included in the Randomized controlled trials (RCTs). ETV: Entecavir; LAM: Lamivudine.

**Table 2** Sensitivity analysis

Index	Total HBV DNA undetectability	
	RR	P value
Removing the inferior quality trials <sup>[13,15,17]</sup>	1.26 (1.15, 1.39)	< 0.0001
Using random-effect model	1.24 (1.16, 1.33)	< 0.00001
Using fixed-effect model	1.29 (1.22, 1.37)	< 0.00001

HBV: Hepatitis B virus.

0.009), (MD = -0.52, 95%CI: -0.82-0.21,  $P = 0.0008$ ), (MD = -0.38, 95%CI: -0.66-0.11,  $P = 0.007$ ), (MD = -0.89, 95%CI: -1.62-0.16,  $P = 0.02$ ), respectively], while at > 48 wk, the CTP score in the two groups was similar, and no statistically significant difference was observed (MD = -0.16, 95%CI: -0.43-0.12,  $P = 0.26$ ) (Figure 2G).

### Drug-resistance

In this analysis, 9 trials reported the rate of drug-resistance. According to  $\chi^2$  and  $I^2$  analysis, heterogeneity was not observed ( $\chi^2 = 2.94$ ,  $P = 0.94$ ,  $I^2 = 0\%$ ); therefore, we used the fixed-effect method to analyze the data. At the end of treatment, the rate of drug-resistance was lower in the ETV group (0.33%) than in the LAM group (14.33%), and the difference was statistically significant (RR = 0.1, 95%CI: 0.04-0.24,  $P \leq 0.00001$ ) (Figure 2I).

### Adverse reactions

In this analysis, 12 trials reported adverse reactions. The difference in adverse reactions between the two groups was not obvious. Patients in the two treatment groups did not experience severe adverse reactions, and common adverse reactions included headache, fatigue, nausea, diarrhea, hypersomnia, and insomnia. Five trials reported mortality. According to  $\chi^2$  and  $I^2$  analysis, heterogeneity was not observed ( $\chi^2 = 1.37$ ,  $P = 0.85$ ,  $I^2 = 0\%$ ); therefore, we used the fixed-effect method to analyze the data. At the end of treatment, the mortality rate in the two

groups (ETV 6.37% *vs* LAM 7.89%) was similar, and no statistically significant difference was observed (RR = 0.81, 95%CI: 0.37-1.80,  $P = 0.61$ ) (Figure 2J).

### Assessment of publication bias

We examined publication bias using a funnel plot. The results showed that the plot was funnel shaped which suggested the absence of significant publication bias (Figure 2K).

### Sensitivity analysis

Sensitivity analysis were performed by excluding certain studies. For example, when considering the rate of HBV DNA undetectability, using the fixed-effect model instead of the random-effect model, 3 inferior quality trials were removed. The ORs of all sensitivity analyses were larger than 1 and statistically significant ( $P < 0.05$ ), suggesting that the results of the meta-analysis were stable (Table 2).

## DISCUSSION

Nucleoside/nucleotide analogues (NUCs) are the only antiviral agents recommended for patients with hepatitis B decompensated cirrhosis<sup>[6]</sup>. As the first NUC used in the treatment of CHB, LAM has been widely used in the treatment of hepatitis B cirrhosis. A number of researchers have shown that LAM can effectively suppress HBV DNA replication and significantly improve liver function in patients with hepatitis B decompensated cirrhosis<sup>[22,23]</sup>. However, a critical weak point of LAM therapy is the frequent occurrence of resistant mutations and high drug-resistance in HBV<sup>[24]</sup>. As liver function in patients with LC is poor and progression of the disease is fast, the selection of appropriate drugs in the later period of treatment is difficult. ETV is a new cyclopentyl guanosine nucleoside analogue which is efficiently phosphorylated to its active triphosphate form by host cellular kinases. It blocks HBV replication by inhibiting HBV polymerase, the DNA strand *via* reverse transcription elongation, and

DNA-dependent plus-strand DNA synthesis<sup>[25]</sup>. ETV has the advantage of a higher rate of HBV DNA suppression, low drug-resistance and high safety, especially in LAM-resistant CHB patients<sup>[26]</sup>. Therefore, some researchers have attempted to use ETV for the treatment of hepatitis B decompensated cirrhosis<sup>[27,28]</sup>. However, it is more expensive than other nucleoside analogues.

In the present study, we included RCTs comparing ETV with LAM in patients with hepatitis B decompensated cirrhosis. We conducted a meta-analysis on virological, serological, biochemical reactions, drug-resistance, mortality and adverse reactions in the included trials to examine the association between pre-specified characteristics (treatment duration) and treatment effect.

HBV DNA level is a primary prognostic marker and risk factor for patients with hepatitis B decompensated cirrhosis<sup>[29]</sup>. The early and sustained suppression of HBV DNA replication is associated with improved long-term virological, serological and biochemical response rates. Rapid and effective suppression of HBV DNA replication can reduce the incidence of LC, HCC and drug-resistance<sup>[30,31]</sup>. The results of our meta-analysis showed that following various treatment durations (12, 24, 36, 48 and > 48 wk), HBV DNA levels were lower in the ETV group than in the LAM group, and the difference between the two groups was statistically significant. At 12, 24 and 48 wk of treatment, ETV showed a significant effect on the rate of HBV DNA undetectability compared with LAM. These results showed that ETV was not only more effective than LAM in the early stages of treatment, but also had a continuous advantage after treatment. This suggests that ETV had a more rapid and effective anti-viral activity in patients with hepatitis B decompensated cirrhosis than LAM. Although HBeAg seroconversion in the ETV group was more pronounced than in the LAM group at 24 wk (27.9% *vs* 26.19%) and 48 wk (31.52% *vs* 25%) of treatment, these differences were not statistically significant.

Following various treatment durations, both ETV and LAM significantly reduced ALT, TBIL and CTP levels and increased ALB and PTA levels. These results indicated that both drugs significantly improved liver function.

ETV has a high genetic barrier to resistance<sup>[32]</sup>. The results in Figure 2D show that the rate of drug-resistance was higher in the LAM group (17.12%) than in the ETV group (0.44%), and this difference was statistically significant. ETV has lower drug-resistance, and is thus more suitable for the treatment of patients with hepatitis B decompensated cirrhosis than LAM.

The results in Figure 2G show that the rate of mortality in the two treatment groups was similar (ETV 6.37% *vs* LAM 7.89%), and no statistically significant difference was observed. No severe adverse reactions were observed in the two treatment groups. These results suggest that both ETV and LAM significantly reduced mortality, with excellent safety and tolerability.

Our study had several limitations. First, the number of included trials was small, and some outcome param-

eters of treatment duration included only 1 trial. Second, the quality of some of the included trials was not high (details on the method of randomization, allocation concealment, blinding method, or the reasons for withdrawals and dropouts were not included). Therefore, future studies should assess high-quality, well-designed, multicenter RCTs with larger sample sizes.

In conclusion, both ETV and LAM have powerful anti-viral activity, with a low incidence of adverse reactions. These drugs also improved liver function and reduced mortality. Therefore, the positive effects of ETV and LAM in patients with hepatitis B decompensated cirrhosis were confirmed. Due to lower cost, LAM has a pharmacoeconomic advantage before 48 wk of treatment. However, LAM has higher drug-resistance, and is thus unsuitable for the long-term treatment of patients with hepatitis B decompensated cirrhosis. ETV can be used as the first-line drug for long-term treatment of patients with hepatitis B decompensated cirrhosis due to its greater anti-viral activity and extremely low drug-resistance.

## ACKNOWLEDGMENTS

We are grateful to Song LY, Zhang SR and Ou-Yang RJ for the data extraction.

## COMMENTS

### Background

The treatment of chronic hepatitis B is a major healthcare problem affecting over 350 million people worldwide. Approximately 25%-40% of infected patients will develop various life-threatening conditions such as liver failure, liver cirrhosis and hepatocellular carcinoma. Recent studies have shown that entecavir (ETV) and lamivudine (LAM) are powerful nucleoside analogues in the treatment of hepatitis B decompensated cirrhosis. However, there were few systematic reviews on this topic.

### Research frontiers

Lamivudine effectively suppressed hepatitis B virus (HBV) DNA replication and significantly improved liver function in patients with hepatitis B decompensated cirrhosis. However, a critical weak point of lamivudine therapy is the frequent occurrence of resistant mutations and high drug-resistance in HBV. ETV is a new cyclopentyl guanosine nucleoside analogue. It has the advantage of a higher rate of HBV DNA suppression, low drug-resistance and high safety. However, it is expensive and long-term use of ETV would result in heavy financial pressures for patients with hepatitis B decompensated cirrhosis and their families.

### Innovations and breakthroughs

There are few systematic reviews on the efficacy of ETV and LAM in the treatment of hepatitis B decompensated cirrhosis. The authors conducted a meta-analysis of randomized controlled trials using the Cochrane methodology and explored the efficacy of ETV and LAM for the treatment of hepatitis B decompensated cirrhosis.

### Applications

Due to its lower cost, LAM has a pharmacoeconomic advantage before 48 wk of treatment. However, LAM has higher drug-resistance, and is thus unsuitable for the long-term treatment of patients with hepatitis B decompensated cirrhosis. ETV can be used as the first-line drug for the long-term treatment of patients with hepatitis B decompensated cirrhosis due to its greater anti-viral activity and extremely low drug-resistance.

### Terminology

HBV DNA undetectability: undetectable levels of HBV DNA (HBV DNA levels < 1000 copies/mL), determined by quantitative polymerase chain reaction. Hepatitis B e antigen (HBeAg) seroconversion: HBeAg loss (HBeAg levels < 1.0 S/CO)

and the presence of anti-HBeAg, determined by microparticle enzyme immunoassay or enzyme-linked immunosorbent assay. CTP score: employs five clinical measures of liver disease [total bilirubin, albumin, Prothrombin time, Ascites, Hepatic encephalopathy]. Each measure is scored 1-3, class A to C by total scores (A:5-6, B:7-9, C:10-15), with C indicating the most severe liver disease.

### Peer review

This is a good meta-analysis comparing the ETV and LAM in treatment of hepatitis B associated decompensated cirrhosis. Based on their analyses, the authors conclude that both ETV and LAM can significantly improve the liver function and reduce mortality for patients with hepatitis B decompensated cirrhosis. However, ETV has a better virological response and lower drug-resistance, which can be used as the first-line drug for long-term treatment of hepatitis B decompensated cirrhosis. The analysis was carefully performed, and the results were clearly presented and summarized.

### Abstract

Lower gastrointestinal hemorrhage presents a common indication for hospitalization and account for over 300000 admissions per year in the United States. Multimodality imaging is often required to aid in localization of the hemorrhage prior to therapeutic intervention if endoscopic treatment fails. Imaging includes computer tomography angiography, red blood cell tagged scintigraphy and conventional angiography, with scintigraphy being the most sensitive followed by computer tomography angiography. Aberrant celio-mesenteric supply occurs in 2% of the population; however failure to identify this may result in failed endovascular therapy. Computer tomography angiography is sensitive for arterial hemorrhage and delineates the anatomy, allowing the treating physician to plan an endovascular approach. If at the time of conventional angiography, the active bleed is not visualized, but the site of bleeding has been identified on computer tomography angiography, provocative angiography can be utilized in

order to stimulate bleeding and subsequent targeted treatment. We describe a case of lower gastrointestinal hemorrhage at the splenic flexure supplied by a celio-mesenteric branch in a patient and provocative angiography with tissue plasminogen activator utilized at the time of treatment to illicit the site of hemorrhage and subsequent treatment.

### INTRODUCTION

Lower gastrointestinal (LGI) hemorrhages present a common indication for hospitalization and account for over 300000 admissions per year in the United States<sup>[1]</sup>. In the majority of these events, modern imaging and endoscopic techniques such as upper and/or lower endoscopy, tagged red blood cell scintigraphy, and visceral angiography can be used to localize the source of an acute hemorrhage<sup>[2]</sup>. Predictors on the ability to find a bleeding source include: (1) being visible on multidetec-

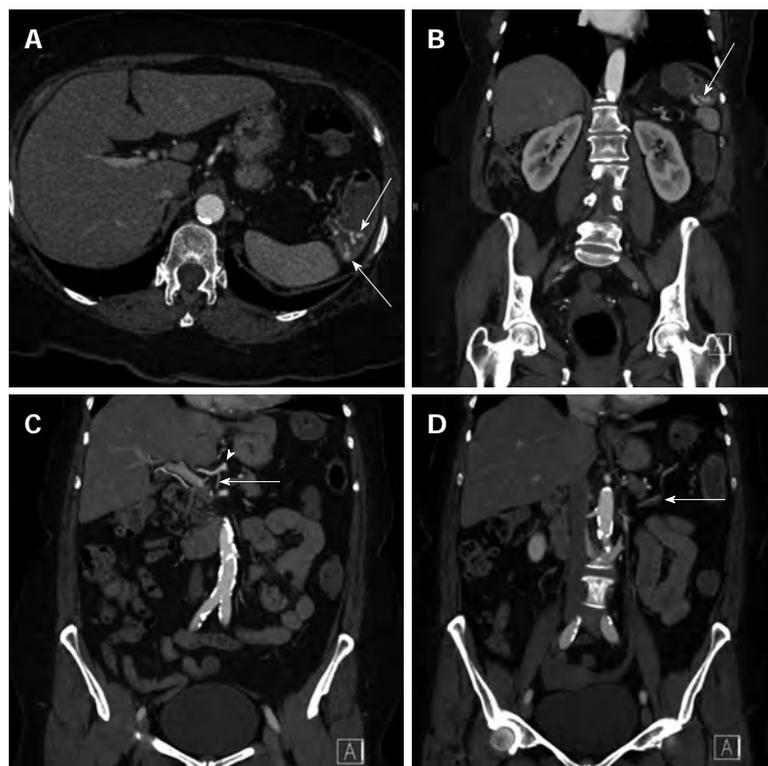

Figure 1 Computed tomography angiography with arterial phase (20 s following injection) acquisition. A, B: Axial image (A) and coronal images (B) demonstrating active contrast extravasation (arrows) at the splenic flexure; C: Coronal reformatted image demonstrating a celio-mesenteric branch (arrow) arising from the common hepatic artery (arrowhead); D: Seen in the large bowel mesentery (arrow) and supplying the splenic flexure.

tor computed tomography angiography (CTA); (2) visible on tagged red blood cell scintigraphy; or (3) patient hemodynamic instability. Yet, in as many as 65% of cases, standard diagnostic evaluation will not identify the source of a bleed and these patients may present with recurrent bleeds from an obscure origin<sup>[3]</sup>. Modern radiologic studies require an active bleed and a minimal rate of bleeding in order to be detected. Since LGI hemorrhages can frequently resolve before imaging is performed, these studies may have difficulty in finding a source of the bleed<sup>[4]</sup>. If the bleeding vessel is not visualized angiographically, a provocative maneuver can be performed using heparin or tissue plasminogen activator (tPA) at the suspected site. This technique is based on the premise that these pharmacologic agents will incite an acute hemorrhage that can then be viewed angiographically. Once visualized, the source may be treated appropriately by embolization to occlude the vessel or by providing visual cues to assist a surgical procedure<sup>[5]</sup>.

In this letter, we discuss the utility of a multidetector CTA scan in the setting of a LGI bleed that revealed the presence of an aberrant vessel supplying the splenic flexure responsible for the hemorrhage. With this information, we describe the use of provocative maneuvers to localize and successfully embolize the source of the bleed.

## CASE REPORT

A 65-year-old female presented with the passage of

bright red blood per rectum, the patient was not hemodynamically unstable (Blood pressure 110/60, pulse 78, saturation on room air 98%). Endoscopy was felt likely to be unhelpful due to the amount of blood passed per rectum and therefore decision was taken to proceed to CT. A subsequent arterial phase CT scan demonstrated an acute hemorrhage at the site of the splenic flexure (Figure 1A and B). Furthermore, a single aberrant vessel was seen arising from the proximal common hepatic artery (CHA) to supply the splenic flexure (Figure 1C and D). The patient was hemodynamically stable and transferred to the angiography suite for therapy.

A celiac angiogram was initiated through the right common femoral artery using a 5-Fr sheath. Access was obtained *via* a Sim 1 catheter (Cook Medical, Bloomington, IN) that extended to the celiac axis. As previously established on CTA, an aberrant celio-mesenteric branch extending from the CHA to the splenic flexure was confirmed. The Sim 1 catheter was engaged further and a Renegade STC catheter (Boston Scientific, Natick, MA) was used to cannulate the vessel supplying the splenic flexure (Figure 2A and B).

Serial angiograms were performed in this area but no acute hemorrhage was visualized (Figure 2B). Decision was made to perform a tPA provocation test. Two milligram of tPA was dissolved in 10ccs of saline. One milligram of tPA was injected selectively through the catheter into the vessel supplying the splenic flexure. This resulted in brisk bleeding in the area of the splenic flexure from the aberrant vessel of the CHA (Figure 2C). At

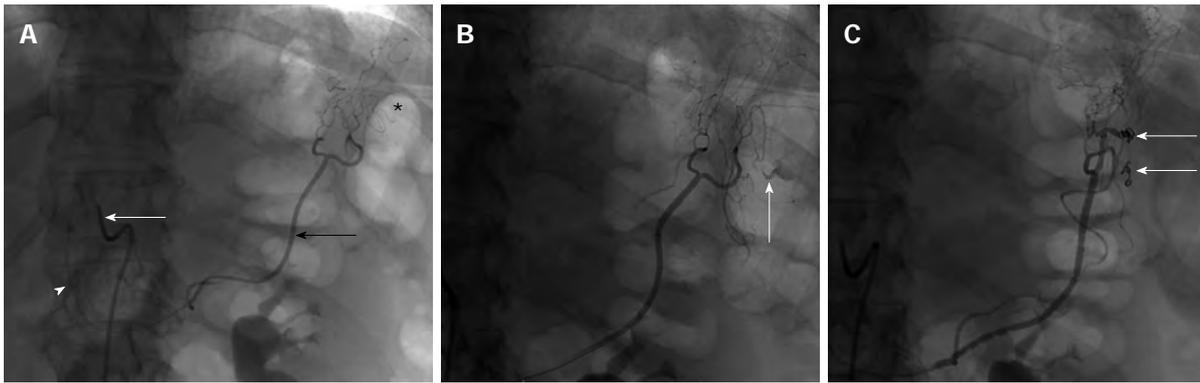

Figure 2 Digital subtraction angiogram. A: Sim 1 catheter (white arrow) engaged in the common hepatic artery and a microcatheter (arrowhead) cannulating the celiac-mesenteric trunk (black arrow) supplying the splenic flexure (asterisk) with no active hemorrhage seen; B: Active contrast extravasation (arrow) following instillation of 1 mg tPA; C: Angiogram following deployment of coils in branches of the celiac-mesenteric vessel and no further active extravasation seen (arrow).

this point, the catheter was advanced and three 3 mm × 3.3 mm Vortex coils were injected in order to close the proximal and distal sites of the bleed. Further selective angiography did not demonstrate any acute contrast extravasation (Figure 2D).

The patient remained hemodynamically stable during the procedure and the blood pressure normalized at approximately 150/70 mmHg following embolization.

## DISCUSSION

Patients with a gastrointestinal bleed of unknown origin present as a challenging population since typical investigations such as CT imaging, red blood cell scintigraphy and endoscopic procedures are unable to find a source to the bleed. Without a known source, these patients are usually subjected to increased risks from repeat bleeding events, invasive investigations, and blood transfusions<sup>[6]</sup>. Pharmacologic agents can be used to incite an acute, local bleed in order to visualize the source of the hemorrhage on CT scan. Although provocative angiography has yet to be a common diagnostic tool, the literature available through case reports and series has shown this to be an effective yet safe technique<sup>[2,4-8]</sup>.

In this particular case, the inclusion of a CT angiogram in the setting of a GI bleed was invaluable in locating the source of the hemorrhage as the patient demonstrated aberrant vasculature from the CHA to the splenic flexure. The presence of variant vessels supplying the descending colon has been well documented and, although uncommon, would be important information in order to guide the management of a bleeding patient<sup>[9-11]</sup>. CTA provides excellent delineation of the arterial anatomy and is more sensitive than conventional angiography in identifying arterial bleeding<sup>[12]</sup>.

The anastomosis between the superior mesenteric artery (SMA) and the inferior mesenteric artery (IMA) at the splenic flexure is normally considered a watershed region with dual arterial supply from the SMA and IMA allowing collateral circulation. This region however is more susceptible to damage in ischemic disease.

In relatively rare cases, this point in the large bowel may receive blood supply from a celiac-mesenteric branch. The anastomosis of atypical coeliac branches represents a rare case for consideration. Awareness of the possibility of embryological variants will assist in minimizing the risk of complications in angiographic procedures. Failure to identify this branch supplying the splenic flexure may lead to an incorrect assessment of the mesenteric vasculature, particularly at the time of angiography. It also provides comprehensive detail of the arterial anatomy and allows the radiologist to assess both access and potential target vessels for treatment.

We propose that in patients with a GI bleed that is difficult to locate, an arterial phase CT scan is a tool that can provide valuable information such as the ability to reveal variant vasculature that would have otherwise gone unnoticed. The protocol does not require oral contrast. Furthermore, if one is confident that there is a bleed but is unable to view angiographically, then a challenge with tPa or heparin may be a useful adjunctive diagnostic approach.

### Abstract

Primary colorectal choriocarcinoma is an extremely rare neoplasm and is usually associated with a poor prognosis. Only 13 cases of colorectal choriocarcinoma have previously been reported. There is no standard chemotherapeutic regimen for this tumor type. A 68-year-old man presented with melena and was diagnosed with sigmoid colonic adenocarcinoma with multiple liver metastases. He underwent a laparoscopic sigmoidectomy. Pathology revealed choriocarcinoma with a focal component of moderately differentiated adenocarcinoma of colon origin. Based on the collagen gel droplet-embedded culture drug sensitivity test (CD-DST) results, mFOLFOX6 and bevacizumab were administered, which suppressed aggressive tumor growth for 4 mo. The patient died 9 mo after the initial diagnosis. Our study results suggest that the standard chemotherapy regimen for colorectal cancer might have suppressive effects against primary colorectal choriocarcinoma. Moreover, CD-DST may provide, at least in part, therapeutic insight for the selection of appropriate antitumor agents

for such patients.

### INTRODUCTION

Choriocarcinoma is an uncommon malignant tumor that originates from the placenta in women and from germ cells of the gonads in men. Choriocarcinoma is more common in men than in women. Non-gestational or extra-gonadal choriocarcinoma are rare tumors that arise at various sites including the mediastinum<sup>[1]</sup>, lung<sup>[2]</sup>, stomach<sup>[3]</sup>, pancreas<sup>[4]</sup>, cervix<sup>[5]</sup>, and ureter<sup>[6]</sup>. Primary

choriocarcinoma of the colon and rectum is an extremely rare neoplasm and is usually associated with a poor prognosis. Only 13 cases of colorectal choriocarcinoma have previously been reported<sup>[7-19]</sup>. According to these reports, systemic chemotherapy also appeared to be an important prognostic factor in these patients; however, no standard chemotherapy regimen exists to treat this tumor.

The collagen gel droplet-embedded culture drug sensitivity test (CD-DST) is a new *in vitro* anticancer drug sensitivity test<sup>[20]</sup> that has been reported to provide valuable therapeutic information for patients with colorectal cancer<sup>[21-23]</sup> and pancreatic tumors<sup>[24]</sup>. We encountered an extremely rare case of primary choriocarcinoma of the sigmoid colon. CD-DST results revealed that the resected tumor was sensitive to several antitumor drugs including oxaliplatin (OHP). Based on the CD-DST results, we administered effective chemotherapy to this patient. To the best of our knowledge, this is the first report of the clinical utility of CD-DST in the treatment of a patient with colonic choriocarcinoma.

## CASE REPORT

A 68-year-old man presented with melena. Colonoscopy revealed an ulcerated tumor that occupied half the diameter of the lumen of the sigmoid colon (Figure 1A). A barium enema revealed the tumor to be approximately 2.5 cm in diameter (Figure 1B). Abdominal computed tomography (CT) revealed multiple hepatic tumors and thickening of the intestinal wall of the sigmoid colon. Biopsy of the tumor in the sigmoid colon suggested moderately to poorly differentiated adenocarcinoma. The alpha-fetoprotein (AFP) level was markedly elevated at 298.7 ng/mL (normal range < 20 ng/mL); however, carcinoembryonic antigen (CEA) and CA19-9 levels were within the normal ranges. The patient underwent laparoscopic sigmoidectomy with lymph node dissection to determine the chemosensitivity of the tumor using CD-DST, after which final clinical staging was determined to be T2, N1a, M1a (Stage IVA; Tumor-node-metastasis Classification of Malignant Tumors, 7<sup>th</sup> Ed.). The surgical specimen was identified as a 20 mm × 20 mm tumor, and was microscopically diagnosed as choriocarcinoma with a focal component of moderately differentiated adenocarcinoma. The adenocarcinoma component was located at the bottom of the ulcer (Figure 2). Regional lymph node metastasis on the primary feeding artery of the tumor was identified. Immunohistochemical staining results were positive for beta-human chorionic gonadotropin (hCG-beta) expression, a marker of choriocarcinoma. The plasma hCG-beta level was elevated to 1.4 ng/mL (normal range < 0.5 ng/mL) even after surgery. CD-DST results revealed that the tumor was sensitive to various chemotherapeutic agents (Table 1).

The patient received his first session of mFOLFOX6 3 wk after surgery. Because the CD-DST results indicated that the tumor was most sensitive to 5-fluorouracil (FU)/OHP, which simulates the FOLFOX combination,

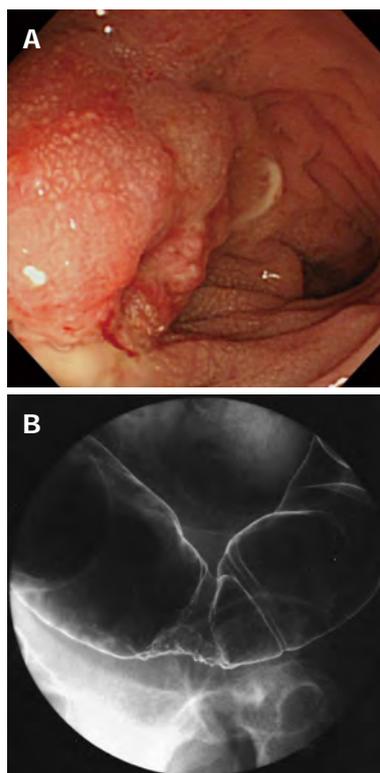

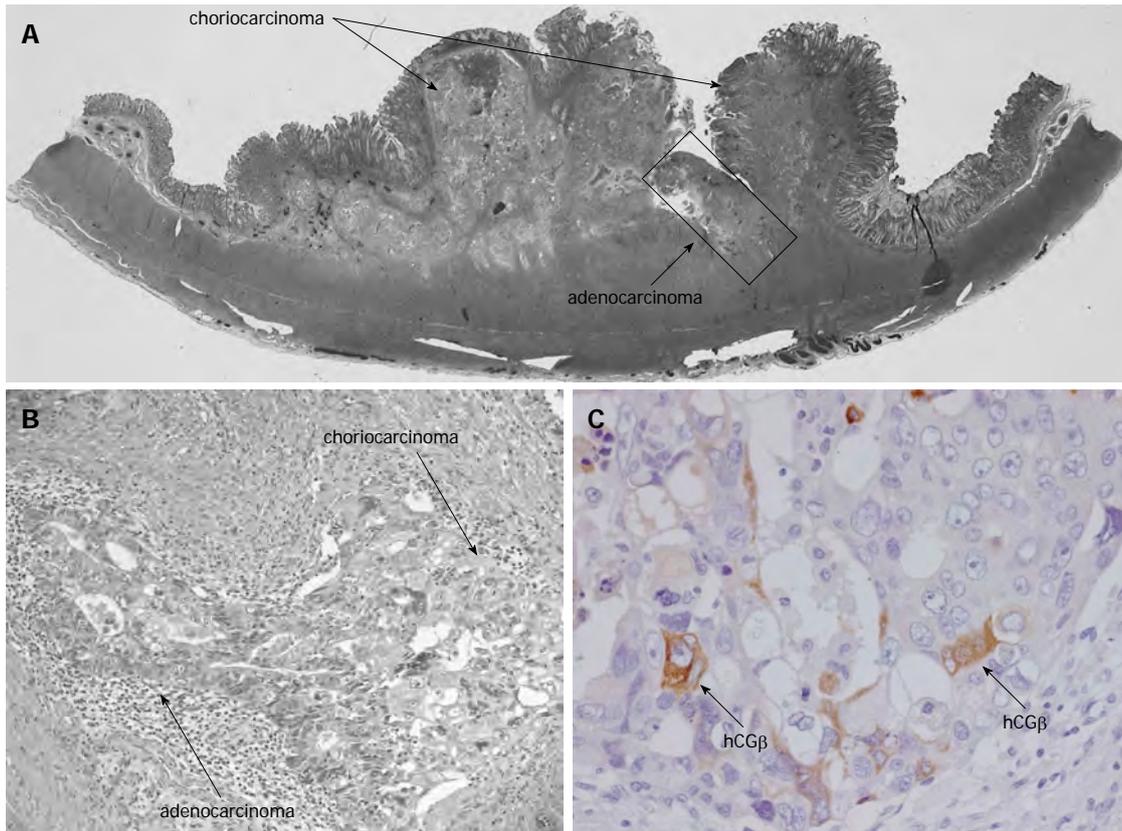

Figure 1 Findings of preoperative examinations. A: Colonoscopy. B: Barium enema.

the patient received a further 8 courses of mFOLFOX6 with bevacizumab. The size of the hepatic metastases remained almost the same as before surgery; however, a small new lesion was observed on abdominal CT 4 mo after surgery. These findings indicated progressive disease according to RECIST criteria. However, at this point we considered the hepatic tumors unlikely to continue growing because of systemic chemotherapy (Figure 3A and B). However, at 6 mo after surgery, serum AFP and hCG-beta levels rapidly elevated to 3929 and 11 ng/mL, respectively. Thereafter, we administered a regimen of FOLFIRI with bevacizumab. Despite this treatment, the hepatic metastases enlarged markedly (Figure 3C), and the patient died 9 mo after the initial diagnosis.

## DISCUSSION

Primary choriocarcinoma of the colon and rectum is extremely rare. To our knowledge only 14 cases including ours have been documented to date. The median age of these patients was 52 years (range, 29-74 years) and included 6 men and 8 women. The median survival period was 4 mo (range, 0.3-60 mo). Metastatic tumors were found in distant organs at the time of colorectal choriocarcinoma diagnosis in 71.4% (10/14) of cases. Of the cases who had no distant metastases at the time of surgery, 80% (4/5) showed rapid development of distant metastases. Only 1 case was reported to have achieved long-term (60 mo), relapse-free survival. These tumors tend to rapidly progress, and are therefore, associated

**Figure 2 Microscopic findings.** A, B: HE staining shows the co-existence of choriocarcinoma and adenocarcinoma cells (A: loupe, B: × 200); C: The tumor cells were positive for β-human chorionic gonadotropin (hCGβ) (× 400).

Table 1 Summary of antitumor drug sensitivity test results	
Agent (μg/mL)	T/C
5-FU (1.0)	53.34%
Gemcitabine (0.03)	58.47%
Docetaxel (0.1)	56.07%
Epirubicin (0.1)	58.47%
Cisplatin (0.2)	UD
5-FU/SN38 (1.0/0.03)	65.85%
5-FU/OHP (1.0/0.5)	46.85%

The culture drug sensitivity test method was employed to study *in vitro* growth inhibition. The *in vitro* sensitivity is expressed as the T/C ratio, where T is the total volume of living cancer cells in the treated group, and C is the total volume of living cancer cells in the control group. 5-FU: 5-fluorouracil; SN38: The active metabolite of irinotecan; OHP: Oxaliplatin; UD: Undetectable because of the limited number of cells.

with very poor prognosis. Almost all of the reported patients [85.7% (12/14)] died within 1 year of diagnosis. The survival rate in patients without chemotherapy was significantly lower than that for patients who received some form of chemotherapy (median survival period, without systemic chemotherapy: 1.0 mo *vs* with systemic chemotherapy: 9 mo, Kaplan-Mayer analysis; Log rank test  $P = 0.0004$ , data not shown). Although intestinal resection with lymph node dissection was the standard treatment for colorectal choriocarcinoma in the previous reports, systemic chemotherapy also appeared to be

an important prognostic factor. However, no standard chemotherapy regimen has been established for the treatment of this tumor type.

Since colorectal choriocarcinoma is generally considered biologically similar to choriocarcinoma of gestational trophoblastic neoplasia (GTN), almost all previously used chemotherapeutic regimens were based on those designed to treat GTN<sup>[25]</sup>. Choriocarcinoma is the most common malignant form of GTN. The standard chemotherapeutic regimen for GTN is EMA/CO (a combination of etoposide, methotrexate, and dactinomycin, alternating with cyclophosphamide and vincristine). EMA/CO is reported to have a 60.0%-90.6% complete remission rate and an 86.2% 5-year overall survival (OS)<sup>[26]</sup>. However, there is no evidence that EMA/CO is effective against colorectal choriocarcinoma.

The prognosis of choriocarcinoma that is of colorectal origin is extremely poor, as shown in this case report. The response of colorectal choriocarcinoma to chemotherapy is much worse than that of choriocarcinoma derived from germ cells. The cause of this difference in chemosensitivity is still unknown. It is known that colorectal choriocarcinoma cells undergo a syncytiotrophoblastic differentiation through retrodifferentiation or metaplasia of the adenocarcinoma component, rather than originating directly from ectopic germ cells. Therefore, it is possible that the differences in chemosensitivity

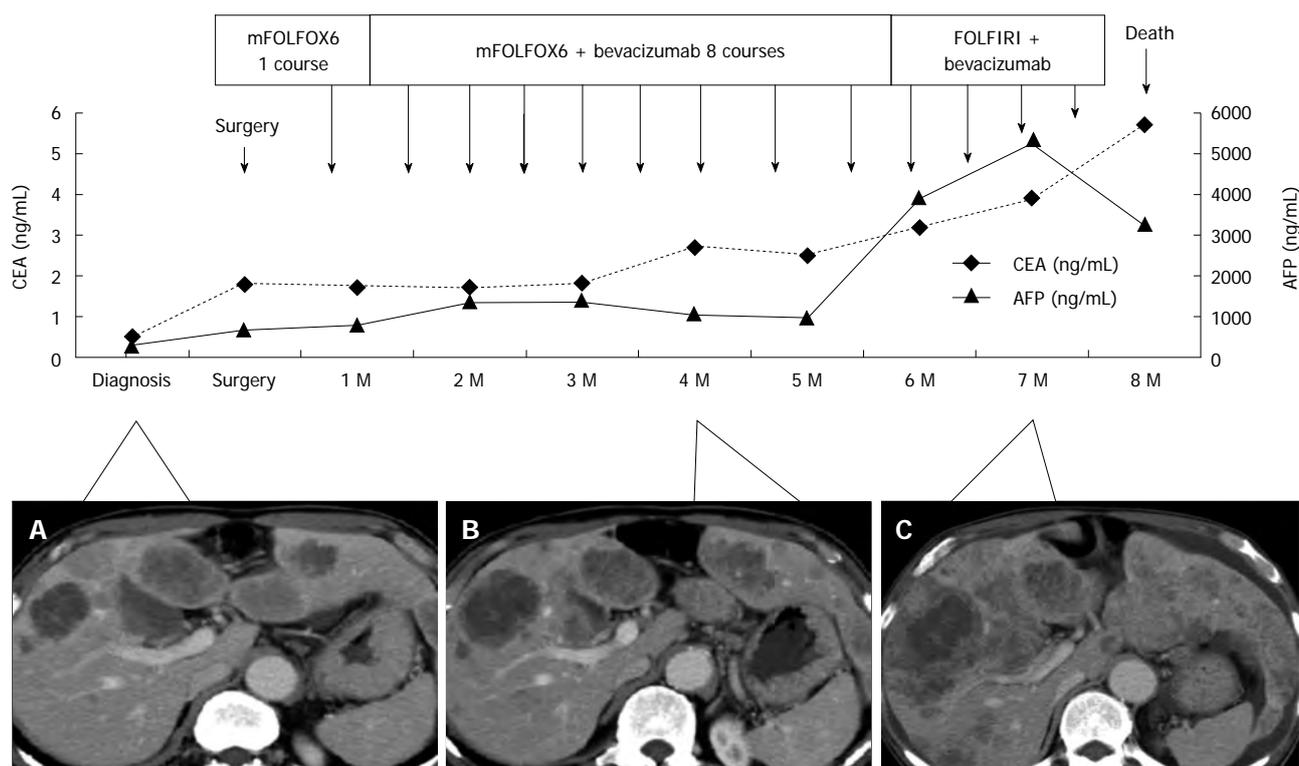

Figure 3 Clinical course of the patient. A, B: Hepatic metastases showed minimal growth until 4 mo after surgery; at 7 mo after surgery; C: The metastases had markedly enlarged, CEA: Carcinoembryonic antigen; AFP: Alpha-fetoprotein.

may be associated with the origin of carcinoma cells.

A study by Harada *et al*<sup>[7]</sup> reported the efficacy of a systemic chemotherapeutic regimen that contained MEA-methotrexate, etoposide, and dactinomycin which targeted the choriocarcinoma, followed by oral administration of tegafur and uracil/leucovorin therapy which targeted the colonic adenocarcinoma. Although this was a report of a single case, the treatment resulted in very long-term, relapse-free survival (60 mo). Therefore, chemotherapy which not only targeted the choriocarcinoma, but also the adenocarcinoma of the large intestine, appeared to be the key to prolonging survival.

Recently, FOLFOX and FOLFIRI have become standard chemotherapeutic regimens for the treatment of colorectal cancer<sup>[27-29]</sup>. However, the use of irinotecan- or OHP-containing regimens to treat colorectal choriocarcinoma has not been reported. In this case, the CD-DST results indicated that the tumor was most sensitive to 5-FU/OHP, which simulates the FOLFOX combination. The tumor sample used in the CD-DST was mainly choriocarcinoma; however, the pathological findings revealed the co-existence of moderate-to-poorly differentiated adenocarcinoma. Noguchi *et al*<sup>[30]</sup> reported that the survival of a patient with gastric choriocarcinoma was prolonged by administering a chemotherapy regimen commonly given to patients with gastric adenocarcinoma, rather than to those with choriocarcinoma. The regimen for adenocarcinoma in the original tissue appeared to be effective against non-gestational or extra-gonadal chorio-

carcinoma. Therefore, we hypothesized that the standard regimen for the treatment of colorectal cancer might be effective against primary colorectal choriocarcinoma. We selected mFOLFOX6 combined with bevacizumab with the approval of the patient.

CD-DST cultures extract cancer cells three-dimensionally in a collagen gel droplet. This three-dimensional culture with collagen matrix is preferable to establish cell cultures from human cancer tissue<sup>[31]</sup>. Here, we report that CD-DST may provide useful information to tailor chemotherapy regimens to individual patients<sup>[21,23,24]</sup>. Our study demonstrates that patients with synchronous stage IV colorectal cancer who were treated with tumor-sensitive chemotherapeutics as evidenced by the CD-DST had higher response rates (85.71%) than patients receiving drugs that the CD-DST did not identify as tumor-sensitive (41.67%). Moreover, progression-free survival (PFS) and OS were superior in patients treated with *in vitro* sensitive drugs by CD-DST (median PFS, 696.5 d *vs* 297.5 d; median OS, 1023.4 d *vs* 518.5 d)<sup>[23]</sup>. Unfortunately, the cell culture was not maintained long enough for additional examination of anti-tumor drugs for the EMA/CO regimen after the results of immunohistochemical staining were obtained. Although the best regimen according to the results of the CD-DST suppressed rapid progression of choriocarcinoma in this case, the therapeutic effect in this patient was not remarkable compared with our previous findings of the CD-DST in common colorectal adenocarcinoma<sup>[23]</sup>. We could not evaluate hepatic meta-

static lesions using the CD-DST in this case. It is possible that the chemosensitivity of the hepatic metastases may be different from that of the primary lesion.

In conclusion, we report an extremely rare case of primary choriocarcinoma of the sigmoid colon. Systemic chemotherapy appeared to improve the patient's survival. This case suggests that the standard regimen for the treatment of colorectal cancer might have suppressive effects against primary colorectal choriocarcinoma. Moreover, CD-DST may provide, at least in part, therapeutic insight for the selection of appropriate antitumor agents which may be effective for treating patients with colonic choriocarcinoma on an individual basis.

### Abstract

Benign multicystic peritoneal mesothelioma (BMPM) is a rare cystic mesothelial lesion that occurs predominantly in reproductive aged women. A 56-year-old Caucasian male was admitted to our surgical department with a chief complaint of a painful mass in his right lower abdomen for almost 2 years. The physical examination revealed a palpable painful mass. Computed tomography demonstrated an irregular, cystic tumor in his right lower abdomen. There was no obvious capsule or internal septations. No enhancement after intravenous administration of contrast was noted. An exploratory laparotomy was performed, and a multicystic tumor and adherent to the caecum was noted. The walls of the cysts were thin and smooth, filled with clear fluid, and very friable. An *en bloc* resection of the tumor, including appendix and caecum, was performed. Histological examination revealed multiple cysts lined with flattened simple epithelial cells, and the capsule walls of

the cysts were composed of fibrous tissue. Immunohistochemical analysis documented positive expression of mesothelial cells and calretinin. The final diagnosis was BMPM. The patient was well at 6-mo follow-up. BMPM is exceedingly rare lesion. A complete resection of the tumor is required. The diagnosis of BMPM is based on pathological analysis.

**Key words:** Benign multicystic peritoneal mesothelioma; Computed tomography; Pathological analysis; Diagnosis; Resection

**Core tip:** Benign multicystic peritoneal mesothelioma (BMPM) is a rare cystic mesothelial lesion that occurs predominantly in reproductive aged women. The preoperative diagnosis of BMPM is difficult, and final diagnosis requires histological evaluation of a surgical specimen. In immunohistochemical analysis, positive expression of mesothelial cells and calretinin is always noted. The best treatment strategy for BMPM is *en bloc* removal, which can avoid recurrence. The recurrent rate after complete resection is about 50%; the recurrent tumor should be completely removed and follow-up including physical examination and imaging studies is required for all cases.

### INTRODUCTION

Benign multicystic peritoneal mesothelioma (BMPM) is uncommon lesion usually occurring in women of repro-

ductive age. Because of its rarity, preoperative diagnosis is difficult and its origin and pathogenesis are uncertain<sup>[1-3]</sup>. Here, we present a case of BMPM in a 56-year-old Caucasian male with a painful mass in right lower abdomen for 2 years. The preoperative diagnosis was angiolymphoma. An *en bloc* removal was performed. The final diagnosis was BMPM according to the findings of histological and immunohistochemical examinations. We hope that this information assists surgeons in recognizing the diagnosis and treatment of BMPM.

## CASE REPORT

Written informed consent was obtained from the patient for publication of this case report and any accompanying images. A 56-year-old Caucasian male was admitted to our surgical department with a chief complaint of a painful mass in his right lower abdomen for almost 2 years. His medical history was negative, and he smoked 20 cigarettes per day and stated mild alcohol consumption for 30 years. His vital signs were normal, and physical examination revealed a palpable painful mass in his right lower abdomen. Laboratory investigations, urine analysis, chest and abdominal radiographs did not reveal any abnormalities.

Computed tomography (CT) demonstrated a 13 cm × 12.9 cm × 6.1 cm irregular, cystic tumor in his right lower abdomen. There was no obvious capsule or internal septations. The Hounsfield value was 8, which demonstrated its cystic nature. No enhancement after intravenous administration of contrast was noted (Figure 1). Angiolymphoma was considered preoperatively.

An exploratory laparotomy was performed under general anesthesia, and a multicystic tumor occupying the right abdomen and adherent to the caecum was noted. The walls of the cysts were thin and smooth, filled with clear fluid, and very friable (Figure 2). The multicystic mass, appendix, and caecum were removed. Histological examination revealed multiple cysts lined with flattened simple epithelial cells, and the capsule walls of the cysts were composed of fibrous tissue (Figure 3A). Immunohistochemical analysis documented positive expression of mesothelial cells (MC, Figure 3B) and calretinin (CR, Figure 3C), while expressions of D2-40, CD31, and CD34 were negative (Figure 3D-F). The final diagnosis was BMPM. The patient was discharged in good condition on postoperative day 10, and was free of symptoms at 6-mo follow-up.

## DISCUSSION

Mesotheliomas always arise from pleural, pericardial, and peritoneal lining cells. BMPM is a rare lesion, and until 2009 only about 146 cases were documented in literature<sup>[2]</sup>. The characteristic behavior of BMPM is benign; however, rare cases of malignant transformation have been noted<sup>[4]</sup>.

The pathogenesis of BMPM is still unclear; however, as the majority of cases occur reproductive aged females,

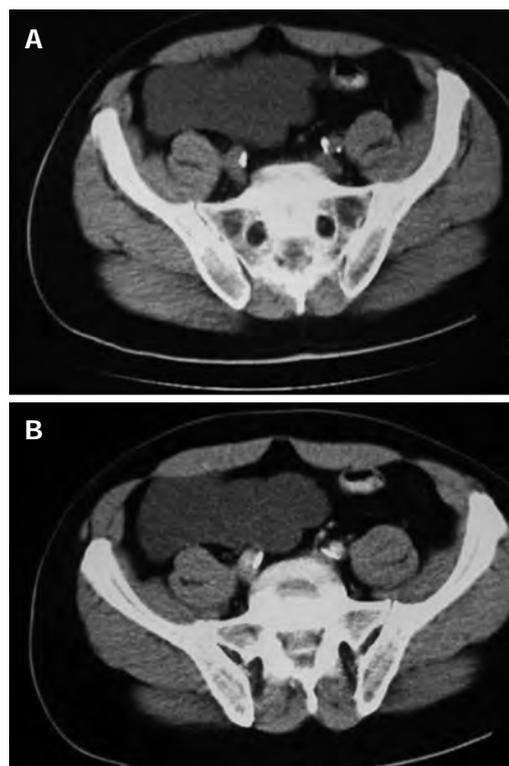

Figure 1 Computed tomography axial image results. A: Plain computed tomography axial image showing a hypodense mass; B: Contrast enhancing computed tomography axial image demonstrating an intra-peritoneal hypodense non-enhancing tumor.

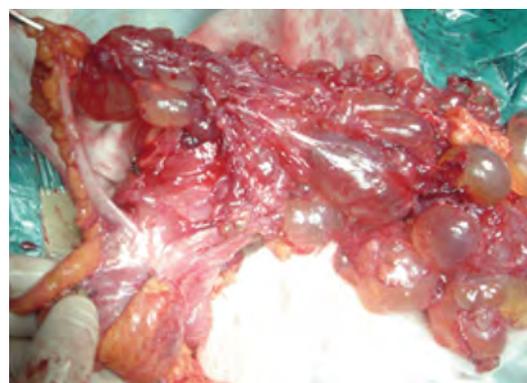

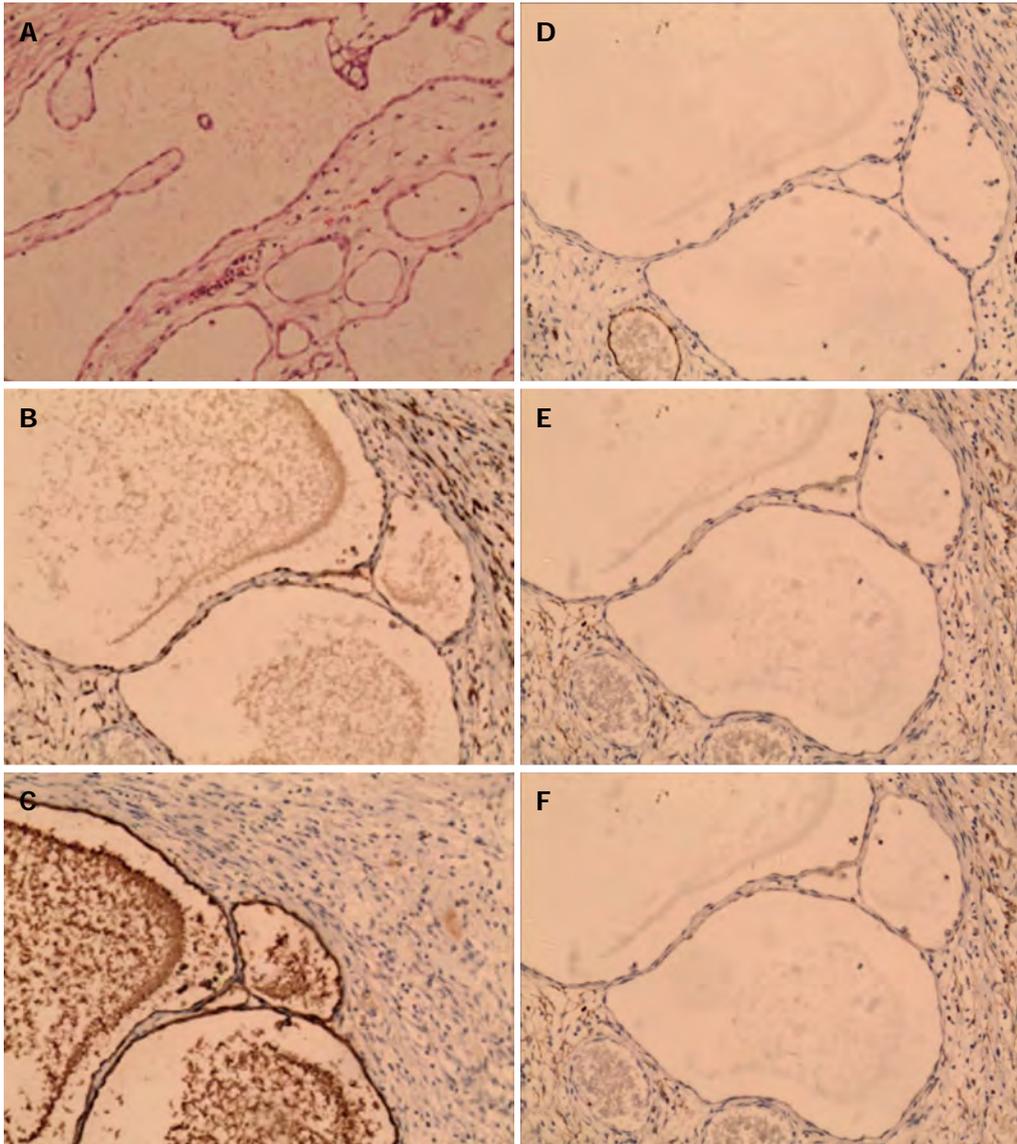

Figure 2 Intraoperative image showing a multicystic mass.

it is believe that female sex hormones play a role in its pathogenesis<sup>[5,6]</sup>. Kurisu *et al*<sup>[7]</sup> reported finding small foci of endometriosis in BMPM cystic walls, and in a second case the lesion was adjacent to endometriotic cysts in the pelvic space. These histologic findings suggest that endometriosis contributes to the origin of BMPM. A history of right oophorectomy and left ovarian cystectomy for an ovarian tumor in a 23-year-old Japanese female with BMPM suggests that previous abdominal surgery is a risk factor for BMPM<sup>[8]</sup>. Husain *et al*<sup>[9]</sup> reported two cases of BMPM in females with concurrent colonic adenocarcinoma arising in the ileocecal region.

The most common presenting symptoms are chronic

**Figure 3** Histological examination revealed results. A: Mesothelial cells lining the cysts ( $\times 400$ ); B-F: Immunohistochemical analysis documented positive expression of mesothelial cells (B,  $\times 400$ ) and calretinin (C,  $\times 400$ ), while expressions of D2-40, CD31, and CD34 were negative (D, F,  $\times 400$ ).

or intermittent abdominal or pelvic pain, tenderness, or distension with an abdominal or pelvic mass. The mean diameter of BMPM has been reported to be 13 cm at the time of diagnosis. On physical examination, the mass always presents as a fixed tumor with slight tenderness. Multiseptated anechoic cysts are always demonstrated by ultrasonography; however, CT is necessary to provide information about the location and extent of the mass and evidence of low-attenuation and non-calcified septa in the cysts<sup>[4]</sup>. Kemp *et al*<sup>[5]</sup> reported a case of BMPM in a middle-aged female that was diagnosed by fine needle core biopsy. An association between BMPM and increased serum CA19-9 concentration has been described, and a minimally invasive laparoscopic approach enabled not only histologic diagnosis but also surgical treatment<sup>[6]</sup>.

Because BMPM is an extremely rare lesion, pre-operative diagnosis is challenging. Definitive diagnosis relies on histological examination, which demonstrates

multiple cysts with thin walls lined with single-layered or cuboidal mesothelia and filled with serous fluid. In immunohistochemical analysis, positive expression of MC and CR, which are markers for mesothelial cells, is always noted. The differential diagnosis primarily includes lymphangioma and malignant peritoneal mesothelioma (MPM). Lymphangioma can be identified if cysts present with predominantly chylous fluid, lymphoid aggregates, smooth muscle, and CD2-40 positive expression on immunohistochemical analysis. MPM always presents a history of exposure to asbestos, abdominal pain, distension, ascites, and weight loss. A plain chest radiograph may show signs of asbestos. An abdominal CT examination may show the presence of ascitic fluid and peritoneal thickening. At laparotomy, widespread nodular thickening of the visceral peritoneum with a striking, diffusely uniform, erythematous appearance can be confirmed to be MPM<sup>[10]</sup>.

The best treatment strategy for BMPM is *en bloc* removal, which can avoid recurrence. The correlation between rupture of cystic lesion of BMPM and recurrence tumor is uncertain. Because of its benign nature, adjuvant chemotherapy and/or radiotherapy are not indicated for patients with BMPM. Other treatments such as hormonal therapy, sclerotherapy, and thermotherapy have not been proven to provided uncertain therapeutic effects. Although the prognosis is excellent, the recurrent rate after complete resection is about 50%; thus, the goal should not be a cure, but symptomatic relief through individualization of treatment. For the rare cases in which malignant transformation occurs, the recurrent tumor should be completely removed and follow-up including physical examination and imaging studies is required for all cases<sup>[11-13]</sup>.

BMPM is a rare tumor, which is not associated with specific complaints, objective signs, or unique appearance on imaging studies. Preoperative diagnosis is very difficult, and the final diagnosis always requires pathological analysis. *En bloc* removal of BMPM is the ideal treatment strategy, and malignant transformation is rare. Further studies are needed to better understand its etiology and pathogenesis.

Laparoscopic transduodenal local resection of periampullary neuroendocrine tumor: A case report. *World J Gastroenterol* 2013; 19(39): 6693-6698 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i39/6693.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6693>

### Abstract

Studies on laparoscopic transduodenal local resection have not been readily available. Only three cases have been reported in the English-language literature. We describe herein a case of 25-year-old woman with periampullary neuroendocrine tumor (NET). Endoscopic ultrasonography revealed a duodenal papilla mass originated from the submucosa and close to the ampulla. The periampullary tumor was successfully managed with laparoscopic transduodenal local resection without any procedure-related complications. Pathological examination showed a NET (Grade 2) with negative margin. The patient was followed up for six months without signs of recurrence. This case suggests that laparoscopic transduodenal local resection is a feasible procedure in selected patients with periampullary tumor.

### INTRODUCTION

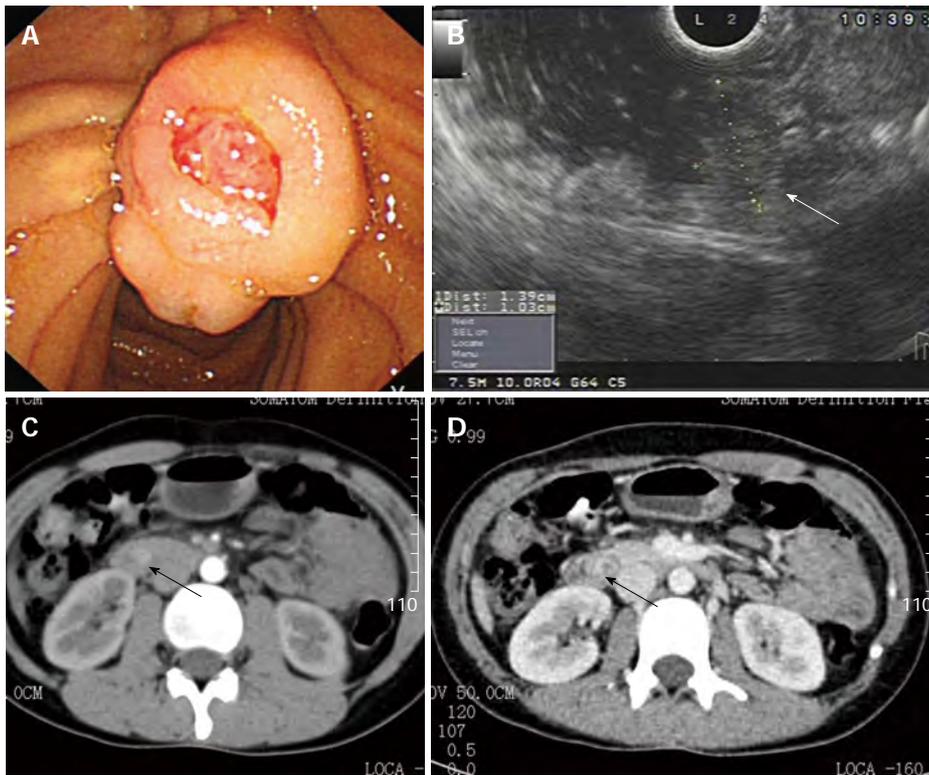

Halsted<sup>[1]</sup> reported the first transduodenal local resection for a patient with adenocarcinoma of the ampulla of Vater. Compared with the traditional Whipple surgery, transduodenal local resection is an organ-preserving operation with low morbidity and mortality<sup>[2]</sup>. Laparoscopic surgery has become widespread because of the improvement of laparoscopic equipment and techniques. However, studies on laparoscopic transduodenal local resection have not been readily available. Only three cases have been reported in the English-language literature (Table 1)<sup>[3,4]</sup>. We herein present our experience in laparoscopic transduodenal local resection in a case of periampullary neuroendocrine tumor (NET).

### CASE REPORT

A 25-year-old woman was admitted to our department because of recurrent melena for 5 mo. She had no fever,

**Table 1** Reported cases of laparoscopic transduodenal local resection

no abdominal pain, no nausea or vomiting, no diarrhea and no weight loss. She had anemic appearance, and other physical examinations were unremarkable. The laboratory tests showed reduced hemoglobin (7.7 g/dL) and fecal occult blood test was positive. Other laboratory tests, including renal and liver function tests and tumor markers (carcinoembryonic antigen, alpha fetoprotein, and carbohydrate antigens 19-9, 724, 242) were all within normal ranges. Gastroscop showed a duodenal papilla mass (1.2 cm in diameter) with ulcer (Figure 1A). Endoscopic ultrasonography (EUS) revealed a duodenal papilla mass (1.0 cm × 1.4 cm) originated from the submucosa and close to the ampulla (Figure 1B). The pathologic report of the endoscopic biopsy showed small intestinal mucosa, chronic inflammation and focal activity. Computed tomography (CT) disclosed a 1.0 cm × 1.4 cm mass in the descending part of duodenum with rich blood supply (Figure 1C and D). According to the medical history and the imaging findings, the preoperative diagnosis was a periampullary tumor with bleeding [either

NET or gastrointestinal stromal tumor (GIST)]. Laparoscopic transduodenal local resection was performed.

The patient was placed in supine position under general anesthesia. The surgeon and the second assistant who held the laparoscope stood on the right side of the patient and the first assistant stood on the left. Carbon dioxide pneumoperitoneum was established (CO<sub>2</sub> at 15 mmHg) using a Veress needle. One initial 10-mm trocar was placed for the laparoscopy below the umbilicus. A 30-degree telescope was inserted to examine the peritoneal cavity to rule out metastatic disease. After general examination, the other four trocars (one 12 mm and three 5 mm) were inserted into the left upper flank, left flank, right upper flank, and right flank quadrants, respectively; and five trocars were arranged in a V-shape (Figure 2).

Dissection of Calot's triangle was performed carefully. After confirming the cystic artery and cystic duct, the cystic artery was clipped with a 10-mm disposable clip and divided. A small incision of cystic duct was made, and a cholangiogram catheter was inserted through

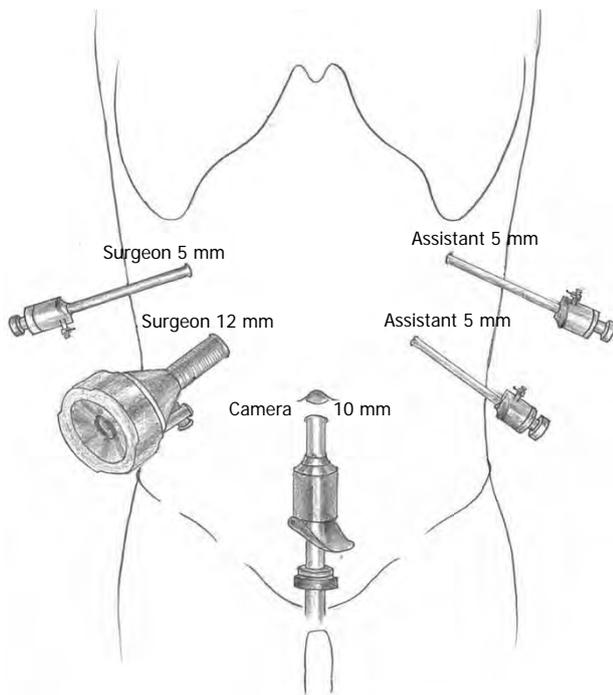

Figure 2 Location of trocars placement.

the cystic duct exiting into the duodenum through the papilla (Figure 3A). The duodenum was mobilized by the Kocher maneuver using harmonic scalpel (Harmonic Ace scalpel, Ethicon Endo-Surgery, Inc., Cincinnati, OH, United States) (Figure 3B). Two stay sutures were placed in the duodenal wall opposite the duodenal papilla, and a longitudinal incision (approximately 3.5 cm) of duodenal wall was made between the stay sutures using harmonic scalpel (Figure 3C). The periampullary tumor was then everted from this duodenotomy by a stay suture without directly manipulating it. The resection was performed circumferentially (inferior to superior) with the harmonic scalpel and electrocautery at a distance of 5 mm from the tumor (Figure 3D). The pancreaticobiliary duct was identified by the cholangiogram catheter passing through it (Figure 3E), and dissected proximally to ensure an adequate margin. Then the specimen was drawn into an endoscopic retrieval bag and removed through the umbilical incision. Intraoperative frozen section confirmed a NET with negative margin. The cut end of pancreaticobiliary duct was visualized within the resected area on the duodenal wall. Under the guidance of cholangiogram catheter, the pancreaticobiliary duct was sutured to the surrounding duodenal mucosa with interrupted 4-0 vicryl suture (Coated polyglactin 910 suture, Ethicon Products, Johnson and Johnson, New Jersey, United States) (Figure 3F). The duodenotomy was closed transversely with an endoscopic linear stapler (Endocutter 60 staple, white cartridge; Ethicon Endo-Surgery, Inc., Cincinnati, OH, United States) and interrupted 3-0 vicryl suture (Figure 3G). The gallbladder was then dissected from the liver bed using harmonic scalpel. The gallbladder was collected in an endoscopic retrieval bag and removed through the

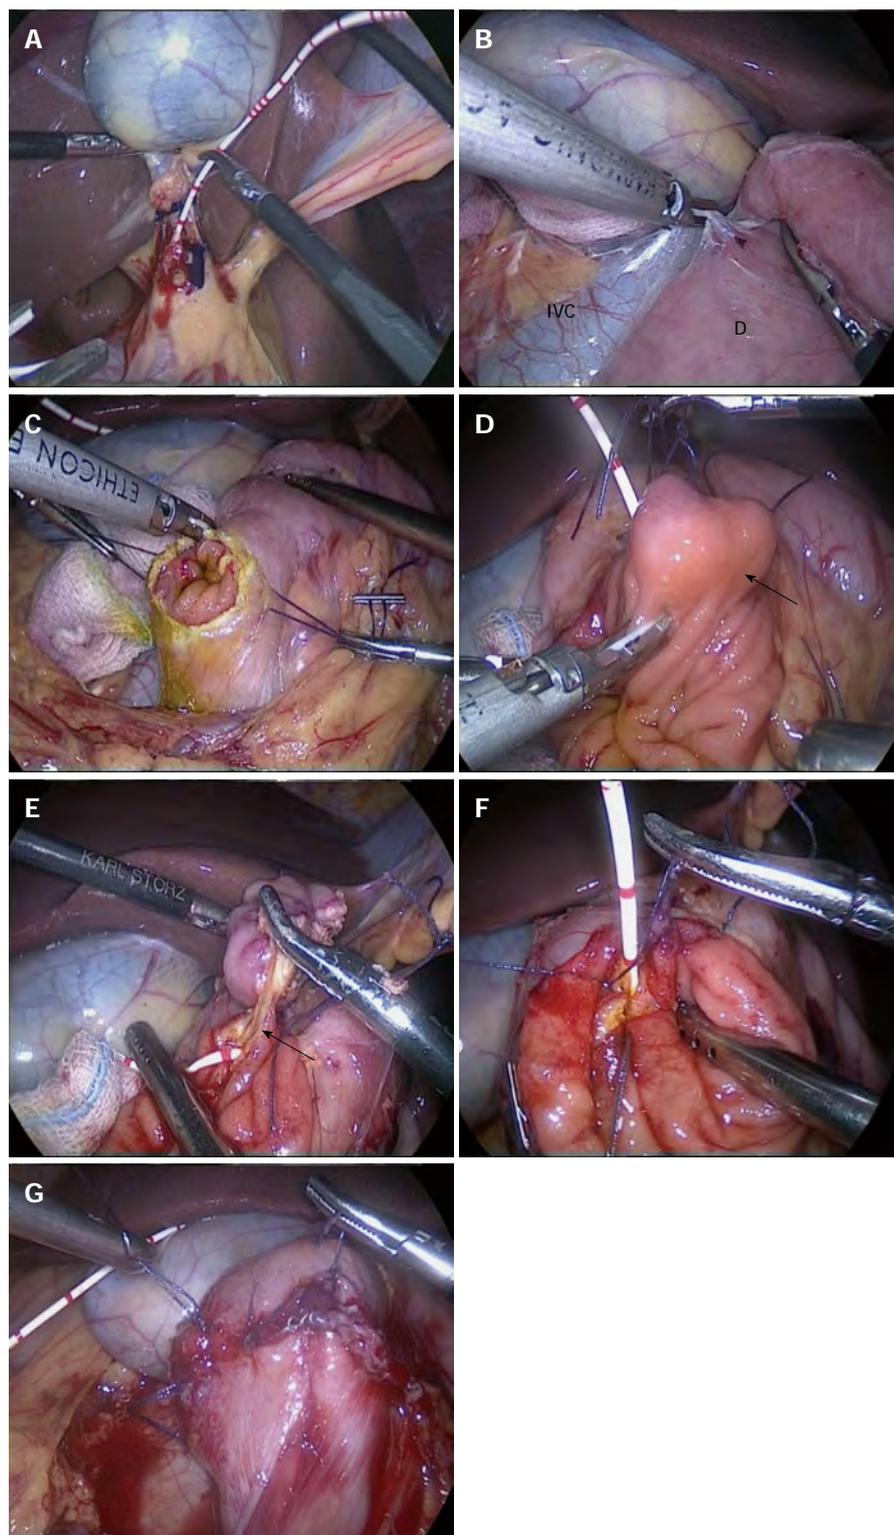

umbilical incision. Two silicon drains were placed adjacent to the duodenum.

The operative time was 180 min and blood loss was 40 mL. The postoperative course was uneventful. The patient started to take semi-fluid on day 6 after surgery, and she was discharged on postoperative day 9. Postoperative pathology showed a NET (Grade 2). The tumor size was 1.3 cm × 0.6 cm × 0.6 cm with negative surgical margin (Figure 4). She was followed up by gastroscopie and CT six months later without signs of recurrence and bleeding.

## DISCUSSION

Duodenal NETs comprises up to 3% of all duodenal tumors and 2%-3% of all endocrine tumors<sup>[5,6]</sup>. Approximately 20% of duodenal NETs occur in the periampullary region<sup>[5]</sup>. Options for resection of small periampullary NETs include pancreaticoduodenectomy (PD), transduodenal local resection, and endoscopic resection<sup>[6]</sup>. Although the mortality rate after PD (less than 4%) has been significantly decreased over recent decades, PD still carries a high morbidity rate ranging from 20% to 60%<sup>[7-9]</sup>. Moreover, pancreatic exocrine insufficiency can affect more than 50% of patients, and diabetes can occur in more than 10% of the patients after PD<sup>[10,11]</sup>. Endoscopic resection is an attractive method for treating benign periampullary tumors<sup>[2]</sup>. But endoscopic resection can only be applied to small tumors without involving the ampulla and pancreatic and biliary ducts<sup>[2]</sup>. Therefore, transduodenal local resection with low morbidity and mortality can be an intermediate treatment option between PD and endoscopic resection in the management of periampullary tumors<sup>[2,12,13]</sup>. In our case, the periampullary tumor had rich blood supply and was close to the ampulla. A probable periampullary NET or GIST was diagnosed before operation. CT and EUS demonstrated the primary tumor, but no sign of locoregional lymph node or distant metastases. Therefore, transduodenal local resection was an optimal choice of treatment for the patient. The final pathological diagnosis was NET (Grade 2), so periodical follow-up after transduodenal local resection for surveillance of recurrence is indispensable.

Because of the complexity of the anatomy of the ampulla and the difficulties in rebuilding the pancreaticobiliary duct system, laparoscopic transduodenal local resection has developed very slowly. Since 2003, when Rosen *et al*<sup>[3]</sup> reported the first case of laparoscopic resection of a periampullary villous adenoma, only three cases using this procedure have been reported in the English-language literature (Table 1)<sup>[3,4]</sup>. The feasibility of this approach is supported by previous cases reported and our successful intraoperative and postoperative results. Compared with the open surgery, the laparoscopic transduodenal local resection is associated with a lower blood loss and perioperative morbidity, and shorter hospital stay, which showed its advantages as a minimally invasive operation (Tables 1 and 2)<sup>[3,4,12-20]</sup>. However, although

**Figure 3** Steps of the surgical procedures. A: Inserting a cholangiogram catheter through the cystic duct to the duodenum; B: Mobilizing duodenum by the Kocher maneuver; C: Making a longitudinal incision of duodenal wall on the opposite site of the duodenal papilla; D: Performing the resection circumferentially at a distance of 5 mm from the tumor (arrow); E: Identifying pancreaticobiliary duct (arrow) by the cholangiogram catheter; F: Suturing the pancreaticobiliary duct to the surrounding duodenal mucosa; G: After closure of the duodenotomy. laparoscopic transduodenal local resection is a promising procedure, it needs to be validated by more clinical data.

Similar to the open surgery, laparoscopic transduodenal local resection raises two key points: (1) An adequate

margin; and (2) Reconstruction skill for restoration of ductal anatomy. To decrease the likelihood of recurrence, it is important to obtain an adequate margin<sup>[2,12]</sup>. Adequate preoperative evaluation and careful performance

Figure 4 Resected specimen of periampullary neuroendocrine tumor (arrow).

of intraoperative frozen section of the margin play a decisive role in ensuring the negative margin<sup>[12]</sup>. Schoenberg *et al*<sup>[21]</sup> performed intraoperative frozen section of the macroscopically normal mucosal tissue 1 cm around the excised lesion in each case with no recurrence after a median 43-mo follow-up. This approach could explain the low recurrence rates in their series. If the margin is involved, conversion to PD should be considered<sup>[12]</sup>. In our case and previous reported cases, intraoperative frozen section of the margins was all performed with negative result. Laparoscopic suturing for restoring ductal anatomy is the most difficult step of the procedure that needs highly skilled suture technique and patience. With the help of high-resolution imaging of the laparoscopy, the surgeon can suture better and ensure each stitch without omission. We inserted a cholangiogram catheter through the cystic duct exiting into the duodenum through the papilla in advance. The catheter was used not only to identify pancreaticobiliary duct during the resection, but also to guide the suturing of pancreaticobiliary duct to the duodenum.

In conclusion, our case suggests that laparoscopic transduodenal local resection is a feasible procedure in selected patients with periampullary tumor. Adequate preoperative evaluation, careful performance of intraoperative frozen section and highly skilled laparoscopic technique are the key factors of success in the laparoscopic transduodenal local resection.

### Abstract

Primary malignant lymphoma of the prostate is exceedingly rare. Here we report a case of a 65-year-old man who presented with increased urinary frequency, urinary urgency, and urinary incontinence for two years. Benign prostatic hypertrophy was suspected at primary impression. Ultrasound revealed a hypoechoic lesion of the prostate. The total serum prostate-specific antigen was within normal range. Positron emission tomography/computerized tomography (PET/CT) showed a hypermetabolic prostatic lesion. Prostate biopsy was consistent with a non-germinal center diffuse large B cell lymphoma. There was complete remission of the prostatic lesion following six cycles of chemotherapy as shown on the second PET/CT imaging.  $^{18}\text{F}$ -fluoro-deoxy glucose

PET/CT is not only a complement to conventional imaging, but also plays a significant role in the diagnosis and evaluation of treatment response of prostatic lymphoma.

**Core tip:** Primary prostatic lymphoma is extremely rare. There is no consensus on the primary prostatic lymphoma management. We report a case of primary diffuse large B cell lymphoma of the prostate incidentally found by  $^{18}\text{F}$ -fluoro-deoxy glucose (FDG) positron emission tomography/computerized tomography (PET/CT), and finally diagnosed by histopathological examination.  $^{18}\text{F}$ -FDG PET/CT is not only a complement to the conventional imaging studies, but also plays a significant role in the diagnosis and treatment of prostatic lymphoma.

Pan B, Han JK, Wang SC, Xu A. Positron emission tomography/computerized tomography in the evaluation of primary non-Hodgkin's lymphoma of prostate. *World J Gastroenterol* 2013; 19(39): 6699-6702 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i39/6699.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i39.6699>

### INTRODUCTION

Primary prostatic lymphoma is extremely rare, to the best of our knowledge, less than 200 cases have been described in the world literature so far<sup>[1]</sup>, mostly as single case reports, and a few as large-series studies. It constitutes 0.09% of prostate neoplasms and 0.1% of all non-Hodgkin lymphomas<sup>[2]</sup>. The most common pathological

**Figure 1** Positron emission tomography/computerized tomography image. A: Whole body positron emission tomography (PET) image (scan) shows nodal hypermetabolic foci in the prostate, and no abnormally high uptake foci in the other sites of the body; B: The PET/computerized tomography (CT) fusion image displays a nodal hypermetabolic lesion located in the right lobe of the prostate, with maximal standardized uptake value (SUV) being 12.7; C: There were no hypermetabolic foci on the whole body PET imaging following six courses of chemotherapy; D: There was complete remission of the prostatic lesion after six cycles of chemotherapy, and the maximal SUV was 2.0.

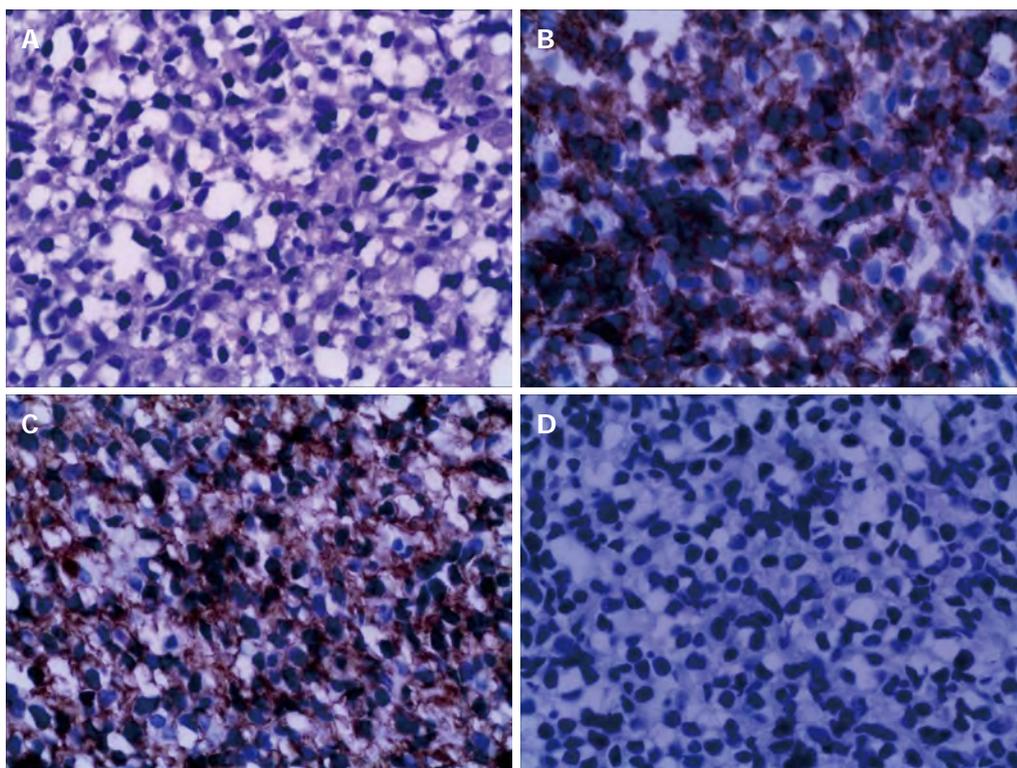

type is diffuse large B cell lymphoma (DLBCL). Because of unspecific clinical symptoms including increased urinary frequency, urinary urgency, occasional hematuria and acute urinary retention, primary prostatic lymphoma is easily misdiagnosed as benign prostatic hyperplasia or prostatitis, especially in elderly men, and it has a poor prognosis<sup>[3,4]</sup>. Serum prostate-specific antigen (PSA) level is usually within normal limits in most patients. Due to the small number of patients reported, there is no consensus on the primary prostatic lymphoma management, including radiotherapy, chemotherapy and radical prostatectomy or combined strategies.

Here we report a case of primary DLBCL of the prostate incidentally found by <sup>18</sup>F-fluoro-deoxy glucose (FDG) positron emission tomography/computerized tomography (PET/CT), and finally diagnosed by histopathological examination.

## CASE REPORT

A 65-year-old man suffered from increased urinary frequency, urinary urgency, urinary endlessness and increased frequency of nocturia for two years. Because of his age and symptoms presenting as benign prostate hyperplasia, he did not take it seriously until the symptoms were aggravating. On examination, the prostate was palpable with degree II of hypertrophy, the median sulcus was shallow, and there was no hepatosplenomegaly. Laboratory findings including blood count, liver and renal function were all normal. Chest X-ray revealed no abnormalities. Serology for human immunodeficiency virus, hepatitis B, and hepatitis C was negative. Tumor markers like alpha-fetoprotein, carcino-embryonic antigen and

total PSA were within normal limits. Ultrasound revealed prostatic hyperplasia and a hypoechoic lesion measuring 3.1 cm × 3.5 cm in size in the right lobe, and the nature of hypoechoic lesion was unidentified. Ultrasound-guided puncture was suggested. The patient was referred for a whole body PET/CT study to identify whether other sites were involved. He was injected with 9.8 millicuries of <sup>18</sup>F-FDG and underwent a whole body scan with a dedicated PET/CT scanner. Except a nodal FDG uptake in the prostate gland with the maximum standardized uptake value (SUV<sub>max</sub>) of 12.7 (Figure 1A and B), all appeared unremarkable. In order to establish the diagnosis, ultrasound-guided transrectal puncture was performed. Biopsy specimens were composed of colorectal mucosal epithelium and aggregated lymphocytes. Immunohistochemical examination demonstrated that CD20 (+), CD79a (+), Pax5 (+), BCL-6 (+), mum-1 (+), and Ki-67 (+, 60%) were positive and CD10 (-), vim (+/-), CD3 (-), CD45RO (-), CD30 (-), CX (-), PSA (-), syn (-), and CGA (-) were negative. Combined morphological and immunophenotyping examinations confirmed a DLBCL of non-germinal center B-cell origin (Figure 2). Myeloproliferation was significant with nuclear shifted to the right, and red-giant cells hyperplasia was also active, and platelets were aggregately distributed, suggesting no evidence of bone marrow involvement. Consequently, Phase I and International Prognostic Index score 1 was considered. He experienced no taboos in chemotherapy, and completed six cycles of mabthera, cyclophosphamide, doxorubicin, vincristine and prednisone (R-CHOP) chemotherapy. Three weeks after the end of chemotherapy, the patient underwent PET/CT scan again, which showed complete remission of the prostatic lesion on CT, with

**Figure 2** Combined morphological and immunophenotyping examinations confirmed a diffuse large B cell lymphoma of non-germinal center B-cell origin. A: Intensive proliferation of lymphoid cells (Hematoxylin and eosin,  $\times 400$ ); B and C: Diffuse and consistent expression of CD79a, CD20 (immunohistochemistry,  $\times 400$ ); D: The expression of serum prostate-specific antigen is negative (immunohistochemistry,  $\times 400$ ).

no active foci in the prostatic lesion on PET (Figure 1C, D), and the SUVmax was 2.0.

## DISCUSSION

Primary malignant lymphoma arising from the prostate is notably rare. We use PubMed search method, with key words of primary prostatic lymphoma, 87 Articles were retrieved by the end of Jan 2013, approximately 200 cases reported in the world literature<sup>[1]</sup>. Non-Hodgkin's lymphoma is the major histological subtype of primary Hodgkin's lymphoma (PHL) and DLBCL is the most common. Morphology of lymphoma in this case is typical, diffuse infiltrate lymphoid cells in prostate tissue. Immunohistochemical examination showed diffuse expression of CD79a and CD20 in tumor cell, which are the typical characteristics of diffuse large B cell lymphoma. CD3 being negative and diffuse expression of Mum-1 suggested that tumor cell originated from B cells. Moreover, CD30 being negative also tips for non-Hodgkin lymphoma. Negative CK suggesting non epithelial malignancies, combined with negative PSA, exclude the possibility of prostate cancer. Positive bcl-6 indicates the biological activity of lymphoma, the proliferation fraction was 60% with Ki67 antibody. Combining these conditions together, a diagnosis of non germinal center origin of diffuse large B cell lymphoma was made. The three criteria for the diagnosis of primary prostatic lymphoma were as follows: (1) tumor limited to the prostate only;

(2) the absence of any other lymphoid node or tissue involvement including blood vessels; and (3) a lymphoma free at an interval of at least 1 mo after diagnosis<sup>[5,6]</sup>. Since the clinical symptoms of primary prostatic lymphoma are atypical, including lower urinary tract symptoms, acute urinary retention or hematuria, it is difficult to establish a diagnosis merely based on clinical grounds, which may easily lead to a misdiagnosis as benign prostate hyperplasia or chronic prostatitis. Computerized tomography (CT) and Trans-Rectal UltraSound (TRUS) prostate plays an important role in the location and staging of the primary prostatic lymphoma, it usually manifests as the enlargement of the prostate with low density or hypoechoic lesions with or without abdominal and pelvic enlargement of lymph nodes on CT or US, in addition, CT and TRUS are also of great significance to treatment response to PPL<sup>[7,8]</sup>, Gallium scan is optional when distant lymph node involvement was suspected<sup>[9]</sup>. There were no specific markers for Lymphoma at present, Prostatic Acid Phosphatase May be a sensitive tumor marker protein indicating development and progression of intravascular LBCL, which was a Subtype of diffuse LBCL<sup>[10]</sup>. Tumor marker like PSA usually is within normal range in most patients. The final diagnosis can be established by surgery or transrectal prostate biopsy.

Because of its rarity, there was no consensus on the optimal treatment of prostatic lymphoma at present. A recent study showed that R-CHOP chemotherapy is superior to CHOP and is the first choice for curative intent,

this combination should become the standard for treating DLBCL<sup>[11-13]</sup>. Surgery or radiation is used only for palliative treatment of local symptoms and when the disease is confined to the prostate<sup>[14]</sup>. The prognosis of either primary or secondary prostatic lymphoma is poor and the median survival is around 23 mo after diagnosis<sup>[6]</sup>. If the disease is confined to the prostate, it could be cured with radiotherapy<sup>[3]</sup>.

The use of FDG PET imaging is uncommon for prostatic lymphoma, and only four cases have been reported in the literature: two cases of mucosa-associated lymphoid tissue lymphoma, revealing mild FDG uptake<sup>[15]</sup>, and two cases of DLBCL, which showed intense hypermetabolism<sup>[16,17]</sup>. The extent of FDG uptake may be associated with histological types. In our case, the foci of the prostate demonstrated intense FDG uptake, which was similar to the cases reported.

<sup>18</sup>F-FDG PET/CT helped diagnose the possibility of PPL in this case, and demonstrated the absence of abnormal hypermetabolic foci in any other nodes or organs. <sup>18</sup>F-FDG PET/CT identified significant treatment response after six cycles of chemotherapy.

In conclusion, <sup>18</sup>F-FDG PET/CT is not only a complement to the conventional imaging studies, but also plays a significant role in the diagnosis and treatment of prostatic lymphoma. In short, when a nodal or diffuse uptake is observed in the prostate on PET/CT and PSA is within normal limits, primary prostate lymphoma should be taken into consideration except for prostatic cancer.

### Abstract

The infection with hepatitis C virus (HCV) is one of the most important global chronic viral infections worldwide. It is estimated to affect around 3% of the world population, about 170-200 million people. Great part of the infections are asymptomatic, the patient can be a chronic carrier for decades without knowing it. The most severe consequences of the chronic infection are liver cirrhosis and hepatocellular carcinoma, which appears in 20%-40% of the patients, leading to hepatic failure and death. The HCV was discovered 25 years ago in 1989, is a RNA virus and classified by the World Health Organization as an oncogenic one. Hepatocellular carcinoma is one of the most important cancers, the fifth worldwide in terms of mortality. It has been increasing in the Occidental world, mainly due to chronic hepatitis C. Hepatitis C is not only a liver disease and a cause of cirrhosis, but also a mental, psychological, familiar, and social disease. The stigma that the infected person sometimes carries is tremendous having multiple consequences. The main cause is lack of adequate information, even in the health professionals setting. But, besides the "drama" of being infected, health professionals, family, society and the infected patients, must be aware of the chance of real cure and

total and definitive elimination of the virus. The treatment for hepatitis C has begun in the last 80's with a percentage of cure of 6%. Step by step the efficacy of the therapy for hepatitis C is rapidly increasing and nowadays with the very new medications, the so called Direct Antiviral Agents-DAA's of new generation, is around 80%-90%.

**Key words:** Hepatitis C; Chronic; Therapy; Hepatocellular carcinoma; Hepatic cirrhosis; Interferon-alpha; Ribavirin; Social stigma; Depression

**Core tip:** Around 3% of the world population, about 170-200 million people are infected with hepatitis C virus. The chronic consequences of the infection are liver cirrhosis and hepatocellular carcinoma, which appears in 20%-40% of the patients. Hepatitis C is not only a liver disease but also a mental, psychological, familiar, and social disease. The stigma that the infected person sometimes carries is tremendous. But, besides the "drama" of being infected, health professionals, family, society and infected patients, must be aware of the chance of real cure and definitive elimination of the virus. Step by step, the efficacy of the therapy for hepatitis C is rapidly increasing and with the new medications, the Direct Antiviral Agents-DAA's, is around 80%-90%.

### HEPATITIS C AND CURE

#### Step by step increasing the efficacy

Hepatitis C is one of the most important global chronic infection worldwide: it is estimated to affect 170-200

million people, while chronic hepatitis B and human immunodeficiency virus (HIV) infection affects respectively 350 million and 34 million. There is no vaccine for hepatitis C. Hepatitis B is easily preventable by vaccination. Another characteristic of hepatitis C virus (HCV) infection is the high risk of evolution to chronicity, more than 50% which can be around 80% in same series<sup>[1]</sup>. Another characteristic is the absence of symptoms for decades before the phase of decompensation of liver cirrhosis and the appearance of hepatocellular carcinoma.

The most severe chronic consequences of the infection are liver cirrhosis and hepatocellular carcinoma, leading to hepatic failure and death, which can appear in 20%-40% of the patients<sup>[2]</sup>.

In effect, cirrhosis is the end-stage of every chronic liver disease. Its natural history is characterized by an asymptomatic phase, called “compensated” followed after several years or decades by a “decompensated” phase. The patient, in the decompensated phase has a median of survival of 2 years<sup>[3]</sup>.

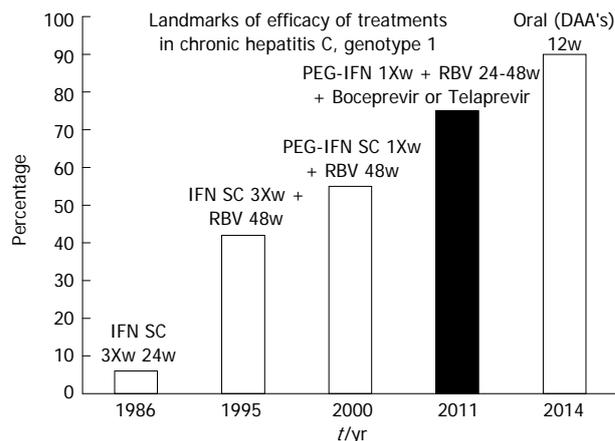

This phase can be characterized by a rapid clinical evolution with all the complications of a cirrhotic liver with portal hypertension: ascites, sepsis (the majority from spontaneous bacterial peritonitis), varices bleeding, jaundice, mental alterations (encephalopathy), renal failure (hepatorenal syndrome), caquexia<sup>[4,5]</sup>.

Liver cirrhosis is one of the most oncogenic situations in medical terms. The development of hepatocellular carcinoma (HCC) is a real fact, occurring in 1%-4% each year and is becoming in some centers the most frequent complication of HCV cirrhosis<sup>[6]</sup>.

The quality of life in the decompensated phase can be very poor with frequent hospitalizations and readmissions<sup>[7]</sup>. At this stage only liver transplantation is really effective for median or long term survival. But if the virus is still active, the reinfection is almost universal<sup>[8]</sup>. But, besides the “drama” of being infected, health professionals, family, society and infected patients, must be aware of the chance of real cure and total and definitive elimination of the virus<sup>[9]</sup>.

The HCV was discovered 25 years ago in 1989, is a RNA virus and classified by the World Health Organization as an oncogenic one<sup>[10]</sup>. The discover of the virus has open the way to a diagnosis test (anti-HCV) and several studies of molecular biology, virology and pharmacology<sup>[11]</sup>. The treatments for hepatitis C has begun in the last 80's with a percentage of cure of 6%<sup>[12]</sup>. Step by step the efficacy of the therapy for hepatitis C is rapidly increasing and nowadays with the very new medications, the oral Direct Antiviral Agents-DAA's, is around 80%-90%<sup>[13]</sup>.

The therapy of hepatitis C is an example of the capacity of modern medicine to translate the basic research to the clinical setting (Figure 1). Several types of medications have been used in to treat hepatitis C throughout these 25 years of success: first, human interferon (INF, three times weekly, 6% of efficacy), in 1995 Ribavirin has appeared to be used in combination with INF (34%-42% of efficacy), in 2001 Pegylated INF once weekly with

**Figure 1** Percentage of cure of hepatitis C genotype 1. IFN: Interferon; RBV: Ribavirine; PEG: Peginterferon; DAA: Direct antiviral agents.

ribavirin (45% of cure for genotype 1 and 70%-80% for genotype 3)<sup>[14]</sup>. In 2011 another step with the combination of Peginterferon and Ribavirin with two Protease inhibitors, region 3/4 (Boceprevir<sup>[15]</sup> and Telaprevir<sup>[16]</sup>), the triple therapy, leading to cure in 70%-80% of cases.

Several clinical trials are in rapid development worldwide with the new DAA's (Direct Acting Antiviral Agents) interacting with several of vital components of the virus (NS 3/4, NS5A, NS5B Polymerase, *etc.*). In effect a new generation medications is rapidly approaching, like Sofosbuvir<sup>[17]</sup>, Daclastavir, Asunaprevir<sup>[17]</sup>, ABT-450<sup>[18]</sup>, Faldaprevir, Simeprevir, Deleobuvir, some of them only using oral agents, for a period of 12 wk, with a few negligible side effects, having a chance of viral eradication of 80%-90%.

In fact, in a quarter of a century, the percentage of cure has increased from 6% to 90% of cure. From three injections a week during 48 wk to some pills a day during 12 wk! Another important development that has positively affected the quality of life of patients, allowing access to treatment and possible cure is the Transitory Elastography (Fibroscan<sup>®</sup>). Is an ultrasonographic device with very good acuity in the diagnosis of liver fibrosis, mainly when there is liver cirrhosis. The number of liver biopsies has decreased<sup>[19]</sup> in some centers around 90%.

The efficacy of the therapy is assessed by an important finding, *i.e.*, the viral load: RNA HCV (by a sensitive test) must be negative 24 wk after stopping therapy. If this happens, more than 99% of patients will never be positive again.

### Cure of hepatitis C

It is the only global chronic viral infection that is possible to cure. The other ones are hepatitis B and HIV infecting respectively 350 and 34 million people worldwide but with no chance of cure in chronic cases.

In the beginning of this story of success, the medical community was afraid of the word cure. But now it is well known this word can be used with property but with some restrictions. In effect is a virological cure for

**Table 1 Benefits of cure of hepatitis C**

Benefits of cure of hepatitis
1 Negative HCV RNA (viral load) for life, in more than 99% of cases
2 Negative HCV RNA in the liver
3 HCV RNA negativation in PBMC
4 No detection of the genotype
5 Sometimes, a few year later, the anti-HCV test can became negative, the so called "seroreversion"
6 Normalization of aminotransferases (AST, ALT) and GGT
7 Changing of ultrasound findings (contours can became regular, reduce of diameter of portal vein in case of portal hypertension)
8 Disappearance of the lymphnodes near the liver (helium)
9 Decrease of the values for Elastography (Fibroscan®)
10 Reducing the risk of progression to cirrhosis
11 Reversion of cirrhosis in some cases
12 Disappearance of oesophageal varices
13 Reducing the risk of progression to liver cancer
14 Reduced risk of decompensated liver disease (ascites, jaundice, rupture of oesophageal varices, encephalopathy)
15 Reducing to zero the risk of recurrence after liver transplantation (if necessary)
16 Improved quality of life (asthenia, fatigue, general well-being)
17 Reducing of the psychological impact (anxiety/depression)
18 Disappearance of the risk of sexual transmission
19 Disappearance of the risk of perinatal transmission
20 Decrease in the insurance premium
21 Cure of associated conditions (porphyria cutanea tarda, polyneuropathy, urticaria, cryoglobulinemia, splenic lymphoma)
22 Reducing personal, family and social stigma
23 The treatment is proved cost-effective
24 Benefit to public health
25 Reduced risk of death from liver disease
26 Neurocognitive improvement
27 Cure of hepatitis C

Benefits of virological response (HCV RNA negative 24 wk after finishing therapy). HCV: Hepatitis C virus; PBMC: Peripheral Blood Mononuclear Cells; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; GGT: Gamma-glutamyl transferase.

life. It is proved that virus is not detected on liver cells or mononuclear blood cells. Nor there is an occult disease as is the case for chronic hepatitis B (HBV DNA negative or with low levels, having HBsAg negative and a risk of relapse in case of immunosuppression).

Albeit is a definitive one, we must be cautious in patients having liver cirrhosis, because the chance of development of hepatocellular carcinoma is strongly reduced, but still remains. It is one of the reasons to treat patients with mild or moderate fibrosis, in order to reduce the chance, while in a stage of a less severe disease, of evolution to cirrhosis and hepatocellular carcinoma. Liver cirrhosis, *per se*, is a disease having a risk of 1%-4% per year of evolution to hepatocellular carcinoma.

The benefits of cure are tremendous. Hepatitis C should be considered a global disease. As for the definition of Health of World Health Organization, ("Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity") chronic hepatitis C is a physical, mental and social disease, affecting globally the individual, the couple, the family, and the society as a whole.

There are some myths about hepatitis C: "almost always lethal, more severe than acquired immunodeficiency

syndrome (AIDS), very contagious disease, not curable, the adverse events of therapy are huge and very severe, *etc.*" But the benefits of cure, in global terms considering the physical, mental and social aspects are several (Table 1).

### **Mental health and quality of life in hepatitis C**

Besides the natural history of this disease, the personal impacts of a diagnosis of hepatitis C infection and its treatment strongly affect the patients' quality of life<sup>[20-22]</sup>. Mental health problems frequently occur in chronic infection with HCV and during the antiviral treatment. These individuals frequently present neuropsychiatric symptoms like fatigue, anxiety, depression and cognitive disorders<sup>[23,24]</sup>.

Regarding neuropsychiatric symptoms, one can identify two distinctive patterns in its relation with HCV infection. On one hand, individuals with chronic hepatitis C have higher prevalence of psychiatric disorders, including depression<sup>[25]</sup>. On the other hand, individuals with psychiatric records present higher HCV infection rates than the average population<sup>[26]</sup>.

A combined therapeutics using Pegylated IFN is commonly used in these patients and proves to be a fundamental and consensual intervention for a favourable change in the natural history of the disease<sup>[27,28]</sup>.

However, this treatment is associated with a high number of adverse reactions like: irritability, insomnia, fatigue and loss of appetite. Apart from these, neuropsychiatric symptoms (especially depression, and sometimes with suicidal ideation) are among the most common secondary effects in therapeutics with IFN, being one of the main causes why patients interrupt their treatment<sup>[24,29,30]</sup>. It is noteworthy that, up to a certain extent, psychopathologic symptoms (depression, cognitive disorders) may be associated to HCV infection, even without an INF treatment, and may be related to direct HCV neurotoxicity<sup>[29-32]</sup>.

A large number of patients undergoing treatment for VHC infection should be referred for psychiatric evaluation and, if necessary, should received treatment for depression and other neuropsychiatric symptoms.

Recognition of depression and other neuropsychiatric symptoms is important, and could improve adherence to VHC treatment. This symptomatology negatively affects the individual's perceived quality of life, its general functioning, work capacities, less participation in life and medical care, increase mobility and mortality, decrease overall well-being and quality of life<sup>[27,33]</sup>. Furthermore, therapeutic used in HCV treatment is associated to impairment in all of these dimensions<sup>[34]</sup>.

Thus, considering the impact in patients' mental health, before and during the treatment, an interdisciplinary approach should be followed and encouraged when dealing with HCV infected patients<sup>[24]</sup>.

### **Stigma and hepatitis C**

Diagnosis with hepatitis C was reported to have pro-

found impacts on social functioning. Perceived stigma associated with HCV infection leads to high levels of anxiety and exaggerated fear of transmission, and it can be a major cause of social isolation and reduced intimacy in relationships<sup>[35]</sup>.

Epidemiological studies suggest that more than 90% of transmission in developed countries takes place through the sharing of non-sterilized needles and syringes in the intravenous drug-using population<sup>[36]</sup>.

Because the vast majority of people with hepatitis C have a history of intravenous drug use, they are frequently blamed for acquiring the disease, and viewed as irresponsible, accountable and “unworthy”<sup>[37]</sup>. Furthermore, as a blood-borne disease, hepatitis C is strongly associated with HIV. This association exists due to the fact that intravenous drug abuse is a significant risk factor for contracting both diseases and this can be a stigmatizing factor for this patients<sup>[38]</sup>.

Stigma can be defined as attitudes expressed by a dominant group, which views a collection of others as socially unacceptable. The notion of stigma denoting shameful relations and deviations from what is considered “normal” has a long history within infectious disease, in particular HIV<sup>[39]</sup>, and more recently in hepatitis C infection.

These norms, behaviours and beliefs surrounding hepatitis C infection can lead to alienation from family and friends, as well as to discrimination (perceived or real) in health services and workplaces<sup>[40]</sup>.

Stigma can affect self-esteem and quality of life. It can also impede the success of diagnosis and treatment, leading to continuing risk of disease transmission. It is a social phenomenon that influences the course of illness and marginalizes patients<sup>[41]</sup>.

Since stigmatization affects not only the individual but also the whole course of the disease, health care workers are not immune to stereotypes and judgements that might influence the course of the treatment of HCV patients. Changing this behaviour will help prevent patients’ isolation, withdrawal of treatment and it will increase the search for medical help<sup>[42]</sup>.

Hepatitis C should have a global approach in its treatment. It requires broad-based educational efforts in order to increase the understanding of this disease, still connected to several pejorative stereotypes<sup>[42]</sup>. These efforts should include patients and their family, health care providers and the society as a whole. Further knowledge of hepatitis C stigma is central to assisting patients in self-managing their illness, and it is important to reduce the disease burden.

### Several benefits of cure hepatitis C

The goal of therapy is to eradicate HCV infection. The endpoint of therapy is sustained virological response (SVR). Once obtained, SVR usually equates to cure of infection in more than 99% of patients<sup>[43]</sup>.

If the test for assessing viral load is negative 24 wk after finishing therapy, we can talk of “cure”. With the new

treatments, the oral DAAs, the assessment of sustained viral response can be shortened to 12 wk after ending the treatment. HCV RNA detection and quantification should be made by a sensitive assay (lower limit of detection of 50 IU/mL or less), ideally a real-time PCR assay. If the patient has already cirrhosis, the risk of develop hepatocellular carcinoma still persist for some years and deserves an abdominal ultrasound every six months.

When the SVR is obtained the global benefit is as it follows: if there is no another reason for AST, ALT or GGT elevation, namely alcohol consumption or obesity, they became persistently normal.

At virological level, the HCV RNA is no longer detected in the liver<sup>[44]</sup> or even in the Peripheral Blood Mononuclear Cells (PBMC) by sensitive tests<sup>[45]</sup>. The genotype becomes and remains negative, because there is no virus for detection.

One of the things that can cause some confusion is the fact that the anti-HCV (a marker of past infection) generally remains positive. The index can decrease slowly and the anti-HCV can become negative, several years after, as it happens in the context of acute hepatitis C<sup>[46]</sup>.

On the Hepatic Elastography (Fibroscan<sup>®</sup>) the values generally decrease along some months<sup>[47]</sup>. At the abdominal ultrasound the findings can change: the liver contours can become regular, the diameter of portal vein reduces in case of presence of portal hypertension. The disappearance of the lymph nodes in the hepatic hilum can be a finding<sup>[48]</sup>. There are some studies showing that dimensions of these lymph nodes are related with the levels of viral replication<sup>[49]</sup>.

Regarding liver disease the risk of progression to cirrhosis decreases. In some cases it occurs a reversion of cirrhosis<sup>[50]</sup>. In fact this is no longer an irreversible situation as was thought some years ago; the disappearance of oesophageal varices is also fact<sup>[51]</sup>. On the other side, there is a decrease of risk of evolution for more severe stages of liver disease like the progression hepatocellular carcinoma<sup>[52]</sup> and risk of the decompensated liver disease (ascites, jaundice, rupture of oesophageal varices, encephalopathy, jaundice, *etc.*)<sup>[53]</sup>.

In the case that a liver transplantation would be necessary the risk of reactivation is no longer present. More than 95% of cases of patients transplanted for cirrhosis associated with HCV will have again HCV RNA positive and 50% will develop severe forms of liver disease a few years after transplant<sup>[54]</sup>. Because of that, to treat patients with cirrhosis or intense fibrosis must be done as soon as possible.

There is an improvement of quality of life<sup>[55]</sup> (asthenia, fatigue, general well-being, *etc.*) assessed by adequate tests and more important on the mental level there is a reduction of the psychological impact (anxiety and/or depression).

In strong relation to cure, the risk of sexual<sup>[56]</sup> and perinatal transmission<sup>[57]</sup> disappear. These are very important advantages of SVR in the treatment of hepatitis C. We must not forget, that hepatitis C, besides a liver

disease is also an infectious and transmissible disease. We can consider the cure as “belonging” to the patient himself but also to his family, his couple, *etc.* Is also a familiar disease. There are some patients who don't tell the family or to the couple afraid of the consequences of the bad news. If patients insist with Insurance Companies they must decrease the insurance premium because there is less risk of clinical evolution.

There are reports of the control and even disappearance of some associated conditions like porphyria cutanea tarda<sup>[58]</sup>, polyneuropathy<sup>[59]</sup>, urticaria<sup>[60]</sup>, cryoglobulinemia<sup>[61]</sup>, splenic lymphoma<sup>[62,63]</sup>.

Depending on the countries and the burden of the infection, the treatment was proved to be cost-effective<sup>[64]</sup>. Reducing of personal, psychological, family and social stigma is a huge benefit for all. Stigma is a fact that must be considered in the setting of HCV therapy and also when considering the real burden of the disease.

## CONCLUSION

Considering the global approach we can consider that to cure HCV chronic infection is a real benefit to public health mainly by reducing the risk of complications and dying because of liver disease. Having access to the most modern therapies, the disease is almost a curable disease and the efficacy of treatment markedly increases the survival of patients infected. Chronic hepatitis C is a silent epidemic, a global disease with a strong stigma, but with high chance of definitive cure<sup>[65]</sup>.

### Abstract

Once a nosocomial disease, *Clostridium difficile* infection (CDI) now appears frequently in the community in the absence of exposure to antibiotics. Prior studies have shown that patients with community-acquired CDI are younger, more likely to be female, and have fewer comorbidities compared to patients with hospital-associated CDI. Because most studies of CDI are hospital-based, comparatively little is known about community-acquired CDI. The recent study by Chitnis has received widespread attention because it used active surveillance to capture all cases of community-acquired CDI within a large population and assessed key risk factors. The authors found that low-level healthcare exposure and proton pump inhibitor use were common among those with non-antibiotics associated, community-acquired CDI. In this commentary, we discuss the changing epidemiology of community-acquired CDI and the evidence basis for the controversial association between proton pump inhibitors and community-acquired CDI.

### COMMENTARY ON HOT TOPICS

*Clostridium difficile* (*C. difficile*) infection (CDI) is the most feared gastrointestinal epidemic in the developed world with increasing incidence, virulence, and case fatality rates<sup>[1-5]</sup>. Formerly a nosocomial disease, CDI has become common in the community<sup>[6,7]</sup>. Early reports suggested that the risk factors associated with community-acquired CDI differ from the traditional risk factors associated with nosocomial CDI with relatively young and healthy individuals affected<sup>[8]</sup>. Thus we read with great interest the recent article by Chitnis *et al*<sup>[9]</sup> describing a multi-center study of the factors associated with community-acquired CDI.

### COMMUNITY-ACQUIRED *CLOSTRIDIUM DIFFICILE* INFECTION

Pseudomembranous colitis was reported in the 19<sup>th</sup> cen-

tury and has long been understood as an antibiotic-associated phenomenon<sup>[10,11]</sup>. In 1978, *C. difficile* was identified as the causative agent of disease; subsequent reports recognized that pseudomembranous colitis caused by *C. difficile* could occur without antibiotics<sup>[12]</sup>. But it was only beginning in 2005 that it became understood that *C. difficile* infection was frequently occurring in the community<sup>[7]</sup>.

Community-acquired CDI differs from hospital-associated disease, although many uncertainties remain. In the United States and Europe, 15%-44% of CDI occurs in the community without an identifiable antecedent healthcare exposure<sup>[8,13-15]</sup>. Compared to individuals with nosocomial CDI, those with community-acquired CDI are younger, have fewer comorbidities, and are more likely to be female<sup>[7]</sup>. Most surprisingly, patients with community-acquired CDI often do not report exposure to antibiotics<sup>[16]</sup>.

If antibiotics are not essential in community-acquired CDI, what are the crucial risk factors? This question has been difficult to answer, in part because it is challenging to study community-acquired CDI in the United States. Cases of CDI arising in the community rarely require hospital admission. However, many studies of community-acquired disease are hospital-based and thus miss a large proportion of disease that both arises and is treated in the community<sup>[17-21]</sup>. In 2009, to address this problem, the Centers for Disease Control and Prevention (CDC) began a population-based program of active surveillance encompassing 11 million people<sup>[22]</sup>. Working with laboratories within the active surveillance area, all newly positive *C. difficile* stool tests were prospectively identified. Based on interviews with affected individuals, cases were classified as hospital-associated (defined as diarrhea and stool collected > 3 d to < 12 wk from a hospitalization) or community-acquired (all other cases). Community-acquired cases were assessed for risk factors including use of antibiotics or proton pump inhibitors (PPIs) and healthcare exposures within the previous 12 wk (classified as high-level exposure for dialysis or emergency department visits or low-level exposure for visits to a physician's office).

Chitnis *et al*<sup>[9]</sup> report on the first results of this valuable project. The authors identified 984 patients with confirmed community-acquired *C. difficile* infection. Patients were relatively young (median age 51 years old) and predominantly female (67%). Yet morbidity and mortality were surprisingly high. One quarter of patients with community-acquired CDI were hospitalized for treatment and there was a 6% combined rate of death, colectomy, or admission to an intensive care unit. Overall, 41% of patients reported a high-level healthcare exposure, 41% of patients reported a low-level healthcare exposure, and 18% of patients reported no healthcare exposure. Sixty-four percent of patients recalled antibiotic use within the preceding 12 wk. Compared to patients who reported recent antibiotic use, those that did not report antibiotic use were slightly more likely to report PPI use (31% *vs* 26%) but not histamine 2-receptor antagonist use (10%

*vs* 9% respectively). The study has no comparison group so its most important findings are essentially descriptive. Nonetheless, the concerning implication is that non-antibiotic associated CDI is rising. Are PPIs to blame?

## CLOSTRIDIUM DIFFICILE INFECTION AND PPIs

Over thirty observational studies and multiple meta-analyses indicate that PPIs are a risk factor for *C. difficile* infection<sup>[17,18]</sup>. Citing these findings in 2012, the United States Food and Drug Administration issued a warning regarding increased risk of CDI among patients taking long term PPIs<sup>[23]</sup>. Yet many questions remain regarding the relationship between PPIs and *C. difficile*. The data connecting PPIs and CDI is observational. Because patients who are prescribed PPIs differ in many ways from those who are not prescribed PPIs<sup>[24,25]</sup>, it is possible that the observed association between PPIs and CDI is attributable to unmeasured confounding<sup>[26]</sup>. And there is comparatively little data that specifically addresses PPIs in community-acquired CDI.

There are a few reasons to suspect that the relationship between PPIs and CDI might be different among those with community-acquired compared to hospital-associated CDI. First, the highly toxigenic North American pulsed-field 1 (NAP1) strain has been linked to hospital-associated<sup>[3,27]</sup> rather than community-acquired cases; it is possible that the relationship between PPIs and CDI is affected by *Clostridial* strain. Second, a potential mechanism by which PPIs increase risk for CDI may be via alteration of the colonic microbiome<sup>[28-31]</sup>. Thus hospitalized patients, who can have altered microbiomes compared to those in the community<sup>[32]</sup>, may be affected differently by PPIs. Finally, antibiotic exposure, which differs between hospitalized and non-hospitalized patients, may modify the relationship between PPIs and CDI<sup>[33]</sup>.

So what is the evidence that PPIs are a risk factor for CDI in the community? Only a handful of studies include disease that is both acquired and treated in the community. A large, population-based study conducted within a United Kingdom dataset identified over 1000 cases of community-acquired CDI from 1994 to 2004<sup>[34]</sup>. The authors found that only 37% of cases had been prescribed antibiotics within the previous 90 d; compared to matched controls, patients prescribed PPIs within the previous 90 d had a nearly 3-fold increased risk for CDI. A Scottish study conducted among adults  $\geq$  65 years old identified all cases of community-acquired CDI<sup>[35]</sup>. After adjusting for covariables, the authors found that patients prescribed PPIs within the previous 6 mo had a 1.7-fold increased risk for CDI compared to matched controls. Finally, a study using a large United States insurance claims database identified all cases of CDI from 2004 to 2007 in Iowa and South Dakota<sup>[13]</sup>. Seventy-three percent of cases had been prescribed antibiotics within the previous 180 d; patients prescribed PPIs or histamine-2 receptor antagonists within the previous 180 d had a 2.3-fold increased

risk for community-acquired CDI compared to matched controls. These findings imply that the association between PPIs and CDI is at least as strong in community-acquired disease as in its more familiar hospital-associated form.

The study by Chitnis *et al*<sup>[9]</sup> was not designed to directly test the hypothesis that PPIs are associated with CDI in the community. Instead, this study yields valuable lessons regarding the epidemiology and risk factors for community-acquired *C. difficile* infection. Using active surveillance to capture all cases of community-acquired CDI, the authors have shown that non-antibiotic associated, community-acquired CDI is common, and that affected patients frequently have some form of healthcare exposure that falls short of actual hospitalization. Overall, rates of PPI use were extraordinarily high, nearly 30% among patients with community-acquired CDI compared to less than 3% in the general population<sup>[36]</sup>. Future studies should test the hypothesis that PPIs are a risk factor for non-antibiotic associated, community-acquired *C. difficile* infection and assess whether interventions causing decreased PPI use can also decrease rates of CDI. For now, the findings of Chitnis *et al*<sup>[9]</sup> highlight the fact that community-acquired CDI is a very real problem and remind us that PPIs should be prescribed only in situations where they are indicated.

### Abstract

Acute hepatitis C is a rare event in pregnancy. The most common scenario is chronic hepatitis C virus (HCV) infection in pregnancy. During pregnancy in women with chronic HCV infection a significant reduction in mean alanine aminotransferase levels has been reported, with a rebound during the postpartum period. In few cases exacerbation of chronic hepatitis C has been reported in pregnancy. A cofactor that might play a role in the reduction of liver damage is the release of endogenous interferon from the placenta. Observations regarding serum HCV-RNA concentration have been variable. In some women HCV-RNA levels rise toward the end of pregnancy. In general, pregnancy does not have a negative effect on HCV infection. Conversely, chronic hepatitis does not appear to have an adverse effect on the course of pregnancy, or the birth weight of the newborn infant. The role of spontaneous abortion is approximately the same as in the general population. The overall rate of mother-to-child transmission for HCV is 3%-5% if the mother is known to be anti-HCV positive. Co-infection with human immunodeficiency virus (HIV) increases the rate of mother-to-child transmission up to 19.4%. Numerous risk factors for vertical transmission have been studied. In general, high viral load defined as at least  $2.5 \times 10^6$  viral RNA copies/mL, HIV co-infection, and invasive procedures are the most important factors. Both interferon and ribavirin are contraindicated

during pregnancy. Viral clearance prior to pregnancy increases the likelihood that a woman remains non-viremic in pregnancy with a consequent reduced risk of vertical transmission.

### INTRODUCTION

The global prevalence of hepatitis C virus (HCV) infection is 2%-3%, with 130-170 million HCV-positive people - most of them chronically infected<sup>[1]</sup>. The epidemiology of HCV is varies among countries and the reported prevalence of HCV in pregnant women has not been extensively studied, due to the lack of preventative screening of infection and the lack of preventative measures of mother-to-child transmission. The pathogenesis of HCV infection during pregnancy remains poorly understood. During pregnancy, the maternal immune system must at the same time develop tolerance to paternal alloantigens to prevent maternal immune aggression against the fetus

and maintain active immunity against HCV to protect both mother and fetus from infection<sup>[2]</sup>. Moreover, it is important to define the effect of pregnancy on HCV and vice versa. Finally, understanding the transmission of HCV to infants and the risk factors correlated with transmission will provide information for counseling and management of HCV infection during puerperium.

### EPIDEMIOLOGY OF HCV IN PREGNANCY

The current prevalence of HCV in pregnant mothers is difficult to be estimated, because of the lack of selective screening in a large proportion of this population. The prevalence of serum HCV antibody in cohorts of  $\geq 3000$  pregnant mothers ranges between 0.1% and 3.6% with a mean of 1.16%, and the prevalence of HCV RNA ranges between 42.5% and 72%<sup>[3-14]</sup> (Table 1). It is particularly interesting that in Egyptian rural villages the prevalence of anti-HCV reaches a mean of 15.5%, with a 30% rate in women aged  $> 35$  years<sup>[15]</sup>. The epidemiological risk factors explaining this dramatic high prevalence include: previous delivery attended by a traditional birth assistant; circumcision by a traditional birth assistant or a “healthy barber”; and injection therapy for schistosomiasis.

In all series the main route of acquiring HCV in pregnant mothers is intravenous drug use, whereas a previous blood transfusion is a risk factor in up to 11% of cases<sup>[4,6,16-22]</sup> (Table 2).

It should be noted that a large study in Japan has demonstrated a significant decline in HCV prevalence in pregnant women<sup>[10]</sup>. In a cohort studied between May 1990 and November 2004, a total of 22664 consecutive serum samples were screened for anti-HCV. Among women known to be transfused, rates fell from 14.8% to 3.1% with the implementation of HCV screening. In non-transfused women rates fell from 1.8% to 0.3%. This reduction has been mainly explained by the hygienic improvements including needles for medical injections and single-use acupuncture needles. The prevalence of HCV infection has been found to be lower in recent years com-

IVDU: Intravenous drug use; BT: Blood transfusion.

pared to the 1990s and 2000s, even in Upper Egypt<sup>[23]</sup>. The lower prevalence rates may be due to the amelioration of standard care and to the hepatitis B virus (HBV) vaccination of all newborns, together with the mandatory testing of blood donors and blood products and careful preoperative measures.

### ACUTE HEPATITIS C

Acute hepatitis C during pregnancy has been rarely reported in pregnancy, and limited to high-risk groups, such as intravenous drug users, whereas the risk in the general population is negligible. Flichman *et al*<sup>[24]</sup> described a case in a 16-year-old pregnant woman who developed icteric acute hepatitis. She was a chronic HIV carrier and was diagnosed with HCV superinfection. HCV infection interfered with HIV replication, because the HIV levels were undetectable during the course of acute HCV infection. Another case of acute hepatitis C was described in a 26-year-old woman at week 16 of pregnancy, who was treated with a short course of interferon<sup>[25]</sup>. Although the therapy was discontinued due to adverse effects, a complete biochemical and virological response was obtained. Premature labor occurred and healthy twin infants were born transvaginally; they did not acquire HCV infection. A case with acute hepatitis C and premature delivery, but no vertical transmission has also been reported<sup>[26]</sup>. Finally, acute hepatitis C was reported in a 29-year-old Japanese woman who developed fatigue, jaundice and ascites after a needle-stick injury<sup>[27]</sup>. When these symptoms were presented, the patient became pregnant by artificial insemination. She was treated with interferon- $\beta$  following eradication of HCV infection without severe side effects. In general, however, it should be said that acute hepatitis C is a rare event in pregnancy and that there is also a publication bias, due to reporting only severe cases<sup>[28]</sup>.

From the epidemiological point of view, however, acute hepatitis C is not a relevant problem in pregnancy<sup>[29,30]</sup>.

The differential diagnosis of acute hepatitis C requires us to rule out hepatitis caused by other hepatotropic viruses (hepatitis A, B, D and E) and liver disorders unique to pregnancy. Hepatitis A is transmitted by the oral-fecal

route. The whole Mediterranean area is endemic for this infection. Acute hepatitis A virus infection in pregnancy has been described only in anecdotal cases, and virtually in 100% of cases it has a favorable outcome<sup>[31]</sup>. To date, acute episodes of HBV infection in Italy have been rare, because HBV vaccination in newborns and adolescents has been compulsory since 1991. However, acute infections in pregnancy can occur in immigrants from developing countries or in high-risk groups, such as intravenous drug users. The clinical course of acute hepatitis B in pregnancy is benign, and the risk of fulminant cases is similar in pregnant and non-pregnant women. Acute infection with hepatitis D virus (HDV) does not represent a relevant risk for death in pregnancy. However, HDV epidemiology has dramatically changed over the past 20 years. Only sporadic cases are recorded in the Mediterranean countries, whereas, it is still a problem in some South American areas (especially in the Amazon Basin) and India<sup>[32]</sup>. Hepatitis E virus (HEV) is endemic in many tropical and subtropical countries, including Central Asia and India<sup>[33]</sup>. Sporadic cases in immigrants from these countries might be seen in developed countries. Generally, symptoms of acute illness including jaundice develop in 80% of cases. The reported risk for fulminant hepatic failure in pregnancy was up to 20% in previous studies<sup>[34]</sup>. Even in mothers who recover from acute hepatitis, an increased frequency of abortion and fetal complications have been reported. Moreover, the severity of acute hepatitis E in pregnant women seems directly correlated with viral load<sup>[35]</sup>. However, the results from recent studies in India and elsewhere indicate that the severity of viral hepatitis during pregnancy is similar to that in non-pregnant women<sup>[36]</sup>.

Acute viral hepatitis in pregnancy requires differential diagnosis from liver disorders unique to pregnancy, in particular the HELLP syndrome, intrahepatic cholestasis of pregnancy (ICP), and acute fatty liver of pregnancy<sup>[37,38]</sup>. The HELLP syndrome is a variant of pre-eclampsia/eclampsia and is characterized by elevated liver enzymes, low platelet count and hemolysis. Its onset is generally in the second trimester of pregnancy, and patients may show initially elevated blood pressure, edema and proteinuria<sup>[39]</sup>. The intrahepatic cholestasis of pregnancy most frequently occurs in the third trimester of pregnancy with pruritus and elevated serum transaminases and bile salts; jaundice is rare and synthetic function of the liver is conserved<sup>[40]</sup>. Acute fatty liver of pregnancy is a severe condition that usually occurs in the third trimester with symptoms of encephalopathy and liver failure<sup>[41]</sup>. Early diagnosis is essential because treatment of acute hepatitis is generally conservative, whereas acute fatty liver of pregnancy and often HELLP syndrome require immediate delivery.

## CHRONIC HEPATITIS C

The most important studies of HCV in pregnancy have dealt with chronically infected women, and the natural

history of the liver disease in pregnant mothers and their offspring is not fully understood.

## EFFECT OF PREGNANCY ON HCV

During pregnancy in chronic HCV infection a significant reduction in the mean alanine aminotransferase (ALT) levels has been reported<sup>[4,42,43]</sup>, with rebound during the postpartum period. However, when we consider a cohort of pregnant women with HCV infection and persistently high aspartate aminotransferase/ALT levels, this trend is not confirmed<sup>[43]</sup>. The release of endogenous interferon from the placenta during pregnancy might partly explain changes in liver enzymes, but does not interfere with viral clearance<sup>[44]</sup>. Other factors, such as hemodilution or immune tolerance, may account for the decrease in serum transaminases during pregnancy. Sex hormones, and possibly immunosuppressive cytokines synthesized during pregnancy, might result in modulation of the immune response against HCV.

Observations regarding serum HCV-RNA concentration have been variable. Gervais *et al*<sup>[21]</sup> investigated a small number of pregnant women tested for viral load at regular intervals, and found that HCV RNA increased toward the end of pregnancy in some women. In our own study of 65 pregnant women tested during all three trimesters, we failed to show significant changes in viral load during and after pregnancy, although there was a trend toward an increase in the third trimester<sup>[43]</sup>. However, monitoring of viral load by monthly testing showed that HCV RNA is relatively stable over time in HCV chronic carriers without biochemical activity of the disease, whereas a low number of viremic flares can occur over a year in patients with biochemical activity of liver disease<sup>[45]</sup>.

Spontaneous clearance of HCV has been described in a single pregnant woman<sup>[46]</sup>. Only two reports describe significant worsening of histological disease consequent to pregnancy<sup>[47,48]</sup>. The study by Fontaine *et al*<sup>[48]</sup> included 12 cases with chronic hepatitis C and 12 controls without HCV infection. The first biopsy was done 1.6 years after delivery and the second at 4.3 years after the first biopsy. The overall Knodell score at initial biopsy was 4.8 in HCV-positive cases *vs* 5.3 in the controls. The Knodell score in the final biopsy was unchanged in controls, and was 8.4 in HCV-positive cases ( $P = 0.016$ ). The necroinflammation score showed 83% deterioration in cases and 25% in controls ( $P = 0.02$ ). The fibrosis score showed 41.6% deterioration in cases and 8.3% in controls ( $P > 0.05$ ). These findings in a small group of subjects, however, did not allow for any definite conclusion to be drawn.

### Effect of HCV on course of pregnancy

There is no unfavorable effect of HCV on pregnancy. In particular, three studies have addressed this question<sup>[18,49,50]</sup> (Table 3). The study from Jabeen *et al*<sup>[49]</sup> is particularly interesting, because it included a large cohort of rhesus-negative women in Ireland who became in-

**Table 3** Effect of hepatitis C virus on the course of pregnancy

NA: Not available.

fectured with HCV following exposure to contaminated anti-D immunoglobulin in 1977-1978. Thirty-six women who had been infected after their first pregnancy were compared to an age- and parity-matched control group of rhesus-positive women. Comparison with the control group showed no increase in spontaneous miscarriage rate, and no significant difference in obstetric complications. Taken together, these three studies have documented a good fetal outcome. The rate of cesarean section was significantly higher in the study by Hilleman *et al*<sup>[19]</sup> compared to controls (42% vs 21%, *P* = 0.004) and was similar to that observed in the Italian study<sup>[50]</sup>. The high rate of cesarean section in our study was due to the local protocol used in the past decade for reducing the rate of transmission of HCV in HCV-positive mothers, rather than peculiar obstetric indications for cesarean section.

In a population-based cohort study using Washington state birth records from 2003 to 2005, including 506 HCV-positive mothers, 2022 randomly selected HCV-negative mothers, and 1439 drug-using HCV-negative mothers, it was shown that infants born to HCV-positive women were more likely to have low birth weight, be small for gestational age, be admitted to the intensive care unit, or require assisted ventilation<sup>[51]</sup>.

In a more recent study using birth certificate records of 1670369 pregnancies, it was found that women with HCV were more likely to have infants born preterm, with low birth weight and congenital anomalies<sup>[52]</sup>. However, that study had several limitations, in particular, its retrospective design and the lack of association with several variables, such as use of tobacco, alcohol or drugs. Indeed, there is no explanation for prematurity and low birth weight in HCV-negative mothers, although increased cytotoxicity of placental natural killer T cells could be hypothesized possibility<sup>[53]</sup>.

It has also been reported that in pregnant women involved in a methadone treatment program, HCV reactivity was associated with an increased risk of neonatal withdrawal regardless of maternal methadone use<sup>[54]</sup>.

Risk factors for the development of ICP in HCV-positive mothers have been described. The first retrospective study reported a highly significant incidence of ICP in HCV-positive pregnant women compared with HCV-negative women<sup>[55]</sup>. Subsequently, another prospective Italian study confirmed these results and suggested the need to investigate the HCV status in women with ICP<sup>[56]</sup>.

In a study population of 21008 women with ICP identified from the Finnish Hospital Discharge Register during 1972-2000, hepatitis C was found to have a significantly higher incidence than in the controls<sup>[57]</sup>. More recently, a study of women with births between 1973 and 2009, registered in the Swedish Medical Birth Registry, confirmed a strong positive association between ICP and hepatitis C both before and after ICP diagnosis<sup>[58]</sup>. The link between ICP and HCV has not been completely explained so far, although several hypotheses can be suggested, including a defect in the transport of sulfated pregnancy hormones in the liver. It has been suggested that HCV downregulates the expression of the ABC transporter multi-drug resistance protein 2 (MRP2) in the liver, thus inducing failure in the transport of various toxic substances<sup>[59]</sup>. Furthermore, another link may be with a defect in the *ABCB11* gene encoding the bile salt export pump<sup>[60]</sup>.

### Vertical transmission of HCV

The overall rate of mother-to-child transmission of HCV from HCV-infected, HIV-negative mothers has been estimated at 3%-5%<sup>[61-66]</sup>. However, in an overview of 77 prospective cohort studies with at least 10 mother-infant pairs, the overall rate was 1.7% if the mother was known to be anti-HCV positive. If the mother was known to be viremic, that is HCV-RNA-positive, the rate was 4.3%<sup>[67]</sup>. At least one-third of infants acquire HCV infection during the intrauterine period; the perinatal transmission is estimated to be as high as 40%-50%, whereas postpartum transmission is rare<sup>[30,68]</sup>. The detection of HCV RNA in the serum of infants in the first 24 h of life suggests that early intrauterine infection may be possible<sup>[68]</sup>. The diagnosis of perinatal transmission should be considered in children born to HCV-positive mothers when: HCV RNA is detected in at least two serum samples at least 3 mo apart during the first year of life; and/or when testing of antibodies against HCV is positive after 18 mo of age<sup>[69]</sup>.

There is an interesting observation reported by the European Paediatric Hepatitis C Virus Network from a multicenter prospective study of HCV-infected pregnant women and their infants<sup>[69]</sup>. In that study girls were twice as likely to be infected as boys. This sex association is an intriguing finding that probably reflects biological differences in susceptibility or response to infection.

Co-infection with HIV increases the rate of mother-to-child transmission up to 19.4%<sup>[67]</sup>. The weighted rate of transmission is 8.6% in mothers who are anti-HCV positive and injecting drug users, compared with 3.4% in anti-HCV-positive mothers without known injecting drug use. A meta-analysis including 2382 infants estimated that the risk of HCV vertical transmission was 2.82 from anti-HCV<sup>+</sup>/HIV<sup>+</sup> co-infected mothers compared with anti-HCV<sup>+</sup>/HIV<sup>-</sup> mothers<sup>[70]</sup>. Vertical transmission of HIV and HCV separately is most likely from HIV/HCV-co-infected mothers; however, transmission of both infections is less frequent<sup>[71]</sup>.

Numerous risk factors for vertical transmission have been studied. In general, high viral load defined as at least

$2.5 \times 10^6$  viral RNA copies/mL, HIV co-infection, and invasive procedures are the most important factors<sup>[22]</sup>. In general, maternal peripheral blood mononuclear cell infection by HCV, membrane rupture > 6 h before delivery, and procedures exposing the infant to maternal blood infected with HCV during vaginal delivery are associated with an increased risk of transmission<sup>[69]</sup>. Abnormal ALT levels in mothers in the year before pregnancy may reflect a more severe liver disease and may help in identifying mothers with an increased risk of vertical transmission<sup>[72]</sup>. Finally, a Japanese study suggested that maternal liver dysfunction, large blood loss at delivery, and vaginal delivery were potential novel risk factors for mother-to-child transmission of HCV<sup>[66]</sup>.

## ANTIVIRAL THERAPY FOR CHRONIC HCV INFECTION

Antiviral therapy for HCV is contraindicated in pregnancy. Pegylated interferon would be problematic because of its psychiatric side effects in these women, who have a high background rate of postpartum depression<sup>[73]</sup>. Ribavirin carries the risk of teratogenicity for up to 7 mo after cessation of treatment. Treatment options should be offered before pregnancy in HCV-infected women. In fact, delay in initiation of antiviral therapy likely to be much longer than 9 mo, taking into account the postpartum recovery, breastfeeding and infant care. The benefits of considering treatment first and pregnancy second are superior to the drawbacks, including eliminating the risk of transmission of HCV to infants and reducing the risk of liver progression in mothers. Furthermore, improved efficacy of new drug regimens will require reassessment of the utility of universal screening for HCV in pregnant women<sup>[74]</sup>.

## MANAGEMENT OF HCV-INFECTED WOMEN

All women should receive antenatal screening for hepatitis B surface antigen and anti-HCV; HCV should be tested for in those found to be HCV positive, immigrants from developing countries, and in those with high-risk behavior (e.g., multiple sexual partners and intravenous drug use)<sup>[75]</sup>. A consensus for management of HCV-infected pregnant women and their children by the European Paediatric Network has been recently published<sup>[76]</sup>. The conclusions of this panel of experts indicate that although several risk factors for vertical transmission have been identified, none are modifiable and there are currently no interventions available to prevent such transmission. Based on the current evidence, it would be prudent to avoid amniocentesis, instrumented vaginal delivery, and prolonged rupture of membranes. A recent meta-analysis including 641 mother-infant pairs showed that cesarean section does not decrease perinatal HCV transmission from HCV-RNA<sup>+</sup>/HIV mothers to infants<sup>[77]</sup>. Thus elective cesarean delivery should not be offered, and breast-

feeding should not be discouraged. HCV/HIV co-infected women should be offered elective cesarean section to prevent HIV transmission and avoid breastfeeding where safe alternatives are available<sup>[78]</sup>.

**Key words:** Sequencing; Exome; Genetics; Inflammatory bowel disease

**Core tip:** The genetic understanding of inflammatory bowel disease (IBD) has progressed over the last twenty years as new technologies and analytic techniques have become available. The nascent revolution in next-generation sequencing will enable us to sequence the exome - all the protein coding genes in the genome - in thousands of individuals. This review discusses the implications of this new approach for diagnosis in very early onset IBD and as a tool to gain understanding of the hereditary basis of the common polygenic form of the disease at the population level.

### Abstract

Approaches to understanding the genetic contribution to inflammatory bowel disease (IBD) have continuously evolved from family- and population-based epidemiology, to linkage analysis, and most recently, to genome-wide association studies (GWAS). The next stage in this evolution seems to be the sequencing of the exome, that is, the regions of the human genome which encode proteins. The GWAS approach has been very fruitful in identifying at least 163 loci as being associated with IBD, and now, exome sequencing promises to take our genetic understanding to the next level. In this review we will discuss the possible contributions that can be made by an exome sequencing approach both at the individual patient level to aid with disease diagnosis and future therapies, as well as

### INTRODUCTION

The inflammatory bowel diseases (IBDs) consist of two main types of pathology: Crohn's disease and ulcerative colitis. Over the preceding decades, genetic epidemiology of twins and families indicated that these diseases have a strong genetic component, but that they do not segregate according to a Mendelian pattern of inheritance such as autosomal dominant, autosomal recessive, or X-linked<sup>[1]</sup>. Twin studies of Crohn's have shown a concordance of 20%-50% for monozygotic twins and 0%-7% for dizygotic twins<sup>[2]</sup>. For ulcerative colitis the concordance is 14%-19% for monozygotic and 0%-7% for dizygotic<sup>[2]</sup>. The fact that the monozygotic concor-

**Figure 1** Relationship between variant frequency and functional impact. Rare and highly damaging variants such as those associated with familial forms of very early onset inflammatory bowel disease (IBD) tend to occur rarely in the population. They are unable to achieve high allele frequencies due to negative evolutionary selection. Variants captured by genome-wide association studies (GWAS), and which account for much of the population attributable risk of IBD, tend to be quite common but have small functional consequences (typically OR < 1.2). Rare variants with small impacts are difficult to assess statistically with the tools of genetics. Exome sequencing is intended to fill in the middle part of the curve: less common variants that have moderate impacts.

dance is well below 100% shows that there are strong environmental contributions and that there is incomplete penetrance of the genetic susceptibility loci. At the same time, the risk is considerably elevated compared to the general population. Supported by the results of recent genome-wide association studies, the most commonly accepted model of IBD susceptibility is a multifactorial model in which polygenic inheritance at hundreds of genetic loci, each with small effects, contribute along with non-genetic factors, such as diet and microbiome composition.

One of the first successful approaches to identify specific risk genes was family-based linkage analysis. This approach seeks to identify chromosomal regions containing causative genes on the basis of recombinations within a family between a microsatellite marker and the trait of interest. Six loci were identified using linkage analysis, including the *IBD3* locus containing the human leukocyte antigen complex on chromosome 6, and the *IBD1* locus, the single largest genetic risk factor for Crohn's, which contains the nucleotide-binding oligomerization domain protein 2 (*NOD2*) gene on chromosome 16<sup>[3-5]</sup>.

The next technology to make a major impact in IBD genetics has been genome-wide association studies (GWAS). These studies involve genotyping hundreds of thousands of single nucleotide polymorphisms (SNPs) throughout the entire genome in order to find direct association between a specific polymorphism and the case/control status. The first successful study found an association between the interleukin (*IL*)23R locus and Crohn's disease in addition to replicating the *NOD2* as-

sociation<sup>[6]</sup>. Expanding the number of cases and controls in the cohort as genotyping prices dropped resulted in identification of *ATG16L1*<sup>[7]</sup>, *IRGM*, *MST1*, *NKX2-3*, and *PTPN2*<sup>[8,9]</sup>. The first IBD GWAS studies in a pediatric cohort were reported by our group, highlighting associations with *TNFRSF6B* and *IL27*<sup>[10,11]</sup>. As studies have grown more powered with increased cohort sizes, genotype imputation techniques<sup>[12]</sup>, and international collaboration through the IBD Genetics Consortium, the tally of associated loci for Crohn's and ulcerative colitis has risen to 163 in the latest meta-analysis<sup>[13]</sup>, demonstrating unequivocally the polygenic nature of IBD inheritance. Notably, the distribution of SNPs genotyped in a GWAS study covers intergenic as well as exonic and intronic regions, so that polymorphisms which predominantly affect the regulation of gene expression through transcriptional control can be assessed. Analysis of data from the ENCODE consortium has advanced the notion that much of the heritability of complex disorders originates in these non-coding regulatory regions of the genome<sup>[14]</sup>. There is no assumption in GWAS that the susceptibility or protective variants are confined to amino acid substitutions in proteins, the type of variation that would be found in exome sequencing. However, a major disadvantage of GWAS studies is that they are much more attuned to detecting common variation, that is, greater than 5% minor allele frequency for a SNP. It is worthy of note that IBD has generated a greater number of associations than any form of pathology studied genetically to date, leading some to suggest that evolutionary selective pressures for variants in the genes underlying the immune response drove autoimmune-risk alleles to relatively high frequencies, a phenomenon known as balancing selection<sup>[15]</sup>. The greater sensitivity of GWAS towards common variants is one reason among many that GWAS studies have only been able to account for a fraction of the heritability of polygenic diseases such as IBD<sup>[16]</sup>. It is becoming increasingly clear that there is more to the story than the common disease-common variant hypothesis<sup>[17]</sup>, and that rare variants, detectable only through sequencing, must also play a role<sup>[18,19]</sup>. Moreover, these coding variants are more likely to have high ORs, greater penetrance, and to be amenable to follow-up by functional experimentation<sup>[18]</sup>. Figure 1 illustrates the relationship between variant frequency and the phenotypic impact of the variant. Highly disruptive mutations will not rise to high frequency due to purifying selection. Exome sequencing is an ideal technology to fill in the intermediate frequency range of variants which may have stronger impacts than the weak associations detected by common GWAS variants.

## PROCESS OF EXOME SEQUENCING

With current technology, sequencing the whole 3 billion-base pair genome at the required depth of coverage to make rare variant calls is an expensive process, making it impractical to use on the scale required to implicate

less-common variants in IBD. Statistically validating less common variants with phenotypic impact would require GWAS-sized datasets comprising thousands of cases and controls<sup>[20]</sup>. A more practical alternative that has arisen since the emergence of next generation sequencing technology is to sequence the exome, the 1% of the genome that encodes protein. It has been estimated that 85% of monogenic, Mendelian disorders are the result of alterations in protein amino acid sequence<sup>[21]</sup>, supporting the idea that exon-focused sequencing will yield the most functionally interesting variants.

The most common way to fractionate the genome for exome sequencing is in-solution hybridization. This can be accomplished by shearing the DNA into small 200-300 bp fragments by ultrasonic or enzymatic methods followed by ligation of common adapter sequences to the 3' and 5' ends of the fragments so that the sequencing primer can anneal. This whole-genome library is captured by hybridization in solution with 50-120 nucleotide-long "baits" that are complementary to the exon sequence being targeted. The library-bound baits are bound to magnetic beads and the non-coding DNA is washed out. The captured fragments are eluted and amplified by PCR. Next generation sequencing instruments that utilize the exome library include the HiSeq and MiSeq (Illumina, Inc.) and Ion Torrent Proton (Life Technologies). The instruments sequence by synthesis with a DNA polymerase, analyzing the incorporation of the next nucleotide by fluorescence imaging with modified nucleotides (Illumina) or by electrical measurement of the protons produced by the incorporation of nucleotides (Ion Torrent). This generates a short "read" typically 100-200 bp in length, significantly shorter than the 700-bp reads produced by traditional Sanger sequencing. The reads are furnished as a list of sequences accompanied by quality metrics, known as a FASTQ file. One of these instruments can generate 20-60 gigabases of sequence per day.

The FASTQ file is analyzed by a read-mapping program, such as the popular Burrows-Wheeler aligner<sup>[22]</sup>, which matches these short reads with a reference genome. The alignment is stored in a common file format called BAM which is interpretable by a variety of analysis tools for visualization and variant identification. When enough independent reads have been aligned at the same nucleotide location in the genome, usually at least 20 reads, a variant calling application, for instance, Genome Analysis Toolkit<sup>[23,24]</sup>, the variant caller for the 1000 Genomes Project, can be used to decide if the site matches the reference sequence or contains an alternate nucleotide. The variant calls can be collected in a variety of formats, typically the Variant Call File (VCF). A range of statistical analyses can be performed on the VCF files for each exome, including annotating them for function (missense, indel, synonymous) and likely impact of the variant (damaging, tolerated) using tools such as ANNOVAR<sup>[25]</sup>, Sorting Intolerant From Tolerant<sup>[26,27]</sup>, and PolyPhen<sup>[28]</sup>. These tools use evolutionary

conservation of the gene across diverse species as well as the chemistry of the amino acid substitution to generate a predictive score of each variant's potential impact. The software tools also integrate information about the frequency of the variants in the general population using databases such as the The National Heart, Lung, and Blood Institute Exome Sequencing Project<sup>[29]</sup> and dbSNP<sup>[30]</sup>, since it is most likely that a damaging and impactful mutation would be quite rare due to purifying evolutionary selection.

In large case/control studies, the coding variants will be rarer than the polymorphisms identified through GWAS, so that any individual rare variant is unlikely to achieve a threshold of statistical significance<sup>[20]</sup>. Therefore, a variety of groups have developed methods to aggregate all of the rare variants in a gene and test them collectively in order to identify a rare variant burden in cases compared with controls or to detect an unusual distribution of variant frequencies between cases and controls for a given gene<sup>[31]</sup>. A number of these tests have the feature of being able to detect association in the presence of a mixture of risk, protective, and neutral variation<sup>[32]</sup>.

## ROLE FOR EXOME SEQUENCING IN IBD

### *Individual- and family-based sequencing for clinical use*

In attempting to identify a role for exome sequencing in inflammatory bowel disease we can appreciate two scenarios where it might be used. The first scenario is that of an individual patient or family with an atypical clinical presentation whose diagnosis or therapeutic decision may be influenced by genetic information. This can be seen in the very young children who present with clinical symptoms of IBD, known as very early onset IBD (VEO-IBD). These children frequently present with a more severe disease and often with a phenotype that is distinct from older children and adults, including extensive colonic disease unresponsive to standard therapy. These findings suggest distinct etiopathogenic pathways. In one well-known case, a 15-mo-old child presented with failure to thrive and perianal fistulae that was refractory to medical care. His disease progressed to pancolonic involvement, however the terminal ileum and upper tract were spared. This early age of onset and severity suggested a severe perturbation of the immune system<sup>[33]</sup>. He underwent numerous surgical procedures and treatment with immunosuppressive drugs, as well as targeted genetic and immunologic testing that did not yield a recognizable diagnosis or remission of symptoms. Sequencing of the child's exome revealed that this patient had an exceedingly rare mutation on the X chromosome in the *XIAP* gene, a potent regulator of the inflammatory response. He was treated by bone marrow transplant resulting in resolution of his disease. In our own IBD center at the Children's Hospital of Philadelphia, we encountered a 5-mo-old patient with colonic inflammatory bowel disease. She presented with severe disease that was unresponsive to medical therapy. Her

course was complicated by frequent episodes of dehydration and she became transfusion dependent despite various treatments. Exome sequencing in this patient revealed a mutation in the *MEFV* gene, resulting in a diagnosis of familial Mediterranean fever. The patient was referred to a pediatric rheumatology specialist and is being successfully treated for FMF with colchicine.

These successes highlight the critical role of exome sequencing in carefully selected patients by providing diagnoses that can guide treatment. Factors that suggest a patient may have a rare genetic perturbation that might be elucidated by exome sequencing would include early onset of disease, unusual severity, familial pattern of transmission, and a refractory response to standard therapies. In these cases, collecting DNA samples from parents so that exome sequencing in a trio setting can be performed is of high value. This will allow the identification of *de novo* variants as well as aiding in the elimination of the numerous false positive variant calls that exome sequencing generates by checking for non-Mendelian transmission of mutations. If a Mendelian inheritance model can be specified, as in the case of a consanguineous family which is likely to be autosomal recessive, such information can be of great help in narrowing down the causal variant. Homozygosity mapping in two consanguineous families was successfully used to identify mutations in the IL-10 receptor genes that resulted in severe VEO-IBD unresponsive to therapy. With this discovery, the disease resolved with bone marrow transplant<sup>[34]</sup>. This critical finding has been replicated in larger cohorts of patients with VEO-IBD and has shed light on an important pathway in the development of VEO-IBD<sup>[35]</sup>. A further appeal of applying exome sequencing in a family setting is in identifying novel monogenic causes of IBD that might yield an unexpected insight into the biology of disease, thereby directing interest towards novel targets for therapeutic development. An example would be the development of monoclonal antibodies that dramatically lower low-density lipoprotein (LDL) cholesterol by inhibiting proprotein convertase subtilisin kexin 9, a protein that was found to be deficient in a small number of individuals which genetically very low LDL<sup>[36]</sup>.

### Somatic mutations

An area where exome sequencing has been impactful is in the sequencing of cancer tissue exomes in comparison with the patient's inherited exome. Some studies have been successful in identifying somatic "driver mutations" which are essential for the growth of the tumor, which can spur the development of chemotherapeutic interventions that will target the cancer specifically<sup>[37,38]</sup>. Great interest has sprung up around the promise of personalized, or precision, medicine for cancer driven by the somatic genomics of tumors<sup>[39]</sup>. Whether sequencing of intestinal biopsies in IBD present an avenue to identify somatic mutations that may be critically important for microbiome interaction is yet to be determined, but studies are underway that are addressing this possibility.

### Exome sequencing as a research tool to complement GWAS

The second scenario in which exome sequencing can be impactful is as a research tool to augment GWAS in uncovering novel susceptibility loci and specific coding variants in the typical polygenic form of Crohn's and ulcerative colitis. Whether exome sequencing will succeed in this role to the same degree as GWAS is still controversial. It is clear that identifying genes carrying a burden of exonic rare variants in a disease with the highly polygenic architecture of IBD will require GWAS-sized cohorts, that is, ones consisting of tens of thousands of cases and controls<sup>[40]</sup>. The high cost and labor intensity of such an effort currently makes these studies prohibitively expensive to all but the most resource-rich groups. Nevertheless, some groups have succeeded in finding rare variant associations through sequencing at the phenotypic extremes of several complex traits in carefully selected candidate genes such as *ANGPTL4* and *ANGPTL5*<sup>[41]</sup> or *LPL*<sup>[42]</sup> in triglycerides, *SLC12A1* in blood pressure<sup>[43]</sup>, and *IFIH1* in type 1 diabetes<sup>[44]</sup>. Targeted next-generation sequencing in IBD has even produced some rare variant associations by following up GWAS hits, such as coding mutations that reduce signaling through the IL-23 receptor<sup>[45]</sup>. Targeted next-generation sequencing by Rivas *et al.*<sup>[46]</sup> identified additional *NOD2* and *IL23R* coding variants, as well as novel coding variants in *CARD9*, *IL18RAP*, *CUL2*, *C1orf106*, *PTPN22* and *MUC19*. Our group has also recently identified rare nonsynonymous variants in the *TNFRSF6B* gene in IBD patients with pediatric onset disease<sup>[47]</sup>, suggesting that this could be true for other GWAS loci as well. Table 1 summarizes genes that have been shown to have nonsynonymous variants with disease relevance in IBD.

Despite the success of these candidate gene efforts, doubts remain about how practical rare variant studies will be when applied to the entire exome. Most of the rare variant associations identified so far in candidate gene sequencing would not meet the stringent Bonferroni correction for multiple testing on an exome scale, estimated to be a  $P < 2.5 \times 10^{-6}$ <sup>[31]</sup>. Investigators must also consider that supporting novel rare variant associations requires replication in additional cohorts since rare variants are often population-specific and frequencies can vary in very inhomogeneous ways in spatially structured populations<sup>[48]</sup>. This type of confounding, known as population stratification, can lead to spurious associations. Therefore, replication would likely require additional sequencing of large cohorts since genotyping of specific variants would likely not be useful in a different geography or ethnicity<sup>[49]</sup>, although the replication sequencing might be limited only to genes of interest in the discovery cohort.

Concerns about the likelihood of uncovering a substantial amount of heritability in common autoimmune diseases was raised by a recent report by Hunt *et al.*<sup>[50]</sup>. This effort selected 25 risk genes that were identified in GWAS of at least two different common autoimmune

**Table 1 Genes implicated as having coding variants in inflammatory bowel disease**

Gene symbol	Description	Ref.
ADAM17	Disintegrin and metalloproteinase domain-containing protein 17	[57]
ATG16L1	Autophagy related 16-like 1	[7]
C1orf106	Chromosome 1 open reading frame 106	[46]
CARD9	Caspase recruitment domain family, member 9	[46]
CUL2	Cullin 2	[46]
DLG5	Discs-large 5	[58]
HEATR3	HEAT repeat containing 3	[59]
IL10RA and B	Interleukin-10 receptor	[34]
IL18RAP	Interleukin 18 receptor accessory protein	[46]
IL23R	Interleukin 23 receptor	[45]
LRBA	LPS-responsive vesicle trafficking, beach and anchor containing	[60]
MDR1	Multi-drug resistance 1	[61]
MUC19	Mucin 19, oligomeric	
NCF2	Neutrophil cytosolic factor 2	[62]
NDP52	Antigen nuclear dot 52 kDa Protein	[55]
NOD2	Nucleotide-binding oligomerization domain containing 2	[3,4]
PRDM1	PR domain containing 1, with Zinc finger domain	[55]
PTN22	Protein tyrosine phosphatase, non-receptor type 22 (lymphoid)	[46]
SLC22A4	Solute carrier family 22 (organic cation/ergothioneine transporter), member 4	[63]
TNFRSF6B	Tumor necrosis factor receptor superfamily, member 6b, decoy	[47]

diseases. The exons of these 25 genes were sequenced with excellent coverage in a cohort of 24892 subjects with six autoimmune disease phenotypes and 17019 controls. They found that the great majority of variants uncovered occurred in a single subject. Five aggregating gene-based tests (rather than individual variant-based tests) were used to identify rare-variant enrichment for any of the genes but none were found to be statistically significant. The authors concluded that there was little support for large-scale whole-exome sequencing projects in common autoimmune diseases. While this report may portend that the impact from rare coding variants is negligible, there are some limitations to the study that leave open the possibility for meaningful discovery. The study considered only 25 genes, while an exome-based approach would survey all 20000 human protein-coding genes. It is likely that the risk conferred by these 25 GWAS genes is carried by non-coding variation, while the risk at some subset of loci in the genome could be carried by rare coding variation that are not captured by GWAS SNPs. This is particularly true for variants in the intermediate 0.5%-5% frequency range which could be impactful in aggregate while escaping detection in GWAS studies due to the weak linkage disequilibrium for variants in this frequency range with common variants<sup>[51]</sup>. Indeed, Hunt *et al*<sup>[50]</sup> did identify three risk mutations at approximately the 5% minor allele frequency. Furthermore, the abundant singleton mutations could still identify IBD risk genes through the use of statisti-

cal tests which weight mutations more or less heavily depending on their frequency, as the very rare variants are the most likely to be impactful functionally. Several methods such as adaptive sum tests<sup>[52]</sup>, Sequence Kernel Association Test<sup>[53]</sup>, and Variable Threshold<sup>[54]</sup> tests have been developed specifically for sustaining a high statistical power with rare variants. Finally, the six autoimmune disease phenotypes were quite heterogeneous in their pathologic nature, ranging from IBD to autoimmune thyroid disease to multiple sclerosis. These diseases have distinct mechanisms with different rare variants underlying them, possibly in none of the 25 genes sequenced. Therefore, it is arguably diluting the power to detect rare variant association by combining diverse diseases.

A recent study by Ellinghaus *et al*<sup>[55]</sup> utilized exome sequencing to identify a role for missense variants in *PRDM1* and *NDP52* in Crohn's disease. Variants in these two genes were discovered in a cohort of 42 whole-exome sequenced individuals, with discovered variants being prioritized by functional impact scores and presence within GWAS-delineated loci. Over 20000 combined Crohn's and ulcerative colitis cases and controls were genotyped to establish that two variants, p.Ser354Asn in *PRDM1* and p.Val248Ala in *NDP52* were associated with IBD. Functional studies showed that the *PRDM1* mutant increased T cell proliferation and cytokine secretion while the *NDP52* mutant impaired the ability of the protein to downregulate nuclear factor kappa B signaling in toll-like receptor signaling pathways. This paper provides an example of how exome sequencing, even in a modest cohort, can refine GWAS signals and uncover less common risk variants, especially when coupled with functional validation.

### Sequencing and risk prediction

Our group recently developed a machine-learning approach to predicting risk for IBD using data from the International IBD Genetics Consortium's ImmunoChip project<sup>[56]</sup>. The ImmunoChip assays 200000 SNPs with very dense coverage in genomic regions that have been associated with autoimmune disease through genome-wide association studies. Due to the ImmunoChip's wide spectrum of variants and the large number of cases and controls genotyped in the project, it was possible to use a penalized logistic regression model to predict risk for IBD with area under the curve of 0.86 for Crohn's disease and 0.83 for ulcerative colitis. With the coming availability of large-scale whole exome data we expect that risk prediction can be improved further and may achieve clinically-useful levels with the comprehensive catalog of variation that would be produced through eventual whole-genome sequencing.

## CONCLUSION

We can predict with some confidence that exome sequencing will have a place in IBD in a patient- or family-based settings where features of the clinical presentation

suggest a likely monogenic, Mendelian basis for the disease. Personalized medicine based on the patient's genome in these carefully selected cases is no longer a far-off dream but a nascent reality. More uncertain are the prospects of large-scale exome sequencing projects for discovery of population-scale heritability for such a common and highly polygenic disease. Theoretical arguments can be made to support either position, but the debate can only be resolved by experimental testing of the common disease-rare variant hypothesis. Exome sequencing of rare variants may not collectively yield much explanation of the population attributable risk of disease, but it has great potential to highlight the key players in the pathogenesis of disease along with variants amenable to functional study and thereby influence the development of potent new therapeutics.

### Abstract

Hepatitis B virus (HBV), a major cause of human liver disease worldwide, encodes three envelope proteins needed for the attachment and entry of the virus into susceptible host cells. A second virus, hepatitis delta virus, which is known to enhance liver disease in HBV infected patients, diverts the same HBV envelope proteins to achieve its own assembly and infection. In the lab, lentiviral vectors based on human immunodeficiency virus type 1 can be assembled using the HBV envelope proteins, and will similarly infect susceptible cells. This article provides a partial review and some personal reflections of how these three viruses infect and of how recipient cells become susceptible, along with some consideration of questions that remain to be answered.

### INTRODUCTION

The following is a very brief introduction to the envelope proteins of hepatitis B virus (HBV) and of how they can be used to facilitate the assembly and infection by HBV and two other viruses. More detailed recent reviews are available elsewhere<sup>[1,2]</sup>. HBV encodes three envelope proteins, commonly referred *via* their size, as large, middle and small, or L, M and S. They have S as a common C-terminal domain. M contains additional N-terminal sequences, referred to as preS2. L, relative to M, has additional N-terminal sequences, referred to as preS1. L, M and S, exist with and without carbohydrate modifications. The L protein undergoes an essential myristoylation of a glycine residue penultimate to the N-terminus.

Hepatitis delta virus (HDV) exists in nature in some patients who are also infected with HBV. While HDV uses a totally different method of genome replication than HBV, its final assembly is entirely dependent upon the envelope proteins of HBV; thus, it only produces infectious progeny in hepatocytes already infected with HBV (or producing envelope proteins from fortuitously integrated HBV DNA). HDV can infect a new hepatocyte in the presence or absence of HBV. In the humanized chimeric uPA mouse model, human hepatocytes infected with HDV alone can persist for at least six weeks in the absence of HBV, a so-called latent infection, with ultimate rescue of virus production dependent on a follow-up infection by HBV<sup>[3]</sup>. Such studies suggest that in patients conversion of a latent HDV mono-infection may contribute to the persistence of HDV even in patients with low HBV replication.

Many labs have produced retrovirus vectors that have

been engineered to carry novel genes, that can be expressed following integration of the provirus; that is, the DNA copy of the viral RNA genome. Such retrovirus vectors have been assembled using envelope proteins of the wild type retrovirus, as well as those derived from other viruses, such as vesicular stomatitis or Ebola viruses<sup>[4]</sup>. However, what is relevant here is that such a retrovirus vector was assembled using the envelope proteins of HBV and acquired the host cell specificity of HBV and HDV<sup>[5]</sup>.

## ENVELOPE PROTEIN DETERMINANTS ESSENTIAL FOR INFECTIVITY

Several labs have shown that an essential determinant for infectivity using HBV envelope proteins is located near the N-terminus of the preS1 domain of the L protein. The data for this are very good and include evidence that a synthetic peptide containing such sequences, especially if it is myristoylated, will act as a potent inhibitor of virus entry<sup>[6]</sup>. Interestingly, unlike the L and S proteins, the M protein can be omitted in experimental situations without a loss of assembly or infectivity, at least for HDV<sup>[7,8]</sup>. Thus, the role of M in HBV infection is unclear. The carbohydrate moieties attached to the three envelope proteins are essential for particle assembly and infectivity<sup>[2]</sup>. The three envelope proteins share at least four trans-membrane domains. One shared loop is presented on the surface of the virus. This loop, containing the so-called "A" determinant, is highly antigenic. Certainly antibodies raised against the S protein will neutralize virus infectivity. A widely used, S protein based vaccine, protects individuals against both HBV and HDV.

## WHAT THE HOSTS PROVIDE

Until last year, almost the only cells that could be infected by these viruses were primary human hepatocyte cultures. Such cultures are difficult both to establish, and can rapidly lose susceptibility to infection. Some non-human primary hepatocyte cultures were similarly susceptible; examples include chimpanzee and tupaia hepatocytes. Also, primary woodchuck hepatocytes are susceptible to HDV. Several years ago a cell line, HepaRG, was derived from a human liver tumor, and it is susceptible to infection by HBV and HDV<sup>[9]</sup>. These cells require specific *in vitro* culture conditions and they are almost as difficult to maintain as primary human hepatocytes.

For many years groups worldwide had struggled to identify, and confirm the functionality of host molecules needed for HBV and HDV entry. Many candidates were identified but none were shown to be sufficient for virus entry and initiation of replication<sup>[6]</sup>. This situation was changed dramatically in late 2012 by a report from Yan *et al.*<sup>[10]</sup>. They used a synthetic peptide corresponding to the myristoylated N-terminus of the HBV preS1 protein to affinity select a candidate virus receptor from hepatocyte cultures. These hepatocytes were derived the treeshrew

(*Tupaia belangeri*). The purification procedure used near-zero-distance photo-cross-linking and tandem-affinity purification and yielded a single protein. Then, with mass spectrometry, they identified the protein as the sodium taurocholate cotransporting polypeptide, NTCP, also known as SLC10A1<sup>[10]</sup>. NTCP transports bile acids from the blood into the liver. Their subsequent findings included evidence that the cDNA clone of human NTCP, when transfected into human hepatocellular carcinoma cell lines, specifically HepG2 and Huh7, conferred susceptibility to both HBV and HDV. Susceptibility could be inhibited by the synthetic preS1 peptide. Furthermore, in susceptible primary hepatocyte cultures and HepaRG cells, suppression of NTCP with specific small interfering RNAs inhibited susceptibility. It remains to be shown whether the NTCP functions *in vivo* as well as *in vitro*. However, the situation is very promising in that other studies have already shown that the synthetic preS1 peptide to which it binds, is a potent inhibitor of *in vivo* infections of human hepatocytes (as transplanted into mice) by both HBV and HDV<sup>[11]</sup>.

In their initial paper, the authors made use of prior studies by others of the established role of NTCP in the liver. This protein is 335 amino acids in length and is predicted to have 9 trans-membrane domains<sup>[12]</sup>. They thus compared the sequence of NTCP of the crab-eating monkey (*Macaca fascicularis*) (since hepatocytes from these monkeys are not susceptible to HBV infection) and humans. They noted that the primary sequence of the monkey protein has a limited number of specific differences relative to the human protein. The authors experimentally demonstrated that replacement of just nine contiguous amino acids of monkey NTCP with the corresponding sequence from the human protein produced a cDNA, that when transfected into nonsusceptible liver cell lines, rendered them susceptible to infection by both HBV and HDV.

Several commentaries by others on the NTCP findings have since been published<sup>[13-16]</sup>. And, several labs, in as yet unpublished studies, have confirmed the ability of recombinant NTCP to facilitate entry of HBV and HDV into otherwise non-susceptible cell lines.

Moreover, two follow-up studies by Wenhui Li and coworkers have been published in 2013. In the first study, the focus was on the woolly monkey hepadnavirus, WMHBV, and its ability to infect tupaia hepatocytes<sup>[17]</sup>. Their findings include evidence that cDNA of the woolly monkey NTCP when transfected into nonsusceptible liver cell lines renders them susceptible to both WMHBV and HDV pseudotyped with WMHBV envelope proteins. The authors thus suggest that orthologs of NTCP might function as receptors for all known primate hepadnaviruses. In the second study they examined mouse NTCP, and considered many exchanges with the human sequence to determine what might be need to achieve susceptibility<sup>[18]</sup>. They did find a region, of only two amino acids, that was sufficient to achieve HDV (but, as discussed below, not HBV) susceptibility. These changes

were not at the same location as the changes needed on the crab-eating monkey NTCP<sup>[10]</sup>. We can infer that the secondary and maybe the tertiary structure of NTCP are needed for susceptibility. It is relevant that a recently published study by Meier *et al*<sup>[19]</sup> reports that cultured mouse hepatocytes will bind the preS1 peptide even though no infection is detected. This suggests that a *bona fide* binding site may be available on the mouse NTCP, but is insufficient for HBV infection. Scheick *et al*<sup>[20]</sup> suggest an additional step might be at the level of membrane fusion.

It is important to note that earlier studies showed that HDV can actually infect mouse hepatocytes *in vivo*, although to only a low extent<sup>[21]</sup>. Therefore, the changes introduced into the mouse NTCP, as described above, may have increased the affinity of preS1 binding without, for HDV, a need to alter a second step (*e.g.*, fusion) in HDV infection. Thus, it is possible that mice made transgenic for the modified NTCP will be readily infected with HDV. (They will not be infected by HBV and as such, may not be sufficient to create a new model of HBV induced hepatocellular carcinoma.) Or, perhaps, even overexpression of the unmodified mouse NTCP would allow more efficient *in vivo* infection by HDV.

## ATTACHMENT AND ENTRY

Recent studies have shown that the initial attachment of HBV to susceptible cells depends upon glycosaminoglycans present on the cell surface<sup>[22-24]</sup>. This is a necessary but not sufficient step. Furthermore, even after virus has attached, entry can be significantly inhibited by a number of agents<sup>[25]</sup>. Of the latter, the most interesting inhibitor is the previously mentioned synthetic peptide, corresponding to the N-terminus of the preS1 domain<sup>[6,11]</sup>. It would seem that even after attachment, (additional) interactions with the putative host cell receptor remain to be made<sup>[25]</sup>. It could also be that multiple such interactions are needed to facilitate entry.

## FURTHER DISCUSSION AND OUTLOOK

Clearly, the combination of attachment, entry, and initiation of HBV replication is more complex than that of HDV. A partial explanation of this difference comes from earlier studies: Firstly, transcription of RNA from HBV covalently closed-circular DNA (CCC DNA) depends upon host transcription factors, some of which are specific for the liver<sup>[2]</sup>. Additionally, CCC DNA formation is inefficient or even absent in transgenic mice<sup>[26]</sup>. Secondly, HDV replication can be initiated in many mammalian cell lines, not necessarily those that are derived from liver tissue<sup>[1]</sup>. Nevertheless, it also remains possible that it is the entry of HBV that differs from that of HDV; that is, it requires host contributions in addition to the expression of NTCP.

As exemplified below, there are now multiple questions that can be asked of the entry mechanisms of other members of the hepadnavirus family. Certainly it is time

to reinvestigate infection of duck hepatocytes by duck hepatitis B virus (DHBV). It was first found by an affinity strategy, that a host protein identified as carboxy peptidase D, binds the DHBV envelope protein<sup>[27]</sup>. However, no study has yet been able to confer susceptibility by expression of this protein<sup>[28,29]</sup>. Some studies have suggested a co-receptor, but again, this has not led to susceptibility<sup>[30]</sup>. Independently, it has been shown that the myristoylated N-terminus of the DHBV preS region is needed for infectivity<sup>[28,31]</sup>. Therefore, maybe an analogous application of the powerful peptide affinity strategy used by Wenhui Li and coworkers<sup>[10]</sup>, will identify a functional DHBV receptor. And, an alternative and specific approach would be to directly test whether the duck NTCP can function as receptor.

Also one can examine the newly reported HBV of bats<sup>[32]</sup>. This virus shows more sequence relationship to the orthohepadnavirus than to the avi hepadnaviruses. Novel questions can now be asked, such as what is the sequence of the bat NTCP, and would the cDNA of this gene when expressed in human cell lines, confer susceptibility to infection.

Another question is why HDV but not HBV will infect primary woodchuck hepatocytes. This may or may not be analogous to the abovementioned situation where human NTCP cDNA transfected into non-liver cell lines will allow HDV but not HBV infection. Presumably the woodchuck hepatocytes provides an acceptable NTCP for HDV infection, but now one can address questions such as whether expression of one or more human cDNAs will make the cells susceptible to HBV.

In all these studies of cells susceptible to HDV or HBV, there is a question of the efficiency with which cells are infected. Even with primary hepatocytes and HepaRG cell line, the efficiency is typically less than 1%. Several possible explanations include low levels of expression of NTCP or low levels of NTCP that is functionally active. This efficiency is increased approximately 10-fold by the presence of 2%-4% polyethylene glycol, PEG<sup>[9,33]</sup>. Studies have shown that infection in the presence of PEG is still be inhibited by the synthetic preS1 peptide, indicating that the infection is still specific for the NTCP receptor. PEG is most likely causing aggregates of virus particles; certainly, at 6%-10% PEG the virus can even be collected by low speed centrifugation. Thus, it may be that the low levels of PEG produce aggregates that can more efficiently make use of the available NTCP receptor present on the surface of the hepatocytes. Future studies with cDNA transfected cell lines will no doubt test the relevance of the amount of NTCP expressed at the cell surface and infection by unaggregated *vs* aggregated virus. Perhaps controlled mixtures of functional and non-functional NTCP cDNAs will also help clarify what is involved.

In summary, the important new finding of NTCP as a functional receptor has opened the way for much more basic research concerning the entry of HBV and HDV into susceptible cells. And, in turn, such information will

allow new applied research, possibly providing additional novel ways in which such entry can be interfered with, all new armamentaria for treating chronic HBV and HDV infections.

### Abstract

Based on the available literature, non alcoholic fatty liver disease or generally speaking, hepatic steatosis, is more frequent among people with diabetes and obesity, and is almost universally present amongst morbidly obese diabetic patients. Non alcoholic fatty liver disease is being increasingly recognized as a common liver condition in the developed world, with non alcoholic steatohepatitis projected to be the leading cause of liver transplantation. Previous data report that only 20% of patients with Cushing's syndrome have hepatic steatosis. Aiming at clarifying the reasons whereby patients suffering from Cushing's syndrome - a condition characterized by profound metabolic changes - present low prevalence of hepatic steatosis, the Authors reviewed the current concepts on the link between hypercortisolism and obesity/metabolic syndrome. They hypothesize that this low prevalence of fat accumulation in the liver of patients with Cushing's syndrome could result from the inhibition of the so-called low-grade chronic-

inflammation, mainly mediated by Interleukin 6, due to an excess of cortisol, a hormone characterized by an anti-inflammatory effect. The Cushing's syndrome, speculatively considered as an *in vivo* model of the hepatic steatosis, could also help clarify the mechanisms of non alcoholic fatty liver disease.

**Key words:** Nonalcoholic fatty liver disease; Cushing's syndrome; Hypercortisolism

**Core tip:** This overview of the literature is related to hepatic steatosis, its prevalence, clinical consequences and, in particular, the pathogenesis of this disorder. The authors focus on the link between hypercortisolism and obesity/metabolic syndrome. The main question of the work relates to the low prevalence of hepatic steatosis (only 20%) described in 50 newly diagnosed patients with Cushing's syndrome based on appropriate computed tomography scans available for retrospective analysis. The authors try to explain this finding by the anti-inflammatory effect of high circulating levels of glucocorticoids.

### INTRODUCTION

In Cushing's syndrome, high circulating glucocorticoid (GC) levels cause visceral obesity, insulin resistance, diabetes mellitus, dyslipidemia, hypertension, hepatic steatosis and an increased risk of coronary artery disease (CAD)<sup>[1,2]</sup>. GCs excess stimulates gluconeogenesis in the

liver and inhibits insulin sensitivity both in the liver and in skeletal muscles, which represent the most important sites responsible for glucose metabolism. In particular, glucocorticoid excess stimulates the expression of several key enzymes involved in the process of gluconeogenesis, with a consequent increase in glucose production, and an impairment of insulin sensitivity either directly by interfering with the insulin receptor signaling pathway or indirectly, through the stimulation of lipolysis and proteolysis and the consequent increase in fatty acids and amino acids, which contribute to the development of insulin resistance (IR). Moreover, the peculiar distribution of adipose tissue throughout the body, with the predominance of visceral adipose tissue, significantly contributes to the worsening of IR and to the development of a metabolic syndrome, which has a role in the onset and maintenance of impaired glucose tolerance<sup>[3]</sup>.

## METABOLIC SYNDROME AND 11 $\beta$ -HYDROXYSTEROID DEHYDROGENASE TYPE 1

The much more prevalent “metabolic syndrome” a medical condition with a clustering of risk factors for cardiovascular disease and type 2 diabetes, such as IR, type 2 diabetes, dyslipidemia and hypertension, typically in association with visceral obesity and hepatic steatosis shares metabolic alterations and physical findings with Cushing’s syndrome<sup>[1]</sup>. However, any pathogenic role for GCs in the metabolic syndrome or idiopathic obesity is still unclear<sup>[4]</sup>. Recent studies in humans and rodents suggest a role for tissue rather than plasma GCs excess in the development of idiopathic obesity and the metabolic syndrome, *via* intracellular steroid reactivation of inert circulating 11-dehydrocorticosterone (cortisone in humans) into active corticosterone (cortisol) by 11 $\beta$ -hydroxysteroid dehydrogenase (11 $\beta$ -HSD) type 1. Surprisingly, this enzyme is highly expressed not only in adipose tissue and brain but in the liver as well<sup>[5]</sup>.

The 2- to 3-fold-increased 11 $\beta$ -HSD1 activity in adipose tissue in obese Zucker rats<sup>[6]</sup> and in some<sup>[7,8]</sup> but not all<sup>[9]</sup> studies on obese humans may be causal to visceral obesity and its metabolic consequences. Supporting this hypothesis, visceral obesity, hyperlipidemia, IR, glucose intolerance/diabetes<sup>[10]</sup> and hypertension<sup>[11]</sup> are driven in transgenic mice by overexpression (2- to 3-fold) of 11 $\beta$ -HSD1 selectively in adipose tissue.

Notably, as with the human metabolic syndrome, circulating plasma corticosterone levels in aP2-HSD1 TG mice are unaltered<sup>[10]</sup>. Conversely, 11 $\beta$ -HSD1 null mice exhibit a protective glycemic, lipid, and lipoprotein profile<sup>[12,13]</sup> and show increased expression of hepatic mRNAs encoding regulators of fatty acid beta-oxidation<sup>[13]</sup>. While intra-adipose but not systemic corticosterone concentrations are elevated in aP2-HSD1 TG mice, corticosterone delivery to the liver is also increased about three-fold *via* spillover of adipose steroid production into

the portal vein. The highest expression of 11 $\beta$ -HSD1 occurs in the liver<sup>[14]</sup>, and hepatic 11 $\beta$ -HSD1 mRNA levels are regulated by diet, gender and hormones<sup>[1,14-16]</sup>. Heterogeneity of hepatic 11 $\beta$ -HSD1 activity may be relevant to the development of specific fatty liver, insulin-resistant, and hypertensive syndromes without obesity in humans; it is also likely to play a role in myotonic dystrophy, where marked insulin resistance and dyslipidemia have been shown to occur with elevated hepatic 11 $\beta$ -reduction of cortisone to cortisol, which is positively correlated to the severity of disease<sup>[17]</sup>.

Dysregulation of the specific action of GCs and not of the alterations of GC levels has been proposed as a central feature of the metabolic syndrome<sup>[18]</sup>. In fact, states of GC excess recapitulate almost all features of the metabolic syndrome, but Cushing’s disease is rare and circulating cortisol levels are normal in the vast majority of patients with obesity and type 2 diabetes. This finding has raised the possibility that the features of the metabolic syndrome could be due to an increase in locally available glucocorticoids through 11 $\beta$ -HSD1<sup>[19-21]</sup>. Subsequently, a range of studies explored the role of 11 $\beta$ -HSD1 in the pathogenesis of the components of the metabolic syndrome including obesity, IR, hyperglycemia, hyperlipidemia and nonalcoholic fatty liver disease (NAFLD), or generally speaking, hepatic steatosis.

### *Hepatic steatosis and visceral fat*

Indeed, only 20% of patients with Cushing’s syndrome have hepatic steatosis<sup>[22]</sup>. NAFLD ranges from fatty liver to non alcoholic steatohepatitis (NASH) and cirrhosis, and is being increasingly recognized as the most common liver disease in the developed world. NASH - which most Authors consider as completely different from the more benign form, *i.e.*, fatty liver - is projected to be the leading cause of liver transplantation. NAFLD has a great prevalence among people with diabetes and obesity and is almost universally present amongst morbidly obese diabetic patients<sup>[23-25]</sup>.

Being a progressive form of liver injury, NASH carries a risk of developing hepatocarcinoma. There is strong evidence that IR and increased free fatty acids are the major cause (“first hit”) of NASH<sup>[26,27]</sup>. Inflammation plays an important additional role (“second hit”) with increased production of reactive oxygen species and proinflammatory cytokines. In addition, studies from different groups support the strict link between visceral adipose tissue and NASH<sup>[28,29]</sup>.

In recent years, research has shown that amplification of GCs action by the intracellular enzyme 11 $\beta$ -HSD1 plays a key role in the development of central obesity<sup>[30,31]</sup> providing a basis for the phenotypic similarity between Cushing’s syndrome and obesity in the metabolic syndrome; 11 $\beta$ -HSD1 increases intracellular glucocorticoid levels by converting inert cortisone to active cortisol.

*In vivo* reductase activity of 11 $\beta$ -HSD1 predominates and is driven by NADPH generated by the microsomal enzyme hexose-6-phosphate-dehydrogenase (H6PDH).

Epidemiological data indicate that hepatic steatosis is associated with IR, dyslipidemia and obesity, especially central obesity<sup>[32]</sup>. In clinical practice, the co-existence of these conditions defines the so-called metabolic syndrome<sup>[33]</sup>. Of note, NAFLD is considered by many authors as the hepatic manifestation of the metabolic syndrome<sup>[34-36]</sup>.

Interestingly, the severity of hepatic steatosis is positively correlated with visceral adipose tissue accumulation in both obese and non-obese subjects, suggesting that hepatic fat infiltration may be influenced by visceral fat adipokines or, possibly, specific enzymes, regardless of body mass index<sup>[37]</sup>.

As previously emphasized, some authors have pointed out the phenotypic similarities between central obesity, metabolic syndrome and patients with endogenous or exogenous glucocorticoid excess. These have led them to propose that cortisol contributes, at least in part, to the pathogenesis of those abnormalities, despite the fact that patients with obesity and metabolic syndrome have consistently normal cortisol levels in plasma and urine<sup>[38-40]</sup>. Accordingly, the concentrations of GCs found in the omental vein, draining into the portal vein, were not different from those detected in peripheral veins<sup>[41]</sup>.

A plausible explanation for this phenomenon could be to consider the metabolic syndrome a result of increased local GC activity in certain organs, suggesting that central obesity might be, as proposed by Bujalska decades ago, a “Cushing’s disease of the omentum”<sup>[42]</sup>. In connection with this concept, recent studies have shown that intracellular GC action not only depends upon the hypothalamo-pituitary-adrenal axis but also on local regulation at the pre-receptor level by the activity of two isoforms of the 11 $\beta$ -hydroxysteroid dehydrogenase enzyme type 1 and 2 (11 $\beta$ -HSD1 and 11 $\beta$ -HSD2)<sup>[43,44]</sup>.

### 11 $\beta$ -hydroxysteroid dehydrogenase type 1 and visceral adipose tissue

Enzyme type 1, 11 $\beta$ -HSD1, is a microsomal enzyme, expressed mainly in the liver and adipose tissue, acting as a NADP (H)-dependent reductase converting inactive cortisone to active cortisol, which locally activates GCs receptors<sup>[45]</sup>. According to this view, progressive expansion of visceral fat would result in an increased production of cortisol by the action of 11 $\beta$ -HSD1, causing splanchnic and portal hypercortisolism, which could contribute to the pathogenesis of such metabolic disorders, including NAFLD<sup>[46-48]</sup>. Recently, it has been demonstrated that 11 $\beta$ -HSD1 expression levels in the liver and in visceral adipose tissue in morbidly obese patients, correlate with dyslipidemia and IR, suggesting that this enzyme might have a pathogenic role in obesity and the related metabolic disorders<sup>[49]</sup>. The role of 11 $\beta$ -HSD1 in NAFLD has been largely studied in humans, with conflicting results<sup>[46,47]</sup>. In any case, in two studies assessing sequential changes of enzyme expression in obese mice developing hepatic steatosis, the Authors found an overexpression of 11 $\beta$ -HSD1 in visceral adipose tissue and hepatic tissue

with the occurrence of portal hypercortisolism<sup>[50,51]</sup>. However, further research is needed to precisely define the role of 11 $\beta$ -HSD1 in the origin and development of NAFLD.

In addition, the effects of treatment with specific 11 $\beta$ -HSD1 inhibitors<sup>[52]</sup> in NAFLD deserve more thorough exploration, as these agents have the potential to improve insulin sensitivity<sup>[53]</sup> and may ultimately add to the available treatment options. Indeed, the rationale behind this type of intervention is challenged by the observation that in NASH, the more severe form of NAFLD, the increased 11 $\beta$ -HSD1 activity and consequent cortisol regeneration is supposed to limit hepatic inflammation<sup>[54]</sup>. This point will be further dealt with later on.

In general, primary pre-adipocyte cultures isolated from human adipose tissue represent heterogeneous cell populations, some of which can be part of the immune system<sup>[55]</sup>. GCs affects the genes associated with immune responses, such as interleukin-6 (IL-6), TNFAIP6<sup>[56]</sup> and CD163. The simultaneous GC-induced downregulation of the TNFAIP6 and IL-6 in human preadipocytes might reflect the interaction between these two genes in adipose tissue inflammation. Glutathione peroxidase 3 precursor (GPX3), the plasma GPX3, catalyses the reduction of hydrogen peroxide, organic hydroperoxide and lipid peroxides, thus protecting cells against oxidative damage. GPX3 was reported to be present in human adipose tissue<sup>[57]</sup>, and GPX3 was identified as being one of the most highly expressed genes in the pre-adipocyte compartment of human adipose tissue as well as a novel GC-target gene.

Recently, adipose tissue has been defined as a major site of production of serum amyloid A (SSA)<sup>[58]</sup>, a well-known risk factor for CAD<sup>[59]</sup>. It has been shown that *ASSA* is a GC-target gene in omental preadipocytes. Together, these findings contribute to the role of omental tissue as a potential link between an inflammatory response and CAD.

## 11 $\beta$ -HSD1 EXPRESSION AND ACTIVITY IN THE LIVER

Conflicting observations have been made regarding this issue. Most studies suggest that 11 $\beta$ -HSD1 expression and activity in the liver is down-regulated in obesity<sup>[54,60]</sup>.

This down-regulation, however, appears to be defective in insulin resistant individuals<sup>[61]</sup>. The failure to down-regulate hepatic 11 $\beta$ -HSD1 could further contribute to IR and, on the basis of the fact that GCs stimulate lipid production, also exacerbate dyslipidemia.

These relationships are complicated by the expression of additional glucocorticoid metabolizing enzymes in the liver, most importantly the A-ring reductases (5 $\alpha$ - and 5 $\beta$ - reductase)<sup>[15,54]</sup>. The expression of these enzymes also appears to be associated with IR and, in a similar manner, to 11 $\beta$ -HSD1, showing a pattern of down-regulation with increased adiposity and insulin resistance. A possible mediator of the hepatic changes seen in the metabolic syndrome could be the increased production of cortisol

from visceral fat in obesity. This increased cortisol would subsequently drain to the liver through portal circulation. However, recent studies examining cortisol and cortisone levels in peripheral, portal, and hepatic vein blood samples indicated that cortisol production from visceral adipose tissue, and thus the amount of exposure of the liver, does not significantly change with increasing obesity<sup>[62-64]</sup>, confirming previous data<sup>[41]</sup>.

## ROLE OF INTERLEUKIN-6

IL-6 is expressed in and released from both the subcutaneous and omental adipose tissues<sup>[65]</sup> with a two- to three-fold higher *in vitro* release of IL-6 from omental compared to subcutaneous adipocytes *in vitro*. The *in vivo* release of IL-6 from fat contributes as much as 35% to the basal circulating levels and may at least in part explain the positive correlation between serum levels of IL-6 and obesity. In rodents, obesity is associated with macrophage accumulation in adipose tissue, and these macrophages release inflammatory mediators and molecules promoting inflammation. Inflammatory mechanisms play a key role in the pathogenesis of type 2 diabetes. This low-grade chronic inflammation has been proposed to be mediated by the IL-6 family of cytokines, tumor necrosis factor- $\alpha$ , interleukin-1 beta, IL-18, and certain other chemokines. In addition to its immunoregulatory actions IL-6 has been proposed to affect glucose homeostasis and metabolism directly and indirectly by its action on skeletal muscle cells, adipocytes, hepatocytes, pancreatic beta-cells and neuroendocrine cells<sup>[66]</sup>. It has been suggested that IL-6 might play a role in the pathogenesis of Cushing's disease<sup>[67]</sup>. Although an increased production of IL-6 has been reported in patients with either active or remitted Cushing's syndrome, elevated GCs levels in these patients may prevent excessive action of IL-6 due to the persistent accumulation of central fat<sup>[68]</sup>. In fact, it has been hypothesized that IL-6 deficiency exacerbates hepatic insulin resistance and inflammation, a process that appears to be related to defects in mitochondrial metabolism<sup>[69]</sup>. On the other hand, higher levels of circulating IL-6 were found in patients with the more severe form of NAFLD<sup>[70]</sup>.

IR is strictly linked to anti-apoptotic serum Bcl-2 values<sup>[71]</sup>, which were higher in simple fatty liver than in NASH patients, suggesting a protective role of the anti-apoptotic process in liver and perhaps in other areas<sup>[72]</sup>. Apoptotic cell death is caspase-dependent and is associated with mitochondrial membrane depolarization and cytochrome c release<sup>[73]</sup>. Adhering to the hypothesis that the exposure of hepatocytes to free fatty acids, resulting in increased reactive oxygen species production and mitochondrial damage, is balanced by the presence of anti-oxidant substances, circulating levels of gamma-glutamyl transferase, cytochrome c, triglycerides and unconjugated bilirubin were explored in patients suffering from non-alcoholic fatty liver disease with different severity<sup>[73]</sup>. The resulting findings likely reflect a balance between oxidative stress and anti-oxidant response rather than a lack

of reliability of cytochrome c as a reliable biomarker of mitochondrial damage<sup>[73]</sup>.

The inflammatory mediators that are biosynthesized in the liver and increased in NAFLD patients include C-reactive protein (CRP)<sup>[74]</sup>, IL-6<sup>[70]</sup>, fibrinogen and plasminogen activator inhibitor-1 (PAI-1)<sup>[75]</sup>. Consequently, fat in the liver represents a site beyond adipose tissue that independently contributes to the inflammatory process. In support of a certain sequence of cellular and molecular events that mediates hepatic IR in NAFLD, recent data lend credence to the fact that hepatic steatosis activates I $\kappa$ B kinase (IKK)- $\beta$  and nuclear factor (NF)- $\kappa$ B<sup>[76]</sup>. Among the inducible transcription factors that control inflammatory gene expression, NF- $\kappa$ B plays a central and an evolutionarily conserved role in coordinating the expression of various soluble pro-inflammatory mediators (cytokines and chemokines) and leukocyte adhesion molecules. In non stimulated cells, NF- $\kappa$ B is sequestered in cytosol by the inhibitor of NF- $\kappa$ B (I $\kappa$ B), which masks the nuclear localization signal present along the NF- $\kappa$ B protein sequence.

Treatment of cells with pro-inflammatory cytokines such as TNF- $\alpha$  and IL-1, or with bacterial products such as lipopolysaccharide, leads to the activation of a specific-IKK complex that phosphorylates I $\kappa$ B and thereby tags it for ubiquitination and degradation by the proteasome<sup>[77]</sup>. The degradation of I $\kappa$ B thus allows NF- $\kappa$ B to translocate into the nucleus where it can act as a transcription factor that upregulates IL-6 production and secretion. IL-6 works locally through paracrine and/or endocrine mechanisms to activate IL-6 signaling in the liver. IL-6 is known to induce IR in hepatocytes<sup>[78]</sup>. Hepatic production of IL-6 also provides a further pathogenic link to extrahepatic organs such as muscle. NF- $\kappa$ B target genes are not upregulated in transgenic mouse muscle, unlike IL-6 target genes and the suppressor of cytokine signaling and signal transducer and activator of transcription proteins. These genes are reversed during IL-6 neutralization, which is consistent with the pathogenic involvement of IL-6. Activation of NF- $\kappa$ B leads to a severe syndrome of muscle wasting, without IR<sup>[79]</sup>.

Fat mass in overweight/obese subjects has a primary role in determining low-grade chronic inflammation and, in turn, IR and ectopic lipid storage within the liver<sup>[80]</sup>. Obesity, aging, and fat mass all influence the growth hormone/insulin-like growth factor (IGF)-I axis, and chronic inflammation might reduce IGF-I signaling. Altered IGF-I axis is frequently observed in patients with hepatic steatosis<sup>[80]</sup>. In our study population, lower IGF-I status is associated with higher fat mass, spleen longitudinal diameter, CRP and more severe hepatic steatosis<sup>[80]</sup>.

## 11 $\beta$ -HSD1 IN INFLAMMATION

At least some of the immunomodulatory effects of GCs in the inflammatory response are dependent on 11 $\beta$ -HSD1 activity. For example, 11 $\beta$ -HSD1-deficient mice suffering from experimental arthritis exhibit a de-

layed resolution of the inflammatory response, probably due, in part, to attenuated macrophage phagocytosis of leukocyte apoptotic bodies<sup>[81,82]</sup>. As GCs regulate both the suppression of the early phase and the promotion of the late phase of the inflammatory response, it is conceivable that in generally deregulated - *i.e.*, both decreased and increased - GC levels could contribute to chronic inflammatory disease. Even if not characteristically for all chronic inflammatory conditions, some of them have been associated with increased 11 $\beta$ -HSD1 expression, in particular inflammatory diseases of the digestive tract, such as inflammatory bowel disease and colitis<sup>[82-85]</sup>, as well as atherosclerosis<sup>[44,86]</sup>. These observations are in line with several reports evidencing the induction of 11 $\beta$ -HSD1 expression by pro-inflammatory cytokines TNF- $\alpha$  and IL-1 $\beta$  in various cell types and lines including fibroblasts, adipocytes, osteoblasts and smooth muscle cells<sup>[5-7,87-91]</sup>.

## PARADOX OF IL-6 IN HUMANS AND ANIMALS

If global deletion of IL-6 not only develops obesity, but also hepatosteatosis and liver inflammation in animal model<sup>[69]</sup>, what is that determines the low prevalence of hepatic steatosis in patients suffering from Cushing's disease<sup>[22]</sup>?

Ahmed *et al.*<sup>[54]</sup> defined hepatic GCs metabolism in progressive NAFLD, which can be summarized into two distinct phases of altered regulation of hepatic cortisol metabolism: (1) increased hepatic cortisol clearance in steatosis; and (2) increased hepatic cortisol regeneration in NASH. Failure to regulate in this way may worsen the phenotype of liver disease driving hepatic steatosis or unchecked progressive hepatic inflammation<sup>[54]</sup>.

Considering the broadly accepted presence of inflammatory elements in the etiology of obesity, 11 $\beta$ -HSD1 probably plays an important causative role in the development of the metabolic syndrome, positioning itself at the interface of inflammation, hepatic steatosis and Cushing's syndrome.

From another perspective, under conditions that avoided changes in food intake, the efficacy of 11 $\beta$ -HSD1 inhibition to up-regulate hepatic fat oxidation gene expression - which reduces the glucocorticoid effects in liver and fat - functionally translates into enhanced hepatic lipid oxidation *in vivo*<sup>[92]</sup>.

## ANSWERED QUESTIONS AND CONCLUDING REMARKS

Considering the 50% five-year survival rate of patients with endogenous Cushing's syndrome (without any treatment)<sup>[93]</sup> and the fact that all patients enrolled into the study by Rockall *et al.*<sup>[22]</sup> were all newly diagnosed patients, should we discuss the question of time exposure as a possible explanation for the relatively low prevalence of

hepatic steatosis in patients with endogenous Cushing's syndrome? Should the relative hypercortisolemia (the increase in free cortisol or circadian disturbance) in patients with metabolic syndrome not be completely disregarded? At least two diagnostic studies aiming to evaluate patients with Cushing's syndrome among patients with obesity have found that late-night salivary cortisol (free cortisol) is increased in patients with obesity. Baid *et al.*<sup>[94]</sup> reported that late night salivary cortisol was frequently above the laboratory-provided reference range in obese and overweight subjects ( $n = 369$ ). In another paper late-night salivary cortisol was statistically significantly increased in patients with obesity and some features of Cushing's syndrome, in whom endogenous Cushing's syndrome was excluded, *vs* healthy, normal BMI control subjects<sup>[95]</sup>. Since IL-6 also plays an anti-inflammatory activity, it seems reasonable to assume that favorable aspects exist, such as inactivating proinflammatory mediators that induce the production of cortisol during exercise, and thus influence insulin sensitivity, with enhanced insulin action at muscle level, immediately at early recovery<sup>[96]</sup>. Could this anti-inflammatory effect of high circulating GCs affect hepatic steatosis in Cushing's disease?

### Abstract

Primary liver cancer is the sixth most common cancer in the world and the third cause of cancer-related death. Hepatocellular carcinoma (HCC) represents more than 90% of primary liver cancers and generally occurs in patients with underlying chronic liver disease such as viral hepatitis, hemochromatosis, primary biliary cirrhosis and non-alcoholic steatohepatitis. Especially cirrhotic patients are at risk of HCC and regular surveillance could enable early detection and therapy, with potentially improved outcome. We here summarize existing evidence for surveillance including ultrasound, other radiological modalities and various serum biomarkers, and current international guideline recommendations for surveillance. Ultrasound and  $\alpha$ -fetoprotein (alone or in combination) are most frequently used for surveillance, but their sensitivities and specificities are still far from perfect, and evidence for surveillance remains weak and controversial. Various other potential surveillance tools have been tested, including serum markers as des-car-

boxyprothrombin, lectin-bound  $\alpha$ -fetoprotein, and (most recently) circulating TIE2-expressing monocytes, and radiological investigations such as computed tomography-scan or magnetic resonance imaging-scan. Although early results appear promising, these tools have generally been tested in diagnostic rather than surveillance setting, and in most cases, no detailed information is available on their cost-effectiveness. For the near future, it remains important to define those patients with highest risk of HCC and most benefit from surveillance, and to restrict surveillance to these categories.

**Key words:** Hepatocellular carcinoma; Surveillance; Chronic liver disease

**Core tip:** Hepatocellular carcinoma is a frequent phenomenon in cirrhotic patients. Survival is generally poor, and curative options only exist if the tumor is detected in an early stage (Barcelona Clinic Liver Cancer stage 0 or A). This review summarizes existing evidence for surveillance including ultrasound, other radiological modalities and various serum biomarkers, and current guideline recommendations for surveillance. Selection of the appropriate high risk populations remains an important tool for cost-effective surveillance.

### INTRODUCTION

Primary liver cancer is the sixth most common cancer

in the world and the third cause of cancer-related death. Hepatocellular carcinoma (HCC) represents more than 90% of primary liver cancers and generally occurs in patients with underlying chronic liver disease. Incidence rates are highest in East Asia and Sub-Saharan Africa, where approximately 85% of all cases occur. The high HCC risk in these regions can be explained at least in part by the high prevalence of underlying risk factors, especially chronic hepatitis B virus (HBV) infection and aflatoxin B1 in the diet<sup>[1,2]</sup>.

Nevertheless, also in countries with relatively low incidence rates such as the United States, incidences have doubled over the last two decades, due to growing impact of chronic liver disease from hepatitis C virus (HCV) and non-alcoholic steatohepatitis (NASH)<sup>[3,4]</sup>. In Europe, there is a mixed pattern, with increasing or decreasing incidence rates in various countries. These geographical differences are thought to be the consequence of changing patterns of underlying risk factors for HCC, such as viral hepatitis, alcohol abuse and NASH. Although NASH conveys relatively modest risks of HCC, the burden of metabolic syndrome and insulin resistance is expected to have significant further impact on HCC incidence in the Western world in the near future. Also, coexistent metabolic syndrome and obesity further increase HCC risk in patients with other underlying liver diseases<sup>[5-7]</sup>. Smoking is another cofactor leading to increased HCC risk<sup>[7]</sup>. Interestingly, the use of cholesterol synthesis inhibitors and metformin and coffee consumption are associated with decreased HCC risk<sup>[8-11]</sup>.

New local treatment options such as radiofrequency ablation (RFA) or transarterial chemo- and radioembolisation (TACE and TARE) have been introduced in recent years. Also, the multikinase inhibitor sorafenib leads to improved survival in patients with advanced stage disease<sup>[12]</sup>. Nevertheless, most patients present at relatively late stage, without options for curative treatment. Survival remains poor under these circumstances [median survival: Barcelona Clinic Liver Cancer (BCLC) stage B, 15 mo; BCLC stage C, 6 mo; BCLC stage D, < 3 mo]<sup>[13]</sup>. Therefore, new strategies are urgently needed to decrease the burden of HCC. First, primary prevention of HCC can be achieved by hepatitis B vaccination, especially in endemic countries<sup>[14]</sup>. Second, antiviral therapies appear to be associated with decreased HCC risks in patients with chronic viral hepatitis. Interestingly, according to recent meta-analyses and systematic reviews, interferon-based antiviral treatment for hepatitis B is associated with only modest decrease of HCC risk (RR = 0.66, 95%CI: 0.48-0.89). Treatment with the nucleoside analog lamivudine is associated with a more substantial risk reduction (RR = 0.22, 95%CI: 0.10-0.50)<sup>[15-17]</sup>. It is reasonable to expect even better results with the currently available potent nucleos(t)ide analogs tenofovir and entecavir<sup>[18]</sup>.

Third, and focus of the current review, surveillance of patients at increased risk because of underlying chronic liver disease might detect HCC at earlier stages, and

could lead to better outcomes with decreased mortality (5-year survival with curative treatment in BCLC stage 0 or A: 40%-70%)<sup>[13]</sup>. Intuitively, this approach is attractive. Indeed, several international guidelines currently advise surveillance programs, defined as the repeated and systematic administration of a screening test, including registration and patient recall where applicable<sup>[19-21]</sup>. Nevertheless, surveillance remains controversial because of limited evidence for its efficiency and potential risk of side effects (for example complication from diagnostic biopsy of liver mass detected during surveillance which subsequently proves to be benign)<sup>[22,23]</sup>. This review offers an overview of current knowledge on HCC surveillance and gives a perspective on current international guidelines.

## BIOMARKERS FOR HCC SURVEILLANCE

When introducing a surveillance program, applying the optimal screening modality is essential. Detection of HCC at intermediate or advanced stage [according to Barcelona Clinic Liver Cancer Staging (BCLC) system] by surveillance could have some impact, by allowing TACE or sorafenib therapy. Nevertheless, surveillance should preferably detect (very) early stage HCC (single lesion  $\leq$  5 cm or  $\leq$  3 lesions each  $\leq$  3 cm without vascular involvement or metastasis), allowing potentially curative therapy. Serological biomarkers can be used at relatively low costs, without burden for the patient. Several biomarkers have been investigated for HCC detection, generally in diagnostic setting rather than in surveillance studies.

$\alpha$ -fetoprotein (AFP) is the most frequently used biomarker for HCC worldwide. AFP is a glycoprotein expressed by fetal hepatocytes or poorly differentiated HCC cells. Nevertheless, not all HCC cells secrete AFP into the circulation. Also, serum AFP levels may be elevated in patients with chronic liver disease in the absence of HCC (related to height of transaminases) and in patients with other malignancies<sup>[24]</sup>. Gupta *et al.*<sup>[25]</sup> published a systematic review with five included studies on diagnostic value of AFP for detecting HCC (all stages combined) in cirrhotic and non-cirrhotic HCV patients. They concluded that even if one assumes best-case estimates of sensitivity and specificity, the case for surveillance by AFP remains weak. By using the usual cut-off point of 20 ng/mL, sensitivities and specificities for detecting all stages of HCC were 41%-65% and 80%-94%, respectively. Positive and negative likelihood ratios ranged from 3.1 to 6.8 and from 0.4 to 0.6, respectively. In a recent large case-control study with 419 included HCC patients and 417 cirrhotic controls (with various underlying etiologies of liver disease), the performance of AFP in early stage HCC was compared with other biomarkers, such as des-carboxyprothrombin (DCP) and lectin-bound AFP, with more encouraging results<sup>[26]</sup>. In this study, diagnosis of HCC was based on current criteria for diagnosis, with appropriate blinding and 6-mo post-enrollment follow-

up for controls to eliminate false negatives. Sensitivity and specificity of AFP for detecting early stage HCC were 53% and 90%, respectively, using the currently recommended clinical cut-off point of 20 ng/mL. When the point in the receiver operating characteristics (ROC) curve with optimal sensitivity and specificity was used as cut off (10.9 ng/mL), sensitivity was 66% and specificity 82%. This finding would suggest that the usual cut off of 20 ng/mL is too high for optimal performance of AFP surveillance. In a previous small case-control study with 170 HCC patients (68 early stage HCC) and 170 matched cirrhotic controls, the cut off of 20 ng/mL appeared to exhibit optimal sensitivities and specificities<sup>[27]</sup>. Nevertheless, at this cut off, sensitivities and/or specificities were often insufficient in other studies<sup>[28,29]</sup>.

DCP is an abnormal protein generated as a result of an acquired defect in the posttranslational carboxylation of the prothrombin precursor in malignant liver cells<sup>[30]</sup>. Several studies investigated the performance of DCP as biomarker for early HCC, with inconclusive results<sup>[26,31-34]</sup>. For example, in a case-control study with 39 HCC patients and 77 matched controls, DCP had a greater accuracy than AFP<sup>[34]</sup>. DCP testing alone had a sensitivity and specificity of 74% and 86%, respectively, using a cutoff value of 40 mAU/mL. Another study reported much lower sensitivities for DCP with the best performance in chronic viral hepatitis<sup>[26]</sup>.

Another potential biomarker for HCC is lectin-bound AFP: One of the three glycoforms of AFP, based on its reactivity in lectin affinity electrophoresis<sup>[35]</sup>. In a multicenter prospective study, the diagnostic accuracy of lectin-bound AFP *vs* AFP was compared in patients with HCV-related cirrhosis<sup>[36]</sup>. The prevalence of HCC at baseline and during the two years of follow-up was significantly higher in patients with elevated lectin-bound AFP than in those with elevated AFP. The relatively high prognostic value of lectin-bound AFP was even higher in patients with concomitantly elevated AFP levels. This suggests that lectin-bound AFP has some clinical utility as secondary test in HCV patients with mildly elevated AFP levels, by identifying a subgroup with a relatively high likelihood of HCC. Nevertheless, this study has important limitations, such as a relatively short follow-up and potential selection bias. Also, other investigators report less encouraging results. For example, in the previously mentioned case-control study of Marrero *et al.*<sup>[26]</sup>, sensitivity of lectin-bound AFP for detecting early HCC was only 37%. Several studies investigated the diagnostic performance of a combination of serum biomarkers. Nevertheless, when combining AFP and DCP, there appeared to be only little or no improvement in sensitivity rates for detecting early stage HCC<sup>[26,33,34]</sup>.

Recently, new serum biomarkers for HCC have been suggested. Tyrosine kinase with Ig and EGF homology domains 2 (TIE2) is a receptor of angiopoietins. TIE2-expressing monocytes (TEMs) were recently reported to be enriched in HCC and other tumors where angiogenesis is known to be important for tumor progression. In

a recent publication on 168 HCV infected patients (89 with HCC), frequency of circulating TEMs in peripheral blood was significantly higher in case of HCC, and independent of tumor stage<sup>[37]</sup>. TEMs were also increased in a separate group of non-HCV HCC patients. Performance of TEMs in discriminating HCC from chronic hepatitis or cirrhosis was superior to AFP or DCP (sensitivities 86% and 71% respectively; specificities 81% and 90% respectively). Nevertheless, another study found increased circulating and intrahepatic TEMs in HCV patients without HCC<sup>[38]</sup>. Although these findings relate to a relatively small cohort of HCV-infected patients, they raise concern that mobilization and expansion of TEMs may not be strictly HCC-driven, but more generally associated with chronic liver infection<sup>[39]</sup>. Several other studies investigated the performance of Glypican-3 (GPC3). GPC3 is a surface protein expressed in high percentages of HCCs, whereas it is not detectable in hepatocytes from normal subjects or patients with benign liver disease<sup>[40-42]</sup>. Another potential marker is Golgi protein 73 (GP73): An amino acid that normally remains in the Golgi complex. Marrero *et al.*<sup>[43]</sup> reported that levels of GP73 are increased in serum of patients with HCC. In this study, sensitivity of GP73 for detecting early HCC was 62%. Also, interleukin-6 (IL-6) has been studied as potential marker for HCC. IL-6 is a cytokine involved in cell growth and differentiation. Serum IL-6 concentrations appeared to be increased in HCC patients (all stages combined) compared to controls<sup>[44,45]</sup>. Sensitivities of IL-6 for discrimination between HCC patients (all stages combined) and controls ranged from 46% to 73% and specificities from 87% to 95%. Also, levels of squamous cell carcinoma antigen (SCCA: A component of serine protease inhibitors) appeared to be significantly higher in HCC patients than in controls<sup>[46,47]</sup>. It remains to be seen, whether these new serum biomarkers will provide satisfactory results in the setting of surveillance in clinical practice.

## ULTRASONOGRAPHY FOR HCC SURVEILLANCE

Currently, ultrasonography (US) is the most widely used method for HCC surveillance. US is not invasive, but time-consuming, relatively expensive and operator-dependent. Also, this investigation is often not suitable in case of overweight. According to a recent meta-analysis with 13 included studies by Singal *et al.*<sup>[48]</sup>, pooled sensitivities and specificities for detecting HCC at any stage were both 94%. However, US was less effective for detecting early stage -potentially curable- HCC, with a pooled sensitivity of 63% (95%CI: 49%-76%).

Another systematic review concluded that US is insufficiently sensitive for HCC surveillance<sup>[49]</sup>. Sensitivities for detecting HCC (all stages combined) of the 14 included studies ranged from 30% to 100% and specificities from 73% to 100%. Possible explanations for the large variability between studies are differences in opera-

tor skills and experience, in tested populations and/or in tumor size.

The potential benefit of combining US with AFP for detection of early stage HCC was also explored in the previously mentioned meta-analysis by Singal *et al*<sup>[48]</sup>. The pooled sensitivities increased from 63% to 69% (95%CI: 53%-81%), but this was not statistically significant ( $P = 0.65$ ). This result suggests that adding AFP to ultrasound is not very useful for HCC surveillance.

The optimal interval for ultrasonographic surveillance is not known. It should be based on rate of tumor growth up to the limit of its detectability: Available evidence on tumor growth suggests that the interval from undetectable to a two cm diameter lesion ranges from 4-12 mo<sup>[50]</sup>. According to the meta-analysis by Singal *et al*<sup>[48]</sup> mentioned above, US sensitivities for detecting early-HCC may be improved by US at 6-mo intervals compared to surveillance intervals between 6-12 mo (pooled sensitivities: 70% *vs* 50%,  $P = 0.001$ ). However, confidence intervals of pooled sensitivities were overlapping (95%CI: 55.6-84.6 *vs* 40.0-59.2).

Two recent retrospective cohort studies from Italy and South Korea report that HCC is detected at earlier stage, with curative therapy more often applied and better survival in case of surveillance interval  $\leq 6$  mo compared to longer surveillance intervals, even after correction for lead time bias<sup>[51,52]</sup>.

A recent randomized control trial investigated whether a 3-mo interval of US surveillance was more effective than a 6-mo interval<sup>[53]</sup>. More focal lesions  $< 10$  mm were found in the group with 3-mo surveillance (5-year cumulative incidence: 41% *vs* 28%,  $P = 0.002$ ). Nevertheless, 44% of all focal liver lesions detected during surveillance remained indeterminate. No differences in detection rates of small HCCs eligible for curative treatment were observed between the two randomized groups. Inadequate compliance occurred in approximately 10% of both groups. Also, overall 5-year survival rates were similar in both groups (85% *vs* 86%,  $P = 0.38$ ).

Finally, a recent cluster-randomized trial from Taiwan compared 4- and 12-mo intervals in chronic HBV or HCV patients with thrombopenia. Although tumors were smaller in the group with 4-mo intervals, and curative treatment modalities more often applied, 4-year overall survival did not differ<sup>[54]</sup>.

## OTHER IMAGING TECHNIQUES FOR HCC SURVEILLANCE

Computed tomography (CT) and magnetic resonance (MR) imaging are potential tools for HCC surveillance. Until now, these imaging modalities are mainly used for further evaluation in case of abnormal findings with ultrasonographic surveillance and to determine extent of disease. Test characteristics of CT and MR imaging reported below are therefore all based on diagnostic studies rather than in a setting of surveillance. According to a systematic review of Colli *et al*<sup>[49]</sup> (studies in the period:

1996-2004 included), spiral CT imaging appeared to offer comparable sensitivities and specificities as US for detecting HCC (all stages) in patients with chronic liver disease. The pooled sensitivities for US and spiral CT imaging were 60% *vs* 68% and the pooled specificities 97% *vs* 93%. In the same systematic review, the reported pooled sensitivities (81%) and specificities (85%) of magnetic resonance imaging (MRI)-scan were, respectively, higher and lower than those obtained with US or CT imaging.

However, diagnostic accuracies of CT-scan and MRI-scan have increased in the past decade due to improvement of techniques<sup>[55-58]</sup>. For example, according to a recent retrospective study, the overall sensitivities of triple-phase multidetector CT (MDCT) imaging for detecting HCC (all stages combined) ranged between various observers from 78% to 81%<sup>[57]</sup>. Sensitivity improved with increasing HCC diameter. Also, in another recent study with prospective design, the diagnostic performances of US, MDCT imaging and contrast-enhanced MRI-scan were compared in a population of cirrhotic candidates for liver transplantation<sup>[58]</sup>. Dynamic MRI-scan with inclusion of the hepatobiliary phase had the highest accuracy with sensitivities for detecting early stage HCC, ranging from 59% to 85%. In contrast to CT imaging, MRI-scan is not associated with radiation exposure. However, MRI-scan is costly and there are no data from clinical practice to support the use of MRI-scan for surveillance.

## SURVEILLANCE EFFICIENCY

The aim of surveillance is to decrease HCC-related mortality. Unfortunately, high-level evidence is limited in this respect. A recent Cochrane review<sup>[59]</sup> identified only one study with data on mortality: Zhang *et al*<sup>[60]</sup> performed a large cluster randomized controlled trial in which a policy of surveillance *vs* no surveillance was compared in 18816 patients with current or prior HBV infection or a history of chronic hepatitis. There proved to be a survival benefit for the strategy of a 6-monthly surveillance with combined AFP and US compared to the no surveillance strategy. Despite poor adherence to surveillance (58%), HCC-related mortality rates were significantly lower in the surveillance group than in the disease control group (83.2/100000 and 131.5/100000, respectively, OR = 0.63). Since this study was performed in chronic HBV patients in China, it is not clear whether its results can be extrapolated to the Western World. Also, according to the Cochrane review, there are some discrepancies between this publication and earlier publications about the same trial<sup>[61-63]</sup>. For example, numbers of disease controls and total numbers of participants dropped from 9711 and 19144, respectively, in the initial preliminary publication in 1997<sup>[62]</sup> to 9443 and 18816, respectively, in two later publications in 1999 and 2004, after completion of the trial<sup>[60,61]</sup>. Also, confidence intervals were computed as if cohorts had been randomly assigned for each individual patient, without taking the cluster randomization into account and statistical significance

was claimed with a 95%CI that was only borderline significant (95%CI: 0.41-0.98)<sup>[22]</sup>. In another large randomized controlled trial from China, the effectiveness of surveillance by 6-monthly AFP measurement in 5581 HBV carriers was investigated<sup>[29]</sup>. HCC-related mortality rates were not significantly different in the surveillance group compared to the control group (1138/100000 and 1114/100000, respectively,  $P = 0.86$ ).

At lower evidence level, several cohort studies suggest that survival is improved with HCC surveillance<sup>[64,65]</sup>. In a population-based study of Alaska natives, 1487 HBV carriers had surveillance with AFP at 6-mo intervals<sup>[64]</sup>. In case of elevated AFP, US was performed. The long-term survival rate for patients whose HCCs were detected by the surveillance program was compared with a historical disease control group of patients with HCC: Survival rates were significantly higher for patients with HCC detected by surveillance (5-year survival rates: 42% and 0%, respectively,  $P = 0.008$ ; 10-year survival rates: 30% and 0%, respectively,  $P = 0.07$ ). Similar results were found in the study of Wong *et al*<sup>[65]</sup>. In this study, 56 HCC patients were retrospectively divided in three groups according to their initial presentation: Symptomatic patients presenting with abdominal pain, mass, bleeding, or weight loss; asymptomatic patients who had ultrasound for abnormal liver enzyme levels or other (unrelated) indications; and asymptomatic patients with underlying chronic liver diseases in a surveillance program. Patients in the surveillance group survived significantly longer than those in the symptomatic group (median survival of 1300 d *vs* 234 d,  $P = 0.009$ ). Median survival of the asymptomatic group without surveillance did not differ significantly from the other groups. However, lead time bias due to disease detection in an early stage could have affected the results of the two previously mentioned studies. Also, length time bias could have biased results by preferential detection of slowly growing lesions that are more likely to remain asymptomatic until late in disease course.

Several studies indicate that surveillance programs could lead to more frequent detection of HCC at early stages, when curative treatment is still possible<sup>[60,61,66,67]</sup>. In the previously mentioned large randomized controlled trial by Yang *et al*<sup>[61]</sup>, more resectable HCC cases were detected in the surveillance group than in the disease control group during five years follow-up (OR = 7.14; 95%CI: 3.53-14.43). In the later publication about the same trial, Zhang *et al*<sup>[60]</sup> reported similar results. Again, detection rates of small HCC (defined as a tumor diameter < 5 cm) were higher in the surveillance group than in the disease control group (45% *vs* 0%,  $P < 0.01$ ).

In the systematic review by Gebo *et al*<sup>[66]</sup> covering publications in the period: 1996-2002, one prospective cohort study was identified that investigated HCC surveillance in HCV patients. This study by Solmi *et al*<sup>[67]</sup>, compared 360 patients in the surveillance group (combined US and AFP measurements at 6-mo intervals) with a disease control group of 2170 patients who received usual care in other hepatology clinics. During

a mean follow-up of 56 mo, the incidence of HCC in the surveillance group was 6.7% and 5.5% in the disease control group. Of note, in the surveillance group, 75% of the HCC's was unifocal and  $\leq 3$  cm in diameter compared to only 16% in the disease control group ( $P = 0.000$ ).

Success of a surveillance program depends in general not only on the surveillance modality or target population. Recall strategy and adherence to follow-up are also important factors. In a large retrospective cohort study in the United States, 1873 HCC patients with a prior diagnosis of cirrhosis were identified in the period: 1994-2002<sup>[68]</sup>. In the three years before HCC diagnosis, 17% received regular surveillance, 38% received inconsistent surveillance and 45% no surveillance. In the regular surveillance group, 52% received both US and AFP, 46% AFP only and 2% US only. In a subset of 541 patients in whom cirrhosis was diagnosed at least three years prior to HCC, 29% received regular surveillance and 33% inconsistent surveillance. In another prospective cohort study, 1005 HCV patients were included in a surveillance program with combined US and AFP at 6- to 12-mo intervals<sup>[69]</sup>. During a mean follow-up of 6.1 years, 83 HCC cases were detected: 28% of those were tumors outside Milan criteria. 70% of patients with HCCs outside Milan criteria had experienced consistent surveillance and follow-up, which was not different from the total study group. Only in a minority of patients, absence of surveillance (13%) or follow-up (17%) could explain failure to detect patients at earlier stages. On multivariate analysis, study site was a strong independent predictor of consistent surveillance ( $P < 0.001$ ). After correction for study site, also platelet counts  $> 150 \times 10^6/\text{mL}$  and complete clinic visit adherence were positively associated with consistent surveillance.

## TARGET POPULATIONS FOR SURVEILLANCE

Most HCCs develop in patients with chronic liver diseases. The decision to start surveillance should depend on the chance of developing HCC, *i.e.*, the incidence of HCC in specific populations. Especially high risk patients should be included in surveillance programs. However, selection of these patients remains a subject of debate. Also, it is important to decide, prior to surveillance, whether the clinical condition of the patient would allow any therapy in case of HCC detection.

### Computer analyses in hypothetical cirrhotic patients

Several studies have investigated cost-effectiveness of HCC surveillance in cirrhotic patients based on computer analyses of theoretical models. In general, surveillance is considered cost-effective, if costs are less than \$50000 per life-year or quality-adjusted life-year (QALY) gained. According to Sarasin *et al*<sup>[70]</sup>, surveillance with combined US and AFP measurements at 6-mo intervals in patients with compensated cirrhosis results in an increase of life

expectancy of 3 mo when HCC incidence is 1.5%/year. However, in this case cost-effectiveness ratio of \$55264 per life year gained exceeds the generally accepted threshold of \$50000 per life year gained. When HCC incidence rates are higher, increase of life expectancy will be even more substantial. Cost-effectiveness ratios of systematic surveillance range between \$26000 (HCC incidence: 6%/year) and \$55000 (HCC incidence: 1.5%/year) for each additional life-year gained, in best case scenarios. Another study, using similar analyses in HCV cirrhotics, suggested that HCC surveillance with combined three-phase CT-scans and AFP measurements at 6-mo intervals was more cost-effective than other surveillance strategies<sup>[71]</sup>. This strategy was associated with an incremental cost-utility ratio of \$25232/QALY compared to no surveillance. These results are based on estimated HCC incidences of 1.4%/year in patients with compensated cirrhosis and 4%/year in patients with decompensated cirrhosis.

Lin *et al.*<sup>[72]</sup> suggested that combined US and AFP measurements at 6-mo intervals was the most effective surveillance strategy in HCV patients with compensated cirrhosis compared to other surveillance strategies (estimated annual HCC incidence: 0.02%-0.1%). However, this strategy entailed higher additional cost per QALY or life-year gained compared to a strategy of annual US and AFP measurements (incremental cost-effectiveness ratio: \$106871/QALY) or no surveillance (incremental cost-effectiveness ratio: \$129915/QALY). In this computerized decision model, surveillance with US at 12-mo intervals and AFP measurements at 6-mo intervals offered the greatest gain in life-expectancy, while still maintaining a cost-effectiveness ratio < \$50000/QALY or life-year gained, regardless of HCC incidence.

Another study in a hypothetical mixed-etiology cohort of compensated cirrhotic patients suggested that combined AFP measurement and US imaging on a 6-monthly basis is the most effective surveillance strategy<sup>[73]</sup>. Compared to no surveillance, this strategy is estimated to increase the numbers of HCCs resectable at time of diagnosis more than three-fold with 50% decrease of HCC-related deaths. Significantly more small and medium-sized HCCs (diameter < 2 cm or diameter 2-5 cm, respectively) would be identified by surveillance. However, when costs were taken into account, it was doubtful whether US should be routinely offered to those with serum AFP levels ≤ 20 ng/mL (> \$45000/QALY). Also, cost-effectiveness varied considerably depending on type of underlying chronic liver disease. In this computerized decision model, annual HCC incidence ranged from 1.2% to 4.1%.

### HCC incidence in cirrhotic patients

Annual incidence rates of HCC in specific populations with cirrhosis have been investigated extensively. Cirrhotic HBV patients have an increased risk for developing HCC. Studies that included only East Asian cirrhotic HBV patients showed HCC incidence rates around 3.2 per 100 person-years and 5-year cumulative HCC inci-

dence of 15%<sup>[74,75]</sup>. Studies in European HBV cirrhotics reported lower incidence rates: 2.2 per 100 persons-years and 5-year cumulative HCC incidence of 9%<sup>[76-79]</sup>.

Several studies have investigated the risk of developing HCC in HCV patients<sup>[76,80-83]</sup>. In a large prospective study of 12008 Taiwanese males, anti-HCV positive subjects had a 20-fold increased risk of developing HCC in comparison with anti-HCV negative subjects<sup>[81]</sup>. In this study, the presence or absence of cirrhosis was not evaluated. Other studies reported that especially cirrhotic HCV patients are at increased risk for developing HCC<sup>[76,80,83]</sup>. In a retrospective cohort study, the annual HCC incidence was 1.4% in European cirrhotic HCV patients<sup>[76]</sup>. Also, Degos *et al.*<sup>[83]</sup> reported HCC incidence rates of 13.4% after five years follow-up in a cohort of French patients with compensated HCV-related cirrhosis. In another study from Germany, 17 of 838 HCV patients (2%) developed HCC during a mean follow-up of 50 mo<sup>[80]</sup>. All HCCs occurred in cirrhotic livers. Cirrhotic patients had a 20-fold higher risk of developing HCC than HCV patients without cirrhosis at study entry (RR = 20.2, 95%CI: 2.4-170.9). Also, Lok *et al.*<sup>[82]</sup> reported that HCC incidence was higher in HCV patients with cirrhosis than in those with bridging fibrosis (annual HCC incidence rates: 1.45% *vs* 0.8%, *P*<sub>trend</sub> = 0.08). This study was performed in the United States.

In patients with cirrhosis due to causes other than viral hepatitis, HCC incidence rates are generally not precisely known. Nevertheless, alcoholic liver disease is a clear risk factor for HCC. In a meta-analysis of Bagnardi *et al.*<sup>[84]</sup>, the consumption of alcohol was associated with an increased risk for developing liver cancer (RR = 1.86, 95%CI: 1.53-2.27 for alcohol consumption of 100 g/d compared to no alcohol). The presence or absence of cirrhosis was not evaluated in this meta-analysis. In a Danish nationwide cohort study, 169 (2%) of 8482 patients with alcoholic cirrhosis developed HCC during a median follow-up of 4.1 years<sup>[85]</sup>. Five-years cumulative HCC risk was 1.0% (95%CI: 0.8-1.3). Kuper *et al.*<sup>[86]</sup> reported a relative risk of HCC of 2.4 for alcoholism alone and 22.4 for alcoholic cirrhosis compared to the general population. Several other studies also reported increased HCC risk in cirrhotic patients with alcohol as primary cause<sup>[87-91]</sup>. In a case-control study, heavy alcohol consumption contributed to a significant part of the 115 included HCC cases (32%), independent of other known risk factors<sup>[92]</sup>.

Patients with cirrhosis due to genetic hemochromatosis also are at increased risk of developing HCC. According to a meta-analysis, patients with genetic hemochromatosis who are homozygous for the C282Y mutation have a 11-fold increased HCC risk compared to controls (OR = 11, 95%CI: 3.7-34)<sup>[93]</sup>. In a Swedish population-based cohort study, patients with genetic hemochromatosis had a 20-fold increased risk for developing primary liver cancer compared to the general population (standardized incidence ratio: 21, 95%CI: 17-28)<sup>[94]</sup>. In both studies, the presence or absence of cirrhosis was not evaluated. Several other studies reported similar results<sup>[95-98]</sup>.

**Table 1** Characteristics and results of studies on risk of hepatocellular carcinoma in patients with autoimmune hepatitis,  $\alpha$  1-antitrypsin deficiency and Wilson's disease

Ref.	Study design	Study period	Patient No.	Duration follow-up	Results
Autoimmune hepatitis					
Yeoman <i>et al</i> <sup>[110]</sup>	Prospective cohort study	1971-2007	243	median: 11 yr (range 1-36)	Annual HCC incidence: 1.1% HCC occurred more often in cirrhotic patients (9.3% vs 3.4%, $P = 0.048$ )
Wang <i>et al</i> <sup>[111]</sup>	Prospective cohort study	Unknown	124	mean: 111 $\pm$ 6 mo	HCC incidence: 1 per 350 patient-year
Werner <i>et al</i> <sup>[112]</sup>	Retrospective cohort study	1990-2003	473	median: 8.8 yr (range 1-45)	HCC incidence in cirrhotics: 1 per 182 patient-year 23-fold increased HCC risk compared to the general population. Only HCC in cirrhotics
Wong <i>et al</i> <sup>[113]</sup>	Retrospective cohort study	1999-2009	322	mean: 6.25 yr	HCC incidence all patients: 459 per 100000 patient-year (0.5%/yr) In cirrhotics: 1920 per 100000 patient-year (1.9%/yr)
Park <i>et al</i> <sup>[114]</sup>	Retrospective cohort study	Unknown	212 (88 cirrhotics)	mean: 123 $\pm$ 9 mo	HCC incidence in cirrhotics: 1 per 1002 patient-year. (0.1%/yr)
Teufel <i>et al</i> <sup>[115]</sup>	Retrospective cohort study	1970-2009	278 (89 cirrhotics)	mean: 4.8 yr (in cirrhotic pts)	No HCC observed in 431 cirrhotic patient-year
$\alpha$ 1-antitrypsin deficiency					
Eriksson <i>et al</i> <sup>[116]</sup>	Autopsy study	1963-1982	38250 (17 pts with A1AD)	NA	Increased HCC risk in patients with A1AD compared to controls. (OR = 20, 95%CI: 3.5-114.3)
Elzouki <i>et al</i> <sup>[117]</sup>	Autopsy study	1963-1994	50333 (31 pts with A1AD)	NA	Increased HCC risk in patients with A1AD compared to controls (OR = 5.0, 95%CI: 1.6-15.8; $P = 0.008$ ). Only significant in males
Propst <i>et al</i> <sup>[118]</sup>	Retrospective cohort study	1990-1992	Group 1: 240 cirrhotics with different etiologies (25% A1AD) Group 2: 130 non-cirrhotic A1AD pts	Unknown	No significant differences in HCC prevalence between cirrhotic A1AD patients and cirrhotic subjects due to other causes No HCC in non-cirrhotic A1AD patients
Wilson's disease					
Walshe <i>et al</i> <sup>[119]</sup>	Retrospective cohort study	1955-1987 1987-2000 1966-2002	159	range: 10-45 yr	9 patients (6%) developed abdominal malignancies (2 $\times$ HCC). Higher incidence compared to the general population
Thattil <i>et al</i> <sup>[120]</sup>	Case report and review	No limitation	NA	NA	19 published case reports of HCC in patients with Wilson's disease

HCC: Hepatocellular carcinoma; A1AD:  $\alpha$  1-antitrypsin deficiency; NA: Not applicable; pts: Patients.

Primary biliary cirrhosis (PBC) is another important risk factor for HCC development. In a recent meta-analysis, PBC patients had a 19-fold higher risk to develop HCC compared to the general population<sup>[99]</sup>. In a large Japanese cohort of PBC patients, HCC incidence was 2.4% during a mean follow up of 80 mo. HCC incidence was higher in males than in females (5.1% vs 2.0%)<sup>[100]</sup>. Caballeria *et al*<sup>[101]</sup> compared HCC incidence in 140 PBC patients and a group of cirrhotic HCV patients. Cumulative HCC incidence in PBC patients was 3.6% during a mean follow-up of 5.6 years. Incidence rates were much higher (11.1%), when considering only those patients with late stages of disease. PBC patients in stages III and IV appeared to have comparable risks for HCC as cirrhotic HCV patients. Other studies reported similar results<sup>[102-105]</sup>.

The exact incidence of HCC in patients with cirrhosis due to non-alcoholic fatty liver disease (NAFLD) is not known. Nevertheless, a recent systematic review of White *et al*<sup>[106]</sup> reported that patients with NASH-cirrhosis had a consistently higher risk of HCC. Cumulative incidence rates ranged from 2.4% over 7 years to 12.8% over 3 years. In cohorts with non-cirrhotic patients with NAFLD and NASH the risk of developing HCC was

minimal: cumulative HCC mortality ranged from 0%-3% for study periods ranging from 6 to 21 years. Ascha *et al*<sup>[107]</sup> reported that annual cumulative HCC incidence in patients with NASH-cirrhosis was 2.6%, compared to 4.0% in patients with HCV cirrhosis ( $P = 0.09$ ). Besides, in several studies features suggestive of NAFLD were occasionally observed in HCC patients without a well-defined other cause of chronic liver disease<sup>[108,109]</sup>.

Cirrhotics patients with autoimmune hepatitis (AIH)<sup>[110-115]</sup> or  $\alpha$  1-antitrypsin deficiency<sup>[116-118]</sup> seem to have an increased HCC risk. However, the HCC incidence is lower than in cirrhotics with viral hepatitis. HCC in patients with Wilson's disease seems to be rare<sup>[119,120]</sup> (Table 1). Only case-reports are available for HCC in patients with cystic fibrosis<sup>[121-123]</sup>.

### HCC incidence in non-cirrhotic patients

The previously mentioned cost-effectiveness analyses were all restricted to cirrhotic patients and cannot be extrapolated to non-cirrhotic patients. However, also in some subgroups of HBV carriers without cirrhosis, HCC surveillance with US and AFP could be cost-effective<sup>[19]</sup>. HCC incidence should exceed 0.2%/year under these circumstances to allow cost-effective surveillance.

**Table 2 Comparison of recommendations regarding hepatocellular carcinoma surveillance in guidelines**

Characteristics	AASLD guideline <sup>[19]</sup>	EASL guideline <sup>[20]</sup>	APASL guideline <sup>[21]</sup>
Recommended target population	Cirrhotic HBV and HCV patients Alcoholic cirrhosis Stage 4 primary biliary cirrhosis Cirrhosis due to genetic hemochromatosis Cirrhosis due to $\alpha$ 1-antitrypsin deficiency HBV carriers of Asian origin (male > 40 yr, female > 50 yr) African/North American Blacks with hepatitis B HBV carriers with family history of HCC	Cirrhotic patients with Child-Pugh stage A and B Cirrhosis patients with Child-Pugh stage C awaiting liver transplantation Non-cirrhotic HBV carriers with active hepatitis or family history of HCC Non-cirrhotic patients with chronic hepatitis C and advanced liver fibrosis F3	Cirrhotic HBV and HCV patients
Surveillance benefit uncertain	HBV carriers younger than 40 (males) or 50 (females) Hepatitis C and stage 3 fibrosis Non-cirrhotic NAFLD		
Surveillance modality	US	US	US and AFP
Interval (mo)	6	6	6

AASLD: American Association for Study of Liver Disease; APASL: Asian Pacific Association for the Study of the Liver; HBV: Hepatitis B virus; HCV: Hepatitis C virus; NAFLD: Non-alcoholic fatty liver disease; US: Ultrasound; AFP:  $\alpha$ -fetoprotein; HCC: Hepatocellular carcinoma; EASL: European Association for the Study of the Liver.

A prospective population study in 22707 Taiwanese male HBV carriers without cirrhosis showed that annual HCC incidence rate was 0.5%<sup>[124]</sup>. Annual rates increased with age. A Japanese study also reported a relatively high incidence of HCC in HBV carriers (0.4%/year)<sup>[125]</sup>. Both studies only included East Asian patients. In this population, with in general early HBV infection through vertical transmission, annual HCC incidence in non-cirrhotic carriers depends on age and starts to exceed the threshold of 0.2% per year around the age of 40 years<sup>[126]</sup>. In two large community-based prospective cohort studies from Taiwan, predictors of progressive disease in chronic hepatitis B were evaluated<sup>[127,128]</sup>. High transaminases, HBeAg positive status and high serum HBV DNA levels were risk factors for developing HCC. Nevertheless, non-Western HBV carriers remain at significant risk for developing HCC, regardless viral replication status<sup>[127,129,130]</sup>. Although HBsAg loss leads to a pronounced reduction of HCC risk, incidence remains higher than in the general population due to HBV DNA integration in the liver cell<sup>[124,131,132]</sup>.

In contrast, uncontrolled prospective cohort studies in North America have indicated that the HCC incidence in HBV carriers could vary considerably<sup>[133,134]</sup>. Annual HCC incidence rates ranged between 0.06% and 0.46%. Non-Asian HBV carriers without cirrhosis are generally infected in adulthood by horizontal transmission and often exhibit low level of viral replication. They appear to be at limited risk of developing HCC<sup>[135-137]</sup>. However, HBV carriers with HCV or HIV co-infection or with a first degree relative with HCC are at increased risk for developing HCC<sup>[138-140]</sup>. Chronic HBV patients from sub-Saharan Africa often develop HCC at young age<sup>[129,141]</sup>.

The HCC incidence in HCV patients without cirrhosis is not clear. A Japanese study investigated HCC incidence in HCV patients and reported that annual

HCC incidences ranged from 0.5% to 7.9% in untreated chronic HCV patients with mild fibrosis and cirrhosis, respectively<sup>[142]</sup>. However, Lok *et al.*<sup>[82]</sup> reported that annual HCC incidence in HCV patients with bridging fibrosis was only 0.8%. The risk of developing HCC in non-cirrhotic patients with chronic liver disease due to other causes than viral hepatitis, is not exactly known.

## RECOMMENDATIONS OF GUIDELINES

In the last decade, several guidelines for management of HCC have been published worldwide. Most relevant are the practice guidelines of the American Association for Study of Liver Disease (AASLD)<sup>[19]</sup>, the EASL-EORTC Clinical Practice Guidelines on the management of hepatocellular carcinoma<sup>[20]</sup> and the Asian Pacific Association for the Study of the Liver (APASL) consensus recommendations on hepatocellular carcinoma<sup>[21]</sup> (Table 2). The AASLD guideline recommends surveillance for selected groups of cirrhotics (viral hepatitis, alcohol, PBC, genetic hemochromatosis,  $\alpha$ -1 antitrypsin deficiency) and high risk HBV patients without cirrhosis<sup>[19]</sup>. It is stated that there is insufficient evidence to recommend surveillance in HCV patients with advanced fibrosis or non-cirrhotic NAFLD. The EASL guideline advises surveillance in cirrhotics (regardless underlying cause)<sup>[20]</sup>. Also for HCV patients with advanced fibrosis and non-cirrhotic HBV carriers with active hepatitis or family history of HCC, surveillance is recommended. Of note, according to the EASL guideline, the presence of advanced (Child-Pugh C) cirrhosis prevents potentially curative therapies to be employed, and surveillance is not cost-effective under these circumstances, except for patients on the waiting list for transplantation. In fact, Child-Pugh C cirrhosis will also exclude radiologic interventions or sorafenib in palliative setting. According

to the APASL recommendations, cirrhotic patients with HBV and/or HCV should undergo surveillance<sup>[21]</sup>. Regarding modality of surveillance, the AASLD and EASL guidelines both recommend surveillance by US<sup>[19,20]</sup>. According to the APASL guideline, surveillance should be performed by combined US and AFP measurements<sup>[21]</sup>. All three guidelines recommend a surveillance interval of 6 mo<sup>[19,21]</sup>.

## CONCLUSION

In the last decade, there has been a marked increase in therapeutic options for HCC. Nevertheless, curative options are only feasible in case of early detection. Although regular surveillance could be beneficial in this respect, there is only limited evidence for its effectiveness in clinical practice. US at 6-mo intervals appears the most promising tool for surveillance, but the debate on serum tumor markers such as AFP has not yet ended. Defining those high risk subgroups who will benefit most from surveillance remains an important research goal for the near future.

### Abstract

Although the liver has a high regenerative capacity, as a result of massive hepatocyte death, liver failure occurs. In addition to liver failure, for acute, chronic and hereditary diseases of the liver, cell transplantation therapies can stimulate regeneration or at least ensure sufficient function until liver transplantation can be performed. The lack of donor organs and the risks of rejection have prompted extensive experimental and clinical research in the field of cellular transplantation. Transplantation of cell lineages involved in liver regeneration, including mature hepatocytes, fetal hepatocytes, fetal liver progenitor cells, fetal stem cells, hepatic progenitor cells, hepatic stem cells, mesenchymal stem cells, hematopoietic stem cells, and peripheral blood and umbilical cord blood stem cells, have been found to be beneficial in the treatment of liver failure. In this article, the results of experimental and clinical cell transplantation trials for liver failure are reviewed, with an emphasis on regeneration.

### INTRODUCTION

The liver provides various vital functions, including protein synthesis, detoxification, bile excretion and storage of vitamins. It is necessary for survival that it should be regenerated following massive damage induced by environmental toxins, infections and alcohol, etc. Although in normal conditions, hepatocytes, the primary cell type of the liver, are in G0 phase of mitosis, following any injury they rapidly enter the G1 phase and undergo mitosis. S-phase hepatocytes can be located in all segments of the lobule in the normal adult liver<sup>[1]</sup>. In the regenerating liver after partial hepatectomy (PH), periportal cells replicate first, probably reflecting their shorter G1 phase<sup>[2]</sup>. The peak of DNA synthesis is within 40-44 h after PH in mice<sup>[3]</sup>. The average life span of the hepatocytes is relatively long, about 5 mo. These long-lived cells are capable of at least 69 cell divisions and can restore normal architecture and impaired function in the injured liver<sup>[4]</sup>. He-

patocytes are the cells that normally shoulder the burden of regenerative growth after liver damage; therefore, they can be considered as the functional stem cells under most circumstances<sup>[5]</sup>.

The liver is the only internal human organ capable of natural regeneration. Detailed studies of the mechanisms that regulate liver growth have been performed in animals subjected to PH or chemical injury. Livers from small animals enlarge after transplantation to reach a liver size in proportion to the size of the recipient animal (e.g., baboons to humans, small dogs to large dogs)<sup>[6]</sup>. In humans, previous studies have shown that the mean liver volume 6 mo after donor hepatectomy was 90.7% of the initial liver volume<sup>[7]</sup>, and that the livers of the right lobe donor group regenerated faster than those of the left lobe donor group<sup>[8]</sup>. In fact, the growth of the liver is a restoration of function; the lobes that are removed do not regrow into their original form<sup>[9]</sup>. Nevertheless, functional restoration may be sufficient for survival of the organism.

The human liver is composed of mainly parenchymal cells, commonly referred to as “hepatocytes”, which are arranged in 1-2 cells-thick plates surrounded by hepatic sinusoids. They constitute 80% of the cell population of the liver. Sinusoidal endothelial cells, perisinusoidal macrophages (Kupffer cells), stellate cells (Ito cells) and liver-specific natural killer cells (pit cells) represent the non-parenchymal cells<sup>[10]</sup>.

Hepatocytes are rich in membranous and non-membranous organelles and inclusions. Bile is secreted into the bile canaliculi, which are a part of the intercellular space isolated by junctional complexes from the rest of the intercellular compartment. Near the portal space, bile canaliculi transform into the canal of Hering, which is lined by both hepatocytes and cholangiocytes<sup>[10]</sup>. The canal of Hering is thought to serve a reservoir of liver progenitor cells. The cell compartment that resides in the canal of Hering has been called the progenitor (in humans) or the oval cell compartment (in rodents)<sup>[11]</sup>. In rodents, the canal barely extends beyond the limiting plate; in contrast, in humans, it extends to the proximate third of the lobule<sup>[12]</sup>. The epithelial cells of the canal, called “oval cells”, are oval in shape and can differentiate into both hepatocytes and cholangiocytes. Thus, it would appear that a name change from oval cells to “hepatic progenitor cells” (HPCs) is required<sup>[13]</sup>. The transdifferentiation of oval cells to hepatocytes may determine survival when it occurs during liver failure in humans.

Adult hepatic stem cells are scarcely detectable under physiological conditions and during the normal process of liver regeneration, presumably because of their small numbers. Analyses of oval cells have raised the possibility that adult hepatic stem cells are present in the canals of Hering, and that oval cells originate from the stem cells and differentiate into both the hepatic and cholangiocytic lineages<sup>[14]</sup>. Kuwahara *et al*<sup>[15]</sup> enumerated four distinct stem cell niches: the canal of Hering (proximal biliary tree), the intralobular bile ducts, the peri-ductal “null”

mononuclear cells and the peri-biliary hepatocytes.

Although the liver has a high regenerative capacity, as a result of massive hepatocyte death, liver failure occurs. Liver transplantation, sometimes the only option for patient survival, often leads to immunological complications. On the other hand, it is limited by the availability of donor organs. In addition to liver failure, for acute, chronic and hereditary diseases of the liver, cell transplantation therapies can stimulate regeneration or at least ensure sufficient function until liver transplantation can be performed. The lack of donor organs and risks of rejection have prompted extensive research in the field of cellular transplantation. In this article, I review hepatic cell types involved in liver regeneration and cell transplantation therapies for liver failure, with an emphasis on regeneration.

## CATEGORIZATION OF STEM CELLS

Stem cells are the main cells of organisms from which all of the mature body cells are derived. Their high proliferative capacity for self-renewal permit them to increase their numbers by symmetric division. They may remain in the undifferentiated state for long periods. When the morphological as well as functional, differentiation begins, these cells differentiate into multiple specialized cell lineages. Stem cells are the source of progenitor cells committed to one or several lineages. The committed progenitor cells exhibit a capacity for active proliferation and supply abundant daughter cells, which in turn give rise to terminally differentiated cells<sup>[14]</sup>.

Stem cells are classified depending on the potential for differentiation into specialized cell types. The most talented stem cells, totipotent cells of the zygote within first 4 d of the intrauterine life, are able to form a full organism in an appropriate microenvironment. However, pluripotent cells, known as “embryonic stem cells” (ESCs), derived from the inner cell mass of the embryo, can form virtually any cell type derived from any of three embryonic germ layers; ectoderm, mesoderm or endoderm. Thus, an embryonic stem cell can form hepatocytes (endodermal in origin), cardiomyocytes (mesodermal in origin), and neurons (ectodermal in origin). Surplus embryos obtained from *in-vitro* fertilization laboratories are the main sources of the ESCs. However, some disadvantages including, high immune reaction risk and ethical concerns, limit their applications. Multipotent stem cells, known as “adult stem cells”, with a relatively limited differentiation potential, can form different cell types of the tissue. These cells reside together with the specialized cell types of the adult tissues and are thought to be responsible for the tissue maintenance and repair. The exact mechanisms that force them to differentiate into a specialized cell type are not fully known. The two major populations of adult stem cells are bone marrow mesenchymal and hematopoietic stem cells (HSCs). Hematopoietic stem cells have a predetermined fate to form all types of mature blood cells. Mesenchymal stem cells

can differentiate into multiple cell lineages, including tendon cells, muscle cells, osteocytes and fat cells. The term “multipotent stromal cell” implies the multipotent stem cells of both bone marrow and of non-marrow tissue, such as umbilical cord blood, adipose tissue, muscle tissue and dental pulp. In laboratory conditions, multipotent cells show plasticity. “Plasticity” or “transdifferentiation” means that the stem cells of an adult tissue can generate differentiated cells types of a different tissue. For instance, HSCs can transform into hepatocytes or brain stem cells or form skeletal muscle fibers. It is not clear if this occurs in the body. Multipotent cells do not cause any immune reaction, because they are genetically identical to their hosts. However, these cells are restricted in their ability to form different cell types. Moreover, they have some disadvantages, including slow rate of cell division and difficulties in isolating sufficient numbers for application because of their scarcity within tissues. The last type of stem cells is unipotent stem cells, which have very limited capacity for differentiation and can give rise to only one type of cell under normal conditions. For example, unipotent stem cells of colony forming unit of erythrocytes (CFU-E) can only give rise to mature blood erythrocytes.

In recent years, stem cells have been widely studied for their potential therapeutic use. However, some of studies were not successful. Researchers agree that as well as isolation of adequate numbers of healthy stem cells, selection of the most convenient transportation route, regulation of stem cell differentiation into a special cell type and obtaining the normal functions of the differentiated cells are very important regarding the benefit of stem cell applications. The most important risk of the transplanted stem cells is generation of tumors if cell division occurs in an uncontrolled manner. Unfortunately, stem cell transplantation therapy may be considered as a double-edged sword.

## HEPATIC CELLS INVOLVED IN REGENERATION

The liver can regenerate itself by increasing the rate of hepatocyte mitosis and differentiation of stem cells into hepatocytes or cholangiocytes. Stem cells are the main cell lineage for liver regeneration. Several studies suggest the existence of one or more population of cells (*e.g.*, stem cells, progenitor cells and extrahepatic stem cells) that are able to differentiate into hepatocytes and biliary epithelial cells. However, the exact location of these cells is not yet clear. In humans and rodents, potential liver stem cells may exist within the biliary tree. Both rodent and human ESCs, bone marrow HSCs, mesenchymal stem cells (MSCs), umbilical cord stem cells, fetal and adult liver progenitor cells, and mature hepatocytes have been reported to be capable of self-renewal, giving rise to daughter hepatocytes both *in vivo* and *in vitro*<sup>[16]</sup>. Although the factors controlling proliferation, differentiation and secretion processes are not well defined, recent studies

emphasize the role of several local (microenvironment) and systemic factors. However, the exact triggering mechanisms for differentiation of these cells into mature hepatocytes are not fully understood.

During embryonic development, hepatoblasts generate the two epithelial cell lineages: hepatocytes and biliary cells<sup>[17]</sup>. The area connecting the terminal segment of the biliary ductular system with parenchymal hepatocytes persists in the adult liver and is known as the canals of Hering<sup>[18]</sup>. The primitive intrahepatic bile ducts expressing both hepatocyte proteins and biliary epithelial markers have consequently been referred to as “transitional cells”<sup>[19-21]</sup>. Transitional cells have properties intermediate between those of oval cells and hepatocytes<sup>[20]</sup>. These cells are believed to remain in the adult liver as bipotential progenitors for both hepatocytes and biliary cells<sup>[21]</sup>.

Many investigators favor the view that the liver harbors facultative stem cells that are located throughout the biliary epithelium. The activation of these cells for transformation into mature hepatocytes is a conditional process that occurs only when the regenerative capacity of hepatocytes is overwhelmed<sup>[22]</sup>. Hepatocyte differentiation within bile ducts in the human liver has been noted, which has led to the belief that small biliary cells, hepatocyte-like cells expressing both markers of bile duct cells and hepatocytes, which repopulate severely damaged liver parenchyma, can function as a progenitor cell population for new hepatocytes<sup>[23]</sup>. In rodents, early reactive bile ductules do not generally resemble hepatocytes, but later acquire features of hepatocytes<sup>[22]</sup>. By contrast, direct evidence for the transformation of hepatocytes into biliary cells provided in cell culture had raised a possibility that hepatocytes themselves may be precursor cells for the biliary epithelium if the latter’s ability to proliferate and repair themselves is compromised for some reason<sup>[24,25]</sup>.

The oval cells represent the progeny of liver stem cells and function as an amplification compartment for the generation of “new” hepatocytes<sup>[22]</sup>. The oval cell compartment, consisting of small ovoid cells with scant, lightly basophilic cytoplasm and pale blue staining oval nuclei<sup>[26]</sup>, is widely used to describe liver progenitors. It is generally accepted that oval cells are bipotential transit-amplified cells derived from normally quiescent “true stem cells”, which reside in the biliary tree and are absent in the healthy liver<sup>[27]</sup>. In fact, to date, whether oval cells pre-exist in the tissue or develop from other adult cell types (*e.g.*, bile duct cells) after injury, is unknown. The restricted potential to differentiate into hepatocytes and cholangiocytes qualifies oval cells more as progenitor cells than as true stem cells<sup>[28]</sup>. The oval cells compartment can probably not to be attributed to a single cell type. A primitive oval cell population that do not express alpha-fetoprotein (AFP), cytokeratin 19 (CK-19), OV-6; a hepatocyte-like oval cell population that express AFP, but not OV-6; and a ductular-like oval cell population that not express AFP, but express CK 19 and OV-6 have been isolated<sup>[29]</sup>. It is presently unclear if antigenically distinct subpopulations of oval cells are derived from different

precursor cells or if their phenotype merely reflects the commitment of an oval cell to a specific lineage<sup>[30]</sup>.

Oval cells form ductular structures that communicate with the biliary system at one end and terminate at a hepatocyte-forming blind end<sup>[31]</sup>. Markers commonly used to assess differentiation and to trace lineages of oval cells include expressed antigenic markers for hepatocytes, biliary ducts and oval cells (BSD7, OC2, OC3, OV-1, and OV-6), intermediate filaments, extracellular matrix proteins (CK8, 18, 19), enzymes and secreted proteins (alpha-fetoprotein and gamma-glutamyl transferase)<sup>[32,33]</sup>. Oval cells also express some markers considered characteristic of stem cells, including stem cell factor<sup>[34]</sup>, bcl-2<sup>[35]</sup> and cytokeratin 14<sup>[36]</sup>. They are also immunoreactive to antibodies generally associated with hematopoietic lineages, such as CD34, and c-kit<sup>[37,38]</sup>; therefore, there may be a common lineage between hematopoietic and liver cell precursors. In a recent study, a population of cells (beta-2-microglobulin-ve, Thy-1+ve) in rat and human bone marrow was identified that also expressed hepatocyte specific functions, suggesting that these cells may be hepatic stem cells. After intraportal infusion into rat livers, rat-derived bone marrow cells integrated with hepatic cell plates and differentiated into mature hepatocytes<sup>[39]</sup>. Moreover, Crosby *et al*<sup>[37]</sup> have shown that *c-kit* and CD34 positive cells isolated from human liver are able to differentiate into biliary epithelial cells and endothelial cells. Thus, biliary cells and endothelial cells may also share some common precursors. It has been postulated that oval cells arise either from cells lining the canals of Hering<sup>[31,40]</sup>, from mature biliary cells<sup>[12]</sup>, liver epithelial or stromal cells<sup>[41]</sup>, or from circulating hematopoietic stem cells<sup>[42,43]</sup>. Additionally, some antigens traditionally associated with hematopoietic cells (c-kit and CD34) can also be expressed by oval cells, leading to the notion that at least some hepatic oval cells are directly derived from a precursor of bone marrow origin<sup>[39,44]</sup>. Fausto *et al*<sup>[45]</sup> suggested that bone marrow stem cells can generate oval cells and hepatocytes; however, transdifferentiation is very rare and inefficient. Bone marrow derived hepatocytes constituted from 0.008% to 0.8% of total parenchymal cells; therefore, differentiation of bone marrow cells into mature hepatocytes is very inefficient under physiological conditions<sup>[46]</sup>. Additionally, the repopulation process is not complete and is relatively slow<sup>[43,47]</sup>.

Studies have demonstrated that HSCs have the capacity to fuse with other cell types<sup>[48]</sup>. Several publications subsequently emerged to demonstrate that the appearance of new hepatocytes from bone marrow precursors in liver repopulation models was not caused by transdifferentiation of the marrow stem cells to hepatocytes, but to fusion of the marrow cells with the hepatocytes of the recipient<sup>[48,49]</sup>. While fusion with hepatocytes in whole animal experiments may have a role, it cannot explain the appearance of hepatocyte-like cells in cell cultures of bone marrow<sup>[25]</sup>.

The periductular stem cells are one of the other cell types related to liver regeneration in some types of liver

injury. These cells are rare in the liver, have a very long proliferation potential, and may be multipotent; however, their full potential has yet to be defined. These cells may be hematopoietic stem cell types that either reside in liver or bone marrow<sup>[50]</sup>.

Another cell type related to the regeneration of rat liver has been identified, referred to as "small hepatocytes" (small hepatocyte-like progenitor cells)<sup>[51,52]</sup>. This cell population is phenotypically different from fully differentiated hepatocytes, cholangiocytes and oval cells. They represent a unique parenchymal (less differentiated) progenitor cell population<sup>[53]</sup>. These cells have an extensive proliferative capacity and may represent a novel progenitor cell population that responds to liver deficit when the replicative capacity of differentiated hepatocytes is impaired, and can restore tissue mass<sup>[52]</sup>. However, there is still controversy as to whether these cells represent an intermediate state in oval cell differentiation or are derived from hepatocytes resistant to stem cells. Best *et al*<sup>[54]</sup> suggested that small hepatocytes are not the progeny of oval cell precursors, but represent an independent liver progenitor cell population. By contrast, Vig *et al*<sup>[55]</sup> showed that oval cells can form small hepatocyte-like progenitor cell nodules during the regeneration stage after chronic hepatocellular liver injury.

A number of studies have been published demonstrating that stem/progenitor cells can be differentiated toward "hepatocyte-like cells", a term that has been used to describe cells generated *in vitro* that show some characteristics of mature hepatocytes, but are still not fully mature and/or characterized<sup>[56]</sup>. Classic studies by Evarts *et al*<sup>[57-59]</sup> demonstrated that oval cells gradually transform themselves into small basophilic hepatocytes, which then become fully mature hepatocytes and replace the lost liver mass. They also showed the transfer of radiolabeled thymidine from oval cells to newly formed hepatocytes *in vivo*. Thus, the precursor-product relationship between oval cells and basophilic hepatocytes has been suggested<sup>[59]</sup>.

Recently, a unique population of liver-derived bipotential liver progenitors was isolated from unmanipulated rat liver<sup>[60]</sup>. These bipotential liver cells express both hematopoietic stem cell markers, such as CD45, CD34 and thy-1, similar to oval cells<sup>[60,61]</sup>, and endodermal/hepatic markers. In contrast to oval cells, these liver progenitors are negative for OV-6, cytokeratin 7 and CK 19, and express very little or no AFP<sup>[60,62]</sup>. Their capacity for hepatic differentiation makes them a valuable resource for important applications such as cell therapies for a variety of liver diseases<sup>[62]</sup>.

Although mature hepatocytes and cholangiocytes represent the first and most important resource for tissue repair, experimental data support the hypothesis that the liver also contains or activates a stem cell compartment<sup>[63,64]</sup>. Herrera *et al*<sup>[65]</sup> isolated a pluripotent population similar to rodent oval cells from adult liver and may be more mesenchymal in lineage. These cells expressed mesenchymal stem cell markers, but not the hematopoi-

etic stem cell markers. The absence of staining for cytokeratin-19, CD117, and CD34 indicated that these cells were not oval stem cells.

Castorina *et al*<sup>[64]</sup> reported that human liver stem cells express several mesenchymal markers, such as CD 44, but not hematopoietic stem cell markers. Additionally these multipotent cells express AFP, albumin, CK7 and CK19, indicating a partial commitment to hepatic and biliary lineages. Schmelzer *et al*<sup>[66,67]</sup> isolated two pluripotent hepatic progenitors: hepatic stem cells and progenitors. The gene expression profile of hepatic stem cells throughout life consists of high levels of expression of cytokeratin 19 (CK19), neuronal cell adhesion molecule (NCAM), epithelial cell adhesion molecule (EpcAM), and claudin-3 (CLDN-3); low levels of albumin; and a complete absence of expression of AFP. By contrast, hepatoblasts, found as < 0.1% of normal adult livers, express high levels of AFP, elevated levels of albumin, low levels of CK19 and a loss of NCAM and CLDN-3.

Notably, both hepatocytes and hepatic progenitor cells may differentiate into hepatocytes and biliary cells, as well indicating their bipotent differentiation capacity. Hence, both cell types meet the minimal definition criteria of a stem cell, *i.e.*, the potential of self-renewal to maintain the stem cell reserve, and a multiple differentiation potential giving rise to progeny of at least two different lineages<sup>[68]</sup>.

## FACTORS RELATED TO HEPATIC REGENERATION

Studies of liver injury have led the identification of several factors that are involved in the regulation of cell activation related to liver regeneration. It is not clear whether the same factors known to be involved in normal hepatic regeneration are also involved in regeneration *via* the stem cell compartment.

As mentioned before, the hepatic progenitor cell niche is located at the level of the canals of Hering. The ductular and periductular area is composed of numerous different cells, such as portal myofibroblasts, stellate cells, endothelial cells, hepatocytes, cholangiocytes, Kupffer cells, pit cells and inflammatory cells. All these cells could interact and crosstalk with hepatic parenchymal cells, influencing their proliferative and differentiative processes through the provision of numerous signals within the niche<sup>[5]</sup>. The local environments of endogenous and transplanted cells mainly affect their proliferation, differentiation, secretion, and other functions<sup>[69,70]</sup>. Hepatocyte growth factor (HGF), epidermal growth factor (EGF), and transforming growth factor- $\alpha$  (TGF- $\alpha$ ), as potent mitogens, are primarily associated with normal hepatic regeneration<sup>[71-73]</sup>. In cultures, the mouse liver progenitor cells differentiated into hepatocytes upon treatment with EGF or differentiated into biliary lineage cells upon treatment with HGF<sup>[74]</sup>. In their quiescent state, hepatocytes do not fully respond to growth factors such as HGF, TGF and EGF, which are potent stimulators of DNA

replication for hepatocytes in primary culture<sup>[75-77]</sup>. In the intact liver, hepatocytes need to be “primed” to enter the cell cycle and respond to growth factors<sup>[73]</sup>. The results show that TNF acts as a primer to sensitize hepatocytes to the proliferative effects of growth factors, and offers a mechanism to explain the initiation and progression phases of liver regeneration after PH<sup>[77]</sup>.

In addition to hepatocyte-autonomous signals, endocrine and paracrine factors are critical to normal regeneration, and extensive work has focused on the role of the liver microenvironment, *i.e.*, non-parenchymal cells and the extra-cellular matrix (ECM), in liver homeostasis and regeneration<sup>[71,78]</sup>. Non-parenchymal cells, such as endothelial cells, Kupffer cells, stellate cell and intrahepatic lymphocytes provide critical signals to hepatocytes during regeneration<sup>[78-80]</sup>. Intercellular interaction seems to be crucial during liver regeneration. Indeed, the initiation of liver regeneration involves the rapid and simultaneous activation of multiple signaling pathways in both hepatocytes and non-parenchymal cells, which are the main sources of tumor necrosis factor, interleukin-6, and heparin binding EGF<sup>[75,76,81]</sup>. Following acute liver injury, release of IL-6 from Kupffer cells and neutrophils and the growth factors including HGF, EGF, TGF- $\alpha$ , and fibroblast growth factor- $\alpha$  released from hepatic stellate cells, stimulate hepatocytes to enter mitosis<sup>[76,81]</sup>. Stellate cells are regarded as the principal source of extracellular matrix proteins during hepatic regeneration<sup>[82]</sup>. A recent study demonstrated that HSCs act as a positive regulator at the early phase and a negative regulator at the terminal phase of liver regeneration through cell-cell interaction and cytokine networks<sup>[83]</sup>. The authors reported that high levels of HGF at early phase of liver regeneration stimulated oval cell proliferation *via* extracellular signal-regulated kinase and p38 pathway, whereas high levels of TGF- $\beta$ 1 at the terminal phase of liver regeneration suppressed DNA synthesis of oval cells. The shift between these two distinct effects depended on the balance between HGF and TGF- $\beta$ 1 secreted by HSCs. Paku *et al*<sup>[31]</sup> demonstrated that proliferating oval cells are closely associated with stellate cells, suggesting that non-parenchymal cells nurture oval cell growth and differentiation through secretion of growth factors and cytokines, and also by direct cell-to-cell interactions. The factors involved in the regulation of oval cell activation include TGF, HGF and its receptor c-met, IL-6 and peroxisome proliferators/peroxisome proliferator activated receptor alpha<sup>[84-87]</sup>. It is clear that from the first stem/progenitor activation phase to the final differentiation phase of the oval cell cycle, several growth factors and other factors are effective.

More recent studies have emphasized the involvement of TNF-like weak inducer of apoptosis (TWEAK), a member of the TNF family, in the proliferation of oval cells. TWEAK expressed by T cells can stimulate hepatic progenitor cell proliferation. It appears that TWEAK selectively promotes proliferation of oval cells without having an effect on hepatocytes<sup>[87]</sup>.

Some of the other key molecules in the liver microen-

environment that determine regenerative behavior include the pro-inflammatory cytokines and angiogenic factors, such as vascular endothelial growth factor (VEGF)<sup>[80,88]</sup>.

Changes in microenvironments may have contributed to the positive outcomes of many liver cell transplantation studies, and might be initiated by the strong outputs (*e.g.*, signaling, secretion) from the transplanted hepatocytes that drastically affect the environments to stimulate endogenous hepatocyte regeneration<sup>[89]</sup>. Improvement of liver microenvironments related to liver regeneration is one of the goals of cell transplantation therapies. Recently, numerous experimental and clinical studies have been performed investigating the factors that increase the benefit of cell transplantation therapies and survival of the patients with liver damage or failure.

## CELL TYPES TRANSPLANTED FOR LIVER FAILURE

Cell transplantation therapy is a promising alternative approach that leads to donor cell-mediated repopulation of the liver and improved survival rates in experimental models of liver disease. It may serve to alleviate the symptoms while the patients are waiting for liver transplantation. However, significant challenges remain before these cells can be used in humans, such as the lack of consensus about the immunophenotype of liver progenitor cells, uncertainty of the physiological role of reported candidate stem/progenitor cells, practicality of obtaining sufficient quantity of cells for clinical use, and concerns over ethics, long-term efficacy, and safety<sup>[16]</sup>. A registered clinical application based on stem cell technology will take at least an additional 5-10 years because of certain limitations; *e.g.*, the lack of suitable cell sources and risk of teratoma formation<sup>[90]</sup>.

Stem cell therapy exerts its beneficial effect through a number of mechanisms, not necessarily transdifferentiation. Paracrine factors also have an important role in the improvement mechanism. Mature hepatocytes, stem/progenitor cells (ESCs, adipose-derived stem cells, umbilical stem cells, bone marrow-derived stem cells and oval cells), and hepatocyte-like cells are the main cell types used for cell transplantation in experimental and/or clinical studies. Transplanted hepatocytes have high function, but short survival time, whereas transplanted stem/progenitor cells have weak function, but high proliferative capacity. Hepatocyte-like cells accumulate over time *via* differentiation and proliferation<sup>[91]</sup>. However, the numbers of hepatocytes needed for transplantation in humans can be quite large<sup>[92]</sup>, cells that can differentiate into mature hepatocytes have been great interest. Additionally, since hepatocytes are large in diameter, up to 70% of transplanted hepatocytes get trapped in the hepatic sinusoids, which leads to temporary obstruction with subsequent portal hypertension<sup>[93]</sup>, and they have a poor engraftment rate<sup>[94]</sup>.

## MATURE HEPATOCYTES

Hepatocyte transplantation has been performed for more than 10 years in humans, meeting with varied degrees of success<sup>[95]</sup>. Data published for almost 70 years have unequivocally shown that hepatocytes are the replicating cells responsible for liver regeneration and that progenitor cell activation leading to lineage generation is not observed during this process<sup>[3,19,96]</sup>. Although the other cell types of the liver are necessary to support hepatocyte replication and hepatic growth, it has now been established that the hepatocyte has a remarkable capacity for cell proliferation and is the most efficient cell for liver repopulation after injury<sup>[45,75]</sup>. Therefore, transplantation of mature hepatocytes into an injured liver seems to be helpful to support recovery process. However, transplanted hepatocytes have a low liver-engraftment rate and survival<sup>[97]</sup>, and hepatocytes are only available from cadaveric donor livers, which mean that the cells largely lack transplantation quality and quantity. Moreover, cryopreservation of mature hepatocytes before use leads to an additional substantial loss of viability and function. Thus, research is aiming to obtain transplantable cells from embryonic and adult stem cells, or liver progenitor cells that can be expanded *in vitro*. One attractive alternative source of transplantable hepatocytes is cells derived from an immortalized hepatocyte cell line that provides an unlimited supply of transplantable cells<sup>[98]</sup>. Immortalized hepatocytes could then grow in tissue culture and subsequently function as differentiated, non transformed hepatocytes following transplantation<sup>[98,99]</sup>.

### Experimental results

Rhim *et al*<sup>[100,101]</sup> showed that a small number of transplanted hepatocytes could repopulate the liver of newborn urokinase-type plasminogen activator (uPA) transgenic mice. Transplantation of rat liver cells into these mice resulted in the complete reconstitution of a mouse liver with rat hepatocytes. The transplanted liver cell populations replaced up to 80 % of the diseased recipient liver. Overturf *et al*<sup>[102]</sup> found evidence that short-term therapeutic liver repopulation does not require progenitor or stem cells. The majority of the transplanted cells apparently participated in the repopulation process and intermediate-size hepatocytes appeared to have a better replicative capacity than small hepatocytes. Recently, transplanted hepatocytes were shown to engraft in the liver of animals with acute liver failure (ALF)<sup>[103]</sup>. However, only 20%-30% of the transplanted hepatocytes survive and engraft in the liver of rats<sup>[104]</sup>. In fact, several studies using rat models of primary hepatocyte transplantation revealed that transplantation leads to efficacious donor chimerism<sup>[105-107]</sup>. When hepatocytes were transplanted *via* the spleen, cells were distributed immediately in periportal areas, fibrous septa and regenerative nodules of the cirrhotic liver<sup>[107]</sup>. However, transplanted cell proliferation in the liver was limited, and animals did not show any dif-

ferences in mortality over a 12-mo period. On the contrary, Kobayashi *et al*<sup>[108]</sup> found that intrasplenic cell transplantation in extremely sick cirrhotic rats was associated with improvement in liver tests, coagulation abnormality and outcomes. Additionally, cell transplantation has been shown to prevent the development of intracranial hypertension in pigs following acute ischemic liver failure<sup>[109]</sup>.

Immortalized hepatocytes have also been shown to improve the survival rate in an ALF model<sup>[110]</sup>. Immortalized hepatocytes that can function as well as primary hepatocytes following transplantation were found to be effective in the treatment of liver failure in rats with end-stage cirrhosis with hepatic encephalopathy<sup>[98,111]</sup>. The immortalized hepatocytes may achieve a meaningful liver population using a clonal cell line; however, the malignant potential of these immortalized cell lines needs to be fully investigated before they could be applied in the clinic.

### Clinical results

In an early study, in 10 Japanese patients with cirrhosis, hepatocytes ( $1-60 \times 10^7$ ) isolated from a piece of their own liver were transplanted into various sites, including the spleen<sup>[112]</sup>. In one of these patients, transplanted hepatocytes were detected in the spleen 11 mo following transplantation. One of these patients recovered. In another trial, five patients with hepatic encephalopathy and multiple organ failure were transplanted with allogeneic hepatocytes ( $2.8 \times 10^7-2.9 \times 10^7$ ) through the splenic artery<sup>[113]</sup>. Biochemical evidence of liver injury improved significantly and blood ammonia levels decreased significantly to normal levels in the hepatocyte-treated patients. Three of these patients bridged to liver transplantation and were normal with more than 20 mo of follow-up. Transplantation of hepatocytes *via* the abdominal cavity also has been found beneficial. Seven patients with fulminant hepatic failure (FHF) were transplanted ( $6 \times 10^7/\text{kgBW}$ ) *via* the abdominal cavity resulting in survival and improved encephalopathy<sup>[114]</sup>.

Cryopreserved hepatocyte transplantation is a bridging method while patients with chronic liver failure await liver transplantation. Three of five patients with ALF who received transplantation of  $1.3 \times 10^9-3.9 \times 10^{10}$  cryopreserved hepatocytes through intrasplenic and intraportal infusion improved afterwards<sup>[115]</sup>. A patient with ALF infused intraportally with  $8 \times 10^9$  cryopreserved human hepatocytes fully recovered 12 wk after transplantation<sup>[116]</sup>. Repeated application of primary human hepatocytes seems to be safe and results in measurable benefits for patients with ALF.

## HEPATIC PROGENITOR/STEM CELLS

Human hepatic stem cells, constituting approximately 0.5%-2.5% of liver parenchyma, can be isolated by immunoselection for epithelial cell adhesion molecule-positive cells (EpCAM+)<sup>[67]</sup>. Isolation of hepatic progenitor cells from human material has proven to be very difficult. In fact, although hepatic progenitor cells express

several markers, their unequivocal isolation as a pure fraction has been a major obstacle in liver progenitor cell research. Novel cell surface markers in adult progenitor cells include tight junction proteins, integrins, cadherins, cell adhesion molecules, receptors, membrane channels and other transmembrane proteins. Cell surface markers, CD133, claudin-7, cadherin 22, mucin-1, ros-1 and Gabrp 9 are overexpressed and are unique for the adult progenitors<sup>[117]</sup>. Thymus cell antigen 1 (Thy-1) is a marker for sorting bipotential progenitor cells from human livers<sup>[118]</sup>. None of the described markers are completely specific; therefore, isolation of viable cells is limited<sup>[119]</sup>.

Much less is known about the mechanisms of oval cell replication and differentiation, although new information on these topics is rapidly accumulating. Regarding cellular aspects of liver growth and regeneration, it needs to be established what kind of signaling mechanisms may exist, direct and/or indirect, between hepatocytes and oval cells that determines whether one cell type or the other is the main or initial target for a growth stimulus<sup>[45]</sup>.

### Experimental results

Schmelzer *et al*<sup>[67]</sup> demonstrated that purified EpCAM+ cells from fetal or postnatal livers are able to engraft the livers of immunodeficient adult mice (with or without prior injury) and give rise to mature human liver parenchymal cells. Similar results were obtained by Weiss *et al*<sup>[118]</sup> through the isolation of Thy-1+ cells from adult human livers and their transplantation in immunodeficient Pfp/Rag2 mice. Analysis of *in situ* material revealed that transplanted cells express human hepatic markers HepPar1 and albumin, indicating functional engraftment.

Oval cell proliferation is prominent in many models of liver injury, including CCl<sub>4</sub> treatment in combination with PH<sup>[120,121]</sup>. A recent study showed that transfer of oval cells to Wistar rats with FHF could significantly increase their survival rate<sup>[122]</sup>. In the study of Wang *et al*<sup>[123]</sup>, 3,5-diethoxycarbonyl-1,4-dihydrocollidine induced oval cell proliferation. Transplantation of murine oval cells could repopulate the recipient liver in fumarylacetoacetate hydrolase-deficient mice, and rescue the phenotype.

### Clinical results

As far as I know, to date, no clinical application has been performed.

## FETAL HEPATOCYTES/FETAL LIVER PROGENITOR CELLS/FETAL STEM CELLS

Fetal human hepatocytes exhibit unique properties, including the capacity for extensive proliferation and excellent recovery following partial liver resection<sup>[124]</sup>. However, experimental studies have predominantly focused on transplantation of fetal hepatic progenitor cells. Oertel *et al*<sup>[125]</sup> purified hepatic stem/progenitor cells from fetal livers that are fully capable of repopulating the normal adult liver. This represents a major advance toward developing

protocols that will be essential for clinical application of liver cell transplantation therapy.

### Experimental results

After transplantation of mouse fetal liver progenitor cells into 14 to 20 d-old uPA-mice with subacute liver failure, donor-derived regeneration nodules were detectable. Fetal liver cells showed a mature hepatic phenotype, as established by gene expression profiling and a functional integration within in the first 4 wk after transplantation<sup>[126]</sup>. Transplanted rat fetal liver epithelial progenitor cells were able to repopulate a recipient liver subjected to PH, alone or with retrorsine, in syngeneic dipeptidyl peptidase IV (DPPIV) mutant rats<sup>[127]</sup>. Progenitor cells were able to differentiate into both hepatocytes and bile epithelial cells, unlike mature hepatocytes that are not able to differentiate to bile epithelial cells. Moreover, progenitor cells continued to proliferate for longer than hepatocytes after transplantation. Likewise, Dlk+ hepatic stem/progenitor cells purified from rat midgestational fetal livers were able to extensively repopulate the host liver in syngeneic DPPIV mutant rats subjected to PH alone<sup>[125]</sup>. In the CCl<sub>4</sub> rat model of FHF with 2/3 hepatectomy, fetal liver stem/progenitor cells were found to be effective to repair the damaged liver<sup>[89]</sup>. Thus, fetal hepatic stem/progenitor cells exhibit potency for reconstitution of the adult liver under a particular set of conditions.

### Clinical results

As far as I know, to date, no clinical application has been performed.

## EMBRYONIC STEM CELLS

### Experimental results

The first report of hepatic differentiation of mouse embryonic cells was in 2001 by Hamazaki *et al*<sup>[128]</sup>, who produced an embryoid body from an ES cell and subsequently added fibroblast growth factor, HGF, oncostatin M (OsM) and dexamethasone (Dex) to induce the differentiation of cells exhibiting hepatocyte-like properties. The results of Heo *et al*<sup>[129]</sup> are particularly noteworthy, as they report that liver precursor cells induced from ES cells in the absence of exogenous growth factors or feeder cell layers also have the ability to differentiate into biliary epithelial cells. In 2003, Yamamoto *et al*<sup>[130]</sup> produced hepatic cells with a high level of liver function by transplanting ES cells into mice livers 24 h after CCl<sub>4</sub> intoxication. In terms of ultrastructural analysis, these ES-derived hepatocytes were generally similar to normal hepatocytes. Additionally, no teratoma formation was observed in the transplant recipients. In the study of Hu *et al*<sup>[131]</sup>, ES-derived hepatocytes could improve the life quality and lengthen the survival time of CCl<sub>4</sub>-induced FHF. Sprague-Dawley rats with surgically induced liver failure *via* 90% hepatectomy, receiving 10<sup>6</sup>-10<sup>8</sup> ESCs as splenic transplantation, showed 100% survival rate up to 3 mo<sup>[132]</sup>. Similarly, hepatocytes derived from ES cells in

a bioartificial assisted liver device were able to improve survival in rats with liver failure induced by galactosamine after 10 h of extracorporeal liver dialysis<sup>[133]</sup>. Additionally, embryonic derived hepatocytes, implanted subcutaneously as a bioartificial liver device into mice subjected to 90% hepatectomy, reversed the liver failure<sup>[134]</sup>. Transplantation of ES cell-derived hepatic cells significantly suppressed the onset of fibrosis in mice<sup>[135]</sup>.

### Clinical results

Embryonic stem cell studies remain at the preclinical stage because of the risk of teratomas. Despite these successful animal studies, there have been no clinical trials using human ES cells to treat liver diseases in human patients, because utilization of human ES cells raises serious ethical questions in many countries.

## MESENCHYMAL STEM CELLS

Mesenchymal stem cells (MSCs) are an adult stem cells population found in numerous living tissues. It has been reported that among MSCs obtained from bone marrow, adipose tissue, umbilical cord blood and placenta, several hepatocyte-like cells have the ability to differentiate<sup>[136-138]</sup>. Besides, MSCs, immune-privileged cells with low MHC I and no MHC II expression have low rejection risk and, as such, are a particularly promising source of cells for the treatment of acute and degenerative liver diseases<sup>[136]</sup>. Chamberlain *et al*<sup>[139]</sup> transplanted clonal human MSCs into preimmune fetal sheep by intrahepatic and intraperitoneal routes in their study. The intrahepatic injection of human MSCs was safe and resulted in more efficient generation of hepatocytes throughout the liver parenchyma at days 56-70. Human MSCs cells accumulated in the injured liver. The injured liver may produce regulatory factors for homing of stem cells to the injury site<sup>[135]</sup>.

### Bone marrow-derived mesenchymal stem cells

The most important source of MSCs is bone marrow.

**Experimental results:** A recent study by Carvalho *et al*<sup>[140]</sup> demonstrated that MSCs injection into the portal vein of mice or rats with liver cirrhosis induced by CCl<sub>4</sub> and ethanol did not reduce hepatic fibrosis or promote any improvement in parameters of liver function. However; Oyagi *et al*<sup>[141]</sup> demonstrated benefits in transplantation of bone marrow-derived mesenchymal stem cells (BMMCs) cultured with HGF in CCl<sub>4</sub>-induced rats. Transplantation of the BMMCs into liver-injured rats restored their serum albumin level and significantly suppressed transaminase activity and liver fibrosis. These effects were not seen when the BMMCs were cultured without HGF. Similar results of Fang *et al*<sup>[142]</sup> supported the beneficial effects of BMMCs on reducing collagen deposition.

**Clinical results:** Autologous BMMC transplantation to 53 patients with liver failure caused by hepatitis B had fa-

avorable short-term efficacy with improved levels total bilirubin, prothrombin time and Model for End-Stage Liver Disease score of patients 2-3 wk after transplantation<sup>[143]</sup>. Patients who received 120 mL of autologous bone marrow fluid *via* a hepatic artery showed improved hepatic function in the early period (1-48 wk). Analysis showed no adverse effects from bone marrow administration a long observation period. Additionally, data obtained from eight patients with liver cirrhosis showed that MSCs injection through peripheral or portal vein under ultrasound guidance could be used for the treatment of end-stage liver disease with satisfactory tolerability<sup>[144]</sup>. The study of Amer *et al*<sup>[145]</sup> reported the safety and short-term efficacy of autologous bone marrow-derived hepatocyte-like cell transplantation in the treatment of patients with end-stage liver cell failure. Comparing hepatic and splenic routes of injection, there was no significant difference, except in the first month. The splenic route was technically easier, although it was associated with a higher incidence of mild complications (fever and transient shivering).

#### **Placenta-derived mesenchymal stem cells**

Another promising source of MSCs is the placenta. Human placental MSCs are free of ethical concerns, are non-invasively accessible, abundant and strongly immunosuppressive<sup>[146,147]</sup>. Placenta derived MSCs can be differentiated into hepatocyte-like cells *in vitro*<sup>[148]</sup>.

**Experimental results:** The experimental study of Cao *et al*<sup>[149]</sup> revealed that human placental MSCs could not only differentiate into hepatocyte-like cells *in vitro* and *in vivo*, but also could prolong the survival time of pigs with ALF. The survival rate was significantly higher in the transplantation group than in the control group (66.7% *vs* 0%). Recently, van Poll *et al*<sup>[150]</sup> provided evidence that MSC-derived molecules directly inhibit hepatocellular death, enhance liver regeneration and ultimately improve survival in rats undergoing D-galactosamine-induced FHF. Systemic infusion of MSC-conditioned medium resulted in a 90% reduction of apoptotic hepatocellular death and a three-fold increment in the number of proliferating hepatocytes. Moreover, transplanted human placental MSCs ameliorate CCl<sub>4</sub>- induced liver cirrhosis by their anti-fibrotic effect in a rat model<sup>[151]</sup>. Mohsin *et al*<sup>[152]</sup> reported that pretreated MSCs expressing high levels of albumin, cytokeratin 8, 18, TAT and HNF1 $\alpha$  transplanted in the left lateral lobe of mice with liver fibrosis resulted in a significant reduction in the fibrotic area in the liver, concomitant with improved serum levels of bilirubin and alkaline phosphatase. Cao *et al*<sup>[149]</sup> compared the effects of transplantation of placental MSCs through the peripheral (jugular) and portal veins; their data suggested that both transplantation routes were safe, with no portal vein thrombosis. However, histological data revealed that transplantation of human placental MSCs *via* the portal vein reduced liver inflammation, decreased hepatic denaturation and necrosis, and promoted liver regeneration.

**Clinical results:** Despite the several positive results gained from experimental studies, the therapeutic role of MSCs in liver regeneration must be further investigated, as the clinical evidence is still limited. As far as I know, to date, no clinical application has been performed.

#### **Adipose tissue-derived mesenchymal stem cells**

Adipose tissue is a source of MSCs that can be easily isolated, selected and induced into mature, transplantable hepatocytes. The fact that they are easy to procure *ex vivo* in large numbers makes them an attractive tool for clinical studies in the context of establishing an alternative therapy for liver dysfunction<sup>[153]</sup>. Adipose tissue-derived MSCs have immunomodulation, differentiation (plasticity), homing, revascularization, anti-apoptotic and tissue regenerating abilities<sup>[136]</sup>.

**Experimental results:** Transplanted adipose-derived MSCs through tail vein injection were able to differentiate into hepatocytes in BALB/c nude mice with CCl<sub>4</sub>-induced liver injury, and were able to function like human mature hepatocytes. Adipose-derived MSCs could be differentiated into hepatocytes within 13 d<sup>[154]</sup>. When approximately 10<sup>5</sup> of adipose-derived human MSCs (0.2 mL of the cell suspension *via* tail vein) transplanted by injection into mice with liver failure, the ammonia concentration fell to near normal levels within 24 h<sup>[153]</sup>. Of the various transplantation routes (tail vein, portal vein, and direct liver parenchymal injections), transplantation *via* the tail vein was found to be the most effective in reducing biochemical parameters in CCl<sub>4</sub>-induced liver failure in mice<sup>[155]</sup>.

**Clinical results:** In the study of Zhang *et al*<sup>[156]</sup> 30 chronic hepatitis B patients with decompensated livers received umbilical cord-derived MSC transfusion. No significant side effects or complications were observed. Liver function improved and the volume of ascites significantly decreased. Umbilical cord-derived MSC have also been found to be safe and beneficial in the treatment of the patients with acute-on chronic liver failure associated with hepatitis B virus infection. The cell transfusions significantly increased the survival rates in ACLF patients<sup>[157]</sup>.

#### **Bone marrow-derived hematopoietic stem cells**

In 1999 Petersen *et al*<sup>[42]</sup> and in 2000 Lagesaa *et al*<sup>[43]</sup> described the contribution of bone marrow-derived stem cells (BMSs) to liver regeneration. Data in the literature increasingly suggest bone marrow as a transplantable source of hepatic progenitors<sup>[158,159]</sup>. Initial reports of the hepatic potential of HSCs were later shown to have resulted from fusion between transplanted donor cells and resident recipient hepatocytes<sup>[48,160]</sup>. The authors analyzed sex-mismatched bone marrow and liver transplantations in rats<sup>[42]</sup>, mice<sup>[158]</sup> and humans<sup>[161]</sup>, and were able to show Y-chromosome-positive hepatocytes as single cells or small clusters in the recipients. Adjusted Y-positive hepatocyte and cholangiocyte engraftment ranged from 4% to 43%, and from 4% to 38%, respectively<sup>[160]</sup>.

**Experimental results:** Cantz *et al*<sup>[162]</sup> have investigated the contribution of intrasplenic bone marrow transplants or *in vivo* mobilized HSCs to the formation of hepatocytes in normal and injured liver by CCl<sub>4</sub>. They concluded that there is little or no contribution of BMSs to the regeneration of normal and injured livers in the animal models used. Kanazawa *et al*<sup>[163]</sup> also demonstrated that there is little or no contribution of BMCs to the replacement of injured livers (both acute and chronic) in three different models, as follows: CCl<sub>4</sub> treatment, albuminurokinase transgenic mouse, hepatitis B transgenic mouse. By contrast, Jang *et al*<sup>[164]</sup> reported that transplantation of a population of bone marrow purified stem cells promoted functional improvement in mice with CCl<sub>4</sub>-induced acute liver injury. Moreover, liver function was restored 2-7 d after transplantation. Fibrosis reduction was also reported in rats with CCl<sub>4</sub>-induced acute liver injury after bone marrow mononuclear cells transplantation *via* the portal vein. The general condition of the rats in the treatment group also improved markedly<sup>[165]</sup>. In the study of Shizhu *et al*<sup>[166]</sup> transplanted bone marrow mononuclear cells *via* tail veins of mice were found to populate the damaged liver around the portal and centrolobular regions, and they appeared to differentiate into albumin-producing hepatocyte-like cells. Animals that received bone marrow mononuclear cells also showed a trend toward improved liver enzymes, as well enhanced survival rates, relative to controls.

**Clinical results:** Although the results of experiments on rodents are conflicting, several clinical trials found that BMSCs were beneficial in the treatment of the patients with liver failure. Autologous BMSCs transplantation *via* the portal vein, peripheral vein or hepatic artery into patients with cirrhosis, resulted in improvement of liver function tests<sup>[167-171]</sup>. Clinical studies by Lyra *et al*<sup>[172,173]</sup> suggested the safety of autologous bone marrow-derived cells through a hepatic artery for chronic liver disease patients. In nine patients with alcohol-related cirrhosis, the reinfusion of CD34+ HSCs into the hepatic artery was well tolerated and beneficial to liver function<sup>[174]</sup>. However, in the study of Cauto *et al*<sup>[171]</sup>, one case of dissection of the hepatic artery and one case of Takotsubo syndrome occurred as early complications. A patient developed a cutaneous immunological disorder and another patient developed hepatocellular carcinoma 12 mo after infusion *via* the hepatic artery. A phase 1 trial using BMSCs injected *via* the hepatic artery after portal embolization was prematurely terminated when a patient with decompensated cirrhosis died from radio contrast nephropathy and hepatorenal syndrome<sup>[175]</sup>.

A recent case report described the use of autologous unsorted BMSCs as rescue treatment for hepatic failure in a 67-year-old man ineligible for liver transplantation<sup>[176]</sup>. Apparent rapid improvement in hepatic synthetic function was obtained after the portal venous infusion of the cells. A liver biopsy performed 20 d after cell transplant

was reported to show increased hepatocyte replication around necrotic foci. Salama *et al*<sup>[177]</sup> reported that near normalization of liver enzymes was observed in 54% of 90 patients with end-stage liver disease received GSF for five days followed by autologous CD34+ and CD133+ stem cell infusion in the portal vein. Similarly, in a phase I clinical trial of five patients with acute on chronic liver failure, administering G-CSF and then reinfusing the CD34+ cells improved liver function in more than 50% of cases during a 60-d follow-up<sup>[167]</sup>. The patients receiving autologous infusion of mobilized adult bone marrow derived CD34+ cells without G-CSF were monitored for up to 18 mo, which confirmed the safety of the procedure, with beneficial effects lasting around 12 mo<sup>[170]</sup>. Terai *et al*<sup>[169]</sup> implemented a clinical trial on nine patients with decompensated liver cirrhosis. These patients were infused with  $5.2 \pm 0.63 \times 10^9$  autologous bone marrow cells from the peripheral vein. At 24 wk after transplantation, significant improvements were observed.

#### Peripheral and umbilical blood stem cells

Stem cells derived from cord blood of human origin exhibit higher plasticity than the respective mouse or rat cells<sup>[178]</sup>. Like the BMSCs, cell fusion has been implicated as the mechanism by which human cells are seen in the recipient's liver. Some researchers observed cell fusion in most cells<sup>[179]</sup> and some claim no evidence of cell fusion<sup>[180]</sup>. Newsome *et al*<sup>[180]</sup> demonstrated that human umbilical cord-blood (hUCB)-derived cells could differentiate into hepatocytes after transplantation into immunodeficient mice. The percentage of human, compared with mouse, hepatocytes reached an average of 0.011% after 16 wk. Kögler *et al*<sup>[181]</sup> reported that these somatic multipotent stem cells could differentiate into hepatocytes after transplantation into a pre-immune fetal sheep model. Human hepatocytes constituted as much as 20% of the liver 11 mo after transplantation<sup>[182]</sup>.

**Experimental results:** Intraperitoneal administration resulted in a rapid liver engraftment using a model of hepatic damage induced by allyl alcohol in nonobese diabetic-severe combined immunodeficient (NOD/SCID) mice<sup>[178]</sup>. Hepatocyte-like cells, known as NeoHeps, which are derived from terminally differentiated peripheral blood monocytes, also seem to be very effective in treating experimental ALF in Wistar rats<sup>[183]</sup>.

**Clinical results:** In a clinical trial, 40 patients with HBV-related cirrhosis were randomized to receive G-CSF alone or in combination with the reinfusion of peripheral blood monocytes in the hepatic artery. Over a 6-mo follow-up, significant biochemical and clinical improvement was seen in both groups<sup>[184]</sup>. In a different setting, Gasbarini *et al*<sup>[176]</sup> transplanted peripheral blood stem cells into a single patient with ALF and showed improvement of liver function over 30 d, although the patient eventually succumbed to sepsis.

## CONCLUSION

Although several cell transplantation trials concerning different types of mature or progenitor/stem cells in rodents succeeded in improving liver failure, cell transplantation therapies for human liver disorders are still in the early stages of development. Animal models of small animals may not reproduce the clinical syndrome of LF adequately, and trials in large animal models are required. Also mechanisms concerning transplanted cell engraftment and proliferation in LF need further analysis. Most of these clinical trials have limitations, being performed on small groups of patients, with no controls and using outcome parameters that are easily biased. The current inability to track transplanted or infused cells in human subjects represents a major challenge in further developing and understanding stem cell therapies. Clinical trials should be planned, with the development of standardized protocols for standardized procedures to define the nature of cells, the patients enrolled, the transplantation procedure and pre-treatment of the liver, as well as standard data collection regarding efficacy, and possible side effects. The results of the experiments are promising; therefore, cell transplantation therapies should be the first choice in the treatment of acute or end-stage liver failure in the near future.

### Abstract

Restorative proctocolectomy is the most common surgical option for patients with familial adenomatous polyposis (FAP). However, adenomas may develop in the ileal pouch mucosa over time, and even carcinoma in the pouch has been reported. We therefore reviewed the prevalence, nature, and treatment of adenomas and carcinoma that develop after proctocolectomy in the ileal pouch mucosa in patients with FAP. In 25 reports that were reviewed, the incidence of adenomas in the ileal pouch varied from 6.7% to 73.9%. Several potential factors that favor the development of pouch polyps have been investigated, but many remain controversial. Nevertheless, it seems certain that the age of the pouch is important. The risk appears to be 7% to 16% after 5 years, 35% to 42% after 10 years, and 75% after 15 years. On the other hand, only 21 cases of ileal pouch carcinoma have been recorded in the literature to date. The diagnosis of pouch carcinoma was

made between 3 to 20 years (median, 10 years) after pouch construction. Although the risk of malignant transformation in ileal pouches is probably low, it is not negligible, and the long-term risk cannot presently be well quantified. Regular endoscopic surveillance, especially using chromoendoscopy, is recommended.

**Key words:** Familial adenomatous polyposis; Restorative proctocolectomy; Ileal pouch; Ileal pouch-anal anastomosis; Ileo-rectal anastomosis; Adenoma; Adenocarcinoma; Pouch polyp; Pouch neoplasm

**Core tip:** To eliminate the risk of colorectal cancer, the majority of patients with familial adenomatous polyposis (FAP) are treated with restorative proctocolectomy and an ileal pouch-anal anastomosis. However, as these patients are followed-up for longer intervals, it has gradually become recognized that adenomas and adenocarcinomas may develop in the ileal pouch. If the standard-of-care surgery for FAP patients does not eliminate all cancer risk, surgical and follow-up strategies may need to be altered. In this review, we summarize the data from the published English literature regarding the incidence of adenomas and carcinomas in the ileal pouch after proctocolectomy in FAP patients.

Risk of ileal pouch neoplasms in patients with familial adenomatous polyposis. *World J Gastroenterol* 2013; 19(40): 6774-6783 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6774.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6774>

### INTRODUCTION

Familial adenomatous polyposis (FAP) is an inherited, autosomal-dominant disease caused by a germline muta-

tion of the adenomatous polyposis coli gene (*APC*)<sup>[1]</sup>. The phenotype is characterized by the development of hundreds of colorectal adenomas, leading to a 100% lifetime risk of colorectal cancer<sup>[2]</sup>. For this reason, a prophylactic colectomy is recommended for patients with FAP to prevent the development of colorectal cancer. The main surgical strategy in patients with FAP is restorative proctocolectomy with ileal pouch-anal anastomosis (IPAA)<sup>[3-6]</sup>. As originally described by Parks *et al*<sup>[7]</sup>, IPAA included an anal mucosectomy to eliminate the risk of malignancy in the remaining anorectal mucosa. However, many surgeons now prefer to preserve the anal transition zone (ATZ) during the double-stapled IPAA technique because of its simplicity and better functional outcome<sup>[8-10]</sup>. The trade-off is a risk of neoplasia developing in the retained ATZ mucosa<sup>[8]</sup>, with a 10%-15% incidence of adenoma<sup>[8,11-13]</sup>. Another widely accepted surgical procedure is colectomy with ileorectal anastomosis (IRA), performed when there are few polyps in the rectum. The major advantage of IRA is preservation of the rectal innervation, with subsequent better quality of life. However, continuing endoscopic surveillance for adenomas in the rectum is necessary, and there is a 13%-25% cumulative risk of rectal cancer after 15-25 years despite surveillance<sup>[14-16]</sup>. On the other hand, it has been thought that IPAA theoretically eliminates the risk of colorectal cancer and adenomas, and perhaps the need for further lower gastrointestinal surveillance. However, there are recent reports of adenomas or carcinomas developing not only in the residual rectal mucosa or anastomosis after IRA, but also in the ileal pouch mucosa after IPAA<sup>[17-39]</sup>. In addition, there are several reports of cancers arising from the ileal pouch mucosa, as opposed to the anastomotic site, in patients with FAP<sup>[31,36,37,40-47]</sup>.

The aim of this review is to describe the prevalence, nature, and treatment of adenomas and carcinoma developing in the ileal pouch mucosa after proctocolectomy in patients with FAP.

## INCIDENCE OF ILEAL POUCH ADENOMAS

The basic premise underlying the popularity of IPAA in patients with FAP is that it results in a significantly lower risk of rectal cancer than IRA. Although this is likely to be true, the risk of pouch polyposis and pouch cancer has not been recognized so far. After the advent of pouch surgery, several reports of adenomatous polyps in the pouches of FAP patients have appeared in the literature. In 1982, Beart *et al*<sup>[17]</sup> first described a FAP patient with continent ileostomy, in whom a large sessile tubulovillous adenoma and multiple smaller adenomatous polyps developed. Since then, there have been at least 25 reports of ileal pouch adenomas developing in these patients (Table 1). We reviewed only those studies that clearly described adenomas appearing within the ileal pouch mucosa. These included 8 case reports, 7 retrospective studies, and 10 prospective studies. The incidence of adenomas in the ileal pouch varied from 6.7%

to 73.9%. This variation in the prevalence of ileal pouch adenomatosis could be due to differences in the way endoscopy was performed in the various studies. Adequacy of bowel preparation, type of instrument employed, use of chromoendoscopy, and other miscellaneous factors influence the detection rates of pouch polyps. Good bowel preparation and a flexible video colonoscope are essential in identifying pouch polyps because most ileal adenomas are flat or sessile, measuring only 1 mm to 3 mm in diameter, and having a morphology different from large bowel adenomas<sup>[36]</sup>. Therefore, a careful examination of the entire pouch, anal canal, and pouch-anal anastomosis should be performed. Although Polese *et al*<sup>[25]</sup> reported the prevalence of ileal pouch adenomas as 6.7%, these investigators used a rigid sigmoidoscope with enema preparation, without chromoendoscopy. These technical factors may explain the low prevalence of ileal pouch adenomas in the study by Polese *et al*.

The only meaningful estimates of adenoma incidence have come from prospective studies, with all 10 prospective studies showing that the incidence of pouch adenomas increases with the follow-up duration<sup>[4,21,22,24,28,29,31,32,35,36]</sup>. The risk appears to be 7% to 16% after 5 years, 35% to 42% after 10 years, and 75% after 15 years. The great majority of pouch polyps described in the literature are small, tubular adenomas with mild atypia. The incidence of adenoma with advanced pathology (size > 1 cm, villous pattern, or moderate-to-severe dysplasia) is less. According to Banasiewicz *et al*<sup>[35]</sup>, the estimated frequency of low-grade dysplasia 4 years after IPAA surgery is 4%, and increases to 50% after 15 years. The same percentage of patients, but with high-grade dysplasia, develop high-grade dysplasia 2.5 years later, that is to say, 17.5 years after IPAA, and with neoplasia 18.5 years after the above procedure. The full impact of pouch polyposis will not be fully understood until most pouch patients reach a follow-up duration of 20 to 40 years<sup>[48]</sup>.

## RISK FACTORS FOR DEVELOPMENT OF ADENOMAS IN THE ILEAL POUCH

### Phenotype

At present it does not seem possible to predict who is at risk for developing polyps in the pouch. Some studies show that there is no apparent high-risk phenotype for the development of ileal polyps<sup>[22,24,30,33]</sup>. However, other studies describe risk factors that favor the development of pouch polyposis. Parc *et al*<sup>[49]</sup> observed that patients with pouch polyps are younger, and have a longer follow-up period since IPAA, than patients without pouch polyps. A more aggressive disease requiring earlier surgery could explain these features. However, Groves *et al*<sup>[28]</sup> analyzed the risk factors by using logistic regression, and found that age was a more significant predictor of pouch adenomas than the follow-up period, sex, or type of primary or secondary procedures. Groves *et al*<sup>[28]</sup> reported that, in their experience, all patients older than 60 years

**Table 1 Summary of 25 reports of ileal pouch adenomas in familial adenomatous polyposis**

Ref.	Study	Year	Operation	n	Type of pouch	Findings	% of adenoma	Time to neoplasia
Beart <i>et al</i> <sup>[17]</sup>	Case	1982	Kock	1	Kock pouch	Tubulovillous Adenomas		6 yr

will develop polyps in the pouch. Tonelli *et al*<sup>[36]</sup> reported that an age of more than 50 years was associated with pouch adenomas, but not sex or elapsed time since restorative proctocolectomy.

Several studies found that the severity of duodenal polyposis was related to the presence of pouch adenomatous polyps. In a multivariate analysis of 118 FAP patients who had undergone surgery, Pommaret *et al*<sup>[39]</sup> discovered that the presence of advanced duodenal adenomas was an independent risk factor for the development of pouch adenomas, in addition to follow-up duration. Tonelli *et al*<sup>[36]</sup> found that patients affected by pouch adenomas had high polyp counts (> 1000) at colectomy, as well as duodenal adenomas.

Several potential factors that favor the development of pouch polyposis have been investigated; a number of them remain controversial, although it seems certain that

the age of the pouch is important.

### Pathogenesis

The mucosa of the ileal pouch may be subjected to not only the tumorigenic consequences of APC gene mutations<sup>[50]</sup>, but also to luminal factors due to fecal stasis, which may also exert an important effect. Fecal stasis, such as occurs in a reconstructed pouch, may promote neoplastic changes in the ileal mucosa. Several authors have implicated colonic metaplasia of the ileal mucosa as a precursor for the development of ileal adenomas<sup>[19,51,52]</sup>, and even carcinomas in the surgically constructed pouches of patients with FAP<sup>[53-55]</sup>. Colonic metaplasia was frequently recognized even in earlier descriptions of the changes observed in the ileal pouch mucosa. Some authors have considered colonic metaplasia as an adaptive response of the ileal pouch to its role as a neo-

rectum<sup>[18,19,56,57]</sup>. Further investigations have shown that colonic transformation is only partial. Small-bowel brush border disaccharidase activity is preserved, as is the ability to absorb vitamin B12, D-xylose, phenylalanine, and bile acids<sup>[52,58-60]</sup>. The mucosal changes described as colonic metaplasia are likely a response to chronic inflammation caused by changes in the luminal contents due to stasis. In FAP, these changes may, at least in theory, favor the development of adenomas in a region of the gut where they are not usually observed. There is an increase in the concentration of luminal short chain fatty acids to levels that are seen in the colon<sup>[61]</sup>, an increase in anaerobic bacterial counts with a more colonic type flora<sup>[62,63]</sup>, and increased deconjugation and dehydroxylation of bile acids by the anaerobic bacteria<sup>[64]</sup>. In particular, deoxycholic acid and lithocholic acid, which are known carcinogens, have concentrations several times higher in an ileal pouch than in an end ileostomy<sup>[65]</sup>. On the other hand, reduction of glutathione S-transferase (GST) detoxification activity in the pouch compared with the afferent ileal loop after IPAA may promote tumorigenesis<sup>[64]</sup>.

### APC gene mutations

FAP develops due to a dominant autosomal mutation of the *APC* gene in more than 80% of patients<sup>[65]</sup>. Recently, it has been discovered that a biallelic mutation of the *MUTYH* gene might exist in 5% of patients with colorectal polyposis and 20% of FAP patients, with no *APC* mutation found<sup>[66]</sup>. Many researchers have investigated *APC* gene mutations in pouch patients with FAP, although none has demonstrated obvious genotype-phenotype correlations that would predict the development of pouch adenomas<sup>[28,30,36,49]</sup>. Hence, the available evidence suggests that systematic surveillance of all patients who undergo IPAA is necessary. Targeted surveillance of a defined subgroup of patients is currently not feasible.

### Type of pouch and anastomosis

There are different pouch configurations. Parks *et al.*<sup>[7]</sup> originally devised a triple-limb S-shaped pouch. This pouch was relatively complicated to construct, and suffered from kinking of the efferent limb if it was left too long<sup>[67]</sup>. Alternative designs have included the high-capacity W-pouch, the H-pouch and the J-pouch. The majority of surgeons now favor the J-pouch due to ease of construction, economical use of the terminal ileum, and reliable emptying<sup>[68]</sup>. Functional results are equal to those of other reservoir designs<sup>[69-71]</sup>. The pouch is formed from the terminal 40 cm of ileum, using several applications of a linear-cutting stapler to join the anti-mesenteric borders of two 20-cm ileal limbs.

Several authors have shown that there is no apparent relationship between the development of pouch polyps and the type of ileal pouch construction<sup>[36]</sup> or the suture used (hand-sewn or stapled)<sup>[25,28,36]</sup>. However, other authors have reported that patients with a stapled IPAA are at a significantly increased risk of developing adenomas at the anastomotic site: 1.5% to 20.9% *vs*

27% to 66% for hand-sewn and stapled anastomoses, respectively<sup>[9,11,22,36,72,73]</sup>. These data suggest that a hand-sewn IPAA may be a preferable strategy for decreasing the occurrence of adenomas at the anastomotic ileo-anal site. Recently, Wasmuth *et al.*<sup>[38]</sup> evaluated the differences between adenoma formation at the anastomotic site and in the ileal pouch after IPAA, with or without mucosectomy. These investigators found that an occurrence of adenomas at the anastomotic site was significantly reduced after mucosectomy. However, there was no difference in the occurrence of ileal pouch adenomas between patients who underwent mucosectomy and those who retained a rectal mucosal remnant (8/39 *vs* 6/22;  $P = 0.57$ )<sup>[38]</sup>.

### Pouchitis

In patients with ulcerative colitis, concern about the risk of neoplasia in ileal pouches was raised after observing a combination of histologic changes in the ileal mucosa of the pouch, including villous atrophy, inflammation and metaplasia<sup>[74-76]</sup>. These transformations in the ileal pouches are likely caused by the chronic inflammatory state. The inflammatory process in pouchitis may lead to dysplasia<sup>[47]</sup> and loss of heterozygosity, consistent with precancerous lesions of the colon<sup>[77]</sup>. Thus, a dysplasia-to-neoplasia progression can occur in ileal pouches and can lead to cancer of the pouch. The cumulative risk of pouchitis is up to 50% in patients with ulcerative colitis<sup>[78-81]</sup>, with most patients experiencing at least one episode of pouchitis during the first ten years after surgical pouch construction. In contrast, the pouchitis rate is below 25% in patients with FAP<sup>[4-6,29,33,35]</sup>. Banasiewicz *et al.*<sup>[35]</sup> analyzed the frequency and progression of dysplasia and inflammation in the intestinal pouch of FAP patients after restorative proctocolectomy. Although these authors diagnosed pouchitis in 20.6% of patients after restorative proctocolectomy, no relationship was found between pouchitis and pouch dysplasia in FAP patients.

---

## THE PREVALENCE OF ADENOMAS IN THE PRE-POUCH ILEUM

---

Although it is currently recognized that adenomas may develop in the ileal pouch, the risk of adenomas occurring in the afferent ileal loop above the pouch is unclear. The incidence of adenomas above the IPAA pouch was rarely recognized previously, and it seemed to be low, with reported figures ranging from 4% to 16%<sup>[22,28,33,82]</sup>. The majority of pre-pouch ileal adenomas have measured 4 mm or smaller. Pommaret *et al.*<sup>[39]</sup> reported that only nine (6.5%) of 118 patients had afferent ileal loop adenomas after an IPAA. The only independent predictive factor for the occurrence of afferent ileal loop adenoma was found to be the presence of pouch adenomas (OR: 2.16; 95%CI: 0.17-26.98;  $P = 0.007$ ). Pommaret *et al.*<sup>[39]</sup> concluded that because afferent ileum loop adenomas are rare and have an unclear pathologic significance, there is no justification for their systematic search, particularly among patients without any duodenal or pouch adeno-

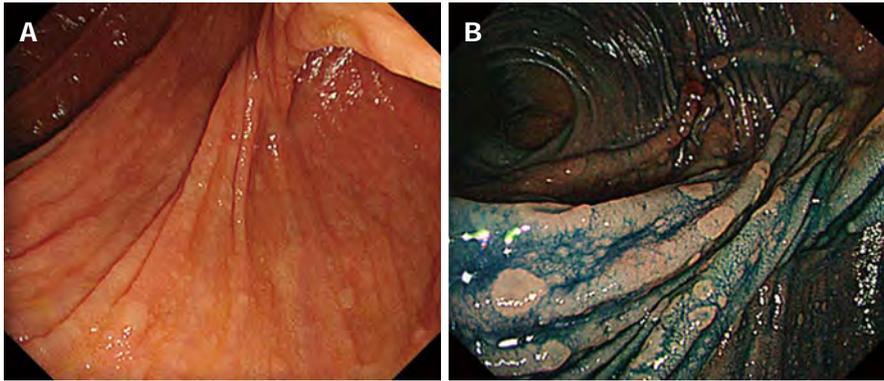

Figure 1 Endoscopic view of ileal pouch adenomas in patients with familial adenomatous polyposis. A: Multiple white flat lesions are observed in the ileal pouch mucosa; B: Multiple sessile polyps are revealed by indigo carmine. The data available from reference [33].

mas. In cases of extensive pouch polyposis with a significant cancer risk, this viewpoint could allow clinicians to consider resection of the adenomatous pouch, with construction of a new one using the afferent ileum.

## SURVEILLANCE OF THE ILEAL POUCH

Saurin *et al.*<sup>[83]</sup> described methods of surveillance and therapeutic indications in FAP patients following colectomy. Although there are no validated data in the literature, on the basis of expert opinion, endoscopic surveillance is performed at 6 mo, 1 year, and then every 2 years after surgery. In the presence of polyps with high-grade dysplasia, and/or polyps > 1 cm size, and/or presence of large polyp number (> 30), surveillance should be repeated every 6 mo<sup>[83]</sup>. Many authors have performed pouch endoscopy every 6-12 mo after surgery<sup>[30,33,35,36,38,84]</sup>. Optimum bowel preparation and the use of indigo carmine surface staining are necessary<sup>[31-33,35]</sup>. The main utility of chromoendoscopy is to highlight the small lymphoid lesions that are characteristic of the terminal ileum in FAP patients, and to distinguish flat polyps (Figure 1). In the experience of the Dutch Registry<sup>[31]</sup>, indigo carmine chromoendoscopy significantly increases the detection rates of adenomas < 5 mm in size. Investigators with the Dutch Registry found that 75.7% of FAP patients harbored adenomas in the pouch at a median follow-up duration of 8 years after IPAA<sup>[31]</sup>. Because some patients have a stricture at the anal anastomosis, a pediatric colonoscope or gastroscopie may sometimes be required<sup>[35]</sup>.

## TREATMENT OF ADENOMAS IN THE ILEAL POUCH

According to Saurin *et al.*<sup>[83]</sup>, no systematic endoscopic treatment of adenomas of the ileal pouch or afferent loop can be recommended. For large adenomas (> 1 cm), or in patients with high-grade dysplasia, endoscopic resection must be considered; however, a skilled team is needed because of the thin ileal mucosa<sup>[83]</sup>. Our current strategy in patients with IPAA is regular follow-up starting at 1 year after surgery, and then every year

thereafter<sup>[33]</sup>. If adenomas are observed in the pouch, we recommend endoscopic resection or argon plasma coagulation where feasible, and then follow-up every 6 mo. Other reports<sup>[30,35,36,84]</sup> also describe polypectomy of large polyps, and ablation by fulguration or electrocoagulation for small lesions. In patients having extensive pouch polyposis with no possibility of endoscopic treatment, together with invasive cancer, pouch excision and terminal ileostomy has to be considered<sup>[40,83]</sup>.

Although there have been some reports suggesting the efficacy of nonsteroidal anti-inflammatory drugs (NSAIDs) in suppressing the development of ileal pouch adenomas<sup>[32,48,85]</sup>, this has not been systematically studied<sup>[34]</sup>.

## THE PREVALENCE OF ADENOCARCINOMAS IN THE ILEAL POUCH

The progression from a dysplastic lesion in the ileal pouch to invasive carcinoma appears to be rare, occurring in no more than 1% of patients with ileal pouches<sup>[31]</sup>. However, in the past few years, several cases of carcinoma have been observed after IPAA, although the majority of them occurred at the level of the anal canal<sup>[8,9,13,27,38,86-91]</sup>. Patients with either hand-sewn or stapled IPAA are at risk for developing a carcinoma in any residual rectal mucosa that harbors dysplasia or is prone to dysplasia. To date, only 21 cases of ileal pouch carcinoma have been recorded in the literature (Table 2). No relationship has been found between the occurrence of pouch carcinoma and the shape (J or S) of the pouch, or the type (hand-sewn or stapled) of IPAA<sup>[36]</sup>. These pouch cancers have clearly appeared in the ileal pouch, and not in the ATZ. The time elapsed between pouch construction and diagnosis of pouch carcinoma has been between 3 and 20 years (median, 10 years).

It is noteworthy that in at least seven patients, the development of advanced cancer was detected within a very short interval-within 1 year since last pouch endoscopy<sup>[25,36]</sup>. Furthermore, in four of the patients, ileal polyps

were not found during endoscopic follow-up until the development of pouch carcinoma. It seems that neoplasia that appears in the ileal pouch may not always follow the classic adenoma-carcinoma sequence. We strongly recommend a strict surveillance program for FAP patients, including annual flexible colonoscopy, irrespective of the phenotype and genotype.

## IRA VS IPAA

In a review of 12 studies containing 1002 patients with FAP (53.4% IPAA, 46.6% IRA), Aziz *et al*<sup>[92]</sup> showed that bowel frequency, nocturnal defecation, and incontinence rates were significantly less in IRA patients, although fecal urgency was less among IPAA patients. There was no significant difference between IPAA and IRA in terms of sexual dysfunction, dietary restrictions, or postoperative complications. In their review, Aziz *et al*<sup>[92]</sup> could not identify any malignancies in IPAA patients, and rectal cancer was a diagnosis only in the IRA patients (5.5%). At the present time, IPAA anastomosis is recommended by a majority of surgical teams as the preferred option for FAP patients<sup>[4-6,10,92,93]</sup>. Although cancer formation after IPAA in patients with FAP may be rare, it is of concern that several of the recently reported patients had an ad-

vanced stage at diagnosis, with poor outcome.

Recent reports of a high frequency of adenomas after IPAA, together with favorable functional outcomes in patients who underwent IRA, may lead to reconsideration of the latter surgical option for some FAP patients, especially when quality of life and fertility criteria are taken into account<sup>[30]</sup>. In clinical practice, the results of preoperative evaluation of the rectal stump using indigo carmine chromoendoscopy are a major deciding factor. A limited number (< 10-20) of rectal polyps without any cancer would lead to preservation of the rectal stump in a majority of patients<sup>[94,95]</sup>. However, with the availability of better endoscopic instruments and resection techniques, and the possibility of enhanced post-operative surveillance, > 20 rectal polyps and/or non-invasive cancers can now also be managed endoscopically. So, there is a possibility that the criteria for IRA will expand in the near future. Of course, based on clinical and genetic data, a stepwise surgical strategy with a primary IRA followed at a later age by a secondary proctectomy and IPAA could be proposed<sup>[5]</sup>.

An ongoing multicenter study in Japan is being conducted by Ishikawa *et al*<sup>[96]</sup> under the title "Intervention trial for colorectal cancer prevention by endoscopic polypectomy in patients with familial adenomatous pol-

yposis" (UMIN000009365). The aim of this study is to evaluate the usefulness and safety of thorough endoscopic polypectomy in FAP patients who have (or had)  $\geq 100$  colonic adenomas and who refuse surgery, as well as post-operative patients who have (or had)  $\geq 100$  colonic adenomas and who have  $\geq 10$  cm of remnant colon.

## CONCLUSION

The development of adenomas with high-grade dysplasia and carcinoma in the ileal pouch is an important issue because the choice between IPAA and IRA is based mainly on the expected low risk of cancer development after the former surgery. Although the risk of malignant transformation in ileal pouches is probably low, it is not negligible, and the long-term risk cannot presently be well quantified. IPAA will not prevent cancer development in the terminal remnant intestine, and patients who undergo IPAA require regular follow-up similar to patients who receive IRA. A detailed analysis of the phenotypes and mutations in the *APC* gene of patients with FAP may allow tailoring of the surgical options in the future.

### Abstract

Like other solid tumors, colorectal cancer (CRC) is a genomic disorder in which various types of genomic alterations, such as point mutations, genomic rearrangements, gene fusions, or chromosomal copy number alterations, can contribute to the initiation and progression of the disease. The advent of a new DNA sequencing technology known as next-generation sequencing (NGS) has revolutionized the speed and throughput of cataloguing such cancer-related genomic alterations. Now the challenge is how to exploit this advanced technology to better understand the underlying molecular mechanism of colorectal carcinogenesis and to identify clinically relevant genetic biomarkers for diagnosis and personalized therapeutics. In this review, we will introduce NGS-based cancer genomics studies focusing on those of CRC, including a recent large-scale

report from the Cancer Genome Atlas. We will mainly discuss how NGS-based exome-, whole genome- and methylome-sequencing have extended our understanding of colorectal carcinogenesis. We will also introduce the unique genomic features of CRC discovered by NGS technologies, such as the relationship with bacterial pathogens and the massive genomic rearrangements of chromothripsis. Finally, we will discuss the necessary steps prior to development of a clinical application of NGS-related findings for the advanced management of patients with CRC.

### INTRODUCTION

Colorectal cancers (CRC) are the third most common human malignancy, and are also the leading cause of cancer-related deaths worldwide<sup>[1]</sup>. Early detection of premalignant

**Table 1** The next-generation sequencing platforms for cancer genome analysis

NGS types	Whole genome sequencing	Exome sequencing	Epigenome sequencing <sup>1</sup>	RNA-seq
Source	Genomic DNA	Genomic DNA (targeted)	Genomic DNA (targeted)	RNA
Alteration types	Point mutations and indels, rearrangements <sup>2</sup> , DNA copy number changes	Point mutations and indels	DNA methylation and posttranscriptional histone modifications	Gene fusions <sup>3</sup> , alternative splicing events, point mutations and indels

<sup>1</sup>Epigenome sequencing can be classified into chromatin immunoprecipitation (ChIP)-based methods to detect genomic domains with epigenetic modifications<sup>[80]</sup> and more direct DNA methylation sequencing such as bisulfite-sequencing<sup>[59,60]</sup>. <sup>2</sup>From whole genome sequencing data, the genomic rearrangements and DNA copy number changes are generally detected by paired-end mapping<sup>[81]</sup> and read-depth based methods<sup>[82]</sup>, respectively; <sup>3</sup>Gene fusions can also be identified by paired-end, high-coverage whole genome sequencing, but the transcription-related events such as exon skipping or other alternative splicing events can only be identified by RNA-seq. NGS: Next-generation sequencing.

nant lesions such as adenomatous polyps has decreased the risk of CRCs<sup>[2]</sup>, however, cases which are initially undetected and progress to advanced CRC with distant metastasis are still unfortunately incurable<sup>[3]</sup>. The development of CRC is a complex and heterogeneous process arising from an interaction between multiple etiological factors, including genetic factors<sup>[4]</sup> and environmental factors such as diet and lifestyle<sup>[5]</sup>. Recently, significant progress has been made in the characterization of genetic and epigenetic alterations in CRC genomes in support of the genomic view of colorectal carcinogenesis. Like other types of human solid tumors, CRC genomes harbor various types of genomic alterations ranging from small-scale changes (*i.e.*, point mutations or small indels) to large-scale chromosomal copy number changes or rearrangements. Some of these alterations may contribute to colorectal carcinogenesis as oncogenic drivers, but the full spectrum of driver genomic alterations in CRC genomes is still incomplete.

For decades, the genome-wide profiling of cancer genomes has been mainly conducted using hybridization-based microarray technologies (*i.e.*, expression microarrays and array-based comparative genomic hybridization)<sup>[6,7]</sup> or low-throughput Sanger sequencing<sup>[8]</sup>. Recently,

the advancement of DNA sequencing technologies - next-generation sequencing (NGS) - has revolutionized the speed and throughput of DNA sequencing<sup>[9,10]</sup>. Table 1 lists the NGS platforms widely used in the characterization of cancer genomes. Since the first attempt at cancer genome sequencing using NGS technology<sup>[11]</sup>, successful sequencing by NGS has been accomplished in many major human cancer types<sup>[12,13]</sup> including gastrointestinal malignancies such as esophageal<sup>[14]</sup>, gastric<sup>[15]</sup>, colorectal<sup>[16]</sup>, and hepatocellular carcinomas<sup>[17,18]</sup>. The NGS-based studies of CRC genomes are summarized in Table 2. These studies identified the unique mutational spectrum and novel targets of genomic alterations in respective cancer types with biological and clinical significance.

## SOMATIC MUTATIONS IN CRC GENOMES

Like other solid tumors, CRC is thought to initiate and progress through a series of genetic and epigenetic alterations. The progression model of colorectal carcinogenesis (*i.e.*, from adenomatous polyp to benign adenoma, eventually progressing to invasive adenocarcinoma) has been referred to as a classical cancer evolution model in

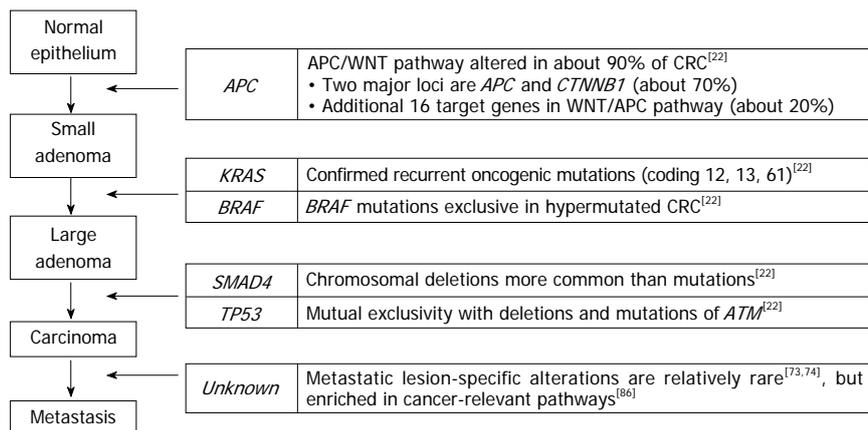

Figure 1 A classical progression model of colorectal carcinogenesis. A classical progression model of colorectal carcinogenesis is illustrated with genes whose alterations are responsible for each of the progressive steps. The right panel shows recent next-generation sequencing-based reports of the corresponding genes. CRC: Colorectal cancer; ATM: Ataxia telangiectasia mutated.

which the CRC genome acquires somatic alterations in a progressive manner throughout several developmental stages. In this model, dysregulation of the APC/WNT pathway *via* the inactivation of *APC* occurs in the normal epithelium as an initiation process, while the loss of *TP53* and *TGF-β/SMAD4* gives rise to clonal expansion of tumor cells in the invasive adenocarcinoma (Figure 1)<sup>[4,19]</sup>. However, the genomic alterations associated with colorectal carcinogenesis may be more complicated than previously assumed. A complete and comprehensive catalogue of oncogenic drivers associated with colorectal carcinogenesis remains to be discovered.

To extend the mutational spectrum in CRC genomes, the first exome-wide screening of approximately 13000 genes was conducted by Sanger sequencing<sup>[20]</sup>. This analysis identified approximately 800 somatic non-silent mutations in 11 CRC genomes. To distinguish oncogenic drivers from neutral passenger mutations, they identified the mutations whose frequency was significantly higher than random. The analysis revealed 69 potential oncogenic driver mutations in CRC genomes, including several well-known cancer-related genes (*i.e.*, *TP53*, *APC*, *KRAS*, *SMAD4*, and *FBXW7*), and a large number of previously uncharacterized genes. Since they examined two distinct tumor types (CRC and breast cancers), they were able to identify the differences in the panel of candidate driver genes as well as

identify the differences in the mutation spectrum between CRC and breast cancer genomes. The difference in the mutation spectrum (*i.e.*, the predominance of C:G to T: A transitions over C:G to G:C transversions in CRC genomes) was confirmed by a subsequent kinase sequencing study across various cancer types<sup>[21]</sup> and by a recent whole-genome sequencing of nine CRC genomes<sup>[16]</sup>.

## NGS-BASED CRC STUDIES - LESSONS FROM THE CANCER GENOME ATLAS CRC STUDY

The advance in sequencing technologies has facilitated the use of genome sequencing for cancer genome studies, including CRC genomes. The largest NGS-based exome sequencing study of CRC genomes to date (approximately 200 CRC genomes) has recently been published as part of the Cancer Genome Atlas (TCGA) projects<sup>[22]</sup>. The platforms used in the multidimensional genomic characterization of CRC genomes were compared with those used for glioblastoma multiforme in 2008 (Table 3)<sup>[23]</sup>. Two important lessons from this large-scale multidimensional TCGA CRC analysis are as follows:

First, similar to previous findings<sup>[20]</sup>, most of the significantly recurrent mutations were observed at

known cancer-related genes, such as *APC*, *TP53*, *KRAS*, *PIK3CA*, *FBXW7*, *SMAD4*, and *NRAS*. The study also revealed frequent coding microsatellite instability (MSI) on *ACVR2A*, *TGFBR2*, *MSH3*, and *MSH6* by manual examination of sequencing reads for 30 known MSI loci. Although the majority of recurrent mutations were previously known, a number of novel mutations were also identified, which may have functional implications on colorectal tumorigenesis. For example, the mutations in *SOX9*<sup>[24]</sup>, *EAM123B*<sup>[25]</sup>, and 14 other genes are known to be implicated in the altered WNT/APC pathway. Although the biallelic inactivation of *APC* and the activating mutation of *CTNNB1* encoding  $\beta$ -catenin are two major events that occurred in about 74% of the total CRC genomes studied, the mutations and deletions of an additional 16 (about 18%) genes in the WNT/APC pathway were not negligible, leading to the conclusion that nearly all CRC genomes (about 92%) have an alteration in the WNT/APC pathway<sup>[22]</sup>.

A study which assigned potential molecular functions to rare mutations in CRC genomes using the pathway-level convergence was previously reported<sup>[26]</sup>. Thus, pathway- or network-level information from available resources (*i.e.*, Gene Ontology<sup>[27]</sup>) and other methodologies to predict the functional impacts of non-synonymous point mutations<sup>[28,29]</sup> may help determine the potential functions of rare mutations and distinguish oncogenic drivers in studies with small-sized cohorts. This issue is also related to the sample-size problem in study design. Due to the limits on sample availability and research budget, many of the cancer mutation studies use a small discovery cohort for the generation of candidate mutations that are subsequently validated in an extended set. Increasing the number of samples in the initial discovery set would be beneficial in identifying events that are not highly recurrent but are still clinically meaningful (*i.e.*, gene fusions involving receptor tyrosine kinases with available inhibitors). For example, the frequency of gene fusions such as *ALK*<sup>[30]</sup> and *RET*<sup>[31]</sup> in lung adenocarcinomas and *FGFR*<sup>[32]</sup> in glioblastoma multiforme are less than 5%. Although the level of recurrence is still the generally accepted functional indicator of genomic alterations<sup>[33,34]</sup>, the incorporation of knowledge from other resources may facilitate the identification of biological or clinically relevant mutations more efficiently in a moderate-sized cohort.

Second, the concordant and discordant relationships between alterations examined across the samples may reveal valuable functional insights. The concordant relationship adopts the concepts of co-expressed networks in which the genes with significantly correlated expression levels (measured by Pearson's correlation coefficients or mutual information) across diverse cellular conditions may have a functional relationship<sup>[35-37]</sup>. Importantly, TCGA-related studies revealed that the exclusivity between the potential oncogenic drivers may be common. For example, TCGA ovarian cancer study showed that the alterations of *BRCA1* and *BRCA2* (including germline or somatic mutations and epigenetic silencing *via* promoter

hypermethylation) are mutually exclusive to each other<sup>[38]</sup>. The method to identify the pairs of exclusive genomic alterations is formulated as a standard analysis pipeline in TCGA projects as Mutual Exclusivity Modules (MEMo) in cancer<sup>[39]</sup>. In CRC genomes, MEMo analysis revealed that nearly half of the TCGA CRC genomes showed an exclusive relationship between the up-regulation of *IGF2* and *IRS2*, and between the mutation of PIK3 pathway genes (*PIK3CA* and *PIK3R1*) and the homozygous deletion of *PTEN*<sup>[22]</sup>. This suggests that the IGF2-IRS2 axis is a major signaling pathway upstream of the PI3K pathway in CRC genomes<sup>[22]</sup>. The mutual exclusivity between the mutations of *TP53* and *ATM* was also identified in the TCGA CRC genomes<sup>[22]</sup>.

## GENOMIC REARRANGEMENTS AND GENE FUSIONS IN CRC GENOMES

Bass *et al.*<sup>[16]</sup> reported whole-genome sequencing (sequencing coverage about 30-fold) of nine CRC genomes. By comparing them with matched normal genomes, they identified approximately 140000 putative somatic mutations per CRC genome, which included approximately 700 non-silent point mutations and indels in coding sequences. One advantage of whole-genome sequencing is that the genome-wide landscape of the mutation spectrum in CRC genomes can be obtained, such as the relative paucity of mutations in exons and higher mutation frequency in intergenic regions than introns. This phenomenon is probably due to the selection pressure and transcription-coupled repair, and is consistent with other types of cancer genomes such as prostate cancers<sup>[40]</sup> and multiple myelomas<sup>[41]</sup>. Since most of the non-synonymous nucleotide substitutions were observed at known cancer genes such as *KRAS*, *APC*, and *TP53*, they focused on novel aspects that can only be identified from paired-end whole-genome sequencing data such as chromosomal rearrangements. Among the approximately 700 candidate rearrangements, 11 events give rise to in-frame fusion genes. The extended screening further revealed that *VTI1A-TCF7L2* fusion is recurrent (3 out of 97 primary CRC genomes) and the siRNA-mediated down-regulation of this fusion transcript reduced the anchorage-independent cell growth *in vitro*, indicative of their potential oncogenic activity.

The low-pass (sequencing coverage approximately 3-4-fold) whole-genome sequencing of 97 TCGA CRC genomes also identified three genomes harboring *NAV2-TCF7L1* fusion<sup>[22]</sup>. The predicted protein structures of fusion proteins lacked the  $\beta$ -catenin binding domain of TCF3 (encoded by *TCF7L1*), which is similar to the fusion of *VTI1A-TCF7L2* that lacks the  $\beta$ -catenin binding domain of TCF4 (encoded by *TCF7L2*). In addition, the inactivation of *TTC28* by genomic rearrangements is of note since this event is recurrent (21 out of 97 cases) and involves multiple partners for rearrangements in TCGA CRC genomes<sup>[22]</sup>. Gene fusions can also be identified from transcriptome sequencing, so called RNA-

seq<sup>[42,43]</sup>. A recent RNA-seq-based study revealed recurrent gene fusions involving R-spondin family members of *RSPO2* and *RSPO3*<sup>[44]</sup>. These fusions were exclusive to *APC* mutations in the observed CRC genomes, suggesting their potential roles in activating the APC/WNT pathway in colorectal carcinogenesis. Cancer-related gene fusion events are gaining attention since there has been no effective gene fusion screening method other than NGS-based paired-end sequencing. More importantly, many of the fusion candidates discovered so far represent oncogenic drivers and clinically actionable events (*i.e.*, the fusion activates potential oncogenes such as tyrosine kinases that can be inhibited by small molecule inhibitors) as shown in recent studies<sup>[30-32]</sup> including the *C2orf44-ALK* fusion in CRC<sup>[45]</sup>.

In addition, it was proposed that the genomic rearrangements in individual cancer genomes can be used as personal cancer markers to trace the disease activity (*i.e.*, to detect recurrences or to evaluate the tumor burden of residual diseases)<sup>[46]</sup>. The proposed method, personalized analysis of rearranged ends, was applied to four cancer genomes, including two CRCs in a pilot test. It was demonstrated that the PCR-based quantification of the rearranged DNA in the plasma correlated well with the treatment course of CRC<sup>[46]</sup>.

## MICROSATELLITE INSTABILITY IN CRC GENOMES

Microsatellites are short tandem repeat sequences present at millions of sites in the human genome<sup>[47]</sup>. MSI defined as the length polymorphism of microsatellite repeat sequences, can arise due to a defect in the DNA mismatch repair system<sup>[48]</sup>. MSI is common in hereditary nonpolyposis colon cancers, also known as Lynch syndrome, where germline mutations of *MLH1* and *MSH2* are commonly observed<sup>[49,50]</sup>. About 15% of sporadic CRC are microsatellite-unstable, where transcriptional silencing of *MLH1* by promoter hypermethylation is common<sup>[51,52]</sup>. The microsatellite-unstable sporadic CRC has distinct clinical and genomic features (*i.e.*, common in right-sided colons and elderly females, and nearly diploid, *etc.*) compared to microsatellite-stable, but aneuploid CRC genomes. The key genes targeted by somatic point mutations and MSI-induced frameshifting mutations are different between the microsatellite-stable and -unstable CRC genomes, as shown in the TCGA CRC study<sup>[22]</sup>. Since the MSI analysis in the TCGA CRC study was limited to a manual search of exome sequencing reads for about 30 known loci with frequent MSI (*i.e.*, *TGFBR2*, *ACVR2A*, *BAX*, *etc.*), a question remains as to whether we can fully exploit the NGS technology to screen the locus-level MSI in an exome- or genome-wide scale. One interesting report by Wang *et al.*<sup>[53]</sup> showed that pancreatic cell lines with a homozygous deletion of *MLH1* (which is a frequent target of promoter hypermethylation in MSI CRC genomes) frequently harbors truncating indels in *TP53* and *TGFBR2*. This suggests that whole genome- or

exome-sequencing data may be used for large-scale MSI screening to identify novel MSI events targeting tumor suppressor genes in cancer genomes.

## NGS AND CRC EPIGENETICS

For decades, DNA methylation has been studied as one of the major cancer-related epigenetic modifications. Until recently, it was recognized that cancer genomes are undermethylated overall, but some genomic loci have focal DNA hypermethylation<sup>[54,55]</sup>. Transcriptional silencing by focal hypermethylation, especially at the CpG islands of gene promoters, is among the putative inactivating mechanisms of tumor suppressor genes in cancer genomes and often preferred over the inactivation by irreversible nucleotide substitutions<sup>[56]</sup>. Yet, the landscape of cancer-associated DNA methylation seems more dynamic than previously anticipated, as revealed by genome-wide CRC methylome studies<sup>[57,58]</sup>. Two recent CRC methylome studies used NGS-based sequencing of bisulfite-treated genomic DNA for bp-resolution methylome profiling<sup>[59,60]</sup>. Both studies proposed the presence of large blocks of DNA hypomethylation that occupied almost half of the genomes. Additionally, they reported that such findings as the genome-wide methylation variability of the adenoma genome is an intermediate between those of normal epithelium and CRC<sup>[60]</sup> and the domains of DNA hypomethylation regionally coincided with those of nuclear lamina attachment<sup>[59]</sup>. In addition, DNA methylation profiling has been also proposed as a means of early CRC diagnosis using non-invasive resources (*i.e.*, blood- or stool-based)<sup>[61,62]</sup>, which can benefit from NGS technologies.

## NOVEL ASPECTS OF CRC GENOMES BY NGS STUDIES

NGS-based genome analysis may facilitate the identification of previously unrecognized, novel features of CRC cancer genomes. For example, owing to its high-throughput nature, NGS analysis may be able to detect the presence of foreign DNA sequences originating from bacterial or viral pathogens. Although the clear association between pathogens and certain human tumor types has been demonstrated in limited cases such as hepatitis B or C viruses with hepatocellular carcinoma, there have been ongoing efforts to use the sequencing data for pathogen discovery<sup>[63,64]</sup>. For instance, Kostic *et al.*<sup>[65,66]</sup> analyzed nine CRC whole genome sequencing data sets<sup>[16]</sup> using their algorithm of PathSeq to identify microbial sequences enriched in CRC genomes compared to those in matched normal genomes. They observed that the sequences of *Fusobacterium* are enriched in CRC genomes, which was also shown in transcriptome sequencing results by independent researchers<sup>[67]</sup>. Although the oncogenic role of *Fusobacterium* in CRC genomes is only beginning to be elucidated<sup>[68]</sup>, these results highlight the possibility that NGS-driven sequencing data will be a valuable resource to identify novel pathogens associated with human cancers.

Chromothripsis is a unique cancer genome-associated phenomenon in which tens to hundreds of chromosomal rearrangements occur in a “one-off” cellular event<sup>[69]</sup>. This phenomenon involves one or a few chromosomes in which massive chromosomal fragmentation is followed by rejoining of the fragments<sup>[70]</sup>. This results in unique genomic signatures that can be identified by paired-end sequencing (*i.e.*, massive intrachromosomal rearrangements in the affected chromosome that can be visualized in a Circos diagram<sup>[71]</sup>) or from copy number profiles (*i.e.*, frequent oscillations between two copy number states indicative of retained and lost chromosomal fragments). After the first discovery of chromothripsis in one chronic lymphocytic leukemia patient by paired-end sequencing<sup>[69]</sup>, Stephens *et al*<sup>[69]</sup> also examined the copy number profiles of 746 cancer cell lines, observing that 2.4% of them (18 cell lines) showed the genomic signatures of chromothripsis. Recently, Kim *et al*<sup>[72]</sup> reported the tumor type-specific frequencies of chromothripsis as measured from a large-scale copy number profile of about 8000 cancer genomes including CRCs. Six out of 366 CRC genomes (1.8%) in the database showed the signature of chromothripsis (*i.e.*, significant frequent alternation between different copy number states<sup>[72]</sup>) and the frequency was not substantially different from the average across the database (1.5%). Of note, Kloosterman *et al*<sup>[73]</sup> reported the paired-end whole-genome sequencing results of four CRC genomes with liver metastases, observing that all cases harbored evidence of chromothripsis. In addition, the comparison between primary and metastatic CRC genomes revealed that most genomic arrangements are shared both by primary and metastatic genomes, indicating that metastasis occurs quite rapidly with few additional mutational events, which was also proposed in mutation-based CRC genome studies<sup>[74]</sup>. Along with chromothripsis, several unique features of cancer genomes have been reported in breast cancer genomes (kataegis; regional hypermutations near rearrangement breakpoints)<sup>[75]</sup> and in prostate cancer genomes (chromoplexy; chains of copy-neutral rearrangements across multiple chromosomes)<sup>[40]</sup>, which may expand the mutational categories in CRC genomes.

## CONCLUSION

We have discussed the recent NGS-based CRC studies in various genomic aspects. The progress of CRC genomic analysis (but not exclusive to CRC) can be summarized into three issues: (1) the screening of clinically actionable targets for personalized targeted medicine; (2) the advancement of pathway-level understanding in colorectal carcinogenesis using a large-scale cohort; and (3) the identification of novel features or mutation types in CRC genomes. In terms of the first issue, Roychowdhury *et al*<sup>[61]</sup> reported an advanced NGS-based cancer patient management protocol that includes low-pass whole-genome, exome, and transcriptome sequencing of cancer genomes. The notable aspects of the protocol are the

timeline (< 4 wk after enrollment) and cost (approximately 3600 USD), as well as the presence of a multidisciplinary sequencing tumor board (STB) to evaluate the mutation profiles of the patients and make a clinical decision. In their pilot study, the STB evaluated the sequencing results from a patient with metastatic CRC harboring *NR4S* mutation and *CDK8* amplification and concluded that BRAF/MEK inhibitors and PI3K and/or CDK inhibitors could be beneficial for the patient. Second, the more complete and comprehensive collection of CRC-related somatic genomic alterations will advance the pathway-level understanding of colorectal carcinogenesis and help distinguish the oncogenic drivers from neutral passengers, as seen in large-scale meta-analyses of cancer genome profiles<sup>[72,77]</sup>. Finally, NGS-driven genomic studies are already reporting novel features of cancer genomes beyond the traditional mutational categories. Besides the MSI and chromothripsis we discussed, some researchers used publicly available genome sequencing data (including those of CRC genomes<sup>[16]</sup>) and reported novel mitochondrial mutations<sup>[78]</sup> and the activity of human retrotranspositions in the cancer genomes<sup>[79]</sup>. Taken together, NGS technology will advance our understanding of CRC genomes and the obtained knowledge will lead to a better diagnosis and personalized targeted therapeutics for CRC management.

### Abstract

Pulmonary abnormalities, dysfunction or hyper-reactivity occurs in association with inflammatory bowel disease (IBD) more frequently than previously recognized. Emerging evidence suggests that subtle inflammation exists in the airways among IBD patients even in the absence of any bronchopulmonary symptoms, and with normal pulmonary functions. The pulmonary impairment is more pronounced in IBD patients with active disease than in those in remission. A growing number of case reports show that the IBD patients develop rapidly progressive respiratory symptoms after colectomy, with failure to isolate bacterial pathogens on repeated sputum culture, and often request oral corticosteroid therapy. All the above evidence indicates that the inflammatory changes in both the intestine and lung during IBD. Clinical or subclinical pulmonary inflammation accompanies the main inflammation of the bowel. Although there are clinical and epidemiological reports of chronic inflammation of the pulmonary and intestinal mucosa in IBD, the detailed mechanisms of pulmonary-intestinal crosstalk remain unknown. The lung has no anatomical connection with the main inflammatory site of the bowel. Why does the inflammatory process shift from the gastrointestinal tract to the airways? The clinical and subclinical pulmonary abnormalities, dysfunction, or hyper-reactivity among IBD patients need further evaluation. Here, we give an overview of the concordance between chronic inflammatory reactions in the airways and the gastrointestinal tract. A better understanding of the possible mechanism of the crosstalk among the distant organs will be beneficial in identifying therapeutic strategies for mucosal inflammatory diseases such as IBD and allergy.

**Key words:** Inflammatory bowel disease; Pulmonary symptoms; Gut-lung crosstalk; Biao-Li relationship; Social manner

**Core tip:** According to traditional Chinese medicine, the lung and the intestine are a pair of related organ systems (Biao-Li). The lung has no anatomical connection with the main inflammatory site of the bowel. Why does the inflammatory process shift from the gastrointestinal tract to the airways? We hypothesize that each individual cell or molecule not only plays its local role in its own organ, but also plays a "social" role to contribute distal communication through the epithelia. Inflammatory bowel disease may be a good example to study crosstalk between the gut and the lungs.

## INTRODUCTION

Ulcerative colitis (UC) and Crohn's disease (CD) are the two major forms of chronic relapsing and remitting inflammatory bowel diseases (IBDs)<sup>[1-3]</sup>. The incidence of UC and CD is increasing<sup>[4]</sup>. IBDs have become a major gastroenterological problem in developed countries<sup>[4-10]</sup>, and there has been an alarming rise in the traditional low-incidence areas, such as East Asia<sup>[11,12]</sup>, the Indian subcontinent<sup>[13]</sup>, the Middle East<sup>[14]</sup>, Latin America<sup>[15]</sup>, and Eastern Europe<sup>[16,17]</sup>. Although the gastrointestinal tract is the main affected site, both UC and CD are systemic inflammatory disorders that often involve organs other than those of the gastrointestinal tract<sup>[18-23]</sup>. Systemic manifestations can present years after the onset of bowel disease and can affect almost all organs<sup>[18,19]</sup>, including the musculoskeletal<sup>[18,24-26]</sup>, mucocutaneous<sup>[18,19,27,28]</sup>, hepatobiliary<sup>[18,29,30]</sup>, cardiovascular<sup>[18,31-33]</sup>, ocular<sup>[18,34,35]</sup>, renal and genitourinary<sup>[18,36-38]</sup>, pancreatic<sup>[18,29,39-42]</sup>, nervous<sup>[18,43-45]</sup> and bronchopulmonary<sup>[18,19,46-48]</sup> Systems. The extraintestinal manifestations tend to follow the clinical course of IBD and have a high impact on quality of life, morbidity, and even mortality in these patients<sup>[18]</sup>. The reported frequency of extraintestinal syndromes in the patients with IBD varies from 6% to 47%<sup>[18,46-49]</sup>.

Pulmonary involvement among IBD patients was first recognized by Kraft *et al*<sup>[50]</sup> about 40 years ago. Both UC and CD can affect any part of the respiratory system. The spectrum of respiratory disorders occurring among patients with IBD includes small and large airway dysfunction, as well as obstructive and interstitial pulmonary diseases<sup>[18,46-49]</sup>. Screening studies using respiratory symptoms, high-resolution computed tomography (HRCT), bronchoscopy, histological examination, and

pulmonary function tests (PFTs) document some of the earliest changes in airways among the respiratory asymptomatic IBD patients<sup>[18,46-49]</sup>. These changes, especially the subclinical alteration of peripheral airways and parenchymal inflammation may not be detected by routine computed tomography (CT) scan and PFTs<sup>[18,46-49]</sup>. The pulmonary involvements trend to follow the clinical course of IBD<sup>[18,49,51]</sup>. Pulmonary impairment appears more pronounced in the patients with active disease than those with inactive disease<sup>[18,49,51,52]</sup>. The airway inflammation affects quality of life, morbidity, and even mortality among these patients<sup>[18,49,51,52]</sup>. This evidence suggests that local intestinal mucosal inflammation is responsible for the distant airways inflammation<sup>[53-57]</sup>. In a population-based cohort study, patients with chronic obstructive pulmonary disease (COPD) had significantly higher risk for both UC and CD<sup>[58]</sup>. IBD and COPD share many similarities in epidemiological and clinical characteristics, as well as in inflammatory pathology<sup>[59,60]</sup>. Exposure to air pollution may be an important environmental factor for IBD<sup>[61,62]</sup>. There appears to be a direct association between increased environmental pollution and hospitalization among adult IBD patients<sup>[63]</sup>. Inhalation injury is often accompanied by the alimentary tract response<sup>[64,65]</sup>. The local mucosal inflammation in airways may also be responsible for the intestine inflammation and vice versa. In view of the above phenomena, the lungs and intestine are a pair of interacting organ systems<sup>[53-57]</sup>. It is most likely that there are similar inflammatory and immune components of these organs that are the cause of the overlap in pathological changes in respiratory and intestinal mucosal diseases<sup>[59,60]</sup>.

Why the inflammatory process shifts from the gastrointestinal tract to the airways or vice versa remains a mystery. Over the years many explanations for the intestine-lung communication have been proposed, however, no definite conclusions have been drawn. The purpose of this article is to update the plausible hypotheses of intestine-lung axis communication underlying the possible mechanism of pulmonary involvement during IBD pathogenesis.

## PULMONARY INVOLVEMENT IN ASSOCIATION WITH IBD OCCURS MORE FREQUENTLY THAN PREVIOUSLY RECOGNIZED

### *Broad spectrum of respiratory disorders in patients with IBD*

Kraft *et al*<sup>[50]</sup> in 1976 first observed that six patients developed severe, unexplained, chronic bronchopulmonary disease 3-13 years after the onset of nonspecific inflammatory disease of the colon. Since then, various pulmonary manifestations including small and large airway dysfunction or obstruction, inflammation of pulmonary parenchyma and vasculature, as well as bronchopulmonary hyper-reactivity have been reported in IBD<sup>[18,46-48,52,66,67]</sup>.

The spectrum of respiratory disorders occurring among patients with IBD is broad<sup>[18,46-52,68]</sup>. Storch *et al.*<sup>[69]</sup> recommend that primary care physicians must take a broader approach while treating patients with IBD and pulmonary diseases.

### ***Epidemiological evidence to support high prevalence of pulmonary involvement in association with IBD***

Lungs are not generally considered to be involved in IBD. In some studies only a few cases of pulmonary complications have been associated with IBD<sup>[59,67]</sup>, but in others, there is a wide range of pulmonary complications associated with IBD<sup>[18,46-52,67,70]</sup>. Edwards *et al.*<sup>[70]</sup> in a study of 624 IBD patients did not find any association with pulmonary complications. Rodgers *et al.*<sup>[67]</sup> found that there were only three cases of pulmonary complications in their study of 1400 IBD cases. However, other epidemiological investigations and clinical case reports have documented that pulmonary complications occur more frequently in IBD patients than previously recognized<sup>[18,46,47,49,51,52]</sup>. Recently, a large population-based study from Canada indicated that pulmonary complications were the most common concomitant chronic disorder in patients with CD and the second most common in patients with UC<sup>[19]</sup>. The increase in incidence of IBD in the past few decades suggests that environmental factors such as air pollution could contribute to disease pathogenesis<sup>[51-57]</sup>. Association of IBD and polymorphism of many innate immunity genes has been identified<sup>[4,18,53,71,72]</sup>. The high concordance of extraintestinal manifestations in siblings and first-degree relatives with IBD suggests that genetic factors also contribute to the link between intestinal and extraintestinal manifestations<sup>[73]</sup>. The association of pulmonary involvement with IBD appears to be mediated by a complicated interaction of environmental and genetic factors, suggesting there are clear, but undefined, multiple centers of loss of homeostasis in cellular and molecular interactions between the environment and host in both respiratory and gastrointestinal systems.

### ***Latent respiratory abnormalities or dysfunction in IBD patients discovered by HRCT, PFTs and bronchoscopy***

HRCT, sensitive PFTs, bronchoscopy and histological examination have been widely used to discover the earliest pulmonary abnormalities or dysfunction among IBD patients. Many respiratory screening studies using HRCT and PFTs support a high prevalence of clinical and subclinical respiratory abnormalities or dysfunction among IBD patients<sup>[18,46-48,51,74]</sup>. Three studies of randomly selected IBD patients showed incidence rates of pulmonary involvement in 44%, 48%, and 50%, respectively<sup>[47,51,75]</sup>. Although overt pulmonary symptoms may be uncommon, abnormalities on PFT have been noted in > 50% of patients with UC and > 60% of those with CD<sup>[51,76,77]</sup>.

Advances in imaging methods over the past decade have led to an increased understanding of anatomical and physiological pulmonary abnormalities in patients with IBD<sup>[77]</sup>. Even though the majority of patients with pul-

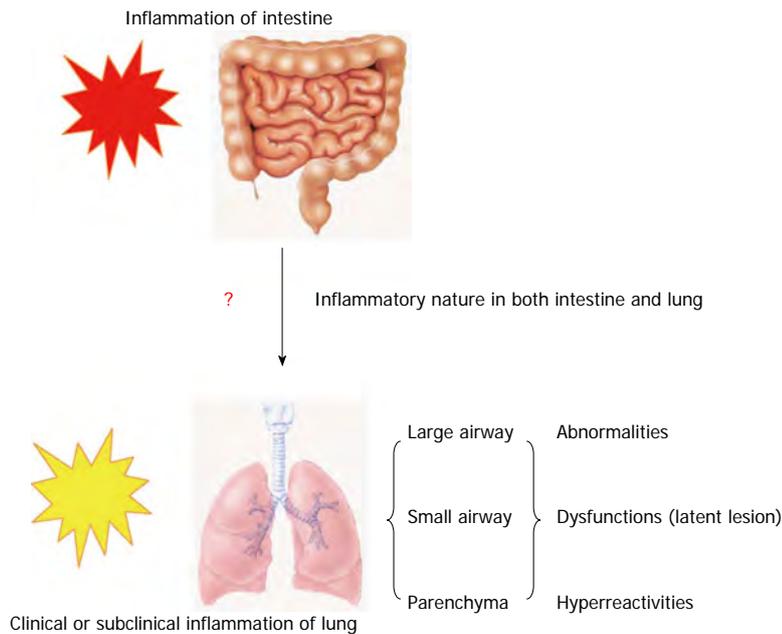

monary abnormalities were asymptomatic, the incidence of at least one abnormality on HRCT of the chest was as high as 39% in UC and 92% in CD patients<sup>[51]</sup>. With the advent of HRCT, it has become obvious that the previously described rarity of pulmonary involvement in IBD is inaccurate<sup>[77]</sup>. HRCT showed changes like bronchiectasis, mosaic perfusion and air trapping, suggestive of obliterative bronchiolitis, and patterns of centrilobular nodules and bronchial linear opacities (“tree in bud” appearance), suggestive of either cellular bronchiolitis or bronchiolectasis with mucoid secretion<sup>[69,78]</sup>. HRCT images also indicate that there are multiple centers of airway responses and mucoid secretion. This suggests that airway epithelium (including goblet cells) has been activated. The response of airway epithelium may be a major contributor to IBD-related lung disease.

Munck *et al.*<sup>[47]</sup> investigated 30 IBD patients (12 with CD, 18 with UC), and found dysfunction of small airways and parenchyma in all IBD patients despite their normal pulmonary physiology. It is likely that the earliest changes occur in the peripheral airways and pulmonary parenchyma, which result in reduced small airways and lung diffusion capacity in all the patients<sup>[49,51]</sup>. Increased disease activity in IBD patients has been shown to be associated with abnormal pulmonary function tests, and suggests a direct pathogenic link<sup>[49,51,79]</sup>.

Bronchoscopy and histological examination from the lung biopsies show changes in the bronchial epithelium, consisting of basal cell hyperplasia, basement membrane thickening, submucosal nonspecific inflammation, small airway fibrosis, and an overall increase in epithelial thickness and granulomatous bronchiolitis<sup>[66,68,79]</sup>. Although the crosstalk mechanism between the bowel and lung remains unknown, the HRCT and histology evaluation show that there is a shift in the inflammatory process from the bowel to the lungs<sup>[49,51,79]</sup>.

### ***Respiratory hyper-responsiveness among IBD patients***

Allergic symptoms, abnormal PFTs and positive skin prick test were more common among the IBD patients compared to the normal population<sup>[28]</sup>. The subclinical nonspecific bronchial hyper-responsiveness, independent of the presence of atopy, in IBD patients who have no other pulmonary symptoms and with normal baseline spirometry, has a high prevalence<sup>[48]</sup>. Colby *et al.*<sup>[80]</sup> reported that the bronchial hyper-reactivity occurred in 48% of patients with UC and CD, even in the absence of any clinical, radiological and functional evidence of airway disease. Bronchial hyper-reactivity occurred in 71% of children and adolescents with CD<sup>[81]</sup>. Allergy is an inappropriate inflammatory reaction to antigen. The allergen triggers an exaggerated immune response, and can aggravate an immediately atopic allergic reaction<sup>[82-84]</sup>. Combination of HRCT and histological examination revealed multiple centers of pulmonary inflammatory responses, which may share many characteristics with atopic allergic reactions<sup>[48,80,81]</sup>. The lungs may duplicate the “social” inflammatory reaction of the intestine (Figure 1).

**Figure 1 Model for inflammatory process in lung and intestine during inflammatory bowel disease.** Clinical or subclinical inflammation in small and large airways and the lung parenchyma accompanies the main inflammation in the bowel during inflammatory bowel disease.

## EPITHELIAL CELLS ARE THE INITIAL AND MAIN TARGET

The epithelial cells are considered not only the frontier sentinels and barriers, but also the central participants in innate and adaptive immune responses during mucosal inflammation<sup>[71,85-88]</sup>. In both the bowel and lungs, these cells provide an important physical barrier to the huge vulnerable biological surface, and are continuously exposed to the external environment. Upon activation, epithelial cells can release large quantities of proinflammatory cytokines, growth factors and chemokines that attract inflammatory cells to initiate and sustain the inflammatory reaction<sup>[71,85-88]</sup>. Direct or indirect interactions of epithelial cells with mast cells, T and B lymphocytes, dendritic cells (DCs), eosinophils, neutrophils, and basophils help to maintain the balance between the environment and the host<sup>[88]</sup>. The airway and gut epithelial cells are at the center of the inflammatory response and play the dominant role in initiation and sustaining the inflammatory reaction<sup>[88]</sup>.

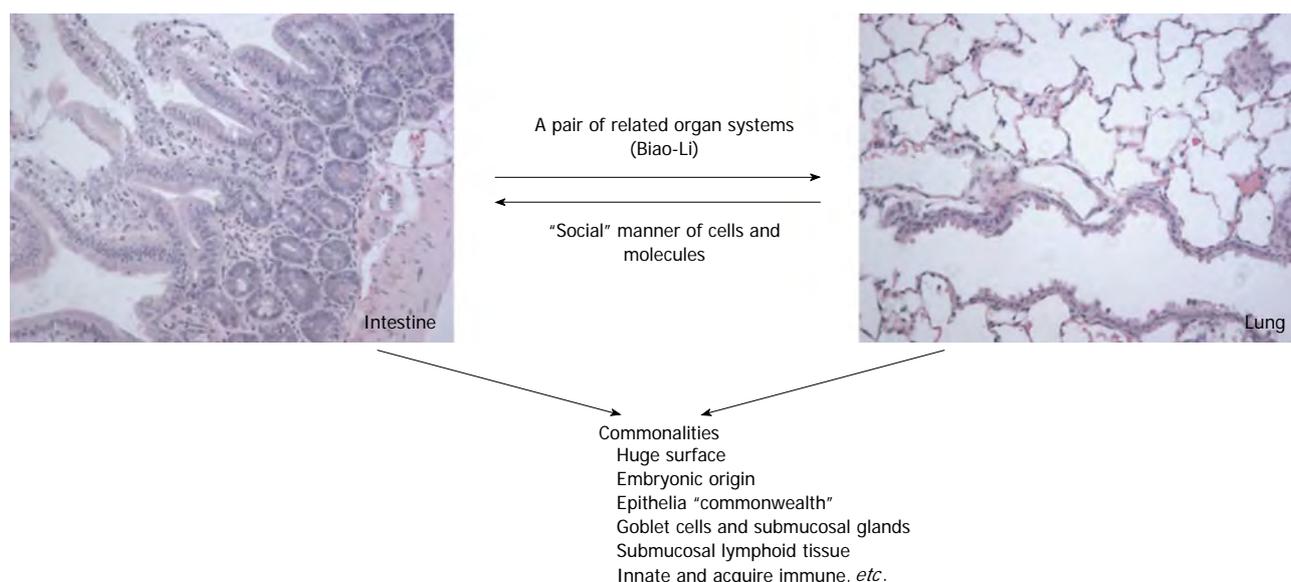

### *Intestinal epithelium is the center of cellular and molecular interaction between host and environment*

The healthy mutual relationship between the microbiota and host depends on the balanced interaction between the microbiota and innate immune activation<sup>[60,71,87,89,90]</sup>. The intestinal barrier plays a crucial role in cellular and molecular interactions between the commensal microflora and possible harmful factors in the intestinal lumen and innate immune system<sup>[60,71,87,89-92]</sup>. The intestinal barrier is composed of a thick mucus layer containing host defense molecules, a monolayer of columnar intestinal epithelial cells, and underlying set of cells (mesenchymal cells, DCs, lymphocytes and macrophages)<sup>[60,71,87,89-92]</sup>. The intestinal epithelial cells are exactly at the center of the

complex system called the intestinal barrier. The intestinal epithelial cells are a single layer of columnar cells consisting of four types of cells: the absorbent enterocytes, goblet cells, Paneth cells, and enteroendocrine cells. It is clear that these four types of epithelial cells present an anatomical and functional barrier to maintain the whole intestinal homeostasis. On the antigen-rich side of the lumen, they secrete and regulate the composition of the thick mucus layer. The intestinal epithelial cells serve as sentinels of innate immunity. The innate immune system is able to recognize bacterial and viral motifs through the toll-like receptors (TLRs) and the nucleotide-binding oligomerization domain families<sup>[93-95]</sup>. The intestinal epithelial cells express several members of the TLRs<sup>[93]</sup>. On the basolateral side, these cells interact and continuously crosstalk with inflammatory cell-rich lamina propria. The intestinal epithelial cells are nonprofessional antigen-presenting cells, which are able to process and present antigens directly to lymphocytes by a highly polarized system with apical antigen sorting, processing and exclusively basolateral presentation. They serve as the major participants in innate and adaptive immune responses<sup>[60,71,87,89-91]</sup>. The intestinal epithelium acts to maintain homeostasis during the steady state, restore the epithelium during insult or injury, and induce inflammatory responses.

### *Airway epithelium is also the center of cellular and molecular interaction between host and environment*

Although initiation of pulmonary inflammation and its association with IBD remains unknown, it is well established that the airway epithelial cells play an important role in the initiation and maintenance of airway inflammation, as well as being the main target<sup>[60,85,88,96-98]</sup>. The airway epithelial cells are also at the center of the airway barrier system because of their anatomical and functional position. On the antigen-rich lumen side, they secrete

**Figure 2 Summary model of plausible mechanisms of lung-intestine communication underlying inflammatory bowel disease-associated pulmonary involvement.** The lungs and intestines are a pair of mutually affected organs. The airways may intrinsically accompany inflammation of the bowel. This distal intrinsic inflammatory response may relate to the common features between the lung and intestine. According to Traditional Chinese Medicine, the lung and intestine have internal and external relationships (Biao-Li). This distal intrinsic inflammatory response may relate to the “social manner” of cells and molecules.

and regulate the composition of the thick mucus layer, while on the basolateral side, they interact and crosstalk with the inflammatory cell-rich lamina propria<sup>[60,85,88,96-98]</sup>. Activated airway epithelial cells can induce synthesis and secretion of immune-cell-mediated host defense molecules such as antimicrobial and antiviral proteins that activate other mucosal innate immune cells<sup>[60,85,88,96-103]</sup>. Activated innate immune responses can secondarily induce the recruitment and activation of DCs and T and B lymphocytes that amplify antigen recognition and antibody production and other adaptive immune responses<sup>[60,96-103]</sup>. Many studies document that the IBD patients develop rapidly progressive respiratory symptoms after colectomy without any identified bacterial pathogens on repeated sputum culture and require oral corticosteroid therapy<sup>[18,66,99,104-106]</sup>, which proves that pulmonary impairment in IBD is not a pathogen-induced inflammation. The pulmonary involvement in IBD may be due to aberrant immunity from the bowel that disrupts airway tissue homeostasis. This aberrant airway epithelial injury/repair may be the mechanism of IBD-related pulmonary involvement<sup>[53-57,107,108]</sup>. Lungs may duplicate atopic inflammation of the bowel. However, the connection between the primary site and the atopic site is unclear. Less attention has been paid to the mechanism of atopic inflammatory reaction that manifests at sites remote from the primary site. The mechanism should be either systemic-factor-mediated cellular and molecular events or some intrinsic connection between the primary and atopic sites. In future, detecting the earliest pulmonary epithelium activation signs or genetic responses during IBD pathogenesis would provide evidence of the linkage between the anatomically disconnected organ systems.

## AIRWAY MAY DUPLICATE THE BOWEL INFLAMMATORY EVENT

Combined HRCT and histological examination have shown that there are multiple centers of airway epithelial (including goblet cells) responses and mucoid secretion in IBD<sup>[78-79,104,109]</sup>. The lung duplicates the inflammatory process of the bowel (Figures 1 and 2). The linkage between the lungs and intestine is hard to understand in the absence of anatomical connections or systemic neuroendocrine immune mediation. Pulmonary inflammation may intrinsically accompany the main inflammation in the bowel, and this distal intrinsic inflammatory response may be related to the “social manner” of cells and molecules, similar to the exaggerated allergen-induced multiple centers of allergy inflammatory response on the surface of the skin, conjunctivae, and airway and digestive tracts<sup>[83-85,88,99,107,108]</sup>.

### *Commonalities between lung and intestine and crosstalk*

There are many commonalities between the lungs and intestines<sup>[18,53,107,108,110,111]</sup>. The gastrointestinal tract and bronchial tree share a common embryological origin that arises from the primitive gut<sup>[10,74,75,77,78]</sup>. Both the lung and intestine possess goblet cells and submucosal glands as part of their luminal structure. In addition, both contain submucosal lymphoid tissue, host defense molecules, and play crucial roles in both innate and acquired immunity<sup>[18,107,108,110,111]</sup>.

In IBD, inflamed bowel mucosa produces many inflammatory mediators and releases them to the circulating system<sup>[4,66,71,86,87,90,102,103]</sup>. The inflamed bowel mucosa also creates the prospect for systemic absorption of

luminal contents, including dietary antigens, digestive enzymes, or specific bacterial products capable of inducing systemic inflammation<sup>[66,102,103]</sup>. Some investigators hypothesize that the pathogenesis of IBD-related airway disease may be associated with circulating inflammatory mediators, specific bacterial products, dietary antigens, or digestive enzymes<sup>[102,103]</sup>. Detectable levels of bacterial lipopolysaccharide and antibodies to bacterial lipid A and peptidoglycan in serum of IBD patients support this theory. However, it is less likely to be accurate in the case of IBD-associated lung disease, because it clearly occurs after colectomy in patients who do not have any ongoing bowel inflammation<sup>[4,66,105,106]</sup>. To the best of our knowledge, none of the circulating inflammatory mediators, dietary antigens, digestive enzymes, or specific bacterial products has been established as being responsible for extraintestinal syndromes during the intestine inflammatory process. In fact, circulating inflammatory mediators are not always enough to drive inflammation from the local mucosa to distal organs. Our previous work suggested that the skin, conjunctivae, airways and digestive tract may join together to fight allergens<sup>[107,108]</sup>. The atopic lesion may duplicate the primary contact site of cellular and molecular events. The atopic march may be due to the intrinsic “social” involvement of the positioned epithelial cells, but may not be totally controlled by the anatomic connection or the circulating systemic factors involved in allergy pathogenesis<sup>[53-57,107,108,112,113]</sup>. Thymic stromal lymphopoietin (TSLP), a general biomarker for skin-barrier defects<sup>[85,107,114]</sup> is an interleukin-7-like cytokine produced by epithelial cells, has emerged as a potential master regulator of both skin and airway inflammation<sup>[85,107,112-115]</sup>. TSLP signaling plays an important role in both airway and skin allergic inflammation. Recently, Zhang *et al.*<sup>[114]</sup> found that increased TSLP expression in skin keratinocytes not only triggers atopic dermatitis-like lesions in skin locally, but also leads to a concomitant ovalbumin (OVA)-induced asthma-like lung inflammation in animals. Furthermore, they elucidated that increased epidermal keratinocyte TSLP expression and subsequent increase in circulating TSLP in a mouse model did not lead to any spontaneous lung inflammation in the absence of OVA sensitization and challenge. High levels of expression of TSLP mRNA in bronchial epithelial cells and submucosa of asthmatic patients<sup>[115]</sup>, suggest that locally produced TSLP could be important for the development and maintenance of asthma<sup>[85,107,112-115]</sup>. TSLP appears to be a crucial factor in driving both skin and lung into inflammation, but solely increased epidermal keratinocyte TSLP expression and subsequent increase in blood circulating TSLP is not sufficient to drive both skin and lung into inflammation<sup>[85,107,112-115]</sup>. The lung inflammation is not triggered by circulating or epidermal TSLP, but requires local TSLP production by pulmonary epithelial cells<sup>[85,107,112-115]</sup>. OVA sensitization and challenge is extremely important to drive both skin and lung into inflammation<sup>[85,107,114]</sup>. The intrinsic connection of skin and lung is through locally produced TSLP after OVA

sensitization and challenge<sup>[85,107,112-114]</sup>.

The plausible mechanism for association of pulmonary involvement with IBD may be the intrinsic airway reactions that accompany the main inflammation in the bowel, as for allergen-triggered, enigmatic, multiple centers of allergic inflammation.

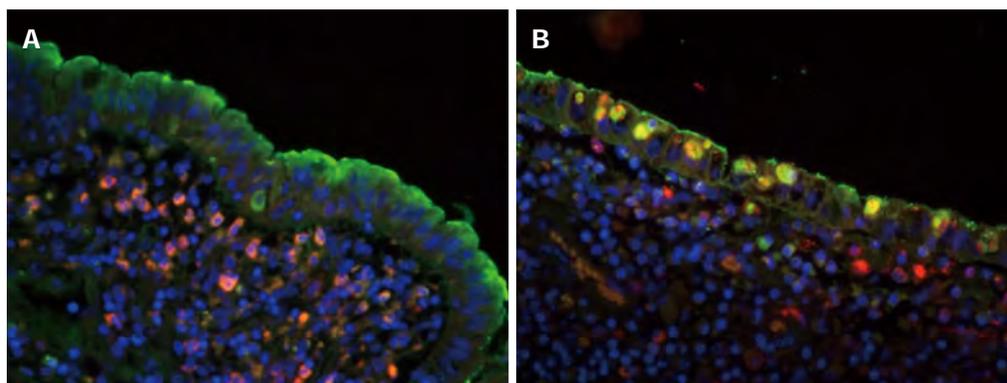

There is clearly communication among organs that share a common embryological origin, or similar cellular and molecular structure without any anatomical interaction<sup>[53-57,65,107,108,110,111]</sup>. Primitive gut has a shared common origin with the gastrointestinal tract, biliary tract, and respiratory system. Our previous work suggested that pulmonary surfactant protein A-like molecule is a frontier host defense protein and that its expression may be associated with some autoimmune diseases<sup>[53,65]</sup>. Latex-mediated allergy is another example of intrinsic activation of non anatomically related organs. During latex-mediated allergy, the skin allergic reaction occurs anywhere in the body and not necessarily at the site of the direct latex contact<sup>[74,75,83]</sup>. How does information transfer from the epidermal keratinocytes at latex-contacted sites to those at uncontacted sites<sup>[107,108,116]</sup>? It is possible that the epidermal keratinocytes at both sites intrinsically communicate because they are close relatives that share common features.

In fact, in IBD, the surface of skin, conjunctivae, and airways is involved in fighting inflammation in the gastrointestinal tract.

As above mentioned, OVA intrinsically drives skin and lung into allergic inflammation by locally produced TSLP<sup>[85,107,112-115]</sup>. Aberrant immune responses to the commensal microbiota in the bowel, which lead to pulmonary inflammation, may be related to some unknown TSLP-like molecules. Detecting these molecules could provide the mechanism of lung-intestine crosstalk.

### ***Pulmonary involvement associated with IBD may be a good example to understand the Biao-Li relationship between lung and intestine***

According to Chinese Medicine, the lung and the intestine are a pair of related organ systems (Biao-Li). The interaction of lung and intestine is mutually affected by internal and external relationships<sup>[47,53-57,107,116-118]</sup>. It means that lung diseases often have colon syndromes and colon diseases may have lung syndromes. The mechanism is complicated, and immunological, environmental and genetic factors should trigger lots cellular and molecular events<sup>[107,108]</sup>. From the pathological findings, the microscopic hallmark of IBD in the intestine and lung is infiltration of chronic inflammatory cells and response of interstitial cells such as fibrocytes and epithelium. In our previous study, we investigated one type of frontier immune cell (CD68-positive macrophages) and one type of frontier host defense molecule [pulmonary surfactant protein (SP)-A], which reside in the lungs and colon. Both frontier immune cell and frontier host defense molecules are overexpressed in inflammatory areas of CD and UC, and in particular, there are many CD68-positive

**Figure 3** Co-localization of surfactant protein-A and CD68 in normal and inflammatory areas. A: Surfactant protein (SP)-A -positive signal was indicated by fluorescence microscopy (green) fluorescence; CD68-positive signal was identified by rhodamine red-X (red) fluorescence; and the cell nucleus was indicated by Hoechst dye (blue). In the normal area, SP-A was located in the surface of the villi, specific epithelium and submucosae, lamina muscularis, mucosae and lymphoid tissues. CD68-positive cells were mainly found in the submucosae, lamina muscularis, mucosae, and lymphoid tissues and in the epithelium; B: In the inflammatory area, CD68-positive cells were dramatically increased in all levels of the bowel wall; especially CD68-positive macrophages in the epithelia of lamina mucosa. The SP-A-positive macrophages were recruited by activated epithelial cells. Double labeled SP-A and CD68 shows that some CD68-positive macrophages expressed SP-A like molecule in the inflammatory bowel disease tissues (original magnification,  $\times 200$ ). Figures reproduced with permission from reference [53].

macrophages among the epithelia of lamina mucosa. The SP-A-positive macrophages are recruited by activated epithelial cells (Figure 3)<sup>[53]</sup>. The epithelium serves as the central participants in innate and adaptive immune responses as well as mucosal inflammation, laboratory evidence of activation of pulmonary epithelium would provide an insight into the “Biao-Li” relationship between lung and intestine during the pathogenesis of IBD associated pulmonary disorders. In view of this, association of pulmonary involvement with IBD may be a good example to understand the Biao-Li relationship between lung and intestine<sup>[53-57,107,116-118]</sup>.

#### *Lung-intestine connection may relate to the “social” property of cells and molecules*

To date, there is a lack of evidence for the participation of any circulating inflammatory mediator, dietary antigens, digestive enzymes, or specific bacterial products as a linkage between the gastrointestinal tract and extraintestinal organs. Both gastrointestinal and airway lesions may be epithelium-mediated chronic inflammation. IBD-associated pulmonary involvement, such as epithelial disease with adoption of a chronic wound scenario, could also be a hypothesis about airway wall and gastrointestinal tract remodeling over the course of the disease<sup>[60,66,80]</sup>. The extraintestinal organs may duplicate “social” inflammation of the gastrointestinal tract. The inflammation of the gastrointestinal tract as a “social” factor drives inflammatory reaction to extra-intestinal organs. There is a clear but undefined communication among organs that share a common embryological origin, or similar cellular and molecular structure despite being located at a distance from each other without any anatomical interaction. The human body originates from a single cell, which makes the whole body a social system. A constant molecular and cellular interaction between the environment and host is required for the establishment and maintenance of homeostasis. Disrupted homeostasis in the gastrointestinal

tract may also affect the airways. Pulmonary involvement associated with IBD as the “social” inflammatory reaction, is a plausible hypothesis. Sharing the common embryological origin or similar cellular and molecular structures may be “closer relatives” in our “social body”. The “social manner” of cell and molecules would also help to attain insight into the pathogenesis of enigmatic complications such as IBD, and the cellular and molecular mechanism of Chinese Traditional medicine.

## CONCLUSION

The frequency of pulmonary abnormalities, dysfunction or hyper-reactivity that occurs in association with IBD is more than previously recognized. More evidence shows that latent inflammation exists in the airways of IBD patients, even without any bronchopulmonary symptoms and with normal pulmonary function. The pulmonary impairment is more pronounced in IBD patients with active disease than in those in remission, and the linkage between lung and intestine may not be easily supported by anatomic connection or systemic neuroendocrine immune mediation. The airways may intrinsically accompany the main inflammation in the bowel. Lung and intestine share a lot of common features. The interaction of lung and intestine is mutually affected by internal and external relationships (Biao-Li). The pulmonary abnormalities, dysfunction or hyper-reactivity in IBD patients may be related to the “social” manner of cells and molecules. Further investigation of epithelium-mediated cellular and molecular events and their interaction in lung and bowel may provide evidence of mutually affected internal and external relationships (Biao-Li) of the lung-intestine axis, and the “social property” of cells and molecules. A better understanding of the mechanism of crosstalk among the distant organs would be beneficial to the elucidation of the etiology and help in identifying therapeutic strategies for mucosal inflammatory diseases such as IBD and

atopic allergic inflammation.

### Abstract

Broadly, complex fistulas are those that are not low transsphincteric or intersphincteric. The objectives of surgical management are to achieve fistula healing, prevent recurrences and maintain continence. The risk of incontinence associated with treatment ranges from 10% to 57%. The objective of this manuscript is to review the current literature to date on the ligation of the intersphincteric fistula tract procedure (LIFT procedure) as a treatment option in these types of fistula. A search was conducted in Medline, PUBMED, EMBASE and ISI Web of Knowledge, and studies published from January 2009 to May 2013 were included. The primary outcomes were fistula healing rates, mean healing time and patient satisfaction with this surgical technique. Eighteen studies were included in this review. The total number of patients included was 592 (65% male). The median age reported was 42.8 years. The most common type of fistula included was transsphincteric (73.3% of cases). The mean healing rate reported was 74.6%. The risk factors for failure discovered were obesity, smoking, multiple previous surgeries and the length of the fistula tract. The mean healing time was 5.5 wk, and the mean follow-up period was 42.3 wk. The patient satisfaction rates ranged from 72% to

100%. No de novo incontinence developed secondary to the LIFT procedure. There is not enough evidence that variants in the surgical technique achieve better outcomes (Bio-LIFT, LIFT-Plug, LIFT-Plus). This review indicates that the LIFT procedure is primarily effective for transsphincteric fistulas with an overall fistula closure of 74.6% and has a low impact on fecal continence. This procedure produces better outcomes at the first surgical attempt.

**Key words:** Fistula-in-ano; Ligation; Intersphincteric; Fistula tract; Incontinence; Recurrence; Transsphincteric fistula

**Core tip:** We review the current literature published until today about the ligation of intersphincteric fistula tract procedure. The paper describes the different types of fistulas in which the technique has been used; the cure rates achieved; the reported recurrence rates; types of failures and morbidity related to it. The paper analyzes the prognostic factors for the success; describes the various modifications of the surgical technique and the results obtained with them. The manuscript classifies the types of failures and gives options for their proper treatments. With all these, it sets the achievements and limitations of the technique, with the scientific evidence available today.

### INTRODUCTION

Perianal abscess and fistulas represent two stages of

the same disease. The main etiology is cryptoglandular. Perianal abscess and fistulas are two of the oldest human surgical entities<sup>[1]</sup>. The objectives of treatment are to achieve fistula healing, prevent recurrences and maintain continence. The risk of incontinence associated with treatment ranges from 10% to 57%<sup>[2]</sup>. The disease has an incidence of 8.6 per 100000 people and nearly 20000 to 25000 fistulas are treated annually in the United States<sup>[1]</sup>. The incidence of fistulae after perianal abscess is 27% to 60%<sup>[3]</sup>. Traditionally, a “complex fistula” is defined by a high risk of recurrence or incontinence following treatment. Broadly, complex fistulas are those that are not low trans-sphincteric or intersphincteric fistulas. The surgical options for these fistulas include fibrin application, plug placement, endorectal advancement flap (ERAF), fistulotomy with primary sphincter repair, partial fistulotomy with seton placement, ultra-low anterior resection and coloanal anastomosis, the ligation of the intersphincteric fistula tract (LIFT) procedure and recently, the video-assisted fistula tract procedure (VAAFT). Trans-sphincteric fistulas comprise 20%-25% of all fistula cases<sup>[3]</sup>. Although plug placement and applying fibrin are still being used, at present, there is a preference for the ERAF and LIFT procedures. The LIFT procedure, which is the topic of this review, involves the following principles: (1) identification of the internal opening; (2) incision at the intersphincteric groove; (3) dissection of the intersphincteric space; (4) identification of the intersphincteric fistula tract; (5) securing ligation and excision of the intersphincteric tract; (6) confirming the removal of correct fistulous tract; (7) opening and curetting the external opening; and (8) closure of the intersphincteric wound. A search was conducted in the Medline, PUBMED, EMBASE and ISI Web of Knowledge databases, using the following terms: LIFT, anal fistula, perianal fistula, fistula-in-ano, rectal fistula, complex anal fistula, ligation of intersphincteric fistula tract, sphincter sparing procedures, clinical trials, outcomes, recurrence, failure, morbidity and incontinence. All of the studies published in the English language from January 2009 to May 2013 were included in this review. We initiated the review from 2009 because the surgical technique was first described in that year. In the studies reported by the same group of authors, the outcomes considered for the analysis were those with a longer follow-up and a larger number of patients<sup>[4-7]</sup>.

## REVIEW OF THE LITERATURE

In the present review, we included 18 papers: eleven were retrospective, two were retrospective and prospective, four were prospective and one was a randomized controlled trial (Table 1). The total number of patients was 592, and 385 were male (65%). The average age reported was 42.82 years. Only a few studies included patients with the following characteristics: rectovaginal fistula, 3 studies with 6 patients in total; cigarette smoking, 2 studies with 21 patients; inflammatory bowel disease, 2 studies; diabetes, 3 studies; HIV, 1 study; and using corticosteroids, 1

study. Other special characteristics mentioned but not numerically specified were the presence of obesity, ischemic heart disease, rheumatoid arthritis and cancer. The most common type of fistula included was trans-sphincteric (73.3%). The percentage of “low” transsphincteric fistulas was 13.5%. The remaining fistulas were classified as horseshoe or hemi horseshoe (48), intersphincteric (11), suprasphincteric (9) and rectovaginal (6). In addition, 34.4% of the population had been previously operated using the same or another surgical technique. The mean operative time reported was 36.16 min. Only two studies reported the length of hospital stay (2.5 d and 1.4 d, respectively), but most of the surgeries were performed on an outpatient basis. The mean healing rate was 74.6% (range: 40%-95%), and the mean healing time was 5.5 wk. The percentage of the population who had a drainage seton before the LIFT procedure was 56% (226/402).

In 2009, Rojanasakul<sup>[8]</sup> first described the technique and reported a success rate of 94%. They included 18 patients, with a recurrence rate of 5.6%.

Bleier *et al*<sup>[4]</sup> conducted a retrospective and prospective trial. They included 39 patients, 51.3% of whom were male. The mean age of the population was 49 years. The average number of previous surgeries to treat perianal fistulas was 2. In addition, 74% of the population had at least one previous failed surgical treatment. The average follow-up period was 20 wk. The success rate was 57%. The latency time to recurrence was 10 wk. Of the total recurrences, 4 recurrences were intersphincteric, 3 were transsphincteric and 1 was a horseshoe type. The incontinence rate was 0%. This represents the first experience in the United States. The same group, recently reported on the treatment of 93 patients (61% male), with a mean age of 43 years<sup>[5]</sup>. A 32% had been previously operated. A drainage seton was placed in 92% of the total patients. The healing rate dropped to 40% with a failure rate of 34%, and 26% of patients suffered a recurrence. The mean recurrence time was 7 mo. Nine patients had a down-staging of the fistula to intersphincteric and were treated with fistulotomy, achieving a secondary healing rate of 57%. The average Wexner score reported was 1. No patient had solid stool incontinence.

Shanwani *et al*<sup>[9]</sup> performed a prospective study. A total of 45 patients were included. In total, 71.1% of patients were male, and the mean age was 41.5 years. The mean operative time was 67.5 min. The average hospital stay was 2.5 d (range: 2-5 d). During an average follow-up period of 9 mo, the cure rate was 82.2%, with an average healing time of 7 wk. The recurrence rate was 17.8%, and the recurrence occurred between 3 and 8 mo after surgery. There were no reported cases of fecal incontinence or morbidity.

There are also variations to the conventional LIFT procedure. Ellis, based on the treatment of rectovaginal fistulas with approximately 92% of success, described the use of a bioprosthetic graft to reinforce the ligation and the closure of the fistula tract, calling it the BioLIFT procedure in a prospective study of 31 patients<sup>[10,11]</sup>. Twenty-

two of these patients were men, with an average age of 48 years. The patch was derived from the submucosa of the porcine small intestine with a size of 4 cm × 7 cm, which overlaps the fistula tract for 1-2 cm. Fixation was performed to the puborectalis muscle and to the external anal sphincter with absorbable material. BioLIFT achieved a 94% success rate during an average follow-up period of 15 mo. There were two recurrences (one intersphincteric and one hemi-horseshoe). There was local induration and drainage from the operative wound that resolved without any intervention other than routine postoperative care in 12 patients. The degree of satisfaction reported was 100%.

Ooi *et al*<sup>[12]</sup> conducted a trial including 25 patients (17 males). The mean age was 40 years. Approximately 40% of the patients had been previously operated on, and the preoperative Wexner score of the cohort was 2. The healing rate was 68% with a mean follow-up period of 22 wk. The mean operative time was 39 min. There was no morbidity. The global postoperative Wexner score was 4. In the subgroup of patients who achieved healing, the Wexner score was 0. The mean healing time was 6 wk. All the recurrences (28%) were in the form of intersphincteric fistulas. The authors achieved a 72% patient satisfaction rate.

Aboulian *et al*<sup>[6]</sup> treated 25 patients (68% male) with 26 LIFT procedures. The mean age was 39 years. Of those patients, 65% had been previously operated on by drainage seton placement, and 27% of patients had failed to heal after treatment with another previous fistula technique. An average follow-up period of 27 wk was achieved. The healing rate was 68%. The morbidity reported was low and unrelated to the surgical procedure. In a later report of their series with a larger cohort and longer follow-up, patients who healed completely were contacted every 6 mo thereafter to assess for any recurrence of symptoms<sup>[7]</sup>. This group categorized patients with persistent symptoms or reappearance of symptoms before 6 mo as early failures. Late failures were those with resolution in the early period but return of symptoms after 6 mo. A total number of 38 patients were followed. The mean follow-up period was 26 mo, but 68% of patients had a follow-up period in excess of 12 mo. Only 18% of patients had previous fistula surgery, but 76% had received a drainage seton prior to the LIFT procedure. The study described a 61% healing rate after the first LIFT procedure. A total of 15 patients with failures were reported with a median time to the diagnosis of 4 mo. Of these patients, 12 failures were early type, and 3 failures were late type. Taking into account all failures, 4 were blind infected sinus, 2 occurred in the form of intersphincteric fistula (down-staging effect), and 9 occurred as the same trans-sphincteric fistula. In this series, the median healing time was 8 wk. No incontinence or morbidity was reported.

Sileri *et al*<sup>[13]</sup>, in a prospective study, treated 18 patients (10 of them male), with a mean age of 39 years. All the patients had a history of abscess drainage and seton

placement over a period of 6 to 8 wk. The healing rate was 83% with only 3 recurrences (one was intersphincteric treated with fistulotomy, and the others were 2 transsphincteric fistulas treated with seton placement and ERAF). The average follow-up period was 6 mo. The only morbidity reported was a thrombosed external hemorrhoid.

In one of the largest series described, Tan *et al*<sup>[14]</sup> analyzed the outcomes of 93 patients (82.8% male). The mean age reported was 40 years. Of the patients, 28% had been operated with another surgical technique before, and only 17.2% had a seton drainage for a mean time interval of 11 wk. The average follow-up period was 23 wk. The success rate was 86%, with a mean healing time reported of 4 wk. The recurrence rate was 6.4%, and the failure rate was 7.5%. Of the 7 patients with failure, 4 were down-staged the fistula to intersphincteric and treated with fistulotomy, and 3 patients had a blind sinus treated with silver nitrate and antibiotics. There were 6 recurrent transsphincteric fistulas. The mean time interval between treatment and failure was 22 wk. The authors described three types of failure. Type 1 is a localized failure or blind sinus characterized by secretion or discharge in the intersphincteric wound without evidence of primary opening and adequate granulation of the external orifice. Type 2 is a partial failure with down-staging of the fistula tract (the fistula is now intersphincteric), and type 3 is a total failure with the same previous fistula tract but without involvement of the intersphincteric wound.

Abcarian *et al*<sup>[15]</sup> reported the results of 40 patients with a mean age of 43 years. The cohort had an average of 2 previous surgeries. The healing rate was 74%, but those patients primarily treated with the LIFT procedure had a healing rate of 90%. In contrast, the patients with one previous surgery had a healing rate of 75%, and the patients with two or more previous surgeries had a success rate of 65%. The mean follow-up period was 18 wk. The authors did not report any functional change in continence.

Tan *et al*<sup>[16]</sup>, in a retrospective study, compared endorectal advancement flap (ERAF) *vs* the LIFT procedure after all the patients had been operated on with seton placement. A total of 31 ERAF procedures were performed. The mean age of this population was 49 years (87.1% male). In this group, 58.8% of patients had been previously operated on, and the time interval between seton placement and ERAF was 13 wk. The total healing rate was 93.5%, with an average follow-up period of 6 mo. A total of 24 patients were included in the group treated by the LIFT procedure, with 87.5% of the patients being male and a mean age of 41 years. Only 25% of patients had been previously operated on, and the time interval between seton placement and the LIFT procedure was 14 wk. The mean follow-up period was 13 mo. A success rate of 62.5% was reported. The ERAF procedure was more effective in this study [healing: ERAF (93.5%) *vs* LIFT (62.5%); failure: ERAF (6.5%) *vs*

LIFT (37.5%),  $P = 0.006$ ].

Mushaya *et al*<sup>[17]</sup>, in a randomized and controlled trial, compared the LIFT and ERAF procedures. A total of 39 patients were included with a mean age of 47.8 years. In the LIFT group, there were 25 patients (17 males), and in the ERAF group, there were 14 patients (10 males). The mean follow-up period was 20 mo. The mean operative time of LIFT group was 10 min *vs* 42.5 min in the ERAF group ( $P < 0.001$ ). The postoperative pain was greater in the ERAF group (visual analogue scale: ERAF 1 *vs* LIFT 0,  $P = 0.017$ ). The satisfaction rate favored the LIFT procedure (9.5 *vs* 8.1,  $P < 0.001$ ). The morbidity did not differ between procedures (4% bleeding in LIFT group, 7% partial dehiscence at the apex in ERAF group, and 8% dehiscence at perianal wound in LIFT group). The healing rate at one month was 85% and 68% for the ERAF and LIFT groups, respectively. At the end of the study, the success rates were 93% and 92%, respectively. The recurrence rates were similar (7% in the ERAF group and 8% in the LIFT group,  $P = \text{NS}$ ). The interval between surgery and resumption of daily activities favored the LIFT procedure ( $P = 0.016$ ). The functional outcomes were equal between both techniques.

In another attempt to improve the results, Han *et al*<sup>[18]</sup> described a technique using the insertion of a bioprosthetic anal plug in the fistula tract (LIFT-PLUG procedure). They reported their experience in 21 patients (19 of the male gender), and none had previously received an operation. The mean operative time was 20 min. The healing rate achieved was 95% over an average follow-up period of 14 mo. In this series, the mean healing time of the secondary opening was 2 wk, and at the intersphincteric wound, it was 4 wk (faster than previously reported). There was no morbidity. Only 5% of patients reported a Wexner score of 1. A larger randomized, multicenter prospective trial comparing LIFT-Plug with LIFT is in progress, including selected cases without previous surgeries (clinical trial number NCT01478139)<sup>[19]</sup>.

Lehmann *et al*<sup>[20]</sup> reported the efficacy of the LIFT for recurrent anal fistulas exclusively. They included 17 patients, including 9 males, with a mean age of 49 years. In total, 47% of the fistulas were located posteriorly. Eleven patients had more than two previous surgeries, and six patients had more than 3 surgeries. Only 4 patients had been placed a seton drainage previously (the mean time of latency until the LIFT was 15 mo). The healing rate reported was 76.4%, but only 65% of patients presented complete healing during the mean follow-up period of 13.5 mo. The operative time was 35 min. In addition, 41% of patients received an operation on an outpatient basis with a length of stay in the cohort of 1.4 d. Only 2 complications were reported (local hematoma and subcutaneous infections). In the follow-up, 2 patients developed a recurrence, and 1 patient had a sinus. The complete healing rate was 47%, and the incomplete healing rate was 13% (a total of 60%). In addition, 40% of patients had persistence or recurrent fistula. No *de novo* incontinence was reported.

There are two interesting studies that have attempted to expand the existing indications for the procedure. In the first, van Onkelen *et al*<sup>[21]</sup> described 22 patients who had low transsphincteric fistula. Thirteen patients were male, and the mean age of the cohort was 45 years. Of the 9 female patients, 8 had an anterior fistula, and 10 patients of the cohort had previously received an operation. The healing rate was 82%, with 4 down-stages to an intersphincteric fistula treated by simple lay open. With these patients, the final success rate was 100%. All of the female patients achieved complete healing using the first LIFT procedure. The mean follow-up period was 19.5 mo. There was no fecal incontinence reported (using the Rockwood fecal incontinence severity index). The same group raises the possibility of use in conjunction the ERAF and LIFT procedure to prevent recurrence due to infection at the residual tissue<sup>[22]</sup>. The researchers analyzed the results of a series with 41 patients (32 of them male). The mean age was 42 years. In total, 48% had received previous operations (3 ERAF procedures). The LIFT procedure was performed first followed by the ERAF. A healing rate of 51% was reported with a mean follow-up period of 15 mo. Of the failures, 12 of the failures had drainage in the external opening and the intersphincteric wound, and only 8 had drainage in the intersphincteric wound alone. This subgroup of patients was treated by lay open fistulotomy with a secondary healing rate of 71%.

With a new modification of the surgical technique, Sirikurnpiboon *et al*<sup>[23]</sup> compared the effectiveness of adding a partial fistulotomy until the external sphincter (called the LIFT-PLUS procedure) in a prospective study of 41 patients. A total of 20 patients underwent the LIFT procedure (with only curettage of the tract and widening of the external opening), and 21 underwent the LIFT-plus procedure. The average age of the population was 40.7 years. The healing rate achieved was 83%, with a mean follow-up period of 19 wk. The median wound healing time was 4 wk, and the mean time to recurrence was 12 wk. There was no incontinence reported. Morbidity cases included one anal fissure and one local bleeding in the LIFT-plus group and one anal fissure in the regular procedure group. There were 7 treatment failures: 4 in the LIFT group (3 recurrences and 1 sinus abscess) and 3 in the LIFT-plus group (2 recurrences and 1 intersphincteric fistula). All of these patients were healed using the same technique without morbidity or change in continence status. The healing rate by group was 81% in the LIFT-procedure and 85% in the LIFT-plus group, respectively ( $P = 0.0529$ ).

Lastly, a patient who underwent stapled hemorrhoid-ectomy and subsequently developed a remnant sinus tract that was successfully treated with the LIFT procedure<sup>[24]</sup>.

## COMPARISON OF THE RESULTS

In 1993, Matos *et al*<sup>[25]</sup> described a technique of excision of intersphincteric anal gland infection. They excised the

entire fistula tract, in addition to primary repair, by means of an intersphincteric approach by suturing the internal anal sphincter defect. Their success with 20 patients was only 45%. These poor results were attributed to blood supply issues that resulted in wound breakdown.

In the two studies comparing the ERAF against LIFT procedure, the results reported effectiveness of 94% *vs* 62.5% and 93% *vs* 92%, respectively<sup>[16,17]</sup>. In the former study, the follow-up was shorter for the ERAF group<sup>[16]</sup>. It is also important is the larger proportion of patients with previous fistula surgeries in the ERAF group, a possible selection bias. The reported success rate of the ERAF group was unusually higher than previously reported in other trials<sup>[26,27]</sup>. In these previous studies, the authors did not objectively evaluate functional outcomes. Nevertheless, there have been reports citing incontinence rates of up to 35% after ERAF<sup>[28]</sup>.

Not all studies specifically stated the types of fistulas treated. Although the procedure is theoretically ideal for high transsphincteric fistulas, the most common type of fistula was transsphincteric. In addition, van Onkelen *et al*<sup>[21]</sup> described the results of the procedure in the treatment of low transsphincteric fistulas. They reported a final and secondary healing rate of 100% without effect on continence. Bokhari *et al*<sup>[29]</sup> reported that major and minor incontinence after fistulotomy for low fistulas reached up to 5% and 11%, respectively. These authors noted that the other factors taken into account for a greater risk of incontinence are female sex and anterior fistulas or at-risk for obstetric history<sup>[29]</sup>. Garcia-Aguilar *et al*<sup>[30]</sup> reported major and minor incontinence after fistulotomy for low transsphincteric fistulas in 44% of their patients. They also observed that female sex and an internal opening located in the midline anteriorly were predictive factors of impaired continence after fistulotomy<sup>[30]</sup>. Cavanaugh *et al*<sup>[31]</sup> demonstrated that only the amount of external anal sphincter divided correlated with fecal incontinence in severity index scores. It appears possible that the division of the lower part of the external anal sphincter can be avoided in the treatment of transsphincteric fistula using the LIFT procedure.

Two studies reported the routine ligation of the primary internal orifice in their application of the LIFT technique<sup>[5,6]</sup>. During the LIFT procedure, Wallin *et al*<sup>[5]</sup> no-touched the primary opening in 87% of cases, ligated them in 8% of cases, performed a partial internal sphincterotomy in 4% of cases, used Alloderm<sup>®</sup> in 5% of cases and created a mucosal flap in 1% of cases. In a univariate analysis, only the use of biologic mesh displayed a tendency for healing, but the proportions of patients were scarce and did not reach statistical significance. In the study written by Aboulain *et al*<sup>[6]</sup>, the primary internal opening was closed in the mucosal side within the anal canal to prevent the entry of new infective agents. They achieved a healing rate of 68%.

Specifically, the use of a bioprosthetic mesh (Bio-LIFT procedure) reported a 94% success rate, and the use of a plug (LIFT-PLUG procedure) resulted in a reported

cure rate of 95%<sup>[11,18]</sup>. The BioLIFT technique has two potential disadvantages. First, it requires a more extensive dissection in the intersphincteric space. The physiologic consequences of this dissection have not been studied and are unknown. The second disadvantage of both techniques is the relatively high cost of the bioprosthetic materials. The healing time in the study that used the PLUG was 2 wk for the secondary external orifice and 4 wk for the intersphincteric wound (faster than previously reported)<sup>[18]</sup>. These series do not conclusively demonstrate a benefit that would justify the increased cost of the use of a bioprosthetic material. The addition of the partial excision of the fistula tract (partial fistulotomy) until the external anal sphincter is reached (LIFT-plus), or the use of both techniques (LIFT and ERAF procedures) simultaneously in the same patients, did not display any advantage<sup>[22,23]</sup>. To date, there have been no prospective randomized trials comparing the modifications made to the original technique.

Although most studies include a high percentage of previously treated patients, the results in a series of patients with only recurrent fistulas indicated a cure rate of 47%. The scarring following the resolution of the inflammatory post-surgical response can result in fibrosis and obliteration of the intersphincteric space. This makes the dissection in the intersphincteric plane difficult. Tan *et al*<sup>[6]</sup> concluded that given the simplicity of the LIFT procedure, clinicians should still perform the LIFT procedure in patients presenting for the first time and recommend the ERAF procedure in patients with multiple previous surgeries and a scarred perianal region.

Only one trial classified the therapeutic failures as early (80%) and late (20%)<sup>[7]</sup>. In this trial, Aboulain *et al*<sup>[6]</sup> recommended that in patients with persistent symptoms it may be prudent to observe and manage symptoms with local care up to 6 mo before planning for additional treatment. The researchers affirmed that it is important to individualize all cases because some patients may require earlier intervention if their symptoms worsen or develop significant sepsis<sup>[6,7]</sup>. Tan *et al*<sup>[6]</sup> considered that meticulous dissection along the intersphincteric plane while maintaining the integrity of the internal sphincter and the anal mucosa is critical. Any breach or button-hole of the anal canal mucosa during the procedure can lead to a higher risk of failure. Taking into account the classification previously described for recurrences and the results of 12 studies, nine cases were type 1 (blind sinus), thirty-two cases were type 2 (intersphincteric fistula) and forty-seven cases were type 3 (transsphincteric fistula)<sup>[4-7,12-14,16,17,21-23]</sup>. The recommended treatments are local measures for type-1 failures, fistulotomy for type-2 failures, and reperforming the LIFT procedure or ERAF procedures for type-3 recurrences.

The risk factors for failure were obesity, smoking, multiple previous surgeries and the length of the fistula track<sup>[7,15]</sup>. In a retrospective study, the healing rate for patients without previous surgery was 95%, whereas the rate for those with multiple surgeries was 65%<sup>[15]</sup>. A pre-

viously unreported finding was that for every one centimeter increase in fistula length, the odds ratio for healing decreased by 0.55 (95%CI: 0.34-0.88,  $P = 0.01$ ). In this study, the median length of fistula tract was shorter in the healed group compared with the failed group (4 cm *vs* 6 cm,  $P = 0.004$ ). After choosing 3 cm as an arbitrary cutoff point, fistula tracts under three centimeters had significantly higher primary healing (85% *vs* 48%,  $P = 0.04$ ). In addition, 66% of this cohort had a tract length of more than 3 cm<sup>[7]</sup>. van Onkelen *et al*<sup>[22]</sup> reported that a past history of previous surgeries, seton placement, lateral localization of primary opening and horseshoe extension showed a trend for recurrence. Sirikurnpiboon *et al*<sup>[23]</sup> described that body mass index was the only predictor factor for failure in a univariate analysis. Failure to identify the fistula tract occurred more often in obese patients with a body mass index of more than 30 kg/m<sup>2</sup> ( $P = 0.001$ ).

There were fourteen complications, which included anal fissures (4), bleeding (3), intersphincteric wound dehiscence (2), vaginal candidiasis (2), chronic anal pain (1), a thrombosed external hemorrhoid (1), and a subcutaneous infection (1). All these were mild and resolved with conservative treatment. It is important to mention that only four trials used a standardized scale to assess functional outcomes<sup>[12,18,21,22]</sup>. In summary, no de novo incontinence developed secondary to the LIFT procedure with an overall follow-up period of 42.3 wk.

Only 10 of 18 studies reported the use of a seton before LIFT procedure<sup>[5,7,11,13,14,16,17,20-22]</sup>. For the LIFT procedure to be effective, an epithelialized well-formed tract is advised. In theory, if the tract is inflamed or in the absence of enough granulation tissue, there may not be adequate tissue strength to permit ligation. However, Mitalas *et al*<sup>[32]</sup>, found no correlation between prior seton drainage and the presence of epithelium. None of the studies in this review indicated a benefit in using a seton before LIFT procedure.

## CONCLUSION

The currently available information indicates that the LIFT procedure is a feasible and effective surgical technique, with low impact on fecal continence. Its main indication is for transsphincteric fistulas in patients without previous surgery and with short fistula tracts. Patients with more complex fistulas, especially with multiple previous surgeries, should be considered for the ERAF procedure. There is a lack of evidence to recommend the combined use of prosthetic materials or to perform the combined LIFT-ERAF procedure. Further randomized controlled trials are needed to recommend routinely the LIFT procedure against other surgical techniques for anal fistulas.

### Abstract

**AIM:** To investigate the effects of phosphatase and tensin homolog deleted on chromosome 10 (PTEN) deficiency on the cytotoxicity of chemotherapeutic agents toward colorectal cancer cells.

**METHODS:** PTEN-deficient colorectal cancer (CRC) cells were generated by human somatic cell gene targeting using the adeno-associated virus system. The cytotoxic effects of compounds including curcumin, 5-fluorouracil (5-FU), dihydroartemisinin (DHA), irinotecan (CPT-11) and oxaliplatin (OXA) on cancer cells were determined using the MTT assay. Enhanced cytotoxicity of curcumin in PTEN-deficient CRC cells was observed, and this was confirmed using clonogenic assays. Apoptosis and cell cycle progression were analyzed by flow cytometry.

Levels of apoptosis and cell cycle-related proteins were examined by Western blotting.

**RESULTS:** We developed an isogenic set of CRC cell lines that differed only in their PTEN status. Using this set of cell lines, we found that disruption of the *PTEN* gene had no effect on the sensitivity of CRC cells to 5-FU, CPT-11, DHA, or OXA, whereas *PTEN* disruption increased the sensitivity of CRC cells to curcumin. Loss of PTEN did not alter the curcumin-induced apoptosis in CRC cells. However, PTEN deficiency led to an altered pattern of curcumin-mediated cell cycle arrest. In HCT116 *PTEN*<sup>+/+</sup> cells, curcumin caused a G2/M phase arrest, whereas it caused a G0/G1 phase arrest in HCT116 *PTEN*<sup>-/-</sup> cells. Levels of cell cycle-related proteins were consistent with these respective patterns of cell cycle arrest.

**CONCLUSION:** Curcumin shows enhanced cytotoxicity toward PTEN-deficient cancer cells, suggesting that it might be a potential chemotherapeutic agent for cancers harboring PTEN mutations.

**Key words:** Phosphatase and tensin homolog deleted on chromosome 10; Curcumin; Chemotherapeutic agents; Cell cycle; AKT signaling

**Core tip:** Phosphatase and tensin homolog deleted on chromosome 10 (PTEN) mutations lead to cancer progression and drug resistance. Chemotherapeutic agents with enhanced effectiveness against cancers with PTEN mutations are urgently required. In this study, we generated an isogenic set of human colorectal cancer cell lines that differed only in their PTEN status. We found that curcumin showed enhanced cytotoxicity in cancer cells deficient in PTEN. Importantly, PTEN deficiency led to an alteration in the pattern of curcumin-induced cell cycle arrest, which was associated with the PTEN/AKT/p21

pathway. Our findings suggest that curcumin is a potential chemotherapeutic agent for PTEN-mutant cancers.

Curcumin cytotoxicity is enhanced by PTEN disruption in colorectal cancer cells. *World J Gastroenterol* 2013; 19(40): 6814-6824 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6814.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6814>

## INTRODUCTION

Cancer is a leading cause of death worldwide and increasing attention has been focused on the strategies to reduce its incidence<sup>[1]</sup>. Chemotherapy is one of the main means of treating cancers; however, resistance to chemotherapeutic drugs remains a major obstacle to effective cancer therapy<sup>[2,3]</sup>. Therefore, novel intervention strategies to enhance the effectiveness of chemotherapeutic drugs and reduce their resistance are urgently required.

Cancer is caused by a series of genetic changes, including mutations in oncogenes and tumor suppressor genes<sup>[4]</sup>. Phosphatase and tensin homolog deleted on chromosome 10 (*PTEN*) is one of the most frequently mutated tumor suppressor genes in human cancers, after *p53*<sup>[5]</sup>. *PTEN* is involved in many important biological processes, including cell proliferation, growth, migration and death<sup>[6]</sup>. Germline mutations of *PTEN* result in several rare cancer predisposition syndromes, such as Cowden disease, Bannayan-Zonana syndrome, Proteus syndrome and Lhermitte-Duclos disease<sup>[7]</sup>. Mice heterozygous for *PTEN* develop spontaneous tumors in a number of organs<sup>[8]</sup>. Conditional deletion of the murine *PTEN* gene leads to tissue-specific tumorigenesis<sup>[9]</sup>. *PTEN* acts as a lipid phosphatase that antagonizes the phosphatidylinositol 3-kinase (PI3K) signaling by dephosphorylating phosphatidylinositol (3,4,5)-trisphosphate (PIP3) back to phosphatidylinositol (4,5)-bisphosphate (PIP2). Mutations in *PTEN* lead to constitutive activation of AKT kinase and other downstream effectors, and thus promote tumorigenesis<sup>[10]</sup>.

*PTEN* mutations are found in a number of human cancers, including cancers of the colon, breast, lung, liver, and lymphatic system<sup>[11-15]</sup>. The fact that mutated *PTEN* is present only in the cancer cells makes *PTEN* an appealing drug target for cancer treatment<sup>[16]</sup>. However, mutational inactivation of *PTEN* leads to cancer progression and chemotherapy resistance. Loss of *PTEN* expression is frequently observed in trastuzumab or tamoxifen-resistant breast cancers<sup>[17,18]</sup>. Drug resistance induced by *PTEN* deficiency is also observed in colorectal cancer (CRC). Loss of *PTEN* occurs in 35% of CRC<sup>[19]</sup>, and *PTEN*-deficient CRC cells are more resistant to cetuximab than *PTEN*-expressing cells<sup>[20]</sup>. In addition, loss of *PTEN* expression results in poor clinical outcome in CRCs treated with anti-EGFR therapy<sup>[21]</sup>. To identify

chemotherapeutic agents that could overcome resistance in *PTEN*-mutant CRC, we developed an isogenic set of human CRC cell lines that differed only in their *PTEN* status. Cytotoxicity analysis of these cell lines with several anti-cancer agents showed that curcumin had enhanced cytotoxicity towards CRC cells deficient in *PTEN*. Moreover, loss of *PTEN* expression led to a change in curcumin-induced cell cycle arrest patterns, which might be associated with *PTEN*-regulated AKT/p21 signaling. Our findings suggest that curcumin might have potential in the treatment of cancers with *PTEN* mutations.

## MATERIALS AND METHODS

### Cell culture

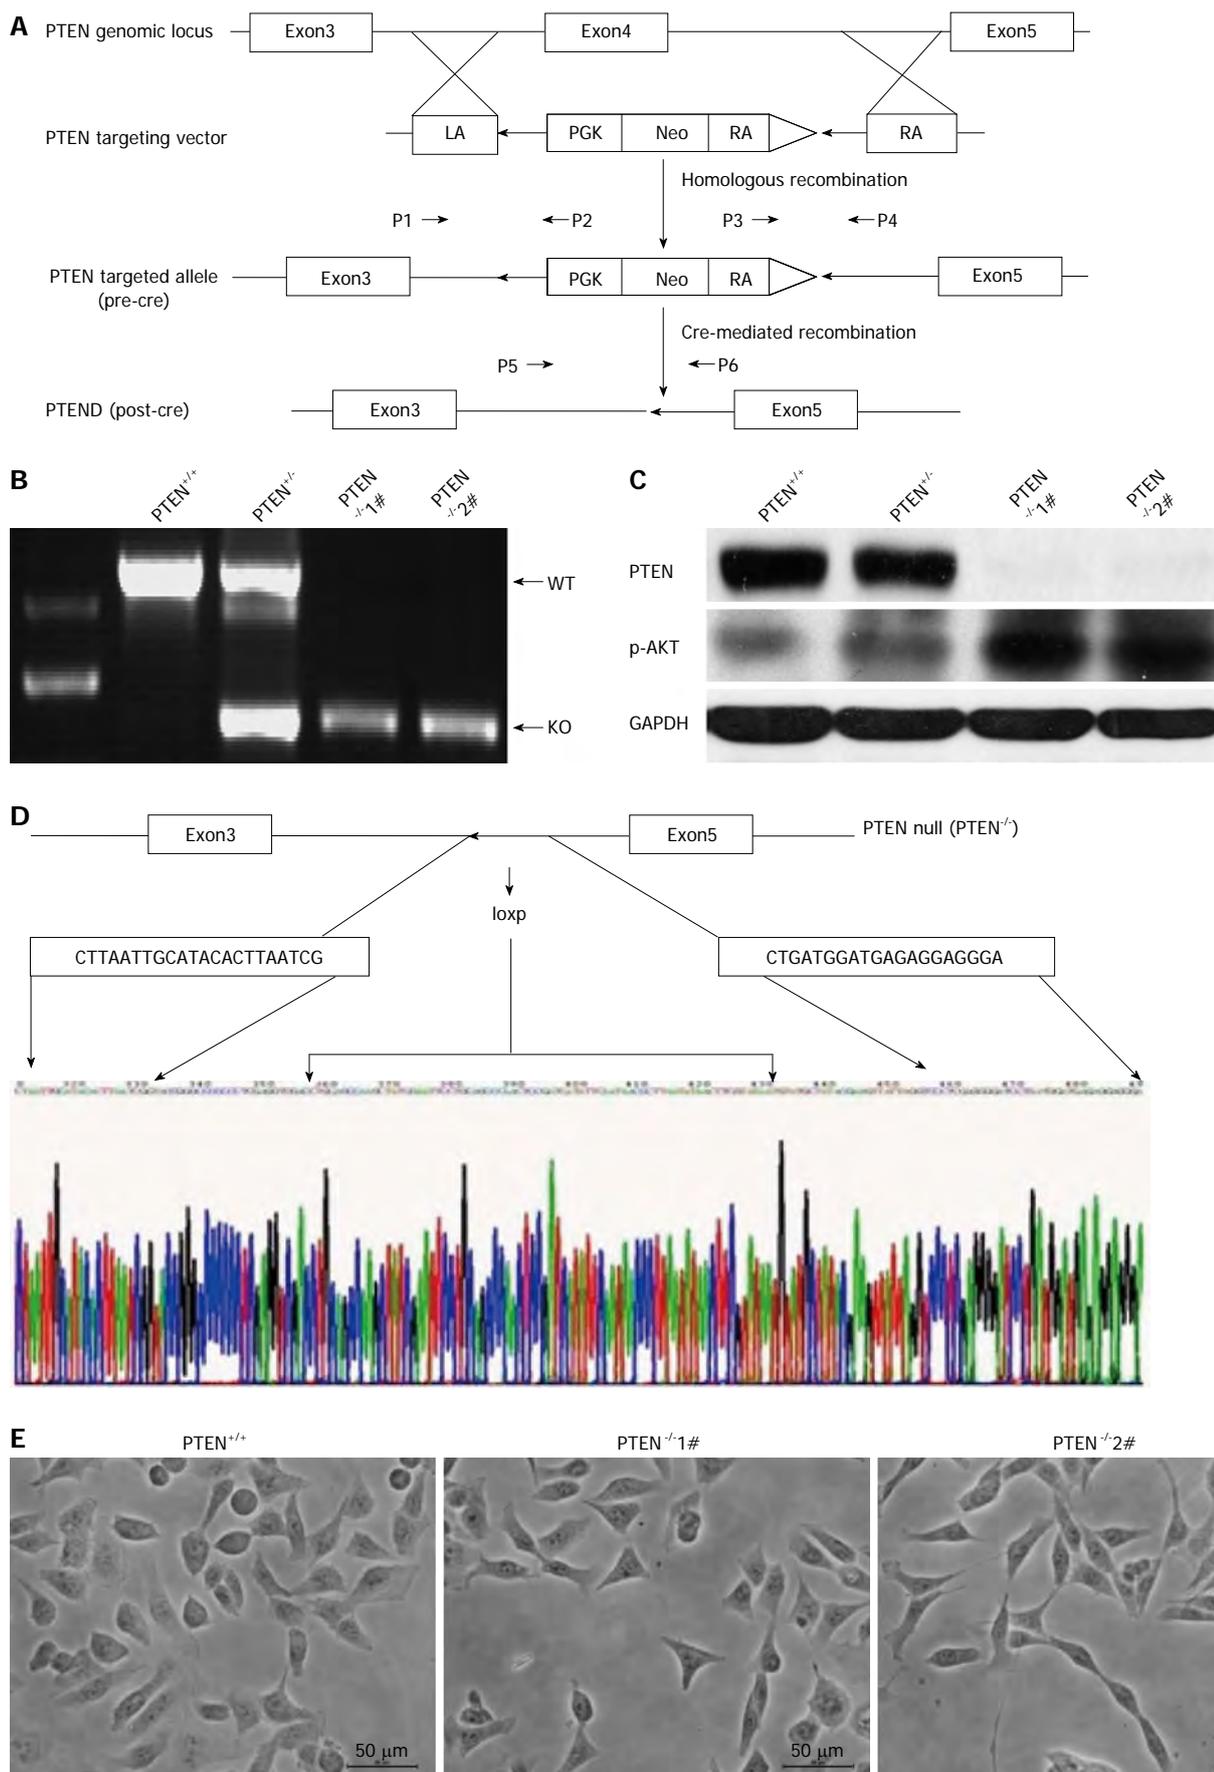

Human colon cancer HCT116 cells were obtained from the American Type Culture Collection (ATCC, Rockville, MD, United States). HCT116 *p53*<sup>-/-</sup> cells were kindly provided by Dr. Bert Vogelstein (The Johns Hopkins University, Baltimore, MD, United States). The cells were maintained in McCoy's 5A medium supplemented with 10% fetal bovine serum and 1% penicillin/streptomycin solution in a humidified incubator at 37 °C with 5% CO<sub>2</sub>. Cells harboring the targeting vector were grown in medium containing 1000 µg/mL G418.

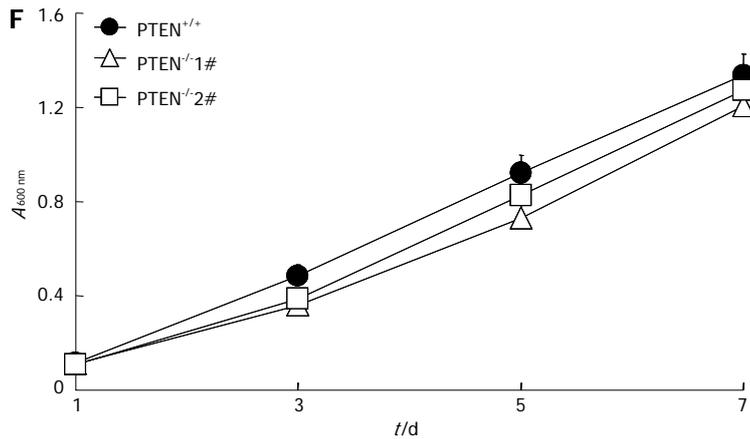

### Reagents and antibodies

Curcumin, 5-fluorouracil (5-FU), dihydroartemisinin (DHA), irinotecan (CPT-11), and oxaliplatin (OXA) were purchased from Sigma-Aldrich. *PTEN*, AKT (pan), phosphorylated AKT (p-AKT), p53, caspase 3, caspase 9, GAPDH, and beta-actin antibodies were obtained from Cell Signaling Technology. Bcl2, p21, p27, Cyclin B1, Cdc2, Cyclin D1, PARP and peroxidase-conjugated secondary antibodies were from Santa Cruz Biotechnology.

### Gene targeting in HCT116 cells

Human somatic cell gene targeting was performed using adeno-associated virus vectors. A *PTEN*-targeting vector was constructed to delete exon 4 of the *PTEN* gene in HCT116 cells. To create this vector, homology arms were amplified from a human genomic DNA template by polymerase chain reaction (PCR), sequentially cloned into the pMD18-T vector (TaKaRa) and sequenced. The constructed targeting vector was co-transfected with pHelper and pAAV-RC plasmids into HEK293 cells to obtain a *PTEN*-AAV viral stock that was used to infect HCT116 cells. After infection with recombinant virus, HCT116 cells were seeded in 96-well plates and selected with 1000 µg/mL G418 for 2 wk. Individual clones were obtained, expanded, cryopreserved, and tested by PCR for the presence of a heterozygous knockout. Heterozygous clones were transfected with the pCX-CRE plasmid, and then plated at a density of 200 cells/well in a 96-well plate to obtain single cell-derived clones. These clones were then screened by PCR to identify those in which the PGK-neo cassette had been deleted. Then the *PTEN*<sup>+/-</sup> cells were re-transfected with the *PTEN*-AAV virus, to obtain

**Figure 1 Gene targeting at the *PTEN* locus.** A: Schematic illustration of the strategy used to inactivate phosphatase and tensin homolog deleted on chromosome 10 (*PTEN*) by somatic cell gene targeting. The primers (P1, P2, P3, P4, P5, and P6) used for polymerase chain reaction (PCR)-based genotyping are indicated; B: Identification of the desired targeted clones by PCR. Primers P5 and P6 were used to amplify a 1,155-bp product from the wild-type *PTEN* allele and a 522-bp product from the final knockout allele, respectively; C: Western blotting analysis of *PTEN* expression; D: Confirmation of *PTEN* exon 4 deletion in *PTEN*-deficient cells by sequencing; E: Morphology of *PTEN*<sup>+/+</sup> and *PTEN*<sup>-</sup> cells. F: Determination of cell viability for *PTEN*<sup>+/+</sup> and *PTEN*<sup>-</sup> cell lines using the MTT assay. *PTEN*<sup>-1#</sup> and *PTEN*<sup>-2#</sup> are two *PTEN* knockout clones. LA: Left arm; RA: Right arm; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

clones in which both *PTEN* alleles had been targeted.

### MTT assays

Cell viability was determined using the MTT assay, as described previously<sup>[22]</sup>. Briefly, *PTEN*<sup>+/+</sup> and *PTEN*<sup>-</sup> cells were seeded in 96-well plates in triplicate. At the indicated time points, 10  $\mu$ L 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT, Sigma) stock solution (5 mg/mL) was added to each well. Plates were incubated at 37 °C for another 4 h. The medium was carefully removed and the formazan produced was dissolved in dimethyl sulfoxide (DMSO). The absorbance was measured at a wavelength of 570 nm on a microplate reader (BioRad Model 550). To test the compounds for cytotoxic effects, cells were seeded at a density of  $1 \times 10^4$  cells/well in 96-well plates and cultured for 24 h. One-hundred microliters of medium supplemented with twice the desired concentration of compounds was then added to each well. After incubation for 72 h, MTT solution was added. Four hours later, formazan production was measured as described earlier. The viability was calculated as % viability = (OD of treated cells/OD of control cells)  $\times$  100.

### Clonogenic assays

A total of 1000 cells were plated in 6-well plates, in triplicate, and incubated for 24 h to allow cells to adhere. After treatment with 10- $\mu$ mol/L curcumin or 0.1% DMSO for 48 h, cells were carefully washed and drug-free medium was added. The plates were incubated at 37 °C for 10-12 d and stained with 0.5% (w/v) crystal violet. Colonies containing more than 50 cells were scored as positive. The experiment was performed at least three times using triplicate cultures.

### Apoptosis analysis

Curcumin-induced apoptosis was quantified by flow cy-

tometry using the Annexin V-FITC Apoptosis Detection kit according to the manufacturer's instructions. Briefly,  $5 \times 10^5$  cells were seeded in 6-well plates and treated with 10- $\mu$ mol/L curcumin or 0.1% DMSO for 48 h prior to analysis. Floating and trypsinized adherent cells were collected, washed with PBS, and resuspended in cold binding buffer. After incubation for 15 min in the dark at 4 °C, 10  $\mu$ L of Annexin V-FITC and 5  $\mu$ L of propidium iodide (PI) solution were added. Samples were analyzed using an FACS-Calibur cytometer (Becton Dickinson).

### Cell cycle analysis

A total of  $5 \times 10^5$  cells were seeded in 6-well plates and treated with 10- $\mu$ mol/L curcumin or 0.1% DMSO for 48 h. Then, the cells were harvested by centrifugation at 1000 rpm for 5 min. Cell pellets were washed twice with PBS, fixed with ice-cold 70% ethanol and stored at -20 °C overnight. Then, the pellets were washed with cold PBS, suspended in 500 mL PBS containing 50 mg/mL PI, 0.1 mg/mL RNase A and 0.05% Triton X-100, and incubated at 37 °C for 40 min in the dark. The cell cycle distribution was determined by flow cytometry (FACSCalibur; Becton Dickinson). The experiment was repeated thrice under the same conditions.

### Western blotting analysis

Cells were grown to 90% confluence in a 6-well plate. After washing twice with PBS, cells were resuspended and lysed in cold lysis buffer (50 mol/L Tris/HCl, pH 7.4, 5 mol/L EDTA, 0.5% NP-40, 150 mol/L NaCl) supplemented with the Protease/Phosphatase Inhibitor Cocktail (Cell Signaling Technology). After incubation on ice for 20 min, the lysate was centrifuged at 12000 rpm for 20 min at 4 °C, and the supernatant was collected. Protein concentration was determined using the Bradford assay (Bio-Rad, Hercules, CA, United States). Equal amounts of total protein were separated by SDS-PAGE and trans-

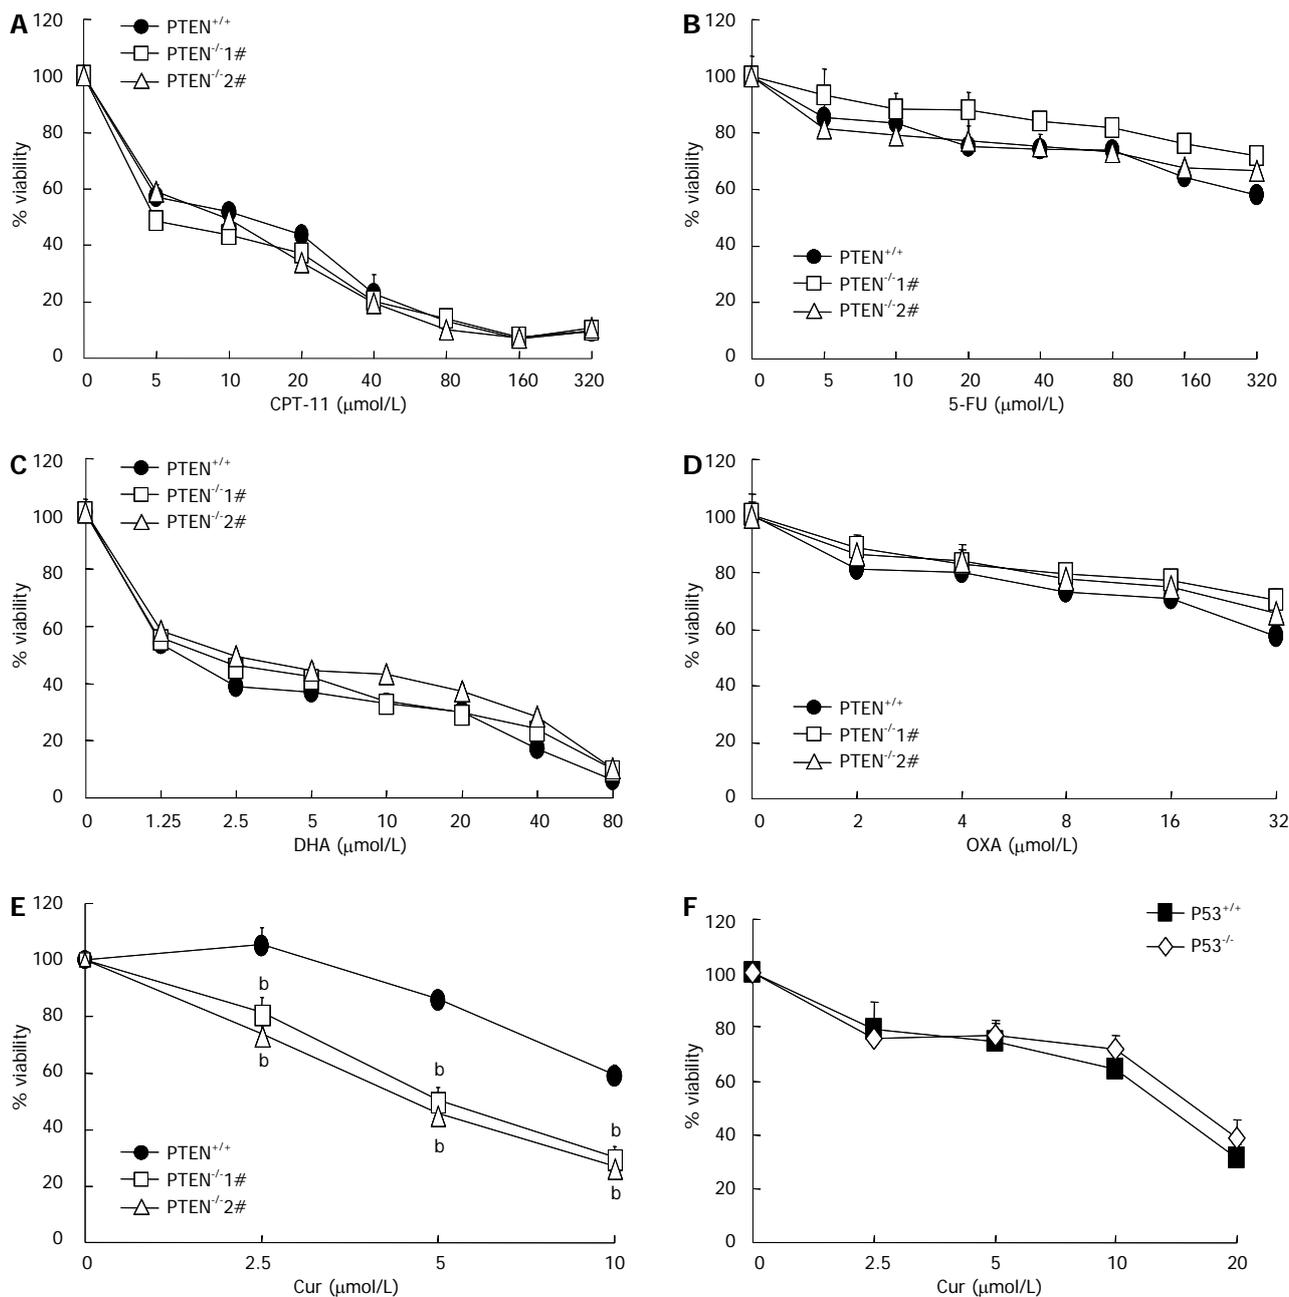

Figure 2 Curcumin shows enhanced cytotoxicity toward *PTEN*-deficient cells. A-E: Cytotoxic effects of irinotecan (CPT-11), 5-fluorouracil (5-FU), dihydroartemisinin (DHA), oxaliplatin (OXA) and curcumin (Cur) on cell viability of HCT116 phosphatase and tensin homolog deleted on chromosome 10 (*PTEN*<sup>+/+</sup> and *PTEN*<sup>-</sup> cells were determined using the MTT assay; F: Cytotoxic effects of curcumin (Cur) on HCT116 *p53*<sup>+/+</sup> and *p53*<sup>-/-</sup> cells (<sup>b</sup>*P* < 0.01 vs control group).

ferred onto polyvinylidene difluoride membranes (Bio-Rad, Hercules, CA, United States). After blocking in 5% milk in TBST [10 mol/L Tris/HCl pH 7.4, 150 mol/L NaCl, and 0.1% (v/v) Tween-20], the membranes were incubated with primary antibodies, followed by secondary antibodies. Protein bands were visualized using an ECL system (Amersham Biosciences, United States).

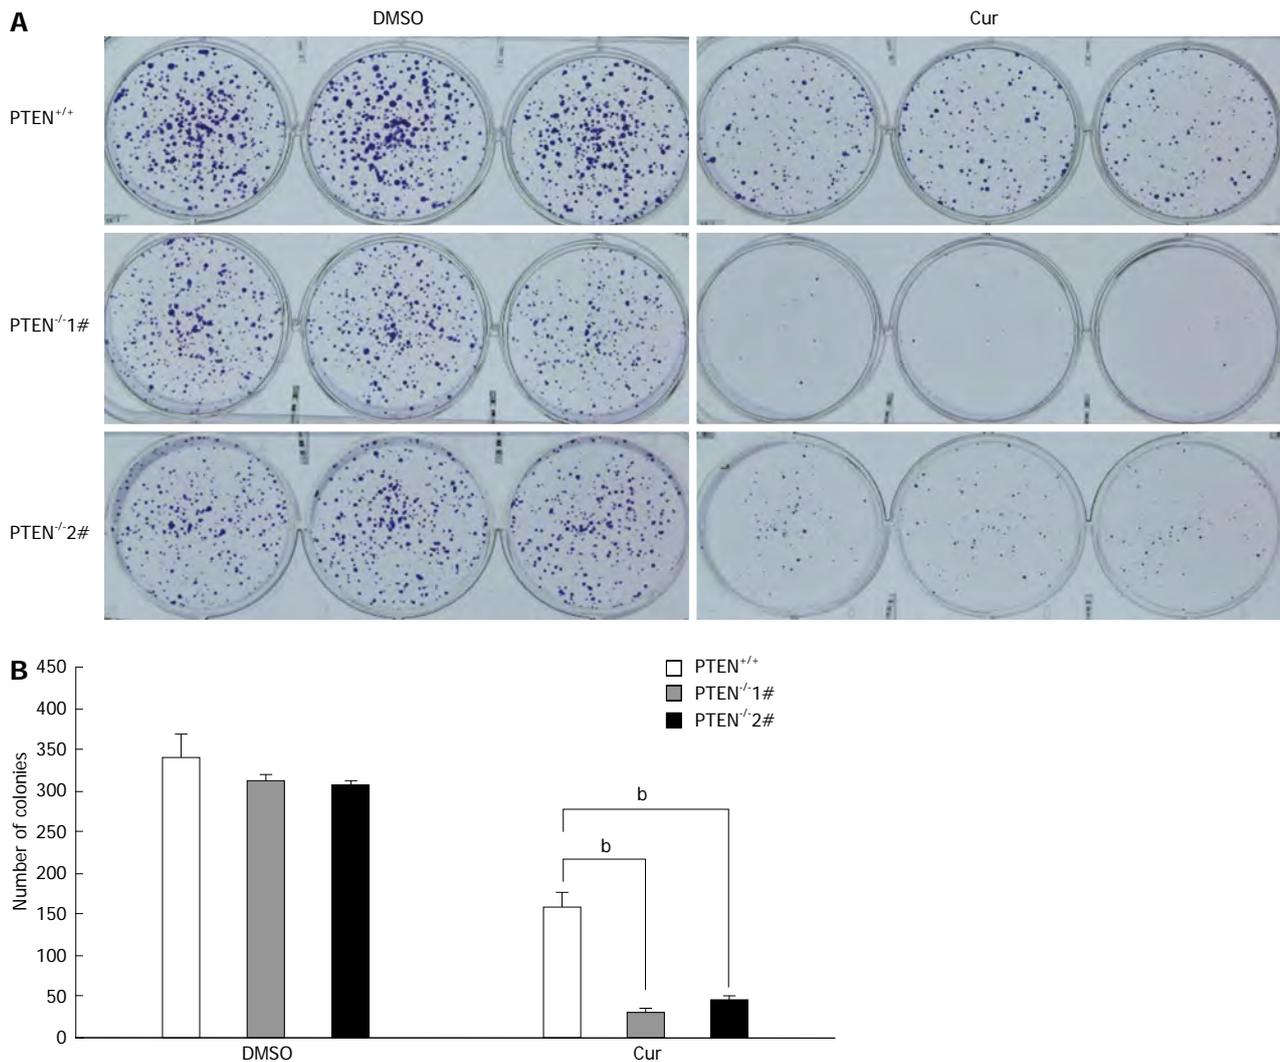

**Statistical analysis**

Data were summarized using means ± SD. Statistical comparisons were made using the Student's *t*-test. *P*-values of less than 0.05 were considered statistically significant.

**RESULTS**

**Targeted deletion of *PTEN* in colorectal cancer cells**

Recombinant adeno-associated virus vectors were used to disrupt the endogenous *PTEN* gene in a near-diploid colon cancer cell line, HCT116, containing two wild-type alleles of *PTEN*. Targeting was directed to the exon 4 of *PTEN*, which resulted in a frame-shift mutation and thus a loss of *PTEN* expression. The detailed strategy is depicted in Figure 1A. The first allele of *PTEN* was disrupted by homologous recombination with the *PTEN*-targeting vector. The *PTEN*<sup>+/−</sup> clones were confirmed

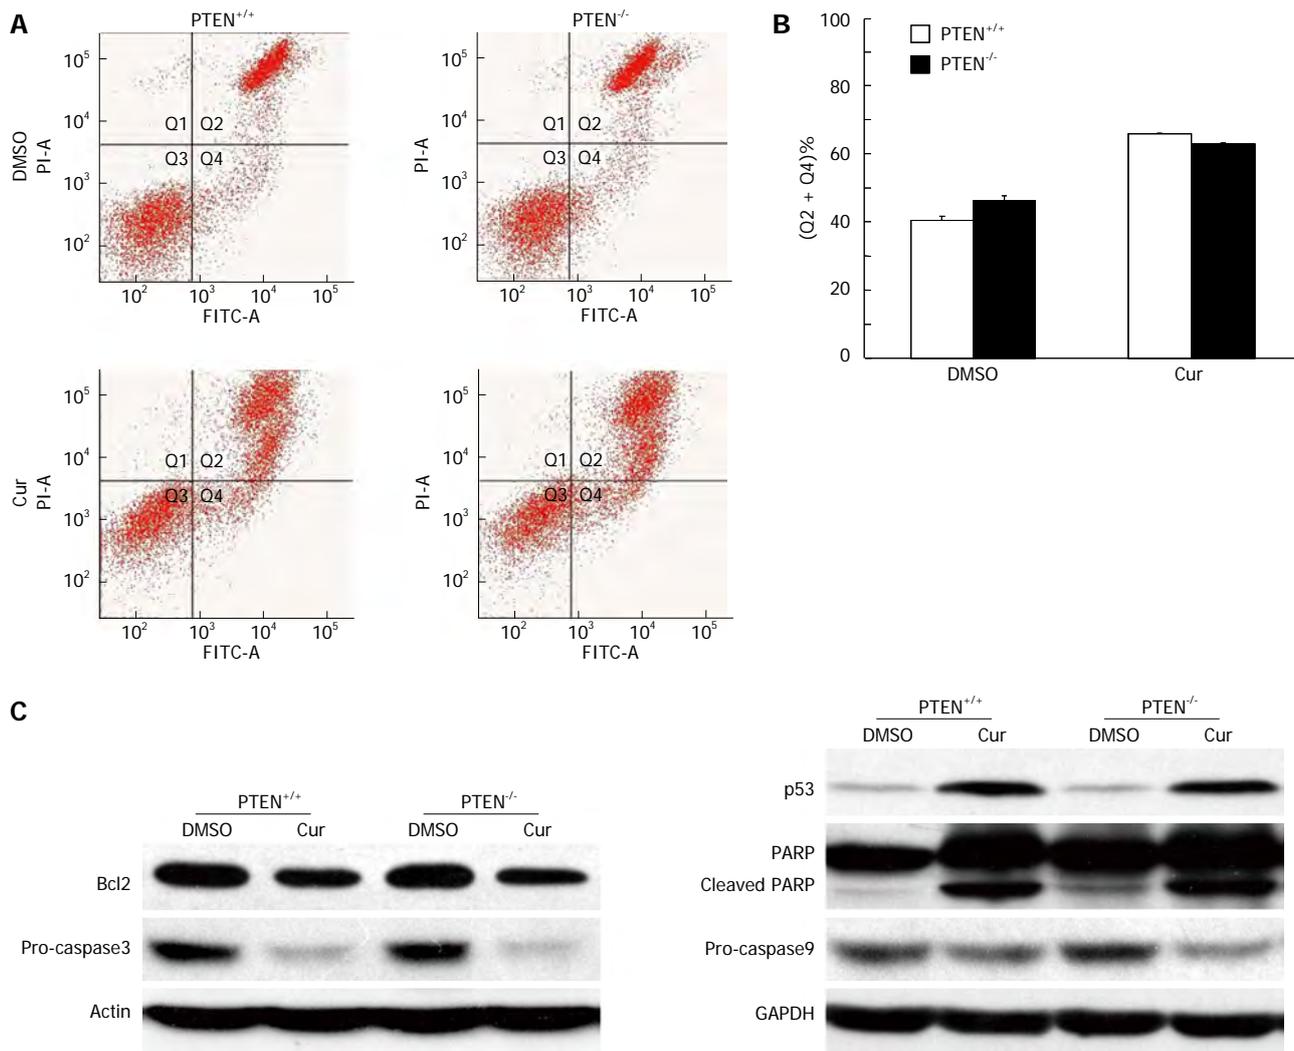

**Figure 3** Curcumin has an increased growth-inhibitory effect on *PTEN*-deficient cells in clonogenic assays. **A:** Photographs of clonogenic assay plates; **B:** Histograms showing clonogenic assay results (<sup>a</sup>*P* < 0.01 vs control group). Cur: Curcumin.

by PCR and transiently exposed to Cre recombinase, mediating the excision of the internal neomycin selection cassette flanked by loxP sites. A *PTEN*<sup>+/+</sup> clone was then used to generate *PTEN*<sup>-/-</sup> cells *via* a second round of recombination with the *PTEN*-targeting vector. The absence of *PTEN* mRNA in *PTEN*<sup>-/-</sup> clones was verified by PCR (Figure 1B). Western blotting analysis confirmed a decrease in *PTEN* levels in *PTEN*<sup>-/-</sup> cells and a complete loss of *PTEN* expression in *PTEN*<sup>-/-</sup> clones, which was accompanied by increased AKT phosphorylation (Figure 1C). Deletion of exon 4 of the *PTEN* gene was further verified by sequencing (Figure 1D). The *PTEN*<sup>-/-</sup> cells displayed a similar morphology to the parental *PTEN*<sup>+/+</sup> cell line (Figure 1E). The effect of *PTEN* deficiency on the viability of HCT116 cells was assessed using the MTT assay. However, no significant difference in cell growth characteristics was observed between *PTEN*<sup>+/+</sup> and *PTEN*<sup>-/-</sup> cells (Figure 1F).

#### Curcumin shows enhanced cytotoxicity toward *PTEN*-deficient cancer cells

*PTEN* acts as a tumor suppressor and its status is as-

sociated with sensitivity to chemotherapeutic agents<sup>[23,24]</sup>. Therefore, we investigated whether *PTEN* disruption affected the cytotoxicity of several clinical drugs and natural anti-cancer compounds. The *PTEN*-deficient cells and isogenic *PTEN* positive cells were exposed to increasing concentrations of anti-cancer compounds and their viability was determined. Disruption of the *PTEN* gene had no effect on the sensitivity of HCT116 cells to 5-FU, CPT-11, DHA, or OXA (Figure 2A-D). Surprisingly, *PTEN*-deficient cells were more sensitive to curcumin as compared with the parental *PTEN*<sup>+/+</sup> cells. The IC<sub>50</sub> value of curcumin for HCT116 *PTEN*<sup>-/-</sup> cells was approximately 2-fold lower than that for *PTEN*<sup>+/+</sup> cells (Figure 2E). Next, we determined whether curcumin also showed increased cytotoxicity toward HCT116 cells deficient in p53. However, we found that disruption of p53 had no effect on the sensitivity of HCT116 cells to curcumin (Figure 2F). The fact that *PTEN* deficiency resulted in increased sensitivity of HCT116 cells to curcumin was further confirmed using a clonogenic assay. Following curcumin exposure, a significantly smaller number of colonies was observed with HCT116 *PTEN*<sup>-/-</sup>

**Figure 4** *PTEN* deficiency does not enhance curcumin-induced apoptosis. **A**: Images showing flow cytometric analysis of apoptosis. Apoptosis was analyzed by flow cytometry with the Annexin V-FITC kit; **B**: Histograms showing apoptosis assay results. Phosphatase and tensin homolog deleted on chromosome 10 (*PTEN*) deletion did not result in increased apoptosis following curcumin treatment; **C**: Western blotting analysis. Cell lysates were separated on SDS-PAGE, transferred to polyvinylidene difluoride membranes, and incubated with indicated antibodies. Cur: Curcumin; PI: Propidium iodide; FITC: Fluorescein isothiocyanate; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

cells than with *PTEN*<sup>+/+</sup> cells (Figure 3). Together, these results suggest that curcumin exhibits enhanced cytotoxicity toward HCT116 cells deficient in *PTEN*.

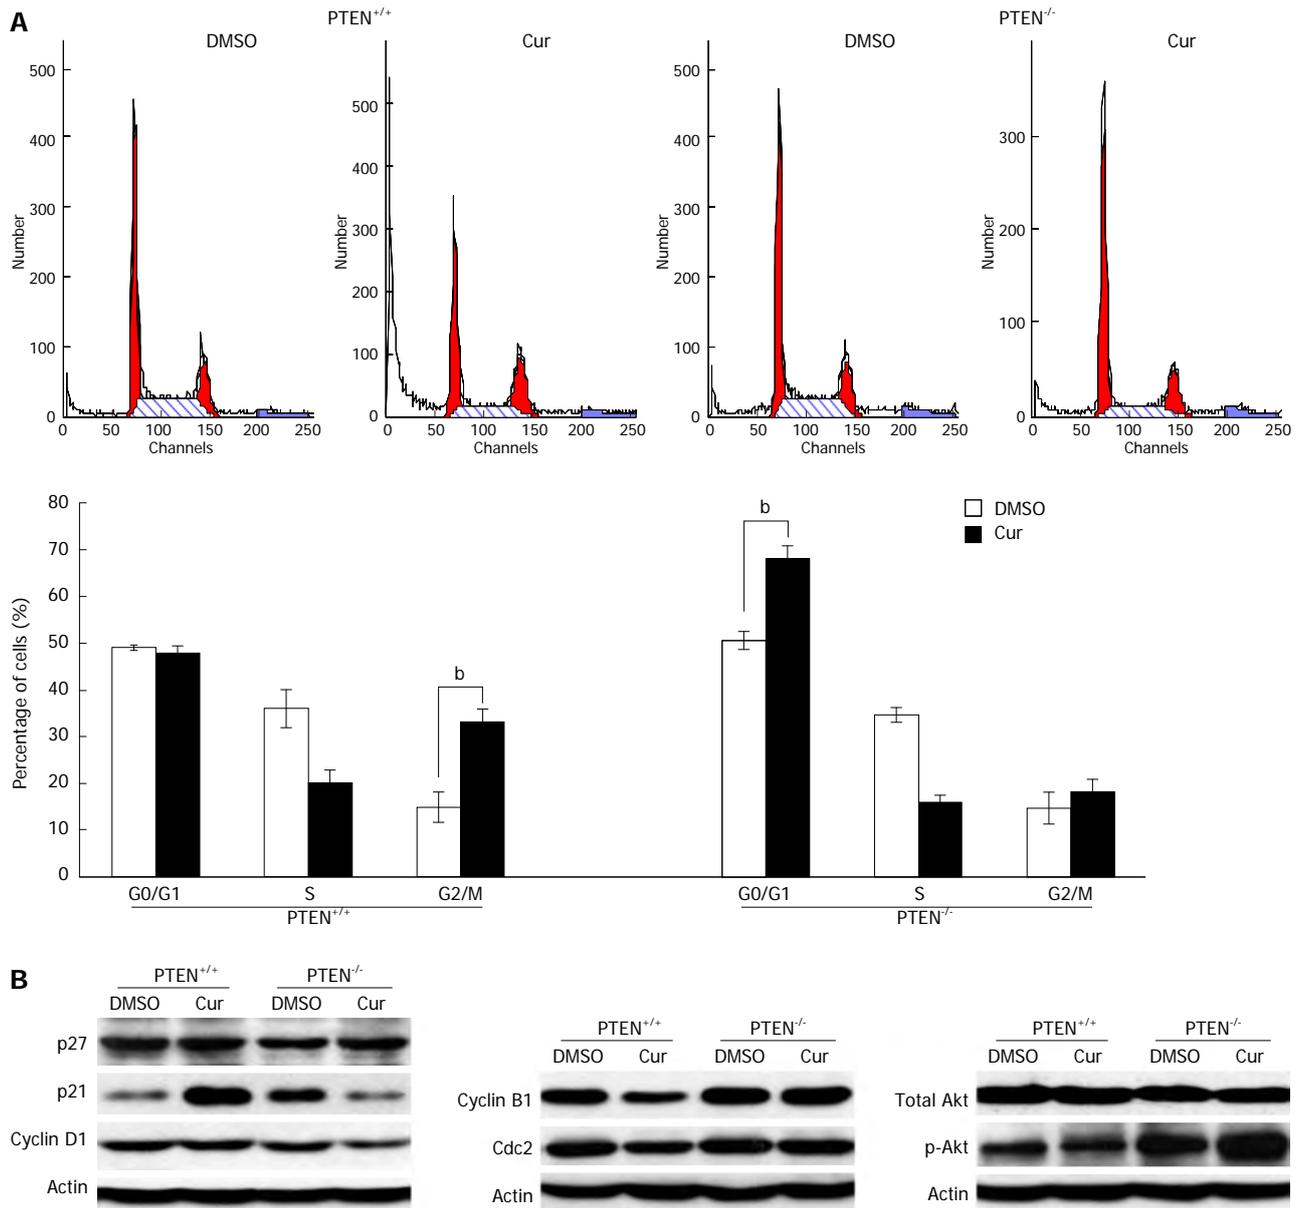

***PTEN* deficiency does not increase curcumin-induced apoptosis**

Curcumin treatment induces cell apoptosis<sup>[25]</sup>. To understand the molecular mechanism underlying the increased cytotoxicity of curcumin toward *PTEN*-deficient CRC cells, we tested whether *PTEN* loss resulted in increased curcumin-mediated apoptosis. Using flow cytometric analysis with FITC-labeled annexin V and propidium iodide staining, we observed significantly increased apoptosis in both HCT116 *PTEN*<sup>+/+</sup> and *PTEN*<sup>-/-</sup> cells after curcumin exposure. However, the apoptotic index was not affected by disruption of the *PTEN* gene, being similar in *PTEN*<sup>+/+</sup> and *PTEN*<sup>-/-</sup> cells (Figure 4A and B). In accordance with these results, the expression patterns of apoptosis-related proteins, such as Bcl-2, procaspase 3 and 9, p53 and PARP were similar in both cell lines fol-

lowing curcumin exposure (Figure 4C). Therefore, these data suggest that the enhanced cytotoxicity of curcumin toward *PTEN*<sup>-/-</sup> colon cancer cells is not due to an increase in curcumin-induced apoptosis.

***PTEN* deficiency results in altered curcumin-induced cell cycle arrest**

Next, we tested whether the enhanced cytotoxicity of curcumin to *PTEN*-deficient cells was caused by altered cell cycle progression. Consistent with a previous report<sup>[26]</sup>, we found that curcumin exposure led to a marked G2/M phase cell cycle arrest in HCT116 cells with wild-type *PTEN* (Figure 5A). Surprisingly, in *PTEN*<sup>-/-</sup> cells, curcumin treatment resulted in a significant accumulation of cells in G0/G1 phase, characteristic of a G0/G1 phase arrest (Figure 5A). To explore the mechanism underlying the altered cell cycle arrest pattern, we investigated the expression of proteins related to AKT signaling and the cell cycle. Curcumin exposure marginally reduced AKT phosphorylation and significantly induced p21 ex-

**Figure 5** Loss of *PTEN* alters curcumin-mediated cell cycle arrest. **A:** Cell cycle distributions of phosphatase and tensin homolog deleted on chromosome 10 (*PTEN*<sup>+/+</sup> (left) and *PTEN*<sup>-/-</sup> (right) cell samples were analyzed by flow cytometry (<sup>b</sup>*P* < 0.01 vs control group); **B:** Western blotting analysis. Whole cell lysate isolated from *PTEN*<sup>+/+</sup> and *PTEN*<sup>-/-</sup> cells were separated on sodium dodecyl sulfate-polyacrylamide gel electrophoresis, transferred to polyvinylidene difluoride membranes, and incubated with the indicated antibodies. Cur: Curcumin.

pression in HCT116 cells harboring wild-type *PTEN*. Interestingly, the opposite results were observed in HCT116 *PTEN*<sup>-/-</sup> cells, which showed a significant induction of AKT phosphorylation. Curcumin exposure further elevated this increase in AKT phosphorylation, which was accompanied by a significant reduction in p21 expression (Figure 5B). In agreement with the differential expression of p21 in curcumin-treated *PTEN*<sup>+/+</sup> and *PTEN*<sup>-/-</sup> cells, we observed a down-regulation of Cyclin B1 and Cdc2 in *PTEN*<sup>+/+</sup> cells, whereas decreased expression of Cyclin D1 was observed in *PTEN*<sup>-/-</sup> cells (Figure 5B), consistent with their respective patterns of cell cycle arrest. p27 is another known regulator of G0/G1 phase; however, we observed no difference in its expression levels between the *PTEN*<sup>+/+</sup> and *PTEN*<sup>-/-</sup> cells following curcumin

exposure (Figure 5B). Together, these data suggest that the enhanced cytotoxicity of curcumin caused by *PTEN* deficiency might be due to an altered pattern of cell cycle arrest that is related to the *PTEN*/AKT/p21 pathway.

## DISCUSSION

*PTEN* is a tumor suppressor gene that is frequently mutated in human colorectal cancers. *PTEN* functions as a lipid phosphatase that negatively regulates PI3K/AKT signaling, which is critical for cell proliferation, apoptosis, and cell cycle progression<sup>[27]</sup>. *PTEN* mutations result in aberrant activation of the AKT pathway, facilitating cancer progression and causing drug resistance in CRC<sup>[28,29]</sup>. Therefore, chemotherapeutic agents, such as natural

products and synthetic compounds, that can enhance therapeutic efficacy for CRC with PTEN mutations, are urgently needed. In the present study, we found that curcumin showed enhanced cytotoxicity toward CRC cells deficient in PTEN. This intriguing finding indicates that curcumin might be applied alone or in combination with other chemotherapeutic agents for the therapy of PTEN-mutant cancers.

Curcumin is a natural pigment extracted from the roots of the turmeric plant (*Curcuma longa*). In addition to its anti-oxidative and anti-inflammatory properties, curcumin inhibits cell proliferation in a number of cancer cell lines, including those derived from colon, breast, lung and bladder cancers<sup>[30-33]</sup>. Moreover, curcumin inhibits tumorigenesis *in vivo*. It has been shown that curcumin effectively prevents tumor implantation and growth in mice, and suppresses the development of bladder cancer in a rat model<sup>[34,35]</sup>. Mechanistic studies demonstrated that curcumin targets a number of molecules, including apoptosis-related proteins such as Bcl-2, caspase 3 and 9, as well as cell cycle regulators<sup>[36,37]</sup>. In this study, we report for the first time that the enhanced cytotoxicity of curcumin toward PTEN-deficient cells is not due to an increase in apoptosis, but rather to altered cell cycle arrest patterns, from the G2/M phase arrest seen in *PTEN*<sup>+/+</sup> cells to a G0/G1 phase arrest in *PTEN*<sup>-/-</sup> cells.

The *PTEN*<sup>+/+</sup> and *PTEN*<sup>-/-</sup> cells used in this study differ only in their PTEN status. Since PTEN is an upstream regulator of AKT signaling, the differential effects of curcumin on cells with and without PTEN might be associated with altered AKT signaling. Consistent with this hypothesis, we observed differences in curcumin-induced AKT phosphorylation in *PTEN*<sup>+/+</sup> and *PTEN*<sup>-/-</sup> cells. In contrast to the slight decrease observed in p-AKT in *PTEN*<sup>+/+</sup> cells, p-AKT was significantly increased in *PTEN*<sup>-/-</sup> cells after curcumin exposure. p21 is a well-known downstream effector of AKT signaling. p-AKT can phosphorylate p21 and restrict it to the cytoplasm for degradation<sup>[38]</sup>. In accordance with this, p21 expression was significantly increased in *PTEN*<sup>+/+</sup> cells, but markedly decreased in *PTEN*<sup>-/-</sup> cells following curcumin exposure. Consequently, the increased expression of p21 led to a down-regulation of Cyclin B1 and Cdc2 and thus a G2/M phase arrest in *PTEN*<sup>+/+</sup> cells, which is consistent with a previous study<sup>[39]</sup>. Despite its function as a negative regulator of the cell cycle, p21 can also positively regulate cell cycle progression by serving as an assembly factor for the Cyclin D/Cdk4 complex and facilitating the transition from G1 phase to S phase<sup>[40-42]</sup>. Consistent with this role, we observed a decrease in p21 expression, accompanied by a reduced level of Cyclin D1 and G0/G1 arrest in *PTEN*<sup>-/-</sup> cells after curcumin exposure. Based on our findings, we speculate that PTEN deficiency alters AKT signaling and thus the expression of p21 induced by curcumin, and that this alteration results in an increased G0/G1 phase arrest, which may account for the enhanced curcumin sensitivity of PTEN-deficient cells. Our results suggest that p21 is a potential regulator in the enhanced cytotoxicity of curcumin toward PTEN-

deficient cells; however, the detailed mechanism remains to be elucidated.

In conclusion, we have shown that curcumin exhibits increased cytotoxicity toward PTEN-deficient cancer cells, and the underlying mechanism might involve cell cycle arrest alterations that are associated with the PTEN/AKT/p21 pathway. These findings also suggest that curcumin might potentially contribute to the therapy of PTEN-mutated cancers.

## COMMENTS

### Background

Resistance to chemotherapeutic drugs remains a major obstacle to the effective treatment of cancers. Phosphatase and tensin homolog deleted on chromosome 10 (*PTEN*) is one of the most frequently mutated tumor suppressor genes in human cancers. Accordingly, mutational inactivation of PTEN leads to cancer progression and chemotherapy resistance. Therefore, chemotherapeutic agents with greater efficacy for cancer with PTEN mutations are urgently required.

### Research frontiers

Curcumin is a major yellow-colored dietary pigment from *Curcuma longa*. Curcumin has demonstrated anticancer properties in various cancers, including colon cancer. This study analyzes the possible effects of curcumin on colorectal cancer cells with PTEN deficiency.

### Innovations and breakthroughs

By gene targeting *PTEN* in HCT116 cells we created PTEN null HCT116 cells, which are isogenic to the PTEN positive HCT116 parental cell line. The authors found that PTEN null cells exhibited greater sensitivity to curcumin than PTEN positive cells. The authors further established that this difference was not due to an increase in apoptosis, but the result of altered cell cycle arrest induced by curcumin in PTEN null cells.

### Applications

Curcumin is a potential chemotherapeutic agent for PTEN mutant cancers, and could be used in individualized cancer therapy. The PTEN-deficient cell line might be a useful tool for screening chemotherapeutic agents against PTEN-mutant cancers.

### Terminology

The PI3K/AktKT pathway is an intracellular signaling pathway important for cell growth, survival, cell cycle progression, and apoptosis.

### Peer review

This is the first report of the effects of PTEN deficiency on the cytotoxicity of curcumin for colorectal cancer cells. The authors found that PTEN deficiency affects the cytotoxicity of curcumin on HCT116 cells. Upon further investigation they found that this effect is related to increased G0/G1 arrest but not to increased apoptosis. The manuscript is consistent and well structured.

### Abstract

**AIM:** To explore the physiopathology and magnetic resonance imaging (MRI) findings in an animal model of acute arterial mesenteric ischemia (AAMI) with and without reperfusion.

**METHODS:** In this study, 8 adult Sprague-Dawley rats

underwent superior mesenteric artery (SMA) ligation and were then randomly divided in two groups of 4. In group I, the ischemia was maintained for 8 h. In group II, 1-h after SMA occlusion, the ligation was removed by cutting the thread fixed on the back of the animal, and reperfusion was monitored for 8 h. MRI was performed using a 7-T system.

**RESULTS:** We found that, in the case of AAMI without reperfusion, spastic reflex ileus, hypotonic reflex ileus, free abdominal fluid and bowel wall thinning are present from the second hour, and bowel wall hyperintensity in T2-W sequences are present from the fourth hour. The reperfusion model shows the presence of early bowel wall hyperintensity in T2-W sequences after 1 h and bowel wall thickening from the second hour.

**CONCLUSION:** Our study has shown that MRI can assess pathological changes that occur in the small bowel and distinguish between the presence and absence of reperfusion after induced acute arterial ischemia.

**Key words:** Acute arterial mesenteric ischemia; Reperfusion; Magnetic resonance imaging; Animal model; Superior mesenteric artery; Bowel ischemia

**Core tip:** Diagnosis of acute arterial mesenteric ischemia depends on early detection and findings with regarding the presence or absence of reperfusion events. Distinguishing between these different conditions is crucial to improving outcome for the patient and represents a challenge for radiologists. The results of this preliminary study in an animal model provide for a time-based definition of the radiological findings in ischemia and reperfusion, showing that magnetic resonance imaging can adequately assess the different pathological changes that occur in acute arterial mes-

## enteric ischemia with or without reperfusion.

Acute arterial mesenteric ischemia and reperfusion: Macroscopic and MRI findings, preliminary report. *World J Gastroenterol* 2013; 19(40): 6825-6833 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6825.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6825>

## INTRODUCTION

Mesenteric ischemia can have various causes<sup>[1]</sup>. One of the most threatening conditions is acute arterial mesenteric ischemia (AAMI), which is characterized by the acute occlusion of the arteries feeding the small bowel<sup>[2]</sup>. AAMI is considered a vascular emergency with a mortality rate of up to 60%-80%<sup>[3]</sup>.

Mortality of patients with AAMI most likely remains high because ischemic changes of the abdominal organs are most frequently detected and diagnosed at a late stage when therapy is ineffective<sup>[4,5]</sup>. Multi-detector computed tomography angiography is currently considered the gold-standard for imaging mesenteric and colonic ischemia<sup>[6,7]</sup>. However, recent papers have shown that magnetic resonance imaging (MRI) has significant potential for detecting subtle changes that may affect the intestinal wall during the ischemic process<sup>[8]</sup>.

Recently, some researchers<sup>[9]</sup> assessed the evolution of ischemic lesions using 7 Tesla-magnetic resonance imaging (7T-MRI) in an animal model of acute colonic ischemia. This work demonstrated that MRI can be used as a reliable diagnostic and grading technique in acute ischemic colitis, which would allow for the early identification of pathology.

The purpose of this study was to explore physiopathology and MRI findings of mesenteric ischemia in an animal model, with and without reperfusion, to define semiological changes of mesenteric ischemia from both a macroscopic and MRI point-of-view.

## MATERIALS AND METHODS

### *Animal preparation*

All procedures performed on animals were approved by the Animal Care and Use Committee of the Biotechnology Center of Cardarelli Hospital. Eight adult male Sprague-Dawley rats (250-340 g; Harlan, United States) were randomly divided in two groups of 4 rats each (group I and group II). The rats were maintained on a 12/12 h light/dark cycle and allowed free access to food and water. They were anesthetized with ketamine hydrochloride 100 mg/kg IM (CU ChemieUetikon GmbH, Lahr, Germany) and Domitor 0.25 mg/kg IM (Medethomidine hydrochloride, Pfizer, NY, United States) injections. Dolorex 0.1 mg/kg *sc* (Butarphanol, Intervet,

Boxmeer, The Netherlands) was used immediately before the procedure to ensure intra-operative analgesia. Further injections of these drugs were provided throughout the operation to maintain a sufficient state of anesthesia. Each rat was allowed to breathe spontaneously. Body temperature was monitored with a rectal probe and maintained at  $37.0 \pm 0.5$  °C with a heating blanket regulated by a homeothermic blanket control unit (Harvard Apparatus Limited, Edenbridge Kent, United Kingdom). After drug injection, rats were prepared for surgery via abdominal depilation. The area was then washed with povidone iodine and alcohol.

### *Surgical procedures*

Surgery and drug administration were performed by a board-certified veterinarian with 5 years of experience in microsurgical and vascular techniques (Scaglione M). In all rats, acute SMA occlusion was induced using a two-step surgical procedure (Figure 1). After midline laparotomy, the bowel was exposed in the abdominal cavity and displaced to the left, allowing identification of the SMA. The bowel and the mesentery were drawn out of the abdominal cavity and a snapshot of exposed organs was taken (Nikon Coolpix S210, 8.0 Megapixels resolution, ISO 2000, Japan) as a basal image.

A 3/0 silk thread was used to wind a loop around the SMA at the origin, not yet tightening the loop. The tips of the thread were brought into a silicon pipe and, through it, carried out to the back of the animal, between its shoulders. The thread tips were attached to the pipe using medical plaster. Muscles and skin were closed in two layers using a 2/0 Vicryl thread. 10 mg/kg of Baytril 10% (Enrofloxacin 2.5%, Bayer AG, Leverkusen, Germany) was topically applied to the wounds to prevent infections. The animals were returned to their cages after awakening, and water and food were provided *ad libitum*. Three days after surgery, the rats underwent a second anesthetic treatment according to the same drug protocol, and acute mesenteric ischemia was induced by pulling the threads out of the pipe. In this way, the loop around the SMA was squeezed, and the arterial inflow through this artery was stopped. In group I rats, the ischemia was maintained for 8 h and during this time all animals were monitored at predetermined time points. In group II rats, the ligation was removed 1 h after SMA occlusion by cutting the thread fixed on the back of the animal; the following reperfusion was monitored for 8 h.

### *7T-magnetic resonance imaging protocol*

All animals underwent MRI of the abdomen using a 7-T micro-MRI scanner (BioSpec 70/16US, Bruker Medical Systems, Ettlingen, Germany). Two abdominal radiologists (Saba L and Grassi R), with 10 and 15 years of experience, respectively, assessed all 7T MR images by consensus. In all the rats, just before pulling the threads and occluding the vessel, a localizer scan along the three orthogonal planes [repetition time (TR) = 6.0 ms, echo time (TE) = 100.0 ms, field of view (FOV) = 8, Averages

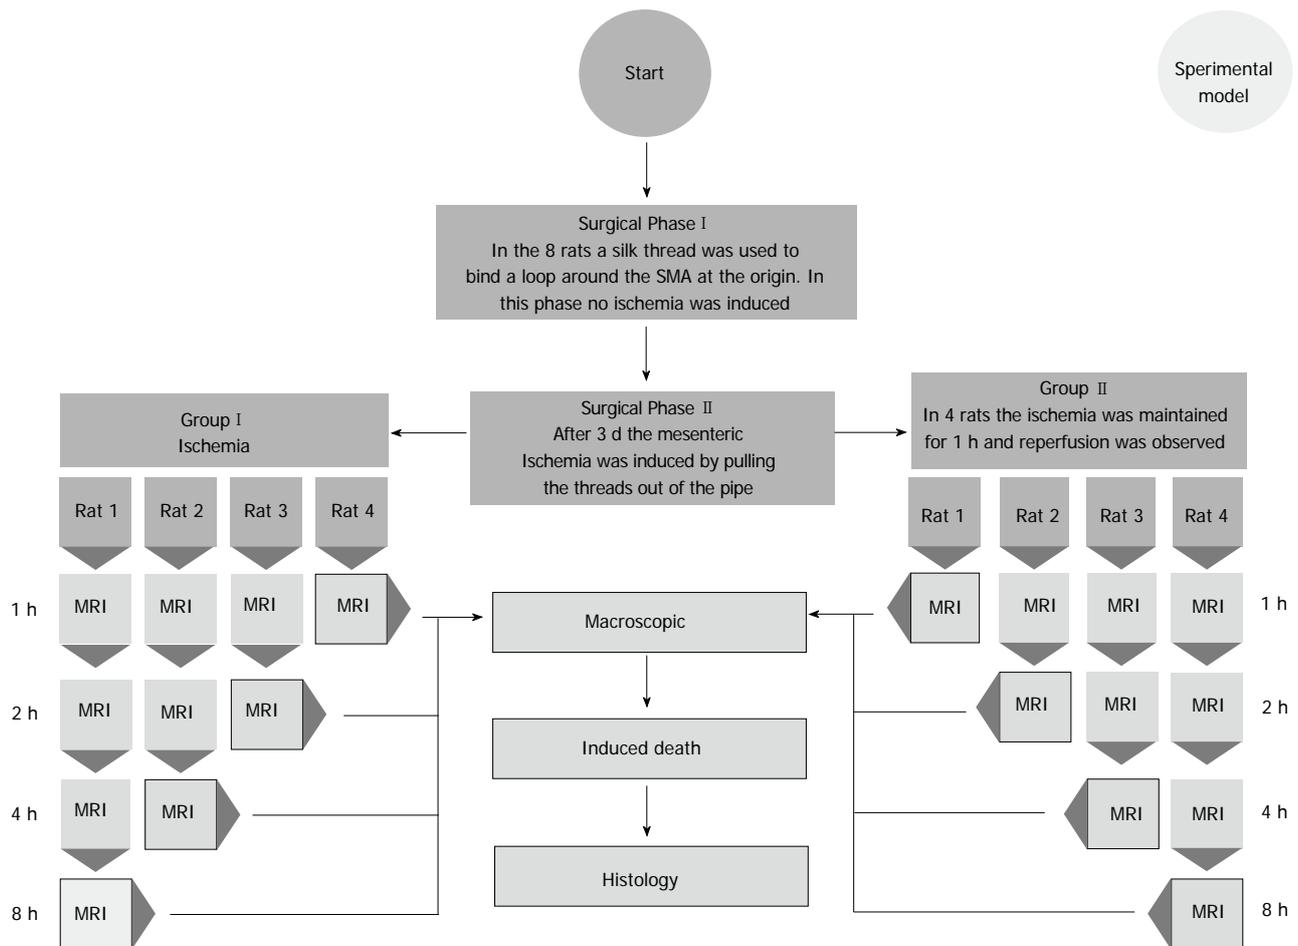

Figure 1 Flow chart. Flow chart shows our procedure to study the 2 different groups of rats. MRI: Magnetic resonance imaging; SMA: Superior mesenteric artery.

= 1, Flip Angle 30 deg, Matrix = 128, Slice thickness = 2.00 mm, Scan time = 12 s 800 ms] and a T2-weighted (T2-W) TurboRare sequence (TR = 4428.7 ms, TE = 36 ms; 180° flip angle; 38 slices; slice thickness 1 mm, interslice distance 1 mm, field of view, 6 cm; acquisition matrix, 256 × 256, scan time = 7 min 5 s 156 ms) were performed to serve as baseline images. Before and after the SMA occlusion, to insure the complete lack of flow in the vessels, a FLASH TOF 2D sequence was performed (TR = 12 ms, TE = 3.5 ms; 90° flip angle; 180 slices; slice thickness 0.4 mm, interslice distance 0.25 mm, field of view, 6 cm; acquisition matrix, 256 × 256, averages = 7, acquisition time 48 min 23 s 40 ms). Maximum intensity projection (MIP) images were reconstructed for each series of images to evaluate SMA occlusion.

For those rats in which lack of flow in the SMA after occlusion was confirmed, additional T2-W TurboRare sequences were performed at predetermined time-points to identify and characterize signs of bowel necrosis. For group II rats, a second FLASH TOF 2D sequence (TR = 12 ms, TE = 3.5 ms; 90° flip angle; 180 slices; slice thickness 0.4 mm, interslice distance 0.25 mm, field of view, 6 cm; acquisition matrix, 256 × 256, averages = 7, acquisition time 48 min 23 s 40 ms) after reperfusion was performed to verify the bloodflow through the SMA.

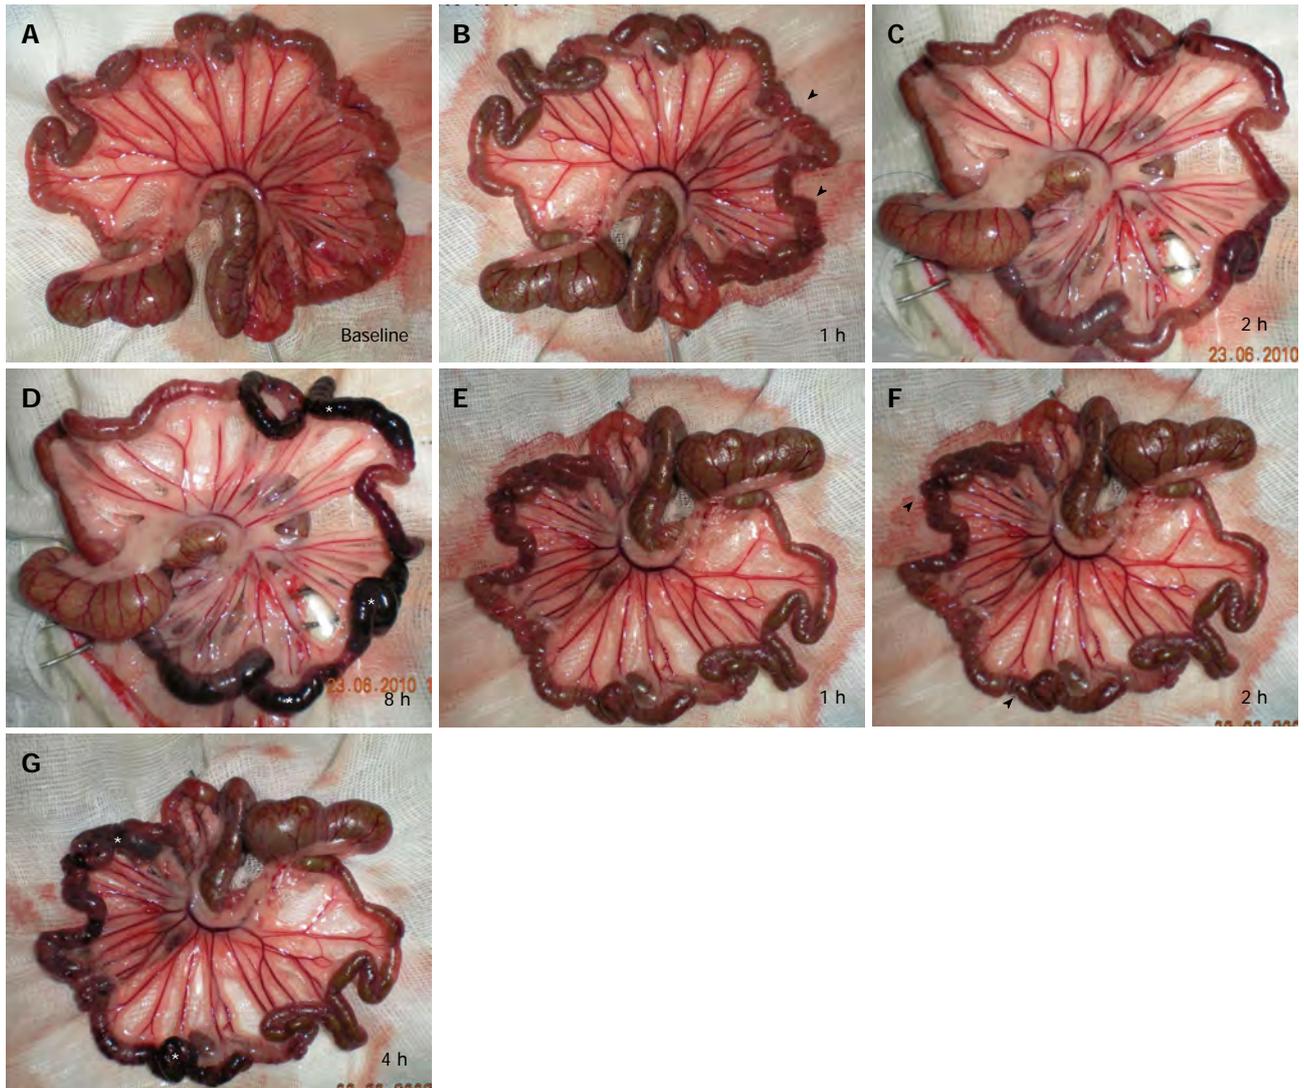

At each time-point in each rat, after opening the pre-existing midline laparotomy, the bowel and the mesentery were drawn out of the abdominal cavity, and a picture of the exposed organs was taken (Nikon Coolpix S210, 8.0 Megapixels, ISO 2000, Japan). The rat was then euthanized by an intrapulmonary injection of Tanax 0.5 mL (Enbutramide + Mebenzonium, Iodide + Tetracaine, Intervet/Shering-Plough Animal Health, Boxmeer; The Netherlands).

MR images were assessed for the following parameters: (1) presence of free fluid in the abdomen; (2) gas filled dilated loops, known as hypotonic reflex ileus (HRI); (3) gas-fluid mixed stasis dilated loops (paralytic ileus, PI); (4) bowel wall thinning or thickening; (5) wall signal intensity on T2-W sequences; (6) mesenteric vessels; (7) wall pneumatosis; and (8) presence of free gas in the abdomen.

## RESULTS

### Macroscopic analysis

Immediately before the SMA ligation the bowel loops presented an average diameter of 1.5 mm (measured with a gauge), uniform serosa and rose-colored mesentery in all segments (Figure 2A). In all rats, 1 h after ischemia

**Figure 2 Macroscopic appearance.** A-D: Group I ; at baseline evaluation, the bowel loops presented an average diameter of 1.5 mm, uniform serosa and rose-colored mesentery in all segments (A). Pale mesentery and spasm of the jejunal loops (arrowheads) were evident 1 h after acute superior mesenteric artery occlusion (B). Spastic reflex ileus was replaced by definite hypotonic reflex ileus 2 h after acute ischemia (C). Eight hours from acute superior mesenteric artery occlusion, a chromatic change to charcoal black was extended to a large ileal segment (white stars) (D); E-G: Group II ; vascular congestion of mesenteric vessels was evident 1 h after reperfusion (E). After 2 h from reperfusion, damaged areas underwent chromatic change from pink to dark red (arrowheads) (F), and became charcoal black after 4 h (stars) (G).

(Figure 2B), pale mesentery with thinning of mesenteric vessels and a spasm of the jejunal loops were evident, compared with the baseline assessment.

In group I rats, 2 h after acute SMA occlusion the spasm was replaced by definite HRI (Figure 2C). The ileal loops underwent the same pathological evolution, but the spasm was observed approximately 2 h after acute SMA occlusion, with transition to definite HRI after approximately 4 h. At this stage, a chromatic change from pink to dark red was observed in the loops of the middle portion of the ileum, then became charcoal black in the rat observed for 8 h, spreading to a cover larger ileal segment - both proximal and distal (Figure 2D). In group II rats, vascular congestion of mesenteric vessels was evident 1 hour after reperfusion (Figure 2E). After 2 h of reperfusion, damaged areas underwent chromatic change from pink to dark red, then became charcoal black at 4 h

and growing more apparent in subsequent hours (Figure 2F and G).

### 7T MRI

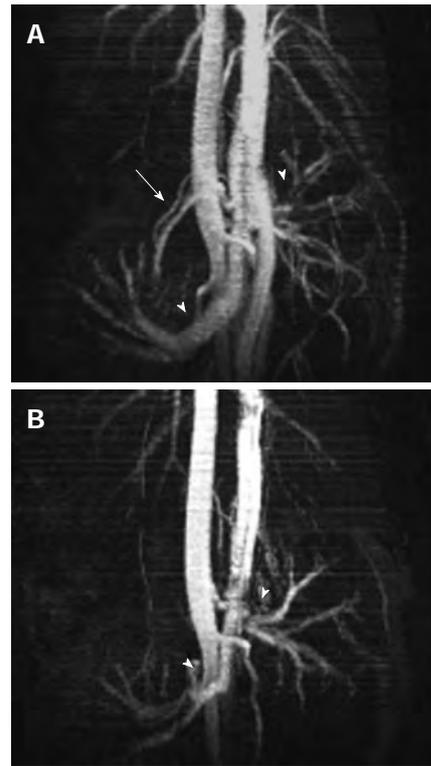

In all cases 7-T micro-MRI identified findings of intestinal ischemia. Immediately before inducing acute SMA obstruction, 3 d after laparotomy, no free gas within the abdominal cavity or signs of visceral or mesentery irritation were found. Compared with the baseline acquisition, the MR angiography sequence at 5 min showed that flow in the SMA had stopped (Figure 3). In group I (Table 1), 1 h after SMA ligation, T2-W sequences showed minimal change - a thin collection of fluid between the loops - compared with control scans (Figure 4A and B).

Dilation of numerous bowel loops (HRI) (mean diameter 4 mm, compared with 2.5 mm in baseline acquisition) and reduced wall thickness (average 0.5 mm com-

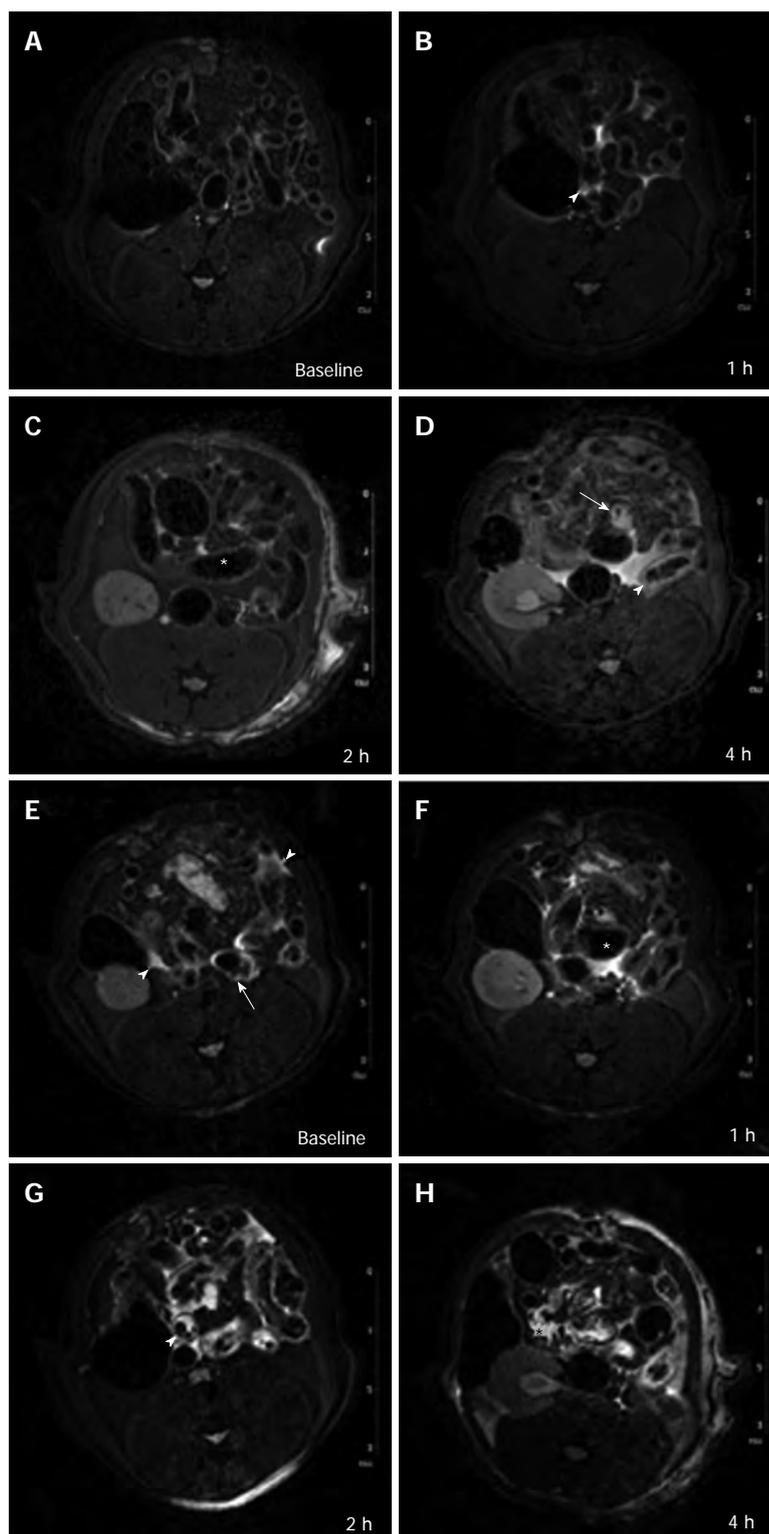

**Figure 3** Magnetic resonance imaging angiography. Maximum intensity projection images through origins of renal arteries (arrowheads) and acute superior mesenteric artery (SMA) (arrow) before (A), and after SMA occlusion (B) (FLASH 2D-TOF), no flow is observed in SMA (B).

pared with 1 mm in baseline acquisition) were already apparent at approximately 2 h of ischemia (Figure 4C). HRI was followed by PI (gas-liquid stasis) that was clearly evident 4 h after SMA ligation. A hyper-intense signal in the bowel wall was evident after 4 h in some loops (Figure 4D).

In group II (Table 1), an early hyper-intense signal of the bowel wall in some loops and a thin layer of peritoneal fluid were detected 1 h after reperfusion (Figure 4E). After 2 h, a small amount of peritoneal free fluid, bowel wall thickening (average thickness of 1.5 mm) and hyperintensity of the intestinal wall (Figure 4F) were observed. HRI in some loops and additional free fluid were related to previous findings. At 4 h, a PI (average diameter of intestinal lumen of 4.5 mm) with a larger amount of peritoneal fluid, a mild mesenteric engorgement and a hyper-intense signal of the intestinal wall became evident in many loops (Figure 4G and H). By comparing the different MRI signal characteristics of the rats that underwent the reperfusion versus those that did not undergo the reperfusion (Table 2), we found differences between the appearances of bowel wall thickening and wall signal (in T2-W).

## DISCUSSION

The morbidity and mortality of mesenteric ischemia are quite high<sup>[10]</sup>; some authors assert that this high mortality is associated with the low sensitivity of diagnostic tools, which may hinder a correct diagnosis in the early

**Figure 4** 7 Tesla-magnetic resonance imaging appearance. A-D: Group I ; at baseline evaluation no free gas within the abdominal cavity or signs of visceral or mesentery irritation were found on T2-W sequences (A). One hour after acute superior mesenteric artery (SMA) ligation, T2-W sequences showed a thin collection of fluid between the loops (arrowhead) (B). After 2 h dilation of numerous bowel loops [(hypotonic reflex ileus (HRI)] with reduced wall thickness were evident (star) (C). Four hours from SMA ligation HRI was followed by paralytic ileus (PI) (gas-liquid stasis) (arrow); also bowel wall hyper-intense signal was evident in some loops (arrowhead) (D). E-H: Group II ; An early hyper-intense signal of bowel wall in some loops (arrow) and a thin layer of peritoneal fluid (arrowheads) were detected 1 h after reperfusion (E). After 2 h, a small amount of peritoneal free fluid, bowel wall thickening, hyper-intense signal of some loops and HRI (star) were observed (F). At 4 h, a paralytic ileus (arrowhead) (G) with a larger amount of peritoneal fluid appeared and a mild mesenteric engorgement (star) became evident beyond a hyper-intense signal of intestinal wall in many loops (H).

phase of ischemia<sup>[11,12]</sup>. Early identification of mesenteric ischemia is critical to plan an appropriate therapeutic approach. Moreover, different characteristics of the bowel corresponding to different pathogenesis are not clearly defined in imaging studies, adding further difficulties to obtaining an early and precise diagnosis<sup>[13]</sup>.

We defined the progress of 2 different mechanisms of mesenteric ischemia - the acute occlusion of SMA and the acute occlusion of SMA followed by reperfusion

- and investigated MRI findings in a time course. Most studies about ischemia/reperfusion reported in literature<sup>[14]</sup> analyze histological or biochemical alteration. In contrast, we focused our research on the development of radiological evidence for intestinal damage because diagnosis by imaging is crucial for the assessment of patients with acute mesenteric ischemia. Thus far, the chronological sequence of early changes that follow mesenteric ischemia and reperfusion has not been described, and the

role of MRI diagnosis is still widely debated.

Intestinal ischemia occurs when there is an interruption of the blood supply to the bowel, or when there is inadequate organ perfusion due to conditions of shock or hypovolemia. The initial damage caused by ischemia could be worsened by oxidative damage during reperfusion. This clinical entity is known as ischemia/reperfusion (I/R) injury<sup>[15]</sup>. Previous studies on mesenteric I/R in felines reported that tissue lesions produced during reperfusion were greater than those produced during ischemia<sup>[16]</sup>. Despite decades of research in this area, I/R injury remains a clinically challenging problem<sup>[17-22]</sup>. Patients are particularly susceptible to the damaging effects of increased neutrophil activation following intestinal I/R<sup>[23]</sup>. Consequently, many cases of intestinal I/R develop into shock, multiple organ failure, and death<sup>[24,25]</sup>.

The absence of reperfusion after acute SMA occlusion is characterized by clear macroscopic differences compared to AAMI with reperfusion. In the first case, there is a pale mesentery with thinning of mesenteric vessels and spasm of the jejunal loops due to the lack of blood flow and the contraction of the semilunar folds. With reperfusion, there is vascular congestion of the mesentery and bowel wall related to hypoxic damage of endothelial cells and subsequent blood extravasation following restoration of blood flow. These findings are in agreement with results obtained by previous authors<sup>[24-26]</sup>.

Analyzing MRI signal characteristics, we found that

the presence of free fluid in the abdomen (from the first hour) and HRI (from the second hour) are common and early findings in AAMI. It has been reported that a small amount of fluid is already visible 30 min after the ischemic event<sup>[24]</sup>; however, another study, in a porcine model, reported that free fluid is a late finding (detectable after 12 h)<sup>[25]</sup>. The presence of ascites is reported in up to 80% of cases<sup>[26]</sup>. HRI is a condition that occurs before PI, and it is considered an early reaction to the ischemic insult.

From the fourth hour, MRI also identified the presence of dilated loops with gas-fluid stasis (PI), reported in the literature in up to 65% of cases<sup>[25,27-29]</sup>, and a hyper-intense signal from the bowel wall in some loops in T2-W sequences. These four findings (free fluid, HRI, dilated loops with gas fluids and bowel wall hyper-intensity) were present in all rats with mesenteric ischemia, with or without reperfusion.

We found important differences between the 2 mechanisms (mesenteric ischemia with or without reperfusion). First of all, the signal intensity of the wall in T2-W sequences: in those rats without reperfusion the signal intensity is normal at the first and second hour and becomes hyper-intense at the fourth and eighth. On the contrary, when we cause a reperfusion the hyper-intense signal is clearly visible from the first hour due to interstitial edema. Another MRI finding is the presence of bowel wall thickening due to blood extravasation and edema, which is visible from the second hour in rats with reperfusion but never found in rats without reperfusion. Bowel wall thickening was previously found in an animal model of mesenteric venous ischemia<sup>[30]</sup>, suggesting that reperfusion produces hemorrhagic damage.

The early bowel wall thickening and hyper-intensity of the wall in T2-W sequence images may be considered signs of acute mesenteric ischemia with reperfusion. The presence of hyper-intense signal in T2-W images may be attributed to the edema of the submucosa caused by the release of vasoconstrictor amines that attract fluid from the bowel lumen<sup>[24,31]</sup>. The absence of mucosal thickening in arterial occlusion without reperfusion is interesting: indeed, the presence of wall thickening has been considered the most important feature of acute mesenteric ischemia<sup>[32]</sup> (with a prevalence of up to 96%). Nonetheless, we found that the wall thickening was only visible when the occlusion was followed by reperfusion. Further, our results showed that bowel wall thinning, detectable from the second hour after the SMA occlusion, is an extremely specific sign of occlusion without reperfusion. This finding was never detected in the cases with reperfusion. In the literature, bowel wall thinning seems to be heavily underestimated, as it is described in only 5% of cases<sup>[33]</sup>.

The treatment of AAMI without reperfusion is significantly different from treatment of AAMI with reperfusion<sup>[34]</sup>. Because mesenteric ischemia with and without reperfusion have different therapeutic approaches, the power to distinguish between these conditions may have a great clinical importance<sup>[35,36]</sup>. Additionally, the radiological findings of mesenteric ischemia have different cours-

es depending on whether the ischemic event followed by reperfusion: bowel wall thickening is a specific sign of reperfusion damage; acute SMA occlusion without reperfusion is characterized by bowel wall thinning. Although computer tomography remains a valid diagnostic tool for the visualization of mesenteric ischemia and for the evaluation of its damage, our study results suggest that MRI, which does not require the use of a contrast medium or ionizing radiation, can play an important role in the early diagnosis of this condition.

Because our model has some limitations, further investigation is necessary to verify whether these results can be translated to human beings. The first limitation is that we used a complete acute occlusion of the SMA, but in human beings it is possible to find partial occlusions. Second, the vessel ligation was performed at the vessel origin; this represents a potential bias because distal occlusions can occur. Other limitations include the small number of animals included in this preliminary report and the lack of histological analysis.

## COMMENTS

### Background

Acute arterial mesenteric ischemia is a life threatening vascular condition caused by the lack of arterial flow to the bowel, which can be occlusive or non-occlusive in origin. The initial damage caused by ischemia could be further worsened by oxidative damage during reperfusion. This entity is known as ischemia/reperfusion (I/R) injury. An early diagnosis of this condition is crucial to ensure a good outcome for the patient.

### Research frontiers

Although computer tomography (CT) remains a valid diagnostic tool for the visualization of mesenteric ischemia and for the evaluation of its damage, magnetic resonance imaging (MRI), which does not require the use of a contrast medium or ionizing radiation, can play an important role in the early diagnosis of this condition.

### Innovations and breakthroughs

Despite decades of research in this area, ischemia/reperfusion injury remains a clinically challenging problem. Patients are particularly susceptible to the damaging effects of increased neutrophil activation following intestinal ischemia/reperfusion. To ensure a good prognosis to these patients an early diagnosis is requested and the prerequisite to do it consists in the knowledge of the timing of the lesions. Important differences between the 2 mechanisms (mesenteric ischemia with or without reperfusion) were found at MRI, regarding the timing of the following findings: the signal intensity of the wall in T2-W sequences and the presence of bowel wall thickening due to blood extravasation and edema. Although CT remains the gold standard in the evaluation of acute mesenteric ischemia, our results suggest that MRI, which does not require the use of a contrast medium or ionizing radiation, could in future play an important role in the early diagnosis of this condition.

### Applications

This study suggests the following points: (1) The reperfusion of the mesenteric region, after 1 h of induced acute arterial ischemia, is characterized by early bowel wall hyperintensity in T2-W sequences, from the first hour, and bowel wall thickening, from the second hour; (2) Bowel wall thinning is a specific sign of acute superior mesenteric artery occlusion without reperfusion, detectable from the second hour; and (3) MRI can assess the various pathological changes that occur in the small bowel after induced acute arterial mesenteric ischemia with and without reperfusion.

### Terminology

Acute arterial mesenteric ischemia/infarction: lack of blood flow to the small bowel caused by a pathologic constriction or obstruction of its blood vessels, or an absence of blood circulation that can lead to ischemic damage of the bowel (involving part of the wall) or infarction (full thickness necrosis). 7T microMRI:

Non-invasive preclinical studies method of demonstrating internal anatomy based on the principle that atomic nuclei in a strong magnetic field (7 Tesla) absorb pulses of radiofrequency energy and emit them as radiowaves which can be reconstructed into computerized images.

### Peer review

The paper presents some new methodology concerning the detection of subtle changes that occurs during the acute arterial mesenteric ischemia and ischemia-reperfusion pathological process. The paper is well designed and the results are meaningful and conceivable.

### Abstract

**AIM:** To investigate the risk factors and characteristics of hepatocellular carcinoma (HCC) in the patients with drug-resistant chronic hepatitis B (CHB).

**METHODS:** A total of 432 patients with drug-resistant CHB were analyzed retrospectively from January 2004 to December 2012. The patients were divided into two groups: the HCC group ( $n = 57$ ) and the non-HCC group ( $n = 375$ ). Two groups compared using logistic regression for various patients and viral characteristics in order to identify associated risk factors for HCC. Secondly, patient and tumor characteristics of HCC patients with naïve CHB (N group,  $n = 117$ ) were compared to the HCC group (R group,  $n = 57$ ) to identify any difference in HCC characteristics between them.

**RESULTS:** A significant difference was found for age,

platelet count, alpha-fetoprotein (AFP), positivity of HBeAg, seroconversion rate of HBeAg, virologic response, the Child-Pugh score, presence of rtM204I, and the duration of antiviral treatment in non-HCC and HCC group. Cirrhosis, age ( $> 50$  years), HBeAg (+), virologic non-responder status, and rtM204I mutants were independent risk factors for the development of HCC. The R group had lower serum C-reactive protein (CRP) and AFP levels, earlier stage tumors, and a shorter mean tumor surveillance period than the N group. However, the total follow-up duration was not significantly different between the two groups.

**CONCLUSION:** 13.2% of patients with drug-resistant CHB developed HCC. Age, cirrhosis, YIDD status, HBeAg status, and virologic response are associated with risk of HCC. Patients with drug-resistant CHB and these clinical factors may benefit from closer HCC surveillance.

**Key words:** Carcinoma; Hepatocellular; Hepatitis B; Drug resistance; Risk factors; Characteristics

**Core tip:** There are few studies on hepatocarcinogenesis in patients with drug-resistant chronic hepatitis B (CHB) or on the characteristics of tumors arising from drug-resistant CHB. In the present study, the cumulative incidence rate of hepatocellular carcinoma (HCC) in patients with drug-resistant CHB was 4.6%, 6.9%, 8.87%, and 11.8% at the end of 1, 2, 3, and 5 years, respectively. Additionally, cirrhosis, age  $> 50$  years, HBeAg (+), YIDD mutations, and a virologic non-responder status were independent risk factors for the development of HCC in CHB patients with drug resistance. Furthermore, there was a trend of poorer survival in patients with HCC arising from resistant CHB than in patients with HCC arising from naïve CHB.

## INTRODUCTION

Chronic hepatitis B (CHB) is an important cause of morbidity and mortality worldwide<sup>[1,2]</sup>. The main goals of therapy for CHB patients are to prevent disease progression and to avoid the development of liver failure and hepatocellular carcinoma (HCC)<sup>[3]</sup>.

The introduction of oral nucleos(t)ide analogue (NA) therapy during the last two decades has revolutionized the CHB treatment<sup>[4,5]</sup>.

Although nucleoside/nucleotide analogues (NAs) are very effective at inhibiting HBV reverse transcriptase, the long-term use of NAs leads to the development of drug resistance. The risk of developing lamivudine (LAM) resistance is 14%-32% in the first year and up to 70% by the fifth year. For LAM resistance, the signature rtM204V/I and rtL180M mutations occur in more than 70% of CHB patients<sup>[6,7]</sup>. The rtM204V/I, a mutation located at the catalytic YMDD motif<sup>[8-10]</sup>, and the rtL180M mutations serve as compensatory mutations<sup>[10]</sup>. The rtA181T mutation has also been reported in a substantial proportion of LAM-resistant patients<sup>[9]</sup>. The risk of developing adefovir (ADV) resistance is 2%-3% and 28%-29% by the second and fifth year of monotherapy treatment in naïve patients, respectively<sup>[11,12]</sup>. The major ADV-resistant mutants were rtN236T and rtA181T/V<sup>[13]</sup>. Resistance to entecavir (ETV) is rare when being used to treat naïve patients (1.5% by the fifth year)<sup>[5]</sup>. However, in the presence of the rtM204I/V mutation, ETV resistance can occur if the rtI169T, rtT184A/F/G/I/L/S, rtS202G/I, or rtM250V mutation also exist<sup>[14,15]</sup>.

It has been demonstrated that in patients with compensated cirrhosis, LAM therapy significantly reduces the risk of liver failure and HCC<sup>[16]</sup>. However, in patients who have developed LAM resistance, this beneficial effect is drastically compromised<sup>[17]</sup>. One study reported that old age, male gender, family history of HCC, HBeAg positivity, genotype C, and increased levels of ALT, HBV DNA and HBsAg were risk factors for the development of HCC in chronic hepatitis B patients<sup>[18]</sup>. However, there are few studies on hepatocarcinogenesis in patients with drug-resistant CHB.

Therefore, we determined the risk factors for the development of HCC in patients with drug-resistant CHB. We also compared the tumor characteristics between HCC patients with drug-resistant CHB and HCC patients with CHB who were treated with antivirals.

## MATERIALS AND METHODS

### Patients and methods

Six hundred and forty-one patients with a documented

CHB mutation who had experienced a viral breakthrough at our institution (Chonnam National University Hospital, Gwangju, Korea) between January 2004 and December 2012 were selected for this retrospective study. The 209 patients who were excluded those whose entire set of laboratory data were not available at the end of the follow-up period, those who were co-infected with HIV, hepatitis C or hepatitis D, those who were chronic alcohol drinkers, those who had poor medication compliance and those who had been diagnosed with HCC before the CHB mutation occurred. In total, the data of 432 CHB patients (most of them, genotype C, we did not check the genotype of all patients ( $n = 90/432$ ), but 100% of the 90 patients whose genotypes were checked were genotype C) with drug resistance were finally evaluated (Figure 1). To determine the risk factors for the development of HCC in patients with drug-resistant CHB, the patients were divided into two groups according to the occurrence of HCC (57 patients with HCC *vs* 375 patients without HCC).

To compare the tumor characteristics between the HCC patients with drug-resistant CHB (R group) and the HCC patients with CHB treated with antivirals, we selected 119 HCC patients who had received first line antiviral treatment without evidence of drug resistance (N group) during the same period (Figure 1).

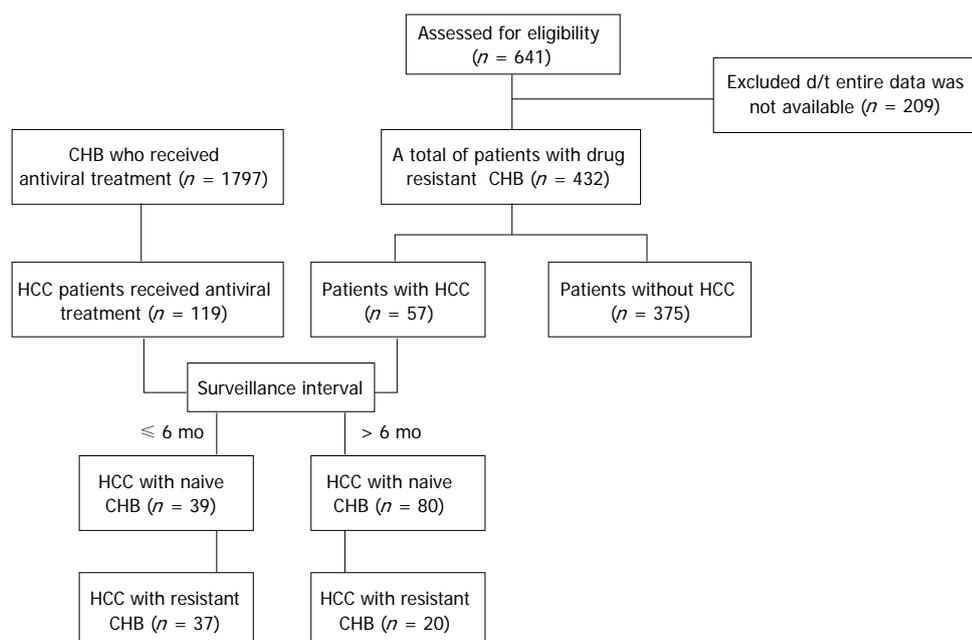

The diagnosis of HCC was based on the following guidelines proposed by the Korea Liver Cancer Study Group and the National Cancer Center<sup>[19]</sup>: (1) nodules > 2 cm in diameter with a typical pattern of HCC in one imaging study or AFP levels > 200 ng/mL; and (2) nodules between 1 and 2 cm in diameter with a coincidental typical vascular pattern in two imaging studies. If these criteria were not met, biopsies were performed. Clinical staging was based on the modified UICC tumor-node-metastasis classification and the Cancer of the Liver Italian Program (CLIP) scores<sup>[19,20]</sup>.

Clinicoradiological and virological variables and the occurrence of HCC were compared between the two groups. The clinicoradiological variables were age, sex, the Child-Pugh score, blood chemistry, AFP level, and the duration of the antiviral treatment. The virological variables were positivity of HBeAg, seroconversion of HBeAg, HBV DNA level, virologic response rate, and mutant type. Informed consent was obtained from all patients about the nature and purpose of the treatment modalities.

### Marker of HBV infection

The hepatitis B e antigen (HBeAg) and antibodies to HBeAg (anti-HBe) were determined by commercially available radioimmunoassay systems (Abbott Laboratories, Abbott Park, IL, United States). The serum HBV DNA was quantified by the TaqMan<sup>®</sup> real time polymerase chain reaction (PCR) system (Applied Biosystems, Foster city, CA, United States). The lower limit of detection was 100 copies/mL.

Mutations were identified at the baseline using restriction fragment mass polymorphism (RFMP) analysis.

**Figure 1 Study patient flow.** HCC: Hepatocellular carcinoma; CHB: Chronic hepatitis B.

### Diagnosis and surveillance of HCC

All patients were examined for HCC by abdominal ultrasonography (US) and/or abdominal computed tomography (CT) ± serum alpha-fetoprotein (AFP) examination every 3-12 mo. If HCC was suspected, additional procedures, such as CT, magnetic resonance imaging (MRI), angiography, and US guided biopsy, were performed as necessary to confirm the diagnosis.

### Definitions

A primary non-response was defined as a less than 1 log copy/mL decrease in the HBV DNA level from the baseline at 3 mo of treatment. A partial virologic response was defined as a ≥ 1 log copy/mL decline in the HBV DNA level from the baseline, but with a detectable load, at week 24. A complete virologic response was defined as an undetectable HBV DNA level by a sensitive PCR assay<sup>[21]</sup>.

The R group was defined as patients with HCC arising from drug-resistant CHB, and the N group was defined as patients with HCC arising from CHB receiving first line antiviral treatment without evidence of drug resistance.

Subgroup analysis according to tumor surveillance interval, the R' group was defined as patients with HCC arising from drug-resistant CHB who underwent frequent tumor surveillance (≤ 6 mo), and the N' group was defined as patients with HCC arising from CHB treated with antivirals who underwent frequent tumor surveillance (≤ 6 mo).

### Statistical analysis

The parametrical data were expressed as the means ± SD when a normal distribution was assumed and were expressed as a median (range) when a normal distribution was not assumed to be present. The group comparisons

were performed using the Pearson's  $\chi^2$  test and Mann-Whitney *U*-test.

Logistic regression analysis was performed to evaluate the factors for the development of HCC. Factors that were significant in the univariate analysis were entered into a stepwise multivariate analysis to find the most significant risk factors. The hazard function data were estimated using the Kaplan-Meier curve and compared using the log rank test. A *P*-value of less than 0.05 was considered to be statistically significant. We performed statistical analysis using SPSS 20.0 (SPSS Inc., Chicago, United States).

## RESULTS

### Baseline characteristics of patients with drug-resistant CHB

The median follow-up duration was 49.3 mo (range: 0-137 mo). The mean age of the patients was 48.48 (range 16-81) years. The mean duration of the antiviral treatment was 30.55 mo (4-120 mo). There were 309 men (71.5%) and 123 women (28.5%) included in the study. Additionally, 127 patients (29.4%) had cirrhosis; 350 patients (81%) were positive for HBeAg; 118 patients (27.3%) were rtM204I-positive; 54 patients (12.5%) were rtM204I/rtL180 M-positive; 39 patients (9.0%) were rtM204I+V/rtL180 M-positive; 125 patients (28.9%) were rtM204 V/rtL180 M-positive; 25 patients (5.8%) were rtA181T-positive; 2 patients (0.4%) were rtA181T/V-positive; 12 patients (2.7%) were rtN236T-positive; and 57 patients (13.2%) were positive for other mutations.

The clinical characteristics of the two groups (HCC-positive group vs HCC-negative group) are shown in Table 1. There were no significant differences between the two groups for gender, initial HBV DNA level, serum aspartate aminotransferase (AST) level, alanine

**Table 1** Characteristics of patients with drug-resistant chronic hepatitis B stratified by hepatocellular carcinoma status *n* (%)

Variables	Patients with HCC ( <i>n</i> = 57)	Patients without HCC ( <i>n</i> = 375)	<i>P</i> -value
Gender (male)	42 (73.7)	267 (71.2)	0.755
Age (mean, yr)	57.44 ± 8.35	47.03 ± 12.25	< 0.001
Presence of cirrhosis	42 (73.7)	85 (22.7)	< 0.001
HBeAg positivity	36 (63.2)	314 (83.7)	0.003
Seroconversion of HBeAg	3 (5.3)	78 (20.8)	0.022
Initial HBV DNA (< 2000 IU)	2 (3.5)	27 (7.2)	0.61

rtA181T/V	1 (1.8)	1 (0.26)	0.224
Duration of antiviral treatment (mo)	24.31 ± 15.28	31.43 ± 19.43	0.004

HCC: Hepatocellular carcinoma; ALT: Alanine aminotransferase; AFP: Alpha-fetoprotein; AST: Aspartate aminotransferase; HBV: Hepatitis B virus.

aminotransferase (ALT) level, or total bilirubin or albumin. A significant difference was found for age, platelet count, AFP, positivity of HBeAg, seroconversion rate of HBeAg, virologic response, the Child-Pugh score, presence of rtM204I, and the duration of antiviral treatment.

### Clinical and virologic factors associated with HCC occurrence

The univariate analysis showed that cirrhosis, age > 50 years, partial virologic response, complete virologic response, the rtM204I (YIDD) mutation, HBeAg (+), platelet count, the Child-Pugh score, and the duration of antiviral treatment were associated with the development of HCC. The multivariate analysis showed that cirrhosis, age > 50 years, negative complete virologic response, HBeAg (+), and the rtM204I (YIDD) mutation were independent risk factors for the development of HCC (Table 2).

### Cumulative incidence of HCC in patients with drug-resistant CHB

**Table 2** Multivariate analysis of the clinical and virologic factors associated with hepatocellular carcinoma occurrence

Variables	HR	95%CI	<i>P</i> -value
Presence of cirrhosis	8.196	3.623-18.518	< 0.01
Age > 50 yr	3.426	1.445-8.123	< 0.01
Complete virologic response	0.164	0.054-0.276	< 0.01
Positivity of HBeAg	2.893	1.143-7.327	< 0.05
Presence of rtM204I mutation	3.412	1.54-6.440	< 0.01

drug-resistant CHB was 4.6%, 6.9%, 8.87%, and 11.8% at the end of 1, 2, 3, and 5 years, respectively.

Kaplan-Meier analysis for the incidence rate of HCC in patients with drug-resistant CHB stratified by the patient and viral factors identified in multivariate analysis is shown in Figure 2.

The cumulative occurrence rate of HCC in cirrhotic patients with drug-resistant CHB was 3.93%, 5.55%, 6.71%, and 9.02% at the end of 1, 2, 3 and 5 years, respectively. The cumulative occurrence rate of HCC in HBeAg (+) patients was 3.0%, 5.09%, 6.01%, and 7.87% at the end of 1, 2, 3 and 5 years, respectively. The cumulative occurrence rate of HCC in rtM204I (YIDD) mutant patients was 2.3%, 3.0%, 4.16%, and 6.01% at the end of 1, 2, 3 and 5 years, respectively. The cumulative occurrence rate of HCC in patients greater than 50 years of age was 6.9%, 11.5%, 20.8%, and 23.1% at the end of 1, 2, 3 and 5 years, respectively.

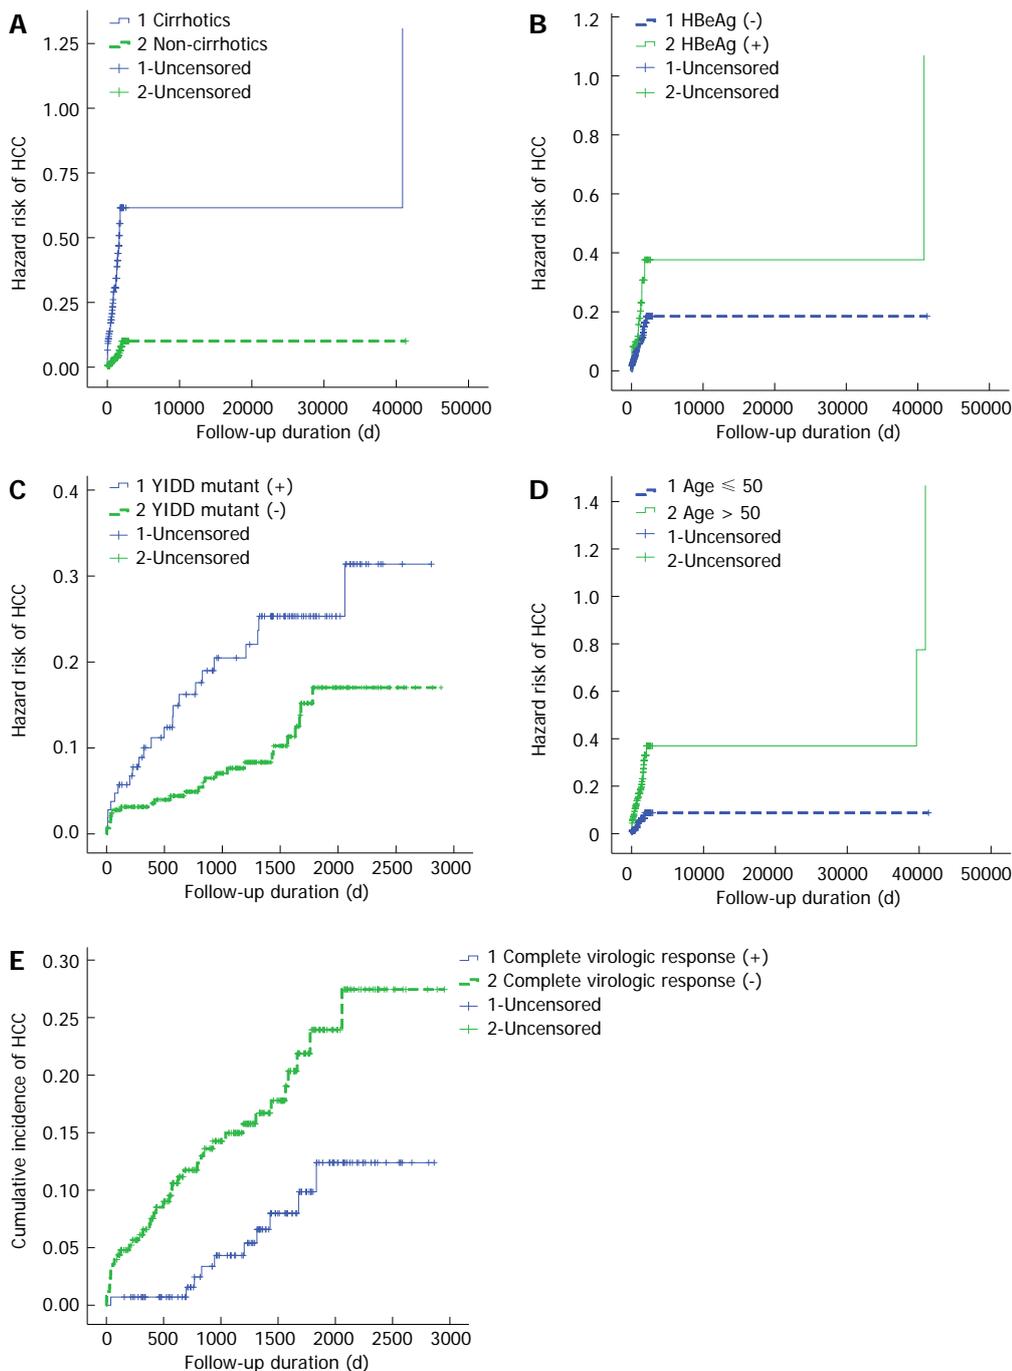

The cumulative occurrence rate of HCC in virologic non-responder patients was 2.3%, 4.6%, 11.5%, and 23.1% at the end of 1, 2, 3 and 5 years, respectively.

### Tumor characteristics of patients with HCC and drug-resistant CHB compared to patients with HCC and naive CHB

To compare the tumor characteristics between HCC patients with drug-resistant CHB (R group) and HCC patients with CHB treated with antivirals, we selected 119 HCC patients with CHB who received antiviral treatment (N group). The clinical characteristics of the two groups (R group *vs* N group) are shown in Table 3. There were no significant differences between the two groups for sex, age, presence of cirrhosis, tumor type, serum ALT, the Child-Pugh score, or the total follow-up duration. A significant difference was found for portal vein thrombosis, tumor stage (CLIP score, modified UICC), distant metastasis, platelet count, serum AST, C-reactive protein (CRP), AFP, and the mean tumor surveillance interval. The R group had lower serum CRP and AFP levels and earlier stage tumors than the N group. The total follow-up duration was not significantly different between the two groups.

### Subgroup analysis according to tumor surveillance interval

The R group had tumors of an earlier stage and a lower AFP than the N group because of frequent tumor surveillance. Therefore, we performed a subgroup analysis to

**Figure 2 Cumulative risk.** A, B: Hepatocellular carcinoma (HCC) in cirrhotic patients and in HBeAg (+) patients with drug-resistant chronic hepatitis B (CHB) (log rank test,  $P < 0.001$ ,  $P = 0.008$ , respectively); C, D: HCC in YIDD patients and in patients  $> 50$  years of age with drug-resistant CHB (log rank test,  $P = 0.007$ ,  $P = 0.001$ , respectively); E: HCC in complete virologic responders with drug-resistant CHB (log rank test,  $P = 0.003$ ).

exclude the frequent tumor surveillance effect on tumor prognosis. Patients were divided into two groups ( $> 6$  mo *vs*  $\leq 6$  mo) according to the interval of their surveillance.

Thirty-seven patients with drug-resistant CHB (R' group) and 39 patients with naïve CHB who received antiviral treatment (N' group) (surveillance interval  $\leq 6$  mo) were selected. The clinical characteristics of the two groups (R' group *vs* N' group) are shown in Table 4. There were no significant differences between the two groups for most variables analyzed. A significant difference was found in the serum CRP and AFP levels, the

duration of the antiviral treatment, and the total follow-up duration. The R' group had lower serum CRP and AFP levels than the N' group at a similar stage. However, the total follow-up duration was shorter in the R' group than the N' group.

In addition, 20 patients with drug-resistant CHB and 80 patients with CHB who received antiviral treatment (surveillance interval  $> 6$  mo) were selected. There were no significant differences between the two groups for most of the variables analyzed, including tumor stage, serum CRP and AFP levels, and total follow-up duration.

## DISCUSSION

Antiviral therapy was shown to significantly reduce the risk of liver failure and HCC in patients with compensated cirrhosis and CHB<sup>[16]</sup>. However, the development of LAM-resistance significantly compromises the effectiveness of this strategy<sup>[17]</sup>. Until now, there have been few studies about hepatocarcinogenesis in patients with drug-resistant CHB.

Data regarding the characteristics of HCC that arise in patients with drug-resistant CHB are also lacking.

Many countries rely on LAM as first-line antiviral therapy for CHB, and over time many patients will develop drug resistance.

Therefore, it is imperative that clinical and virologic factors associated with the development of HCC in this group of patients be delineated.

In our study, we demonstrated that the cumulative incidence rate of HCC in patients with drug-resistant CHB was 4.6%, 6.9%, 8.87%, and 11.8% at the end of 1, 2, 3, and 5 years, respectively, and that cirrhosis, age >

50 years, HBeAg (+), the rtM204I (YIDD) mutation, and virologic non-responder status were independent risk factors for the development of HCC in CHB patients with drug resistance.

Previous studies primarily identified the rate of hepatocarcinogenesis with varying results. Akuta *et al*<sup>[22]</sup> reported a cumulative hepatocarcinogenesis rate in LAM resistant hepatitis B genotype C patients of 2.2%, 5.9%, and 8.1% at the end of 1, 2, and 3 years, respectively, and they indicated that these hepatocarcinogenesis rates were similar to those in cirrhosis patients who had not received antiviral therapy (namely, the high-risk group for HCC development)<sup>[23]</sup>. Hosaka *et al*<sup>[24]</sup> reported that HCC developed in 18 of the 247 (7.3%) patients who had received adefovir add-on lamivudine during a 5-year period. Consistent with the results of other studies, the cumulative incidence rate of HCC in patients with drug-resistant CHB in our study was 4.6%, 6.9%, 8.87%, and 11.8% at the end of 1, 2, 3, and 5 years, respectively; however, our study had a larger number of cases than the other two studies.

Regarding the risk factors that influence the development of HCC, Hosaka *et al*<sup>[24]</sup> reported that AST > 70 IU/L, the rtM204I (YIDD) mutation, age > 50 years and cirrhosis were independent risk factors for the development of HCC. Additionally, Yeh *et al*<sup>[9]</sup> reported

that the rtA181T mutation, age > 50 years, and liver cirrhosis were significantly associated with the occurrence of HCC. In another study<sup>[22]</sup>, the cumulative HBV DNA non-detectable rate and ALT normalization rate were not significantly different with regards to the development of HCC. Our study showed, distinctly from other studies, that cirrhosis, age > 50 years, a negative complete virologic response, the rtM204I (YIDD) mutation, and HBeAg (+) were independent risk factors for the development of HCC. In our study, the rtA181T mutation and HBV DNA level at the time of the documentation of the drug mutation were not associated with the occurrence of HCC. Consistent with other studies on naïve CHB patients<sup>[18]</sup>, HBeAg (+) and a negative complete virologic response were associated with the development of HCC.

HCC arising from drug-resistant CHB (R group) had lower serum CRP and AFP levels and earlier stage tumors than HCC arising from naïve CHB (N group). Although the R group had an earlier stage tumors and lower serum CRP and AFP levels, the total follow-up duration was not significantly different between the two groups. We think these differences may be attributed to more frequent tumor surveillance in the R group. The R group may have had the same survival rates even if the R group had better prognostic factors, such as low tumor stage and low AFP and CRP levels compared to the N group. Therefore, we performed a subgroup analysis to exclude the frequent tumor surveillance effect on the tumor prognosis. The subgroup analysis showed that the patients with HCC arising from drug-resistant CHB who underwent frequent tumor surveillance ( $\leq 6$  mo) (R' group) had lower serum CRP and AFP levels than patients with HCC arising from CHB treated with antiviral treatment who underwent frequent tumor surveillance ( $\leq 6$  mo) (N' group) at the same stage. However, the total follow-up duration was shorter in the R' group than the N' group, paradoxically. Recent studies reported that an increased serum CRP level is associated with poor prognosis (tumor recurrence after a surgical resection, large tumor size, and poorly defined tumor type) of patients with HCC<sup>[25,26]</sup>. Additionally, serum AFP is well known as a prognostic factor for patients with HCC<sup>[27,28]</sup>. These findings suggest that HCC patients with naïve CHB may have a better prognosis than HCC patients with resistant CHB, irrespective of the tumor stage or serum CRP or AFP levels in the frequent tumor surveillance group. That is, patients with HCC arising from resistant CHB may have poorer survival than patients with HCC arising from naïve CHB. These findings may be explained by the R group having poorer liver function because of incomplete viral suppression during follow-up. In fact, hepatic failure was the main cause of death in the R group (data not shown). To us, this is the most striking finding.

However, in the HCC surveillance group, in which the surveillance exceeded 6 mo, there were no significant differences between the two subgroups for most of the variables analyzed, including tumor stage, serum CRP and AFP levels, and total follow-up duration.

The first limitation of our study is that it was a retrospective single center study. Therefore, our results may not be generalizable to other patient populations.

The second limitation is a single data point for various viral markers (*e.g.*, viral DNA) and laboratory values is another limitation since these factors are not static over time. Third, the relationship between risk factors, such as nucleotide substitution and the development of HCC, could not be presented. Fourth, we did not check the genotype of all patients ( $n = 90/432$ ), but 100% of the 90 patients whose genotypes were checked were genotype C. In South Korea, it is well known that the genotype of CHB patients is almost always genotype C.

Larger, prospective studies will be needed to confirm these findings.

In summary, frequent HCC surveillance may identify early HCC in these high-risk patients, and patients with HCC arising from resistant CHB may have poor survival, irrespective of tumor stage or serum CRP or AFP levels.

## COMMENTS

### Background

In patients with compensated cirrhosis, antiviral therapy significantly reduces the risk of liver failure and hepatocellular carcinoma (HCC). However, in patients who have developed drug resistance, this beneficial effect is drastically compromised. However, there are few studies on hepatocarcinogenesis in patients with drug-resistant chronic hepatitis B (CHB) or on the characteristics of tumors arising from drug-resistant CHB.

### Related publication

Hosaka *et al* reported that aspartate aminotransferase > 70 IU/L, the rtM204I (YIDD) mutation, age > 50 years and cirrhosis were independent risk factors for the development of HCC. Yeh *et al* reported that the rtA181T mutation, age > 50 years, and liver cirrhosis were significantly associated with the occurrence of HCC.

### Innovations and breakthroughs

Cirrhosis, age > 50 years, HBeAg (+), YIDD mutants, and virologic non-responder status were independent risk factors for the development of HCC in CHB patients with drug resistance, and there was a trend of poorer survival in patients with HCC arising from resistant CHB than in patients with HCC arising from naïve CHB.

### Applications

Frequent HCC surveillance may identify HCC early in these high-risk patients.

### Peer review

This is a large ( $n = 432$ ) monocenter study aimed at evaluating the relationship between drug-resistant HBV chronic infection and the development of HCC. It is well written.

### Abstract

**AIM:** To investigate the clinical characteristics of left primary epiploic appendagitis and to compare them with those of left colonic diverticulitis.

**METHODS:** We retrospectively reviewed the clinical records and radiologic images of the patients who presented with left-sided acute abdominal pain and had computer tomography (CT) performed at the time of presentation showing radiological signs of left primary epiploic appendagitis (PEA) or left acute colonic diverticulitis (ACD) between January 2001 and December

2011. A total of 53 consecutive patients were enrolled and evaluated. We also compared the clinical characteristics, laboratory findings, treatments, and clinical results of left PEA with those of left ACD.

**RESULTS:** Twenty-eight patients and twenty-five patients were diagnosed with symptomatic left PEA and ACD, respectively. The patients with left PEA had focal abdominal tenderness on the left lower quadrant (82.1%). On CT examination, most (89.3%) of the patients with left PEA were found to have an oval fatty mass with a hyperattenuated ring sign. In cases of left ACD, the patients presented with a more diffuse abdominal tenderness throughout the left side (52.0% vs 14.3%;  $P = 0.003$ ). The patients with left ACD had fever and rebound tenderness more often than those with left PEA (40.0% vs 7.1%,  $P = 0.004$ ; 52.0% vs 14.3%,  $P = 0.003$ , respectively). Laboratory abnormalities such as leukocytosis were also more frequently observed in left ACD (52.0% vs 15.4%,  $P = 0.006$ ).

**CONCLUSION:** If patients have left-sided localized abdominal pain without associated symptoms or laboratory abnormalities, clinicians should suspect the diagnosis of PEA and consider a CT scan.

**Key words:** Acute abdomen; Differential diagnosis; Appendix epiploica; Colonic diverticulitis; Multidetector computed tomography

**Core tip:** The clinical symptoms of primary epiploic appendagitis (PEA) and acute colonic diverticulitis (ACD) are similar in patients presenting with left-sided abdominal pain. In our study, the patients with PEA had well-localized abdominal tenderness, whereas those with ACD presented with slightly diffuse abdominal

tenderness. The patients with ACD showed fever, rebound tenderness, and leukocytosis more often than those with PEA. When patients have well-localized abdominal tenderness without associated systemic manifestation or laboratory abnormalities, clinicians should suspect a diagnosis of PEA and consider a computer tomography (CT) scan. The characteristic CT findings of PEA may enable clinicians to accurately diagnose the disease.

Differential diagnosis of left-sided abdominal pain: Primary epiploic appendagitis vs colonic diverticulitis. *World J Gastroenterol* 2013; 19(40): 6842-6848 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6842.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6842>

## INTRODUCTION

Epiploic appendages are small pouches of peritoneum filled with fat and small vessels that protrude from the serosal surface of the colon<sup>[1-4]</sup>. Primary epiploic appendagitis (PEA) is an inflammation in the epiploic appendage caused by either torsion or spontaneous thrombosis of an appendageal draining vein<sup>[5-9]</sup>.

PEA is a rare cause of localized abdominal pain in otherwise healthy patients. The only clinical feature of PEA is focal abdominal pain and tenderness, without pathognomonic laboratory findings. Clinically, it can be often mistaken for either diverticulitis or appendicitis, and may be treated with antibiotic therapy or even surgical intervention.

Historically, the diagnosis of PEA had been made at diagnostic laparotomy, performed for presumed appendicitis or diverticulitis with complications<sup>[7,8,10,11]</sup>. With advancements in radiologic techniques, such as ultrasonography or computed tomography (CT), PEA can be distinguished preoperatively due to its characteristic radiologic findings, and it is already being diagnosed increasingly<sup>[8,12]</sup>.

Diverticulitis is the disorder most likely to be confused with PEA in a patient presenting with localized abdominal pain. In South Korea, as diverticulitis occurs much less in the left colon and PEA occurs quite frequently in the left colon; both diseases of the left colon remain difficult to differentiate.

Given that PEA is a benign and self-limited condition, the recognition of this diagnosis is important to clinicians to avoid unnecessary hospitalizations, antibiotic therapy, surgical interventions, and overuse of medical resources<sup>[7,10,13]</sup>. However, PEA cases are still infrequent and may often be missed even after imaging studies<sup>[8,10]</sup>.

There are no previous studies specifically designed to compare the clinical characteristics of left PEA with those of left acute colonic diverticulitis (ACD). The pres-

ent study was carried out to describe the clinical characteristics and characteristic CT findings of left PEA and to compare them with those of left ACD.

## MATERIALS AND METHODS

This study was performed on patients who presented with acute left-sided abdominal pain and diagnosed with left PEA or left ACD on CT findings at Konyang University Hospital from January 2001 to December 2011.

We retrospectively reviewed the clinical records and CT images of the study patients after obtaining approval from the institutional review board with regard to the clinical characteristics, presumed diagnosis before the imaging studies, laboratory findings, radiologic findings, and treatments. If data for specific findings were missing, they were not included in the final analysis.

All official CT scans were retrospectively reviewed by two radiologists to determine whether the imaging findings corresponded to PEA or ACD. We selected patients who were given the same diagnosis by two radiologists. The diagnosis of PEA was based on characteristic CT findings as shown below<sup>[10,11,14-16]</sup>: (1) ovoid fatty mass; (2) hyperattenuated ring sign; (3) disproportionate fat stranding; (4) bowel wall thickening with or without compression; (5) central hyperdense dot/line; and (6) lobulated appearance. The diagnosis of ACD was based on CT findings such as the presence of inflamed diverticula or thickened colonic wall more than 4 mm<sup>[7,16-18]</sup>.

The left colon was defined as the segment of colon under the splenic flexure, which included the descending and sigmoid colon. The size of PEA was the largest diameter on the radiologic findings. The shapes were oval, semicircular, and triangular.

We evaluated symptom recurrence in the patients with PEA by reviewing the records of subsequent visits. One patient with PEA was lost to follow-up.

### Statistical analysis

Statistical analysis was performed with SPSS, Windows version 18.0 (SPSS Inc., Chicago, IL, United States), using the  $\chi^2$  test and the Fisher's exact test. The averages were compared by using the *t*-test. A *P*-value of less than 0.05 was considered significant.

## RESULTS

### Clinical characteristics of patients with left primary epiploic appendagitis

There were 28 consecutive patients diagnosed as having left PEA on the CT reports and their clinical characteristics are shown in Table 1. The mean age (mean  $\pm$  SD) was 45.0  $\pm$  11.6 years (range, 24-65 years), and they were more common in males (ratio of males to females = 16: 12). All the patients had sudden onset of abdominal pain. Two patients (7.1%) showed nausea and vomiting, and fever up to 38.3 °C was present in two patients (7.1%). The abdominal tenderness was localized in the left lower

(82.1%) and left upper (3.6%) quadrant. Rebound tenderness was found only in four patients (14.3%), and one patient (3.6%) showed palpable mass. The presumptive clinical diagnoses after medical history and physical examinations were ACD (57.1%), PEA (25.0%), acute gastritis (7.1%), ureter stone (3.6%), constipation (3.6%), and acute appendicitis (3.6%) (Table 2).

**Laboratory and radiologic findings of patients with left primary epiploic appendagitis**

Elevated white blood cell (WBC) count up to 10000/mm<sup>3</sup> was noticed in four of the 26 patients (15.4%). The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) were increased in two of the 13 patients (15.4%) and one of the 14 patients (7.1%), respectively. All patients underwent CT scans, and the average size of the PEA was 2.3 ± 0.6 cm (range, 1.0-3.7 cm). It was de-

tected most frequently in the descending colon (64.3%), the sigmoid colon (25.0%), and the sigmoid-descending junction (10.7%) in that order. The characteristic CT findings (Figure 1A) were demonstrated in all patients; ovoid fatty mass was found in all patients (100%), hyperattenuated ring sign was detected in 25 patients (89.3%), disproportionate fat stranding was noticed in 4 patients (14.3%), bowel wall thickening with or without compression was observed in 6 patients (21.4%), and central hyperdense dot/line (Figure 1B) was detected in 5 patients (17.9%) (Table 3). We performed follow up CT scans in five patients between 1 and 3 wk, and they showed resolution of the inflammation.

**Treatments and clinical results of patients with left primary epiploic appendagitis**

Surgical management was not required in any of the cases. Twenty-two patients (78.6%) were hospitalized, and the mean length of hospital stay was 5.4 ± 5.0 d (range, 0-24 d). Twenty-two patients (78.6%) received antibiotic therapy, and 6 patients (21.4%) were managed conservatively with hydration and mild analgesics. The duration of antibiotic therapy was 10.5 ± 8.4 d (range, 3-28 d) (Table 4). All patients had clinical follow up except one. No patient experienced symptoms of recurrence within the follow-up period (range, 21 d-105 mo).

**Clinical characteristics, laboratory findings, and treatments of patients with left acute colonic diverticulitis**

During the study period, 25 patients were diagnosed with left ACD. The mean age was 58.8 ± 16.3 years (range, 16-86 years), and 60.0% (15/25) of them were males. The major symptom was sudden onset of localized abdominal pain. Nausea occurred in two patients (8.0%), vomiting in two patients (8.0%), and fever in ten patients (40.0%). The abdominal tenderness was slightly

**Table 4** Treatments and clinical results of patients with left primary epiploic appendagitis and left acute colonic diverticulitis

	Lt. PEA (n = 28)	Lt. ACD (n = 25)	P-value
Hospitalization	22 (78.6)	25 (100.0)	0.014

Conservative management	6 (21.4)	3 (12.0)	
Duration of hospital stay (d)	5.4 ± 5.0	10.2 ± 4.0	< 0.001
Duration of abdominal pain (d)	3.3 ± 2.9	5.6 ± 3.6	0.012
Duration of abdominal tenderness (d)	3.3 ± 1.9	7.2 ± 3.8	< 0.001
Duration of antibiotic therapy (d)	10.5 ± 8.4	16.5 ± 12.6	0.045

Values are presented as mean ± SD or n (%). PEA: Primary epiploic appendagitis; ACD: Acute colonic diverticulitis.

diffuse over the left side of the abdomen (52.0%), and definite rebound tenderness was present in thirteen patients (52.0%) (Table 1). Laboratory tests showed that the WBC, ESR, and CRP were increased in thirteen of the 25 patients (52.0%), nine of the 12 patients (75.0%), and fifteen of the 20 patients (75.0%), respectively. All the patients were hospitalized, and the mean hospitalization period was 10.2 ± 4.0 d (range, 4-20 d). Except for three patients, all were treated with antibiotics (88.0%), and the mean duration of antibiotic therapy was 16.2 ± 12.6 d (range, 6-60 d) (Table 4).

#### Comparison of clinical characteristics and laboratory findings: left primary epiploic appendagitis vs left acute colonic diverticulitis

The mean age was 13.8 years younger in patients with PEA than in ACD (45.0 ± 11.6 years *vs* 58.8 ± 16.3 years, *P* = 0.001). There were no significant differences on sex, body mass index, and underlying disease. All patients showed sudden onset of abdominal pain, but the location of the tenderness was different. In PEA, the pain was more localized (85.7% *vs* 48.0%, *P* = 0.003) in the left lower quadrant (LLQ) area (82.1%), whereas the pain was slightly diffuse throughout the left side of the abdomen in ACD (14.3% *vs* 52.0%, *P* = 0.003). Fever and rebound tenderness were more frequently noted in ACD, and this was statistically significant (7.1% *vs* 40.0%, *P* = 0.004; 14.3% *vs* 52.0%, *P* = 0.003; respectively) (Table 1). WBC, ESR, and CRP were more frequently increased in ACD, which were significantly different from those in PEA (15.4% *vs* 52.0%, *P* = 0.006; 15.4% *vs* 75.0%, *P* = 0.003; 7.1% *vs* 75.0%, *P* < 0.001; respectively).

#### Comparison of treatments and clinical results: left primary epiploic appendagitis vs left acute colonic diverticulitis

The mean duration of hospital stay was about five days shorter (5.4 ± 5.0 d *vs* 10.2 ± 4.0 d, *P* < 0.001), and the mean duration of antibiotic therapy was 6-d shorter (10.5 ± 8.4 d *vs* 16.5 ± 12.6 d, *P* < 0.05) in PEA than in ACD (Table 4). Patients with PEA experienced an improve-

ment of the abdominal pain and tenderness after 3.3 d on average, but in ACD, the abdominal pain and tenderness resolved more than 5 d after treatment. The pain duration was shorter in PEA than in ACD (3.3 ± 2.9 d *vs* 5.6 ± 3.6 d, *P* = 0.012; 3.3 ± 1.9 d *vs* 7.2 ± 3.8 d, *P* < 0.001; respectively) (Table 4).

## DISCUSSION

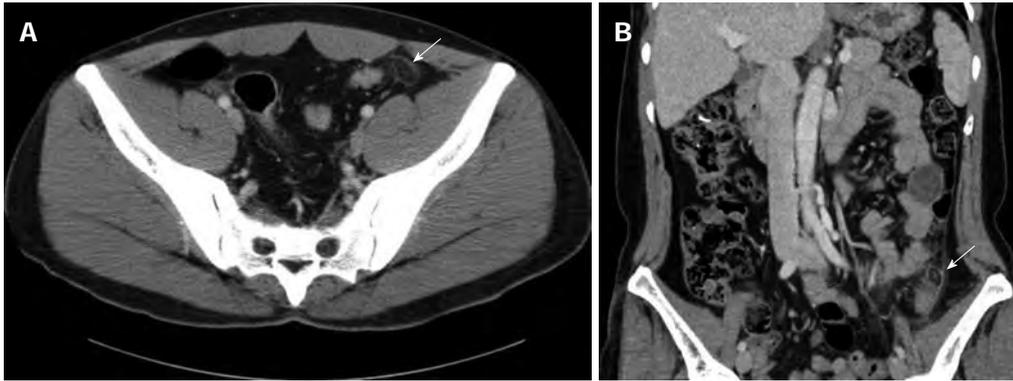

Epiploic appendages, first described in 1543 by Vesalius, are small (1-2 cm thick, 0.5-5.0 cm long) pouches of fat-filled, serosa-covered structures present on the external surface of the colon<sup>[1-4]</sup>. These appendages have not been found to demonstrate any physiologic functions, but are presumed to serve as protective cushions during peristalsis or to provide a defensive mechanism against local inflammation like that of the greater omentum<sup>[2,9,13]</sup>.

PEA, first introduced by Dockerty *et al*<sup>[6]</sup>, is an ischemic inflammatory condition of the epiploic appendages without inflammation of adjacent organs. Each epiploic appendage has one or two small supplying arteries from the colonic vasa recta and has a small draining vein with narrow pedicle<sup>[2,9,14,19,20]</sup>. These appendages are susceptible to torsion due to their pedunculated shape with excessive mobility and limited blood supply<sup>[2,5,9]</sup>. PEA occurs usually from torsion of epiploic appendages which can result in ischemia, or spontaneous venous thrombosis of a draining vein<sup>[5-9]</sup>.

PEA can occur at any age (reported range, 12-82 years<sup>[13]</sup>) with a peak incidence in the fourth to fifth decades, and men are slightly more affected than women<sup>[3,5,7,12,19,20]</sup>. In the current study, the mean age of patients with PEA was 45 years and there was a slight male predominance (16 male *vs* 12 female). They were younger than patients with ACD, and this is consistent with the results of previous studies<sup>[12]</sup>.

Patients with PEA most commonly present with sudden onset of abdominal pain over the affected area, more often in the LLQ mimicking acute sigmoid diverticulitis<sup>[3,15,19,20]</sup>. They usually are afebrile and don't have nausea or vomiting<sup>[2,7,8,19]</sup>. A well-localized abdominal tenderness is present in most patients on physical examination and rebound tenderness is also commonly detected<sup>[8,21]</sup>. A mass may be palpable in 10%-30% of patients<sup>[22]</sup>. In the present study, patients with PEA all showed sudden onset of abdominal pain, and the tenderness was well-localized in the LLQ area. Rebound tenderness was found only in 14.3%, and a palpable mass was noted in 3.6%. In ACD, the patients also had sudden onset of abdominal pain, but the tenderness was diffusely distributed throughout the left side of the abdomen. They more frequently presented with nausea, vomiting, fever, and rebound tenderness, which corresponded well with those of an earlier study<sup>[19]</sup>.

There are no pathognomonic diagnostic laboratory findings in PEA. The WBC and ESR are normal or only moderately elevated<sup>[3,7,8,19]</sup>. In the current study, WBC, ESR, and CRP of the patients with PEA were elevated

**Figure 1** Computer tomography image of a 31-year-old man who presented with acute left lower quadrant pain. A: A 31-year-old man who presented with acute left lower quadrant pain. An oval fatty mass with a hyperattenuated ring and surrounding inflammation adjacent to the sigmoid colon (arrow) is noted. The lesion corresponds to the site of tenderness and is characteristic of primary epiploic appendagitis; B: A 48-year-old female who presented with left lower quadrant pain. An ovoid fat attenuated mass with a central high attenuation area within the inflamed epiploic appendage in the distal descending colon (arrow) is shown.

only in 7%-15% of patients. The patients with ACD more often showed elevations of WBC, ESR, and CRP.

Normal epiploic appendages are usually not identifiable at CT scan without surrounding intraperitoneal fluid such as ascites or hemoperitoneum<sup>[3]</sup>. These appendages typically have fat attenuations, but the attenuation is slightly increased when inflamed<sup>[2,7]</sup>. In the past, PEA has been diagnosed incidentally at laparotomy<sup>[7,8,10]</sup>, but currently it may be possible to make the correct diagnosis with the pathognomonic radiologic findings before operation.

PEA can arise on any segment of the colon. The most frequently involved sites of PEA are the sigmoid colon<sup>[3,15]</sup> and the descending colon followed by the cecum<sup>[15,19]</sup>, where they have more elongated epiploic appendages<sup>[23]</sup>. The characteristic CT finding of PEA is an ovoid fatty lesion with a hyperattenuated ring sign surrounded by inflammatory changes<sup>[9-11,14-16,24]</sup>. A high-attenuated central dot within the inflamed appendage was found in 42.9% by Ng *et al*<sup>[14]</sup>, and in 54% by Singh *et al*<sup>[15]</sup>. It may be due to a thrombosed vessel in the epiploic appendages<sup>[8,10,11,14-16,25]</sup>, or fibrous septa<sup>[26]</sup>. In addition, PEA can appear lobulated when two or more contiguous epiploic appendages lying in close proximity are affected<sup>[8,14,26]</sup>, which would help to differentiate a PEA from an omental infarction<sup>[14]</sup>. In the present study, an ovoid fatty mass with a hyperattenuated ring sign was detected in most PEA patients (89.3%), which is similar to previous studies<sup>[8-10,14,15,23]</sup>. However, we did not find any lobulated appearing PEA on the CT scans.

The common presumptive clinical diagnosis for patients with PEA before radiologic interventions was either diverticulitis or appendicitis. Mollà *et al*<sup>[26]</sup> reported that 7.1% of patients investigated to exclude sigmoid diverticulitis had radiologic findings of PEA. Rao *et al*<sup>[10]</sup> reported that among eleven PEA found on CT scans, seven patients were initially misdiagnosed as having diverticulitis or appendicitis. In the current study, diverticulitis accounted for 57.1% of the presumptive diagnosis in patients with PEA. Only 25.0% of the patients were

suspected of having PEA, most of which were made after the year 2005 when clinicians began to recognize this disease entity.

Early radiologic examination with an abdominal CT scan has aided in the differentiation of PEA from other diseases that require antibiotic therapy or surgical management<sup>[26]</sup>. With the increasing use of CT in the evaluation of an acute abdomen, the incidence of PEA is likely to increase as well<sup>[8,11,12]</sup>. In the present study, only four patients were diagnosed with PEA before 2005, and the rest were diagnosed after 2005.

PEA is a benign and self-limited condition with recovery occurring in less than 10 d without antibiotic therapy or surgery<sup>[7,10,13,23,26]</sup>. In general, patients with PEA can be managed conservatively with oral anti-inflammatory medications<sup>[7,8]</sup>. However, Sand *et al*<sup>[3]</sup> showed 40% recurrence rate in PEA. They believed that conservative treatment may lead to a tendency for recurrence and surgical interventions may be necessary for recurrent cases<sup>[3,12]</sup>. In the current study, most patients (78.6%) with PEA received antibiotic therapy due to the possibility of a more severe diagnosis. No recurrence was noted during the follow-up period, even in cases that were managed conservatively. The follow up CT scan for five patients showed resolution of PEA.

No previous studies were specifically designed to compare the clinical characteristics of patients presenting with left-sided abdominal pain. However, there are some limitations to this study, such as being a relatively small series, retrospective analysis, and no pathologic confirmation of PEA. Further prospective, larger, and comparative studies between left PEA and left ACD are needed.

In conclusion, the clinical symptoms of left PEA and left ACD are very similar in that both types of patients present with left-sided abdominal pain. Although PEA is rare, if a patient has a well-localized abdominal tenderness without associated fever, rebound tenderness, or laboratory abnormalities, we should suspect the diagnosis of PEA and early CT scans should be performed.

PEA can show characteristic CT findings that may allow clinicians to diagnose it correctly and avoid unnecessary hospitalization, antibiotic therapy, or even surgical interventions.

## COMMENTS

### Background

Primary epiploic appendagitis (PEA) is a rare cause of localized abdominal pain. In the past, PEA has been diagnosed incidentally at laparotomy, but currently, it may be possible to make the correct diagnosis with the characteristic radiologic findings before operation. On clinical examination, left PEA can mimic left acute colonic diverticulitis (ACD) owing to the lack of pathognomonic clinical features. No previous studies were specifically designed to compare the clinical characteristics of left PEA with those of left ACD.

### Research frontiers

PEA could be managed conservatively without antibiotic therapy or surgery, but ACD should be treated with antibiotics. Therefore, definitive diagnosis of PEA is important to avoid unnecessary hospitalizations, antibiotic therapy, or even surgical interventions. Early radiological examination with abdominal computer tomography (CT) is useful in obtaining an accurate diagnosis of PEA. The present study was designed to describe the clinical characteristics of left PEA and to compare them with those of left ACD. In addition, authors investigated the characteristic CT findings of PEA.

### Innovations and breakthroughs

The patients with PEA and those with ACD all showed sudden onset of abdominal pain, but the location of the tenderness was different. The patients with PEA had a well-localized abdominal tenderness in the left lower quadrant area, whereas those with ACD presented with slightly diffuse abdominal tenderness throughout the left side of the abdomen. In the ACD cases, fever and rebound tenderness were more often noted, and white blood cell count, erythrocyte sedimentation rate, and C-reactive protein levels were more frequently increased. PEA showed characteristic CT findings like an ovoid fatty lesion with a hyperattenuated ring sign surrounded by inflammatory changes.

### Applications

When patients have well-localized abdominal tenderness without associated systemic manifestation or laboratory abnormalities, clinicians should suspect a diagnosis of PEA and consider performing a CT scan. The data could be useful in obtaining an accurate diagnosis of PEA. The characteristic CT findings and specific clinical features of PEA make it easy to differentiate the disease from diverticulitis.

### Terminology

PEA is an ischemic inflammatory condition of the epiploic appendages without an inflammation of adjacent organs.

### Peer review

The authors demonstrated the clinical features and CT findings of PEA by comparison with those of ACD. The manuscript is well organized and well written.

### Abstract

**AIM:** To investigate the effect of antiviral therapy with nucleoside analogs in hepatitis B virus (HBV)-related cirrhosis and esophageal varices.

**METHODS:** Eligible patients with HBV-related cirrhosis and esophageal varices who consulted two tertiary hospitals in Beijing, China, the Chinese Second Artillery General Hospital and Chinese PLA General Hospital, were enrolled in the study from January 2005 to December 2009. Of 117 patients, 79 received treatment with different nucleoside analogs and 38 served as controls. Bleeding rate, change in variceal grade and non-bleeding duration were analyzed. Multivariate Cox proportional hazard regression was used to identify factors related to esophageal variceal bleeding.

**RESULTS:** The bleeding rate was decreased in the

antiviral group compared to the control group (29.1% vs 65.8%,  $P < 0.001$ ). Antiviral therapy was an independent factor related to esophageal bleeding in multivariate analysis (HR = 11.3,  $P < 0.001$ ). The mean increase in variceal grade per year was lower in the antiviral group ( $1.0 \pm 1.3$  vs  $1.7 \pm 1.2$ ,  $P = 0.003$ ). Non-bleeding duration in the antiviral group was prolonged in the Kaplan-Meier model. Viral load rebound was observed in 3 cases in the lamivudine group and in 1 case in the adefovir group, all of whom experienced bleeding. Entecavir and adefovir resulted in lower bleeding rates (17.2% and 28.6%, respectively) than the control ( $P < 0.001$  and  $P = 0.006$ , respectively), whereas lamivudine (53.3%) did not ( $P = 0.531$ ).

**CONCLUSION:** Antiviral therapy delays the progression of esophageal varices and reduces bleeding risk in HBV-related cirrhosis, however, high-resistance agents tend to be ineffective for long-term treatment.

**Key words:** Nucleoside analog; Esophageal variceal bleeding; Hepatitis B virus; Cirrhosis; Resistance; Entecavir; Lamivudine; Adefovir

**Core tip:** Antiviral therapy with nucleoside analogs improves clinical outcome in hepatitis B virus (HBV)-related decompensated cirrhosis. However, the emergence of resistance results in liver injury. The consequences may be worse in patients with esophageal varices (EV), in which bleeding and death often occur. This study evaluated the efficacy of antiviral treatment over 5 years in patients with HBV-related cirrhosis and EV and found that antiviral therapy decreased the risk of bleeding. However, agents with a high rate of virological breakthrough were ineffective in preventing bleeding. These findings provide evidence-based suggestions for the treatment of this special group of patients.

delays esophageal variceal bleeding in hepatitis B virus-related cirrhosis. *World J Gastroenterol* 2013; 19(40): 6849-6856 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6849.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6849>

## INTRODUCTION

Liver cirrhosis is a common disease that poses a serious threat to the health of patients, and hepatitis B virus (HBV) infection is one of the main causes of cirrhosis. The 5-year survival rate of decompensated liver cirrhosis is reported to be only 14%-28%<sup>[1,2]</sup>. Nucleoside analogs, by inhibiting HBV polymerase and decreasing HBV load, have been widely used in the treatment of hepatitis B. Antiviral therapy with sustained suppression of viral replication has shown benefits in decompensated cirrhotic patients. However, there are no detailed reports of the effects of antiviral therapy in esophageal variceal bleeding, one of the most dangerous and life-threatening complications of cirrhosis.

About 30% of patients with cirrhosis and esophageal varices (EV) will experience bleeding during their lifetime<sup>[3]</sup>. A single episode of uncontrolled variceal bleeding results in immediate death in 5%-8% of patients and has a six-week mortality rate of at least 20%<sup>[4]</sup>. Therefore, prevention of variceal bleeding is of paramount importance.

A number of studies have shown that antiviral therapy with nucleoside analogs is associated with improved clinical outcome in patients with HBV-related decompensated cirrhosis<sup>[5,6]</sup>. However, the problem of drug resistance has also emerged with the long-term use of these agents<sup>[7,8]</sup>. The emergence of resistance results in a loss of virological suppression, which in turn causes progressive liver injury and even severe liver failure<sup>[9]</sup>. The consequences may be worse in patients with EV. Virological breakthrough in patients with EV usually results in EV bleeding or even death.

A retrospective study by Koga *et al*<sup>[10]</sup> demonstrated an improvement in patients with esophageal varices following lamivudine (LAM) treatment. However, the study consisted of only 12 patients treated with LAM and 6 controls, and there were no data on bleeding rate and the effect of virological breakthrough. As patients usually experience bleeding when virological breakthrough takes place, it is necessary to separate the patients and evaluate the harm of drug resistance and the benefit of HBV suppression in these patients to provide evidence-based treatment suggestions. The aim of the present study was to evaluate the efficacy of antiviral treatment over 5 years in patients with HBV-related cirrhosis and EV.

## MATERIALS AND METHODS

### Study design

This study evaluated the efficacy of antiviral therapy with different nucleoside analogs in patients with HBV-related

cirrhosis and EV. Eligible patients with HBV-related cirrhosis who consulted two tertiary hospitals in Beijing, China, the Chinese Second Artillery General Hospital and Chinese PLA General Hospital, were enrolled in the study from January 2005 to December 2009.

The study population had HBV-related cirrhosis and EV. All patients had serum HBV DNA > 500 copies/mL as measured by polymerase chain reaction (PCR) (Fluorescence Quantitation kit; Shanghai Kehua Bio-engineering, Shanghai, China). Exclusion criteria included: history of hepatitis C or D, viral hepatitis, evidence of alcoholic cirrhosis, history of surgery for portal hypertension (splenectomy, shunt or devascularization), suspected liver cancer, hepatic encephalopathy or hepatorenal syndrome, or life-threatening diseases.

In accordance with clinical practice guidelines<sup>[11-13]</sup>, endoscopic eradication of varices was performed in cases with a history of bleeding. Other treatment modalities, such as polyene phosphatidylcholine, reduced glutathione and diuretics, were administered as required. Propranolol was prescribed to all patients except for those who could not tolerate, or had contraindications to, beta-blocker use.

Because no evidence-based suggestions on antiviral therapy in patients with esophageal varices were available, the benefit and potential harm (such as drug resistance and adverse effects) of antiviral therapy were introduced to the patients. Patients received one of the following antiviral treatments immediately after enrollment: lamivudine (LAM) (100 mg/d, Glaxo Wellcome, United Kingdom), adefovir (ADV) (10 mg/d, Tianjin Pharmaceutical, China), entecavir (ETV) (0.5 mg/d, Bristol-Myers Squibb, United States), telbivudine (LdT) (600 mg/d, Novartis, Switzerland), a combination of LAM and ADV (LAM 100 mg/d + ADV 10 mg/d), or no antiviral therapy according to their wishes. As antiviral therapy may have a greater risk in patients with esophageal varices, it was not prescribed if the patients refused it for reasons such as adverse effects and resistance.

The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Ethics Committee of both Hospitals. All patients provided written informed consent prior to enrollment in the study.

### Efficacy assessment

Patients were followed up at a 3-mo interval over 5 years, and levels of HBV DNA, glutamic-pyruvic transaminase (GPT), glutamic-oxaloacetic transaminase (GOT), total bilirubin, serum albumin, prothrombin time, platelet count, diameter of portal vein and splenic area on ultrasound scan were recorded.

Endoscopic findings were graded according to the criteria of the Japanese Association of Portal Hypertension<sup>[14]</sup> as Grade I, II or III, and given a score of 1, 2 or 3, respectively. Bleeding was scored as 4. Patients whose varices were eradicated were scored as 0. Those who showed newly visible, small vessels after endoscopic

EV: Esophageal varices; HBV DNA: Hepatitis B virus DNA; GPT: Glutamic-pyruvic transaminase; GOT: Glutamic-oxaloacetic transaminase; TB: Total bilirubin; ALB: Serum albumin; PT: Prothrombin time; PLT: Platelet count.

eradication, but did not reach grade I were scored as 0.5. Patients without a history of bleeding underwent endoscopic examination every 2 follow-up visits (at a 6-mo interval). Cases with a history of bleeding underwent endoscopic eradication of the varices and follow-up at month 3, and then at a 6-mo interval over the remaining study period. Variceal scores were recorded.

The end-point of this observational study was bleeding or time to study conclusion (December 2009) if the patient did not experience any bleeding. The duration from study enrollment to bleeding or to study conclusion was defined as non-bleeding duration.

### Safety

The incidence of adverse events, discontinuations and deaths were documented. Complete blood counts, blood urea nitrogen, creatinine, creatine kinase, lactic acid and electrolytes were also monitored.

### Statistical analysis

The software STATA 10.0 (Stata Corporation, United States) was used in the statistical analysis of data. The bleeding rates (defined as the cumulative proportion of patients who experienced an esophageal variceal bleeding episode during the study) in the antiviral and control groups were compared using the  $\chi^2$  test. Multivariate Cox proportional hazard regression was used to identify factors related to esophageal variceal bleeding. Non-bleeding duration of the different groups was determined using the Kaplan-Meier model. Increases in variceal score were compared between groups using the Student's *t* test. The portal vein diameter and splenic area on ultrasound scan, levels of GPT, GOT, total bilirubin, serum albumin, prothrombin time and platelet counts were also compared using the Student's *t* test. All tests were two-sided and a *P* value of < 0.05 was considered statistically significant.

## RESULTS

### Patient characteristics

A total of 117 patients who fulfilled the study criteria were enrolled from January 2005 to December 2009. Of these, 79 patients received antiviral therapy, including ETV (*n* = 29), ADV (*n* = 28), LAM (*n* = 15), LdT (*n* = 4) and combination treatment with LAM and ADV (*n* = 3). Patients not receiving antiviral therapy (*n* = 38) were followed up as a control group, and received the same treatment as the antiviral group minus antiviral therapy. Of the total study population, 63 patients (42 in the antiviral group and 21 in the control group) who had a history of bleeding underwent endoscopic eradication of varices, while the other 54 cases (37 in the antiviral group and 17 in the control group) without a history of esophageal variceal bleeding did not undergo endoscopic eradication treatment. Primary prevention was not performed in this study population. In addition, a total of 95 patients (65 patients in the antiviral group and 30 patients in the control group) received propranolol. Both propranolol and endoscopic eradication patterns were not significantly different between the two groups (*P* = 0.801 and *P* = 0.846, respectively). The antiviral treatment and control groups were well matched with regard to gender, age, hepatic function, grade of EV, HBV DNA level, HBeAg status, portal vein diameter and splenic section area on ultrasound (Table 1).

### Virological response

By week 12 of treatment, HBV DNA decreased to undetectable levels (defined as < 500 copies/mL, by PCR) in 58 (73.4%) of the 79 patients in antiviral treatment group. This was observed in 23 (79.3%) patients in the ETV group, 19 (67.8%) patients in the ADV group, 12 (80.0%) patients in the LAM group, 2 patients in the Ldt group (*n* = 4) and 2 patients in the LAM/ADV treatment group (*n* = 3). The number of patients achieving undetectable

**Table 2** Laboratory examination results, portal diameter and splenic area in antiviral and non-antiviral groups during the study (mean  $\pm$  SD)

	Non-antiviral ( <i>n</i> = 38)	Antiviral ( <i>n</i> = 79)	<i>P</i> value
GPT (IU/L)	19.2 $\pm$ 53.1	-28.6 $\pm$ 58.8	< 0.001
GOT (IU/L)	19.9 $\pm$ 52.8	-34.9 $\pm$ 86.2	0.001
TB (mmol/L)	3.9 $\pm$ 9.6	-3.8 $\pm$ 9.5	0.009
ALB (g/L)	-2.8 $\pm$ 5.5	1.2 $\pm$ 6.1	0.003
PT (s)	1.4 $\pm$ 2.2	-0.2 $\pm$ 2.1	0.001
PLT ( $10^{12}$ /L)	-18.9 $\pm$ 28.8	-10.3 $\pm$ 16.9	0.029
Diameter of portal vein (mm)	1.0 $\pm$ 0.9	0.2 $\pm$ 0.8	< 0.001
Splenic section area (cm <sup>2</sup> )	8.6 $\pm$ 7.2	3.6 $\pm$ 9.8	0.012

GPT: Glutamic-pyruvic transaminase; GOT: Glutamic-oxaloacetic transaminase; TB: Total bilirubin; ALB: Serum albumin; PT: Prothrombin time; PLT: Platelet count.

HBV DNA levels increased to 67 at week 24. At week 48, a total of 71 patients in the antiviral group achieved undetectable HBV DNA levels. None of the patients in the control group (*n* = 38) achieved undetectable HBV DNA during the study.

#### Reduced deterioration of cirrhosis due to antiviral therapy

The portal vein diameter and area of splenic section tended to increase at the conclusion of the study compared to baseline. However, there was a smaller mean increase in the diameter of the portal vein and area of splenic section on ultrasound in the antiviral group compared to the control group (Table 2). Analysis of biochemical profiles (alanine aminotransferase, aspartate aminotransferase, serum albumin, total bilirubin and prothrombin time) showed progressive improvements in liver function in the group receiving antiviral treatment (Table 2). Median Child-Pugh score increased from 8 to 10 in control patients (*P* = 0.018), and decreased from 8 to 7 in the antiviral group (*P* = 0.686).

#### Reduced bleeding rate and delayed progression of variceal grade due to antiviral therapy

By the end of the study, the bleeding rate was significantly decreased in the antiviral group (*n* = 79) compared to the control group (*n* = 38) (29.1% vs 65.8%, *P* < 0.001). The bleeding rate was also statistically different when all the patients were stratified into the endoscopic eradication group and non-endoscopic intervention group (Table 3). The mean  $\pm$  SD increase in variceal score was reduced in the antiviral treatment group compared with the control group (Table 3).

Multivariate Cox regression analysis was performed to identify the factors associated with increased or decreased esophageal bleeding. The results showed that antiviral therapy (OR = 11.3, 95%CI: 3.1-38.5; *P* < 0.001), endoscopic eradication of varices (OR = 15.8, 95%CI: 4.1-51.1; *P* < 0.001), baseline portal vein diameter (OR = 39.1, 95%CI: 1.6-842.6; *P* = 0.025) and baseline serum HBV DNA level (OR = 0.8, 95%CI: 0.6-1.1; *P* = 0.042)

**Table 3** Increase in score of varices/year in antiviral and non-antiviral therapy

	Non-antiviral	Antiviral	<i>P</i> value
All the cases ( <i>n</i> = 117)	1.7 $\pm$ 1.2	1.0 $\pm$ 1.3	0.003
Endoscopic eradication ( <i>n</i> = 63)	1.8 $\pm$ 1.5	1.1 $\pm$ 1.6	0.098
No endoscopic intervention ( <i>n</i> = 54)	1.6 $\pm$ 0.7	0.8 $\pm$ 0.9	0.003

were independent factors related to esophageal bleeding.

#### Virological breakthrough hindered the benefit of antiviral therapy

Four cases showed undetectable HBV DNA initially, however, viral load rebound was observed during follow-up, which was defined as virological breakthrough. All 4 cases bled in contrast to other patients who benefited from antiviral therapy.

In the LAM group (*n* = 15), three cases were found to have virological breakthrough during the study. All 3 cases had no history of bleeding and therefore were not treated with endoscopy. In the first case, virological breakthrough was detected at week 48 ( $1.8 \times 10^5$  copies/mL) and ADV was administered immediately, however, the patient exhibited re-bleeding at week 53 and the HBV DNA level reached  $3.3 \times 10^5$  copies/mL. In the second case, the patient bled at week 192 and eventually died due to bleeding. Examination revealed HBV DNA at  $5.1 \times 10^5$  copies/mL. In the third case, the patient bled at week 90 and HBV DNA breakthrough was detected on examination ( $3.1 \times 10^8$  copies/mL). The patient was treated with vasoactive drugs, endoscopic eradication of varices and switched to ETV after cessation of bleeding. HBV DNA levels were subsequently undetectable at 12 wk after treatment, and the patient was bleed-free for 48 wk by the end of the study.

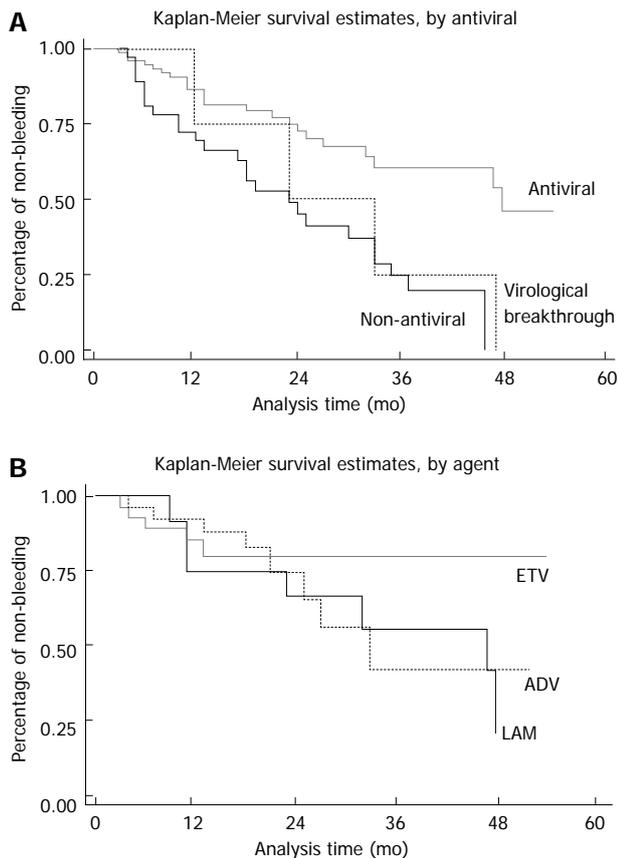

One patient in the ADV group (without a history of bleeding and endoscopic intervention) experienced bleeding at week 130. HBV DNA was  $9.8 \times 10^3$  copies/mL at examination. The patient was switched to ETV after cessation of bleeding and was bleed-free for 36 wk by the end of the study.

As more cases suffered from virological breakthrough and bleeding, the bleeding rate in the LAM group was not statistically different from that in the control group (8/15 vs 25/38, *P* = 0.531), while the ETV (5/29) and ADV (8/28) groups showed a lower bleeding rate (*P* < 0.001 and *P* = 0.006, respectively) compared to the control group. ETV was statistically better than LAM (*P* = 0.019), and no significant differences were found between the other agents.

There was one case of bleeding in both the LdT (*n* = 4) and combination treatment (LAM/ADV) groups (*n* = 3), and due to the small number of cases, they were not included in the statistical analysis.

#### Kaplan-Meier analyses of non-bleeding duration

Kaplan-Meier analyses demonstrated that bleeding was

**Figure 1** Kaplan-Meier analysis of non-bleeding duration. A: Non-bleeding duration in antiviral and control cases was compared using the Kaplan-Meier survival model. Bleeding was defined as a failed event. The occurrence of bleeding was reduced and delayed in the antiviral treatment group compared to the control group. The curve of virological breakthrough cases (dashed line) was close to that of the control group, demonstrating reduced efficacy when virological breakthrough occurred; B: Non-bleeding durations for entecavir (ETV), adefovir (ADV) and lamivudine (LAM) therapy were compared using the Kaplan-Meier survival model. Bleeding was defined as a failed event. The non-bleeding durations for ETV, ADV and LAM were similar in the first 2 years, however, differences became clear following long-term treatment, which may have been due to cumulative resistance and bleeding.

postponed in the antiviral treatment group compared to the control group (Figure 1A). However, the curve of virological breakthrough cases was close to that of the control group (Figure 1A). The Kaplan-Meier curves of ETV, ADV and LAM crossed each other within the first 2 years, but deviated beyond the 2-year mark (Figure 1B).

### Safety

One patient died of esophageal variceal bleeding as stated above; no other severe adverse events were reported in the study. Most reported side effects were mild such as fatigue ( $n = 1$ ), headache ( $n = 1$ ), dyspepsia ( $n = 2$ ), nausea ( $n = 1$ ), dizziness ( $n = 1$ ) and insomnia ( $n = 1$ ). Discontinuation of treatment due to adverse events was not observed.

### Overall survival

In this study, follow-up ended if the patient bled. Additional follow-up was included to determine the effect

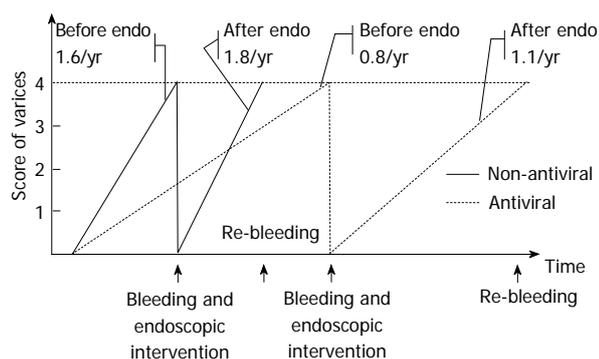

of antiviral therapy on patient survival. The cumulative 1-year survival rate was 97.5% (77/79) and 89.5% (34/38) for the antiviral group and control group, respectively ( $P = 0.086$ ). The cumulative 2-year survival rate was 93.7% (74/79) and 86.3% (29/38) for the antiviral group and control group, respectively ( $P = 0.012$ ). However, 8 patients in the control group switched to antiviral therapy. When these 8 patients were excluded, the cumulative 2-year survival rate in the control group was 70.0% (21/30), which was also lower than in the antiviral group ( $P = 0.002$ ). Most of the patients in the control group switched to antiviral therapy during the additional follow-up period, and a comparison of the 5-year survival rate of the control group and antiviral group was not available. In addition to the patient who died of drug resistance and bleeding, 17 patients died (9 due to bleeding, 3 due to hepatic encephalopathy, 2 due to chronic liver failure and 3 due to liver cancer) and 17 were lost during the additional follow-up in the antiviral group. The overall 5-year survival rate in the antiviral group was 71.0%, which was higher than in the general cirrhotic patients<sup>[1]</sup>.

## DISCUSSION

Esophageal variceal bleeding is a life-threatening complication of decompensated cirrhosis, and bleeding from varices is a medical emergency which requires immediate treatment. If bleeding is not controlled quickly, the patient may go into shock or die. Aside from the urgent need to stop the bleeding, treatment is also aimed at the prevention of future bleeding. Treating the underlying cause of variceal bleeding can help prevent recurrence and early treatment of liver disease may prevent the development of varices.

Propranolol is accepted as the main treatment modality for the prevention of esophageal variceal bleeding in cirrhotic patients<sup>[15,16]</sup>. Preventive endoscopic intervention is advocated by some medical experts in high-risk cases. For patients who have experienced bleeding, the accepted modalities for the prevention of re-bleeding include endoscopic eradication of varices (secondary prophylaxis)<sup>[11-13]</sup>, continuous administration of propranolol and regular endoscopic follow-up plus supplementary endoscopic intervention<sup>[17-19]</sup>. The present study examined the role of antiviral therapy as an additional option for the prevention of esophageal variceal bleeding in hepatitis B patients.

Nucleoside analog treatment in decompensated cirrhosis has been widely accepted in recent years<sup>[20-22]</sup>, however, there have been no studies on the efficacy of antiviral treatment in patients with both cirrhosis and esophageal varices. In this study, antiviral therapy delayed progression of EV and decreased bleeding rates in cirrhotic patients with actively replicating HBV. Figure 2 shows the model of varices development. The grade of EV increases with time resulting in bleeding. After endoscopic eradication, the variceal score increases again until bleeding recurs. Antiviral therapy delayed both the progression of varices before and after endoscopic therapy

**Figure 2** Sketch of delayed progression of esophageal varices by antiviral therapy. Varices were scored according to the criteria of the Japanese Association of Portal Hypertension: grade I, II, and III and given a score of 1, 2 and 3, respectively. Bleeding was scored as 4. Endoscopic eradication was scored as 0. The dark line shows the development of esophageal varices in hepatitis B virus-related cirrhosis without antiviral therapy. The dashed line is the development of varices with antiviral therapy. The grade of esophageal varices increases with time and then bleeding occurs. After endoscopic eradication, the varices score increases again until bleeding recurs. Antiviral therapy delayed both the progression of varices before and after endoscopic therapy and postponed esophageal variceal bleeding. Before endo: Before endoscopic intervention; After endo: After endoscopic intervention.

and postponed esophageal variceal bleeding (*i.e.*, effective in both primary and secondary prophylaxis).

The delayed progression of EV and decreased bleeding rates in patients receiving antiviral therapy may be explained by relief of portal hypertension. Decreased inflammation due to antiviral therapy might contribute to lower pressure of hepatic sinusoids. In addition, it has been reported that long-term antiviral therapy can lead to histological improvement of cirrhosis, slowing the rate of deterioration<sup>[23]</sup>. Although biopsy of the liver was not performed in this study, the improvement in liver structure was reflected by the delayed dilation of portal veins, delayed increase in spleen size, the reversion of levels of GPT, GOT, bilirubin, prothrombin time, albumin and delayed decrease in platelets count. These clinical benefits, together with delayed bleeding, are the ultimate aims in clinical practice. Recently, an on-line published study reported that ETV therapy reduced the risks of hepatic events in hepatitis B cirrhosis patients within 5 years<sup>[24]</sup>. The results of our study are in accordance with the findings of this published study.

However, drug-resistance was found to be the main obstacle in the benefit of antiviral therapy for the prevention of EV bleeding. All 3 LAM-resistant cases and 1 ADV-resistant case experienced bleeding. As a result, the efficacy of LAM in the prevention of EV bleeding decreased to a level that was not statistically different from that of the control group in the present study. The Kaplan-Meier curves of ETV, ADV and LAM crossed each other within the first 2 years, but deviated beyond the 2-year mark. It is known that drug resistance increases with time. A plausible explanation for this is that the high incidence of virological breakthrough observed with LAM reduced the efficacy of LAM in the preven-

tion of esophageal bleeding. As studies have reported a lower rate of resistance for ETV<sup>[25]</sup>, this agent may be a better choice in the prevention of esophageal bleeding in cirrhotic patients with active viral hepatitis B replication. The LAM/ADV combination has also been reported to have lower drug resistance rates<sup>[26]</sup>. However, combination therapy may be more expensive and result in more adverse events, and therefore, may not be well received by patients.

One limitation of the present study is that genetic screening for emergence of antiviral resistance was not performed. This is an important issue as current treatment guidelines recommend long-term treatment of patients with cirrhosis. Consequently, it is unknown whether the patients who experienced virological breakthrough also had emergence of genotypic resistance. In this study, the levels of HBV DNA, GOT, GPT and other biochemical parameters were tested in all patients at a 3-mo interval, however, only one case was found to have developed virological break through during routine examination. Although rescue treatment with additional ADV was administered immediately, the patient still experienced esophageal bleeding after a few weeks. In the other three patients who experienced bleeding, virological breakthrough had not been previously detected. As all four cases with virological breakthrough were compliant with the antiviral treatment, the most likely explanation for virological breakthrough is antiviral resistance. Investigations of the underlying gene mutations and switching to a more appropriate treatment regimen as early as possible may be useful in enhancing the effectiveness of antiviral therapy.

In conclusion, antiviral therapy with nucleoside analogs may delay progression of varices, decrease the risk of bleeding and improve liver function in patients with HBV-related cirrhosis and EV. However, drug resistance usually leads to bleeding in this special group of patients. Agents with a high rate of virological breakthrough may not be effective in the long-term prevention of esophageal variceal bleeding. The major limitation of the present study is the relatively small sample size of heterogeneous use of antiviral agents. These conclusions should be confirmed in further randomized controlled clinical studies.

## COMMENTS

### Background

Antiviral therapy with nucleoside analogs improves the clinical outcome of hepatitis B virus (HBV) infection. However, the emergence of resistance results in liver injury. The consequences may be worse in patients with esophageal varices (EV), in which bleeding and death often occur.

### Research frontiers

Recently, an on-line published study demonstrated that entecavir therapy re-

duced the risks of hepatic events in hepatitis B cirrhosis patients within 5 years. Koga *et al* reported an improvement in esophageal varices in patients following lamivudine (LAM) treatment in a retrospective study. However, the study only consisted of 12 patients treated with LAM and 6 controls, and there were no data on bleeding rate and the effect of virological breakthrough. As patients usually experience bleeding when virological breakthrough takes place, it is necessary to separate the patients and evaluate the harm of drug resistance and the benefit of HBV suppression in these patients to provide evidence-based treatment suggestions.

### Innovations and breakthroughs

The present study evaluated the efficacy of antiviral treatment over 5 years in patients with HBV-related cirrhosis and EV, and found that antiviral therapy decreased the risk of bleeding; and agents with a high rate of virological breakthrough were ineffective in preventing bleeding. These findings for the first time provide evidence-based treatment suggestions for this special group of patients.

### Applications

Antiviral therapy with nucleoside analogs may delay progression of varices, decrease the risk of bleeding and improve liver function in patients with HBV-related cirrhosis and EV. Agents with a high rate of virological breakthrough may not be effective in the long-term prevention of esophageal variceal bleeding.

### Terminology

Nucleoside analogs, are molecules that can inhibit HBV polymerase, and therefore decrease HBV load. They have been widely used in the treatment of hepatitis B. Virological breakthrough indicates that the viral load decreased to an undetectable level initially, and rebounded during follow-up. Virological breakthrough often leads to progressive liver injury and even severe liver failure.

### Peer review

The article provides statistical analysis of data from HBV patients who went through antiviral therapy to determine the role of antiviral therapy in esophageal varices and bleeding in HBV-related cirrhosis. This article provides information important to clinicians and HBV patients in general.

### Abstract

**AIM:** To investigate the feasibility and safety of Natural orifice trans-umbilical endoscopic cholecystectomy with a water-jet hybrid-knife in a non-survival porcine model.

**METHODS:** Pure natural orifice transluminal endoscopic surgery (NOTES) cholecystectomy was performed on three non-survival pigs, by transumbilical approach, using a water-jet hybrid-knife. Under general anesthesia, the following steps detailed the procedure: (1) incision of the umbilicus followed by the passage of a double-channel flexible endoscope through an overtube into the peritoneal cavity; (2) establishment of pneumoperitoneum; (3) abdominal exploration; (4) endoscopic cholecystectomy: dissection of the gallbladder performed using water jet equipment, ligation of the cystic artery and duct conducted using nylon loops; and (5) necropsy with macroscopic evaluation.

**RESULTS:** Transumbilical endoscopic cholecystectomy was successfully completed in the first and third pig, with minor bleedings. The dissection times were 137 and 42 min, respectively. The total operation times were 167 and 69 min, respectively. And the lengths of resected specimen were 6.5 and 6.1 cm, respectively. Instillation of the fluid into the gallbladder bed produced edematous, distended tissue making separation safe and easy. Reliable ligation using double nylon loops insured the safety of cutting between the loops. There were no intraoperative complications or hemodynamic instability. Uncontrolled intraoperative bleeding occurred in the second case, leading to the operation failure.

**CONCLUSION:** Pure NOTES trans-umbilical cholecystectomy with a water-jet hybrid-knife appears to be feasible and safe. Further investigation of this technique with long-term follow-up in animals is needed to confirm the preliminary observation.

**Key words:** Natural orifice transluminal endoscopic surgery; Cholecystectomy; Water-jet; Hybrid-knife; Triangulation

**Core tip:** Flexible single-incision surgery (FSIS), one of recent advances in endoscopic surgery, is a promising single-incision approach, which has exploited the advantages of single-incision laparoscopy and narrow sense of natural orifice transluminal endoscopic surgery (NOTES). Compared to NOTES, FSIS uses the navel to facilitate the extraction of the specimen and the umbilical closure is quick and easy. Compared to SILS, FSIS does not need any specialized device for the entry ports. Furthermore, water-jet hybrid knife technology enables a quick switch between blunt and sharp dissection. This study assessed the feasibility and safety of endoscopic cholecystectomy using transumbilical approach and water jet hybrid knife technology.

Trans-umbilical endoscopic cholecystectomy with a water-jet hybrid-knife: A pilot animal study. *World J Gastroenterol* 2013; 19(40): 6857-6862 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6857.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6857>

## INTRODUCTION

Laparoscopic cholecystectomy (LC)<sup>[1]</sup> remains the gold standard for the treatment of benign gallbladder diseases, showing superiority such as better cosmetic results, less postoperative pain, and shorter recovery time compared with open cholecystectomy. Under the guidance of the Holy Grail of minimal invasive surgery, namely, scarless surgery, natural orifice transluminal endoscopic surgery (NOTES) has made substantial progress. However, it is also technically difficult due to lack of appropriate devices and loss of triangulation. To achieve both minimal invasiveness and effectiveness, we proposed the following technique for pure NOTES cholecystectomy, by transumbilical approach, using an endoscopic water jet system applied to perform blunt and sharp dissection without accessory switch.

## MATERIALS AND METHODS

### Animals

Natural Orifice Trans-umbilical Cholecystectomy with a new water-jet dissector Erbejet 2 was performed on three non-survival TiBet experimental pigs (two were female weighing 30 kg, the other was male weighing 35 kg).

### Experimental site

Experimental site: Olympus training center for animal experimental study in Peking, China.

### Animal preparation and post-operative management

Animal preparation and post-operative management: fasting 48 h pre-operation and took polyethylene glycol 4 g/kg orally for intestinal preparation before procedure. Preoperative intramuscular ketamine 20 mg/kg and Xylazine 2 mg/kg mixture induced anesthesia, retaining animal on the operating table in a supine position and performing endotracheal intubation, connecting anaesthesia apparatus following inhalational anesthesia by 4%-5% isoflurane. When the animals entered into complete general anesthesia condition, regulating gas concentration to 1%-2% for anesthesia maintenance and intraoperative intravenous management with 5% glucose-saline. After the operation ended, intravenous pentobarbital sodium 100 mg/kg was injected to the porcine, along with the autopsy to observe the wound and adjacent organs for any damages.

### Instruments and devices

Instruments and devices: forward-looking double channel

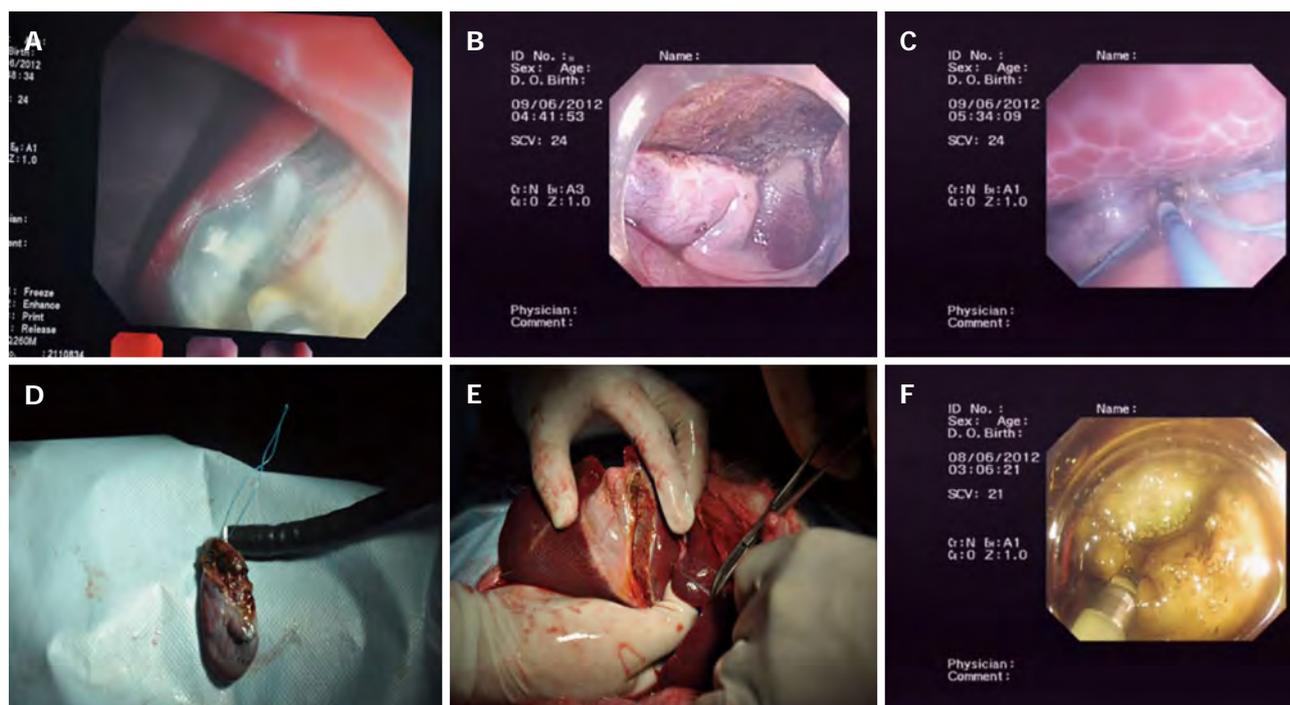

gastroscope(GIF-2TQ260M, olympus), non-invasive forceps (FQ-46L-1, olympus), thermal hemostatic forceps (endoscopic hemostatic forceps FD-410LR, olympus), nylon cord snare (MAJ-340, olympus) and ligation device (HX-20L-1, olympus), overtube (overtubeMD48618, Sumitomo Bakelite, Tokyo Japan), Trocar, co2 air pump, digestive endoscopic surgery workstation (ERBE VIO-300D, Germany), T-type Erbejet2 (ERBEjet2; ERBE Elektromedizin, Germany), endoscopic clips and trip gear (endoclips, HX-610-135OLYMPUS, olympus), methylene blue, normal saline.

### Experimental procedure

**Establishment of pneumoperitoneum:** Porcines were placed under supine position, routine preoperative skin disinfection, spread towel, making a 1.5 cm longitudinal incision through the umbilicus, puncturing into abdominal cavity with trocar then overtube was inserted. Surrounding skin was clamped by using towel clamp in order to avoid air leakage, so endoscope can be inserted into peritoneal cavity through overtube, (being unable to gear co2 air pump directly), the latter is connected to endoscopic air supply device to maintain pneumoperitoneum which can be adjusted by endoscopic inspiration button.

**Abdominal exploration:** After the establishment of pneumoperitoneum, exploration of intra-abdominal viscera from epigastrium to hypogastrium was done. Stomach, diaphragm, gallbladder, spleen, small intestine and large intestine can be viewed meanwhile retroperitoneal organs kidney, pancreas for instance cannot be explored. A swollen light blue gallbladder can be seen from endoscope due to abrasion. Sometimes gallbladder is covered by the lobes of liver that requires removing the lobes of liver to reveal cholecyst by operating endoscope.

**Cholecystectomy:** The assistant manipulated overtube to advance the endoscope to the surgery field and to reveal cholecyst and liver bed. High-pressure injection of methylene blue solution dyed normal saline by using T-type ERBEjet2 through endoscopic work channel into fibrous tissue between gallbladder and liver bed. The water-injection pressure was set to 30-50 bar. Blue cushion formation taking place following the local injection (Figure 1A), demarcates the liver parenchyma. Then the dissection of fibrous tissue was done between gallbladder's serous membrane and liver parenchyma by T-type ERBEjet2 (coagulation-cut hybrid model, power 45w, effect 2) starting from fundus or neck of gallbladder from left to right side. Every separation was done following the cushion formation and was operated in the raised or lift cushion. Once catching the sight of small blood vessels or encountering haemorrhage, prophylactic hemostasis with electro-tome or hemostatic forceps would be required. The gallbladder would fall off liver bed while dissected carefully up to the neck or fundus of gallbladder (Figure 1B). Dissected clearly and completely to reveal calot's triangle and cystic duct, cystic artery, hepatic duct and common bile duct has been identified. Ligation of

**Figure 1** Picture demonstrating a concept of a novel method of cholecystectomy. A: Methylene blue mixed with normal saline solution injected into fibrous tissues between gallbladder and liver bed; B: The gallbladder falling off liver bed; C: Cystic duct and artery cut using the water-jet hybrid-knife between loops; D: The resected gallbladder grasped by forceps; E: Macroscopic view of the liver fossa on necropsy; F: Clipped gallbladder perforation.

cystic duct and cystic artery with nylon cord snare instead of endoclips for fast ligation. During the procedure, non-invasive forceps and ligation device were introduced into abdominal cavity through endoscopic double channels respectively. Cholecyst was clamped and empocketed into nylon cord snare and then ligation of the cystic duct and cystic artery together was done on the distal end of cystic duct, three snares placed in all; the proximal and distal end of cystic duct and then cut in the middle of snares (Figure 1C). Confirmed no active haemorrhage and no biliary fistula. Consequently, cholecyst retracted through overtube applying forceps or basket (Figure 1D). Ultimately, autopsy was performed to check the dissection wound and adjacent viscera for injury.

## RESULTS

Transumbilical endoscopic cholecystectomy was successfully completed in the first and third pig, with minor bleedings (Tables 1, 2). The dissection times were 137 and 42 min, respectively. The total operation times were 167 and 69 min, respectively. The time required decreased with experience. And the lengths of resected specimen were 6.5 and 6.1 cm, respectively. Instillation of the fluid into the gallbladder bed produced edematous, distended tissue making separation safe and easy. Reliable ligation using double nylon loops insured the safety of cutting between the loops. There were no intraoperative complications or hemodynamic instability. At necropsy, the loops on the cystic duct and artery were secure and that neither bile nor blood leakage was observed from this site. Both the gallbladder bed and the liver bed were dry

(Figure 1E).

During the dissection in the second pig (Tables 1 and 2), unexpected gallbladder rupture occurred, and the perforation site was quickly clipped (Figure 1) after being identified. Subsequently, uncontrolled intraoperative bleeding occurred in the second case, leading to the operation failure.

## DISCUSSION

To date, most of pure NOTES procedures are still performed only in animals<sup>[2-4]</sup> due to several technical barriers. NOTES cholecystectomy has been successfully introduced into clinical application based on preliminary animal experimental researches. Several approaches has been reported in the literatures such as transgastric, transvaginal and transcolonic route, but most finished cholecystectomy with the assistance of laparoscopic instruments in humans<sup>[5-7]</sup>. Meanwhile, pure NOTES only has several case reports<sup>[8-10]</sup>. Transvaginal approach is the most widely used in the clinical practices and is considered<sup>[5]</sup> to be the best approach for NOTES surgery. However, it only apply to females with underlying complications like dyspareunia, infertility and pelvic adhesions<sup>[11,12]</sup>. Pugliese *et al*<sup>[5]</sup> showed no above-mentioned discomfort and incision related complications. Transgastric approach was originally studied<sup>[13,14]</sup>, but rarely applied to clinical practices because of technical difficulties<sup>[13,15,16]</sup>, to overcome these difficulties, the innovation of new technology and use of new devices has been reported in several literatures<sup>[9]</sup>. Furthermore, Marescaux *et al*<sup>[16]</sup> considered this approach for NOTES surgery would be

**Table 1** Transumbilical endoscopic cholecystectomy was successfully completed in the first and third pig, with minor bleedings

Animal	Sex	Weight (kg)	Time of pneumoperitoneum (min)	Time of dissection (min)	Time of ligation and resection (min)	Total time (min)
1	Female	30	2	137	28	167
2	Male	35	2	61 (incomplete)	-	-
3	Female	33	2	42	25	69

**Table 2** Experimental indicators in transumbilical endoscopic cholecystectomy

Animal	Blood loss (mL)	Perforation	Adjacent viscera injury	Size of specimen	Postoperative management
1	10	No	No	6.5 cm × 3.4 cm × 1.2 cm	Autopsy
2	50	Yes	Vascular injury	-	Autopsy
3	5	No	No	6.1 cm × 3.3 cm × 1.8 cm	Autopsy

the major route in future. Transcolonic NOTES similar to transvaginal approach has an advantage for upper abdominal organs, however, its major problem lies in potential contamination as a result of bacterial colonization. In this study, we performed cholecystectomy through umbilicus similar to single-port laparoscopic surgery. Truly speaking, to some extent it does not follow the true concept of NOTES. This approach compared to other approaches has no blind region in enterocoelia, in the other hand, it cannot support stable platform due to soft abdominal wall resulting in difficulties in manipulating endoscope<sup>[17]</sup>. Perforation occurred in our study owing to unstable platform. Therefore, experienced surgeon and endoscopist would be needed to cooperate with each other to complete cholecystectomy by using endoscope *via* umbilical approach. Any surgery require an appropriate and clear operative field vision achieved by manipulating overtube. We realized in practice that overtube was easy to displace because of its smoothness and flexibility which results in the lost operative field and had to re-reveal the gallbladder. So operator and assistant must keep tacit cooperation, the latter also plays a very important role who needs to regulate overtube from time to time in accordance with the procedure to support clear vision for operator which is significant in reducing operation time, avoiding accidental injury involving viscera, blood vessels and smoothly completing surgery. In a sentence, not a single perfect approach for the NOTES has been established till now. The development of endoscopic instruments and the evolution of technology have to be explored. Whether pure NOTES achieves full approval and advocacy from clinical practice depends on how the related challenges can be resolved practically.

The mechanism of water-jet is to employ high-pressure jet of water to cut materials fine, primarily used in manufacture. In 1982, water-jet was firstly introduced to medical application and performed liver resection<sup>[18,19]</sup>. German RAU firstly introduced professional designed water-jet into clinical application in 1990. From then on, its applications gradually extended to maxillofacial surgery, plastic surgery, urinary surgery, ophthalmosurgery, *etc*<sup>[20]</sup>. To date, its use is limited to the dissection of mesenchymal tissue and parenchymal organs<sup>[21,22]</sup>. In this field, German company ERBE is always ahead. Its

Helix-Hydro-jet device can perform precise, controllable tissue-selective (indicating water-rich tissue such as liver parenchyma) with minimal injury to the surrounding fibrous structures and has achieved favorable results in open and laparoscopic operations<sup>[18,23,24]</sup>. However, the above-mentioned Helix-Hydro-jet device cannot be passed through a standard working channel of the current flexible endoscope because its outer-diameter is larger than endoscopic operative channel, so do not match with NOTES procedures. ERBEJet2 water-jet system incorporates high-pressure water-jet with high-frequency electrocautery function with the characteristics of more flexibility, smaller size, easier handling, more precision and less foam formation compared with the precursor model Helix-Hydro-jet<sup>[25]</sup>. This new technology is mainly used to perform endoscopic submucosal dissection for gastrointestinal tumors. Studies showed that water-jet hybrid-knife could effectively shorten operation time and avoid endoscopic accessory-switch with lower haemorrhage and perforation rate, consequently improve the safety and efficiency of resection compared with conventional endoscopic knife<sup>[26-30]</sup>. Isayama *et al*<sup>[29]</sup> reported that transgastric pure NOTES successfully performed cholecystectomy using injection-dissection technology in the animal experiment with long operation time because the procedure of injection and dissection required the need of different instruments and keeps on frequently changing.

The work pressure of water-jet ranges from 30 to 80 bar. If lower than 30 bar, it cannot produce valid cushion, acting on mucous layer when more than 70 bar. While exceeding 100 bar may cause injury to deeper layer such as muscular layer<sup>[24,31]</sup>. Selective-tissue injection results in a selective deposition of mixed solution in the submucosa followed by mucosal elevation when the dissector placed directly on the mucous layer. High-pressure injection of solution into loose connective tissue between gallbladder and liver bed can produce a fluid lift cushion avoid the thermal damage to surrounding tissues, making dissection easier and safer<sup>[29]</sup>. In our study, neither uncontrolled hemorrhage of the liver fossa nor perforation of the gallbladder occurred, indicating the superiority of the ERBEJet2 water-jet system. What is worth mentioning, the lack of surgical triangulation, an important adjunct for

pure NOTES procedure, becomes less important, since the fluid lift cushion produced by the ERBEjet2 water-jet system facilitates dissection even there is no satisfactory traction or countertraction.

Refer to the selection of injecting Solution, perfect solution should have following advantages of being non-toxic to health, no injury to the injection site, low dispersion velocity, easy to access and cheap. Currently, normal saline solution is the most commonly employed with the drawback of being fast absorption, other selective solutions include hyaluronic acid, plasma expanders, gelatin, *etc.* Among them, hyaluronic acid is considered to be the best selection but most expensive<sup>[21,31,32]</sup>. Adding optimal adrenaline can delay solution absorption speed, prolong elevation time and decrease injection times. In our study, injection solution we used was saline solution that is easy to get and cheap. Furthermore, we had added methylene blue dye into saline solution in order to make the solution blue. Furthermore, it had helped clearing the boundaries between gallbladder's serosal layer and liver parenchyma by using high pressure injection with more precise and safe dissection along with maintaining prophylactic hemostasis. This can be seen from blood loss during the operation in our study.

In the functional cholecystectomy performed by Liu *et al.*<sup>[33]</sup>, the cystic duct was isolated and closed with an endoscopic clip. Since standard endoscopic clip may not be safe for use on the cystic duct as it has a hinge gap between the arms of the clip when deployed, in our study, the Olympus ligating device (Polyloop-detachable loop ligating device) was used to tie off the base of the gallbladder once exposed and isolated, and then the gallbladder was cut between the loops using the endoscopic polypectomy snare.

Calot's triangle complete exposure is very important for both the ligation of cystic duct, cystic artery and the avoidance of damage to biliary duct. Although double-channel endoscope has elevator, parallel correlation of double-channel cannot produce surgical triangulation resulting in limited orientation to manipulate. It is still difficult to ligate the cystic duct and cystic artery for pure NOTES that need more attention during the operation. The exposure of CVS (critical view of safety) can decrease the possibility of bile duct injury before ligating the cyst duct and artery<sup>[6]</sup>. We successfully performed pure NOTES cholecystectomy without laparoscopic support.

In conclusion, this study demonstrated the feasibility and safety of trans-umbilical NOTES cholecystectomy using the water-jet hybrid-knife. Due to absence of control study, the advantages of ERBEjet2 cannot be highlighted but possesses potential superiority. Therefore, further study will be designed to compare this new dissector with other endoscopic knife.

## COMMENTS

### Background

Laparoscopic cholecystectomy remains the gold standard for the treatment of benign gallbladder diseases, showing superiority such as better cosmetic

results, less postoperative pain, and shorter recovery time compared with open cholecystectomy. Under the guidance of the Holy Grail of minimal invasive surgery, namely, scarless surgery, natural orifice transluminal endoscopic surgery (NOTES) has made substantial progress. However, it is also technically difficult due to lack of appropriate devices and loss of triangulation.

### Research frontiers

To achieve a nonvisible scar, transumbilical endoscopic/laparoscopic cholecystectomy, single-incision laparoscopic surgery were proposed early or late.

### Innovations and breakthroughs

This is the first study evaluating feasibility and safety of a new method of cholecystectomy using NOTES transumbilical approach and water jet hybrid knife technology. The study demonstrated that the endoscopic water jet system can create a fine stream of unidirectional high-pressure saline solution to penetrate tissue, and instillation of the fluid into the gallbladder bed can produce edematous, distended tissue making separation safe and easy.

### Applications

Generally, transumbilical endoscopic cholecystectomy using a water-jet hybrid-knife is feasible and safe. How to avoid the injury of the cystic artery requires further investigation.

### Terminology

Hydraulic energy from pressurized fluid has been widely used in medical procedures. Instillation of fluid under high pressure into closed spaces can produce edematous, distended tissue, and the resulting increased weight and gravity force is enough to separate filmy avascular tissue without sharp dissection (electrosurgery).

### Peer review

This is a very interesting study about the feasibility and safety of Natural orifice trans-umbilical endoscopic cholecystectomy with a water-jet hybrid-knife in a non-survival porcine model. In this study, pure NOTES cholecystectomy was performed on three non-survival pigs, by transumbilical approach, with a double-channel flexible endoscope, and a water-jet hybrid-knife. The authors found that pure NOTES trans-umbilical cholecystectomy with a water-jet hybrid-knife appear to be feasible and safe.

### Abstract

**AIM:** To evaluate the effects of estrogen (E2) on systemic and splanchnic hyperdynamic circulation in portal hypertensive rats.

**METHODS:** Fifty castrated female Sprague-Dawley rats were divided into five groups: sham operation (SO), partial portal vein ligation (PPVL) + placebo (PLAC), PPVL + E2, PPVL + ICI and PPVL + E2 + ICI. Hemodynamic measurements were performed using ultrasonography. Mesenteric arteriole contractility in response to norepinephrine was determined using a vessel perfusion system. Oxidative stress in the mesenteric artery was investigated by *in situ* detection of the superoxide anion ( $O_2^{\cdot-}$ ) and hydrogen peroxide ( $H_2O_2$ ) concentrations.

**RESULTS:** Treatment with E2 resulted in a significant decrease of portal pressure ( $P < 0.01$ ) and portal venous inflow ( $P < 0.05$ ), and higher systemic vascular resistance ( $P < 0.05$ ) and splanchnic arteriolar resis-

tance ( $P < 0.01$ ) in PPVL + E2 rats compared to PPVL + PLAC rats. In the mesenteric arterioles of PPVL + E2 rats, the dose-response curve was shifted left, and the  $EC_{50}$  was decreased ( $P < 0.01$ ). E2 reduced  $O_2^{\cdot-}$  production and  $H_2O_2$  concentration in the mesenteric artery. However, ICI182, 780 reversed the beneficial effects of E2, therefore, the systemic and splanchnic hyperdynamic circulation were more deteriorated in ICI182, 780-treated rats.

**CONCLUSION:** Treatment with estrogen improved the systemic and splanchnic hyperdynamic circulation in PPVL rats, in part due to the alleviation of oxidative stress.

**Key words:** Estrogen; Hyperdynamic circulation; Partial portal vein ligation; Oxidative stress

**Core tip:** Vascular hyporeactivity is affected by gender and estrogen. The aim of the present study was to investigate whether estrogen could attenuate the severity of hyperdynamic circulation and the underlying mechanism in pre-hepatic portal hypertensive rats without cirrhosis, with a focus on oxidative stress. The authors proposed that treatment with estrogen could improve the systemic and splanchnic hyperdynamic circulation in partial portal vein ligation rats, in part due to the alleviation of oxidative stress.

Estrogen improves the hyperdynamic circulation and hyporeactivity of mesenteric arteries by alleviating oxidative stress in partial portal vein ligated rats. *World J Gastroenterol* 2013; 19(40): 6863-6868 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6863.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6863>

## INTRODUCTION

Portal hypertension (PHT) is a major complication of liver cirrhosis and is associated with the development of hyperdynamic circulation, characterized by elevated portal pressure (PP), increased splanchnic (small intestine) blood flow, increased cardiac output, and development of an extensive network of portosystemic collaterals<sup>[1]</sup>. PP is determined by extrahepatic factors such as portal blood flow and collateral resistance in addition to intrahepatic resistance. Therefore, it would be triggered by persistent splanchnic vasodilation. Functional changes can be found in the portal hypertensive splanchnic vasculature, including splanchnic vasodilation and decreased responsiveness to vasoconstrictors as a result of endothelial dysfunction and impaired activation of vasoconstrictive mechanisms<sup>[2]</sup>. Although the levels of vasoconstrictors such as norepinephrine (NE) and angiotensin- II (Ang- II) are increased in the blood circulation and are accompanied by enhanced sympathetic excitability in PHT, the splanchnic vasculature remains dilated<sup>[3]</sup>. Hyporeactivity of the artery in response to vasoconstrictors plays a key role in blood vessel dilation and hyperdynamic circulation<sup>[4,5]</sup>. Vascular hyporeactivity has been observed in PHT animals in both the systemic circulation and in the mesenteric artery, and it is also affected by gender and estrogen<sup>[6]</sup>. In addition, experimental studies have shown that estradiol (E2) reduces PP and increases hepatic blood flow in castrated and cirrhotic model rats, but the effect is significantly inhibited by the estrogen antagonist ICI182, 780<sup>[7,8]</sup>.

Both acute and chronic liver diseases are characterized by an increased formation of reactive oxygen species (ROS), as indicated by increased superoxide anion in the whole blood of cirrhotic patients with decompensated liver and increased urinary F2-isoprostanes and lipoperoxidation and decreased superoxide dismutase in experimental PHT models<sup>[9]</sup>. Increased oxidative stress may lead to impaired endothelium dysfunction and be involved in the pathogenesis of PHT. It has therefore been a subject of interest<sup>[10,11]</sup>.

The aim of the present study was to investigate whether estrogen could attenuate the severity of hyperdynamic circulation and the underlying mechanism in PHT rats without cirrhosis, with a focus on oxidative stress. Thus, to exclude the hepatoprotective and antifibrogenic effects of estrogen, the PHT was induced by partial portal vein ligation (PPVL) but not by the injection of hepatotoxic drugs, such as CCl<sub>4</sub> and dimethylnitrosamine, or by bile duct ligation.

## MATERIALS AND METHODS

### *Animal model and treatment*

This animal study was approved by the local animal ethics committee of Renji Hospital and performed according to the guidelines of the Laboratory Animal Care and Use Committee at School of Medicine, Shanghai Jiao Tong University (Shanghai, China). Fifty female Sprague-Dawley rats weighing 200-220 g underwent ovariectomy

before the study. Three weeks after the initial surgery, the rats underwent PPVL or sham operation (SO) as previously described by Reiberger *et al*<sup>[1]</sup> and were divided into five groups: SO, PPVL + placebo (PLAC), PPVL + E2, PPVL + ICI and PPVL + E2 + ICI. Briefly, under ketamine anesthesia (intramuscular injection of 10 mg/100 g body weight), the portal vein was isolated, and stenosis was induced by a single ligature of 3-0 silk placed around both the portal vein and a 20-gauge blunt-tipped needle. The needle was then removed, leaving a calibrated stenosis of the portal vein. Portal hypertension was considered present at 14 d after surgery. In SO animals, the portal vein was isolated and similarly manipulated but not ligated. Starting on the day of surgery, the PPVL + E2, PPVL + ICI and PPVL + E2 + ICI groups were subcutaneously administered  $\beta$ -estradiol (2  $\mu$ g/100 g body weight/d, R and D Systems, United States) or/and ICI182, 780 (2  $\mu$ g/100 g body weight/d, R and D Systems, United States) for 14 d. The SO and PPVL groups were subcutaneously administered the same volume of the placebo (ethanol).

### *Hemodynamic measurements*

Under anesthesia induced by an intramuscular injection of ketamine (10 mg/100 g body weight), the velocity and inside diameter of the portal vein (PV) proximal to the ligation and stroke volume (SV) were obtained using a Vevo770 High-Resolution Imaging System (Visual Sonics, Canada). A 22 G catheter filled with heparin saline was inserted into the femoral artery to obtain the mean arterial pressure (MAP) and heart rate (HR). Another 22 G catheter was introduced into the portal vein to measure PP, and one was inserted into the inferior vena cava to measure central venous pressure (CVP) after making an incision at the midline of the abdomen. All parameters were recorded using an SP840 pressure transducer and a multichannel recorder (Philips, United States).

Cardiac output (CO), cardiac index (CI), PV blood flow, portal venous inflow (PVI), systemic vascular resistance (SVR) and splanchnic arteriolar resistance (SAR) were calculated as follows: CO = SV  $\times$  HR; CI = CO  $\times$  100/body weight (g); PVI = PV blood flow  $\times$  100/body weight (g); SVR = (MAP - CVP)/CI; SAR = (MAP - PP)/PVI. PV blood flow and CO were normalized by body weight and presented as CI and PVI. Resistances in the vascular systems were calculated from the ratio between the perfusion pressure (*P*) and blood flow (*Q*) of each vascular territory.

### *Determination of mesenteric arteriole reactivity to NE*

Following the determination of hemodynamic measurements, the mesenteric arteries and the mesentery were removed. Using an SMZ-168 dissecting microscope (Motic, China), the third-order arterioles in the mesentery were carefully dissected and transferred to a vascular perfusion system containing a 3-(*N*-morpholino) propanesulfonic acid-buffered physiological salt solution (MOPS-PSS, 0-4 °C, pH 7.4; NaCl 145 mmol/L, KCl 5.0 mmol/L, CaCl<sub>2</sub> 2.0 mmol/L, MgSO<sub>4</sub> 1.0 mmol/L, NaH<sub>2</sub>PO<sub>4</sub> 1.0

mmol/L, glucose 5.0 mmol/L, pyruvate 2.0 mmol/L, EDTA 0.02 mmol/L and MOPS 3.0 mmol/L). A glass micropipette containing MOPS-PSS (top diameter, 50 μm) was inserted into one end of the arteriole and fixed with 11-0 single strands. Blood was flushed out at a perfusion pressure of 8 mmHg. Another glass micropipette was then inserted into the other end of the arteriole and fixed. The two glass micropipettes were suspended in organ baths containing 60 mL of MOPS-PSS (37 °C, pH 7.4). The arteriole was equilibrated under a pressure of 80 mmHg for 30 min prior to the experiments. After the equilibration period, cumulative NE concentration response curves (10<sup>-8</sup> mol/L-10<sup>-4</sup> mol/L) were obtained by increasing the concentration in quarter-log increments. The inner diameter was measured using a BA310 microscope camera system (Motic, China). The vasoconstriction rate and the logarithm of the NE concentration were used as the vertical axis and the abscissa, respectively.

### Superoxide anion detection

The oxidative fluorescent dihydroethidium (DHE, Sigma, United States) was used to evaluate in situ production of superoxide anion (O<sub>2</sub><sup>•-</sup>)<sup>[12]</sup>. Frozen, enzymatically intact, 10-μm-thick sections of the superior mesenteric arteries were incubated with DHE (10 μmol/L) in PBS for 30 min at 37 °C in a humidified chamber protected from light. DHE is freely permeable to cells and is oxidized in a reaction with O<sub>2</sub><sup>•-</sup> to ethidium bromide, which binds to DNA in the nucleus and fluoresces red. Images were obtained with an IX71 fluorescence microscope (Olympus, Japan).

### Hydrogen peroxide determination

The level of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) was measured using a hydrogen peroxide assay kit (Abcam, United States). In the presence of horseradish peroxidase (HRP), the OxiRed Probe reacts with H<sub>2</sub>O<sub>2</sub> to produce product with color. The superior mesenteric artery was cleaned of connective tissue, precipitated with RIPA (Beyotime, China; 200 μL RIPA/20 mg tissue) for 15 min and then centrifuged for 15 min at 1000 g. A total of 5 μL of

the supernatant was diluted with 46 μL of assay buffer, mixed with 50 μL of the Reaction Mix (assay buffer 46 μL, OxiRed Probe 2 μL, HRP 2 μL) and then incubated at room temperature for 10 min. The OD570 nm was read with a Synergy 4 Multi-Mode Microplate Reader (BioTek, United States), and the H<sub>2</sub>O<sub>2</sub> concentration was calculated according to a standard concentration curve.

### Statistical analysis

The change in the reactivity of the mesenteric arteriole in response to NE was presented as a dose-response curve, which was fitted by a nonlinear regression analysis (GraphPad Software Inc., San Diego, CA, United States). Maximal responses (Emax) and effective concentrations causing half maximum responses (EC<sub>50</sub>, calculated by regression analysis) were obtained from concentration response curves. Values are expressed as the means ± SD. Statistical comparisons were performed using one-way ANOVA. *P* values < 0.05 were considered significant. All statistical analyses were performed using the Statistical Package for the Social Sciences 13.0 (SPSS Inc., United States).

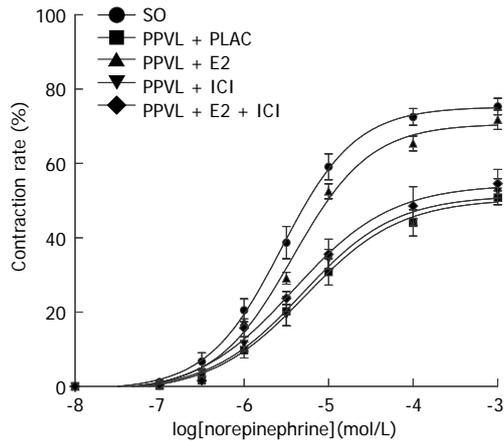

## RESULTS

### Hemodynamics

Compared to SO, PPVL resulted in a lowered HR (*P* < 0.05) and MBP (*P* < 0.05) and significantly increased PP (*P* < 0.01) in the four groups of prehepatic PHT. However, measurement of MAP and HR revealed no significant differences between the four PPVL groups (*P* > 0.05). PP significantly decreased by 18.5% in PPVL + E2 rats with a mean PP of 12.2 ± 1.6 mmHg compared to a mean PP of 14.9 ± 1.4 mmHg in PPVL + PLAC rats (*P* < 0.01) (Table 1).

PVI was significantly increased in the four groups of rats that underwent PPVL compared to the corresponding SO group (*P* < 0.01). Treatment with E2 resulted in a reduction in PVI in PPVL + E2 rats compared to PPVL + PLAC rats (3.98 ± 1.4 mL/min per 100 g vs 4.87 ± 1.6 mL/min per 100 g, *P* < 0.05) (Table 1).

Although CI was slightly increased in the four groups

**Figure 1** Dose-response curves for isolated rat mesenteric arteriole contractility in response to norepinephrine at different concentrations. The dose-response curves in the four partial portal vein ligation (PPVL) groups were lowered and shifted to the right compared to the sham operation (SO) group. Treatment with estrogen (E2) reversed the curve to left, whereas ICI182, 780 decreased the response to norepinephrine of arterioles treated with E2. PLAC: Placebo.

of PPVL rats compared to the SO group, there were no significant differences among the five different groups ( $P > 0.05$ ). SVR was lower in the four groups of PPVL rats compared to SO rats due to the decreased MBP ( $P < 0.05$ ), which was increased 16.9% by E2 treatment in PPVL + E2 rats compared to PPVL + PLAC rats ( $3.95 \pm 0.41$  mmHg·min·100 g/mL *vs*  $3.38 \pm 0.35$  mmHg·min·100 g/mL,  $P < 0.05$ ) (Table 1).

SAR was significantly lower in the four groups of PPVL rats compared to SO rats ( $P < 0.01$ ). Rats treated with E2 showed significantly higher SAR, with a 34.1% increase compared to PPVL + PLAC rats ( $19.29 \pm 1.8$  mmHg·min·100 g/mL *vs*  $14.39 \pm 2.2$  mmHg·min·100 g/mL,  $P < 0.01$ ) (Table 1).

ICI182, 780 treatment alone did not influence PP, PVI, CI, SVR or SAR compared to PPVL + PLAC rats, except that the body weight was slightly lower ( $P < 0.05$ ). However, ICI182, 780 reversed the beneficial effects of E2 on PVI, CI, SVR and SAR. Thereby, the systemic circulation and splanchnic hyperdynamic circulation were more deteriorated (Table 1).

### Contractility of isolated rat mesenteric arterioles in response to NE

Compared with the SO group, the dose-response curve of the mesenteric arteriole in response to NE was lower and shifted right, with decreased  $E_{max}$  ( $P < 0.01$ ) and increased  $EC_{50}$  ( $P < 0.01$ , Figure 1; Table 1) in the four PPVL groups. In the mesenteric arterioles of PPVL rats treated with E2, the dose-response curve was shifted left, and the  $EC_{50}$  was decreased ( $P < 0.01$ ), compared with the PPVL + PLAC rats. ICI182, 780 alone did not influence the dose-response curve or  $EC_{50}$  compared to PPVL rats treated with placebo ( $P > 0.05$ ). However, ICI182, 780 decreased the response to NE of arterioles treated with E2, thereby the dose-response curve was shifted right.

### Superoxide anion production

Low-intensity fluorescence was observed throughout SO vessels, confirming that all layers of the normal vessel produced low amounts of  $O_2^{\bullet-}$ . Fourteen d after the surgery,  $O_2^{\bullet-}$  production was increased in the four groups of PPVL rats (Figure 2). However, the staining was particularly weak in PPVL + E2 rats, and the administration of ICI182, 780 blocked the beneficial effect that E2 provided.

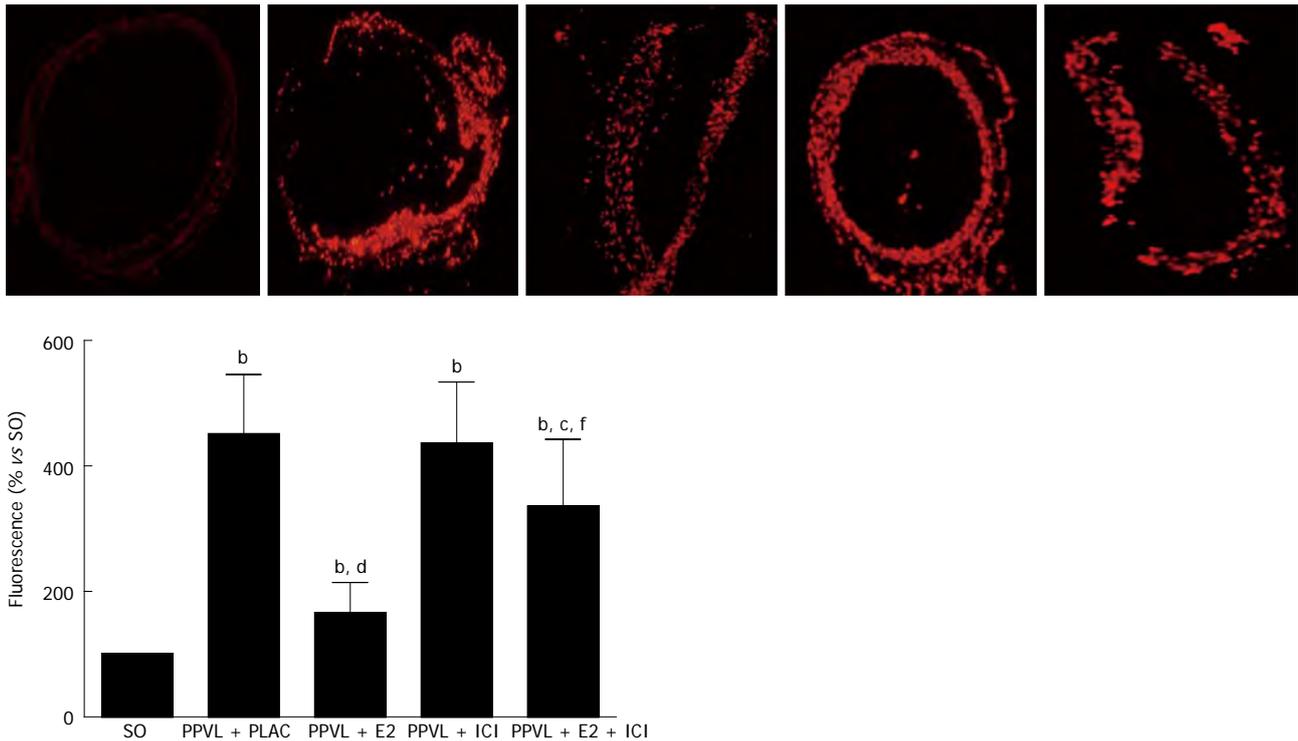

### Hydrogen peroxide production

In the superior mesenteric arteries,  $H_2O_2$  generation was nearly 2.5-fold higher in PPVL + PLAC rats than in SO rats ( $8.2 \pm 1.5$   $\mu$ mol/L *vs*  $3.3 \pm 0.9$   $\mu$ mol/L,  $P < 0.01$ ; Figure 3). Exogenous E2 reduced  $H_2O_2$  levels in PPVL + E2 rats when compared with those in PPVL + PLAC rats ( $4.9 \pm 1.0$   $\mu$ mol/L *vs*  $8.2 \pm 1.5$   $\mu$ mol/L,  $P < 0.01$ ). The  $H_2O_2$  levels in mesenteric arteries treated with ICI182, 780 alone were similar to those found in PPVL + PLAC rats ( $7.9 \pm 1.8$   $\mu$ mol/L *vs*  $3.3 \pm 0.9$   $\mu$ mol/L,  $P < 0.01$ ). However, the administration of ICI182, 780 to PPVL + E2 rats suppressed the antioxidant effect of E2 ( $6.6 \pm 1.3$   $\mu$ mol/L *vs*  $4.9 \pm 1.0$   $\mu$ mol/L,  $P < 0.05$ ).

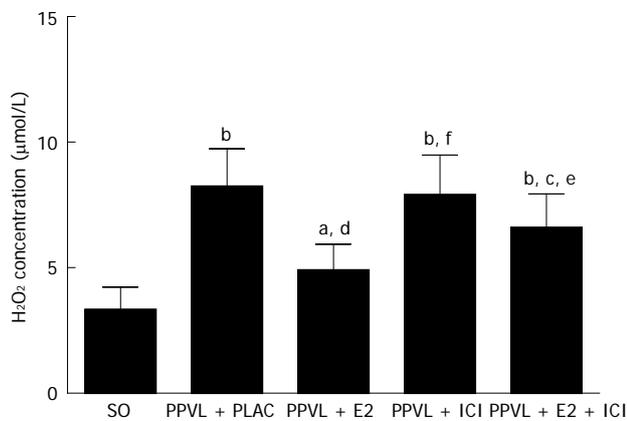

## DISCUSSION

Recent studies have already provided evidence of the importance of vascular hyporeactivity in the development and maintenance of PHT. Aortic ring hyporeactivity has been investigated both in bile duct ligation and  $CCl_4$  induced cirrhotic models<sup>[13-15]</sup>. Ferlitsch *et al*<sup>[16]</sup> have shown that forearm artery responses to NE and Ang-II are decreased in patients with cirrhosis. Clear sex differences have also been observed in the vasoconstrictor responsiveness of aortic rings from rats with and without PHT<sup>[17]</sup>. In contrast to male rats, PHT does not induce vascular hyporesponsiveness in female rats. Estrogen has been shown to be effective in animal models of established PHT with cirrhosis by suppressing hepatic fibrosis and relaxation of the hepatic sinusoid<sup>[7,18]</sup>. However, the efficacy of estrogen in the setting of *de novo* PHT and the underlying mechanism had not been characterized in detail. To exclude the effect of cirrhosis on oxidative status and inflammatory cytokines, we established this animal model of prehepatic PHT to further describe both the hemodynamic and anti-oxidant effects of estrogen treatment in the PPVL rat model. The hypothesis of our study was that estrogen could reverse the severity of hyperdynamic circulation and the vascular hyporeactivity of the mesenteric arteries by alleviating oxidative stress in portal hypertensive rats without cirrhosis in which liver function was normal.

The results of our study suggested that mesenteric arteriole sensitivity and contractility in response to NE were decreased in PPVL rats, indicating the hyporesponsiveness of the splanchnic vessels to vasoconstrictors, in accordance with deteriorative splanchnic hemodynamics. Treatment with E2 significantly ameliorated the hyperdynamic splanchnic circulation in PPVL rats. The reduction

**Figure 2** *In situ* detection of superoxide anion. Fluorescence micrographs of superior mesenteric arteries stained with the  $O_2^{\cdot-}$ -sensitive dye DHE (red fluorescence) were obtained from sham operation (SO) and partial portal vein ligation (PPVL) rats at 14 d after surgery. Images were acquired at identical settings. <sup>b</sup> $P < 0.01$  vs SO; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs PPVL + placebo (PLAC); <sup>f</sup> $P < 0.01$  vs PPVL + estrogen (E2).

**Figure 3** Hydrogen peroxide determination. The hydrogen peroxide concentrations of the superior mesenteric arteries were obtained from sham operation (SO) and partial portal vein ligation (PPVL) rats 14 d after surgery. <sup>a</sup> $P < 0.05$ , <sup>b</sup> $P < 0.01$  vs SO; <sup>c</sup> $P < 0.05$ , <sup>d</sup> $P < 0.01$  vs PPVL + placebo (PLAC); <sup>e</sup> $P < 0.05$ , <sup>f</sup> $P < 0.01$  vs PPVL + estrogen (E2).

in splanchnic blood inflow represented by decreased PVI could be explained by an improved contractile reaction of the splanchnic vessels to the vasoconstrictor and a subsequently increased SAR. Additionally, the production of ROS was decreased in PPVL-E2 rats compared to PPVL-SA rats, indicating a profound amelioration of oxidative stress and corresponding to the improvement of systemic and splanchnic hyperdynamic circulation.

The fact that PPVL resulted in oxidant injury was first demonstrated by Fernando *et al.*<sup>[18]</sup>, who concluded that the formation of ROS may be important in the patho-

genesis of hemodynamic changes and that anti-oxidants can ameliorate oxidant injury and prevent the development of hyperdynamic circulation<sup>[19]</sup>. Estrogen played a protective role by acting as an antioxidant, which granted it action as a scavenger of free radicals, decreasing the formation of ROS. In castrated rats, significant increases in the activity of antioxidant enzymes were observed, which may have occurred to compensate for the absence of circulating E2 promoted by castration; even then, it was not effective in reducing lipid peroxidase levels<sup>[8,20,21]</sup>. Estrogen replacement can reverse this effect, reducing lipid peroxidase to the values of control animals<sup>[21]</sup>. In addition, estrogen stimulates eNOS expression in SECs and increases NO production, contributing to a reduction in portal pressure in a model of intrahepatic PHT<sup>[7]</sup>.

In summary, we conclude that improvements in oxidative stress after estrogen administration manifest as a functional improvement in the contractile response to vasoconstrictors. Indeed, we observed improvements in both the systemic and splanchnic hyperdynamic circulation. Further studies on the clinical administration of estrogen should be performed.

## COMMENTS

### Background

Portal hypertension, a major complication of liver cirrhosis, is associated with the development of hyperdynamic circulation and would be triggered by persistent splanchnic vasodilation. Functional changes can be found in the portal hypertensive splanchnic vasculature, including splanchnic vasodilation and decreased responsiveness to vasoconstrictors as a result of endothelial dysfunction and impaired activation of vasoconstrictive mechanisms.

**Research frontiers**

Increased oxidative stress may lead to impaired endothelium dysfunction and be involved in the pathogenesis of portal hypertension. It has therefore been a subject of interest

**Innovations and breakthroughs**

The authors found that improvements in oxidative stress after estrogen administration manifest as a functional improvement in the contractile response of mesenteric arteries to vasoconstrictors in partial portal vein ligation (PPVL) rats.

**Applications**

The authors proposed that treatment with estrogen could improve the systemic and splanchnic hyperdynamic circulation in PPVL rats.

**Peer review**

The manuscript is an interesting manuscript with novel observations. The authors delineated the effect of estrogen treatment on the systemic and splanchnic hyperdynamic circulation in portal hypertensive rats. The findings are straight forward and manuscript is well written and nicely discussed.

### Abstract

**AIM:** To evaluate the clinical results of angiography and embolization for massive gastrointestinal hemorrhage after abdominal surgery.

**METHODS:** This retrospective study included 26 patients with postoperative hemorrhage after abdominal surgery. All patients underwent emergency transarterial angiography, and 21 patients underwent emergency embolization. We retrospectively analyzed the angiographic features and the clinical outcomes of transcatheter arterial embolization.

**RESULTS:** Angiography showed that a discrete bleeding focus was detected in 21 (81%) of 26 patients. Positive angiographic findings included extravasations of contrast medium ( $n = 9$ ), pseudoaneurysms ( $n = 9$ ), and fusiform aneurysms ( $n = 3$ ). Transarterial embolization was technically successful in 21 (95%) of 22 patients. Clinical success was achieved in 18 (82%) of

22 patients. No postembolization complications were observed. Three patients died of rebleeding.

**CONCLUSION:** The positive rate of angiographic findings in 26 patients with postoperative gastrointestinal hemorrhage was 81%. Transcatheter arterial embolization seems to be an effective and safe method in the management of postoperative gastrointestinal hemorrhage.

**Key words:** Transcatheter arterial embolization; Postoperative hemorrhage; Complications; Surgery

**Core tip:** Postoperative gastrointestinal hemorrhage is a potentially fatal complication after abdominal surgery. It is difficult for surgeons to deal with it. Reoperation is often difficult or even unsuccessful in patients with postoperative hemorrhage, especially those with two or more previous abdominal operations, due to the anatomical inaccessibility of the arteries, postoperative adhesions, and inflammatory reactions. This study showed that transcatheter embolization was a useful microinvasive treatment option for the identification and occlusion of a massive bleeding site after abdominal surgery.

Transarterial embolization for massive gastrointestinal hemorrhage following abdominal surgery. *World J Gastroenterol* 2013; 19(40): 6869-6875 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6869.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6869>

### INTRODUCTION

Postoperative gastrointestinal hemorrhage is a potentially

fatal complication after abdominal surgery. It prolongs hospital stay, requires urgent radiological or surgical intervention, and increases mortality after abdominal surgery. The incidence of postoperative gastrointestinal hemorrhage after abdominal surgery is low, but increases with an increase in surgical procedures, severity of illness, and comorbid conditions. The incidence of postoperative gastrointestinal hemorrhage has been reported as 0.4%-4% in a recent series<sup>[1-7]</sup>, and 2%-18% in earlier series<sup>[8-14]</sup>. Although recent studies have shown that its mortality has decreased, it remains a serious and life-threatening condition.

Traditionally, open ligation or excision has been considered to be the first-line therapeutic option for patients with massive gastrointestinal hemorrhage after abdominal surgery. However, the bleeding site is difficult to establish because of local inflammatory response after abdominal surgery. In addition, patients with postoperative gastrointestinal hemorrhage are reported to be poor candidates for emergency surgery because of cicatrization and friability of postoperative tissues<sup>[15]</sup>.

Transcatheter angiographic embolization is a less invasive procedure that is known to be a safe and effective treatment to control massive gastrointestinal hemorrhage. With the development of endovascular techniques over the past decade, transarterial embolization has been widely used clinically for treatment of postoperative gastrointestinal hemorrhage after abdominal surgery, despite the possibility of gastrointestinal infarction<sup>[16-19]</sup>.

In this study, we retrospectively reviewed and analyzed the angiographic findings and clinical outcomes of transarterial angiography and embolization in 26 patients with postoperative hemorrhage after abdominal surgery.

## MATERIALS AND METHODS

This study was approved by our institutional review board, and all patients gave their informed consent before the procedure. This study included 26 patients (22 male and 4 female) who underwent emergency transarterial angiography and embolization for postoperative hemorrhage after abdominal surgery between August 2007 and April 2012 at our hospital. The mean age was 57.2 years (range, 35-86 years). The average time of onset of postoperative hemorrhage was 27.7 d (range, 3-65 d). The abdominal surgery included surgery for gastric carcinoma ( $n = 13$ ), pancreatic head carcinoma ( $n = 2$ ), common bile duct carcinoma ( $n = 2$ ), duodenal papilla carcinoma ( $n = 2$ ), ascending colon carcinoma ( $n = 1$ ), severe pancreatitis ( $n = 1$ ), gallbladder carcinoma ( $n = 1$ ), cholangiolithiasis ( $n = 1$ ), and intra-abdominal abscess ( $n = 1$ ), as well as splenomegaly ( $n = 1$ ), and mesenteric torsion ( $n = 1$ ). Clinical presentations included hematemesis, hemochezia/melena, and bleeding from surgical drains. The volume of bleeding was  $> 1$  L in 24 h.

The diagnostic angiography was performed via transfemoral approach, using a 5-F angiographic catheter (Cook, Bloomington, IN, United States) and a 5-F sheath

(Terumo, Tokyo, Japan). In all cases, celiac and superior mesenteric angiography was routinely performed to detect the bleeding points. If this did not detect any bleeding points, inferior mesenteric angiography was performed. Hemorrhage was diagnosed based on the presence of extravasation of contrast agent, a pseudoaneurysm, and a fusiform aneurysm on angiography. Immediately after bleeding points were identified, transarterial embolization was performed with microcoils (Cook) and/or gelatin sponge (gelfoam particles) through a coaxial 2.7-F microcatheter (Terumo). Transarterial embolization was also performed with gelfoam in one patient without positive angiographic findings. Technical success was defined as devascularization of the target vessels on postembolization angiography. Clinical success was defined as cessation of clinical symptoms (including melena, hematemesis, and hemochezia), and no requirement for subsequent hemostatic interventions (such as surgery, endoscopic therapy, and second embolization).

The diameter of microcoils we used was from 2 to 6 mm. The length of microcoils was from 3 to 8 cm. The diameter of gelfoam particles was approximately 1 mm. Clinical follow-up period was 3 mo in all patients.

## RESULTS

Fifteen patients presented with hematemesis/melena, and 11 patients presented with bleeding from surgical drains. Twenty-two patients had signs of shock (systolic blood pressure  $< 100$  mmHg and pulse rate  $> 100$  beats/min). The clinical features and angiographic findings are summarized in Table 1. Results of transarterial embolization are summarized in Table 2.

Bleeding points near the surgical fields were detected by angiography in 21 (81%) of 26 patients. Positive angiographic findings included extravasation of contrast medium ( $n = 9$ ) (Figure 1), pseudoaneurysms ( $n = 9$ ) (Figures 2 and 3), and fusiform aneurysms ( $n = 3$ ). Extravasation of contrast medium was observed from the jejunal artery ( $n = 2$ ), gastroduodenal artery ( $n = 2$ ), right hepatic artery and gastroduodenal artery ( $n = 1$ ), great pancreatic artery ( $n = 1$ ), inferior pancreaticoduodenal artery ( $n = 1$ ), dorsal pancreatic artery ( $n = 1$ ), and ileocolic artery ( $n = 1$ ). Pseudoaneurysms were found in the gastroduodenal artery ( $n = 3$ ), common hepatic artery ( $n = 1$ ), right hepatic artery ( $n = 1$ ), inferior pancreaticoduodenal artery ( $n = 1$ ), splenic artery and right gastroepiploic artery ( $n = 1$ ), jejunal artery ( $n = 1$ ), and superior rectal artery ( $n = 1$ ). The fusiform aneurysms were identified in the gastroduodenal artery ( $n = 2$ ), and the proper hepatic artery ( $n = 1$ ).

Transarterial embolization was performed in 20 of 21 patients with positive angiographic findings and one patient without positive angiographic findings. The embolized arteries are summarized in Table 2. Transarterial embolization of bleeding arteries was performed using a combination of microcoils and gelatin sponge in six cases, microcoils in 13 cases, and gelatin sponge in two cases. Transarterial embolization was not performed in

Case	Sex	Age (yr)	Diseases	Surgical procedure	Interval from operation to bleeding (d)	Clinical presentations
1	Male	61	Gastric carcinoma	Gastrectomy	11	Haematemesis/melena
2	Male	72	Pancreatitis	Pancreatitis necrosectomy	15	Bleeding from drain
3	Male	46	Duodenal papilla carcinoma	Pancreaticoduodenectomy	38	Bleeding from drain
4	Male	64	Gastric carcinoma	Gastrectomy	14	Bleeding from drain
5	Male	37	Gastric carcinoma	Gastrectomy	27	Haematemesis/melena
6	Female	44	Gastric carcinoma	Gastrectomy	18	Bleeding from drain
7	Male	51	Gastric carcinoma	Gastrectomy	20	Haematemesis/melena
8	Male	35	Gastric carcinoma	Gastrectomy	28	Haematemesis/melena
9	Male	41	Gastric carcinoma	Gastrectomy	64	Haematemesis/melena
10	Male	56	Pancreatic carcinoma	Pancreaticoduodenectomy	10	Haematemesis/melena
11	Female	45	Gallbladder carcinoma	Extended cholecystectomy	25	Haematemesis/melena
12	Male	86	Ascending colon carcinoma	Right hemicolectomy	34	Hematochezia/melena
13	Male	59	Gastric carcinoma	Gastrectomy	50	Haematemesis/melena
14	Male	69	Gastric carcinoma	Gastrectomy	49	Bleeding from drain
15	Male	61	Intra-abdominal abscess	Excision of Intra-abdominal abscess	3	Bleeding from drain
16	Male	65	Common Bile duct carcinoma	Pancreaticoduodenectomy	29	Bleeding from drain
17	Male	73	Gastric carcinoma	Gastrectomy	38	Hematochezia/melena
18	Male	60	Bile duct carcinoma	Pancreaticoduodenectomy	29	Bleeding from drain
19	Female	62	Gastric carcinoma	Gastrectomy	21	Haematemesis/melena
20	Male	80	Duodenal papilla carcinoma	Pancreaticoduodenectomy	8	Bleeding from drain
21	Male	42	Pancreatic carcinoma	Pancreaticoduodenectomy	46	Haematemesis/melena
22	Male	45	Splenomegaly	Splenectomy	9	Bleeding from drain
23	Male	56	Bile duct stone	Choledocholithotomy	26	Bleeding from drain
24	Female	62	Gastric carcinoma	Gastrectomy	65	Hematochezia/melena
25	Male	76	Gastric carcinoma	Gastrectomy	29	Haematemesis/melena
26	Male	40	Mesenteric torsion	Partial intestinal resection	15	Haematemesis/melena

one patient with positive angiographic finding, because the bleeding vessels were capillaries and could not be superselected. This patient underwent a second surgery after angiography immediately, and recovered after second surgery. However, there were five patients without positive angiographic findings in our study. Among these five patients, one died of rebleeding after blind embolization; one recovered after conservative treatment; and the other three also recovered after a second operation. In the surgical procedure, we found that the bleeding vessels were the splenic vein, portal vein behind the gastrointestinal anastomotic stoma, and left gastro-omental vein, respectively.

Technical success was achieved in 21 (95%) of 22 patients (20 patients with positive angiographic findings and one without positive angiographic findings). Clinical success was achieved in 18 (82%) of 22 patients. Three patients were unsuccessfully treated, including two with rebleeding after embolization, and one with rebleeding after blind embolization.

Postembolization complications such as intestinal ischemia and liver infarction did not occur in any patients during the follow-up period. Three patients (two with positive angiographic findings and one without positive angiographic findings) died of rebleeding after embolization.

## DISCUSSION

Postoperative gastrointestinal hemorrhage is a life-threatening complication that occurs after abdominal surgery,

particularly in the case of pancreaticoduodenectomy. The incidence of postoperative gastrointestinal hemorrhage after abdominal surgery is not high (0.4%–18%)<sup>[1–4]</sup>. Early hemorrhagic complications occur during the first 24 h postoperatively, and are usually caused by intraoperative technical failure, such as improper ligation of vessels in the operative area, and damages to small vessels during lymph node dissection. Delayed postoperative hemorrhage has a different pathophysiology of bleeding from early postoperative hemorrhage, and is complicated with intra-abdominal lesions such as marginal ulcer, anastomotic leakage, intra-abdominal abscess, and sepsis. In this study, the interval from surgery to bleeding ranged from 3 to 65 d, and was > 5 d for the majority of patients. The intra-abdominal complications such as pancreatic juice leakage, intestinal juice leakage, and intra-abdominal abscess were the main causes of gastrointestinal bleeding in our study. In order to reduce the rate of postoperative gastrointestinal hemorrhage after abdominal surgery, we must decrease abdominal surgery complications, such as stomal leak, marginal ulcer, and abscess.

Early diagnosis and prompt treatment are necessary to decrease the mortality of patients with postoperative hemorrhage after abdominal surgery. Endoscopy is usually served as the first-line diagnostic procedure. However, exact diagnosis via urgent gastrointestinal endoscopy can be severely impaired by excessive blood and clots in the gastrointestinal tract<sup>[20,21]</sup>. computed tomography angiography, Doppler ultrasound, and radionuclide scanning can also be used in the diagnosis of postoperative hemorrhage<sup>[5,22,23]</sup>. Compared with these diagnosis

**Table 2** Angiographic findings and clinical results of patients with postoperative hemorrhage after abdominal surgery

Case	Angiography finding	Embolized artery	Embolic agent	Clinical results
1	Negative	None	None	Conservative treatment and clinical success
2	Negative	None	None	Repeat surgery and clinical success
3	Negative	None	None	Repeat surgery and clinical success
4	Negative	None	None	Repeat surgery and clinical success
5	Extravasation	None	None	Conservative treatment and clinical success
6	Extravasation	Inferior pancreaticoduodenal artery	Microcoil	Clinical success
7	Extravasation	Jejunal artery	Microcoil	Clinical success
8	Extravasation	Jejunal artery	Microcoil	Clinical success
9	Extravasation	Inferior pancreaticoduodenal artery	Microcoil	Clinical success
10	Extravasation	Great pancreatic artery	Gelfoam	Clinical success
11	Negative	Right hepatic artery and gastroduodenal artery	Gelfoam	Die of rebleeding
12	Extravasation	Ileocolic artery	Microcoil	Clinical success
13	Pseudoaneurysm	Gastroduodenal artery	Microcoil	Clinical success
14	Extravasation	Gastroduodenal artery	Microcoil	Clinical success
15	Pseudoaneurysm	superior rectal artery	Microcoil	Clinical success
16	Pseudoaneurysm	Gastroduodenal artery	Microcoil	Clinical success
17	Fusiform aneurysm	Gastroduodenal artery	Microcoil	Clinical success
18	Pseudoaneurysm	Common hepatic artery	Microcoil	Clinical success
19	Extravasation	Gastroduodenal artery	Microcoil	Die of rebleeding
20	Pseudoaneurysm	Gastroduodenal artery	Microcoil	Die of rebleeding
21	Fusiform aneurysm	Proper hepatic artery	Microcoil + gelfoam	Clinical success
22	Pseudoaneurysm	Splenic artery and Right gastroepiploic artery	Microcoil + gelfoam	Clinical success
23	Pseudoaneurysm	Right hepatic artery	Microcoil + gelfoam	Clinical success
24	Pseudoaneurysm	Inferior pancreaticoduodenal artery	Microcoil + gelfoam	Clinical success
25	Fusiform aneurysm	Gastroduodenal artery	Microcoil + gelfoam	Clinical success
26	Pseudoaneurysm	Jejunal artery	Microcoil + gelfoam	Clinical success

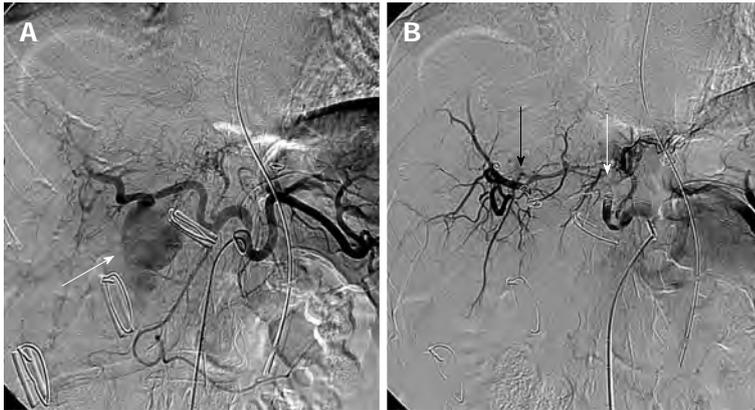

**Figure 1** A 35-year-old man with massive upper gastrointestinal bleeding after gastrectomy of gastric carcinoma. Selective superior mesenteric arteriography showed active arterial contrast extravasation (white arrow) from the jejunal artery.

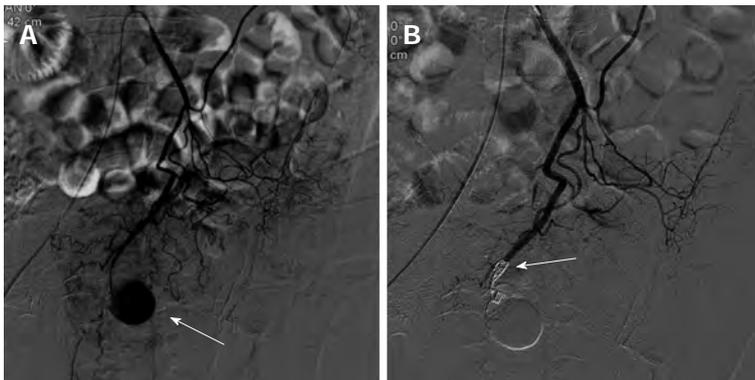

methods, angiography is quicker, safer, and more accurate to localize the bleeding points. In addition, angiography allows immediate embolization to stop gastrointestinal hemorrhage. Angiographic findings of postoperative gastrointestinal hemorrhage differ slightly from those of gastrointestinal hemorrhage without surgery. Positive angiographic findings of gastrointestinal hemorrhage without surgery mainly included extravasation of contrast medium, tumor staining, and vascular malformation. Charbonnet *et al*<sup>[24]</sup> reported that angiography had a positive angiographic rate of 31% in all consecutive patients without abdominal surgery. Kim *et al*<sup>[19]</sup> reported a positive angiographic rate of 79% in patients after abdominal surgery. However, positive angiographic find-

ings of postoperative gastrointestinal hemorrhage mainly included extravasation of contrast medium and pseudoaneurysms. In our study, the positive findings were 81% (21 of 26 patients), and the rate of positive findings was higher than that of gastrointestinal hemorrhage without abdominal surgery, and was similar to that of gastrointestinal hemorrhage with surgery. Therefore, angiography should be the first-choice option for postoperative gastrointestinal hemorrhage after abdominal surgery, especially for patients with hemodynamic instability and poor general conditions. If celiac angiography fails to identify a source of bleeding, superselective angiography near the surgical field should be performed. However, angiography also has some limitations. For example, the result of angiography could be negative because the gastrointestinal bleeding is often intermittent or directly comes from veins or has been controlled by vasoactive agents. In this study, angiography demonstrated bleeding points in 21 of 26 patients. Reoperation was performed in three patients with negative angiographic findings. We found that the bleeding vessels were the left gastro-omental vein, portal vein behind the anastomotic stoma, and splenic vein.

Reoperation to control postoperative bleeding is the traditional approach to manage gastrointestinal hemorrhage after abdominal surgery. However, emergency surgical exploration has been reported to be associated with a mortality rate of as high as 64% in high-risk patients with hemodynamic instability and poor general conditions<sup>[25,26]</sup>. In addition, the surgical approach is often difficult or even unsuccessful in patients with postoperative hemorrhage, especially those with two or more previous abdominal operations, due to the anatomical inaccessibili-

**Figure 2** A 56-year-old man presented with massive bleeding from surgical drains after choledocholithotomy due to common bile duct stone. A: Selective celiac arteriography showed a pseudoaneurysm (arrow) arising from the right hepatic artery; B: Selective celiac arteriography after embolization with microcoils and gelfoam demonstrated disappearance of the pseudoaneurysm. Embolic agents were inserted proximally (white arrow) and distally (black arrow) to the origin of the pseudoaneurysm.

**Figure 3** A 61-year-old man presented with massive bleeding from surgical drains 3 d after excision of the intra-abdominal abscess. A: Selective inferior mesenteric arteriography shows a pseudoaneurysm (arrow) arising from the superior rectal artery; B: Selective inferior mesenteric arteriography after embolization with microcoils demonstrated complete occlusion (arrow) of the distal end of the superior rectal artery.

ty of the arteries, postoperative adhesions, and inflammatory reaction. Endoscopy is another approach to manage postoperative hemorrhage<sup>[1-4,27-32]</sup>. However, emergency endoscopy for postoperative hemorrhage may be difficult owing to excessive blood and clots in the gastrointestinal tract, and inaccessibility of the bleeding sites in the small intestine.

Transarterial embolization is effective for postoperative hemorrhage, especially in patients with hemodynamic instability and poor general condition. However, the safety and clinical results of embolization have not been assessed in a large patient group. Beyer *et al*<sup>[5]</sup> reported that embolization had a success rate of 100% in nine patients with delayed hemorrhage after pancreaticoduodenectomy. Miyamoto *et al*<sup>[33]</sup> demonstrated a success rate of 80% with superselective embolization in 10 patients with massive upper gastrointestinal hemorrhage after upper abdominal surgery. Compared with these studies, the clinical success rate (82%) of the present study was similar. However, the technical success rate in this study was 95% because we used high-resolution digital angiography and microcatheterization. Three patients died during the follow-up period. The cause of death was rebleeding after embolization, including one blind embolization.

The clinical results of blind embolization (defined as embolization without positive angiography) are controversial. Morris *et al*<sup>[34]</sup> found that blind embolization of the left gastric artery was effective in preventing rebleeding when an active bleeding site was localized by endoscopy. Kim *et al*<sup>[19]</sup> successfully treated four patients

with blind embolization after an active bleeding site was identified by endoscopy or scintigraphy, or was suspicious on angiography. In our study, blind embolization was performed only in one patient after the bleeding site was localized by endoscopy. However, the patient died of rebleeding 3 d after the interventional procedure.

The most serious complications of postembolization are liver infarction and irreversible bowel ischemia. However, the liver can tolerate considerable arterial embolization without significant liver infarction, because the liver has a dual blood supply by the hepatic artery and portal vein, and the hepatic artery has abundant collateral pathways. Arterial embolization in the upper gastrointestinal tract above the ligament of Treitz is generally considered safe because of the rich collateral supply to the stomach and duodenum<sup>[34]</sup>. In contrast to the upper gastrointestinal tract, the lower gastrointestinal tract does not have a rich collateral artery, and is susceptible to embolization-induced ischemia. However, significant ischemia may be avoided if the embolic agent is delivered precisely to the bleeding sites. In our study, postembolization complications such as liver infarction and bowel ischemia were not encountered. Therefore, we believe that transarterial embolization is a safe method to treat postoperative gastrointestinal hemorrhage.

In conclusion, we retrospectively analyzed the angiographic findings and clinical outcomes of transarterial angiography and embolization in 26 patients with postoperative hemorrhage after abdominal surgery. Angiography was found to be a sensitive approach to detect the

bleeding site, especially for patients with postoperative gastrointestinal hemorrhage. Transarterial embolization is an effective and safe method for the treatment of postoperative hemorrhage.

## COMMENTS

### Background

Gastrointestinal hemorrhage after abdominal surgery is an unusual complication. However, when it occurs, it can cause hemorrhagic shock that has a fatal outcome. This complication may occur as a result of anastomotic leakage, localized infection, or intraoperative arterial injury. Traditionally, reoperation is regarded as the first-line therapy. However, its usage is largely limited by the poor condition of patients with postoperative gastrointestinal hemorrhage and the difficulty in indentifying the bleeding sites during surgery. With advances in technology, a newer and less-invasive technique, transcatheter arterial embolization, has been developed and is reported to be safe and effective, especially in high-risk surgical patients.

### Research frontiers

For postoperative gastrointestinal hemorrhage, the first important thing is to localize the bleeding site. Transarterial angiography is considered to be a better tool than endoscopy or noninvasive diagnostic imaging examinations such as computed tomography angiography and ultrasound. Transarterial access not only can provide diagnostic information but also has the advantage of intra-arterial embolization of the bleeding site simultaneously.

### Innovations and breakthroughs

The surgical approach to control postoperative bleeding is often difficult or even unsuccessful in patients with postoperative hemorrhage, especially those with two or more previous abdominal operations, due to the anatomical inaccessibility of the arteries, postoperative adhesions, and inflammatory reaction. Therefore, its mortality rate was as high as 64% in high-risk patients with hemodynamic instability and poor general condition. However, with advances in techniques and microcatheters, transcatheter arterial embolization was performed to control postoperative bleeding. In this retrospective study, the technical success rate was 95%, and the clinical success rate was 82%. There were no procedure-related complications.

### Applications

The results of the present study suggest that transcatheter arterial embolization is a safe and effective treatment for massive gastrointestinal hemorrhage following abdominal surgery.

### Peer review

This was a good descriptive study in which the authors evaluated the clinical results of angiography and embolization for massive gastrointestinal hemorrhage after abdominal surgery. The results are interesting and suggest that transcatheter arterial embolization is a safe and effective treatment for massive gastrointestinal hemorrhage following abdominal surgery, especially for patients with hemodynamic instability and poor general condition.

clinicopathological characteristics was also analyzed. Univariate and logistic multivariate regression analyses were adopted to determine the independent factors of radioresistance.

**RESULTS:** Nuclear  $\beta$ -catenin overexpression was more evident in radioresistant rectal adenocarcinoma than in radiosensitive rectal adenocarcinoma (57.6% vs 16.7%,  $P < 0.001$ ). Nuclear  $\beta$ -catenin was overexpressed in favor of poor TRG ( $\leq 2$ ), whereas membrane  $\beta$ -catenin was expressed in favor of good TRG ( $\geq 3$ ). Nuclear  $\beta$ -catenin expression in tumor cell differentiation ( $P = 0.018$ ), lymph node metastasis ( $P = 0.022$ ), and TRG ( $P < 0.001$ ) showed significant differences. Univariate analyses demonstrated that radioresistance is associated with nuclear  $\beta$ -catenin overexpression ( $P < 0.001$ ). In addition, logistic multivariate regression analysis indicated that only three factors, namely, tumor size ( $P < 0.001$ ), tumor cell differentiation ( $P < 0.001$ ), and nuclear  $\beta$ -catenin overexpression ( $P < 0.001$ ), are associated with radioresistance. By using radioresistance as a prediction target, nuclear  $\beta$ -catenin-based prediction alone achieved 83% accuracy, 65% sensitivity, and 88% specificity.

**CONCLUSION:** Nuclear  $\beta$ -catenin overexpression may be a valuable candidate to predict the response of rectal adenocarcinoma to preoperative radiotherapy.

**Core tip:** In this paper we investigated the relationship between overexpression of nuclear  $\beta$ -catenin in rectal adenocarcinoma and radioresistance. We first confirmed that nuclear  $\beta$ -catenin overexpression in rectal adenocarcinoma is associated with radioresistance. Most importantly, we found that nuclear  $\beta$ -catenin-based prediction achieved a 83% accuracy, 65% sen-

### Abstract

**AIM:** To investigate the association between nuclear  $\beta$ -catenin overexpression in rectal adenocarcinoma and radioresistance.

**METHODS:** A retrospective analysis was conducted. The analysis involved 136 patients with locally advanced rectal adenocarcinoma who underwent short-course preoperative radiotherapy and radical resection. The expression of  $\beta$ -catenin in both pretreatment biopsy specimens and resected primary tumor tissues was examined by immunohistochemistry. The correlation of  $\beta$ -catenin expression with radioresistance was evaluated using the tumor regression grading (TRG) system. The relationship between  $\beta$ -catenin expression and

sitivity and 88% specificity for radioresistance. We provided a novel possible molecular mechanism to explain the radioresistance in rectal adenocarcinoma and thus may provide a new therapeutic target for enhancing radiosensitivity.

## INTRODUCTION

Colorectal cancer (CRC) is the third most common malignancy and the fourth most frequent cause of cancer deaths worldwide. Surgery is the predominant therapy for rectal cancer. However, rectal cancer treatment with surgery alone is insufficient because of the high incidence of local recurrence. During the past decades, preoperative radiotherapy and surgery have been increasingly used together for locally advanced rectal cancer to reduce local treatment failure<sup>[1-4]</sup>. However, many rectal cancer patients are resistant to preoperative radiotherapy because of the heterogeneity of treatment response. Therefore, predicting neoadjuvant radiotherapy response may allow individualization and more rational selection of patients that will most likely benefit from this therapy. A growing number of studies have investigated molecular markers for the prediction of tumor response to radiotherapy. XIAP<sup>[5]</sup>, human phosphatidylethanolamine-binding protein 4<sup>[6]</sup>, and epidermal growth factor receptor<sup>[7]</sup> are the molecular markers associated with tumor response to radiotherapy in rectal cancer.

$\beta$ -catenin, a component of the Wntless/Wnt signaling pathway, can activate target genes linked to the *APC* gene in CRC. The localization of  $\beta$ -catenin is related to its function in cancer growth<sup>[8]</sup>.  $\beta$ -catenin in the cytoplasm and membrane binds with the intracellular domain of E-cadherin, a cell-to-cell adhesion molecule, and maintains normal tissue architecture. In the presence of a Wnt signal,  $\beta$ -catenin translocates to the nucleus and interacts with the lymphoid enhancing factor/T-cell factor to promote the transcription of several target genes involved in cell proliferation<sup>[9]</sup>.

A previous study indicated that Wnt/ $\beta$ -catenin mediates the radiation resistance of mouse mammary progenitor cells and Sca1+ progenitors in an immortalized mammary gland cell line<sup>[10,11]</sup>. Thus, an active interaction probably exists between the radiotherapy response of cancer cells and Wnt/ $\beta$ -catenin signal pathway. However, no direct evidence about the correlation between nuclear  $\beta$ -catenin expression in rectal cancer and radiotherapy sensitivity has been reported to date. In this study, we enrolled 136 rectal adenocarcinoma patients treated with

fractionated preoperative radiotherapy and radical resection. We investigated the expression of nuclear  $\beta$ -catenin in rectal adenocarcinoma using biopsy specimens and resected primary tumor tissues to determine whether nuclear  $\beta$ -catenin expression can be a predictive marker of tumor response to preoperative radiotherapy.

## MATERIALS AND METHODS

### Study population

The study cohort comprised 136 rectal cancer patients who had undergone consecutive preoperative radiotherapy (25 Gy in five fractions for 1 wk) and radical surgery at Qilu Hospital and Shandong Tumor Hospital and Institute from November 2008 to June 2011. The subjects included 98 men and 38 women with a mean age of 64 years (range: 35 years to 78 years). First, rectal cancer was diagnosed by contrast computed tomography (CT) and colonoscopy. Afterward, archival paraffin-embedded biopsy tumor specimens and post-surgery resected tumor tissues were histologically identified as rectal adenocarcinoma.

The inclusion criteria were as follows: (1) patients histologically diagnosed with rectal adenocarcinoma; and (2) rectal cancer clinically diagnosed as stage III. The exclusion criteria were as follows: (1) hereditary nonpolyposis CRC patients and patients with familial adenomatous polyposis; and (2) patients with distant metastasis. All 136 patients met the inclusion criteria and were included in this study. However, 11 cases with distant metastasis and 1 case with familial adenomatous polyposis were excluded.

All cancers were clinically diagnosed as stage III with no distant metastasis. Tumor stage was based on the American Joint Committee on Cancer (AJCC) TNM staging system (7<sup>th</sup> edition, 2009). The TNM stages of the patients in this cohort were as follows: 28 patients with stage IIIA, 46 patients with stage IIIB, and 62 patients with stage IIIC.

All patients received preoperative radiotherapy and underwent Miles' operation. The distance from distal margin of rectal cancer to anal edge was less than 7 cm in all patients. The interval between preoperative radiotherapy and surgery was 10 d to 14 d.

### Data collection and design of the study

This study was approved by the Ethics Committees of Qilu Hospital, Shandong University, and Shandong Tumor Hospital and Institute. Informed consent was obtained from each patient. Clinical information related to diagnostic procedures and tumor characteristics was collected from medical records. Clinical and pathological data, including sex, age, tumor size, tumor invasion depth, tumor cell differentiation, and lymph node metastasis, were collected. Firstly, the association between expression of nuclear  $\beta$ -catenin in biopsy specimens and respective resected tumor tissues was retrospectively analyzed. Meanwhile, tumor regression grading (TRG) of rectal ad-

enocarcinoma after radiotherapy was evaluated. Then, the relationship between nuclear  $\beta$ -catenin expression in rectal adenocarcinoma and clinicopathological characteristics was retrospectively analyzed. Finally, univariate analysis and logistic multivariate regression analysis were adopted to discriminate independent factors of radioresistance.

### Immunohistochemistry

Biopsy specimens obtained through colonoscopy and resected tumor tissues collected after surgery were embedded in paraffin and cut into sections for immunohistochemical staining using the streptavidin peroxidase complex method. Tissue sections (4  $\mu$ m thick) were deparaffinized and microwaved for 15 min, incubated twice in 10 mmol/L citrate buffer at 100 °C to retrieve the antigens, and then incubated in 3% H<sub>2</sub>O<sub>2</sub> for 10 min to quench endogenous peroxidase. Nonspecific binding of antibodies was inhibited by incubation in 5% normal goat serum for 20 min in a humid chamber. The tissue sections were then incubated with mouse monoclonal anti- $\beta$ -catenin antibodies (diluted 1:50, mouse IgG1; Cell Signaling Technology, Boston, United States) overnight at 4 °C. The tissue sections were washed three times with PBS and then incubated with biotinylated goat antimouse IgG for 30 min at room temperature. After washing, the slides were incubated in a streptavidin-peroxidase complex for 20 min at 37 °C, washed three times, visualized using 3,3'-diaminobenzidine, and then counterstained with hematoxylin. Sections that were stained without the primary antibodies served as the negative control.  $\beta$ -catenin expression is defined as brown colored staining on the membrane or in the cytoplasm and nucleus. For immunohistochemical assessment, six slides were randomly selected and observed at a magnification of  $\times$  200 by two pathologists. The immunostained slides were scored as previously described<sup>[12]</sup>. In brief, the immunostained slides were scored using the sum of the signal intensity (0 = no expression; 1 = weak expression; 2 = moderate expression; 3 = strong expression) and the percentage of positive cells (% tumor cells: 0 = 0%; 1 = 1% to 25%; 2 = 26% to 50%; 3 = 51% to 75%; and 4 = 76% to 100%). Nuclear  $\beta$ -catenin immunoreactivity at the invasive front was considered positive if moderate or strong expression was observed in the nuclei. Nuclear  $\beta$ -catenin overexpression was considered positive when the expression was observed in > 50% of the tumor cells.

### TRG

The response of rectal cancer to preoperative radiotherapy was evaluated in the hematoxylin and eosin-stained slides using the TRG system as previously described<sup>[13]</sup>. The characteristics of each grade were as follows: TRG 0, no regression; TRG 1, dominant tumor mass with obvious fibrosis in 25% or less of the tumor mass; TRG 2, dominant tumor mass with obvious fibrosis in 26 to 50% of the tumor mass; TRG 3, dominant fibrosis outgrowing the tumor mass; and TRG 4, no viable tumor cells

(only a fibrotic mass).

### Statistical analysis

Statistical analysis was performed using SPSS16.0.  $\chi^2$  test and Fisher exact test were used to analyze the correlation between nuclear  $\beta$ -catenin expression and clinicopathological characteristics. Univariate and logistic multivariate regression analyses were performed to determine the independent factors of TRG.  $P < 0.05$  was considered statistically significant.

## RESULTS

### $\beta$ -catenin expression in biopsy specimens and in respective resected tumor tissues

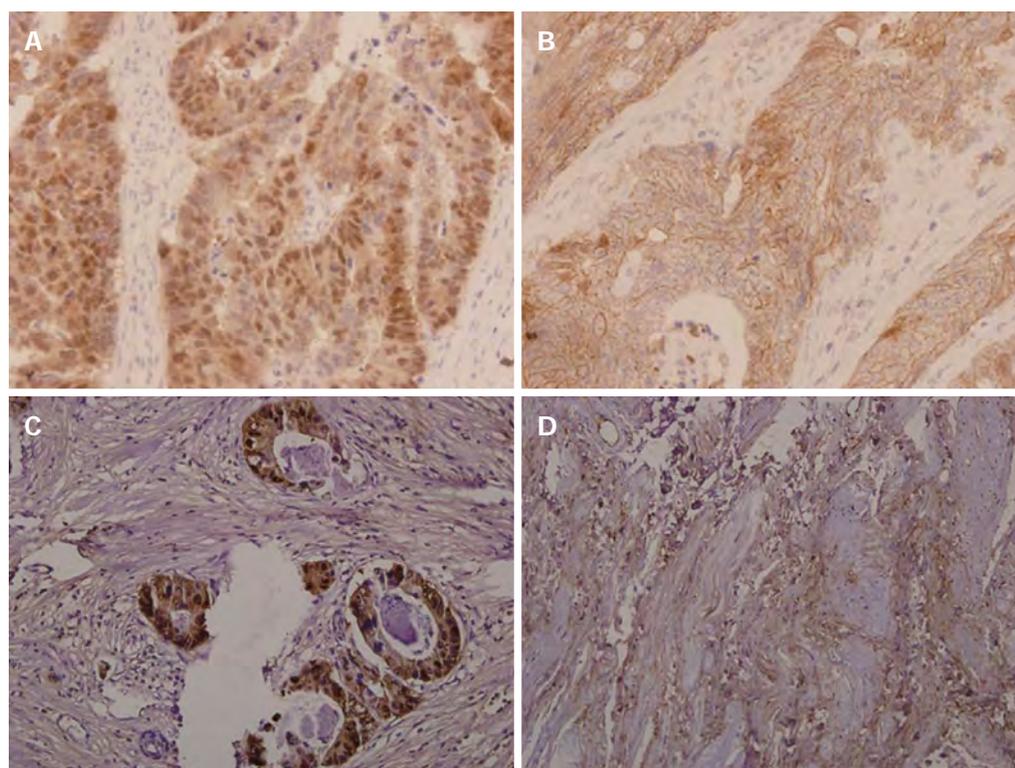

The expression of  $\beta$ -catenin in the biopsy and respective resected tumor tissues is presented in Figure 1.  $\beta$ -catenin expression was observed in all rectal cancer specimens.  $\beta$ -catenin was expressed mostly in a nuclear-associated staining pattern in patients who exhibited resistance to preoperative radiotherapy (Figure 1A). Conversely,  $\beta$ -catenin was expressed mostly in a membrane-associated staining pattern in patients who exhibited hyper-radio-sensitivity (Figure 1B). Nuclear  $\beta$ -catenin overexpression was observed in 68 cases who exhibited radioresistance (57.6%). However, this overexpression was only observed in three patients who exhibited radiosensitivity (16.7%). Therefore, nuclear  $\beta$ -catenin overexpression is more evident in radioresistant patients than in radiosensitive patients ( $P < 0.001$ , Table 1). After preoperative radiotherapy, nuclear  $\beta$ -catenin was overexpressed in favor of poor TRG ( $\leq 2$ ) (Figure 1C), whereas membrane  $\beta$ -catenin was overexpressed in favor of good TRG ( $\geq 3$ ) (Figure 1D). This result suggests that nuclear  $\beta$ -catenin overexpression is a predictive marker of radioresistance.

### Relationship between nuclear $\beta$ -catenin expression in rectal adenocarcinoma and clinicopathological characteristics

$\chi^2$  test was performed to investigate the relationship between nuclear  $\beta$ -catenin expression and clinicopathological features. The correlations between nuclear  $\beta$ -catenin expression level and clinicopathological variables are shown in Table 1. Nuclear  $\beta$ -catenin expression in tumor cell differentiation ( $P = 0.018$ ), lymph node metastasis ( $P = 0.022$ ), and TGR ( $P < 0.001$ ) showed significant differences.

### Predictive value of nuclear $\beta$ -catenin overexpression for radioresistance

Clinicopathological characteristics were divided into two groups according to tumor response to radiotherapy to confirm the predictive value of nuclear  $\beta$ -catenin overexpression as a biomarker of radioresistance. Univariate and multivariate analyses were performed to determine the factors related to radioresistance. Univariate analysis results (Table 2) demonstrated that radioresistance was associated with tumor size ( $P < 0.001$ ), tumor cell differ-

**Figure 1**  $\beta$ -catenin expression in biopsy specimens and resected tumor tissues ( $\times 200$ ). A: Nuclear  $\beta$ -catenin was overexpressed in biopsy specimens from patients who exhibited resistance to preoperative radiotherapy; B:  $\beta$ -catenin presented mostly in a membrane-associated staining pattern in biopsy specimens from patients who exhibited hyper-radiosensitivity; C: Nuclear  $\beta$ -catenin was overexpressed in specimens with poor tumor regression grading (TRG) ( $\leq 2$ ); D:  $\beta$ -catenin presented mostly in a membrane-associated staining pattern in specimens with good TRG ( $\geq 3$ ).

entiation ( $P < 0.001$ ), tumor invasion depth ( $P = 0.027$ ), and nuclear  $\beta$ -catenin expression ( $P < 0.001$ ). However, logistic multivariate regression analysis retained only three factors in the model, namely, tumor size ( $P < 0.001$ ), tumor cell differentiation ( $P < 0.001$ ), and nuclear  $\beta$ -catenin overexpression ( $P < 0.001$ ). By using radioresistance as a prediction target, nuclear  $\beta$ -catenin-based prediction alone achieved 83% accuracy, 65% sensitivity, and 88% specificity (Table 3).

## DISCUSSION

In the present study, the expression of  $\beta$ -catenin in 136 rectal adenocarcinoma patients was detected and its relationship with radioresistance was investigated. Our data demonstrated that overexpression of nuclear  $\beta$ -catenin is associated with radioresistance in rectal adenocarcinoma. To the best of our knowledge, few studies have been done to investigate the prognostic value of nuclear  $\beta$ -catenin overexpression for radioresistance in rectal cancer. The clinical significance of the current study is that we might provide promising biomarkers to predict sensitivity of rectal cancer to radiotherapy.

Preoperative radiotherapy has become a standard treatment for locally advanced rectal cancer. Obtaining an accurate prediction of cancer cell response to radiothera-

**Table 3** Predictive value of nuclear  $\beta$ -catenin as a marker of radioresistance in 136 patients of rectal adenocarcinoma

Nuclear $\beta$ -catenin expression	Good response	Poor response
≤ 50%	15%	50%
> 50%	3%	68%
Accuracy		83%
Sensitivity		65%
Specificity	88%	
Positive predictive value		79%
Negative predictive value	48%	

py to determine if a patient would benefit from adjuvant therapy is challenging<sup>[14]</sup>. Previous studies indicated that molecules involved in signaling pathways are crucial to the sensitivity of cancer cells to radiotherapy<sup>[15,16]</sup>. Numerous studies have investigated biomarkers to predict rectal cancer sensitivity to radiotherapy<sup>[17-19]</sup>. However, only a few scholars have focused on the Wnt/ $\beta$ -catenin signaling pathway, which is vital in the progression of rectal cancer.

$\beta$ -catenin is a component of the Wntless/Wnt signaling pathway. Previous studies have demonstrated that  $\beta$ -catenin is associated with the sensitivity of some cancers to radiotherapy. Kim *et al.*<sup>[20]</sup> found that glioblastoma (GBM) cell lines enriched with cells positive for active  $\beta$ -catenin are increased by *in vitro* radiation treatment. This finding suggests that the radiation resistance of GBM is partly mediated by the activation of stem cell-associated pathways, including Wnt. Watson *et al.*<sup>[21]</sup> found that the expression of a kinase dead mutant GSK3 $\beta$  endows Panc1 and BxPC3 pancreatic cancer cells with radioresistance.  $\beta$ -catenin silencing results in radiosensitization, whereas a nondegradable  $\beta$ -catenin construct induces radioresistance. These data support the

hypothesis that GSK3 $\beta$  modulates the cellular response to radiation in a  $\beta$ -catenin-dependent mechanism. In the current study, only stage III rectal adenocarcinoma patients who accepted preoperative radiotherapy were included to eliminate the effects of different therapeutic methods, such as concurrent chemoradiotherapy. The results indicated that nuclear  $\beta$ -catenin overexpression is more evident in tumor biopsy specimens from patients who exhibited radioresistance. We also found that tumor tissues were relatively intact when nuclear  $\beta$ -catenin was overexpressed in tumor cells after preoperative radiotherapy. These immunohistochemical data indicated that the accumulation of nuclear  $\beta$ -catenin in tumor cells is critical in the radioresistance of rectal adenocarcinoma.

Regarding the correlation between nuclear  $\beta$ -catenin expression and clinicopathological characteristics, previous investigators reported contradictory results. Zhang *et al.*<sup>[22]</sup> believed that nuclear  $\beta$ -catenin accumulation is related to tumor stage and/or metastasis. However, correlations between nuclear  $\beta$ -catenin and pertinent clinicopathological variables were not observed in Baldus's study<sup>[23]</sup>. Our data demonstrated that nuclear  $\beta$ -catenin overexpression is related to low tumor cell differentiation and lymph node metastasis. Hyper-radiosensitivity is associated with low tumor cell differentiation. In the current study, a relationship was found between nuclear  $\beta$ -catenin overexpression and low tumor cell differentiation. However, tumor tissues in which nuclear  $\beta$ -catenin was overexpressed exhibited resistance to preoperative radiotherapy. This result suggests that nuclear  $\beta$ -catenin overexpression is a potential mechanism by which rectal adenocarcinoma cells avoid the destructive effect of radiotherapy.

Univariate and multivariate analyses were used to determine the factors related to radioresistance and thus confirm the predictive value of nuclear  $\beta$ -catenin overex-

pression for radioresistance. Univariate analysis demonstrated that nuclear  $\beta$ -catenin overexpression is associated with tumor response to radiotherapy. This finding coincides with the immunohistochemical result. A multivariate logistic regression analysis model was constructed to distinguish the independent factors for radioresistance and obtain a more precise estimate of the effect of nuclear  $\beta$ -catenin overexpression on tumor response to radiotherapy. As shown in Table 2, tumor response to radiotherapy is associated with nuclear  $\beta$ -catenin overexpression. This result suggests that nuclear  $\beta$ -catenin overexpression may affect radioresistance independently. When radioresistance was used as a prediction target in this study, nuclear  $\beta$ -catenin overexpression-based prediction alone achieved 83% accuracy, 65% sensitivity, and 88% specificity. These data confirmed that our conclusion is consistent with previous findings and suggested that nuclear  $\beta$ -catenin overexpression in rectal adenocarcinoma is a useful marker of radioresistance. Prediction of rectal cancer patient response is critical in tailoring preoperative radiotherapy to individuals. In addition, the search for predictive markers of radiotherapy is similar to the development of targeted therapy to some extent. We believe that  $\beta$ -catenin is a potential target for reducing radioresistance in rectal adenocarcinoma. In the future,  $\beta$ -catenin-targeting molecular drugs and radiation therapy may be used in combination to improve the efficacy of radiotherapy for rectal adenocarcinoma.

There are some potential limitations of this study. First, this is a retrospective study, and the confounding effects associated with a design of this kind are surely present. Second, only those patients who accepted preoperative radiotherapy were included in order to study the prognostic value of nuclear  $\beta$ -catenin overexpression for radioresistance in this study. Having only a small number of patients in the study also prevented us making further analysis about the correlation of nuclear  $\beta$ -catenin overexpression with clinical outcome. We believe that a larger prospective trial and long-term follow up study will allow us to confirm our conclusions.

In conclusion, nuclear  $\beta$ -catenin overexpression in rectal adenocarcinoma is associated with radioresistance. Both clinical and pathological data support our conclusion. Therefore, nuclear  $\beta$ -catenin overexpression in rectal adenocarcinoma can be used as a valuable predictor of radioresistance. However, these preliminary findings must be verified in a larger, prospective, controlled clinical study and in a subsequent experimental study.

## COMMENTS

### Background

Radiotherapy is a major treatment for rectal cancer. During previous decades, preoperative radiotherapy has increasingly been used together with surgery for locally advanced rectal cancer in order to reduce local treatment failures. However, many rectal cancer patients are actually resistant to preoperative radiotherapy due to the heterogeneity of treatment response. Therefore, the ability to predict response for neoadjuvant radiotherapy may allow individualization and more rational selection of patients that will most likely benefit from this therapy.

### Research frontiers

A previous study indicated that Wnt/ $\beta$ -catenin mediates radiation resistance of mouse mammary progenitor cells and Sca1+ progenitors in an immortalized mammary gland cell line. Thus, there seems to be active interaction between the response to radiotherapy of cancer cells and the Wnt/ $\beta$ -catenin signal pathway. However, there is no direct evidence about the correlation between nuclear  $\beta$ -catenin expression in rectal cancer and radiotherapy sensitivity up to now.

### Innovations and breakthroughs

In this paper the authors investigated the relationship between overexpression of nuclear  $\beta$ -catenin in rectal adenocarcinoma and radioresistance. To the best of the knowledge, this is the first study that analyzes the relation between nuclear  $\beta$ -catenin overexpression in rectal adenocarcinoma and radioresistance. The authors provided a novel possible molecular mechanism to explain the radioresistance in rectal adenocarcinoma and thus may provide a new therapeutic target for enhancing radiosensitivity.

### Applications

By studying the relationship between overexpression of nuclear  $\beta$ -catenin in rectal adenocarcinoma and radioresistance, this study may provide a new therapeutic target for enhancing radiosensitivity for rectal adenocarcinoma.

### Terminology

$\beta$ -catenin is a component of the Wntless/Wnt signaling pathway and can activate target genes linking with the APC gene in colorectal cancer. Its localization relates to its function in cancer growth.  $\beta$ -catenin in the cytoplasm and membrane binds with the intracellular domain of E-cadherin, which is a cell-to-cell adhesion molecule, and to play a significant role in maintaining the normal tissue architecture.

### Peer review

The authors studied the clinical significance of  $\beta$ -catenin overexpression and radioresistance in patients with rectal adenocarcinoma. This paper is very interesting and the information is up to date. The study provided a novel possible molecular mechanism to explain radioresistance in rectal adenocarcinoma and thus may provide a new therapeutic target for enhancing radiosensitivity.

### Abstract

**AIM:** To investigate the mRNA expression of cyclooxygenase-2 (COX-2) in benign and malignant ascites, and to explore the difference in COX-2 mRNA expression among different diseases.

**METHODS:** A total of 36 samples were collected from the Fifth Affiliated Hospital of Sun Yat-Sen University and divided into two experimental groups: benign ascites ( $n = 21$ ) and malignant ascites ( $n = 15$ ). Benign ascites included cirrhotic ascites ( $n = 10$ ) and tuberculous ascites ( $n = 5$ ). Malignant ascites included oophoroma ( $n = 7$ ), cancer of colon ( $n = 5$ ), cancer of the liver ( $n = 6$ ), gastric cancer ( $n = 2$ ), and bladder carcinoma ( $n = 1$ ). The mRNA expression of COX-2 in ascites was examined with reverse transcriptase polymerase chain reaction (RT-PCR) technology, and the

positive rate of COX-2 mRNA was compared between different diseases.

**RESULTS:** The positive rate of COX-2 mRNA in malignant ascites was 42.9% (9/21), which was significantly higher than in benign ascites, 6.7% (1/15), difference being significant between these two groups ( $\chi^2 = 4.051$ ,  $P = 0.044$ ). The proportion of the positive rate in the malignant ascites was as follows: ovarian cancers 57.1% (4/7), colon cancer 40.0% (2/5), liver cancer 33.3% (2/6), gastric cancer 50.0% (1/2), and bladder cancer 0.00% (0/1). However, there was no significant difference in COX-2 mRNA expression among various tumors with malignant ascites ( $\chi^2 = 1.614$ ,  $P = 0.806$ ). Among the benign ascites, COX-2 mRNA levels were different between the tuberculous ascites (0/5) and cirrhotic ascites (1/10), but there was no significant difference ( $P = 1.000$ ).

**CONCLUSION:** COX-2 mRNA, detected by RT-PCR, is useful in the differential diagnosis of benign and malignant ascites, which also has potential value in the clinical diagnosis of tumors.

**Key words:** Ascites; Cyclooxygenase-2 mRNA; Reverse transcriptase polymerase chain reaction; Malignant tumor

**Core tip:** Ascites is a common symptom caused by a variety of diseases, the differential diagnosis between benign ascites and malignant ascites is one of the most important issues in clinical practice. Cytologic examinations and ascites tumor markers can provide important evidence, but their sensitivity and specificity are far from satisfactory. Our study aimed to explore the difference in cyclooxygenase-2 (COX-2) mRNA expression among different diseases. Our research suggests that COX-2mRNA can be detected by reverse transcriptase polymerase chain reaction, but there are no significant differences in the expression of COX-2 mRNA among

various disease types with benign or malignant ascites.

Expression and significance of cyclooxygenase-2 mRNA in benign and malignant ascites. *World J Gastroenterol* 2013; 19(40): 6883-6887 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6883.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6883>

## INTRODUCTION

Ascites is a gastroenterological term for an accumulation of fluid in the peritoneal cavity, which might result from cirrhosis, tuberculous peritonitis or a malignant tumor.

The detection of exfoliated ascites cells is often used to identify these diseases in the clinic, but there is no economic, practical, or effective index with a high specificity. Therefore, it is important to discriminate benign from malignant ascites for clinical diagnosis and treatment<sup>[1,2]</sup>.

In recent years, cyclooxygenase-2 (COX-2) has been extensively studied as an inducible expression protein, and has been detected in various tumor tissues in epidemiologic and cytologic researches<sup>[3,4]</sup>, such as pancreatic cancer, colorectal carcinoma, non-small lung cancer and so on. Research has found that COX-2 expression is unregulated in precancerous lesions and preinvasive carcinoma and positively correlates with tumor invasion and lymphatic metastasis<sup>[5,6]</sup>. Therefore, increasing expression of COX-2 might occur in the early stages of the tumor and the detection of COX-2 level is helpful for early diagnosis.

However, there are only few studies regarding COX-2 expression in benign and malignant ascites. We employed reverse transcriptase polymerase chain reaction (RT-PCR) technology to detect the expression level of COX-2 in benign and malignant ascites, and analyzed the difference in mRNA expression of COX-2 among different diseases.

## MATERIALS AND METHODS

### Subjects

A total of 36 patients with ascites who underwent abdominocentesis at the Fifth Affiliated Hospital of Sun Yat-Sen University between August 2011 and March 2012 were selected. The subjects were divided into benign and malignant groups according to medical history, physical examination, B ultrasound, computed tomography (CT), pathology and the presence of exfoliated tumor cells. There were 15 patients with benign ascites, including nine males and six females, aged 43-75 years with an average age of  $62.5 \pm 1.8$  years; the patients consisted of 10 cases of cirrhosis and five cases of tuberculous peritonitis according to disease type. There were 21 patients with malignant ascites, including 11 males and 10 females, aged 41-79 years with an average age of  $58 \pm 2.3$  years; the

**Table 1** Primer sequences of cyclooxygenase-2 and glyceraldehyde-3-phosphate dehydrogenase genes

Primer	Primer sequence	Product size	
COX-2	Forward primer	5'-CTTGGGTGTCAAAGGTAA-3'	581 bp
	Reverse primer	5'-AGGGACTTGAGGAGGGTA-3'	
GAPDH	Forward primer	5'-GTGGGGCGCCAGGCACCA-3'	146 bp
	Reverse primer	5'-CTCCTATGTCACGCACATTC-3'	

COX-2: Cyclooxygenase-2; GAPDH: Glyceraldehyde-3-phosphate dehydrogenase.

patients consisted of seven cases of ovarian cancer, five cases of colon cancer, six cases of liver cancer, two cases of gastric cancer and one case of bladder cancer according to disease type.

The samples were centrifuged at 3000 r/min for 15 min immediately after collection from the patients, and the supernatant was removed. The pellet was stored in -80 °C refrigerator for total RNA extraction.

The sample collection was approved by the Ethics Committee of the hospital and all patients provided written informed consent.

### RT-PCR

**Primer design:** The gene sequences of the primers were designed with Primer Premier 5.0 software according to the literature<sup>[5,6]</sup> and mRNA sequences for human COX-2 reported by NCBI; GAPDH was selected as the positive control primer for RT-PCR and synthesized by the Shanghai ShengGong Biological Engineering Co., Ltd., China (Table 1).

**Total RNA extraction:** Total RNA was extracted from benign and malignant ascites with RNA extraction reagent (Trizol, Invitrogen, United States), and its content and purity were measured by ultraviolet spectrophotometry [ $1.9 < D(260)/D(280) < 2.1$ ].

**Synthesis of cDNA by reverse transcription:** Reverse transcription was performed to synthesize cDNA with the Avian Myeloblastosis Virus (AMV) Reverse Transcriptase Kit, which contained AMV reverse transcriptase and olig(dt)<sub>18</sub> primer. The RT-PCR reaction mixture of 10 μL contained 1 μL extracted total RNA, 2 μL MgCl<sub>2</sub>, 1 μL 10 × RNA PCR buffer, 3.75 μL RNase free dH<sub>2</sub>O, 1 μL dNTP mixture, 0.25 μL RNase inhibitor, 0.5 μL AMV reverse transcriptase and 0.5 μL Oligo dT-adaptor primer. The reaction conditions were set at 30 °C for 10 min, 50 °C for 30 min, 99 °C for 5 min and 5 °C for 5 min.

**PCR amplification:** After reverse transcription, cDNA was used as the template in PCR amplification with primers for COX-2 and glyceraldehyde-3-phosphate dehydro-

**Table 2** mRNA expression of cyclooxygenase-2 *n* (%)

Group	COX-2 mRNA expression		$\chi^2$	<i>P</i> value
	Positive	Negative		
In benign and malignant ascites <sup>1</sup>			4.051	0.044
Benign ascites	1 (6.7)	14 (93.3)		
Malignant ascites	9 (42.9)	12 (57.1)		
Among different disease types in benign group <sup>2</sup>				1.000
Cirrhosis with ascites	1 (6.7)	9 (60)		
Tuberculous ascites	0 (0.0)	5 (33.3)		
Among different disease types in malignant group <sup>3</sup>			1.614	0.806

Colon cancer	2 (9.5)	3 (14.3)		
Liver cancer	2 (9.5)	4 (19.0)		
Gastric cancer	1 (4.8)	1 (4.8)		
Bladder cancer	0 (0.0)	1 (4.8)		

<sup>1</sup>Comparison was made between groups using Yates' continuity correction;

<sup>2</sup>Comparison was made between groups using Fisher's exact probability

test; <sup>3</sup>Comparison between groups utilized  $\chi^2$  test;  $P > 0.05$  was considered not statistically significant.  $P < 0.05$  was considered statistically significant. COX-2: Cyclooxygenase-2.

genase (GAPDH); a negative control was established. The PCR reaction mixture of 50  $\mu$ L contained 3  $\mu$ L MgCl<sub>2</sub>, 4  $\mu$ L 10  $\times$  LA PCR buffer II (Mg<sup>2+</sup> + free), 31.75  $\mu$ L sterilized distilled water, 0.25  $\mu$ L TaKaRa LA Taq and 1  $\mu$ L the COX-2 or GAPDH primers. The PCR cycle consisted of the following steps: denaturing at 94  $^{\circ}$ C for 30 s, annealing at 60  $^{\circ}$ C for 30 s and elongation at 72  $^{\circ}$ C for 1.5 min, which was repeated for 30 cycles. Amplification products were utilized for electrophoresis in a 1.5% agarose gel, and were observed and photographed under ultraviolet light.

### Statistical analysis

Statistical analysis was performed with SPSS 13.0 software, and qualitative data was described by frequency and rate; the comparison between groups of qualitative data was made using the  $\chi^2$  test with Yates' continuity correction and Fisher's exact probability test;  $P < 0.05$  was considered significant.

## RESULTS

### mRNA expression of COX-2 in benign and malignant ascites

The positive rate of COX-2 mRNA in malignant ascites was 42.9% (9/21), which was significantly higher than in benign ascites, 6.7% (1/15), the difference being significant between the two groups ( $\chi^2 = 4.051$ ,  $P = 0.044$ ), (Table 2).

### mRNA expression of COX-2 among different disease types in benign group

Among the benign ascites, COX-2 mRNA levels were different between the tuberculous ascites (0/5) and cirrhotic ascites (1/10), but the difference being not significant ( $P = 1.000$ ), (Table 2).

### mRNA expression of COX-2 among different disease types in malignant group

The proportion of the positive rate in the malignant ascites was as follows: ovarian cancers 57.1% (4/7), colon cancer 40.0% (2/5), liver cancer 33.3% (2/6), gastric cancer 50.0% (1/2), and bladder cancer 0.00% (0/1). However, there was no significant difference in COX-2 mRNA expression among various tumors with malignant ascites ( $\chi^2 = 1.614$ ,  $P = 0.806$ ;  $P > 0.05$ ), (Table 2).

## DISCUSSION

COX, or prostaglandin-endoperoxide synthase (PGH), is a major rate-limiting enzyme in the synthesis of prostaglandin, which is able to metabolize arachidonic acid into prostaglandin products<sup>[7-9]</sup>. COX-2, an inducible protein expression, is absent in normal cells and tissues, but is rapidly synthesized and expressed under pathological conditions or after stimulation (such as inflammation, hypoxia, laser radiation, ultraviolet radiation, *etc.*). COX-2 is involved in a variety of pathophysiological processes, such as the occurrence and development of inflammation and cancer<sup>[10]</sup>. At present, mRNA expression of COX-2 in various tumor tissues has been extensively investigated; increasing numbers of research have demonstrated that COX-2 expression is unregulated in precancerous lesions and preinvasive carcinoma and positively correlates with tumor invasion and lymphatic metastasis<sup>[11-14]</sup>. Therefore, increased expression of COX-2 might occur in the early stage of the tumor and the detection of COX-2 level is helpful for early diagnosis<sup>[15,16]</sup>.

Ascites is a common symptom of many diseases and the differential diagnosis of benign and malignant ascites is important in clinical practice. So far, smear tests of exfoliated cells from ascites and the detection of tumor markers, such as CA-125, CA19-9 and AFP, have been employed to identify ascites induced by malignant tumors, but these indices are far from satisfactory in terms of sensitivity and specificity, so it is important to search for a new indicator of benign and malignant ascites<sup>[17-21]</sup>. Since COX-2 has a close relationship with tumors, its expression in malignant ascites has become an issue that is worth exploring.

We used RT-PCR to assess the mRNA expression of COX-2 in 21 cases of malignant ascites. The positive rate of COX-2 mRNA was 42.9% (9/21), which was significantly higher than in benign ascites, 6.7% (1/15) ( $P < 0.05$ ). This result indicated that the measurement of COX-2 mRNA facilitates the identification of benign and malignant ascites and has a potential value for clinical diagnosis and screening of tumors. In previous studies on COX-2, its expression was usually detected in malignant tumor tissues<sup>[22-24]</sup>, but our experiment used ascites as the samples. They were convenient to collect from patients, with less pain and being easy for clinical application. In addition, COX-2 is absent in normal cells and tissues as an inducible expression protein with specificity, so is a

potential indicator for the identification of benign and malignant ascites, and an effective supplement to common indices, such as CA125, CA19-9 and AFP.

There were no significant differences in the expression of COX-2 mRNA among various disease types with benign or malignant ascites ( $P > 0.05$ ), which was probably associated with the small number of samples and requires further confirmation. We employed one step RT-PCR, which was easy to perform, required little contact with experimental samples and avoided unnecessary contamination, and also facilitated further research and the development of clinical detection kits.

In conclusion, differential diagnosis between benign and malignant ascites is of importance and is helpful for designing a treatment plan. We hope our study can provide a new insight to explore this field in the future.

## COMMENTS

### Background

In recent years, cyclooxygenase-2 (COX-2) has been extensively studied as an inducible expression protein, and has been detected in various tumor tissues in epidemiological and cytological research. Therefore, increased expression of COX-2 might occur in the early stage of the tumor and the detection of COX-2 level is helpful for early diagnosis.

### Research frontiers

At present, mRNA expression of COX-2 in various tumor tissues has been extensively investigated; more and more research has demonstrated that COX-2 expression is upregulated in precancerous lesions and preinvasive carcinoma and positively correlates with tumor invasion and lymphatic metastasis. Therefore, increased expression of COX-2 might occur in the early stages of the tumor and the detection of COX-2 level is helpful for early diagnosis.

### Innovations and breakthroughs

This study employed RT-PCR to assess the mRNA expression of COX-2 in 21 cases of malignant ascites. The positive rate of COX-2 mRNA was 42.9% (9/21), which was significantly higher than in benign ascites, 6.7% (1/15), ( $P < 0.05$ ). This result indicated that the measurement of COX-2 mRNA facilitates the differential diagnosis between benign and malignant ascites and has a potential value for clinical diagnosis and screening of tumors.

### Applications

Differential diagnosis between benign and malignant ascites is of importance and is helpful for designing a treatment plan. The study can provide a new insight to this field in the future.

### Peer review

This is an interesting manuscript about mRNA expression of COX-2 in benign and malignant ascites. The authors made a good research on this topic. Differences in COX-2 mRNA expression among different diseases were explored. The data is well present and discussed.

### Abstract

**AIM:** To identify the relationship between tag single nucleotide polymorphisms (tag SNPs) of interleukin-6 (*IL-6*) gene and susceptibility to chronic hepatitis B virus (HBV) infection in a Han Chinese population.

**METHODS:** We performed a case-control study of 501 Chinese patients with chronic HBV infection and 301 self-limiting HBV-infected individuals as controls. Genomic DNA was isolated from the whole blood of all subjects using phenol/chloroform with MaXtract high-density tubes. Tag SNPs were identified using genotype data from the panel (Han Chinese in Beijing) of the phase II HapMap Project. Four tag SNPs in *IL-6* (*rs17147230A/T*, *rs2066992G/T*, *rs2069837A/G* and *rs2069852A/G*) were genotyped by the Multiplex Snap-

shot technique. The genotype and allele frequencies were calculated and analyzed.

**RESULTS:** Five haplotypes were involved in the analysis, with frequencies higher than 0.03. One of the haplotypes, TTAA, was significantly different between the two groups. Overall haplotype *P* values were: ATAA, *P* = 0.605, OR (95%CI) = 1.056 (0.860-1.297); TGAG, *P* = 0.385, OR (95%CI) = 1.179 (0.813-1.709); TGGG, *P* = 0.549, OR (95%CI) = 1.087 (0.827-1.429); TTAA, *P* = 0.004, OR (95%CI) = 0.655 (0.491-0.873); TTAG, *P* = 0.266, OR (95%CI) = 1.272 (0.832-1.944). However, the four SNPs showed no significant genotype/allele associations with susceptibility to chronic HBV infection. Overall allele *P* values were: *rs17147230*, *P* = 0.696, OR (95%CI) = 1.041 (0.850-1.276); *rs2066992*, *P* = 0.460, OR (95%CI) = 1.090 (0.868-1.369); *rs2069837*, *P* = 0.898, OR (95%CI) = 0.983 (0.759-1.274); *rs2069852*, *P* = 0.165, OR (95%CI) = 0.859 (0.693-1.064). Overall genotype *P* values were: *rs17147230*, *P* = 0.625; *rs2066992*, *P* = 0.500; *rs2069837*, *P* = 0.853; and *rs2069852*, *P* = 0.380.

**CONCLUSION:** The four tag SNPs of *IL-6* gene may be associated with susceptibility to chronic HBV infection in the Han Chinese population.

© 2013 Baishideng. All rights reserved.

**Key words:** Chronic hepatitis B virus infection; Interleukin-6; Single nucleotide polymorphism; Genetic susceptibility; Haplotype

**Core tip:** This study included a large number of subjects with a single ethnic background (Chinese). This would further add to the statistical power of the analysis and identify more single nucleotide polymorphisms. We selected self-limiting hepatitis B virus-infected subjects, but not unexposed subjects as controls, therefore, our results may be more reliable than other studies that

recruited blood donors as controls. In addition, we included only antiviral-naive subjects.

## INTRODUCTION

The outcome of hepatitis B virus (HBV) infection is mainly influenced by the virus, immune response and genetic diversity<sup>[1-3]</sup>. Many studies strongly support that host genetic variety plays an important role in determining the outcome of HBV infection<sup>[4,5]</sup>. Host genetics such as single nucleotide polymorphisms (SNPs) of a variety of genes have been implicated in the diversity of HBV clinical course<sup>[6-9]</sup>. Recent studies have shown that cytokine genetic polymorphisms are associated with the development of chronic HBV infection and progression of the infection<sup>[10]</sup>.

Interleukin-6 (IL-6) is a pleiotropic cytokine with a pivotal function in regulation of the biological responses of several target cells including hepatocytes<sup>[11]</sup>. Kuo *et al.*<sup>[12]</sup> found that IL-6 was able to effectively suppress HBV replication and prevent the accumulation of HBV covalently closed circular DNA (cccDNA) in a human hepatoma cell line. Cussigh *et al.*<sup>[13]</sup> found that *IL-6* promoter polymorphisms influence the development of chronic hepatitis C virus infection. Another study suggested that *IL-6* gene polymorphisms may be associated with the outcome of allogeneic hematopoietic stem cell transplantation, particularly in patients transplanted from a related donor<sup>[14]</sup>. However, the exact mechanism involving *IL-6* in the outcome of HBV infection is unknown. The present study investigated the association between the tag SNPs of the *IL-6* gene and genetic susceptibility to chronic HBV infection.

## MATERIALS AND METHODS

### Patients

Eight hundred and two Han Chinese with HBV infection were enrolled in this study. Following recruitment, the subjects gave informed consent for genetic analysis. No abnormalities were observed in these subjects based on physical examination, chest radiography, electrocardiogram, urinalysis and routine laboratory blood testing. Liver, renal, endocrine and cardiovascular disorders were excluded. Five hundred and one were chronic HBV infected patients (221 males and 280 females). The remaining 301 were HBV natural clearance individuals and served as the control group (143 females and 158 males). The average age was 44.2 years for HBV chronic carri-

ers and 44.9 years for controls. All patients with chronic HBV infection fulfilled the diagnostic criteria: positive for hepatitis B surface antigen (HBsAg) for a period of at least 6 mo, serum HBV DNA level > 1000 copies/mL, and elevated alanine aminotransferase or aspartate aminotransferase (> 40 IU/mL). The clinical criteria for self-limiting HBV infected patients were: positive for hepatitis B surface antibody and hepatitis B core antibody, but negative for HBsAg, and no history of HBV vaccination. Controls were age- and sex-matched subjects ( $P > 0.1$ ). All cases and controls were followed for more than 6 mo. None of the patients had received anti-HBV therapy.

### Isolation of DNA from whole blood

Genomic DNA was isolated from the whole blood of all subjects using phenol/chloroform with MaXtract high-density tubes. Genomic DNA was extracted from the peripheral blood leukocyte pellet using a DNA extraction kit (Yuan Ping-Hao Biotechnology Co., Ltd. Tianjin, China), according to the manufacturer's instructions. The DNA samples were stored at -80 °C at a concentration of 100 ng/ $\mu$ L.

### Tag SNP selection

We selected SNPs on the basis of the following principal criteria: tag SNPs were identified using genotype data from the panel (Han Chinese in Beijing) of the phase II HapMap Project. The criteria for tag SNPs were  $r^2 > 0.8$ , minor allele frequency (MAF) > 0.1, functional relevance and importance, and SNPs significantly associated with diseases in previous studies. Four tag SNPs in the *IL-6* gene (*rs17147230A/T*, *rs2066992G/T*, *rs2069837A/G* and *rs2069852A/G*) were selected, which captured 100% of common SNPs (MAF > 0.1) in the HapMap Chinese database at  $r^2 > 0.8$ .

### Genotyping

The four SNPs in *IL-6* were genotyped using the Multiplex SNaPshot technique. The primers and probes were designed by Primer 5.0 software and were *rs17147230* (5' to 3'): forward primer: AAAAGGGCAAGGAAGGGAGGTA, reverse primer: CACGA GTCATTTG AGCCATCTTTG, and extension primer: TTTTTTTTTTTTTTTTTTTTTTTTGAGTT CAGTGTCATCAGCAGAACT; *rs2066992* (5' to 3'), forward primer: CTTCTGCTGGAACATTC-TATGGC, reverse primer: TTTCTGCCAGTGC CTCTTTGC, and extension primer: TTTTTTTTTTT TTTTTTTTTTTTTTTTTT TCCTAAAACAAACAC-CACTAGAGGG. *rs2069837* (5' to 3'), forward primer: CTTCTGCT GGAACATTCTATGGC, reverse primer: TTTCTGCCAGTGC CTCITTTGC, and extension primer: TTTTTTTTAAATTTGTTTTGAAGATTAG ACACAATATTTAT. *rs2069852* (5' to 3'): forward primer: CGTCATTTAACCCAGCACTTG, reverse primer: GGATTTTCTACATCAT CCCTCAGTTCC, and extension primer: TTTTTT TTTTGCCTTG-CACA CTCTTTCTG. The polymerase chain reaction

(PCR) amplification conditions were: a 15- $\mu$ L final volume containing 10  $\times$  1.5  $\mu$ L buffer, 0.3  $\mu$ L dNTPs (10 mmol/L), 0.9  $\mu$ L MgCl<sub>2</sub> (25 mmol/L), 0.1  $\mu$ L Taq DNA polymerase (TAKARA Biotechnology Co. Ltd., Dalian, China), 0.5  $\mu$ L each primer (10 pmol/L), and 1  $\mu$ L DNA template (20 mg/L). Conditions for the multiplex PCR reaction using Touch-down PCR response procedures included initial denaturation at 95 °C for 15 min, denaturation at 94 °C for 40 s, annealing at 63 °C for 1 min, and recursive-descent at 0.5 °C, followed by extension at 72 °C for 1.5 min, for a total of 15 cycles. This was followed by 25 cycles of denaturation at 94 °C for 40 s, annealing at 56 °C for 40 s, and extension at 72 °C for 1.5 min, with a final extension at 72 °C for 8 min. Amplified samples were stored at 4 °C. After amplification, 1.5  $\mu$ L PCR product was examined on an agarose gel to test for successful amplification.

### SNaPshot reaction

The purified PCR product, each concentration of 0.2  $\mu$ mol/L SNaPshot primer mixtures, and SNaPshot fluorescent mixtures (containing Taq DNA polymerase and different fluorescently labeled ddNTP, TAKARA Biotechnology Co. Ltd., Dalian, China) consisted of a PCR system. SNaPshot response procedures were: initial denaturation at 96 °C for 10 s; denaturation at 96 °C for 10 s, annealing at 53 °C for 5 s, extension at 60 °C for 30 s, for a total of 25 cycles, and finally extension at 60 °C for 30 s. Amplified samples were stored at 4 °C. SNaPshot PCR products using SAP purification, in 10  $\mu$ L SNaPshot PCR product with 1 U SAP or 1 U CIP, were mixed and incubated at 37 °C for 1 h, and 75 °C for 15 min to inactivate the enzyme. The samples can be stored at 4 °C for 24 h or -20 °C permanently.

### DNA sequencing

The SNaPshot product was diluted 20-fold. In a total volume of 10  $\mu$ L, we mixed 8.6  $\mu$ L HiDiFormamide (high-purity formamide), 0.9  $\mu$ L GeneScan-120 LIZ Size Standard, and 0.5  $\mu$ L SNaPshot purification product. Samples were incubated at 95 °C for 5 min, chilled quickly for 4 min, and then loaded on an ABI 3730XL Genetic Analyzer (Applied Biosystems, CA, United States) for capillary electrophoresis, running GeneMapper 4.0 software for analysis of the experimental results.

### Statistical analysis

Allele and genotype frequencies were obtained by direct counting, and the  $\chi^2$  test was used to compare allele and genotype distributions. The quality of the genotype data was assessed by Hardy-Weinberg equilibrium in the case and control samples using Fisher's exact test ( $P > 0.05$ ). OR and 95%CI were calculated according to Woolf's method.

## RESULTS

We investigated the distribution of the four SNPs in

501 Chinese HBV-infected patients (cases) and 301 self-limiting HBV-infected patients (controls). All genotypes of the *IL-6* polymorphisms were in Hardy-Weinberg equilibrium in both the cases and controls.

The genotype frequencies and allele distributions of the *IL-6* polymorphisms in each subgroup of HBV-infected patients are summarized in Table 1. The genotype frequencies for AA, AT, and TT of *IL-6* rs17147230 were 30.9%, 48.1%, and 21.0% in case samples, and 28.2%, 51.5%, and 20.3% in control samples, respectively, without significant differences between cases and controls ( $P = 0.625$ ). The genotype frequencies for GG, GT and TT of *IL-6* rs2066992 were 9.0%, 37.9%, and 53.1% in case samples, and 6.6%, 39.2%, and 54.2% in control samples, respectively, without significant differences between cases and controls ( $P = 0.510$ ). The genotype frequencies for AA, AG, and GG of *IL-6* rs2069837 were 66.1%, 30.1%, and 3.8% in case samples, and 67.1%, 28.6%, and 4.3% in control samples, and no significant differences were noted ( $P = 0.853$ ). The genotype frequencies for AA, AG and GG of *IL-6* rs2069852 were 41.5%, 44.7%, and 12.8% in case samples, and 45.8%, 43.9%, and 10.3% in control samples, and no significant differences were noted ( $P = 0.380$ ). In addition, no statistically significant differences were found when the allele frequencies of SNPs rs17147230, rs2066992, rs2069837 and rs2069852 were compared between patients with chronic HBV infection and controls. Overall allele  $P$  values were: rs17147230,  $P = 0.696$ , OR (95%CI) = 1.041 (0.850-1.276); rs2066992,  $P = 0.460$ , OR (95%CI) = 1.090 (0.868-1.369); rs2069837,  $P = 0.898$ , OR (95%CI) = 0.983 (0.759-1.274); rs2069852,  $P = 0.165$ , OR (95%CI) = 0.859 (0.693-1.064).

### Haplotype analysis

We also estimated the *IL-6* haplotype frequencies and evaluated the association among these variants and HBV infection. We observed five haplotype combinations, but found no significant association in the distribution of the haplotype frequencies between cases and controls ( $P > 0.05$ ) except "TTAA" where the protective haplotype was associated with lower disease susceptibility. The haplotype "TTAA" was observed to be significantly associated with control subjects compared with patients [ $P < 0.05$ , OR (95%CI) 0.655 (0.491-0.837)]. Haplotype frequencies lower than 0.03 were ignored in the analysis (Table 2).

## DISCUSSION

Several cytokine polymorphisms are associated with the natural history of HBV infection. Zhang *et al.*<sup>[15]</sup> proved that persistent HBV infection susceptibility is associated with the gene polymorphism *IL-10* -1082 GA in the Chinese population and that clearance of HBV is associated with the gene polymorphism *IL-10* -592 CA in the Chinese population. *IL-10* -1082 G/G and *IL-12 $\beta$*  -10993 C/G are associated with early, spontaneous HBeAg seroconversion<sup>[16]</sup>. Another study indicated that the -148C,

+8925G and +13925C alleles of the *IL-18* gene are likely associated with HBV clearance in a Korean population<sup>[17]</sup>. However, Lee *et al*<sup>[18]</sup> found that the polymorphisms near the *IL-28B* gene, rs8099917T>G, rs12979860C>T and rs12980275A>G, are not significantly associated with the natural course of chronic HBV infection.

IL-6 acts as both a pro-inflammatory and anti-inflammatory cytokine. Hösel *et al*<sup>[19]</sup> found that IL-6 ensures early control of the virus, limiting activation of the adaptive immune response and preventing death of HBV-infected hepatocytes. IL-6 may play an extremely important role in determining liver progression<sup>[20]</sup>. Polymorphism of the *IL-6* promoter -572 loci may be associated with HCC occurrence in men<sup>[21]</sup>. Fabris *et al*<sup>[22]</sup> found that fewer patients aged < 50 years who carried one of the IL-6 high producer (G/G or G/C) genotypes experienced HBsAg loss in comparison with patients aged > 50 years and/or carriers of the IL-6 low producer C/C genotype. This indicates that possessing an IL-6 low producer phenotype may provide some advantage to older patients with

chronic HBV infection. This is consistent with other findings which showed that *IL-6* -174 G>C polymorphism may play a role in the clinical evolution of HBV infection at least in European countries where a higher prevalence of the C allele was detected in comparison with patients from the Far East<sup>[23]</sup>. However, Park *et al*<sup>[24]</sup> found that variants in the *IL-6* gene are not associated with subsequent HBV outcomes, although *IL-6* has been found to be functionally significant in other diseases<sup>[25-27]</sup>.

To identify the relationship between the SNPs of *IL-6* gene and genetic susceptibility to chronic hepatitis B virus infection in the Han Chinese population, we selected four SNPs in *IL-6* (rs1714230, rs2066992, rs2069837 and rs2069852) using genotype data from the panel (Han Chinese in Beijing) of the phase II HapMap Project. The four tag SNPs captured 100% of common SNPs (minor allele frequency > 0.1) in the HapMap Chinese database at  $r^2 > 0.8$ . We analyzed the associations of four SNP alleles with chronic HBV infection compared with self-limiting HBV infection. The results indicated that tag

SNPs of *IL-6* may be a prognostic factor for chronic hepatitis B infection. There are several advantages of this study which strengthen it compared with previous similar studies, and increase the reliability of our results. First, our study included a large number of subjects with a single ethnic background (Chinese). This would further add to the statistical power of the analysis and identify more SNPs. Second, we selected self-limiting HBV-infected subjects, but not unexposed subjects, as controls, therefore, our results may be more reliable than other studies that recruited blood donors as controls. Third, we included only antiviral-naïve subjects. In contrast, previous similar studies which investigated the natural course of chronic HBV infection did not set any limitation regarding antiviral treatment.

In conclusion, *IL-6* is a functional gene which plays a relevant role in the pathogenesis of HBV. Our study demonstrates that the tag SNPs of *IL-6* may be related to genetic susceptibility to chronic HBV infection in Chinese patients. Further genetic studies are needed to examine other SNPs in *IL-6* and their possible association with disease progression in chronic HBV infection.

## COMMENTS

### Background

Persistent hepatitis B virus (HBV) infection is considered a multifactorial and polygenic disorder with viral, environmental, and genetic components, as well as contributions from HBV genomic variability, host age, gender, concurrent infection with the hepatitis C virus, hepatitis D virus, and human immune deficiency virus. Interleukin-6 (IL-6) plays an important role in the response of the innate immune system to viral infection. *IL-6* polymorphisms affect induction of IL-6 expression.

### Research frontiers

This study is the first to investigate the association between four tag single nucleotide polymorphisms (tag SNPs) (*rs17147230A/T*, *rs2066992G/T*, *rs2069837A/G* and *rs2069852A/G*) of *IL-6* and genetic susceptibility to chronic HBV infection in Chinese patients using the Multiplex SNaPshot technique.

### Innovations and breakthroughs

The four tag SNPs of *IL-6* may be related to genetic susceptibility to chronic HBV infection.

### Applications

Based on the results of this study, further genetic studies are needed to examine the roles of other *IL-6* SNPs and their association with disease progression in chronic HBV infection.

### Terminology

IL-6 is a pleiotropic cytokine with a pivotal function in regulation of the biological responses of several target cells including hepatocytes. It acts as both a pro-inflammatory and anti-inflammatory cytokine.

### Peer review

The manuscript analyzed the association between polymorphisms of *IL-6* and clinical outcomes of HBV infection. Four SNPs of *IL-6* were genotyped using Multiplex SNaPshot technique and compared between chronic HBV infection and self-limiting HBV infection patients. The overall data showed that SNPs of *IL-6* may affect the outcome of HBV infection. The data may have a significant clinical implication.

### Abstract

**AIM:** To determine the expression of the catalytic subunit of DNA-dependent protein kinase (DNA-PKcs) and the Ku70/Ku80 heterodimer (Ku 70/80) in gastric carcinoma.

**METHODS:** Gastric biopsies were obtained from 146 gastric carcinoma patients [*Helicobacter pylori* (*H. pylori*)-negative: 89 and *H. pylori*-positive: 57] and 34 from normal subjects (*H. pylori*-negative: 16 and *H. pylori*-positive: 18) via surgery and endoscopic detection from April 2011 to August 2012 at the First Affiliated Hospital of Nanchang University. Pathological diagnosis and classification were made according to the criteria of the World Health Organization and the updated Sydney system. An "in-house" rapid urease test and modified Giemsa staining were employed to detect *H. pylori* infection. The expression of DNA-PKcs and the Ku 70/80 protein was detected by immunohistochemistry.

**RESULTS:** Overall, the positive rates of both DNA-PKcs and Ku 70/80 were significantly increased in gastric cancer ( $\chi^2 = 133.04$ ,  $P < 0.001$  for DNA-PKcs and  $\chi^2 =$

13.06,  $P < 0.01$  for Ku) compared with normal gastric mucosa. There was hardly any detectable expression of DNA-PKcs in normal gastric mucosa, and the positive rate of DNA-PKcs protein expression in patients with a normal gastric mucosa was 0% (0/34), whereas the rate in gastric cancer (GC) was 93.8% (137/146). The difference between the two groups was statistically significant. Additionally, the positive rate of Ku 70/80 was 79.4% (27/34) in normal gastric mucosa and 96.6% (141/146) in gastric cancer. The DNA-PKcs protein level was significantly increased in gastric cancer (Mann-Whitney  $U = 39.00$ ,  $P < 0.001$ ), compared with normal gastric mucosa. In addition, there was a significant difference in the expression of Ku 70/80 (Mann-Whitney  $U = 1117.00$ ,  $P < 0.001$ ) between gastric cancer and normal gastric mucosa. There was also a significant difference in Ku70/80 protein expression between GC patients with and without *H. pylori* infection ( $P < 0.05$ ). Spearman analysis showed a negative correlation between tumor differentiation and DNA-PKcs expression ( $r = -0.447$ ,  $P < 0.05$ ). Moreover, Ku70/80 expression was negatively correlated with both clinical stage ( $r = -0.189$ ,  $P < 0.05$ ) and *H. pylori* colonization ( $r = -0.168$ ,  $P < 0.05$ ).

**CONCLUSION:** Overall, this research demonstrated that enhanced DNA-PKcs and Ku 70/80 expression may be closely associated with gastric carcinoma.

**Key words:** *Helicobacter pylori*; Catalytic subunit of the DNA-dependent protein kinase; Ku70/Ku80 heterodimer; Gastric carcinoma; Immunohistochemistry

**Core tip:** This is the first study to clarify the two key promoters of the non-homologous end joining (NHEJ) pathway, DNA-dependent protein kinase (DNA-PKcs) and Ku 70/80, in human gastric carcinoma tissues. The present study found an upregulated expression of DNA-PKcs and Ku 70/80 in gastric cancer tissues compared

with normal gastric mucosa, which suggests that there is an enhanced function of NHEJ in gastric carcinogenesis. As NHEJ is an error-prone and non-specific repair mechanism and can be induced before homologous recombination, its excessive activation is capable of regulating cell cycle arrest, cell apoptosis, chromosome recombination and genome instability.

Li W, Xie C, Yang Z, Chen J, Lu NH. Abnormal DNA-PKcs and Ku 70/80 expression may promote malignant pathological processes in gastric carcinoma. *World J Gastroenterol* 2013; 19(40): 6894-6901 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6894.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6894>

## INTRODUCTION

Gastric carcinoma is a worldwide malignant disease with high incidence and mortality, and it is characterized by genome instability through severe DNA damage caused by various factors, including *Helicobacter pylori* (*H. pylori*) infection, heredity and living habits<sup>[1,2]</sup>. The catalytic subunit of the DNA-dependent protein kinase (DNA-PKcs) and the Ku 70/Ku 80 heterodimer (Ku 70/80) can instantly combine into DNA-dependent protein kinase (DNA-PK), which is a crucial promoter of the non-homologous end joining (NHEJ) pathway<sup>[3,4]</sup>. First, DNA-PKcs receives a DNA damage signal and launches a damage response. Next, Ku 70/80 binds to the damaged DNA ends and then attracts DNA-PKcs to form DNA-PK, which can trigger NHEJ repair activities<sup>[4,5]</sup>. Accumulating evidence has shown that dysregulation of DNA-PKcs and Ku 70/80 is associated with pathological processes in various tumors<sup>[6]</sup>. The expression changes and biological function of DNA-PKcs and Ku 70/80 in gastric cancer (GC) are still unclear. It is possible that DNA-PKcs and Ku 70/80 play a dual role in tumorigenicity, as both a rapid repair method and error-prone mechanism. The inability to activate the promoter of this repair pathway could increase the mutation rate within the genome, promoting malignant cellular changes associated with carcinogenesis. Malignant tissues induce unbalanced NHEJ activities to handle metabolic stress and promote tumor infiltration. However, normal repair activities within tumor tissues may also lead to cell death and genome instability, as well as create a microenvironment that is predisposed to cancer. To determine a possible pathological role of DNA-PKcs and Ku 70/80-mediated DNA repair pathways in human gastric cancer tissues and to verify whether *H. pylori* infection disturbs the regular repair function of gastric mucosal epithelial cells through a series of DNA damage responses and the NHEJ repair pathway, we measured the expression of DNA-PKcs and Ku 70/80 by immunohistochemistry in biopsies or surgical specimens of 180 patients with or without gastric carcinoma.

## MATERIALS AND METHODS

### Patient tissue

Gastric samples of patients who underwent upper gastroduodenoscopy from January 2007 to September 2009 at The First Affiliated Hospital of Nanchang University were retrospectively reviewed and examined. A total of 180 patients (76 females and 104 males, with a mean age of  $55.37 \pm 14.05$  years) were enrolled in this study, including 34 patients with a normal gastric mucosa (NGM, *H. pylori*-negative: 16 cases and *H. pylori*-positive: 18 cases), and 146 with gastric carcinoma (GC, *H. pylori*-negative: 89 cases and *H. pylori*-positive: 57 cases). There was no significant difference in the age or gender distribution among these groups. None of the patients had been treated with any regimens to eradicate *H. pylori* infection. This study was approved ethically by the First Affiliated Hospital of Nanchang University. All of the patients gave written informed consent to participate in the study.

### Detection of *H. pylori* infection

An “in-house” rapid urease test (RUT) and modified Giemsa staining were employed for detecting *H. pylori* infection. The effectiveness of RUT is more than 95% (data not shown). The modified Giemsa staining was carried out in a double-blind fashion. An *H. pylori* infection was diagnosed as positive only if both of the methods produced positive results. An *H. pylori*-negative diagnosis was confirmed if both of the methods yielded negative results<sup>[7]</sup>.

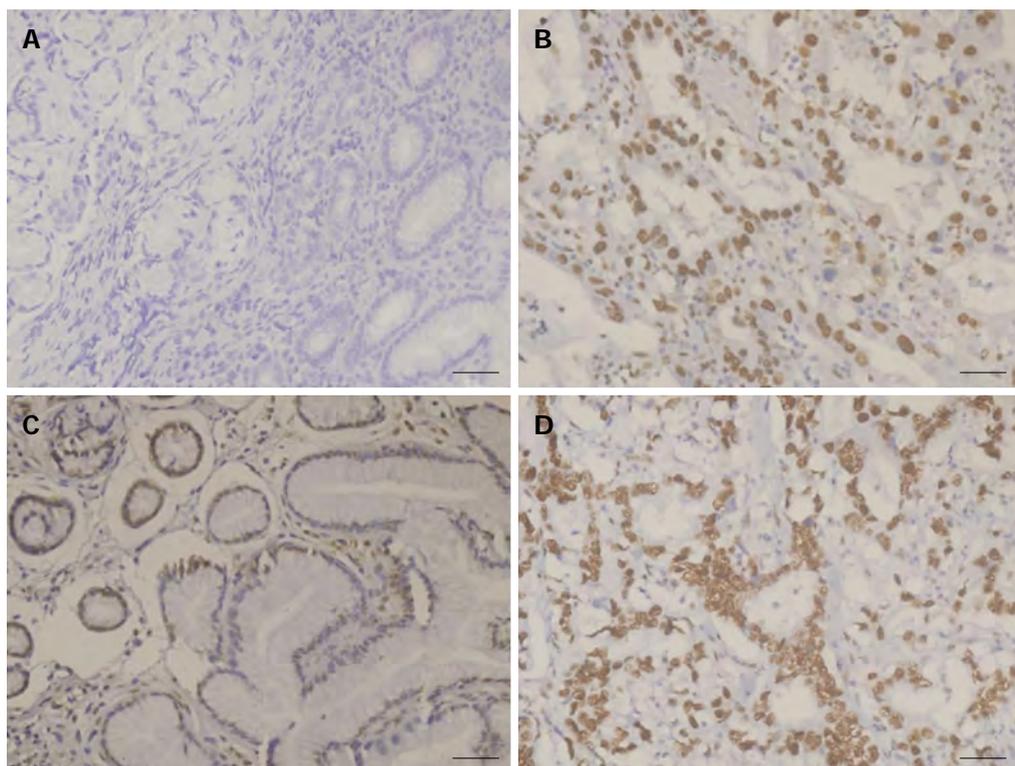

### Histological examinations of gastric samples

Gastric samples were obtained from patients who underwent endoscopy of the upper gastrointestinal tract. All of the biopsies were taken from the gastric antrum and the lesions of individual patients. The tissues used for histological analysis were fixed in 10% formaldehyde in  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$  free phosphate-buffered saline (PBS) overnight at 4 °C before paraffin embedding. Paraffin sections of 4  $\mu\text{m}$  were cut with a microtome and stored at room temperature. Pathological diagnosis and classification were performed according to the criteria of the World Health Organization<sup>[8,9]</sup>.

### Immunohistochemistry

Primary antibodies used in this study were as follows: mouse monoclonal antihuman DNA-PKcs (Abcam, Cambridge, United Kingdom) and rabbit polyclonal antihuman Ku 70/Ku 80 (Anbobio, San Francisco, CA). The anti-human DNA-PKcs antibody was diluted 1:400, and the anti-human Ku70/80 antibody was diluted 1:3500.

The paraffin sections were mounted on slides and dewaxed in xylene and sequentially dehydrated in 100%, 95% and 85% ethanol. The sections were stained using the PV-6000 Polymer Detection System (Zhongshan Goldenbridge, Beijing, PRC) staining protocol. The sections were then washed in PBS, and endogenous peroxidase was blocked using 3%  $\text{H}_2\text{O}_2$ . After the specimens

**Figure 1** Immunohistochemistry assay of DNA-dependent protein kinase and Ku 70/80 protein expression. Immunostaining showing that the expression of DNA-dependent protein kinase was significantly upregulated in gastric cancer (B) compared to normal gastric mucosa (A). Ku 70/80 expression was significantly increased in gastric cancer (D) compared to normal gastric mucosa (C). Scale bar = 40  $\mu\text{m}$ .

were incubated with the primary antibody overnight at 4 °C, they were washed with PBS, followed by incubation with polymer helper for 30 min and poly peroxidase-antimouse or rabbit IgG for 30 min. After the sections were washed with PBS, they were incubated with 3,3-diaminobenzidine (DAB, Zhongshan Goldenbridge). The control sections incubated with PBS instead of the primary antibodies were used as negative controls. The sections were counterstained with hematoxylin.

The slides were examined under a light microscope. The cells that stained a yellow or brown color in the nucleus and/or cytoplasm were defined as positive. Five randomly selected fields per section were analyzed. In a randomly selected field from representative areas, the immunoreactive cells among 100 cells were assessed and quantified by percentage. Then, the average percentage of the five fields was used to assess the area of immunostaining (0 = 0%-5%; 1 = 6%-25%; 2 = 26%-50%; 3 = 51%-75%; 4 = 76%-100%). In addition, the intensity of immunostaining was also semi-quantitatively assessed (0 = negative, 1 = weak, 2 = moderate, 3 = intense). Then, the integrals of the “area  $\times$  intensity” were calculated, by which the overall expression levels of the proteins in the section were defined as follows: negative (-): score 0-2; weakly positive (+): score 3-5; moderately positive (++) : score 6-8; and strongly positive (+++) : score 9-12. The positive rate was the sum of weakly, moderately and strongly positive staining. The assessment of the sections was performed blindly by two pathologists, and when two

views were not consistent, the assessment was judged by a third person.

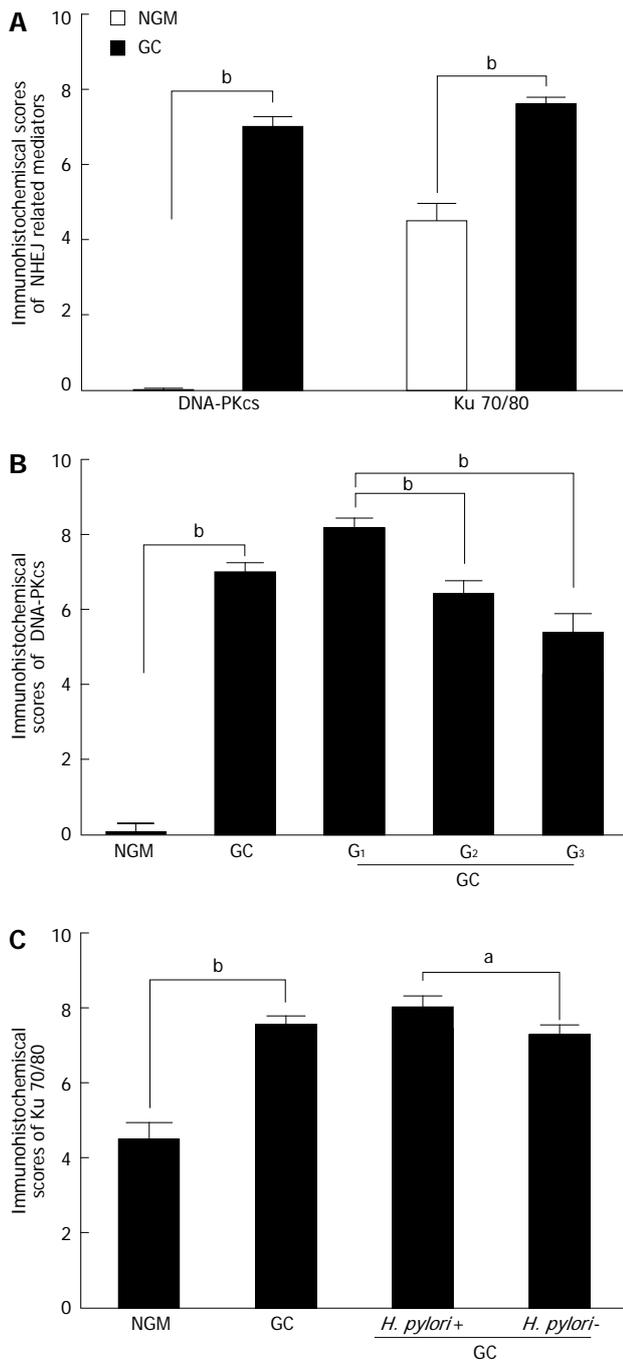

### Statistical analysis

All of the data are presented as the mean  $\pm$  SD or percentage. The  $\chi^2$  test (SPSS v.16.0 for Windows; SPSS, Inc., Chicago, IL) was used to evaluate the difference in categorical variables, such as the positive rate between groups. The Mann-Whitney *U* test (SPSS v.16.0) was used to determine the differences in numerical variables between differently defined groups. Correlations were analyzed using Spearman's rank correlation co-efficient (SPSS v.16.0). A *P* value of less than 0.05 was considered statistically significant.

## RESULTS

### Overall expression of DNA-PKcs and Ku 70/80 in gastric mucosa tissues

Overall, the positive rates of both DNA-PKcs and Ku 70/80 were significantly increased in GC ( $\chi^2 = 133.04$ ,  $P < 0.001$  for DNA-PKcs and  $\chi^2 = 13.06$ ,  $P < 0.01$  for Ku) compared with NGM. In fact, there was hardly any detectable expression of DNA-PKcs in normal gastric mucosa, and the positive rate of DNA-PKcs protein expression in patients with NGM was 0% (0/34), whereas the rate in GC was 93.8% (137/146). The difference between the two groups is statistically significant. Additionally, the positive rate of Ku 70/80 was 79.4% (27/34) in NGM

nificant difference in the average immunohistochemistry scores of Ku 70/80 (Mann-Whitney *U* = 1117.00, *P* < 0.001) between GC and NGM (Figure 2A, Table 1).

**Correlation between the expression of DNA-PKcs and Ku 70/80 and different clinical parameters in gastric carcinoma patients**

Overall, DNA-PKcs expression was negatively correlated with differentiation degree (*r* = -0.447, *P* < 0.01) in patients with GC (Figure 2B, Table 2). Its expression increased from well differentiated (G1) tumor tissues to moderately differentiated (G2) tissues and from G1 to poorly differentiated (G3) tumor tissues, but there was no significant increase from G2 to G3 (Table 3). Ku 70/80 expression was negatively correlated with *H. pylori* infection (*r* = -0.168, *P* = 0.043) and clinical stage (*r* = -0.189, *P* = 0.022) in patients with GC (Figure 2C, Table 2). There was no correlation between DNA-PKcs expression and Ku 70/80 expression.

**DISCUSSION**

NHEJ is a key source of genomic rearrangements, which are typically found in cancer cells<sup>[10]</sup>. Presently, numerous reports have demonstrated that chromosome transloc-

<sup>1-4</sup>Distinguish the *P* value between each histological type. DNA-PKcs: DNA-dependent protein kinase.

tions are a common cause of malignancy, and oncogenic fusion genes have been found in many hematological and solid tumors<sup>[11-13]</sup>. The over-expression of DNA-PKcs and Ku 70/80 has been found in various human tumors, but the pathways that promote translocations in gastric cancer are still unclear<sup>[14-16]</sup>. It is well-established that *H. pylori* infection is a definite etiological factor in gastric carcinogenesis<sup>[17-19]</sup>. However, the mechanism through which *H. pylori* infection contributes to the development of gastric cancer has not been fully elucidated. Obst *et al*<sup>[20]</sup> reported that *H. pylori* infection could cause DNA damage in gastric epithelial cells. Because Toller *et al*<sup>[21]</sup> showed an increased expression of  $\gamma$ -H2AX in *H. pylori*-infected GES-1 cells and indicated that GC may be associated with DNA double strand breaks (DSBs), we expected to detect increased DNA-PKcs expression in GC to explain the error-prone repair pathway found in the gastric mucosa.

In this study, we found that the expression of DNA-

PKcs and Ku 70/80 was increased in GC compared with NGM. Spearman analysis indicated a negative correlation between the expression of DNA-PKcs and tumor differentiation degrees. Moreover, Ku 70/80 was increased in *H. pylori*-positive GC patients compared with the negative group. Analysis of the data from 146 cases of GC did not show an obvious association between DNA-PKcs or Ku 70/80 expression levels and invasive lymph node metastasis or tumor histological type. We hypothesized that the enhanced DNA-PKcs and Ku 70/80 expression in gastric cancer may result from *H. pylori*-induced DNA damage in gastric epithelial cells. We initially analyzed the relationship between DNA-PKcs and Ku 70/80 protein expression and *H. pylori* infection status. As shown in the right panel of Figure 1C, the Ku 70/80 protein expression level was higher in *H. pylori*-positive GC tissues than in the *H. pylori*-negative tissue.

Numerous studies have indicated that genome instability can be induced by NHEJ, which may increase the

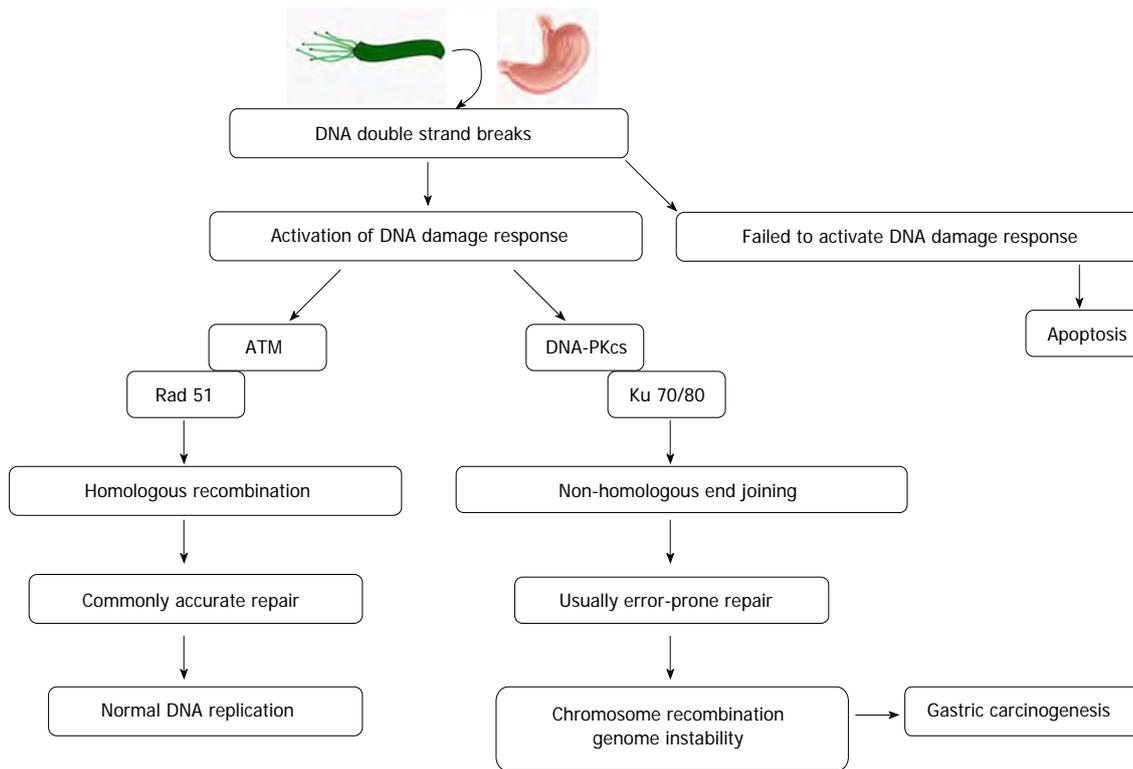

Figure 3 A model depicting the effect of *Helicobacter pylori* infection on the DNA-dependent protein kinase and Ku 70/80-mediated non-homologous end joining repair pathway in gastric epithelial cells that might ultimately promote carcinogenesis. ATM: Ataxia telangiectasia mutated; DNA-PKcs: DNA-dependent protein kinase.

risk of malignant transformation in cells<sup>[6]</sup>. In line with our results, Hu *et al.*<sup>[22]</sup> reported that the expression of Ku70 proteins in precancerous lesions and GC tissue was significantly higher than that in normal gastric mucosal tissue. Moreover, the expression of Ku70 proteins in GC tissue was significantly higher than in precancerous lesions. Lee *et al.*<sup>[23]</sup> verified that DNA-PKcs expression status was increased in consecutive cases of gastric cancer (450/564) by immunohistochemistry. Moreover, they found that DNA-PKcs expression was negative in the foveolar epithelium of normal gastric mucosal tissues but was positive in most *H. pylori*-associated gastritis, intestinal metaplasia and gastric adenoma tissues. Lim *et al.*<sup>[24]</sup> found that Ku70 and Ku80 expression is mediated by constitutively activated NF-kappaB and constitutively expressed COX-2 in gastric cancer cells and indicated that Ku70 and Ku80 expression may be related to gastric cell proliferation and carcinogenesis. These data are consistent with our findings. Here, we show that exposure to *H. pylori* significantly upregulated Ku 70/80 expression but did not influence the expression of DNA-PKcs. We speculated that a lack of effectively activated DNA-PKcs might be responsible for the severe DNA damage and abnormal NHEJ repair activities due to *H. pylori* infection in gastric epithelial cells. In addition, environmental factors, such as *H. pylori* infection, stress and behavioral habits, may upset the balance between DNA-PKcs and Ku 70/80, and thus the damaged cells cannot launch the rapid and non-specific repair mechanism, leading to more serious and irreparable damage.

To our knowledge, this is the first study to clarify the two key promoters of the NHEJ pathway in human gastric carcinoma tissue, DNA-PKcs and Ku 70/80. The upregulated expression of DNA-PKcs and Ku 70/80 in GC tissues compared with NGM confirms that there is enhanced NHEJ in human gastric carcinoma. As NHEJ is an error-prone and non-specific repair mechanism and can be induced before homologous recombination (HR), its excessive activation is capable of regulating cell cycle arrest, cell apoptosis, chromosome recombination and genome instability<sup>[25,26]</sup>. Our finding that Ku 70/80 expression is positively correlated with *H. pylori* colonization suggests that this alteration may be highly relevant for pathological processes during *H. pylori* infection. Infection with *H. pylori* can serve as a unique model system to determine the role of Ku 70/80-mediated abnormal NHEJ repair activities in gastric carcinogenesis (Figure 3).

We found the following results: (1) gastric carcinogenesis is associated with enhanced non-homologous end joining repair; and (2) *H. pylori* mainly upregulates the expression of Ku 70/80 as opposed to DNA-PKcs to trigger NHEJ in gastric epithelial cells. Our data contribute to the complexity of the NHEJ function in GC. To illustrate the molecular mechanism underlying DNA-PK function in gastric carcinogenesis, further studies with larger samples in the various stages of gastric carcinoma are needed.

In conclusion, the present study provides new perspectives into the role of DNA-PKcs and Ku 70/80 in gastric carcinogenesis. Our data indicated that dysregula-

tion of DNA-PK occurs frequently in GC and is associated with GC progression, which may be another important mechanism leading to abnormal repair activities in damaged gastric epithelial cells, especially the upregulated Ku 70/80 expression in *H. pylori*-related GC. In the current study, we found that both DNA-PKcs and Ku 70/80 were over-expressed in GC tissues. These results suggest that altered expression of DNA-PKcs and Ku 70/80 may function as a potential factor that may lead to genome instability in gastric carcinoma.

## COMMENTS

### Background

Gastric carcinoma (GC) is characterized by genome instability through severe DNA damage caused by various factors, including *Helicobacter pylori* (*H. pylori*) infection, heredity and living habits. The incidence of gastric carcinoma is currently rising rapidly throughout the world, especially in developing countries. The exact pathogenesis of this disease is still unknown. Abnormal expression of DNA-dependent protein kinase (DNA-PKcs) and Ku 70/80 is associated with tumor growth, invasion and metastasis and may also play a crucial role in error-prone DNA repair activities in gastric epithelial cells, thus leading to genome instability and gastric carcinogenesis.

### Research frontiers

DNA-PKcs and Ku 70/80 are crucial promoters of the non-homologous end joining (NHEJ) pathway. Accumulating evidence has shown that dysregulation of DNA-PKcs and Ku 70/80 is associated with pathological processes in various tumors. The expression changes and biological function of DNA-PKcs and Ku 70/80 in gastric carcinoma are still unclear. In this study, the authors demonstrate that the overexpression of DNA-PKcs and Ku 70/80 could be a potential mechanism for mediating error-prone DNA repair pathways in human gastric cancer tissues and verified that *H. pylori* infection may increase the expression of Ku 70/80, disrupting the standard activation of the NHEJ repair pathway, which is associated with gastric epithelial malignancies.

### Innovations and breakthroughs

Recent reports have highlighted the importance of genome instability-related DNA repair promoters, including DNA-PKcs and Ku 70/80, in gastric carcinogenesis. Both DNA-PKcs and Ku 70/80 are over-expressed in gastric carcinoma compared to normal gastric mucosa. This is the first study to explore the change in expression of DNA-PKcs and Ku 70/80 in gastric carcinoma, to analyze the correlation between the expression of DNA-PKcs and Ku 70/80 and to investigate a series of clinical parameters to illustrate the potential pathological mechanism of carcinogenesis.

### Applications

By verifying the changes of DNA-PKcs and Ku 70/80 and their relationship with gastric carcinoma, this study may provide new insights into the pathological mechanism of gastric cancer. Furthermore, the combination of DNA repair molecules and targeting drugs may offer a synergistic effect in the therapeutic treatment of gastric carcinoma.

### Terminology

The catalytic subunit of the DNA-PKcs and the Ku 70/Ku 80 hetero-dimer (Ku 70/80) are crucial promoters of the error-prone NHEJ pathway. First, DNA-PKcs receives a DNA damage signal and launches a damage response. Next, Ku 70/80 binds to the damaged DNA ends and then attracts DNA-PKcs to form DNA-PK, which can trigger NHEJ repair activities. Accumulating evidence has shown that dysregulation of DNA-PKcs and Ku 70/80 is associated with pathological processes in various tumors.

### Peer review

The authors examined the expression of DNA-PKcs and Ku 70/80 in gastric carcinoma. The study revealed that both DNA-PKcs and Ku 70/80 were increased in gastric carcinoma. The increase of DNA-PKcs expression was negatively correlated with differentiation degree, and Ku 70/80 expression was negatively correlated with *H. pylori* infection and the clinical stage of patients with GC. The results are interesting and may represent a new horizon for exploring the pathological mechanism of gastric carcinoma.

### Abstract

**AIM:** To investigate the association and quantify the relationship between diabetes mellitus (DM) and gastric cancer (GC) by an updated meta-analysis.

**METHODS:** The initial PubMed search identified 1233 publications. Studies not reporting GC or those not reporting actual number of GC were excluded. Twelve pertinent studies were retrieved from the PubMed database or from a manual search and considered for the meta-analysis. Pooled risk ratios and 95%CI were estimated by a random-effects model. Subgroup analysis was performed according to gender or geographical regions. Heterogeneity and publication bias were evaluated by  $I^2$  and funnel plot analysis, respectively.

**RESULTS:** DM was significantly associated with GC with a RR of 1.41 ( $P = 0.006$ ) (95%CI: 1.10-1.81). Subgroup analyses revealed that both sexes showed a significant association with GC, with a greater magnitude of risk in females (RR = 1.90; 95%CI: 1.27-2.85;  $P = 0.002$ ) than in males (RR = 1.24; 95%CI: 1.08-1.43;  $P = 0.002$ ). In addition, the link between DM and GC was significant in East Asian DM patients (RR = 1.77; 95%CI: 1.38-2.26;  $P < 0.00001$ ) but not in Western DM patients (RR = 1.23; 95%CI: 0.90-1.68;  $P = 0.2$ ). There was no evidence of publication bias, but the re-

sults indicated significant heterogeneity.

**CONCLUSION:** This updated meta-analysis has provided evidence of positive DM-GC associations. The limited information on potentially important clinical confounding factors in each study deserves further investigation.

**Key words:** Gastric cancer; Diabetes mellitus; Meta-analysis; Hyperglycemia; Hyperinsulinemia

**Core tip:** Diabetes mellitus (DM) was significantly associated with gastric cancer (GC) with a risk ratio of 1.41. This positive DM-GC association was also observed in both sexes with a greater magnitude of risk in females than male, and in East Asian patients but not in Western patients. This study could provide one answer to current inconsistent knowledge across trials concerning a positive/inverse DM-GC association. Since DM patients are less likely to be screened for cancers, clinicians caring for DM patients should remain alert to detect GC especially in females, since there are fewer female than male GC patients in the general population.

### INTRODUCTION

A growing body of evidence, derived largely from case-control studies, cohort studies, and meta-analyses, suggests that diabetes mellitus (DM) is associated with an increased risk of a number of cancers. The risk increases 2-fold for cancers of the liver, pancreas, and endome-

trium, and 1.2-1.5-fold for cancers of the colon and rectum, breast, bladder, and kidney<sup>[1]</sup>, while prostate cancer shows a positive<sup>[2]</sup> or inverse<sup>[1]</sup> association with DM. In fact, DM is a disease of global epidemic proportions. The DM population has increased from 171 million in 2000 to 366 million in 2011, a figure projected to increase to 552 million by 2030<sup>[3,4]</sup>. This increasing prevalence of DM with its anticipated 200 million more patients over the next two decades suggests that even a small increase in cancer risk will have an undeniable impact on the health of the general population. Therefore, in addition to the dramatic increase in the prevalence of DM and the consequences of its complications, a DM-cancer association may greatly affect worldwide health levels.

Despite the heightening clinical awareness of the DM-cancer association, however, the risk of gastric cancer (GC) in DM patients has seemingly attracted little attention among diabetes researchers and healthcare providers, and this topic has been scarcely addressed in the English literature with contradictory findings. This dearth of data may be attributable to the fact that the disease *per se* has been paid little attention in the West, with fewer established regular screening programs for GC. Consequently, the risk of GC in DM patients is still overshadowed by the more common acute and chronic DM complications such as cardiovascular and renal diseases, which largely account for the 2-fold increase in mortality associated with DM<sup>[5]</sup>. Under these circumstances, the reported risks of GC in DM patients have been inconsistent, being high<sup>[6,7]</sup>, neutral<sup>[8]</sup>, or inverse<sup>[9]</sup> with an odds ratio or incidence RR of 1.14 (95%CI: 1.03-1.31) to 2.07 (95%CI: 1.40-3.08), 1.2 (95%CI: 0.74-1.70) to 1.6 (95%CI: 0.79-2.32), and 0.67 (95%CI: 0.46-0.99), respectively. Mixed results were also observed while evaluating the association between fasting glucose and GC risk; the Japanese Hisayama study<sup>[10]</sup> showed a positive association, but European<sup>[11]</sup> and Korean<sup>[12]</sup> studies did not. Furthermore, the studies investigating DM-GC associations comprised heterogeneous participants without distinguishing between type 1 DM (T1DM) and type 2 DM (T2DM)<sup>[13]</sup>, or were based on different DM criteria such as treatment<sup>[14,15]</sup>, fasting blood glucose<sup>[11]</sup>, or self-report<sup>[16,17]</sup>. Even three recent meta-analyses have provided mixed results with neutral<sup>[18]</sup>, marginal<sup>[19]</sup>, and positive<sup>[20]</sup> DM-GC associations. This article aims to update the DM-GC association by including several of the most recent articles as well as others investigating the actual number of GC patients in DM and non DM cohorts.

## MATERIALS AND METHODS

All publications concerning the DM-GC association were retrieved from the English literature. A computerized literature search between the years 1950 and January 2013 was conducted in PubMed using Boolean operators, with (“cancer” or “carcinoma”) and “diabetes” as keywords. Additional studies that were considered pertinent were sought by a manual search through reference lists

in the retrieved publications. The reference retrieval was additionally complemented by a manual search of references from previous meta-analyses<sup>[18-20]</sup>. When more than one analysis of the same cohort was published, the most recent was selected. Articles which apparently reported cancers other than GC in their title/abstract were excluded. Afterwards, following a thorough review of the selected articles, 12 studies reporting comparisons on actual numbers of GC patients between DM and non DM subjects were finally judged to qualify<sup>[11,15-17,21-28]</sup>. The reference lists of the identified meta-analyses were searched to identify original research reports on this topic. Reports from Japan<sup>[16,21,22]</sup> and Taiwan<sup>[15,23]</sup> were defined as East Asian studies, and those from the United States<sup>[17,24,25]</sup> and Europe<sup>[11,26,27]</sup> defined as Western studies.

## Statistical analysis

Each GC incidence in each publication was treated as a dichotomous variable. Data from all relevant studies were combined to estimate the pooled RR with a 95%CI using the random effects model<sup>[29]</sup> provided by the Cochrane Library software Review Manager 5. An RR less than or greater than 1.0 meant respectively a negative or positive DM-GC association. Heterogeneity was quantified using the  $I^2$  measure, in which  $I^2 < 30\%$  indicated mild heterogeneity, 30%-70% moderate heterogeneity, and  $> 70\%$  severe heterogeneity<sup>[30]</sup>. Publication bias was evaluated by funnel plot analysis using Comprehensive Meta Analysis version 2 software.  $P < 0.05$  was considered significant.

## RESULTS

The initial PubMed search identified 1233 publications. After the title and abstract review, studies reporting cancers other than GC in DM patients were excluded, and 152 articles deemed potentially relevant were retrieved for further evaluation. Excluding studies not reporting the actual number of GC patients in DM and nonDM cohorts, 12 publications were ultimately selected (Figure 1), yielding a total of 16725 GC patients: 2150 DM and 14575 non-DM. T1DM and T2DM were not differentiated in these publications except for two in which only T2DM patients were investigated. Five<sup>[15,16,21-23]</sup> studies were from East Asia, 6<sup>[11,17,24-27]</sup> were from the West, and one<sup>[28]</sup> was from Israel. Each publication provided mixed results concerning the DM-GC association with adjustment of confounders (Table 1).

The pooled results showed a significant increase in GC risk in the DM cohort (RR = 1.41; 95%CI: 1.10-1.81;  $P = 0.006$ ) with significant statistical heterogeneity ( $I^2 = 95\%$ ;  $P < 0.00001$ ) (Figure 2A). The subgroup analyses stratified by gender or geographical regions revealed positive GC associations in both sexes, with a larger magnitude of correlation in females (RR = 1.90; 95%CI: 1.27-2.85;  $P = 0.002$ ) than in males (RR = 1.24; 95%CI: 1.08-1.43;  $P = 0.002$ ) (Figure 2B and C). East Asian subjects showed a 77% increased risk of GC (RR = 1.77; 95%CI: 1.38-2.26;  $P < 0.00001$ ) but Western subjects did not (RR = 1.23; 95%CI: 0.90-1.68;  $P = 0.2$ ) (Figure 2D

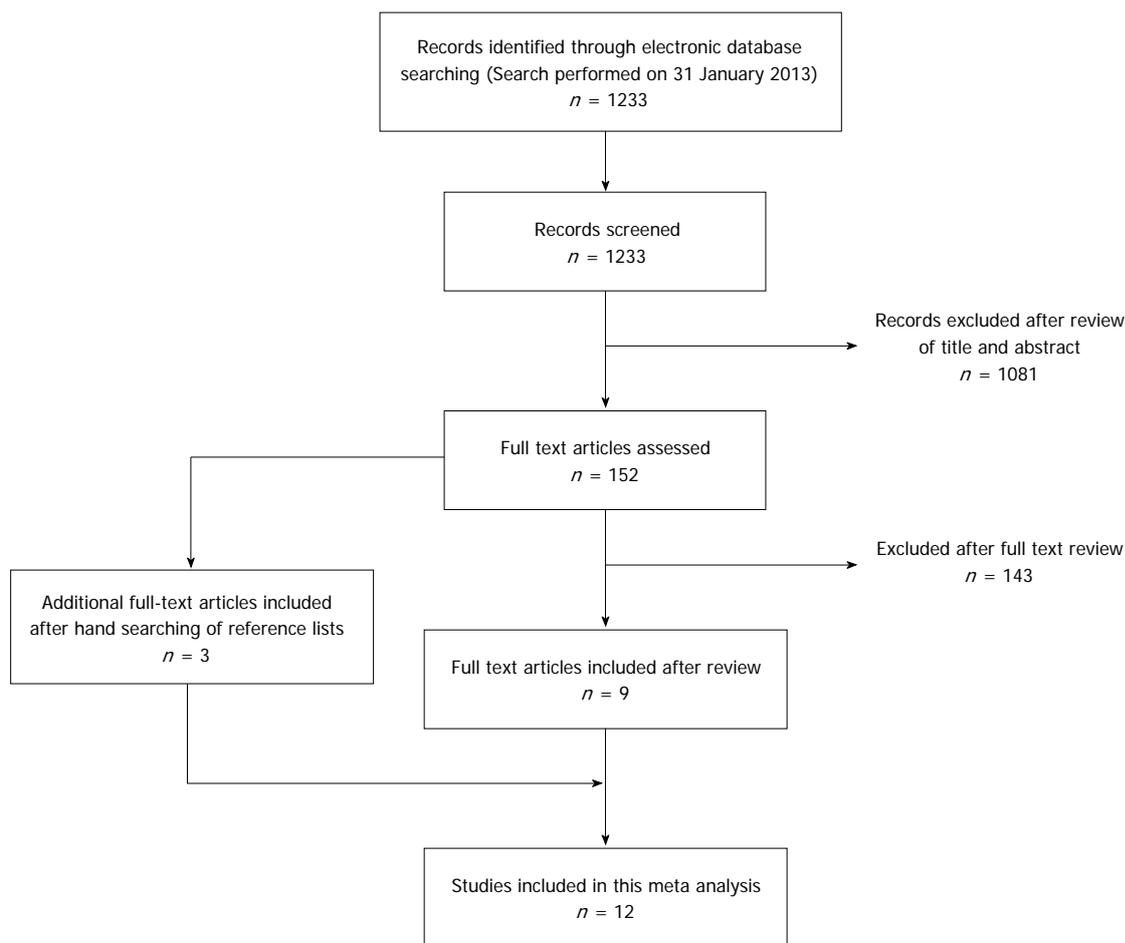

Figure 1 Flow chart of the publication selection process.

and E). The visual inspection of the funnel plots seemed basically symmetric, and Egger’s test did not indicate statistically significant asymmetry for all included studies (intercept = 0.70, one-tailed  $P = 0.37$ ), indicating no evidence of publication bias (Figure 3).

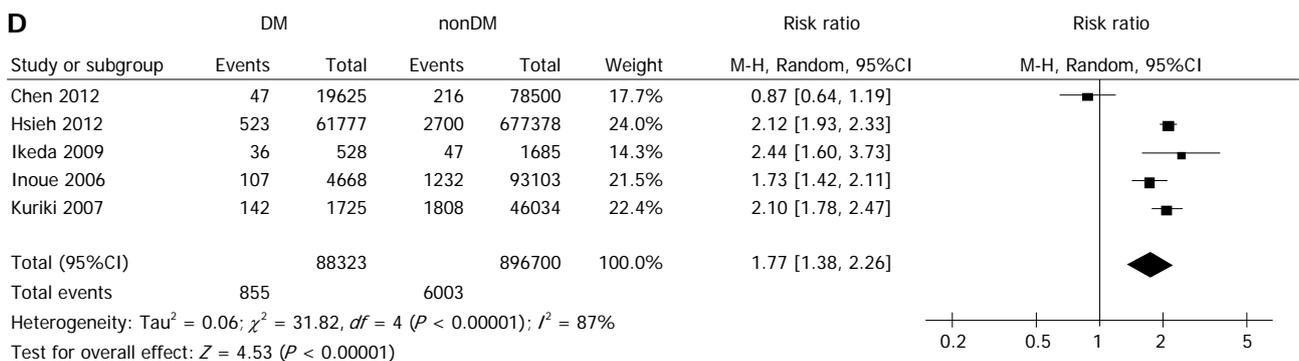

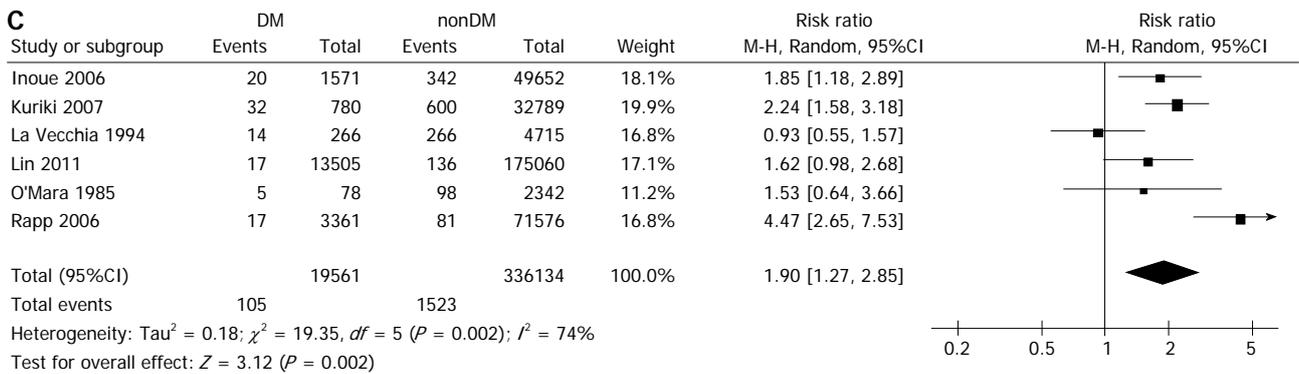

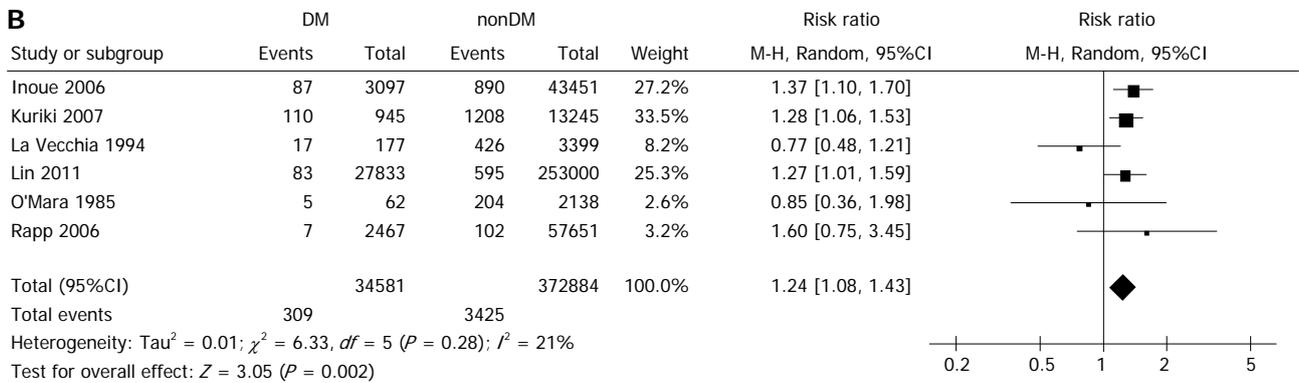

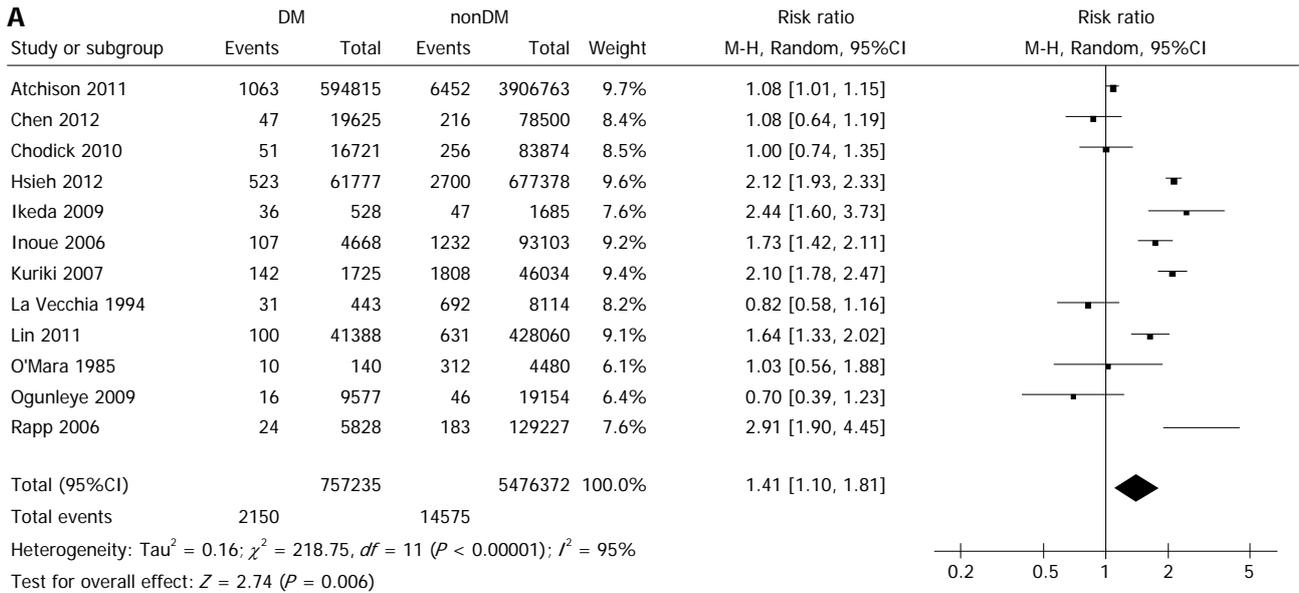

## DISCUSSION

This updated meta-analysis, with GC as the disease in focus in articles published up to January 2013, has elucidated a positive DM-GC association, the findings being consistent with one previous meta-analysis<sup>[20]</sup>. A subgroup analysis has provided the first evidence of a significantly increased risk of GC in both sexes, with a more prominent association in females than in males. Furthermore, the DM-GC association was positive for East Asians but not for Western subjects.

This meta-analysis focused on GC incidence rather than GC mortality, because GC mortality could be mainly influenced by the treatment modalities for GC such as extent of surgery and chemotherapy regimens, which differ markedly between countries. These are the reasons for the relatively fewer number of papers included in this meta-analysis compared with the previous ones<sup>[19,20]</sup>. However, against the background of controversial findings<sup>[18-20]</sup> in this matter in the literature, this study pro-

vided data supporting a positive DM-GC association.

There is a consensus that T2DM is associated with a spectrum of cancers. Although the exact underlying mechanisms linking DM and cancers remain unknown, several possible mechanisms have been debated and proposed: (1) the association between DM and cancer is direct through hyperglycemia; (2) diabetes is preceded by hyperinsulinemia and insulin resistance that alter cancer risk; and (3) the DM-cancer association is due to common risk factors such as obesity. Each of these represents a hallmark metabolic abnormality identified in T2DM and can potentially underlie the association between DM and GC. First, Swedish T1DM patients had more than twice the relative risk of GC than the general population<sup>[31,32]</sup>, suggesting that the associations between GC and hyperglycemia are biologically plausible since T1DM is an autoimmune disease manifesting as hyperglycemia due to pancreatic beta-cell destruction and insulin deficiency. Several mechanisms have been proposed that could explain the relationship between hyperglycemia and cancer. Hyperglycemia causes oxidative stress which promotes the formation of advanced glycation products (AGEs) and the expression of their receptor (RAGE); the AGE/RAGE interaction in turn stimulates oxidative stress. Furthermore, the crosstalk between the AGE/RAGE system and oxidative stress has been known to

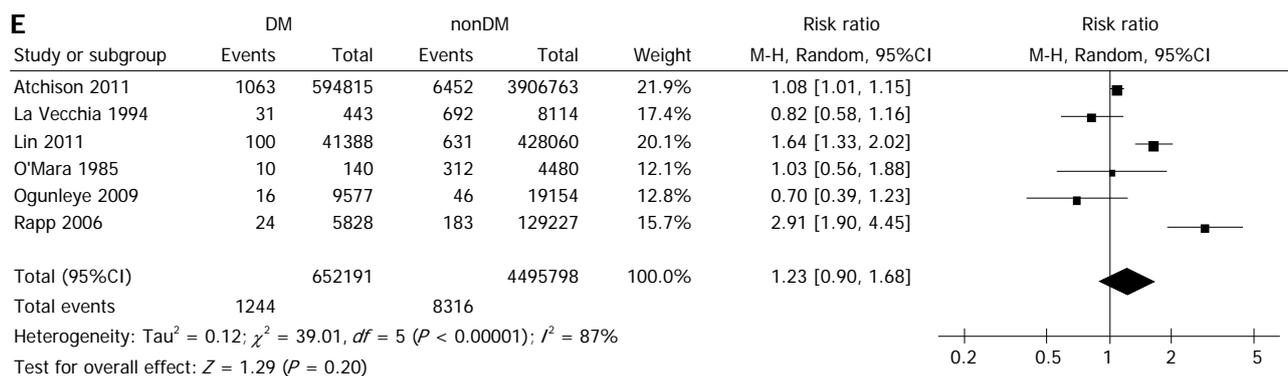

Figure 2 Forest plot representation-random-effects model. A: All included publications. Stratified by sex; B: Male; C: Female, and stratified by geographical area; D: East Asia; E: The West. The individual block squares denote the RR for each study of gastric cancer risk among diabetes mellitus (DM) patients, with an area proportional to the amount of statistical information in each study. The horizontal line denotes a 95%CI, ending with an arrowhead when CI extends beyond the scale. The pooled estimate and its 95%CI are represented by a diamond. Squares or diamonds plotted in the right half indicate increased gastric cancer risk. The risk is considered significant only if the horizontal line or diamond does not overlap the solid vertical line.

activate numerous cell signaling pathways related to cell growth and apoptosis<sup>[33]</sup> that could eventually promote carcinogenesis and cell invasion<sup>[34]</sup>. Indeed, *in vitro* analyses have revealed the AGE/RAGE interaction positively correlating with the invasion and metastasis of gastric<sup>[35]</sup>,

pancreatic<sup>[36]</sup>, and biliary<sup>[37]</sup> cancers. However, considering that epidemiological studies failed to find any increased risk of pancreatic, breast, colorectal, kidney, liver, or bladder cancers in T1DM patients<sup>[31,32]</sup>, which in turn are associated with cases of T2DM, and that the association

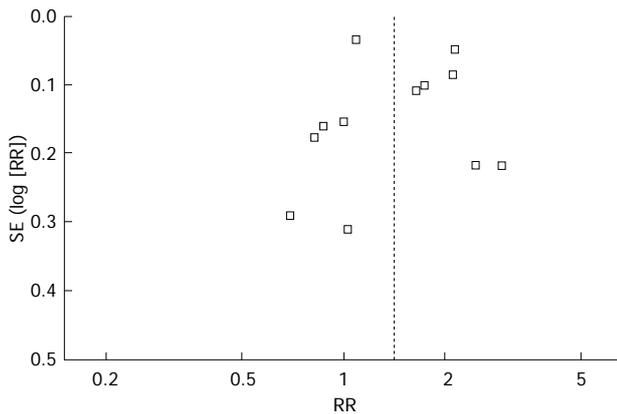

Figure 3 Funnel plot analysis of all the included publications.

between T1DM and a greater risk of developing cancer is equivocal<sup>[38]</sup>, factors other than glucose may play an important role. Besides hyperglycemia, a second hallmark of T2DM is hyperinsulinemia, resulting from insulin resistance in peripheral tissues for many years both before and after diagnosis; in fact, hyperinsulinemia may be the main culprit for cancer development. Insulin is capable of activating insulin-like growth factor (IGF)- I by enhancing hepatic IGF- I synthesis and is also capable of increasing the bioavailability of IGF- I by reducing hepatic production of the IGF-binding proteins<sup>[39,40]</sup>. Enhanced insulin and IGF- I signals through insulin and IGF- I receptors, respectively, promote cell proliferation and growth via multiple cellular signaling cascades<sup>[39-41]</sup>. Indeed, the overexpression of IGFs and the IGF- I receptor was observed in GC tissues<sup>[42,43]</sup>, and increased expression of the IGF- I receptor was correlated with cancer aggressiveness<sup>[44]</sup> or poor survival<sup>[45]</sup>, suggesting a functional insulin-IGF axis in GC.

Third, the etiology of GC is multifactorial and may be associated with several confounding factors such as increased body mass index and *Helicobacter pylori* (*H. pylori*) infection. Visceral fat *per se* contributes to cancer risk<sup>[46]</sup>, and possible underlying molecular mechanisms linking with obesity that foster cancer development have been demonstrated<sup>[39,46,47]</sup>. Accordingly, one recent meta-analysis has revealed that overweight and obesity correlated with GC<sup>[48]</sup>, findings which are consistent with other types of cancer<sup>[39,46,47]</sup>. Regarding *H. pylori* infection, DM patients showed a higher frequency than non DM subjects both in the West<sup>[49]</sup> and in the East<sup>[50]</sup>, and *H. pylori* infection was in turn correlated with insulin resistance<sup>[51]</sup>, suggesting that DM is liable to cause *H. pylori* infection and *vice versa*. Accordingly, GC risk was dramatically increased when DM and *H. pylori* infection coexisted<sup>[21]</sup>.

One novel finding in this study is a positive DM-GC association in both sexes with a more prominent association in females than in males, which contrasts with the male preponderance of GC in the general population. Such a seemingly inverse sex distribution of GC in DM subjects may be attributable to the decreased sex hormone-binding globulin under increased IGF-

I and hyperinsulinemia<sup>[52]</sup>, leading to increased bioavailability of estrogen in both sexes and increased levels of bioavailable testosterone in women but not in men<sup>[53]</sup>. These mechanisms are plausible explanations for an increased risk of hormone-dependent cancers such as breast cancer in female DM patients. Therefore, it can be speculated that the alterations of sex hormones may influence the magnitude of GC risk by gender in DM patients. On the other hand, the present study revealed the increased risk of GC in populations in East Asia but not in the West, findings which are consistent with one previous study<sup>[20]</sup>. These results can be explained partly by the geographical difference in GC risk<sup>[54]</sup>, and partly by the more established screening program in East Asian countries than in the Western countries. This speculation is supported by similar findings of a greater gastric cardia cancer risk in East Asia than in the West among the *H. pylori*-infected patients<sup>[55]</sup>. Interestingly, a similar geographical difference was also observed in the DM-prostate cancer association<sup>[1,2]</sup>.

There are several limitations to this meta-analysis. First, besides obesity and *H. pylori* infection, GC development appear to be confounded by the possible presence of shared cancer-promoting or -preventing factors such as an unhealthy diet (*e.g.*, high salt intake<sup>[56]</sup> or heavy alcohol drinking<sup>[57]</sup>), sedentary lifestyle with lack of physical activity, duration of the DM state, and the consumption of vegetables, fruit<sup>[58]</sup>, and green tea<sup>[59]</sup>. In addition, some diabetes treatments may increase or decrease cancer risk. These confounding factors make it difficult to accurately assess GC risk in DM patients. Therefore, investigation into the actual GC risk in DM patients requires adjustment based on these confounding factors. This is reflected by the significant heterogeneity, which has been also observed in the previous three meta-analyses; thus, further analyses are warranted. A second limitation is that most studies included in this study reported a DM and GC risk without distinction between T1DM and T2DM. Since T1DM is less prevalent than T2DM<sup>[38]</sup>, most patients in this meta-analysis can be regarded as T2DM. However, the DM-GC association should be further elucidated with distinction between the two types since they differ considerably in their metabolic characteristics.

The diversity of DM conditions and cancer biology, as well as the complexity of the potentially contributory mechanisms, preclude a definitive description of the association between DM and cancer risk at present. Although the precise biological mechanisms that might link DM to cancer remain a matter of debate, the recent surge in attempts to explore the relationship between the two diseases has motivated considerable investigation among the clinical and research communities. This meta-analysis suggests that newer, comprehensive approaches must be developed for the treatment of DM patients as a whole rather than as a single disease. However, it is also true that DM patients are less likely to be screened for several types of cancers<sup>[60-62]</sup>, which may be attributable to the patient preference to focus on the treatment of DM

rather than prevention of cancer<sup>[62]</sup>, when DM consumes his/her attention. Clinicians caring for patients with DM should remain alert to GC and minimize the number of missed opportunities for its treatment.

## COMMENTS

### Background

Besides cardiovascular complications, evidence has accumulated that diabetes mellitus (DM) patients are highly predisposed to many types of cancer. Among the cancer subtypes investigated, however, knowledge on the link between gastric cancer (GC) and DM has been insufficient and inconsistent even in previous meta-analyses.

### Research frontiers

Several meta-analyses have been published to investigate the association between DM and GC, however, the results have been inconsistent and varied, from inverse to positive DM-GC associations, indicating that the link between the two diseases has been unclear.

### Innovations and breakthroughs

DM exhibited significantly increased GC risk by 41% overall, and by 90% in females, 24% in males, and 77% in East Asians in subgroup analyses. These findings provide evidence in the current debate concerning the DM-GC association. Furthermore, a larger GC risk in female DM patients than in males was found to be marked.

### Applications

Evidence of a positive DM-GC association, together with the positive link between DM and many other types of cancer, suggest a need for development of newer, comprehensive approaches for the treatment of DM patients as a whole rather than as a single disease. Clinicians caring for DM patients should remain alert to GC and minimize the number of missed opportunities for its treatment.

### Terminology

Advanced glycation end products (AGEs) are proteins or lipids that become glyated after exposure to sugars. AGEs contribute to a variety of microvascular and macrovascular complications by engaging the receptor for advanced glycation end products.

### Peer review

This meta-analysis provides useful information to clinical and research field for establishing comprehensive management to DM patients.

### Abstract

**AIM:** To investigate the relationship between the gut-liver axis and nonalcoholic fatty liver disease (NAFLD), we performed a meta-analysis to evaluate the effects of probiotic therapy in NAFLD.

**METHODS:** We searched PubMed, Medline, Embase, Web of Science, the Cochrane Library and Chinese Biomedicine Database for all relevant randomized controlled trials on probiotics in patients with NAFLD/non-alcoholic steatohepatitis (NASH). A statistical analysis was performed using RevMan 5.0 software.

**RESULTS:** Four randomized trials involving 134 NAFLD/NASH patients were included. The results showed that probiotic therapy significantly decreased alanine aminotransferase (ALT), aspartate transaminase (AST),

total-cholesterol (T-chol), high density lipoprotein (HDL), tumor necrosis factor (TNF)- $\alpha$  and homeostasis model assessment of insulin resistance (HOMA-IR) [ALT: weighted mean difference (WMD) -23.71, 95%CI: -33.46--13.95,  $P < 0.00001$ ; AST: WMD -19.77, 95%CI: -32.55--7.00,  $P = 0.002$ ; T-chol: WMD -0.28, 95%CI: -0.55--0.01,  $P = 0.04$ ; HDL: WMD -0.09, 95%CI: -0.16-0.01,  $P = 0.03$ ; TNF- $\alpha$ : WMD -0.32, 95%CI: -0.48--0.17,  $P < 0.0001$ ; HOMA-IR: WMD -0.46, 95%CI: -0.73--0.19,  $P = 0.0008$ ]. However, the use of probiotics was not associated with changes in body mass index (BMI), glucose (GLU) and low density lipoprotein (LDL) (BMI: WMD 0.05, 95%CI: -0.18-0.29,  $P = 0.64$ ; GLU: WMD 0.05, 95%CI: -0.25-0.35,  $P = 0.76$ ; LDL: WMD -0.38, 95%CI: -0.78-0.02,  $P = 0.06$ ).

**CONCLUSION:** Probiotic therapies can reduce liver aminotransferases, total-cholesterol, TNF- $\alpha$  and improve insulin resistance in NAFLD patients. Modulation of the gut microbiota represents a new treatment for NAFLD.

**Key words:** Probiotics; Nonalcoholic fatty liver disease; Nonalcoholic steatohepatitis; Liver function; Insulin resistance; Meta-analysis

**Core tip:** For many decades, researchers have carried out studies on the treatment of nonalcoholic fatty liver disease (NAFLD). However, no firm conclusions have been made regarding the efficacy of various treatments for NAFLD. Here we conducted a meta-analysis of the pooled data from randomized controlled trials to assess the efficacy of probiotic therapies and showed that probiotic therapy significantly decreased alanine aminotransferase, aspartate transaminase, total-cholesterol, high density lipoprotein, tumor necrosis factor- $\alpha$  and homeostasis model assessment of insulin resistance. Thus, probiotics may help to improve liver function, fat metabolism and insulin resistance in NAFLD patients.

Ma YY, Li L, Yu CH, Shen Z, Chen LH, Li YM. Effects of probiotics on nonalcoholic fatty liver disease: A meta-analysis. *World J Gastroenterol* 2013; 19(40): 6911-6918 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6911.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6911>

## INTRODUCTION

Nonalcoholic fatty liver disease (NAFLD) is characterized by large vacuoles of triglyceride which accumulate in liver cells *via* the process of steatosis in non-alcohol users. The condition can progress into more serious liver diseases, such as nonalcoholic steatohepatitis (NASH), liver fibrosis, cirrhosis, and more rarely, liver carcinoma<sup>[1]</sup>. It is increasingly recognized as a major cause of liver-related morbidity and mortality. NAFLD is common in Western countries. However, an increase in the prevalence of NAFLD has been observed in China. The underlying mechanisms of disease progression are poorly understood. Diet and lifestyle changes are primary therapies in the management of these patients. Specific pharmacologic treatments for NAFLD/NASH are progressing, such as insulin-sensitizers<sup>[2-4]</sup>, lipid-lowering drugs<sup>[5-6]</sup>, antioxidants<sup>[7-8]</sup>, and anti-tumor necrosis factor (TNF)- $\alpha$  agents<sup>[9-11]</sup>. However, most of these are not licensed therapies for NAFLD, despite the abundance of clinical trials.

Recently, a new treatment strategy using probiotics was proposed. A probiotic is a live microbial culture or cultured dairy product, which plays a fundamentally important role in health and disease<sup>[12-14]</sup>. The human intestinal microbiota is composed of  $10^{13}$ - $10^{14}$  microorganisms whose collective genome contains at least 100 times as many genes as our own genome, representing 500-1000 species in total<sup>[15-16]</sup>. Miele *et al.*<sup>[17]</sup> provided the first evidence that NAFLD in humans was associated with increased intestine permeability, and that this abnormality was related to the increased prevalence of small bowel bacterial overgrowth (SIBO) in these patients. The increased permeability appears to be caused by disruption of intercellular tight junctions in the intestine, and it may play an important role in the pathogenesis of NAFLD. Loguerio *et al.*<sup>[18]</sup> have shown that probiotics may reduce NAFLD liver injury and may improve liver function. Probiotics can inhibit the proliferation of harmful bacteria, reduce SIBO, restore gastrointestinal barrier function and modulate the immune system<sup>[19-21]</sup>, all of which contribute to the improvement of NAFLD.

Therefore, the aim of this study was to conduct a meta-analysis of the pooled data from RCTs to assess the efficacy of probiotic therapies in modifying liver function, fat metabolism and insulin resistance.

## MATERIALS AND METHODS

### Search strategy

We searched Medline, Embase, Web of Science, Chinese

Biomedicine Database and the China Journal Full Text Database with no language restriction. The search terms were: “(NASH or NAFLD or “nonalcoholic steatohepatitis” or “nonalcoholic fatty liver disease” or “fatty liver”) and (probiotic\* or prebiotic\* or synbiocit\* or bifidobacter\* or Lactobacill\* or flora)” and “[“Fatty Liver” (Mesh)] AND “Probiotics”(Mesh)”. We also searched the reference lists of each selected study by hand.

### Inclusion and exclusion criteria

Inclusion criteria were as follows: randomized controlled trials (RCTs) with participants of any sex or ethnic origin with NAFLD/NASH, diagnosed on the basis of radiological/histological evidence of fatty liver. Exclusion criteria were as follows: other causes of hepatic steatosis or steatofibrosis such as hepatitis B, hepatitis C, autoimmune hepatitis, liver decompensation or malignancy, and genetic liver disease such as Wilson’s disease and hemochromatosis.

The trials should have measured at least one of the following items: BMI, ALT, AST, total-cholesterol, LDL, HDL, GLU, TNF- $\alpha$  and HOMA-IR. Studies must have objective outcome measures, otherwise they were excluded from this review.

### Data extraction and methodological quality

Data were abstracted independently by two reviewers and included: author, publication year, study design, population, intervention, duration and outcome. Disagreement was resolved by discussion.

Scored using the Jadad scale, we assessed the quality of the studies by the randomization method, allocation concealment, blinding of outcome assessment and follow-up. All included studies scored  $\geq 4$ .

### Statistical analysis

We analyzed the data using Review Manager 5.0. Dichotomous data were presented as odds ratio with 95%CI. Statistical heterogeneity was measured using the  $\chi^2$  test and the  $I^2$ . A  $\chi^2$  P value  $< 0.05$  was considered to indicate statistically significant heterogeneity. If there was obvious heterogeneity, the random effects model was chosen; otherwise, the fixed effects model was adopted.

## RESULTS

The electronic searches yielded 475 items from Medline, Embase, Web of Science, Chinese Biomedicine Database and the China Journal Full Text Database. Publication dates ranged from 1996 to 2013. After reviewing each publication, we selected 4 original studies (Figure 1).

Table 1 contains specific information on study design, randomization methods, sample size, intervention, duration of treatment and follow-up. Allocation concealment was adequate in three studies. All the studies were double-blind and included a follow-up period. The diagnosis of NAFLD/NASH was confirmed by percutaneous liver biopsy in three studies. All gave detailed

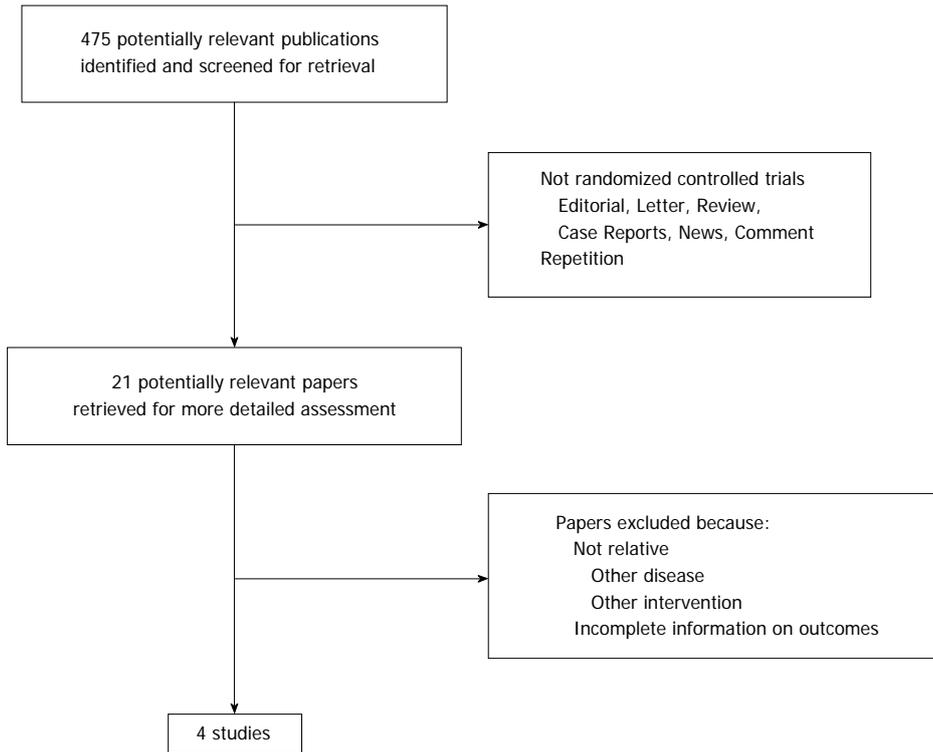

Figure 1 Selection of studies.

Wong <i>et al</i> <sup>[25]</sup>	20 (10/10)	Computer generated	Double-blind	Histological	Lepicol probiotic and prebiotic formula <i>vs</i> nothing	6 mo	Yes

baseline information. The main characteristics of the patients included in the two groups were well matched in all RCTs.

All four RCTs<sup>[22-25]</sup> reported on BMI, but did not show a significant difference in the experimental group compared with the control group [weighted mean difference (WMD) 0.05, 95%CI: -0.18-0.29, *P* = 0.64]. Significant homogeneity was observed among the studies (*I*<sup>2</sup> = 0%, *P* = 0.77) (Figure 2A).

Four RCTs<sup>[22-25]</sup> assessed the effect of probiotics on the level of serum ALT and showed a significant difference between patients treated with probiotics compared with those treated with placebo (WMD -23.71, 95%CI: -33.46--13.95, *P* < 0.00001). The included studies were homogeneous (*I*<sup>2</sup> = 0%, *P* = 0.72) (Figure 2B).

Three RCTs<sup>[22,24,25]</sup> analyzed the effect of probiotics on AST and T-chol in NAFLD/NASH patients compared with placebo. Probiotics had a significantly better effect on normalizing AST and T-chol (AST: WMD -19.77, 95%CI: -32.55--7.00, *P* = 0.002; T-chol: WMD -0.28, 95%CI: -0.55--0.01, *P* = 0.04). The included studies on AST were not homogeneous (*I*<sup>2</sup> = 56%, *P* = 0.1), while the studies on T-chol were significantly homoge-

neous (*I*<sup>2</sup> = 0%, *P* = 0.75) (Figure 2C, D).

Three RCTs<sup>[22,24,25]</sup> reported the effects of probiotics on LDL, HDL and GLU in patients with NAFLD/NASH compared with placebo. Probiotics had a significantly better effect in reducing HDL (WMD -0.09, 95%CI: -0.16-0.01, *P* = 0.03), but no significant difference in reducing LDL and GLU (LDL: WMD -0.38, 95%CI: -0.78-0.02, *P* = 0.06; GLU: WMD 0.05, 95%CI: -0.25-0.35, *P* = 0.76). The included studies were homogeneous (LDL: *I*<sup>2</sup> = 47%, *P* = 0.15; HDL: *I*<sup>2</sup> = 0%, *P* = 0.53; GLU: *I*<sup>2</sup> = 0%, *P* = 0.84) (Figure 2E, F, G).

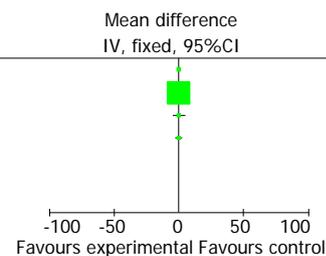

Three RCTs<sup>[22-24]</sup> provided sufficient data to compare the effects of probiotics with those of placebo and showed a statistically significant effect for TNF-α in NAFLD/NASH patients (WMD -0.32, 95%CI: -0.48--0.17, *P* < 0.0001). Significant homogeneity was observed among the studies (*I*<sup>2</sup> = 0%, *P* = 0.56) (Figure 2H).

Only two RCTs<sup>[22,24]</sup> reported the effects of probiotics on HOMA-IR in NAFLD/NASH patients. There was a significant reduction in HOMA-IR in NAFLD/NASH patients in the experimental group compared with the control group (WMD -0.46, 95%CI: -0.73--0.19, *P* =

0.0008). Significant homogeneity was observed among the studies ( $I^2 = 0\%$ ,  $P = 0.96$ ) (Figure 2I).

**DISCUSSION**

NAFLD is a relevant issue in public health due to its epidemiologic burden. The prevalence of NAFLD has apparently increased in proportion to the increasing incidence of obesity in both adults and children<sup>[26]</sup>. NAFLD is closely associated with obesity and insulin resistance, and is now recognized to represent the hepatic manifestation of the metabolic syndrome. At present, there is no registered drug for the treatment of NAFLD. Although lifestyle intervention is often advocated<sup>[27-28]</sup>, it is difficult to maintain. In 2009, Socha *et al*<sup>[29]</sup> performed a meta-analysis of the pharmacological interventions for NAFLD in adults and children, including pioglitazone, vitamin E, ursodeoxycholic acid, probucol, N-acetylcysteine, and low-dose carnitine. However, he was unable to draw firm conclusions on the efficacy of the various treatments for NAFLD. In 2011, Musso *et al*<sup>[30]</sup> found that weight loss improved liver histology and the cardio-metabolic profile, as did pioglitazone. It is also important to explore new treatment strategies.

It is well known that liver and intestine have the same origin in embryology the foregut. In addition, the liver continuously receives blood from the gut through the portal system. Therefore, there is a close relationship between the intestine and liver. Evidence has shown that SIBO is present in 50% of patients with non-alcoholic steatosis<sup>[17,31]</sup>. High-fat diet-induced obesity is associated with changes in the composition of intestinal bacteria in rats<sup>[32-33]</sup> and in humans<sup>[34]</sup>. Therefore, changes in the composition of the intestinal bacterial content may be associated with NAFLD or obesity.

Intestinal bacteria may be involved in the etiology of NAFLD by enhancing intestinal permeability<sup>[35]</sup>, direct

activation of inflammatory cytokines *via* release of lipopolysaccharide (LPS) and favoring absorption of endotoxins<sup>[36]</sup>. Endotoxins activate Kupffer cells in the liver and increase the production of TNF- $\alpha$  and IL-6, which contributes to the onset of liver fibrosis<sup>[31,37-38]</sup>. Furthermore, a complex mechanism involving extensive lipid accumulation, systemic inflammation, oxidative stress, and insulin resistance causes cytotoxicity and exacerbated hepatopathy<sup>[39-40]</sup>.

Serum ALT and AST levels are well-recognized clinical markers of liver damage and may be involved in the pathogenesis of NAFLD. Cholesterol is also a risk factor for NAFLD. Liver damage can lead to elevated cholesterol or reduced HDL in the blood. TNF- $\alpha$  is secreted directly by hepatocytes and Kupffer cells in the liver<sup>[41]</sup>. Many studies have shown a relationship between TNF- $\alpha$  expression and NAFLD<sup>[42-43]</sup>. Assessment of insulin resistance by HOMA-IR has been widely utilized in clinical studies of NAFLD<sup>[44-45]</sup>. In four RCTs, ALLER, Wong *et al*<sup>[25]</sup> reported that probiotics improved liver aminotransferase levels in patients with NAFLD, while Malaguarnera concluded that probiotics reduced TNF- $\alpha$ , serum AST levels and HOMA-IR. Our meta-analysis showed that probiotics significantly reduced ALT, AST, T-chol, TNF- $\alpha$  and HOMA-IR, which are all related to the process, development and consequences of NAFLD. However, the level of HDL was significantly increased in the placebo treatment compared with probiotic treatment, which was contrary to expectation. It is possible that the elevation in HDL requires long-term treatment or there are other mechanisms which have not been explored.

The change in cholesterol level in our study should be emphasized, as Gilliland *et al*<sup>[46]</sup> in the early 1990s found that regular consumption of probiotics reduced cholesterol levels. Over several decades, more and more researchers confirmed that probiotics can lead to a de-

crease in serum cholesterol in animals and humans<sup>[47-50]</sup>. However, these RCTs did not report the positive effects of probiotics on reducing cholesterol in NAFLD/NASH patients, while the findings of the present meta-analysis supported the reduction of cholesterol in NAFLD/NASH patients. From this meta-analysis, we can conclude that probiotics have positive effects in patients with NAFLD/NASH.

Of the four RCTs included in this meta-analysis, the studied probiotics included lactobacillus, bifidobacterium and streptococcus. Two studies also determined the effect of probiotics combined with fructo-oligosaccharides in NAFLD<sup>[24,25]</sup>. Bifidobacteria colonize the intestinal tract soon after birth and are the major components of the microbial barrier in healthy humans. Bifidobacteria produce a range of beneficial effects on host health<sup>[51-52]</sup>. Lactobacilli and streptococcus are also beneficial, although they are present at much lower levels in the human colon<sup>[52]</sup>. Probiotics have been shown to enhance the barrier function of epithelial cells<sup>[53]</sup> and decrease intestinal permeability and endotoxemia in patients with liver disease<sup>[54]</sup>. At the same time, probiotics can also influence host metabolism in several other ways, such as regulation of energy extraction from nutrients and modulation of genes involved in substrate metabolism<sup>[55]</sup>. A prebiotic is a nondigestible food ingredient. Due to the general properties of prebiotics, they can influence the growth, activity and metabolites of probiotics<sup>[56]</sup>. Fructo-oligosaccharides are now becoming increasingly popular due to their prebiotic effects. They can be fermented by bifidobacteria and lactobacilli<sup>[57]</sup>. Fructo-oligosaccharides can lead to bifidobacteria becoming the dominant species in the large bowel<sup>[58]</sup> and may help to control or reduce the growth of harmful bacteria<sup>[59]</sup>. In animal models, treatment with oligofructose reduced adipose tissue inflammation, oxidative stress and led to an improvement in glucose tolerance and to a reduction in body weight, which were beneficial in patients with NAFLD<sup>[60]</sup>. In conclusion, probiotics and prebiotics are important mediators of diet-induced metabolic disturbances in NAFLD.

There are several limitations to this review. It is well known that liver histology is the gold standard for NAFLD/NASH. Although ultrasonography is reasonably accurate, it cannot identify fatty infiltration of the liver below a threshold of 30%. In our review, three RCTs used liver histological response as an outcome index evaluating the effectiveness of probiotics in the treatment of NAFLD. Regrettably, only one RCT had post-treatment histology results. The diagnostic criteria for NAFLD in another trial included increased ultrasonographic bright liver. Three trials included patients aged 18-70 years, while one trial included children. The researchers ignored the dietary restrictions, exercise and physical activities as in almost all studies they were not described. The sample sizes in some trials, as well as the number of trials for some comparisons, were small. Existing data are difficult to reconcile, given the use of different

strains, dosages and duration of treatment.

## COMMENTS

### Background

The prevalence of and mortality due to nonalcoholic fatty liver disease (NAFLD) are increasing worldwide. Diet and lifestyle changes are primary therapies in the management of NAFLD patients. However, most drug therapies are not licensed for NAFLD. Recent evidence suggests that malfunction of the gut-liver axis contributes to hepatic damage in rats and humans with NAFLD, and probiotics play a fundamentally important role in health and disease. Thus, it was necessary to conduct a meta-analysis to assess the effects of probiotics on liver function, fat metabolism and insulin resistance in NAFLD patients.

### Research frontiers

A probiotic is a live microbial culture or cultured dairy product and the human intestinal microbiota is composed of  $10^{13}$ - $10^{14}$  microorganisms. The gut-liver axis indicates that changes in the composition of the intestinal bacterial content are associated with NAFLD. Most therapies are not licensed for the prevention of NAFLD. Therefore, a research hotspot is whether treatment with probiotics is effective in patients with NAFLD.

### Innovations and breakthroughs

In 2009, Socha *et al* performed a meta-analysis of pharmacological interventions for NAFLD in adults and children, including pioglitazone, vitamin E, ursodeoxycholic acid, probucol, N-acetylcysteine, and low-dose carnitine. However, he was unable to draw firm conclusions on the efficacy of various treatments for NAFLD and he did not study the effect of probiotics. Research on probiotics in rats is popular. However, there have only been a few large randomized controlled trials (RCTs), and the results were inconsistent. Therefore, the aim of this study was to conduct a meta-analysis of the pooled data from RCTs to assess the efficacy of probiotic therapies in modifying liver function, fat metabolism and insulin resistance in patients with NAFLD/nonalcoholic steatohepatitis.

### Applications

Probiotic therapies can reduce liver aminotransferase levels, serum cholesterol and tumor necrosis factor- $\alpha$  and improve insulin resistance in patients with NAFLD. Thus, modulation of the gut microbiota using probiotics may represent a new method of treating or preventing NAFLD.

### Terminology

NAFLD is characterized by large vacuoles of triglyceride which accumulate in liver cells via the process of steatosis in non-alcohol users. The condition can progress into more serious liver diseases, such as nonalcoholic steatohepatitis, liver fibrosis, cirrhosis, and more rarely, liver carcinoma. A probiotic is a live microbial culture or cultured dairy product, which plays a fundamentally important role in health and disease. The human intestinal microbiota is composed of  $10^{13}$ - $10^{14}$  microorganisms whose collective genome contains at least 100 times as many genes as our own genome, representing 500-1000 species in total.

### Peer review

This meta-analysis is an interesting revision on the present knowledge on probiotics and NAFLD but again introduces the difficulty in obtaining unequivocal correlations between biochemical changes and pharmacological treatment or lifestyle modifications, including the inclusion of probiotics in diet. This meta-analysis suggests that liver inflammatory markers become significantly reduced with the use of probiotics and this has been interpreted as indirect evidence of the effect on inflammation and liver damage by the intervention. Nevertheless, the meta-analysis concludes that many of the data analyzed remain without modification on pooled analysis with the inclusion of probiotics. All of these data make it difficult to assess the real effect of probiotics on NAFLD. Nevertheless, the data obtained by this meta-analysis are interesting since they demonstrate the complexity of the factors which may influence the development of NAFLD.

### Abstract

**AIM:** To compare the outcome of upper gastrointestinal bleeding (UGIB) between patients receiving restrictive and liberal transfusion.

**METHODS:** PubMed, EMBASE, and Cochrane Library databases were employed to identify all relevant randomized controlled trials regarding the outcome of UGIB after restrictive or liberal transfusion. Primary outcomes were death and rebleeding. Secondary outcomes were length of hospitalization, amount of blood transfused, and hematocrit and hemoglobin at discharge or after expansion.

**RESULTS:** Overall, 4 papers were included in this

meta-analysis. The incidence of death was significantly lower in patients receiving restrictive transfusion than those receiving liberal transfusion (OR: 0.52, 95%CI: 0.31-0.87,  $P = 0.01$ ). The incidence of rebleeding was lower in patients receiving restrictive transfusion than those receiving liberal transfusion, but this difference did not reach any statistical significance (OR: 0.26, 95%CI: 0.03-2.10,  $P = 0.21$ ). Compared with those receiving liberal transfusion, patients receiving restrictive transfusion had a significantly shorter length of hospitalization (standard mean difference: -0.17, 95%CI: -0.30--0.04,  $P = 0.009$ ) and a significantly smaller amount of blood transfused (standard mean difference: -0.74, 95%CI: -1.15--0.32,  $P = 0.0005$ ) with a lower hematocrit and hemoglobin level at discharge or after expansion.

**CONCLUSION:** Restrictive transfusion should be employed in patients with UGIB.

© 2013 Baishideng. All rights reserved.

**Key words:** Upper gastrointestinal bleeding; Blood transfusion; Meta-analysis; Randomized controlled trial

**Core tip:** Current international consensus recommends restrictive transfusion for upper gastrointestinal bleeding. However, this recommendation is largely based on expert opinions. We have performed the present meta-analysis of randomized controlled trials, which potentially supported the superiority of restrictive over liberal transfusion for upper gastrointestinal bleeding.

Restrictive vs liberal transfusion for upper gastrointestinal bleeding: A meta-analysis of randomized controlled trials. *World J Gastroenterol* 2013; 19(40): 6919-6927 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6919.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6919>

## INTRODUCTION

Acute upper gastrointestinal bleeding is a common cause for emergency hospitalization with a relatively high annual incidence of 50-200/100000 population and a mortality of 10%-30%<sup>[1-3]</sup>. Red blood cell transfusion is often required in such patients due to the reduction of tissue perfusion after acute blood loss<sup>[4-6]</sup>. Current international consensus on the management of upper gastrointestinal bleeding recommends that the threshold for initiating blood transfusion is a hemoglobin level of 70 g/L or less in patients with nonvariceal upper gastrointestinal bleeding<sup>[5]</sup> and a hemoglobin level of 80 g/L or less in patients with variceal bleeding<sup>[6]</sup>. However, these recommendations are largely based on expert opinions or international guidelines regarding transfusion requirement in critically ill patients without upper gastrointestinal bleeding<sup>[7-9]</sup>. Accordingly, the grade of evidence for these recommendations is low<sup>[5,6]</sup>.

A previous Cochrane Collaboration systematic review of three randomized controlled trials has shown a tendency in decreasing the mortality of patients with upper gastrointestinal bleeding after restrictive transfusion<sup>[10,11]</sup>. But a small number of participants and a high proportion of missing data limit the significance of these findings<sup>[10,11]</sup>. These authors concluded that their review might not provide useful data regarding outcomes following red blood cell transfusion for acute upper gastrointestinal bleeding<sup>[10,11]</sup>. Recently, several large-scale observational studies demonstrated that blood transfusion after non-variceal upper gastrointestinal bleeding might increase the rate of mortality and rebleeding<sup>[12,13]</sup>. More recently, a large and well-organized randomized controlled trial showed a significant benefit of restrictive transfusion strategy in improvement of outcome in patients with upper gastrointestinal bleeding<sup>[14]</sup>.

Herein, we performed an updated meta-analysis of randomized controlled trials to compare the outcome of upper gastrointestinal bleeding between patients treated with restrictive and liberal transfusion. Primary outcomes were death and rebleeding. Secondary outcomes were length of hospitalization, amount of blood transfused, and hematocrit and hemoglobin at discharge or after expansion.

## MATERIALS AND METHODS

This work was performed according to the PRISMA statement for reporting systematic reviews and meta-analyses of studies that evaluate health care interventions<sup>[15]</sup>.

### Eligibility criteria

(1) randomized controlled trials were included, if they compared the outcome of upper gastrointestinal bleeding between patients treated with restrictive and liberal blood transfusion; (2) no publication date, publication language, or publication status was restricted; (3) basic studies were excluded; (4) comments, editorials, or letters were excluded; (5) introductions for Cochrane groups were excluded; (6) narrative reviews, systematic reviews, or meta-analyses were excluded; (7) study design reports, case reports, non-

comparative case series were excluded; (8) non-randomized comparative studies were excluded; and (9) randomized controlled trials unrelated to our topics were excluded.

### Literature selection

Studies were identified using a search strategy in the PubMed, EMBASE, and Cochrane Library databases. Search items were listed as follows: (“gastrointestinal” [All Fields] OR “digestive” [All Fields] OR “peptic” [All Fields] OR “alimentary tract” [All Fields] OR “esophageal” [All Fields] OR “esophagus” [All Fields] OR “gastric” [All Fields] OR “stomach” [All Fields] OR “duodenal” [All Fields] OR “duodenum” [All Fields]) AND (“hemorrhage” [All Fields] OR “haemorrhage” [All Fields] OR “bleeding” [All Fields] OR “bleed” [All Fields] OR “melena” [All Fields] OR “melaema” [All Fields] OR “hematemesis” [All Fields] OR “haematemesis” [All Fields]) AND (“transfusion” [All Fields] AND (“blood” [All Fields] OR “red cell” [All Fields]) AND (“randomized” [All Fields] OR “randomized” [All Fields] OR “randomly” [All Fields])). The last search was performed on January 5, 2013. Study eligibility was independently judged by two authors. In cases of disagreement between the two authors, they would be discussed with another author. When two or more studies were conducted by one affiliation, only the studies with more complete data and more extensive interval of enrollment were included in the meta-analysis.

### Data extraction

We developed a data extraction sheet, including the authors, journal, publication year, whether articles were published in peer-reviewed journals or not, regions where the study was conducted, period of enrollment, study design, target population, study endpoints, eligibility criteria, sample size, and demographic data (age and sex), source of upper gastrointestinal bleeding, hematocrit, and hemoglobin of two groups. Data were independently extracted by two authors. In cases of disagreement between the two authors, they would be discussed with another author. We used Google to translate the information in the non-English language full-texts.

### Assessment of study quality

Quality of included randomized controlled trials was scored by Jadad composite scale<sup>[16,17]</sup>, in which the description of randomization, blinding, and withdrawals were assessed. The quality scale ranged from 0 to 5 points. If the score was 2 or less, the quality of the study would be considered lower. If the score was beyond 2, the quality of the study would be high.

### Statistical analysis

Data were collected, using Microsoft Office Excel 2003. For the dichotomous variables (*i.e.*, incidence of death and rebleeding), number of events and total patients were extracted from these included studies. Then, OR with 95%CI was calculated. For the continuous variables (*i.e.*, length of hospitalization, amount of blood transfu-

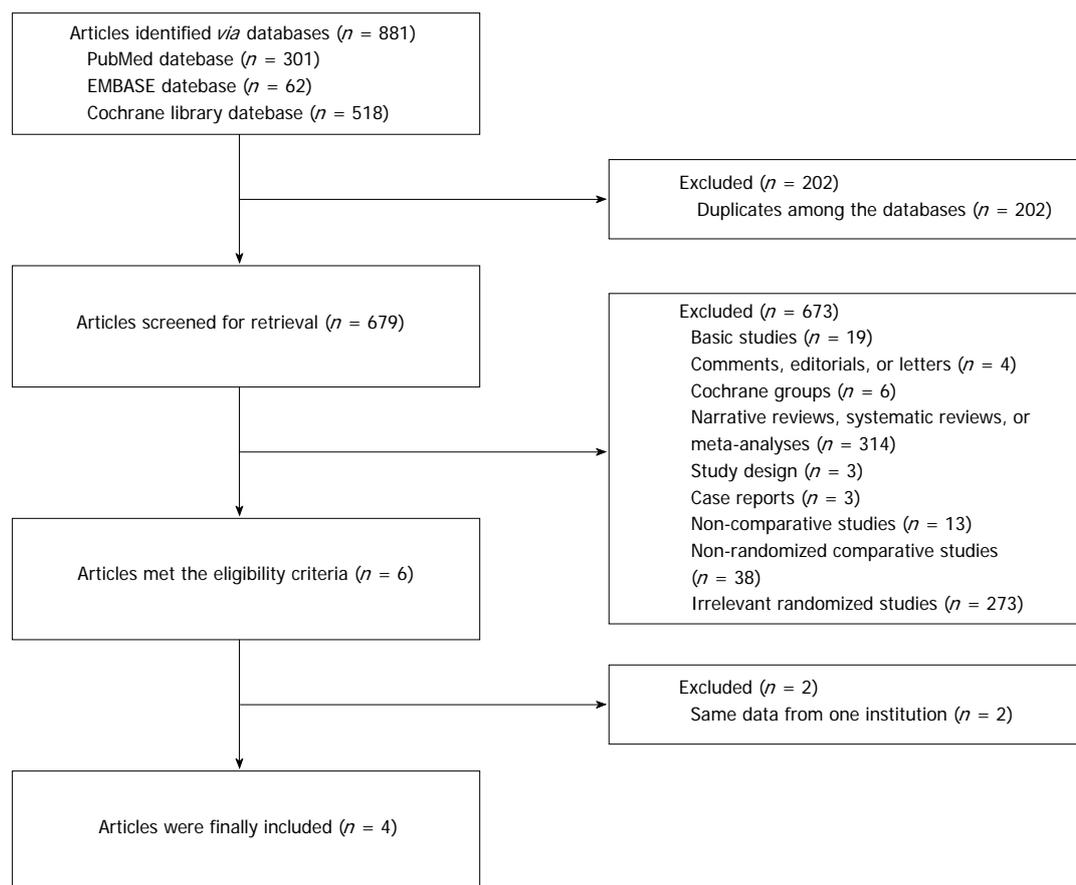

Figure 1 Flowchart of study inclusion.

sion, and hematocrit and hemoglobin), mean value and standard deviation were extracted from these included studies. Then, standard mean difference with 95%CI was calculated. Finally, the OR and standard mean difference of each study were pooled, using both fixed-effects (Mantel-Haenszel method)<sup>[18]</sup> and random-effects model (DerSimonian-Laird method)<sup>[19]</sup>. When heterogeneity was not significant, the pooled data using fixed-effects model were considered appropriate. When significant heterogeneity was observed, only the pooled data using random-effects model were considered appropriate. Heterogeneity between studies was assessed by using the  $I^2$  statistic ( $I^2 > 50\%$  was considered as having substantial heterogeneity) and the  $\chi^2$  test ( $P < 0.10$  was considered to represent significant statistical heterogeneity)<sup>[20]</sup>. Funnel plots were not performed due to a small number of included studies. Sensitivity analyses were done to assess the reliability of meta-analysis. All analyses were conducted using the statistical package Review Manager version 5.1 (Copenhagen, The Nordic Cochrane Center, The Cochrane Collaboration, 2011).

## RESULTS

### Literature selection

Overall, 881 papers were initially identified by the search strategy. Among them, six papers met eligibility crite-

ria<sup>[14,21-25]</sup>. Of note, three papers were reported by the same one affiliation<sup>[14,21-22]</sup>. Among them, two papers with a smaller number of patients were excluded<sup>[21,22]</sup>. Thus, four randomized controlled trials were finally included in the meta-analysis<sup>[14,23-25]</sup> (Figure 1), in which 982 patients with upper gastrointestinal bleeding were treated with restrictive or liberal blood transfusion.

### Description of these included studies

All of four randomized controlled trials were single-center studies, and were published in peer-reviewed journals between 1986 and 2013 (Table 1). Three randomized controlled trials were published in three English-language priority journals<sup>[14,24,25]</sup>, and another one was published in one Spanish-language journal<sup>[23]</sup>. Target population was patients with upper gastrointestinal bleeding from variceal or non-variceal source. Of note, a total of 60 patients were randomized in one study<sup>[23]</sup>, but only 27 patients were finally observed (restrictive transfusion,  $n = 14$ , and liberal transfusion,  $n = 13$ ). The detailed eligibility criteria of these studies were described in Table 2. The baseline characteristics were comparable between the two groups (Table 3).

### Quality of these included studies

In the four studies, double-blinding technique was not feasible due to the nature of interventions. Two studies were scored as 3 points and considered to be of higher

**Table 1 Characteristics of included studies**

Ref.	Design	Regions	Target population	Intervention	Outcome measures
Blair <i>et al</i> <sup>[25]</sup>	Single center RCT	London, United Kingdom	Acute severe UGIB; no esophageal varices	Early transfusion group (liberal transfusion): at least 2 units of blood No transfusion group (restrictive transfusion): no blood transfusion unless hemoglobin fell below 8 g/dL or they were shocked	Observed results: coagulation results (impedance clotting time, kaolin cephalin clotting time); haematological results (hematocrit); eventual blood transfused; number of rebleed; number of death
Elizalde <i>et al</i> <sup>[24]</sup>	Single center RCT	Barcelona, Spain	Liver cirrhosis with an acute variceal bleeding episode	PRC group (liberal transfusion): 2 units of packed red cells PPL group (restrictive transfusion): 500 mL of a 5% plasma protein solution	Observed items: hemodynamic measurements (cardiopulmonary pressures, cardiac output, wedged and free hepatic venous pressures, mean arterial blood pressure, systemic vascular resistance); hormonal measurements (plasma renin activity, aldosterone levels, norepinephrine); rheological parameters (plasma volume, blood viscosity)
Villarejo <i>et al</i> <sup>[23]</sup>	Single center RCT	Buenos Aires, Argentina	Acute digestive hemorrhage with stable haemodynamics	Treatment group (restrictive transfusion): patients underwent normovolemic hemodilution with crystalloid solutions, and the hematocrit value was maintained as $\geq 21\%$ and $< 28\%$ ; red cell transfusion was given if angina, shock, hemodynamic instability, or hematocrit $< 21\%$ Control group (liberal transfusion): the target of transfusion in these patients was the hematocrit value of $\geq 28\%$	Observed results: organ failure, hospital stay, APACHE II score, red cell transfused, hematocrit, haemoglobin
Villanueva <i>et al</i> <sup>[14]</sup>	Single center RCT	Barcelona, Spain	Upper gastrointestinal bleeding	Liberal transfusion: the hemoglobin threshold for transfusion was 9 g/dL, with a target range for the post-transfusion hemoglobin level of 9-11 g/dL Restrictive transfusion: the hemoglobin threshold for transfusion was 7 g/dL, with a target range for the post-transfusion hemoglobin level of 7-9 g/dL	Primary endpoints: the rate of death from any cause within the first 45 d Secondary endpoints: the rate of further bleeding and the rate of in-hospital complications

PPL: Plasma protein solution; PRC: Packed red cells; RCT: Randomized controlled trial; UGIB: Upper gastrointestinal bleeding.

**Table 2 Eligibility criteria of included studies**

Ref.	Eligibility criteria
Blair <i>et al</i> <sup>[25]</sup>	Consecutive patients with acute severe upper gastrointestinal haemorrhage were prospectively randomized on arrival to receive during their first 24 h in hospital Only known cases of oesophageal varices were excluded as they frequently have abnormal coagulation due to liver disease
Elizalde <i>et al</i> <sup>[24]</sup>	The study population consisted of patients with cirrhosis of the liver admitted for the management of an acute variceal bleeding episode Only patients in whom hemostasia had been achieved within the previous 24-72 h by means of endoscopic sclerotherapy, and who were still anemic (hematocrit $< 30\%$ ) and normovolemic as defined by clinical parameters (systolic pressure $> 100$ mmHg, right atrial pressure $> 2$ cm H <sub>2</sub> O, heart rate $< 100$ beats/min, and urine output $> 0.5$ mL/kg per hour) were eligible for the study Age $< 18$ or $> 80$ yr, renal failure as defined as serum creatinine $> 2$ mg/dL, portal thrombosis, diffuse or multinodular hepatocellular carcinoma, arterial hypertension, peripheral vasculopathy, previous surgical or transjugular intrahepatic portosystemic shunt, bacterial infection, and use of vasoactive drugs to prevent or treat portal hypertension-related bleeding were considered exclusion criteria
Villarejo <i>et al</i> <sup>[23]</sup>	Inclusion criteria: acute high digestive haemorrhage with stable haemodynamics and any aetiology; age $> 15$ yr old Exclusion criteria: history of angina; shock not responsive to volume expansion; requirement of surgery; established renal insufficiency; poliglobulina; bleeding diathesis; acute or chronic liver dysfunction; chronic anemia; pregnancy; sepsis; acute or chronic respiratory failure; haematocrit $< 20\%$ on admission; religious objection to transfusion
Villanueva <i>et al</i> <sup>[14]</sup>	Patients older than 18 yr of age who had hematemesis (or bloody nasogastric aspirate), melena, or both, as confirmed by the hospital staff, were considered for inclusion Patients were excluded if they declined to undergo a blood transfusion Additional exclusion criteria: massive exsanguinating bleeding, an acute coronary syndrome, symptomatic peripheral vasculopathy, stroke, transient ischemic attack, or transfusion within the previous 90 d; a recent history of trauma or surgery; lower gastrointestinal bleeding; a previous decision on the part of the attending physician that the patient should avoid specific medical therapy; and a clinical Rockall score of 0 with a hemoglobin level $> 12$ g/dL

quality, and another two studies were scored as 1 point and considered to be of lower quality (Table 4).

### Death

Three studies reported the incidence of death in two

**Table 3** Baseline characteristics of patients in included studies

Ref.	Groups	No. Patients	Age (yr)	Sex (male: female)	Source of bleeding	Hematocrit at admission	Hemoglobin at admission (g/dL)
Blair <i>et al</i> <sup>[25]</sup>	Restrictive transfusion	26	60 ± 4.5	2:1	Gastric ulcer ( <i>n</i> = 4); duodenal ulcer ( <i>n</i> = 13); carcinoma ( <i>n</i> = 2); Mallory-Weiss tear ( <i>n</i> = 3); not visualized ( <i>n</i> = 4)	29 ± 1.6	NA
	Liberal transfusion	24	64 ± 3.6	2:1	Gastric ulcer ( <i>n</i> = 2); duodenal ulcer ( <i>n</i> = 17); carcinoma ( <i>n</i> = 1); Mallory-Weiss tear ( <i>n</i> = 2); not visualized ( <i>n</i> = 2)	28 ± 1.2	NA

	Liberal transfusion	445	NA	NA	Peptic ulcer ( <i>n</i> = 209); gastroesophageal varices ( <i>n</i> = 109); Mallory-Weiss tears ( <i>n</i> = 30); erosive gastritis or esophagitis ( <i>n</i> = 29); neoplasms ( <i>n</i> = 20); other ( <i>n</i> = 48)	NA	9.4 ± 2.4

**Table 4** Quality assessment of included studies

Ref.	Randomization	Blinding	Withdrawals and dropouts	Jadad Score
Blair <i>et al</i> <sup>[25]</sup>	Yes (inadequate)	No	Unclear	1
Elizalde <i>et al</i> <sup>[24]</sup>	Yes (inadequate)	Unclear	Unclear	1
Villarejo <i>et al</i> <sup>[23]</sup>	Yes (adequate)	Unclear	Clear	3
Villanueva <i>et al</i> <sup>[14]</sup>	Yes (adequate)	Unclear	Clear	3

groups<sup>[14,23,25]</sup>. One study did not observe any death during the study period in both groups<sup>[23]</sup>, so the OR of this study was not estimable. Another two studies showed a higher incidence of death in patients receiving liberal transfusion<sup>[14,25]</sup>. Heterogeneity among the three studies was not significant ( $I^2 = 0\%$ ;  $P = 0.47$ ). Using a fixed-effect model, the pooled OR was significant (OR = 0.52, 95%CI: 0.31-0.87,  $P = 0.01$ ) (Figure 2A).

### Rebleeding

Two studies reported the incidence of rebleeding in two groups<sup>[14,25]</sup>. Both studies showed a higher incidence of rebleeding in patients receiving liberal transfusion. Heterogeneity among the two studies was significant ( $I^2 = 74\%$ ;  $P = 0.05$ ). Using a random-effect model, the pooled OR was not significant (OR = 0.26, 95%CI: 0.03-2.10,  $P = 0.21$ ) (Figure 2B).

### Length of hospitalization

Two studies reported the length of hospitalization in two groups<sup>[14,23]</sup>. Heterogeneity among the two studies was not significant ( $I^2 = 0\%$ ;  $P = 0.99$ ). Using a fixed-effect mod-

el, the pooled standard mean difference was significant (standard mean difference: -0.17, 95%CI: -0.30--0.04,  $P = 0.009$ ) (Figure 2C).

### Amount of blood transfused

Four studies reported the amount of blood transfused in two groups<sup>[14,23,25]</sup>. Heterogeneity among the four studies was significant ( $I^2 = 54\%$ ;  $P = 0.09$ ). Using a random-effect model, the pooled standard mean difference was significant (standard mean difference: -0.74, 95%CI: -1.15--0.32,  $P = 0.0005$ ) (Figure 2D).

### Hematocrit

Three studies reported the value of hematocrit at discharge or after expansion in two groups<sup>[23,25]</sup>. Heterogeneity among the three studies was significant ( $I^2 = 85\%$ ;  $P = 0.001$ ). Using a random-effect model, the pooled standard mean difference was not significant (standard mean difference: -1.07, 95%CI: -2.36-0.21,  $P = 0.10$ ) (Figure 2E).

### Hemoglobin

Three studies reported the hemoglobin concentration at discharge or after expansion in two groups<sup>[14,23,24]</sup>. Heterogeneity among the three studies was significant ( $I^2 = 56\%$ ;  $P = 0.10$ ). Using a random-effect model, the pooled standard mean difference was significant [standard mean difference: -1.12, 95%CI: -1.73--0.51,  $P = 0.0003$ ] (Figure 2F).

### Sensitivity analysis

Sensitivity analyses were performed after one study with

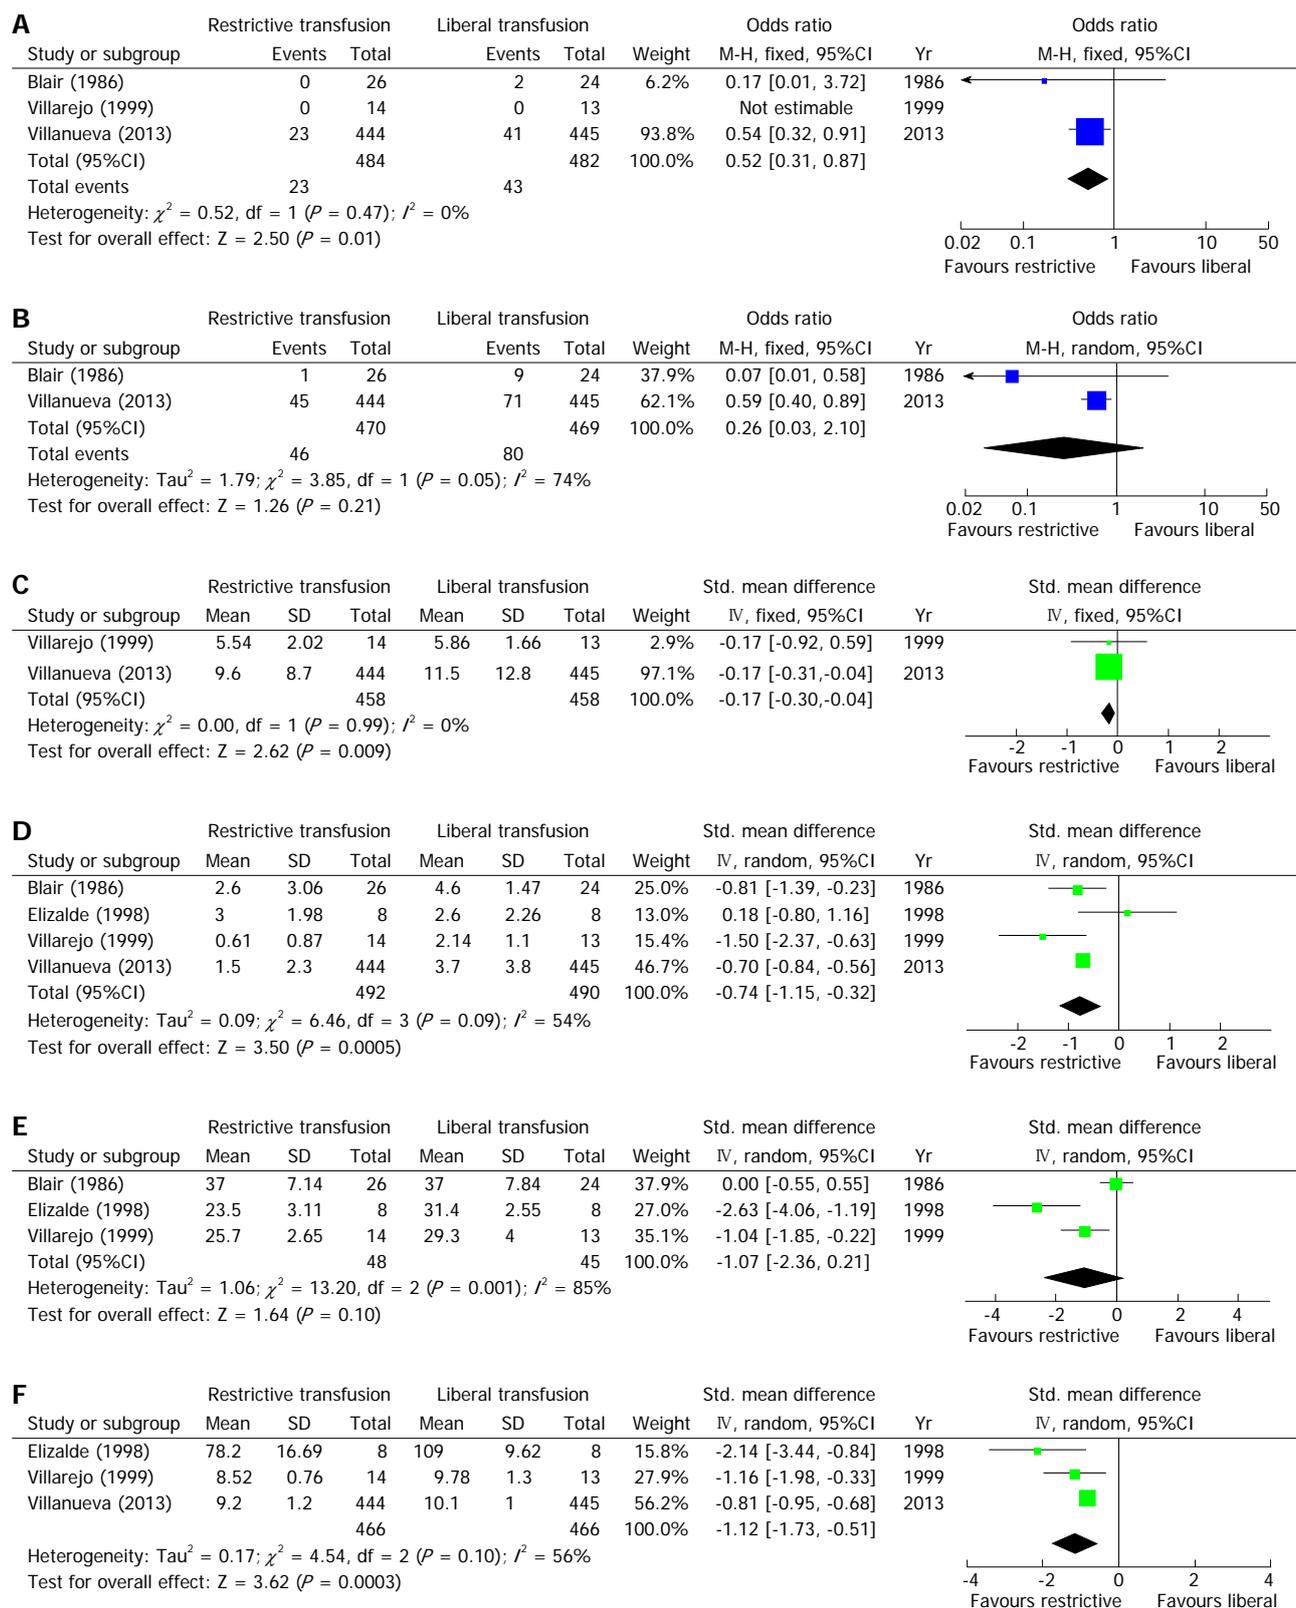

Figure 2 Forest plots comparing the incidence of death (A), incidence of rebleeding (B), length of hospitalization (C), amount of blood transfused (D), and hematocrit (E) and hemoglobin (F) level at discharge or after expansion between patients treated with restrictive and liberal transfusion. Studies are arranged by publication year.

a high proportion of loss to follow-up was excluded<sup>[23]</sup>. Results of all meta-analyses were consistent with those of previous meta-analyses. For death, the pooled OR was 0.52

(95%CI: 0.31-0.87,  $P = 0.01$ ). For length of hospitalization, the pooled standard mean difference was -0.17 (95%CI: -0.31--0.04,  $P = 0.01$ ). For amount of blood transfused,

the pooled standard mean difference was -0.64 (95%CI: -0.97--0.30,  $P = 0.0002$ ). For hematocrit, the pooled standard mean difference was -1.23 (95%CI: -3.79-1.34,  $P = 0.35$ ). For hemoglobin, the pooled standard mean difference was -1.31 (95%CI: -2.57--0.06,  $P = 0.04$ ).

## DISCUSSION

This updated meta-analysis of randomized controlled trials showed the following important findings. First, restrictive transfusion could significantly decrease the incidence of death in patients with upper gastrointestinal bleeding. The survival benefit of restrictive transfusion might be attributed to a lower incidence of further bleeding and transfusion-related adverse events. Second, two randomized controlled trials were included in our meta-analysis and unanimously supported the effectiveness of restrictive transfusion in decreasing the incidence of rebleeding. Our meta-analysis demonstrated a trend in decreasing the incidence of rebleeding in patients treated with restrictive transfusion, but it did not reach any statistical significance. This unexpected finding could be explained by the fact that a random-effect model was employed due to a significant heterogeneity among studies, and the number of patients included in the two randomized controlled trials was substantially different. Third, patients treated with restrictive transfusion had a significantly shorter length of hospitalization and a smaller amount of blood transfused, although the value of hematocrit and hemoglobin at discharge or after expansion was lower in patients treated with restrictive transfusion than in those with liberal transfusion. Generally, these findings accorded with the current international consensus recommendation in which restrictive transfusion should be employed in patients with upper gastrointestinal bleeding. However, we should acknowledge that the threshold of restrictive transfusion strategy was various among these included studies. Accordingly, further studies should be warranted to elucidate the accurate threshold of transfusion in these patients.

The strengths of our study were as follows. First, only randomized controlled trials were included into our meta-analysis. Second, a comprehensive literature search was performed by searching three databases. Third, no publication language was restricted. One Spanish-language full text paper was retrieved by contacting the journal secretary and was translated by Google<sup>[23]</sup>. Fourth, a random-effect model was employed to produce a conservative result with wider confidence intervals, as the heterogeneity among studies was significant<sup>[19]</sup>.

Several limitations of our study should be fully emphasized. First, the publication date of the four studies spanned from 1986 to 2013. This was a relatively long time during which many diagnostic techniques and treatment modalities had been improved. But it should be noted that heterogeneity among studies was not significant for death. Second, three earlier randomized controlled trials had a relatively small sample size<sup>[23-25]</sup>. By comparison, the latest randomized controlled trial had a

larger number of participants included<sup>[14]</sup>. Therefore, the weight of this trial was larger than that of other studies in meta-analyses. In future, more randomized controlled trials are needed to perform a further meta-analysis regarding this topic. Third, one randomized controlled trial had a relatively high proportion of loss to follow-up, thereby increasing the possibility of selection bias<sup>[23]</sup>. Fourth, one randomized controlled trial primarily aimed to observe the hemodynamic effects of an acute increase in blood hemoglobin levels<sup>[24]</sup>. Thus, the data regarding the survival and rebleeding could not be extracted. Fifth, results of one large randomized controlled trial were partially published in two previously published abstracts<sup>[21,22]</sup>. A total of 277 patients with cirrhosis with acute variceal bleeding were enrolled in this study<sup>[14]</sup>. By contrast, the outcome of 147 participants with cirrhosis with acute variceal bleeding was described in one abstract, and the outcome of 214 participants was reported in another abstract<sup>[21,22]</sup>. Importantly, no interim analysis or so called “early stopping rule” was planned in the study. Accordingly, the misbehavior that the authors looked at the data and reported the partial results before the study was completed would introduce the chance of falsely rejecting the null hypothesis (*i.e.*, type I error). Finally, we could not do a meta-analysis according to the different source of bleeding due to a small number of studies included.

In conclusions, this meta-analysis provides preliminary evidence to support that the restrictive transfusion should be employed in patients with upper gastrointestinal bleeding, although the limitation of our study is obvious. Further well designed and conducted randomized controlled trials should be warranted to confirm whether or not restrictive transfusion should be beneficial in different sources of upper gastrointestinal bleeding.

## ACKNOWLEDGEMENTS

We are indebted to Mariela García Muñoz (Secretary Acta Gastroenterológica Latinoamericana, Organo oficial de la Sociedad Argentina de Gastroenterología) for literature retrieval.

## COMMENTS

### Background

Acute upper gastrointestinal bleeding is a common cause for emergency hospitalization with a relatively high morbidity and mortality. Red blood cell transfusion is often required in such patients due to the reduction of tissue perfusion after acute blood loss. Current international consensus recommends restrictive transfusion for upper gastrointestinal bleeding. However, this recommendation is largely based on expert opinions.

### Research frontiers

Recently, several large-scale observational studies demonstrated that blood transfusion after nonvariceal upper gastrointestinal bleeding might increase the rate of mortality and rebleeding. More recently, a large and well-organized randomized controlled trial showed a significant benefit of restrictive transfusion strategy in improvement of outcome in patients with upper gastrointestinal bleeding.

### Innovations and breakthroughs

A previous Cochrane Collaboration systematic review of three randomized

controlled trials has shown a tendency in decreasing the mortality of patients with upper gastrointestinal bleeding after restrictive transfusion. But a small number of participants and a high proportion of missing data limit the significance of these findings. These authors concluded that their review might not provide useful data regarding outcomes following red blood cell transfusion for acute upper gastrointestinal bleeding. Thus, authors performed an updated meta-analysis of randomized controlled trials to compare the outcome of upper gastrointestinal bleeding between patients treated with restrictive and liberal transfusion. Results of their meta-analysis demonstrated that patients receiving restrictive transfusion had a lower incidence of death and rebleeding, a shorter length of hospitalization, and a smaller amount of blood transfused than those receiving liberal transfusion.

### Applications

Evidence suggested that restrictive transfusion should be employed in patients with upper gastrointestinal bleeding.

### Peer review

Restrictive transfusion for acute upper gastrointestinal bleeding will become a hot topic in recent years. This study is very interesting. It is valuable to be published.

### Abstract

Collagenous sprue (CS) is a pattern of small-bowel injury characterized histologically by marked villous blunting, intraepithelial lymphocytes, and thickened sub-epithelial collagen table. Clinically, patients present with diarrhea, abdominal pain, malabsorption, and weight loss. Gluten intolerance is the most common cause of villous blunting in the duodenum; however, in a recent case series by the Mayo Clinic, it has been reported that olmesartan can have a similar effect. In this case report, a 62-year-old female with a history of hypothyroidism and hypertension managed for several years with olmesartan presented with abdominal pain, weight loss, and nausea. Despite compliance to a gluten-free diet, the patient's symptoms worsened, losing 20 pounds in 3 wk. Endoscopy showed thickening, scalloping, and mosaiform changes of the duodenal mucosa. The biopsy showed CS characterized by complete villous atrophy, lymphocytosis, and thickened

sub-epithelial collagen table. After 2 mo cessation of olmesartan, the patient's symptoms improved, and follow-up endoscopy was normal with complete villous regeneration. These findings suggest that olmesartan was a contributing factor in the etiology of this patient's CS. Clinicians should be aware of the possibility of drug-induced CS and potential reversibility after discontinuation of medication.

Angiotensin-II inhibitor (olmesartan)-induced collagenous sprue with resolution following discontinuation of drug. *World J Gastroenterol* 2013; 19(40): 6928-6930 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6928.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6928>

### INTRODUCTION

Collagenous sprue (CS) is a pattern of small-bowel injury characterized histologically by marked villous blunting, increased intraepithelial lymphocytes, and thickened collagen table. Clinically, patients present with diarrhea, abdominal pain, malabsorption, and subsequent weight

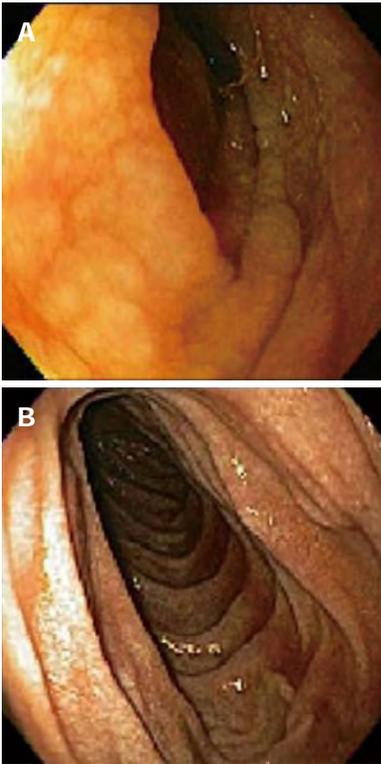

Figure 1 Scalloped mucosa (A) and normal duodenum (B) (endoscopy).

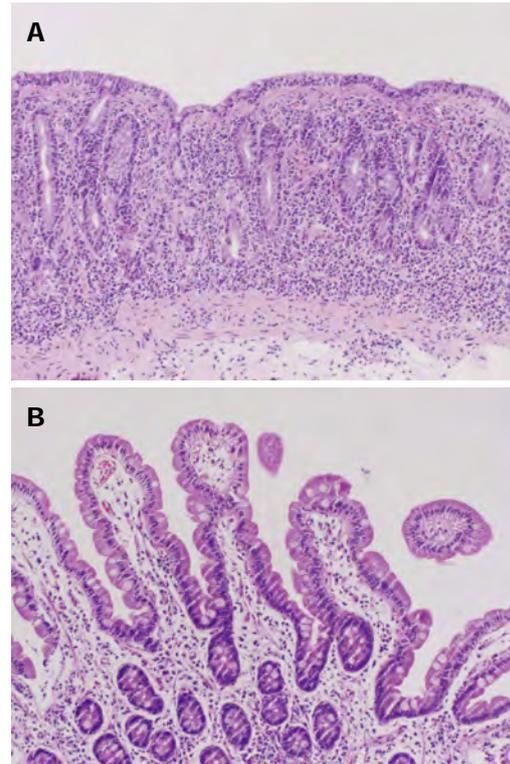

Figure 2 Complete duodenal villous blunting (A) and villous regeneration (B) (hematoxylin and eosin,  $\times 400$ ).

loss. Gluten intolerance is the most common cause of villous blunting in the duodenum; however, in contrast to celiac disease, many patients with CS do not respond to a gluten-free diet<sup>[1]</sup>. Recently, the Mayo Clinic reported in a series of 22 cases that olmesartan can cause a similar severe spruelike enteropathy<sup>[2]</sup>. We report one such case of a woman who had been managing her hypertension with olmesartan for the previous couple years.

## CASE REPORT

A 62-year-old female with a history of hypothyroidism and hypertension presented with abdominal pain, weight loss, change in bowel habits, nausea, and increased bloating/gas; she denied any new medications or nonsteroidal antiinflammatory drugs use. Initial endoscopy was normal; however, the histologic findings showed a CS characterized by complete villous atrophy, up to 100 intraepithelial lymphocytes per 100 epithelial cells, and focally thickened sub-epithelial collagen table. Immunohistochemical stains showed prevalent CD3 positive intraepithelial lymphocytes with no evidence of lymphoma. Celiac markers and anti-enterocyte antibodies were negative; however, histocompatibility leukocyte antigen (HLA)-DQ2 was present. Despite compliance to a gluten-free diet, the patient's symptoms worsened, losing 20 pounds in 3 wk. A second esophagogastroduodenoscopy (EGD) showed thickening and scalloping of duodenal mucosa (Figure 1A). Subsequent histology revealed increased thickness of the collagen band, compared to the previous biopsies, persistent complete villous blunting, and intra-

epithelial lymphocytosis (Figures 2A and 3A). A few days later, the patient was admitted to the Emergency Department for bloody stools and advised to discontinue taking olmesartan because her blood pressure was "normotensive". After cessation of olmesartan the patient's symptoms improved, and 3 mo later EGD (Figure 1B) and biopsy findings were normal, with histologic examination demonstrating complete villous regeneration in the duodenum (Figures 2B and 3B). These findings suggest that olmesartan was a contributing factor in the etiology of this patient's CS.

## DISCUSSION

Many authors still regard CS as a part of the spectrum of celiac disease and designate non-responsive patients as being a "refractory sprue"<sup>[3]</sup>. Both infectious agents and allergic reactions are speculated to be involved in the mucosal injury for a CS, but the etiology and pathogenesis are still unknown<sup>[4]</sup>. Previous accounts of non-gluten sensitivity-related small bowel villous flattening have been reported. In one case series, seven patients all experienced symptoms suggestive of gluten sensitivity and had morphologically-similar mucosal injury in their small bowel biopsy specimens. Regardless of their gluten consumption, all patients experienced clinical improvement and mucosal regeneration. The cause and resolution of their injury is unknown, demonstrating that celiac sprue is not the only disease which can cause villous blunting<sup>[4]</sup>.

In a recent study at Mayo Clinic, 22 patients with

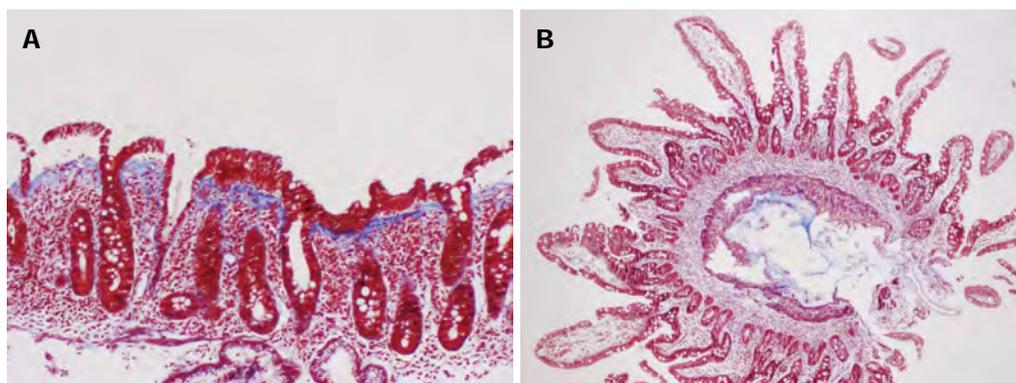

Figure 3 Thickened collagen table (A) and normal histology (B) (trichrome, × 400).

unexplained chronic diarrhea and enteropathy and no response to treatments for celiac disease experienced clinical improvement after suspension of olmesartan. All patients had either partial or total duodenal villous atrophy, 6 of which showed a thickened collagen table. Additionally, 7 patients had collagenous or lymphocytic gastritis, and 5 patients had microscopic colitis. Many of these patients were on olmesartan for months or even years before onset of symptoms. Follow-up biopsy confirmed histologic improvement of the duodenum in 18 patients with sprue-like changes<sup>[2]</sup>, demonstrating that CS can be induced by an autoimmune response to drugs and that morphologic pattern of injury is not necessarily indicative of underlying, specific etiology. As in our patient, 68% of these patients had HLA-DQ2, which is significantly higher than the prevalence reported in the general population of 25%-30%<sup>[2]</sup>.

In conclusion, we report a clear case of an angiotensin- II inhibitor that caused villous blunting of the duo-

denum and gastrointestinal symptoms similar to those of celiac disease. Clinicians should be aware of the possibility of olmesartan-induced CS, with potential reversibility after discontinuation of the drug.

### Abstract

The use of weight reduction surgeries has increased over the years with a higher proportion of these surgeries being sleeve gastrectomies, this has been associated with some complications including staple line leaks. We report a 32-year-old male who had undergone a laparoscopic gastric band surgery and subsequently a laparoscopic sleeve gastrectomy, this was complicated by both an staple line leak at the gastroesophageal junction as well as a large (> 4 cm) posterior gastric wall defect due to gastric wall necrosis. We used two co-axially inserted self-expandable stents (SEMS) in the management of this patient, 5 stents were used over repeated endoscopy sessions and 20 wk. Both defects had resolved without the need for surgical intervention. This is the first reported case where SEMS are used for

both a staple line leak as well as a gastric wall defect. We also review the literature on the use of SEMS in the management of leaks post weight reduction surgeries.

**Key words:** Stents; Self-expandable metal stents; Laparoscopic sleeve gastrectomy; Staple line leak; Esophageal leak; Gastric necrosis

**Core tip:** Management of staple line leaks has incorporated, in recent years, a non-surgical approach which mainly depends on elimination of oral intake, parenteral nutrition, antimicrobial therapy, and drainage procedures and more recently the use of esophageal self-expandable metal stents for sealing of these leaks as well as the induction of tissue hyperplasia that would close these leaks. This case is the first, to our knowledge, that reports the successful use of self-expandable metal stents for the closure of a posterior gastric wall necrosis as a consequence of repeated bariatric surgery.

Resolution of an esophageal leak and posterior gastric wall necrosis with esophageal self-expandable metal stents. *World J Gastroenterol* 2013; 19(40): 6931-6933 Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6931.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6931>

### INTRODUCTION

The morbidity and mortality associated with obesity has been well recognized and in some clinical settings the method to curtail such an epidemic is *via* weight reduction surgeries, such an intervention is associated with some complications of which surgical leaks are one of the most unfavorable as they are associated with considerable morbidity and mortality<sup>[1]</sup>. The management of

these complications has evolved from surgical reoperation to a more conservative approach with elimination of oral intake, parenteral nutrition, antimicrobial therapy, and drainage<sup>[1]</sup>. A more recent trend has been to use esophageal self-expandable metal stents (SEMS) or self-expandable plastic stents (SEPS)<sup>[1]</sup> as a method of occluding these leaks. We present an unusual case where SEMS were used in the management of a patient who developed both a staple line leak at the gastroesophageal junction as well as necrosis of the posterior gastric wall.

## CASE REPORT

A 32-year-old male was referred to our institution with a diagnosis of an esophageal leak after a laparoscopic sleeve gastrectomy (LSG). The patient had already undergone a laparoscopic gastric band weight reduction surgery about 5 years before his presentation with a sub-optimal weight loss reduction. Subsequently the patient underwent a LSG and in the first postoperative week the patient developed clinical signs of an enteric leak with the development of tachycardia as well as fever.

A barium swallow demonstrated a leak at the level of the distal end of the esophagus and a computerized tomography (CT) demonstrated a fluid collection close to the surgical bed. The patient was started on broad-spectrum antibiotics and oral intake was stopped. An endoscopic line of management was planned and an esophagogastroduodenoscopy (EGD) was performed and demonstrated an opening in the distal esophagus that corresponded to the leak seen on a barium study, distal to that defect the pouch above the gastric band was seen and a large defect was seen in the posterior wall of the stomach remnant, which through fluid and the drains left post surgery could be seen (Figures 1 and 2). A single A 12 cm fully-covered SEMS, Niti-S (Taewong Medical, Seoul, South Korea), was deployed with the proximal end of the stent left above the level of the leak and the distal end was just proximal to the pylorus.

A month latter the patient presented with nausea and vomiting and the stent was found to have migrated, a repeat EGD found that the distal end of the SEMS caused an ulcer in the antrum of the stomach, The stent was removed and the patient was kept on a proton pump inhibitor and 12 d later two 15 cm long partially covered SEMS, Ultraflex (Microvasive, Boston Scientific, United States), were deployed in a co-axial fashion, the proximal end of the first stent lied at 30 cm from the incisors above the level of the leak while the distal end of the second stent lied in the duodenum (Figure 3). A few days after the procedure the patient was started on a liquid diet and subsequently the output from the drains had stopped. After 11 and half weeks a rat-tooth forceps was used for removing both stents but the defects in the lower esophagus and the stomach were still present although they had decreased substantially in size, another two partially covered SEMS esophageal stents (Ultraflex) were inserted in a similar fashion to the initial insertion. After

Figure 1 Appearance of a large defect in the posterior wall of the stomach with the post-operative drains seen through it.

Figure 2 A closer look at the drains through the defect.

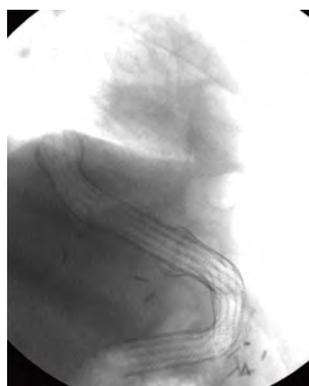

Figure 3 Two co-axially inserted partially covered self-expandable esophageal metal stents extending from the esophagus to the duodenum.

4 wk both stents were removed easily (Figure 4) and the defects had resolved. The patient had a subsequent CT scan of the abdomen with oral contrast that demonstrated resolution of both leaks and the drains were removed.

## DISCUSSION

The use of enteric stents has evolved from the management of malignant diseases to benign strictures as well as leaks. LSGs are complicated by leaks in 2.2%<sup>[3]</sup>-2.4%<sup>[4]</sup>

Figure 4 Self expandable metal stent being removed from the distal aspect with a rat-tooth forceps.

of cases based on two systematic reviews with the majority of these leaks (85%-89%) being located in the proximal third of the stomach near the gastroesophageal junction<sup>[1,4]</sup> and are associated with a non-trivial mortality rate (6%-14.7%)<sup>[1]</sup>. The management options for this complication vary from repeat surgery to a more conservative management with an attempt to seal these leaks through enteric stenting. Surgical management has been associated with a high morbidity (up to 50%) and mortality (2%-10%)<sup>[1]</sup>, as a result, initial management has moved towards a more conservative endoscopic treatment. Although there are no randomized controlled trials to assess the efficacy of this approach, a systematic review that included 25 studies, incorporating 267 patients showed that the success rate with the use of SEMS was about 85% with no difference in the rate of clinical success between the type of SEMS used whether they were partially or fully-covered SEMS or SEPS ( $P = 0.97$ )<sup>[5]</sup>, of note this systematic review included cases who had esophageal anastomotic leaks or a benign rupture of the esophagus<sup>[5]</sup>. A second meta-analysis for patients who exclusively had leaks post bariatric surgery and were managed by stenting found a success rate of 87.8% (95%CI: 79.4%-94.2%)<sup>[6]</sup>.

The case we present is unique due to the simultaneous presence of a leak at the gastroesophageal junction as well as a large area of necrosis in the posterior wall of the stomach both of which were eliminated using SEMS for a prolonged period of time and the use of a total of 5 stents and five endoscopy sessions spanning a period of 20 wk. SEMS are usually kept in place on average for 6 wk<sup>[5]</sup>. In the case reported the duration of stenting was 20 wk mainly due to the large defect seen in the gastric wall.

Stent migration occurred with the first fully covered

SEMS that necessitated its removal and exchange. This complication is acceptable as the rate of migration in general in a meta-analysis was 16.9% (95%CI: 9.3%-26.3%)<sup>[6]</sup> and van Boeckel *et al*<sup>[5]</sup> found that fully covered SEMS had a higher migration rate when compared to partially covered SEMS (26% *vs* 12% respectively,  $P \leq 0.001$ )<sup>[5]</sup>. Although endoscopic repositioning/removal might suffice in the majority of cases, as in our case, some of these stents passed per-rectum spontaneously or had to be removed surgically<sup>[6]</sup>.

The longer the SEMS are left in place the higher the risk of ingrowth of tissue within the stent and subsequently the more difficult its removal<sup>[1]</sup>. Removal of these SEMS usually require the insertion of a SEPS within the SEMS to induce ingrowth tissue necrosis and after a few days both the SEMS and SEPS can be removed, successful removal of the SEMS after leak closure is 91.6% (95%CI: 84.2%-96.8%)<sup>[6]</sup>. We intentionally removed the SEMS after predefined durations to reduce the risk of failure to remove the SEMS. Furthermore, due to the initial use of fully covered and then partially covered SEMS they were removed without requiring the insertion of SEPS.

This case is the first to our knowledge where both a staple line leak post LSG and posterior gastric wall necrosis were simultaneously treated using SEMS without the need for repeated surgery.

### Abstract

Patients with Stage IV cholangiocarcinoma are currently not considered to be surgical candidates and are typically offered systemic chemotherapy. Recently, several novel systemic chemotherapy regimens have allowed an initially unresectable cholangiocarcinoma to be resectable. The aim of this article is to present the usefulness of adjuvant surgery in a case of advanced cholangiocarcinoma that was successfully treated with gemcitabine. A 72-year-old man was diagnosed with distal cholangiocarcinoma with liver metastases (cT2N0M1, Stage IV). He underwent metal stent placement in the duodenum to alleviate jaundice. After 18 courses of chemotherapy using gemcitabine without severe drug toxicities, a computed tomography scan showed that the liver metastases in S6 and S7 had disappeared. The patient underwent subtotal stomach-preserving pancreaticoduodenectomy and lymph node dissection. The pathological stage was pT2N0M0, Stage I B. The patient underwent 6 cycles of adjuvant chemotherapy using gemcitabine. The patient is alive

and well 6 years and 9 mo after the diagnosis.

**Key words:** Extrahepatic cholangiocarcinoma; Adjuvant surgery; Conversion surgery; Chemotherapy; Gemcitabine

**Core tip:** Patients with Stage IV cholangiocarcinoma are currently not considered to be surgical candidates and are typically offered systemic chemotherapy. Recently, several novel systemic chemotherapy regimens have allowed an initially unresectable cholangiocarcinoma to be resectable. In a patient with advanced extrahepatic cholangiocarcinoma, gemcitabine (GEM) induced a dramatic reduction of the tumor, which led to curative resection and a long-term survival of 6 years and 9 mo. This result suggests the possibility of advantages of using GEM for the treatment of advanced cholangiocarcinoma, and GEM-based chemotherapy could be performed more often for unresectable cholangiocarcinomas.

Available from: URL: <http://www.wjgnet.com/1007-9327/full/v19/i40/6934.htm> DOI: <http://dx.doi.org/10.3748/wjg.v19.i40.6934>

### INTRODUCTION

Cholangiocarcinoma continues to exhibit poor survival rates compared with other gastrointestinal malignancies<sup>[1-4]</sup>. Most cholangiocarcinoma patients are not surgical candidates. Patients with Stage IV cholangiocarcinoma are currently inoperable and are typically offered systemic chemotherapy. The most promising approaches involve

the use of single agents such as gemcitabine (GEM), which has been shown to be effective against cholangiocarcinoma in phase II trials<sup>[5-7]</sup>. In these trials, the response rates for GEM ranged from 8% to 36%, and the overall survival (OS) ranged from 6.3 to 16 mo. We describe a rare case of stage IV cholangiocarcinoma with liver metastases that was initially deemed unresectable and became resectable after GEM chemotherapy and showed a favorable outcome.

## CASE REPORT

The patient was a 72-year-old man referred from a local hospital complaining of jaundice. The laboratory data on admission showed the following elevated values: total bilirubin (T-bil), 6.2 mg/dL (normal range, 0.2-1.2 mg/dL); lactic acid dehydrogenase, 243 U/L (124-232 U/L); alkaline phosphatase 354 U/L (120-320 U/L); and  $\gamma$ -glutamyl transpeptidase, 181 U/L (5-55 U/L). All the tumor markers tested were within the normal limits: carcinoembryonic antigen (CEA), 2.3 ng/mL (normal range, < 5.0 ng/mL), and carbohydrate antigen 19-9, 12.0 U/mL (< 37 U/mL). Abdominal computed tomography (CT) and ultrasonography showed mild dilatation of the common bile duct and bilateral dilation of the intrahepatic bile ducts. Abdominal computed tomography angiography (CTA) detected wall thickening in the distal common bile duct, and the lesion was enhanced by contrast (Figure 1). CT and CTA showed two liver metastases, which measured 8 mm (S6) and 8 mm (S7) in diameter (Figure 2). According to the Union Internationale Contre le Cancer (UICC) guidelines, the patient was diagnosed with lower cholangiocarcinoma (cT2N0M1, Stage IV)<sup>[8]</sup>.

The patient underwent successful placement of a self-expandable metal duodenal stent to relieve jaundice. The patient received a total of 18 cycles of GEM. GEM was administered intravenously at a dose of 800 mg/m<sup>2</sup> per day on days 1, 8, and 15 in a 28-d cycle. Adverse events were graded according to the National Cancer Institute Common Toxicity Criteria Grading System (Version 2.0, April 1999)<sup>[9]</sup>. Severe drug toxicities (grade 3 or 4) were not observed.

After 18 cycles of chemotherapy, CT showed that the two liver metastases in S6 and S7 disappeared. The tumor was clinically downstaged to Stage I B (cT2N0M0).

Four weeks after the completion of chemotherapy, the operation was successfully performed. Peritoneal lavage cytology demonstrated no cancer cells in the abdominal cavity. No microscopic invasion of the resected bile duct stump was observed in an intraoperative frozen specimen. The patient underwent curative resection consisting of SSPPD with D2 lymphadenectomy without resecting any other organs.

Tumor cells were detected in the distal bile duct upon microscopic examination (Figure 3). According to the UICC guidelines, the pathological classification of the tumor was cT2N0M0 Stage I B. The patient was discharged on postoperative day 61 in good condition.

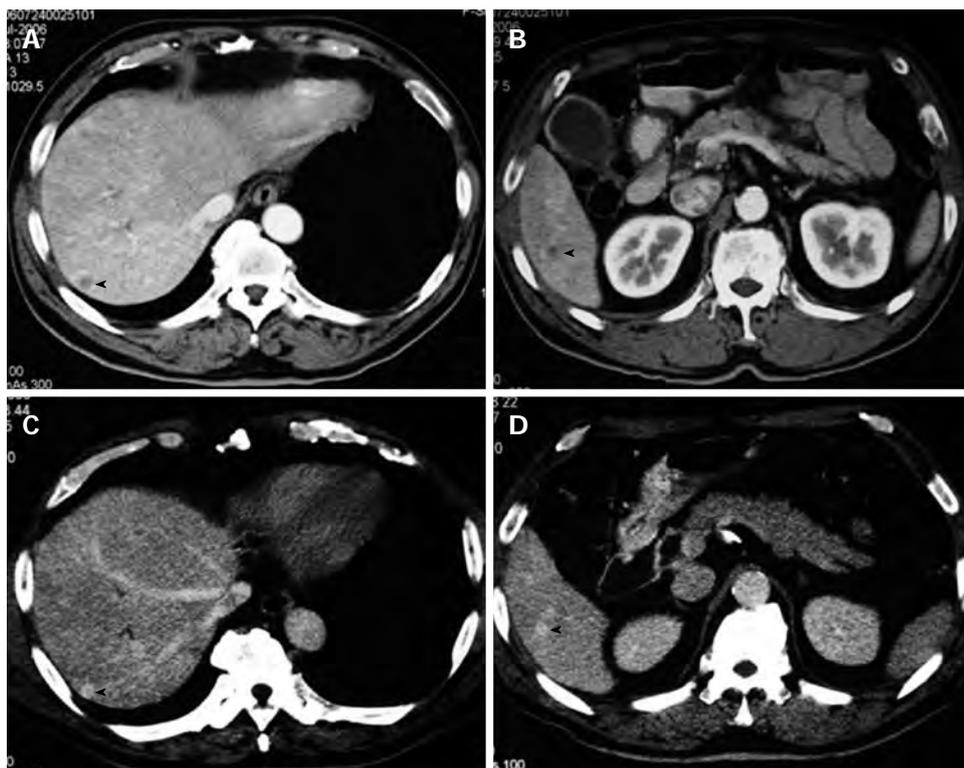

**Figure 1** Abdominal computed tomography angiography image of the common bile duct. Thickening of the wall of the distal common bile duct, which enhances with contrast, was observed (arrowhead).

The patient subsequently received six cycles of adjuvant GEM chemotherapy similar to the preoperative regimen. The patient is alive at 6 years and 9 mo after the diagnosis and 5 years after the surgery.

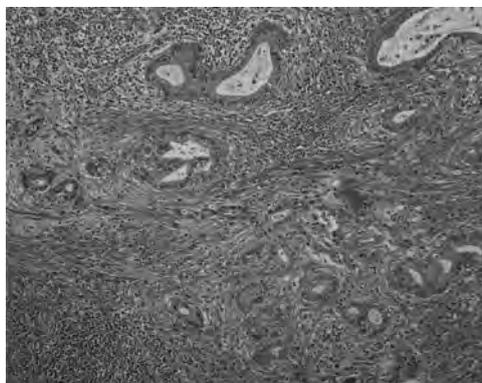

## DISCUSSION

The prognosis of patients with cholangiocarcinoma is poor, with a five-year survival rate of approximately 25% to 55%<sup>[1-4]</sup>. To overcome this clinical challenge, several strategies, including adjuvant chemotherapy, adjuvant radiotherapy, and adjuvant chemoradiotherapy have been considered for treating cholangiocarcinoma<sup>[10-13]</sup>. Few randomized clinical trials have evaluated the utility of adjuvant therapy following R0 resection of cholangiocarcinoma, and most of the current studies are small and retrospective. Therefore, no standard adjuvant modalities have been universally adopted for the treatment of cholangiocarcinoma, and the role of chemotherapy for unresectable cholangiocarcinoma has not been established. Although there has been no standard chemotherapy for cholangiocarcinoma, GEM has been the most actively used agent against cholangiocarcinoma. We treated a patient with advanced extrahepatic cholangiocarcinoma with liver metastases. The patient showed a dramatic response to GEM, which led to curative resection and long-term survival of more than 6 years. GEM may be an effective chemotherapeutic agent for treating cholangiocarcinoma, and a randomized clinical trial needs to be performed.

The feasibility of adjuvant surgery for cholangiocarcinoma has not been determined. Recently, in colorectal, gastric, and pancreatic cancer, several authors have reported “conversion surgery” or “adjuvant surgery”<sup>[14-16]</sup>. Suzuki *et al.*<sup>[14]</sup> demonstrated that adjuvant surgery was effective in 20 advanced gastric cancer patients (Stage IV) based on liver or distant lymph node metastasis. The overall survival of patients in the partial response and curative resection groups was prolonged. The survival of patients with H or N factor was also prolonged when they received curative surgery. However, the survival of

**Figure 2** Abdominal computed tomography and computed tomography angiography images at two different levels are shown. A: Computed tomography (CT) showed a low-density mass measuring 8 mm in diameter located in segment 7 of the liver (arrowhead); B: CT showed a low-density mass measuring 8 mm in diameter in segment 6 (arrowhead); C: Computed tomography angiography (CTA) demonstrated an enhancing mass lesion at the same location as in Figure 2A (arrowhead); D: CTA demonstrated an enhancing mass lesion at the same location as in Figure 2B (arrowhead).

**Figure 3** Histopathologic appearance of the cholangiocarcinoma (hematoxylin and eosin,  $\times 200$ ). Tumor cells were detected in the distal bile duct on microscopic examination.

patients with P factor was not prolonged. Locally advanced pancreatic cancer may be a good indication for adjuvant surgery after sustained favorable responses to chemotherapy, even in patients with initially unresectable disease<sup>[6]</sup>. In 2013, Kato *et al*<sup>[17]</sup> reported that eight patients with initially unresectable advanced biliary tract cancer who underwent adjuvant surgery had significantly longer survival than 14 patients who were unable to undergo surgery. Of the eight patients in the surgery group, four patients had gallbladder carcinoma and four patients had intrahepatic cholangiocarcinoma. To our knowledge, from 1983 to 2013, in the field of bile duct cancer, only

16 cases in nine reports underwent adjuvant surgery, including the cases in the report<sup>[17-25]</sup> (Table 1). Of the 16 patients, 10 patients received GEM, 3 received S-1, 2 received GEM and S-1, 1 received GEM combined with cisplatin and fluorouracil, and 1 received cisplatin/interferon  $\alpha$ -2b/doxorubicin/fluorouracil-combination chemotherapy. None of the 16 cases involved extrahepatic cholangiocarcinoma. To the best of our knowledge, this is the first report of adjuvant surgery for extrahepatic cholangiocarcinoma.

Medical oncologists and surgeons have identified surgical candidates among patients with initially unresectable colorectal and gastric cancer who responded favorably to multimodal treatment<sup>[14,15]</sup>. In some cases, the addition of surgery resulted in increased long-term survival. Surgical resection coupled with multimodal treatment is called “adjuvant surgery.” Surgical resection can be classified as curative (no evidence of remaining disease after surgery) or palliative (remaining disease after surgery). Therefore, adjuvant surgery aims to be curative and not palliative after the response to chemotherapy<sup>[14]</sup>.

In a strategy involving adjuvant surgery, adjuvant chemotherapy is considered necessary after the operation. In our patient, the liver metastases showed a surprising complete response without severe toxicity after GEM chemotherapy. Additionally, the patient received adjuvant chemotherapy using GEM as an outpatient and developed no adverse reactions. In previous phase II studies using single-agent GEM, major adverse reactions included

neutropenia, leukopenia, and anemia were observed with little severe toxicity<sup>[5-7]</sup>. The results suggest that GEM is suitable for outpatients because of its mild toxicity.

The UK ABC-02 study defined the standard of care for unresectable advanced biliary tract cancer<sup>[26]</sup>. Valle *et al*<sup>[26]</sup> reported that cisplatin with GEM (GEMC) was associated with a significant survival advantage compared with GEM alone. The median OS was 11.7 mo for GEMC and 8.1 mo for GEM alone<sup>[26]</sup>. A Japanese trial of 83 patients using the same treatment regimens as UK ABC-02 showed the median survival and overall response rate of GEMC *vs* GEM alone were 11.2 mo *vs* 7.7 mo and 19.5% *vs* 11.9%, respectively. These results were consistent with the results of the UK ABC-02 study. GEMC was found to be effective and well tolerated, which indicates that it could also be a standard regimen for Japanese patients<sup>[27]</sup>.

In conclusion, in a patient with advanced extrahepatic cholangiocarcinoma, GEM induced a dramatic reduction of the tumor, which led to curative resection. The patient was still living 6 years and 9 mo after the study. The results suggest possible advantages of using GEM for the treatment of advanced cholangiocarcinoma. GEM-based chemotherapy could be more commonly administered for unresectable cholangiocarcinoma. Furthermore, "adjuvant surgery" (*i.e.*, R0 resection) may significantly contribute to curing cholangiocarcinoma. An evidence-based consensus should be developed on potentially resectable cholangiocarcinoma with liver metastases in each hospital.

### Abstract

Isolated gastric varices (IGV) can occur in patients with left-sided portal hypertension resulting from splenic vein occlusion caused by thrombosis or stenosis. In left-sided portal hypertension, blood flows retrogradely through the short and posterior gastric veins and the gastroepiploic veins, leading to the formation of an IGV. The most common causes of splenic vein occlusion are pancreatic diseases, such as pancreatic cancer, pancreatitis, or a pseudocyst. However, various other cancers, such as colon, gastric, or renal cancers, have also been known to cause splenic vein occlusion. Our patient presented with a rare case of IGV bleeding induced by splenic lymphoma-associated splenic vein occlusion. Splenectomy, splenic artery embolization, and stenting of the splenic vein are the current treatment choices. Chemotherapy, however, is an alternative ef-

fective treatment for splenic vein occlusion caused by chemotherapy-sensitive tumors. Our patient responded well to chemotherapy with a cyclophosphamide, hydroxydaunorubicin, oncovin, and prednisolone regimen, and the splenic vein occlusion resolved after the lymphoma regressed.

**Key words:** Isolated gastric varices; Splenic vein; Lymphoma; Occlusion; Hematemesis

**Core tip:** Isolated gastric varices occur in patients with splenic vein occlusion caused by thrombosis, stenosis, or cancer, such as pancreatic, colon, gastric, or renal cancers. Here, we describe a rare case of an isolated gastric varices in an elderly woman who presented with tarry stool and bloody vomitus. The diagnostic tests revealed a splenic B-cell lymphoma, which caused splenic vein occlusion that resulted in isolated gastric variceal bleeding. Splenectomy, splenic artery embolization, and stenting of the splenic vein are the current treatment choices. In this patient, chemotherapy was an alternative treatment, and the splenic vein occlusion resolved after the lymphoma regressed.

### INTRODUCTION

Hematemesis is a medical emergency, and in most cases, it is caused by esophageal varices or peptic ulcers. However, there are other rare, but important and treatable causes of hematemesis, such as isolated gastric vari-

ces. We report one such case and review the literature, focusing on the unusual entities presenting as isolated gastric variceal bleeding.

## CASE REPORT

A 77-year-old woman was admitted to our hospital due to two episodes of bloody vomitus and three episodes of tarry stool. She did not have a significant medical or surgical history or any known allergies, nor was she taking any medication. The physical examination revealed pale conjunctiva without any jaundice, lymphadenopathy, or pedal edema. An abdominal palpation demonstrated an enlarged spleen, palpable below the left costal margin, and a digital rectal examination showed melena. The remainder of the patient's systemic examination results was unremarkable. The blood pressure was 97/55 mmHg, the pulse rate was 96/min, the hemoglobin level was 8.9 g/dL, the platelet count was 118000/ $\mu$ L, and the stool occult blood test was positive. The patient's biochemistry tests, including those for liver and renal function, were within the normal limits, apart from a high serum lactate dehydrogenase level (1112 U/L). Esophagogastroduodenoscopy demonstrated an isolated gastric varices (IGV) at the cardia and high body of the stomach, with active bleeding (Figure 1); thus, sclerotherapy with cyanoacrylate was successfully performed. Abdominal computed tomography (CT) showed a large mass in the enlarged spleen, with near total occlusion of the splenic vein (Figure 2A). This splenic vein occlusion led to the development of a gastric varices at the fundus (Figure 2B), and the portal and superior mesenteric veins were patent. The laboratory findings indicated the patient's carcinoembryonic antigen and carbohydrate antigen 19-9 levels were normal.

The patient underwent ultrasound-guided aspiration biopsy, and histopathology confirmed a high-grade B-cell lymphoma (Figure 3). Thereafter, the patient received chemotherapy with a cyclophosphamide, hydroxydaunorubicin, oncovin, and prednisolone (CHOP) regimen, and the splenic vein occlusion resolved after the lymphoma regressed (Figure 2C).

## DISCUSSION

IGVs are observed in up to 5% of patients with cirrhosis and in up to 10% of patients with non-cirrhotic portal hypertension<sup>[1]</sup>. Such varices can occur in patients with segmental or left-sided portal hypertension (LSPH), and the incidence has increased over the past three decades because of increased awareness of the entity and advances in diagnostic approaches<sup>[2,3]</sup>. When a segment of the portal venous bed is obstructed, varices can develop in the area to decompress the blocked segment. In cases of segmental portal hypertension, the blood drains in a retrograde manner through the short and posterior gastric veins and the gastroepiploic veins. This process results in blood flow and a pressure increase, which causes dilation

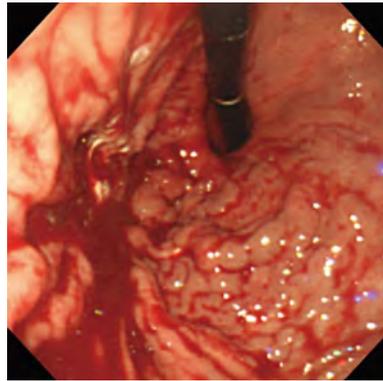

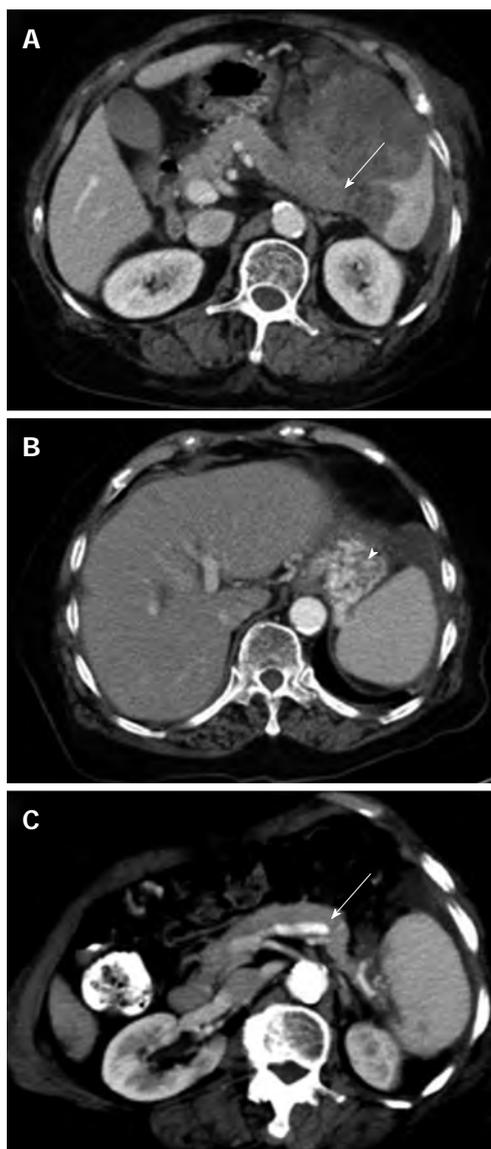

Figure 1 Engorged varices at the cardia and high body of the stomach, with active bleeding.

of the submucosal structures, leading to the formation of a gastric varice<sup>[4]</sup>.

LSPH primarily occurs as a result of splenic vein obstruction, most commonly resulting from pancreatic disorders<sup>[5]</sup>. Because the splenic vein is posterior to the pancreas and in direct contact with it, any type of pancreatic disease, including cancer, pancreatitis, abscess formation, or a pseudocyst, can affect the splenic vein<sup>[6-8]</sup>. In a study by Moosa *et al.*, pancreatitis, diagnosed by either biopsy or surgery, was part of the LSPH etiology in 87 (60%) of 144 cases, while pancreatic malignancy was detected in only 13 (9%) patients<sup>[9,10]</sup>. Various disorders other than pancreatic diseases, such as partial gastrectomy, metastatic carcinoma, retroperitoneal fibrosis, or protein S deficiency, have a wide spectrum of mechanisms involved in causing splenic vein occlusion<sup>[5,11-13]</sup>. Among the metastatic carcinomas, oat cell carcinoma<sup>[14]</sup>, colon cancer<sup>[5]</sup>, gastric cancer<sup>[5]</sup>, renal cancer<sup>[12]</sup>, and rare retroperitoneal liposarcoma<sup>[9]</sup> have been reported to cause splenic vein occlusion. Primary pancreatic lymphoma, with splenic vein thrombosis and IGV bleeding, has been reported as well<sup>[15]</sup>. Our patient had a rare case of splenic B-cell lymphoma that caused splenic vein occlusion and IGV bleeding.

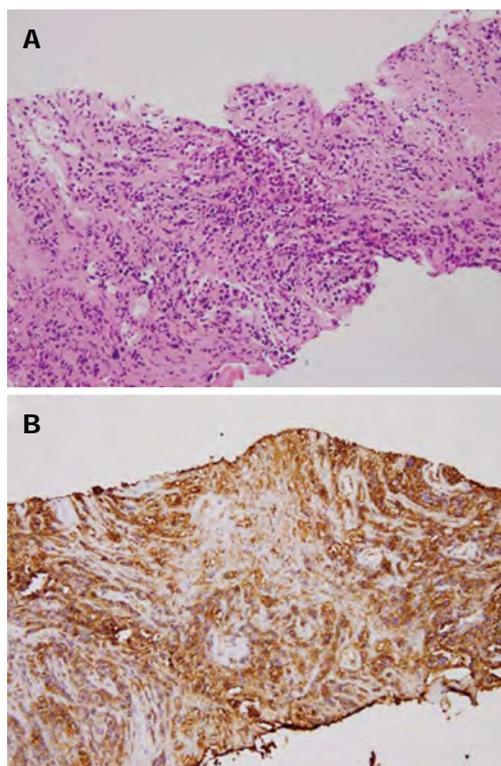

In general, IGVs are asymptomatic and identified incidentally. In symptomatic cases, the most common clinical manifestation is gastrointestinal bleeding from ruptured gastric varices; statistically, 45%-72% of patients with LSPH present with the above-mentioned symptom<sup>[3]</sup>. Splenomegaly and abdominal pain are observed in 71% and 25%-38% of patients with LSPH, respectively<sup>[15,9]</sup>, whereas ascites seldom develop<sup>[16]</sup>. Various radiological examinations can assist in making an IGV diagnosis, including upper gastrointestinal endoscopy, angiography, ultrasonography, contrast-enhanced CT portography, and magnetic resonance imaging. In one study, gastric varices could be accurately diagnosed and localized in nearly 90% of cases by endoscopy<sup>[17]</sup>. Endoscopic ultrasound (EUS) appears to be a more accurate test than transabdominal ultrasonography, which is useful for evaluating the pancreatic parenchyma and splenic vasculature<sup>[18]</sup>. Contrast-enhanced CT portography can

**Figure 2 Imaging findings.** A: Axial contrast-enhanced abdominal computed tomography (CT) at the level of the splenic hilum shows a large low-attenuation mass in the enlarged spleen. The mass involves the splenic vein with near total occlusion (arrow); B: The development of a gastric varice (arrowhead) at the fundus; C: The 6-mo follow-up CT shows that the splenic mass has almost completely resolved, allowing the splenic vein (arrow) to return to patency.

quickly elucidate the portal venous system, but it requires a large amount of iodinated contrast material. Magnetic resonance angiography with gadopentetate dimeglumine is a promising noninvasive test that is being increasingly used to diagnosis patency or thrombosis of the portal venous system<sup>[19]</sup>.

The treatment of IGV bleeding should be directed toward the splenic side of the portal circulation because the pressure increases only on that side<sup>[14]</sup>. Several choices such as conservative therapy (*e.g.*, pharmacotherapy, balloon tamponade, endoscopic therapy with sclerotherapy or band ligation) and interventional radiologic techniques, are available for bleeding control. Japanese endoscopists have reported using a combination technique of endoscopic variceal ligation injection sclerotherapy to treat

**Figure 3 Pathologic findings (hematoxylin/eosin staining) and immunohistochemical staining.** A: The predominant fibrous tissue with necrotic foci and scattered atypical cells characterized by pleomorphic and hyperchromatic nuclei with discohesive arrangement. B: The B-lymphocyte marker (CD20) was strongly positive in the atypical cells.

acute gastric varice bleeding; when using this procedure, the rebleeding rate was low (0%-8%), the gastric varice eradication rate was 85% at up to 2 years post-treatment, and hemostasis was achieved in 100% of patients<sup>[20]</sup>. Transcatheter splenic artery embolization has also been attempted with varying degrees of success, but it has not become a preferred approach. If a patient with active bleeding is unresponsive to conservative management, then splenectomy is indicated. A large splenectomy series that included patients with isolated splenic vein thrombosis showed that none of the patients had recurrent bleeding during the 11-mo mean follow-up period after splenectomy<sup>[9]</sup>.

The current case was a rare incidence of IGV bleeding induced by splenic lymphoma-associated splenic vein occlusion. In this patient, chemotherapy was an alternative treatment for splenic vein occlusion caused by chemotherapy-sensitive tumors. Our patient responded well to chemotherapy, and the splenic vein occlusion resolved after the lymphoma regressed.

### Abstract

Bouveret's syndrome is an extremely rare type of gallstone-induced ileus with atypical clinical manifestations, such as abdominal distension and pain, nausea and vomiting, fever or even gastrointestinal bleeding, which may easily be misdiagnosed. In the present case, a 55-year-old male was admitted to the hospital with upper gastrointestinal obstructive symptoms but without pain, fever, jaundice or melena. At first, gastrolithiasis and peptic ulcer combined with pyloric obstruction were suspected after gastroscopy revealed a large, hard stone in the duodenal bulb. A revised diagnosis of Bouveret's syndrome was made following abdominal computed tomography. Subsequently, the patient exhibited a good postoperative recovery after laparoscopic duodenotomy for gallstone removal and subtotal cholecystectomy. The condition of the patient

remained stable after being followed up for 6 mo. The successful application of laparoscopic therapy to treat Bouveret's syndrome has seldom been reported. Laparoscopic enterolithotomy is safe and effective, with good patient tolerability, rapid postoperative recovery and few wound-related complications. The laparoscopic treatment of Bouveret's syndrome is worth exploring.

**Key words:** Bouveret's syndrome; Gallstone; Gastric outlet obstruction; Laparoscopic therapy; Cholecysto-enteric fistula

**Core tip:** Bouveret's syndrome is a rare cause of gastric outflow obstruction and is easily misdiagnosed. In this case, the patient was middle-aged and did not present any chronic systemic disease. The clinical symptoms were atypical, with neither infection nor abdominal pain. The onset suggested peptic ulcer and pyloric obstruction, which was initially suspected as gastrolithiasis. An imaging study from a year prior provided important data regarding the evolution and diagnosis of the disease. The successful application of laparoscopic therapy to treat Bouveret's syndrome has seldom been reported. This patient obtained satisfactory results after laparoscopic duodenotomy for gallstone removal and subtotal cholecystectomy.

### INTRODUCTION

Bouveret's syndrome is a rare complication of choleli-

thiasis that was first reported and named by Bouveret in 1896; this condition comprises a series of syndromes caused by a gastric outflow obstruction due to the migration of gallstones to the pylorus and duodenum *via* a gallbladder-duodenal fistula<sup>[1]</sup>. We have only rarely encountered this condition in clinical work, and few cases have been reported in the literature. The most common site of gallstone-induced ileus is the terminal ileum, followed by the proximal ileum and jejunum; only 1%-3% of cases occur in the duodenum, and an obstruction caused by incarcerated stones in the pylorus and duodenal bulb is the rarest form encountered in the clinical setting<sup>[2]</sup>. Gallstone-induced ileus is 3 to 16 times more common in females than in males, and Bouveret's syndrome predominately affects older women<sup>[3]</sup>. Because it often presents in the elderly and with multiple comorbidities, it is associated with a high rate of mortality. The first treatment choice for this syndrome remains debatable.

## CASE REPORT

A 55-year-old male was admitted to the hospital with a 2-wk history of upper abdominal distension and vomiting. Nausea and vomiting frequently occurred 4-5 h after a meal. Undigested food was sometimes present in the vomitus. Pain, fever, jaundice and melena were not reported by the patient. Several assays were performed in the outpatient department; the results of the blood analysis, urine analysis, amylase test and lipase test were normal. The patient had experienced a duodenal ulcer 20 years prior. There was a history of acute epigastric pain due to acute cholecystitis and gallbladder stone during the previous year. The pain was relieved by anti-inflammation treatment, and no surgery was performed.

Physical examination revealed mild tenderness in the epigastric area. Succession splash and Murphy's sign were negative. Bowel sounds were normal. Gastroscopy was arranged for the following day and indicated that chyme could be observed in the gastric antrum and duodenal bulb. A large yellowish-brown hard stone was observed in the duodenal bulb, and a 1.2-cm-wide ulcer was located on the greater curvature side of the bulb. The diagnosis of gastric retention, gastrolithiasis and duodenal bulb ulcer was considered based on the medical history and gastroscopy results. The symptoms, including abdominal distension, nausea and vomiting, were quickly alleviated following a therapy of liquid diet, antacid, gastric mucosa protectant and supportive treatment and litholytic therapy with oral sodium bicarbonate solution.

However, on the third day after admission, computed tomography (CT) of the abdomen revealed a thick gallbladder wall and the presence of gas shadows in the gallbladder. The choledoch was slightly wider, and the walls of the gallbladder and the pylorus were indistinct from each other. Additionally, a calcified mass of approximately 2 cm in diameter was observed in the pylorus. A comparison to the CT scan from one year prior (Figure 1A) revealed an inflammatory perforation of the gallblad-

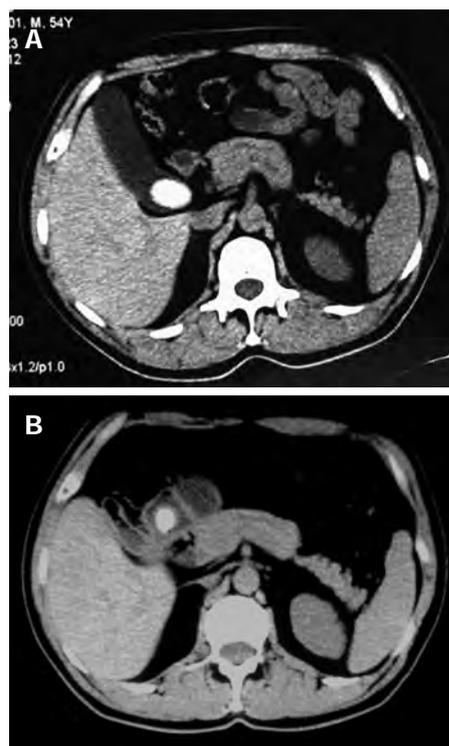

Figure 1 Abdominal computed tomography. A: Revealing a large calcified mass in the gallbladder (one year prior); B: Indicating the migration of the large stone from the gallbladder to the pylorus and gas shadows seen in the gallbladder (this time).

der and pylorus, the presence of an internal fistula and the migration of the gallstone from the gallbladder to the pylorus (Figure 1B). The upper gastrointestinal contrast also revealed a large round filling defect with a smooth border in the descending part of duodenum. Therefore, a revised diagnosis of Bouveret's syndrome was made. The patient was transferred to the laparoscopic ward and underwent duodenotomy for gallstone removal, duodenal fistulation and subtotal cholecystectomy using a laparoscope. During the operation, multiple adhesions among the gallbladder, duodenal bulb and omentum were observed. After the adhesions were released, the gallbladder-duodenal fistula could be seen. A large stone with a diameter of approximately 3.0 cm × 4.0 cm was located below the fistula-duodenal opening. After making an incision in the gallbladder wall, it was observed that the cystic duct and sinus crossings had closed. Subsequently, duodenum incision, stone removal, placement of a drainage tube into the duodenum incision and interrupted suture were performed to close the duodenum. A subtotal cholecystectomy was also performed simultaneously. After post-operative hemostatic and anti-inflammatory treatment, the patient was discharged. Three weeks later, the patient was readmitted to remove the duodenal drainage tube. On the next day after the removal, fever and abdominal pain were observed. However, an abdominal CT revealed no obvious abnormalities. After a 5-d controlled diet and anti-inflammatory treatment, the patient recovered and was discharged without further incident.

## DISCUSSION

A gastric outlet obstruction caused by the migration of large gallstones to the pylorus and duodenum *via* a gallbladder-duodenal fistula, Bouveret's syndrome, is a special type of gallstone-induced ileus that comprises only 1%-3% of cases<sup>[2,4]</sup>. This syndrome is extremely rare and appears predominantly in older women, at an average age of 74.1 years<sup>[2]</sup>. Most of these patients experience complications, such as hypertension, diabetes, chronic obstructive pulmonary disease or other systemic diseases. Bouveret's syndrome presents with the common symptoms of abdominal distension; abdominal pain; nausea; vomiting; fever; and occasionally gastrointestinal hemorrhage, such as hematemesis or melena<sup>[5,6]</sup>. Abdominal CT, upper gastrointestinal imaging and endoscopy offer important diagnostic value for diagnosing the disease<sup>[7,8]</sup>. In this case, the patient was a middle-aged male, rather than a member of the susceptible population, who presented the main manifestations, including abdominal distension, nausea, vomiting undigested food and a past history of duodenal bulb ulcer. As a result, his condition was easily misdiagnosed as duodenal bulb ulcer and pyloric obstruction. After a foreign body was observed in the duodenal bulb through endoscopy, gastrolithiasis was suspected. However, several doubts remained. First, there was no clear predisposition for gastrolith. Second, the foreign body was too large to have passed through the pylorus to arrive at the duodenum. Based on these doubts surrounding the diagnosis, the patient was submitted to further examination during litholytic and acid suppression therapy. The diagnosis was suddenly clearer based on the results of an abdominal CT. Compared with a CT image of the patient taken one year prior, it was apparent that the original large gallstone near the neck of the gallbladder had disappeared, and the gallbladder had shrunk with some gas remaining in it and a gallstone shadow in the pyloric cavity next to the gallbladder. These abdominal CT results suggested that the endoscopic finding was not a gastrolith but rather that the gallstone had penetrated into the duodenal bulb. Consequently, Bouveret's syndrome was diagnosed. Upper gastrointestinal imaging results further supported the diagnosis. The treatment choice for Bouveret's syndrome remains debatable and can include endoscopic treatment, extracorporeal shock-wave lithotripsy, intracorporeal electrohydraulic lithotripsy, surgery and laparoscopic treatment<sup>[9]</sup>. Currently, 1-stage or 2-stage surgery is often adopted<sup>[10-12]</sup>. One-stage surgery refers to a combination of enterolithotomy plus cholecystectomy and fistula repair within a single surgery. Two-stage surgery entails dividing the enterolithotomy and cholecystectomy into two operations. However, surgery is often associated with significant postoperative complications and mortality<sup>[3,13]</sup>. With the development of laparoscopic and other minimally invasive techniques, the successful application of laparoscopic treatment as a therapy for Bouveret's syndrome has also been reported<sup>[14,15]</sup>. In this case, subtotal cholecystectomy, duodenotomy for gallstone removal and duodenal fistulation

using a laparoscope were performed, taking into account the large size of the stones, the good general condition of the patient, the closed gallbladder and the duodenal fistula. The patient recovered and was discharged quickly. After the duodenal drainage tube was unplugged, no duodenal fistula was observed, and the condition of the patient remained stable after being followed up for 6 mo. The present case included the following features: (1) The patient was middle-aged, had no chronic systemic disease and did not belong to the usual susceptible population of Bouveret's syndrome; (2) The clinical symptoms were atypical, with neither infection nor abdominal pain. The onset was similar to that of peptic ulcer and pyloric obstruction, which was initially suspected as gastrolithiasis; (3) Imaging data from one year prior provided an important basis to observe the evolution of the disease and make a diagnosis; and (4) Based on the condition of the patient, disposable laparoscopic lithotomy and cholecystectomy were conducted. The effect was satisfactory, and there were no obvious postoperative complications.

In conclusion, Bouveret's syndrome is a rare cause of gastric outflow obstruction and is easily misdiagnosed. Therefore, when a patient presents an outbreak of symptoms that are similar to pyloric obstruction with a previous history of gallbladder stones, the clinician should consider Bouveret's syndrome, which can be differentially diagnosed through a combination of endoscopy and abdominal imaging. As laparoscopic technology gradually matures, the advantages of the laparoscopic treatment of this syndrome have been realized in recent years. Laparoscopic enterolithotomy is safe and effective, with good patient tolerability, rapid postoperative recovery and few wound-related complications.
